or nitrate. At the same time, it can also be seen that the rate is practically independent of the ligand concentration when it is higher than 2.0M, in which region the concentration of the complexes and, consequently, that of free beryllium decreases. The authors have not yet found any reasonable explanation of this.

Although there are such exceptions, we may still conclude that the rate of extraction is generally represented by Eq. (15); this indicates that the rate-determining step is the first 1:1 complex formation in the aqueous phase, as Freiser *et al.* have pointed out with regard to the divalent metal dithizonate extractions. The unit reactions for the extraction can be described as:

$$HA(org) \rightleftarrows HA \quad (17a)$$
$$HA \rightleftarrows H^+ + A^- \quad (17b)$$
$$Be^{2+} + A^- \longrightarrow BeA^+ \quad (17c)$$
$$BeA^+ + A^- \rightleftarrows BeA_2 \quad (17d)$$
$$BeA_2 \rightleftarrows BeA_2(org) \quad (17e)$$

Probably only the unit reaction in Eq. (17c) is responsible for the rate given by Eq. (15). As carbon tetrachloride is a nonpolar solvent, the extraction of beryllium species other than the bis-TTA complex is probably very poor. At the same time, the dissociation of TTA in this nonpolar solvent into A^- should be very small (the presence of the TTA anion is necessary in order to explain the rate of extraction in the MIBK systems, as will be shown below). Thus, only the above mechanism is dominant in the carbon tetrachloride system where $[A^-]$ is larger than $10^{-6.0}$M in the 0.1M media and in all the regions studied in the 4.0M ionic media.

In Fig. 4, a difference is observed in the apparent rate of extraction from 0.1M and 4.0M ionic media; the apparent rate constant in Eq. (9c) is ten times larger in the 0.1M media than that in the 4.0M media. However, this is due to the differences in the acid dissociation and two-phase distribution constants, K_a and K_D, in Eqs. (2) and (3). The rate constants for the unit reaction in Eq. (17c), given in Table 1, are not very different in these two ionic media.

In the MIBK systems, the rate of extraction is very much enhanced by the perchlorate ions in the aqueous phase. It seems that this can be explained in terms of the extraction of beryllium ion-pairs with perchlorate ions.

When the ionic concentrations in the aqueous phase is 0.1M and no perchlorate is present, the rate constants in the MIBK systems given by Eq. (15) are practically the same as that in the carbon tetrachloride systems. Thus, the rate-determining step should be the formation of the first complex in the aqueous phase, both in the MIBK systems containing no perchlorate in the aqueous phase and in all the cases in the carbon tetrachloride systems. When sodium perchlorate is added to the aqueous phase instead of the nitrate or chloride, ion-pairs such as $Be(NO_3)(ClO_4)$ or $BeCl(ClO_4)$ and $Be(ClO_4)_2$ are extracted. If these extracted ion-pairs react with the dissociated TTA anion in the organic phase, and if this reaction in the organic phase is faster (although the authors cannot give any reasonable explanation for the faster reaction in the organic phase) than the reaction in the aqueous phase, the enhancements of the rate which are proportional to $[ClO_4^-]$ and $[ClO_4^-]^2$ can be explained; the over-all extraction rate should be given by the sum of these rates, as is described by Eq. (12).

In the MIBK systems, the rate of extraction in the absence of perchlorate ions, that is, k, is already larger than the rate in the carbon tetrachloride systems containing the same aqueous solutions. As was pointed out in a previous paper,[4] the extraction of beryllium in these nitrate or chloride solutions could not be measured within the limits of experimental accuracy ($D_{Be} < 10^{-2}$). However, still it is possible to assume that an extraction of the ion-pairs, $BeCl_2$ or $Be(NO_3)_2$, occurs from such salt solutions into MIBK. This extracted beryllium nitrate or chloride in MIBK (this extraction should be negligible into carbon tetrachloride or from a 0.1M ionic solution into MIBK) could react with TTA anions in the organic phase; the overall effect of that reaction in the aqueous phase which should occur simultaneously may explain why the rate is larger in this solvent than in carbon tetrachloride.

As has been pointed out,[4] the extraction of beryllium perchlorate in the aqueous phase increases with the increase in the aqueous perchlorate concentration. The first-order dependence of the rate on the perchlorate concentration is probably due to the extraction of the mixed species, $Be(NO_3, ClO_4)$ or $Be(Cl, ClO_4)$, while the second-order dependence is probably due to the extraction of the perchlorate, $Be(ClO_4)_2$. These ion-pairs may react in the organic phase and form TTA complexes by exchanging the inorganic anion with the TTA anion.

It is remarkable that the extraction reaction in the MIBK systems is always dependent on the first order of $[A^-]$ and not on $[HA]_{org}$. Until now, no information has been available about the dissociation constant of TTA and the hydrogen-ion concentration in the MIBK phase in an equilibrium with the aqueous phase, and the authors have no knowledge whether or not a portion of the TTA in the MIBK phase is in the dissociated anion, or whether or not the concentration of this TTA fraction, $[A^-]_{org}$, is proportional to that in the aqueous phase, $[A^-]$. However, it may be reasonable to assume that a part of weak acid, TTA, the concentration of which is more than two orders higher than that in the aqueous phase, is also in the dissociated anionic form or is in other forms such as NaA, than the HA form, and that this fraction of TTA reacts with the extracted beryllium ion-pairs in the MIBK phase. When this assumption is accepted, the enhancement of the rate of extraction can be explained as occurring when the rate of this 1:1 complex formation in the organic phase is larger than that in the aqueous phase. It is also reasonable that the complex formation in the organic phase is not assumed in the carbon tetrachloride system, for in this nonpolar solvent, not only does the extraction of the ion-pairs occur, but also the concentration of the TTA anion, which is indispensable for the complex formation in the organic phase, is probably very low.

Eigen,[18] has pointed out that Be^{2+}, Al^{3+}, and other

18) M. Eigen, *Pure Appl. Chem.*, **6**, 97 (1963).

strongly-hydrolysing trivalent metal ions show quite a slow substitution rate of water with a ligand and that the splitting of a water molecule (hydrolysis) is faster than the substitution. Thus, a ligand specificity (basicity) on the rate may be observed in these metal ions. The characteristic rate constants for water substitution in the inner coordination sphere of Be^{2+} given by Eigen is $10^{1.5}$—$10^{2.5}$ (sec^{-1}) or $10^{3.3}$—$10^{4.3}$ (min^{-1}) (Fig. 5 in Ref. 19). The reaction constants for the 1:1 beryllium-TTA complex in the carbon tetrachloride systems in the present study (which is independent of the concentration of the perchlorate ion and can thus be assumed to take place in the aqueous phase) are $10^{4.3}$ and $10^{4.5}$ (min^{-1}). As the pH in the present study is 2.0—3.5 and the metal concentration is very low, the hydrolysis of this metal ion may not be important.[19]

As has been pointed out, the distribution of the TTA in the organic phase into the aqueous phase has been recognized as a slow reaction. In the present study, TTA was initially added to the organic phase and beryllium(II) was initially added to the aqueous phase, and the agitation was started just after the two phases had come in contact in the vessels. When the distribution of this TTA into the aqueous phase in which the reaction between Be^{2+} and A^- occurs is very slow, the concentration, $[A^-]$, at a certain pH should be lower than the value at the equilibrium if the agitation has been carried out for such a short interval as 10 min or less, as in the present experiments. When this occurs, the apparent value of the rate constant, k, calculated by using the value of K_D at the equilibrium should be smaller than the true value, which could be calculated if the K_D value after such a short interval (this value of K_D should be larger than that at the equilibrium) were available. However, as has been described, the present authors have observed that the rate of the extraction of beryllium(II) obtained when the TTA has been distributed between the two phases before the addition of the metal ions is identical with the values obtained when the distribution of TTA is started at the same time as the metal extraction. The authors cannot yet explain why the results of these two series of experiments agree with each other. Further information seems to be necessary before a full explanation of this situation can be given.

The early stage of this work was carried out by Mr. Mitsuo Sakairi. The authors are grateful to him. They are also grateful to Messers Yukio Arai, Teijūrō Ariu, and Yasuki Obi of the present laboratory for their experimental aid. Part of this work was done at the Laboratory of Nuclear and Analytical Chemistry, Institute of Physical and Chemical Research; the authors are grateful to Professor Nobufusa Saito, the head of the Laboratory.

(Received March 8, 1971)

Electrophoretic measurements were made on polyphthalamide microcapsules containing aqueous solution of bovine serum albumin and their membrane at various hydrogen ion concentrations. The microcapsules moved toward the anode at any pH, while the membrane migrated to the anode above pH 3.5 and to the cathode below this pH. These results were explained on the assumption that a fraction of albumin molecules is chemically incorporated into the microcapsule membrane through the microencapsulation and that the net electrical charge of the microcapsules is highly dependent on the charge of the outer surface of their membrane.

A previous paper of this series[1] has reported the electrophoretic behavior of polyphthalamide microcapsules containing aqueous solution of various polyelectrolytes. The microcapsules containing anionic or cationic polyelectrolyte, such as sodium heparinate or poly(1,2-dimethyl-5-vinyl pyridinium methyl sulfate), were found to move towards the anode or cathode according to the sign of charge on the polyelectrolyte encapsulated. When the microcapsules contained aqueous solution of amphionic polyelectrolyte, such as 2-methyl-5-vinylpyridine methyl acrylate-methacrylic acid copolymer, they migrated either to the anode or the cathode depending on the pH of the medium, showing the existence of an isoelectric point.

1) M. Shiba, Y. Kawano, S. Tomioka, M. Koishi, and T. Kondo, *Kolloid-Z. Z. Polym.*, submitted.

On the other hand, it was strongly suggested that bovine serum albumin, a typical amphoteric polyelectrolyte, participates in the interfacial polycondensation reaction between diamine and acid dichloride because albumin molecules, contrary to the amphionic polyelectrolyte molecules used in the previous paper,[1] have many amino groups which are able to react readily with acid chloride.[2] If it is really the case, a different electrophoretic behavior may be expected for microcapsules containing aqueous solution of bovine serum albumin from that for those containing aqueous solution of the polyampholyte.

This paper describes the experimental results on the electrophoresis of polyphthalamide microcapsules containing aqueous solution of bovine serum albumin and their possible implications.

Experimental

Preparation of Microcapsules. Polyphthalamide microcapsules containing aqueous bovine serum albumin solution used in this work were prepared by the same method as described in the previous paper[2] by making use of the interfacial polycondensation reaction between terephthaloyl dichloride and piperazine, and dispersed in water with the aid of dispersing agent. The microcapsule dispersion so obtained was dialyzed in a cellulose tubing (Visking) against distilled water at 40°C with shaking until a constant specific conductance of the dispersion was attained in order to remove any remaining ionogenic impurities. The dialyzed microcapsule dispersion could be conveniently stored in a refrigerator at 2—4°C before use. A fraction of the stored microcapsules was broken by subjecting to a high centrifugal field. This was done because it was expected that there may be a difference in surface charge between the outside and the inside of the membrane in view of the possibility that some of the albumin molecules encapsulated participate in the interfacial polycondensation reaction. The membranes thus obtained was washed and dispersed in buffer solution.

Measurement of Electrophoretic Mobility. Electrophoretic measurements of the microcapsules and their membrane were taken in a quartz flat microelectrophoretic cell. The media for the measurements were acetate buffer (pH 3—6) and HCl-sodium acetate buffer (pH 2—3), the ionic strength of which was maintained at 0.01 by the addition of NaCl throughout the measurement unless otherwise stated. For each measurement 40 specimens were timed in each direction to eliminate the polarization effect of the electrodes. Mobilities were taken at room temperature and corrected to water at 25°C.

Calculation of Zeta-Potential. At first sight, mobilities seemed to be convertible into zeta-potentials (ζ) by means of the simple Smoluchowski-Henry equation,[3]

$$\zeta = \frac{f \cdot \pi \cdot \eta}{D \cdot X} \cdot U$$

where U is the mobility, η the viscosity of the medium, D the dielectric constant, X the potential gradient, and f the numerical factor depending on the product of the reciprocal thickness of double layer and the particle diameter. However, some correction was necessary because the surface conductance was found to be of the order of $10^{-7}\Omega^{-1}$ which could not be neglected in the calculation. Zeta-potentials of the microcapsules were, therefore, calculated by the Henry equation,[4]

$$\zeta = \frac{6 \cdot \pi \cdot \eta}{D \cdot X} \cdot U[1 + \lambda'\{3f(\kappa a) - 2\}]$$

where κ represents the reciprocal thickness of double layer, a the microcapsule diameter, and $f(\kappa a)$ a function of κa. λ' is given by the following equation,

$$\lambda' = \frac{\mu_0 - \frac{2\mu_s}{a}}{2\left(\mu_0 + \frac{\mu_s}{a}\right)}$$

where μ_s is the surface conductance and μ_0 the specific conductance of the suspending medium. The surface conductance was evaluated by the method proposed by Fricke and Curtis.[5]

The Henry equation was also used for calculating the zeta-potential of microcapsule membrane. In this case, the value of a was assumed to be the same as the average diameter of the microcapsules though the shape of the membrane was not necessarily spherical. Therefore, the zeta-potential of the membrane should be regarded as being apparent.

Results and Discussion

Figure 1 shows the change in the specific conductance of the microcapsule dispersion during dialysis in a cellulose tubing against the volume of distilled water used. As the ionogenic impurities diffused out through the microcapsule membrane and the cellulose tubing, the specific conductance of the microcapsule dispersion decreased and then levelled off. The final value of specific conductance increased with increasing concentration of albumin encapsulated, being presumably due

to the dissociation of albumin molecules in water.

The microcapsule dispersions used in this work were those having the final specific conductance given in the figure.

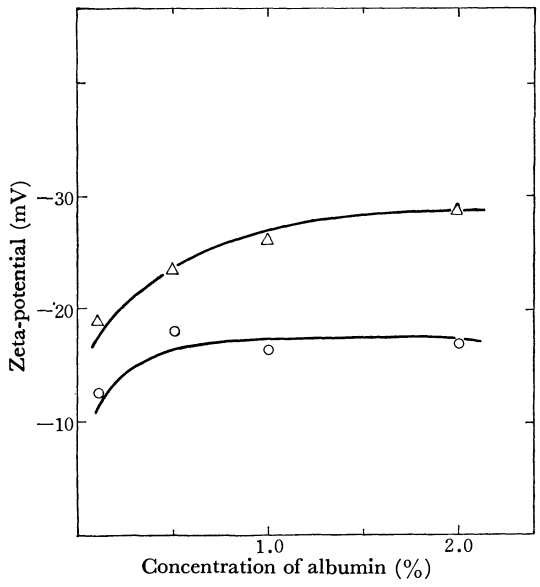

Fig. 2. Zeta-potential of microcapsules containing aqueous albumin solution as a function of albumin concentration in acetate buffers.
(○) pH 4.7, (△) pH 5.7

The zeta-potential of the microcapsules is given in Fig. 2 as a function of the concentration of albumin solution used in their preparation. The potential increased as the concentration of albumin increased and then became nearly constant above a concentration of 1% albumin irrespective of the pH of the medium. This tendency is quite similar to that observed for the microcapsules containing aqueous polyelectrolyte solution.[1)]

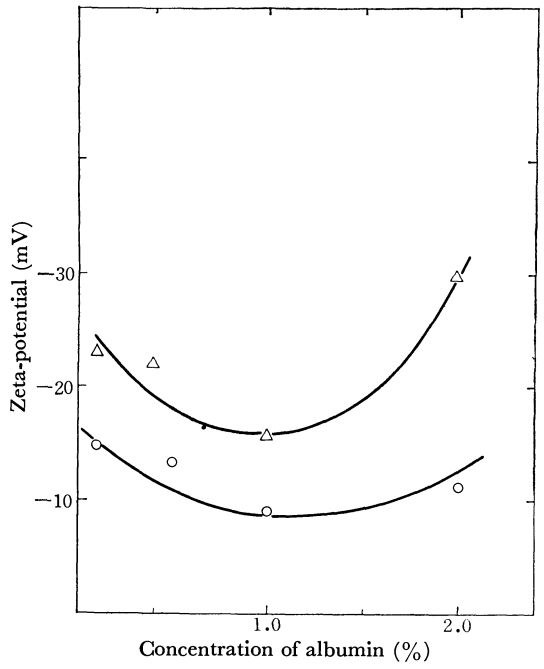

Fig. 3. Zeta-potential of microcapsule membrane as a function of albumin concentration used for preparing microcapsules in acetate buffers.
(○) pH 4.7, (△) pH 5.7

In Fig. 3 is plotted the zeta-potential of microcapsule membrane against the concentration of albumin solution. In contrast to the microcapsule themselves, the membrane showed a minimum zeta-potential when the albumin concentration varied. The appearance of the minimum may be interpreted as follows. An increase in the albumin concentration will increase the number of albumin molecules chemically incorporated in the membrane, causing an increase in the number of dissociable carboxyl groups. The increase in the number of dissociable carboxyl groups will facilitate the fixation of counter ions, thereby lowering the zeta-potential. However, it may outweigh the fixation of counter ions at high albumin concentration, resulting in an increase of negative charge of the microcapsule membrane.

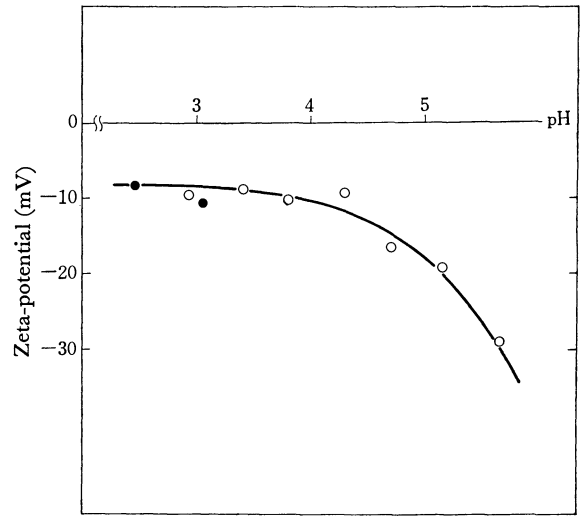

Fig. 4. Zeta-potential of microcapsules containing aqueous 1 wt% albumin solution as a function of pH in CH_3COONa–CH_3COOH (○) and CH_3COONa–HCl (●) buffers at a constant ionic strength of 0.01.

Figure 4 illustrates the zeta-potential *versus* pH curve of the microcapsules. They were negatively charged at all pH, even at lower pH than that of the isoelectric point of albumin (pH 4.8). This differs from what has been reported in the previous paper[1)] in that the microcapsules do not necessarily bear a charge of the same sign as that of albumin molecules encapsulated. The polyphthalamide microcapsules containing aqueous solution of cationic or anionic polyelectrolyte always moved towards the cathode or anode in an electric field in accordance with the sign of charge on the encapsulated polyelectrolyte.[1)]

The dependence of apparent zeta-potential of the microcapsule membrane on the pH of the medium is shown in Fig. 5. What is evident from this figure is a charge reversal of the membrane occurred in the vicinity of pH 3.5, indicating the existence of isoelectric point. This should be related to the chemical incorporation of albumin molecules into the membrane through the reaction with acid chloride.[2)]

Of the dissociable groups of albumin, the carboxyl groups of aspartic and glutamic acids give negative

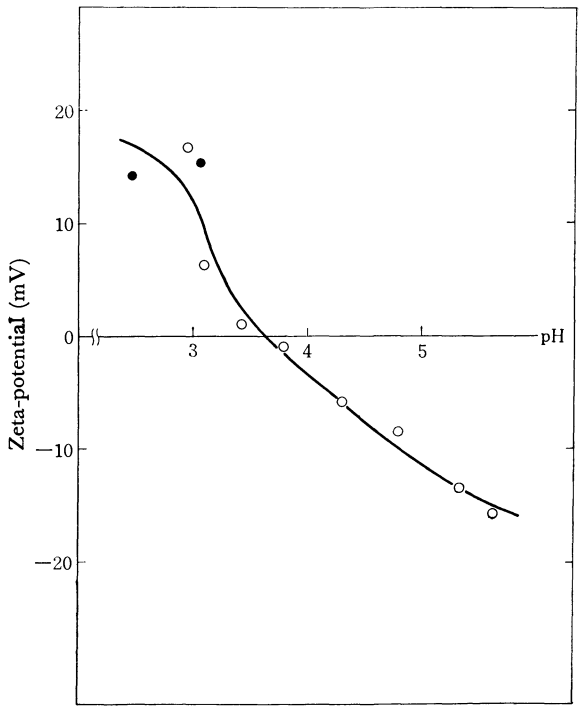

Fig. 5. Zeta-potential of microcapsule membrane as a function of pH in CH_3COONa–CH_3COOH (○) and CH_3COONa–HCl (●) buffers at a constant ionic strength of 0.01.

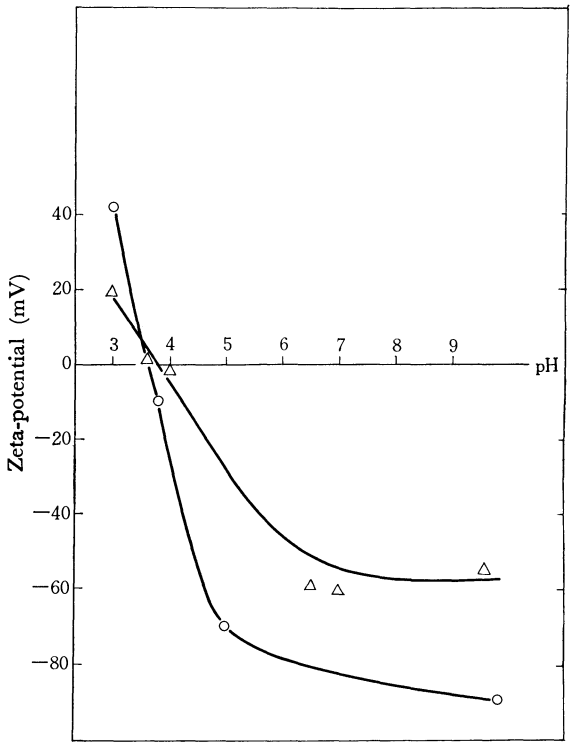

Fig. 6. Zeta-potential of microcapsules containing aqueous 1 wt% MPM solution as a function of pH in acetate buffers. Ionic strength: (△) 0.01 and (○) 0.001

charge (the dissociation of the hydroxyl groups of tyrosine and the sulfhydryl groups of cystein may also contribute to the negative charge at high pH) while the amino groups of lysine and arginine, and imino groups of histidine can produce positive charge. In view of this and the pK of each group,[6] it may be assumed that about 60% of the amino groups of lysine and arginine have reacted with acid chloride to shift the isoelectric point of the chemically incorporated albumin from pH 4.8 to 3.5.

As to the albumin molecules in the encapsulated solution, preliminary tests were made to check whether they were modified or not during the microencapsulation process. The Ouchterlony method,[7] which is frequently used in immunochemistry, and paper-electrophoresis proved that the albumin molecules are not subjected to any detectable changes immunochemically or electrophoretically during the microencapsulation process as compared with native albumin molecules.

Before making an attempt to elucidate the difference in the pH dependence of zeta-potential between the microcapsules and their membrane, an examination is made of the electrophoretic behavior of polyphthalamide microcapsules containing solution of a copolymer of 2-methyl-5-vinylpyridine-methyl acrylate and methacrylic acid (Fig. 6). This polymer (abbreviated as MPM) is practically insoluble in water in the range of pH 4—7.5.[8] However, the polymer is readily soluble in water outside of this pH region and has a net negative charge above pH 7.5 and a net positive charge below pH 4. Moreover, the polymer is unable to react with acid chloride. As is seen from the figure, the microcapsules containing aqueous MPM solution are negatively charged above pH 7.5 and positively charged below pH 4. It may be inferred, therefore, that the sign of charge of microcapsules is determined solely by that of amphoteric polyelectrolyte unless the membrane acquires electrical charge by chemically incorporating the polyelectrolyte.

TABLE 1. SIGN OF CHARGE OF ALBUMIN MOLECULES, MICROCAPSULES, AND THEIR MEMBRANE

Species	pH region		
	Below 3.5	3.5—4.8	Above 4.8
Encapsulated albumin	+	+	−
Microcapsules	−	−	−
Microcapsule membrane	+	−	−

In Table 1 are summarized the sign of charge of the encapsulated albumin, microcapsules, and their membrane in three pH regions. When the pH of the medium was above 4.8, all of the encapsulated albumin molecules, microcapsules, and their membrane were negatively charged. In the region of pH 4.8—3.5, the microcapsules and their membrane had a negative charge while the albumin molecules bore a positive charge. This may result from the screening of the positive charge of albumin molecules in the encapsulated solution by the negative charge of the membrane. Very curiously, however, the microcapsules were negatively charged below pH 3.5 in spite of

positive charges on the encapsulated albumin molecules and the membrane. This makes it necessary to consider the distribution of charged sites in the membrane.

It is evident that polyphthalamide molecules constituting the microcapsule membrane form and grow on the organic solvent side of the organic solvent-water interface.[9] The presence of albumin molecules in the water phase to be encapsulated will not change the features of the polycondensation reaction except that albumin molecules may participate in the polymerization. The amino groups of albumin molecules are very likely to react at the interface with acid chloride molecules coming from the interior of the organic phase to form amide linkages since albumin molecules can spread in a more expanded state at the oil-water interface than at the air-water interface[10] with the amino groups directing towards the oil phase.[11] As the polycondensation reaction proceeds, the amount of acid chloride reaching the interface will decrease with time and thereby will increase the number of amino groups remained unreacted of the following albumin molecules. The number of dissociable amino groups in the microcapsule membrane will increase, therefore, in the direction from the outside to the inside of microcapsules whereas the dissociable carboxyl groups are uniformly distributed in the membrane. As the result, the negative charge on the outer surface of the membrane may screen and surpass the positive charge on the inner surface and albumin molecules in the encapsulated solution. Based on this assumption, the positive zeta-potential observed for the microcapsule membrane below pH 3.5 (Fig. 5) may be interpreted as indicating that the breakdown of the microcapsules by centrifugation turned their membrane inside out, probably because the inner surface is likely to be more hydrophilic than the outer surface, thus making prevail the positive charge due to the amino groups of albumin incorporated in the membrane over the negative charge arising from the dissociation of the carboxyl groups.

Photochemical Reactions of Uranyl Ions with Organic Compounds. IV. The Uranyl Fluorescence Quenching by Aliphatic Alcohols

Shukichi SAKURABA and Ryoka MATSUSHIMA
Faculty of Engineering, Shizuoka University, Hamamatsu

(Received March 15, 1971)

The relative rates for uranyl fluorescence quenching by aliphatic alcohols (methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, isobutyl, and *s*-butyl alcohols) were measured under various conditions. The rates were increased in proportion to the perchloric acid concentration at pH <1, whereas the rates were smaller and nearly constant at the pH's between 1—4; thus showing the involvement of both acid-dependent and acid-independent processes. Though the rates for both processes changed with the change in the alcohol structure (the polar substituent effect), the ratio of the two rate constants was nearly constant. The inhibitory effects of cupric ions (as a scavenger for the one-equivalent redox intermediates) suggested that the acid-dependent quenching process involves a two-equivalent redox or two consecutive one-equivalent redox steps between the same partners. The mechanisms of these quenching processes are discussed.

A kinetic study has been made of the photo-redox reaction of the uranyl ions with alcohols in solution with pH's ranging from 1 to 3, where the rates seemed to be insensitive to the acidity of the medium.[1] However, in the course of the investigation of the effects of the acid concentration (up to 2M in perchloric acid) on the rates, it appeared that the rates of both the quenching and the photo-redox reactions were increased with the acid concentration in the pH region below 1, suggesting the involvement of an acid-catalyzed process as well as an acid-independent process. Further, the former process seemed to involve a two-equivalent redox or two consecutive one-equivalent redox steps between the same partners, while the latter process features *via* α-hydrogen abstraction (followed by proton liberation) *i.e.*, a one-equivalent redox process, followed by the disproportionation reactions to produce the photo-redox products. The quenching mechanisms are discussed in connection with photo-redox reaction mechanisms.

1) S. Sakuraba and R. Matsushima, This Bulletin, **43**, 2359 (1970).

Experimental

Guaranteed reagents and doubly-distilled water were used. Preliminary experiments showed that traces of such impurities as halogen ions and aldehydes or ketones which might be present in the reagents were negligible under the present conditions.

Aqueous solutions of the 0.02M uranyl nitrate containing various concentrations of the substrates and perchloric acid

were prepared. After the desired temperature (usually 20°C) was attained, the relative fluorescence intensities were rapidly measured. The fluorescence measurements were carried out using a fluorescence spectrophotometer (Hitachi 204 Type) without an attachment for temperature control. The errors in the determination of the temperature inherent in the procedure were estimated to be within ±1°C. De-oxygenation with oxygen-free nitrogen (keeping air-tight) produced no change in the fluorescence intensities. The relative intensities at the 510 nm peak of the uranyl fluorescence were measured with 405 nm excitation, though no significant changes in the quenching constants were observed with the changes in the analyzing (490, 510, 533 nm) and the excitation (313, 366, 405 nm) wavelengths with the exception of a slight lowering in the quenching constants with the 436 nm excitation. The methods for the analysis of the photo-redox products and the measurements of their quantum yields were previously described.[1]

Results and Discussion

Effects of pH and Ionic Strength on the Rate. The quenching constants of the uranyl fluorescence by some alcohols at various pH's are shown in Fig. 1. In the pH region below 1 the quenching constant was markedly increased with the increase in acidity, while it was nearly constant in the pH region from 1 to 4. Perchloric acid did not quench the fluorescence of a 0.02M uranyl solution in the absence of alcohols. Thus, the quenching reaction involves both acid-dependent and acid-independent processes. The rates of these processes, then, can be expected to result in a difference in their sensitivities to ionic strength. The effects of the ionic strength on the rates at different acid concentrations are shown in Fig. 2. The slope of the plot for the 0.5M $HClO_4$ solution was 0.28, larger than that for the solutions of pH 1 and 2, 0.07. Since the quenchers (alcohols) have no net charge, the rate for a simple bimolecular quenching process between the excited uranyl ion and the quencher should not be affected largely by the ionic strength, while the rate of the quenching process in which the hydrogen ions participate should show a greater sensitivity to the ionic strength.[2]

Inhibitory Effects by Cupric Ions. Table 1 shows the inhibitory effects of cupric ions (as scavengers for one-equivalent redox intermediates[1,3]) on the formation of the photo-redox products. The direct quenching of the uranyl fluorescence by cupric ions was negligible. Cupric ions can only scavenge the one-equivalent redox intermediates, U(V) and/or R· species; the effect should be less sensitive to the two-equivalent redox process. Therefore the change in the effects on the ratio of the products, [U(IV)]/[Ox], with the acid concentration suggests that the acid-dependent chemi-

cal quenching process involves a two-equivalent redox or two consecutive one-equivalent redox steps between the same partners within a solvent cage. Table 1 also shows that cupric ions mainly scavenge the U(V) species, since the amount of the oxidation product, [Ox], is only slightly decreased in the presence of cupric ions.

△: Ethyl alcohol, ▲: Methyl alcohol.

Separation of the Quenching Constants. The quenching constants, K's, in the Stern-Volmer equation[4] (1), were measured as a function of the perchloric acid concentration (Fig. 3):

$$I_f^0/I_f = 1 + K[\mathrm{R}] \quad (1)$$

Figure 3 shows that the quenching constants, K, can be represented by the following equation:

$$K = K_1 + K_2[\mathrm{H}^+] \quad (2)$$

where K_1 and K_2 refer to the quenching constants for the acid-independent and the acid-dependent processes respectively. In Table 2, K_1 (the intercept) and K_2 (the slope) obtained from the plot of K *vs.* $[H^+]$ are listed. It may be noticed that the ratio of the quenching constant for the acid-dependent process to that for the acid-independent process, K_2/K_1, is nearly constant, whereas both K_1 and K_2 vary considerably, with the variation in the alcohol structure.

TABLE 2. THE QUENCHING CONSTANTS, K_1 AND K_2 IN Eq.(2), FOR ALIPHATIC ALCOHOLS (from Fig. 3).

Alcohols	K_1, M^{-1}	K_2, M^{-2}	K_2/K_1, M^{-1}
Methyl	16	60	3.8
Ethyl	60	180	3.0
n-Propyl	90	340	3.8
Isopropyl	107	340	3.2
n-Butyl	105	400	3.8
Isobutyl	130	480	3.7
s-Butyl	140	490	3.5

The Mechanism. The following mechanism may be assumed for the quenching reaction of the uranyl fluorescence by aliphatic alcohols in an acidic aqueous solution:

$$\mathrm{U} + h\nu \xrightarrow{I_a} \mathrm{U} \quad (3)$$

$$\mathrm{U}^* \xrightarrow{k_f} \mathrm{U} + h\nu' \quad (4)$$

$$\mathrm{U}^* \xrightarrow{k_d} \mathrm{U} + \text{heat} \quad (5)$$

$$\mathrm{U}^* + \mathrm{U} \xrightarrow{k_s} 2\mathrm{U} + \text{heat} \quad (6)$$

$$\mathrm{U}^* + \mathrm{R} \xrightarrow{k_1} \mathrm{U(V)} + \mathrm{R}\cdot + \mathrm{H}^+ \quad (7)$$

$$\mathrm{U}^* + \mathrm{R} \xrightarrow{k_1'} \mathrm{U} + \mathrm{R} + \text{heat} \quad (8)$$

$$\mathrm{U}^* + \mathrm{R} + \mathrm{H}^+ \xrightarrow{k_2} \mathrm{U(IV)} + \mathrm{Ox} + 3\mathrm{H}^+ (\text{or } \mathrm{U(V)} + \mathrm{R}\cdot + 2\mathrm{H}^+) \quad (9)$$

$$\mathrm{U}^* + \mathrm{R} + \mathrm{H}^+ \xrightarrow{k_2'} \mathrm{U} + \mathrm{R} + \mathrm{H}^+ + \text{heat} \quad (10)$$

Here, U, R, U(V), R·, U(IV), and Ox refer to $(UO_2^{2+})_{aq}$, R_1R_2CHOH, $(UO_2^{+})_{aq}$ $R_1R_2\dot{C}OH$, U(IV) species, and R_1R_2CO respectively; I_a is the rate of the light absorption in einsteins$\cdot l^{-1}$sec^{-1}; k_1 and k_2 refer to the rate constants for the acid-independent and the acid-dependent quenching processes respectively. Process (7) has been shown to involve a one-equivalent redox (α-hydrogen abstraction[1,5]), followed by fast disproportionation reactions:

$$2\mathrm{U(V)} \xrightarrow{\mathrm{H}^+} \mathrm{U(IV)} + \mathrm{U}, \text{ and } 2\mathrm{R}\cdot \longrightarrow \mathrm{R} + \mathrm{Ox}.$$

The acid-dependent chemical quenching process (9) may involve a two-equivalent redox or two consecutive one-equivalent redox steps between the same partners. This is suggested by the facts that (i) the product quantum yield is higher than 0.5 in the 1N $HClO_4$ solution (the maximun quantum yield for the photoredox products expected from the one-equivalent transfer is 0.5), and (ii) the cupric ions have minor inhibitory effects. However, the initial reacting species in the process has not yet been clarified, and the description drawn here may not be valid; alternative mechanisms, such as those involving a fast pre-equilibrium of proton-addition on the uranyl ion or of the formation of a complex or an ester-intermediate, may explain the results equally well.

Since neither the change in the concentration of alcohol nor that of perchloric acid resulted in a change in the absorption of the system (pH<2), the steady state assumption for U* leads to the following expression:

$$I_f^0/I_f = 1 + \tau_0\{k_1+k_1'+(k_2+k_2')[\mathrm{H}^+]\}[\mathrm{R}] \quad (11)$$

$$= 1 + \tau_0(k_1+k_1')[\mathrm{R}] + \tau_0(k_2+k_2')[\mathrm{R}][\mathrm{H}^+] \quad (12)$$

$$\tau_0 = \{k_f+k_d+k_s[\mathrm{U}]\}^{-1} \quad (13)$$

From Eqs. (1), (2), (11), and (12), the following equations result:

$$K_1 = \tau_0(k_1+k_1') \quad (14)$$

4) O. Stern and M. Volmer, *Physik. Z.*, **20**, 183 (1919).

5) To be published.

$$K_2 = \tau_0(k_2+k_2') \quad (15)$$

$$K_2/K_1 = (k_2+k_2')/(k_1+k_1') \quad (16)$$

While both K_1 and K_2 in Table 2 decrease with the increase in the polar substituent effect, $\sum\sigma^*$[6] of the substrate (alcohol), the K_2/K_1 ratio is nearly constant; *i.e.*, the sensitivities of the rates of the two processes (acid-dependent and independent processes) are similar. This suggests that the rate-determining steps of the two processes involve the same primary act, *i.e.*, α-hydrogen abstraction. The two processes, however, differ in their secondary steps: the secondary step of the acid-dependent process involves a second one-equivalent redox reaction between the same partners, whereas that of the acid-independent process involves the disproportionation reaction of the UO_2^+ species, each of which is formed in a separate solvent cage.[1] The change in the rate with the acid concentration may be attributable to the change in the species of the uranyl ions excited or to be excited. One can assume, for example, that the protonated uranyl ions are formed through a fast equilibrium[7]: $UO^{2+}+H^+ \rightleftharpoons UO_2H^{3+}$, and have stronger oxidation power in their excited states (and/or intermediate states) than the unprotonated uranyl ions. The formation of a complex[8] or an ester-like intermediate[9] (as has been proposed for the thermal oxidations by many transition metal ions) prior to the photolysis is also conceivable. However, no evidence for such pre-equilibria was found from absorption, emission, and excitation spectra. At this stage we cannot decide the initial species in the acid-dependent process; hence, only a tentative stoichiometry has been outlined here. These problems will be discussed later in detail, with more experimental date.

Desorption of Spread Monolayer of 1-Dodecanol into Aqueous Sodium Dodecyl Sulfate Substrate

Tsutomu SEIMIYA, Kazuo OHBU,* Akio NAKAMURA, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received March 19, 1971)

The process of desorption of dodecanol monolayer into the aqueous sodium dodecyl sulfate (SDS) solutions of varying concentrations was studied by the surface tension measurement. The rate of desorption in its early stage obeyed the simple diffusion law and the plot of logarithms of surface pressure against the square root of time showed a linear relationship. The rate constant of desorption decreased slightly and linearly with an increasing concentration of SDS up to CMC. Beyond CMC it increased rapidly and linearly owing to the increase of dodecanol solubility due to the solubilization. Further, from these rate constants and the surface tension *vs.* concentration curve, the diffusion coefficient of dodecanol in water and in aqueous SDS solutions, its solubilization in aqueous SDS solution and the partition coefficient of dodecanol between water and SDS micelles were calculated. Critical micelle concentration of sodium dodecyl sulfate was also determined as a break point of desorption constant *vs.* concentration curve.

The dissolution of and penetration into a monolayer spread on an aqueous surface have been studied by many investigators referring to the state of monolayer or the mechanism of interaction between the monolayer constituents,[1] reaction kinetics of the monolayer,[2] and the mechanism of desorption.[3-5]

In the present report, the mechanism of the rate of dissolution of spread dodecanol monolayer into an underlying aqueous solution of sodium dodecyl sulfate (SDS) was studied by measuring the change of surface tension due to its dissolution. When the rate constant

of dissolution was expressed as a function of SDS concentration, two straight lines were obtained which intersected with each other at the critical micelle concentration (CMC) of SDS. Saraga's equation for the monolayer dissolution[3] was extended to explain the rate of dissolution of the monolayer into SDS solution below and above CMC.

Experimental

Materials. Dodecanol used was fractionally distilled and its purity was checked by the gas chromatography to be 98%. It contained no higher homologues. SDS was synthesized by the usual method[6] and was purified by repeated extraction with ether and recrystallization from ethanol until a minimum in the surface tension *vs.* concentration curve disappeared. Benzene used as a spreading solvent was purified by shaking with concentrated sulfuric acid and distilling over sodium hydroxide. Water used as a substrate was purified first by refluxing with an alkaline permanganate solution and then distilling thrice using a Hysil flask.

Apparatus. The Wilhelmy's vertical plate method was adopted for the surface tension measurement. A small displacement of the glass plate due to the change of surface tension was recorded by means of a differential transformer, which was driven by 13 V alternating current input supplied from a 1 kHz oscillator, stabilized by a Zenar diode. The output current from the differential transformer was rectified, properly attenuated, biassed and recorded on a Hitachi QPD recorder. The surface tension change of about 28 dyn/cm could be measured by this apparatus with the error of ± 0.14 dyn/cm, when a ground glass plate of 4 cm in perimeter was used.

Procedure. From 5 to 10 μl of benzene solution of dodecanol (5.3×10^{-4} mol/l) was spread from a 50 μl microsyringe on an aqueous surface of SDS solution contained in a glass dish of 7 cm in diameter and 1 cm in depth, and the change in the surface tension was recorded. Typical example of the surface tension change when the benzene solution was spread on the aqueous surface is schematically shown in Fig. 1, where the line AB represents the initial surface tension of the aqueous solution. The surface tension fell to C when the dodecanol solution was spread on the aqueous surface from a single drop at B. The surface tension remained constant from C to D during which period the benzene solution continued to spread, then the surface tension suddenly decreased from D to E and it gradually returned to the value of the substrate solution (AB) as the desorption of dodecanol monolayer proceeded. Five microliter of the spreading solution was confirmed best for the instantaneous completion of the spreading on the aqueous surface. The time required from C to D was a few seconds. So the time for the spreading was negligible compared with the whole period of desorption measurement and the point E was safely taken as the start of the desorption. The evaporation loss during the surface tension measurement was minimized by covering the aqueous surface with a glass plate having a small opening for the passage of the rod attached to the Wilhelmy plate. To facilitate the evaporation of benzene, the monolayer was exposed to open air during the initial period of 30 sec. A special care was taken to ensure the zero contact angle in the advancing meniscus condition. This was confirmed by a slight pushing-down of the plate from an equilibrium position into the solution and checking it to return to the original position when left free.

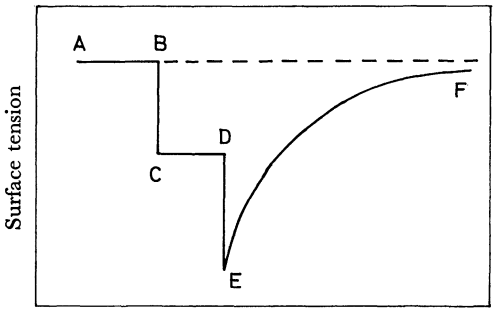

Fig. 1. Surface tension change due to spread benzene.

Results and Discussion

According to the theory proposed by Saraga,[3] a monolayer spread on an aqueous surface partly desorbs to form a sublayer with which the rest of the monolayer establishes a temporary equilibrium, and the rate determining process of desorption is the diffusion of solute from the subsurface through the stagnant layer to the bulk of the solution where the convection current makes the concentration uniform.[7] Thus, the following equation was derived,

$$-\mathrm{d}\Gamma/\mathrm{d}t = C(D/\pi t)^{1/2} \quad (1)$$

where Γ expresses the amount of adsorption (mol/cm^2) at time t (sec), C the subsurface concentration of the solute (mol/1000 g) in equilibrium with Γ and D the diffusion coefficient (cm^2/sec). Assuming $C/\Gamma = k$ and $C/F = q$ (F being the surface pressure of the spread monolayer) to be constant throughout the period of desorption, Eq. (1) after integration gives the following relation, which is in accordance with the relation shown experimentally by Roylance.[8]

$$\ln F/F_0 = -2k(D/\pi)^{1/2} \cdot t^{1/2} \quad (2)$$

where F_0 is the value of F at $t=0$. Equation (2) predicts a linear relationship between the logarithm of the surface pressure F and the square root of time t. The observed plot of $\ln F$ against $t^{1/2}$ for varying concentrations of aqueous SDS substrate is shown in Fig. 2. Here, the difference in surface tension between the aqueous SDS solutions with and without dodecanol monolayer was taken as the surface pressure F of dodecanol monolayer, the assumption being valid for the mixed films containing dodecanol of such low surface pressure as in the present experiment.

In Fig. 2, a good linear relationship was observed to hold between $\ln F$ and $t^{1/2}$. The rate constant of desorption was calculated from the slope of these straight lines and plotted against the concentration of SDS as shown in Fig. 3. In this figure, the value of G for lower concentration of SDS in the substrate ($=G_s$) is seen to decrease slightly and linearly from

the value for water up to a point, beyond which G ($=G_m$) increased linearly and steeply with the concentration of SDS. The break point of the curve, 7.7×10^{-3} mol/l, agreed with CMC reported by others.[9] The value of G_s is given by

$$G_s = 2k(D/\pi)^{1/2} \tag{3}$$

The linear increase of G_m above CMC may reasonably be explained by the solubilization of dodecanol by SDS micelles. According to Eq. (2), the increase of G_m may be due to the increase of k and/or D. However, the solubilization of dodecanol cannot be expected to increase the coefficient of diffusion from the subsurface into the bulk of the solution appreciably, while actual value of $k=C/\Gamma$ is considered to increase to $k'=(C+\Delta C)/\Gamma$, provided that the solubilization equilibrium is instantaneous like surface/subsurface equilibrium. Here, $\Delta C=CC_mPM\times 10^{-3}$ is the increase of dodecanol concentration due to the solubilization, C_m being the concentration of SDS micelles in mol/1000 g water, M the molecular weight of SDS, and P the partition coefficient of dodecanol expressed by

$$\frac{\text{intramicellar concn. of dodecanol (mol/1000 g micelles)}}{\text{intermicellar concn. of dodecanol (mol/1000 g solution)}}$$

Then the following relation holds

$$k' = k(1+C_mPM\times 10^{-3})$$

and Eq. (2) is replaced by

$$\ln F/F_0 = -2k(1+C_mPM\times 10^{-3})(D/\pi)^{1/2}t^{1/2} \tag{4}$$

where

$$2k(1+C_mPM\times 10^{-3})(D/\pi)^{1/2} = G_m \tag{5}$$

Equations (4) and (5) well explain the linear relationship above CMC shown in Figs. 2 and 3.

From the Eqs. (3) and (5) we obtain

$$G_m = G_{sm}(1+C_mPM\times 10^{-3}) \tag{6}$$

Here G_{sm} expresses the value of G_s for SDS solution of critical micelle concentration. According to Eq. (6), P can be calculated from G_{sm} and the slope of G_m *vs.* C_m plot shown in Fig. 3. The value of P thus obtained was 3.62×10^3, which may be compared with similar data obtained for other substances by Herries.[10]

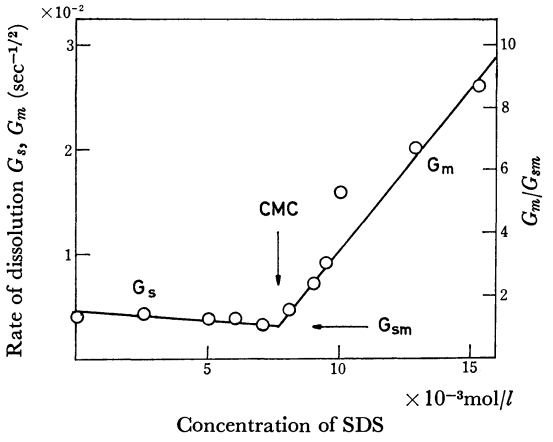

Fig. 3. Rate of dissolution of DOH monolayer into aqueous SDS.

Using this value of P, the amount of solubilization of dodecanol, C_{DOH}, was calculated from the following relation,

$$C_{DOH} = C_s(1+C_mPM\times 10^{-3}) \tag{7}$$

where C_s denotes the solubility of dodecanol in the aqueous SDS solution of CMC.

For the measurement of C_s, the solutions were prepared by adding varying amounts of DOH as small volumes of alcoholic solutions to the aqueous SDS solutions of CMC, and the transmittance of the solutions measured at the wave length of 350 mμ was plotted against DOH concentration. The value of C_s was evaluated as the DOH concentration corresponding to the intersection of two straight lines for the transparent and the turbid solutions. $C_s=2.2\times 10^{-4}$ mol/l was obtained at 25°C which is in agreement with the value estimated from the published data,[11] and with the data obtained by surface tension method.[12] Using this value and 7.7×10^{-3} mol/l for the CMC of SDS, C_{DOH} for instance of 7.9×10^{-4} mol/l, for SDS solution of 1×10^{-2} mol/l concentration, was obtained which agrees with 8×10^{-4} mol/l, calculated from the published data.[11,13]

The diffusion coefficients D of DOH in pure water

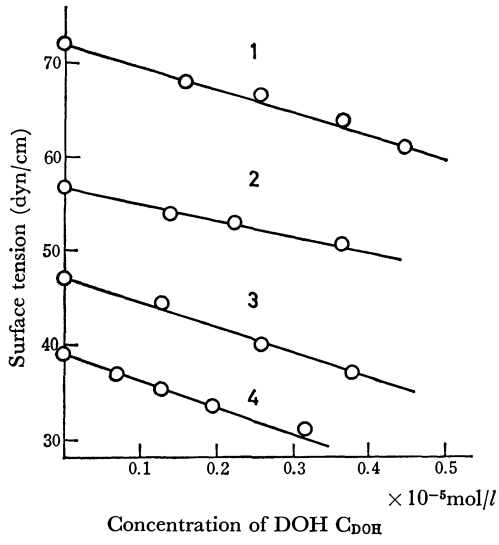

Fig. 4. Surface tension of aq. DOH solution containing SDS.
Conc. of SDS ($\times 10^{-3}$ mol/l)
1; 0 2; 0.77 3; 4.0 4; 7.7

and in aqueous SDS solution were estimated according to the Eq. (3). For this purpose, the measurements of surface tension σ against concentration C were made for the aqueous solutions of dodecanol containing SDS of a given concentration as shown in Fig. 4, from which k was calculated from the linear part of the curve at sufficiently dilute concentration, by applying the Gibbs adsorption isotherm,

$$1/k = \Gamma/C = -\frac{1}{RT}\frac{d\sigma}{dC}$$

From these values of k and the rate constant G_s for aqueous SDS solution, the diffusion coefficients of 16×10^{-6}, 6.9×10^{-6}, 12×10^{-6}, and 8.4×10^{-6} cm^2 sec^{-1} were obtained for 0, 0.77×10^{-3}, 4.0×10^{-3}, and 7.7×10^{-3} mol/l SDS solutions, respectively. Two of these values, especially the value for water, seem too high, presumably due to the evaporation of DOH not being negligible when we consider a fairly small solubility of DOH in pure water. Other values of diffusion constant are considered to be of right order of magnitude, compared with the value for a similar substance.[14]

The authors are grateful to the Ministry of Education for a grant in aid of scientific research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2921—2925 (1971)

Evidence of a Preresonance Raman Effect of the Base Residue in a Nucleic Acid

Masamichi TSUBOI and Seizo TAKAHASHI
Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo
Shuichi MURAISHI and Teruo KAJIURA
Japan Electron Optics Laboratory, Company, Nakagami, Akishima, Tokyo

(Received March 22, 1971)

The Ramam spectra of β-uridine-5′-phosphoric acid (UMP), its deuterated product, β-uridine-3′-β-uridine-5′-phosphoric acid (U_pU), and polyribouridylic acid (poly U) have been observed in their aqueous solutions; and the Raman lines assignable to the phosphate group and to the base residue have been indicated. For UMP, the intensity ratio of a Raman line of the base residue *versus* that of the phosphate group was found to become greater on changing the exciting line from the 6328 Å line of a helium-neon laser to the 4880 Å line of an argon ion laser. This fact has been taken as indicating that a preresonance Raman effect takes place of the base residue with the effective absorption at 2600 Å.

In the course of our investigation on the Raman effects of the nucleic acids, we noticed that the apparent intensity ratio of a Raman line assignable to a base residue *versus* that assignable to the phosphate group was often found to be markedly greater in the spectrum obtained with an argon ion laser than that in the spectrum obtained with a helium-neon laser. We suspected that this fact is ascribed to the so-called preresonance Raman effect. As is now well known, each base residue in a nucleic acid has a strong absorption band at about 2600 Å (molar extinction coefficient at 2600 Å is about 10^4), whereas the phosphate group has no strong absorption band in the spectral region from 7000 Å down to 1800 Å. Therefore, it seems quite probable that a great contribution comes from the electronic excited state corresponding to the 2600 Å band (*i.e.* a preresonance with the 2600 Å band takes place) in some Raman lines of base residues while it does not in the Raman lines of the phosphate group. In general, the intensity (I) of a Raman line is given, in an approximation,[1] by

$$I = C\mu^4_{eg}(\nu_0-\nu)^4(\nu^2_{eg}+\nu_0^2)^2/(\nu^2_{eg}-\nu_0^2)^4. \quad (1)$$

Here, C is a constant, ν_0, ν, and ν_{eg} are the frequencies

1) J. Behringer, in "Raman Spectroscopy", ed. by H. A. Szymanski, Plenum Press, New York (1967), p. 191.

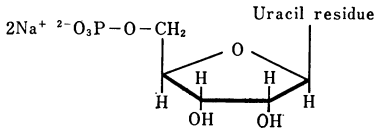
respectively of the exciting light, of a molecular vibration, and of the transition from the ground state to the lowest exicted electronic state; and μ_{eg} is the corresponding transition moment. If ν_{eg} is assumed to be 3.846×10^4 cm^{-1} (2600 Å) for the base residue and 5.556×10^4 cm^{-1} (1800 Å) for the phosphate group, the intensity ratio I(base)/I(phosphate) may be greater for $\nu_0=2.0487\times10^4$ cm^{-1} (4879.9 Å) line of argon ion laser than that for $\nu_0=1.5798\times10^4$ cm^{-1} (6328.2 Å) line of helium-neon laser. If the same value of μ_{eg} is assumed for the phosphate group as that for the base, for example, the value of ϕ defined by

$$\phi = \frac{[I(\text{base})/I(\text{phosphate})]_{Ar^+}}{[I(\text{base})/I(\text{phosphate})]_{He-Ne}} \qquad (2)$$

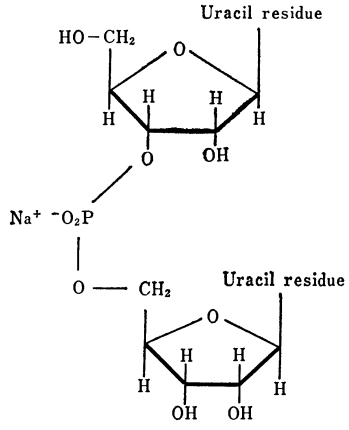
should be 1.6. Thus, the ϕ value is expected to be useful in characterizing each Raman line observed—it would tell whether the 2600 Å band is responsible for the Raman line in question, and if so how much. We attempted, in the present work, a measurement of these quantities for several Raman lines of β-uridine-5′-phosphoric acid in a neutral aqueous solution.

Experimental

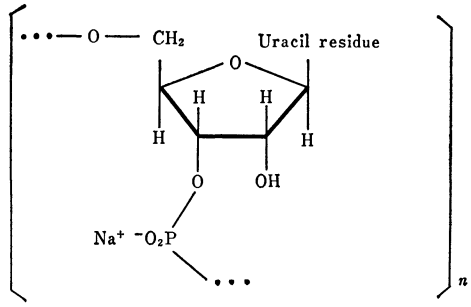
In the present paper the following three compounds are subjected to our examination: di-sodium salt of β-uridine-5′-phosphoric acid (5′ UMP),



sodium salt of β-uridine-3′-β-uridine-5′-phosphoric acid (U_pU),



and polyribouridylic acid,



The sample of 5′UMP was a gift from Takeda Chemical Industries, Ltd., and that of U_pU was purchased from Miles Chemical Company. The purity of these samples was confirmed by a chromatographic method. Poly U with the sedimentation constant $S_{20,w}=6.95$ S was purchased from Miles Chemical Company. For the observation of the Raman spectrum, about 0.2 m*l* of an aqueous solution of each nucleic acid was prepared. The concentration was about 5%. A small amount of NaOH was added in the solvent, and the pH of the solution was adjusted to 7.5 in every case. Each solution was placed in a cylindrical glass tube of 2 mm in inside diameter and 15 mm in length. The tube was placed vertically, and the laser beam was sent along the length of the tube through the flat glass plates at the lower and upper ends of the cylinder (see Fig. 1). The

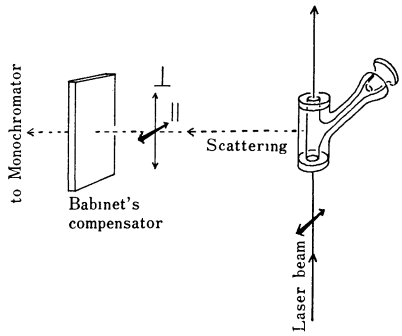


Fig. 1. Raman cell for aqueous solutions of nucleic acids. Polarization directions of excited light and scattered light.

Raman light scattered along a direction perpendicular to the excited beam (*i.e.* along a horizontal direction) was examined by the use of a JRS-Ul spectrophotometer of Japan Electron Optics Laboratory Co., Ltd. The polarization directions of the excited and scattered beam are shown in Fig. 1. The depolarization ratio ρ is defined by $\rho=I_\perp/I_{//}$, where $I_\perp$ and $I_{//}$ are the intensities of the scattered beams whose polarization directions are $\perp$ and // to that of the excited beam (see Fig. 1).

Results and Interpretations

First, in order to provide the data of assignments of the Raman lines of uridylic acids, those of 5′UMP, U_pU, and poly U (*i.e.* monomer, dimer, and polymer of uridylic acid) are shown in Fig. 2. For 5′UMP, Raman spectrum was observed not only in a H_2O solution but also in a D_2O solution, and the result is given in Fig. 2b. Frequencies, approximate intensities, and depolarization ratios of the Raman lines observed are listed in Table 1.

In a solution of pH (or pD)=7.5, the phosphate group of 5′UMP takes the form PO_3^{2-} with three P⋯O bonds having equal amounts (about one-third) of double-bond character. The phosphate group of U_pU or poly U, on the other hand, takes the form PO_2^- with two P⋯O bond having equal amounts (about one-half) of double-bond character. The characteristic vibrations of these PO_3^{2-} and PO_2^- groups were previously examined in detail,[2,3] and it was shown that symmetric

3) T. Shimanouchi, M. Tsuboi, and Y. Kyogoku, in Advances in Chemical Physics, Vol. VII, "The Structure and Properties of Biomolecules and Biological Systems," ed. by J. Duchesne, Wiley-Interscience, New York (1964), pp. 435—498.

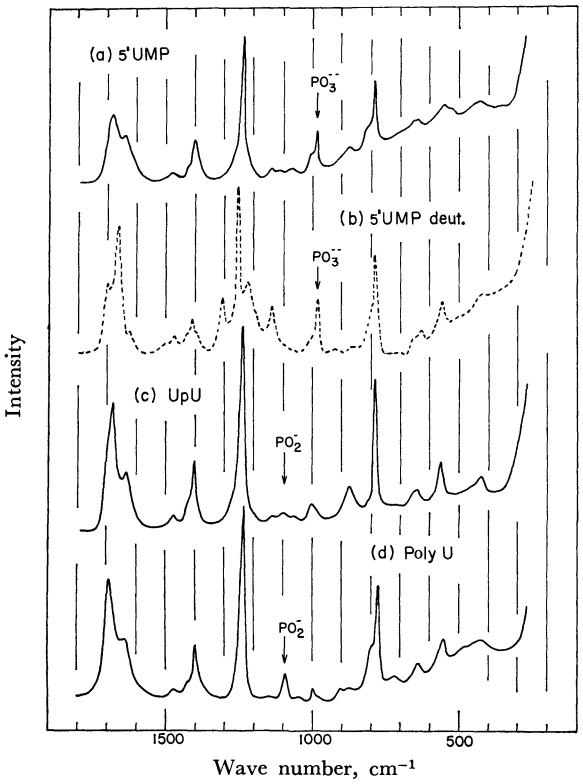

Fig. 2. Raman spectra of (a) 5'UMP, (b) deuterated 5'UMP, (c) U_pU, and (d) poly U in their 5% aqueous solutions at room temperature and at pH 7.5. Observed by the use of an argon ion laser (4880 Å line).

stretching vibrations of the PO_3^{2-} and PO_2^- groups give strong Raman lines respectively at 980 and 1100 cm^{-1}. This is found to be the case for 5'UMP, U_pU, and poly U. Thus, a sharp Raman line at 980 cm^{-1} is found for both of undeuterated and deuterated 5'UMP but not for U_pU and poly U, while a peak at 1100 cm^{-1} is observed only for U_pU and poly U. It is certain that the former is assignable to the PO_3^{2-} symmetric stretching vibration and the latter to the PO_2^- symmetric stretching vibration. The relative intensity of the 1100 cm^{-1} line is lower in U_pU than that in poly U. This is understandable because in U_pU only one half PO_2^- group is involved per uracil residue, whereas in poly U one PO_2^- group per uracil residue.

Most of the other Raman lines observed for 5'UMP are found also for U_pU and poly U at nearly the same frequencies (Fig. 2). Their relative intensities and depolarization ratios are also almost equal to those of the corresponding Raman lines of 5'UMP (Fig. 2, Table 1). This fact may be taken as indicating that these Raman lines are all assignable to vibrations in the uracil residue. At the same time, the fact indicates that the intra-molecular interactions, if any, are so weak between the uracil residues in the U_pU and poly U molecules, that they are hardly detected in the Raman spectra.

In Fig. 3, the result of our experiment for determining the ϕ values (defined by Eq. 2) of these Raman lines due to the base residue is shown. The two curves were recorded for the Raman scatterings from the same sample (20% 5'UMP in H_2O) by the use of the same

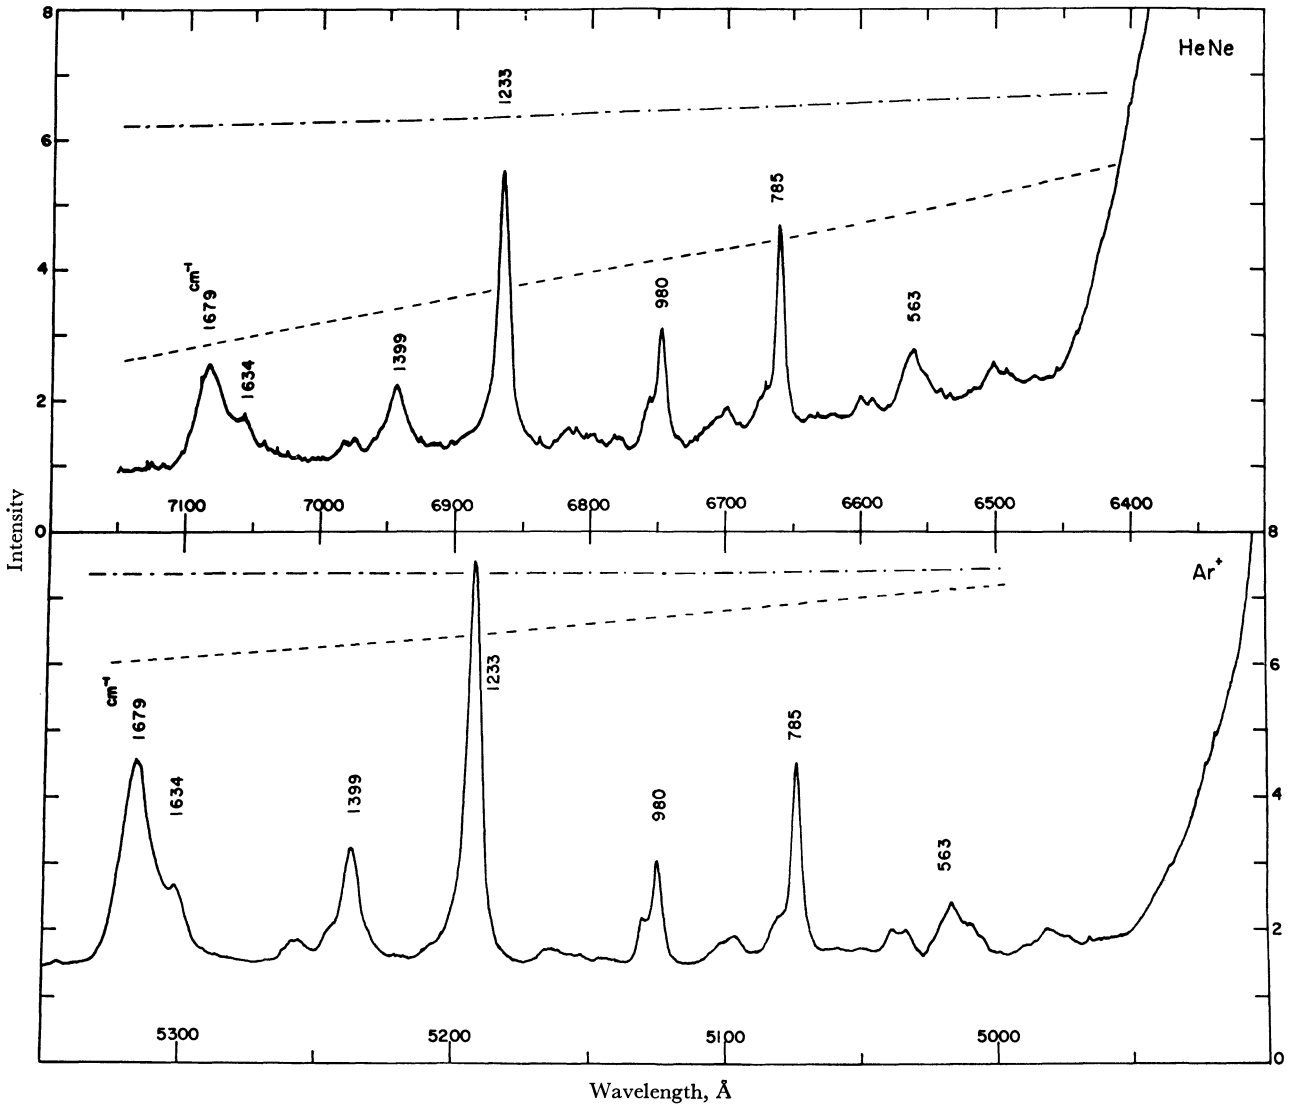

Fig. 3. A reproduction of the recorded curves for the Raman scattering from an aqueous solution (20%) of 5′UMP.
Upper: a helium-neon laser was used as the source of the exciting light (6328 Å beam).
Lower: an argon ion laser was used as the source of the exciting light (4880 Å beam).
Spectral slit width: 10.7 cm^{-1}. -·-·- shows the efficiency of the diffraction grating in the monochromator, and ------ shows the spectral response of the photomultiplier used.

spectrophotometer. One of them (upper) was obtained on exciting with the 6328 Å line of a helium-neon laser, whereas the other (lower) with the 4880Å line of an argon ion laser. The slit widths were adjusted (400 μ for the run with the helium-neon laser and 235 μ for that with argon ion laser) so that the spectral slit widths were approximately equal (10.7 cm^{-1}) for the two runs. As is readily seen in Fig. 3, the relative intensity of the 1233 cm^{-1} peak (base residue), for example, with respect to the 980 cm^{-1} peak (PO_3^{2-}) is greater in the curve (lower) with Ar^+ than that (upper) with He-Ne.

For obtaining the ϕ values (Eq. 2), corrections have been made for the efficiency of the diffraction gratings in the monochromator and for the spectral response of the photomultiplier. The monochromator contains two Jarrell-Ash No. 1297 Gratings (Cat. No. 980-45-20-22, 1180 grooves/mm 5000 Å blaze) and the efficiency-wavelength curve for each grating (reproduced by -·-·- in Fig. 3) was given by the manufacturer. The efficiency of the two gratings at each wavelength was assumed to be the square of the efficiency of one grating. The spectral response of the photomultiplier used (EMI 9558B) is given in EMI Technical Data and is reproduced by ------ in Fig. 3.

In Table 2, the ϕ values thus determined for six

Table 2. The values of ϕ defined by Eq. (2) for some Raman lines of 5′UMP.

Frequency, cm^{-1}	ϕ
563	1.1_2
785	1.2_1
980	(1.00)
1233	1.5_6
1399	1.6_0
1634	1.4_2
1679	1.6_3

stronger Raman lines (all assignable to vibrations in the uracil residue) are given. The ϕ values for the 1233, 1399, 1634, and 1679 cm^{-1} lines are approximately equal to the value 1.6 predicted above on the basis of Eq. (1) with $\nu_{eg}=3.846\times10^4$ cm^{-1} (2600 Å), and therefore it is now evident that a preresonance Raman effect takes place in each of these lines. All of these Raman lines are strongly polarized (depolarization ratio $\ll$ 0.75) and they are assignable to in-plane vibrations in the uracil residue.

For the strong Raman line at 785 cm^{-1}, on the other hand, the ϕ value is found to be much smaller (1.2). The depolarization ratio is very small for this line (0.2), and therefore this line is also assignable to an in-plane vibration in the uracil residue. Lord and Thomas[4] suggested that this line is caused by a ring-breathing type of motion. Eaton and Lewis[5] observed a vibrational structure in the 2600 Å band of a 1-methyluracil crystal with a spacing of 750 cm^{-1}, and they suggested that this frequency corresponds to the ground state frequency, 785 cm^{-1}. Thus, it is probable that the excited electronic state corresponding to the 2600 Å band of the uracil residue has its potential minimum at a position appreciably shifted from that of the ground state along the normal coordinate corresponding to the 785 cm^{-1} line. If so, one would expect a rather stronger preresonance effect and therefore rather greater ϕ value for the 785 cm^{-1} Raman line, in contrast to what is actually found. Professor T. Miyazawa (Osaka University), in his private communication, suggested that in the normal vibration corresponding to the Raman line at 785 cm^{-1} the atomic movements are not necessarily localized in the base residue. If the 785 cm^{-1} vibration consists of movements of the uracil and ribose groups, for example, and if an appreciable contribution to the intensity of the 785 cm^{-1} Raman line comes from the ribose part, the observed low ϕ value is certainly understandable.

A low ϕ value is found also for the 563 cm^{-1} line. This line shows somewhat greater depolarization ratio (Table 1), and it is probable that this is caused by an out-of-plane vibration of the uracil residue.

It has now been shown that the intensities of the Raman lines at 1233, 1399, 1634, and 1679 cm^{-1} are caused almost exclusively by the excited state of the uracil residue corresponding to the 2600 Å band, while the intensity of the 785 cm^{-1} Raman line is caused only partly by the 2600 Å excited state. In other words, Eq. (1) is nearly valid for the first four Raman lines while it is not for the 785 cm^{-1} line (other terms are necessary in the right side of Eq. (1)). If Eq. (1) is valid, the intensity of the Raman line should be proportional to μ^4_{eg}, *i.e.*, to the square of the ultraviolet absorption intensity of the 2600 Å band. Therefore, when an inter-base interaction (such as a hydrophobic stacking interaction[6]) causes a hypochromicity in the 2600 Å band of a uracil residue, it should cause a much more marked lowering in the intensities of the Raman lines at 1233, 1399, 1634, and 1679 cm^{-1}. Tomlinson and Peticolas[7] made a similar prediction on the basis of their theory,[8] but they actually found the intensity of the Raman line at 720 cm^{-1} of adenine residue to show a rather linear dependence on the ultraviolet absorbance.[7] We suspect that the 720 cm^{-1} line of the adenine residue has a similar nature to the 785 cm^{-1} line of the uracil residue. If so, what they found is understandable, because only a part of its intensity comes from the 2600 Å excited state, and only that portion of the intensity is proportional to μ^4_{eg} (2600 Å).

Structure and Rotational Isomerism of Ethylenediamine as Studied by Gas Electron Diffraction

Akimichi YOKOZEKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 22, 1971)

The structure and the rotational isomerism of ethylenediamine have been investigated by means of gas electron diffraction. Evidence has been given for the presence of one conformer (*gauche*) in the vapor phase (at 50—120°C); the N–C–C–N dihedral angle measured from the *cis* position is $64._0 \pm 4°$, and the fraction of any other isomer, if present, is estimated to be less than 5%. A theoretical prediction based on the SCF-CNDO/2 method has essentially accounted for this finding. The r_g distances and the angles based on the r_a structure determined by a least-squares analysis on molecular intensities, with estimated limits of error, are as follows: C–C=1.545± 0.008 Å, C–N=1.469 ±0.004 Å, ∠C–C–N=110.2 ±0.7°, C–H=1.10_9 ±0.01 Å, ∠C–C–H=$111._9$ ±5°, and ∠H–C–H=$112._7$ ±8°.

A previous paper[1] has reported on the molecular structure of triethylenediamine. One of the characteristic aspects is that this molecule has a twisting motion around the N···N axis, where the ethylenediamine bridges have a large-amplitude torsion about the *cis* conformation. Moreover, the C–C distance in the bridge is longer than those in normal alkanes by more than 0.02 Å.

On the other hand, the structure of free ethylenediamine has not been studied in detail, in contrast with extensive studies of its complexes by X-ray crystallography,[2] and the existing assignment of the vibrational data (infrared and Raman) to a single (*cis*) conformer was only tentative[3] (see Fig. 1). Under these circumstances, an electron-diffraction study was initiated in order to elucidate the structure and rotational isomerism of ethylenediamine in the gas phase. A preliminary result[4] has given evidence for a dominant *gauche* conformer. In the present paper a further analysis has been made in consideration of the hydrogen positions of the amino groups.

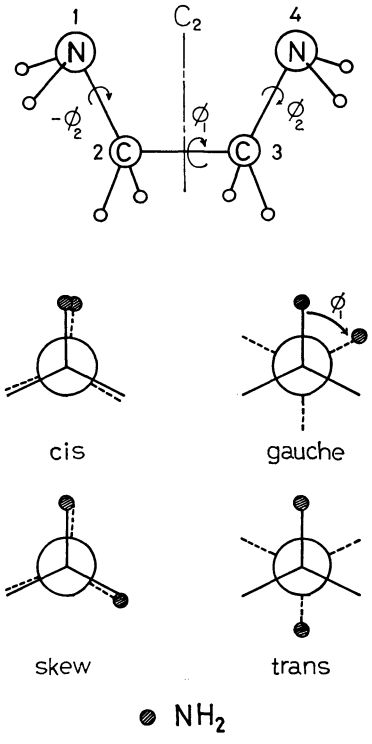

Fig. 1. Rotational isomerism for ethylenediamine. (See text).

Experimental

Anhydrous ethylenediamine (Guaranteed Reagent) obtained from the Tokyo Chemical Industry Co., Ltd. was used in this work. Diffraction photographs were taken on Fuji Process Hard plates at 55, 65, 90, and 118°C using an apparatus equipped with an r^3 rotating sector.[5] The sample was introduced into the diffraction chamber through a heated nozzle assembly,[1] and the above-mentioned temperatures were kept within ±1°C at the nozzle tip and in the sample flask during the experiment. The accelerating voltage was about 40 kV and was stabilized to within 1×10^{-4}. Two camera lengths of 114 and 249 mm were used, and the scale factors of the diffraction patterns were calibrated with reference to the r_a(C–O) distance of carbon dioxide (1.1646 Å)[5] for the shorter camera length and to the r_a(N–N) distance of nitrogen (1.1007 Å)[6] for the longer camera length. Four plates taken at each camera length with photographic densities ranging from 0.19 to 0.57 were used for the analysis. A typical experimental

molecular intensity $qM(q)$ ($q=7-130$ Å^{-1}) is illustrated in Fig. 2.[7] The intensity curves[8] derived from plates taken at different temperatures were not distinguishable from one another beyond the uncertainties in the measurement. Most of the calculations were carried out by the HITAC-5020E in the Computer Centre of the University of Tokyo.

Analysis

Ethylenediamine has two axes of internal rotation (C–C and C–N) as illustrated in Fig. 1. The parameters ϕ_1 and ϕ_2 represent, respectively, the dihedral angle between the N_1–C_2–C_3 and C_2–C_3–N_4 planes measured from the *cis* position and that between the planes which bisect the H–N_1–H and the H–C_2–H angles measured from the eclipse position.

In order to make the analysis tractable, the following assumptions were made.

1) The bond lengths and bond angles are independent of internal rotation.

2) The C–C–N plane is perpendicular to the H–C–H plane and bisects the H–C–H angle.

3) The C–N–H and H–N–H angles are equal to those in methylamine:[9] ∠C–N–H=112.1° and ∠H–N–H=105.9°.

4) The N–H bond distance is equal to that in ammonia,[10] r_g (N–H)=1.0302 Å.

5) The molecule has C_2 symmetry; *i.e.*, the ϕ_2 angles for the amino groups have equal values with opposite signs (Fig. 1).

On the above assumptions, seven parameters were chosen for the subsequent analysis: the C–C, C–N, and C–H bond distances, the C–C–N and H–C–H bond angles, and the ϕ_1 and ϕ_2 dihedral angles.

In addition, the mean amplitudes of vibration and shrinkage corrections[11] for all the atom pairs were calculated by a normal-coordinate analysis based on the force constants listed in Table 1, where the torsional force constants Y(C–C) (0.16 md·Å) and Y(C–N) (0.12 md·Å) were estimated so as to roughly reproduce the observed torsional frequencies[3] of 186 cm^{-1} for the C–C axis and 327 cm^{-1} for the C–N axis. The estimated value of Y(C–C) is justified in a later section. The calculated vibrational frequencies based on a staggered conformation ($\phi_1=\phi_2=60°$) by the use of the above force constants are given in Table 2. No refine-

ment of the force constants was made, since only a provisional assignment of the observed frequencies[3] was available. The mean amplitudes calculated for a number of conformers are given in Table 3. They were treated as constants until the final stage of the conformational analysis.

Conformational Analysis (I). The structural parameters were first estimated from a preliminary analysis of the molecular intensity on the assumption that the ϕ_2 angle was 60°. As a result of a least-squares analysis,[4] the following parameters were derived: C–C=1.55 Å, C–N=1.47 Å, and ∠C–C–N=110°. This analysis also gave the ϕ_1 angle of about 60°, *i.e.*, the "*gauche*" conformation about the skeleton.

This conformation was also evidenced in the radial distribution (RD) curve for $r \gtrsim 2.5$ Å. For the calculation of the RD curve with a damping factor of exp $(-0.00014q^2)$, a small-angle region (q=0—7 Å^{-1}) of the molecular intensity curve was spliced by a set of theoretical intensity curves computed for different ϕ_1 angles: 0° (*cis*), 60° (*gauche*), 120° (*skew*), and 180° (*trans*). As for the hydrogen positions in the NH_2 groups, contributions from three staggered positions were averaged. The experimental and theoretical RD curves for *cis*, *gauche*, *skew*, and *trans* forms are compared in Fig. 3. The N···N peak shown by vertical lines shows that the *gauche* form is dominant in the vapor phase. A further conformational analysis is made in later sections.

Refinements of Structural Parameters. In the preceding section, the skeletal parameters were determined on the basis of the ϕ_2 angle fixed to 60°. This parameter was now treated as an additional variable. When the analysis was started from 60, 180, and 300° (three staggered positions), it converged to 81, 200, and 308° with standard deviations of about 9°, and hence, the equilibrium hydrogen positions of the amino groups about the C–N axes seem to be staggered.

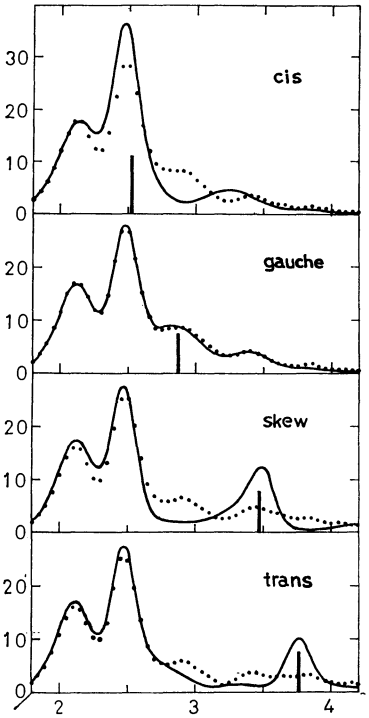

Fig. 3. Radial distribution curves for ethylenediamine. Dots: experimental; solid lines: corresponding theoretical curves for *cis*, *gauche*, *skew*, and *trans* conformers about the C–C axis with the index of resolution of 100%. Vertical line indicates the nonbonded N···N distance for each conformer.

In order to refine the structural parameters, the contribution to the scattering intensity from the atom pairs dependent on the internal rotation about the C–N axis was calculated by taking a weighted average of the intensity at every position of the ϕ_2 angle.[12,13] The weight was given by the Boltzmann distribution with a three-fold potential, $V(\phi_2)=\frac{1}{2}H_3(1+\cos 3\phi_2)$, where the barrier height H_3 was assumed to be 3.8 kcal/mol from the torsional force constant Y(C–N) of 0.12 md·Å mentioned above. In this treatment a rotation-inversion coupling was ignored, since the frequency of the NH_2 wagging motion is much higher than that of the torsion about the C–N axis.[3] Contributions from the skeletal vibrations to the mean amplitudes, $l(\phi_2)$, were obtained as a function,

$$l_i = a_i \sin\phi_2 + b_i \cos\phi_2 + c_i, \quad (1)$$

and the three parameters given in Table 3 were determined so as to reproduce the mean amplitudes calculated for several ϕ_2 angles.[12,13]

On the above-mentioned assumptions, the independent parameters and some of the mean amplitudes were determined by a least-squares analysis on the molecular intensity curves. The error matrix[14] derived from the analysis is given in Table 4. The results are listed in Tables 5 and 6 with the estimated limits of error including possible systematic errors. The experimental systematic errors primarily depend on the uncertainty in the electron wavelength (0.07%) and sector imperfection (0.05%),[15] whereas the systematic errors due to the assumptions made in the above analysis were estimated by the method described elsewhere[16] with moderate changes in the assumed values to be of the order of the corresponding random standard errors.

Conformational Analysis (II). For a quantitative examination of the fractions of the *gauche* conformer and other possible candidates, a background analysis[17] was undertaken by the use of the scattering intensity observed in a small-angle region (q=7—20 Å^{-1}). The background function $I_b(q)$ is given by $I_b(q)=I_0(q)/[1+kM_c(q)]f(q)$. "Smoothness" of the $I_b(q)$ function, which should have no systematic fluctuation with a period similar to that of the molecular intensity, was taken as a criterion for the choice of a correct structural model. The index of resolution k was assumed to be unity, and an empirical quartic function $f(q)$ was used

for leveling the total intensity $I_0(q)$. Theoretical molecular intensities $qM_c(q)$ were based on the structural parameters determined above, except that the ϕ_1 parameter was taken to be 0, 60, 120, and 180°. Typical I_b curves are illustrated in Fig. 4. The I_b curve corresponding to 100% *gauche* population is flat to within 0.5% of I_b, while other models are definitely unacceptable because of the systematic oscillations in the I_b curves.

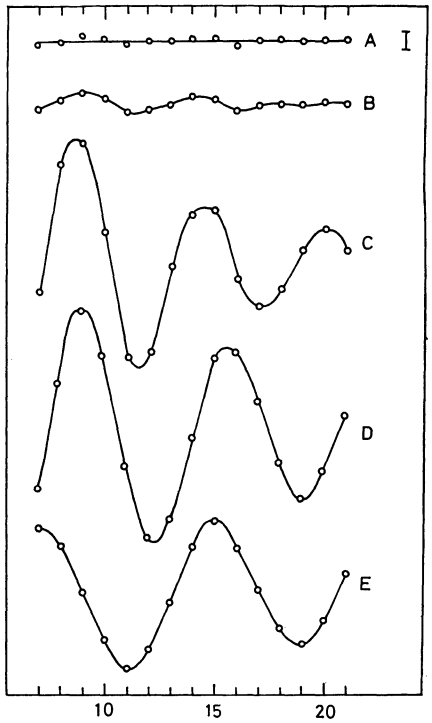

Fig. 4. Background functions I_b for different compositions of the *gauche* and other conformers. (See text).
(A) *gauche* (100%); (B) *gauche-trans* (95%: 5%); (C) *trans* (100%); (D) *skew* (100%); (E) *cis* (100%). The vertical bar represents the magnitude of 0.5% of I_b.

The limit of uncertainty in the above results was estimated from two principal sources of errors:[17] (A) random errors in the intensity measurement and (B) uncertainties in the structural parameters assumed in the analysis. The noise levels in I_b due to (A) was estimated to be 0.2% from the reproducibility of photographic measurements. Furthermore, the I_b function of nitrogen obtained by the same procedure had no fluctuation exceeding 0.2%. On the other hand, the

uncertainties due to (B) originated principally from the assumption of the ϕ_2 parameter. In this analysis, the amino-hydrogen positions were averaged with a threefold potential $V(\phi_2)$ as mentioned in the preceding section. The systematic error due to this assumption was estimated to be 0.3% of I_b from similar analyses using the ϕ_2 parameter fixed to the staggered positions.

Therefore, the total uncertainty level of I_b was estimated to be 0.4%, corresponding to the limit of uncertainty in the concentration of 5%. Hence, in the temperature range from 50 to 120°C at least 95% of the molecule takes the *gauche* conformation in the gas phase.

Discussion

Structural Parameters. The C–C bond distance, 1.545 Å, seems to be about 0.01 Å longer than that in ethane, 1.534 Å,[18] while the C–N bond distance, 1.469 Å, is similar to that in methylamine, 1.467 Å.[19] The C–C–N bond angle, 110.2°, is nearly equal to the tetrahedral angle and is smaller than the C–C–C angles in normal alkanes (*e.g.*, 112° for butane).[20] The azimuthal angle ϕ_1, found to be 64°, is similar to that in butane[20] and is about 10° smaller than those in 1, 2-dichloroethane[21] and ethylene glycol.[22]

A related bicyclic compound, triethylenediamine,[1] has analogous C–C–N angle and C–N distance, whereas the C–C distance in triethylenediamine, 1.562 Å, is significantly longer than that in ethylenediamine. A similar lengthening in the C–C bond in a bicyclic compound as compared with normal alkanes has also been suggested for bicyclo[2.2.2]octane.[12]

The observed mean amplitudes, listed in Table 6, agree with the calculated values, which have comparable uncertainties. The calculated N···N amplitude is sensitive to the choice of Y(C–C): *e.g.*, 0.1641 Å for Y=0.11 md·Å and 0.1805 Å for Y=0.083 md·Å[23] (corresponding to that in ethane). Therefore, from the observed N···N amplitude of $0.145_4 \pm 0.037$ Å one can estimate Y(C–C) to be 0.16_7 md·Å. The Y value determined in this way[24] is about twice as large as that for ethane and is nearly equal to that for the *gauche* form of 1,2-dichloroethane, 0.16 md·Å.[25]

Rotational Isomerism. The *gauche* conformer is found to be by far the most stable in the gas phase; the fractions of any other conformers, if present, should not exceed 5%. This is analogous to the case of ethylene glycol[22] and contrasts with that in 1,2-dichloroethane,[21,26] where the *trans* form is about 1.14 kcal/mol more stable than the *gauche* form.

In order to examine the rotational isomerism in this molecule, a conformational analysis was carried out by a SCF-MO (CNDO/2) method[27] by the use of a program written by Segal.[28] The azimuthal angles ϕ_1 and ϕ_2 were varied systematically in all directions. Other structural parameters were fixed to the values determined in the present study. The results are illustrated in Fig. 5 as a contour map. The areas where

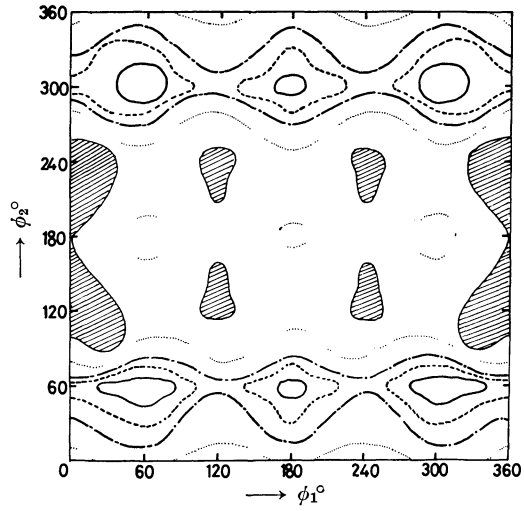

Fig. 5. Contour map for the potential energy of internal rotation of ethylenediamine calculated by the SCF-CNDO/2 method. (See text).
——: limits within 1 kcal/mol above the deepest minimum; ------: 2 kcal/mol; —·—: 3 kcal/mol; ·····: 5 kcal/mol. Shaded regions indicate local maxima 10 kcal/mol above the minimum.

the energies are less than 1 kcal/mol above the deepest minimum, enclosed in solid lines, are located in the neighborhood of ϕ_1=60° (*gauche*) and 180° (*trans*), with ϕ_2=60° or 300° (staggered). The cross sections of the energy surface at ϕ_2=60° or 300° show that the *gauche* form (ϕ_1=60°) is about 0.9 kcal/mol more stable than the *trans* form (corresponding to the equilibrium fraction of about 10% around 100°C) and that the barrier heights at ϕ_1=0° and 120° are about 1.5 and 2.8 kcal/mol, respectively. The theoretical prediction about the *gauche*-minimum agrees with the present experiment, whereas the predicted energy difference between the *trans* and *gauche* forms is much too small. This discrepancy seems to be due to the fault in the theory, since the CNDO/2 method often gives proper estimates of molecular geometry but fails to predict correct energies.[29] More reliable information on the potential function should await future spectroscopic measurements.

Solvent Effects on the Spin-Lattice Relaxation Times and Chemical Shifts of *N*-Methylacetamide and *N*,*N*-Dimethylacetamide in Hydrogen Bonding Solvents

Kazuo SATO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received April 3, 1971)

The proton spin-lattice relaxation and the chemical shift were studied in *N*-methylacetamide (NMA) and *N*,*N*-dimethylacetamide (DMA) in *p*-dioxane and chloroform. In the *p*-dioxane solution, it has been found that the self-association of NMA does affect its spin-lattice relaxation, whereas the amide-solvent association does not affect it entirely. This was interpreted in terms of the lifetime of the inter-amide ($\simeq 10^{-11}$—10^{-12} sec) and the amide-solvent association (much shorter than 10^{-11}—10^{-12} sec). On the other hand, the effect of the amide-solvent association on the spin-lattice relaxation is pronounced in chloroform, as is the effect of the self-association of NMA. The inter-amide interaction which leads the double-bond character of DMA to be more stable was not reflected distinctly in the concentration dependence of the spin-lattice relaxation times of DMA.

The inter-molecular interactions and self-association phenomena of amides in solutions have been the subjects of a considerable number of experimental and theoretical discussions, and have been studied quantitatively by using IR, the NMR-chemical shift, the thermodynamic technique, *etc.*[1]

In our previous paper,[2] we studied the proton spin-lattice relaxation and chemical shift of *N*-methylacetamide (NMA) and *N*,*N*-dimethylacetamide (DMA) in aqueous (D_2O) and non-polar (CCl_4) environments, and pointed out that, in addition to the chemical shift, the spin-lattice relaxation time (T_1) measurements are useful in providing basic information for understanding the molecular motion, the non-equilibrium properties, and the inter-amide interactions.

In this paper, we will report on T_1 and chemical-shift measurements of NMA and DMA as well as of solvent molecules, *p*-dioxane, and chloroform, which have been well known to act as hydrogen-bonding proton acceptors and donors respectively. We will discuss the molecular motion and the inter-amide and amide-solvent interactions in these solutions on the basis of our experimental results on the T_1's and chemical shifts of the protons of solute and solvent molecules. Moreover by comparing the results of the NMA solutions with those of the DMA solutions, further information on the peptide-bond character will be obtained.

It is useful to compare the results of the T_1's with those of the chemical shifts on amide solutions in order to understand the hydrogen-bonding phenomena in detail, for the former depends on non-equilibrium properties, whereas the latter depends on equilibrium properties.

Experimental

Materials. The NMA, DMA, *p*-dioxane, and chloroform were reagent-grade samples purchased from the Tokyo Kasei Co., Ltd. The chloroform-*d* and *p*-dioxane-d_8 were provided by E. Merck A G., Darmstadt. The atmospheric oxygen dissolved in the samples was carefully removed by several freeze-pump-thaw cycles in a NMR tube; then, under a vacuum, the sample tube was sealed off.

NMR Measurements. The NMR instrument used was a JNM-C-60H spectrometer operated at 60MHz; the measurements of T_1 were performed at 25 ± 1°C by adiavatic-rapid-passage or saturation-recovery methods. The experimental errors were smaller than $\pm5\%$ in every case. Two T_1's of the non-equivalent *N*-methyl protons of DMA were in agreement with each other within the range of experimental errors, so we adopted the T_1 of *N*-methyl as the average value. The chemical shifts were measured at 25 ± 1°C by the usual side-band-technique, using tetramethylsilane as the internal reference. Other experimental details appeared in the previous paper.

Results and Discussion

Before discussing the results of the spin-lattice relaxation and chamical-shift measurements, we should like to mention the method of analyzing the data. The obserbed spin-lattice relaxation time, $(T_1)_{obs}$, is expressed as follows for solute and solvent molecules respectively, taking all the possible contributions into account:

$$(T_1^{-1})_{obs}^{solute} = (T_1^{-1})_{intra} + (T_1^{-1})_{inter}^{solute\text{-}solute} + (T_1^{-1})_{inter}^{solute\text{-}solvent} \quad (1)$$

$$(T_1^{-1})_{obs}^{solvent} = (T_1^{-1})_{intra} + (T_1^{-1})_{inter}^{solvent\text{-}solvent} + (T_1^{-1})_{inter}^{solvent\text{-}solute} \quad (2)$$

where $(T_1^{-1})_{intra}$ and $(T_1^{-1})_{inter}^{solute\text{-}solute}$ represent the intramolecular and the solute-solute intermolecular magnetic dipolar contributions respectively, and where $(T_1^{-1})_{inter}^{solute\text{-}solvent}$ refers to the solute-solvent intermolecular contribution, which indicates the magnetic effects of the solvent protons on the spin-lattice relaxation of solute protons. Deuteron and chlorine are considered to contribute negligibly to the relaxation of the protons because of their small magnetogyric ratios. Each term in Eq. (2) represents a similar contribution.

$(T_1^{-1})_{intra}$ and $(T_1^{-1})_{inter}$ depend on the rotational and the relative translational motions of the molecules. $(T_1^{-1})_{intra}$ can be expressed as Eq. (3) in terms of

1) For example, S. Mizushima, "Structure of Molecules and Internal Rotation," Academic Press, New York (1954), Chap. 6; G. C. Pimentel and A. L. McClellan "The Hydrogen Bond," W. H. Freeman and Company, San Francisco, California (1960), Chap. 3.

the interprotonic distance, r_{ij}, and the rotational correlation time, τ_c: [3,4]

$$(T_1^{-1})_{\text{intra}} = \frac{3}{2}\hbar^2\gamma^4\sum_j\langle r_{ij}^{-6}\rangle\cdot\tau_c \qquad (3)$$

where $\hbar$ is Plank's constant divided by 2π, and where γ is the magnetogyric ratio of the proton. We estimated the $(T_1^{-1})_{\text{intra}}$ of NMA and DMA by the extrapolation procedure to infinite dilution, and calculated τ_c by Eq. (3), taking into account the molecular geometries of NMA and DMA.[5]

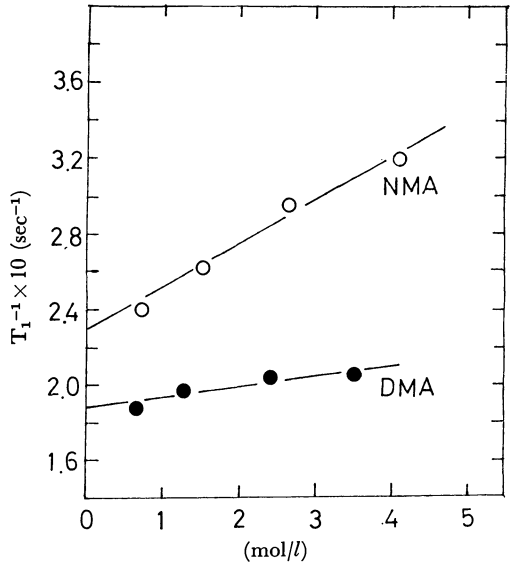

Fig. 1. Relaxation rate of methyl protons of amides *vs.* concentration of NMA (○) and DMA (●); *p*-dioxane solutions.

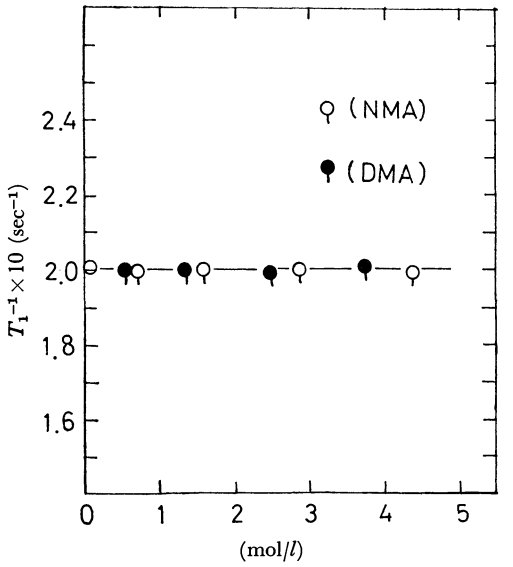

Fig. 2. Relaxation rate of solvent protons *vs.* solute concentration; *p*-dioxane solutions.
solute; NMA-♀, DMA-♀

p-Dioxane Solution. The concentration dependences of the spin-lattice relaxation rates, T_1^{-1}, of NMA, DMA, and the solvent are shown in Figs. 1 and 2 respectively. The T_1 values of the *C*-methyl protons are almost equal to those of *N*-methyl in both amides within the limits of experimental error. From the observed linear plot of T_1^{-1} *vs.* the concentration of the amide, we can extrapolate the results to infinite dilution. The T_1's of the solvent are almost independent of the concentration of the amide. This means that $(T_1^{-1})^{\text{solvent-solute}}_{\text{inter}}\simeq 0$ and $(T_1^{-1})_{\text{intra}}$, $(T_1^{-1})^{\text{solvent-solvent}}_{\text{inter}}$ are not affected by the amide-solvent interactions. It is interesting to note that the hydrogen bonding with NMA does not affect the spin-lattice relaxation of *p*-dioxane.

The spin-lattice relaxation is governed by the microscopic molecular motions and the ratio of the correlation times of the motion to the lifetime of molecular association. Recently, Anderson and Fryer[6,7] and Marshall[8] have discussed theoretically and experimentally the effect of molecular association on the spin-lattice relaxation, and concluded that, if the lifetime of the associated molecules moving as a unit is longer than the correlation times of motion (for most liquids, the correlation times are of the order of 10^{-11}—10^{-12} sec), the effect of association is pronounced, whereas the effect is small if the lifetime is shorter. In view of this, the lifetime of the hydrogen bonding between NMA and *p*-dioxane is probably much shorter than 10^{-11}—10^{-12} sec. We have previously studied the effects of the molecular association on the spin-lattice relaxation in mixtures of chloroform and proton-acceptor solvents, such as dimethyl sulfoxide, pyridine, acetone, and benzene, and shown that the association with a larger association constant does more remarkably affect the spin-lattice relaxation of chloroform, while the weak association has no effect at all.[9] Thus, it is considered that the association between NMA and *p*-dioxane through the hydrogen bonding is very weak and that the association constant may be small.

LaPlanche, Thompson, and Rogers[10] have studied theoretically the chain-association equilibria based on the model that the solute molecules form chain-like polymers through self-association, and that either the solvent molecules associate with the solute or do not. They have also applied the theory to the chemical-shift measurements of *N*-monosubstituted amides in solutions. From the equilibrium constants found for *N*-isopropylacetamide in *p*-dioxane and chloroform, they have concluded that chloroform and *p*-dioxane

compete with approximately the same efficiency for the hydrogen bonding of *N*-isopropylacetamide. They have also studied NMA in chloroform, and found that chloroform associates with NMA; however, they have not examined it in *p*-dioxane. There is no guarantee that their conclusion about *N*-isopropylacetamide mentioned above holds also in the case of NMA in *p*-dioxane. Moreover, we must give attention to the fact that they measured the chemical shift on the basis of an internal reference. It has been established that the resonance frequncies of internal-reference compounds are often considerably influenced by solvent effects.[11] In order to discuss the results in detail and quantitatively, it will be necessary to measure the chemical shifts on the basis of an external reference and to correct for differences in the bulk diamagnetic susceptibility between the sample and the reference compound. It seems necessary to reexamine this problem over a wide range of experimental conditions for both the T_1 and the chemical shift.

From the experimental facts mentioned above, that $(T_1^{-1})_{inter}^{solvent\text{-}solute} \simeq 0$, and that the amide-solvent association does not affect the spin-lattice relaxation of *p*-dioxane, it can reasonably be assumed that the T_1's of amide protons are also not affected by *p*-dioxane. We measured the T_1 of NMA in *p*-dioxane-d_8(2.7 mol/*l* of NMA) and found that $T_1^{-1}=2.8\times10^{-1}(sec^{-1})$. This value is almost equal to that in *p*-dioxane, and the assumption that $(T_1^{-1})_{inter}^{solute\text{-}solvent} \simeq 0$ holds. Therefore, the values extrapolated to infinite dilution are identical to the $(T_1^{-1})_{intra}$ of amides. The values of $(T_1)_{intra}$ and τ_c of NMA and DMA are shown in Table 1. The τ_c's of *C*-methyl and *N*-methyl protons in the same molecule are almost equal for both NMA and DMA, but the values of NMA are longer than those of DMA by a factor of about 1.2—1.3. We consider that this is the effect of the self-association of NMA in solutions. Klotz and Fransen[12] also con-

cluded, on the basis of IR measurements, that, in *p*-dioxane, the self-association of NMA is appreciable at moderate concentrations. The low-field shift of the N–H proton with an increase in the concentration of NMA is considered to support the self-association of NMA in *p*-dioxane (Fig. 3).

The τ_c's of NMA estimated in the present study are considered to characterize the rotational motions of NMA restricted slightly in a weakly-associated chain. Moreover, it is concluded that the lifetime of the inter-amide hydrogen bonding may be of the order of 10^{-11}—10^{-12} sec. The larger concentration dependence of the T_1^{-1} of NMA than that of DMA also means that the rotational and translational mobilities of NMA are reduced through the hydrogen bonding.

In Fig. 4, the concentration dependence of the chemical shift between the two *N*-methyl protons of DMA is shown in *p*-dioxane as well as in chloroform. The origin of the nonequivalence of the two *N*-methyl groups has been understood to be due to the double-bond character of the central C–N linkage.[13] The increase in the chemical shift with an increase in the concentration of amide has been considered to be due to the inter-amide interaction, which leads the double-bond character to be more stable.[14–16] This inter-amide interaction has no appreciable effect on the concentration dependence of T_1, which is almost linear over the experimental range of the concentrations of amide. In carbon tetrachloride, remarkable effects of the inter-amide interaction on T_1 of DMA have been observed, and the concentration dependence of T_1 at moderate concentrations differs from that at dilute concentrations.[2] The absence of the effects of the inter-amide interaction on T_1 is considered to be due to the fact that, in *p*-dioxane, the lifetime of the inter-amide interaction is shorter than that in carbon tetrachloride. The chemical shift between two *N*-methyl protons in *p*-dioxane is smaller than in carbon tetrachloride; we consider this also to be due to the weak inter-amide interaction in *p*-dioxane. The slight increase in the relaxation rate with an increase in the concentration of amide may be the result of the increase in the spin-densities of the solutions.

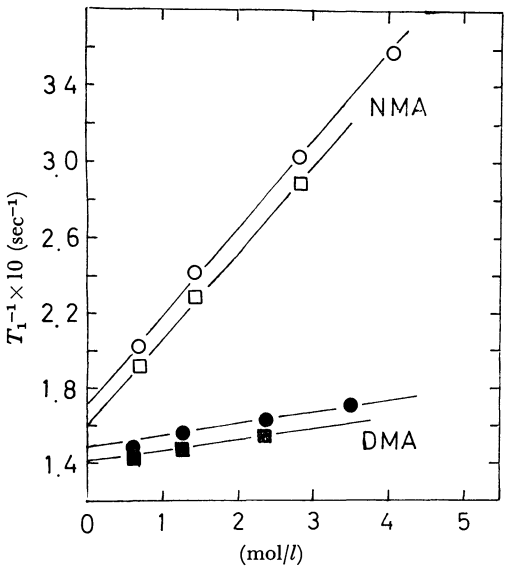

Fig. 5. Relaxation rate of methyl protons of amides *vs.* concentration of NMA (○-chloroform solutions, □-deuteriochroform solutions) and DMA (●-chloroform solutions, ■-deuteriochloroform solutions).

Chloroform Solution. The concentration dependences of the T_1^{-1}'s of NMA and DMA are shown in Fig. 5. As in the case of *p*-dioxane solutions, the T_1's of *C*-methyl and *N*-methyl protons in the same molecule are identical with each other, and the plot of T_1^{-1} *vs.* the concentration of the amide is also linear. By extrapolation in chloroform-*d* solutions, we obtained $(T_1)_{\text{intra}}$ and calculated the values τ_c of both amides (Table 1). The fact that the τ_c's of NMA are longer than those of DMA by a factor of about 1.2, and the large concentration dependence of T_1^{-1} of NMA are attributable to the self-association. Moreover, the lifetime of the association is considered to be almost identical to that in the *p*-dioxane solution. The effect of the association on the N–H proton chemical shift can easily be seen; it moves to a low field with an increase in the concentration of amide (Fig. 3).

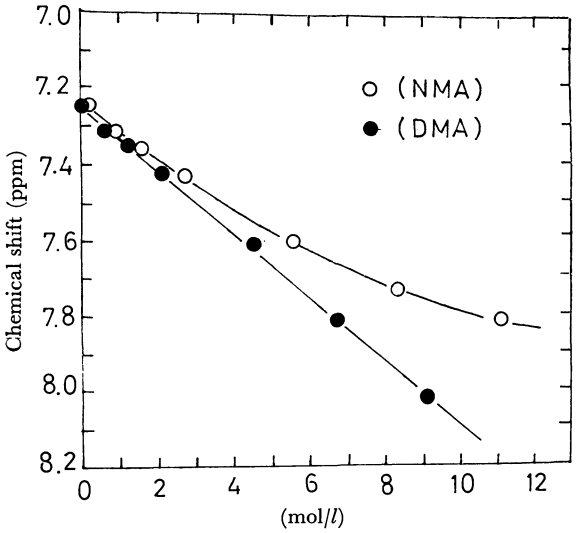

Fig. 6. Chemical shift of chloroform proton *vs.* solute concentration. solute; NMA-○, DMA-●. Chemical shift were measured downfield from internal TMS.

The chemical shifts of the chloroform proton depend upon the concentrations of the amides, as is shown in Fig. 6. A linear relation is observed in the DMA solution, but not in the NMA solution. The low-field shift of the chloroform proton is caused by the formation of hydrogen bonding with amides and the magnetic anisotropy effect due to the carbonyl group. The linear low-field shift in the DMA solution may be the result of the approximate 1 : 1 amide-solvent association. On the other hand, the smaller and non-linear change in the NMA solution suggests that the inter-amide hydrogen bonding becomes predominant over the amide-solvent hydrogen bonding with an increase

in the concentration and, consequently, decreases the fraction of the solvent molecules participating in the hydrogen bonding with amide.

In Fig. 7 the dependence of T_1^{-1} of the chloroform proton on the concentrations of the amides is shown. The spin-lattice relaxation of the solvent is considerably affected by the presence of amides; this is strikingly different from the case with *p*-dioxane solutions. This pronounced effect of amides can be interpreted in terms of the amide-solvent association, whose lifetime is almost equal to or longer than 10^{-11}—10^{-12} sec. As has been mentioned above, in the NMA solution the fraction of solvents participating in the hydrogen bonding with amides is considered to be smaller than in the DMA solution. Nevertheless, the effect of the NMA on the T_1's of the chloroform proton is more remarkable. In the NMA solution, chloroform associates with amide and breaks up the self-associated chain to some degree, and it must interact with the terminal carbonyl group of the broken chain. The molecular motion of chloroform associating with the chain-terminal is restricted to a greater degree than that in the DMA solution. Thus, the effect of the hydrogen bonding with NMA on the spin-lattice relaxation of the chloroform proton is considered to be more pronounced in spite of the samller fraction of associated chloroform molecules. As in the case of the *p*-dioxane solution of DMA, the effect of the inter-amide interaction of DMA which leads the double-bond character to be more stable is not observable distinctly over the range of experimental concentrations.

In our previous paper, we have estimated the τ_c's of NMA and DMA in D_2O solutions: $\tau_c=2.5\times10^{-12}$ sec. These values are almost equal to those in chloroform solutions. The BPP theory predicts $\tau_c=4\pi\eta a^3/3kT$ for the rigid molecules, where η and a represent solution viscosity and the radius of a spherical molecule respectively.[3] The solution viscosities of D_2O solutions are larger by a factor of about 2 than those of chloroform solutions;[17] therefore, according to this theory, the τ_c's in chloroform must be shorter than those in D_2O. This can be explained by considering that, in chloroform, the molecular motion of amides is reduced through the amide-solvent association and the self-association of amide (NMA), which may in turn lead the micro-viscosities of the solutions to be higher.

An MO-theoretical Interpretation of the Nature of Chemical Reactions III. Bond Interchange

Hiroshi FUJIMOTO, Shinichi YAMABE, and Kenichi FUKUI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received April 5, 1971)

The wave functions of a system composed of two mutually-interacting molecules have been expressed in terms of configuration interaction wave functions. The electron configurations have been taken into account with respect to the states of adiabatic interaction, delocalization interaction, and polarization interaction. The electron populations in all of these states have been obtained separately. It has been demonstrated that the adiabatic interaction between two closed-shell molecules can not be the origin of the bond interchange in chemical reactions. The inclusion of charge-transferred states has been shown to be of great importance in explaining the formation of new bonds and the weakening of old bonds in the case of chemical interaction between two molecules. On the basis of the results of numerical calculations on some typical reaction models, the important role of the orbital overlapping interaction of the highest occupied molecular orbital and the lowest unoccupied molecular orbital has been pointed out.

The interaction energy between two mutually-reacting molecules has been investigated by partitioning it into the Coulomb-interaction, exchange-interaction, delocalization, and polarization terms on the assumption of no nuclear configuration change.[1] Expressions for these four energy terms have been derived. The important role of electron delocalization in determining the favorable position and spatial direction of chemical interaction with respect to each of the two reacting molecules has been pointed out on the basis of the three governing principles of chemical interaction.[2] The significance of the cooperation of the charge-transfer and the nuclear configuration change has been stressed in relation to the nodal properties of the highest occupied (HO) molecular orbital (MO) and of the lowest unoccupied (LU) MO. The purpose of the present paper is to show how and why the formation of new bonds and the cleavage of old bonds take place in chemical reactions. This seems to be one of the most fundamental problems in understanding the nature of chemical reactions.

Wave Functions

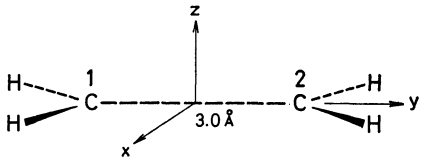
Let us consider the chemical interaction between the molecules A and B. Here we set limits to the case in which both A and B have closed-shell structures in the isolated state. Only a slight modification should be needed for other systems. We represent the wave function of the combined system of the two molecules, A and B, by the configuration interaction (CI) wave function;

$$\Psi = C_0\Psi_0 + \sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}\Psi_{i\to l} + \sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}\Psi_{k\to j} + \sum_i^{\text{occ}}\sum_j^{\text{uno}} C_{i\to j}\Psi_{i\to j} + \sum_k^{\text{occ}}\sum_l^{\text{uno}} C_{k\to l}\Psi_{k\to l} + \cdots \quad (1)$$

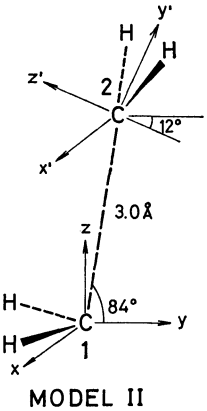
The meanings of the wave functions Ψ_0, $\Psi_{i\to l}$, $\Psi_{i\to j}$, $\cdots$ are the same as those in Ref. 1. These wave functions are constructed by means of the Slater determinants, composed of the MO's, a_i's, and a_j's of the molecule A and the b_k's and b_l's of the molecule B, according to each electron configuration. Other highly-transferred and highly-excited configurations can be neglected, provided the interaction is not too strong. The coefficients, C_0, $C_{i\to l}$, $C_{i\to j}$, $\cdots$, can be obtained by solving the secular equations. The integrals which are necessary in constructing the secular determinant have already been derived in Ref. 1. The coefficients of the wave function, Ψ, are taken so as to satisfy the normalization condition:

$$\int \Psi^2 d\tau = 1 \quad (2)$$

In order to obtain the expressions of the electron populations of the interacting systems by the use of Ψ, it is convenient to represent them as the sum of the electron populations in each of the terms appearing in Eq. (1). For this purpose, we present the first-order density matrices[3] of some of the terms in Appendix. In the following



MODEL I



MODEL II

discussions, the contribution from polarized configurations may be disregarded so long as we concentrate our attention on the intermolecular charge-transfer between A and B. The off-diagonal terms $\rho_{JJ'}$ $(J \neq J')$ (see Appendix), in which neither J nor J' is 0, are put equal to zero in a first approximation.

The example taken here to show the numerical results is the dimerization of singlet methylenes to form ethylene. This system was discussed by Hoffmann and his coworkers in order to demonstrate the preference of the non-least motion to the least motion in the mutual approach of methylenes by the use of the extended Hückel calculation.[4] We will compare the two modes of approach by means of our method, from the standpoint of mutual electron-donating and electron-accepting interactions. The two models are schematically illustrated in Fig. 1. The relative nuclear positions of the two methylenes are the same as those determined by Hoffmann. In Tables 1 and 2 we present the coefficients, C_0, $C_{i\to l}$'s, and $C_{k\to j}$'s, with respect to the two models in Fig. 1. The method of calculation and the approximations employed are the same as those adopted in our previous calculation.[5] It is clear that the charge-transfer interaction is by far more effective in Model II than in Model I.

Formation of New Bonds

Let us divide the electron populations into two parts, intermolecular and intramolecular. First, let us try to connect this concept to the origins of the formation of new bonds between A and B. The AO bond population between the AO t of A and the AO u of B is given by:

$$\phi_{tu} = \phi_{tu}^{(E)} + \phi_{tu}^{(D)} \tag{3}$$

$\phi_{tu}^{(E)}$ is the AO bond population between t and u due to the exchange interaction:

$$\phi_{tu}^{(E)} \cong C_0^2(\phi_{tu}^{(E)})_0 + \sum_i^{\text{occ}} \sum_l^{\text{uno}} C_{i\to l}^2(\phi_{tu}^{(E)})_{i\to l} + \sum_k^{\text{occ}} \sum_j^{\text{uno}} C_{k\to j}^2(\phi_{tu}^{(E)})_{k\to j} \tag{4}$$

$$(\phi_{tu}^{(E)})_0 \cong -4(M!)\mathcal{N}_0^2 \sum_i^{\text{occ}} \sum_k^{\text{occ}} c_t^{(i)} c_u^{(k)} s_{tu} S_{ik} \tag{5}$$

where $c_t^{(i)}$ is the coefficient of the AO t in the MO a_i and where s_{tu} is the overlap integral between the AO's, t and u.

$$(\phi_{tu}^{(E)})_{i\to l} \cong -2(M!)\mathcal{N}_{i\to l}^2 \Big(2\sum_{i'}^{\text{occ}} \sum_k^{\text{occ}} c_t^{(i')} c_u^{(k)} s_{tu} S_{i'k} - \sum_k^{\text{occ}} c_t^{(i)} c_u^{(k)} s_{tu} S_{ik} + \sum_{i'}^{\text{occ}} c_t^{(i')} c_u^{(l)} s_{tu} S_{i'l} - 2c_t^{(i)} c_u^{(l)} s_{tu} S_{il}\Big) \tag{6}$$

$(\phi_{tu}^{(E)})_0$, $(\phi_{tu}^{(E)})_{i\to l}$, and $(\phi_{tu}^{(E)})_{k\to j}$ indicate the AO bond populations of a bond newly formed between the AO t of A and the AO u of B due to the electron exchange in Ψ_0, $\Psi_{i\to l}$, and $\Psi_{k\to j}$ states respectively.

The quantity $\phi_{tu}^{(D)}$ implies the AO bond population between t and u due to the electron delocalization:

$$\phi_{tu}^{(D)} \cong \sum_i^{\text{occ}} \sum_l^{\text{uno}} \{(\phi_{tu}^{(D)})_{0,i\to l} + (\phi_{tu}^{(D)})_{i\to l,0}\} C_0 C_{i\to l} + \sum_k^{\text{occ}} \sum_j^{\text{uno}} \{(\phi_{tu}^{(D)})_{0,k\to j} + (\phi_{tu}^{(D)})_{k\to j,0}\} C_0 C_{k\to j} \tag{7}$$

$$(\phi_{tu}^{(D)})_{0,i\to l} \cong \sqrt{2}\, c_t^{(i)} c_u^{(l)} s_{tu} \tag{8}$$

In Table 3 are given $(\phi_{tu}^{(E)})_0$ and $\phi_{tu}^{(E)}$ with respect

Table 3. The intermolecular AO bond populations due to the exchange

		Carbon of Methylene 1			
		s	x	y	z
Carbon of Methylene 2	s'	−0.0038 (−0.0035)	0 (0)	−0.0000 (−0.0000)	−0.0001 (0)
	x'	0 (0)	−0.0001 (−0.0001)	0 (0)	0 (0)
	y'	−0.0051 (−0.0048)	0 (0)	−0.0000 (−0.0000)	0.0005 (0)
	z'	0.0000 (0)	0 (0)	0.0000 (0)	0 (0)

The values in parentheses indicate $(\phi_{tu}^{(E)})_0$.

Table 4. The intermolecular AO bond populations due to the electron delocalizations from methylene 1 to methylene 2 and from methylene 2 to methylene 1

		Carbon of Methylene 1			
		s	x	y	z
Carbon of Methylene 2	s'	−0.0021 −0.0035	0 0	0.0000 0.0003	0 0.0139
	x'	0 0	0.0001 −0.0002	0 0	0 0
	y'	0.0015 −0.0052	0 0	0.0000 0.0003	0 0.0372
	z'	0.0002 0	0 0	0.0014 0	0 0

The upper value in each set indicates the AO bond population due to the electron delocalization from methylene 1 to methylene 2 and the lower value that arising from the electron delocalization from methylene 2 to methylene 1.

to Model II. The contribution of mono-transferred states to $\phi_{tu}^{(E)}$ is negligibly small. It can be seen that the sum of $\phi_{tu}^{(E)}$'s over all the pairs of the t of A and the u of B is negative. This demonstrates an antibonding contribution of the exchange interaction in the chemical interaction between two methylenes. Table 4 shows the $\phi_{tu}^{(D)}$ due to the electron delocalization from methylene 1 to methylene 2 and that due to the electron delocalization from methylene 2 to methylene 1. Adding $\phi_{tu}^{(D)}$ to $\phi_{tu}^{(E)}$, we can find the positive atomic bond population arising in the region between the carbon atoms of two methylenes. It should be noted that the greatest contribution comes from the combination of the p_z orbital of methylene 1 and $p_{y'}$, orbital of methylene 2, and that the next largest is that of the p_z orbital of methylene 1 and the $2s$ orbital of methylene 2.

The intermolecular chemical bonding can be interpreted in terms of the mixing of charge-transferred states into the Ψ_0 state. Thus, the importance of delocalization interaction in the process of bond formation is clear.

Weakening of Old Bonds

The changes in the bond populations of the intramolecular AO pairs in A and B due to the electron-exchange interaction may be given by:

$$\varphi_{tt'}^{(E)} = C_0^2(\varphi_{tt'}^{(E)})_0 + \sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}^2(\varphi_{tt'}^{(E)})_{i\to l} + \sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}^2(\varphi_{tt'}^{(E)})_{k\to j} \tag{9}$$

$$\varphi_{uu'}^{(E)} = C_0^2(\varphi_{uu'}^{(E)})_0 + \sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}^2(\varphi_{uu'}^{(E)})_{i\to l} + \sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}^2(\varphi_{uu'}^{(E)})_{k\to j} \tag{10}$$

$$(\varphi_{tt'}^{(E)})_0 \cong 4(M!)\mathcal{N}_0^2\sum_i^{\text{occ}}\sum_k^{\text{occ}} c_t^{(i)}c_{t'}^{(i)}s_{tt'}S_{ik}^2 \tag{11}$$

$$(\varphi_{tt'}^{(E)})_{i\to l} \cong 2(M!)\mathcal{N}_{i\to l}^2\{\sum_{i'}^{\text{occ}} c_t^{(i')}c_{t'}^{(i')}s_{tt'}(2\sum_k^{\text{occ}} S_{i'k}^2 + S_{i'l}^2) - c_t^{(i)}c_{t'}^{(i)}s_{tt'}(\sum_k^{\text{occ}} S_{ik}^2 + 2S_{il}^2)\} \tag{12}$$

$$(\varphi_{tt'}^{(E)})_{k\to j} \cong 2(M!)\mathcal{N}_{k\to j}^2\{\sum_i^{\text{occ}} c_t^{(i)}c_{t'}^{(i)}s_{tt'}(2\sum_{k'}^{\text{occ}} S_{ik'}^2 - S_{ik}^2) + c_t^{(j)}c_{t'}^{(j)}s_{tt'}(\sum_{k'}^{\text{occ}} S_{jk'}^2 - 2S_{jk}^2)\} \tag{13}$$

The changes in the AO bond populations of A and of B due to the mixing of charge-transferred states into Ψ_0 are given by:

$$\varphi_{tt'}^{(D)} \cong 2(-\sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}^2 c_t^{(i)}c_{t'}^{(i)}s_{tt'} + \sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}^2 c_t^{(j)}c_{t'}^{(j)}s_{tt'} - 2\sqrt{2}C_0\sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}c_t^{(i)}c_{t'}^{(i)}s_{tt'}S_{il}) \tag{14}$$

$$\varphi_{uu'}^{(D)} \cong 2(-\sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}^2 c_u^{(k)}c_{u'}^{(k)}s_{uu'} + \sum_i^{\text{occ}}\sum_l^{\text{uno}} C_{i\to l}^2 c_u^{(l)}c_{u'}^{(l)}s_{uu'} - 2\sqrt{2}C_0\sum_k^{\text{occ}}\sum_j^{\text{uno}} C_{k\to j}c_u^{(k)}c_{u'}^{(l)}s_{uu'}S_{kj}) \tag{15}$$

Table 5. The changes in the AO bond populations of the C–H bond of methylene 1 and methylene 2

	Carbon			
	s'	x'	y'	z'
Hydrogen s'	0.0053	0.0000	−0.0083	0

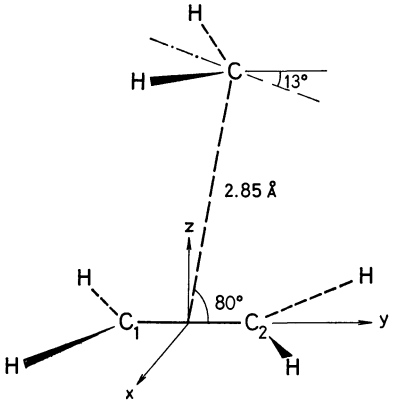

Fig. 2. A schematic representation of assumed model of the addition of methylene to ethylene.

Table 6. The changes in the bond populations of the carbon-carbon bond of ethylene due to the interaction with methylene

		Carbon 1			
		s	x	y	z
Carbon 2	s	−0.0020	0	0.0002	0
	x	0	0.0003	0	0
	y	−0.0002	0	−0.0003	0
	z	0	0	0	−0.0397

Table 5 shows the changes in the AO bond populations in methylenes. However, the numerical values are too small to show the importance of the bond weakening caused by electron delocalization, since carbon-hydrogen bonds in methylenes never break down in the process of dimerization to form an ethylene molecule. In order to obtain a more distinct result, we had better proceed to the addition of singlet methylene to ethylene[6] (Fig. 2). The results of the calculation of the changes in the AO bond populations of the carbon-carbon bond of ethylene are shown in Table 6. We can find that the AO bond population between the $2p_z$ orbital of the carbon 1 and the $2p_z$ orbital of the carbon 2 decreases conspicuously, while the others remain almost unchanged. This demonstrates the start of the disappearance of the π bond in ethylene to form σ bonds with methylene.

Extending Mulliken's concept of population analysis[7] to an AO pair between two interacting molecules, the electrons flow into the intermolecular region through the orbital overlapping between the AO t of A and the AO u of B may be divided into two, one of which reverts to the AO t, and the other, to the AO u. Therefore, the changes in the AO populations of AO t and AO u due to the electron delocalization are given by:

$$\Delta N_t^{(D)} = \frac{1}{2}\left(\sum_u^B \phi_{tu}^{(D)} + \sum_{t'}^A \varphi_{tt'}^{(D)}\right) \tag{16}$$

$$\Delta N_u^{(D)} = \frac{1}{2}\left(\sum_t^A \phi_{tu}^{(D)} + \sum_{u'}^B \varphi_{uu'}^{(D)}\right) \tag{17}$$

Table 7 shows the changes in the AO populations of methylenes in Model II. We can see that methylene 2 serves as an electron donor, and methylene 1, as an electron acceptor.

Intramolecular Electron Rearrangement Due to Interaction

The other terms in the diagonal elements of Eqs. (A. 1), (A. 3), and (A. 5), which have not appeared in Eqs. (4)—(17), stand for the reorganization of the electron populations in both A and B caused by the mutual interaction. We may define the partial AO populations of the AO t as:

$$n_t^{(ii')} + n_t^{(i'i)} = (p_t^{(ii')} + v_t^{(ii')}) + (p_t^{(i'i)} + v_t^{(i'i)}) \tag{18}$$

$$p_t^{(ii')} = c_t^{(i)} c_t^{(i')} \qquad (i \neq i')$$

$$v_t^{(ii')} = \sum_{t'}^A c_t^{(i)} c_{t'}^{(i')} s_{tt'} \qquad (t \neq t')$$

where $p_t^{(ii')}$ stands for the valence-inactive part, and $v_t^{(ii')}$ for the valence-active part.[8] The quantity $n_t^{(ii')} + n_t^{(i'i)}$ gives a non-zero value, in general, although the sum over all the t's of the molecule A vanishes. We represent the changes in the AO bond populations in the molecules A and B by $\varphi_{tt'}^{(R)}$ and $\varphi_{uu'}^{(R)}$ respectively. Therefore, the changes in the AO populations of the AO's t and u resulting from the intramolecular electron rearrangement may be given by:

$$\Delta N_t^{(R)} = \frac{1}{2}\sum_{t'}^A \varphi_{tt'}^{(R)} \tag{19}$$

$$\Delta N_u^{(R)} = \frac{1}{2}\sum_{u'}^B \varphi_{uu'}^{(R)} \tag{20}$$

The changes in the AO populations and AO bond populations caused by the electron rearrangement are shown in Table 8 with respect to Model II. Although the changes in the electron populations due to the intramolecular electron rearrangement are small in comparison with the other terms discussed above, they are hardly negligible in the systems where one or both of the reactants involve highly-polarized bonds. In Fig. 3 we present the changes in the atomic popula-

Fig. 3. The changes in atomic populations and in atomic bond populations due to the intramolecular electron rearrangement. The values in [ ] indicate the changes in atomic bond populations.

tions and in the atomic bond populations due to the intramolecular electron rearrangement with regard to the chemically-interacting system shown in the figure.[5] It is interesting to see that the carbon-chlorine bond is loosened and that electron migration takes place in the direction from carbon to chlorine.

Changes in Electron Populations

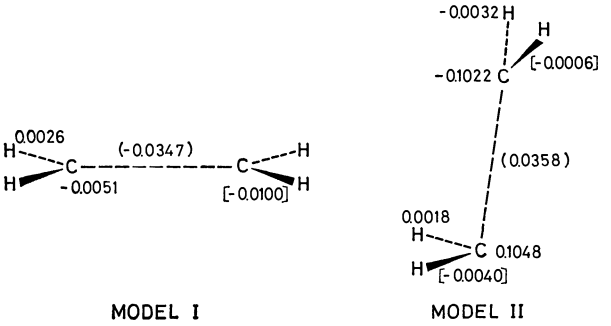
The difference in the population of the AO t before and after interaction will be:

$$\Delta N_t \cong \frac{1}{2}\sum_{u}^{B}\phi_{tu} + \frac{1}{2}\sum_{t'}^{A}(\varphi_{tt'}^{(D)}+\varphi_{tt'}^{(E)}+\varphi_{tt'}^{(R)}) \qquad (21)$$

Similarly, the change in the AO bond population between the AO's t and t' of A is given by:

$$\varphi_{tt'} \cong \varphi_{tt'}^{(D)} + \varphi_{tt'}^{(E)} + \varphi_{tt'}^{(R)} \qquad (22)$$

Summing up the changes in AO populations and AO bond populations discussed above gives the final results on Model I and Model II for the dimerization of methylenes shown in Fig. 4.



MODEL I MODEL II

Fig. 4. The changes in atomic populations and in atomic bond populations due to the interaction. The values in ( ) indicate the intermolecular atomic bond populations and the values in [ ] stand for the changes in atomic bond populations.

As has been discussed above, the delocalization interaction has a close connection to the bond-interchange in chemical reactions of two closed-shell molecules. It has been demonstrated that the formation of new bonds between reagent and reactant and the weakening of old bonds in both can be interpreted only by the inclusion of charge-transferred configurations. Among various charge-transferred terms, the orbital interaction between the HO MO of the reactant and the LU MO of the reagent, and the reverse interaction, play the most dominant role. Those electron configurations which have been omitted in the present calculation can also be included in a similar fashion in the population calculation, although it will take too much computer time to be performed. It is believed that the main consequences would not be seriously different from those presented here.

This calculation has been limited to the cases in which both reactant and reagent are closed-shell systems. Extension to other cases is now in progress.

The authors wish to express their appreciation to the Data Processing Center of Kyoto University for the generous permission to use the FACOM 230–60 computer.

Appendix

Taking the terms up to the second order of the overlap integrals S_{ab} between the MO's, a's of the molecule A and b's of the molecule B, we have the first order spinless density matrix given by:

$$\begin{aligned}\rho(1'|1)_{0,0} &= M\int \Psi_0(1', 2, \cdots, M)\Psi_0(1, 2, \cdots, M)\mathrm{d}\xi_1\mathrm{d}\tau_2\cdots\mathrm{d}\tau_M \\ &\cong 2\sum_{i}^{occ} i(1')i(1) + 2\sum_{k}^{occ} k(1')k(1) \\ &\quad + \{2\sum_{i}^{occ}\sum_{i'}^{occ}\sum_{k}^{occ} i(1')i'(1)S_{ik}S_{i'k} \\ &\quad + 2\sum_{k}^{occ}\sum_{k'}^{occ}\sum_{i}^{occ} k(1')k'(1)S_{ik}S_{ik'} \\ &\quad - 2\sum_{i}^{occ}\sum_{k}^{occ}(i(1')k(1)+k(1')i(1))S_{ik}\}\mathcal{N}_0^2(M!)\end{aligned} \qquad (A.1)$$

where M is the total number of electrons of the system composed of A and B, $i(1')k(1)$, for instance, is the abbreviation of $a_i(1')b_k(1)$, and the normalization factor for Ψ_0 is:

$$\mathcal{N}_0 \cong (1-2\sum_{i}^{occ}\sum_{k}^{occ}S_{ik}^2)^{-1/2}(M!)^{-1/2} \qquad (A.2)$$

With respect to $\Psi_{i\to l}$, we have

$$\begin{aligned}\rho(1'|1)_{i\to l, i\to l} &\cong 2\sum_{i'}^{occ} i'(1')i'(1) \\ &\quad + 2\sum_{k}^{occ} k(1')k(1) - i(1')i(1) + l(1')l(1) \\ &\quad + \{i(1')i(1)(\sum_{k}^{occ}S_{ik}^2+2S_{il}^2) + l(1')l(1)(\sum_{i'}^{occ}S_{i'l}^2-2S_{il}^2) \\ &\quad - 2\sum_{i'}^{occ}\sum_{k}^{occ}(i'(1')k(1)+k(1')i'(1))S_{i'k} \\ &\quad + \sum_{k}^{occ}(i(1')k(1)+k(1')i(1))S_{ik} \\ &\quad - \sum_{i'}^{occ}(i'(1')l(1)+l(1')i'(1))S_{i'l} + 2(i(1')l(1)+l(1')i(1))S_{il} \\ &\quad + \sum_{i'}^{occ}\sum_{i''}^{occ} i'(1')i''(1)(2\sum_{k}^{occ}S_{i'k}S_{i''k}+S_{i'l}S_{i''l}) \\ &\quad - \sum_{i'}^{occ}(i(1')i'(1)+i'(1')i(1))(\sum_{k}^{occ}S_{ik}S_{i'k}+2S_{il}S_{i'l}) \\ &\quad + \sum_{k}^{occ}\sum_{k'}^{occ} k(1')k'(1)(2\sum_{i'}^{occ}S_{i'k}S_{i'k'}-S_{ik}S_{ik'}) \\ &\quad + \sum_{k}^{occ}(k(1')l(1)+l(1')k(1))(\sum_{i'}^{occ}S_{i'k}S_{i'l}-2S_{ik}S_{il})\}\mathcal{N}_{i\to l}^2(M!)\end{aligned} \qquad (A.3)$$

and

$$\mathcal{N}_{i\to l} \cong (1-2\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} S_{i'k}^2+\sum_{k}^{\mathrm{occ}} S_{ik}^2-\sum_{i'}^{\mathrm{occ}} S_{i'l}^2+2S_{il}^2)^{-1/2}(M!)^{-1/2} \tag{A.4}$$

The next to be considered is the term which represents the mixing in of monotransferred configuration into zero-configuration. Neglecting the terms smaller than S_{ab}^2, we have:

$$\begin{aligned}\rho(1'|1)_{0,i\to l} \cong{}& \sqrt{2}\,S_{il}(2\sum_{i'}^{\mathrm{occ}} i'(1')i'(1)+2\sum_{k}^{\mathrm{occ}} k(1')k(1))\\ &-\sqrt{2}\,(\sum_{i'}^{\mathrm{occ}} i(1')i'(1)S_{i'l}+\sum_{k}^{\mathrm{occ}} k(1')l(1)S_{ik}-i(1')l(1))\end{aligned} \tag{A.5}$$

Similar expressions are obtained from $\Psi_{k\to j}$. The elements of the density matrix due to the mixing in of the monoexcited states are:

$$\begin{aligned}\rho(1'|1)_{i\to j,i\to j} \cong{}& 2\sum_{i'}^{\mathrm{occ}} i'(1')i'(1)\\ &+2\sum_{k}^{\mathrm{occ}} k(1')k(1)-i(1')i(1)+j(1')j(1)\\ &+\{j(1')j(1)\sum_{k}^{\mathrm{occ}} S_{jk}^2+i(1')i(1)\sum_{k}^{\mathrm{occ}} S_{ik}^2\\ &+2\sum_{i'}^{\mathrm{occ}}\sum_{i''}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} i'(1')i''(1)S_{i'k}S_{i''k}\\ &-\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}}(i(1')i'(1)+i'(1')i(1))S_{ik}S_{i'k}\\ &+\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}}(j(1')i'(1)+i'(1')j(1))S_{jk}S_{i'k}\\ &-2\sum_{k}^{\mathrm{occ}}(j(1')i(1)+i(1')j(1))S_{jk}S_{ik}\\ &+\sum_{k}^{\mathrm{occ}}\sum_{k'}^{\mathrm{occ}} k(1')k'(1)(2\sum_{i'}^{\mathrm{occ}} S_{i'k}S_{i'k'}-S_{ik}S_{ik'}+S_{jk}S_{jk'})\\ &-2\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}}(i'(1')k(1)+k(1')i'(1))S_{i'k}\\ &+\sum_{k}^{\mathrm{occ}}(i(1')k(1)+k(1')i(1))S_{ik}\\ &-\sum_{k}^{\mathrm{occ}}(j(1')k(1)+k(1')j(1))S_{jk}\}\mathcal{N}_{i\to j}^2(M!)\end{aligned} \tag{A.6}$$

and:

$$\mathcal{N}_{i\to j} \cong (1-2\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} S_{i'k}^2+\sum_{k}^{\mathrm{occ}} S_{ik}^2-\sum_{k}^{\mathrm{occ}} S_{jk}^2)^{-1/2}(M!)^{-1/2} \tag{A.7}$$

and;

$$\begin{aligned}\rho(1'|1)_{0,i\to j} \cong{}& \sqrt{2}\,\{(2\sum_{i'}^{\mathrm{occ}} i'(1')i'(1)\\ &+2\sum_{k}^{\mathrm{occ}} k(1')k(1))(-\sum_{k}^{\mathrm{occ}} S_{ik}S_{jk})\\ &+\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} i(1')i'(1)S_{jk}S_{i'k}+\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} i'(1')j(1)S_{ik}S_{i'k}\\ &+\sum_{k}^{\mathrm{occ}}\sum_{k'}^{\mathrm{occ}} k(1')k'(1)S_{ik}S_{jk'}-\sum_{k}^{\mathrm{occ}} i(1')k(1)S_{jk}\\ &-\sum_{k}^{\mathrm{occ}} k(1')j(1)S_{ik}\}+\sqrt{2}\,i(1')j(1)\,(1-2\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} S_{i'k}^2)^{1/2}\\ &\times(1-2\sum_{i'}^{\mathrm{occ}}\sum_{k}^{\mathrm{occ}} S_{i'k}^2+\sum_{k} S_{ik}^2-\sum_{k}^{\mathrm{occ}} S_{jk}^2)^{-1/2}\end{aligned} \tag{A.8}$$

and similar formulas corresponding to the contributions from $\Psi_{k\to l}$.

Studies of the Liquid-Liquid Partition Systems. VIII. Stabilities and Extractabilities of Copper(II) and Zinc(II) Complexes with Acetylacetone, Trifluoroacetylacetone, and Hexafluoroacetylacetone in Aqueous Sodium Perchlorate Solution-Carbon Tetrachloride Systems

Tatsuya SEKINE and Naohiko IHARA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 7, 1971)

The distribution of copper(II) and zinc(II) chelates with three β-diketones, acetylacetone (AA), trifluoroacetylacetone (TFA), and hexafluoroacetylacetone (HFA) between carbon tetrachloride and aqueous sodium perchlorate solutions at 0.1M, 1M, and 3M has been determined at 25°C as a function of the concentration of the dissociated chelate anions. The stability constants for the metal chelates in the aqueous phase and the two phase-distribution constants for the uncharged complexes have been determined by a graphic analysis of the distribution data. The distribution was also measured when the carbon tetrachloride phase was added with tributylphosphate (TBP) or trioctylphosphine oxide (TOPO) and the adduct-formation constants of the uncharged chelate with these ligands have been determined by a graphic analysis of the increase in the distribution ratio as a function of the ligand concentration. The results are as follows: (i) Copper(II) forms first and second complexes with these chelating ligands in the aqueous phase, whereas zinc(II) forms the third complex (except with HFA) besides the first and the second ones; the complexes are more stable in the ligand order of AA>TFA>HFA. (ii) The stability constants of the copper(II) complexes are much higher than those of the corresponding zinc(II) complexes. (iii) The distribution constant of the uncharged copper(II) complex is higher than that of the corresponding zinc(II) complex. (iv) No remarkable relation has been found among the distribution constants of the chelating acid and those of the uncharged metal chelates. (v) The adducts of the metal chelates are more stable in the ligand order of HFA>TFA>AA. The zinc(II) complex forms more stable adducts than does the corresponding copper(II) complex, and TOPO forms more stable adducts than does TBP. (vi) Changes in the concentration of the background salt alter the stability constants of the metal chelates and the distribution constants of the uncharged chelate (salting-out); the effects are, however, very complicated. On the basis of these results, the distribution constants of the uncharged chelates were discussed from the standpoint of the interactions of the central metal ions in the complexes with the water molecules, and a qualitative relationship between these interactions and the stabilities of the adduct chelate complexes was pointed out.

The solvent extraction of metal ions with various weakly acidic chelating reagents has been studied by many authors from the standpoint of the chemical equilibria involved in the extraction processes. The distribution ratios of the metal ions in these systems have been determined as a function of the concentration of the extractants, and the statistical treatments of the distribution data are now very well established.

As will later be discussed in detail, the distribution ratio in metal-chelate extraction systems is represented by the successive complex formations in the aqueous phase and the distribution of the uncharged complex among them.

The stability constants of metal complexes with various chelating anions are an important chemical characteristic of the complexes, and they have been studied by many coordination chemists. However, the two-phase distribution behavior of the uncharged complex is rather a special problem of solvent-extraction chemistry, and, as it is difficult to determine the distribution constant of the uncharged complex in many systems directly, not very much has been established.

In this investigation, the present authors have studied the extraction of copper(II) and zinc(II) mainly from this standpoint. Three β-diketones, acetylacetone (AA), trifluoroacetylacetone (TFA), and hexafluoroacetylacetone (HFA) have been used as the extractants. They were chosen because we desired to know how the distribution behavior of chelate complexes is changed by the substitution of the trifluoromethyl group for the methyl group in acetylacetone; they were also chosen because of the practical reason that the distribution constants are not too high to make an accurate measurement.

Sodium perchlorate solutions were used as the aqueous phase. The concentration of this salt was adjusted at 0.1M, 1.0M, or 3.0M in order to observe the effect of this "*inert*" salt on the stability and the extractability of the metal complexes. In some experiments, the carbon tetrachloride phase was added with tributylphosphate (TBP) or triocytlphosphine oxide (TOPO) in order to determine the enhancements of the distribution due to the adduct-chelate formation and in order to determine the equilibrium constants of the complexes more accurately. The equilibrium constants were determined by a curve-fitting method, on the basis of these data, and some discussion was made of the extractability from the standpoint of the interactions of the metal complexes in the aqueous phase.

Experimental

Reagents. A radioactive tracer, copper-64, and zinc-65 were used in order to determine the distribution ratio of the metal ions. The three β-diketones were obtained from Dojindo & Co. The TBP was obtained from the Tokyo Kasei Co. It was washed perchloric acid, water, and an aqueous sodium hydroxide solution, and then several times with water. The TOPO was obtained from Dojindo & Co.

Standard sodium hydroxide solutions were prepared from a 50% sodium hydroxide solution and decarbonated water. It was standardized to potassium acid phthalate. The sodium perchlorate was prepared from sodium carbonate and perchloric acid. It was recrystallized three times from water. The other reagents were of an analytical grade and were used without further purification.

A certain amount of a β-diketone was dissolved in carbon tetrachloride. The concentration was determined by a two-phase titration; a 5 m*l* portion of the organic solution was pipetted and transferred into a flask containing a certain amount of water, after which the solution was titrated with a standard sodium hydroxide solution by using a suitable indicator (phenolphthalein or azoblue). The concentration of the TBP or TOPO solution was calculated from the weight of the reagent dissolved. The water-saturated TBP was regarded as $TBP \cdot H_2O$. The concentration of the sodium perchlorate stock solution was calculated from the weight of the residue left after a certain amount of the stock solution had been evaporated in an air-bath at 120°C.

Procedures. All of the experiments were carried out in a thermostatted room at 25±0.3°C. An aqueous solution initially containing sodium perchlorate, sodium hydroxide, and 1.0×10^{-5}M copper ions labeled by copper-64 or 1.2×10^{-6}M zinc ions labeled by zinc-65 and carbon tetrachloride containing one of the extractants was placed in the tube. In the highest $-\log[H^+]$ region, the chelating acid distributed into buffered the aqueous phase, and no other buffering reagent was added. In the lower region, however, acetate was used for the experiments with copper(II) and an acetate or acid carbonate buffer was used for the experiments with zinc(II). The initial concentration of the buffer was 0.01M in the aqueous phase, and practically no difference in the distribution ratio was observed when the buffer concentration was changed to a half: it was thus concluded that the effect of the buffer was negligible. The initial volume of the two phases was always 5 m*l*.

The two phases in the tubes were settled on a rotating framework, agitated mechanically for one hour, and centrifuged. A 2-m*l* portion was pipetted from each phase, and the portions were transferred into small test tubes. The γ-radioactivities of the samples were measured with a scintillation counter, and the distribution ratio was calculated as;

$$D = \frac{\gamma\text{-count-rate per m}l\text{ of the org. phase}}{\gamma\text{-count-rate per m}l\text{ of the aq. phase}}$$

Some portion was also pipetted from the aqueous phase and transferred into a small glass vessel. The hydrogen-ion concentration in the stoichiometric scale was determined by potentiometry using solutions containing 1.00×10^{-2}M perchloric acid and 0.09M, 0.99M, or 2.99M sodium perchlorate as the standard of $-\log[H^+]=2.00$ in a 0.1M, 1M, or 3M constant ionic medium.

Statistical

When a weak acid, HA, is distributed between an organic and an aqueous phase, the distritution constant is described as:

$$HA \rightleftarrows HA_{(org)}$$

$$K_D = \frac{[HA]_{org}}{[HA]} \quad (1)$$

The acid dissociation of HA in the aqueous phase is described as:

$$HA \rightleftarrows H^+ + A^-$$

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad (2)$$

If the volumes of the two phases are the same, the initial concentration of the acid in one phase (in the present study, it was the organic phase), C_{HA}, is described, on the basis of the concentrations after the equilibrium is established, as:

$$C_{HA} = [HA]_{org} + [HA] + [A^-] \quad (3)$$

By introducing Eqs. (1) and (2) into Eq. (3), we obtain:

$$C_{HA} = [A^-]\left(\frac{K_D+1}{K_a}[H^+]+1\right) \quad (4)$$

Equation (4) shows that the aqueous concentration of the anion from the acid in a liquid-liquid distribution system can be calculated from the initial acid concentration, from the hydrogen-ion concentration at the equilibrium, and from the distribution constant and the dissociation constant of the acid.

The complex formation of a divalent metal ion, M^{2+}, with a ligand anion, A^-, is described as follows:

$$M^{2+} + nA^- \rightleftarrows MA_n^{2-n}$$

$$\beta_n = \frac{[MA_n^{2-n}]}{[M^{2+}][A^-]^n} \quad (5)$$

Among these complexes, the uncharged one, MA_2, could be extracted into a non-polar organic solvent. The distribution constant of this metal complex is described as:

$$MA_2 \rightleftarrows MA_{2(org)}$$

$$K_{DM} = \frac{[MA_2]_{org}}{[MA_2]} \quad (6)$$

When the organic phase contains only the MA_2 species, and when the aqueous phase contains a series of metal complexes, the distribution ratio is described as follows:

$$D = \frac{[MA_2]_{org}}{[M^{2+}]+[MA^+]+[MA_2]+[MA_3^-]+\cdots} \quad (7)$$

By introducing Eqs. (5) and (6), Eq. (7) can be rewritten as:

$$D = \frac{K_{DM}\beta_2[A^-]^2}{1+\beta_1[A^-]+\beta_2[A^-]^2+\beta_3[A^-]^3+\cdots} \quad (8)$$

When the complex, MA_2, in the organic phase undergoes further complex formation with a neutral organophilic ligand, L, the equilibrium is described as:

$$MA_{2(org)} + nL_{(org)} \rightleftarrows MA_2L_{n(org)}$$

$$\beta_{n(org)} = \frac{[MA_2L_n]_{org}}{[MA_2]_{org}[L]^n_{org}} \quad (9)$$

When this type of adduct formation occurs in the organic phase, the distribution ratio can be described as follows:

$$D = \frac{K_{DM}\beta_2[A^-]^2(1+\beta_{1(org)}[L]_{org}+\beta_{2(org)}[L]^2_{org}+\cdots)}{1+\beta_1[A^-]+\beta_2[A^-]^2+\beta_3[A^-]^3+\cdots} \quad (10)$$

If the distribution ratio under a certain $[A^-]$ and $[L]_{org}$ is denoted by D, and when that under the identical $[A^-]$, but in the absence of L, is denoted by D_0, the following can be obtained from Eqs. (8) and (10):

$$D/D_0 = 1 + \beta_{1(org)}[L]_{org} + \beta_{2(org)}[L]^2_{org} + \cdots \quad (11)$$

When the distribution constant, K_{DM}, into a non-polar solvent is very small, it is very difficult to deter-

mine the stability constants of the metal complexes in the aqueous phase from the extraction data by using Eq. (8). However, if a certain amount of an adduct-forming ligand is added to the organic phase, the distribution ratio is increased. When the concentration of the adduct-forming ligand is kept constant throughout a series of experiments, the value in the parentheses in Eq. (10) is always constant. In such a case, the $K_{DM}(1+\sum\beta_{n(org)}[L_1]^n_{org})$ value, where $[L_1]_{org}$ is the concentration of the adduct-forming ligand, can be used instead of the K_{DM} value, in Eq. (8) and the stability constants can be determined from these data.

In many papers, the extraction equilibrium of M^{2+} with a chelating extractant is described as:

$$M^{2+} + 2HA_{(org)} \rightleftarrows MA_{2(org)} + 2H^+$$

$$K_{ex} = \frac{[MA_2]_{org}[H^+]^2}{[M^{2+}][HA]^2_{org}} \quad (12)$$

When the distribution ratio can be described as:

$$D = \frac{[MA_2]_{org}}{[M^{2+}]} \quad (13)$$

$$= K_{ex}[HA]^2_{org}[H^+]^{-2} \quad (14)$$

Thus, when no aqueous chelate complex is formed, the distribution ratio is proportional to the square of the concentration of the chelating extractant in the organic phase or is inversely proportional to the square of the hydrogen ion concentration in the aqueous phase. However, when the distribution ratio is given by Eq. (7), it can be described as:

$$D = \frac{K_{ex}[HA]^2_{org}[H^+]^{-2}}{1+\beta_1[A^-]+\beta_2[A^-]^2+\beta_3[A^-]^3+\cdots} \quad (15)$$

as $K_{DM}\beta_2[A^-]^2 = K_{ex}([HA]_{org}/[H^+])^2$;

$$K_{ex} = K_{DM}\beta_2 K_a^2 K_D^{-2} \quad (16)$$

The equilibrium constants in the above equations may be determined from the following graphic method.[1,2]

When the distribution ratio given by Eq. (8) is plotted as log D *vs.* log$[A^-]$:

$$Y = \log K_{DM}\beta_2 - \log([A^-]^{-2}+\beta_1[A^-]^{-1}+\beta_2+\beta_3[A^-]+\cdots) \quad (17)$$

If the complexes higher than the MA_2 are negligible, Eq. (17) can be rewritten as:

$$Y = \log K_{DM} - \log(\beta_2^{-1}[A^-]^{-2}+\beta_1\beta_2^{-1}[A^-]^{-1}+1) \quad (17')$$

The plot should have the following two asymptotes:

$$\lim_{[A^-]\to 0} Y = \log K_{DM}\beta_2 + 2\log[A^-] \quad (18\text{-}1)$$

$$\lim_{[A^-]\to \infty} Y = \log K_{DM} \quad (18\text{-}2)$$

The plot in Eq. (17′) could be fitted with the following family of standard curves:

$$Y = \log(1+pv+v^2) \quad (19\text{-}1)$$

$$X = \log v \quad (19\text{-}2)$$

From the two asymptotes, Eqs. (18-1) and (18-2), the K_{DM} and β_2 values can be obtained, and from the parameter, p, of the best-fit standard curve, β_1 is obtained as:

$$p = \beta_1\beta_2^{-1/2}$$

When the aqueous phase also contains the MA_3^- complex, the graphic analysis of the data was made as follows. In the lower $[A^-]$ region, the log D *vs.* log$[A^-]$ plot was first fitted with the standard curves in Eqs. (19-1) and (19-2). From this, approximate values of K_{DM}, β_1, and β_2 were determined. Then, by using these constants and an assumed value of β_3, a calculated curve was made and compared with the observed experimental data in the higher $[A^-]$ region. After several trials, the best-fit β_3 was found from the parameter of the best-fit curve.

When a set of constants were thus obtained, the extraction curve was calculated from these constants; it was then compared with the experimental points in order to check whether or not they are reasonable.

When a log D/D_0 *vs.* log $[L]_{org}$ plot, where factors other than $[L]_{org}$ are always kept constant, is made for an adduct-formation system, the data can also be analyzed by the curve-fitting as follows.[3] If the data are represented by:

$$D/D_0 = 1 + \beta_{1(org)}[L]_{org} \quad (20)$$

that is, if only the first complex is formed, the data could be fitted with the standard curve:

$$Y = \log(1+v) \quad (21\text{-}1)$$

$$X = \log v \quad (21\text{-}2)$$

When the data are represented by:

$$D/D_0 = 1 + \beta_{1(org)}[L]_{org} + \beta_{2(org)}[L]^2_{org} \quad (22)$$

they could be fitted with the standard curves given by Eqs. (19-1) and (19-2). If the asymptote for the log-D/D_0 *vs.* log$[L]_{org}$ plot of the data given by Eq. (20) intersects the X axis at $(X_1, 0)$, the value of log $\beta_{1(org)}$ should be $-X_1$. If the asymptote for the log D/D_0 *vs.* log $[L]_{org}$ plot of the data given by Eq. (22) intersects with the X axis at $(X_2, 0)$, the value of log $\beta_{2(org)}$ should be $-2X$; $\beta_{1(org)}$ can then be obtained from this $\beta_{2(org)}$ and the p of the best-fit standard curve as:

$$p = \beta_{1(org)}\beta_{2(org)}^{-1/2} \quad (23)$$

Results

The results of the measurements were, in general, reproducible. The recovery of the γ-radioactivity from the two phases was always quantitative within the limits of experimental accuracy. The concentration of the chelating anion in the aqueous phase was calculated by using Eq. (4); the dissociation and the distribution constants of these reagents, reported in another paper,[4] are also given in Table 1 of the present paper.

Figure 1 shows the dependence on the hydrogen-ion concentration of the distribution of copper(II) between carbon tetrachloride and a 1 M sodium perchlorate solution. Figure 2 shows the dependence on the hydrogen-ion concentration of the distribution of zinc(II) between carbon tetrachloride (open symbols) or carbon tetrachloride containing a certain amount of TBP (closed

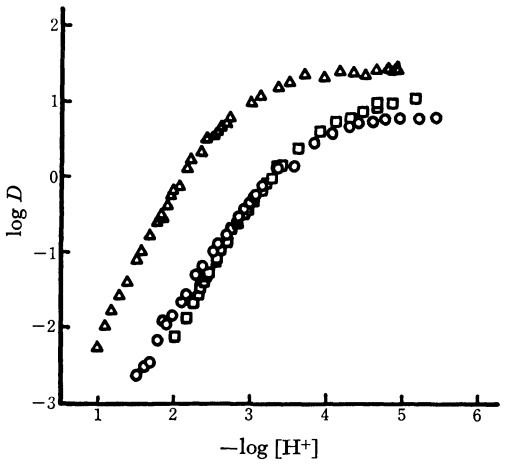

Fig. 1. Extraction of copper(II) complexes with AA(circles), TFA(triangles) and HFA(squares) as a function of the hydrogen ion concentrations.
organic phase: carbon tetrachloride
aqueous phase: 1M $Na(ClO_4)$

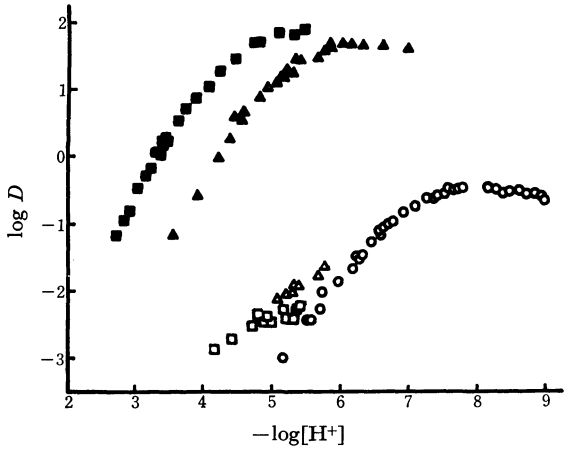

Fig. 2. Extraction of zinc(II) complexes with AA(circles), TFA(triangles) and HFA(squares) as a function of the hydrogen ion concentrations.
organic phase: (open symbols) carbon tetrachloride, (closed symbols) carbon tetrachloride containing 1×10^{-1}M TBP for the TFA or 6×10^{-3}M TBP for the HFA extractions.
aqueous phase: 1M $Na(ClO_4)$

symbols) and a 1M sodium perchlorate solution.

As may be seen from Fig. 2, the distribution ratio of zinc(II) in the TFA or HFA extraction is very low in the absence of TBP. However, the distribution ratio is much enhanced by the addition of TBP, and the extraction curves could be determined accurately in these systems. The stability constants of the zinc(II) complexes with TFA and HFA were obtained from these data; they are indicated by the closed symbols in Figs. 2 and 4.

The curves of zinc(II) extraction with TFA and HFA in the absence of TBP in the organic phase are indispensable in determining the distribution constants of the uncharged complexes, K_{DM}, in Eq. (6). Although the distribution ratios were low, the results of the extraction with TFA (open triangles) were reproducible and, as will be shown later, resonable values of K_{DM} and the formation constants of the adducts with TBP

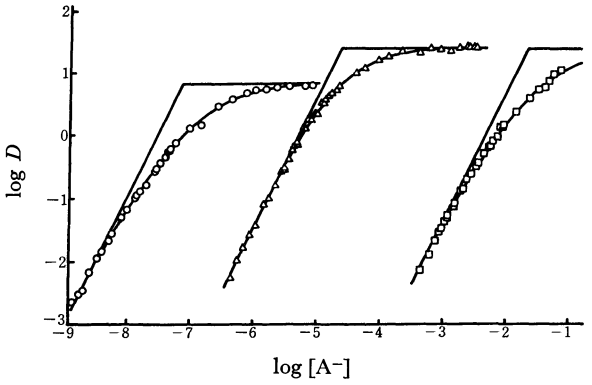

Fig. 3. Extraction of copper(II) complexes with AA(circles), TFA(triangles) and HFA(squares) as a function of the concentrations of the chelate anions.
organic phase: carbon tetrachloride
aqueous phase: 1M $Na(ClO_4)$
The solid curves are drawn by the equation,
$\log D=\log K_{DM}\beta_2[A^-]^2-\log(1+\beta_1[A^-]+\beta_2[A^-]^2)$

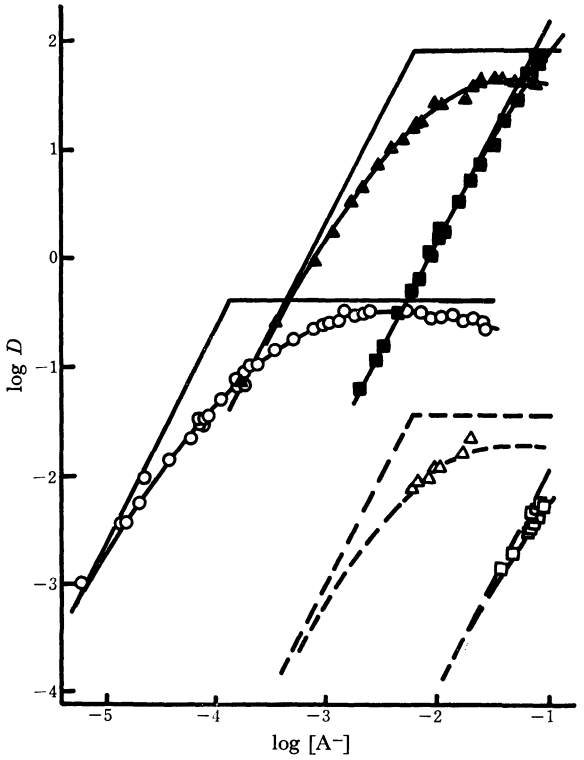

Fig. 4. Extraction of zinc(II) complexes with AA(circles), TFA(triangles) or HFA(squares).
organic phase: (open symbols) carbon tetrachloride, (closed symbols) crabon tetrachloride containing 1×10^{-1}M TBP for the TFA extraction or 6×10^{-3}M TBP for the HFA extractions.
aqueous phase: 1M $Na(ClO_4)$
The solid curves are drawn by the equation,
$\log D=\log K_{DM}\beta_2 f[A^-]^2-\log(1+\beta_1[A^-]+\beta_2[A^-]^2+\beta_3[A^-]^3)$
here, f is the enhancement factor due to the synergism, that is, D/D_0 in Eq. (22). When TBP is absent, f is unity and when 1×10^{-1}M TBP is present in the TFA extractions, f is $10^{3.35}$ and when 6×10^{-3}M TBP is persent in the HFA extractions, f is $10^{4.2}$.

The literature values for the extraction of copper (II) and zinc (II) in 1 M $NaClO_4$ with AA in benzene are as follows[11];

	$\log \beta_1$	$\log \beta_2$	$\log K_{DM}$
Cu(II)	8.05(8.22)[b]	14.75(14.81)[b]	1.10(1.10)[b]
Zn(II)	4.63	8.59	−0.19

a) The values of pK_a and $\log K_D$ are taken from another work[4] in which they are determined by a titration and a spectrophotometry.
b) Experiments at varying acetylacetone concentration.
c) The $\log K_{DM} \times \beta_2$ for the extraction of zinc(II) with HFA are 0.2(0.1M), 0.0(1M), and 1.1(3M).

or TOPO, $\beta_{n(org)}$ in Eq. (9), could be determined for the zinc(II)-TFA chelate. However, the extraction with HFA into carbon tetrachloride containing no TBP is scattered for some unknown reason; only representative data of these extractions are given in Fig. 2 (open squares). Thus, the extraction constant of zinc(II) with HFA, K_{ex} in Eq. (12), in Table 1 and the adduct-formation constants of the HFA chelate, which can be determined only by using the data of the extraction into carbon tetrachloride containing no TBP, may be somewhat erroneous.

In order to analyze these extraction data by using Eq.(8) or Eq.(10), the distribution ratios are plotted against the chelating-anion concentration in the aqueous phase. Figures 3 and 4 show the plot. In Fig. 3, it may be seen that each plot has an asymptote with a slope of +2 and an asymptote with a slope of zero. By the curve-fitting, the constants, β_1, β_2, and K_{DM}, were determined to be as is shown in Table 1. The solid curves in the figures are those calculated by introducing these constants into Eq.(8). The values of K_{ex} defined by Eq.(12) for these extractions were also calculated by using the K_a and K_D values of the chelating acid and Eq.(16).

Figure 4 gives the log D *vs.* log[A^-] plot of the zinc(II) extractions. As the extraction with HFA into carbon tetrachloride is too low to determine the equilibrium constants, the analysis was made by using the plot when the organic phase contains 1×10^{-1}M TBP for the TFA and 6×10^{-3}M TBP for the HFA extractions. As is shown in Eq.(10), the figure of the log D *vs.* log[A^-] plot should be the same even when the organic phase contains a certain amount of the adduct-forming ligand, L (here it is TBP); in this case, $K_{DM} \times (1 + \beta_{1(org)}[L_1]_{org} + \beta_{2(org)}[L_1]^2_{org} + \cdots)$, where $[L_1]_{org}$ is the concentration of the adduct-forming ligand, is the apparent distribution constant, which should be used instead of K_{DM} in Eq.(8), as has already been described.

The equilibrium constants for the extraction zinc(II) with AA were obtained by an analysis of the data given by the open circles, whereas those for the extractions with HFA or TFA were obtained by an analysis of the data given by the closed symbols.
The distribution constants, K_{DM}, for these extractions were obtained from these apparent distribution constants and the enhancements of the extraction by the TBP, which are given in Fig. 6.

It may be seen from Fig. 4 that the curve for the zinc(II) extraction with HFA is quite close to a straight line with a slope of +2. As can be seen from Eqs. (8) or (10), and (17), the log D *vs.* log[A^-] plot should deviate from a straight line with a slope of +2 when the MA^+ and MA_2 complexes are formed. However, in the [A^-] range studied in this paper ([A^-]<0.1M), the range where the MA_2 species is formed in an appreciable amount could not be covered; in other words, the deviation is too small to determine the stability constants for the second complex, β_2, and consequently, it was not possible to devide the $K_{DM} \times \beta_2$ value into the two constants. Thus, only the values for β_1 and $K_{DM} \times \beta_2$, together with K_{ex}, are listed in Table 1 for the zinc(II) complexes with HFA.

As can be seen from Fig. 4, the extraction curve with AA or TFA does not approach an asymptote with a slope of zero, but it decreases somewhat after the maximum. It was assumed to be due to the formation of the third complex, ZnA_3^-; the constants were changed until the best-fit of the calculated curve with the experimental data was obtained. The constants given in Table 1 were thus obtained. The solid curves in Fig. 4 were calculated by the use of these constants.

The above results are for the systems containing 1M sodium perchlorate solutions as the aqueous phase. In order to ascertain the effect of the concentrations of the coexisting salt on these constants, similar experiments

were also carried out in systems containing 0.1M or 3M sodium perchlorate solutions, while the equilibrium constants were also obtained by a similar graphic analysis. The constants are also given in Table 1.

The enhancements of these extractions by the addition of a neutral organophilic ligand, TBP or TOPO, which are due to the adduct formations (*cf.* Eq. (9)), were determined as a function of the concentration of the neutral ligand. Figure 5 gives the results of the copper(II) extractions, while Fig. 6 gives those of the zinc(II) extractions. In both cases, the addition of TBP did not enhance the extraction with AA. The data were also analyzed by means of curve-fitting; the formation constants of the adduct-chelate complexes were determined to be as is shown in Table 2. The solid curves were calculated by introducing the constants in Table 2 into Eq. (11).

The effect of the background salt on the stability

constants and on the distribution constants is complicated. Figures 7 and 8 summarize these results.

Discussion

As can be seen from Figs. 1 and 2, the $-\log[H^+]$ range studied in the present paper is from 1 to 5.5 for the copper(II) extraction and from 2.5 to 9 for the zinc(II) extraction; the hydrolyses of these metals in the aqueous phase should be negligible.[5,6] Thus, the decrease in the distribution ratio of zinc(II) in the highest $-\log[H^+]$ region after the maximum can not be due to the hydrolysis, but must be due to the formation of the third complex.

Acetylacetone and its derivatives have been used for the extraction of various metal ions.[7] The extraction of copper(II) with AA in benzene,[8] in chloroform,[9] or in carbon tetrachloride,[10] and the extraction of zinc(II) with AA in benzene[8] have been reported not to be complete. Recently, Liljenzin, Stary, and Rydberg[11] made a very comprehensive study of the AA extraction of these metal ions in a 1.0M sodium perchlorate solution into benzene in the range from 10°C to 40°C. Their results can be compared directly with the present results except for K_{DM} (they used benzene, while the present authors used carbon tetrachloride as the organic phase). These recent data almost completely agree with the present results, although the former are somewhat higher than the latter (the values of K_a and K_D of acetylacetone used for the calculation were not given in Ref. 11). The other two β-diketones, TFA and HFA, have also been used for the extraction of various metal ions,[12] but no systematic studies of the extraction equilibria of these metal ions seem to have been made and no constants which can be compared with the present results seem to be available.

The well-known general tendency of the order of the stability constants also appears in the present results shown in Table 1; that is, copper(II) forms more stable complexes than does zinc(II), and the weaker bases which are produced by the substitution of the trifluoromethyl group for methyl groups form less stable complexes.

It can be seen from Table 1 that the highest complexes for copper(II) are the second ones, while those for zinc(II) are the third ones. The four coordination for copper(II) and zinc(II) seem to have been well established; the six coordination for zinc(II) in some cases has been also pointed out. The coordination number of zinc(II) in the third complex with AA or TFA should be six, but it is not possible to confirm the coordination number from only the distribution data.

The effect of the coexisting sodium perchlorate on the stability constants is complicated. However, it can be pointed out, on the basis of Table 1 and Fig. 7, that the stability constants are, in most cases, lowest in the 1M ionic medium and highest in the 3M ionic medium (the exceptions are β_1 for the Cu(II)-AA complex, β_1 for the Zn(II)-HFA complex, and β_3 for the Zn(II)-TFA complex).

Suzuki and his co-workers have made a series of studies of the distribution constant of metal-chelate complexes, MA_m, in liquid-liquid systems.[13-21] They

have pointed out that the distribution constants of metal-chelate complexes can be well explained by the regular solution theory.[22] They have demonstrated how the distribution constants of a certain metal-chelate into various non-solvating solvents are parallel to that of the chelating acid, HA, for scandium(III) with some β-diketones and zinc(II) chelates with TTA. Furthermore, they have suggested that the distribution of scandium(III)-β-diketonates are satisfactorily explained in the various solvent systems by:

$$\log K_{DM} = \frac{V_{MA_m}}{V_{HA}} \log K_D + \text{constant} \qquad (24)$$

where V_{HA} and V_{MAm} denote the molar volume of the chelating reagent and that of the metal chelate complex respectively.[14,17,18,20] This relation was also pointed out for the distribution of Zn(II)-TTA chelates into various solutions.[21]

In the present study, only one organic solvent, carbon tetrachloride, has been used, and so no comparison of the distribution constants into different organic solvents is possible. Thus, only the comparison of the distribution constant of a certain chelating acid, K_D, with that of the bis-complex of copper(II) or zinc(II) with the same chelating acid, K_{DM}, may be made. As may be seen from Table 1 and Fig. 8, the distribution constants of the chelating reagents and of the chelate complexes of the two metal ions change in a very complicated manner upon the change in the coexisting salt concentration. The salt effect is parallel neither among three different reagents nor among a certain reagent, HA, and its metal-chelates, CuA_2 and ZnA_2. Actually, the relation given in Eq. (24) is seen only in the extraction of copper(II) in the 1M ionic medium with AA. Except for this, the relation between K_D and K_{DM} is very irregular. Even for the copper(II) extraction with AA, the relation in Eq. (24) is not observed in the extraction from a 0.1M or 3M ionic medium. The distribution constants, K_{DM}, of the copper(II) chelates are here higher than that of the chelating reagents, K_D, whereas they are much lower in the zinc(II) chelates.

The treatments by the regular solution theory are made on the assumption that there is no special strong interaction between the solute and the solvent molecules. As far as the interactions in the carbon tetrachloride phase are concerned, this assumption can be accepted for all the reagents and metal-chelates. However, in aqueous solutions, it is difficult to assume that the central metal ions in the copper(II) and zinc(II) chelates with a certain ligand have the same interactions with water molecules. It can also be supposed that the interactions of the coexisting salt on the two metal complexes with different central metal ions and the same ligand are somewhat different. As will be considered below, the central copper(II) ion in a chelate complex with a certain ligand should interact with polar molecules weaker than those with which the central zinc(II) ion in the complex with the same ligand interacts. Thus, the zinc(II) complex is retained in the aquoues phase more than is the copper(II) complex.

Until now, not many K_{DM} values in chelate-extraction systems have been reported. Dyrssen has, however, reported the K_{DM} values for a series of divalent metal-chelates with β-isopropyltropolone (IPT) between chloroform and a 0.1M sodium perchlorate ionic medium.[23] He reported, for example, that the K_{DM} of the copper(II)-IPT chelate ($\log K_{DM}=4.12$) is much higher than that of the zinc(II)-IPT chelate ($\log K_{DM}=2.25$), and he described how the K_{DM}^{-1} value presumably shows the affinity of the uncharged chelate for the aqueous phase, that is, the tendency for MA_2 to form a hydrate in the aqueous phase, and how this tendency of hydration reveals a fundamental difference in the remaining coordinating power of the central metal ion in the chelate complex.

It seems that the above hypothesis can be adopted even for the present results. The extraction of copper(II) chelates into carbon tetrachloride is always better than that of zinc(II) chelates; this can be explained in terms of the lower K_{DM} of the latter, which in turn is due to the larger interactions of the central zinc(II) ion with water molecules (hydration) than those of the central copper(II) ion in the complex with the same ligand. This may also be seen in the following discussions.

There have been many studies of the adduct formation of metal-chelates with various organophilic neutral ligands, as has been reviewed by Irving[24] and Healy.[12] A general tendency has been observed in the stabilities of the adduct-chelates in the organic phase—those chelates which are extracted better—(or which are extracted in a lower pH region or in a lower chelating reagent concentration) form less stable adducts than do other metal-chelates with the same ligand, but when the central metal ion is the same but the ligand is different, those extracted better form more stable adducts. At the same time, it has been known that more basic neutral ligands form more stable adduct-chelates.

This tendency can also be observed in the results shown in Table 2; zinc(II) chelates form more stable adducts than do the corresponding copper(II) chelates. The chelates of copper(II) or of zinc(II) form more stable adducts in the ligand order of AA<TFA<HFA, which is the inverse of the order of the stabilities of the complexes in the aqueous phase, but the same order as the extraction constants, K_{ex}, in Eq. (12).

The stability of an adduct-chelate should be influenced by many factors, and a too simplified consideration of this problem would lead to an erroneous conclusion. However, as far as the results shown in Tables 1 and 2 are concerned, it may be possible to make the following conclusions: (i) the central metal ion retains more ability to accept further coordination with the neutral ligands in the zinc(II) chelate complexes than in the copper(II) complexes, and (ii) the

central metal ion among the complexes with the same metal ion retains more ability to accept further coordination with other ligands if the stability of the chelate in the aqueous phase is lower.

When the ability of the central metal ion to accept a further ligand is larger, the stability of the adduct should be larger. At the same time, it would interact with water molecules more strongly; this seems to explain the stability order of the adduct-chelates. The molar volumes of CuA_2 and ZnA_2 would not be very much different from each other, and, as was assumed by Suzuki and his co-workers,[13,14] the solubility parameters of the reagent and of the chelate are practically the same. Thus, the lower K_{DM} value of zinc(II) chelates than that of the copper(II) chelates is probably due to the stronger interactions of the central metal ion in the zinc(II) chelates with water molecules than those in the copper(II) chelates. However, further information seems to be necessary if we are to make a detailed consideration of this problem.

The authors are very grateful to Misses Nobuko Saito, Katsue Asami, and Etsuko Yamaguchi for their experimental aid. Part of the work has been carried out in the Laboratory of Nuclear and Analytical Chemistry, Institute of Physical and Chemical Research. The authors are especially grateful to Professor Nobufusa Saito, the head of the Laboratory.

Electron Spin Resonance Study of Short-Lived Free Radicals in Photoreduction of Benzophenone

Hiroshi YOSHIDA and Tetsuo WARASHINA*

Faculty of Engineering, Hokkaido University, Sapporo
**Research Reactor Institute, Kyoto University, Kumatori-cho, Osaka*

(Received April 13, 1971)

By observing electron spin resonance spectra during photolysis at room temperature, kinetic behaviors of short-lived free radicals are studied in photoreduction of benzophenone in alcohols, especially in ethanol, with and without sodium methoxide. In neutral solution, diphenylhydroxymethyl radicals and hydroxyethyl radicals are observed simultaneously. This is a firm evidence, obtained from ESR, of hydrogen abstraction of excited benzophenone from ethanol. Results indicate that (1) free radicals are the most efficiently generated by the light of ~350 nm, (2) hydroxyethyl radicals transform into diphenylhydroxymethyl radicals if the concentration of benzophenone is high, and (3) the latter radicals disappear following the second order reaction. In the presence of sodium methoxide, diphenylhydroxymethyl radicals transform into benzophenone ketyl anions.

Rate constants are determined, being 3×10^7 and $\sim10^4$ $mole^{-1}\cdot l\cdot sec^{-1}$ for the combination reaction between diphenylhydroxymethyl radicals and the proton transfer reaction from diphenylhydroxymethyl radical to methoxide ion, respectively.

Photoreduction of benzophenone in alcohols is one of the most extensively studied subjects in photochemical reactions. Triplet excited benzophenone abstracts hydrogen from the solvent molecule to form diphenylhydroxymethyl radicals, which combines with each other to benzpinacol in neutral solutions.[1] Porter and Wilkinson proved directly by flash photolysis technique that the diphenylhydroxymethyl radicals were formed as intermediates in the photoreduction of benzophenone, and also that they converted to benzophenone ketyl anions in alkaline solutions.[2] Beckett and Porter determined the rate constant of reactions involving the diphenylhydroxymethyl radicals and ketyl anions.[3]

Since Livingston and Zeldes developed a technique of observing electron spin resonance (ESR) spectra of transient free radicals in liquids during photolysis,[4] the technique has been successfully employed to several photochemical reactions. Among them, Wilson studied free radicals photolytically generated from aromatic carbonyl compounds,[5-9] and found that diphenylhydroxymethyl radical was formed from benzophenone in alcohols, tetrahydrofuran,[6] and triethylamine.[9] From the observed hyperfine coupling constants, the structure of the free radical, especially the effect of hydrogen bond on the coupling constant of hydroxy proton, was studied in detail in referring to a molecular orbital calculation. The ESR observation gave an evidence that the photoreduction process involves the transient diphenylhydroxymethyl radical,

though the counterpart radical formed from solvent was unable to be detected.

These investigations encouraged us to extend ESR study to kinetical behavior of transient free radicals during photolysis. In the present investigation, the ESR technique is employed to study the photoreduction of benzophenone in alcohols with the intention of elucidating the kinetical behavior of radicals, their formation and decay, in neutral and alkaline solutions.

Experimentals

Apparatus used was essentially the same as described by Livingston and Zeldes.[4] Illuminating light from a superhigh pressure mercury lamp (Philips, SP-500, 500 watts) passed throuth a quartz lens and a grid plate of a resonance cavity (Varian, Model E-4531), connected to a conventional ESR spectrometer (Varian, E-3), to a quartz flat cell. A glass cut-off filter or a mesh was inserted between the lens and the grid plate, if necessary, to regulate the illuminating light.

Analytical grade chemicals were used without further purification. Air dissolved in solutions was removed by bubling helium gas for at least half an hour before photolysis.

Flow rate of solutions was 4.3 m*l* per min. As the effective volume of the cell was 0.052 m*l*, the resident time of the solution in the cell was estimated to be 0.7 sec, during which free radicals were generated by light, and their ESR spectra were detected. Flowing through the cell, the solutions were heated by the light to about 5° higher than the room temperature (20°±2°C).

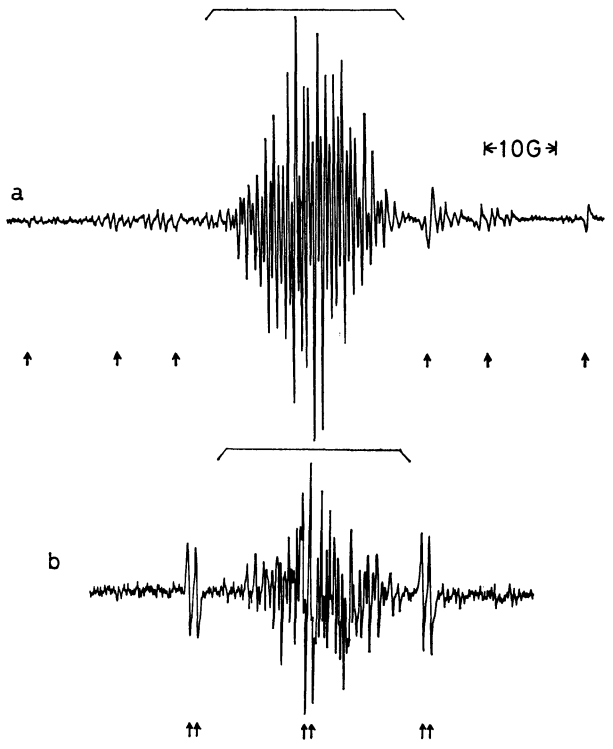

Fig. 1. Electron spin resonance spectra observed during the photolysis of benzophenone (0.44 mol·l^{-1}) in (a) ethanol and (b) methanol at room temperature. Brackets and arrows indicate the spectra of free radicals formed from benzophenone and those formed from alcohols, respectively. Amplitude of magnetic field modulation: 0.5G.

Results

Figure 1 shows the ESR spectra observed from solutions of benzophenone in ethanol and methanol. They are composed of three components: the spectra indicated with arrows due to free radicals, $CH_3\dot{C}HOH$ and $\dot{C}H_2OH$, formed by hydrogen abstraction from ethanol and methanol, respectively, central complex spectra indicated with blackets due to free radicals formed from benzophenone, and other spectra which are rather weak and are not identified. The free radicals fromed from solvent molecules are identical with those reported by Livingston and Zeldes.[4]

The yield of free radicals was larger in ethanol than in methanol. Therefore, ethanol is used as solvent in all experiments described below.

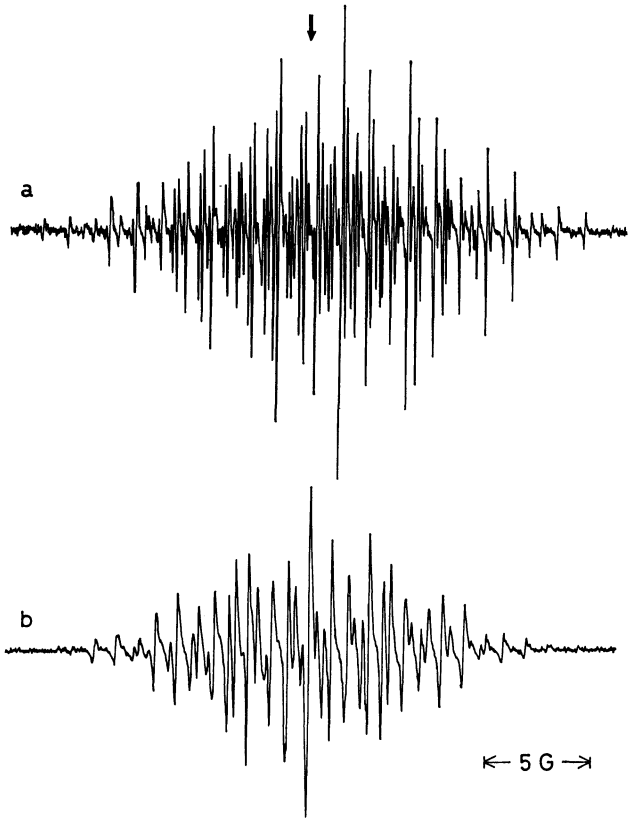

Fig. 2. Electron spin resonance spectra observed during the photolysis of benzophenone (0.44 mol·l^{-1}) in ethanol at room temperature. Amplitude of magnetic field modulation: 50 mG. (a) Diphenylhydroxymethyl radical formed in neutral solution and (b) benzophenone ketyl anion formed in the presence of sodium methoxide. Arrow indicates the center of spectra.

When the central spectrum is recorded with a small amplitude of magnetic field modulation, well resolved hyperfine structure is observed as shown in Fig. 2, *a*. The structure is described by equivalent four protons at the ortho-positions of the rings with hyperfine coupling constant of 3.1G, four protons at meta-positions with the coupling constant of 1.2G, two protons at the para-positions of the rings with the constant of 3.6G, and a proton in hydroxy group with the constant of 2.9G, and it is reasonably attributed to diphenyl-

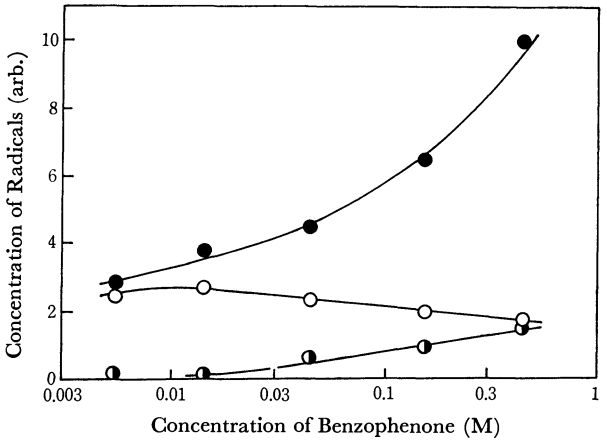

Fig. 3. Dependence of observed concentration of free radicals formed during the photolysis of benzophenone in ethanol on the concentration of benzophenone. ●; Diphenylhydroxymetyl radical, ○; hydroxyethyl radical, ◑; unidentified radical.

hydroxymethyl radical. The observed hyperfine coupling constants are compared with those reported, 3.23, 1.23, 3.64, and 2.91G, respectively.[6] The spectrum of $CH_3\dot{C}HOH$ vanishes if recorded with the small amplitude of field modulation, because of its larger width of hyperfine lines.

Observed intensity of the three spectra are plotted as a function of the concentration of benzophenone in solution, as shown in Fig. 3. At the lowest concentration examined, the observed yield of diphenylhydroxymethyl radical is about the same as that of $CH_3\dot{C}HOH$. With the increasing concentration of benzophenone, the yield of diphenylhydroxymethyl radical increases remarkably, while that of hydroxyethyl radical reaches the maximum and then gradually falls down.

The unidentified spectrum also increases in its intensity with the increasing concentration of benzopheneone. It is probably due to free radicals formed by the reaction between the primarily formed radicals and benzophenone.

The intensity of observed spectra was calibrated with reference to that of diphenylpicrylhydrazyl solution in ethanol. The concentration of diphenylhydroxymethyl radical was estimated to be 4.5×10^{-7} mol·l^{-1} for the highest concentration of benzophenone examined (0.44 mol·l^{-1}), though the value includes the uncertainty factor of 2.

The yield of diphenylhydroxymethyl radical was studied as a function of light intensity, at the benzophenone concentration of 0.14 mol·l^{-1}. It was found to be proportional to the 0.37th power of the light intensity. The radicals disappear probably in combining with each other following the second order kinetics rather than the first order one. The deviation of exponent from 0.5 may have been caused by the fact that the resident time of solution in the resonance cavity is so short that the steady state concentration of the radicals is not completely attained.

The lifetime of diphenylhydroxymethyl radical was determined, for the benzophenone concentration of 0.44 mol·l^{-1} by recording the transient change of the intensity of its spectrum, when the illuminating light was rapidly shut off and lit on repeatedly. Representative results are shown in Fig. 4, *a*. The most probable curve of transient change is obtained as Fig. 4, *b*, which gives the rise and decay times of 0.8 and 0.2 sec, respectively. Difference between the rise time and the decay time is resulted from an effective lifetime due to the flowing of radicals out of the cell, t_f. They are approximated by the following relations:

$$1/t_d = 1/\tau + 1/t_f \quad (1)$$

$$1/t_r = 1/\tau - 1/t_f, \quad (1')$$

where t_d and t_r stand for the decay and rise time, and τ is true half life of the radical.[10] The half life is determined from Fig. 4, *b*, being 0.3 sec. The calculated t_f is 0.5 sec, which is in agreement with the resident time of solution in the cell (a half of the resident time, 0.7/2=0.35 sec, is the expected value for t_f).

To determine the wavelength of light effective to

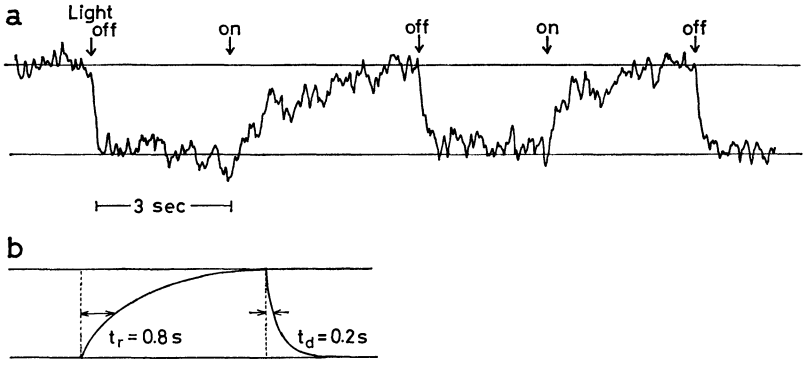

Fig. 4. Transient change in the intensity of electron spin resonance specta due to short-lived free radicals during the photolysis of benzophenone (0.14 mol·l^{-1}) in ethanol, when the light is shut off and lit on rapidly, recorded with response time of 0.1 sec. (a) An example of recorded curves, (b) the most probable curve estimated from several observations.

10) When the plateau of curves in Fig. 4 indicates the steady state concentration under the photo-illumination, the relations (I) and (I′) enable us to estimate the value of $\tau(\approx 1/\sqrt{k_5 R}$, R is the rate of radical formation and k_5 is the rate constant of bimolecular decay of free radicals, as seen in eq. (7)) and t_f. If the plateu value is much less than the steady state concentration, the relations should be replaced by $1/t_d > 1/\tau + 1/t_f$ and $1/t_r < 1/\tau - 1/t_f$. However, in this experiment, the calculated t_f of 0.5 sec is rather close to the expected value of 0.35 sec. Therefore, the relations are thought to be valid for rough estimation of τ.

generate free radicals, the intensity of ESR spectra was examined by inserting a cut-off filter to the light path. The relative values of intensity were 100, 92, 83, 60, and 14 for $\lambda>250$ (without filter), >270, >310, >350, and >390 nm, respectively. Referring a factory-provided datum of the lamp, relative quantum efficiencies are estimated, being 0.3, 1.0, and 1.0 for the wavelength region of 270~310, 310~350, and 350~390 nm. The light of wavelength around 350 nm is the most effective.

When the solution was made alkaline by adding sodium methoxide, the spectrum of diphenylhydroxymethyl radical was replaced by the spectrum shown in Fig. 2, *b*. The latter has the hyperfine structure due to four equivalent protons with the coupling constant of 2.8G, four protons with 1.0G and two protons with 3.5G, and is identical with that of benzophenone ketyl anion reported previously.[11] The *g*-factor of ketyl anion is found to be larger than that of diphenylhydroxymethyl radical by 0.0003. Therefore, $g=2.0033$ for the ketyl anion, because $g=2.0030$ for the latter radical.[6]

At small concentration of sodium methoxide added, ESR spectra show the coexistence of both diphenylhydroxymethyl radical and bonzophenone ketyl anion. With the increasing concentration of sodium methoxide, the former decreases and the latter increases in their concentration. Concurrently, the sum of them increases from 4.5×10^{-7} mol·l^{-1} to a plateau value of 4×10^{-6} mol·l^{-1}, for 0.44 mol·l^{-1} of benzophenone, as shown in Fig. 5.

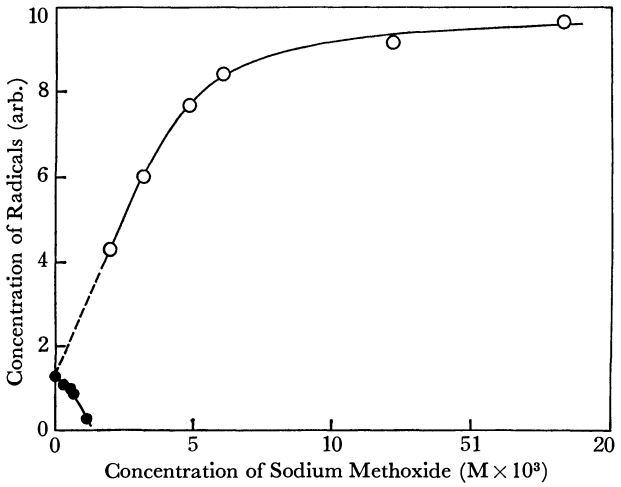

Fig. 5. Observed concentration of diphenylhydroxymethyl radical (●) and benzophenone ketyl anion (○) formed during the photolysis of benzophenone (0.44 mol·l^{-1}) in ethanol as a function of sodium methoxide added to the solution.

Discussion

Photoreduction of benzophenone in alcohols has been studied by means of conventional photochemical analysis method and, later on, by flash photolysis technique. Generally accepted mechanism, for ethanol as solvent, is as follows:[1,3]

11) P. B. Ayscough and R. Wilson, *J. Chem. Soc.*, **1963**, 5412.

$$(C_6H_5)_2C{=}O \xrightarrow{h\nu} (C_6H_5)_2{=}O^* \quad (2)$$

$$(C_6H_5)_2C{=}O^* + CH_3CH_2OH \longrightarrow (C_6H_5)_2\dot{C}OH + CH_3\dot{C}HOH \quad (3)$$

$$CH_3\dot{C}HOH + (C_6H_5)_2C{=}O \longrightarrow CH_3CH{=}O + (C_6H_5)_2\dot{C}OH \quad (4)$$

$$2(C_6H_5)_2\dot{C}OH \xrightarrow{k_5} (C_6H_5)_2COHCOH(C_6H_5)_2 \quad (5)$$

Very primary process is the excitation of benzophenone. Radicals are generated the most efficiently by the light of wavelength around 350 nm, which indicates that $n\rightarrow\pi$ transition of benzophenone is responsible for the hydrogen abstraction reaction (3), as the transition has the band maximum at about 340 nm in alcoholic solutions. The reaction (3) is directly evidenced by observing simultaneously the ESR spectra of both diphenylhydroxymethyl radical from benzophenone and hydroxyethyl radical from ethanol.

Results shown in Fig. 3 strongly suggest the conversion of hydroxyethyl raidcal to diphenylhydroxymethyl radical, by the reaction (4). If the concentration of benzophenone, and therefore that of diphenylhydroxymethyl radical, is enough high, the radical disappear following the second order reaction, as expected from the reaction (5). In the presence of sodium methoxide, the reaction competes with its conversion to benzophenone ketyl anion,

$$(C_6H_5)_2\dot{C}OH + CH_3O^- \xrightarrow{k_6} (C_6H_5)_2CO^- + CHO_3H. \quad (6)$$

As the ketyl anion is much more stable than diphenylhydroxymethyl radical,[3,5] the sum of both the anion and the radical increases in their yield with the increasing concentration of added sodium methoxide. The plateau of curve in Fig. 5 is thought to be attained by the complete conversion to the ketyl anion without loss of diphenylhydroxymethyl radical; $k_5[(C_6H_5)_2\dot{C}OH]\ll k_6[CH_3O^-]$.

The competing reactions are described by the following kinetical relations:

$$\frac{d[(C_6H_5)_2\dot{C}OH]}{dt} = R - k_5[(C_6H_5)_2\dot{C}OH]^2 - k_6[(C_6H_5)_2\dot{C}OH][CH_3O^-] \quad (7)$$

$$\frac{d[(C_6H_5)_2CO^-]}{dt} = k_6[(C_6H_5)_2COH][CH_3O^-], \quad (8)$$

where R stands for the rate of formation of diphenylhydroxymethyl radical. In the absence of sodium methoxide, the concentration of diphenylhydroxymethyl radical follows eq. (9) obtained by integrating eq. (7) with the initial condition of null concentration for $t=0$,

$$[(C_6H_5)_2\dot{C}OH] = \sqrt{\frac{R}{k_5}}\cdot\frac{\exp(2\sqrt{k_5R}\cdot t)-1}{\exp(2\sqrt{k_5R}\cdot t)+1}, \quad (9)$$

For the concentration of sodium methoxide enough high, the loss of free radical may be ignored, and

$$[(C_6H_5)_2CO^-] = R\cdot t. \quad (10)$$

Flowing solutions are photolyzed for their resident time in the cell, t_0. Therefore, the observed intensity of spectra is proportional to

$$\int_0^{t_0}[(C_6H_5)_2\dot{C}OH]dt = \frac{1}{k_5}\cdot\ln\{\exp(2\sqrt{k_5R}\cdot t_0)+1\} - \sqrt{\frac{R}{k_5}}\cdot t_0 \quad (11)$$

and

$$\int_0^{t_0}[(C_6H_5)_2CO^-]dt = \frac{R}{2}\cdot t_0^2. \quad (12)$$

The observed concentration without sodium methoxide (the left hand side of eq. (11), 4.5×10^{-7}) and that at the plateau of curve (the left hand side of (12), 4×10^{-6}) both indicated in Fig. 5 and $t_0=0.7$ sec lead to $k_5=3\times10^7$ mol$^{-1}\cdot l\cdot$sec^{-1}. Thus obtained k_5 is compared with the value derived from flash photolysis study, 5.9×10^7 mol$^{-1}\cdot l\cdot$sec^{-1}, in 50 vol% isopropanol-water mixture.[3]

On the other hand, the value of k_5 can be roughly estimated from the true half life of diphenylhydroxymethyl radical in the absence of sodium methoxide (see Fig. 4). From the relation,

$$k_5 = 1/[(C_6H_5)_2\dot{C}OH]_0\cdot\tau, \quad (13)$$

$[(C_6H_5)_2\dot{C}OH]_0\approx4.5\times10^{-7}$ mol$\cdot l^{-1}$ and $\tau\approx0.3$ sec, k_5 is calculated to be 0.7×10^7 mol$^{-1}\cdot l\cdot$sec^{-1}. If one consider local sensitivity of ESR depending on the sinusoidal distribution of microwave magnetic field, H_1, along the flow of solution, which is ignored in the above treatments, and the uncertainty involved in eqs. (1) and (1'), this value of k_5 is thought to agree rather well with the value of 3×10^7 mol$^{-1}\cdot l\cdot$sec^{-1}.

The yield of benzophenone ketyl anion reaches to 50% of its plateau value at 2.5×10^{-3} mol$\cdot l^{-1}$ of sodium methoxide. At this concentration, the following reaction can be used to evaluate the rate constant, k_6;

$$k_5[(C_6H_5)_2COH] = k_6[\dot{C}H_3O^-], \quad (14)$$

Assuming that sodium methoxide dissociates completely in ethanol at this low concentration, estimation of the order of magnitude gives 10^4 mol$^{-1}\cdot l\cdot$sec^{-1} for the rate constant of proton transfer from diphenylhydroxymethyl radical to methoxide ion, reaction (6).

The authors express their sincere thanks to Prof. Koichiro Hayashi of Hokkaido University and Prof. Takenobu Higashimura of Kyoto University, for their continual encouragement and valuable discussion throughout this work.

(Received April 21, 1971)

The structure of 1,4-Bis(*p*-bromophenoxy)butane has been determined by means of a single-crystal X-ray analysis. The compound crystallizes in the monoclinic space group *Cc*, with four molecules per unit cell: $a=13.426$, $b=15.249$, $c=7.650$ Å, and $\beta=89.39°$. The structure has been solved by the heavy-atom method. The final discrepancy index is 0.068 for 970 non-zero reflections. The conformation of the methylene chain in the $-O(CH_2)_4O-$ group is *gauche-trans-gauche*, with internal rotation angles of 61.0, 181.0, and 55.2° respectively.

High polymers consisting of the repeating unit $X-C_6H_4-O-(CH_2)_n-O-C_6H_4-X$ generally show high melting and glass-transition points and high elastic moduli. It is generally accepted that this behavior is not only due to the rigidity of the benzene rings in the molecular chains, but also to the length and conformation of the methylene chain between the phenoxy groups.[1-4]

As a crystallographic approach to this problem, Yasuoka *et al.* have determined the crystal structures of a series of model compounds of the above type of polymer. Among the compounds are 1,2-Bis(phenoxy)-ethane,[5] 1,2-Bis(*p*-chlorophenoxy)ethane,[6] and 1,3-Bis-(*p*-bromophenoxy)propane.[7] As a part of this series of studies, the crystal structure analysis of 1,4-Bis(*p*-bromophenoxy)butane, $BrC_6H_4O(CH_2)_4OC_6H_4Br$ was undertaken by means of X-ray diffraction.

Experimental

Single crystals of 1,4-Bis(*p*-bromophenoxy)butane were recrystallized from a methanol-benzene solution. From oscil-

lation and Weissenberg photographs, the approximate dimensions of the unit cell were determined; they were later redetermined precisely by using a Rigaku on-line controlled four-circle diffractometer. The crystal belongs to the monoclinic system. The systematic absences of reflections, $h+k\neq 2n$ for hkl and $l\neq 2n$ for $h0l$, indicate that the probable space group is $C2/c$ or Cc. The density of the crystal was measured by the flotation method in a carbon tetrachloride-bromoform solution at room temperature. The crystal data are listed in Table 1.

Table 1. Crystal data

$Br_2C_{16}H_{16}O_2$	Mol wt 400.1
	mp 118—120°C
$a=13.426$ Å	$D_m=1.70$g·cm^{-3}
$b=15.249$	$D_x=1.69$g·cm^{-3}
$c=7.650$	$Z=4$
$\beta=89.39°$	Space group Cc

The three-dimensional intensity data were at first collected by multiple-film equi-inclination Weissenberg photographs. Subsequently, the redetermination of the intensity data was carried out using a Rigaku single-crystal diffractometer. A total of 1034 independent reflections (970 non-zero reflections) were collected by means of zirconium-filtered Mo$K\alpha$ radiation. The dimensions of the crystal used were $0.1\times 0.12\times 0.20$ mm. The intensities were corrected for usual Lorentz and polarization factors, but the absorption correction was ignored (the linear absorption coefficient was $\mu=54.6$ cm^{-1} for Mo$K\alpha$).

Structure Determination and Refinement

Though $C2/c$ or Cc was postulated for the structure at the beginning, the space group is determined to be Cc, since the center of symmetry is not found by the N(z) test and since it is impossible to solve the Patterson map if the space group is $C2/c$.

The approximate coordinates of the two bromine atoms were determined from two-dimensional Patterson maps, $P(u,v)$ and $P(u,w)$. The coordinates of the other non-hydrogen atoms were determined by the successive use of Fourier syntheses. Thus, the molecular shape was determined at this stage, and the discrepancy index, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ was 0.21. Further refinement was carried out by using the counter data.

The atomic and isotropic thermal parameters were refined by a block-diagonal least-squares procedure. After seven cycles, the R index was reduced to 0.136 for 970 non-zero reflections. At this stage, anisotropic thermal parameters for non-hydrogen atoms were introduced; six subsequent cycles of the refinement gave $R=0.076$. The function minimized was $\Sigma w\Delta^2$, where the weighting scheme used was:

$$w = 200.0/|F_0| \quad (|F_0|\geqq 200.0),$$
$$w = 1 \quad (200.0>|F_0|>4.0), \text{ and}$$
$$w = 0.2 \quad (|F_0|\leqq 4.0).$$

The atomic scattering factors for all atoms were taken from the International Tables for X-ray Crystallography.[8]

8) "International Tables for X-ray Crystallography," Vol. III, The Kynoch Press, Birmingham (1961), p. 202.

A difference Fourier synthesis (ρ_o-ρ_c) was computed; however, several hydrogen atoms among the total of sixteen could not be found as sharp peaks. Therefore, the coordinates of the hydrogen atoms were fixed; all the C–H bond lengths were taken as 1.08 Å. The anomalous dispersion of the bromine atoms ($\Delta f'=-0.30$ and $\Delta f''=2.60$) was introduced in the refinement, and the R index reached 0.068. At this stage, it was found that the parameter shifts were insignificant compared to the estimated standard deviations, and so the refinement was terminated.

+ Supposed conformation on the bases of the fact that Br- and Cl-derivatives are isostructural in the case of n=3.

Discussion

Figure 1 shows the crystal and physical data of a series of homologous compounds, X-C_6H_4-O-$(CH_2)_n$-O-C_6H_4-X (X=H or halogen atom). The crystal structures of the homologues with n=2 had previously been determined.[5,6] For n=3, only the crystal structure of the Br-derivative[7] has been determined; however, the Cl-derivative can be expected to have a similar structure, since they have the same space group, similar unit-cell parameters, and an equal number of chemical units per unit cell, Z, suggesting that these crystals are isostructural.

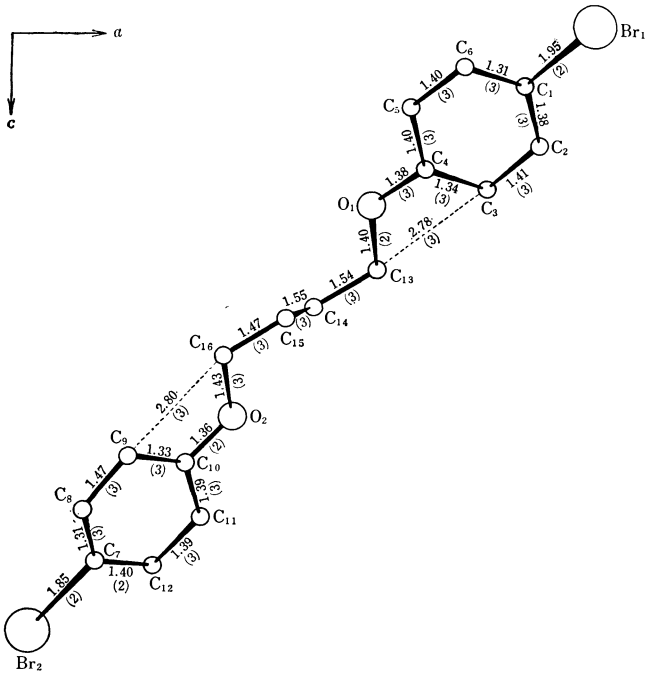

Fig. 2. The molecular shape viewed along the b axis, and bond lengths (Å) with estimated standard deviations ($\times 10^{-2}$Å) in the molecule.

In the case of n=4, there is a difference between the crystal data of the Cl- and Br-derivatives. Thus, the space group and the value of Z are $P2_1/n$ and eight respectively, for the Cl-derivative, while they are Cc and four for the Br-derivative. Therefore, it must be noticed that the information on the packing of molecules in the unit cell and the molecular conformation of the Br-derivative obtained in the present study is not always applicable to that of the Cl-derivative.

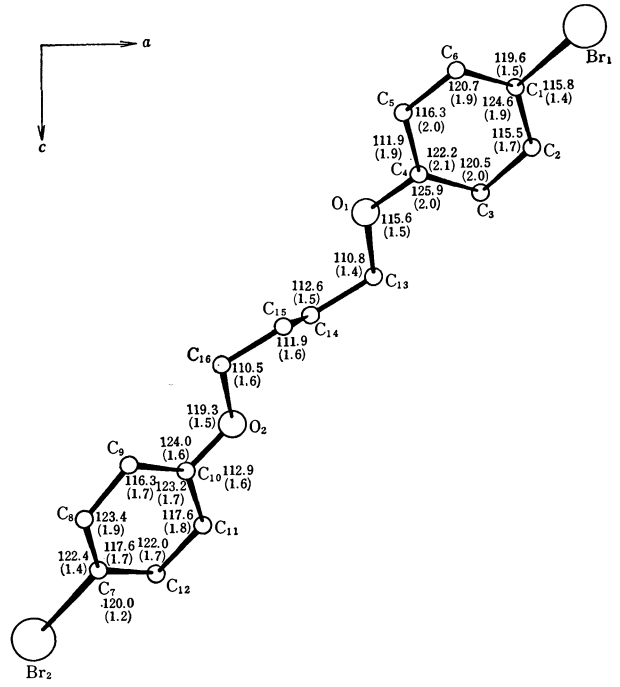

Fig. 3. The molecular shape viewed along the b axis, and bond angles with estimated standard devistions (°) in the molecule.

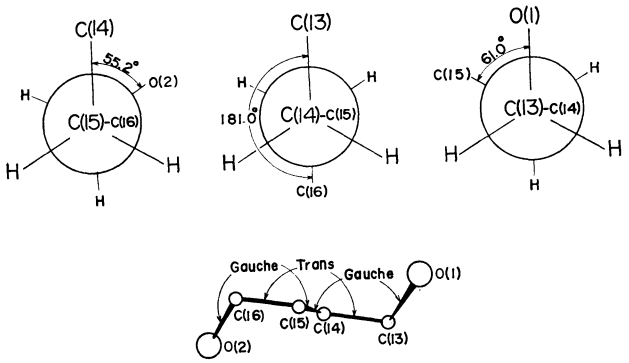

Fig. 4. The conformation of the methylene groups and the internal rotation angles (°).

The molecular shape viewed along the *b* axis is shown in Fig. 2. In Fig. 2 the bond lengths are also given, along with their estimated standard deviations. The bond angles are listed in Fig. 3.

The most remarkable feature of the molecular structure is that the conformation of the methylene groups is in the *gauche-trans-gauche* form (Fig. 4). The internal rotation angles are also shown in Fig. 4. On the other hand, the conformations of the methylene groups found in other, shorter homologues are *gauche* for $n=2$ in $XC_6H_4O(CH_2)_nOC_6H_4X$ and *gauche-gauche* for $n=3$.

The benzene rings are approximately planar, and the best least-squares planes are:

$$0.09254X + 0.94475Y + 0.31445Z + 2.42683 = 0$$

(benzene 1)

and:

$$0.40188X + 0.81185Y + 0.42354Z + 2.62451 = 0$$

(benzene 2)

where $X=ax+cx\cos\beta$, $Y=by$, and $Z=cz\sin\beta$. The maximum deviation of the atom from the plane is 0.024 Å for C(3). As is shown in Fig. 2, the nonbonded intramolecular distance from C(3) to C(13) is 2.78 Å, and that one from C(9) to C(16) is 2.80 Å. C(13) and C(16) lie almost on the plane containing the benzene ring, the displacements from the plane being 0.08 and 0.10 Å respectively.

The crystal structure, as viewed along the *b* and *c* axes, is shown in Fig. 5 and 6 respectively. In these figures short intermolecular atomic contacts of less than 4.0 Å are given. As may be seen in Fig. 5, molecules are piled up along the *b* axis; the benzene ring, 1, of a molecule is above the benzene ring, 2, of the other molecule, and the dihedral angle between two benzene rings in a molecule is 20.39°.

The authors wish to express their deep thanks to Dr. Tadanao Ando of Government Industrial Research Institute, Osaka for supplying crystals. Their thanks are also due to Mr. Yasushi Kai of Osaka University for helping a part of experiment. The authors are also indebted to Dr. Tamaichi Ashida of Institute for Protein Research of Osaka University for his computer programs.

Anodic Oxidation of Aniline in Aqueous Alkaline Solution

Yoshiharu MATSUDA, Akira SHONO, Chiaki IWAKURA, Yoshiki OHSHIRO, Toshio AGAWA, and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received April 21, 1971)

The anodic oxidation of aniline in an aqueous alkaline solution was studied. The anode materials were Ni, C, Pt, and Pb. An organic deposit (film) was formed on the anodes. The reaction mechanism was estimated through electrochemical measurements, chemical analysis, thin-layer chromatography, and UV, NMR, and IR spectrometries. The de-electronation of lone-pair electrons of the N atom in an aniline molecule caused the radical cation to be produced,  , and this process was the rate-determining step. Some of the radical cations were found to couple together to produce azo-benzene *via* hydrazobenzene. The other radical cations led to *p*-amino diphenylamine by head-to-tail coupling; this product was de-electronated again to give the polymer with a quinoid structure.

Since Letheby[1] obtained aniline black through the anodic oxidation of aniline, many works have been presented on the anodic oxidation of aromatic compounds. Yasui[2] reported that aniline black was obtained from *p*-amino-diphenylamine and emeraldine in aqueous hydrochloric acid. Recently, discussion[3,4] was focussed on the reaction mechanism of the anodic oxidation of aniline derivatives in aqueous acidic solutions and also in nonaqueous solvents. Adams and his co-workers[5] observed the amino radical in the process of the anodic oxidation of aromatic amines. However, in an aqueous alkaline solution, the anodic oxidation of aniline has not been investigated. The present authors found film formation on the anode in an aqueous alkaline solution containing aromatic amines in their study of the electrochemical behavior of aniline derivatives.[6] In the present work, the anodic oxidation of aniline in an aqueous alkaline solution was carried out in order to elucidate the mechanism of this process by the analysis of the product and by electrochemical measurements.

Experimental

Test Electrode. The test electrodes were platinum, nickel, lead, and carbon. The metal electrodes were plates, 1 cm × 1 cm, equipped with a wire and sealed in glass tube. The carbon electrode was a carbon rod for spectroscopic analysis whose available area was made 1 cm^2 by blinding with Daifloil. The test electrodes were polished with emery paper, rinsed with a 1N aqueous solution of potassium hydroxide and a 1N aqueous solution of hydrochloric acid, and then immersed in a 10% aqueous solution of hydrazine. However, in the case of the lead electrode, the treatments with alkaline and acid were omitted.

Electrolytic Cell. The electrolytic cell was a H cell (100 m*l*) with a sintered glass disk diaphragm and a Luggine capillary connected to a reference electrode (Hg/HgO/1N KOH). The counter electrode was a platinum plate (2 cm × 2.5 cm). Triangular potential waves were generated by using a potentiostat HP-E and a frequency function generator NS_2 (by Nichia Keiki Co., Ltd.). The temperature was 30°C.

Materials. An alkaline solution was prepared with a commercial, analytical-grade reagent and deionized water. The aniline was commercial and at an analytical grade, too.

Results and Discussion

Current-potential Curves of Aniline by Cyclic Voltammetry. A typical current-potential curve of aniline in 1N potassium hydroxide, determined by cyclic voltammetry with a platinum electrode, is shown in Fig. 1.

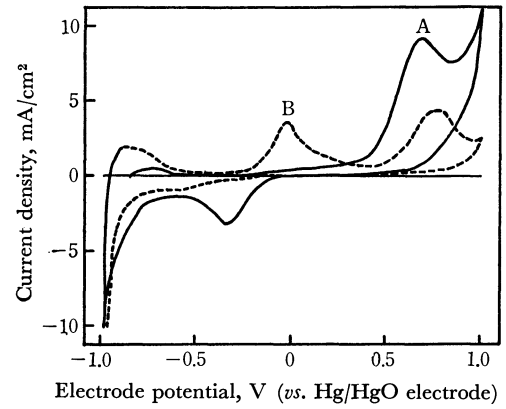

Fig. 1. Voltamgram of aniline in aqueous KOH solution. Potential sweep rate: 0.2 V/sec, 30°C, Electrode: Platinum plate, Electrolyte solution: 1N KOH + 10^{-2}M aniline.

The potential sweep range was −1.0—+1.0 V (*vs.* Hg/HgO electrode); the potentials for the reactions of hydrogen and oxygen evolutions were outside this potential sweep range. The potential was anodically swept first from −1.0 V (*vs.* Hg/HgO electrode); then the direction of the current was reversed at +1.0 V, and the same procedures were repeated.

When aniline was absent in the solution, the current peaks, A and B in Fig. 1, were not observed. At the first anodic sweep with the existence of aniline, only the current peak A was ovserved; after the second sweep, both current peaks, A and B, were obtained.

2) T. Yasui, This Bulletin, **10**, 305 (1935).
3) S. Wawzonek, T. W. McIntyre, *J. Electrochem. Soc.*, **114**, 1025 (1967).
4) T. Mizoguchi and R. N. Adams, *J. Amer. Chem. Soc.*, **84**, 2058 (1962).
5) E. T. Seo, R. F. Nelson, J. M. Fritsch, L. S. Marcoux, D. W. Leedy, and R. N. Adams, *ibid.*, **88**, 3498 (1966).
6) H. Tamura, Y. Matsuda, and M. Iijima, *Kogyo Kagaku Zasshi*, **72**, 1077 (1969).

When the cyclic voltammetry was applied, the current peaks corresponding to A and B became lower and reddish-brown film was precipitated on the electrode as time passed. When the potential sweep range was only between −1.0 and +0.4 V, the B peak was not observed on the current-potential curve. From the results mentioned above, the two current peaks, A and B, might be assumed to be caused by the anodic reaction of aniline or the intermediate products. The anodic oxidation of aniline, therefore, might be initiated with the electrochemical reaction corresponding to the current peak A. Moreover, it can be assumed that the decrease of the current with cyclic sweeps might be caused by the increase in the resistance on the electrode resulting from the film formation. Therefore, as will be discussed later, this initial reaction is shown by Eq. (1):

$$C_6H_5\ddot{N}H_2 - e^- \longrightarrow C_6H_5\dot{\overset{+}{N}}H_2 \qquad (1)$$

Moreover, the B peak may be assumed to correspond to the anodic oxidation of *p*-amino-diphenylamine, the intermediate product. Mohilner and his co-workers[7] have already observed this phenomenon at *ca.* 0.1 V (*vs.* SCE) in dilute sulfuric acid containing aniline.

Anodic Oxidation of Aniline at a Controlled Potential. As has previously been mentioned, the initial electrochemical reaction corresponded to the A peak in Fig. 1. In this potential range, a Tafel relation was observed when the current was measured 1 min later after setting the potential; the relation between the current and the concentration of aniline was found to be as is shown in Fig. 2. The electrochemical reaction order was found to be one from the slope of the line in Fig. 3.

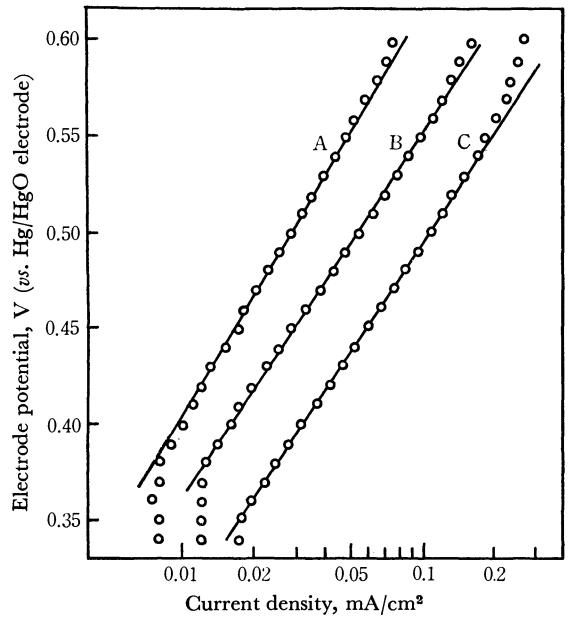

Fig. 2. Tafel lines for anodic oxidation of aniline in aqueous KOH solution.
Under stationary state, Electrode: platinum plate, 30°C
A: 1N KOH+1×10^{-3}M aniline
B: 1N KOH+2.5×10^{-3}M aniline
C: 1N KOH+5×10^{-3}M aniline

7) D. M. Mohilner, R. N. Adams, and W. J. Argersinger, Jr., *J. Amer. Chem. Soc.*, **84**, 3618 (1962).

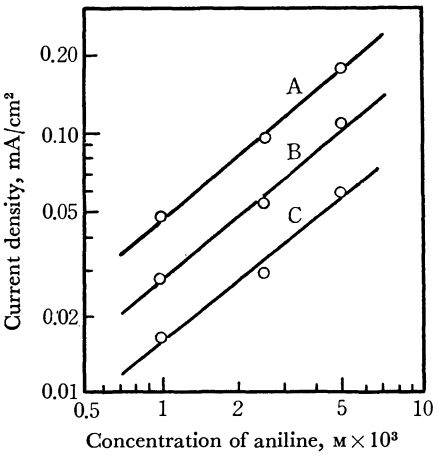

Fig. 3. Relation between current density and concentration of aniline for anodic oxidation of aniline in aqueous KOH solution.
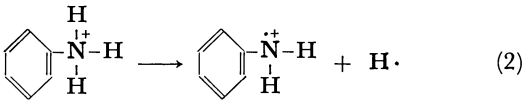
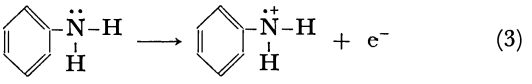
Electrode: platinum plate, 30°C
A: 550 mV (*vs.* Hg/HgO electrode)
B: 500 mV (*vs.* Hg/HgO electrode)
C: 450 mV (*vs.* Hg/HgO electrode)

Mohilner and his co-workers[7] reported that the initial anodic reaction of aniline in an acidic solution was the formation of the cation radical, shown in Eq. (1). Other reports[3-5] on the anodic oxidation of aromatic amines in nonaqueous solvents have pointed out mechanisms similar to Eq. (1). For Eq. (1) to proceed in an acidic solution, a protonated aniline molecule must be de-hydrogenated, as in Eq. (2), because aniline in an acidic solution is usually protonated:



(2)

However, in an alkaline solution, an aniline molecule is only to be de-electronated as in Eq. (3), which is the same as Eq. (1), because aniline is a free amine in an aqueous alkaline solution:



(3)

If we compare the two mechanisms, the reaction shown by Eq. (3) should be easier than the reaction shown by Eq. (2) because the de-electronation is usually easier than the de-hydrogenation. At the same time, the reaction order, one, suggests that the reaction shown by Eq. (1) is the initial anodic reaction.

Furthermore, this process is the rate-determining process for the anodic oxidation in an aqueous alkaline solution, because a Tafel relation was observed at the potential for the current peak A in Fig. 1.

Materials for the Anode. By using carbon, nickel, and lead electrodes, cyclic voltammetric measurements were made at the alkaline solution containing aniline. The current peak potentials corresponding to the A peak in Fig. 1 for these systems are shown in Table 1. This table also shows the slopes of the Tafel lines which were measured by the procedures described in the previous section.

The potential of the current peak and the slope of

TABLE 1. PEAK POTENTIALS AND SLOPES OF TAFEL LINES ON VARIOUS ELECTRODES

Electrode	Peak potentials corresponding to the peak A in Fig. 1 (*vs.* Hg/HgO electrode)	Slope of Tafel line V/log *i*
Ni	0.52 V	0.100
C	0.55	0.131
Pt	0.71	0.188
Pb	0.73	0.501

Tafel line give measures of the electrochemical reaction rate, and nickel is the most active electrode in an aqueous alkaline solution for the initial anodic reaction of aniline corresponding to the A peak in Fig. 1, with carbon and platinum following next. From the data in Table 1, the lead electrode can be said to be the most inactive electrode among them.

Characterization of the Deposit (film) on the Anode. The anodic oxidation of aniline was made by using nickel electrode (3×4 cm^2) and a beaker-type electrolytic cell. The anode potential was +0.5 V (*vs.* Hg/HgO electrode), the electrolyte solution was an aqueous solution of 1N potassium hydroxide with 10^{-2}M aniline, and the temperature was 30°C±0.1°C. The samples for UV and NMR spectrometries, the measurement of the molecular weight, the elementary analysis, and thin-layer chromatography were obtained by the extraction of the film on the electrode with benzene.

After the electrolysis, the IR spectrum of the film on the anode was taken with a polarized IR spectrometer.

TABLE 2. ANALYTICAL RESULTS BY IR SPECTROMETRY FOR DEPOSIT ON THE ELECTRODE

(Nickel anode potential: +500 mV *vs.* Hg/HgO/1N KOH, Polarized reflective IR spectrum)

1560—1580 cm^{-1}	(–C=C–, –C=N– conjugate)
1480 cm^{-1}	(–N=N–)
830 cm^{-1}	750 cm^{-1}, 690 cm^{-1}	
There was no absorption corresponding to $-NH_2$ or –NH– in the range of 3200—3500 cm^{-1}.

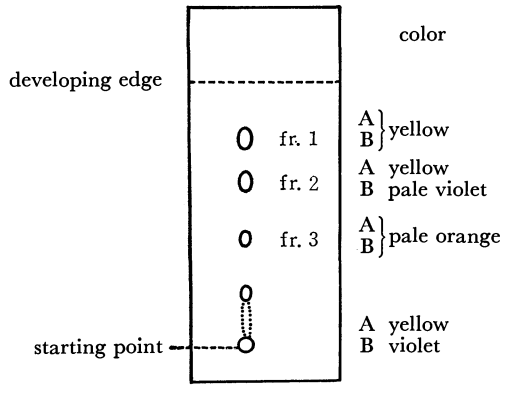

Fig. 4. Thin layer chromatogram of the deposit on the electrode.
A: Colour during the development,
B: Colour after spraying dilute H_2SO_4.

The results are shown in Table 2. The absorption band at 1560—1580 cm^{-1} was found to correspond to the –C=C– and –C=N– bonds with a quinoid structure, while that at 1480 cm^{-1}, and, those at 750 and 690 cm^{-1}, were caused by the –N=N– group of azobenzene and the mono-substituted phenyl ring respectively. Moreover, the absorption at 830 cm^{-1} was probably due to the disubstituted phenyl ring.

The results of thin-layer chromatography are shown in Fig. 4. The thin-layer consisted of silica gel, and the developing agent was benzene. As is shown in Fig. 4, two different groups were detected when the sample was developed and sulfuric acid was sprayed on the chromatogram. The R_f values of fraction 1 were identical with those of the authentic sample.

TABLE 3. ANALYTICAL RESULTS THROUGH COLUMN CHROMATOGRAPHY FOR THE DEPOSIT ON THE ELECTRODE

Fraction 1 (eluted with hexane)

UV: 375 mμ, 298mμ (–C=N–)
cf. UV: 288 mμ Ph_2NH
292 mμ PhNHNHPh

Furthermore, the sample of the film was divided into 3 fractions by column chromatography, and these fractions were analysed by UV spectrometry. These results are shown in Table 3. When the fraction 1 was

TABLE 4. ANALYTICAL RESULTS OF THE FRACTION BY BENZENE EXTRACTION OF THE DEPOSIT ON THE ELECTRODE

Mean molecular weight: 440 (V.P.O. -benzene)

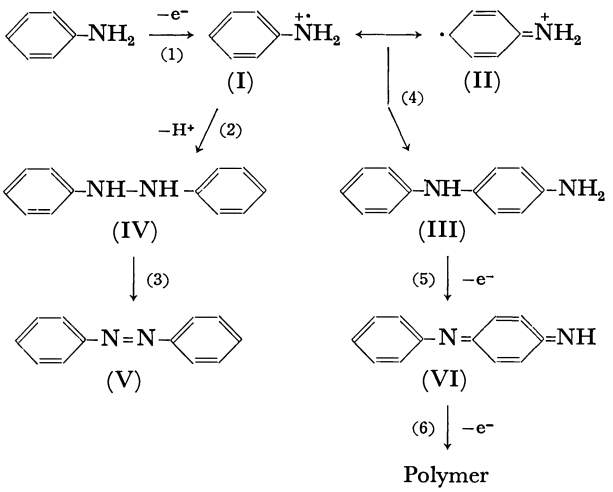
NMR: 2.0—2.4ppm 
2.5—2.8ppm 
2.7—3.4ppm 
Elementary analysis:

	C	H	N	
Found	76.99	5.25	14.03	$C_{12.2}H_{10}N_{1.9}$
Calculated				
for aniline	77.38	7.58	15.04	
for azobenzene	79.09	5.53	15.38	

eluted with hexane, reddish-orange crystals were isolated. The IR and UV spectra and the melting point agreed with those of the authentic sample of azobenzene. The fraction 1′ was the first fraction with a benzene eluant; this fraction was determined by UV spectrometry to be a mixture of a substance containing an azo group and a quinoid structure. For the fraction 2, the UV spectrum showed λ_{max} at 375 mμ and 298 mμ corresponding to the n-π^* transition of the –C=N– group in the quinoid structure and the n-π^* transition of –N–H respectively; this fraction was assumed to consist of polymers with a quinoid structure and an N–H group.

The mean molecular weight of the film was 440, as is shown in Table 4. Because the azo-benzene content in the film, which was separated by column chromatography, was about 30%, the mean molecular weight of the residual polymer should be about 1100; this was assumed to be the dodecamer of the aniline.

The results of NMR spectrometry are shown in Table 4. The signals of the NMR spectrum were observed at τ 2.0—2.4, 2.5—2.8, and 2.7—3.4. These signals were identified as the signals of protons at the ortho position of azo benzene, the protons at the *meta* and *para* positions of azo benzene, and the protons at the quinoid ring respectively.



Scheme 1

From the results presented above, it seems that the film was formed on the anode during the electrolysis of aniline in the aqueous alkaline solution; its composition consisted of azo benzene and of polymers with a quinoid structure, but its structure was not clear in detail.

Reaction Mechanism. The reaction mechanism of the anodic oxidation of aniline in an aqueous alkaline solution is assumed to be as in Scheme 1.

At first, the de-electronation of lone-pair electrons of the nitrogen atom in the aniline molecule caused the production of the radical cation,  ; this process is the rate-determining step. Some of the radical cations are coupled together and form azobenzene *via* hydrazobenzene. The other radical cations led to *p*-amino-diphenylamine by head-to-tail coupling between the radical cation and its resonance form,  ; this product is de-electronated again and changed to the polymer step by step. The formation of phenyl-hydroxylamine may be considered in this reaction between the radical cation and hydroxyl ion. However, it is not probable, because the current-potential curve of phenyl-hydroxylamine was quite different from that of aniline in cyclic voltammetry. There are many radical cations on the electrode, and so the probability for the coupling is high and paths (2) and (4) in Scheme 1 must proceed simultaneously. In view of other experiments in which hydrazobenzene oxidized easily to azobenzene with air or alkali, the path (3) must proceed chemically.

On the anodic oxidation of aniline in an acidic solution, the formation of the octamer, emeraldine, had been reported by Mohilner and his co-workers.[7] However, in the anodic oxidation of aniline in an alkaline solution, the mechanism was different from that in an acidic solution, and the products were azo benzene and the polymer with a quinoid structure.

Thermoelectric Powers of Molten I_2+Te Solutions

Kazuhiko ICHIKAWA and Mitsuo SHIMOJI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 23, 1971)

The initial and steady-state potentials of thermocells of the liquid I_2+Te system were measured at temperatures 250—600°C. Cells with a vapor path were used, together with those in which a vapor transport was forbidden. The difference due to these types of cells was found in the values of not the initial thermoelectric powers but the steady-state ones for only solutions with low Te compositions. In the I_2-rich region, the mechanism is discussed by using the model of charge-transfer due to I_3^- as in the case of conductivities and absorption spectra. The thermoelectric data in both the Te-rich and intermediate composition regions suggest that electronic contributions are highly predominant and a transition to delocalized states continuously appears with increasing Te concentration. Some experiments were carried out in order to examine the formation of concentration gradient due to the thermal effect in low Te compositions.

In this paper we report measurements of thermoelectric powers on the molten I_2+Te system, for which the conductivity measurements[1] have been made over the entire composition range. For the measurements cells in which a vapor transport was completely forbidden and those in which it was slightly permitted were used. The effect of vapor transport is negligible usually for the initial thermoelectric power measured before the concentration gradient due to thermal effects is formed. However, it is important for the stationary-state thermoelectric power of a system containing highly volatile components, as demonstrated in the case of molten Bi+$BiBr_3$ solutions by Kelner *et al.*[2] The data we obtained (with or without a vapor shunt) also indicate a marked difference in the stationary-state values in the region of low Te compositions, but no difference in the other regions. Experiments were carried out in order to examine the transport number of electron in the TeI_4 liquid and the formation of the concentration gradient in the low Te composition range.

The conductivity data[1] suggest that this system shows a transition from ionic transport to electronic transport; in the I_2-rich region the electrical conduction can be determined largely by the migration of the I_3^- ion, the presence of which could be confirmed by absorption spectra,[3] and by the movement of electron in the Te-rich and intermediate concentration region. The thermoelectric data are discussed by means of the same mechanisms, together with formulas[4] based upon thermodynamics of irreversible process.

Experimental

Materials. The purity of the tellurium and iodine used was described previously.[3]

Apparatus and Procedure. (i) Thermoelectric power: Measurements were carried out with three different thermocells. The Hario thermocell (cell A) with a gas shunt was of the same type as described.[5] For cell A′, all the upper surface of the solution was kept in equilibrium with a gaseous phase across the desired small temperature difference. The horizontal cell (cell B) of J-type, was designed in such a manner that no vapor path between the electrodes was permitted.

The initial thermoelectric power θ_{in} was determined from the slope of a curve of cell emf plotted against ΔT in the range 0.5°—5°. The measurements were carried out at 2 min intervals. In the case of stationary-state thermoelectric power θ_{st} all the emf values were checked to be constant by the recorder. The thermoelectric powers were measured at temperatures 300—550°C and for the compositions 3, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95, and 100 at.% Te in I_2.

(ii) Electronic transport number: Wagner's polarization technique[6,7] was used to determine the electronic transport numbers of molten TeI_4. A constant current (0.1—0.3 mA) supplied by an automatic current regulator was passed through the cell, represented by

$$W|Te(S)|TeI_4(L)|C|W,$$

where W denotes a tungsten lead, Te(S) a solid tellurium cathode and C a graphite rod. The stoichiometric TeI_4 liquid prepared from the samples crystallized by Bridgman's method was enclosed in a capillary with length 60 mm and inner diameter 0.5 mm. The potential applied was so low that the decomposition of the TeI_4 melt could be avoided.

Results

The thermocell used in this work can be regarded as a symmetrical cell $W|I_2+Te|W$.[5] The temperature effects on θ_{st} for the I_2+Te solutions are shown in Figs. 1—4. For the iodine solutions containing 30, 40, 50 at.% Te, the magnitude and temperature dependence of θ_{st} measured with cells A and A′ differ significantly from those measured with cell B. On the other hand, no difference was found in the values of θ_{in} for the three types of thermocells. In Fig. 5 θ_{in} and θ_{st} (measured with cell B), are plotted against the Te concentrations, giving minima at about 50 at.% Te. Figure 6 shows that the difference between the initial and stationary values, $\Delta(\equiv\theta_{in}-\theta_{st})$, reaches a maximum at about 30 at.% Te composition, and continuously approaches zero with increasing Te concentration.

The electronic transport number t_e in the TeI_4 liquids varies from 0.03 to 0.08 at 300—350°C.

Discussion

The stationary-state data obtained using cells A and A′ seem inadequate for discussing uniquely the thermoelectric powers of the some iodine solutions (*i.e.*, 30, 40, 50 at.% Te), since in these cells with gas shunts the effect of mass transport (mainly due to the I_2 molecule), taking place simultaneously through the gaseous space, is too large to be neglected. Thus, we confine our attention to the results of thermoelectric powers to which no gaseous transport contributes.

As has been pointed out in our conductivity work, the electrical properties of the present system should be examined with three kinds of models applied to the solutions of limited composition ranges.

Charge-Transfer due to I_3^-. In the I_2-rich region (above 95 at.% I), where the contribution of the I_3^- ion to the electrical conduction is predominant, the thermoelectric power θ can be represented by[5]

$$\theta = \theta(\text{hom}) + \theta(\text{het}) + Q. \tag{1}$$

Here, the homogeneous contribution θ (hom) arising from thermal diffusion of the I_3^- ion is approximately given by

$$\theta(\text{hom}) = [\text{grad}\,\mu(I_3^-)]_T/e\,\text{grad}\,T + q^{**}(I_3^-)/eT, \tag{2}$$

where the notation is the same as in our previous paper[5] (except for $q^{**}(k)$ in place of $Q^{**}(k)$). Heterogeneous contribution of the solution θ (het) can be written using the entropy factors of electron arising from some chemical reaction at the surface of electrodes (as proposed for the case of a contact between a solid electrolyte and inert electrodes[8]), and Q represents the absolute thermoelectric power of metal leads. The factor containing $[\text{grad}\,\mu(i)]_T$ is zero for the initial state. Thus we get

$$\theta_{\text{in}}(\text{hom}) = q^{**}(I_3^-)/eT. \tag{3}$$

For the stationary state the concentration gradient formed in the melt can be in local equilibrium.

$$\theta_{\text{st}}(\text{hom}) = [h_V(I_3^-) + q^{**}(I_3^-)]/eT, \tag{4}$$

where $h_V(I_3^-)$ is the heat of formation for the I_3^- ion.

The application of the Fokker-Planck equation to the thermoelectric phenomena predicts[5,8,9] that the heat of transport is equal to the heat of activation for migration. Inferring from the temperature dependence of mobilities of I_3^-, we can estimate the value of $q^{**}(I_3^-)$ to be 0.12 eV.[1] The value of $h_V(I_3^-)$, which may be equivalent to $-eT\Delta$ with the condition that the heterogeneous value is unchanged in both cases, is found to be negative as seen in Fig. 6. This fact $[h_V(I_3^-)<0]$ is reasonably expected also in our works on the conductivities[1] and the absorption spectra[3] for these compositions. The negative value of θ (het) (*e.g.*, at 300°C for 5 at.% Te θ (het) $=-192\ \mu\text{V deg}^{-1}$) is sufficiently probable in the case of inert electrodes. As an example, θ (het) for molten $PbCl_2$ in contact with graphite, tungsten or platinum electrodes was estimated[10] to be negative (their average value of about $-300\ \mu\text{V deg}^{-1}$), with the aid of data obtained from cells with reversible electrodes.

Electronic Conduction. Case I, Te-rich Region: We showed that the 90 at.% Te solution may be on the borderline of the hopping conduction,[1] and the transition to nonlocalized states may continously appear with increasing Te concentration. As seen in Fig. 6, above the 90 at.% Te composition Δ is negligible within experimental error, and the electronic transport number can be exepcted to be nearly equal to unity. Thus, the total thermopower can be given by

$$\theta = -Q(\text{sample}) + Q(\text{leads}), \tag{5}$$

with the absolute thermoelectric power Q(sample) of the solutions

$$Q(\text{sample}) = -(\pi^2 k_B^2 T/3e)[\partial \ln \kappa_e(\varepsilon)/\partial\varepsilon]_{\varepsilon=\varepsilon_F}, \tag{6}$$

where the notation is the same as in our previous paper.[5] According to Mott,[11] for some disordered structures a minimum or pseudogap is expected in the curve of the density of states $N(\varepsilon)$. If the Fermi energy ε_F has a chance of being located at the side lower than the minimum, then the positive values of Q(sample) will be obtained. On the other hand, a negative Hall effect may be expected as in the case of the pure Te liquid.[12] This contradicts the conclusion of the conventional band model. No conduction electrons in liquid Te can, however, be interpreted in terms of a localized model due to Tiéche and Zareba.[12] It is well-known[13] that the sign of thermoelectric power in many electron-conducting liquids is not always in agreement with that of the Hall coefficient, although no satisfactory theoretical interpretations have been proposed.

Electronic Conduction. Case II, Intermediate composition region: In the 60—80 at.% Te solutions, conductivity κ varies from 1 to 300 $\text{ohm}^{-1}\cdot\text{cm}^{-1}$ and $d\kappa/dT>0$. The transport number of electron t_e is considerably small in the TeI_4 liquid. The magnitude of ionic conductivity in the 20—40 at.% Te solutions can be regarded as nearly constant (*i.e.* 0.4 $\text{ohm}^{-1}\cdot\text{cm}^{-1}$ from the conductivity data at 300—400°C). The rapid increase in κ above the 60 at.% solutions should mainly be interpreted in terms of some electron transport mechanism. In other words, the electron-pair exchnage between the ionicpairs (*e.g.* Te^{2+}, Te^{4+}, Te^{6+} etc.) may be responsible for the electrical conduction under conditions where the composition flunctuations in their environments bring the ions to a level of equal energy.[5]

For the homogeneous part of thermoelectric power at the initial state we can write

$$\theta_{\text{in}}(\text{hom}) = q^{**}(2e)/2eT \tag{7}$$

and for that at the stationary state

$$\theta_{st}(\text{hom}) = [h_V(2e)+q^{**}(2e)]/2eT, \quad (8)$$

which are analogous to Eqs. (3) and (4). Here, $h_V(2e)$ is the heat needed to form the site containing the electron-pair, and $q^{**}(2e)$ the heat of transport of the electron-pair. As in Case I, the value of $h_V(2e)$ can be estimated by the experimental data of Δ. Thus we have $h_V(2e)=-0.03$ eV at 70 at.% Te and at 500°C. No magnitude of $q^{**}(2e)$ can, however, be evaluated only from the data of the thermoelectric powers, since the temperature dependence of the heterogeneous part might be so large that it masks that of the homogeneous part. The heterogenous quantity of the solution can be considered to have a configurational entropy term[14] involving permutation of electron pairs among available states such as $Te^{(n-2)+}$ and Te^n, the concentrations of which might depend significantly on temperature. On the other hand, the value of $q^{**}(2e)$, using the Fokker-Planck equation from the slope $(\Delta h_s+\Delta h^*)$ of $\log(\kappa_e T)$ *vs.* $1/T$ (see Eq. (15) in Ref. (5a)), can be estimated to be 0.33 eV at 70 at.% Te and 500°C.

Formation of concentration gradient In the course of time t the concentration gradient, resulting from the term of $[\text{grad}\,\mu(i)]_T/\text{grad}\,T$ in the expression such as Eq. (2) for the species i, is represented by[4,15]

$$\text{grad}\,c_i = (\text{grad}\,c_i)_\infty[1-\exp(-t/\Theta_i)], \quad (10)$$
$$\Theta_i = l^2/\pi^2 D_i$$

in which $(\text{grad}\,c_i)_\infty$ denotes the concentration gradient in the stationary state, Θ_i a characteristic time, l the length of diffusing species taking in the cell, and D_i the interdiffusing coefficients. Equation (10) states that the time needed to reach the stationary state becomes longer as l becomes longer. For example, in this work it was observed that the time required for attainment of stationary state in the cells (cell B) with $l=32$ and 59 mm, containing the 30 at.% Te solution, is 20 and 65 (—95) min, respectively, after the temperature difference across the cell was kept constant.

Formation of the concentration gradient in cell B also can be confirmed also by observing the absorption spectra, characteristic to some species, for the quenching samples. For instance, the I_2 solution containing 30 at.% Te, which had been in the stationary state under conditions where the temperature difference ΔT is 15° at the average temperature 298°C, was rapidly quenched at the liquid nitrogen temperature, and cut into three parts, corresponding to the cool (C), average (A) and hot (H) regions. The absorption spectra of these parts, measured with a diffuse reflectance method, show an increase in relative peak intensity arising from the existence of the I_3^- ion[3] in the order (C), (A), and (H) (or numerically 1 : 1.14 : 1.36).

The authors wish to express their gratitude to Mr. A. Yoshida for his help at an early stage of this experiment, and to Mr. Kiya for technical services related to the apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2967—2971 (1971)

Properties of Water in Macromoleular Gels. III. Dilatometric Studies of the Properties of Water in Macromolecular Gels

Masuo AIZAWA and Shuichi SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received April 22, 1971)

The dilatometric properties of W_1, W_2, and W_3, which were proposed by the present authors, for the classification of water in macromolecular gels, are studied over the range from −30 to 60°C. From the results of the thermal expansion of agarose gels and Sephadex (cross-linked dextrans), higher water contents of gel were found to show an extremely sharp volume change at 0°C; on the contrary, lower water contents of gel exhibited no anomalous change in the specific volume in the range from −30 to 0°C, and a gradual decrease in the specific volume was detected with an increase in the temperature in the range from −20 to 0°C for medium water contents of the gel, though the gel was expected to increase in its volume in that temperature range. Thus, the new classification for the states of water in macromolecular gels was shown to be reasonable, at the same time, the transition temperatures of W_1, W_2, and W_3 were evaluated on the basis of the above results.

The thermal expansion of water in macromolecular gels, even of W_1, was found to be extremely depressed by the polymers of such gels.

In contrast with the conventional classification of water in macromolecular gels, namely, bound water and free water, the present authors previously proposed that water in gels be classified into three groups, W_1, W_2, and W_3, according to its electrochemical properties, where both W_1 and W_2 correspond to conventional free water, and W_3, to bound water.[1,2]

Most physicochemical properties of ordinary water

1) J. Mizuguchi, M. Takahashi, and M. Aizawa, *Nippon Kagaku Zasshi* **91**, 723 (1970).

2) J. Mizuguchi, M. Takahashi, and M. Aizawa, *ibid.*, **91**, 961 (1970).

are well known to change markedly at 0°C. For example, the electric conductivity for high water contents of agarose gel was found to change greatly at 0°C and to decrease gradually with a decrease in the temperature below 0°C, while that for lower water contents of gel shows no marked change at 0°C, but decreases linearly with a decrease in the temperature. Therefore, various states of water with different transition temperatures are speculated to coexist in gels.[1)]

Since W_1, W_2, and W_3 are all supposed to have different transition temperatures, the thermal expansion for varied water contents of agarose gels is expected to be quite different from case to case. In addition, the above W_2 and W_3 were found to have different properties from those of ordinary water, but no difference from ordinary water was detected in W_1 throughout the electrochemical investigations. In W_1, however, the gels are prevented from flowing out. Therefore, the thermal expansion of water is considered to be obstructed in macromolecular gels, which are constructed of a network of macromolecules.

In view of the above facts, the dilatometric properties, especially those of water at lower temperatures, for typical polysaccharide gels, such as agarose gels and cross-linked dextran gels have been investigated over the range from −30 to 60°C, and this has been with the thermal expansion of ordinary water.

Experimental

Materials. The agarose for immuno-electrophoresis, Sephadex G-10, G-50, and G-200 (cross-linked dextrans purchased from Pharmacia) were prepared for gels with various water contents.

The gels were assayed for their water contents by weighing them after drying at 105°C for 24 hr.

Glossary of Principal Symbols. The definition of the principal symbols used in the report are as follows: s, the capillary sectional area of the dilatometer (cm^2); v_{Hg25}, the volume of mercury at 25°C (cm^3); α_{Hg}, the thermal expansion coefficient of mercury (1.34×10^{-5} $degree^{-1}$); t, the temperature (°C); m_s, the weight of the sample (g); p, and w, the weight fractions of polymer and water respectively in the sample, $p+w=1$; h, the mercury height difference in the dilatometer between t and 25°C (cm); $\Delta\Phi_g$, $\Delta\Phi_{wg}$, and $\Delta\Phi_w$, the specific volume changes in the gel, in the water in the gel, and in pure water respectively, as compared with the corresponding specific volume at 25°C (cm^3/g).

Methods. In the thermal-expansion measurements, the above gels were determined for their volume over the range from 25 to −30°C by means of a dilatometer filled with the sample and mercury. The apparent specific volume change, $\Delta\Phi_g$ of the gel was calculated in accordance with the following equation.[3)]

$$\Delta\Phi_g = \{h-(1/s)\alpha_{Hg}V_{Hg25}(t-25)\}s/m_s \qquad (1)$$

Results and Discussion

Hysteresis in the Thermal Expansion of Macromolecular Gels. To profile the general features of the thermal expansion of macromolecular gels, Sephadex G-200, G-50, and G-10 at the same water fraction ($w=0.50$) were measured for their volume changes with an increase and with a decrease in the temperature over the range from 25 to −30°C. The results are presented in Figs. 1, 2, and 3. The specific volume change is de-

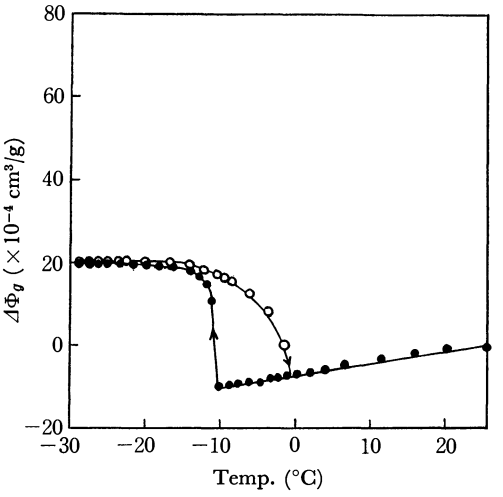

Fig. 1. Hysteresis in thermal expansion of Sephadex G-200 gel ($w=0.50$)

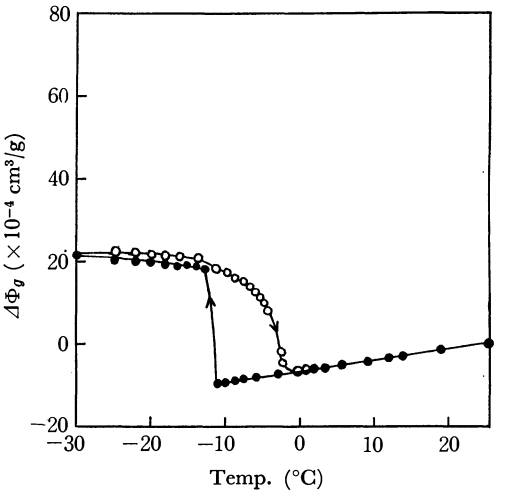

Fig. 2. Hysteresis in thermal expansion of Sephadex G-50 gel ($w=0.500$)

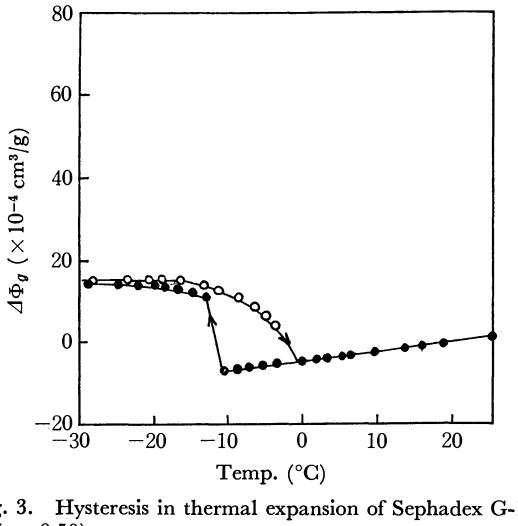

Fig. 3. Hysteresis in thermal expansion of Sephadex G-10 gel ($w=0.50$)

3) Soc. Polymer Sci. Japan, ed., "Experimental Polymer Science. IV", Kyoritsu, Tokyo (1961) p. 43.

noted by the coordinate, taking 25°C as the standard temperature. The specific volume for each gel decreases upon cooling, there is an abrupt increase at approximately −10°C and a gradual decrease with a decrease in the temperature to −30°C. The specific volume of the above gel cooled at −30°C shows a gradual increase with an elevation in the temperatures, even around −10°C, though it decreases markedly near 0°C.

Sephadex gels were found to show hysteresis in thermal expansion over the range of approximately −10 to 0°C.

Relationship between Water Content and the Thermal Expansion of Macromolecular Gels. The thermal expansion of gels is expected to be extremely dependent on the water content as has been described above.

The specific volume changes for agarose are presented in Figs. 4, 5, and 6. The curve with closed circles shows the specific volume change with a decrease in the temperature, while the curve with open circles indicates that with an increase in the temperature. In agarose gel with a higher water content (w=0.974),

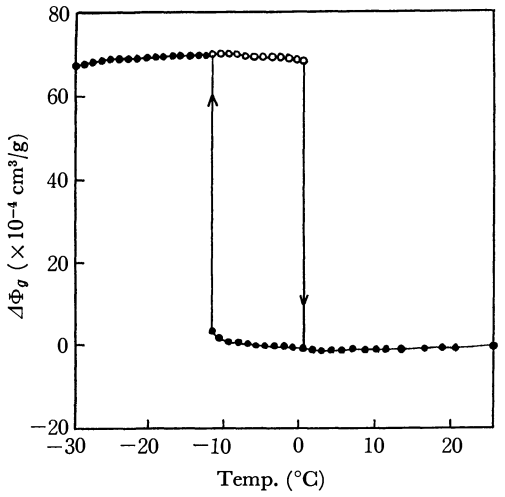

Fig. 4. Hysteresis in thermal expansion of agarose gel (w= 0.974)

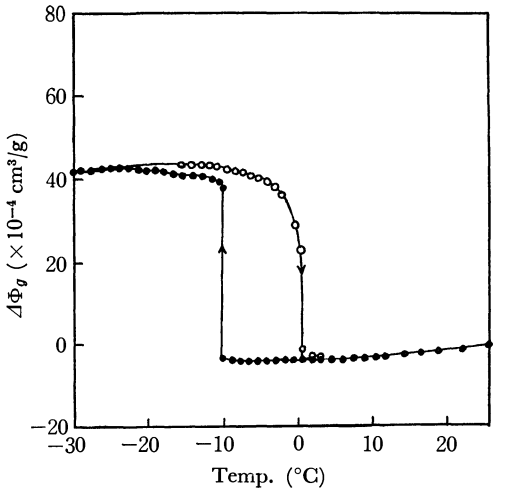

Fig. 5. Hysteresis in thermal expnsion of agarose gel (w= 0.772)

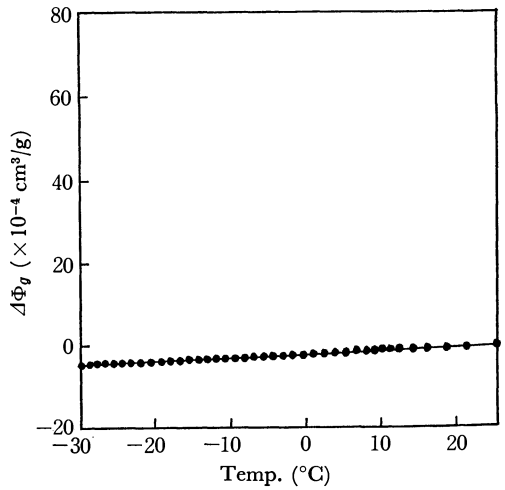

Fig. 6. Hysteresis in thermal expansion of agarose gel (w= 0.290)

the specific volume changes sharply at about −10°C with a decrease in the temperature and at 0°C with a decrease in the temperature. As for the gel whose water fraction is 0.974, it is notable that the specific volume decreases gradually with an increase in the temperature over the range from −20 to 0°C, though it was expected to increase in this temperature range. On the contrary, the agarose gel with a lower water content (w=0.290) shows neither hysteresis in thermal expansion nor any anomalous change in the specific volume around 0°C.

In Fig. 7, the thermal expansions of Sephadex G-50 at various water contents (w=0.833, 0.500, and 0.288) with an increase in the temperature from −30°C up to 25°C are shown. The gel with a lower water content (w=0.288) shows no marked change around 0°C, much like the agarose gel with a lower water content. On the other hand, the specific volumes for the other two gels (w=0.500 and 0.833) decrease gradually over the range from −20 to 0°C.

Since no anomalous change was detected for gels with lower water contents, the water in such gels is considered to show no transition in this temperature range. Most

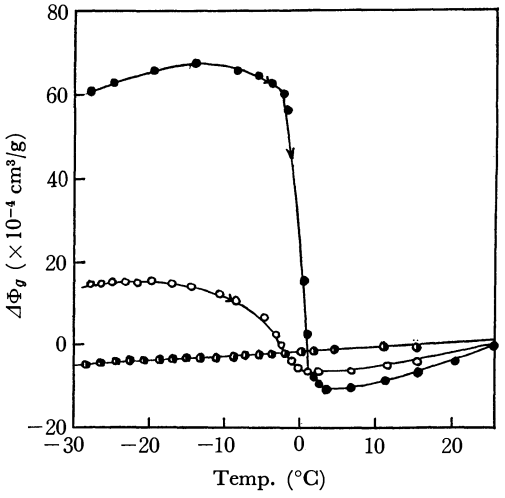

Fig. 7. Thermal expansion of Sephadex G-50 gels -●- w=0.833, -○- w=0.500, -◑- w=0.288

of the water in such lower-water-content gels is supposed to be w_3, as is indicated previously. Therefore, w_3 may have no transition over the range from −30 to 0°C.

Judging from the extremely sharp change in the specific volume for higher water contents of the gel, the transition temperature of w_1 may be 0°C, for w_1 is presumed to be the main component of the gel in higher water contents.

The gradual decrease in the specific volume with an increase in the temperature over the range from −20 to 0°C is considered to indicate that the transition temperatures, perhaps for w_2, should be distributed over this temperature range.

These results lead us to conclude that: (1) the transition temperature of w_1 may be 0°C, (2) that of w_2 may be distributed over the range from −20 to 0°C, and (3) w_3 may have no transition temperature in the range from −30 to 0°C. The above conclusions quite agree with those of electrochemical studies.

Thermal Expansion of Water in Macromolecular Gels. The apparent specific volume changes for agarose gels are shown in Fig. 8. The dotted curve in Fig. 8 presents the specific volume change for pure water. The thermal expansion of agarose gels was found to depend greatly on their water contents and to be extremely retarded as compared with that of ordinary water. In order to evaluate the thermal expansion of water in gels, the apparent specific volume changes, $\Delta\Phi_{w_g}$ were calculated on the basis of the following equation;[4]

$$\Delta\Phi_{wg} = (\Delta\Phi_g - p\Delta\Phi_p)/w \qquad (2)$$

Where the symbols are as defined in the glossary. The specific volume change, $\Delta\Phi_w$, for ordinary water was determined from its specific volume,[5] Φ_w, at the temperature t, which was expressed by

$$\Phi_w = (1+b_1t)/(\sum_{n=0}^{5} a_nt^n) \qquad (3)$$

$a_0 = 0.9998396$ $10^3a_1 = 78.224944$ $10^6a_2 = -7.922210$
$10^9a_3 = -55.44846$ $10^{12}a_4 = 149.7562$ $10^{15}a_5 = -393.2952$
$10^3b_1 = 18.159725$,

$\Delta\Phi_p$ was measured for dried agarose or Sephadex.

The calculated specific volume changes in the water in agarose gels are listed in Tables 1, 2, and 3. The data in the fifth column in each table concern the apparent specific volume change in the water in the gel relative to that of ordinary water at the temperature t.

For agarose gels, the $\Delta\Phi_{w_g}/\Delta\Phi_w$ ratios in all cases deviate greatly from 1.0. The thermal expansions of water in gels with high water contents may be retarded to approximately 7%, and that in lower-water-content gels, to approximately 3%, as compared with that in ordinary water.

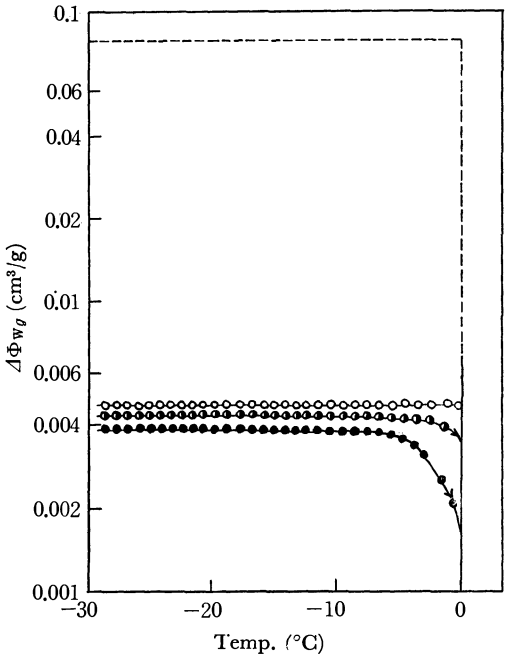

Fig. 9. Thermal expansion of water in agarose gels on the comparison with that of ordinary water.
------ ordinary water
-○- agarose gel (w=0.974)
-◑- agarose gel (w=0.867)
-●- agarose gel (w=0.772)

Since most of the water in lower-water-content gels (w=0.290) may be W_3, thermal expansion coefficient for W_3 can be evaluated as about 3% of that for ordinary water. On the other hand, high-water-content gels (w=0.974 and 0.772) may be occupied much by W_1, and W_2 and little by W_3. Thus, it may be reasonable to conclude that the thermal expansion of most water, even of W_1, is extremely depressed in agarose gels, as was expected.

Volume Change in the Transition of Water in Gels as Compared with That of Ordinary Water. The apparent specific volume change for water in agarose gels is shown in Fig. 9 and compared with that of ordinary water. As is indicated in the figure, the apparent specific volume change in the transition at 0°C for water in gels is extremely retarded to less than 10% of that for ordinary water. Therefore, most of the water in gels may be considered to be obstructed, even in thermal expansion at the transition, by the network of the polymer.

Summary

The dilatometric properties of water in macromolecular gels indicate that our proposed new classification for the states of water, namely, W_1, W_2, and W_3, is reasonable, and that the transition temperature of W_1 may be 0°C, that of W_2 may be distributed over the range from −20 to 0°C, and W_3 may have no transition temperature in the range from −30 to 0°C.

The thermal expansion of most water, even W_1, was found to be extremely depressed in macromolecular gels.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2971—2975 (1971)

Reactions of Aliphatic Amines with *p*-Benzoquinone and Its Chloro Derivatives

Tsuguo YAMAOKA* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received May 8, 1971)

The reactions of various aliphatic amines with *p*-benzoquinone and its chloro-derivatives were studied by detecting reaction intermediates by means of the rapid scan spectrophotometric method. A detailed kinetic study on the reaction intermediate and the final product was made for the system including *n*-butylamine and chloranil in ethanol; the result shows that the system produces 2,5-di-*n*-butylamino-3,6-dichloro-*p*-benzoquinone *via* the chloranil anion and the *n*-butylamine cation with the rate constant of 9.8×10^2 $sec^{-1}mol^{-1}l$ at 275.2°K. On the basis of reaction mechanisms, the reactions of various aliphatic amines with *p*-benzoquinone and its chloro-derivatives were classified into five types. Stabilization energies due to the amino-substitution of *p*-benzoquinone were calculated by the composite molecule method; the result shows that the 2,5-derivative is most stable among the disubstituted *p*-benzoquinones.

In previous papers,[1] we reported on the interactions of aniline and its *meta*-derivatives with chloranil and concluded that the substitution reactions occur through the outer(π)- and inner(σ)-complexes as reaction intermediates. In these cases, we could find no ion radical as a reaction intermediate. On the other hand, there are many systems consisting of electron donors and acceptors which are led to ionization and produce

* Present address: Department of Printing, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba.

the anion and cation radicals.[2] Furthermore, in some cases, the substitution or other reactions occur *via* these ion radicals. As an example, Eastman[3] reported that the reaction of *N,N*-dimethylaniline with chloranil proceeds through the ionized state to yield crystal violet.

In a previous paper[4] concerning the interactions of aliphatic amines with quinones, we demonstrated that ionization occurs and a quinone anion exists stably as a final product or transiently as a reaction intermediate. In the present paper, we focus our attention on reaction processes following ionization.

Studies have been carried out to clarify the mechanism of the reaction between alkylamine and quinone,[5] but details are not yet known. The S_N2 mechanism has hitherto been presented[5c] for the reactions of *p*-benzoquinone or its derivatives with alkylamines which act as nucleophilic reagents. In this mechanism, the ionization process is disregarded in the consideration of the reaction mechanism. However, the fact that the anion radicals of quinones exist transiently as a result of the interaction with alkylamines suggests that the reaction can proceed through ionized states. In view of this, we have undertaken to study the reaction mechanism with various systems including aliphatic amines as electron donors and *p*-benzoquinone or its chloro-derivatives as electron acceptors.

Experimental

Materials. *p*-Benzoquinone and chloranil were purified by recrystallization and sublimation at reduced pressure. Commercially available *n*-butylamine and tri-*n*-butylamine of GR grade were used without further purification. Their purities were checked by means of gas chromatography technique. Ethanol used as a solvent was refluxed with magnesium ethylate and was distilled. Ethyl ether was distilled after being kept with sodium metal.

Measurement. Electronic absorption spectra at various stages of a reaction path in solution were measured by a Hitachi rapid scan spectrophotometer RSP-2 located at the Institute of Industrial Science, The University of Tokyo. The apparatus is equipped with an automatically controlled mixing cell. Spectra could be measured every 1/3 sec in the wavelength range from 200 nm to 700 nm.

Results and Discussion

Rapid Scan Spectra of Systems Consisting of Alkylamines and Quinones. In order to clarify the mechanisms of reactions of aliphatic amines with *p*-benzoquinone and its chloro-derivatives in polar solvents, we measured the changes of absorption spectra with time by the rapid scan spectrophotometric method. First, let us explain the results obtained with the ethanol solution containing *p*-benzoquinone and *n*-butylamine ($BuNH_2$). As is seen in Fig. 1, the system shows a couple of peaks at 320 nm and 420—440 nm in the spectrum 1/3 sec after mixing. The peak intensities increase in parallel with each other up to 1 sec after mixing and afterward decrease gradually. As these peaks decrease in intensity, new absorption bands appear at 350 and 480 nm. The initial absorption spectrum is undoubtedly due to the *p*-benzoquinone anion radical judging from its position and shape in literature.[6] The final spectrum coincides with that of 2,5-dibutylamino-*p*-benzoquinone given in literature.[7] These facts show that electron transfer occurs from amine to quinone prior to the formation of 2,5-dibutylamino-*p*-benzoquinone. It should be noticed that the spectrum due to mono-butylaminated *p*-benzoquinone can not be observed. A similar time dependency of absorption spectra was also observed for the ethanol solutions including *n*-butylamine-2,5-dichloro-*p*-benzoquinone, *n*-butylamine-chloranil, and methylamine-*p*-benzoquinone. The reaction mechanism was studied in detail for the *n*-butylamine-chloranil system.

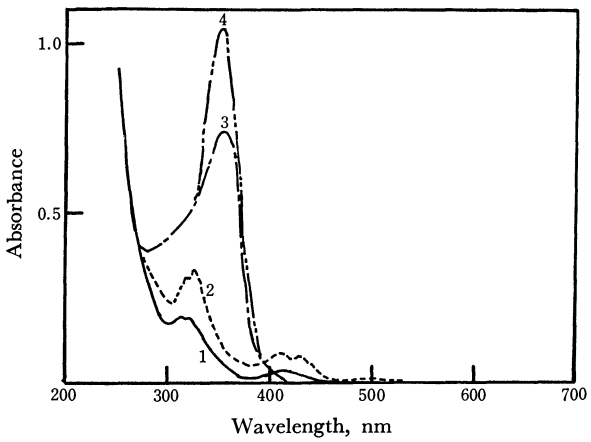

Fig. 1. Rapid scan spectra observed with the ethanol solution containing *n*-butylamine (5.1×10^{-2} mol/*l*) and *p*-benzoquinone (3.1×10^{-5} mol/*l*). Curves 1, 2, and 3 are the spectra measured 1/3 sec, 1 sec, and 10 sec, respectively, after the mixing, and curve 4 is the spectrum of the final product.

When trimethylamine is mixed with chloranil in ethanol, the absorption due to the chloranil anion radical rapidly appears. With the decrease of this absorption, an intense absorption occurs at 545 nm, which is due to 2-dimethylamino-3,5,6-trichloro-*p*-benzoquinone judging from its position and intensity.[7] As this absorption decreases in intensity, there appears the spectrum of the final product. This spectrum is the same as that of 2,5-bis(dimethylamino)-3,6-dichloro-*p*-benzoquinone given in literature.[7] This system is an example in which the absorptions due to the anion radical, the mono-alkylaminated quinone, and the final dialkylaminated product are separately observed with the progress of the reaction. Similar changes in ab-

sorption spectra were also observed for the ethanol solutions containing dimethylamine-*p*-benzoquinone and the diethylamine-*p*-benzoquinone, and for the ethereal solution of methylamine-*p*-benzoquinone.

Tri-*n*-butylamine is ionized by *p*-benzoquinone, 2,5-dichloro-*p*-benzoquinone, and chloranil in such a polar solvent as ethanol but does not cause the substitution reaction.[4] However, trimethylamine reacts with chloranil gradually in ethanol to give 2,5-bis(dimethylamino)-3,6-dichloro-*p*-benzoquinone. This difference in the chemical reactivity between tri-*n*-butylamine and trimethylamine might be due to the great steric hindrance of the *n*-butyl group.

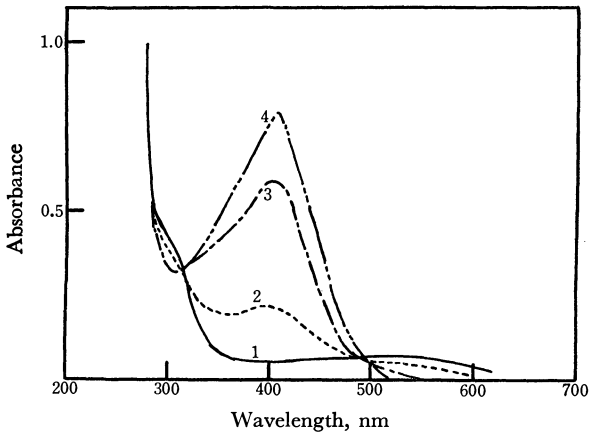

Fig. 2. Rapid scan spectra observed with the ethereal solution containing chloranil (7.9×10^{-5} mol/*l*) and an excess amount of dimethylamine. Curves 1, 2, and 3 are the spectra measured 1/3 sec, 2 sec, and 10 sec respectively, after the mixing, and curve 4 is the spectrum of the final product.

When we use ethyl ether as a solvent instead of ethanol, systems containing electron donors and acceptors show a general tendency for ionization to be difficult. When dimethylamine was mixed with chloranil in ethyl ether, the spectra shown in Fig. 2 were obtained. The absorption peaks appear at 300 and 500 nm in the spectrum 1/3 sec after mixing. These peaks are attributed to 2-dimethylamino-3,5,6-trichloro-*p*-benzoquinone.[7] As their intensities decrease, a new peak due to 2,5-bis(dimethylamino)-3,6-dichloro-*p*-benzoquinone[7] appears at 420 nm. In this case, the absorption of the chloranil anion radical could not be observed. A similar phenomenon was also observed for the ethereal solution containing *n*-butylamine and *p*-benzoquinone.

The ethereal solutions including methylamine-chloranil and *n*-butylamine-2,5-dichloro-*p*-benzoquinone give nothing but the absorption due to the final product, 2,5-dimethyl(or 2,5-di-*n*-butyl)aminated-*p*-benzoquinone.

Classification of the Amine-Quinone Reaction. The spectroscopic changes due to the progress in the reactions between alkylamines and quinones used as electron donors and acceptors, respectively, are greatly dependent on their properties as well as the polarity of the solvent. According to the present spectroscopic study, the reactions were phenomenologically[8] classified as shown in Table 1. The table clearly shows a general tendency for the spectra of the anion radicals of quinones to be easily observed in some stages of the reactions in ethanolic solutions, but not so in ethereal solutions. This may be due to the fact that the anion radical can be stabilized in such a polar solvent as ethanol. It may be noticed that the dimethylamine-chloranil system does not show the absorption of the

Table 1. Classification of the interactions of aliphatic amines with *p*-benzoquinone and its chloro-derivatives

Type of interaction[a]	System[b]
1) D+A→(D⁺)+A⁻ →(MS)→DS	$BuNH_2$-Q, QCl_2, QCl_4(EtOH) $MeNH_2$-Q(EtOH)
2) D+A→(D⁺)+A⁻ →MS→DS	Me_2NH-Q(EtOH) Me_3N-Q(EtOH) Et_2NH-Q(EtOH) $MeNH_2$-Q(Et_2O)
3) D+A→(D⁺)+A⁻	Bu_3N-Q, QCl_2, QCl_4(EtOH)(Et_2O)
4) D+A→MS→DS	$BuNH_2$-Q(Et_2O) Me_2NH-Q, QCl_2, (Et_2O) Me_2NH-QCl_4(EtOH)
5) D+A→(MS)→DS	Me_2NH-QCl_4(Et_2O) $BuNH_2$-QCl_2(Et_2O)

a) D, A, D⁺, A⁻, MS, and DS represent the electron donor, the electron acceptor, the donor cation, the acceptor anion, the monosubstituted species, and disubstituted species, respectively. The specimen in parentheses has not yet been observed directly by the spectrophotometric method.

b) Q, QCl_2, and QCl_4 indicate *p*-benzoquinone, 2,5-dichloro-*p*-benzoquinone, and chloranil, respectively. (EtOH) and (Et_2O) indicate that ethanol and ethyl ether are used as solvents.

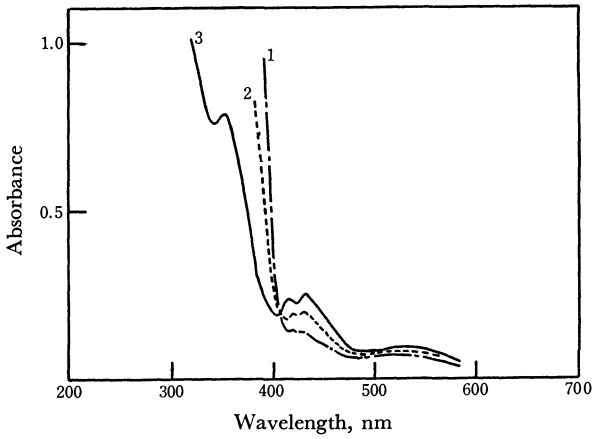

Fig. 3. Rapid scan spectra observed with the ethanol solution containing *n*-butylamine (5.1×10^{-2} mol/*l*) and chloranil (5.0×10^{-5} mol/*l*). Curves 1, 2, and 3 are the spectra measured 1/3 sec, 10 sec, and 40 sec respectively, after the mixing.

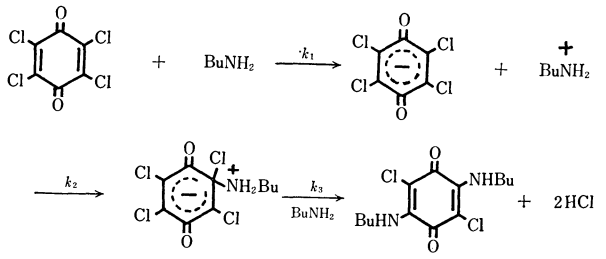
8) This classification is made on the basis of the spectroscopic behaviors observed for the systems containing aliphatic amines and *p*-benzoquinone or its chloro-derivatives. This is inevitable at the present stage when the reaction mechanism for the systems belonging to classes (4) and (5) is not yet clarified. Some minor modifications might be necessary when we succeed in clarifying it, though very difficult. For example, the Me_2NH-QCl_4(EtOH) system might move to class (2).

chloranil anion radical even in ethanol, in spite of the fact that the system containing dimethylamine and benzoquinone which is weaker as an electron acceptor than chloranil is ionized in ethanol. Although the reason for this is not clear, it may probably be due to the fact that the ionization process is slower than the succeeding substitution reaction process.

Reaction of n-*Butylamine and Chloranil.* Let us explain the reaction processes in detail, taking the ethanol solution containing *n*-butylamine and chloranil as an example. The time-dependence of the spectrum observed for this system is shown in Fig. 3. In the spectrum 1/3 sec after the mixing, the absorption of the chloranil anion radical[6] can clearly be observed at 420—450 nm. With the decrease in absorption intensity, a new peak due to 2,5-di-*n*-butylamino-3,6-dichloro-*p*-benzoquinone[7] appears, andthe isosbestic point is found at 410 nm. Thus, the following mechanism is proposed for the reaction of *n*-butylamine with chloranil. Here the first step of the reaction is



the electron transfer from *n*-butylamine to chloranil to form the anion radical. In the second step, the chloranil anion radical reacts with the *n*-butylamine cation to produce 2-*n*-butylamino-3,5,6-trichloro-*p*-benzoquinone,[7] which reacts further with *n*-butylamine to yield 2,5-di-*n*-butylamine-3,6-dichloro-*p*-benzoquinone.

In order to confirm the mechanism, we carried out a kinetic study for the *n*-butylamine-chloranil system. According to the above mechanism, the rate equation concerning the chloranil anion is given as follows:

$$\begin{aligned} d[Q^-]/dt &= k_1[A][Q] - k_2[Q^-]^2 \\ &= k_1'[Q] - k_2[Q^-]^2 \end{aligned} \quad (1)$$

where [A], [Q], and [Q^-] are the concentrations of *n*-butylamine, chloranil, and the chloranil anion radical, respectively. In our system, [A]>[Q] is satisfied and [A] may be regarded as constant during the reaction. From the time dependence of the peak intensity of the chloranil anion radical, the rate constant for the first step k_1, is known to be apparently much larger than that for the second step k_2. Therefore, after some stage of the reaction, the k_1[A][Q] term in Eq. (1) may be disregarded and we obtain the following equation:

$$k_2t = 1/[Q^-] - 1/[Q_0^-] \quad (2)$$

where [Q_0^-] is the apparent concentration of the chloranil anion radical at $t=0$, the reciprocal of which can be obtained by extrapolating the $1/[Q^-]-t$ relation to the initiation time of the reaction, and may be expected to be almost equal to the initial concentration of chloranil.[9] In the present system, [Q^-] can be determined spectroscopically with considerable accuracy. This is because its absorption spectrum in the 420—450 nm region is not overlapped with the absorptions of the other specimens in this system and the molar extinction coefficient is known.[10] Plotting the observed $1/[Q^-]$ values against reaction time t, we can obtain a straight line as is shown in Fig. 4. This means that Eq. (2) is satisfied and supports the proposed mechanism given by this equation. From the slope of the straight line, the value of k_2 was estimated to be $9.8(\pm0.5)\times10^2$ sec^{-1} mol^{-1} l at 275.2°K.[9]

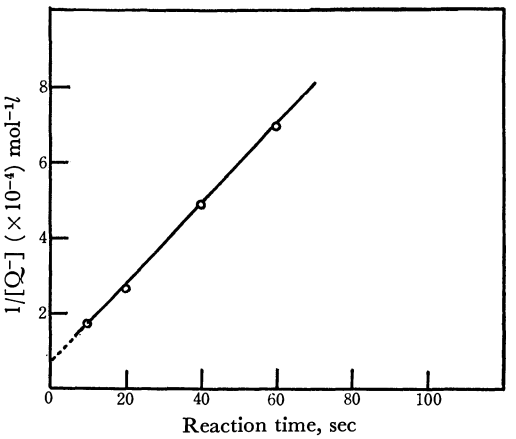


Fig. 4. Plots of the reciprocal of the concentration of the chloranil anion radical against the reaction time. The concentrations of *n*-butylamine and chloranil are 5.05×10^{-2} mol/l and 1.80×10^{-4} mol/l, respectively.

The value of k_2 was also obtained from the rate of the formation of the final product by the aid of the following equation:

$$k_2t = [P]/([Q_0^-]^2 - [Q_0^-][P]) \quad (3)$$

where [P] is the concentration of the final product. Equation (3) can be derived by combining Eq. (2) with the relation $[Q^-]=[Q_0^-]-[P]$ which is reasonable from the reaction mechanism presented by us. The value of k_2 obtained from the time dependence of the observed [P]'s by the aid of Eq. (3) is $8.5(\pm0.4)\times10^2$ sec^{-1} mol^{-1} l at 275.2°K and is consistent with the value obtained by the aid of Eq. (2) within experimental errors.

It is concluded that the replacement reaction observed for the chloranil-*n*-butylamine system proceeds through the ionic species, the chloranil anion and the *n*-butylamine cation, as reaction intermediates. Thus it may be said that the present study gives experimental support to the electron transfer mechanism for the substitution reaction proposed by one of the authous (S.N.) and Tanaka from the consideration of the molecular orbitals of substrates and reagents.[11]

9) The [Q^-] value obtained from the intercept of the straight line with the ordinate is almost equal to the initial concentration of chloranil. This shows the adequateness of the present treatment and supports the reaction mechanism.

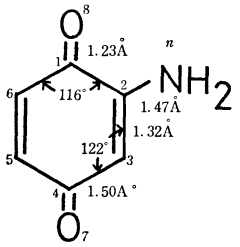

Fig. 5. Geometrical structure and numbering of 2-amino-benzoquinone.

Stabilization Energies of the Aminated p-*Benzoquinones.* The stabilization energies of aminated *p*-benzoquinones were calculated by the composite molecule method.[12] Let us explain the calculation procedure taking 2-amino-*p*-benzoquinone as an example. The system was divided into two components; *p*-benzoquinone and the amino group. The numbering of the atoms and geometry of the molecule are shown in Fig. 5. The Hückel orbitals of *p*-benzoquinone were taken as the component orbitals[13] since they do not differ appreciably from the SCF MO's evaluated by the P-P-P method.[14] The interaction between *p*-benzoquinone and the amino group was taken into account by the configuration interaction between the ground (G), several locally-excited (LE), and charge-transfer (CT) configurations.

The energy of the ground configuration was taken to be standard. The energies of the lowest two locally excited configurations (LE_1, LE_2) were taken to be equal to the observed transition energies corresponding to the first and second bands of *p*-benzoquinone. The energies of CT configurations were calculated by the relation, $I-A+\Delta C$, where I, A, and ΔC represent the ionization potential of amino group (8.40 eV),[15] the electron affinity of *p*-benzoquinone (2.02 eV),[16] and the electrostatic interaction energy between the positive and negative charges caused by an electron transfer from the amino group to *p*-benzoquinone, respectively. The Pariser-Parr approximation[17] was used for evaluating the two center Coulomb repulsion integrals necessary for the evaluation of ΔC. The energies of the configurations are shown in Fig. 6.

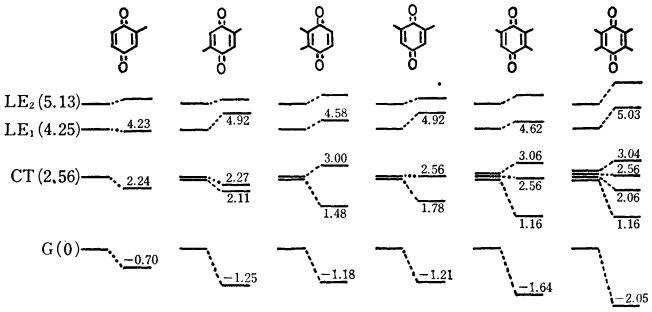

Fig. 6. Configurations used for the composite molecule calculation and the calculated energies (eV) of amino-substituted *p*-benzoquinones. For example, the configurations for 2-amino-*p*-benzoquinone are represented as follows:
$G=|1\,\bar{1}\,2\,\bar{2}\,3\,\bar{3}\,n\,\bar{n}|$ $LE_1=0.9794\,\Phi\,(3\to5)-0.2021\,\Phi(4\to6)$
$LE_2=\Phi\,(3\to6)$
$CT=\Phi\,(n\to4)$
where, $\Phi\,(a\to b)=\{|1\ldots a\bar{b}\ldots\bar{n}|+|1\ldots b\bar{a}\ldots\bar{n}|\}/\sqrt{2}$
and 1, 2,... are the Hückel MO's of *p*-benzoquinone, and n is the 2p AO of amino-nitrogen.

The non-zero off-diagonal matrix elements for each of the interactions between the CT configurations and the G or LE configurations can be represented by the aid of the resonance integral β_{CN} between the neighboring nitrogen and carbon atoms. The value was taken to be −2.0 eV after several trial calculations.

The stabilization energies of *p*-benzoquinone caused by the amino substitutions were evaluated as the difference in energy between the ground configuration and the calculated lowest state. The results are shown in Fig. 6. We see that the 2,5-isomer is most stable among diaminobenzoquinones. This may be related to the fact that the substitution reaction preferably occurs on the 2,5-positions of *p*-benzoquinone.

We are greatly indebted to Prof. Shigeo Hayano and Dr. Masamichi Fujihira, the Institute for Industrial Science, the University of Tokyo, for permitting us to use the rapid scan spectrophotometer and also for their advice about the rapid scan absorption measurement. One of the authors (T.Y.) would like to thank Prof. Takahiro Tsunoda, Chiba University, for encouragement throughout the study.

Semiclassical Calculation of the Vibrational Transition Probabilities of Diatomic Molecules in Collision. The Effect of Vibrational Anharmonicity

Yoshiro YONEZAWA and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 10, 1971)

The multi-state semiclassical method proposed by Sharp and Rapp for calculating the vibrational transition probabilities of harmonic oscillators in collision was extended to Morse oscillators. Model calculations have been carried out for the excitation of a vibrational ground-state hydrogen molecule colliding with a helium atom at varying relative velocity. It has been shown that the Morse oscillator model gives greater transition probabilities than the corresponding harmonic oscillator model.

The basic problem in quantitative investigations of molecular excitation processes involved in chemical reactions is to calculate the vibrational transition probabilities P_{ij} for a target molecule undergoing a transition from an initial state i to a final state j due to perturbation by incident particles. For the calculation of such probabilities, several theoretical treatments based on the classical, semiclassical, and quantum-mechanical approximations have been published.[1)]

The purpose of the present work is to examine the effects of anharmonicity of molecular vibration on the transition probability. To this end, the multi-state semiclassical theory presented by Sharp and Rapp[2)] has been extended to the treatment of Morse-type diatomic oscillators. A computer program was written out and applied to the vibrational excitation of a ground-state hydrogen molecule colliding with a helium atom at temperatures 1000—5000°K. It has been shown that even for lower level transitions a Morse oscillator model leads to transition probabilities several times greater than those obtained from the harmonic oscillator model.

Method of Calculation

We shall deal with a head-on collision between a mass point A and a diatomic molecule BC. The coordinate system is defined in Fig. 1. Two coordinates which characterize the collision are x, the distance between A and the center of mass of BC, and y, the internuclear separation of BC. The intramolecular potential $U(y)$ is approximated by the harmonic or Morse potential, both of which have well-known energy eigenvalues and eigenfunctions.

Let us denote the engenvalues and eigenfunctions of unperturbed oscillator hamiltonian H_0 by E_n and ϕ_n.

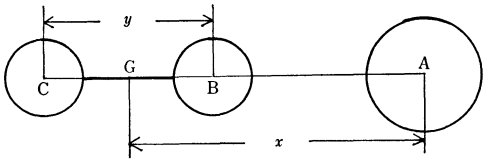

Fig. 1. Coordinate system for the one-dimensional collision between a BC molecule and an incident particle A.

When BC is a harmonic oscillator, we have

$$U_H(y) = \frac{1}{2}\mu\omega^2(y-y_e)^2 \tag{1}$$

$$E_n = \left(n+\frac{1}{2}\right)\hbar\omega \tag{2}$$

$$\phi_n(q) = M_n H_n(\sqrt{\alpha}q)\exp\left(-\frac{1}{2}\alpha q^2\right), \tag{3}$$

where ω is the angular frequency of the oscillator, y_e the equilibrium distance, H_n the Hermite polynomial, $q=y-y_e$ the instantaneous displacement of the oscillator, and μ, α, and M_n are quantities defined as follows:

$$\mu = m_B m_C/(m_B+m_C) \tag{4}$$

$$\alpha = \mu\omega/\hbar \tag{5}$$

$$M_n = (\alpha/\pi)^{1/4}/(2^n n!)^{1/2}. \tag{6}$$

When BC is a Morse oscillator, we can write[3)]

$$U_M(y) = D_e[\exp\{-a(y-y_e)\}-1]^2 \tag{7}$$

$$E_n = \frac{4}{\beta}D_e\left\{\left(n+\frac{1}{2}\right)-\left(n+\frac{1}{2}\right)^2/\beta\right\} \tag{8}$$

$$\phi_n(s) = N_n(-1)^n\Gamma(\beta-n)\exp(-s/2)s^{(\beta/2-n-1/2)} \tag{9}$$

$$\text{for } n = 0, 1, \cdots < (\beta-1)/2.$$

In Eq. (9), Γ(x) is the gamma function and

$$\beta = (8\mu D_e)^{1/2}/\hbar a \tag{10}$$

$$s = \beta\exp(-aq) \tag{11}$$

$$N_n = \{(\beta-1-2n)a/n!\Gamma(\beta-n)\}^{1/2}. \tag{12}$$

The intermolecular potential $V(x, y)$ is assumed to be of the simple exponential repulsion type:

$$V(x,y) = C\exp\left\{-\left(X-\frac{m_C}{m_B+m_C}y\right)/R\right\} \tag{13}$$

with the collision length R. In the semiclassical method the effect of energy transfer upon the trajectory of A is usually ignored, so that $V(x, y)$ is reduced to the following form:

$$V(X, Y) = E\exp\left(-\frac{X(t)}{R}\right)\exp\left(\frac{m_C}{m_B+m_C}\cdot\frac{Y}{R}\right) \tag{14}$$

where

$$X = x - x_T \tag{15}$$

$$Y = y - y_T \tag{16}$$

$$E = \frac{1}{2}mv^2 \tag{17}$$

3) F. H. Mies, *ibid.*, **40**, 523 (1964).

$$m = m_A(m_B+m_C)/(m_A+m_B+m_C), \quad (18)$$

x_T and y_T being the values of x and y at the classical turning point in the relative motion of A to BC, and v the relative incident velocity. Reduction of Eq. (13) to Eq. (14) is justified when the total energy exchange ΔE is a small fraction of the relative translational energy E.

The classical trajectory $X(t)$ as a function of time t for the present collision model is obtained by neglecting the vibration of BC and solving the classical equation of motion

$$\frac{1}{2}m\left(\frac{dX}{dt}\right)^2 + E\exp(-X/R) = E. \quad (19)$$

The analytical solution of this equation is well-known, but we have made a computation program to solve it numerically, as we intend it to be useful for any assumed form of intermolecular potential between A and BC.

The behavior of the oscillator under the influence of intermolecular interaction can be traced by solving the time-dependent Schrödinger equation

$$\{H_0+V(t, Y)\}\Psi = i\hbar\frac{\partial\Psi}{\partial t}, \quad (20)$$

where $V(t, Y)$ involving t instead of X as a variable constitutes the time-dependent perturbation toward the oscillator.

The time-dependent wavefunction $\Psi(t)$ of the oscillator can be expanded with the complete set $[\phi_n(q)]$. Thus

$$\Psi(t) = \sum_n a_n(t)\phi_n(q)\exp(-iE_nt/\hbar). \quad (21)$$

Insertion of Eq. (21) into Eq. (20) gives

$$\frac{da_j}{dt} = \frac{1}{i\hbar}\sum_n a_n(t)V_{nj}(t)\exp\{-i(E_n-E_j)t/\hbar\}, \quad (22)$$

where $V_{nj}(t)$ is defined by

$$V_{nj}(t) = \int\phi_n(q)V(t, Y)\phi_j(q)dq. \quad (23)$$

In order to evaluate Eq. (23), Y must be related to the oscillator coordinate q for every collision of varying initial phase angle of the oscillator. To avoid this complexity in procedure, we have made use of an averaging convention by setting

$$Y = q - \langle q\rangle_n \quad (24)$$

for the initial nth vibrational state of the oscillator, where

$$\langle q\rangle_n = \int\phi_n(q)q\phi_n(q)dq, \quad (25)$$

which represents the average displacement from the equilibrium nuclear separation of the oscillator in the nth level. Integration of Eq. (25) was carried out numerically for the Morse oscillator using Simpson's integration formula. Note that for a harmonic oscillator $\langle q\rangle_n=0$.

On the above assumption, the factor $V_{nj}(t)$ can be written as

$$V_{nj}(t) = U_{nj}E\exp\{-X(t)/R\}\exp\left(-\frac{m_C}{m_B+m_C}\cdot\frac{\langle q\rangle_n}{R}\right), \quad (26)$$

where U_{nj} is a vibrational matrix element defined by

$$U_{nj} = \int\phi_n(q)\left\{\exp\left(\frac{m_C}{m_B+m_C}\cdot\frac{q}{R}\right)\right\}\phi_j(q)dq. \quad (27)$$

When BC is a harmonic oscillator, Eq. (27) is reduced to[2]

$$U_{ij} = \{\exp(\Delta^2)\}(2^{i-j}i!/j!)^{1/2}\Delta^{i-j}L_i^{(j-i)}(-2\Delta^2), \quad (28)$$

where $L_i^{(j-i)}$ is a generalized Laguerre polynomial and

$$\Delta = \{m_C\hbar/m_B(m_B+m_C)\omega\}^{1/2}/2R. \quad (29)$$

When BC is a Morse oscillator, Eq. (27) takes the form[3]

$$U_{ij} = \{\beta^\eta N_iN_ji!\Gamma(\beta-i)/a\} \times\sum_{m=0}^{i}\frac{(-1)^{m+i-j}\Gamma(1+\eta+i-m)\Gamma(\beta-1-\eta-i-j+m)}{m!(i-m)!\Gamma(1+\eta+i-j-m)\Gamma(\beta-2i+m)}, \quad (30)$$

where

$$\eta = m_C/(m_B+m_C)Ra. \quad (31)$$

To obtain the transition probability P_{ij}, we must solve Eq. (22) for a_i.

For this purpose we used the Runge-Kutta-Gill method retaining lower N vibrational states of the oscillator. If before collision ($t=-\infty$) the molecule BC is in state i, the initial condition for Eq. (22) is $|a_j(-\infty)|^2=\delta_{ij}$. The probability of molecule undergoing the transition to the state j on collision is $P_{ij}=|a_j(+\infty)|^2$.

We have applied the above method of calculation to the excitation of a vibrational ground-state hydrogen molecule colliding with a helium atom at varying incident velocity. The appropriate molecular constants are $m_A=6.64\times10^{-24}$ g, $m_B=m_C=1.673\times10^{-24}$ g, $y_e=0.741$ Å, $\omega=9.378\times10^{14}$ sec^{-1}, $D_e=7.6\times10^{-12}$ erg, and $a=(\mu\omega^2/2D_e)^{1/2}=2.2$ Å^{-1}. R was assumed to be 0.2 Å.

All the numerical procedures were programmed in FORTRAN and calculations were carried out on the FACOM Computer at the Kyoto University Computation Center. Integration of Eq. (22) was started with a distance of 3 Å from the classical turning point and continued until the mass point A passed the 3 Å point on its departure. The integration step size was held below 1.0×10^{-16} sec, which required 1000 to 3000 steps to complete tracing one collision. The number of lower vibrational levels N included for solving Eq. (22) was 6. The incident velocity v was varied between 1.0×10^6 and 4.0×10^6 cm/sec.

Results and Discussion

For calculating the transition probability P_{ij}, it is necessary to evaluate the average displacements $\langle q\rangle_n$ and the vibration matrix elements U_{ij} of the oscillator.

Table 1 lists the values of $<q>_n$ together with the energy E_n of the lowest six vibrational levels of a hydrogen molecule in its harmonic and Morse oscillator models. Table 2 gives U_{ij} pertinent to these levels in the harmonic and Morse oscillators.

The fractional populations $|a_j(t)|^2$ of various vibrational levels in a Morse oscillator H_2 molecule are shown in Fig. 2 as a function of time during its collision with an He atom incident with an initial velocity of 1.0×10^6 cm/sec. The H_2 molecule was assumed to be initially on the ground vibrational level. Thus the population of each given level at infinity of time should correspond to the transition probability from zero level to the level in question. It can be seen that P_{01} takes a value of approximately 0.01 on this collision, but the probabilities of transitions to higher levels are negligibly small. This is natural, since the initial velocity chosen in this specific example corresponds to $E_{tr}=1.112\times10^{-12}$ erg, which exceeds the vibrational quantum only slightly, so that none of the 0—2, 0—3, and 0—4 transitions is an energetically attainable transition in a classical-mechanical sense. Quantum-mechanically, however, the 2, 3, and 4 levels are all populated appreciably for some short period around $t=0$, which produces an important contribution to the final magnitude of P_{01}.

The transition probabilities P_{01} calculated for the harmonic model of H_2 are shown in Fig. 3 as the functions of collision velocity v. Figure 4 represents similar results obtained for the Morse model. All these probabilities initially increase with increasing v until they attain maximum values, and then decrease oscillatingly with v. Such a behavior is also observed in

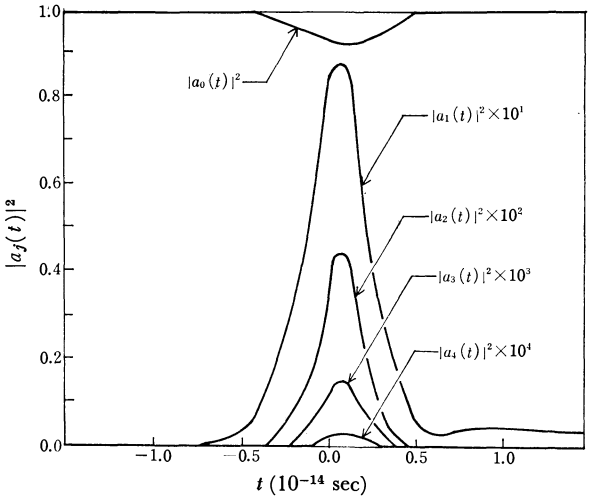

Fig. 2. Population of vibration levels, $|a_j(t)|^2$, as a function of time during a collision of a Morse oscillator H_2 molecule with an incident He.
$|a_j(-\infty)|=\delta_{0j}$; $v=1.0\times10^6$ cm/sec.

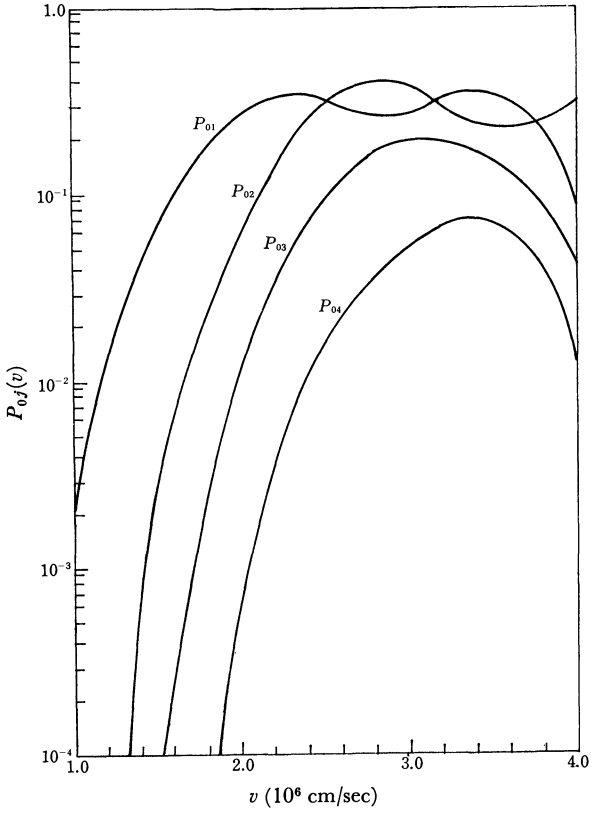

Fig. 3. Vibrational transition probabilities, $P_{1j}(v)$, of a ground-state H_2 (harmonic) molecule on collision with an He atom as the functions of velocity.

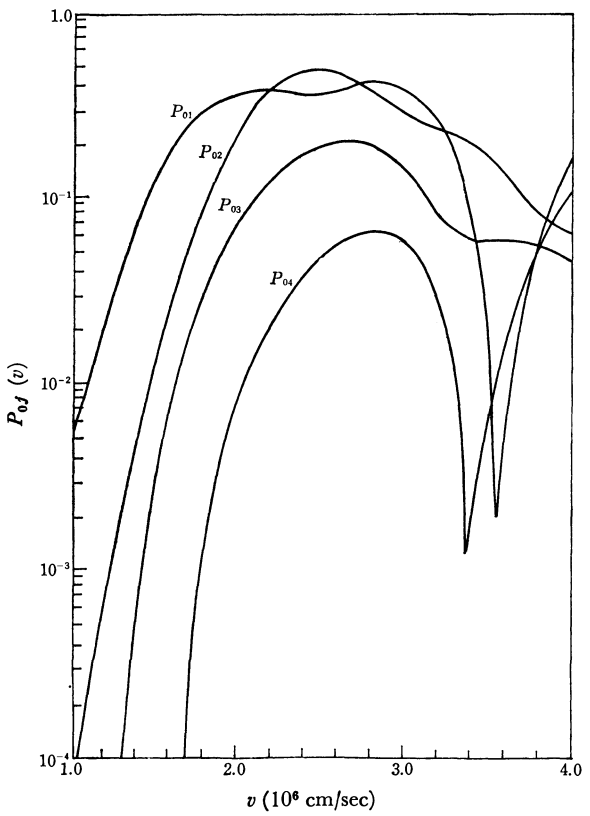

Fig. 4. Vibrational transition probabilities, $P_{ij}(v)$, of a ground-state H_2 (Morse) molecule on a collision with an He atom as the functions of velocity.

both the "exact" classical[4] and quantum-mechanical[5] transition probabilities.

Comparison of Fig. 4 with Fig. 3 shows that the Morse oscillator model leads to greater P_{0j} values than the harmonic model, until the P_{0j}'s calculated from the former model reach maximal values. The results are apparently contradictory to the theoretical demonstration of Mies,[3] who claims that the anharmonicity of diatomic molecules generally reduces the "usually" calculated P_{01} values by a factor of 10^{-1} to 10^{-2}. In order to avoid confusion between these two results, some comments are desirable.

The "anharmonicity factor" proposed by Mies is essentially a correction factor for the conventional adiabaticity assumption $U_{ii}=U_{jj}$, which was invoked in the original two-state distorted-wave approximation (DWA) of Jackson and Mott.[6] In the harmonic oscillator model the assumption is tolerably satisfied. However, if a Morse model is adopted, the assumption becomes no longer justifiable as can be seen in Table 2. Calculations show that use of precisely evaluated U_{ii}'s generally tends to reduce the P_{ij} values. Even in the case of harmonic oscillators, the Jackson-Mott transition probabilities need to be corrected by a factor of 10^0 to $10^{-1.7}$. Thus, in this sense the "anharmonicity factor" might better be termed the "nonadiabaticity correction factor."

In the case of the two-state approximation, the effects of nonadiabaticity are certainly more conspicuous in Morse oscillators than in harmonic oscillators, as Mies emphasizes. Such nonadiabaticity corrections have authomatically been embodied in our multi-state semiclassical treatments. Auxiliary calculations made by forcing all the U_{ii} elements to be 1 have led to the P_{0j} values which are 10^0 to 10^1 times greater than those of more precise calculations. The P_{01} values for the Morse model relative to the harmonic were not altered materially from those given in Figs. 3 and 4. That the Morse model gives greater P_{0j} values than the harmonic model is due primarily to the narrower spacings of the vibrational levels in the former.

The effects of narrow energy level spacings may become clearer in the energy exchange of a highly excited oscillator. We calculated P_{ij} of excited Morse oscillator ($i=10$) at the initial velocity of 1.0×10^{-6}cm/sec. The multi-state semiclassical method gave $P_{10\text{–}11}=0.820$, $P_{10\text{–}12}=0.158$, $P_{10\text{–}13}=0.281$ and $P_{10\text{–}14}=0.102$. The two-state approximation (Jackson-Mott-Mies), on the other hand, resulted in $P_{10\text{–}11}=4.79\times10^{-3}$, $P_{10\text{–}12}=6.22\times10^{-6}$, $P_{10\text{–}13}=9.21\times10^{-4}$, and $P_{10\text{–}14}=1.47\times10^{-4}$. It seems that these values are unreasonably small.

The effects of anharmonicity are thus reflected in both the vibrational matrices U_{ij} and the level heights E_i. Whether the anharmonicity enhances or diminishes the calculated transition probabilitics depends on the approximation used as well as the collision ve-

locity chosen.

The 0—j vibrational transition probability averaged over thermal velocity distributions for collisions at a temperature T may be written as

$$\langle P_{0j} \rangle = \int_{v_c}^{\infty} P_{0j}(v) \mathrm{d}n(v), \tag{32}$$

where

$$\mathrm{d}n(v) = (m/kT)v \exp(-mv^2/2kT)\mathrm{d}v \tag{33}$$

and

$$v_c = \{2(E_j - E_0)/m\}^{1/2}. \tag{34}$$

We calculated the $\langle P_{0j} \rangle$ at temperatures 1000—5000°K for every 1000°. The results are given in Table 3, where it may be seen that the $\langle P_{0j} \rangle$ values calculated for the Morse oscillator are always larger than the corresponding values obtained from the harmonic oscillator model.

Our value of $\langle P_{01} \rangle$, 3.486×10^{-4}, calculated for the Morse model at 2000°K agrees well with the value 3.7×10^{-4} which McElwain and Pritchard[8] assumed (based on DWA method) for an anharmonic H_2 molecule at the same temperature. Although the agreement may be fortuitous, the $\langle P_{01} \rangle$ value of *ca.* 10^{-4} will probably be in a correct order of mganitude for the H_2—He system at 2000°K. The $\langle P_{0j} \rangle$ values decrease with the increasing quantum number j of the final state. The decrease is, however, much more moderate than that derived from the usual two-state approximations. The conclusion stresses the need of care in the choice of the $\langle P_{ij} \rangle$ values to be used for high-energy collision processes.

It should be noted that we have used the classical trajectories for the present inelastic collision processes. In the "exact" semiclassical method proposed by Locker and Wilson,[9] the effect of energy exchange on the $X(t)$ and hence on the P_{ij} is evaluated properly. However, the method gives different transition probabilities for different initial phase angles, so that an appropriate averaging procedure is required, if the method is to be really useful for obtaining the average probability on a collision. In our method, on the other hand, such an averaging process is included automatically, though in a crude manner. Thus, our method may be less rigorous but is certainly more tractable than the method of Locker and Wilson.

Conclusion

The multi-state semiclassical method coupled with a proper procedure of averaging the initial vibration phase angles provides a tractable means of evaluating the vibrational transition probabilities of diatomic molecules. When the H_2 molecule is assumed to be a Morse oscillator the probabilties calculated for the H_2 (i=0)—He system at 1000—5000°K are greater than when it is assumed to be harmonic. This seems to have an important bearing with the kinetics of the bimolecular dissociation process of diatomic molecules.

The Crystal and Molecular Structure of Bis(*o*-ethoxyphenyl)butadiyne

Tooru TAGA,* Norio MASAKI,* Kenji OSAKI,* and Tokunosuke WATANABÉ**

Faculty of Sciences, Osaka University, Osaka

(Received May 15, 1971)

The crystal structure of bis(*o*-ethoxyphenyl)butadiyne has been determined by the statistical method of X-ray analysis. The space group is $P2_1/a$ with two molecules in the unit cell of dimensions $a=14.64$, $b=11.27$, $c=5.19$ Å, and $\beta=105.6°$. The crystal structure is built up from columns of the molecules packed along the *c*-axis. The molecule has a center of symmetry and is almost planar. The diacetylene group is slightly twisted and the three conjugated bond distances of the diacetylene group are 1.434, 1.201, and 1.371 Å.

This is the first paper of a series on the crystal structure of ω,ω'-diphenylpolyynes and their derivatives. A short note on the crystal structure of ω,ω'-diphenyltetrayne and ω,ω'-diphenylpentayne has been repotred by Watanabé, Taguchi, and Masaki.[1]

In a number of papers dealing with the molecular structure of compounds containing the diacetylene group,[2-11] it was reported that the carbon atoms of the diacetylene group are almost linear, and the three conjugated diacetylene bonds lie between 1.44—1.47 Å for the side C–C, 1.18—1.21 Å for the triple C–C and 1.33—1.39 Å for the central C–C bonds, respectively.

The aim of this investigation is to provide accurate values for bond distances and angles in the molecule of bis(*o*-ethoxyphenyl)butadiyne using three-dimensional data. The influence of the ethoxy group substituted in the phenyl ring on the molecular structure as well as on the molecular packing was also investigated.

Experimental

Crystals for the experiment were obtained from ethanol solution. They are monoclinic, colorless needles elongated along the direction of the *c*-axis. The crystallographic data and some physical properties are listed in Table 1. The cell dimensions were determined from Weissenberg and oscillation photographs about the *c*-axis and the space group was determined unambiguously from the systematic absence of reflections. The crystal density was measured by the flotation method in ammonium chloride solutions, and was in good agreement with the calculated density value assuming two molecules per unit cell.

Systematic absences of the reflections;	
$h0l$ for $h=2n+1$, $0k0$ for $k=2n+1$	

Intensities of the reflections $hk0$ to $hk4$ were visually estimated from the Weissenberg photographs, recorded with nickel-filtered *Cu* $K\alpha$ radiation. They were reduced to 1033 independent structure factors after corrections for the layer scale, the Lorentz, polarization and spot shape factors being applied. No absorption corrections were applied, since the size of the crystal was small ($0.12\times0.15\times1.3$ mm). The scale factors for each layer, used in the above correction, were estimated from a preliminary examination in which the reflections of the different layers were recorded on the same film, using the anti-equi-inclination Weissenberg technique. The normalized structure factors were calculated from the observed structure factors, using the scale and overall temperature factors obtained by the Wilson method. The average values of $|E|$ and $|E^2-1|$ are 0.852 and 0.981, respectively. The maximum value of $|E|$ is 3.99 and the number of the reflections with $|E|$ value above 1.7 is 124.

Structure Determination

The structure was determined by the statistical method.[12] The origin was specified by assinging positive signs to three reflections, 121, 211, and $86\bar{3}$.[13] For the sign-determining procedure, the sign relation formula $S(E_h)=S(\sum_k E_k E_{h-k})$ was applied to the reflections with $|E|$ value above 1.7. In this procedure the value of the triple product $E_h E_k E_{h-k}$ was required to exceed 8.1 if a single sign indication was accepted, and the new signs were added to the list of known signs and subsequently used to determine other signs. At the end of the procedure, signs of 124 reflections were

determined and an E-map was synthesized from them. The highest eleven peaks in this map correspond to all the nonhydrogen atoms in the structure.

The structure was refined first by the isotropic diagonal least squares method. After three cycles of refinement the R index was 0.179. The positions of the hydrogen atoms were found from the difference Fourier map calculated at this stage. Further refinements were carried out by the block diagonal least squares method, including the positional parameters of the hydrogen atoms and the anisotropic thermal parameters of the nonhydrogen atoms. Five cycles of this refinement with the Cruickshank weighting scheme reduced the R index to 0.084 for all the observed reflections.[14] The parameter shifts of all the nonhydrogen atoms in the last cycle were less than 2σ.

Results and Discussion

The resulting crystal structure is shown in Figs. 2 and 3, as viewed in the projections along the c- and b-axes, respectively. The center of the molecule lies

14) D. W. J. Cruickshank, "Computing Methods and the Phase Problem in X-ray Analysis," ed. by Pepinsky *et al.*, Pergamon Press, New York (1961), p, 45.

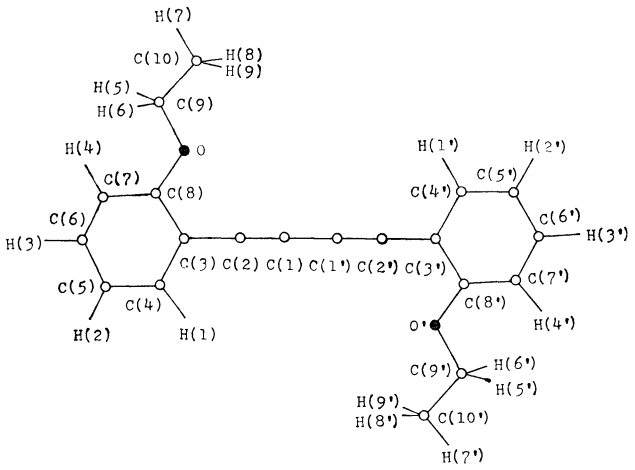

Fig. 1. Conventional numbering and identification of the atoms in bis(*o*-ethoxyphenyl)butadiyne molecule.

at the special position of crystal symmetry ($\bar{1}c$), so that the molecule has a center of symmetry and is almost planar (Fig. 1). The diacetylene chain lies approximately on a plane perpendicular to the *c*-axis and the plane of the phenyl ring is inclined about 49.5° to this plane. The crystal structure is built up from columns of the molecules packed along the *c*-axis, since a large number of short contacts occur between atoms of the molecules related by translation along the *c*-axis, *viz*; 3.49 Å between C(4) and O, 3.59 Å between C(3) and C(9) and 3.59 Å between C(3) and C(10). Only one very short intermolecular distance is found between the columns, namely 3.50 Å between C(4) and C(9). However all other intermolecular distances between the columns are larger than 3.7 Å. These intermolecular distances are considered to be the normal van der Waals distances.

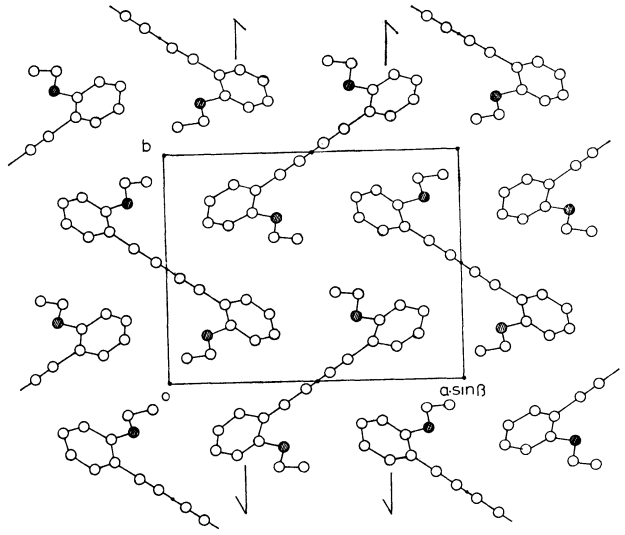

Fig. 2. Projection of the crystal structure along the *c*-axis.

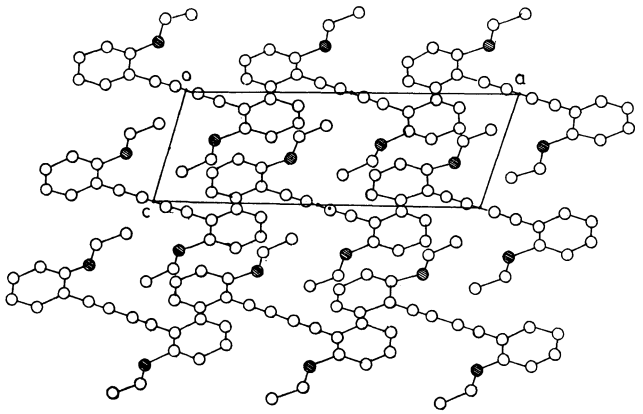

Fig. 3. Projection of the crystal structure along the *b*-axis.

The covalent bond distances and angles in the molecule are listed in Table 5. The carbon-carbon distances of the diacetylene group were corrected for the effect of the thermal motion. The mean square displacement of each atom from its equillibrium position was calculated from the anisotropic thermal parameters given in Table 3. The results indicate that the thermal motion of the molecule cannot be treated as a rigid body motion, and the dominant motion of the atoms of the diacetylene group are considered to be caused by the torsional oscillation about the axis perpendicular to the bond vector, plus the translational motion of the molecule as a whole. Since atoms C(1) and C(1′) are related by the center of symmetry, the C(1)–C(1′) distance was corrected on the basis of the assumption of the upper limit model of Johnson, which corresponds

		O–C(9)–H(5)	111.4(2.6)
		C(0)–C(9)–H(6)	111.3(2.5)
		O–C(9)–H(6)	107.4(2.5)
		H(5)–C(9)–H(6)	111.5(3.3)
		C(9)–C(10)–H(7)	105.9(2.7)
		C(9)–C(10)–H(8)	110.8(2.8)
		C(9)–C(10)–H(9)	108.9(2.8)
		H(7)–C(10)–H(8)	108.6(3.7)
		H(7)–C(10)–H(9)	114.2(3.4)
		H(8)–C(10)–H(9)	108.5(3.7)

to the out-of-phase displacement of these-atoms perpendicular to the bond.[15] The corrections to distances C(1)–C(2) and C(2)–C(3), although small, were also calculated by the lower limit model.

The central C(1′)–C(1) bond distance 1.371 Å and the triple C(1)–C(2) bond distance 1.201 Å found in this investigation, agree with the corresponding values 1.376 and 1.205 Å, for diacetylene reported by Callomon and Stoicheff and the values 1.375 and 1.199 Å, for dimethyldiacetylene reported by Himes within experimental errors,[6,9] while the side C(2)–C(3) bond distance 1.434 Å, is close to that of diphenyldiacetylene, 1.44 Å, given by Wiebenga.[11] From these values, the bond order of the C(1′)–C(1) and C(2)–C(3) bonds are estimated to be about 1.63 and 1.27, respectively, indicating that the C(1′)–C(1) bond has considerable double bond character.[16] Concerning the bonds in the ethoxy group, the C(8)–O bond of 1.367 Å has a partial double bond character through the influence of the aromatic ring, while the C(9)–O bond of 1.447 Å and the C(9)–C(10) bond of 1.520 Å are normal paraffinic single bonds. The mean value of the carbon-carbon distances in the phenyl ring is 1.396 Å, which is in good agreement with the normal value 1.395 Å. The mean value of the C–H distances is 1.006 Å.

Table 6. Deviations of each atom from the best plane (see text) and their estimated standard deviations in the direction of the plane normal

Atom	Deviation(Å)	E.S.D.(Å)
C(1)	0.011	0.006
C(2)	0.028	0.006
C(3)	0.030	0.006
C(4)	0.007	0.007
C(5)	−0.020	0.007
C(6)	−0.008	0.007
C(7)	−0.005	0.006
C(8)	0.006	0.006
C(9)	−0.111	0.006
C(10)	−0.078	0.007
O	−0.010	0.004

The best plane equation of the molecule except for the four atoms of the ethyl groups is expressed by

$$0.2224x + 0.6368y + 0.7376z = 3.589,$$

where x, y, and z are the orthogonal coordinates in Ångstrom unit. Deviations of each atom from this plane are given in Table 6. Atoms C(9) and C(10) of the ethyl group deviate from this plane about 0.111 Å and 0.078 Å, respectively, and the plane through these atoms and the nearest oxygen atom is inclined about 4.7° to the above best plane. The deviations of atoms C(2) and C(3) from the best plane are about 0.028 Å and 0.030 Å, respectively, which are significantly large in comparison with their estimated standard deviations of positions. Four atoms of the diacetylene group lie approximately on the straight line, while atoms C(2), C(3), and C(6) also are almost linear. However, atoms C(3) and C(6) do not lie on the line connecting atom C(2) to the center of the molecule, so that the diacetylene chain is slightly bent at atoms C(2) and C(2′), and the ethoxy groups are kept away from the center of the molecule. The diacetylene group has no short intermolecular contacts in the crystal, while the ethoxy and phenyl groups have a large number of short contacts with the nearest molecules. Thus the diacetylene chain can be bent by the intramolecular interactions based upon asymmetry of the molecule about the diacetylene group. It may be also affected by steric effects induced from the side groups which are closely packed in the crystal.

The authors wish to express their gratitude to Dr. F. Toda and Prof. M. Nakagawa for the supply of the specimen. They also thank Mr. H. Iizuka for his assistance in the experiment. The computations were performed with the use of the block diagonal least squares program, HBLS, written by Dr. T. Ashida, UNICS, and the symbolic addition procedure program and others written by one of the authour (T. T.) on the FACOM 230-60 of the Data Processing Center, Kyoto University.

Effects of External Pressure on the Light Absorption and Fluorescence of s-Tetracyanobenzene Complexes

Yoshikazu TORIHASHI, Yoshifumi FURUTANI, Kiyoshi YAGII, Noboru MATAGA,[1] and Akira SAWAOKA*

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

**Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo*

(Received May 19, 1971)

The effects of high pressure on the charge-transfer (CT) absorption and fluorescence spectra of tetracyanobenzene (TCNB) complexes at room temperature have been examined. The pressure-induced change in the absorption intensity indicated the reduction of the distance between donor and acceptor in the complex and the increase in the overlap between their electron clouds. The pressure-induced red shifts of the absorption and fluorescence spectra were almost equal to each other in the case of the TCNB-toluene system, but the former shift was larger than the latter shift in the case of the TCNB-mesitylene system. These results were interpreted in terms of the reduction of the donor-acceptor distance in the complex as well as in terms of electrical solute-solvent interactions. It has been confirmed that the fluorescence quantum yield and the decay time of the complex decrease with the increase in the pressure, and that the rate of the decrease of the former is much larger than that of the latter, in the case of TCNB-toluene system. These results have been interpreted as being due to the pressure-induced increase in the quenching process at the Franck-Condon excited state as well as in the course of the relaxation process from the excited Franck-Condon state to the equilibrium fluorescent state.

It is well-known from recent experimental results that, on going from vapor to the condensed phase, optical-absorption spectra of weak EDA (electron donor-acceptor) complexes undergo quite remark able changes.[2-5] That is, the CT absorption bands of such complexes as tetracyanoethylene-aromatic and iodine-aromatic systems show red shifts of 1000—4000 cm^{-1} and an intensity enhancement of 200—800% upon this phase change. Furthermore, these effects can be facilitated by an external high pressure added to the condensed phase.[5,6]

It should be noted that the above spectral changes are much larger in the case of weak complexes than in the case of strong complexes or free molecules. It has been argued[4,5,7-9] that these spectral changes in the weak EDA complexes may be related to the reduction in the distance between the component molecules in the complex, which is itself caused by the internal compressional force of the solvent or the host and also by the external pressure. For example, Trotter[7] has pointed out on the basis of statistical mechanical calculations, that liquids exert an internal mechanical pressure of the order of 10^3—10^4 atm on dissolved molecules, and this pressure causes a very large vapor-to-liquid change in the spectra of weak complexes.

It seems that it would be interesting and important to study the effect of high pressure not only on the absorption spectra but also on the fluorescence spectra of EDA complexes. Offen and his co-workers[8,9] have examined the high pressure effect on the absorption and fluorescence spectra of some EDA complexes contained in high polymer matrices. According to their results, *e.g.*, in the case of the TCPA (tetrachlorophthalic anhydride) complexes with aromatic hydrocarbons in a polymethylmethacrylate matrix, the fluorescence spectra showed a much smaller pressure-induced red shift than the absorption spectra. This difference was explained in terms of the potential energy curves for the ground and excited states characterizing the molecular complex. Moreover, the absorption intensity increased, while the fluorescence intensity decreased, as the pressure was increased. The extent of the decrease in the fluorescence intensity was larger than that of the enhancement of the absorption intensity. At any rate, this fact appears to indicate an increase in the quenching process due to the external pressure, though its mechanism is not clear.

As far as we know, there has been no quantitative study of the EDA complex in a liquid solution in which the pressure effects upon both fluorescence and absorption spectral shifts, and upon the fluorescence quantum yields and decay times are investigated. We have, therefore, undertaken a systematic study concerning the high pressure effects on the EDA interactions in the electronic ground state as well as in the excited state, including the weak EDA complex formation, the contact CT interactions, and the exciplex formation in solution. In the present report, we shall describe the results of our study of the TCNB-toluene system, the fluorescence behavior of which has been studied previously in some detail under 1 atm,[10] and also the results of some studies of the TCNB-mesitylene system.

Experimental

The TCNB was the same sample as was used before.[10]

The toluene was purified by the method described in the literature.[11] The mesitylene was distilled carefully under reduced pressure. The fluorescence spectra were measured with an Aminco-Bowman spectrophotofluorometer which had been calibrated to obtain the correct fluorescence quantum spectrum, while the absorption spectra were measured by means of a Cary 15 spectrometer. The fluorescence spectra were excited exclusively at the wavelength of the first CT absorption band. The fluorescence decay times were measured with a giant pulse ruby laser which has an output powder of 1.5 J and a 15—20 nsec pulse width, or with a pulsed nitrogen gas laser. The exciting light pulse from the ruby laser was produced by an ADP frequency doubler which converted *ca.* 8 per cent of the energy of the 694 nm beam to that of the 347 nm beam. The light pulse of the nitrogen gas laser had an output power of 10 kW and a duration of 3 nsec. Its repetition rate was *ca.* 50 Hz. The fluorescence emission was observed with a travelling wave-pulsed photomultiplier. The outputs from the photomultiplier with a delay line were displayed on an X-Y recorder.

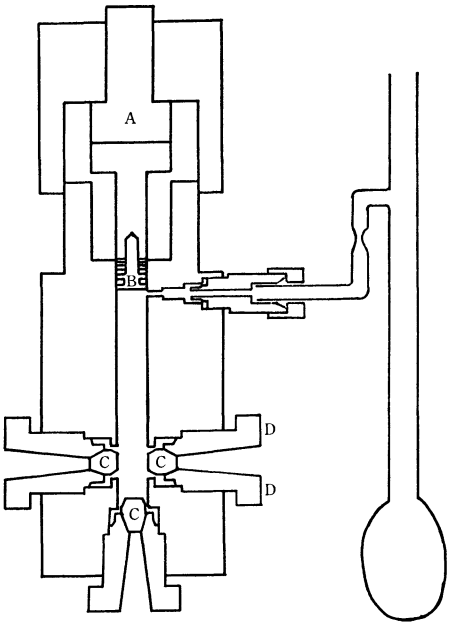

Fig. 1. High pressure optical cell.
A. Low pressure piston, B. High pressure piston
C. Sapphier window, D. Window plug.

Figure 1 shows a cross section of the high-pressure optical cell, the cell is reasonably small, is portable, and can be introduced into various spectrometers and other optical setups. All the metallic parts of the cell, including the pistons and window plugs, are made of copper-beryllium alloy. In order to prevent the leakage of solutions through gaps in the regions of the sapphire-metal contact and metal-metal contacts at the windows and piston parts, various packings, such as teflon, lead, and Viton A of du Pont, were used. The deaeration of the solution was conducted as follows. The solution in an ampoule, which was connected with the high-pressure cell, was deaerated by freeze-pump-thaw cycles. The deaerated solution was then transferred to the high-pressure cell and the transfer glass tube was sealed off. The highest pressure which could be applied to the solution in our high-pressure optical cell was *ca.* 8000 atm.

Results and Discussion

The absorption and fluorescence spectra of the TCNB-toluene system under various external pressures are indicated in Fig. 2. The first absorption band of the TCNB-toluene complex appears only as a shoulder at *ca.* 29000 cm^{-1}; one cannot observe any distinct peak, even under 7000 atom. However, as is shown in Fig. 3, the rate of the pressure-induced increase in its absorbance is much larger than that of the density of the solvent. Moreover, the rate of the absorbance increase is much larger at longer wavelengths than at shorter wavelengths. The latter fact indicates that the pressure-induced red shift of the first absorption band occurs. We have estimated the wave numbers of the first absorption maximum at various external pressures by subtracting the contributions of the strong second band from the spectra. The results are shown in Fig. 4, where a similar spectral shift of the fluorescence band is also indicated.

We have also carried out quite similar studies of the spectra of the TCNB-mesitylene two-component system. The TCNB-mesitylene complex is stronger than the TCNB-toluene complex and shows a distinct CT

see that the results are rather different from those in the TCNB-toluene system.

The pressure-induced change in the absorbance corrected for the volume contraction might be attributed to the increase in the solvent refractive index, n, at high pressures. Although n values of mesitylene[12] have been observed under various external pressures, we have no such values for toluene. We have estimated the n values for toluene by means of the Debye equation as well as by means of the Onsager equation for dielectric polarization,[13] using the observed values of density and the dielectric constant of toluene under various external pressures.[14,15] The two equations gave practically the same values. By employing these n values, we have made a rough estimation of the pressure-induced absorbance change according to Chako's simplified equation;[16]

$$A \propto f(n) \equiv \left(\frac{n^2+2}{3}\right)^2 / n$$

One can see from Table 1 that the pressure-induced absorbance increases as corrected for the change in the refractive index, are rather small. However, the corrected increase for the TCNB-mesitylene system appears a little larger than that of the TCNB-toluene system.

One should note here that there are opposing effects of the external pressure upon the intensity of the CT absorption band of TCNB complexes. That is, there occurs a reduction in the donor-acceptor distance in the complex; this reduction, on the one hand, increases the orbital overlap between the partners in the complex, causing the enhancement of the CT absorption intensity. On the other hand, the decrease in the donor-acceptor distance in the complex presumably makes the excited state more ionic, thus reducing the con-

tribution from the locally-excited configuration, which in turn decreases the absorption intensity because of the decrease in the intensity borrowing from the locally-excited state of TCNB. Moreover, if a pressure-induced change in the geometrical structure of the complex from an unsymmetrical structure to a symmetrical overlapping one occurs, the CT transition probability is decreased.[17,18] Becasuse these effects cancel each other out, the appearent increase in the absorption intensity may be rather small. Therefore, one should not exclude the possibility of the pressure-induced reduction of the donor-acceptor distance in the complex in interpreting the other spectral behavior of these complexes, even if the pressure-induced net increase in the absorbance is small.

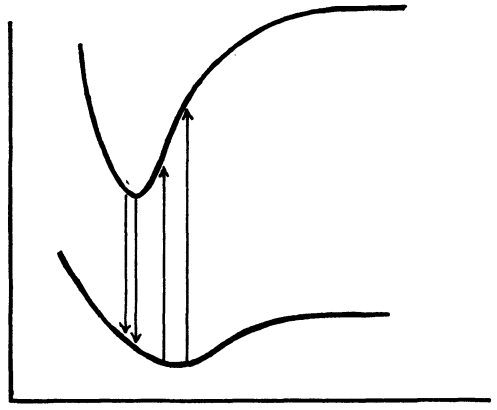

Fig. 7. Potential energy curves for the excited and ground state of an EDA complex.

The above-described circumstances are illustrated in Fig. 7, where one can see also that the decrease in the distance, R_{AD}, between the partners in the complex may cause the red shift of the fluorescence as well as the absorption band. One may suppose from Fig.7 that the amount of the fluorescence red shift is smaller than that of the absorption red shift for the same added external pressure, as a result of the difference between the potential energy curves for the excited and ground states of the complex. Such an example was actually observed, as we have previously described, in the case of TCPA complexes in high polymer matrices.[8,9] In the case of a liquid solution, however, dielectric polarization interactions between the surrounding solvent molecules and the complex in the fluorecent state may be larger than in the case of solid solution, leading to a stronger fluorescence red shift. Nevertheless, the extent of the fluorescence red shift is considerably smaller than that of the absorption in the case of the TCNB-mesitylene system (Fig. 6). The solute-solvent dielectric interaction seems to be larger in the case of the TCNB-toluene system than in the case of the TCNB-mesitylene system. Thus, for the former system, the magnitude of the pressure-induced red shift of the fluorescence spectrum is almost the same as that of the absorption spectrum. On the other hand, the fact that both the absorption and fluorescence spectral shifts became almost saturated at about 6500 atm in the case of the TCNB-toluene does not seem to be interpreted satisfactorily by the ordinary theory of the solvent shift of spectra, since the solvent refractive index and the dielectric constant do not show such a strong saturation effect at pressures of 6000—7000 atm. We can also observe, in the case of the TCNB-mesitylene system (Fig. 6), a tendency for the spectral shifts to become saturated, even at 3000 atm. These results can be explained, at least qualitatively, as due to the structure change in the complex caused by the external pressure. That is, when R_{AD} becames smaller, the complex becomes stronger, and the pressure effect on the spectral shift becomes smaller, because of the enhanced blue-shift contribution from the resonance interaction between the no-bond and CT structure, as has been suggested by Kadhim and Offen.[9] Thus, the pressure-induced spectral shift in our present system may be ascribed to combined effects due to CT forces and potential energy curves appropriate for weak complexes as well as to dielectric polarization interactions between the complex and surrounding solvent molecules.

a) The values in parenthesis are absolute quantum yield. The values of the absolute quantum yield at 1 atm were taken from: T. Kobayashi, Y. Yoshihara, and S. Nagakura, The Symposium on EDA Complex (Osaka), 1970, Preprint.

For a closer examination of the behavior of the excited complex, it is necessary to measure the fluorescence quantum yields and decay times under various external pressures. The results of our measurements are indicated in Table 2. One can see from Table 2 that both the relative fluorescence quantum yield and the fluorescence decay time decrease with the increase in the external pressure. In the case of the TCNB-toluene system, where the fluorescence decay time was measured by means of the giant pulse laser, the rate of decrease in the quantum yield is considerably larger than that of the decay time. Therefore according to the $K_F=\eta_F/\tau_F$ equation, the radiative transition probability decreases with the pressure increase. However, it should be noted here that the above statement is valid only if the quenching process at the excited

Franck-Condon (F.C.) state as well as in the course of the relaxation from the excited F.C. state to the equilibrium (e.q.) fluorescent state is not affected by the added pressure.

On the other hand, as has been elucidated in previous works,[10,19,20] the energy and the electronic structure of the excited F.C. state of the TCNB-toluene system are very different from those of the e.q. excited state. It has been confirmed that the observed fluorescence decay time is much longer than the radiative lifetime calculated from the intensity of the absorption band, and there must occur a change in the electronic structure in the course of the relaxation from the excited F.C. state to the e.q. state. It was assumed that the anomalously long fluorescence decay time was due to the very polar structure of the excited e.q. state.[10] This assumption has been proved to be correct by measuring the absorption spectra of the complex in the fluorescent state, using the nanosecond laser photolysis method.[18,19,21] The relaxation from the excited F.C. state to the e.q. state is accompanied by a change in the geometrical structure of the complex from an asymmetrical structure to a symmetrical overlapping sandwich one as well as by a rearrangement of the surrounding solvent molecules, leading to stronger solvation, which in turn makers the probability of radiative transition smaller. Since the dielectric constant of the solvent increases with the pressure, it seems that the fluorescent state of the complex will become more strongly solvated under higher external pressure, leading to a decrease in the probability of radiative transition. However, this statement is not wholly valid, since the pressure-induced red shifts of the spectra cannot be interpreted satisfactorily in terms of the pressure-induced change in the macroscopic dielectric constant and the refractive index of the solvent, as has been discussed already.

According to the interpretation indicated in Fig. 7, the probability of radiative transition for the fluorescence will be enhanced by an increase in the external pressure, as a result of the increase in the orbital overlap between donor and acceptor. Then, it seems to be necessary to assume that the inner quenching processes at the excited F.C. state as well as in the course of the F.C.→ e.q. relaxation are enhanced by the external pressure.

According to the measurement of the time-resolved fluorescence spectra of the TCNB-toluene system under 1 atm,[20] the excited F.C.→ e.q. relaxation is very rapid (relaxation time $<10^{-9}$ sec) and the fluorescence can be regarded as being emitted exclusively from the e.q. state at room temperature. The time-resolved fluorescence spectrum becomes measurable only in a quite viscous, almost rigid solution at 147°K, by means of an apparatus with nanosecond time-resolving power.[20] Since the external pressure enhances the viscosity of the solution, the F.C.→ e.q. relaxation process might be slowed under high pressure. However, the fluorescence decay times of the TCNB-toluene system measured under 7500 atm at different wavelengths of the fluorescence band agreed with each other. Moreover, although we have tried to measure the time-resolved fluorescence spectrum of the TCNB-toluene system under 7500 atm by exciting the solution with nitrogen-gas laser, the spectra observed at various delay times from exciting pulse were not essentially different from each other. Thus, the F.C.→ e.q. relaxation under the high pressures applied here occurs rather rapidly during times smaller than nanosecond. Therefore, the pressure-induced inner quenching process at the F.C. state, and that in the course of the F.C.→ e.q. relaxation process, may occur far more rapidly than that at the e.q. state, which has a lifetime of 10^{-7}—10^{-8} sec.

Contrary to the case of the TCNB-toluene system, the rate of the decrease in the fluorescence quantum yield and that of the decay time caused by the external pressure are not very different from each other in the case of the TCNB-mesitylene system, where the decay time is measured by means of the nitrogen-gas laser. Therefore, the pressure-induced fluorescence quenching of the TCNB-mesitylene system may be said to occur mainly at the excited e.q. state.

Although the explanation for the different behavior of the TCNB-toluene and TCNB-mesitylene systems with respect to the pressure-induced fluorescence quenching is not clear at the present stage of investigation, the difference in the quenching process might be ascribed to the essential difference in electronic structures between the two system. That is, the energy difference and the difference in electronic structure between the excited F.C. and e.q. states are much greater in the case of the TCNB-toluene system than in the case of the TCNB-mesitylene system.

Mercury Photosensitized Reaction of Deuterio-Propylene Studied by Microwave Spectroscopy

Yuzo Sakurai, Takaharu Onishi, and Kenzi Tamaru
Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 25, 1971)

The mercury photosensitized reaction of propylene-*cis*-1-d_1 and 1-butene-*cis*-1-d_1 was studied by means of microwave spectroscopy combined with gas chromatography and mass spectrometry. At pressures above 100 mmHg *cis-trans* isomerization was the main reaction for both the propylene and 1-butene. The number of the absorbed quanta of photons and the number of molecules reacted was almost equal. However, at lower pressures, this condition was not satisfied. At pressures less than 30 mmHg, substantial amounts of the 2-d_1 and 3-d_1 propylene species were detected in the reaction mixtures. Decomposition of propylene into an allylic radical and a hydrogen atom with subsequent "recombination," was proposed to account for this observation. Similar results were obtained with 1-butene-*cis*-1-d_1.

Several investigations on the mercury photosensitized reaction of simple olefins such as *cis*- or *trans*-dideuterioethylene,[1-3] 2-butene,[4,5] and 1-butene[6] have been reported. Usually the reaction was followed by means of gas chromatography, and in the reaction of dideuterioethylene infrared spectroscopy was employed to determine the extent of the reaction. Quite recently another application of infrared spectroscopy to this type of reactions, *e.g.*, photosensitized reaction propylene-1,3,3,3-d_4 has been reported by Hirokami and Sato.[7] In this paper an attempt has been made to apply microwave spectroscopy to the study of the mercury photosensitized reaction of propylene-*cis*-1-d_1 and 1-butene-*cis*-1-d_1.

Experimental

Methylacetylene was treated with weakly alkaline deuterium oxide to replace its acetylenic hydrogen with deuterium. By repeating this procedure several times, the concentration of methylacetylene-1-d_1 was made greater than 90%. The methylacetylene-1-d_1 thus obtained was selectively hydrogenated to propylene-*cis*-1-d_1 by the procedure developed by Rabinovitch and Looney.[8] 1-Butene-*cis*-d_1 was synthesized from ethylacetylene by a similar method. Deuterium contents in the synthesized olefins were determined by mass spectrometry, while the *cis-trans* distribution was analyzed by means of microwave spectroscopy.

Microwave spectra of propylene and its mono-deuterated species were observed by Lide and Christensen,[9] and applied to the quantitative determination of the deuterium contents at each hydrogen position of propylene-d_1 by Hirota and Morino.[10] Microwave spectra of 1-butene and its mono-deuterated species have been reported by Kondo, Hirota, and Morino[11] and were employed as a useful tool to study *n*-butene isomerization over solid acid catalysts.[12] Analysis by means of microwave spectroscopy revealed that more than 96% of the mono-deuterated species of both the propylene and the 1-butene was *cis*-1-d_1, the remainder was *trans*-1-d_1. Other mono-deuterated species such as 2-d_1 and 3-d_1 (and also 4-d_1 in the case of 1-butene) were not observed within the detection limits of the microwave spectroscopy. The prefixes *cis* and *trans* represent the configuration of deuterium relative to the methyl or ethyl group attached to the C_2 atom.

The 10 W low pressure mercury lamp and the quartz-made cylindrical reaction vessel employed in this work were of a conventional type. The light intensity of the 2537 Å resonance line was estimated by the amounts of hydrogen produced in the decomposition reaction of ethylene under the same reaction conditions. The quantum yield of this reaction was assumed to be 0.351 at an ethylene pressure of 13.3 mmHg.[13]

The reaction products were analyzed mainly by means of microwave spectroscopy and mass spectrometry. In some cases gas chromatography was employed in order to identify the reaction products of the decomposition process and also to determine their composition.

Results and Discussion

Table 1 shows some of the results obtained in the mercury photosensitized reaction of propylene-*cis*-1-d_1. The deuterium concentration of the starting propylene was about 80%, but it did not change appreciably in the course of the reaction. (The change in the deuterium content was less than 0.3%.) Table 1 shows the relative, not the absolute concentrations of each mono-deuterated species. The starting reactant listed at the top of the Table contained neither the 2-d_1 nor 3-d_1 species. Especially at pressures less than 15 mmHg, considerable amounts of both the 2-d_1 and 3-d_1 species were formed as the reaction progressed, as well as the *trans*-1-d_1

species produced by the *cis-trans* isomerization. The fraction of the 2-d_1 species was always smaller than that of the 3-d_1 species, and both became negligible at pressures above 40 mmHg. The quantum yield of the *cis-trans* isomerization was calculated on the basis of the following reaction scheme (A), and the results are plotted against the pressure of propylene in Fig. 1:

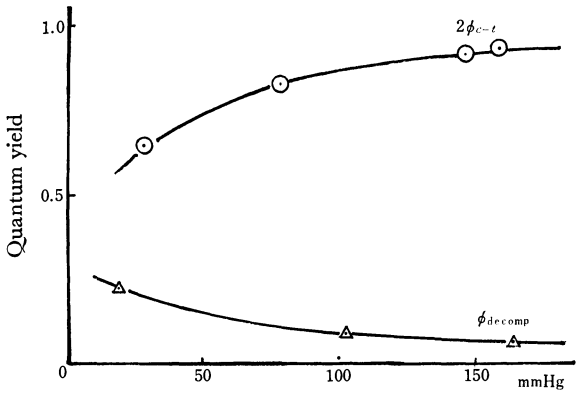

Fig. 1. Pressure dependence of quantum yield of Hg photosensitized *cis-trans* isomerization of propylene-*cis*-1-d_1. (ϕ_{decomp} is for C_3H_6.)

Scheme (A)

$$cis\text{-P} + Hg^* \longrightarrow P^* + Hg$$

$$trans\text{-P} + Hg^* \longrightarrow P^* + Hg$$

$$P^* + M \longrightarrow 1/2\ trans\text{-P} + 1/2\ cis\text{-P} + M$$

Here P* represents an excited state of propylene, possibly the lowest triplet state, and M a third body. The quantum yield of the decomposition reaction, ϕ_{decomp} was calculated for normal propylene after the method of Hirokami and Sato,[7] and the results are shown in Fig. 1 together with $2\phi_{c-t}$.

The pressure dependence of $2\phi_{c-t}$ and ϕ_{decomp} agrees rather well with the results reported by Hirokami and Sato,[7] and the balance between the number of the absorbed quanta of photons and the number of molecules which underwent either isomerization or decomposition is nearly satisfied above 100 mmHg. At pressures less than 100 mmHg, however, this balance can not hold owing to the significant decrease in the quantum yield of the *cis-trans* isomerization. This phenomenon

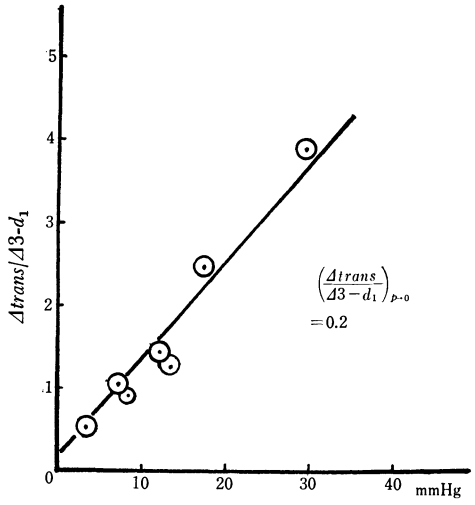

Fig. 2. Hg photosensitized isomerization of propylene-*cis*-1-d_1. Pressure dependence of the ratio ($\Delta trans$-1-$d_1/\Delta 3$-d_1)

was also observed in the mercury photosensitized reaction of 2-butene[5] and propylene-1,3,3,3-d_4.[7] The formation of vibrationally excited propylene or 2-butene, which could not contribute to the isomerization, was assumed in order to explain these observations. However, as is shown in Table 1, 3-d_1 and 2-d_1 species were formed in considerable amounts from propylene-*cis*-1-d_1 at pressures less than 30 mmHg. When the increase in the fraction of *trans*-1-d_1 species ($\Delta trans$-1-d_1) to that of 3-d_1 ($\Delta 3$-d_1) was plotted against the pressure of propylene, the ratio $\Delta trans$-1-$d_1/\Delta 3$-d_1 gave a *linear curve* with a zero intercept of about 0.2 (Fig. 2). On the other hand, the ratio $\Delta 2$-$d_1/\Delta 3$-d_1 was constant and equal to about 0.2 in the pressure region less than 30 mmHg, as shown in Fig. 3.

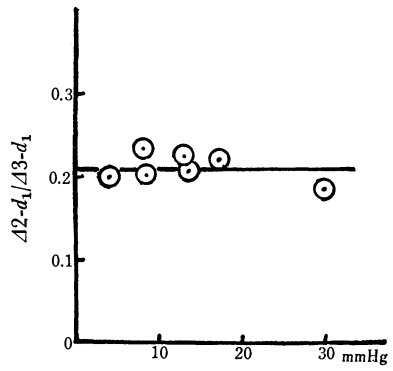

Fig. 3. Hg photosensitized isomerization of propylene-*cis*-1-d_1. Pressure dependence of the ratio ($\Delta 2$-$d_1/\Delta 3$-d_1)

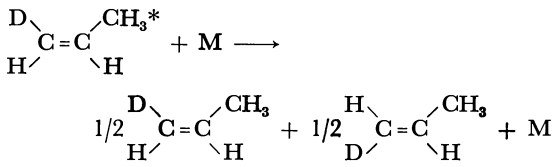
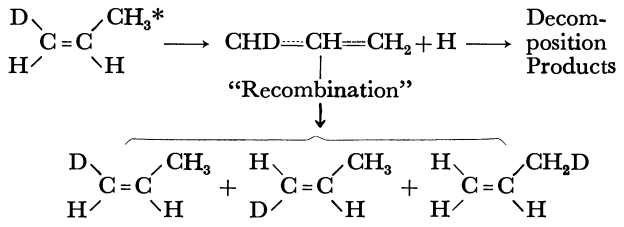
The results in Fig. 2 suggest that the calculation of the quantum yield of the *cis-trans* isomerization on the basis of scheme (A) is open to question at pressures less than 30 mmHg, where the fraction of 3-d_1 species is nearly comparable to that of *trans*-1-d_1. Due attention being paid to the considerable contributions of 2-d_1 and 3-d_1 species in the low pressure region, it was assumed that the mercury photosensitized reaction of propylene-*cis*-1-d_1 proceeds in the following way.

Scheme(B)
Main reaction at high pressures:



At low pressures:



In a rough approximation, the "recombination" reaction of an allylic radical and a hydrogen atom may be expected to yield *cis*-1-d_1, *trans*-1-d_1, and 3-d_1 species in the ratio of 1:1:2. Hydrogen abstraction by an allylic radical from another propylene molecule may also lead to similar results. As this reaction can not be ruled out completely, the term "recombination" is here rather tentatively employed to express the reaction of an allylic radical with a hydrogen atom either in the free or bound state in a hydrocarbon molecule.

The fraction of 3-d_1 species was 1.1% at a pressure of 28.8 mmHg. This suggests that the *trans*-1-d_1 fraction of 0.6% may have resulted from a "recombination" reaction. When this fraction and the original portion of *trans*-1-d_1 in the starting material were substracted, the fraction of *trans*-1-d_1 in the reaction mixture was found to be about 3.7%. In this case the contribution of *cis-trans* isomerization and "recombination" reaction was estimated to be approximately in the ratio of 3.4:1. The $2\phi_{c-t}$ under these conditions was about 0.65 (Fig. 1), and this gave rise to a value of about 0.19 for the quantum yield of the "recombination" reaction.

The quantum yields of *cis-trans* isomerization, "recombination" and decomposition were summed and gave a value of about 1.0, showing that the balance between the number of the absorbed quanta and the number of the reacted molecules was nearly satisfied. Similar results were obtained for reaction at 16.6 mmHg, with a quantum yield of *cis-trans* isomerization being taken from Fig. 1 as 0.55. At pressures less than 15 mmHg the fraction of Δ3-d_1 may become comparable to, or even exceed that of Δ*trans*-1-d_1, as can be seen in Fig. 2. In this pressure region even such very qualitative discussions as described above may not hold.

The above mentioned discussions are rather crude in nature, but they still serve to elucidate the reaction paths involved in the mercury photosensitized reaction of propylene-*cis*-1-d_1. Decomposition of propylene into an allylic radical and a hydrogen atom with subsequent "recombination" to yield the 3-d_1 species of propylene as well as the *cis*- and *trans*-1-d_1 species can not be neglected in the low pressure regions. The formation

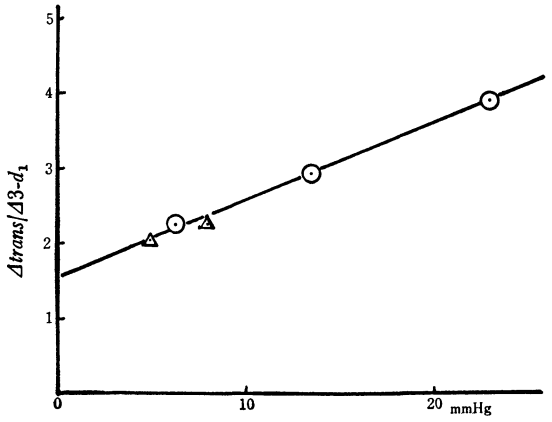
of 2-d_1 species was tentatively explained by an intramolecular hydrogen shift within the allylic radical resulting in $CH_2{=}CD{=}CH_2$, which then reacted with a hydrogen atom to yield $CH_2{=}CD{-}CH_3$.

Some of the results obtained in the mercury photosensitized reaction of 1-butene-*cis*-1-d_1, especially those



Pressure of 1-butene

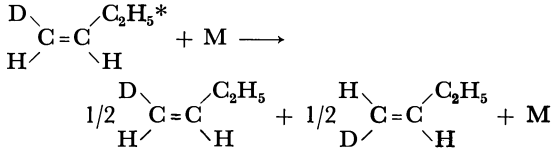
Fig. 5. Pressure dependence of quantum yield of Hg photosensitized *cis-trans* isomerization of 1-butene-*cis*-1-d_1.

in the low pressure regions, are given in Table 2. The 3-d_1 species of 1-butene (CH_2=$CHCHDCH_3$) was formed in appreciable amounts after reaction at lower pressures. The 2-d_1 species (CH_2=$CDCH_2CH_3$) was not detected within the limits of the microwave spectroscopy. When the ratio *Δtrans*-1-d_1/*Δ*3-d_1 was plotted against the pressure of 1-butene, a *linear curve* with a zero intercept of about 1.5 was obtained (Fig. 4).

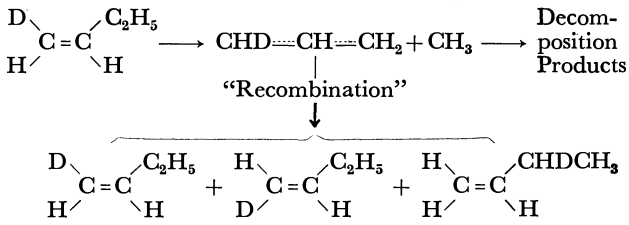
The pressure dependence of the quantum yield of *cis-trans* isomerization, $2\phi_{c-t}$, gave a curve which is shown in Fig. 5; the quantum yield was calculated with a reaction scheme similar to scheme (A) for the reaction of propylene. Owing to the considerable inherent difficulties in the analyses of 1-butene and its mono-deuterated species by microwave spectroscopy, the experimental data showed considerable scattering. Nevertheless Fig. 5 clearly showed that $2\phi_{c-t}$ continuously decreasesed with decreasing pressure and attains a value of 0.45 at the zero pressure intercept. The results in Fig. 4 and Table 2 lead to the conclusion that the mercury photosensitized reaction of 1-butene-*cis*-1-d_1 proceeds *via* scheme (C) which is quite similar to scheme (B) for the reaction of propylene-*cis*-1-d_1.

Scheme(C)

Main reaction at high pressure:



At low pressure:



In the reaction of 1-butene-*cis*-1-d_1 the decomposition products were not analyzed accurately, and the pressure dependence of ϕ_{decomp} or an estimation of the quantum yield of the "recombination" reaction was not available for discussion. However, when the data for the deuterium distribution within 1-butene was compared with that for propylene, their similarity strongly suggested that the same conclusion concerning the balance between the number of the reacted molecules and the absorbed photons may also be derived for 1-butene-*cis*-1-d_1.

Thus, microwave spectroscopy was applied to the study of the mercury photosensitized reactions of propylene-*cis*-1-d_1 and 1-butene-*cis*-1-d_1, and some of the reaction paths involved in these reactions were revealed.

The authors are grateful for the assistance of Dr. A. C. Herd in preparing this manuscript.

Re-examination of the Cycloaddition of Cycloheptatriene with Maleic Anhydride

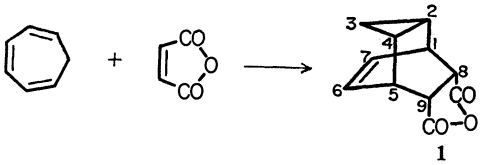
Hiroyuki ISHITOBI, Hiroshi TANIDA, Kazuo TORI, and Teruji TSUJI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received May 28, 1971)

Cycloaddition of cycloheptatriene to maleic anhydride was re-examined and found to produce, in addition to the reported main product *anti*-tricyclo[3.2.2.$0^{2,4}$]non-6-ene-*endo*-8,*endo*-9-dicarboxylic anhydride (**1**), the exo, exo isomer of this compound (**4**) and bicyclo[3.2.2]nona-2,6-diene-*endo*-8,*endo*-9-dicarboxylic anhydride (**5**). Evidence for these structures involving the orientation of the cyclopropane ring in **1** and **4** and the configuration of the carboxylic anhydride was provided by PMR spectroscopy using the intramolecular nuclear Overhauser effect and paramagnetic induced shift due to tris(dipivalomethanato)europium(III). The structure assignment by Alder and Jacobs for **1** was found to be correct, but not the one by Schenk *et al.* The difference in free energies of activation leading to **1** and **4** was determined.

An addition reaction of cycloheptatriene to maleic anhydride was first reported by Kohler and his coworkers.[1] For this adduct, the structure of *anti*-tricyclo[3.2.2.$0^{2,4}$]non-6-ene-*endo*-8,*endo*-9-dicarboxylic anhydride (**1**) was assigned by Alder and Jacobs.[2] Although the structure of the ring system seems to be



1

unequivocal from the data on chemical transformations, conclusive evidence has not yet been obtained for the *anti* orientation of the cyclopropane ring and the *endo*

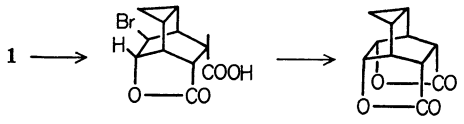
2) K. Alder and G. Jacobs, *Chem. Ber.*, **86**, 1528 (1953).

configuration of the carboxylic anhydride group.[3,4] An important result by Alder and Jacobs[2] favourable to the *endo* configuration of the carboxylic group is the fact that the adduct could be lactonized to the bromolacto acid (**2**) by treatment with bromine in water and,

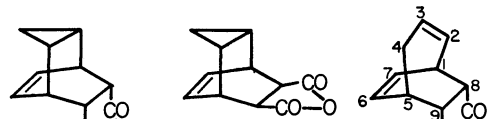


2 **3**

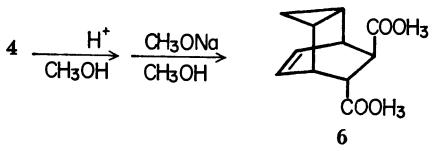
furthermore, to the dilactone (**3**). It was, however, pointed out that such a reaction causes Wagner-Meerwein rearrangements whereby even an *exo* acid forms lactone.[5,6] More recently, Schenk and his co-workers found that the photosensitized addition between cycloheptatriene and maleic anhydride gave mainly Alder's adduct, in addition to two minor compounds, and they assigned the *exo* configuration for the carboxylic anhydride group on the grounds that treatment of the adduct with a basic iodine-potassium iodide solution did not cause iodolactonization.[7,8] However, such a result is worthless for a stereochemical determination unless it is proven that in the treatment one isomer is positive and the other negative. However, this other isomer is still unknown. Prematurely accepting the Alder and Jacobs's structure, one of us (K.T.) used the adduct as a model for the investigation of anisotropic long-range shielding effects of a cyclopropane ring in PMR spectroscopy.[9]

Accordingly, we undertook a re-examination of the cycloaddition reaction and a determination of the configuration of the adduct, mainly by means of PMR spectroscopy. It was found that the reaction produces, besides the reported adduct, another carboxylic anhydride isomer and a bicyclo[3.2.2]nona-2,6-diene derivative, the last compound indicating a new behavior of cycloheptatriene in cycloaddition.

Products. The reaction mixtures were prepared at the indicated reaction temperature by mixing a slight excess of cycloheptatriene and a 0.1 M solution of maleic anhydride in xylene. The reaction at 120°C took about 3 hr for completion. Sampling from the reaction mixture was carried out at given time intervals in order to analyze the products by VPC. The analysis revealed the formation of three products which were isolated for structure determination by a combination of recrystallization and elution chromatography. Relative yields of these products were determined by VPC as a function of reaction temperature and are presented in Table 1. The melting point of the predominant product (**1**), 100.5—101°C, was identical with that reported by Kohler[1] and Alder[2] for their adduct and that by Schenk *et al.* for their most important product.[7] Hydrolysis of the second major product (**4**), mp 112—113°C, in methanol containing a drop of sulfuric acid, followed by epimerization with



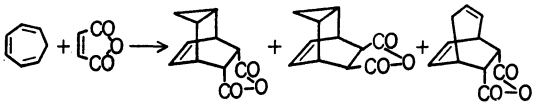
1 **4** **5**



6

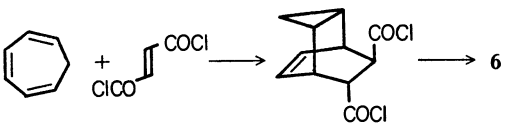
sodium methoxide in methanol, yielded a *trans*-dicarboxylic ester (**6**), which was identical with the compound obtained by the cycloaddition of cycloheptatriene to fumaryl chloride followed by methanolysis.[2]

Table 1. Reaction temperature-dependence of product ratio



1 **4** **5**

Temp (°C)	Reaction time (hr)	**1** (%)	**4** (%)	**5** (%)	log **1**/**4**
80	2.0	90.20	9.30	~0.5	0.987
80	4.0	91.26	8.24	~0.5	1.044
120	1.0	88.16	11.18	0.66	0.897
120	2.0	88.19	11.32	0.49	0.892
120	3.0	87.59	11.70	0.73	0.874
149.5	0.5	87.72	13.66	0.62	0.798
149.5	1.0	86.12	12.96	0.92	0.822
176.5	0.5	82.03	16.85	1.12	0.687
176.5	1.0	83.83	15.01	1.16	0.747



Since **6** was also obtained from the adduct of Alder and Jacobs, the compounds of mp 100—101°C and 112—113°C are concluded to be *exo* and *endo* carboxylic anhydride isomers and to have an identical orientation concerning the cyclopropane ring. The standard procedure of iodolactonization[7,10] was found to be unsuccessful for both **1** and **4**, so that the assignment of

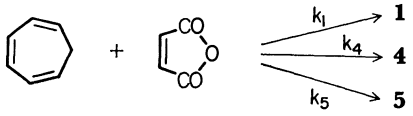
configuration of the carboxylic anhydride by Schenk *et al.* is inconclusive. Bromolactonization with **1** proceeded smoothly with the formation of colorless crystals, but the reaction with **4** gave a viscid tar. The structure of the bromolactone from **1** and the possibility of Wagner-Meerwein rearrangement in this reaction were not investigated. Confirmatory evidence for the tricyclic nature, the orientation of the cyclopropane ring, and the configuration of the carboxylic anhydride group in the structures of **1** and **4** was obtained from their PMR spectroscopic studies.

The minor third product (**5**) showed a melting point, 112—113°C, identical with that recorded by Schenk *et al.* for their bicyclic adduct.[7] Iodolactonization of **5** gave an iodolactone, whose melting point was the same as that reported.[7] The bicyclic structure of **5** was evident on integrating the vinyl proton signals in its PMR spectrum. The thermal conversion of **1** into **5** was observed on heating 1 at 220°C, but not under the mild conditions employed for the present cycloadditon.[11] To our knowledge, **5** is the first cycloadduct from cycloheptatriene which is formed without precedence of the norcaradiene transition state or intermediate.

Kinetic Treatment. Since the relative yields of products in Table 1 were confirmed to be independent of the reaction time within maximum experimental error of 0.9%, they are kinetically controlled ones. If we assume that the formation of all three products in a given run follows rate laws of the same form, the yield ratios are equal to those of the specific rate coefficients, $k_1 : k_4 : k_5$. Since the ground state reactants leading to the transition states in the independent pathways (k_1, k_4, and k_5) are identical, $\log(k_1/k_4)$ is



directly proportional to the free energy difference between the two transition states in the k_1 and k_4 pathways. The k_5 pathway is omitted from this treatment because of experimental errors which are unavoidable owing to the very small yield of **5**. The temperature dependence

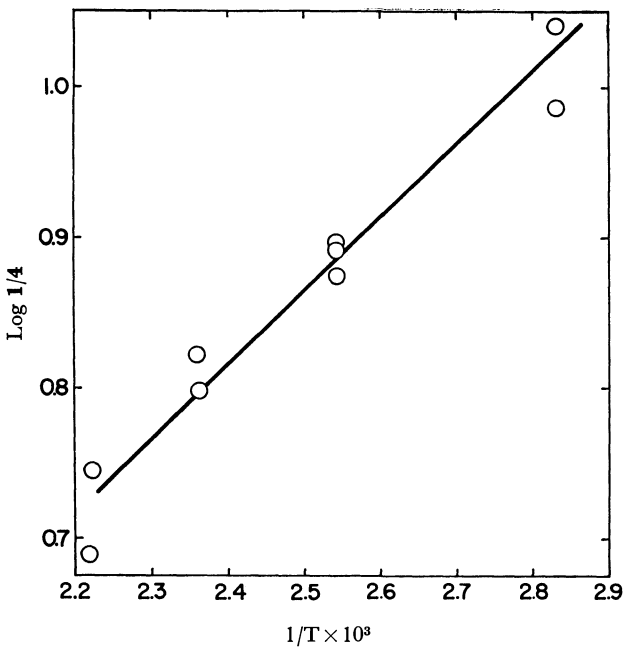


Fig. 1. Arrhenius plots of product ratios, **1/4**.

of the product ratio, expressed in the Arrhenius form gives

$$\log(k_1/k_4) = \log(A_1/A_4) + (E_4 - E_1)/2.303RT \quad (1)$$

for the ratio of the pre-exponential factors and for the difference in empirical activation energy from the intercepts and slope, respectively, of plots of $\log(k_1/k_4)$ *vs.* 1/T. The difference in entropy of activations is given by

$$\Delta S_1^{\ddagger} - \Delta S_4^{\ddagger} = 2.303R \log(A_1/A_4) \quad (2)$$

while the difference in enthalpy of activation is identical with the difference in the Arrhenius activation energy.[12] Regression analysis of logarithms of the relative yields of **1** and **4** on 1/T gave a good linear relationship with a slope of 0.481×10^3 (correlation coefficient 0.9760) as shown in Fig. 1. The equations gave 2.20 ± 0.18 kcal/mole for $\Delta H_1^{\ddagger} - \Delta H_4^{\ddagger}$ and -1.6 ± 0.5 cal/deg for $\Delta S_1^{\ddagger} - \Delta S_4^{\ddagger}$. Since the relative yields in Table 1 were

constant during the reaction periods with in $\pm 0.9\%$, the values for $\log(k_1/k_4)$ are reliable for 0.02—0.06 units.

It has been reported by Diels and Alder[13] that cyclopentadiene and 1,3-cyclohexadiene show extreme stereospecificity in their additions with maleic anhydride by the formation of a single endo adduct. We traced the reaction with 1,3-cyclohexadiene by means of VPC and confirmed the absence of the exo adduct in amounts greater than 0.2%. Therefore, the decreased stereospecificity of cycloheptatriene presently observed is very notable.

PMR studies. The 100-MHz PMR spectra of **1**, **4**, and their hydrogenation products, **7** and **8**, in

13) O. Diels and K. Alder, *Ann. Chem.* (Justus Liebigs), **460**, 98 (1928). Also, see M. C. Kloetzel "Organic Reactions," Vol. IV, John Wiley & Sons, Inc., New York, N. Y. (1948), p. 1.

$CDCl_3$ are shown in Fig. 2. The spectra of these compounds were also measured in benzene-d_6. The data obtained are listed in Table 2. Signals due to H_{3s} and H_{3a} were assigned according to the known general sequence of the J values between cyclopropane ring protons.[14] The assignment of other signals though simple was confirmed by spin-decoupling experiments.

The anisotropic long-range shielding effect of a cyclopropane ring is well understood,[14] and it is apparent that the cyclopropane rings in **1** and **4** are *syn* to their double bonds in view of the abnormally high-field positions of their olefinic-proton signals. Accordingly, **1** and **4** are determined to be *endo*-8,*endo*-9- and *exo*-8,*exo*-9-isomers, respectively, from the fact that the $H_{8(9)}$ signal of **7** appears at a lower field than that of **8** (see Table 2). The anisotropic shielding effect of the C-6: C-7 double bond[15] upon H_{3s} and H_{3a} and that of the two carbonyl groups[16] upon $H_{6(7)}$ are also consistent with the molecular configurations.

However, the use of chemical shift difference to determine molecular structure is sometimes risky, particularly for bridged bicyclic compounds.[17,18] Therefore, intramolecular nuclear Overhauser effect (NOE)[19] measurements and paramagnetic shifts induced by tris-(dipivalomethanato)europium(III). $Eu(DPM)_3$,[20] have been applied to assign the configurations of the cyclopropane and the acid-anhydride rings of **1** and **4**.

The NOE measurements on **1, 4, 7,** and **8** in $CDCl_3$ are summarized in Table 3. The nuclear Overhauser effects observed for the H_{3s} signals on saturating the $H_{6(7)}$ signals and *vice versa* by double irradiation evidence the *syn* configurations of the cyclopropane rings to the double bonds. The fact that the NOE's between the $H_{2(4)}$ and $H_{8(9)}$ signals were observed for **1** and **7**, but not for **4** and **8**, show that the configurations of the acid-anhydride rings are as illustrated by their formulas. Further, the five-bond long-range spin-couplings[21] observed between H_{3a} and $H_{8(9)}$ ($|J|=0.2$ Hz) in **4** and **8** are consistent with their assigned configurations. Figure 3 shows some results with double and triple resonance experiments on **1** and **4**; the experiments on **4** are shown with the spectra taken in acetone-d_6 because the H_{3s} and H_{3a} signals appeared as the first-order patterns in this solvent.

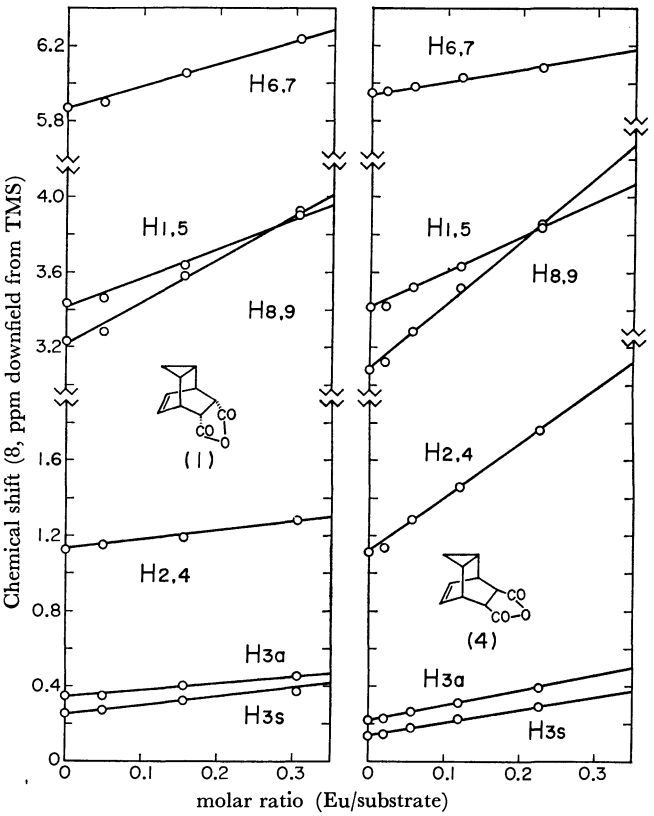

Fig. 4. Paramagnetic induced shift measurements for **1** and **4** using $Eu(DPM)_3$ in $CDCl_3$.

Much interest has been shown in the application of paramagnetic shifts induced by lanthanide complexes such as $Eu(DPM)_3$ in the PMR spectra of molecules having substituents with lone-pair electrons.[20] The paramagnetic shifts caused by $Eu(DPM)_3$ has been considered to result mainly from the pseudocontact shift.[20,22] Therefore, the stereostructure of a compound

1	−0.41	−0.67	−0.37	−0.42	−0.50	−0.71
4	−0.53	−0.40	−0.40	−0.54	−0.72	−0.87
7	−0.45	−0.73	∼−0.55	∼−0.55	−0.39 −0.59	−0.86
8	−0.51	−0.42	−0.59	∼−0.61	−0.73 −0.81	−0.98

can sometimes be determined by a consideration of paramagnetic shift parameters, *S*-values,[23] measured for each proton signal.[24] The *S*-value is represented by the equation $\delta_E=\delta+S\cdot\mathrm{Eu(DPM)_3/substrate}$ (molar ratio), where δ_E and δ are the chemical shifts of a proton in complexed and uncomplexed molecules, respectively.[23]

Examinations of Dreiding models show that S-values for $H_{2(4)}$ and $_{6(7)}$ in **1** should be respectively smaller and larger than those in **4**. Figure 4 shows the relationships between the chemical shifts of proton in **1** and **4** and the molar ratios of $Eu(DPM)_3$ added to the substrates. The *S*-values obtained are listed in Table 4.

Table 4 shows that the S-value of $H_{2(4)}$ is considerably larger in **4** than in **1**, and the value of $H_{6(7)}$ is smaller in **4** than in **1**. The *S*-values of H_{3s} and H_{3a} in both compounds are small, as was expected. These facts confirm the stereostructutes of **1** and **4**. It should be noted that the complexing ability of the acid-anhydride function with $Eu(DPM)_3$ is fairly weak. The difference in the *S*-values of $H_{8(9)}$ between **1** and **4** cannot immediately be explained.

The benzene induced shift, $\Delta\delta_{C_6D_6-CDCl_3}$,[25] also supports the structures of the present compounds, because thay have an acid-anhydride function. Table 5 lists the benzene-induced shifts for **1**, **4**, **7**, and **8**. The high-field shift values of $H_{2(4)}$ for **1** and **7** are larger than those for **4** and **8**, respectively, whereas the corresponding shift values of $H_{6(7)}$ show opposite trends. These facts are consistent with the structure of the compounds.

Experimental

All melting points were determined in capillary tubes and are corrected. Infrared spectra were determined with a Nippon Bunko IR-S spectrometer. VPC analysis was carried out on a Hitachi-Perkin-Elmer gas chromatograph F-6D equipped with a hydrogen flame ionization detector, using a 1 m×3 mm stainless steel column packed with 5% XE 60 on Chromosorb W.

The 100-MHz PMR spectra were taken with a Varian HA-100 spectrometer using about 5% (w/v) carefully degassed solutions in $CDCl_3$, benzene-d_6, and(or) acetone-d_6 in the frequency-swept and internal $CHCl_3$-locked mode. Calibration of the charts was carried out by direct readings of resonance frequencies, using a Hewlett-Packard HP-5212A electronic counter to an accuracy of ±0.1 Hz. PMDR and PMTR experiments were performed using the spectrometer and two Hewlett-Packard HP-200ABR audiooscillators. Chemical shifts are expressed in δ, ppm downfield from tetramethylsilane as an internal standard with an accuracy of ±0.01 ppm, and coupling constants are in Hz with an accuracy of ±0.1 Hz.

Reaction of Maleic Anhydride with Cycloheptatriene. A solution of 24.4 g of cycloheptatriene and 20 g of maleic anhydride in 100 m*l* of xylene was refluxed for 3 hr. VPC analysis of the reaction solution, operated at 180°C with a flow pressure of 1.3 kg/cm², showed three peaks at retention times of 6 min 30 sec, 7 min 20 sec, and 11 min and with relative areas of 11: 1: 88. The solvent was evaporated under reduced pressure and the residue was recrystallized from ligroin to give 27 g of *anti*-tricyclo[3.2.2.0^{2,4}]non-6-ene-*endo*-8,*endo*-9-dicarboxylic anhydride (**1**) in 69.7% yield, mp 100.5—101°C (lit.,[2] mp 101°C), corresponding to the peak at 11 min. The mother liquor was concentrated to dryness and subjected to elution chromatography on 150 g of silica gel using ether-pentane to give 3.8 g of a mixture of the two minor products in a ratio of 13: 1 as the first fraction eluted. Absence of of the *endo* product in this mixture was confirmed by VPC. The mixture was recrystallized twice from hexane to afford 2.1 g (5.4%) of *anti*-tricyclo[3.2.2.0^{2,4}]non-6-ene-*exo*-8,*exo*-9-dicarboxylic anhydride (**4**), mp 112—113°C, which corresponded to the peak at 6 min 30 sec; IR (CCl_4) 1870, 1782, and 1220 cm^{-1} (C=O), NMR ($CDCl_3$) τ 9.85 (m, 2H at C-3), 8.85 (m, 2H at C-2 and 4), 6.95 (t, J=1.5 Hz, 2H at C-8 and 9), 6.6 (m, 2H at C-1 and 5), and 3.08 (d-d, J=5 and 3.3 Hz, 2H at C-6 and 7).

Found: C, 69.74; H, 5.46%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

Catalytic reduction in a mixed solution of acetic acid and acetic anhydride (15: 1) gave *anti*-tricyclo[3.2.2.0^{2,4}]nonane-*exo*-8,*exo*-9-dicarboxylic anhydride, which was recrystallized from ligroin to give a pure sample, mp 153—154°C.

Found: C, 68.54; H, 6.25%. Calcd for $C_{11}H_{12}O_3$: C. 68.73; H, 6.29%.

Quantitative Products Distribution. Cycloheptatriene sealed in a thin-walled glass capillary, a clean iron bar and 3 m*l* of a 0.1M solution of maleic anhydride dissolved in xylene were placed in a heavy-walled glass ampoule and sealed. The ampoule was immersed in a constant temperature bath (±0.03°C). After temperature equilibrium had been reached, the cycloheptatriene capillary was crushed with the iron bar and the reaction allowed to proceed. Analysis of the products was carried out by VPC, and relative yields of the three adducts were determined by integration of the component peaks with a planimeter with correction for the relative sensitivity of the detector. The control experiments showed that the proportions of adducts were strictly independent both of the yields of the products and of initial proportions of the reactants. The reaction time necessary for detection of the products by VPC varied from 10 min at at 176.5°C to 1 hr at 80°C, but further heating did not affect the relative proportions of the product. Table 1 gives the

data thus obtained.

Dimethyl anti-*Tricyclo*[3.2.2.$0^{2,4}$]*non-6-en-8,9*-trans-*dicarboxylate (6)*. A solution of 300 mg of the anhydride (**4**) and 0.3 m*l* of concentrate sulfuric acid in 8 m*l* of methanol was refluxed for 2.5 hr. After the usual work-up, the *exo-exo* dimethylcarboxylate obtained was dissolved in 8 m*l* of basic methanol, prepared by dissolving 60 mg of sodium into methanol and then refluxed for 5 hr. After removal of the solvent the reaction product was diluted with water and extracted with ether. Evaporation of the ether gave 280 mg of **6** which was identical with an authentic sample[2] obtained by quenching cycloheptatriene-fumaryl chloride adduct with methanol.

Iodolactonization of Adducts. A mixture of 1.0 g of the bicyclic adduct (**5**), 1.8 g of sodium bicarbonate and 30 ml of water was stirred for 20 min at room temperature, and then 13.5 m*l* of a iodine-potassium iodide solution (prepared by dissolving 5 g of iodine and 15 g potassium iodide into 50 m*l* of water) was added to the mixture. During the course of the reaction the initially suspended **5** gradually dissolved and the red colour of the mixture faded. After 4 hr the reaction mixture was made acidic with hydrochloric acid and extracted with dichloromethane. The extract was washed with aqueous sodium thiosulfate and water, and dried over sodium sulfate. After removal of the solvent, 1.3 g of the iodolactone was recrystallized from benzene to give a pure sample, mp 147°C (lit,[7] 147—148°C).

Similar attempts to prepare iodolactones from **1** and **4** failed, the red colour of iodine remaining almost unchanged even after treatment for 24 hr.

Bromolactonization of the Tricyclic Adducts. A solution of 500 mg of the *endo* tricyclic adduct and 230 mg of sodium hydroxide in 7.5 m*l* of water was stirred for 30 min under ice-cooling, and bromine was added slowly until the colour of the bromine persisted. The resulting milky solution was further stirred for 30 min and acidified with hydrochloric acid to give 450 mg of the bromolactone which was recrystallized from ether-hexane to give a pure sample mp 197—198°C (lit,[2] 185°C).

Found: C, 46.29; H, 3.93; Br, 27.55%. Calcd for $C_{11}H_{11}O_4Br$: C, 46.02; H, 3.86; Br, 27.84%.

The same procedure for the *exo* anhydride resulted in the formation of a high molecular product.

Kinetics of Silver(I) Ion Catalysed Oxidation of Glycine by Peroxodisulphate Ion

G. CHANDRA and S. N. SRIVASTAVA
Chemical Laboratories, Agra College, Agra, India

(Received December 10, 1970)

The kinetics of Ag(I) ion catalysed oxidation of glycine by peroxodisulphate in aqueous medium has been studied. The reaction is found to be first order in peroxodisulphate and Ag(I) ions and almost independent of glycine concentration. The rate constant is found to decrease with the increase in the concentration of peroxodisulphate ion. Addition of neutral salts shows a retarding effect. A suitable mechanism has been proposed and a theoretical rate law has been derived to account for the results.

The peroxodisulphate ion is one of the strongest oxidizing agents known in aqueous solution. The standard oxidation-reduction potential for the reaction

$$2SO_4^{2-}\,(aq.) \longrightarrow S_2O_8^{2-}\,(aq.) + 2e^-$$

is estimated to be -2.01 V.[10] The reactions involving this ion are generally very slow in the absence of suitable catalysts.[2] The most thoroughly investigated catalyst is Ag(I) ion although reactions involving Cu(II) and Fe(III) ions also have been studied.[3]

Only a very few kinetic studies have been made so far on organic nitrogen compounds. The kinetics of oxidation of urea and acetamide[4] has been studied by Agarwal and Mushran. Ag(I) ion catalysed oxidation of formamide[5] by peroxodisulphate was also investigated by the above authors. Recently Bacon and his coworkers[6] studied certain aspects of Ag(I) ion oxidation of primary aliphatic amines and α-amino acids.

This paper deals with the kenetics of Ag(I) catalysed oxidation of glycine by peroxodisulphate. A mechanism has been proposed and a theoretical rate law has been derived to account for the kinetic data.

Experimental and Results

Potassium peroxodisulphate of G.R.E. Merck quality, glycine and silver nitrate A.R. B.D.H. quality were dissolved in redistilled water for preparing standard solutions. All other chemicals used were also of analytical grade. Potassium peroxodisulphate solution was always prepared fresh. The standard solutions were stored in Jena glass bottles and the same solutions were used throughout the course of investigation.

a) neglected

All reactions were carried out in pyrex conical flasks coated outside with black japan. Calculated volumes of silver nitrate and glycine were taken in a reaction vessel and were put in a thermostat maintained at 35±0.1°C. To start the reaction the calculated quantities of potassium peroxodisulphate solution were added to the reaction flasks. The progress of the reaction was studied by estimating the remaining peroxodisulphate iodometrically by a slightly modified method of Bartlett and Cotman[7] adopted by Saxena and Singhal.[8] First order rate constants with respect to peroxodisulphate were calculated and the order with respect to glycine was obtained by changing the concentration of glycine keeping the concentrations of other reactants constant.

Effect of Peroxodisulphate Concentration. The results obtained at three different initial concentrations of $K_2S_2O_8$ on the oxidation of glycine are shown in Table 1. First order rate constants were calculated and found to be fairly constant.

The rate constants k calculated from the Table 1 for three different concentrations of $K_2S_2O_8$ *viz.* 0.005M, 0.01M, and 0.02M are 22.70×10^{-3}, 16.22×10^{-3}, and 8.49×10^{-3} min^{-1}, respectively.

It is evident that the reaction is first order in peroxodisulphate at all concentrations of peroxodisulphate. However, as the concentration of $K_2S_2O_8$ is increased, the value of the first order rate constant decreases due to the specific inhibitory effect of K^+ ion.[4,9]

From the data shown in the last row of the 6th column of Table 1 it may be concluded that the equimolecular consumption of $S_2O_8^{2-}$ and glycine takes place. The stoichiometry can be given as

$$S_2O_8^{2-} + NH_2CH_2COO^- + H_2O \xrightarrow{Ag^+} CO_2 + HCHO + NH_3 + SO_4^{2-} + HSO_4^-$$

Effect of Changing Glycine Concentration. Results showing the effect of the change of initial concentrations of glycine on reaction rate are shown in Table 2.

Table 2

$K_2S_2O_8$=0.01M, $AgNO_3$=0.0005M, Temp.=35°C

Initial concentration of glycine (M)	Rate constant $k\times10^3$ min^{-1}
0.005	16.22
0.010	16.22
0.015	16.01
0.020	15.91
0.025	15.98

We see that the rate is uneffected by a chang in glycine concentration and that the reaction is zero order with respect to glycine concentration because the total order is one at equimolecular concentrations of the reactants.

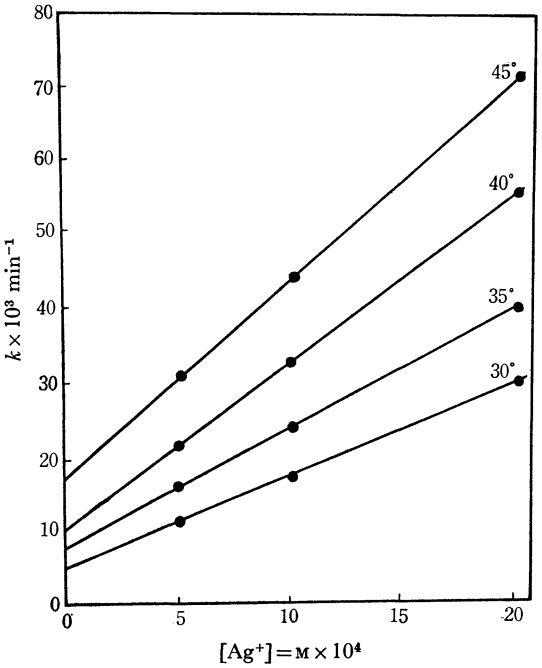

Fig. 1. Variation of rate constant k with the change in the concentration of Ag(I) ion at different temperatures.
$K_2S_2O_8$=0.01 M Glycine=0.01 M

7) P. D. Bartlett and J. D. Cotman, *J. Amer. Chem. Soc.*, **71** 1419 (1949).

9) M. M. Khan and S. P. Srivastava, *J. Indian Chem. Soc.*, **46**, 574 (1969).

Effect of Ag(I) Ion Concentration. The reaction is carried out with different initial concentrations of silver nitrate (the concentrations of other reactants are kept constant) to find the order of reaction with respect to silver ion. In order to show the catalytic activity a graph is plotted between the concentrations of silver ion and rate constants at different temperatures. The plots obtained are straight lines showing direct dependence of reaction rate on silver ion concentration (Fig. 1). As these strainght lines do not pass through origin, it is evident that the uncatalysed oxidation of glycine by peroxodisulphate is also possible. It has been observed that the reaction is slower in absence of Ag(I) ion.

The reaction has also been studied at various temperatures to obtain energy of activation, entropy of activation, frequency factor, *etc.* The results are given in Table 3.

TABLE 3

$K_2S_2O_8$=0.01M, Glycine=0.01M, $AgNO_3$=0.0005M

$k_{35}\times10^3$ min^{-1}	$k_{45}\times10^3$ min^{-1}	Temp. Coeff.	E kcal	A sec^{-1}	S e.u.
16.22	31.32	1.93	12.76	3.27×10^5	−33.45

The entropy of activation is negative. This can be explained on the basis of reaction sequence (5) of the proposed reaction scheme, where a water molecule is incorporated. This will decrease the entropy of activation.[10] A graph showing linear relationship between $\log k$ and $1/T$ has been plotted (Fig. 2).

Effect of Various Neutral Salts. The results of the addition of various neutral salts on the reaction rate are shown in Table 4.

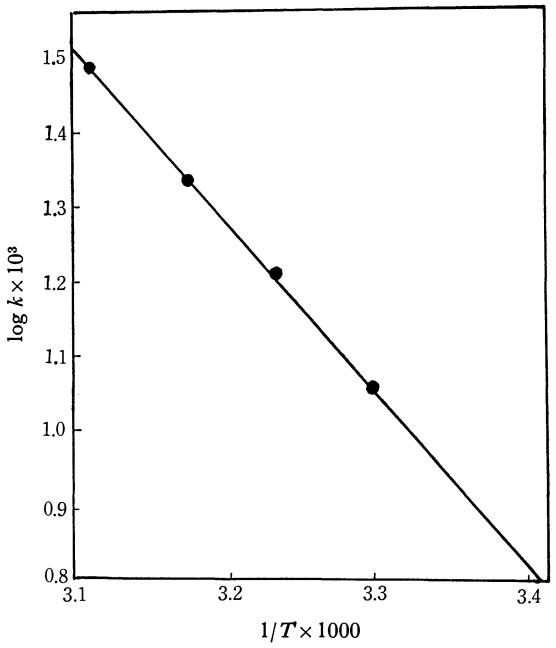

Fig. 2. Linear relationship between $\log k$ and $1/T$.
$K_2S_2O_8$=0.01M, Glycine=0.01M, $AgNO_3$=0.0005M

10) K. J. Laidler, "Chemical Kinetics," McGraw-Hill, London (1965), p. 500.

TABLE 4

$K_2S_2O_8$=0.01M, Glycine=0.01M, $AgNO_3$=0.0005M, Temp.=35°C

Neutral salt	Concentration M×10³	Ionic strength contributed $\mu\times10^3$	Rate constant $k\times10^3$ min^{-1}
NH_4NO_3	1.0	1.0	16.12
	2.0	2.0	16.01
	4.0	4.0	15.82
KNO_3	1.0	1.0	16.07
	2.0	2.0	15.92
	4.0	4.0	15.71
K_2SO_4	1.0	3.0	15.12
	2.0	6.0	14.75
	4.0	12.0	14.12
$Al(NO_3)_3$	1.0	6.0	15.53
	2.0	12.0	15.31
	4.0	24.0	14.89

This shows the retarding effect of some ions on the reaction rate of Ag(I) ion catalysed oxidation of glycine by peroxodisulphate. The rate constants in the presence of 4×10^{-3}M NH_4NO_3, K_2SO_4, and $Al(NO_3)_3$ are 15.82, 14.12, and 14.89×10^{-3} min^{-1}, respectively, and the ionic strength contributed by these salts are 4.0, 12.0, and $24.0\times10^{-3}\mu$, respectively. The decrease in the rate constant is not strictly related to the increase in ionic strength and evidently there is a considerable specific effect of the ions. Similar observations have been obtained by Levitt and Malinowski,[11] and Bartlett and Cotman.[7]

Discussion

Peroxodisulphate oxidation of some organic and inorganic compounds has been reported.[12] It was suggested by Bartlett and Cotman that the initial step in peroxodisulphate oxidation is the formation of two sulphate free radical ions as follows:

$$S_2O_8^{2-} = 2SO_4^-$$

The decomposition may be initiated by dust or impurities present in the solution.

The catalytic activity of silver(I) ion is due to the formation of higher valent silver species. In the case of peroxodisulphate oxidation of oxalate ion catalysed by Ag(I) Allen and Kalb[13] have proposed the formation of bivalent silver. In silver catalysed oxidation of several organic compounds the active species is trivalent silver.[14] However, single electron change in oxidation state of silver ion as catalyst is known.[15,16]

There is a first order dependence of reaction rates with respect to both silver(I) ion and peroxodisulphate concentrations and zero order dependence on glycine. Thus the rate determining step seems to be bimolecular

11) L. S. Levitt and E. R. Malinowki, *J. Amer. Chem. Soc.*, **72**, 4517 (1955).
12) D. A. House, *Chem. Rev.*, **62**, 185 (1962).
13) T. L. Allen and A. J. Kalb, *J. Amer. Chem. Soc.*, **86**, 5107 (1964).
14) D. M. Yost, *ibid.*, **48**, 160 (1926).
15) W. C. Higginson and J. W. Marshall, *J. Chem. Soc.*, **1957**,447
16) S. K. Singhal and S. P. Srivastava, *J. Indian Chem. Soc.*, **46**, 705 (1969).

but gives first order rate constant at constant Ag(I) concentration. The following scheme has been proposed.

$$Ag^+ + S_2O_8^{2-} \xrightarrow{k_1} Ag^{2+} + SO_4^- + SO_4^{2-} \quad (1)$$

The sulphate free radical further reacts with silver ion to produce higher valent silver[17] as follows:

$$SO_4^- + Ag^+ \xrightarrow{k_2} Ag^{2+} + SO_4^{2-} \quad (2)$$

The bivalent silver reacts with glycine and regenerates Ag(I)

$$Ag^{2+} + NH_2CH_2COO^- \xrightarrow{k_3} Ag^+ + NH_2CH_2COO\cdot \quad (3)$$

Like similar radicals[18] $NH_2CH_2COO\cdot$ also decomposes and evolves carbon dioxide

$$NH_2CH_2COO\cdot \xrightarrow{k_4} NH_2\dot{C}H_2 + CO_2 \quad (4)$$

followed by

$$NH_2\dot{C}H_2 + H_2O \xrightarrow{k_5} NH_3 + CH_2O + H\cdot \quad (5)$$

Hydrogen free atom reacts with $S_2O_8^{2-}$ as follows:

$$S_2O_8^{2-} + H\cdot \xrightarrow{k_6} HSO_4^- + SO_4^- \quad (6)$$

The chain terminating step may be

$$SO_4^- + H\cdot \xrightarrow{k_7} HSO_4^- \quad (7)$$

From the foregoing mechanism the rate law is given by equation

$$-\frac{d}{dt}[S_2O_8^{2-}] = k_1[S_2O_8^{2-}][Ag^+] + k_6[H\cdot][S_2O_8^{2-}] \quad (8)$$

Applying the steady state to Eqs. (1)—(7) the following equation can be derived:

$$[H\cdot] = (k_1k_2/k_6k_7)^{1/2}[Ag^+] \quad (9)$$

Substituting this value of $[H\cdot]$ into Eq. (8) we obtain the final rate expression:

$$-\frac{d}{dt}[S_2O_8^{2-}] = \{k_1 + (k_1k_2/k_6k_7)^{1/2}\cdot k_6\}[Ag^+][S_2O_8^{2-}] \quad (10)$$

which is a satisfactory representation of the kinetic rate law, for it explains the observed first order kinetics of peroxodisulphate and zero order dependence on glycine concentration. It is also evident that there is a linear relationship between silver ion concentration and reaction rate when the concentrations of other reactants are kept constant.

Reaction sequence (6) is also supported by the observed increase in the reaction rate caused by the addition of reductant (glycine). Furthermore, the reaction rate is also increased by 20% in N_2 medium. This difference in reaction rate may be explained on the basis of the formation of peroxo radical in presence of air[19] as follows:

$$H\cdot + O_2 = HO_2$$

In this case Eqs. (6) and (7) take the following forms, and k_6' and k_7' will be different from k_6 and k_7.

$$S_2O_8^{2-} + HO_2 \xrightarrow{k_6'} SO_4^- + HSO_4^- + O_2$$

$$SO_4^- + HO_2 \xrightarrow{k_7'} HSO_4^- + O_2$$

Deamination is characteristic of amino acids. Kovats[20] has oxidatively deaminated glycine in the presence of KOH and Cu, the oxidant being KIO_4. The kinetics of reaction between glycine and $KMnO_4$ has been investigated by Pokrovskya.[21] The products were NH_3 and HCN. However, in the present investigation the evolution of CO_2 indicates the degradation of glycine. Identification of formaldehyde was not successful probably because of the reaction with NH_3. However, in the presence of NaOH, formaldehyde has been identified by preparing 2,4-dinitrophenyl hydrazone and determining its melting point.

The Dehydrogenation of Butyl Alcohols by the Molten-metal Catalysts

Ken KASHIWADATE, Yasuo SAITO, Akira MIYAMOTO, and Yoshisada OGINO
Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aramaki, Aoba, Sendai
(Recieved May 29, 1971)

In order to investigate the catalytic activity of molten metals, the dehydrogenation reactions of *n*-butyl alcohol, *iso*-butyl alcohol, and *sec*-butyl alcohol were carried out in the presence of molten zinc and molten indium (molten gallium was also used for the dehydrogenation of *iso*-butyl alcohol). According to the experimental results, all of these molten metals showed persistent catalytic activities and high selectivities for all the test reactions, and the decreasing order of the reactivity of the butyl alcohol isomers was found to be *sec*-butyl alcohol > *iso*-butyl alcohol > *n*-butyl alcohol. Among the three molten metals, *i.e.* Zn, Ga, and In, the activity and the selectivity of the molten zinc catalyst was outstandingly high. Further, kinetic analyses of the data showed that a compensation effect exists between the apparent activaiton energy, E_a, and the logarithmic frequency factor, log A.

Since the pioneer work of Ipatiew[1] was published, only a few works[2,3] about the catalysis of molten metals have appeared in the literature. However, it was expected that the use of molten metals as catalysts would have many advantages in studying the catalysis. Thus, the present authors undertook a systematic study of the catalysis of the molten metal. According to the preceding work,[4] which is the first of this series, some molten metals, such as zinc, gallium, aluminum, indium, and thallium, showed considerable activities for the dehydrogenation of methanol. This finding prompted an investigation with some other alcohols as reactants. It is the purpose of the present paper to show the catalytic activities of such molten metals as zinc and indium for the dehydrogenation of *n*-butyl alcohol (*n*-butanol), *iso*-butyl alcohol (*iso*-butanol), and *sec*-butyl alcohol (*sec*-butanol).

Experimental

Catalysts. Molten zinc (Zn-L) and molten indium (In-L) were used as catalysts (sometimes molten gallium was also used). They were of the highest quality among the commercially available metals, and no purifications were carried out.

Alcohols. *n*-Butanol, *iso*-butanol, and *sec*-butanol were obtained commercially. The gas chromatographic analyses showed that no significant amounts of impurities were present in these alcohols. Therefore, the purifications of these alcohols were not carried out.

Apparatus. The apparatus shown in Fig. 1 was used in the measurement of the catalytic activity of the molten metal. The reactor was made from Pyrex glass; its dimensions are given in Fig. 2.

Procedures. After a given amount (50 g) of a desired metal was charged into the reactor, ③, the air in the reactor as well as in the whole reaction system was driven out by streaming helium. Then, the temperature of the reactor was raised and the melting of the catalyst metal was confirmed directly by sight. (The electric furnace was constructed from two concentric Pyrex tubes, with a nichrome heater wound on the outer wall of the inner tube. Therefore, the interior of the reactor could be observed.) After the desired temperature was reached, the stream of helium was stopped and alcohol was fed in at a rate of 0.088—0.094 mol/hr from a micro-feeder, ①. The preheater, ②, which was packed with glass-wool and maintained at a temperature of ~200°C, served for the vaporization of alcohol. The vapor of alcohol

was led to the bottom of the reactor and made to bubble from a small opening into the molten metal. The effluent containing the reaction products and unreacted alcohol was cooled by a condenser, ④; the condensable materials were separated from the gaseous products and collected in separators, ⑤ and ⑥, which were immersed in ice baths. The gaseous products were led to a scrubber, ⑧. Then, the flow rate of the gas was measured by means of a soap film-meter, ⑨. Finally, the gas was purged into the atmosphere.

The liquid products collected in the separators were weighed and analyzed by gas chromatography. The gaseous products were collected from a port, ⑦, and analyzed by gas chromatography.

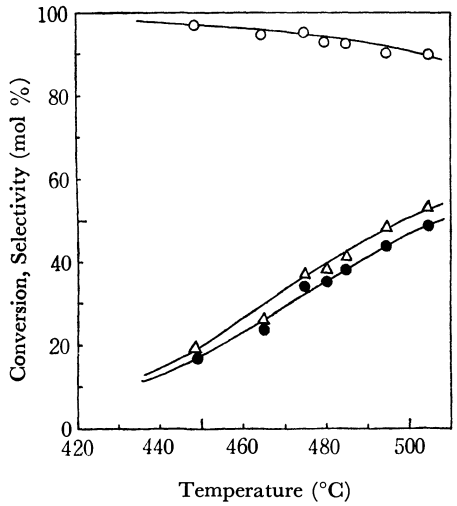

Fig. 3. Temperature dependencies of the catalytic activity of Zn-L for the dehydrogenation of *n*-Butanol:
-○- selectivity for the formation of *n*-butyraldehyde,
-△- total conversion of *n*-butanol,
-●- conversion to *n*-butyraldehyde.

Results and Discussion

Dehydrogenation of n-*Butanol.*

Activity of Zn-L. As can be seen in Fig. 3, molten zinc (Zn-L) showed a catalytic activity for the dehydrogenation of *n*-butanol. The main liquid product was *n*-butyraldehyde, but very small amounts of butylbutyrate, butyl ether, and water were also obserbed. From these results, the following reactions were considered to occur;

$$n\text{-}C_4H_9OH \longrightarrow H_2 + n\text{-}C_3H_7CHO \quad (I)$$

$$2n\text{-}C_4H_9OH \longrightarrow C_4H_9OC_4H_9 + H_2O \quad (II)$$

$$2C_3H_7CHO \longrightarrow C_3H_7CO_2C_4H_9 \quad (III)$$

Reaction I is the main reaction, while Reaction II and III are the side reactions.

The compositions of the gaseous products are given in Fig. 4. As can be seen in this figure, the hydrogen content was very high. This fact supports the idea that Reaction I is the main reaction. Further, the existence of CO, CH_4, C_2H_4, and C_2H_6 in the gaseous products suggests that the following decomposition reaction;

$$C_3H_7CHO \longrightarrow CH_4 + C_2H_4 + CO \quad (IV)$$

occurred together with the reaction;

$$C_2H_4 + H_2 \longrightarrow C_2H_6 \quad (V)$$

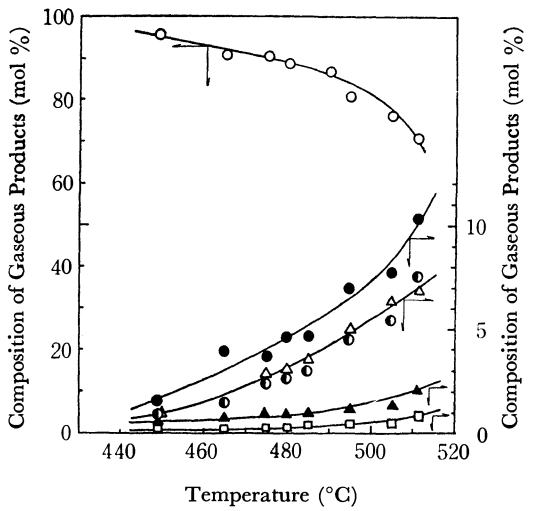

Fig. 4. Temperature dependencies of the compositions of gaseous products produced by the Zn-L catalyst from *n*-butanol:
-○- H_2, -●- CO, -△- CH_4, -◐- C_2H_4,
-▲- C_2H_6, -□- CO_2.

According to these reactions, *i.e.* IV—V, the ratio of CO: CH_4: $C_2H_4+C_2H_6$ should be 1: 1: 1. The experimental results shown in Fig. 4 indicate a somewhat higher CO content than the above-mentioned stoichiometric ratio. In addition, the existence of small amounts of CO_2 in the products seems to suggest that some unknown side reactions also occurred. At any rate, however, the side reactions were small, and the selectivity of the main reaction was higher than 90%.

Activity of In-L. As can be seen in Fig. 5, molten indium (In-L) also showed a catalytic activity for the butanol dehydrogenation, though the conversion was considerably smaller than the value obtained by the use of Zn-L catalyst (Fig. 3). The main liquid product was *n*-butyraldehyde, and the same sorts of by-products as those produced by the Zn-L catalyst were also found in the liquid products. Therefore, the main reaction may be I, and the same sorts of side reactions as for the Zn-L catalyst may be considered to occur.

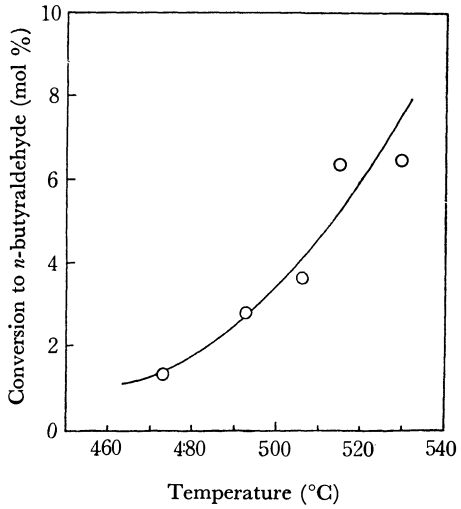

Fig. 5. Temperature dependency of the catalytic activity (conversion to *n*-butyraldehyde) of In-L for the dehydrogenation of *n*-butanol.

Comparison with Solid Catalysts. Dunbar[5] investigated the dehydrogenation of *n*-butanol, using copper chromite as a catalyst. According to his work, the conversion of *n*-butanol was 30—60% in the temperature range of 330—350°C. As can be seen in Fig. 3, nearly the same conversion value as above was obtained in the present work by employing the Zn-L catalyst. However, the reaction temperature employed in the present work is about 150°C higher than that employed by Dunbar. Thus, with respect to the reaction temperature, the copper chromite catalyst is preferable to the Zn-L catalyst. On the contrary, according to Dunbar, the selectivity for the formation of *n*-butyraldehyde was 40—80%, while the selectivity obtained in the present work was higher than 90%.

Excellent copper-containing catalysts have also been proposed by some other workers.[6,7] It is said that the catalysts are effective at temperatures lower than 300°C, and that selectivities higher than 90% are obtainable with these catalysts. However, it must be noted that the activities of copper-containing catalysts are specially sensitive to sintering and poisons. Further, great care is necessary for the preparation of a highly effective solid catalyst. On the contrary, no such difficulties as those described above are encountered in the use of a molten-metal catalyst. Of course, efforts to make more active molten metal catalysts are necessary. The application of molten-alloy catalysts seems to be hopeful.

Dehydrogenation of iso-*Butanol.*

Activity of Zn-L. As can be seen in Fig. 6, molten zinc (Zn-L) showed a catalytic activity for the dehydrogenation of *iso*-butanol, and this activity was found to persist for a long time. Figure 7 shows the relations between the reaction temperature and the degree of conversion as well as the composition of gaseous products. As can be seen in this figure, the conversion increased with the increase in the reaction temperature and reached ~80% at 500°C. Isobutyraldehyde was the main product, while the content

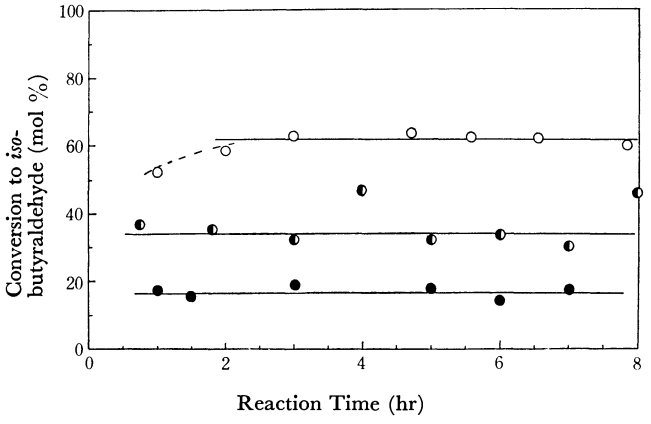

Fig. 6. Relations between the conversion to *iso*-butyraldehyde and the reaction time: -○- Zn-L 500°C, -◐- Zn-L 450°C, -●- In-L 550°C. (Zn 50 g, butanol feed rate=0.089 mol/hr, In 50 g, butanol feed rate=0.089 mol/hr).

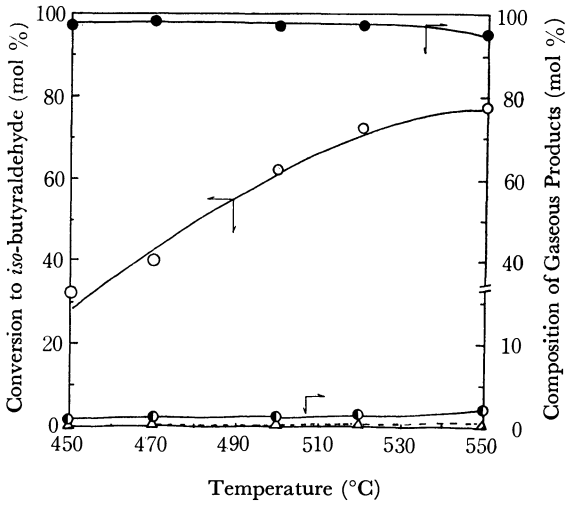

Fig. 7. Temperature dependencies of the catalytic activity of the Zn-L catalyst for the dehydrogenation of *iso*-butanol and the compositions of the produced gas; -○- conversion to *iso*-butyraldehyde, -●-H_2, -◐- CO, -△- CH_4.

of the other products in the liquid products was very small (smaller than 2%). Further, the hydrogen content in the gaseous products was very high, while the contents of CO and CH_4 were very small. On the basis of these results, the selectivity for the reaction;

$$iso\text{-}C_4H_9OH \longrightarrow iso\text{-}C_3H_7CHO + H_2$$

was calculated in order to obtain Fig. 8. This figure demonstrates a very high selectivity (higher than 95%) of the Zn-L catalyst.

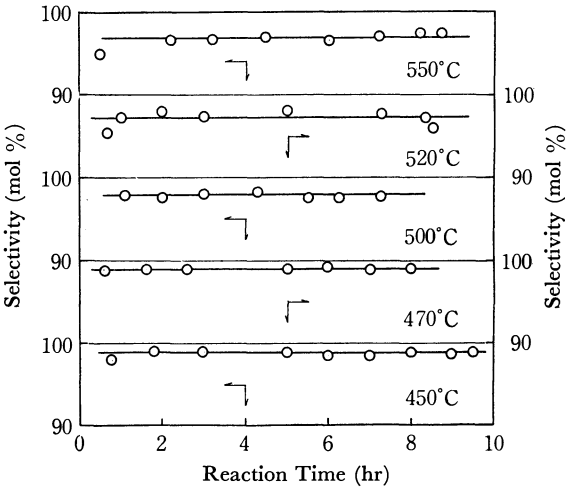

Fig. 8. Selectivities of the Zn-L catalyst for the *iso*-butyraldehyde at various temperatures.

Activity of In-L. As can be seen in Fig. 6, molten indium (In-L) also gave a persistent catalytic activity for the dehydrogenation of *iso*-butanol. The relation between the conversion and the reaction temperature is given in Fig. 9. Over the whole range of reaction temperatures, the conversion value was considerably lower than the value obtained by the use of the Zn-L catalyst.

Further, a comparison of Fig. 7 with Fig. 9 shows that the hydrogen content in the gaseous products for

5) P. E. Dunbar, *J. Org. Chem.*, **3**, 242 (1938).

6) "Monograph on the Science and Engineering of Catalysis." edited by the Catalysis Society of Japan, Vol. 7, Chijinshokan Co. Ltd., Tokyo, Japan (1964), p. 209.

7) S. Yata and S. Kudo, *Kagaku Kogaku*, **28**, 687 (1964).

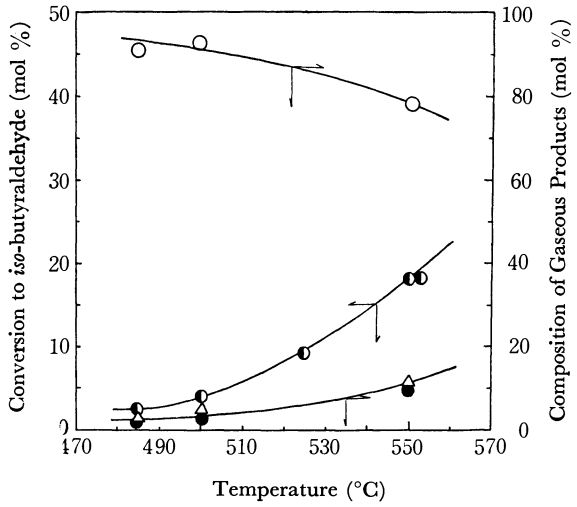

Fig. 9. Temperature dependencies of the catalytic activity of the In-L catalyst for the dehydrogenation of *iso*-butanol and the compositions of the produced gas:
-◐- conversion to *iso*-butyraldehyde, -○- H_2, -△- CO, -●- CH_4.

the In-L catalyst is lower than the content for the Zn-L catalyst. This is due to the higher contents of CO and CH_4 in the gaseous products for the In-L catalyst. From these facts, it can be said that the selectivity of the In-L catalyst is somewhat lower than that of the Zn-L catalyst.

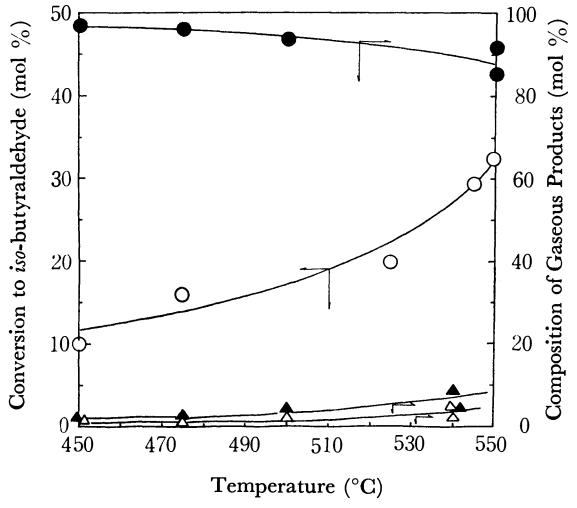

Fig. 10. Temperature dependencies of the catalytic activity of the Ga-L catalyst for the dehydrogenation of *iso*-butanol and the compositions of the produced gas:
-○- conversion to *iso*-butyraldehyde, -●- H_2, -▲- CO, -△- CH_4.

Activity of Ga-L. As can be seen in Fig. 10, Ga-L also showed a catalytic activity. The conversion value was higher than that obtained by the use of the In-L catalyst, while it was lower than the conversion value obtained by the use of the Zn-L catalyst. The hydrogen content in the gaseous products was somewhat higher than the value obtained by the use of the In-L catalyst. Further, the CO content and the CH_4 content were both lower than the corresponding values obtained by the use of the Zn-L catalyst. From these results, it was expected that the *iso*-butyraldehyde content in the liquid products would be higher than that obtained by the use of the In-L catalyst. However, as can be seen in Fig. 11, the selectivity for the formation of the *iso*-butyraldehyde of the Ga-L catalyst was the lowest among the three molten metal catalyst, *i.e.*, Zn-L, In-L, and Ga-L. This may be attributed to the higher content of an unidentified component (presumably isobutylene dissolved in the liquid phase) in the liquid products produced by the Ga-L catalyst.

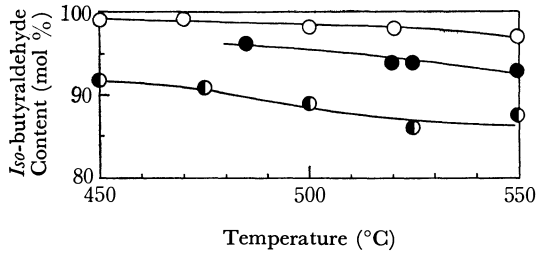

Fig. 11. Temperature dependencies of *iso*-butyraldehyde contents in the liquid products produced by dehydrogenating *iso*-butanol by the molten metal catalysts:
-○- Zn-L, -●- In-L, -◐- Ga-L.

Dehydrogenation of sec-*Butanol.*

Activity of Zn-L. As can be seen in Fig. 12, and

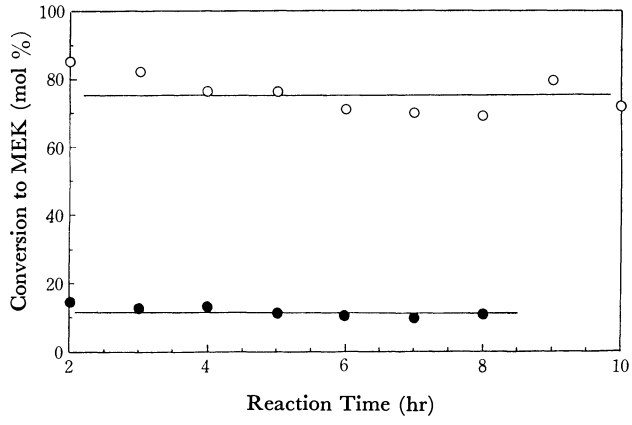

Fig. 12. Relations between the reaction time and the catalytic activities (conversion to MEK) of the Zn-L catalyst (-○-, 462°C) and the In-L catalyst (-●-, 500°C).

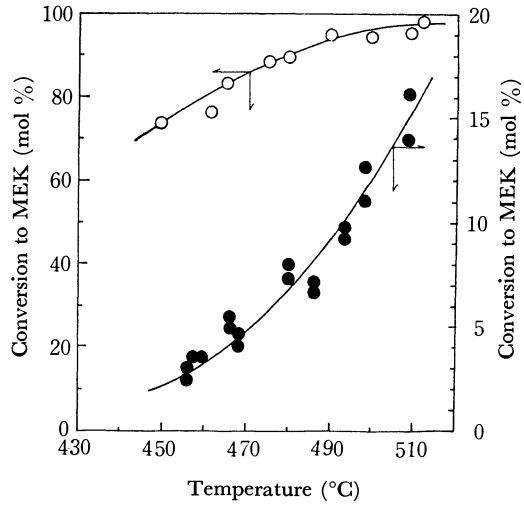

Fig. 13. Temperature dependencies of the catalytic activities (conversion to MEK) of the Zn-L catalyst (-○-) and the In-L catalyst (-●-).

Fig. 13, Zn-L showed a persistent and very high catalytic activity for the dehydrogenation of *sec*-butanol. Further, the liquid products were mainly methylethylketone (MEK). The by-products were acetone and propionaldehyde, and the total content of these materials was less than 1%. Further, the hydrogen content in the gaseous products was very high, and only a small amount of CH_4 was produced at reaction temperatures higher than 500°C. All of these facts indicate that the main reaction may be written as;

$$\begin{matrix} CH_3 \\ C_2H_5 \end{matrix}\!\!>\!CHOH \longrightarrow \begin{matrix} CH_3 \\ C_2H_5 \end{matrix}\!\!>\!CO + H_2$$

and that the selectivity of the Zn-L catalyst for the dehydrogenation of *sec*-butanol is satisfactory.

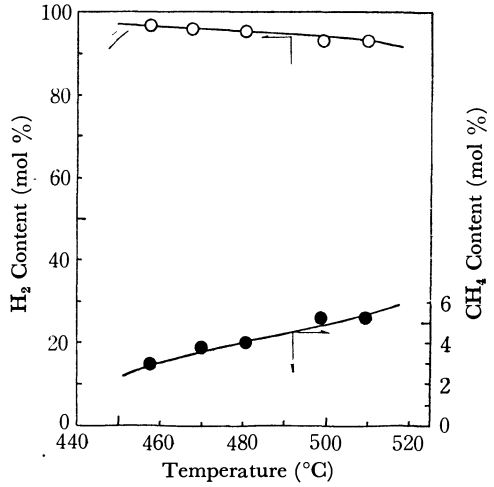

Fig. 14. Temperature dependencies of the composition of the gaseous products produced by the In-L catalyst:
-○- H_2, -●- CH_4.

Activity of In-L. As can be seen in Fig. 12, and Fig. 13, In-L also showed a persistent activity for the dehydrogenation of *sec*-butanol. The main liquid product was MEK, and the main gaseous product was hydrogen, as in the case of the Zn-L catalysts. However, compared with the Zn-L catalyst, the activity of the In-L catalyst was quite low. In addition, the selectivity of the In-L catalyst was somewhat lower than that of the Zn-L catalyst. That is, the content of CH_4 in the gaseous products was considerable (Fig. 14). Further, 2—3% of acetone was found in the liquid products. In addition, a small amount of propionaldehyde was also contained in the liquid products. Considering from these facts, the over-all reaction may be written as follows:

$$\begin{matrix} CH_3 \\ C_2H_5 \end{matrix}\!\!>\!CHOH \longrightarrow \begin{matrix} CH_3 \\ C_2H_5 \end{matrix}\!\!>\!CO + H_2 \longrightarrow \begin{matrix} CH_3 \\ CH_3 \end{matrix}\!\!>\!CO + CH_4$$

$$\begin{matrix} CH_3 \\ C_2H_5 \end{matrix}\!\!>\!CO \longrightarrow CH_3CH{=}CO + CH_4$$

$$CH_3CHCO + H_2 \longrightarrow CH_3CH_2CHO$$

Comparison with Solid Catalyst. The manufacturing of MEK by the dehydrogenation of *sec*-butanol is an industrially important reaction. Thus, several catalysts which can be used for this process have been proposed. For instance, Dunbar and his co-workers[8] proposed the copper chromite catalyst. According to their data, the conversion of *sec*-butanol to MEK was ~68% at 300—325°C. Kolb and his co-workers[9] used the Ni-Cu catalyst, which converted 84% of *sec*-butanol at a pressure of 308 mmHg and at a temperature of 472.2°K. As can be understood from these

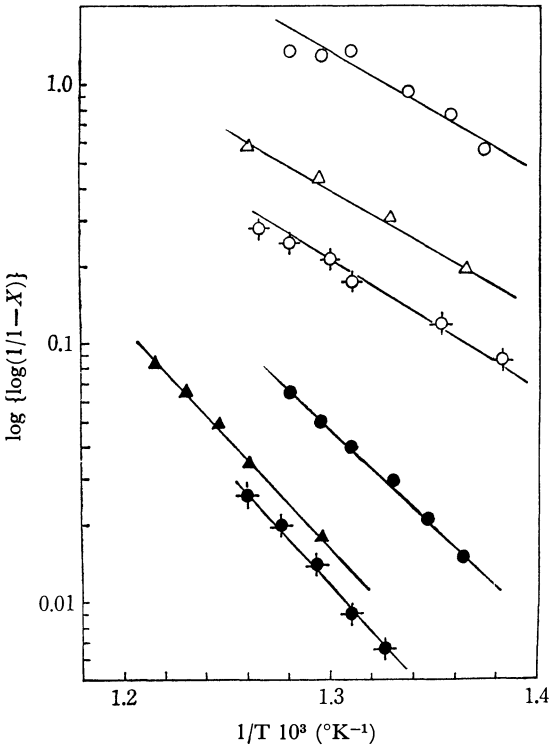

Fig. 15. Arrhenius plots for various reactions:

data, the reaction temperature for the solid catalyst is lower than that for the molten-metal catalyst.

At first sight, this seems to indicate a superiority of the solid catalysts. However, it must be noted that the selectivity of the molten metals, especially the Zn-L catalyst, was very high. Further, the merit of the easier method of the preparation of the molten-metal catalyst must also be taken into consideration.

Kinetic Treatments. As has been described in the preceding sections, the selectivities of the molten-metal catalysts were generally high. This permits us to assume that the side reactions can be disregarded for an approximate kinetic treatment. Further, it may be assumed that the dehydrogenation of alcohol on the metallic catalyst is first order with respect to alcohol,[10] and that the reaction will be approximately irreversible under the present experimental conditions. Thus, the first order rate constant, k, will be proportional to $\log(1/1-X)$, where X is the conversion.

On the basis of the above considerations, $\log\{\log(1/1-X)\}$ was plotted against $1/T$. The results are shown in Fig. 15. As can be seen in this figure, good linear relationships were obtained, and it was possible to evaluate the apparent activation energies, E_a, as well as the frequency factors, A. Interestingly, the apparent activation energy, E_a, was found to be proportional to the logarithmic frequency factor, $\log A$ (Fig. 16). That is, the so-called "compensation effect"[11] was observed. This relation seems to suggest that the catalysis of the liquid metal obeys a simple rule; Schwab's work[3] seems to throw some light on this problem. However, considering the qualitative nature* of the present experiments, this effect will not be discussed further.

10) A. C. Neish, *Can. J. Res.*, **23**, 49 (1945).

11) E. Cremer, "Advances in Catalysis," edited by W. G. Frankenburg, V. I. Komarewsky, and E. K. Rideal, Vol. 7, Academic Press, New York (1955), p. 75.

* In order to discuss the kinetic data further, the following problems must be clarified: i) the relations between the catalytic activity and the size of the bubble, which is affected by the experimental conditions (temperature, pressure, feed rate, catalyst, etc.); ii) the catalysis of metal vapor; iii) the catalysis of the metal film which is formed on the inner wall of the reactor, and iv) the extent of the oxidation of the molten metal and the catalysis of the oxide.

The i) problem is important not only from the scientific point of view but also from the engineering point of view, in which the practical use of the molten-metal catalyst is taken into consideration. Unfortunately, however, little information on this point is available at present, separate investigations to solve the problem seem to be necessary.

Concerning the ii)—iv) problems, somewhat detailed discussions have been given in the preceding paper;[4] these effects have been considered to be minor, though they can not be ignored. The reasons are given briefly in the following table.

Catalyst	Reasons which support to consider the minor effects of		
	ii	iii	iv
In-L	Very low vapor pressure.	Very low vapor pressure and little formation of the film.	Easily-reduible property of indium oxide.
Ga-L	Very low vapor pressure.	Very low vapor pressure and little formation of the film.	No significant oxidation was detected by X-ray diffraction study.
Zn-L	Comparison of the data with the data of Cd vapor and Zn vapor (a).	High activities observed at the initial reaction stage, wherein little metal films were found.	No significant oxidation was detected by X-ray diffraction. Different selectivity of ZnO from that of Zn-L.

Vibrational Spectra and Normal Coordinate Calculations of $HgNH_2Cl$ and $HgNH_2Br$*

Kiyoshi NIWA, Hiroaki TAKAHASHI, and Keniti HIGASI
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo
Teruo KAJIURA
Japan Electron Optics Laboratory Co. Ltd. Akishima-shi, Tokyo
(Received May 29, 1971)

Infrared spectra of $HgNH_2Cl$ and $HgNH_2Br$ and the Raman spectrum of $HgNH_2Cl$ have been measured in the region from 4000 cm^{-1} to 30 cm^{-1}. Effects of changing the X(X=Cl,Br) ion were observed mainly in N–H stretching bands and in lattice vibrations. Calculations of normal frequencies were carried out using a force field which includes inter-molecular forces. An assignment of the lattice vibrations was proposed and the force constants were also calculated. The force constants of the inter-molecular hydrogen bonds N–H···Cl and N–H··· Br were obtained as 0.212 mdyn/Å and 0.142 mdyn/Å, respectively.

The structure of orthorhombic crystal of mercuric amidohalide $HgNH_2X$ (X=Cl, Br) consists of halogen ions and infinite chains of alternating Hg and NH_2 with linear bonds about Hg and tetrahedral bonds about N.[1-3] The vibrational assignment of the infrared bands observed between 4000 to 400 cm^{-1} has already been given for the infinite chain of $(HgNH_2^+)_n$ by Nakagawa *et al.*[4,5] And the force constants associated with the $(HgNH_2^+)_n$ chain have also been computed.[4]

However, the lattice vibrations of these compounds have not been studied. It is considered interesting to examine the effects of changing the halogen ion on the vibrational frequencies. The effects are expected to appear mainly in the lattice vibrations and also in the N–H stretching vibrations because of the possible N–H ···X type hydrogen bonds.

We have measured the infrared spectra of $HgNH_2X$ (X=Cl, Br) and the Raman spectrum of $HgNH_2Cl$ in the region from 4000 to 30 cm^{-1}. The calculation of the normal frequencies was carried out including Cl^- and Br^- ions, and hence both the intra-molecular force constants and the inter-molecular ones were obtained. It then becomes possible to discuss quantitatively about the hydrogen bond N–H···X (X=Cl, Br) and its effects on the N–H stretching force constant.

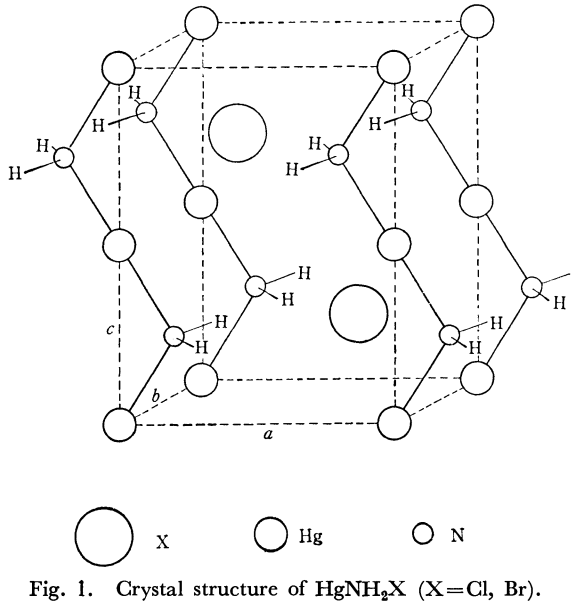

Fig. 1. Crystal structure of $HgNH_2X$ (X=Cl, Br).

Experimental

Mercuric amidochloride $HgNH_2Cl$ of special grade (Sanko Seiyaku Kogyo Co. Ltd.) was used without further purification. Although mercuric amidobromide $HgNH_2Br$ has two types of modifications, namely orthorhombic and cubic, only the orthorhombic one was prepared by the reaction of 150 m*l* of 14 N aqueous ammonia with 2 g of mercury bromide Hg_2Br_2.[2,6] The infrared spectrum of the prepared $HgNH_2Br$ coincided with that of the orthorhombic modification reported by Nakagawa et al.[5]

The infrared spectra of these substances dispersed in Nujol and in KBr disks were recorded by a Hitachi EPI G3 spectrometer (4000—400 cm^{-1}) and these in Nujol by a Hitachi FIS 3 spectrometer (400—30 cm^{-1}). However, the KBr disk method was not adequate for $HgNH_2Cl$ because it was found that a part of chlorine ions in the sample were exchanged by bromine ions in KBr. The Raman spectrum of $HgNH_2Cl$ crystal powder pressed to a disk was obtained by a laser Raman spectrometer (Japan Electron Optics Laboratory Co. Ltd.). The 5145 Å line of argon ion was used as the light source for excitation.

Observed spectra

The infrared spectra of $HgNH_2Cl$ and $HgNH_2Br$ observed from 4000 to 400 cm^{-1} are shown in Figs. 2 and 3, respectively. The far-infrared spectra from 400 to 30 cm^{-1} are given in Figs. 4 and 5. In Fig. 6, the Raman spectrum of $HgNH_2Cl$ is reproduced.

Vibrations of $HgNH_2$. Nakagawa *et al.*[4,5] have

already measured the infrared spectra of $HgNH_2Cl$ and $HgNH_2Br$ from 4000 to 400 cm^{-1} and have given the assignment of the infrared active vibrations (B_{1u}, B_{2u} and B_{3u} symmetry species) of $HgNH_2^+$. The frequencies which we observed and the assignment which we have made are in substantial agreement with theirs, hence the complete list is not reproduced here. Our contribution is to measure Raman spectrum which was not reported previously and to present the assignment of the Raman active vibrations (A_g, B_{1g}, B_{2g}, and B_{3g} symmetry species).

One interesting feature in the infrared spectra, however, should be pointed out. The NH_2 anti-symmetric stretching vibration is observed at 3200 cm^{-1} in $HgNH_2Cl$ while it is observed at 3220 cm^{-1} in $HgNH_2Br$. The same phenomenon is observed in the NH_2 symmetric stretching also: 3175 cm^{-1} for $HgNH_2Cl$ and 3180 cm^{-1} for $HgNH_2Br$. These high-frequency shifts in N–H stretching vibrations when Cl^- is substituted by Br^- are explained by the existence of the N–H···X (X=Cl, Br) hydrogen bond. All the other vibrations shift to the side of lower frequencies when Cl^- is exchanged by Br^-.

In the Raman spectrum of $HgNH_2Cl$, ten bands are observed above 400 cm^{-1}. The assignment of these Raman bands presented in Table 2 was made by analogy with that of the infrared bands. However, the observed two doublets of NH_2 wagging and of NH_2 rocking vibrations are not explained unambiguously at present. They may be either due to combination bands or to impurities in the sample.

Chain bending and lattice vibrations. There has been no work of the far-infrared spectra below 400 cm^{-1} of these compounds. We have observed the bands due to chain bending vibrations and lattice vibrations of $HgNH_2Cl$ and $HgNH_2Br$ for the first time. They are shown in Figs. 4 and 5, respectively. In the spectrum of $HgNH_2Cl$, six bands are observed at 241, 148, 126, 116, 97, and 51 cm^{-1}. The corresponding bands in $HgNH_2Br$ spectrum are 207, 120, 96, 86, 70, and 45 cm^{-1}. These bands are considered to be due to chain bending vibrations and lattice vibrations or the mixture of these.

In the low frequency region of the Raman spectrum of $HgNH_2Cl$, four bands are observed at 176, 117, 97,

and 78 cm^{-1}. The assignment of these low frequency bands observed in the infrared and Raman spectra are made according to the results of the normal frequency calculations.

Normal coordinate treatment

The crystal structure of $HgNH_2X$ (X=Cl, Br) is orthorhombic with two $HgNH_2X$ units in a Bravis unit cell as shown in Fig. 1. The lattice parameters and the bond-lengths are summarized in Table 1.[1,2]

Table 1. Lattice parameters and bond lengths[1,2]

	$HgNH_2Cl$	$HgNH_2Br$
Lattice parameter	a=5.167 Å	a=5.439 Å
	b=4.357	b=4.487
	c=6.690	c=6.761
Bond length		
N—H	1.04 Å	1.04 Å
Hg—N	2.05	2.07
H···H	1.70	1.70
H···Hg	2.59	2.61
Hg···Hg	3.35	3.38
H···X	2.18	2.36
Hg···X	3.21	3.30
X···X	3.83	3.91

The calculation of the normal frequencies[7] was made assuming a modified Urey-Bradly type force field[8] and a few coordinates corresponding to inter-molecular forces were also taken into account. These coordinates are given below.

	X=Cl	X=Br
q (H···X)	2.18 Å	2.36 Å
q (Hg···X)	3.21 Å	3.30 Å
h (N-H···X)		

The coordinate q(X···X) was omitted because of the large X···X distance: 3.83 Å for X=Cl and 3.91 Å for X=Br.

The potential function was expressed as

$$U = U_l + U_1$$

$$\begin{aligned} U_l = 1/2\{&\sum K_{N-H}(\Delta r_{N-H})^2 + \sum K_{Hg-N}(\Delta r_{Hg-N})^2 \\ &+ \sum F_{H\cdots H}(\Delta q_{H\cdots H})^2 + \sum F_{H\cdots Hg}(\Delta q_{H\cdots Hg})^2 \\ &+ \sum H_{H-N-H}(\Delta\alpha_{H-N-H})^2 + \sum H_{H-N-Hg}(\Delta\alpha_{H-N-Hg})^2 \\ &+ \sum H_{Hg-N-Hg}(\Delta\alpha_{Hg-N-Hg})^2 + \sum H^{\perp}_{N-Hg-N}(\Delta\alpha^{\perp}_{N-Hg-N})^2 \\ &+ \sum H^{//}_{N-Hg-N}(\Delta\alpha^{//}_{N-Hg-N})^2 + \sum Y_{N-Hg-N}(\Delta\tau_{N-Hg-N})^2\} \\ &+ \sum \text{angle interaction constant } l_{ij} \text{ term}^{9} \end{aligned}$$

$$\begin{aligned} U_1 = 1/2\{&\sum f_{H\cdots X}(\Delta q_{H\cdots X})^2 + \sum f_{Hg\cdots X}(\Delta q_{Hg\cdots X})^2 \\ &+ \sum h_{N-H\cdots X}(\Delta\phi_{N-H\cdots X})^2\} \end{aligned}$$

where

U_l is the potential function associated with the $(HgNH_2^+)_n$ chain.

U_1 is that of the lattice vibration.

K, F, H, and Y denote bond-stretching, repulsive, angle-bending and torsional force constants, respectively. f and h are, respectively, stretching and angle-bending force constants associated with the lattice vibrations.

The calculation of the normal frequencies was carried out by the Cartesian coordinate method.[7] The coordinates, with which the potential function is expressed, are transformed into Cartesian displacement coordinates X. And then the optically active potential energy matrix F_{op} is set up in terms of the optically active Cartesian displacement coordinates. The secular equation

$$|M^{-1}F_{op} - E\lambda| = 0$$

gives the eigenvalues and eigenvectors which correspond to the frequencies and the vibrational modes respectively, where M is a diagonal mass matrix and E is a unit matrix.

Results and Discussions

Normal frequency calculation. Lipscomb *et al.* have reported from X-ray studies that the space groups of both $HgNH_2Cl$[1] and $HgNH_2Br$[2] belong to C^1_{2v}-P2mm. However, as can be seen in Table 2, there are very few infrared frequencies which correspond to Raman fre-

quencies. This fact would suggest that the vibrational spectra of $HgNH_2Cl$ (and also $HgNH_2Br$) are explained more adequately by a D_{2h} symmetry than a C_{2v}. Therefore we have carried out normal frequency calculations assuming a D_{2h} symmetry instead.

The calculated frequencies listed in Table 2 are in good agreement with the observed values. As the Bravis unit cell contains one $(HgNH_2^+)_n$ chain and two X atoms, one rotational and six translational lattice vibrations are expected to appear. The assignment of lattice vibrations and also of chain bending vibrations are given in the same table. The L_x matrices of lattice vibrational modes and chain bending modes are shown schematically in Figs. 7, 8, and 9. L_x is the transformation matrix between the Cartesian coordinates X and the normal coordinates Q. These figures demonstrate that the low frequency bands cannot be distinctly classified into either lattice vibrations or chain bending vibrations; rather, they are more or less coupled with each other. The low-frequency shifts in the chain bending vibrations, when Cl^- is substituted by Br^-, are well understood from this viewpoint. The chain bending vibrations in the A_u species of $HgNH_2Cl$ and $HgNH_2Br$, however, are both calculated to be almost of the same value: 68 cm^{-1} for $HgNH_2Cl$ and 66 cm^{-1} for $HgNH_2Br$. As can be seen in Table 2 and in Fig. 9, this mode is a pure chain bending vibration so that the effect of changing the halogen ion is negligible. Low-frequency shifts in the lattice vibrations when Cl^- is exchanged by Br^- are explained mainly both by the difference of atomic weight of halogen and by the difference of inter-molecular force constants which will be discussed below.

a) mdyn·Å

N–H···X (X=Cl, Br) hydrogen bond. The values of the force constants obtained by the least squares method are shown in Table 3. In the course of the calculation, all the force constants except for K (N–H), f (H···X), f (Hg···X), h (N–H···X) and four kinds of angle interaction constant l[9] were set to be equal for $HgNH_2Cl$ and $HgNH_2Br$ in spite of the slight difference of the bond lengths summarized in Table 1. Nakagawa *et al.* determined F (H···H) to be 0.06 mdyn/Å[4], however, in this calculation it was fixed to 0.10 mdyn/Å according to Harada and Shimanouchi.[10]

The force constants K(N–H) are calculated as 5.276 mdyn/Å for $HgNH_2Cl$ and 5.371 mdyn/Å for $HgNH_2Br$. High-frequency shifts in the N–H stretching vibrations when Cl^- is substituted by Br^- are explained by the fact that K (N–H) of $HgNH_2Br$ is larger than that of $HgNH_2Cl$. This difference in K (N–H) between $HgNH_2Cl$ and $HgNH_2Br$ may suggest that the hydrogen bond of H···Cl is stronger than that of H···Br. And actually, the calculated values of the force constant f (H···Cl) and h (N–H···Cl) become larger than those of f (H···Br) and h (N–H···Br), respectively, as shown in Table 3. Therefore, low-frequency shifts in the lattice vibrations when Cl^- is exchanged by Br^- are understandable. All the other force constants obtained are considered reasonable.

Far-infrared Reflection Spectra, Optical and Dielectric Constants, and Lattice Vibrations of Some Fluoride Crystals

Ichiro NAKAGAWA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 11, 1971)

The reflection spectra of the crystals of the NaCl structure (LiF, NaF, and NiO), the fluorite structure (CaF_2, BaF_2, and CdF_2), and the rutile structure (MgF_2 and MnF_2) were measured. The optical and dielectric constants were derived from the measured reflectivities using the Kramers-Kronig transformation. The absorption indices (k) for these crystals are rather large and the peak values of the imaginary dielectric constants amount to 30.0 or more. However, unlike the ferroelectric substances such as oxide perovskites and rutile, these fluoride crystals do not show any anomalous dielectric behaviour. From the real and imaginary dielectric constants $\varepsilon'(\nu)$ and $\varepsilon''(\nu)$, the transverse and longitudinal frequencies for the lattice modes are determined. These frequencies are reasonably interpreted on the basis of the crystal structures and satisfy the Lyddane-Sachs-Teller relation. The effective charge on the positive and negative ions and the force constant associated with the short-range elastic force against the ion displacement are obtained for the cubic crystals.

Several investigations on the optical and dielectric properties of the fluoride crystals have been made using reflection data as well as transmission spectra by Hunt and Perry,[1] Perry,[2] Barker,[3] Axe and Pettit,[4] Balkanski *et al.*,[5] Bosomworth,[6] and Denham *et al.*[7] In the course of our studies on the lattice vibrations of inorganic salts, we have investigated the transmission spectra of some fluoride perovskites.[8,9] On the basis of the dynamical model we obtained the potential constants associated with the short-range repulsive force without taking into account the long-range interaction. The longitudinal frequencies as well as the transverse frequencies supply further information on the interionic forces in the crystal, specifically on the long-range, electrostatic interaction.

The purpose of the present study is to establish the optical and dielectric constants of various kinds of fluoride crystals from the reflectivity data and to determine the longitudinal frequencies as well as the transverse frequencies for the crystal lattice modes, by which the effective charge on the positive and negative ions can be obtained.

The crystals investigated are those of the NaCl structure (LiF, NaF, and NiO), the fluorite structure (CaF_2, BaF_2, and CdF_2), and the rutile structure (MgF_2 and MnF_2). Reflection and transmission measurements for crystals other than MnF_2 and NiO have been made by several researchers. Except for the fluorites, however, the data are rather old and the observed frequency range and procedure for obtaining the frequencies are not always satisfactory. It is therefore worth while to make a remeasurement for these crystals also and compare the optical and dielectric constants and the lattice frequencies determined in different laboratories with one another, since the procedure for obtaining these parameters is not straightforward and contains a wide variety of technique.

Experimental

The room temperature reflectivity at near normal incidence was measured down to 30 cm^{-1} with a Hitachi FIS-21 single-beam vacuum far infrared spectrometer attached with a specular reflectance accessary (incidence angle 11°). The reflectivity measurement in the region 700—300 cm^{-1} was made with a Hitachi EPI-L double-beam infrared spectrometer attached with a IRR-3 type reflectance accessary (incidence angle 12°).

For the measurement of a crystal of small dimension (~5 mm × 5 mm), a reflectance attachment with two spherical mirrors and two plane mirrors was designed for the use of a Hitachi FIS-1 vacuum infrared spectrometer as a single-beam use, as shown in Fig. 1 (incidence angle 10°).

Determination of Optical Constants

The optical and dielectric constants, n(refractive index), k(absorption index), ε' and ε''(real and imaginary dielectric constants), are derived from the measured reflectivity using the Kramers-Kronig relation.[10] At normal incidence it is possible to proceed from a measurement of R(the reflectivity for unpolarized radiation), since the distinction between R_s and R_p (the reflectivities for perpendicular and parallel polarized radiations) is meaningless. The complex reflected amplitude ($\hat{r}$) is expressed in terms of its phase angle θ as

$$\hat{r} = |r| \exp(i\theta) = \sqrt{R} \exp(i\theta) = \frac{n-ik-1}{n-ik+1}, \quad (1)$$

from which one obtains

$$n = \frac{1-R}{1+R-2\sqrt{R}\cos\theta}, \quad (2)$$

$$k = \frac{-2\sqrt{R}\sin\theta}{1+R-2\sqrt{R}\cos\theta}, \quad (3)$$

$$\varepsilon' = n^2 - k^2, \quad (4)$$

$$\varepsilon'' = 2nk. \quad (5)$$

The phase angle θ at any particular frequency ν_0 is calculated by the Kramers-Kronig transformation

$$\theta(\nu_0) = \frac{2\nu_0}{\pi}\int_0^\infty \frac{\ln R(\nu)}{\nu^2-\nu_0^2}d\nu. \quad (6)$$

The reflectivity measurements are limited to some finite spectral region(ν_L to ν_H), and the correction terms due to the contributions from all the frequencies above the high-frequency limit(ν_H) and below the low-frequency limit(ν_L) were calculated according to the procedure proposed by Roessler.[11] The value of $\theta(\nu_0)$ is given as

$$\theta(\nu_0) = \frac{2\nu_0}{\pi}\int_{\nu_L}^{\nu_H}\frac{\ln R(\nu)-\ln R(\nu_0)}{\nu^2-\nu_0^2}d\nu + \frac{1}{2\pi}\ln\left|\frac{\nu_0-\nu_L}{\nu_0+\nu_L}\right|\ln\left[\frac{R(\nu_L)}{R(\nu_0)}\right] - \frac{1}{2\pi}\ln\left|\frac{\nu_H-\nu_0}{\nu_H+\nu_0}\right|\ln\left[\frac{R(\nu_H)}{R(\nu_0)}\right]. \quad (7)$$

Numerical integration of Eq. (7) and subsequent calculations of the optical and dielectric constants were performed with a HITAC 5020E Computer of the Computation Center, the University of Tokyo. The measured reflectivity data and the obtained optical and dielectric constants are shown in Figs. 2~9.

Transverse and Longitudinal Optical Frequencies

On the basis of the damped oscillator model with several modes, the dielectric constants are expressed as

$$\varepsilon'(\nu) = \varepsilon_\infty + \sum_j 4\pi\rho_j\nu_j^2\frac{\nu_j^2-\nu^2}{(\nu_j^2-\nu^2)^2+\gamma_j^2\nu^2}, \quad (8)$$

$$\varepsilon''(\nu) = \sum_j 4\pi\rho_j\nu_j^2\frac{\gamma_j\nu}{(\nu_j^2-\nu^2)^2+\gamma_j^2\nu^2}, \quad (9)$$

where ν_j, ρ_j and γ_j are the resonance frequency, oscillator strength and damping constant, respectively, of the j-th mode. It is found from Eqs. (8) and (9) that for the small damping γ_j the poles of $\varepsilon'(\nu)$ curve and the maxima of $\varepsilon''(\nu)$ curve coincide and they are located around $\nu=\nu_j$. These frequencies give the optically active lattice frequencies of the long-wavelength transverse modes.[3,4] The corresponding longitudinal frequencies are given by the frequencies where $\varepsilon'(\nu)$ becomes zero in changing from negative to positive values.[3,4,12]

ν_T: transverse frequencies, ν_L: longitudinal frequencies, ν_{pole}: pole of $\varepsilon'(\nu)$ curve, σ_{max}: peak of conductivity, sh: shoulder.

The transverse and longitudinal frequencies determined by the procedure mentioned above are listed in Table 1. This table also includes the results of other researchers for some of the crystals, since a comparison of the frequencies from different sources is significant to justify various methods for the determination of the transverse and longitudinal frequencies. The argument for each type of crystal listed in Table 1 will be given in the following.

Crystals of NaCl structure. For this type of crystal one infrared active mode is observed as a transverse component and a longitudinal component. The peak values of absorption index(k) and imaginary dielectric constant(ε'') are very large for LiF and NaF, while those for NiO are rather small.

Crystals of fluorite structure. The crystal of this type has the space group O_h^5 with one formula unit and one f_{1u} mode is infrared active. The transverse frequencies of CaF_2, BaF_2 and CdF_2 obtained by this study are in agreement with those by Denham *et al.*[7] and by Bosomworth.[6] The longitudinal frequency of CdF_2 by Denham *et al.* which was determined using the Berreman method[14] by depositing a thin film on a mirror surface differs slightly from that by the present study and by Bosomworth.

Crystals of rutile structure. MgF_2 and MnF_2 have this structure with the space group D_{4h}^{14} and the Bravais primitive cell contains two formula units. This type of crystal is not cubic but uniaxial and 1 $a_{2u}(E//c\text{-axis})$ and 3 $e_u(E\perp c\text{-axis})$ lattice modes are infrared active. As is shown in Fig. 8 the reflectivities of the *ab*-plane and *ac*-plane for MgF_2 are somewhat different. The transverse and longitudinal frequencies obtained in both cases also differ to some extent as is seen in Table 1. From the result of the *ab*-plane measurement shown in Fig. 8(a), the e_u mode frequencies are determined as 448 cm^{-1}, 405 cm^{-1}, and 245 cm^{-1}, which are in good agreement with those obtained by Barker using a $E\perp c$ polarized radiation.[3] In the *ac*-plane measurement, if the crystal is set properly so that the *c*-axis may take a direction perpendicular to the incidence plane, the two peaks of $k(\nu)$ and $\varepsilon''(\nu)$ around 400 cm^{-1} observed in the *ab*-plane spectrum do not appear clearly and instead one peak at 395 cm^{-1} is observed as shown in Fig. 8(b). This *ac*-plane spectrum of Fig. 8(b) is similar to that of $E//c$ by Barker, superimposed with a small amount of *ab*-plane spectrum, though Barker only carried out measurement down to 280 cm^{-1} and could not observe the peak around 250 cm^{-1}. From the above result it is concluded that the peak at 395 cm^{-1} is related to the a_{2u} species and the one around 250 cm^{-1} may also arise from the a_{2u} mode.

For MnF_2 crystal, a sample having sufficient area for the *ab*-plane and *ac*-plane could not be obtained, and accordingly the symmetry species of the observed transverse frequencies have not been determined experimentally. However, the plane for which the reflectivity measurement was performed was found to be almost 101 plane by crystal analysis. Due to the closeness of the transverse frequencies of 172 cm^{-1} and 161 cm^{-1}, two corresponding longitudinal frequencies could not be determined.

Discussion

The dielectric constants $\varepsilon'(\nu)$ and $\varepsilon''(\nu)$ were well interpreted on the basis of the lattice modes expected from the crystal symmetry, except for very weak extra

bands or shoulders contributed from another extra oscillators which may arise from (a) a forbidden transition, (b) a two-phonon process, or (c) a localized mode due to impurities or a crystal surface. The observed data of ν_T and ν_L frequencies are checked by the Lyddane-Sachs-Teller relation,[15]

$$\prod_j \frac{(\nu_L)_j}{(\nu_T)_j} = \left[\frac{\varepsilon_0}{\varepsilon_\infty}\right]^{1/2} \tag{10}$$

where ε_0 is a static dielectric constant and ε_∞ is a high-frequency dielectric constant and can be obtained from the refractive index for the visible light, n^2. In Table 2 the values of $\prod_j[(\nu_L)_j/(\nu_T)_j]$ calculated from the ν_T and ν_L frequencies determined in Table 1 are compared with $(\varepsilon_0/\varepsilon_\infty)^{1/2}$. The agreement is satisfactory.

Table 2. Application of Lyddane-Sachs-Teller relation to some fluoride crystals

	$\prod_j(\nu_L/\nu_T)_j$	$(\varepsilon_0/\varepsilon_\infty)^{1/2}$

BaF_2	1.84	1.82
CdF_2	1.90	1.88
MgF_2 (e_u)	1.65	1.68

A short comment will be made concerning the peak values of $k(\nu)$ and $\varepsilon''(\nu)$. As described before there is some approximation in the procedure to get $k(\nu)$ and $\varepsilon''(\nu)$ curves, due to the limited range of the observed reflectivity data. According to the procedure utilized, the peak values of $k(\nu)$ and $\varepsilon''(\nu)$ are more or less affected but not those of ν_T and ν_L. Thus, no quantitative discussion on the peak values of $k(\nu)$ and $\varepsilon''(\nu)$ will be given. Nevertheless, it should be noted that for these ionic crystals of fluorides the values of the absorption indices(k) are rather large compared with those for liquid samples such as $CHCl_3$ and C_6H_6 (organic compounds)[16,17] and may take values larger than 2.0. ε'' may amount to 30.0 or more for the strong peaks, which are also much larger than the value of the order of 5.0 for liquid samples of organic compounds. However, it should be emphasized that the fluoride crystals studied here do not reveal any anomalous dielectric behavior, as compared with the dielectric constants of the oxide perovskites and rutile which amount to the order of 500.

Splitting of Transverse and Longitudinal Frequencies and Effective Charge

The transverse frequencies of some fluorides were analysed previously,[8,9] on the basis of the normal coordinate treatment of the dynamical model, taking into account the short-range interactions. Therefore, in the present treatment only the elastic force or restoring force against the ion displacement has been taken. The availability of the longitudinal frequencies as well as the transverse frequencies makes it possible to get information on factors other than the elastic force, such as electrostatic interaction.

On the basis of a polarizable ion model for the cubic diatomic crystals given by Born and Huang,[12] the transverse and longitudinal frequencies are derived as

$$4\pi^2\nu_T^2 = \frac{\beta}{\bar{M}} - \frac{4\pi}{3}\frac{1}{v}\left[\frac{Z^2e^2}{\bar{M}}\right]\left[1-\frac{4\pi}{3}\frac{\alpha^+ + \alpha^-}{v}\right]^{-1} \tag{11}$$

$$4\pi^2\nu_L^2 = \frac{\beta}{\bar{M}} + \frac{8\pi}{3}\frac{1}{v}\left[\frac{Z^2e^2}{\bar{M}}\right]\left[1+\frac{8\pi}{3}\frac{\alpha^+ + \alpha^-}{v}\right]^{-1} \tag{12}$$

where $\bar{M}$ is the reduced mass of unit cell ions$=M^+M^-/(M^+ + M^-)$, α^+ and α^- the ionic polarizabilities of the positive and negative ions, $\pm Ze$ the effective charge, β the force constant associated with the elastic force against the ion displacement, and $v=2(r_0/2)^3$ the volume of unit cell (r_0=cell constant). When the ions are assumed to be non-polarizable, this is reduced to a rigid ion model discussed by Denham *et al.*[7]

Eqs. (11) and (12) can be written in terms of ε_∞ instead of α^+ and α^- as

$$4\pi^2\nu_T^2 = \frac{\beta}{\bar{M}} - \frac{4\pi(Z^2e^2)(\varepsilon_\infty+2)}{9v\bar{M}}, \tag{13}$$

$$4\pi^2\nu_L^2 = \frac{\beta}{\bar{M}} + \frac{8\pi(Z^2e^2)(\varepsilon_\infty+2)}{9v\bar{M}\varepsilon_\infty}, \tag{14}$$

using Clausius Mosotti's relation

$$\frac{4\pi}{3}\frac{\alpha^+ + \alpha^-}{v} = \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2}. \tag{15}$$

Eqs. (13) and (14) are reduced to the expressions based on a shell model developed by Cochran[18] and Axe.[19] Using the observed values of ν_T and ν_L listed in Table 1, the effective charges are obtained for both non-polarizable and polarizable ion models as shown in Table 3.

Table 3. Effective ionic charge (Z)

result is also given in Table 3.

In the infrared active mode of the XF_2 cubic crystal of fluorite structure, the reduced mass $\bar{M}=2M_FM_X/(2M_F+M_X)$ is used in Eqs. (11—16). $-Ze/2$, $-Ze/2$ and $+Ze$ correspond to the effective charges, respectively, on the two fluorine ions and on the metal ion.

In Table 3 it is found that the effective charge may be 15—20% below the formal charge for the fluoride crystals. However, for NiO the effective charge is 0.81 against the formal charge 2.0, which means that the electron delocalization is much larger in NiO than in the fluorides.

The contribution of factors other than the elastic force to the lattice frequencies can be estimated from the ratio of the second term of Eq. (11) to the first term for a rigid ion model. The ratio is given in Table 4 which also includes the short-range interionic elastic force constant $K(M\text{-}X)$. $K^*(M\text{-}X)$ is the calculated interionic force constant when the electrostatic term (second term) is neglected in Eqs. (11) and (13). It should be noted that the short-range elastic force constant between the positive and negative ions, calculated without taking into account the long-range electrostatic interaction, $K^*(M\text{-}X)$, is somewhat smaller than the true value $K(M\text{-}X)$.

The Crystal and Molecular Structure of Miyaconitine Hydrobromide Dihydrate

Hirotaka SHIMANOUCHI, Yoshio SASADA, and Tatsumichi TAKEDA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 1, 1971)

The structure of an *Aconitum* alkaloid, miyaconitine, $C_{23}H_{29}O_6N$, has been determined by the X-ray analysis of crystals of the hydrobromide dihydrate, which are monoclinic with four formula units in a unit cell of the dimensions; $a=10.41$, $b=13.85$, $c=9.63$ Å and $\beta=113.8°$; space group, $P2_1$. The structure was solved by the heavy-atom method and was refined by the least-squares method. The final R index was 0.151. The absolute configuration was determined using the anomalous dispersion effect of the bromine atom. It was thus established that miyaconitine is a novel type of *Aconitum* alkaloid.

Introduction

Miyaconitine, $C_{23}H_{29}O_6N$, was isolated from *Aconitum miyabei* Nakai as a major alkaloid; the first preliminary investigation of its structure by chemical methods was reported in 1950.[1] Since then the structure has been investigated by many workers,[2-4] but certain reactions still remained uninterpretable, thus precluding a conclusive elucidation of the structure. Miyaconitine seemed to have an unusual skeleton, capable of a facile cyclization. In view of this, an X-ray structure analysis was undertaken in cooperation with the chemical work by Ichinohe, Yamaguchi, Katsui, and Kakimoto.[5]

A heavy-atom derivative, miyaconitine hydrobromide dihydrate, was prepared and supplied by Professor Ichinohe. A preliminary report of the present X-ray work has already been published.[6]

Experimental

Crystals of miyaconitine hydrobromide dihydrate are colorless scales, the (001) plane being well developed. The unit-cell dimensions were determined from zero-layer Weissenberg photographs about the a and the b axes, calibrated with superimposed Al-powder photographs.

Multiple-film equi-inclination Weissenberg photographs were taken at room temperature for the layer lines from 0 to

7 about the a axis and from 0 to 9 about the b axis, using Cu$K\alpha$ radiation. The crystals used were square in cross-section, with rectangular dimensions of 0.02×0.002 cm and 0.05×0.002 cm for the a and b axis rotation respectively. Almost no reflections were observed with $2\theta>100°$. Therefore, only 1342 were indexed out of the 2900 possible independent reflections within the limiting sphere for Cu$K\alpha$. The intensities of those 1342 reflections were estimated by visual comparison with a standard scale prepared with the same crystal, of which 211 were unobserved above the background. The accuracies of the intensity data were rather low, because only very thin crystals were available. The corrections for the Lorentz and polarization factors were made in the usual way, and those for the spot-size variation in the high-layer photographs, by the method of Phillips.[7] The correction for absorption was omitted.

Crystal Data

The crystallographic and physical data obtained are: Miyaconitine hydrobromide dihydrate $C_{23}H_{29}O_6N\cdot HBr\cdot 2H_2O$, mp 270°C (decomp.). Monoclinic, $a=10.41$ Å, $b=13.85$ Å, $c=9.63$ Å and $\beta=113.8°$. Absent spectra, $(0k0)$ when k is odd. Space group, $P2_1$. Two molecules per unit cell. Volume of the unit cell, 1270.5 Å^3. Density (by flotation), 1.399 g·cm^{-3}. Density (calculated), 1.391 g·cm^{-3}. Linear absorption coefficient for Cu$K\alpha$ radiation, $\mu=28.4$ cm^{-1}. Total number of electrons per unit cell, $F(000)=556$.

Table 1. Final atomic coordinates and temperature factors

The anisotropic temperature factors are expressed in the form of

$$\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}.$$

Structure Determination

The three-dimensional sharpened Patterson function was synthesized, and the bromine atom was easily located. A three-dimensional Fourier synthesis was subsequently carried out using the phases of the bromine atom. The resulting map necessarily exhibited the space group symmetry of $P2_1/m$, causing the superposition of the real atoms with their related mirror-image peaks. The 108 peaks were picked out within the asymmetric unit; we then tried to assemble them together to give a three-dimensional molecular model. By studying the distances and angles between peaks, the twenty-three peaks were tentatively assigned to

light atoms after many trials; nine of them were later found to be incorrect. The difficulty was the presence of many spurious peaks, probably because of the low accuracies of the diffraction data mentioned in the previous section. To find the remaining atoms, a successive Fourier synthesis and the least-squares refinement were executed in combination. The atoms whose temperature factors became unreasonably large in the least-squares refinement were abandoned. The atoms of the molecular skeleton were revealed step by step, but some of the atoms in the acetoxyl group and a water of crystallization did not appear in this stage. Finally, difference syntheses gave all the non-hydrogen atoms. The oxygen atoms were easily distinguished from the carbon atoms by inspecting the electron-density, the bond lengths, and the hydrogen bonding scheme, as will be described later.

Since the evidence for assigning the nitrogen atom was not conclusive at this stage, the electron-density values at the peaks and the chemical information were taken into account. This assignment is consistent with that of other related diterpenoid alkaloids of a known structure.[8-10]

The atomic parameters were refined by the block-diagonal matrix least-squares method. Anisotropic temperature factors, of the form $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$, were applied to the bromine atom, while the thermal motion of the light atoms was assumed to be isotropic. The final discrepancy index, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, was 0.151 for the observed reflections. The atomic scattering factors used were taken from International Tables for X-ray Crystallography (1962).[11] The final atomic coordinates and temperature factors are given in Table 1, and their standard deviations, in Table 2. The ob-

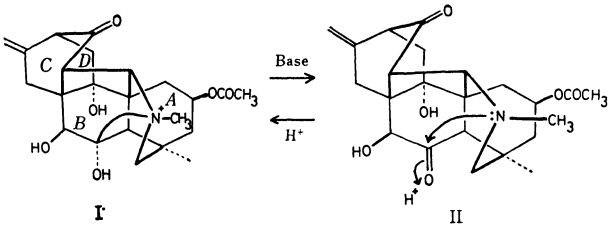
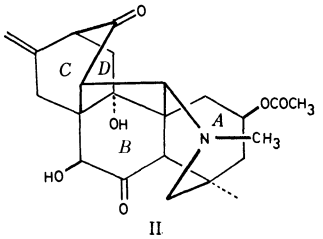
bonds. That is, the C(sp^3)–O bond lengths are in the range of 1.35—1.47 Å, while the length of the C(4)—C(18) bond is 1.66 Å.

The equations for the least-squares planes of the planar groups are summarized in Table 5. The C(12), C(16), C(15), and C(17) atoms are essentially planar within the limits of error, and the O(5), C(12), C(13), and C(14) atoms are completely planar, showing that the C(13) and C(16) atoms are in the sp^2 hybridization. The bond lengths, 1.20 Å for C(13)–O(5) and 1.37 Å for C(16)–C(17), clearly distinguish the C=O group from the C=C bond.

The O(1), O(6), C(21), and C(22) atoms are also nearly planar, compatible with the identification of the acetoxyl group. Although there is no significant difference between the C(21)–O(6) and C(21)–C(22) distances, the peak of the electron-density of O(6) was higher than that of C(22) throughout all the stages of Fourier synthesis, so the oxygen atom can tentatively be assigned to the O(6).





Determination of Absolute Configuration

The absolute configuration of the present compound was determined by means of the anomalous scattering of the Cu$K\alpha$ radiation by the bromine atom. The Bijvoet pairs selected as most advantageous for visual comparison are given in Table 6. From these observations, it can be concluded that the atomic coordinates in Table 1 should be referred to a left-handed coordinate system. All the drawings in this paper are based on the correct absolute configuration. The absolute configuration found is in agreement with those of related compounds.[8–10]

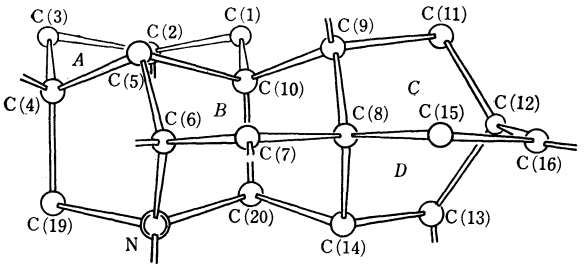


Fig. 3. Molecular skeleton, viewed down the vector between C(7) and the midpoint of C(10)–C(20).

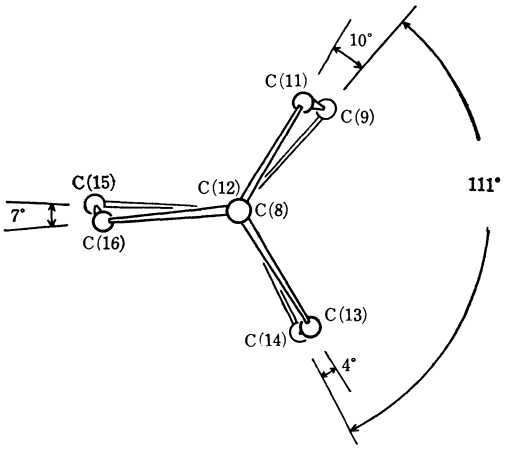

Fig. 4. Rings *C* and *D*, viewed down the C(12)···C(8) vector showing the twisting of the carbocycle.

Results and Discussion

From the X-ray analysis described in the preceding sections, the structure of the present molecule has been determined to be I, including the absolute configuration. A three-dimensional view of the molecule can be obtained from the stereodrawings in Fig. 2. On the basis of the present results, the structure of miyaconitine itself can be deduced to be II, which can easily be converted to I in acidic media.[5] Although the skeleton of the resultant hydrobromide molecule (I) is identical with those of hetisine[8] and kobusine methiodide,[9] the free alkaloid, miyaconitine itself (II), has a new type of skeleton. This is the first substance isolated as a biogenetic intermediate in the transformation from an atisine to a hetisine skeleton in *Aconitum* alkaloids.[5]

The drawing of the skeleton viewed along the vector between the C(7) and the midpoint of the C(10)–C(20) bond is shown in Fig. 3. The *A* ring takes the chair form, with the acetoxyl group in the axial position. If the fusion of the *A* ring and the difference in atomic species are disregarded, the main skeleton possesses an approximate mirror plane through the C(6), C(7), and C(8) atoms. The *C* and *D* rings make a bicyclo-[2,2,2]octane-like system, as is shown in Fig. 4. The conformation of this system is slightly staggered, with the projected angles ranging from 4° to 10°. The presence of a bridge between C(9) and C(14) through the C(10)–C(20) bond causes an appreciable closing of the projected angle, C(9)–C(8)–C(14) (111°). These indicate a significant deviation from D_3 symmetry.[13]

O(3)	C(3)	*2*	3.43
C(19)	O(5)	*5*	3.32
C(23)	O(6)	*5*	3.44
C(18)	O(5)	*5*	3.41
	Br^-···C shorter than 4.00 Å		
Br	C(11)	*1*	3.93
C(17)	Br	*2*	3.82
C(7)	Br	*4*	3.67
C(22)	Br	*5*	3.93

Atom (position 1)	Atom	in position	Distance
	Br^-···O shorter than 4.00 Å		
Br	OW(1)	*1*	3.18
OW(2)	Br	*3*	3.51
O(3)	Br	*4*	3.26
	O···O shorter than 4.00 Å		
O(4)	OW(1)	*1*	2.78
OW(2)	OW(1)	*1*	2.65
O(3)	OW(1)	*4*	3.30
O(2)	O(4)	*4*	3.41
O(2)	OW(1)	*4*	2.76
Position[a)]	General coordinates		
1	x,	y,	z
2	x,	y,	$1+z$
3	$\bar{x}$,	$\frac{1}{2}+y$,	$\bar{z}$
4	$\bar{x}$,	$\frac{1}{2}+y$,	$1-z$
5	$1-x$,	$\frac{1}{2}+y$,	$1-z$
6	$1-x$,	$\frac{1}{2}+y$,	$2-z$

a) These are also indicated in Fig. 5.

The UV spectrum of this compound shows a somewhat higher intensity at 295 nm than that of normal saturated ketones.[5] This may correlate with the distance between, and the relative orientation of, the carbonyl and the exocyclic methylene groups; the C(13)···C(16) distance is 2.46 Å ,and the tilt of the C=O bond with respect to the C=C bond is 62°.

The packing diagrams of the crystal viewed along the a and b axes are shown in Figs. 5 and 6 respectively. The intermolecular distances are listed in Table 7.

All the C···C intermolecular distances can be considered to be normal: only four of them are shorter than 4 Å, the shortest being 3.42 Å of the C(sp^3)···C(sp^2) approach shown in Fig. 5. The closest C···O distance is 3.32 Å ,while the Br^-···C distances are all larger than 3.67 Å. The close Br^-···O and O···O approaches are also given in Fig. 5, suggesting that the hydrogen bonds may play an important role in the packing. The shortest N^+···Br^- distance is 5.09 Å, which might indicate no simple cation-anion interaction in the crystal structure.

The authors are grateful to Professor Yoshiyuki Ichinohe for supplying the sample and for his helpful discussions, and to Dr. Tsukasa Iwadare for his continued encouragement. Thanks are also due to Miss Makiko Yamaguchi for her assistance.

The Extraction of the Cesium Ion with Some Nitrophenols into Nitrobenzene. II. Homoconjugation Studies by Means of Conductivity Measurements

Osamu TOCHIYAMA,* Mutsuo KOYAMA, and Taitiro FUJINAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

**Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki-aza-aoba, Sendai*

(Received December 19, 1970)

In connection with the liquid-liquid extraction study of alkali metal nitrophenolates, ionic equilibria taking place in the systems were studied by means of conductivity and solubility measurements. It was revealed that the adduct formation of *p*- and *m*-nitrophenolates consisted of homoconjugation, that is, free nitrophenols are attached not to cations, but to the nitrophenolate anions, thus forming the larger anions and being stabilized in the organic phase. Homoconjugation constants of the nitrophenolates, which are independent of the cations present, were measured. The difference in extraction behaviors was interpreted in terms of the solubilities in both aqueous and organic phases and in terms of the homoconjugation constants.

In the previous paper,[1] it was demonstrated that the process of extracting cesium as nitrophenolates could be interpreted in terms of the dissociation of cesium phenolates and in terms of conjugation or adduct formation with free nitrophenols in the nitrobenzene phase. In that study, the interpretation was based on the fact that the experimental data agreed well with the equations which were postulated; no direct evidence has been given for the existence of dissociated forms of extracted species in the nitrobenzene phase. Besides, no confirmation was possible whether anions or cations participate with free nitrophenol molecules.

Kolthoff *et al.*[2-4] have demonstrated a method of estimating anion conjugation constants, in which the solubility product of the slightly soluble salt and the total ionic solubility were measured in the presence of varying concentrations of conjugating reagents.

In the present study, the method[2-4] was applied in order to clarify the ionic equilibria in the organic phase. As a result, it was found that the mono-nitrophenols are conjugated with anions present in the organic phase, whereas di- and tri-nitrophenols are less conjugated, in this order. The conjugation constants and solubilities of several salts in both organic and aqueous phases were determined. The extraction mechanisms and the participation of the solvent are discussed.

Experimental

Reagents. The alkali nitrophenolates were prepared by adding a slight excess of the alkali hydroxide to aqueous solutions of nitrophenols, concentrating the resulting solutions with a rotary evaporator, filtering off the precipitates, and recrystallizing them from acetone or ethanol solutions. The precipitates were dried for about an hour at 50°C *in vacuo* and then stored in a silica-gel desiccator. Nitrophenols and alkali hydroxides used were of reagent grade purity. The nitrobenzene was prepared by vacuum-distilling special-grade nitrobenzene. Titration with Karl-Fisher reagent using dead-stop indication showed a water content of 0.0035 wt% in the nitrobenzene. The nitrobenzene had a specific conductance of *ca.* 4×10^{-9}.

Apparatus. The conductivity measurements were performed in a glass cell equipped with platinized platinum electrodes by the use of a universal bridge, Type BV-Z-13B, supplied by Yokogawa Electric Works, Ltd. During the measurements, the temperature of the cell was controlled at 25 ± 1°C in a thermostat.

Procedure. The ionic mobility of cesium picrate in nitrobenzene was measured by dissolving a standard cesium picrate solution with nitrobenzene; because of the slight solubility, the concentration of the standard solution was of the order of 10^{-4} M (see Fig. 1).

The ionic mobilities of cesium *p*-nitrophenolate (*p*-NP(Cs)), cesium *m*-nitrophenolate (*m*-NP(Cs)), cesium *o*-nitrophenolate (*o*-NP(Cs)), and cesium 2,4-dinitrophenolate (α-DNP(Cs)) were measured in nitrobenzene in the presence of 0.1 M nitrophenol; the salt was dissolved in a 0.1 M nitrophenol solution and diluted with a 0.1 M nitrophenol solution.

The conductivity measurements of a saturated solution in the presence of nitrophenols were carried out as follows; 100—200 mg of salt, which had previously been washed with nitrobenzene, were introduced into the conductivity cell, 10 m*l* of nitrobenzene were added, and the conductance was measured. The nitrophenol dissolved in nitrobenzene was added from a microsyringe, and after each addition of the reagent, the cell and the contents were shaken until the conductance remained constant within a 1% deviation.

The solubilities of nitrophenolates in distilled water were obtained by the use of ^{137}Cs; a labeled salt was saturated in water at 25 ± 1°C, and the concentration was determined by measuring the γ-ray activities of ^{137}Cs.

Theoretical

(1) Dissociation of Cesium Nitrophenolates in Nitrobenzene. The dissociation of cesium nitrophenolates was ascertained by plotting the equivalent conductances, Λ, against the square roots of the concentration, C, of cesium nitrophenolates.

The relation between λ and $\sqrt{C}$ can be represented by the following expression:[5]

5) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolyte Solutions," Reinhold Publishing Corporation, New York, N.Y., (1958) pp. 164, 178, 286.

$$\Lambda = \Lambda^0 - (B_1 \cdot \Lambda^0 + B_2)\frac{\sqrt{\alpha C}}{1 + B\mathring{a}\sqrt{\alpha C}} \quad (1)$$

where B_1, B_2, and B are the constants for the solvent; α, the degree of the dissociation; C, the concentration, and $\mathring{a}$, the distance of the approach of the ions in angstrom units.

The dissociation constants of the salts were obtained by the method of Shedlovsky.[5]

(2) Homoconjugation of Nitrophenolate Anions. If the chemical form of the species is a free ion in the solvent, the method reported by Kolthoff can be employed to determine the degree of the dissociation and participation of the nitrophenol in nitrobenzene.

The solubility product, $K_{sp,o}$, in nitrobenzene is obtained by measuring the conductivity of the saturated solution of the one-to-one salt MOR:

$$K_{sp,o} = [M^+]_o[OR^-]_o \cdot f^2 \quad f = f_{M^+} = f_{OR^-} \quad (2)$$

where f is the activity coefficient. When free nitrophenol ROH is added to this solution, the homoconjugation of the anion occurs and the new equilibrium represented below must be considered:

$$(OR^-)_o + n(ROH)_o = (OR \cdot nROH^-)_o \quad (3)$$

$$K_n^f = \frac{[OR \cdot nROH^-]_o}{[OR^-]_o[ROH]_o^n} \qquad f_{OR^-} = f_{OR \cdot nROH^-} \quad (4)$$

The shifts of the equilibrium to the right direction cause a rise in the solubility of the cesium ion, according to the demands of the electrical neutrality relation:

$$\begin{aligned}[M^+]_o &= [OR^-]_o + [OR \cdot ROH^-]_o \\ &\quad + [OR \cdot 2ROH^-]_o + \cdots \\ &= [OR^-]_o(1 + \sum_n K_n^f[ROH]_o^n) \end{aligned} \quad (5)$$

Supposing that $K_{sp,o}$ is constant over the concentration range of the nitrophenol examined, the next expression can be obtained:

$$\begin{aligned} f^2[M^+]_o^2/K_{sp,o} &= 1 + K_1^f[ROH]_o \\ &\quad + K_2^f[ROH]_o^2 + \cdots \end{aligned} \quad (6)$$

This expression means that homoconjugation constants can be estimated from the plots of $f^2[M^+]_o^2/K_{sp,o}$ against $[ROH]_o$.

In the application of Eq. (6), the following assumptions have to be made:

(i) Nitrophenol is considered monomeric, and the activity of nitrophenol is taken to be equal to the equilibrium concentration; this assumption was verified previously by the results of the distribution studies of nitrophenols.[1]

(ii) Only the unconjugated salt MOR is present in the solid phase, and the solubility product, $K_{sp,o}$, is considered to be constant. The water in the salt and nitrobenzene has little effect on the $f^2[M]_o^2/K_{sp,o}$ value.

(iii) The independent anion conjugation of the nitrophenol is assumed; that is the K_n^f values of anions are independent of the nature of the cations. This assumption was ascertained by the experiments shown in Fig. 3.

(iv) The limiting Debye-Hückel relation was used to evaluate ionic activity coefficients:[5]

$$\log f_\pm = -A|z_+||z_-|\sqrt{I} \quad (7)$$

$$A = \frac{1.8246 \times 10^6}{(DT)^{3/2}} \quad (8)$$

where D: dielectric constant of nitrobenzene (34.5)

T: Kelvin temperature (273+25)

$|Z_+||Z_-|$: magnitudes of valences of ions (1)

I: ionic strength

(v) The limiting equivalent conductances of the anions, $(OR^-)_o$, $(OR \cdot ROH^-)_o$, and $(OR \cdot 2ROH^-)_o$, are assumed to be equal to the value obtained from Fig. 1. In fact, $\Lambda^0_{OR^-}$, $\Lambda^0_{OR \cdot ROH^-}$, and $\Lambda^0_{OR \cdot 2ROH^-}$ are not equal and the obtained value are mixtures of these values. If, however, $[ROH]_o$ is constant in Eqs. (4) and (5), the ratio of $(OR^-)_o$, $(OR \cdot ROH^-)_o$, and $(OR \cdot 2ROH^-)_o$ remains constant. Therefore, the experimental value can be used in place of each equivalent conductance unless the values, $\Lambda^0_{OR^-}$, $\Lambda^0_{OR \cdot ROH^-}$, and $\Lambda^0_{OR \cdot 2ROH^-}$ differ too much from each other.

(vi) In order to calculate the true conjugation constants, the following mathematical treatments have been made.

First, the relationship between $f^2[M^+]_o^2/K_{sp,o}$ and the total concentration of added nitrophenol, $[ROH]_t$, is obtained experimentally.

Then the relationship between $[ROH]_t$ and $[ROH]_o$ described below is used for the calculation of the concentration, $[ROH]_o$, of free nitrophenol.

$$\begin{aligned}[ROH]_t &= [ROH]_o + [OR \cdot ROH^-]_o \\ &\quad + 2[OR \cdot 2ROH^-]_o + \cdots \\ &= [ROH]_o + [OR^-]_o \sum_n n K_n^f [ROH]_o^n \end{aligned} \quad (9)$$

As the first approximation, the values of K_n^f are estimated from Eq. (6), assuming that $[ROH]_t$ is equal to $[ROH]_o$. By using the K_n^f value thus obtained, $[ROH]_o$ can be calculated according to Eq. (9). The new relationship between $f^2[M^+]_o^2/K_{sp,o}$ and the calculated $[ROH]_o$ gives improved K_n^f values. This procedure was repeated until the calculated value settles to give a converged curve which can be taken to represent a true $f^2[M^+]_o^2/K_{sp,o}$ against $[ROH]_o$.

Results and Discussion

(1) Dissociation of Cesium Nitrophenolates in Nitrobenzene. The relationships between the equivalent conductance and the square root of the concentration of cesium nitrophenolates are shown in Fig. 1. In the experiment, cesium nitrophenolates were dissolved and diluted in a 0.1M free nitrophenol solution except in the case of cesium picrate. When the concentration of a dissolved salt is quite small compared with that of 0.1M free nitrophenol, $[ROH]_o$ can be considered to be constant in Eq. (6).

This means that the ratio of the free anion $(OR^-)_o$ and the conjugated anions $(OR \cdot nROH^-)_o$ is constant in the experiment. Under these conditions, the limiting conductances, Λ^0, were estimated by the following relationship:[5]

$$\Lambda = \Lambda^0 - A\sqrt{C}, \quad (1')$$

The results are shown in Table 1.

In the case of cesium picrate, no picric acid was added in nitrobenzene, and the dissociation constant

PA(H)	7.4[7]	23.0[8]	

was determined from the results to be $pK_o=2.2$. This value is compared with the dissociation constants of other alkali picrates given by Kraus.[6] In Fig. 1, the Λ *vs.* $\sqrt{C}$ plots of cesium *p*-nitrophenolate, cesium *m*-nitrophenolate, and cesium α-dinitrophenolate present fairly gentle slopes. This may perhaps be attributed to the formation of larger conjugated anions, thus giving the larger $\mathring{a}$ value in Eq. (1).

The dissociation of all cesium salts in nitrobenzene can be concluded from these data.

(2) Homoconjugations of Nitrophenolate Anions. Plots of $f^2[M^+]_o^2/K_{sp,o}$ *vs.* $[ROH]_o$ on a logarithmic scale are presented in Figs. 2 and 3, where f is the activity coefficient of the dissociated metal ions in nitrobenzene. $[ROH]_o$ is the concentration of the added nitrophenol minus the concentration of the conjugated

nitrophenol. $K_{sp,o}$ represents the solubility product, which was calculated from the conductance of the saturated solution and the limiting equivalent conductance. The $K_{sp,o}$ values of metal nitrophenolates were calculated on the assumption that the Λ^0 value of metal nitrophenolates were equal to those of cesium nitrophenolates. The $K_{sp,o}$ values and homoconjugation constants obtained from Figs. 2 and 3 are summarized in Table 2. The results shown in the table give some suggestions for extraction studies; the $K_{sp,o}$ values increase in the order Na<K<Cs in any nitrophenolate. This difference is the cause of the difference in the distribution behavior. On the contrary, the values do not differ much among cesium nitrophenol-

ates of different kinds. Only cesium *o*-nitrophenolate gives a little smaller value. This similarity must be caused by the fact that nitrobenzene is a basic solvent and, therefore, combines with cations, but not with anions.

A bare anion which has a localized charge can be stabilized by homoconjugation. Figure 3 shows that the degree of the conjugation is independent of the species of cations.

This fact demonstrates that only the anion conjugation expressed by Eq. (4) takes place preferentially and that free nitrophenols have little capability of interacting with cations in nitrobenzene. In Table 2, it is shown that *p*-and *m*-nitrophenols have homoconjugation constants of considerable extents. *Ortho*-substituted phenols are, however, poor hydrogen-bond donors and form only monoconjugates $(OR\cdot ROH^-)_o$, whereas *p*- and *m*-nitrophenols can form higher conjugates, *e.g.*, $(OR\cdot 2ROH^-)_o$. This seems to be the main reason why there is less possibility of extracting cesium with *o*-nitrophenol.

(3) A Comparison of Solubility Measurements with Extraction Studies. Cesium nitrophenolates which are present as one-to-one salts are not extracted appreciably into nitrobenzene except in the case of cesium picrate, as is reported previously.[1] In the expression of the extraction of cesium:

$$D_{Cs} = K_{Cs}^{*1/2}(1+\sum_n K_n^f[ROH]_o^n)^{1/2}\frac{[OR^-]_a^{1/2}}{[Cs^+]_a^{1/2}} \quad (10)$$

n was obtained from the slope of log D_{Cs} *vs.* log $[ROH]_{total}$, and $K_{Cs}^* K_n^f$ was also calculated as the extraction constant.

These values are shown in Table 3. It was also shown in the previous paper that cesium ions are extracted to a considerable extent with picric acid or α-dinitrophenol, whereas the conductivity experiments have shown that both have small K_n^f values and that

9) W. M. Fischer, *J. Physik. Chem.*, **92**, 581 (1918).

their cesium salts show values of $K_{sp,o}$ similar to those of other nitrophenolates.

These facts imply that cesium picrate and cesium α-dinitrophenolate have a very small solubility in water if the distribution equilibria are determined solely according to the ratio of the solubilities of the solutes in both organic and aqueous solutions. In Table 2, the solubilities, S_a, of sodium or cesium nitrophenolates in water are shown. The S_a values of cesium salts were obtained by the use of ^{137}Cs, while those of sodium salts were taken from the literature.[9]

From the solubility and conjugation data, the extraction constants can be estimated according to the following equation.

$$K_M^{**} = S_o^2/S_a^2,\ S_o^2 = K_{sp,o}/f^2 \quad (11)$$

Table 4. Calculated distribution coefficients and exchange constans

		p-NP	α-DTP	PA
K_{Cs}^{**}	$n=0$	2.7×10^{-7}	8.1×10^{-5}	2.3×10^{-3}
K_{Na}^{**}		9.0×10^{-10}	2.8×10^{-9}	3.0×10^{-7}
$K_{Cs}^{**}K_n^f$	$n=1$	—	1.9×10^{-2}	—
	$n=2$	1.4	—	—
K_{Cs}^{**}/K_{Na}^{**}		3.0×10^{2}	2.9×10^{4}	7.7×10^{3}

The values of K_{Cs}^{**}, $K_{Cs}^{**}K_n^f$, K_{Na}^{**}, and K_{Cs}^{**}/K_{Na}^{**} which are the constants calculated from the solubility and conjugation data, are shown in Table 4. These values can be compared with those shown in Table 3, which were obtained from the extraction studies. In the case of *p*-nitrophenol, only $K_{Cs}^* K_2^f$ ($n=2$) can be obtained from the extraction studies, while in the cases of α-dinitrophenol and picric acid, both $K_{Cs}^* K_1^f$ ($n=1$) and K_{Cs}^* ($n=0$) were obtained from the data when the pH was small and when the pH was very large ($[ROH]_o=0$), respectively. In Tables 3 and 4, K_{Cs}^* and K_{Cs}^{**}, $K_{Cs}^* K_n^f$ and $K_{Cs}^{**}K_n^f$, are in good agreement. For example, in the case of α-dinitrophenol, K_{Cs}^* was obtained as 4.7×10^{-5} from the extraction study when the pH was very large. This value is in fairly good agreement with the value of $K_{Cs}^{**}=8.1\times10^{-5}$ obtained as the square of the ratio of the solubilities of one-to-one cesium α-dinitrophenolate in the organic and aqueous phases.

When the pH was quite small, $K_{Cs}^* K_1^f$ was obtained as 1.6×10^{-2}. This value indicates the distribution constant of one-to-two cesium α-dinitrophenolate CsORROH; the value is also in good agreement with

$K^{**}_{Cs}K^{f}_{1}=1.9\times10^{-2}$, which is the product of $K^{**}_{Cs}=8.1\times10^{-5}$ and $K^{f}_{1}=2.4\times10^{2}$. These facts suggest that water molecules distributed in the nitrobenzene phase have little effect on the distribution of cesium ions. The K^{*}_{Cs}/K^{*}_{Na} values and K^{**}_{Cs}/K^{**}_{Na} values are different in the cases of *p*-nitrophenol and α-dinitrophenol. This disagreement may be attributed to the difference between K^{*}_{Na} and K^{**}_{Na}; the fairly high solubility of sodium salt in water and the very slight solubility of the salt in nitrobenzene seem to have given unsatisfactory data; the extracted water in nitrobenzene affects the solubility seriously.

The agreement of extraction constants and of the *n* value obtained from the extraction experiments with those obtained from the conductivity measurements indicates that Eq. (10) and Eq. (6) are equally meaningful and correlate with each other. Therefore, it must be emphasized that both methods offer equivalent information about the chemical interaction in organic solvents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3032—3035 (1971)

Anomalous Gas Chromatogram Due to the Oxidation of Porous Polymer Beads by a Sample Containing Oxygen Gas

Reisuke SODA

National Institute of Industiral Health, Kizukisumiyoshi, Kawasaki

(Received March 29, 1971)

By the gas-chromatographic analysis of the organic vapor in the air by means of a Porapak column, a broad peak accompanied by long tailing was observed at column temperatures above a certain value with a flame-ionization or an electron-capture detector. The cause of that peak was investigated using various gases and columns by changing the column temperature. The conclusion was that oxygen in air reacted with polymer beads even at temperatures lower than that cited in the catalogue as temerature to be employed, and the reaction products gave the anomalous broad peaks. The reaction was considered to consist of the oxygenation of polymer beads to produce carbon monoxide, carbon dioxide, formic acid, and the other organic compounds. For Porapak Q and P, the maximum temperature which can be used in safety may be 120°C for an analysis of a sample which consists in greater part of air.

In the field of occupational health, the analysis of toxic gases in very low concentrations is necessary in order to estimate the contamination of the ambient air by the gases, and many analytical methods have been developed. Of these methods, gas chromatography is one of the most reliable and useful methods.[1-6] For the analysis of relatively higher concentrations of toxic gases in the air, a gas sampler attached to a gas chromatograph can be used to introduce the sample air directly into the column. For example, 1 m*l* of air which contains 1 ppm of benzene is sufficient to obtain a satisfactory chromatogram with an ordinary flame-ionization detector. A Porapak column is suitable for the analysis of those samples.[7] Furthermore, the characteristics of columns are not weakened, for no stationary liquid phase is used. Stationary liquid frequently is eluted, even if very slowly, and causes noise.[8] Therefore, a Porapak column is very useful for an analysis of gases in the ambient air in an industrial environment and in the atmosphere.

By the practical use of a Porapak column for the analysis of gases in the air, sometimes an anomalous broad peak has been observed, and it has interfered with the other peaks of the minor components to be determined. For instance, in a sample of organic solvent vapors in the air, a satisfactory chromatogram has been observed at relatively lower temperatures, but with a rise in the temperature an anomalous broad peak has been found, as is shown in Fig. 1. With a Porapak Q column, a few ppm of hexane present in the air has shown a good chromatogram with a clear peak at a column temperature of 132°C. However, for the xylene air sample a broad peak has followed the xylene peak at 183°C. That broad peak has appeared under those experimental conditions at temperatures higher than 160°C and has been enhanced with an increase in the column temperature.

The cause of that broad peak has been investigated in order to avoid such an unfavorable phenomena.

Experimental

Materials. The gases used were nitrogen, carbon monoxide, air, and oxygen, all of which were supplied from a gas cylinder without any purification except in special cases, when air was purified by several methods. The

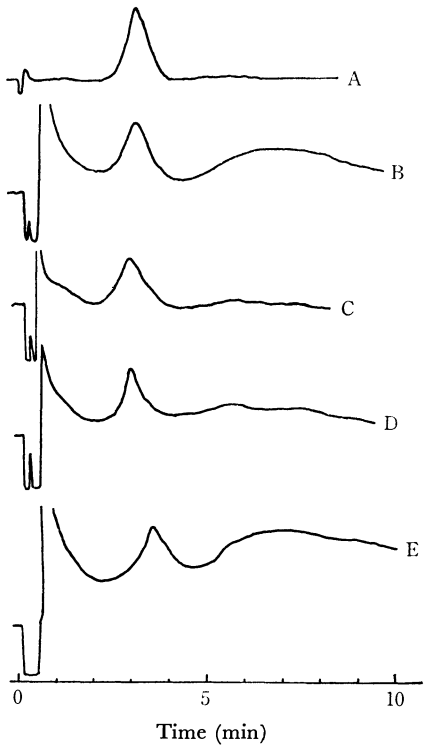

Fig. 1. Gas chromatogram of organic solvent vapor in the air by Porapak Q column of 1/8 in (o.d.) with flame ionization detector.

Flow rate of carrier gas was 30 m*l*/min and volume of gas sampler 4 m*l*.

Samples and column temperatures were with (1) column length of 47 cm, (A) *n*-hexane and 132°C; and (B) *o*-xylene and 183°C; with (2) column of 3 ft, (C) 2,3-dimethyl butane and 164°C; (D) benzene and 174°C; and (E) toluene and 192°C, respectively.

polymer beads were Porapak P and Q (50 to 80 mesh) of Water Associates Co.

Gas Chromatograph. Two types of gas chromatographs were used in the present experiment. The main experiment on the oxygen effect on the column was carried out by means of an Ohkura gas chromatograph Model 6000 equipped with a flame-ionization detector. The column used was made of U-shaped stainless steel tubing. The sample was injected into a chromatograph with an automatic gas sampler (1 m*l*), the temperature of which was regulated at 60°C. A few chromatograms were obtained by means of a Perkin Elmer Model 800 Vapor Fractometer equipped with a dual flame-ionization detector or an electron-capture detector. The column used consisted of coiled stainless steel tubing. The volume of the gas sampler was 4 m*l*. The latter instrument was also used to analyze the pyrolytic products of Porapak P and Q. The column was washed with hydrochloric acid and water, and then dried by nitrogen flushing. Polymer beads were packed into the column by means of a vibrator.

Infrared Spectrometer. A Hitachi EPI G 2 infrared spectrometer was equipped with a 10-cm gas cell and used to identify the gaseous components of pyrolytic products.

Differential Thermal Analysis. The differential thermal analysis and thermogravimetric analysis of polymer beads were done by means of a Rigakudenki DTA, compact-type TGA thermoflex. The temperature was programmed from room temperature to about 500°C at the rate of 5°C/min. For each polymer beads, one curve was observed in a nitrogen-gas flow environment and another in an air flow in the same temperature range.

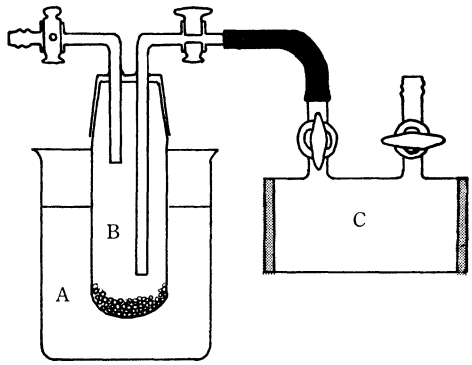

Fig. 2. Schematic diagram of vessel for pyrolysis and sampling of products in a gas cell.

A, Silicone oil bath; B, Vessel for pyrolysis of polymer beads; C, Infrared gas cell.

Analysis. Polymer beads were pyrolyzed in the specially-prepared vessel shown in Fig. 2. The vessel was immersed in an oil bath heated at from 190 to 210°C. The gaseous product in the vessel was introduced into a infrared gas cell which had previously been evacuated at 1 mmHg. The product was also collected in a 10-m*l* hypodermic syringe in order to be introduced into the gas sampler of the gas chromatograph. In this case, the column temperature was maintained at about 120°C, because below 120°C the anomalous chromatogram was not observed by means of a Porapak column.

Results

Any sample the major component of which was air showed an anomalous chromatogram with a highly sensitive detector like a flame ionization or an electron capture at column temperatures above a certain limiting value. As a chromatogram obtained with a flame ionization detector was similar to that obtained with an electron capture detector at the column temperature of 170°C, this paper summarized the results obtained with a flame ionization detector. Air was introduced only into the gas chromatograph with a gas sampler, and chromatograms were taken at various column temperatures. The experimental results are summarized in Fig. 3 for the Porapak Q and P columns. Chromatograms of column temperatures lower than about 140°C did not show any anomalous peaks. For the Porapak Q column, above 170°C broad and long tailed peaks were observed, while for Porapak P above 160°C a large and broad peak with a long tail was observed. If those peaks were caused by a pressure drop or by some other shock of the sampling process, similar phenomena might be observed upon the use of nitrogen gas through a gas sampler. However, that possibility can be excluded on the basis of Fig. 4, where the chromatogram of nitrogen gas shows a little peak with a short interval by injection and no other large or broad peaks appeared. It was considered reasonable that no impurity in the sample or contaminant in the gas sampler caused the anomalous chromatogram, because inactive gases, like nitrogen or carbon monoxide, did not show a broad peak and the braod peak with the air sample could not be removed by the purification of the air.

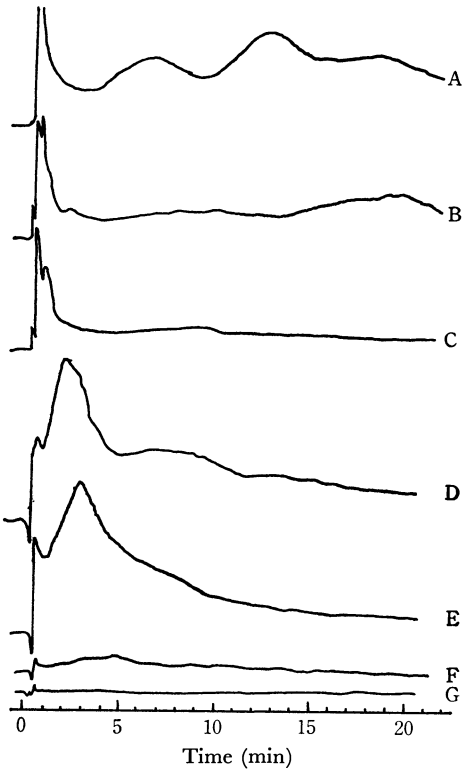

Fig. 3. Anomalous chromatogram by air and column temperature.

Porapak Q column of 6 mm (o.d.) and 200 cm (length) was used for (A), (B), and (C), and Porapak P column of 6 mm and 150 cm for the others. Volume of the gas sampler was 1 m*l*. Column temperature and carrier flow rate were, (A) 182°C and 50 m*l*/min; (B) 170°C and 48 m*l*/min; (C) 137°C and 45 m*l*/min; (D) 180°C and 62 m*l*/min; (E) 164°C and 46 m*l*/min; (F) 144°C and 52 m*l*/min; and (G) 122°C and 48 m*l*/min, respectively.

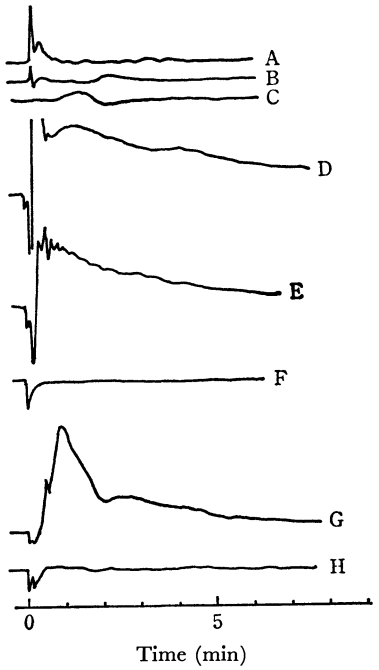

Fig. 4. Chromatograms of a few kinds of gases by Porapak P column, and gas sampler of 1 m*l*.

Column temperature, column size and carrier flow rate were; (1) 116°C, 6 mm (o.d.) and 50 cm (length), and 36 m*l*/min, respectively for samples of (A) oxygen, (B) air, and (C) nitrogen; (2) 170°C, 1/8 in and 6 ft, and 30 m*l*/min, respectively for samples of (D) oxygen, (E) air, and (F) nitrogen; (3) 192°C, 6 mm and 150 cm, and 47 m*l*/min, respectively for samples of (G) air and (H) nitrogen.

The main components of air are oxygen and nitrogen. The former reacts possibly with polymer beads to cause an anomalous broad peak. In fact, the peak with an air sample was enhanced by oxygen at 170°C, as is shown in Fig. 4. The anomalous chromatogram was considered to be due to the pyrolytic product of the polymer beads in the column produced by oxygen at higher temperatures, as organic acid, aldehydes and degraded compounds. The elution of those products could be changed by connecting the Porapak column and another column, like an active carbon, a molecular-sieve, or a silica gel column, in series. The connection of those columns before the Porapak column did not produce any chromatogram different from that produced by the Porapak column only, but in connection after the Porapak column, the active carbon column did not show any detectable broad peaks in the present experiment, and the molecular sieve column greatly delayed the elution of the main broad peaks.

In order to confirm the above estimation, polymer beads were pyrolyzed and the product was analyzed. The temperature at which polymer beads were pyrolyzed was determined by a DTA experiment. By the DTA of a sample in a nitrogen atmosphere, the degradation or decomposition started about 250°C for Porapak Q and about 230°C for Porapak P. However, in oxygen or air the decomposition was observed above 160°C for both polymers. The DTA curve passed a maximum near 210°C. Therefore the pyrolysis was carried out at from 190 to 210°C, and the gaseous product was analyzed by gas chromatography and infrared spectrometry. The infrared spectrum is shown in Fig. 5. The spectrum showed bands of water near 3800, 1600, and 600 cm^{-1}, bands of carbon dioxide near 3800, 2350, and 660 cm^{-1}, band of carbon monoxide near 2100 cm^{-1}, and bands of formic acid near 1780, 1100, and 630 cm^{-1}. Peaks of other many components were observed by gas chromatography, as is shown in Fig. 6. At present, not each component has been identified gas-chromatographically.

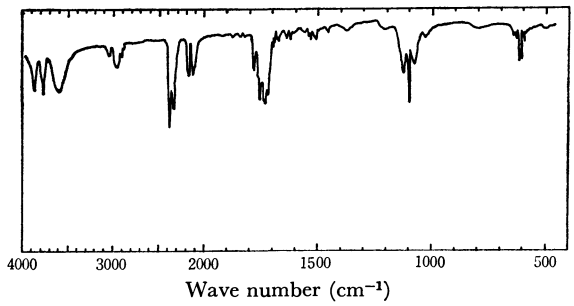

Fig. 5. Infrared spectrum of gaseous product from pyrolysis of Porapak Q.

Temperature of pyrolysis was 210°C.

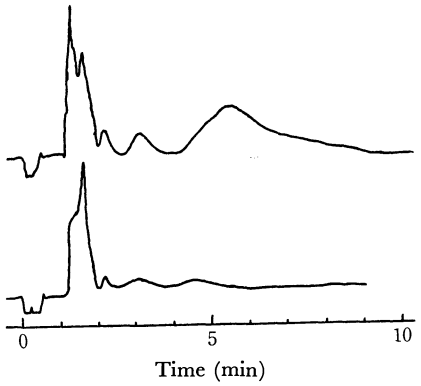

Fig. 6. Chromatograms of gaseous product by pyrolysis of polymer beads at 195°C.

Porapak Q column of 1/8 in (o.d.) and 3 ft (length) was used at 125°C. Flow rate of carrier gas was 30 m*l*/min and volume of gas sampler 4 m*l*. Flame ionization detector was used.

Upper chromatogram was observed with gaseous product of pyrolysis of Porapak P and lower with Porapak Q.

Discussion

An anomalous chromatogram of a sample containing air has been observed with a Porapak column at temperatures higher than about 160°C. Considering the cause of the chromatogram in the basis of the experimental results, it is deduced that the oxygen in the air reacts with polymer beads. Some of the reaction products (mainly oxides) may be identified as carbon monoxide, carbon dioxide, formic acid and other oxidized organic compounds. The Porapak column is stable below the temperature cited in the catalogue only when an inactive carrier gas is used. However, if a sample contains more air or oxygen gas than the components to be analyzed, the chromatogram inevitably produces an anomalous broad peak with a long tailing at temperatures which do not exceed the maximum temperature cited in the catalogue as stable.[9] That chromatogram is not successful for use in determining minor components because of the interference of the broad peak.

Barta and Gordon have reported that Porapak Q has active sites which caused an exchange of hydrogen in ketones.[10] Active sites may also possibly react with oxygen to produce the pyrolytic compounds.

At present not all substances produced by pyrolysis have been identified and experiments are easy in only a few cases. Nevertheless, several significant pieces of information can be obtained from the results. Below 120°C, Porapak P and Q columns apparently do not react with oxygen and no anomalous chromatogram is found. More precisely, the temperature limit of no anomalous peak may be 130°C for the Porapak Q column and 120°C for the Porapak P column, both column materials of 50 to 80 mesh.

The cause of the anomalous peak is apparently the reaction of the polymer beads in the column with oxygen. Several procedures are considered to avoid such unfavorable chromatograms, which frequently interfere with the peak to be observed. These considerations are necessary in making an analysis to monitor the concentration of gas in the air continuously. One procedure is a temperature programming, *i.e.*, air passes through the column at a lower temperature, 120°C or so, and then the temperature is raised at a suitable rate. This temperature programming procedure may avoid the effect of oxygen on the chromatogram when the Porapak column is used. Another method is to make the column shorter. When the particular components to be analyzed are one or two, and when their retention times are far from those of the other peaks, it is possible to make the column shorter than that used usually for the analysis of a sample containing many components, and the column temperature can be lowered. Figure 1 shows one example. When the Porapak Q column 3 ft long is used, the retention time of 2,3-dimethylbutane is about 3 min when the temperature is 164°C and the carrier gas flow rate is 30 m*l*/min. However, the present results show that the retention time becomes shorter (2.6 min) with the 47-cm column at 132°C, and the separation of the peaks is sufficient. By lowering the column temperature with shorter column, it is thus possible to suppress the anomalous chromatogram.

The process of concentrating a sample in the air may also preclude those effects of oxygen on the chromatogram, but the process is rather complicated compared with the direct analysis of the air without any concentration procedures. Furthermore, the procedure of concentrating the samples to be determined involves several problems, such as the efficiency of concentration for each component, the contamination of the sampling apparatus, and the recovery process of the collected compounds.[3-6]

Hot-atom Chemistry of Cobalt-60 Atoms in Neutron Irradiated Organic Solutions of Tris(acetylacetonato)cobalt(III)

Takeshi TOMINAGA, Takuhiko SAKAI, and Kitao FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received April 15, 1971)

Thermal neutron irradiation has been carried out on the solutions of tris(acetylacetonato)cobalt(III) in benzene, ethanol, acetone and acetic acid containing various additives such as metallic salts and mineral acids. The ^{60}Co retention in the irradiated solutions has been found to decrease sharply with the increase in the concentration of various metallic salts. This indicates that the thermal diffusive reactions which contribute greatly to the apparent retention in the irradiated solutions can be suppressed by the addition of adequate metallic salts as scavengers. Salts of the metals which can form more stable complexes with acetylacetone (*i.e.*, Fe(III), Cu(II), Al(III), *etc.*) work as more effective scavengers in these systems. The upper limit for the primary retention of tris(acetylacetonato)cobalt(III) in the benzene solutions has been estimated as $0.00\pm0.02\%$. The use of adequate scavengers appears to be a useful technique to determine the primary retention in the irradiated solution systems. The ^{60}Co retention of the solid complex irradiated at dry ice temperature was 1.4—1.5% irrespective of the organic solvents used for dissolution if they contain ferric chloride, while it increased to 2.0% in the absence of the scavenger.

While a lot of detailed works have been made on the recoil and subsequent reactions of metal complexes in solid state, only a few studies have been reported for such reactions in solutions of these compounds.[1-5]

In 1970 we initiated a systematic study to irradiate the organic solutions of metal complexes with thermal neutrons in order to elucidate the mechanism of hot-atom reactions in these systems.[6] Our results on the irradiated benzene solutions of tris(acetylacetonato) cobalt(III)[7] indicated that the thermal diffusive reactions in the irradiated solutions could be suppressed effectively by the addition of ferric chloride as scavenger for free acetylacetone. Since the addition of scavengers appears to be a useful technique for investigating the hot-atom chemistry of complexes in solutions, we have studied the influence of various scavengers and solvents in more detail. This paper deals with our recent data on the ^{60}Co hot-atom reactions and the scavenger effect in the neutron irradiated solutions of tris(acetylacetonato)cobalt(III) in organic solvents.

Experimental

Reagents. Tris(acetylacetonato)cobalt(III), $Co(acac)_3$, was prepared as described in literature.[8] This was further purified by repeating recrystallization from acetone. Found: C, 50.6%; H, 5.71%. Calcd for $Co(C_5H_7O_2)_3$: C, 50.6%; H, 5.94%.

All the solvents and scavengers (metallic salts, acids, *etc.*) used in the experiments were purchased from Wako Pure Chemical Industries Ltd. as of G.R. grade.

Preparation of $Co(acac)_3$ Organic Solutions with Scavengers. Various $Co(acac)_3$ solutions containing scavengers were prepared for neutron irradiation.

Benzene Solutions: $Co(acac)_3$ benzene solutions containing anhydrous $FeCl_3$ were prepared by simply adding various amounts of $FeCl_3$ to $Co(acac)_3$ benzene solutions. To prepare $Co(acac)_3$ benzene solutions containing other metallic salts or inorganic acids as scavengers, various amounts of the scavengers were dissolved first in ethanol and then they were added to $Co(acac)_3$ benzene solutions so that the resulting solutions contained 10% by volume of ethanol.[9] To investigate the influence of the other organic solvents as additives, they were directly added to $Co(acac)_3$ benzene solutions.

Ethanol, Acetone and Acetic Acid Solutions: Ferric chloride, $FeCl_3\cdot6H_2O$, was added directly to the solutions of $Co(acac)_3$ in ethanol, acetone or acetic acid.

Neutron Irradiation. About 1 m*l* each of the $Co(acac)_3$ organic solutions was placed in a quartz tube with a Teflon stopper and irradiated with slow neutrons for 5 min at room temperature in the rotary specimen rack of a TRIGA Mark II reactor at Rikkyo University. Thermal neutron flux was 5×10^{11} n/cm^2·sec. The accompanying γ dose was 7×10^4R. The solutions were frozen 15—20 min after the completion of the irradiation and stored in dry ice for 2—3 hr before chemical separation.

For making a comparison with the solution systems, solid $Co(acac)_3$ samples were irradiated for 5 min at dry ice or room temperature. After the irradiation they were stored in dry ice until chemical separation.

Chemical Separation. The solvent extraction method was mainly employed in chemical separation of the irradiated complex in order to determine the ^{60}Co retention.[10]

Solutions: One milliliter of the irradiated organic solutions

9) The scanvenger-free $Co(acac)_3$ solutions also contained 10% of ethanol. It was confirmed that the scavenger effect of metallic salts and acids was not affected by the presence of about 10% of ethanol in the benzene solutions.

10) The retention obtained corresponds to the percentage of the ^{60}Co activity retained in the form of $Co(acac)_3$.

was diluted to 5 m*l* with benzene and extracted with three 5-m*l* portions of 3% EDTA aqueous solution containing 0.8% sodium potassium tartrate and 10 mg of $CoSO_4 \cdot 7H_2O$ as carrier. On mixing with Co^{2+} carrier and EDTA aqueous solution, all the ^{60}Co-labeled species other than $^{60}Co(acac)_3$ are extracted into the aqueous phase, whereas only $^{60}Co(acac)_3$ remains in the organic phase.[11] For the irradiated solutions of $Co(acac)_3$ in ethanol, acetone, or acetic acid, the ion exchange method was also used for the purpose of comparison: after being mixed with water containing Co^{2+} carrier, the irradiated solution was passed through a cation exchange column. The effluent contains only the neutral ^{60}Co-labeled species which does not exchange with Co^{2+} (*i.e.*, $^{60}Co(acac)_3$). Since the radiochemical yield of the neutral fraction by the ion exchange separation was in good agreement with that of the organic phase by the solvent extraction, it is evident that the retention as $^{60}Co(acac)_3$ can be determined by either method for the solutions in these solvents.

Solid Samples: The irradiated solid samples (30—50 mg) were dissolved in 5 m*l* of benzene (containing 10% of ethanol) ethanol, chloroform, carbon tetrachloride, or acetic acid, all with or without ferric chloride additive, and analyzed by means of solvent extraction or ion exchange.

Radioactivity Measurement. The radioactivity of each fraction was counted with a well-type NaI scintillation counter at least one week after neutron irradiation. All the solvents and scavengers (metallic salts and acids) used in the experiments were irradiated separately and the radioactivity of the organic phase after solvent extraction was measured to check the upper limit of induced radioactivity other than ^{60}Co. It was confirmed that the possible contribution to organic phase activities (*i.e.*, retention) from induced activities other than ^{60}Co did not exceed 0.03% when measurements were carried out at least one week after irradiation. Since this contribution was generally smaller than the statistical errors in counting, no correction was necessary.

Results and Discussion

Recoil Species Formed in the Irradiated $Co(acac)_3$ Systems. Various metastable recoil species can be formed as a result of hot-atom reactions in the irradiated solid $Co(acac)_3$ systems. As an example, existence of ligand deficient species such as [bis(acetylacetonato)cobalt (III)]$^+$ has been suggested in the irradiated and unannealed solid $Co(acac)_3$ systems.[11,12] However, all the chemical procedures of separation involving aqueous media (*i.e.*, ion exchange, solvent extraction and paper electrophoresis) have revealed only two ^{60}Co-labeled species which are identified as $Co(acac)_3$ and Co^{2+}.[7,11,12] This indicates that the metastable recoil species are converted into more stable entities on dissolution in an organic solvent and mixing with an aqueous medium.

Although similar metastable recoil species might be produced through hot-atom reactions in the irradiated solutions of $Co(acac)_3$ in organic solvents, only two ^{60}Co-labeled species (*i.e.*, $Co(acac)_3$ and Co^{2+}) were found after chemical separation by means of solvent extraction or ion exchange, both of which involved aqueous media. It is presumed that all the metastable recoil species are finally converted into the stable species in aqueous solutions (*i.e.*, Co^{2+}). Accordingly, the ^{60}Co recoil reactions and scavenger effect in the $Co(acac)_3$ systems have been studied in terms of the ^{60}Co retention which is not perturbed by the procedures of chemical separation.

Retention and Scavenger Effect in the Irradiated Solutions of $Co(acac)_3$ in Benzene Containing 10% of Ethanol. In the absence of scavengers, the apparent ^{60}Co retention in the irradiated 0.2M solutions of $Co(acac)_3$ in benzene (containing 10% of ethanol) was found to be about 7± 1% which was higher than the retentions in the irradiated solid samples. No appreciable concentration dependence was observed for 0.01—0.25M solutions of $Co(acac)_3$ in benzene. The apparent retention increases gradually when the irradiated solutions are kept at room temperature[7] whereas it remains nearly unchanged at dry ice temperature. When acetylacetone was added to the solutions before irradiation, the apparent retention was found to increase with acetylacetone concentration. Thus the ^{60}Co retention in the irradiated benzene solutions containing 50% by volume of acetylacetone was about 25%. A retention value of 90% was observed in the irradiated solution of $Co(acac)_3$ in pure acetylacetone after being kept standing for three days at room temperature. Thus it can be concluded that thermal diffusive reactions taking place during and after the irradiation contribute greatly to the apparent retention in the irradiated solutions without scavengers. The higher apparent retention in solutions than in solid can be explained by assuming that the thermal diffusive reactions proceed more rapidly in irradiated solutions than in irradiated solid.

In order to study the hot-atom reactions in these systems, the thermal diffusive reactions should be suppressed so that the true primary retention can be determined. Although the scavenger technique has been used successfully to suppress thermal diffusive reactions in organic systems, it has seldom been applied to the hot-atom reactions in inorganic systems. We found that ferric salts could be used as good scavengers to minimize the thermal reactions in the irradiated $Co(acac)_3$ solutions.[7] In the present work we have studied the effect of the addition of various metallic salts on the ^{60}Co retention in the irradiated 0.2M solutions of $Co(acac)_3$ in benzene containing 10% of ethanol (Fig. 1).

We see that the ^{60}Co retention in the irradiated solutions decreases sharply on addition of most metallic salts as scavengers although no decomposition of the parent complex is detected spectrophotometrically. Ferric chloride appears to be the most effective scavenger while magnesium chloride is the least effective. The hydrate might be slightly more effective as scavenger than the anhydride of the corresponding salt. However, the ^{60}Co retention was not influenced by the presence of water up to 0.5% (about 0.25M) in the irradiated benzene solutions. For the convenience of comparison, the scavenging power may be expressed in terms of the percentage of the thermal diffusive reactions scavenged by the addition of an equal molar concentration of the salt. The scavenger curves in Fig. 1 reveal that the scavenging power of the metallic salts generally increases in the order:

$$Mg(II)<Co(II)<Ni(II)<Cu(II)\sim Al(III)<Fe(III)$$

Although the stability constants of the acetylacetonates of these metals in benzene or benzene-ethanol solutions are not known, it has been reported that the stability constants in aqueous media (and in 50% or 75% dioxane) increase in the order:

$$Mg(II)<Co(II)<Ni(II)<Cu(II)<Al(III)<Fe(III)$$[13-18]

Thus the scavenging power of the salts of these metals are correlated well with the stability constants of their acetylacetonates in aqueous media,[19] that is, salts of the metals which can form more stable complexes with free acetylacetone work as more effective scavengers. Thus a probable mechanism of the metal scavenger effect in the irradiated solutions of $Co(acac)_3$ in benzene-ethanol is as follows. The metallic salt competes with the ^{60}Co recoil species (ligand deficient species, *etc.*) in thermal diffusive reactions to combine with free acetylacetone in solutions, thus minimizing the apparent ^{60}Co retention effectively.

Since the ^{60}Co retention in the well-scavenged solutions shows a minimum value of $0.00\pm0.02\%$, this can be considered as an upper limit for the primary retention in the irradiated $Co(acac)_3$ benzene solutions. In other words, the probability of the rupture of at least one ligand of this complex is nearly 100% in the solution systems.

Mineral acids such as HCl and HNO_3 are also good scavengers to reduce the apparent retention (Fig. 1). Acetic acid appears to be less effective in the concentration range below 0.1M, yet it can be used as a good scavenger if its concentration exceeds about 0.2M (Fig. 2).

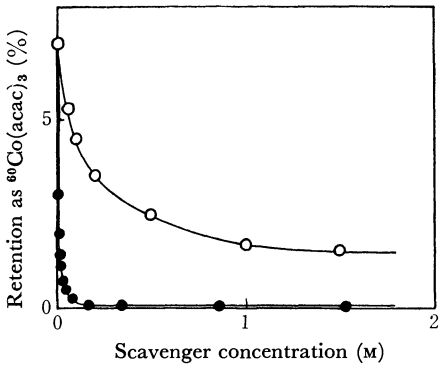

Fig. 2. Scavenger effect of acetic acid and carbon tetrachloride on ^{60}Co retention in the irradiated 0.2M solutions of $Co(acac)_3$ in benzene.
-●- CH_3CO_2H; -○- CCl_4.

We see that the addition of carbon tetrachloride (well-known electron scavenger) gradually decreases the apparent retention. However, the effect is slight as compared with the scavenger effect of metallic salts: the retention cannot be reduced to below 1% even if 1.6M (several hundred times as concentrated as the metallic scavengers) of carbon tetrachloride is present in the irradiated solutions. The results suggest that a different mechanism may be proposed to account for the effect of carbon tetrachloride on the ^{60}Co retention.

The ^{60}Co retention was not influenced significantly by the addition of ethanol (up to 15% by volume) or acetone (up to 100%).

Retention in the Irradiated Solutions of $Co(acac)_3$ in Ethanol, Acetone and Acetic Acid. The effect of ferric chloride on the ^{60}Co retention in the irradiated solutions of $Co(acac)_3$ in ethanol (0.017M) or acetone (0.03M) was similar to the effect observed in the benzene solutions. The apparent retention decreases sharply with the increase in the ferric chloride concentration and reaches nearly 0% if more than 3×10^{-4}M of ferric chloride is present in the solutions.

A different behavior was observed with the irradiated 0.1M $Co(acac)_3$ solutions in acetic acid. The ^{60}Co retention remains at 0%, independent of the ferric chloride concentration since acetic acid can work as both scavenger and solvent.

Retention in the Irradiated Solid $Co(acac)_3$ Samples. Table 1 summarizes the ^{60}Co retentions in the irradi-

ated solid $Co(acac)_3$ samples. Retentions of the samples irradiated at dry ice temperature generally fall within the range 1.4—1.5% irrespective of solvents used for dissolution, if they contain $3—5\times10^{-3}$M ferric chloride. The ^{60}Co retention remains unchanged even after standing the solutions of the irradiated solid complex for three days if they contain ferric chloride. In the absence of ferric chloride, however, the ^{60}Co retention is 2.0±0.1% for irradiations at dry ice temperature and increases further after the solutions of the irradiated solid samples were kept standing for three days.[20] The increment of the retention is accelerated considerably when the irradiated complex is dissolved in a benzene-acetylacetone mixture. The results indicate that the thermal reactions after the dissolution of the irradiated solid complex contribute appreciably to the apparent retention. Therefore, the retention obtained in the presence of an adequate scavenger can be considered to be a true retention of the irradiated solid systems.

It is concluded that the thermal reactions taking place in the irradiated organic solutions of the complex or after the dissolution of the irradiated solid complex are effectively suppressed by using adequate scavengers such as metallic salts which can form more stable complexes with the free ligand molecules, ions or radicals. We believe that this technique will be useful for determining the primary retention in solution systems or the initial retention in solid systems.

The authors wish to thank Prof. Nobufusa Saito, the University of Tokyo, for his encouragement and support.

20) A similar increase of retention after dissolution has been observed in the methanol and benzene solutions of irradiated solid tris(acetylacetonato)chromium(III) (I. Găinar and A. Ponta, *Rev. Roum. Chem.*, **13**, 401 (1968); T. Omori and T. Shiokawa, *Radiochem. Radioanal. Lett.*, **3**, 39 (1970)).

A Comparison of 4-Hydroxynaphthalene-2,7-disulfonic Acid with Chromotropic Acid as a Coupling Component of Azo-type Metallochromic Indicators

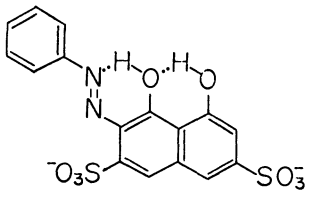
Takeshi KATAYAMA, Haruo MIYATA, and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

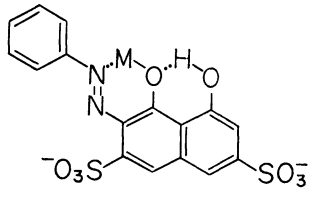
(Received May 6, 1971)

In order to clarify the effect of the hydroxyl group at the 5-position of chromotropic acid on the chelate stabilization, the following six reagents were synthesized by the coupling with 4-hydroxynaphthalene-2,7-disulfonic acid or 4,5-dihydroxynaphthalene-2,7-disulfonic acid(chromotropic acid): 2-(*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid(I), 2-(*o*-methoxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid(II), 2-(*o*-hydroxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid(III), 2-(*m*-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid(IV), 2-(*o*-methoxy-*m*-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid (V), and 2-(*o*-hydroxy-*m*-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid(VI). The acid dissociation constants of these reagents and the stability constants of their metal chelates with magnesium and calcium were measured by the pH titration method at an ionic strength of 0.10 and at 25°C. From the results obtained, it has become apparent that the hydroxyl group at the 5-position exerts a remarkable influence on the chelation of metal ions with the bidentate ligand, such as 2-(*m*-sulfophenylazo)-chromotropic acid, but that it has very little effect on those ions with the terdentate ligand, such as 2-(*o*-hydroxy-*m*-sulfophenylazo)-chromotropic acid. Such an effect appears even in the bidentate ligand with the methoxy group at the *ortho*-position of the benzene ring. That is to say, it may be concluded that the effect of the number of the chelate ring formed with a metal ion is preferred to stabilize the metal chelate over the effect of the hydroxyl group at the 5-position in the terdentate ligand.

Heller and Schwarzenbach[1] have reported that the values of the acid dissociation constants for the two hydroxyl groups of chromotropic acid are 5.36 and 15.6 respectively (pK_a values). The larger value of the latter dissociation of hydroxyl group results from a strong hydrogen bond between two oxygen atoms of chromotropic acid. On the other hand, the pK_{a_1} value of phenylazochromotropic acid is 9.15,[2] which corresponds to the 5.36 value of chromotropic acid; the pK_{a_2} value could not be determined under ordinary experimental conditions because of a strong intramolecular hydrogen bond. It is considered that the phenylazochromotropic acid and its metal chelate have the structures indicated by Formulas (1) and (2) respectively, and that the hydroxyl group at the 5-position of the naphthalene ring probably does not produce chelation with metal ion.



Formula (1)



Formula (2)

The present work will compare the chelate formation ability of 4-hydroxynaphthalene-2,7-disulfonic acid with that of chromotropic acid (4,5-dihydroxynaphthalene-2,7-disulfonic acid) as a coupling component. Namely, 2-(*m*-sulfophenylazo)-, 2-(*o*-methoxy-*m*-sulfophenylazo)- and 2-(*o*-hydroxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acids as well as 2-(*m*-sulfophenylazo)-, 2-(*o*-methoxy-*m*-sulfophenylazo)- and 2-(*o*-hydroxy-*m*-sulfophenylazo)-chromotropic acids were synthesized, and the acid dissociation constants and the stability constants of their chelates with magnesium and calcium were determined by the pH titration method at an ionic strength of 0.10 and at 25°C. The effect of the hydroxyl group at the 5-position will be discussed in comparison with the constants thus obtained.

Experimental

Reagents. The azo compounds, 2-(*m*-sulfophenylazo)-, 2-(*o*-methoxy-*m*-sulfophenylazo)-, and 2-(*o*-hydroxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acids, and 2-(*m*-sulfophenylazo)-, 2-(*o*-methoxy-*m*-sulfophenylazo)-, and 2-(*o*-hydroxy-*m*-sulfophenylazo)-chromotropic acids, were synthesized by the coupling reaction of 4-hydroxynaphthalene-2,7-disulfonic acid or chromotropic acid with each diazotized *m*-aminophenylsulfonic acid, 2-aminophenol-4-sulfonic acid and *o*-anisidine-*p*-sulfonic acid respectively. After the purification of these six reagents, their disodium salt were obtained as fine crystals by salting out. The stock solutions of these reagents were standardized by pH titration with a standard 0.10N potassium hydroxide solution.

The stock solutions of magnesium and calcium were prepared by dissolving $Mg(NO_3)_2 \cdot 6H_2O$ and $Ca(NO_3)_2 \cdot 4H_2O$ of a guaranteed reagent grade in distilled water; these solutions were then standardized by chelatometric titration.

pH Titration Method. The apparatus and the procedure

1) J. Heller and G. Schwarzenbach, *Helv. Chim. Acta*, **34**, 1876 (1951).

2) S. Nakashima, H. Miyata, and K. Tôei, This Bulletin **41** 2635 (1968).

for the pH titration were described in a previous paper[2]; the temperature and ionic strength of a solution were maintained at 25°C and at 0.10 respectively with potassium nitrate.

Calculations

Acid Dissociation Constants of the Reagents. The reagents I(2-(*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid), II(2-(*o*-methoxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid), IV(2-(*m*-sulfophenylazo)-chromotropic acid), and V(2-(*o*-methoxy-*m*-sulfophenylazo)-chromotropic acid) are considered to be monobasic acids, while the reagents III(2-(*o*-hydroxy-*m*-sulfophenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid) and VI(2-(*o*-hydroxy-*m*-sulfophenylazo)-chromotropic acid are considered to be dibasic acids. The acid dissociation constants, K_a, of these reagents are defined as follows:

(1) Monobasic acid.

$$HL \rightleftarrows H + L$$

$$K_a = \frac{[H][L]}{[HL]} = \frac{[H](T_{OH}+[H]-[OH])}{T_L - T_{OH} - [H] + [OH]}$$

where T_L and T_{OH} represent the total concentrations of the ligand and the alkali added to the system respectively; the ionic charge is disregarded for the sake of convenience.

(2) Dibasic acid,

$$H_2L \rightleftarrows H + HL \qquad K_{a_1} = \frac{[H][HL]}{[H_2L]}$$

$$HL \rightleftarrows H + L \qquad K_{a_2} = \frac{[H][L]}{[HL]}$$

$$1/K_{a_1} = AK_{a_2} + B$$

where:

$$A = \frac{2T_L - T_{OH} - [H] + [OH]}{[H]^2(T_{OH}+[H]-[OH])}$$

$$B = \frac{T_L - T_{OH} - [H] + [OH]}{[H](T_{OH}+[H]-[OH])}$$

Stability Constants of the Chelates. The stability constants, K, of the chelates are defined as follows:

$$M + L \rightleftarrows ML$$

$$K = \frac{[ML]}{[M][L]} = \frac{T_L - F}{[L](F + T_M - T_L)}$$

where T_M represents the total concentration of the metal ion, and where [L] and F represent as follows:

(1) Monobasic acid

$$[L] = \frac{K_a}{[H]}(T_L - T_{OH} - [H] + [OH])$$

$$F = \left(\frac{K_a}{[H]} + 1\right)(T_L - T_{OH} - [H] + [OH])$$

(2) Dibasic acid

$$[L] = \frac{2T_L - T_{OH} - [H] + [OH]}{\frac{[H]}{K_{a_2}} + \frac{2[H]^2}{K_{a_1}K_{a_2}}}$$

$$F = [L]\left(1 + \frac{[H]}{K_{a_2}} + \frac{[H]^2}{K_{a_1}K_{a_2}}\right)$$

Results and Discussion

Titration Curves. The titration curves for Reagent I in the presence and in the absence of calcium and magnesium ions are illustrated in Fig. 1, while for Reagents II and III the curves are shown in Figs. 2 and 3 respectively. The titration curves for Reagents

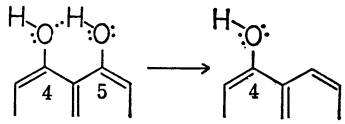
2-(*o*-Hydroxy-*m*-sulfophenylazo)-1,8-dihydroxy naphthalene-3,6-disulfonic acid (VI)	6.68	10.20	6.08	5.04

IV, V and VI are similar to those of Reagent I, II, and III in Figs. 1, 2, and 3 respectively. The acid dissociation constants of these reagents can be calculated by the use of the titration curve of the ligand only. As is shown in Figs. 1, 2, and 3, those curves for Reagents I and II are almost the same as that of phenylazochromotropic acid,[2] and the curve for Reagent III corresponds to that of phenolazochromotropic acid.[2] The inflection at a=1 in the titration curve of the ligand in Fig. 3 shows the dissociation of the phenolic proton of Reagent III. No inflection is observed at all on the neutralization of the naphtholic proton of the reagents. The titration curve in the presence of the metal ion shows a lower pH value than that of the ligand only. Such a depression of the titration curves indicates the formation of the metal chelate species; the chelate stability order, calcium< magnesium, can easily be expected from the extent of the depression of pH. Evidently, Reagents III and VI formed a more stable chelate with calcium and magnesium than did the other reagents investigated.

Acid Dissociation Constants. The acid dissociation constants of the six reagents are summarized in Table 1. In Table 1, the pK_{a_1} and pK_{a_2} values correspond to the dissociation of the phenolic and naphtholic protons respectively. The other naphtholic proton of chromotropic acid in the reagents is not dissociated by the presence of a strong hydrogen bridge between two oxygen atoms. The basicities of these reagents are expressed as a sum of the dissociation constants, $pK_A = pK_{a_1} + pK_{a_2}$; these values for the reagents decrease as follows: Reagent III>VI>II>I>V>IV. On the effect of the substituents, the sulfo group at the 5-position of the benzene ring decreases the pK_a value for the reagent by means of its electron-withdrawing effect, as is shown in Table 2. On the other hand, the elimination of the naphtholic hydroxyl group at the 5-position of Reagent IV, V, and VI shows a depression of the dissociation of the naphtholic proton at the 4-position of the reagent. This means that the oxygen atom at the 4-position will become more electron-rich than that of chromotropic acid, as is indicated by the following scheme;



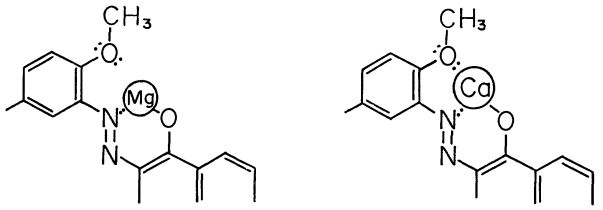
The dissociation of the hydroxyl group is disturbed for this reason.

Stability Constants. The chelate stability constants of their 1:1 chelates with magnesium and calcium ions are also listed in Table 1. Reagents I, II, IV, and V are considered to be bidentate ligands, and Reagents III and VI are considered to be terdentate ligands for metal ions. In these studies, the stabilization of the metal chelate depends mainly on the following factors: (1) the basicity of the reagent, (2) the number of rings formed with a metal ion, and (3) the stabilizing resonance interaction. As for Factor (1), from the concept of Lewis acids and bases, it seems that the strong basic ligand would form the more stable chelate. However, the order of the stability constants of these reagents, VI>III>V>IV>II>I, is not proportional to the basicities of the reagents, III>VI>II>I>V>IV. (2): In the case of Reagents III and VI, the pK_a values of the reagents and the stability

TABLE 2. THE EFFECT OF *m*-SO_3H GROUP ON THE pK_a OF THE REAGENTS

Reagents	pK_a	Reagents	pK_a
2-(Phenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid	10.48	→ I	10.33
2-(*o*-Methoxyphenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid	11.05	→ II	10.88
Phenylazochromotropic acid	9.19	→ IV	8.97
o-Methoxyphenylazochromotropic acid	9.92	→ V	9.64
o-Hydroxyphenylazochromotropic acid	7.60	→ VI	6.68
	10.60		10.20

constants, log K, of magnesium and calcium chelates is almost the same as shown in Table 1. This means that the number of chelate rings exerts a remarkable influence upon the stabilization of their chelates. (3): The effect of the oxygen atom as a donor atom is considered to be almost the same in each reagent. However, the very large difference in the values of log K between Reagents I and IV appeared as the effect of having or not having the naphtholic hydroxyl group at the 5-position. This may be caused by a stabilizing resonance of the chelate ring. The same tendency appears in the difference in the stability constants between the copper chelate of phenylazochromotropic acid and that of 2-(phenylazo)-1-hydroxynaphthalene-3,6-disulfonic acid; these log K's values are 17.23 and 8.84 respectively.[3] In the case of Reagents II and V, the values of the stability constants are between Reagents I and III, or Reagents IV and VI, respectively. Such a stable deviation of the reagent with the OCH_3 group at the *o*-position would be due to the coordination of the oxygen atom of the group to metal ions; this coordination is more suitable for calcium ionic radii than for magnesium ones, as is shown in the following scheme:



Therefore, the calcium chelate with Reagent II behaves a bidentate ligand or, rather, a terdentate one. In fact, from the comparison of the stability constants of the magnesium or calcium chelate of Reagent II with those of Reagent IV, it can be assumed that the effect of the number of the chelate ring is preferable to the calcium chelate with Reagent II; on the contrary, the effect of the stabilizing resonance interaction by the hydroxyl group at the 5-position is preferred to that of the magnesium chelate with the same reagent.

The present work has been supported in part by a Grant for Science Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3043—3046 (1971)

The Phase Equilibria in the FeO-Fe_2O_3-V_2O_3 System at 1500°K

Masataka WAKIHARA and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 7, 1971)

The phase equilibria in the FeO–Fe_2O_3–V_2O_3 system have been determined at 1500°K by varying the oxygen partial pressure. The following three oxide phases have been stable in equilibrium: a sesquioxide solid solution with a corundum-type structure (approximate composition Fe_2O_3–V_2O_3), a ternary solid solution with a spinel-type structure (approximate composition $FeO \cdot Fe_2O_3$–$FeO \cdot V_2O_3$), and a ternary wüstite solid solution with a periclase-type structure which dissolves vanadium ions up to about 10 mol per cent. The extent of the solid-solution areas and the location of the oxygen isobars have been determined. The spinel phase coexisted partly with metallic iron and partly with the wüstite solid solution, corresponding to lower and higher iron contents respectively. The standard free energies of the $Fe+V_2O_3+{}^1/_2O_2=FeV_2O_4$ and $0.05\ Fe+V_2O_3+Fe_{0.95}O=FeV_2O_4$ reactions to produce FeV_2O_4 have been calculated to be -45500 ± 200 cal and -5800 ± 400 cal respectively at 1500°K on the basis of the equilibrium oxygen partial pressure.

The Fe–V–O system is of a great deal of interest to metallurgists as well as to ceramists and geochemists. The accurate phase equilibria, however, have not yet been presented, particularly at high temperatures. Binary systems of Fe–O and V–O have been studied by Darken and Gurry[1] and many other investigators.[2–9] Vanadium is a minor element in the earth's crust, and it is often found in magnetite (Fe_3O_4) upon the replacement of iron ions. Burdese[10] studied the phase equilibria of the Fe–V–O system and synthesized FeV_2O_6, FeV_2O_4, and $FeVO_4$. Vorob'ev *et al.*[11] investigated Fe_3O_4–FeV_2O_4 and wüstite solid solutions at 1000°K.

Kunnmann *et al.*[12] synthesized some transition metal oxides in the temperature range from 1073° to 1380°K and calculated the standard free energy of FeV_2O_4. Recently, Schmahl and Dillenburg[13] studied the phase equilibria of the Fe–V–O system at 900°C and calculated the activities for the Fe_3O_4–FeV_2O_4 solid-solution series and the standard free energy of FeV_2O_4. Also, they recognized that the Fe_2O_3–V_2O_3 solid solution has an immiscible region in the range of 78—93 mol per cent V_2O_3 at 900°C. In this solid-solution series, Cox *et al.*[14] also found an immiscibility gap in the range of 80—90 mol per cent V_2O_3 on the basis of their magnetic data collected at 1000°C. Wakihara *et al.*[15] synthesized the Fe_3O_4–FeV_2O_4 spinel solid solution at 1500°K and measured the magnetic properties. They proposed these cation distributions: $Fe^{3+}(Fe^{2+}Fe^{3+}_{\mu}V^{3+}_{1-\mu})O_4$ $(0\leqq\mu\leqq1)$ for the Fe_3O_4–Fe_2VO_4 series, and $Fe^{3+}_{\lambda}Fe^{2+}_{1-\lambda}(Fe^{2+}_{\lambda}V^{3+}_{2-\lambda})O_4$ $(0\leqq\lambda\leqq1)$ for the Fe_2VO_4–FeV_2O_4 series.

In the present study, accurate phase equilibria of the FeO–Fe_2O_3–V_2O_3 system has been determined at 1500°K by varying the oxygen partial pressure. The standard free energy of the reaction to produce FeV_2O_4 has been calculated at 1500°K on the basis of the equilibrium oxygen partial pressure.

Experimental

1) General Procedure. Different experimental methods were used in the present study; the quenching and thermogravimetric methods have previously been described by Katsura and Muan[16] and by Katsura and Kimura.[17]

In the quenching method, oxide samples were heated at 1500°K and at a chosen oxygen partial pressure until equilibrium was attained among the gas and condensed phases. The samples were then quenched rapidly to the temperature of cold water and the phases present were determined by the X-ray diffraction method. The total compositions were determined by means of the gravimetric weight-gain method.

In the thermogravimetric method, a pellet of an oxide mixture was suspended in a vertical tube-quenching furnace by means of a thin platinum wire stretched from the bottom of the quick weighing balance. The weight changes were recorded as a function of the oxygen partial pressure at 1500°K.

The furnace temperatures were kept constant to approximately ±3°K throughout this investigation.

2) Materials. The V_2O_5 was obtained by the decomposition of the reagent grade of ammonium meta vanadate at 450°C in air for 12 hr. Analytical-grade Fe_2O_3 was fired at 700°C in air for 12 hr. Mixtures of the desired ratios of the above two oxides were then prepared. The mixture was loosely pressed into a small-size platinum crucible, and then heated at 650°C in a mixed gas of $CO_2/H_2=1$ for 20 min. The griding, pressing, and heating were repeated to obtain an uniform mixture. An error in the atomic ratio of V/Fe in the mixture was estimated to be within ±0.1 per cent. The prepared sample was a mixture of reduced forms of vanadium and iron oxides. The pellet of the oxide sample was suspended in a furnace tube; here it was heated at 1500°K in a desired CO_2–H_2 gas mixture for 10—18 hr until equilibrium was attained among the gas and the solid phases. The details of the procedure have been described by Katsura and Kimura.[17]

3) Analysis of Total Compositions. The total compositions of the quenched samples were determined by the gravimetric weight-gain method. About 1 g of the quenched sample was accurately weighed. Then, the sample was completely oxidized to the mixture of V_2O_5 and Fe_2O_3 at 800°C in air for 24—48 hr, and then again it was weighed. As the Fe_2O_3/V_2O_5 mol ratio of starting materials was known, the total compositions of the quenched sample were evaluated by means of the difference in weight between before and after the oxidation. The vaporization of V_2O_5 was insignificant during heating within the present limits of accuracy. The error in the total compositions was estimated to be within ±0.2 per cent.

4) Control of Atmosphere. A desired partial pressure of oxygen was provided by using a gas mixture of CO_2 and H_2 or CO_2 and O_2. The mixed gas was prepared by a gas mixer similar to that used by Darken and Gurry.[1] The actual oxygen partial pressure was measured by means of a solid electrolyte cell composed of stabilized zirconia, $(ZrO_2)_{0.85}(CaO)_{0.15}$. The principles and procedure have been described previously.[7,8]

5) Thermogravimetry. The rate of the approach to equilibrium was observed thermogravimetrically. Also, the method was used to determine the ranges of the oxygen partial pressure and the composition in which both spinel and wüstite solid solutions exist in equilibrium. The technique was described in detail in previous papers.[7,8,17]

6) Identification of Phases. The phases present in the quenched samples were identified by an X-ray diffraction method using FeK_α radiation.

The presence of metallic iron in the phase assemblages was evidenced by the liberation of hydrogen gas when samples were dipped in hydrochloric acid. This test is sensitive enough to detect iron in amounts as small as 0.2 per cent, as has been described in a previous study.[17]

Results and Discussion

1) Phase Equilibria. The equilibrium data obtained at 1500°K are summarized in Table 1 and are illustrated graphically in Fig. 1.

Three solid solution phases are stable under the present expreimental conditions: the sesquioxide solid solution, the spinel solid solution, and the wüstite solid solution. The compositions of the sesquioxide phase were stoichiometric within the limits of experimental error and were well represented by the formula $(Fe\cdot V)_2O_3$. Sesquioxides of 80—90 mol per cent Fe_2O_3 were prepared by using a gas mixture of CO_2 and O_2. Each phase of the sesquioxide solid solution was identified by the X-ray diffraction method.

The spinel phase is a ternary solid solution with a stable existence at 1500°K within the composition area, Fe_3O_4–FeV_2O_4–Fe_2O_3. The range of oxygen partial pressure in which the spinel solid solution exists in equilibrium is shown in Fig. 2. The figure illustrates

the relationship between the oxygen partial pressure and the compositional parameter, x, for the general formula of the spinel: $Fe_{1+2x}V_{2-2x}O_4$ ($0 \leqq x \leqq 1$). The solid lines in the range indicate the values of the atomic ratio of 4(Fe+V)/O. No spinel with a greater metal-to-oxygen ratio than 3:4 was found in the present study. These situations are quite similar to the case of the other spinel solid solutions, Fe_2TiO_4–Fe_3O_4[18] and $FeCr_2O_4$–Fe_3O_4[16].

The wüstite phase has a extensive homogeneous range with some V^{3+} ions in the structure. The extent of these compositional ranges is shown in Fig. 1.

The results in the present study at 1500°K on the binary FeO–Fe_2O_3 system are consistent with those obtained by Darken and Gurry[1] within the limits of experimental error.

Schmahl and Dillenburg[13] and Cox *et al.*[14] reported an immiscible gap of the sesquioxide phase with a rhombohedral (corundum-type) structure in the range about from 80 to 90 mol per cent V_2O_3 at 900°C and 1000°C respectively. The gap, however, was not found in the present study throughout the Fe_2O_3–V_2O_3 system at 1500°K, within our limits of experimental error.

The phase equilibria of the FeO–Fe_2O_3–V_2O_3 system were similar to those of the FeO–Fe_2O_3–Cr_2O_3 system previously investigated.[16] Some characteristic differences were these: no deviation of the oxygen-to-cation ratio below the stoichiometric 3:2 ratio in the sesquioxide phase was found in the present study, and the

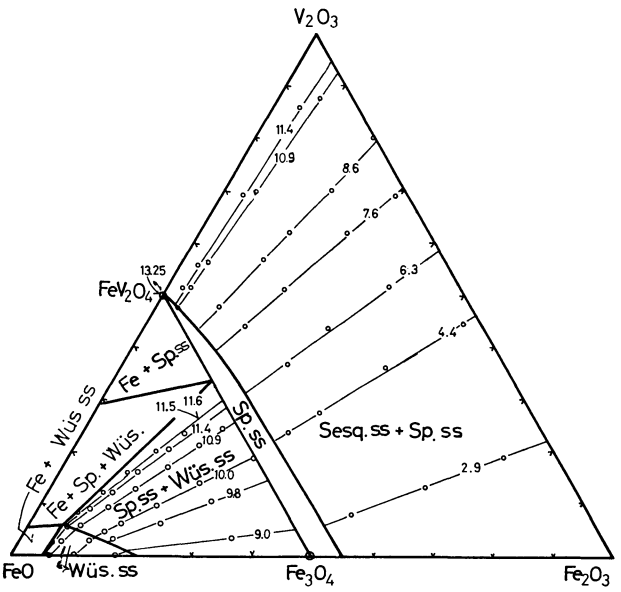

Fig. 1. Graphical representation of equilibrium data obtained for the FeO–Fe_2O_3–V_2O_3 system at 1500°K (mol per cent). Lines in the composition triangle indicate oxygen isobar and numbers on the lines are values of $-\log P_{O_2}$.

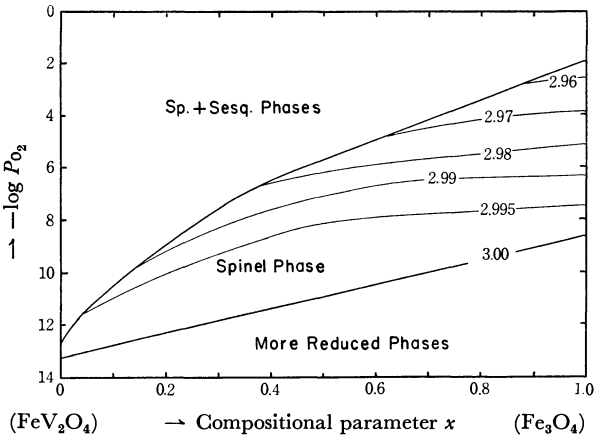

Fig. 2. Relationship between log P_{O_2} and compositional parameter x for $Fe_{1+2x}V_{2-2x}O_4$ at 1500°K; here, lines in the spinel phase region indicate the value of mole ratio, 4(Fe+V)/O.

spinel-phase region in equilibrium with metallic iron (almost from FeV_2O_4 to Fe_2VO_4) was larger than those of the magnetite–iron chromite solid solution series.[16] The latter result may be partly due to the difference in the experimental temperature between the present and previous studies.[16]

2) Thermodynamic Calculations. The oxygen partial pressure at which metallic iron, FeV_2O_4, and V_2O_3 coexist in equilibrium was determined in this investigation ($\log P_{O_2} = -13.25 \pm 0.05$). This value was obtained thermogravimetrically, as is shown in Fig. 2. Therefore, the standard free energy of the reaction to produce FeV_2O_4 from metallic iron and sesquioxide components at 1500°K may be calculated as follows:

$$Fe + V_2O_3 + 1/2O_2 = FeV_2O_4 \qquad (A)$$

The standard free energy of Reaction (A) is given by the following equations:

$$\Delta G^\circ(A) = -RT\ln\frac{a_{FeV_2O_4}}{a_{Fe}\cdot a_{V_2O_3}\cdot P_{O_2}^{1/2}} = 1.152RT\log P_{O_2} \qquad (A')$$
$$= -45500 \pm 200 \text{ cal}$$

where the a_{Fe}, $a_{V_2O_3}$, and $a_{FeV_2O_4}$ activities are equal to unity because these components are pure compounds at the oxygen partial pressure of $\log P_{O_2}(A) = -13.25$.

The standard free energy of Reaction (A) was determined by Kunnmann *et al.*[12] over the temperature range from 1073° to 1380°K by varying the oxygen partial pressure using CO_2/CO gas mixtures. The standard free energy resulting from the present investigation at 1500°K was reasonably consistent with the extrapolated value of their data. According to the data of Darken and Gurry,[1] the oxygen partial pressure at which metallic iron and wüstite phases are stable in equilibrium was logarithmically estimated to be $\log P_{O_2} = -11.58 \pm 0.05$ at 1500°K. Thus, the standard free energy of the formation of wüstite from metallic iron can be readily calculated:

$$0.95Fe + 1/2O_2 = Fe_{0.95}O \qquad (B)$$

$$\Delta G^\circ(B) = -RT\ln\frac{a_{Fe_{0.95}O}}{a_{Fe}^{0.95}\cdot P_{O_2}^{1/2}} = 2.303/2RT\log P_{O_2}(B) \qquad (B')$$
$$= -39700 \pm 200 \text{ cal}$$

where $\log P_{O_2}(B) = -11.58 \pm 0.05$, and where the a_{Fe} and $a_{Fe_{0.95}O}$ activities are unity.

The substraction of Eq. (B) from Eq. (A) gives the following equation:

$$0.05Fe + V_2O_3 + Fe_{0.95}O = FeV_2O_4 \qquad (C)$$

while the standard free energy of Reaction (C) is given by:

$$\Delta G^\circ(C) = \Delta G^\circ(A) - \Delta G^\circ(B) = RT\ln\frac{P_{O_2}(A)}{P_{O_2}(B)} \qquad (C')$$
$$= -5800 \pm 400 \text{ cal}$$

Kinetics of the Reaction of Americium(III) with Peroxydisulfate[1]

Akira OHYOSHI, Akinori JYO, and Tetsuo SHINOHARA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received May 17, 1971)

Kinetic studies of the americium(III) oxidation have been made in aqueous solutions. The reaction rates are dependent on the concentrations of hydrogen, peroxydisulfate and the silver ion as catalyzers, and on the reaction temperature. The period of induction observed in the initial stage of reaction varies with the concentration of the reactant and with the reaction temperature. The data follow this rate expression:

$$-\frac{d[Am(III)]}{dt} = K_h(k_1+k_2[Ag^+])[S_2O_8^{2-}][Am(III)]\cdot 1/[H^+]$$

where K_h is the dissociation constant of hydrogen peroxydisulfate, and where k_1 and k_2 refer to the silver-ion uncatalyzed and catalyzed paths respectively. The energies of activation were determined to be 28.6 kcal/mol for k_1 and 17.4 kcal/mol for k_2.

The oxidation of americium(III) with the peroxydisulfate ion in the presence of the silver ion is well known.[2,3] This reaction is used to prepare americium isotopes from the spent reactor fuels. Although many papers on the oxidation of Am(III) have been published,[4-7] our knowledge concerning the reaction kinetics of oxidation is rather limited, especially when a tracer concentration is involved. In previous papers[1,8] it was found that the rate data obtained by the tracer technique using the coprecipitation method were in good agreement with those measured specctrophotometrically and that the rate of oxidation appeared to be influenced by the concentrations of the reactants and the acidity of the reaction media. Kinetic studies of this reaction were carried out in order to obtain further information and in order to determine the reaction-rate law.

Experimental

Reagent. Americium-241 oxide which had been obtained from the Radiochemical Centre, Amersham, was dissolved in nitric acid. The solution was then evaporated to dryness, and the residue was dissolved in 0.1 M of a desirable acid. This solution served as the stock solution of americium. Before use, an aliquot of the stock solution was diluted to a suitable concentration with respect to americium and definite acids. The absorption spectrum indicated the tripositive state.[9] The radiochemical purity of ^{241}Am was confirmed by gamma-ray spectrometry.

Ammonium peroxydisulfate, silver nitrate and, all the other chemicals used were of an analytical reagent grade. The solution of ammonium peroxydisulfate was prepared freshly before use.

Apparatus. In order to check the radiochemical purity of ^{241}Am, the gamma-ray spectra were measured with a $2''\times 2''$ NaI(Tl) detector connected with a TMC 400-channel pulseheight analyzer. For the determination of the distribution ratio of ^{241}Am by the coprecipitation method, the gamma-activity of ^{241}Am was counted with a $2''\times 2''$ well-type NaI(Tl) detector connected with an Aloka scaler, Model TDC-5. A Hitachi Model EPS-2U and 124 spectrophotometer were used to determine the absorption spectra of americium. The samples were contained in silica cell which had a 1-cm path length and which contained about 0.8 m*l* of the solution. The silica cell was set in a cell holder thermostated with circulating water of a constant temperature. A Hitachi-Horiba pH meter, Model M-5, was used for the pH measurements.

Procedures. The solutions studied were made up from weighed amounts of ammonium peroxydisulfate, standardized nitric or perchloric acid, and an analyzed stock solution of americium salt. Solutions of ammonium peroxydisulfate containing silver nitrate and Am(III), which upon mixing would give the desired initial composition, were prepared separately and brought to the reaction vessel in a thermostat maintained to within ± 0.2°C of the desired temperature. The reactions were followed by radiometry by means of the lanthanum trifluoride coprecipitation method.[8] In a typical experiment, the reaction mixture was pipetted out into a 10-m*l* centrifuge tube containing a cold solution of the lanthanum carrier and nitric acid. The unoxidized Am(III) was coprecipitated with the lanthanum trifluoride by the addition of an ammonium fluoride solution. The lanthanum trifluoride was centrifuged, and the americium content of the supernatant was determined by the measurement of the gamma-activity of ^{241}Am. The fraction of Am(III) may be described as:

$$1-\frac{\text{Am-remaining}}{\text{Am-taken}}$$

This determination was made for three samples at the same time. The mean value of the three measurements was employed for the kinetic data.

Results and Discussion

Changes in Absorption Spectra during the Reaction. The changes in the absorption spectra of americium during the course of oxidation were measured under

two different sets of experimental conditions. The spectral changes in the visible region of a weak acidic solution are given in Fig. 1. It may be seen that Am(III) exhibits λ_{max} at 814 and 1050 mμ, and that the absorbances at 995 and 666 mμ due to Am(VI) increase with the decrease in those of Am(III) during the reaction time elapsed. In a highly acidic solution, the absorption peak of 503 mμ due to Am(III) does not change immediately after the reactants are mixed, but the broad absorptions in the UV and visible regions obviously change, as is shown in Fig. 2. These absorption band decreased for about 30 min; then, the absorption at 503 mμ began to decrease and a new broad absorption began to appear over the range from 600 to 800 mμ. After this absorption band reached a maximum, it then decreased with the longer reaction time, as is shown in Fig. 3. These changes can be attributed to both the disintegration of Am(III) and the formation of some intermediate compounds. This absorption band shifted towards the lower wavelength region with its increase. After about one hour, this broad band began to decrease, and the absorption peak at 660 mμ due to Am(VI) appeared, though it was not visible because of the low extinction coefficient. The plot of log D_{814} (absorbance at 814 mμ) against the reaction time shows a linear relationship. The same relation was found in the results obtained from the radiochemical measurements.[8] The plots on the

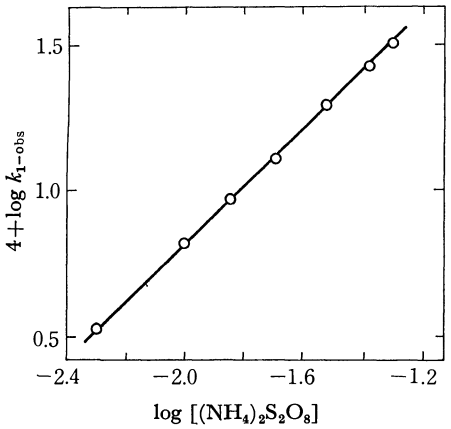

Fig. 5. The plot of log k_{1-obs} *vs.* log$[(NH_4)_2S_2O_8]$
$[Am(III)]_0=3.3\times10^{-7}$M, $[AgNO_3]_0=5.0\times10^{-4}$M, $[HNO_3]_0=8.0\times10^{-2}$M, $\mu=0.50$, Temp.=50°C.

straight lines indicate that the oxidation of Am(III) is first-order with respect to Am(III) over the temperature range of 40—70°C, as is shown in Fig. 4. Thus, the rate of oxidation may be expressed as follows:

$$\text{Rate} = k_{1-obs}[Am(III)] \quad (1)$$

Effects of Other Reactant Concentrations. The variation in the rates as a function of the concentration of the peroxydisulfate ion was studied at 50°C. Assuming the observed rate constants, k_{1-obs}, to be k_{2-obs} $[S_2O_8^{2-}]^n$, the slope of the straight line (Fig. 5) obtained by plotting log k_{1-obs} against log$[S_2O_8^{2-}]$ indicated that n was equal to unity; thus, the rate of oxidation may be expressed by the following equation:

$$\text{Rate} = k_{2-obs}[Am(III)][S_2O_8^{2-}] \quad (2)$$

In order to ascertain the role of the silver-ion catalyst in the kinetics of the oxidation, the study was carried out using $AgNO_3$ of different concentrations. The plots of $[k_{2-obs}-k_1]$ *vs.* $[AgNO_3]$ give curves, as is illustrated in Fig. 6, where the k_1 value is the rate constant obtained in the case of $[AgNO_3]=0$. It appears that the effect of the silver nitrate concentration makes the reaction rate increase and approach a limiting value. Therefore, the k_{2-obs} is given by the following equation under the limiting conditions.

$$k_{2-obs} = k_1 + k_2[Ag^+] \quad (3)$$

where the k_1 is the rate constant of the uncatalyzed reaction and where the k_2 obtained from the initial slope of the linear part of the curve in Fig. 6 corresponds to the rate constant of the catalyzed path of the oxidation. These values are exhibited in Table 1.

Effect of the Hydrogen-ion Concentration on the Rate. The experiment were performed at a constant ionic strength and temperature. The hydrogen-ion concentration was varied by the addition of nitric acid. The ionic strength was maintained constant with sodium nitrate. At concentrations of the hydrogen ion higher than 0.4M, no oxidation of Am(III) was observed. The rate increases with the decrease in the hydrogen ion concentration and reaches a constant value at $[H^+]=0.06$M.

A kinetic study of the decomposition of peroxydisulfates has been made by Kolthoff and Miller.[10] It decomposes according to the reaction(4) in a dilute acid solution:

$$S_2O_8^{2-} + H_2O = 2HSO_4^- + 1/2O_2 \quad (4)$$

10) K. I. M. Kolthoff and I. K. Miller, *J. Amer. Chem. Soc.*, **73**, 3055 (1951).

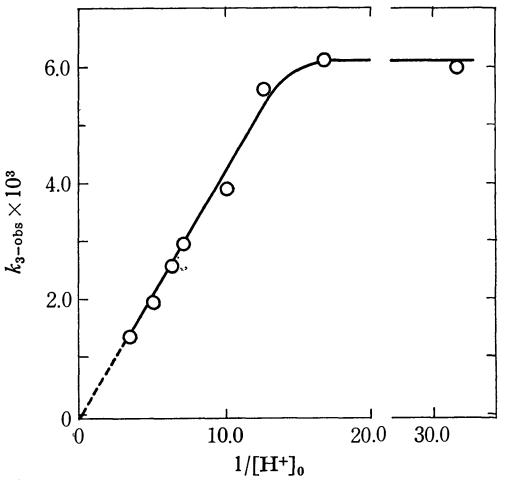

Fig. 7. A plot of the observed rate constants *vs.* reciprocal of the initial hydrogen ion concentration.
$[Am(III)]_0=4.0\times10^{-6}$M, $[(NH_4)_2S_2O_8]_0=2.0\times10^{-2}$M, $[AgNO_3]_0=1.0\times10^{-3}$M, $\mu=0.50$, Temp.=60°C.

In highly acidic solutions, though, reactions(5) and (6) occur:

$$H_2S_2O_8 + H_2O = H_2SO_5 + H_2SO_4 \quad (5)$$

$$H_2SO_5 + H_2O = H_2O_2 + H_2SO_4 \quad (6)$$

The oxidation of Am(III) with the peroxydisulfate ion may be disturbed by the H_2O_2 produced in Eq. (6) because the hydrogen peroxide is an efficient reductant of Am(VI). Figure 7 represents the plot of the observed rate constants against $1/[H^+]_0$. The rate increases with the decrease in the hydrogen-ion concentration but eventually reaches at a constant value, $k_{3-obs}=6.0\times10^{-3}$ min^{-1} at $[H^+]=0.06$M. The results shown in Fig. 7 clearly indicate an inverse first-order dependence of the oxidation rate on the hydrogen-ion concentration. The reaction can thus be expressed by a relation of the type:

$$k_{3-obs} = A\cdot K_h/[H^+] \quad (7)$$

where A is the constant defined by the experimental conditions. The K_h constant, which has the dimension of molarity, was determined from the slope of straight line in Fig. 7 as follows: $K_h=1.4\times10^{-2}$M. This value is close to the secondary dissociation constant of H_2SO_4 ($K_2=1.2\times10^{-2}$M). Thus, it is possible to consider that K_h is the dissociation constant of the hydrogen peroxydisulfate ion, $HS_2O_8^-$.

From the results obtained by the effects of the reaction variables, the over-all rate equation of the Am(III) oxidation reaction may be expressed as follows:

$$-\frac{d[Am(III)]}{dt} = K_h(k_1+k_2[Ag^+])[Am(III)][S_2O_8^{2-}]\cdot 1/[H^+] \quad (8)$$

where k_2 and k_1 refer to the reaction paths catalyzed and uncatalyzed by the silver ion respectively.

From the kinetic relationship, it may be concluded that Am(III) disappears upon reaction with the SO_4^- produced in the decomposition reaction. The kinetics are consistent with the following mechanism:

$$S_2O_8^{2-} \longrightarrow 2SO_4^- \quad (9)$$

$$SO_4^- + Am(III) \longrightarrow Am(VI) \quad (10)$$

If the radicals produced in the reaction(9) react rapidly with Am(III), then the rate is proportional to the concentration of the peroxydisulfate ion and it follows that the measured rate law refers to the unimolecular dissociation of the peroxydisulfate ion. Kolthoff and Miller[10] have shown that a second decomposition reaction occurs in acid media:

$$H^+ + S_2O_8^{2-} \rightleftharpoons HS_2O_8^- \longrightarrow HSO_4^- + SO \quad (11)$$

The fact that the rate of the disappearance of Am(III) was dependent of the reversed hydrogen-ion concentration showed conclusively that Am(III) did not react with SO_4; furthermore, the oxidation of Am(III) might be hindered by the reaction (11). This is in agreement with the above-described mechanism that the two modes of dissociation occur at a comparable rate at these particular hydrogen-ion concentrations.

A mixture of the silver ion and the peroxydisulfate ion forms more powerful oxidizing system than $S_2O_8^{2-}$ alone. The existence of the divalent silver ion is well established,[11] and the influence of Ag^+ in the decomposition of the peroxydisulfate ion can be accounted for by the formation of Ag^{2+} according to the reaction:

$$Ag^+ + S_2O_8^{2-} \longrightarrow Ag^{2+} + SO_4^{-\cdot} + SO_4^{2-} \quad (12)$$

The Period of Induction. When the Am(III) solution was added to a solution containing the ammonium peroxydisulfate and silver nitrate, the oxidation reaction did not start immediately, but after a certain time interval following the mixing of the reactants. This time interval is termed the induction period and is listed in Table 2 for various experimental conditions.

Table 2. Variations of the induction period

		Induction Period, min					
$[AgNO_3]\times10^3$M		0	0.1	0.3	0.5	0.6	1.0
Temp, °C	40	1800	100	35	—	10	0
	50	385	60	25	—	16	1
	60	41	28	8	—	7	6
	70	9	8	5	—	2	2
$[(NH_4)_2S_2O_8]$ $\times10^2$M	0.5				11		
	1.4				7		
	2.0				5		
	3.0				5		
	4.2				10		
	5.0				6		
μ[a]	0.12	25	15	5	—	2	1
	0.25	47	18	8	—	3	2
	0.50	41	28	8	—	7	6
	0.75	120	35	15	—	13	7
	1.00	68	34	10	—	4	6

a) μ was adjusted by the addition of sodium nitrate.

No change in the absorption spectrum due to Am(III) was observed at 503 mμ; however, visible changes were observed in the wavelength region lower than 503 mμ during the induction period (Fig. 2). An increase in the concentration of any of the reactants or an increase in the temperature decreased the period of induction. Thus, it appears that the induction period is related to

11) C. E. H. Bawn and D. Margerison, *Trans. Faraday Soc.*, **51**, 925 (1955).

the mechanism of the oxidation of Am(III). In view of the mechanism, the induction period is the time required for the thermal activation of the peroxydisulfate ion to split into SO_4^- radicals, which then produce the Ag^{2+} responsible for the oxidation of Am(III). An increase in the temperature increases the rate of the chain-initiating process, resulting in a decrease in the induction period. Similarly, an increase in the concentration of either the silver ion or the peroxydisulfate ion increases the rate of SO_4^- radical production by means of reaction (12) or (13) respectively, thereby decreasing the period of induction.

$$S_2O_8^{2-} \rightleftarrows S_2O_8^{2-*} \longrightarrow 2SO_4^- \qquad (13)$$

where (*) denotes the activated state; therefore,

$$SO_4^- + Am(III) \longrightarrow SO_4^{2-} + Am(VI) \qquad (14)$$

Energies of Activation. The plots of log k_1 and k_2 against $1/T$ have been represented in Fig. 8. From the slopes of the straight lines, the activation energies of the silver-ion-catalyzed and uncatalyzed reactions were calculated to be 17.4 ± 0.6 kcal/mol and 28.6 ± 0.8 kcal/mol respectively.

These values are the same as the activation energies calculated in the decomposition of the peroxydisulfate ion[11] in the absence or presence of a silver-ion catalyzer. Such an agreement of values suggests that the same mechanism may be involved in the rate-determining steps of the reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3051—3055 (1971)

Metal Complexes Containing Six-Membered Chelate Rings. I. Preparation and Structure of 2,4-Pentanediaminetetraacetato Complexes of Cobalt(III)

Fujio MIZUKAMI, Haruko ITO, Junnosuke FUJITA, and Kazuo SAITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received May 31, 1971)

New cobalt(III) complexes with 2,4-pentanediaminetetraacetate (2,4-ptnta^{4-}) have been prepared. The optically active 2,4-ptnta^{4-} (RR or SS) forms a sexadentate complex and determines the absolute configuration around the metal ion. The *meso*-2,4-ptnta^{4-} (RS) coordinates to the metal ion as a quinquedentate with a free acetate branch. Such stereospecific formations of sexa- and quinquedentate complexes from the optically active and the *meso* 2,4-ptnta^{4-} have been attributed to the steric regulation coming from the methyl groups on the α-carbon atoms.

Recently van Saun and Douglas[1] and Ogino *et al.*[2] prepared and resolved cobalt(III) complexes of trimethylenediaminetetraacetate (trdta^{4-}), and suggested that the ligand acts as a sexadentate with less strain as compared with the sexadentate ethylenediaminetetraacetate (edta^{4-}) in an octahedral complex.

The trdta^{4-} complex involves a six-membered chelate ring with puckered skeletal structure in the trimethylenediamine part, for which the following four conformers are possible; chair, two twist (δ) and (λ), and boat form, as shown in Fig. 1. Molecular models clearly indicate that when trdta^{4-} forms a stable octahedral complex as sexadentate, the six-membered chelate should have twist form,[2] and that the δ twist should give a complex with Λ configuration and the λ twist that with Δ configuration. The trdta^{4-} in chair form can not behave as sexadentate, but does as quinquedentate ligand with a free acetate branch. (Fig. 2)

It is generally understood that methyl groups on carbon atoms in puckered chelate rings always tend to take equatorial position.[3] Hence a stereospecific or stereoselective complex formation may be expected by use of such ligands as *l*-propylenediaminetetraace-

tate.[4] In this paper, we report the preparation of cobalt(III) complexes of 2,4-pentanediaminetetraacetate (2,4-ptnta^{4-}) which has two methyl groups on the α-carbon atoms adjacent to the amino nitrogen, and discuss the relationship between the structure of these complexes and the optical isomerism of 2,4-pentanediamine, from which the 2,4-ptnta^{4-} ligand is derived.

Experimental

Preparation of Ligands. *2,4-Pentanediamine*: This diamine exists in three isomers, *meso* (RS) and a pair of racemic (RR) and (SS), as shown in Fig. 3. Very recentlyAppleton and Hall[5] reported the separation and the resolution of these isomers. The present method was almost the same as theirs.

Acetylacetone dioxim was reduced with metallic sodium in ethanol by Harries and Haga's [6] and Dippel's[7] metod, and the product was collected by steam distillation. The aqueous ethanol solution of the diamine was acidified with hydrochloric acid and evaporated almost to dryness under reduced pressure. The product, a mixture of *meso* and racemic diaminedihydrochloride, was separated by the following method; a suspension of 100 g of the mixture in 500 m*l* of 95% ethanol was heated to boiling with stirring, and then filtered in hot. The insoluble material was treated further twice with ethanol in the same way, the volume of ethanol being adjusted according to the amount of insoluble material. The residue was almost pure racemic dihydrochloride. Its purity can be examined by the PMR spectrum in deuterium oxide. (Fig. 4) The filtrate was united, cooled to room temperature, the precipitate filtered off, washed with absolute ethanol and ether, and air dried. This product consists of mostly racemate, but contains a small amount of *meso* isomer, which can be removed by repeating the method described above. Ether was added slowly to the filtrate with stirring until the solution became turbid, which was kept in a refrigerator over night. A mixture of racemic and *meso* isomer was precipitated. Here the *meso* isomer formed large prismatic crystals, while the racemate gave fine needle crystals. Thus, these two isomers can be easily separated by decanting the latters with absolute ethanol repeatedly. A small amount of almost pure *meso* isomer was obtained by evaporating all the filtrates under reduced pressure.

Found: racemic isomer C, 34.69; H, 9.27; N, 15.99%. meso isomer C, 34.19; H,9.34; N, 15.99%. Calcd for $C_5H_{16}Cl_2N_2$: C,34.30; H, 9.21; N, 16.00%

The dihydrochloride was converted into free diamine by the following method. An aqueous solution containing a slight excess of potassium hydroxide was added to the dihydrochloride in a small amount of water below 5°C with stirring. The solution was filtered to remove potassium chloride. Free diamine was obtained in aqueous solution by distilling the filtrate under reduced pressure. The concentration was determined by titrating with aqueous 0.1N perchloric acid solution.

As was pointed out by Appleton and Hall,[5] Dippel's assignment of these isomers should be reversed; his racemic (α-isomer) is meso and his meso (β-isomer) is racemic, since his meso was resolved into optical isomers.

Resolution of racemic 2,4-pentanediamine: This was resolved by Appletonand Hall's method as *d*-tartrate. Effective resolution was also substantiated by use of *trans*-1,2-cyclohexanedicarboxylic acid. The specific rotation was the same as that by use of *d*-tartrate.

The tartrates were converted into free diamines by the following method; a small excess of aqueous barium hydroxide solution (1:1) was added to an aqueous solution of the tartrate. The precipitate was filtered off, washed with a small amount of water and the filtrate and the washings were distilled under reduced pressure. The product contained a significant amount of water, and the diamine concentration was determined by titration with 0.1N perchloric acid solution.

The specific rotation of the enantiomers in water are as follows; $[\alpha]_D = -8.33°$ from crystalline *d*-tartrate

$[\alpha]_D = +8.46°$ from oily *d*-tartrate

$(+)_D$-Isomer can be assigned to (SS) configuration, and $(-)_D$-isomer to (RR) configuration, as discussed later.

2,4-Pentanediaminetetraacetate: Free acid and the barium salt of RR-2,4-pentanediaminetetraacetate were synthesized according to a similar method to that for trimethylenediaminetetraacetate by Weyh and Hamm.[8] Monochloroacetic

acid (13.9 g) in 14 m*l* of water was neutralized with 9 g of potassium hydroxide in 15 m*l* of water below 20°C with stirring, and treated with 3.16 g of $(-)_D$-diamine in 5 m*l* of water. The solution was heated at 80°C for 2 hr and 9 g of potassium hydroxide in 10 m*l* of water was added. The solution was evaporated to about 30 m*l* at 80°C, cooled to 0°C and filtered to remove potassium chloride. To the filtrate was added 15.4 g of barium chloride dihydrate in 30 m*l* of hot water with stirring, and the solution was evaporated at 80°C to about 35 m*l*. The barium salt was filtered off, washed with hot water (80°C) several times and air dried.

Found: C, 23.38; H, 3.50; N, 4.37%. Calcd for $C_{13}H_{24}N_2O_{11}Ba_2=Ba_2$(RR-2,4-ptnta)$\cdot 3H_2O$: C, 23.69; H, 3.67; N, 4.25%.

Barium salts of racemic- and meso-2,4-pentanediaminetetraacetate were prepared similarly, but the latter was obtained as powder by adding methanol to its concentrated aqueous solution. Both barium salts give only approximate coincidence between found and calculated analytical results, but their cobalt complexes give very satisfactory analytical results.

Preparation of Metal Complexes. Cobalt(III) complexes of isomers of 2,4-ptnta^{4-} were prepared from $Na_3[Co(NO_2)_6]$[9]. The yields of the complexes were rather low because cobalt(III) was reduced to cobalt(II) during the reaction. Preparation from cobalt(II) salt, 2,4-ptnta^{4-} and an oxydizing agent such as hydrogen peroxide and lead dioxide yielded a large amount of cobalt(II) complex, which could hardly be removed.

The racemic barium salt was treated with an equivalent amount of dilute sulfuric acid, centrifuged and the supernatant evaporated to dryness. The residue was extracted with ethanol and the ethanol evaporated off.

H[Co(RR- and SS-2,4-ptnta)]$\cdot 3H_2O$: An aqueous solution (100 m*l*) containing 6.6 g of racemic $H_4$2,4-ptnta (prepared from 13 g of barium salt) and 8 g of $Na_3[Co(NO_2)_6]$ was warmed at 50°C for 3 hr, cooled to room temperature and filtered. The filtrate was passed through a column of the anion exchanger Dowex 1-X4 in chloride form. The column was washed with water to remove the cobalt(II) ion and the adsorbed purple band was eluted with 0.1N hydrochloric acid. The eluate was condensed in a vacuum desiccator over potassium hydroxide to about 10 m*l*. Purple crystals were deposited by adding ethanol under cooling, which were filtered off, washed with ethanol, air dried and recrystallized from water by cooling together with ethanol.

Found: C, 34.77; H, 5.33; N, 6.13%. Calcd for $C_{13}H_{25}N_2O_{11}Co$: C, 35.14; H, 5.67; N, 6.31%.

K[Co(RR-2,4-ptnta)]$\cdot H_2O$: This complex was prepared from RR-H_4-2,4-ptnta and $Na_3[Co(NO_2)_6]$ by a similar method to that for the racemic-2,4-ptnta complex. Acid complex was converted into potassium salt by treating with aqueous potassium iodide and ethanol. The product was recrystallized from water by adding ethanol.

Found: C, 34.16; H, 4.41; N, 6.02%. Calcd for $C_{13}H_{20}N_2O_9KCo$: C, 34.98; H, 4.55; N, 6.28%.

The rotation of this complex in water shows plus sign at Na D line.

Resolution of H[Co(RR- and SS-2,4-ptnta)]$\cdot 3H_2O$ A solution containing 1.5 g of H[Co(RR- and SS-2,4-ptnta)]$\cdot 3H_2O$ in 25 m*l* of water was stirred with a slight excess of silver oxide, and filtered. The filtrate was added to a suspension containing 1.2 g of $(+)_D$-$[Co(NO_2)_2en_2]Br$[10] in 60 m*l* of water. The mixture was stirred for 20 min, filtered to remove silver bromide, and condensed in a vacuum desiccator over phosphorus pentoxide. When the volume of the filtrate became about 50 m*l*, the first fraction of crystalline diastereomer (0.5 g) was obtained with specific rotation of +887° at Na D line (fraction 1). Recrystallization from water did not increase the rotation. The filtrate was evaporated again to decrease the volume to about 42 m*l*. The second fraction (0.5 g) was obtained with specific rotation of −696° at Na D line (fraction 2). The recrystallized sample from water showed the same specific rotation. By repeating such a fractional crystallization, three more fractions were obtained, but their specific rotations showed smaller absolute values than those of the fractions 1 and 2. Pure diastereomers were further obtained from these three fractions by repeated fractional crystallization from water.

$(+)_D$-*d*-$[Co(NO_2)_2en_2][Co$(2,4-ptnta)$]\cdot 2H_2O$, $[\alpha]_D=+887°$, Found: C, 28.98; H, 5.36; N, 16.28%. Calcd for $C_{17}H_{38}N_8O_{14}Co_2$: C, 29.32; H, 5.36; N, 16.09%.

$(-)_D$-*d*-$[Co(NO_2)_2en_2][Co$(2,4-ptnta)$]\cdot 6H_2O$, $[\alpha]_D=-696°$, Found: C, 26.63; H, 5.95; N, 14.71%. Calcd for $C_{17}H_{46}N_8O_{18}Co_2$: C, 26.57; H, 6.03; N, 14.58%.

These diastereomers were converted into potassium salts by the following method. A solution containing 0.67 g of either $(+)_D$- or $(-)_D$-isomer in 15 m*l* of water was treated with 0.53 g of potassium iodide, warmed at 70°C for 10 min, kept at 0°C for 2 hr and filtered to remove the precipitated $(+)_D$-$[Co(NO)_2en_2]I$. Addition of ethanol to the filtrate gave violet crystals (0.37 g), which were recrystallized from aqueous solution by adding ethanol.

$(+)_D$-[Co(2,4-ptnta)]$\cdot H_2O$, $[\alpha]_D=+1446°$, Found; C, 34.40; H, 4.55; N, 6.31%.

$(-)_D$-[Co(2,4-ptnta)]$\cdot H_2O$, $[\alpha]_D=-1420°$, Found: C, 34.61; H, 4.53; N, 6.27%. Calcd for $C_{13}H_{20}N_2O_9KCo$: C, 34.98; H, 4.55; N, 6.28%.

H[CoCl(RS-2,4-ptntaH)]: Barium salt of *meso*-2,4-ptnta was similarly converted into $H_4$2,4-ptnta. When an aqueous solution containing 7 g of this *meso*-$H_4$2,4-ptnta and 8 g of $Na_3[Co(NO_2)_6]$ was warmed at 60°C for 3 hr, a reddish brown solution was obtained. This was treated with dilute hydrochloric acid at 60°C for 30 min to give a blue solution. This was evaporated almost to dryness in a vacuum desiccator over potassium hydroxide. The residue was dissolved in a small amount of water and passed through a column containing the anion exchanger Dowex 1-X4 in chloride form. The column was washed with water and the adsorbed blue band was eluted with 0.1N hydrochloric acid. The eluate was condensed in a vacuum desiccator over potassium hydroxide and treated with ethanol. Blue crystals were precipitated on cooling, filtered off, washed with ethanol, air dried and recrystallized from 0.1N hydrochloric acid by adding ethanol.

Found: C, 36.35; H, 5.58; N, 6.55%. Calcd for $C_{13}H_{19}N_2O_8ClCo$: C, 36.59; H, 4.72; N, 6.57%.

When the reddish brown solution was submitted to the anion exchange and then treated with 0.1N hydrochloric acid *in situ*, the brown band changed the color into blue with evolution of bubbles and eluted. The same blue crystals were obtained on a similar treatment of the eluate.

K[CoCl(RS-2,4-ptntaH)]: H[CoCl(RS-2,4-ptntaH)] was dissolved in a small amount of 0.1N hydrochloric acid and an excess of potassium acetate was added. Blue crystals obtained on adding ethanol to the solution were filtered off, washed with ethanol, air dried and recrystallized from 0.1N hydrochloric acid by adding ethanol.

Found: C, 33.35; H, 4.07; N, 6.06%. Calcd for $C_{13}H_{19}N_2O_8ClKCo$: C, 33.59; H, 4.12: N, 6.03%.

Elemental analysis and the pH measurement of the aqueous solution suggest that the product is in the given form with free acetic acid branch.

tra were recorded with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. with its CD attachment. PMR spectra were obtained with a Varian T-60 spectrometer using Na-TMS as an internal standard. Infrared spectra were recorded with a Hitachi EPI-2G spectrophotometer. All the measurements were made at room temperature.

Results and Discussion

Structure of the Complexes

As Fig. 5 and Table 1 show, the absorption spectrum of [Co(RR- and SS-2,4-ptnta)]$^-$ is very similar to that of [Co(trdta)]$^-$ [1,2], in which the trdta^{4-} coordinates to the cobalt(III) ion as a sexadentate ligand. The infrared spectrum of H[Co(RR- and SS-2,4-ptnta)]·$3H_2O$ exhibits no absorption of free carboxylate. It is thus clear that the complex contains sexadentate ligand (RR- or SS-ptnta^{4-}) with twist form of the six-membered chelate as stated previously. Studies with molecular models made it clear that both RR- and SS-2,4-ptnta^{4-} could form two possible configurational isomers, Δ and Λ-complex. The orientation of both

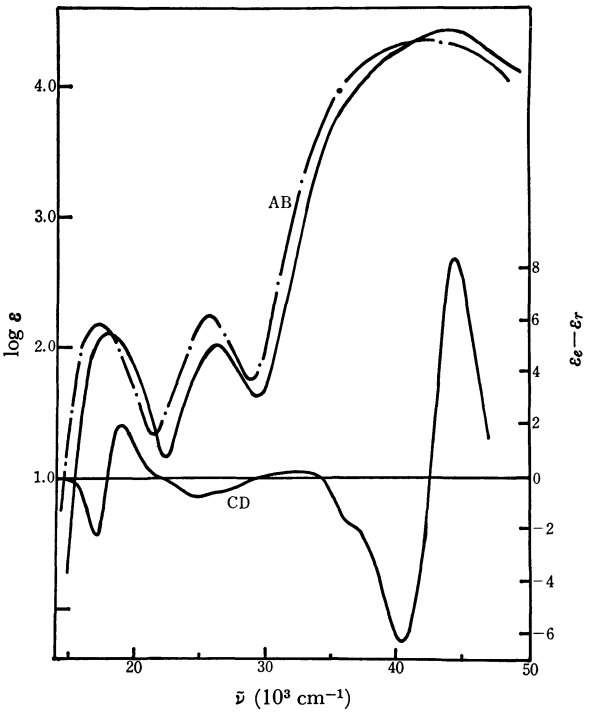

Fig. 5. Absorption (AB) and circular dichroism (CD) spectra of (+)D-K[Co(RR-2,4-ptnta)]·H_2O in H_2O (——), and AB spectrum of H[CoCl(RS-2,4-ptntaH)] in dil. HCl (—·—·).

methyl groups of the Δ complex of RR-2,4-ptnta^{4-} is equatorial to the six-membered ring (λ twist), while that of its Λ complex is axial to the chelate ring (δ twist) (Table 2). However, the existence of the diastereoisomer with the axial methyl groups has not been known so far in such chelate complexes. Thus, the complex which was prepared from racemic 2,4-ptnta^{4-} consists most likely of only a racemic pair, Δ-[Co(RR-2,4-

Table 2. Conformations of diamine part in 2,4-pentanediaminetetraacetates

ptnta)]$^-$ and Λ-[Co(SS-2,4-ptnta)]$^-$. Fig. 5 shows the CD spectrum of $(+)_D$-[Co(2,4-ptnta)]$^-$ in water. This isomer gives a CD pattern very similar to that of Δ-[Co(trdta)]$^-$ in the region of the first absorption band (18000 cm^{-1})[1,2]. It seems that the $(+)_D$-isomer has Δ-configuration and the 2,4-ptnta^{4-} ligand must have RR-configuration. The reaction of $Na_3[Co(NO_2)_6]$ with 2,4-ptnta^{4-} which was prepared from $(-)_D$-2,4-pentanediamine produced only $(+)_D$-Δ-[Co(2,4-ptnta)]$^-$ under the given condition. These results indicate that the complex formation between the cobalt(III) ion and the optically active ptnta^{4-} is stereospecific. It is also clear that the absolute configuration of the carbon atoms of the $(-)_D$-2,4-pentanediamine could be assigned to RR.

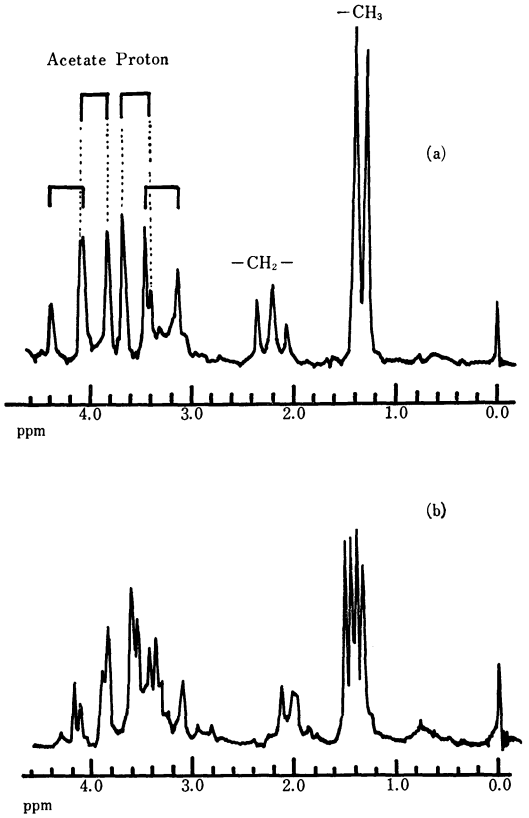

Fig. 6. PMR spectra of (a) [Co(RR- and SS-2,4-ptnta)]$^-$ (D_2O), (b) [CoCl(RS-2,4-ptntaH)]$^-$ (DCl-D_2O), (60 MHz).

The PMR spectrum of the [Co(RR- and SS-2,4-ptnta)]$^-$ in deuterium oxide provides useful information. The spectrum exhibits only one methyl signal and two kinds of acetate methylene signal. (Fig. 6). In this figure is given a tentative assignment for the observed signals.[2] The complex ion, [Co(RR- and SS-2,4-ptnta)]$^-$ has a two-fold axis through the cobalt ion and the β-carbon atom of the six-membered ring, and therefore, the two methyl groups are in an equivalent environment.

The complex, [CoCl(RS-2,4-ptntaH)]$^-$ on the other hand, is considered to involve a quinquedentate ligand. Its infrared absorption spectrum at about 1600 cm^{-1} is much broader than that of the violet complex with sexadentate RR- or SS-2,4-ptnta^{4-}. The free carboxylate absorption may overlap the strong band due to the coordinated carboxyl stretching vibration.

Figure 5 compares the visible and ultraviolet absorption spectra of the quinquedentate and the violet sexadentate complex. The first absorption band of the former complex shows at lower wave number than that of the latter complex. This is in good accord with the spectrochemical series,[11] indicating that the chloride ion coordinates to the cobalt(III) ion in the meso-2,4-ptnta complex.

The PMR spectrum of the chloro complex will also support the quinquedentate coordination of RS-ptnta^{4-}. As Fig. 6 shows, the [CoCl(RS-2,4-ptntaH)]$^-$ in DCl-D_2O gives two kinds of methyl signal, and the signals of acetate methylenes are much more complicated than those of the violet sexadentate complex with racemic or optically active 2,4-ptnta^{4-}. Such a quinquedentate coordination of the meso ligand may be caused by a steric requirement due to the methyl groups on the six-membered ring as stated previously. Molecular models indicate that so far as the methyl groups orientate equatorially to the chelate ring, the six-membered ring should take the chair form and only three out of four acetate branches seem to be allowed to coordinate to the cobalt(III) ion. Figure 2 illustrates this structure schematically. Its structure has no symmetry element and gives a racemic pair which depends on the coordination of either of the two out-of-plane acetate branches. Attempts for optical resolution of this pair have been unsuccessful so far.

Such a stereospecific formation of sexa- and quinquedentate complex from racemic and meso ptnta^{4-} clearly indicates that the steric regulation coming from the methyl group on the α-carbon atom is very strong in the six-membered rings as well as in the five-membered rings

We wish to thank the Ministry of Education for the financial support granted to this research.

Kinetic Studies of the Electron Transfer Reaction in Iron(II) and Iron(III) Systems. IV. The Reaction in Mixed Solvents of Dimethyl Sulfoxide and Water[1]

Goro WADA and Michiko AOKI

Department of Chemistry, Faculty of Science, Nara Women's University, Nara

(Received July 5, 1971)

The rate constants, k_{app}, of the electron transfer reaction between iron(II) and iron(III) in mixed solvents of DMSO and water were measured at various acid and DMSO concentrations at μ=0.50M and 25°C. The k_{app} decreased linearly with the increase in [DMSO] at a constant [H^+] and increased linearly with the increase in 1/[H^+] at a constant [DMSO]. The reaction is considered to proceed through two paths: $Fe^{2+}+{}^*Fe^{3+}\rightarrow Fe^{3+}+{}^*Fe^{2+}$ and $Fe^{2+}+{}^*FeOH^{2+}\rightarrow FeOH^{2+}+{}^*Fe^{2+}$, with the rate constants of k_O and k_H respectively. Both k_O and k_H were suppressed by the addition of DMSO to water because of the occurrence of molecular association between DMSO and water. The hydration number of DMSO in a very dilute aqueous solution was approximately six, as revealed by the cryoscopic measurements. The suppression of k_O and k_H was proportional to [DMSO], with a common proportional constant. Consequently, DMSO was deduced to destroy the chains of water molecules connected by hydrogen bondings and to interfere with the ease of hydrogen atom transfer between the reducing and oxidizing iron species. DMSO itself did not serve as a ligand to catalyze the reaction as *N*-methylacetamide, *N*,*N*-dimethylacetamide, and various other anions do.

In aqueous media, the electron transfer reaction between iron(II) and iron(III), Fe(II)+*Fe(III)→Fe(III)+*Fe(II), has been concluded to proceed generally *via* the hydrogen atom transfer mechanism[2] except when the iron species were complexed with some catalytic ligands with a bridging nature or with conjugate double bond systems, in which cases the reaction occurred predominantly *via* the inner- or outer-sphere mechanism respectively instead.[3]

In pure dimethyl sulfoxide (DMSO), however, the reaction between the simply solvated iron species was found to occur faster than in water in the absence of any complexing ligands, although DMSO had no exchangeable hydrogen atoms which might have promoted the reaction to proceed *via* the hydrogen atom transfer mechanism;[4] therefore, the electron transfer reaction between the solvated iron species may occur not only at a different rate, but also through a different path, as the reaction medium changes.

When either *N*-methylacetamide or *N*,*N*-dimethylacetamide was added to water, the reaction was slightly accelerated in quite a similar way. This can be accounted for by the fact that the coordination of one of these substances to the iron ion favored the transfer of hydrogen atoms of water molecules, as a non-bridging ligand attaching to the central ions at the opposite side of the reactive site.[5]

The reaction in mixed solvents of DMSO and water was first observed by Menashi and others,[4] who recognized that the reaction rate exhibited a broad minimum at a certain mole fraction range of DMSO when the hydrogen ion concentration was not very low. In the present paper, the effect of the addition of a small amount of DMSO on the reaction mechanism was investigated in more detail in order to clarify the cause of the decrease in the reaction rate. This phenomenon seems to be related to the strong associative nature of DMSO with water molecules.

Experimental

The methods of preparing the chemical materials used and of the kinetic measurements were quite the same as have been described previously.[1,4] The temperature and the ionic strength of the reaction systems were kept at 25°C and μ=0.50M respectively, unless otherwise noted.

Since the iron(III) species was initially labelled with ^{59}Fe, the iron(II) species gradually became radioactive as time passed after the initiation of the reaction. If the total concentrations of the iron(II) and iron(III) species in the reaction system are represented as [Fe(II)] and [Fe(III)] respectively, and the radioactivities of the iron(II) species at time, t, and infinite time, t_∞, as x and x_∞ respectively, the McKay relation will hold as follows:

$$\ln\left(1-\frac{x}{x_\infty}\right)=-\frac{[Fe(II)]+[Fe(III)]}{[Fe(II)][Fe(III)]}Rt \qquad (1)$$

where R is the total rate of the electron transfer reaction.[6]

The freezing-point depression of water by the addition of DMSO was measured by the usual method in order to determine the hydration number of DMSO in their mixtures.

Results and Discussion

A typical plotting of the linear relation of $\log(x_\infty-x)$ against t is shown in Fig. 1. The slope of the straight line gives the half-life period of the reaction, $t_{1/2}$; thus, the total rate of the electron transfer reaction, R, is obtained:

$$R=\frac{0.693[Fe(II)][Fe(III)]}{([Fe(II)]+[Fe(III)])t_{1/2}} \qquad (2)$$

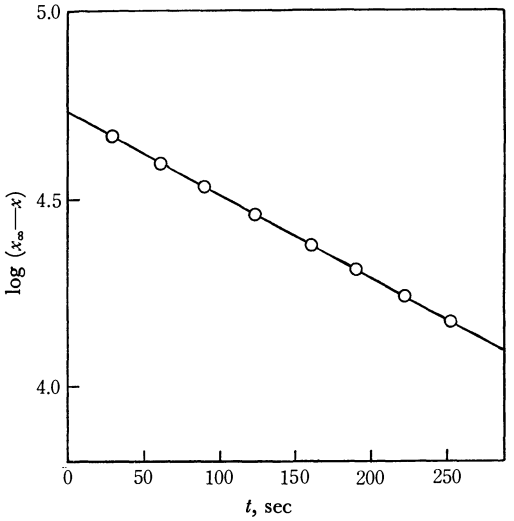

Fig. 1. Plot of log (x_∞—x) *vs.* time at μ=0.50M and 25°C.
[Fe(II)]=9.99×10^{-5}M [Fe(III)]=2.28×10^{-5}M
[DMSO]=1.50M [H+]=0.07M

The results of the measurements are listed in Table 1. In the table, there are some groups of data on the cases in which both the [H+] and [DMSO] used were kept constant; for example, there is a set of data for four kinetic runs performed at [H+]=0.20M and [DMSO]=0.188M, with the half-lives of the respective runs being different from one another. If the rate is proportional to both [Fe(II)] and [Fe(III)], the second-order rate

(a) [H+]=0.05M (b) [H+]=0.07M (c) [H+]=0.10M
(d) [H+]=0.15M (e) [H+]=0.20M (f) [H+]=0.30M
(g) [H+]=0.45M

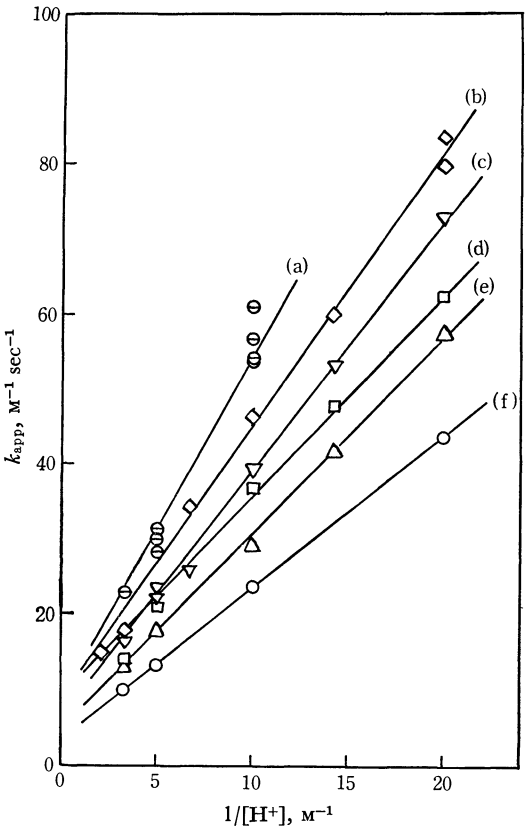

Fig. 3. Plot of k_{app} *vs.* 1/[H$^+$] at various [DMSO] at μ= 0.50M and 25°C.
(a) [DMSO]=0M (b) [DMSO]=0.601M
(c) [DMSO]=0.940M (d) [DMSO]=1.22M
(e) [DMSO]=1.50M (f) [DMSO]=2.00M

constant, k_{app}, is obtained by the following equations:

$$R = k_{app}[Fe(II)][Fe(III)] \quad (3)$$

$$k_{app} = \frac{0.693}{([Fe(II)]+[Fe(III)])t_{1/2}} \quad (4)$$

The values of k_{app} obtained in this way at fixed [H$^+$] and [DMSO] values show a good constant value within the range of experimental error. Therefore, this fact indicates that the reaction can be considered to be of the first order with respect to both [Fe(II)] and [Fe(III)]. In Table 1, the k_{app}'s derived by means of Eq. (4) are shown as the observed values.

It is noticeable that the values of k_{app} in Table 1 vary as the concentration of the hydrogen ion or of DMSO varies. Fig. 2 shows that the k_{app} decreases linearly as the DMSO concentration increases at a constant [H$^+$], and Fig. 3, that the k_{app} is also linear with respect to the reciprocal hydrogen-ion concentration at a constant [DMSO].

When *N*-methylacetamide or *N,N*-dimethylacetamide was added to water instead of DMSO, the matter was quite different from the case of DMSO, with the result that the k_{app} grew larger as the concentration of *N*-methylacetamide or *N,N*-dimethylacetamide became higher.[5] In other words, *N*-methylacetamide and *N,N*-dimethylacetamide are accelerators, while DMSO acts as an inhibitor, of the present reaction.

In aqueous solvents, the main paths of the electron transfer between iron(II) and iron(III) species are the following two reactions:

$$Fe^{2+} + *Fe^{3+} \xrightarrow{k_0} Fe^{3+} + *Fe^{2+} \quad (5)$$

$$Fe^{2+} + *FeOH^{2+} \xrightarrow{k_H} FeOH^{2+} + *Fe^{2+} \quad (6)$$

The respective rate constants are represented as k_0 and k_H. Fe^{2+} and Fe^{3+} represent solvated species, and $FeOH^{2+}$, an iron(III) one of whose solvating water molecules has been hydrolyzed to lose a proton.

When a foreign substance is added to the reaction system, the possibility of the occurrence of an electron transfer between the species coordinated with the substance as a ligand must be taken into account in addition to the paths of (5) and (6). This consideration has been successful in the cases of various anions and mono- and di-methylacetamide, where these substances promote the reaction, while in the present case of DMSO, this kind of procedure can not interpret the decrease in k_{app} at all. The decrease in k_{app} due to the addition of DMSO seems to be attributable to the depression of the activity of water in the mixed solvent.

It is well known that the electron transfer processes expressed by (5) and (6) occur predominantly *via* the hydrogen atom transfer mechanism, in which water molecules used as the solvent play an important role through the chains connected by hydrogen bondings.[2] When DMSO is added to water, it strongly interacts with water, depressing the water activity, as will be described below. If the rate constants, k_0 and k_H, are assumed to be lowered in proportion to the concentration of DMSO, these constants in the mixed solvent may be expressed in the following forms where k_0^0 and k_H^0 represent the constants in the absence of DMSO and where a and b are proportional constants:

$$k_0 = k_0^0(1-a[DMSO]) \quad (7)$$

$$k_H = k_H^0(1-b[DMSO]) \quad (8)$$

Then, according to the usual method of calculation, the k_{app} can be expressed as a function of [H$^+$] and [DMSO]:

$$k_{app} = \frac{k_0^0(1-a[DMSO])+k_H^0K_H(1-b[DMSO])/[H^+]}{1+K_H/[H^+]} \quad (9)$$

in which K_H is an equilibrium constant for the hydrolysis, $Fe^{3+} \rightleftharpoons FeOH^{2+}+H^+$, being equal to 1.59×10^{-3}M.[7] Even at the lowest value of [H$^+$]=0.05M used in the present experiment, the denominator on the right-hand side of Eq. (9) may reasonably be regarded as unity. Thus, the rearrangement of Eq. (9) leads us to the following:

$$k_{app} = \left(k_0^0+\frac{k_H^0K_H}{[H^+]}\right)-\left(ak_0^0+\frac{bk_H^0K_H}{[H^+]}\right)[DMSO] \quad (10)$$

$$= k_0^0(1-a[DMSO]) + \frac{k_H^0K_H(1-b[DMSO])}{[H^+]} \quad (11)$$

Eq. (10) demonstrates the linear relationship between the k_{app} and [DMSO] as is pictured in Fig. 2, and Eq. (11), that between the k_{app} and 1/[H$^+$], as is pictured in Fig. 3. If the slope of a straight line in Fig. 2 is

7) A. S. Wilson and H. Taube, *J. Amer. Chem. Soc.*, **74**, 3509 (1952).

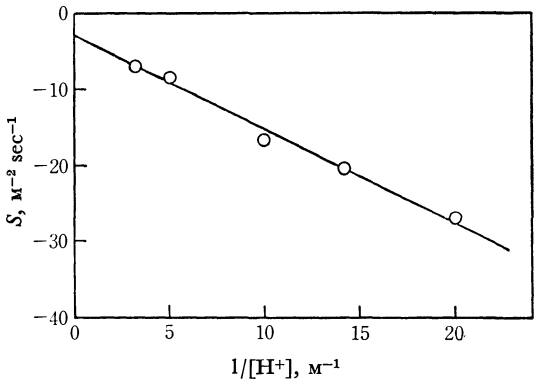

Fig. 4. Plot of slopes of straight lines in Fig. 2 *vs.* $1/[H^+]$.

denoted by S, S is expressed by this equation:

$$S = -ak_0^0 - \frac{bk_H^0K_H}{[H^+]} \tag{12}$$

which also indicates the linear relationship between the S and $1/[H^+]$, as is shown in Fig. 4, with an intercept of $-ak_0^0 = -3\,M^{-2}sec^{-1}$ and with a slope of $-bk_H^0K_H = -1.4\,M^{-1}sec^{-1}$. Since k_0^0 and $k_H^0K_H$ are known from the intercept and the slope of the straight line at [DMSO]=0 in Fig. 3 as $k_0^0 = 9\,M^{-1}sec^{-1}$ and $k_H^0K_H = 4.6\ sec^{-1}$ respectively,[8] a and b can be approximately calculated as follows:

$$a \doteqdot 0.3\,M^{-1}$$

$$b \doteqdot 0.3\,M^{-1}$$

These numerical results for a and b suggest that the addition of DMSO to water equally depresses the rates of both reactions, (5) and (6). Thus, the calculated values of k_{app} using the various constants obtained above are listed in the last column in Table 1. The agreement between the observed and the calculated results is pretty good.

The characteristic interactions between DMSO and water have been recognized from several points of view; the viscosities and local liquid structures in DMSO-water mixtures[9] and the heat of solution of DMSO in water[10] were especially investigated, indicating that a molecular association occurs between DMSO and water.

If there were no molecular association between them, the ideal freezing-point depression of water, ΔT_f^0, would be expected to be given by the following equation:

$$\Delta T_f^0 = \frac{1000gK_f}{GM} \tag{13}$$

in which G and g are the weights of water and DMSO contained in the system respectively, M, the molecular weight of DMSO, and K_f, the molar depression of freezing point of water. However, the actually observed depression of the freezing point of water, ΔT_f, was always much larger than the expected value by Eq. (13). This is because DMSO associates with water; therefore, there occurs a decrease in the amount of water as the solvent, by as much as p:

$$\Delta T_f = \frac{1000gK_f}{(G-p)M} \tag{14}$$

Consequently, the hydration number of DMSO, h, can be defined from Eq. (14) as follows:

$$h = \frac{p}{18m_{DMSO}} = \frac{m_W}{m_{DMSO}} - \frac{55.5K_f}{\Delta T_f} \tag{15}$$

where m_W and m_{DMSO} represent the numbers of the moles of water and DMSO contained in the system, being equal to $G/18$ and g/M respectively. The observed h is plotted against the mole fraction of DMSO in Fig. 5. Although the hydration numbers are slightly scattered, they seem to decrease gradually with the increase in the concentration of DMSO. At a very dilute concentration, a DMSO molecule associates with approximately five or six molecules of water, the structure of the associate being not known yet. This kind of interaction of DMSO with water seems to be quite characteristic, because a similar experiment done with dimethylformamide in place of DMSO exhibited only a small number of hydration, about 0.7. Thus, the strong formation of molecular associates may depress the activity of water and suppress the ease of the hydrogen atom transfer along the chains of hydrogen bondings.

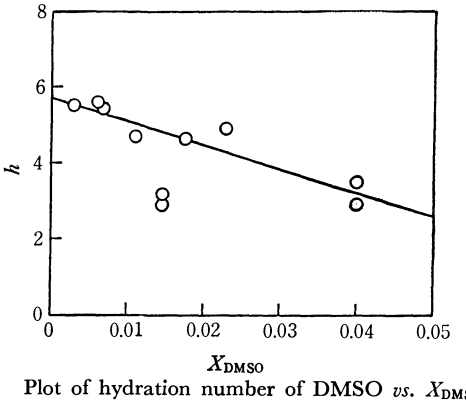

Fig. 5. Plot of hydration number of DMSO *vs.* X_{DMSO}.

Depending upon the NMR investigation concerned with the ionic solvation,[11] Al^{3+} was found to be preferentially solvated with water when water is present in a larger amount than DMSO and with DMSO when DMSO is present in a larger amount than water, in the mixed solvents of DMSO and water. A similar phenomenon may be supposed to occur in the case of Fe^{3+}; it may be solvated overwhelmingly with water in a dilute aqueous solution of DMSO. According to our unpublished data on the optical densities of the systems containing Fe^{3+}, H^+, and DMSO in water, iron(III) was observed to be solvated with DMSO in no noticeable amount, at least not by the optical method.

8) Values appearing in the literature[7] are $k_0^0 = 4.0\,M^{-1}\,sec^{-1}$, $k_H^0 = 3.0\times10^3\,M^{-1}\,sec^{-1}$, $K_H = 1.59\times10^{-3}\,M$ and therefore $k_H^0K_H = 4.8\ sec^{-1}$.

9) S. A. Schichman and R. L. Amey, *J. Phys. Chem.*, **75**, 98 (1971).

10) J. M. Corkill, J. F. Goodman, and J. R. Tate, *Trans. Faraday Soc.*, **65**, 1742 (1969).

11) S. Thomas and W. L. Reynolds, *Inorg. Chem.*, **9**, 78 (1970).

This is the reason why any reaction paths in which the solvated iron species with DMSO take part have been ignored in the present case, only the (5) and (6) reactions being paid much attention to.

Summarizing the above-mentioned considerations, the electron transfer reaction between iron(II) and iron(III) in mixed solvents of DMSO and water when the DMSO concentration is less than 2M proceeds predominantly through the hydrogen atom transfer mechanism, which is retarded by the addition of DMSO to the reaction system because of the strong formation of molecular associates between DMSO and water and, consequently, because of the depression of the activity of water, the depression being proportional to the concentration of DMSO.

At higher DMSO concentrations, DMSO begins to coordinate with iron and to participate in the electron transfer as a catalytic ligand through the inner- or outer-sphere mechanism. In pure DMSO,[4] the latter path only is of importance, with a higher reaction rate than that through the hydrogen atom transfer mechanism in pure water.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3060—3062 (1971)

Mass Spectrometry of Dyes. IV.[1] Electron Impact Reaction of Nitrophenyl Phenyl Ethers and Their Charge Migration

Kazutoshi YAMADA, Takeo KONAKAHARA, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba

(Received April 13, 1970)

By the electron impact reaction of substituted 4-nitrodiphenyl ethers (1), the substituents on ring B of (1) cause a reasonable change in the intensity of fragment ions which result from the nitro→nitrite ester rearrangement. There is a linear correlation of the M^+–NO fragment ion intensity of (1) with the ionization potential of the molecules, and with Hammett σ constants. These evidences suggest that the charge of ring B will be free to migrate to ring A in the ion state, even if they are separated by O-atom.

In elucidating the mass spectral fragmentation mechanism, two concepts about the mobility of charge, that is, localization and migration, have been reported. The first concept of localized charge as a driving force for unimolecular decomposition reactions induced by electron impact has been used by a number of authors to explain and correlate a large variety of reactions observed in mass spectra.[2] As an extention of this concept, it has been proposed that most decomposition reactions which yield abundant ions can be interpreted as being initiated by the positive charge or the unpaired electron at a particular site.[2c,3]

Biemann and Mandelbaum, however, have documented the mobility of a charge in the mass spectral fragment ions of a series of substituted 1-(valerylphenyl)-3-phenylcyclopentanes,[4] of which two aromatic rings are separated by a cyclopentane ring. On the other hand, Kinstle and Oliver have reported a charge localization by the fact that substituents on ring B of 4-nitrodiphenyl ethers (1) cause a considerable change in the intensity of fragment ions which result from the nitro→nitrite ester rearrangement.[5] However, their examination seemed to indicate some dissatisfaction.

(1)

We will now attempt to re-examine their results. This is based on the fact that there is a linear correlation of the M^+–NO fragment ion intensity in the electron impact reactions of (1) with the ionization potential I_M of the molecules, which are calculated by simple LCAO MO method, and with Hammett σ constants, and that the M^+–NO (or M^+–NO_2) ions, fragment further by the action of substituents X on the other ring B. These evidences suggest that the charge will be free to migrate to the other ring in the ion state.

Experimental

Materials. 4,4′-Dinitrodiphenyl ether was obtained commercially, while 4-nitrodiphenyl ether, 4-chloro-4′-nitrodiphenyl ether, and 4-methoxy-4′-nitrodiphenyl ether were prepared by a known method.[6] Mp and the spectral propeties (UV and mass spectra) confirm the structure.

Electron Impact Reactions. The reactions were carried out using a Hitachi RMU-6E double-focusing mass spectrometer and operating under the following conditions for the

above materials: ionizing voltage 80, 70, and 20 eV, heated inlet system at 130—150°C except for 4,4'-dinitrodiphenyl ether (direct inlet system at 180°C), total emission current 80 and 10μA. Other electron impact reaction data were quoted from Ref. 5.

Calculation. The ionization potential I_M values were calculated by simple LCAO MO method,[7] according to the following equation

$$I_M = -\varepsilon_{H.O.}$$

where $\varepsilon_{H.O.}$ is the energy of the highest occupied orbital for the molecule.

The least-squares value of the plot (M^+–NO ion intensity *vs.* Hammett σ) was computed by the usual program.

Results and Discussion

Electron impact reactions are considered as a set of competing consecutive unimolecular decompoiton reactions under highly reduced pressure. The quasi-equilibrium theory (QET) of the electron impact reactions[8] in its simplest form predicts that the rate constant k varies with internal energy E, according to the following equation

$$k = \nu\left(\frac{E-E_0}{E}\right)^{s-1}$$

where ν is a frequency facter, E_0 is the activation energy, and s is the effective numbers of oscillators. In our reaction, Bentley's treatment gives the following

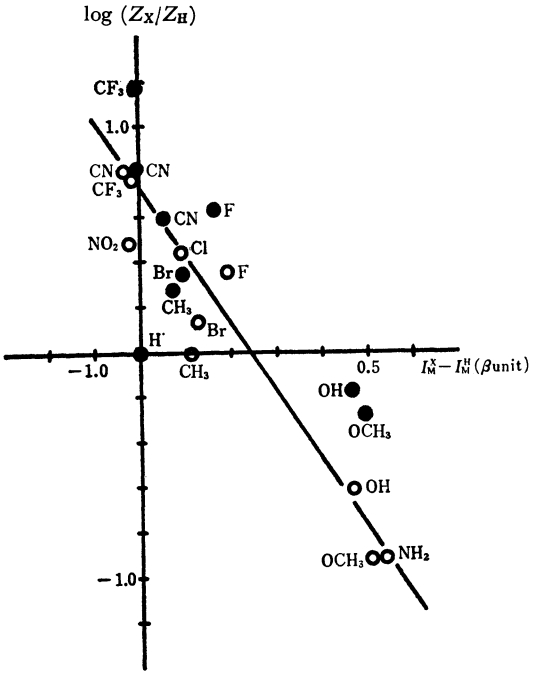

Fig. 1. Correlation of M^+—NO ion intensity with the ionization potential I_M.

$$Z_H = \frac{[OC_6H_4OC_6H_5]^+}{3[O_2NC_6H_4OC_6H_5]^+};\quad Z_X = \frac{[OC_6H_4OC_6H_4X]^+}{[O_2NC_6H_4OC_6H_4X^+]^+}$$

$I_M = -\varepsilon_{H.O.}$; Calculated by simple LCAO MO method.

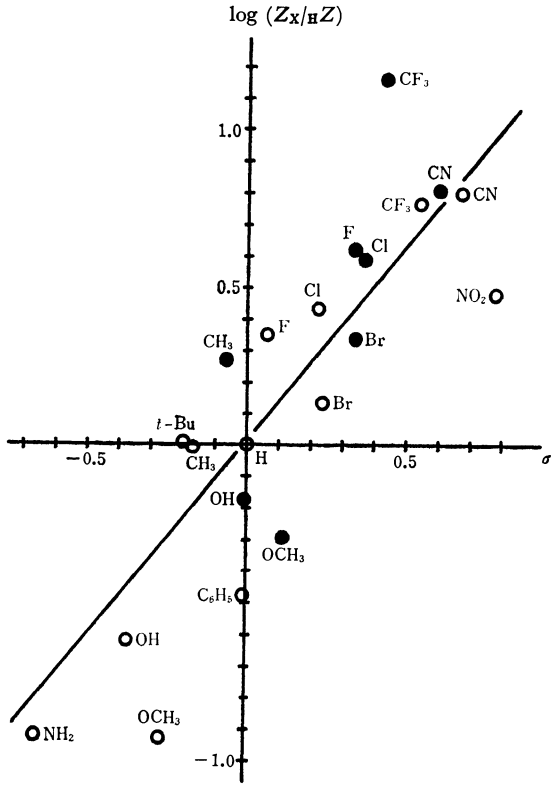

Fig. 2. Correlation of M^+—NO ion intensity with Hammett σ. Least-squares slope (ρ) = +1.24 ($0.85 \leqq \rho \leqq 1.63$), standard deviation=0.29. ○: *para*; ●: *meta*

relationship theoretically[9,10]

$$\log (k_X/k_H) = \log (Z_X/Z_H) \cong [(s-1)/E][(I_M^X - I_M^H) - (I_B^X - I_B^H)]$$

$$\log (Z_X/Z_H) \cong [(s-1)/E](K_M - K_B)\sigma = K\sigma$$

$$(Z = [A]/[M])$$

where [A] and [M] are the relative abundances of the peaks due to the M^+–NO fragment and the molecular ion respectively, I_M and I_B are the ionization potentials, K, K_M, and K_B are constants. The subscripts and/or the superscripts, X and H, refer to substituted and parent compound, and the subscripts M and B to the molecule and the M^+–NO ion. The log (Z_X/Z_H) *vs.* ($I_M^X - I_M^H$) plot, ignoring the effect of I_B, was shown in Fig. 1. I_M values were calculated by simple LCAO MO method. In Fig. 2, which are the correlation between log(Z_X/Z_H) and Hammett σ, the use of σ constants gave a plot with slightly less scatter than did Brown's σ^+ values and the least-squares value of the slope (ρ) is +1.24. This value for our reaction ($M^+ \rightarrow$ M^+–NO) represents a larger numerical reaction constant than most of those previously reported for the rate of an electron impact reaction.[11] Thus, it appears that the reaction is enhanced by an increased positive charge at the reaction site, that is, that the nature of

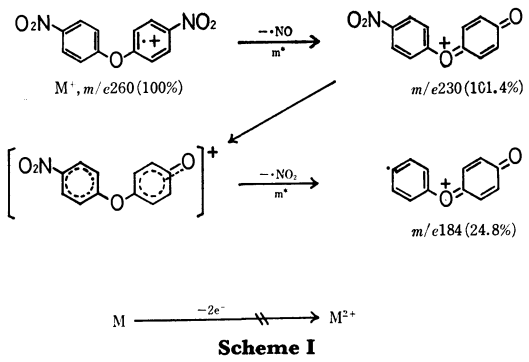
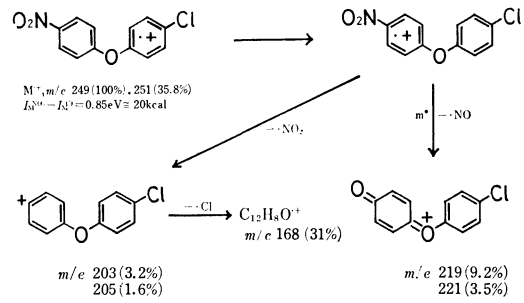
the substituent greatly affects the ionization of the molecule and/or the electronic distribution in the molecular ion. Indeed, the decomposition of the molecular ions seems to depend on the substituents X as described in Ref. 2. It is clear in Fig. 2, that the formation of M^+–NO ion is inhibited by electron-donating substituents X on ring B and facilitated by electron-withdrawing groups X with a large, often "flat-topped" metastable ion, which has been observed in this NO loss from some nitroaromatics.[12]

The ionization potential of the polyfunctional molecule is determined by the functional group with the lowest ionization potential,[13] and the ionization potential of nitrobenzene is the highest in all of the monosubstituted benzenes.[14] Therefore, I_M^X of substituted 4-nitrodiphenyl ethers is determined by the substituent X, and it seems, the initial site of ionization to be localized on substituted ring B. The more electron-withdrawing is the substituent, the more intense is the M^+–NO ion peak. This is undoubtedly the effect of the substituents X. The electron-withdrawing X groups facilitate the charge and/or radical migration to electron-deficient ring A in the odd-electron fragment ions. Initially, this seemed surprising in view of the results of Kinstle *et al.* who documented the localization of a charge in the odd-electron fragment ions.[5] However, unlike their study, in electron impact reaction (both 70 and 20 eV) of 4-nitrodiphenyl ethers with the electron-withdrawing X groups (*e.g.* X=4′-NO_2, 4′-Cl), M^+–NO (or M^+–NO_2) fragment ions displayed, with considerable intensity, further decompositions because of the substituents X on ring B (Scheme I and II). Likewise, in the case of the electron-donating groups X, it seemed that the initial fragment ions due to the substituents X further decomposed by nitro group on ring A (Scheme III).

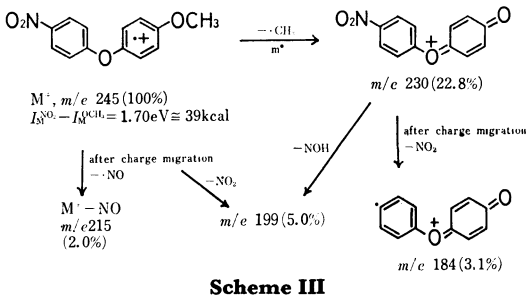
The remainder of the ionization potentials between nitro- and chloro- or methoxybenzene (20 and 30 kcal) shows the ease of ionization on ring B. This process



Scheme I



Scheme II



Scheme III

is the same as that of Biemann's report.[4]

These results suggest that the substituent X on ring B of substituted 4-nitrodiphenyl ethers (1) has an important effect on the electronic state of ring A, and that the charge and/or radical migration to electron-deficient ring A in the odd-electron fragment ion is possible by through-conjugation of oxygen *p*-orbital.

The Reactions of Grignard Reagents with Transition Metal Halides: Coupling, Disproportionation, and Exchange with Olefins

Masuhiko TAMURA* and Jay K. KOCHI

Department of Chemistry, Indiana University, Bloomington, Indiana 47401, U. S. A.

(Received December 26, 1970)

The reactions of transition metal halides (Mn, Fe, Co, Ni, Pd, Cu, and Ag) with the low-molecular-weight alkyl Grignard reagents in tetrahydrofuran and diethyl ether, especially in the presence of styrene were reinvestigated. An alkyl transition metal species formed *in situ* by metathesis decomposed to a dialkyl (oxidative dimerization) or to an alkene and an alkane (oxidative disproportionation). Silver(I) and copper(II) were particularly effective in oxidative dimerization of primary alkyl groups. Alkyl groups which contain no β-hydrogen were also coupled by iron, cobalt, nickel, palladium, and copper(I) halides with varying degrees of efficiency. Oxidative disproportionation was generally the more common route to decomposition for alkyl groups which have β-hydrogens. It seemed to proceed directly *via* a bimolecular interaction of alkylmetals or indirectly by elimination of a hydrido-metal species. If the latter added to an alkene reversibly, exchange was observed between Grignard reagent and alkene. Styrene was reduced to ethylbenzene during the reaction both in tetrahydrofuran and in diethyl ether in varying yield with transition metal halide and Grignard reagent. In addition to alkyl exchange, dehydrogenation of the ethereal solvent by active (reduced) metal species complicated the stoichiometry of decomposition as measured by the value of the empirical parameter, Q(R). The selection of transition metal in addition to the temperature, solvent and triphenylphosphine was effective variables in promoting the efficiency of the exchange process.

The reactions of various transition metal salts and Grignard reagents in which alkane, alkene and coupling dimer are obtained as products have been studied for some time.[1] In some cases, there is evidence for stable and isolable organometallic compounds.[1] However, the transition metal salt is generally reduced to the metallic state in the presence of excess Grignard reagent, and the stoichiometry of the reaction is represented

$$n\mathrm{RMgX} + \mathrm{MY}_n \longrightarrow [\mathrm{RH},\ \mathrm{R(-H)},\ \mathrm{R\text{-}R}] + n\mathrm{MgXY} + \mathrm{M}^\circ \qquad (1)$$

as follows:

$$Q(R) = \frac{\mathrm{R(-H)} + \mathrm{RH} + 2\mathrm{R\text{-}R}}{\mathrm{MY}_n} = n \qquad (2)$$

The distribution of products is dependent on the transition metal salt as well as the Grignard reagent, and also varies with the reaction conditions. Most of the studies reported for these reactions are so fragmentary that the differences in reactivity of various transition metal salts cannot be compared directly.[1] We have examined the mechanism of the Kharasch reaction catalyzed by various transition metal salts in which we postulated organometallic compounds as intermediates.[2,3] To provide support for our studies of the mechanism of the Kharasch reaction we felt that it was desirable to learn about the chemical properties of such organometallic compounds under the reaction conditions.

Metathesis of transition metal salts and organometallic compounds such as organolithium species and Grignard reagents is often the simplest method of obtaining σ-bonded transition metal alkyl complexes.[1] In this study we examined the reactions

$$n\mathrm{RMgX} + \mathrm{MY}_n \longrightarrow \mathrm{R}_n\mathrm{M} + n\mathrm{MgXY} \qquad (3)$$

of transition metal halides and Grignard reagents in tetrahydrofuran (THF) and diethyl ether ($\mathrm{Et_2O}$) under comparative conditions. The reactions were also examined in the presence of styrene and other olefins in order to probe for exchange processes.

Results

The Reactions of Transition Metal Halides and Grignard Reagents in Tetrahydrofuran. The reactions of transition metal halides with various Grignard reagents in THF are summarized in Table 1 and Table 2, which show clearly that the distribution of products was greatly dependent on the transition metal halide and the Grignard reagent. The yield of coupling dimer was almost quantitative independently of the Grignard reagent in the cases of argentous and cupric halides. It was also generally larger with the higher oxidation state of a given metal, *i.e.*, cupric chloride$\gg$cuprous chloride and ferric chloride$>$ferrous chloride.

Coupling dimer was also formed in fairly good yield almost independently of the transition metal halide from the reaction with methyl, neopentyl, benzyl, vinyl or phenylmagnesium bromide which has no available β-hydrogens. For a given transition metal salt, the yield of coupling dimer increased generally in the sequence: methyl$>$neopentyl, benzyl.

The yield of ethyl chloride was negligibly small and the formation of *n*-butane was predominated in the reaction of cupric chloride and ethylmagnesium bromide. This result was quite different from that in the

a) In 21 *ml* THF containing 1.0 mmol of transition metal halide and excess Grignard reagents (4.0~9.0 mmol) for 60 minutes at 2.0°C. All reactions were complete under these reaction conditions.
b) Based on Q(R), % of R-R was doubled.
c) After acidic hydrolysis
d) In the presence of 26.1 mmol styrene
e) No determination
f) Varying amount of ethylene (less than 30%) was included in R-R.
g) After hydrolysis

same reaction in Et_2O (see below).

On the other hand, the yield of coupling dimer was negligibly small and ethane and ethylene were main products in the reactions of ferrous, cobaltous, nickelous, palladous, manganous and cuprous halides with ethylmagnesium bromide which has β-hydrogens. The ratio of ethane to ethylene obtained was almost 1 : 1 with palladous, cupric and cuprous chlorides. Conversely, this ratio was approximately 2—5 with ferric, ferrous, cobaltous, nickelous and manganous halides.[4)] When excess of styrene was added to the reaction in order to learn about the heterolytic cleavage of alkyl-transition metal bond and to check the material balance of hydrogen, the ratio of ethane : ethylene approached one. Under these conditions styrene was partially reduced to ethylbenzene. Styrene was also partially reduced to ethylbenzene even in the reactions of cobaltous and palladous halides with methyl, neopentyl, and phenylmagnesium bromides which have no β-hydrogens.

Q(R) given by Eq. 2 was independent of the presence of styrene in all cases. Q(Et) was also somewhat higher than n when ferric, cobaltous and nickelous halides were used. The high value of Q(Et) may be related to the abstraction of hydrogen from solvent.[2)]

In those reactions involving argentous, cupric, cuprous and manganous halides, a black precipitate was formed and a colorless supernatant solution appeared after the reaction was completed. On the other hand, ferric, ferrous, cobaltous, nickelous, and palladous halides produced black-brown solutions in addition to varying amounts of black precipitate.[5)]

4) Sneeden and Zeiss have also observed these phenomena. R. P. A. Sneeden and H. H. Zeiss, *J. Organometal. Chem.*, **22**, 713 (1970).

a) In 21 m*l* THF containing 1.0 mmol of transition metal halide and excess Grignard reagent (3.0—8.0 mmol). All reactions were complete under these reaction conditions unless otherwise mentioned.
b) Based on Q(R). % of R–R was doubled.
c) In the presence of 8.7 mmol styrene, 0.17 mmol of ethylbenzene was obtained after hydrolysis.
d) Partial decomposition; *ca.* 20%
e) Partial decomposition; *ca.* 50%
f) After hydrolysis
g) Included 6% of EtCl in R–R
h) No determination, Calculated from $Q(R)=n$
i) In the presence of 26.1 mmol styrene, none of ethylbenzene was detected after hydrolysis.

The results in Table 1 and Table 2 show that the yield of coupling dimer was generally higher in the presence of styrene, and this effect may be attributed to styrene as a π-ligand. In order to support this point, the reactions of palladous chloride and Grignard reagents were carried out in the presence of triphenylphosphine, since the bis-triphenylphosphine complex with palladous chloride is readily formed.[6)] Table 3 shows that the yield of coupling dimer was indeed increased in the presence of triphenylphosphine.

Q(R) was not altered by the presence of triphenylphosphine.

The Reactions of Lithium Chlorocuprate and Grignard Reagents in Tetrahydrofuran. The reaction of cupric chloride and Grignard reagent is obscure because the reaction is occurring mainly on the surface (Table 2).

a) In 21 m*l* THF containing 2.5 mmol $CuCl_2$ and 5.8 mmol LiCl for 20 minutes.
b) Molar ratio
c) $\frac{\text{R–R or R–Cl}}{\text{R–R+R–Cl}} \times 100$. Total yield of R–R and R–Cl was more than 80% based on RMgBr or Cu(II) in all runs. R–R and R–Cl did not form from Cu(I) in the case of ethylmagnesium bromide (Table 2).

6) F. G. Mann and A. F. Wells, *J. Chem. Soc.*, **1938**, 702; J. Chatt and L. M. Venanzi, *ibid.*, **1957**, 2351.

Cupric chloride became soluble by the formation of lithium chlorocuprate[7] (λ max. 444 mμ, ε: *ca.* 10^3) when two or more equivalent lithium chloride was mixed in THF. The reactions of lithium chlorocuprate with Grignard reagents were examined in THF in order to find the differences in the mechanisms of the formations of coupling dimer and alkyl chloride in the reaction of cupric chloride and Grignard reagent. It is obvious from Table 4 that the yield of ethyl chloride was larger at the smaller ratio of ethylmagnesium bromide to lithium chlorocuprate. Temperature also influenced the distribution of products.

Ethane was major product in the reaction with methylmagnesium bromide and neopentyl chloride was favorably formed from neopentylmagnesium bromide.

Evolutions of *n*-butane and ethyl chloride were completed immediately and the resulting solution turned to purple gradually in the case of ethylmagnesium bromide (molar ratio: 2.5). At this stage, none of ethane or ethylene was evolved.

Both total yield and distribution were not altered by the presence of excess styrene.

A following competitive mechanism may be applicable to the explanation of these results.

$$\underset{\text{(I)}}{[Cu^{II}Cl_4]^{-2}} + RMgBr \longrightarrow \underset{\text{(II)}}{[RCuCl_3]^{-2}} + MgBrCl \quad (4)$$

$$\text{(II)} \xrightarrow{\text{(I)}} R\text{-}Cl + 2[Cu^{I}Cl_2]^{-} + 2Cl^{-}$$
$$\text{(II)} \xrightarrow{\text{(II)}} R\text{-}R + 2[Cu^{I}Cl_2]^{-} + 2Cl^{-} \quad (5)$$

A predominant yield of *n*-butane in the reaction of cupric chloride and excess ethylmagnesium bromide (Table 2) can also be explained by this mechanism.

The Reactions of Transition Metal Halides with a Mixture of Two Grignard Reagents in Tetrahydrofuran. The reactions of transition metal halides with a mixture of Grignard reagents in THF were also examined in order to learn about the mechanism of the disproportionation of alkyl transition metal complex which is assumed to be formed in the Kharasch reaction. The results are summarized in Table 5. In the combination con-

f) In the presence of 8.7 mmol styrene, the yield of ethylbenzene was 0.38 mmol after hydrolysis

g) 25°C

h) In the presence of 8.7 mmol styrene, the yield of ethylbenzene was 1.10 mmol after hydrolysis.

i) In the presence of 8.7 mmol styene, the yield of ethylbenzene was 1.14 mmol after hydrolysis.

7) R. P. Eswain, E. S. Howald, R. A. Howald, and D. P. Keeton, *J. Inorg. Nucl. Chem.*, **29**, 437 (1967).

sisting of methyl and *n*-propylmagnesium bromides, disproportionation afforded methane from the methyl moiety and propylene from the *n*-propyl group. The selectivity was more pronounced when styrene was added to the reaction consisting of cobaltous or palladous halide. Styrene was partially reduced to ethylbenzene. The formation of cross coupling dimer (*n*-butane) was facilitated by cuprous chloride. On the other hand, more random coupling occurred with ferric, argentous, and cupric halides.

In the combinations involving ethyl/*n*-propyl and ethyl/isopropyl, ethane was formed mainly from the ethyl group and propylene mainly from the propyl group. Furthermore, in these combinations, the trend became more conspicuous when styrene was added to the reaction. In the reaction of palladous chloride with a mixture of ethylmagnesium bromide and *n*-propyl or isopropylmagnesium bromide, the yield of alkene (ethylene and propylene) and the yield of alkane (ethane and propane) were approximately equal. The further hydrogenation of the initially formed olefin was not significant. In fact, the amount of ethylbenzene was much smaller from the reactions carried out with palladous chloride compared to cobaltous bromide (Table 5).

In the combination of ethyl/*n*-propylmagnesium bromide, the ratio of ethylene: ethane was 0.9 and the ratio of propylene: propane was also 0.9. On the other hand, in the combination of ethyl/isopropylmagnesium bromide, the ratio of ethylene: ethane was 0.4, whereas the ratio of propylene: propane was 2.6. That is, the tendency for alkane to be formed mainly from the ethyl group and alkene from the propyl group was more conspicuous in the latter combination. With cuprous or cupric halide, ethane was formed mainly from the ethyl group and propylene from *n*-propyl group: Conversely, propane was formed mainly from the isopropyl group and ethylene from the ethyl group. This observation has been discussed previously.[2)]

The Reactions of Transition Metal Halides with Grignard Reagents in Diethyl Ether. All the reactions discussed above were carried out in THF. In most studies examined heretofore, Et_2O has usually been the medium of choice. For comparison, a number of the same reactions were carried out in Et_2O, especially in the presence of styrene. As seen in Table 6, the yield of ethylene was much higher in the presence of styrene than that in the absence of styrene with all transition metal halides except argentous and cupric bromides. At the same time, styrene was reduced to ethylbenzene in high yield, especially with ferric, ferrous, cobaltous, and nickelous halides. In the reaction of methylmagnesium bromide with nickelous chloride, the amount of ethylbenzene was also small. In the reactions of cupric chloride with methyl and ethylmagnesium bromides, methyl and ethyl chlorides, respectively, were formed in fairly good yields.[2,8)] The higher yield of ethyl chloride and the formations of ethane and ethylene from copper(II) complex (based on Q(Et)) were sharp contrast with the results in THF (Table 2). The ratio of ethane to ethylene was closer to one in Et_2O than in THF (Table 1) with most of transition metal halides, in the reaction with ethylmagnesium bromide, in the absence of styrene. The

rates of decompositions of diethylmanganese and ethylcopper were approximately 6 times faster in Et_2O than in THF.[2)] These solvent dependencies will be discussed later in this paper.

The mixture on completion of reaction was usually a seemingly black-brown solution[5)] (at least partially) except when argentous, cuprous, cupric, and manganous halides were used. The latter gave colorless solutions and black precipitates. These observations were similar to those obtained in THF.

The rate of conversion of ethylmagnesium bromide with nickelous and ferrous chlorides to ethylene and ethane is shown in Fig. 1, which shows that the yield of ethane rapidly reached a plateau, but the yield of ethylene continued to increase with time, in the presence of styrene. The yield of ethylene shown in Fig. 1 and Table 6 was greater than the stoichiometric amount based on Q(Et) and indicated that part of the ethylene was produced from the exchange between ethylmagnesium bromide and styrene (see below). In order to confirm this point, the exchange between ethylmagnesium bromide and styrene was studied in the presence of catalytic amounts of ferric and cobaltous halides. It can be seen in Table 7 that equivalent amounts of ethylene and ethylbenzene were obtained at 2.0°C in Et_2O. The amount of ethane was negligibly small in both cases. At 25°C, the yields of ethylene and ethylbenzene were quite small. Furthermore, the yields of ethylene and ethylbenzene were negligibly small in THF at 2.0°C, but at 25°C they were almost the same as those formed in Et_2O at 2.0°C. Thus, the effect of temperature on the exchange reaction was highly dependent on the solvent. In the case of methylmagnesium bromide, the amount of ethylbenzene was quite small even in Et_2O at 2.0°C.

a) In 21 m*l* solution containing 3.0 mmol Grignard reagent, 2.0 mmol olefin and 0.025 mmol ferric chloride for 60 min. No appreciable amounts of R'H was detected before hydrolysis in all runs.

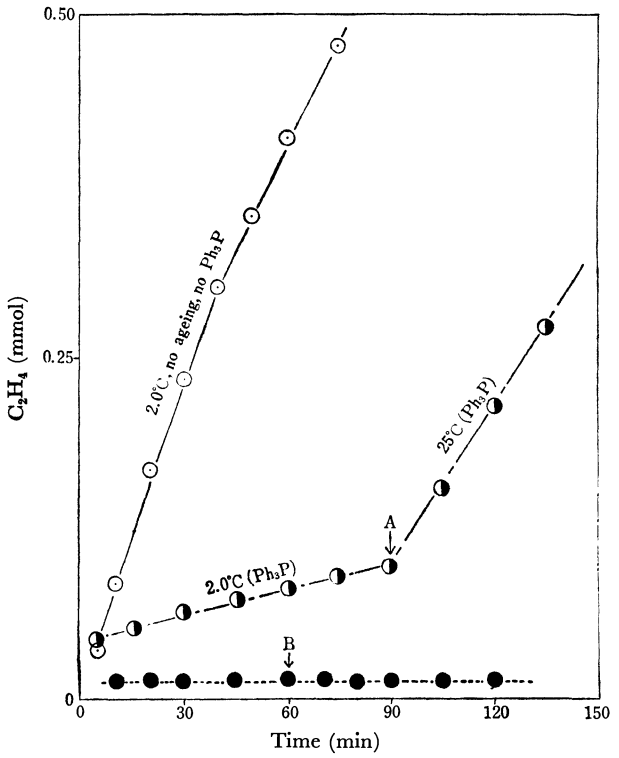

Fig. 2. The iron-catalyzed exchange between EtMgBr and styrene in Et_2O (Et_2O+styrene 21 ml, 0.18M EtMgBr, 1.24M styrene, 2.4×10^{-4}M $FeCl_3$) at 2.0°C.
⊙ 2.0°C, no Ph_3P, no ageing, ◑ In the presence of Ph_3P (0.18M), A; Warmed up to 25°C at this point, ● 2.0°C, no Ph_3P, B; Styrene was added at this point (ageing).

Ethylene and propylene were also used in the iron-catalyzed exchange with various Grignard reagents in THF at 25°C and in Et_2O at 2.0°C. The results are summarized in Table 8 which shows that olefins were formed in high yields from *n*-propyl, isopropyl, and *t*-butylmagnesium bromides in THF at 25°C and in Et_2O at 2.0°C when ethylene was present in the reaction. The amount of ethane after acidic hydrolysis was exactly equal to the yield of olefin derived from the Grignard reagent. On the other hand, the yields of ethylene and propane from ethylmagnesium bromide and propylene were low in Et_2O at 2.0°C and in THF at 25°C. Exchange between Grignard reagent and olefin is, thus, dependent on the particular combination chosen. Additional experiments were performed in order to probe the mechanism of this reaction. The rate of formation of ethylene from the iron-catalyzed exchange of ethylmagnesium bromide and styrene is shown in Fig. 2. No ethylene was formed if styrene was added to an aged catalyst solution, that is 60 minutes after ethylmagnesium bromide and ferric chloride were mixed. The rate of formation of ethylene in the presence of a large excess of triphenylphosphine was also very slow at 2.0°C, but was accelerated when the temperature was raised to 25°C. The effect observed with triphenylphosphine is consistent with those obtained by variation of the temperature and the solvent (Table 7). Finally, the composition of ethylbenzene formed after deuterolysis was shown by NMR analysis (Table 7), to consist of the following:

$PhCHCH_3$	$PhCH_2CH_2D$	$PhCH_2CH_3$
D	5%	24%
71%		

The deuterium content in the ethylbenzene was much smaller at high concentrations of catalyst (Table 6) than at low concentrations (Table 7).

Discussion

I The Distribution of Products from the Reactions of Transition Metal Halides with Grignard Reagents

The Formation of Coupling Dimer. The yield of coupling dimer is strongly dependent on the transition metal halide and the Grignard reagent. The coupling dimer is formed quantitatively from argentous bromide almost independently of the structure of the alkyl of the Grignard reagent except for secondary and tertiary alkyl Grignard reagents.[2] We have proposed a bimolecular mechanism for the silver-catalyzed coupling of a Grignard reagent and an alkyl bromide in order to explain the effects of catalyst concentration, the reaction temperature and the presence of styrene on the yield and stereochemistry of coupling.[2]

$$RAg + R'Ag \longrightarrow R\text{-}R'(R\text{-}R,\ R'\text{-}R') + 2Ag^{\circ} \quad (6)$$

Methyl and ethyl chlorides are formed together with coupling dimers from the reactions of cupric chloride with methyl and ethylmagnesium bromides in Et_2O and that of lithium chlorocuprate with these Grignard reagents in THF. The yield of alkyl chlorides are dependent on the solvent and the molar ratio of Grignard reagent to lithium chlorocuprate and the reaction may also proceed by a bimolecular mechanism expressed by Eq. 5.

Radical mechanism can be neglected for coupling since large excess of styrene does not influence $Q(R)$. Whitesides have also emphasized this point for the decompositions of alkenylcopper and alkenylsilver complexes.[9]

The reaction of ethylmagnesium bromide and ferrous, cobaltous, nickelous, palladous or cuprous halide produces little or no coupling dimer. The coupling dimer is formed, however, in fairly good yields when the Grignard reagent is methyl, neopentyl, phenyl, vinyl, and benzylmagnesium bromides which have no available β-hydrogens.

The yield of coupling dimer is also dependent on the structure of the alkyl group because for a given transition metal salt, the yield of coupling dimer increases generally in the sequence: methyl>neopentyl, benzyl, and ethane and neopentyl chloride are preferably formed in the reactions of lithium chlorocuprate with the corresponding Grignard reagents.

The yield of coupling dimer is enhanced by styrene and triphenylphosphine (Table 3) and it is generally higher in THF than in Et_2O. The salutary effect of these compounds on the yield of coupling dimer may be attributed to the stabilization of the transition metal-carbon bond[10] and or occupation of the coordination

9) G. M. Whitesides and C. P. Casey *J. Amer. Chem. Soc.*, **88**, 4541 (1966).
10) J. Chatt and B. L. Shaw, *J. Chem. Soc.*, **1959**, 4020.

sites necessary for elimination or disproportionation. A similar effect may be applicable to vinyl and phenylmagnesium bromides.[11]

As a conclusion the coupling reaction is thought to proceed by a following bimolecular mechanism.

$$RMX_{n-x} + RMX_{n-x} \longrightarrow R\text{-}R + 2MY_{n-x} \quad (7)$$

Thus the stability of transition metal-carbon bond (transition metal, solvent, ligand as well as reaction temperature), the availability of β-hydrogen and bulkiness of alkyl group are effective factors for coupling. The higher yield of coupling dimer with a higher oxidation state of a given metal may be due to the formation of stable MY_{n-x} salt (Cu and Fe). This mechanism is also supported by the facts that the order of the yield of coupling dimer is primary>secondary> tertiary for argentous bromide and three coupling dimers are formed in the reaction of cupric, argentous or ferric halide with a mixture of two Grignard reagents (Table 5).

The Disproportionation. The disproportionation to afford alkene and alkane is also strongly dependent on the transition metal, the availability of β-hydrogens and the presence of styrene. Styrene is reduced to ethylbenzene except when the reactions are carried out with argentous and cuprous halides. For example, the ratio of ethylene to ethane is 1.0 in the presence of styrene when cobaltous bromide reacts with ethylmagnesium bromide in THF. This ratio is approximately 0.2 in the absence of styrene (Table I). The yield of ethylbenzene is also high when Grignard reagents which have β-hydrogens reacts with cobaltous bromide but it is low from methyl, neopentyl and phenylmagnesium bromide. We deduce from the value of Q(Et) and the ratio of ethylene to ethane (Table 1 and Table 7) that the exchange between ethylmagnesium bromide and styrene can be neglected under these reaction conditions. Thus, *both* hydrogens in ethylbenzene could not have been derived only from the ethyl moiety. Furthermore, the formation of ethylbenzene from methyl, neopentyl, and phenyl Grignard reagents indicates that the hydrogen was derived partially from the solvent.[2] Since the yield of ethylbenzene is much higher with those Grignard reagents possessing β-hydrogens, at least *one* of the hydrogens in ethylbenzene is derived from an alkyl group present in an intermediate.

In the reaction of transition metal halides with a mixture of two Grignard reagents, the trend is for the alkane to be formed mainly from one alkyl group and the alkene to be derived from the other alkyl group (Table 5). This selectivity is more conspicuous when one alkyl group has no β-hydrogen. In all of our experiments, Q(R) is not changed by the presence of styrene and indicates that alkyl radicals does not complicate the interpretation of the mechanism.[2]

Two mechanisms are plausible for the formation of alkane and alkene in the reaction of transition metal halides with Grignard reagents:

A. "Hydride Mechanism"[12]

$$RCH_2CH_2M \longrightarrow RCH{=}CH_2 + HM \quad (8)$$

$$RCH_2CH_2M + HM \longrightarrow RCH_2CH_3 + 2M \quad (9)$$

B. "Direct Hydride Migration (or Bimolecular) Mechanism"

$$RCH_2CH_2M + RCH_2CH_2M \longrightarrow RCH{=}CH_2 + RCH_2CH_3 + 2M \quad (10)$$

These two mechanisms have been discussed in the light of the decompositions of alkylcopper and alkylmanganese species.[2]

We infer that hydride mechanism is generally more common for Mn, Fe, Co, Ni, and Pd. On the other hand, bimolecular mechanism is more plausible for Cu(I) and Ag (especially for secondary and tertiary alkyls). The former groups possess great hydrogenation activity and the latter groups do not have it for olefins under the comparative condition. However, even in the former groups, participation of bimolecular interaction between alkyl metals for decomposition should also be considered in the case of special alkyl groups. The formation of cross coupling dimer in the reaction of cuprous chloride with a mixture of methyl and *n*-propylmagnesium bromides, the higher stability of neopentylcopper than methylcopper (bulkiness) and the adverse relationship between *n*-propyl and isopropylcoppers[13] (Table 5) may support this mechanism.

Thus bimolecular interaction between alkyl metals is very important for both coupling and disproportionation. Direct hydride mignation may not be easily occurred when THF is used as a solvent because THF has a great coordination affinity for metal[14] (occupation of coordination site). This effect of THF may be similar to that of triphenylphosphine. In fact, THF as a solvent and the addition of triphenylphosphine render the high yield of coupling dimer. The ratio of alkane: alkene also becomes greater than one in these cases. Dehydrogenation of coordinated ligand is known in analogous situation.[15] Organocopper clusters in ethereal solvent has been reported recently.[16] We have also observed the interaction between two copper nuclei during the decomposition of alkylcopper species.[2] Moreover, degradation of catalytic activity by aging in the Kharasch reaction is more pronounced in Et_2O than in THF. The ratio of alkane to alkene is greatly dependent on the catalyst concentration in the iron-catalyzed Kharasch reaction.[2] Metal-metal interaction (formation of aggregates), therefore, must be considered in these reactions.

II The Exchange between Grignard Reagent and Olefin by Iron Catalyst

Exchange reactions between Grignard reagents and

15) W. H. Knoth and R. A. Schumn, *ibid.*, **91**, 2400 (1969) and references cited therein.

16) A. Cairncross and W. A. Sheppard, *ibid.*, **93**, 247 (1971).

olefins catalyzed by transition metals including titanium,[17] nickel and cobalt[18] salts have been reported. The mechanism of this reaction has remained unclear, but transition metal hydrides have been postulated as catalysts.

$$\mathrm{RCH{=}CH_2 + R'CH_2CH_2MgBr \xrightarrow{\text{catalyst}} R'CH{=}CH_2 + \underset{\mid \atop MgBr}{RCHCH_3} + RCH_2CH_2MgBr} \quad (11)$$

Table 7 and 8 show that the exchange between Grignard reagent and olefin is induced by catalytic amounts of ferric chloride. Thus, the amount of olefin produced from the Grignard reagent is equal to the alkane formed from the olefin. The combination of *n*-propyl or isopropylmagnesium bromide and ethylene affords propylene and ethylmagnesium bromide. On the other hand, the combination of ethylmagnesium bromide and propylene produces no significant exchange (Table 8).

$$\mathrm{CH_3CH_2CH_2MgBr + CH_2{=}CH_2 \overset{\text{Fe catalyst}}{\rightleftarrows} CH_3CH{=}CH_2 + CH_3CH_2MgBr} \quad (12)$$

As shown in Fig. 2 and Table 7, no appreciable exchange is detected when styrene is added after the catalyst is aged for 60 minutes at 2.0°C in Et_2O. The catalytic activity is also poor at 25°C even without ageing or at 2.0°C in the presence of excess triphenylphosphine. The effects of ageing and temperature have also been observed in the exchange between Grignard reagent and olefin by nickelous chloride.[18]

We postulate that an iron hydride, *e.g.*, HFe,[19] is the catalytically active species in the exchange reaction, and the following mechanism is proposed:

$$\mathrm{FeCl_3 + RCH_2CH_2MgBr \xrightarrow{\text{solvent}} RCH{=}CH_2 + RCH_2CH_3 + HFe + MgBrCl} \quad (13)^{20)}$$

$$\mathrm{HFe + R'CH{=}CH_2 \rightleftarrows \underset{\mid \atop Fe}{R'CHCH_3} \rightleftarrows R'CH_2CH_2Fe} \quad (14)$$

$$\mathrm{\underset{\mid \atop Fe}{R'CHCH_3} + RCH_2CH_2MgBr \rightleftarrows \underset{\mid \atop MgBr}{R'CHCH_3} + RCH_2CH_2Fe} \quad (15)$$

We relate the effect of ageing the catalyst and the temperature dependence of the exchange to the deactivation of the catalytic species, *e.g.*

$$\mathrm{2HFe \longrightarrow H_2 + Fe_2} \quad (16)$$

The adverse effect of triphenylphosphine and the temperature requirements for exchange in Et_2O and in THF can be related to coordination of the active metal species by these ligands in competition with the olefin. The addition of metal hydride to alkenes has been observed in a variety of situations.[21] The decomposition of alkylmanganese to alkenes has been shown to proceed *via* a facile α,β-elimination of a hydridomanganese species.[2] The latter process, however, is not readily reversible under these reaction conditions. In order to obtain catalytic activity in the exchange of alkylmagnesium halides and alkenes, both addition as well as elimination must be facile. Iron, cobalt, and nickel species apparently fulfill both requirements.

Experimental

Materials. Triply sublimed magnesium was supplied from Dow Chemical Co., (analysis; Cu, $<$0.001; Fe, $<$0.003; Mn, $<$0.001; Ni, $<$0.0005; Pb, $<$0.003; Co, $<$0.005; Cr $<$0.005; Ag, $<$0.001; Rh, $<$0.005; Pd, $<$0.001; Mo, $<$ 0.005; Ti, $<$0.005%). Anhydrous nickelous chloride was prepared from the reaction of its hexahydrate and thionyl chloride.[22] Anhydrous ferrous chloride was prepared from metallic iron and anhydrous ferric chloride in THF.[23] Commercial anhydrous manganous chloride was dried *in vacuo* at 130°C for 50 hrs. Anhydrous cobaltous bromide, palladous chloride, ferric chloride, cupric chloride, cuprous chloride, argentous bromide, and lithium chloride were commercial grade substances and used without further purification. Styrene and all organic halides were purified by distillation before use. Triphenylphosphine was commercial grade and used without further purification. Neopentyl bromide was prepared from neopentyl alcohol and tri-*n*-butylphosphine dibromide.[24]

Solvents. THF was refluxed over lithium aluninum hydride under nitrogen over 2 days, fractionated under a nitrogen atmosphere and stored under helium. Et_2O was refluxed over metallic sodium under nitrogen for 24 hrs, distilled under a nitrogen atmosphere and stored over metallic sodium under helium.

Preparation of Grignard Reagent. All Grignard reagents were prepared using excess of magnesium metal (1.5~2.0 times excess of the theoretical amount) in order to minimize the amount of unreacted organic halide. Reaction temperature was varied from 5 to 35°C according to the reactivity of organic halide. All solutions of Grignard reagent were filtered under a nitrogen atmosphere and were almost colorless. The exception, vinylmagnesium bromide, had a red brown color. The concentrations of all Grignard reagents were determined by titration and by quantitative analysis of the hydrocarbon produced on acidic hydrolysis (0.5—1.8 M).

Product Analysis. All products were analyzed by gas chromatography using the internal standard method.

Reaction of Cobaltous Bromide with Ethylmagnesium Bromide in Tetrahydrofuran in the Presence of Styrene (A Representative Example). A 250 m*l* round-bottom flask was equipped with a magnetic stirrer bar and a rubber septum. The flask was flushed with nitrogen and 0.224 g (1.0 mmol) cobaltous bromide was added. After the apparatus was tightly sealed, the atmosphere within the flask was swept with helium for 30 min. To this flask, 14.25 m*l* of THF, 1.0 m*l* of standard solution of toluene in THF (1.0M, 1.0 mmol) and 3.0 m*l* of styrene (26.1 mmol) were added with hypodermic syringes. The flask was then immersed in a dry-ice acetone bath and 25 m*l* of methane and 25 m*l* of isobutane were added with syringes. The flask was transferred to an ice-water bath, and after 5 minutes agitation 2.75 m*l* of ethylmagnesium bromide solution (4.0 mmol) was added to the mixture with a syringe. The color of solution changed from sky blue to dark brown immediately. The evolutions of ethane and ethylene was complete within 5 min after the addition of ethylmagnesium bromide. After 30 min agitation at the same temperature (2.0°C), a small sample of gas was taken out and analyzed by gas chromatography (ethylene; 1.26 mmol, ethane; 1.32 mmol, *n*-butane; 0.05 mmol). An aliquot of the reaction mixture was removed with a microsyringe purged with nitrogen. The amount of ethylbenzene (before hydrolysis)[25] was measured immediately by gas chromatography (1.15 mmol). After hydrolysis with 1.0 m*l* of dilute sulfuric acid solution, the amount of ethylbenzene (after hydrolysis) was again analyzed by gas chromatography (1.16 mmol).

25) Part of ethylbenzene may be formed from the thermal decomposition of phenethylmagnesium bromide in gaschromatography. M. Lefrançois and Y. Gault, *J. Organometal. Chem.*, **16**, 7 (1969).

Exchange between Ethylmagnesium Bromide and Styrene in Diethyl Ether with Catalytic Amounts of Ferric Chloride. In a similar experiment, 14.0 m*l* of Et_2O, 3.0 m*l* of styrene, 2.0 m*l* of a solution of EtMgBr in Et_2O (3.8 mmol), 1.0 m*l* of a solution of toluene in Et_2O (1.0 mmol) and 25 m*l* of methane were added to the reaction vessel. After the flask was immersed in an ice-water bath and the mixture agitated for 10 min, 1.0 m*l* of a solution of ferric chloride in Et_2O (0.025 mmol) was added. The color of the solution changed from colorless to pale brown immediately. The rate of evolution of ethylene was determined by periodically removing a small aliquot of gas followed by gas chromatographic analysis. After 90 min the amount of ethylene was 0.57 mmol and the amount of ethylbenzene after hydrolysis was 0.60 mmol (Table 7). Isolation of deuterated ethylbenzene from the reaction mixture was made by the following method. To the reaction mixture obtained in the exchange between ethylmagnesium bromide and styrene (see above), 1.0 m*l* of deuterium oxide was added and the mixture was agitated for 30 min at the same temperature. The resulting mixture was extracted with Et_2O and the ethereal layer was dried over anhydrous sodium sulfate. After filtration, Et_2O was removed *in vacuo*. Ethylbenzene was separated from the residue by preparative gas chromatography (10F′–FFAP, 150°C). The distribution of isomers in deuterated and undeuterated ethylbenzene was determined by NMR. (see Table 7).

Exchange between n-Propylmagnesium Bromide and Ethylene in Tetrahydrofuran with Ferric Chloride Catalyst THF (18.5 m*l*) and 2.5 m*l* of *n*-propylmagnesium bromide (3.0 mmol), 25 m*l* of methane, 50 m*l* of ethylene and 25 m*l* of isobutane were added to the flask in dry-ice acetone bath. The flask was immersed in a temperature controlled water bath (25°C) and the mixture agitated for 10 min. 1.0 m*l* of solution of ferric chloride in THF (0.025 mmol) was added to the mixture

under agitation. The color of the solution changed to pale brown immediately. The rates of formations of propylene and propane were followed by gas chromatography. The evolution of propylene was almost complete within 10 min after the addition of ferric chloride solution. After 60 min the amount of propylene was 0.68 mmol and the amount of propane was 0.06 mmol. None of ethane was detected before hydrolysis whereas 0.70 mmol of ethane was recovered after acidic hydrolysis.

We wish to thank the National Science Foundation for generous financial support, the Du Pont Company for the THF and the Dow Chemical Company for the billet of magnesium used in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3073—3077 (1971)

The Stereochemistry of 5-Substituted 2-Oxo-3-aryl-1,2,3-oxathiazolidines

Tomihiro NISHIYAMA and Fukiko YAMADA

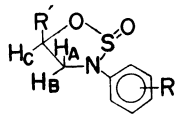
Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received February 4, 1971)

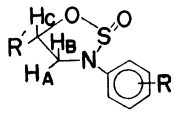
New six 2-oxo-3-aryl-5-methyl-1,2,3-oxathiazolidines and six 2-oxo-3-aryl-5-chloromethyl-1,2,3-oxathiazolidines have been prepared in good yields by the reactions of *N*-sulfinylanilines with propylene oxide and epichlorohydrin respectively in the presence of catalysts. The compounds obtained exist in isomeric *cis* and *trans* forms at the S=O bond. The configurations of their stereoisomers were discussed by means of NMR.

Recently, a few studies have been reported on the preparations of some oxathiazolidines. For example, Etlis *et al.*[1] reported that, in the presence of NEt_4Br, *N*-sulfinylanilines (**1**) reacted with alkene oxides at 95—100°C to give 2-oxo-3-aryl-1,2,3-oxathiazolidines. On the other hand, Deyrup and Moyer[2] have prepared oxathiazolidines by the reactions of β-amino alcohols with thionyl chloride in the presence of a base; the stereochemical structures of the compounds thus obtained have also been determined by means of their NMR spectra. In a previous paper, we reported that, in the absence of a catalyst, **1** reacted with ethylene oxide at a low temperature to form the corresponding oxathiazolidines.[3] The studies have now been extended to some substituted oxathiazolidines with a view to obtain a clearer picture of the stereoisomers.

In this paper, we wish to describe the reaction of **1** with propylene oxide (**2**) or epichlorohydrin (**3**) in the presence of catalysts and the configurations of the reaction products, oxathiazolidines (**4**), by means of a study of their NMR spectra.



4 *cis*
R=H, CH_3, Cl



4 *trans*
R′=CH_3, CH_2Cl

Experimental

Measurements. All the melting and boiling points are uncorrected. All the NMR spectra were recorded at 60 MHz with a Japan Electron Optics Model JNM-3H-60 spectrometer. The chemical shifts were described in parts per million downfield from the internal TMS (δ). The IR spectra were recorded on a Hitachi Model EPI-2 grating spectrophotometer. GLC analysis was carried out on a Yanagimoto Gas Chromatograph, Model GCG-550-T, using a 2.15-m column packed with Silicone SE-30 (10 wt%). The percentage composition of the products was estimated by means of the relative peak areas (uncorrected).

Materials. *N*-Sulfinylanilines, *N*-sulfinylaniline (R=H), *N*-sulfinyltoluidines (R=*o*-CH_3, *m*-CH_3, and *p*-CH_3), and *N*-sulfinylchloroanilines (R=*o*-Cl, *m*-Cl, and *p*-Cl) were prepared as has been described in the literatute.[4] **2** and **3** were commercially-available and were of pure in grade. All the reagents used were of an analytical grade.

General Procedure for the Reaction of 1 with 2 or 3. To a vigorously-stirred mixture of **1** with **2** or **3**, a solution of the catalyst in dimethylformamide (DMF) was added. After the mixture had been stirred for an appropriate time at a constant temperature, the residual catalyst was either filtered off or was washed off with water. The removal of DMF left a red-brown colored oily product which, on distillation *in vacuo*, gave oxathiazolidine. The progress of the reaction was periodically checked by measuring the NMR spectrum and glc of the reaction mixture.

Acid Hydrolysis of 2-Oxo-3-phenyl-5-methyl-1,2,3-oxathiazolidine (5). A mixture of 2.9 g of oxathiazolidine (**5**) in 10 m*l* of ethylalcohol and hydrochloric acid (60 mg, 1.64 mmol in 10 m*l* of water) was refluxed for 4 hr. The reaction mixture was extracted in methylene chloride, and then the solution was washed with water. The organic layer was dried; the subsequent removal of methylene chloride left a pale yellow product which, on distillation *in vacuo*, gave a clear pale yellow liquid (122—123°C/3 mmHg, 1.9 g, 83%) and which was identified as *N*-(β-hydroxypropyl)aniline by comparing its infrared spectrum with that of an authentic sample.[5] IR spectrum: 3375, 2970, 1603, 1501, 745, 688 cm^{-1}

Results and Discussion

The Reaction. The products of these reactions and their physical properties are summarized in Tables 1 and 2. The conversion rate of each reaction can be determined by means of the data of the integrated ring protons in its NMR spectrum. These results indicate that the rate is influenced by the composition of the catalyst and by the reaction temperature. The rate of the reaction in the presence of lithium chloride (LiCl) is almost the same as that in the presence of lithium bromide (LiBr), but the rate in the presence of tetraethylammonium bromide (NEt_4Br) is slower than that in the presence of LiCl. This is also brought out clearly by a comparison of the values of the yields (Tables 1 and 2).

General Structure and Assignment of the Configuration. Let us now discuss how the general structure of the reaction products was determined. For example, the compound **5** (Table 1) can be converted to *N*-(β-hydroxypropyl)-aniline by acid-catalyzed hydrolysis. *N*-(β-hydroxypropyl)-aniline was further identified by comparing its infrared spectrum with that of an authentic sample, prepared by another route,[5] and by the results of the elemental analysis. All of the above facts, the results of the elemental analyses, and the spectral data (Tables 1 and 2) support the idea that the products have the structure of **4**.

The structure of **4** indicates the possibility that the reaction product consists of a pair of isomers, namely, the *cis* and *trans* configurations between the S=O group and the substituent, R'. After the reaction had been completed, the NMR spectrum of the reaction mixture always indicated the presence of the two isomers in the product. Therefore, we considered that the two isomers in the reaction product coincide with the *cis* and *trans*

isomers of the oxathiazolidine. The *cis* or *trans* configuration was assigned by means of NMR spectroscopy.

In each reaction product, the *cis* or *trans* isomer can be separated by recrystallization from carbon tetrachloride. As can be seen in Table 1, the *cis* configuration was assigned to the products **8** and **9**, and the *trans* one, to the products **5**, **6**, **7**, **10**, and **11**. On the other hand, in Table 2, the *trans* configuration is assigned to the products **14** and **17**, and the *cis* one, to the products, **12**, **13**, **15**, **16**, and **18**. As is shown by these results, in each case only one of the isomeric pair can be separated; the other could not be isolated in a pure grade.

The ratio of the *cis* to the *trans* isomer in the reaction product can be determined by comparing the data of the integrated signal due to the methyl (in the case of the reaction of **1** with **2**) or methyne protons (in the reaction of **1** with **3**). The results obtained are also listed in Tables 1 and 2. The ratios are dependent mainly upon the substituents R and R′. The electron-releasing nature of R′ seems to be unfavorable to the formation of the *cis* isomer. The ratios are practically unaffected by the amount and the structure of the catalyst.

NMR Spectra of Oxathiazolidines. The chemical shifts of the oxathiazolidines are listed in Tables 3 and 4. The results show that a pair of isomeric 2-oxo-3-aryl-5-methyl (or chloromethyl)-1,2,3-oxathiazolidines was yielded by each reaction of **1** with **2** or **3**. The sulfoxide bond is well known to have acetylenic-like anisotropy.[6] For this reason, the deshielding of oxathiazolidine-ring substituents which are *cis* to the sulfoxide bond results. As can be seen in Table 3, **5a** and **5b** are identified as a pair of isomers. The methyl-proton signal in the *trans* isomer (**5b**) appeared at δ 1.42 ppm, while those in the *cis* isomer (**5a**) were observed at δ 1.59 ppm. On the other hand, the chloromethyl-proton signal in the *trans* isomer (**12b**) appeared at δ 3.65 ppm and, in the *cis* isomer (**12a**), further

downfield at δ 3.83 ppm.

Several NMR spectra of oxathiazolidines are first-order spectra and show *cis* and *trans* coupling constants which can be interpreted in terms of the geometry around C–4 and C–5 single bonds. The coupling constants are shown in Tables 3 and 4.

Moyer reported that the coupling constants, J *trans*, J *cis*, and J *gem*, for *trans* 2-oxo-3-*t*-butyl-5-phenyl-1,2,3-oxathiazolidine are 6.5, 6.5, and 8.5 Hz respectively.[7] These values are very close to those of the compounds, as is shown in Table 3.

Solvent Effects. The signal of the methylene protons (C–4) of **18a** appeared as a two-proton doublet in a carbon tetrachloride solution. In a methylene chloride solution, the doublet form was transformed to a quartet form, as is shown in Fig. 1. This phenomenon indicates that the signal of the C–4 methylene protons overlaps that of the C–5 chloromethyl protons. The coupling constant of the C–4 methylene protons was 6.0 Hz in a carbon tetrachloride solution as well as in a methylene chloride solution.

Fig. 1. NMR spectra for methylene protons of **18a**.

In the carbon tetrachloride solution, the equilibrium composition of the compound **11** was 42% *cis* and 58% *trans*, based on the integration of the NMR spectra of the methyl protons. After this solution had been heated at 80—85°C for 13 hr, the *trans* isomer composition increased from 58% to 72%. The *cis* isomer, however, did not entirely disappear. In the case of the carbon disulfide solution, no change in the composition was observed even upon heating under the same conditions. It is clear that both the solvent and temperature effects may markedly affect the equilibration of the *cis* and *trans* isomers. This suggests that the oxathiazolidine ring interacts with a solvent such as carbon tetrachloride and that then the *cis*-form is turned into the *trans*-form at a suitable temperature.

On the other hand, the NMR spectral data of the *cis* and *trans* isomers of some oxathiazolidines in a benzene solution exhibit benzene-induced shifts, as is shown in Table 5. Figure 2 shows the proposed geometry of the benzene-solute collision complex of the oxathiazolidines. As for the aromatic solvent effect on the sulfoxides, recent papers have described studies con-

cerning the stereochemistry of the penicillin sulfoxides[8] or the methylthiolane oxides.[9] In these compounds, the situation of the methyl group in question is the α-position relative to the sulfoxide group. In the case of the oxathiazolidines, in spite of the situation of the methyl group in the β-position, it was found that the stereochemical assignment is nearly in line with the arguments presented in the above papers. As can be seen in Table 5, however, the shifts of the protons of the compound **6b** were somewhat different. This difference may be ascribed to some effect of the *o*-methyl substituent.

The authors are grateful to the members of the Laboratory of Analysis, Faculty of Science, of Osaka University and the staff of the Research Laboratories, Fujisawa Pharmaceutical Co., Ltd. for the elementary analyses.

The Reactions of Pyridinium Bromides with Sulfenamides

Teruaki MUKAIYAMA and Kazuhiko SAIGO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 5, 1971)

It was found that three different types of products, phenylthiomethylpyridinium bromide, ethoxy-bis(phenylthio)-methane and ethyl ethoxy-bis(phenylthio)acetate were obtained by the reactions of pyridinium bromides, such as phenacylpyridinium bromide, acetonylpyridinium bromide and ethoxycarbonylmethylpyridinium bromide, with sulfenamides in ethanol, depending on the nature of the carbonyl carbon of the starting pyridinium bromides.

Recently, it was reported that α-hydroxyiminopyridinium bromides were obtained in good yields by the reactions of pyridinium bromides such as phenacylpyridinium bromide and acetonylpyridinium bromide with alkyl nitrite.[1] The results indicate that hydrogen atom attached to α-carbon of pyridinium bromide becomes acidic by the influence of both positively charged nitrogen atom and carbonyl group. It was also found that active methylene compounds react with sulfenamides to give mono- or di-sulfenylated products in good yields.[2]

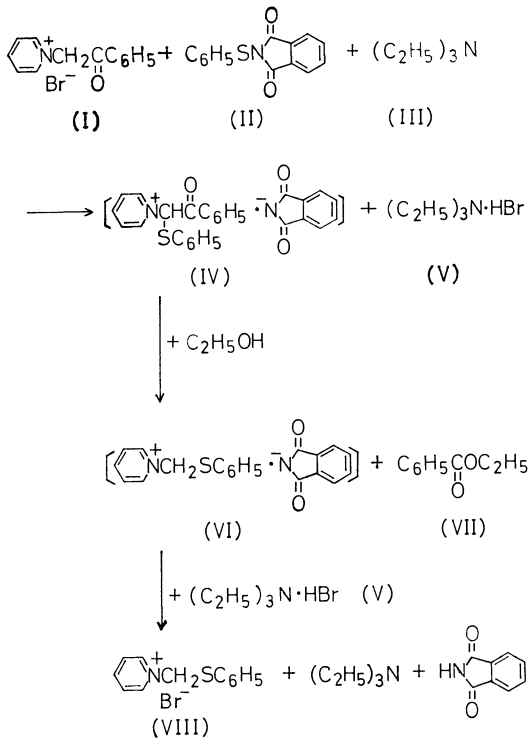
In the present experiment, the reactions of pyridinium bromides with sulfenamides were investigated with the expectation that α-sulfenylated pyridinium bromides would be obtained as in the formation of α-hydroxyiminopyridinium bromide. When phenacylpyridinium bromide (I) was allowed to react with *N*-phenylthiophthalimide (II) in the presence of triethylamine (III) in ethanol for 2 hr, phenylthiomethylpyridinium bromide (VIII) and ethyl benzoate (VII) were obtained in quantitative and 64% yields, respectively, instead of the expected α-phenylthiophenacylpyridinium bromide. Similary, phenylthiomethylpyridinium bromide was obtained in quantitative yield by the reaction of phenacylpyridinium bromide with *N*-phenylthiosuccinimide and triethylamine or *N,N*-diethylbenzenesulfenamide in the absence of triethylamine.

The result indicates that pyridinium salt (VI) and ethyl benzoate are produced by way of a nucleophilic attack of ethoxide anion to carbonyl carbon of the initially formed intermediate (IV) with active carbonyl carbon induced by an electronegative phenylthio group attached to the α-carbon. The subsequent anion exchange between pyridinium salt (VI) and triethylammonium bromide (V) results in the formation of phenylthiomethylpyridinium bromide.

The reactions of acetonylpyridinium bromide with

1) T. Mukaiyama, K. Saigo, and H. Takei, This Bulletin, **44**, 190 (1971).

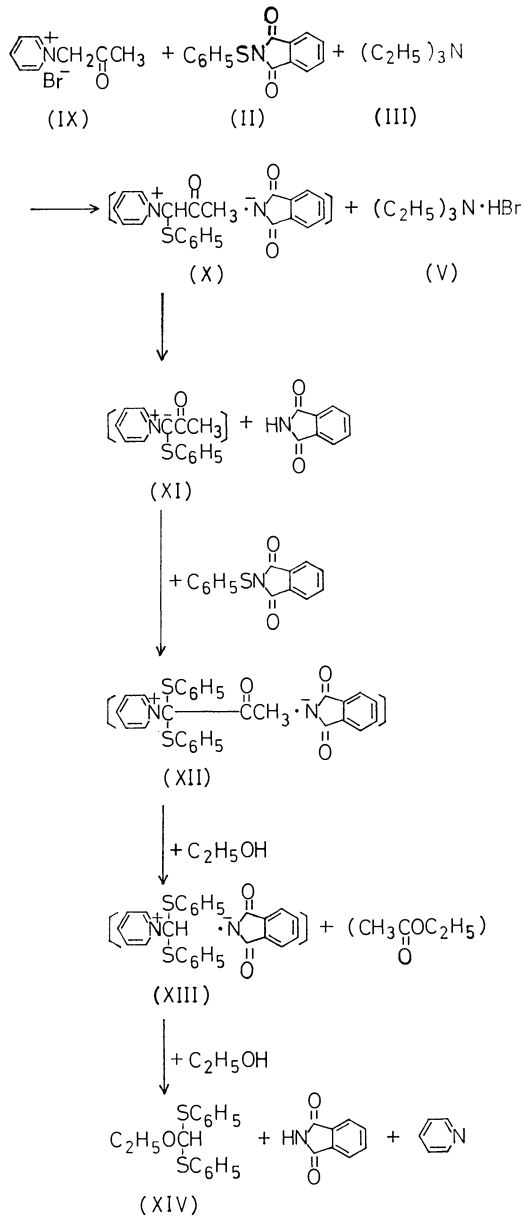
2) T. Mukaiyama, S. Kobayashi, and T. Kumamoto, *Tetrahedron Lett.*, **1970**, 5115.



sulfenamides were tried. When an equimolar amount of acetonylpyridinium bromide (IX) was allowed to react with *N*-phenylthiophthalimide (II) and triethylamine (III), α-phenylthioacetonylpyridinium bromide could not be isolated and a tarry product resulted. On the other hand, when the same reaction was carried out in the presence of two equimolar amounts of *N*-phenylthiophthalimide, ethoxy-bis(phenylthio)methane (XIV) was obtained in 20% yield. Similarly, ethoxy-bis(phenylthio)methane (XIV) was isolated in 40% yield by the reaction of acetonylpyridinium bromide with two equimolar amounts of *N*-phenylthiosuccinimide.

This result can be explained as follows; the intermediate (X) is produced as expected from acetonylpyridinium bromide and *N*-phenylthiophthalimide. In this stage, deprotonation of X by imide anion predominates over the nucleophilic attack of ethoxide anion to the carbonyl carbon to form pyridinium ylide (XI), probably due to the slightly higher electron density of the carbonyl carbon of X in comparison with that of IV. XI reacts with another phenylthiophthalimide to give pyridinium salt (XII). The nucleophilic attack of ethoxide anion to the carbonyl carbon of XII followed by the nucleophilic attack by ethoxide anion to the α-carbon of pyridinium salt (XIII) gives ethoxy-bis(phenylthio)methane (XIV).

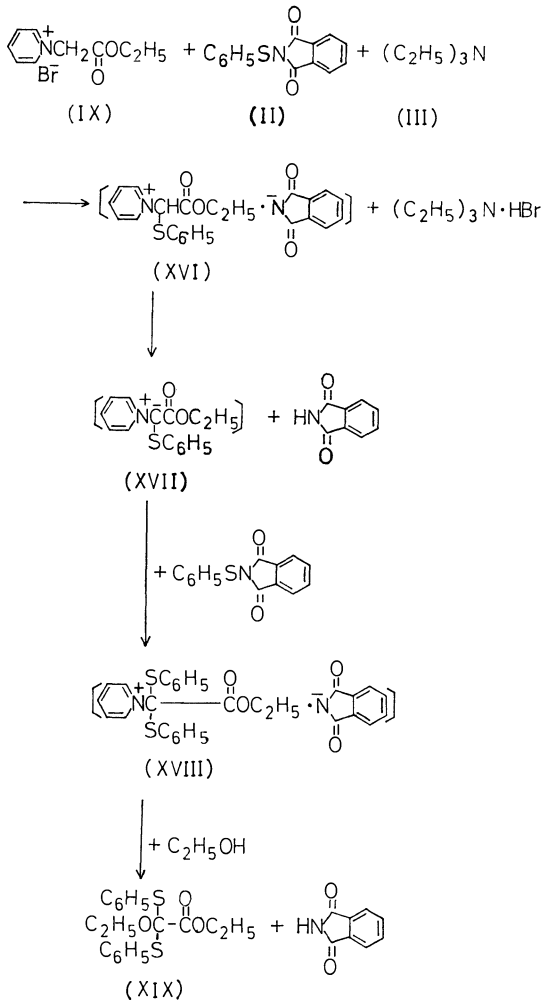
It was found that the reaction of ethoxycarbonylmethylpyridinium bromide (XV) with two equimolar amounts of *N*-phenylthiophthalimide (II) in the presence of triethylamine (III) gave ethyl ethoxy-bis(phenylthio)acetate (XIX) in 84% yield. In a similar way, ethyl ethoxy-bis(phenylthio)acetate was obtained in 77% yield by the reaction of ethoxycarbonylmethylpyridinium bromide with two equimolar amounts of *N*-phenylthiosuccinimide in the presence of triethylamine.



This result may be explained by considering the initial formation of intermediate (XVIII) in a similar manner to the case of the reaction of acetonylpyridinium bromide with sulfenamide. The nucleophilic displacement of ethoxide anion to the α-carbon of XVIII predominates over the nucleophilic attack to carbonyl carbon to form ethyl ethoxy-bis(phenylthio)-acetate.

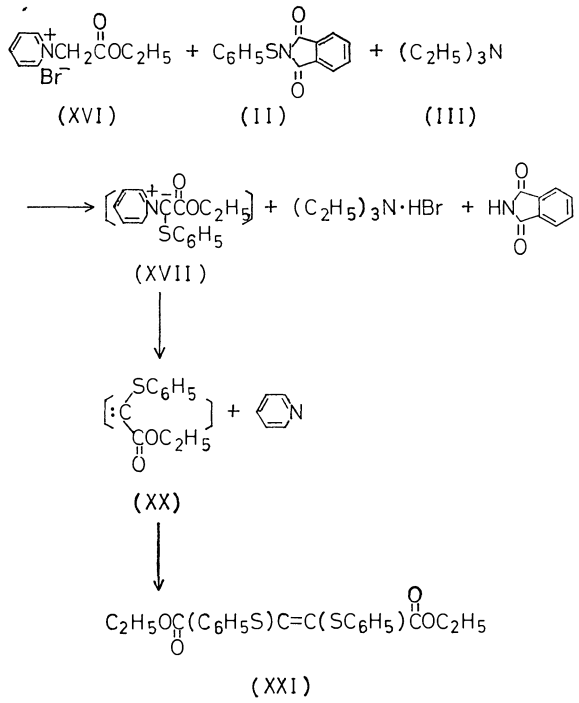
The different types of products, phenylthiomethylpyridinium bromide, ethoxy-bis(phenylthio)methane and ethyl ethoxy-bis(phenylthio)acetate were obtained according to the nature of the carbonyl carbon of the starting pyridinium salts, by the reactions of phenacylpyridinium bromide, acetonylpyridinium bromide and ethoxycarbonylmethylpyridinium bromide, respectively, with sulfenamide.

The reaction of ethoxycarbonylmethylpyridinium bromide with *N*-phenylthiophthalimide and triethylamine in dichloromethane was investigated in order

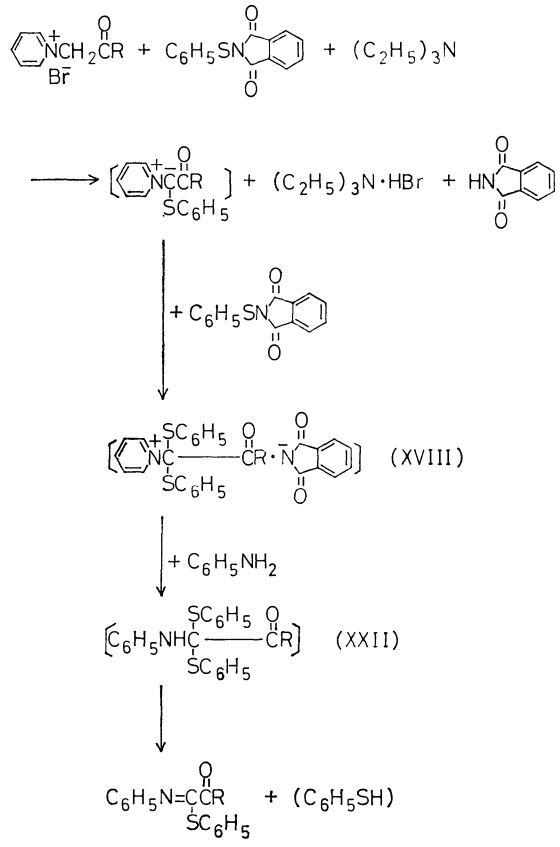


to isolate α-sulfenylated pyridinium ylide. When ethoxycarbonylmethylpyridinium bromide (XV) was allowed to react with *N*-phenylthiophthalimide (II) in the presence of triethylamine (III), 1,2-bis(ethoxycarbonyl)-1,2-bis(phenylthio)ethylene (XXI) was unexpectedly obtained in 50% yield. In contract to the above mentioned reaction at 0°C, carbene (XX) was formed by the thermal decomposition of unstable pyridinium ylide (XVII) at a temperature above 20°C. Carbene (XX) might be dimerized to form 1,2-bis-(ethoxycarbonyl)-1,2-bis(phenylthio)ethylene (XXI).[3]

The reaction of ethoxycarbonylmethylpyridinium bromide, triethylamine and two equimolar amounts of *N*-phenylthiophthalimide in dichloromethane was tried with the purpose of isolating α,α-di-sulfenylated pyridinium bromide. It was found that under the above mentioned conditions, ethoxycarbonyl-bis(phenylthio)-methylpyridinium salt could not be obtained but only a tarry product. When aniline was added the above mentioned reaction mixture, ethyl α-phenylimino-α-phenylthioacetate (XXIII, R=OC_2H_5) was obtained in 49% yield accompanied by the elimination of benzenethiol from the intermediate (XXII), formed by the nucleophilic displacement of aniline to the α-carbon of ethoxycarbonyl-bis(phenylthio)methylpyridinium salt



(XVIII). Similarly, α-phenylimino-α-phenylthioacetophenone (XXIII, R=C_6H_5) was obtained in 48% yield by the reaction of phenacylpyridinium bromide.



Experimental

Reaction of Phenacylpyridinium Bromide with N-*Phenylthiophthalimide in the Presence of Triethylamine.* Into a solution of

3) The compound is assigned to a mixture of *trans* and *cis* isomers by gas-liquid phase chromatography.

phenacylpyridinium bromide (2.78 g, 0.01 mol) and *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in ethanol (100 m*l*), triethylamine (1.01 g, 0.01 mol) in ethanol (10 m*l*) was added drop by drop under ice cooling and the reaction mixture was stirred for 2 hr. After removal of the solvent, a mixture of water and ether (1:1) was poured into the residue and resulting crystals, phthalimide, were filtered off. The filtrate was separated into water and ether layers. From the water layer, white crystals, phenylthiomethylpyridinium bromide (mp 121.5—123.0°C) were obtained in quantitative yield after removal of the solvent.

Found: C, 51.59; H, 4.30; N, 4.92; S, 11.20%. Calcd for $C_{12}H_{12}BrNS$: C, 51.81; H, 4.29; N, 4.96; S, 11.34%.

The ether layer was evaporated under reduced pressure to give oily residue. Distillation *in vacuo* gave ethyl benzoate (bp 88—90°C/15 mmHg), 0.96 g (64%), identified by IR spectrum.

Reaction of Acetonylpyridinium Bromide with Two Equimolar Amounts of N-*Phenylthiophthalimide in the Presence of Triethylamine.* Into a solution of acetonylpyridinium bromide (1.06 g, 0.005 mol) and *N*-phenylthiophthalimide (1.28 g, 0.005 mol) in ethanol (100 m*l*), triethylamine (0.51 g, 0.005 mol) in ethanol (10 m*l*) was added dropwise and the reaction mixture was stirred for 30 min under ice cooling. Another one mol of *N*-phenylthiophthalimide (1.28 g, 0.005 mol) was added to the reaction mixture with stirring. After a few minutes, the color of the reaction mixture changed from red brown to yellow and the precipitate of phthalimide increased in amount rapidly. The reaction mixture was stirred for additional 3 hr under ice cooling. After the solvent was evaporated under reduced pressure, the residue was extracted with ether. Removal of the ether gave oily residue. The residue was chromatographed on silica gel. Elution with benzene gave ethoxy-bis(phenylthio)methane (mp 88.0—89.5°C), 0.28 g (20%), recrystallized from cyclohexane, and identified by IR and NMR spectra.

Found: C, 65.49; H, 5.93; S, 22.98%. Calcd for $C_{15}H_{16}OS_2$: C, 65.21; H, 5.84; S, 23.16%.

Similarly, by the reaction of ethoxycarbonylmethylpyridinium bromide (1.23 g, 0.005 mol) with two equimolar amounts of *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in the presence of triethylamine (0.51 g, 0.005 mol), ethyl ethoxy-bis(phenylthio)acetate was obtained, 1.47 g (84%), mp 54.0—54.5°C, identified by IR and NMR spectra.

Found: C, 61.87; H, 5.84; S, 17.88%. Calcd for $C_{18}H_{20}O_3S_2$: C, 62.02; H, 5.79; S, 18.37%.

Reaction of Ethoxycarbonylmethylpyridinium Bromide with N-*Phenylthiophthalimide in the Presence of Triethylamine in Dichloromethane.* Into a solution of ethoxycarbonylmethylpyridinium bromide (2.46 g, 0.01 mol) and *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in dichloromethane (100 m*l*), triethylamine (1.01 g, 0.01 mol) in dichloromethane (10 m*l*) was added at room temperature and the reaction mixture was stirred for 3 hr. After removal of the solvent, the residue was extracted with ether. The ether layer was evaporated under reduced pressure and the resulting oily product was chromatographed on silica gel. Elution with benzene, gave 1,2-bis(ethoxycarbonyl)-1,2-bis(phenylthio)ethylene, 0.82 g (50%).

Found: C, 65.33; H, 5.96; S, 19.58%. Calcd for $C_{18}H_{20}O_2S_2$: C, 65.05; H, 6.07; S, 19.26%.

Formation of Ethyl α-Phenylimino-α-phenylthioacetate. By a similar procedure as in the formation of ethoxy-bis(phenylthio)methane, ethoxycarbonylmethylpyridinium bromide (1.23 g, 0.005 mol) was allowed to reacted with triethylamine (0.51 g, 0.005 mol) and two equimolar amounts of *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in dichloromethane (100 m*l*). After stirring for 30 min under ice cooling, aniline (0.47 g, 0.005 mol) in dichloromethane (10 m*l*) was added to the reaction mixture. The solvent was evaporated under reduced pressure after stirring for additional 6 hr under ice cooling, and the residue was extracted with ether. After removal of ether, the resulting oily product was chromatographed on silica gel. Elution with benzene gave ethyl α-phenylimino-α-phenylthioacetate (mp 78—79°C), 0.70 g (49%), identified by IR and NMR spectra.

Found: C, 67.58; H, 5.54; N, 5.19; S, 11.33%. Calcd for $C_{16}H_{15}O_2NS$: C, 67.36; H, 5.30; N, 4.91; S, 11.21%.

Similarly, in the reaction of phenacylpyridinium bromide, α-phenylimino-α-phenylthioacetophenone was obtained in 48% yield, mp 75—76°C, identified by IR and NMR spectra.

Found: C, 75.40; H, 4.58; N, 4.52; S, 10.18%. Calcd for $C_{20}H_{15}ONS$: C, 75.69; H, 4.76; N, 4.41; S, 10.09%.

We thank Dr. H. Takei and Dr. T. Kumamoto for valuable discussions.

A Study of the Catalytic Partial Oxidation of Hydrocarbons. XI. The Catalytic Activity of the MoO_3-P_2O_5 and the MoO_3-Bi_2O_3-P_2O_5 in the Selective Oxidation of Butene, Butadiene, and Furan

Mamoru Ai and Sadao Suzuki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 18, 1971)

In the present work, the vapor-phase partial oxidation of *cis*-2-butene, butadiene, furan, and maleic anhydride was carried out over MoO_3–P_2O_5 (1 : 0.2 atomic ratio) and MoO_3–Bi_2O_3–P_2O_5 (1 : 1 : 0.2) with a contact time of 1.6 sec, at a concentration of 0.6—1.0%, and in air, in order to elucidate the difference between the two catalysts in their catalytic specificity for the oxidation of these reactants to maleic anhydride. Over the MoO_3–P_2O_5 catalyst, the selectivities of butene, butadiene, and furan to maleic anhydride were 13, 50, and 78% respectively. Over the MoO_3–Bi_2O_3–P_2O_5 catalyst, the formation of maleic anhydride from the reactants was very small, that of CO_2 was important, and the rate of maleic anhydride destruction was fairly high. It is considered that the MoO_3–Bi_2O_3–P_2O_5 catalyst has almost the same catalytic specificity as the MoO_3–P_2O_5 in the $C_4H_8 \rightarrow C_4H_2O_3$ step, but that its activity for maleic anhydride destruction is so high that maleic anhydride cannot be accumulated.

In a previous paper,[1,2] the selective oxidation of crotonaldehyde and butadiene over various vanadium- and molybdenum-type catalysts has been investigated from the viewpoint of furan production. Among the catalysts tested, the MoO_3–P_2O_5 catalyst system (P/Mo= 0.1—0.3 atomic ratio) showed the best selectivity to furan in the oxidation of the both reactants; in addition, this system showed a fairly stable activity even at 500°C.

Regarding the ternary catalyst system of MoO_3–Bi_2O_3–P_2O_5, this is well-known as a catalyst which has an excellent selectivity for such an allylic oxidation of olefins as 1-butene to butadiene and propylene to acrolein. Therefore, a good deal of work has been devoted to the investigation of the two reactions mentioned above and that of the physicochemical properties of the catalyst system. However, no literature gives definitive data on the important difference in the catalytic specificity between MoO_3–P_2O_5 and MoO_3–Bi_2O_3–P_2O_5, and past studies over molybdenum-type catalysts were limited to investigations under low oxygen concentrations.

In the present work, we compared the results over MoO_3–P_2O_5 and MoO_3–Bi_2O_3–P_2O_5 catalysts on the relative rate and selectivity in the oxidation of butene, butadiene, furan, and maleic anhydride in excess oxygen, and attempted to clarify the difference between the two catalysts in the catalytic features for each reaction step in the step-by-step oxidation of butene to maleic anhydride, and to elucidate how far the mechanism and the selectivity of the partial catalytic oxidation of these reactants depend on the presence of Bi_2O_3 in the MoO_3–P_2O_5 system.

Experimental

The vapor-phase air oxidation of *cis*-2-butene, butadiene, furan, and maleic anhydride was performed over MoO_3–P_2O_5 (Mo: P=1:0.2 atomic ratio) and MoO_3–Bi_2O_3–P_2O_5 (Mo: Bi:P=1:1:0.2) oxide catalysts in an ordinary flow-type reaction system, as has been shown in previous papers.[3,4]

The volume concentrations of the reactants were 0.6—1.0% in air, the flow rate (at 25°C) was kept at 1.5 *l*/min, and the catalyst volume was 40 m*l* (contact time=1.6 sec). The reaction temperature was varied from 200 to 600°C. The experimental and analytical procedures were the same as those employed in pervious works.[1-6]

The catalysts used in the experiments were prepared as follows: the required quantities of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ and H_3PO_4 were dissolved in hot water, and in the case of the MoO_3–Bi_2O_3–P_2O_5 catalyst, an acidified $Bi(NO_3)_3$ solution was mixed with the former solution; pumice of a mesh size of 10 to 20 was added to the above mixture, and then the solution was evaporated with constant stirring and finally dried in an oven at 130°C. The amount of pumice was 500 m*l*/g atom of molybdenum. The catalyst was calcined under flowing air at 550°C for 5 hr.

The color of the MoO_3–P_2O_5 after sintering or use in the experiment was black, while that of the MoO_3–Bi_2O_3–P_2O_5 was light-yellow. This indicates that the state of molybdenum in the former catalyst is more reduced than that in the latter. The surface areas, measured with nitrogen by the BET method at −195°C, were about 3 m^2/g for both the catalysts.

Results and Discussion

Oxidation of cis-*2-Butene.* The oxidation of *cis*-2-butene was carried out over the MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–P_2O_5 catalysts in order to clarify the difference in the catalytic features between the two catalysts. The relationship of overall conversion (excluding isomerization) *vs.* the temperature is shown in Fig. 1. The MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–P_2O_5 have almost the same catalytic activity for the overall oxidation of butene.

The oxidation of butene is always accompanied by its isomerization. Oxygen is necessary in the isomerization as well as in the oxidation.[6] The sum of the conversion of *cis*-2-butene to such isomers as *trans*-2-

butene and 1-butene is plotted as a function of the reaction temperature in Fig. 2. It rises to a maximum due to the further oxidation of the isomers. The MoO_3–P_2O_5 has a higher isomerization activity than the MoO_3–Bi_2O_3–P_2O_5. This is in agreement with the data of Echigoya *et al.*[7,8] obtained by the use of MoO_3 and MoO_3–Bi_2O_3 in the oxidative dehydrogenation.

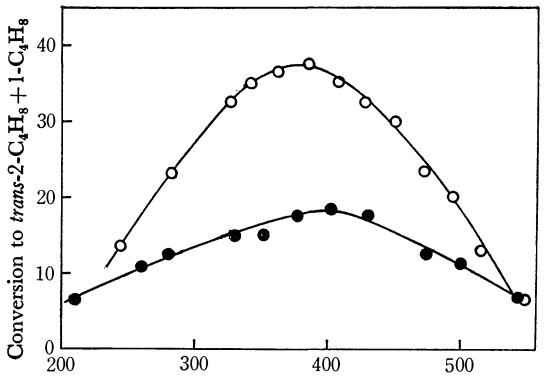

Fig. 2. Formation of isomers of *cis*-2-butene as a function of temperature.
MoO_3–P_2O_5: ○ MoO_3–Bi_2O_3–P_2O_5: ●

The formation of butadiene, which may be considered to be a primary intermediate in the step-by-step oxidation of butene to maleic anhydride, is shown as a function of the over-all conversion of butene (excluding isomerization) in Fig. 3. The slopes of these plots correspond to the differential selectivity at each conversion. Over the MoO_3–Bi_2O_3–P_2O_5 catalyst, the amount of butadiene passed through a maximum at a butene conversion of about 70% and was three times higher than that over the MoO_3–P_2O_3. It can thus be assumed that butadiene is less reactive than butene on the MoO_3–Bi_2O_3–P_2O_5, and that the catalyst is less

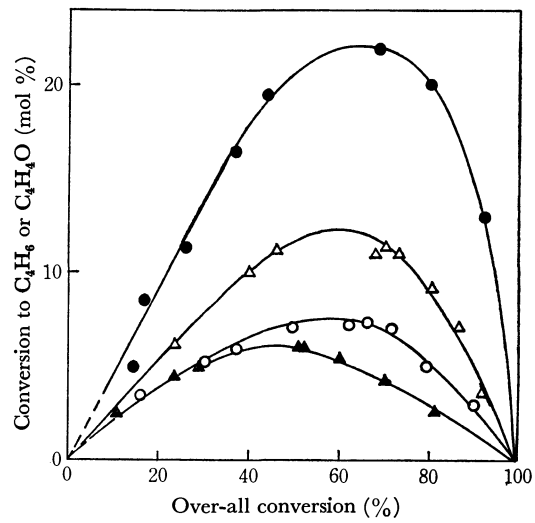

Fig. 3. Formation of intermediates (butadiene and furan) as a function of over-all conversion.
MoO_3–P_2O_5: C_4H_6, ○ C_4H_4O, △
MoO_3–Bi_2O_3–P_2O_5: C_4H_6, ● C_4H_4O, ▲

active than MoO_3–P_2O_5 for butadiene oxidation, probably because butadiene is adsorbed weakly on the MoO_3–Bi_2O_3–P_2O_5 catalyst.[5,9,10]

The formation of maleic anhydride over the MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–P_2O_5 catalysts is shown as a function of over-all conversion of butene in Figs. 4 and 5 respectively. Over the MoO_3–P_2O_5 catalyst, the maximum selectivity to maleic anhydride is 13% at the butene conversion of about 80%, and the amount of maleic anhydride does not exceed 10%. It is found

that the result is much inferior to that obtained by the use of vanadium-containing catalysts.[4-6] On the other hand, the MoO_3–Bi_2O_3–P_2O_5 shows a much lower maleic anhydride formation; it is less than 1% even at a butene conversion of 80—90%.

Figure 6 shows the formation of carbon dioxide (CO_2) and carbon monoxide (CO). Over the MoO_3–P_2O_5 catalyst, the formation of CO is superior to that of CO_2, while over the MoO_3–Bi_2O_3–P_2O_5, that of CO is inferior to that of CO_2, and the MoO_3–Bi_2O_3–P_2O_5 gives more CO_2 and less CO than the MoO_3–P_2O_5. The results indicate that, on the MoO_3–Bi_2O_3–P_2O_5 catalyst, a relatively good butadiene formation is obtained even in the presence of a large excess of oxygen, but the further oxidation of butadiene may proceed to complete oxidation. It may be concluded that neither the MoO_3–P_2O_5 nor the MoO_3–Bi_2O_3–P_2O_5 catalyst is adequate for the selective oxidation of butene to maleic anhydride.

* 1/4 of the real amount of the formation.

Oxidation of Butadiene. Butadiene conversion-temperature data for both the catalysts are shown in Fig. 1. The MoO_3–P_2O_5 has a considerably higher activity for butadiene oxidation than the MoO_3–Bi_2O_3–P_2O_5. Figure 1 indicates also that, on the MoO_3–Bi_2O_3–P_2O_5 catalyst, butadiene is less reactive than butene, while, on the MoO_3–P_2O_5, butadiene is more reactive than butene. These results agree with the data of butadiene formation from butene (Fig. 3).

The formation of furan, a primary intermediate of butadiene oxidation, is shown in Fig. 3. Contrary to the case of butadiene formation from butene, the amount of furan produced over the MoO_3–Bi_2O_3–P_2O_5 was only half that obtained over the MoO_3–P_2O_5 catalyst.

Over the MoO_3–P_2O_5 catalyst, the selectivity to maleic anhydride increases slightly with an increase in the butadiene conversion, reaching 50% at a butadiene conversion of about 100% (Fig. 4). It is found that the catalyst shows almost the same selectivity of butadiene to maleic anhydride as does the MoO_3–V_2O_5 catalyst (Mo/V=1—4), although its oxidation rate is far lower than that of the latter.[6,11] On the other hand, over the MoO_3–Bi_2O_3–P_2O_5 catalyst, only a small amount of maleic anhydride was obtained (less than 1%) (Fig. 5), much as in the case of butene oxidation.

As is shown in Fig. 7, the formation of CO_2 and CO is not so great in the case of the MoO_3–P_2O_5 catalyst,

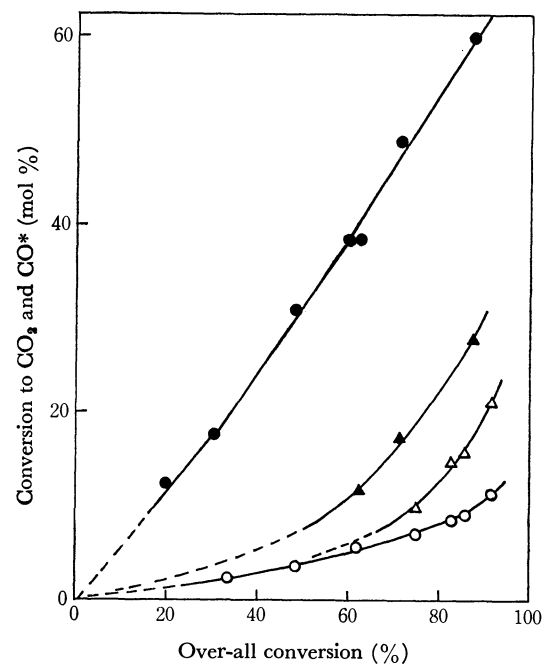

Fig. 7. Conversion of butadiene to CO_2 and CO as a function of over-all conversion.

11) M. Ai, *Kogyo Kagaku Zasshi*, **73**, 950 (1970).

but in the case of the MoO_3–Bi_2O_3–P_2O_5 catalyst, both of them, especially CO_2, are produced to a significant extent. From these results, it may be concluded that the MoO_3–P_2O_5 catalyst shows relatively good results in the selective oxidation of butadiene to furan and maleic anhydride, but that the MoO_3–Bi_2O_3–P_2O_5 catalyst is not adequate to these formations, especially maleic anhydride formation.

Oxidation of Furan. Furan is considered as an intermediate in the consecutive oxidation of butene or butadiene to maleic anhydride.[2,3,5,10] Thus, the oxidation of furan was tested over the MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–P_2O_5 catalysts in order to ascertain the catalytic action of the catalysts on this reaction step. The relationship between the furan conversion and the temperature is shown in Fig. 8. The MoO_3–P_2O_5 catalyst has a higher activity than the MoO_3–Bi_2O_3–P_2O_5 for furan oxidation, much as in butadiene oxidation. We cannot explain why the two catalysts show different results in the formation of furan from butadiene (Fig. 3). It can be estimated, though, that this difference probably results from the character of the adsorption on the catalyst surface.

The conversion of furan to maleic anhydride is shown in Figs. 4 and 5. Over the MoO_3–P_2O_5 catalyst, the selectivity to maleic anhydride is quite good, reaching about 78% at a furan conversion of 80—90%. These results are superior to those obtained from V_2O_5, V_2O_5–P_2O_5, and V_2O_5–MoO_3 catalysts.[3,5,6,11] The MoO_3–Bi_2O_3–P_2O_5 catalyst gives a considerably smaller formation of maleic anhydride than does the MoO_3–P_2O_5 catalyst, and the amount of maleic anhydride passed through a maximum at a furan conversion at about 30%. These results reveal that, under the reaction conditions used here, the degradation of maleic anhydride occurs on the catalyst—that is, maleic anhydride is an intermediate in the oxidation of furan to CO_2 and CO, and that the rate of maleic anhydride decomposition is about 6 times faster than that of its formation.[9,10]

For lack of a suitable method of analysis, the amount of the polymer was obtained as the remainder in the mass-balance of the other products (Fig. 9). The formation of the polymer is higher on the MoO_3–Bi_2O_3–P_2O_5 catalyst than on the MoO_3–P_2O_5 catalyst. It is considered that the greater part of the reaction in this step preceeds on a side pathway on the MoO_3–Bi_2O_3–P_2O_5 catalyst rather than on the MoO_3–P_2O_5. The formation of CO_2 and CO is very low over the MoO_3–P_2O_5, while over the MoO_3–Bi_2O_3–P_2O_5 considerably great amount of them are formed and CO_2 is a major product (Fig. 10).

Oxidation of Maleic Anhydride. The oxidation of maleic anhydride was examined in order to ascertain the activity of the MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–

* 1/4 of the real amount of the formation.

P_2O_5 catalysts in the oxidation. Over the MoO_3–P_2O_5 catalyst, maleic anhydride was scarcely oxidized, even at 550°C. This indicates that the MoO_3–P_2O_5 catalyst was almost inactive for maleic anhydride degradation. On the other hand, the MoO_3–Bi_2O_3–P_2O_5 was considerably active in the reaction (Fig. 8). It is also found that, on the catalyst, maleic anhydride is more liable to be oxidized than are butene, butadiene, and furan. Besides CO_2 and CO, no other products were detected. In the degradation of maleic anhydride, the formation of CO was not important; the major product was CO_2 (85%) (Fig. 10).

A Discussion of the Effect of Bi_2O_3 Addition to MoO_3–P_2O_5 on the Reaction Mechanism. The selectivities of the reactants to maleic anhydride over the MoO_3–P_2O_5 catalyst may be summarized as follows: C_4H_8, 13; C_4H_6, 50; and C_4H_4O, 78%. An assumption has been made that the main reaction in the oxidation of butene to maleic anhydride proceeds as follows, in the same manner as over V_2O_5–P_2O_5: $C_4H_8 \rightarrow C_4H_6 \rightarrow C_4H_4O \rightarrow C_4H_2O_3$.[3,5] The selectivites towards the main reaction pathway in each consecutive step have been calculated from the data of selectivity to maleic anhydride in a manner similar to that used in earlier works:[5,6] $C_4H_8 \rightarrow C_4H_6$; 26, $C_4H_6 \rightarrow C_4H_4O$; 64, and $C_4H_4O \rightarrow C_4H_2O_3$; 78%. It has been concluded that this catalyst has an excellent selectivity for the furan-to-maleic anhydride step and a relatively good one for the butadiene-to-furan step, but a low selectivity for the butene-to-butadiene step, much like the V_2O_5-alone catalyst.[4,6]

On the other hand, over the MoO_3–Bi_2O_3–P_2O_5 catalyst, it is hard to get any information about the reaction scheme, from the data on maleic anhydride. Therefore, we will attempt to discuss the reaction on the basis of the data on CO_2 and CO. As regards CO_2 and CO, over such catalyst as V_2O_5, V_2O_5–P_2O_5, V_2O_5–MoO_3, and MoO_3–P_2O_5, whose activity for maleic anhydride oxidation, is very low, the amount of CO_2 formed in the oxidation of butene, butadiene, and furan was always less than that of CO,[1-6,10] but in the case of maleic anhydride oxidation, the main product was CO_2—that is, maleic anhydride undergoes destructive oxidation to CO_2. Margolis and others[12] indicate that, over the MoO_3–Bi_2O_3–P_2O_5 catalyst, the oxidation of CO to CO_2 is difficult and that the main sources of CO_2 formation are acids, while those of CO formation are aldehydes, and that this catalyst has a high activity for acid destruction.

12) A. P. Gorshkov, I. K. Kolchin, A. M. Gribov, and L. Ya. Margolis, *Kinet. Katal.*, **9**, 1089 (1967).

In the first approximation, an assumption is made that, over the MoO_3–Bi_2O_3–P_2O_5 catalyst, the amount of CO_2 formed in each step from C_4H_8 to $C_4H_2O_3$ is the same as that of CO. From the data of the selectivities to CO_2 and CO for each reactant (Table 1), the portion of each reactant destined to maleic anhydride and decomposed immediately to CO_2 and CO is roughly calculated; for example, in the case of butene, the selectivities to CO_2 and CO are 37 and 27% respectively. As those in the oxidation of maleic anhydride are 85 and 15%, the balance of CO_2 and CO can be expressed by the equation:

$$37 = 0.85x + A$$

$$27 = 0.15x + A$$

where x is the portion of butene destined to maleic anhydride ($0.85x$ and $0.15x$ indicate the CO_2 and CO originated from the decomposition of maleic anhydride) and where A is the CO_2 and CO formed in the steps before $C_4H_2O_3$. After the elimination of A, x is 14%. If the amount of CO_2 formed in the steps before $C_4H_2O_3$ is less than that of CO, the value of x becomes a little higher. The results are shown in Table 1.

Table 1. Maximum selectivity to CO_2 and CO and value of x

Reactant	C_4H_8	C_4H_6	C_4H_4O	$C_4H_2O_3$
Selectivity to CO_2	37	68	70	85
Selectivity to CO	27	37	13	15
x	14	44	82	(100)

These results indicate that the approximate selectivity of each reactant to maleic anhydride is: C_4H_8, 14; C_4H_6, 44; and C_4H_4O, 82%. This means that the MoO_3–Bi_2O_3–P_2O_5 catalyst has about the same selectivity to maleic anhydride as the MoO_3–P_2O_5 catalyst. It is considered that the MoO_3–BiO_3–P_2O_5 catalyst has nearly the same catalytic specificity as the MoO_3–P_2O_5 catalyst in the oxidation step from C_4H_8 to $C_4H_2O_3$, but its activity for maleic anhydride oxidation is so very high that maleic anhydride cannot be accumulated. The difference in the catalytic features between the MoO_3–P_2O_5 and the MoO_3–Bi_2O_3–P_2O_5 catalysts may be mainly attributed to that in the activity of maleic anhydride destruction. Thus, we can conclude that no satisfactory maleic anhydride yield can be expected by the use of the MoO_3–Bi_2O_3–P_2O_5 catalyst.

Imidazole Catalyses in Aqueous Systems. VIII. Spontaneous Hydrolysis and Michaelis-Menten-type Catalytic Hydrolysis of Phenyl Esters in the Presence of Cholic Acid and Its Histamine Derivative[1]

Seiji SHINKAI and Toyoki KUNITAKE*

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received March 22, 1971)

Spontaneous hydrolyses of cationic and anionic phenyl esters in the presence of cholic acid (VI) and their catalytic hydrolyses with a histamine amide of cholic acid (VII) were investigated using a pH-stat at 30°C in 1.0M aqueous KCl. The rates of spontaneous hydrolysis decreased by 30—70% upon binding of substrates with cholic acid. The variation of the apparent binding constant (7-3650M^{-1}) was considered to reflect the magnitude of hydrophobic forces between cholic acid and substrates, although the values may have to be corrected for the possible involvement of self-association of cholic acid molecules. Imidazole derivative VII catalyzed the hydrolysis of phenyl esters according to Michaelis-Menten kinetics. The long methylene chain in the substrate molecule contributed appreciably to the binding of substrate with cholic acid and its derivative. The magnitude of substrate binding with VII appears to be comparable to the true binding constant with cholic acid. The intra-complex rate constants did not differ much from those expected with other enzyme-like catalysts. Thus, the steroid ring seems to provide a non-specific hydrophobic binding site for the substrates used.

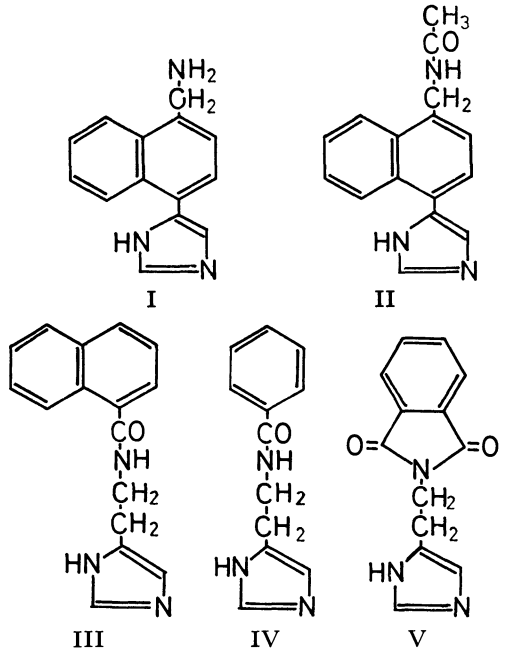
We showed that some imidazole derivatives catalyzed the hydrolysis of *p*-acetoxybenzoic acid (ABA) by second-order kinetics (Eq. (1)) or by the Michaelis-Menten kinetics (Eq. (2)):[2,3]

$$C + S \xrightarrow{k'} C + P \quad (1)$$

$$C + S \underset{K_m}{\rightleftharpoons} CS \xrightarrow{k_{cat}} C + P \quad (2)$$

where C, S, and P denote catalyst, substrate, and product, respectively.

The Michaelis-Menten kinetics were observed when imidazole catalysts contained naphthalene ring (I, II, III). The catalysis by less hydrophobic imidazole compounds (IV, V) followed second-order kinetics. Substrate binding in the enzyme-like catalysis was concluded to be ascribable to the hydrophobic interaction. This was also supported by the thermodynamic data obtained for formation of the catalyst-substrate complex.



The intra-complex product formation in the Michaelis-Menten pathway was not very efficient because of extraordinarily large negative $\Delta S^{\ddagger}$ values (*ca.* −50 eu). The unfavorable $\Delta S^{\ddagger}$ term was conceivably related to destruction of the hydrophobic interaction between catalyst and substrate in the transition state of the intra-complex reaction.[3]

Since the intra-complex process would be affected by the structure of the binding site it is interesting to study the catalytic behavior of imidazole compounds with different hydrophobic groups. The steroid ring might provide an interesting binding site as considered from its physiological role. In particular, desoxycholic acid and related compounds are known to form stable inclusion compounds in aqueous solutions.[4] Thus,

imidazole derivatives of these steroids would give rise to interesting catalytic systems. In this paper we report the influence of complexation of cholic aicd (VI) on the spontaneous hydrolysis of several phenyl esters and the catalytic hydrolysis of these phenyl esters by a histamine derivative of cholic acid (VII). Attempts to synthesize a similar catalyst have been reported by French workers.[5]

Experimental

Materials. Commercial cholic acid (Nakarai Chemicals Ltd., Guaranteed Reagent) was used without further purification. Imidazole catalyst VII was prepared from cholic acid (VI) and histamine. Cholic acid (5.1 g, 12.5 mmol) was dissolved in a mixture of tetrahydrofuran (150 m*l*) and acetonitrile (50 m*l*) containing 10 m*l* of triethylamine. The reaction mixture was cooled in an ice bath and 1.5 g (16 mmol) of methyl chloroformate was added with stirring. After stirring for 36 hr, precipitates (triethylamine hydrochloride) were filtered and the filtrate was evaporated to dryness *in vacuo*. The solid residue was dissolved in 60 m*l* of ethanol containing 2 m*l* of 4N aqueous NaOH and was allowed to stand at room temperature for 2 hr. The solvent was again removed *in vacuo* and the residue was dissolved in absolute alcohol in order to separate inorganic materials. Alcohol was evaporated, and the residue which was dissolved in 1N hydrochloric acid was reprecipitated by pouring into a saturated solution of aqueous sodium carbonate. Reprecipitation was repeated once more. Yield 66%. The infrared spectrum showed an amide peak at 1640 cm^{-1} and characteristic peaks of imidazole at 1440 and 1530 cm^{-1}. Another reprecipitation gave a product of mp 117—120°C in 48% overall yield: $pK_a=7.14$ (1.0M KCl, 30°C).

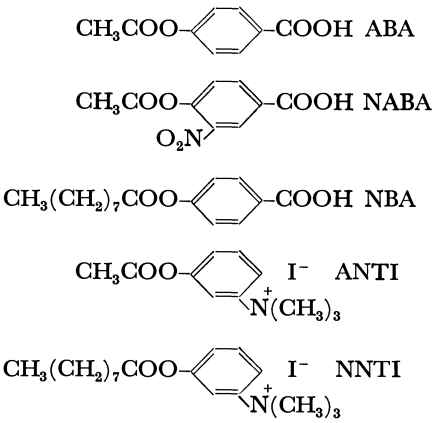
Found: C, 72.12; H, 9.43; N, 7.19%. Calcd for $C_{29}H_{47}N_3O_4$: C, 69.43; H, 9.44; N, 8.38%.

Two spots were observed at $R_f=0.07$ and 0.52 on a silica-gel thin layer chromatogram with acetic acid as developing solvent. The weak spot at $R_f=0.52$ was due to cholic acid. Purity based on the nitrogen content was 85.8%. This preparation containing cholic acid as probably the sole organic contaminant was used as catalyst. When the reprecipitation was repeated five more times, the product showed mp 122—124°C.

Found: C, 70.69; H, 9.47; N, 7.99%; Calcd for $C_{29}H_{47}N_3O_4$: C, 69.43; H, 9.44; N, 8.38%.

Precipitation and characterization of *p*-acetoxybenzoic acid (ABA, mp 192—194°C), 3-nitro-4-acetoxybenzoic acid (NABA, mp 156—158°C), *m*-acetoxy-*N*-trimethylanilinium iodide (ANTI, mp 223—224°C) and *m*-nonanoyloxy-*N*-trimethylanilinium iodide (NNTI, mp 134—135°C) were described previously.[3,6] *p*-Nonanoyloxybenzoic acid (NBA) was prepared from *p*-hydroxybenzoic acid and nonanoyl chloride: 8.4 g (30 mmol) of *p*-hydroxybenzoic acid and 2.8 g (65 mmol) of NaOH were dissolved in water, and 5.3 g (30 mmol) of nonanoyl chloride (bp 126—130°C/30 mmHg. lit,[7] bp 93—96°C/11 mmHg) was added dropwise with stirring. The reaction flask was immersed in an ice bath. White precipitates were formed at the end of the addition. Stirring was continued for 1 hr and pH of the reaction mixture was adjusted to 2—3 by concentrated hydrochloric acid. The precipitates were filtered, washed with water, dried, and recrystallized two times from benzene, yield 76%, mp 113—115°C, IR(KBr): 1750 cm^{-1}(ester), 1675 cm^{-1}(carboxyl).

Found: C, 68.95; H, 7.90%. Calcd for $C_{16}H_{22}O_4$: C, 69.04; H, 7.97%.



Titration and Hydrolysis Procedures. Titration and hydrolysis were carried out at 30.0±0.05°C using a pH-stat connected with a recorder (TOA Electronics Ltd., Models HS-1B and EPR-2T, respectively). The reaction rate was determined from the amount of alkali automatically added to the reaction mixture in order to neutralize the acid formed. The degree of dissociation of the product phenols under the reaction conditions was taken into account in determining the rate of reaction. Details of the procedure have been described.[8]

Results and Discussion

Spontaneous Hydrolyses in the Presence of Cholic Acid. Phenyl esters are hydrolyzed spontaneously in an alkaline medium by the pseudo-first-order kinetics.[3,6,8]

$$v_{spont} = k_s[S] \quad (3)$$

The rate of spontaneous hydrolysis decreased upon addition of cholic acid. Figures 1 and 2 show the effect of cholic acid on the relative rate of spontaneous hydrolysis of five substrates: ABA, NBA, NABA, ANTI, and NNTI. Hydrolysis of NBA was carried out at pH 9.4, because v_{spont} was too small at pH 8.0 to be determined accurately. The relative rate v/v_0 decreased with increasing concentration of cholic acid, and in the case of NBA it decreased to a saturation value with a small amount of cholic acid. The results can be explained by assuming that phenyl esters form complexes with cholic acid and that the resulting complexes show decreased reactivity.

Retardation (or inhibition) of spontaneous hydrolyses of esters in the presence of additives has been studied by some groups of researchers. In particular, Connors and his coworkers made a detailed study on the effect of theophylline and related heterocyclic compounds in the alkaline hydrolysis of several esters.[9-11]

NNTI: 0.020M, $v_0=2.34\times10^{-5}$M min^{-1} (30°C, 1.0M KCl, pH 8.0)

The spontaneous hydrolysis of phenyl esters in the presence of cholic acid may be described by the following equations, if substrate S and additive A (cholic acid) interact to form a 1:1 complex SA.

$$S + A \overset{K_c}{\rightleftharpoons} SA \quad (4)$$

$$S \xrightarrow{k_s} \text{products} \quad (5)$$

$$SA \xrightarrow{k_{SA}} \text{products} + A \quad (6)$$

where K_c is the binding constant of phenyl esters and cholic acid and k_{SA} is the pseudo-first-order rate constant for spontaneous hydrolysis of phenyl esters in the complexed state.

The following equation has been obtained according to Connors *et al.* for [A]≫[S]:

$$\frac{k_s}{k_s-k'} = \frac{1}{qK_c[A]} + \frac{1}{q} \quad (7)$$

where k' is the apparent pseudo-first-order rate constant and $q=1-k_{SA}/k_S$. K_c and q are determined by plotting $k_s/(k_s-k')$ against $1/[A]$.

On the other hand, when the simplifying assumption ([A]≫[S]) cannot be made, the overall rate is expressed by

$$v = k_s[S] + k_{SA}[SA]$$
$$= k_s[S] + k_{SA}\{[S]_0-[S]\} \quad (8)$$

where $[S]_0$ is the total concentration of substrate and [S] is the concentration of free substrate. The following equation holds simultaneously.

$$K_c = \frac{[SA]}{[S][A]} = \frac{[S]_0-[S]}{[S]\{[A]_0-([S]_0-[S])\}} \quad (9)$$

where $[A]_0$ is the total concentration of cholic acid.

We see from Figs. 1 and 2 that the additive concentration is not small compared to the substrate concentration. Therefore, Eqs. (8) and (9) were employed and the values of K_c and k_{SA} were determined by computational trial-and-error as follows. Approximate K_c and k_{SA} values were first estimated from Eq. (7). The corresponding rate v_{calcd} was calculated for respective additive concentrations from the known k_s, $[S]_0$ and $[A]_0$ values and compared with the observed rate v_{obsd}. Then a set of K_c and k_{SA} values was sought which minimized the relative error.

$$\text{relative error} = \sum\left\{\frac{(v_{calcd}/v_{obsd}-1)^2}{n}\right\}^{1/2} \quad (10)$$

where n is the number of experimental runs.

Kinetic constants for the spontaneous hydrolysis of phenyl esters and their complexes with cholic acid are summarized in Table 1. As can be expected from Fig. 1, NBA showed a much greater tendency of binding ($K_c=3650$M^{-1}) than other substrates. This might be attributed to hydrophobic forces between the steroid skeleton of cholic acid and the long methylene chain of the substrate. The increased binding due to the long alkyl chain is also evident in the different K_c values between ANTI and NNTI. The carboxyl group in cholic acid is dissociated completely at pH 8 or 9.4. Therefore, it is possible that both hydrophobic and electrostatic forces contribute to binding of cationic substrates ANTI and NNTI. However, their K_c values were lower than those of related anionic sub-

Table 1. Spontaneous hydrolyses with and without cholic acid[a)]

Substrate	M	K_c[b)] M^{-1}	k_s min^{-1} $\times10^3$	k_{SA}[b)] min^{-1} $\times10^3$	k_{SA}/k_s	relative error[c)] %

d) Hydrolysis conditions, 30°C, pH 9.4, 1.0M KCl.

strates (ABA and NBA, respectively). This suggests that the carboxylate group of cholic acid did not contribute noticeably to the binding of the cationic substrates.

In the above experiments, high concentration of cholic acid was employed relative to the substrate concentration except for NBA. Cholic acid molecules might be associated at high concentrations as considered from its tendency to form molecular compounds.[4] If, this is the case, the kinetic analysis based on Eqs. (4) (5), and (6) becomes unreliable for high concentrations of cholic acid. Therefore, it is possible that K_c values are underestimated except for NBA because association of cholic acid is assumed to be absent. Nevertheless, the relative tendency of substrates to form molecular complexes is probably not altered by the occurrence of association.

Underestimation of K_c necessarily leads to that of k_{SA} of the 1 : 1 complex according to Eqs. (8) and (9). As shown in Table 1, retardation of the spontaneous hydrolysis due to complexation was the smallest for NBA substrate. If k_{SA} is underestimated because of the neglect of association of cholic acid, the true k_{SA} value will be greater except for NBA substrate, and the extent of retardation might be closer with each other than that given in Table 1.

In any way, the retardation was not very efficient, k_{SA}/k_s being 0.24 to 0.73. On the other hand, in the alkaline hydrolysis of methyl cinnamate in the presence of theophylline, the corresponding relative rate was close to zero, indicating almost complete inhibition of hydrolysis due to complexation.[9] This contrast is interesting in connection with the nature of the binding site. The chemical environments of the ester group of substrates complexed with cholic acid do not appear to differ much from those of the ester group of free substrates. In the case of inhibition by theophylline, Connors *et al.* suggested that the molecular complexes of theophylline with cinnamate esters were formed in such a way as to permit extensive local dipole and induced dipole interactions in the face-to-face orientation.[11] The electronic interaction of the ester group may be much greater with a dipolar, flat theophylline molecule than with a hydrocarbon-like skeleton of cholic acid.

Catalytic Hydrolysis. Catalyst VII was not completely free from cholic acid as shown by elemental analysis and thin layer chromatography. However, cholic acid present as contaminant (*ca.* 10^{-5}M) would show negligible influence. Catalyst concentration was corrected for the purity of the catalyst. The results of catalytic hydrolysis are shown in Figs. 3 and 4. The catalytic rate v_{cat} clearly tends to level off at high substrate concentrations. The results are similar to those previously observed with imidazole catalysts containing naphthalene rings,[2,3] and can be described by the Michaelis-Menten kinetics. In the case of the enzyme-like catalytic pathway (Eq. (2)), the catalytic rate is given by

$$v_{cat} = \frac{k_{cat}[C][S]}{K_m + [S]} \qquad (11)$$

The kinetic constants K_m and k_{cat} can be determined from Lineweaver-Burk plotting between $1/v_{cat}$ and $1/[S]$.[12]

$$\frac{1}{v_{cat}} = \frac{1}{k_{cat}[C]} + \frac{K_m}{k_{cat}[C]} \cdot \frac{1}{[S]} \qquad (12)$$

The Lineweaver-Burk plots of the data of Figs. 3 and 4 were linear, and K_m and k_{cat} values for respective substrates were obtained from the slope and the intercept as given in Table 2. The binding tendency varied with substrates in approximately the same manner as with K_c values. The catalyst concentrations were much smaller than the cholic acid concentration of the spontaneous hydrolysis. In addition, substrates were used in excess of the catalyst in all the catalytic hydrolyses. Therefore, association of the catalyst molecules can be neglected in catalytic hydrolysis in contrast to spontaneous hydrolysis, and $1/K_m$ will reflect the true binding capacity of the catalyst.

TABLE 2. CATALYTIC HYDROLYSES[a)]

Substrate	Catalyst M × 10^4	K_m mM	k_{cat} min^{-1}	k_{cat}/K_m $min^{-1}M^{-1}$	$1/K_c$ mM
ABA	4.05	8.0	0.028	3.0	63
NBA[b)]	4.50	0.53	0.033	62	0.27
ANTI	2.02	20	0.099	5.0	150
NNTI	2.02	0.94	0.075	80	9.4
ABA	8.2[c)]	16.4	0.021	1.3	—

a) Hydrolysis conditions: 30°C, pH 8.0, 1.0M KCl, unless otherwise stated.
b) Hydrolysis condtions: 30°C, pH 9.4, 1.0M KCl.
c) Catalyst, III. From Ref. 3.

It is obvious that the nonanoyl group enhanced substrate binding due to hydrophobic interaction. The binding tendency of cationic substrates was smaller relative to that of the anionic substrates (ABA *vs.* ANTI, NBA *vs.* NNTI). Since the catalytic species VII does not carry a negative charge, it is not necessary to take into account the electrostatic interaction between the opposite charges in the catalytic hydrolysis. Table 2 includes the rate data of ABA with naphthoylhistamine III. From a comparison of K_m values it is indicated that the steroid skeleton is twice as effective as the naphthalene ring as a hydrophobic binding site. As for the k_{cat} term, these catalysts showed very similar efficiencies, suggesting that the reactivity of the histamine moiety is not affected by this extent of difference in the binding site.

The binding capacities of cholic acid and its histamine derivative can be compared by using $1/K_c$ and K_m given for each substrate in Table 2. As mentioned above, K_c may be underestimated except for NBA. If this is taken into consideration, the $1/K_c$ values for ABA, ANTI, and NNTI will be smaller than those given in Table 2, and K_m and $1/K_c$ values may become close in the respective substrate. It is probable that the nature of the binding site is not greatly altered by incorporation of the histamine moiety.

TABLE 3. FREE ENERGIES OF SUBSTRATE BINDING

Substrate	ΔG_u kcal/mol	$\Delta\Delta G_u$ kcal/mol	Free energy of binding per methylene group, $\Delta\Delta G_u/7$, kcal/mol.
ABA	−5.33	−1.63	−0.23
NBA	−6.96		
ANTI	−4.78	−1.84	−0.26
NNTI	−6.62		

The unitary free energy change ΔG_u (kcal/mol) for substrate binding is defined as follows.[13)]

$$\Delta G = -RT\ln(1/K_m) \quad (13)$$

$$\Delta G_u = \Delta H - T\Delta S_u = \Delta H - T(\Delta S + 7.98) \quad (14)$$

ΔG_u values in the catalytic hydrolysis are summarized in Table 3. The $\Delta\Delta G_u$ value reflects the contribution of the nonanoyl group to substrate binding, and is similar in the anionic and cationic substrates. The contribution of the methylene unit to binding, *ca.* −0.25 kcal/mol, was in the same range as observed with some polymer catalysts.[6)] The hydrophobic contribution of the methylene group has been estimated to be *ca.* −0.75 kcal/mol. The smaller contribution of the methylene unit in the present case suggests that the alkyl chain is not fully available for the hydrophobic interaction with the catalyst.

In conclusion, the steroid ring in cholic acid and its derivative was shown to constitute a substrate binding site based on hydrophobic forces. This hydrophobic region did not show specific interactions at least with the substrates used, contrary to our expectation.

The authors are deeply grateful to Professor Chuji Aso, head of our research group, for his unfailing encouragement and advice.

S_N2 Reactions in Dipolar Aprotic Solvents. Chlorine Isotopic Exchange Reactions of 2-Arylethyl Chlorides, Chloromethyl Aryl Ethers, and Chloromethyl Aryl Sulfides in Acetonitrile[1)]

Jun-ichi HAYAMI,[2)] Nobuo TANAKA, Syuji KURABAYASHI, Yasuhiro KOTANI, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 29, 1971)

The S_N2 reactions having a symmetrical transition state were studied in a dipolar aprotic solvent. A good Hammett correlation was found for the chlorine isotopic exchange reactions in acetonitrile between tetraethylammonium chloride and three types of substituted methyl chlorides, 2-arylethyl chlorides, chloromethyl aryl ethers, and chloromethyl aryl sulfides. The reaction constant was positive for 2-arylethyl chlorides and negative for the methyl chlorides possessing an α-heteroatom. The presence of oxygen and sulfur atom on the α-position to the reaction center resulted in a rate enhancement of about 10^5 times and 10^3 times, respectively. Features of the transition states of these S_N2 reactions are discussed.

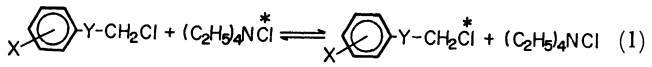
Nucleophilic substitution at a saturated carbon atom has been extensively studied.[3)] As compared to abundant studies on unimolecular reactions, not much has been carried out on the features of the S_N2 reactions. Timing of bond-breaking and bond-forming and also the electronic requirement of the transition state are less extensively studied. Parker examined the solvent effect on bimolecular reactions.[4)] However, little information is presented concerning the effect of the structures of the substrates.

In the present study, attempts were made to bring about a clean S_N2 reaction of which the examination of the Hammett relationship is feasible.

Methyl chlorides with a substituent at the α-position were prepared and subjected to isotopic exchange reaction in dry acetonitrile. Smaller solvation of anions in a dipolar aprotic solvent implies a slight change in anion solvation, minimizing the difficulties due to desolvation-solvation phenomena of anionic entities involved in an S_N2 displacement.[5)] As is proved in this communication, kinetics suffered little from the change of ion-pair dissociation equilibria of the quaternary ammonium salt. In solvent acetonitrile, such a salt shows fairly good dissociation and little trouble is anticipated.

Results and Discussion

Three substituted methyl chlorides, 2-arylethyl chlorides, aryloxymethyl chlorides (chloromethyl aryl ethers), and arylthiomethyl chlorides (chloromethyl aryl sulfides) were prepared. These substrates were treated in dry acetonitrile with tetraethylammonium chloride-^{36}Cl. The reactions are summarized as follows.



(1)

I Y: CH_2, X: a) *p*-NO_2, b) *m*-Cl, c) *p*-Cl, d) H, e) *p*-CH_3, f) *p*-OCH_3, g) *p*-OC_3H_7-*i*

II Y: O, X: a) *p*-NO_2, b) *m*-Cl, c) *p*-Br, d) *p*-Cl, e) H, f) *p*-CH_3, g) *p*-OCH_3

Rates of the bimolecular substitution reactions with a symmetrical transition state were followed by examining the radioactivities incorporated in the organic compounds and also the radioactivities remaining in the ionic chloride. In every case, a good first order kinetics was observed. Second order rate coefficients were deduced by dividing the observed first order rate constants by pertinent chloride concentrations. Typical kinetic data are given in Table 1.

Examination was made of the effect of ion-pair dissociation of the quaternary ammonium chloride in

acetonitrile. A slight but not serious change in k_2 was observed in changing the concentration of the ammonium chloride present. This shows that a slight change in ion-pair dissociation equilibrium took place in the concentration range studied (an implication of essentially complete dissociation). The results are in contrast to reactions in dimethylformamide, where the rate increment of about 30% was observed for the seven fold variation in chloride ion concentration.[6] A slight decrease in the rate observed in the presence of an inert salt may be attributed to a common ion effect which affects the ion-pair dissociation equilibrium in the reaction system.

The reaction was essentially of second order, first order in the substrate and also in tetraethylammonium chloride. Second order rate coefficients calculated were constant, the deviation being within the experimental error for the change in the ten fold variation of chloride concentration. The results for chloromethyl aryl ethers and sulfides present a rare case where molecularity of the reaction is well defined for the reaction of this class of compound. The results are shown in Table 2.

Hammett relationship holds for these second order rate coefficients. Typical examples are given in Fig. 1 and the results are summarized in Tables 3, 4, and 5.

These tables clearly show that the reaction constant ρ was positive for the 2-arylethyl chlorides and negative for both the chloromethyl aryl ethers and sulfides. Such a trend is not without precedent but the present instance is perhaps the first case where linear free energy relationship holds. Negative ρ which holds for the varieties of the substituents is rarely reported.

As pointed out by Jaffé,[7] S_N2 reactions of 2-arylethyl chlorides with iodide ion in acetone gave ρ= 0.590 with a correlation coefficient r=0.870. An example of 2-chloroethyl aryl sulfides was also reported,

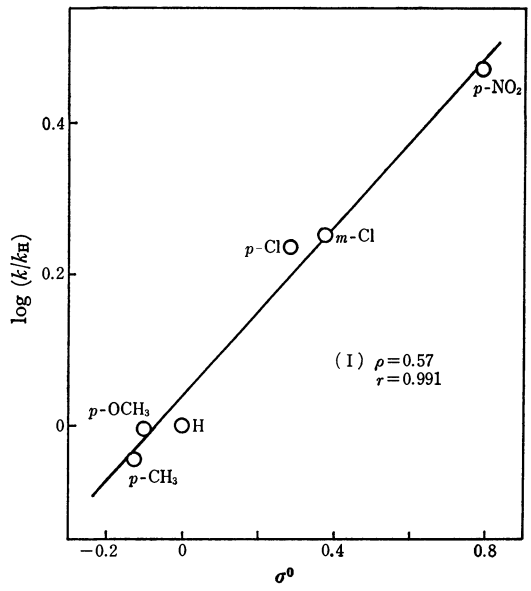

Fig. 1. a) Hammett plot for the chlorine exchange of 2-arylethyl chlorides (I) at 60°C.

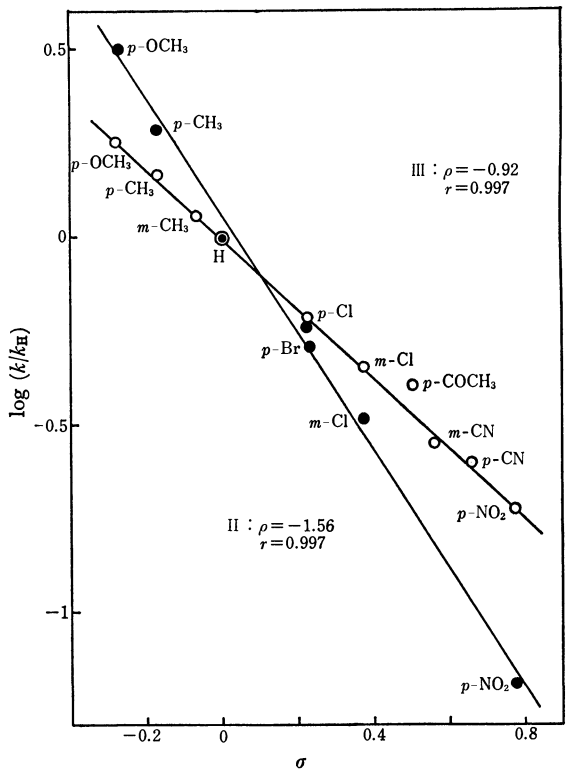

Fig. 1. b) Hammett plot for the chlorine exchange of chloromethyl aryl ethers (II: ●) and sulfides (III: ○) at −15.9°C and 20.0°C, respectively.

where electron-withdrawing substituents accelerate the reaction, ρ being 0.626 with r=0.918.

In the present instance, the rate accelerating effect of the heteroatom located on α-position to the reaction center is fairly large. The oxygen accelerates the reaction by a factor of 10^5—10^6 and the sulfur atom by a factor of 10^2—10^3 compared to the 2-arylethyl system. These values are compatible with the one reported in

literature.[3c,8)] Ballinger and his co-workers[8c)] showed the accelerating effect of the α-heteroatom to be 10^5 for oxygen in a methoxy group in an S_N2 solvolysis of methoxymethyl chloride.

The acceleration may be ascribed to the electron deficiency of the reaction center caused by the presence of an electronegative heteroatom. This can be ruled out by the negative ρ found for the isotopic exchange reactions. The results show definitely that the effects

	S	20.1	−10.0

of the α-oxygen and of the α-sulfur atom are due to electron-donation. The electron-donating conjugation of oxygen and sulfur seems to surpass the electron-withdrawing inductive effect in this case.

In other words, in the case of the S_N2 reaction of chloromethyl aryl ethers and sulfides, the important factor should be the stabilization of the transition state by the electron-donating conjugation of an α-heteroatom with the reaction center. The conjugation brings about the delocalization of the developing fractional positive charge on the central carbon atom. The $2p$–$2p$ overlap between carbon and oxygen may exert a larger effect than $2p$–$3p$ overlap provided by sulfur.[8a)] The smaller activation energy for the ethers may support this interpretation. An electron-donating group can facilitate the bond dissociation in a nucleophilic displacement, and also can retard the bond formation to the incoming nucleophile. Accordingly, the effect of such a group should be self-canceling and should not reflect on the rate of the bimolecular symmetrical substitution.

In the case of 2-arylethyl chlorides, the ease of approach of the entering chloride ion seems to be essential.[9)] The effect of substituents is essentially polar (inductive), and the linear free energy relationship with a positive ρ holds for Taft's σ^0,[10)] a polar parameter.

It should be noted that as far as the S_N2 reactions in the present instance are concerned, there seems to be no clue to the fact that the ion-pair mechanism of Sneen[11)] is operative. Potential cation from 2-arylethyl chlorides may accept the participation of aryl group (*cf.* ethylenephenonium cation), showing the accelerating effect by electron-donating substituents which generally obeys the ρ–σ^+ relationship. However, this is not the case. Also in the other two cases, where electron-donating substituents accelerated the reaction, ion-pair mechanism is less probable. Hammett ρ values were −1.56 and −0.92 for these compounds. These values seem too small to imply the interaction of an α-heteroatom with the fully developed

9) The polar effect observed in the present study is tentatively ascribed to the importance of bond formation at the transition state. The interpretation based on a field effect proposed by Holtz and Stock is noteworthy. However, the establishment of ρ-σ^0 rather than ρ-σ_I relationship seems to prefer the present interpretation. H. positive center.[12]

A report was given by the authors showing that the E2 reaction from 2-arylethyl chlorides in acetonitrile gave a ρ value close to 2.[13] This implies that electronic requirement of the S_N2 reaction with chloride ion is quite different from that of the E2 reaction promoted by fluoride ion.

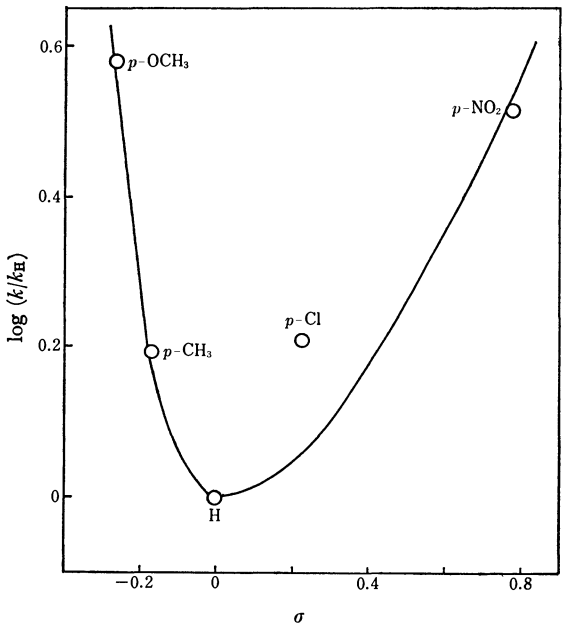

Fig. 2. Hammett plot for the chlorine exchange of benzyl chlorides at 40.0°C.

The U-shaped Hammett plots were reported for the S_N2 reactions of benzyl halides in some cases.[14] The authors carried out the chlorine exchange reaction between substituted benzyl chlorides and tetraethylammonium chloride. The symmetrical S_N2 reaction showed an ordinary U-shaped Hammett plot as shown in Fig. 2. The result implies that the tightening factor in a symmetrical transition state after Parker[15] is not effective enough to make the intrinsically loose transition state tighter.

12) The observed rate constants, or ρ values, can be affected by the ion-pair return that makes the interpretation of ρ values ambiguous.[a] It is quite plausible, however, that the solvent separated ion-pair intermediate is effectively intercepted by chloride and/or perchlorate ion, and external ion-pair return from this intermediate is minimized by the presence of tetraethylammonium salt in a concentration range studied.[b] It is difficult to confirm or disprove the intervention of an intimate ion-pair. However the enhanced internal return should result in a high ρ value reaching the limiting value for S_N1 reactions. Bordwell and his coworkers reported that an S_N1 reaction of chloromethyl aryl sulfides gave $\rho=-2.6$ at 34.85°C.[c] a) S. G. Smith and D. J. W. Goon, *J. Org. Chem.*, **34**, 3127 (1969). b) S. Experimental

Preparation of materials. a) 2-Arylethyl chlorides (Ib—Ig) were prepared from corresponding 2-arylethyl tosylates by heating to reflux with tetraethylammonium chloride in acetonitrile. The products were purified by distillation under reduced pressure. 2-*p*-Nitrophenylethyl chloride (Ia) was obtained by nitration of 2-phenylethyl chloride (Id).

b) Chloromethyl aryl ethers (IIa—IIg) were prepared from sodium aryloxymethanesulfonates with phosphorus pentachloride, and purified by vacuum distillation except for chloromethyl *p*-nitrophenyl ether (IIa) and chloromethyl *p*-bromophenyl ether (IIc) which were recrystallized from petroleum ether containing a small amount of benzene.[16]

c) Chloromethyl aryl sulfides (III) were prepared by either of the two following methods. (A). Corresponding thiophenols were allowed to react with paraformaldehyde and gaseous hydrogen chloride in methylene chloride. (B). Corresponding methyl aryl sulfides were chlorinated with sulfuryl chloride in methylene chloride.[17] Chloromethyl *p*-nitrophenyl sulfide (IIIa) and chloromethyl *p*-cyanophenyl sulfide (IIIb) were purified by recrystallization from methylene chloride. Chloromethyl *m*-cyanophenyl sulfide (IIIc) and chloromethyl *p*-acetylphenyl sulfide (IIId) were recrystallized from methylene chloride after distillation under reduced pressure. The structures of new compounds were confirmed by their NMR and IR spectra and by elemental analyses.

Physical constants of alkyl chlorides (I, II, III) are summarized in Tables 7,8, and 9.

a) Ref. 12 b) Ref. 17

d) Tetraethylammonium chloride labeled with Cl-36 was prepared by titration of tetraethylammonium hydroxide with hydrochloric acid labeled with Cl-36. Tetraethylammonium chloride having suitable specific radioactivity was obtained by dilution and recrystallization with non-active tetraethylammonium chloride from chloroform containing a small amount of petroleum ether. Essentially no loss of radioactivity due to exchange reaction between chloroform and the chloride was observed. The reagent was dried *in vacuo* at 110°C before use. Acetonitrile was purified according to the procedure described previously.[20]

Kinetic measurements. Batch method was used for kinetic runs. Aliquots of the acetonitrile solutions of an alkyl chloride and tetraethylammonium chloride were put separately into an ampoule with double stems, and the tube was flame-sealed. After the temperature equilibrium was attained, the kinetic run was initiated by inverting and shaking the ampoule. The reactions of 2-arylethyl chlorides and chloromethyl aryl sulfides were quenched by cooling with an acetone-dry ice bath at appropriate intervals. Organic chloride was taken up in benzene while ammonium chloride was extracted in water. The reaction of chloromethyl aryl ethers was carried out in an ampoule equipped with a double rubber septum. The reaction was quenched by addition of a mixture of diisopropyl ether and *n*-hexane (10:1) precooled in an acetone-dry ice bath. The resulting mixture was extracted with three 5 m*l* portions of water. In all cases, the organic layer containing alkyl chlorides, and the aqueous layer containing tetraethylammonium chloride was made up to 25 m*l*. Chlorine-36 radioactivity was measured by liquid scintillation counting.[21] Exchange rates were calculated by the equation[22]

$$k = \frac{1}{t}\frac{1}{a+b}\ln\frac{X_e}{X_e - X},$$

where t, time; a, b, initial concentration; X, radioactivity of organic layer at time t; X_e, radioactivity of organic layer at infinite time.

Blank tests were performed with the non-active materials. Titration proved that alkyl chlorides underwent essentially no hydrolysis during extraction.

The tracer experiments were carried out at Radioisotope Research Center of Kyoto University. Sincere thanks are due to the staff of this institution.

The Effects of Solvents and Acid Catalysts on the Rearrangement of 2-Benzylidenecyclohexanone Oxide

Kenichi HINOUE, Masatomo NOJIMA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received April 12, 1971)

The rearrangement of 2-benzylidenecyclohexanone oxide (I) to 2-phenylcycloheptane-1,3-dione (II) was carried out in the presence of a Lewis acid or a Brønsted acid in various media-liquid sulfur dioxide, benzene, and ether. The only reaction product of I with a Brønsted acid in these solvents was the rearranged compound, II. In addition to II, 2-(α-halobenzyl)-2-hydroxycyclohexanone, (III) or (IV), was also obtained in the reaction of I with a Lewis acid in solutions. Drastic solvent effects were observed on the rate and the distribution of products in this reaction; however, no solvent effect was observed when a Brønsted acid, which could donate a proton to I, was used as the catalyst. From the variations in the concentrations of the reactant, the intermediate, and the product during the reaction course, the solvent effects upon the reaction pathways were discussed.

In a preceding paper[1] the rearrangement of 2-cyclohexylidenecyclohexanone oxide in the presence of a Lewis acid or Brønsted acid in a solvent, cyclohexane or liquid sulfur dioxide, was reported. The yield of the derived spiro [5.6]-dodecane-7,12-dione was discussed on the basis of its dependence on the solvent and the acid catalyst used. The combined use of a Lewis acid as the catalyst and liq. SO_2 as the solvent gave an excellent conversion, as large as a 93% yield of the spiro compound.

Although the rearrangement of α,β-epoxyketones under acidic conditions has been studied comprehensively from the synthetic point of view,[2] only a few studies have been undertaken to clarify the effects of the solvents and the catalysts.[3]

In the present communication, the results of the reaction of 2-benzylidenecyclohexanone oxide with an acidic catalyst in benzene, ether, or liq. SO_2 will be reported. As was reported previously, 2-cyclohexylidenecyclohexanone oxide has a hydrogen atom which can be eliminated as the proton during the reaction. The purpose of the present work is to study the solvent effects and also the role of the Lewis or the Brønsted acid on the α,β-epoxyketone rearrangement by selecting another compound, 2-benzylidenecyclohexanone oxide (I), which has no hydrogen atom to be drawn off during the reaction. In the reaction of 2-benzylidenecyclohexanone oxide (I), a procedure[1] similar to that used in the case of cyclohexylidenecyclohexanone oxide was followed.

Results and Discussion

The rearrangement of I was carried out at 20°C in sulfur dioxide, in benzene, and in ether. The reaction proceeds instantaneously in liq. SO_2, while in benzene the reaction is completed within thirty minutes. The reaction product of I with Brønsted acids in various solvents consisted only of the rearranged compound, 2-phenylcycloheptane-1,3-dione (II), mp 76.5—78.0°C.

Two products were obtained by the reaction with a Lewis acid, boron trifluoride etherate in benzene or ether. One was the rearranged product (II), while the other was 2-(α-fluorobenzyl)-2-hydroxycyclohexanone (III). The reaction of I with another Lewis acid, antimony pentachloride in benzene or ether, also gave two products, the rearranged compound, II and 2-(α-chlorobenzyl)-2-hydroxycyclohexanone (IV).

In Table 1 the results of experiments under various conditions are listed.

TABLE 1. ACID-CATALYZED REACTIONS OF I AT 20°C FOR 30 MIN

Catalyst	Solvent	Products, %		
		II	III	IV
H_2SO_4	SO_2	90.2	—	—
H_2SO_4	Benzene	90.1	—	—
FSO_3H	SO_2	80.7	—	—
FSO_3H	Benzene	83.2	—	—
$BF_3 \cdot OEt_2$	SO_2	70.3	0	—
$BF_3 \cdot OEt_2$	Benzene	36.1	50.6	—
$SbCl_5$	SO_2	50.0	—	8.7
$SbCl_5$	Benzene	6.7	—	73.9

II: 2-Phenyl-cycloheptane-1,3-dione.
III: 2-(α-Fluorobenzyl)-2-hydroxycyclohexanone.
IV: 2-(α-Chlorobenzyl)-2-hydroxycyclohexanone.

As is indicated in Table 1, when a Brønsted acid, H_2SO_4 of FSO_3H, was used, the product was exclusively the rearranged product (II), and the yields in the two solvents, liq.SO_2 and benzene, were almost the same.

However, the use as the catalyst of a Lewis acid, $BF_3 \cdot OEt_2$ or $SbCl_5$, which has no protonic hydrogen to donate, causes a drastic change in the solvent effects, affording a large quantity of III or IV in benzene. A similar trend was also observed when ether was used as the solvent.

It has well been established that fluorohydrins are formed by the reaction of epoxide with boron trifluoride etherate if the experimental conditions are right.[4,5] H.O.House showed that the treatment of I with boron

trifluoride etherate in ether led to the formation of the fluorohydrin (III).[6] The reaction of III with boron trifluoride etherate in ether to produce II was also examined; II was obtained directly from the reaction of I with boron trifluoride etherate in benzene. However, there was no conclusive evidence to indicate whether III was an intermediate in the formation of the carbonyl compound or merely a by-product. We examined the concentrations-time curves for the reactant and three products, I, II, and III, in an effort to decide whether or not III is an intermediate in the formation of 1,3-dione, boron trifluoride etherate being used as the catalyst.

Figure 1 reveals the concentration-time relationship between the constituents of the reaction mixture and the reaction process in the reaction in ether. In this case, only fluorohydrin (III) was formed at the early stage of the reaction; it reached a maximum value of 36%, and then slowly decreased with the reaction time. The yield of 1,3-dione (II) increased with an increase in the reaction time, and after 48 hr the yield reached 74%. These results seems to show that III is the intermediate for the formation of 1,3-dione under these conditions.

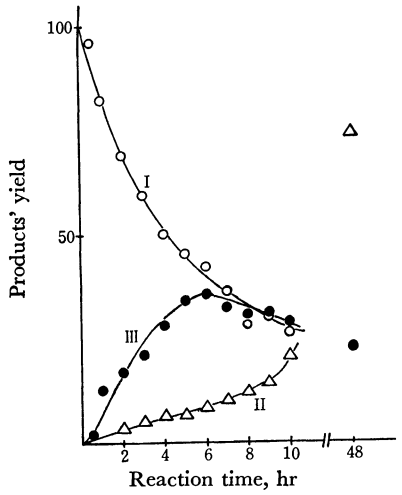

Fig. 1. The reaction of I with $BF_3 \cdot OEt_2$ in ether.

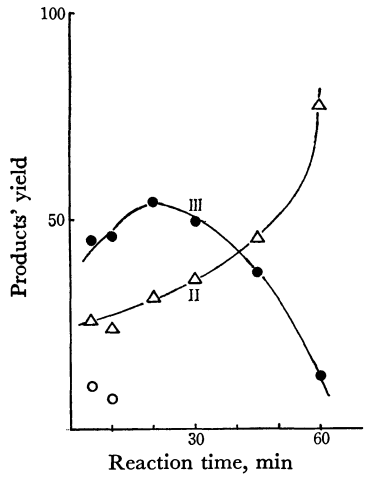

Fig. 2. The reaction of I with $BF_3 \cdot OEt_2$ in benzene.

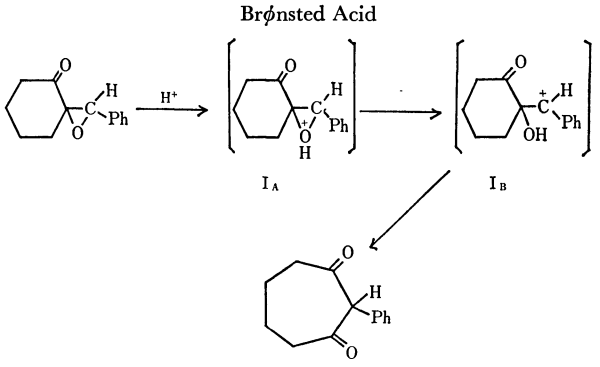
6) H. O. House and D. J. Reif, *J. Amer. Chem. Soc.*, **77**, 6525 (1955).

Figure 2 illustrates the behavior of I in a benzene solution. These curves indicate that III is produced at the first stage of the reaction and is then converted to 1,3-dione. However, at the early stage of the reaction periods *ca.* a 20% yield of 1,3-dione was formed; this result indicates that onestep (direct) formation of 1,3-dione may contribute in some degree.

In liquid sulfur dioxide the following results were obtained. At 20°C only the rearranged product (II) was formed. To explain these results, two mechanisms seem to be plausible. One is that, as the reaction rate of III is rapid in liquid sulfur dioxide, II is obtained as the sole product, although III is produced as the short-lived intermediate. The other possible explanation for these results is the one-step formation of II from I. To distinguish between the above two pathways, we carried out a reaction at −70°C. Under these reaction conditions we could not detect the formation of III, the only product being II at any reaction period. These results seem to show that the reaction of I with Boron trifluoride etherate in liquid sulfur dioxide proceeds directly to form 1,3-dione.

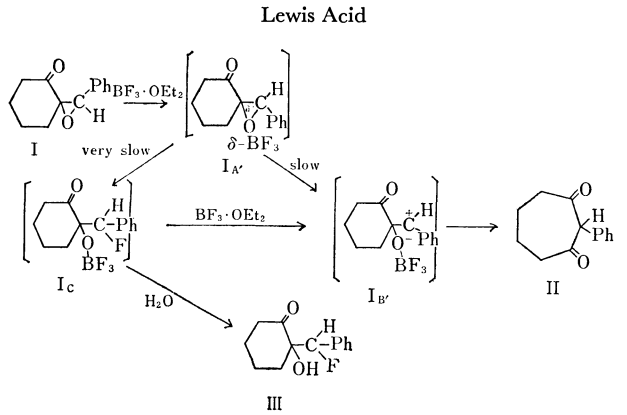
From these data, Scheme I may be taken to illustrate the probable reaction process. When Brønsted acid is used as the catalyst, I is attacked by a proton to form the intermediate, I_B, after the ring opening, and the migration of the acyl group may subsequently produce 1,3-dione, (II). Since the nucleophilicities of HSO_4^- and FSO_3^- in liq.SO_2 are very small, the intramolecular reaction (rearrangement) must occur predominantly.



Scheme I

Contrary to the above results, however, halohydrins were formed by the intermolecular epoxide cleavage reaction when Lewis acid was used as the catalyst in ether or benzene. Thus, the reaction pathways with boron trifluoride etherate are greatly dependent on the differences in the solvents. These results may indicate that the reaction rate is slowed down by the decrease in the electrophilicity of the catalyst for the formation of the cordinated complex and that the ionization necessary for the formation of 1,3-dione may be inhibited; the alternative reaction leading to fluorohydrin can then be operative, as is shown in Scheme II.

The fluorohydrin formed in an ether solution seems to arise through a cationic intermediate, I_A' (Scheme II), in which the carbon-oxygen bond is, for the most



Scheme II

part, maintained. The opening of the epoxide ring of I in benzene seems to involve a transition state of a greater ionic character than the reaction in ether. It seems likely that the rearrangement of the intermediate, I_B', to form II is accelerated by the stabilization of the intermediate due to the solvation of the counter anion by liquid sulfur dioxide. When benzene or ether is used as the solvent, however, there is little means to stabilize the transition state and the displacement to form III seems to be competitive.

To examine further the reactivity of the reactant in this rearrangement, 2-*p*-chloro (IV) and 2-*p*-methyl derivatives (VI) of benzylidenecyclohexanone oxide were prepared and subjected to the same reaction. The reaction was carried out as has been described above, and the same procedure was used to separate the products.

In liquid sulfur dioxide, both the compounds gave over 90% yields of rearranged products, V and VII, when boron trifluoride etherate was used as the catalyst. In benzene, the same catalyst gave 94.7% of V; however, VI (*p*-chlorobenzylidenecyclohexanone oxide) gave 57.7% of the rearranged product, VII, and 28.3% of a fluorohydrine, VIII.

Thus, the electrodonative *p*-methyl group may facilitate the formation and stabilization of a carbonium ion of such a type as I_B' in Scheme II, which is a prime requisite for the rearrangement.

Experimental

Materials. The liquid SO_2 was dehydrated with H_2SO_4 and P_2O_5 successively and distilled. The benzene and ether were purified by ordinary methods.

Apparatus. The IR spectra were run on an EPIS2-type Hitachi IR Spectrometer. The NMR spectra were obtained with a Japan Electron Optics Spectrometer, JNM3H-60.

The mass spectra were recorded on a Hitachi RMU-6E single focusing instrument.

2-Benzylidenecyclohexanone Oxide (I). 2-Benzylidenecyclohexanone oxide was prepared by the method of House.[6] From 30.0 g of 2-benzylidenecyclohexanone and 60 m*l* of a 30% hydrogen peroxide solution, 10.0 g (32.6% yield, based on 2-benzylidenecyclohexanone) of 2-benzylidenecyclohexanone oxide was obtained; mp 124.5—125.0°C (lit,[6] mp 124.5—125.0°C).

2-p-Methylbenzylidenecyclohexanone Oxide (IV). 2-*p*-Methylbenzylidenecyclohexanone was prepared by the condensation of 2-*p*-methylbenzaldehyde with cyclohexanone, using sodium hydroxide as the catalyst. IV was obtained by the reaction of 2-*p*-methylbenzylidenecyclohexanone with 30% H_2O_2 according to the directions of House.[6] Mp 117°C (recryst. from *n*-hexane), IR(KBr), 1710 cm^{-1}; NMR($CDCl_3$), τ, 6.0(1H), 2.85(4H), 7.65(3H). Found: C, 77.52; H, 7.50%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%

2-p-Chlorobenzylidenecyclohexanone Oxide (VI). VI was prepared by the condensation of 2-*p*-chlorobenzaldehyde and cyclohexanone, followed by epoxidation. Mp 116.0—116.5 (rec. from *n*-hexane), IR(KBr), 1710 cm^{-1}; NMR ($CDCl_3$), τ, 6.0(1H), 2.69(4H). Found: C, 66.05; H, 5.53%. Calcd for $C_{13}H_{13}O_2Cl$: C, 65.95; H, 5.54%.

The General Procedure of the Reaction of I with the Acid Catalyst. To 200 mg of I and 10 m*l* of a solvent, we added 0.1 m*l* of the acid catalyst, after which the mixture was allowed to react at 20°C for 30 min. The reaction mixture was cooled, diluted with water, and extracted three times with ether. The combined organic layers were washed with saturated brine and dried over anhydrous sodium sulfate. The light yellow solid remaining after the evaporation of the solvent was analyzed by NMR spectroscopy. The relative integrals at the τ values 6.05 (I), 5.20 (II), 4.25 (III), and 4.6 (IV), were used to estimate the constituents in the products.

The Measurement of the Concentration-Time Relationship of the Reactant and of the Products in the Rearrangement. The Reaction with Boron Trifluoride Etherate as the Catalyst. To 2.0 g of I and 200 m*l* of the solvent, we added 2.0 m*l* of boron trifluoride etherate, after which the mixture was allowed to react at 20°C. A 10-m*l* aliquot was withdrawn periodically and diluted with water. Then it was worked up as has been described previously, and the relative ratios of the components were calculated from the relative integrals of the NMR spectra as has been described above.

Identification of the Reaction products. Reaction Products of I with Boron Trifluoride Etherate in Benzene. I(2.0 g), 1 m*l* of freshly-distilled boron trifluoride etherate, and 100 m*l* of benzene were maintained at 20°C for 30 min and then worked up as in the previous case. The residue after the removal of the solvent was chromatographed on 50 g of silica gel. After elution with five 50-m*l* portions of petroleum ether, elution with ten 50-m*l* portions of benzene gave 0.6 g (yield%) of a solid, which was then recrystallized from *n*-hexane. 2-Phenylcycloheptane-1,3-dione, (II); mp 76.5—78.0°C (lit,[6] mp 76.5—78.0°C). Mass; *m/e*, 202, Calcd for $C_{13}H_{14}O_2$, 202. NMR($CDCl_3$); τ, 2.73(5H singlet), 5.20(1H, singlet), 5.20(1H singlet), 7.40 and 8.00(8H multiplet). The physical data were also identical with those in the literature.[6]

Elution with ten 50-m*l* portions of benzene gave 1.2 g (yield%) of a solid, which was then recrystallized from *n*-hexane; 2-(α-fluorobenzyl)-2-hydroxycyclohexanone, (III), mp. 129—130°C (lit,[6] mp 129.5—130°C). IR(KBr), 1720, 3460 cm^{-1}; NMR($CDCl_3$), τ, 2.70(5H singlet), 4.25(1H, J: 40.2 Hz), 5.90(1H, singlet), 7.4 and 8.2(multiplet); Mass, *m/e*, 222, Calcd for $C_{13}H_{15}O_2F$, 222.

Reaction Products with Antimony Pentachloride in Benzene. The products was treated as above. Elution gave 1,3-dione (II) and a product, a white crystalline solid, (IV). IV was recrystallized from *n*-hexane and identified as 2-(α-chlorobenzyl)-2-hydroxycylcohexanone (IV); mp 103.5—105.0°C; IR (KBr) 1710, 3460 cm^{-1}; NMR ($CDCl_3$); τ, 4.6 (1H), 5.3(1H singlet); Mass, *m/e*, 238, Calcd for $C_{13}H_{15}O_2Cl$, 238.

The authors wish to thank the Seitetsu Kagaku K.K. for its donation of liquid sulfur dioxide. The present work was made possible by the support of the Scientific Research Fund of the Ministry of Education.

Polymerization of Methyl Methacrylate by the Bis(benzoylacetonato)-Copper(II)-1,10-Phenanthroline System

Kyoji KAERIYAMA and YUKIO YAMAZAKI*

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama
**Okamoto Riken Rubber Co. Ltd., Hongo 3-27-12, Bunkyo-ku, Tokyo*

(Received April 15, 1971)

The addition of 1,10-phenanthroline accelerates the polymerization of methyl methacrylate by a β-diketonato chelate of Cu(II), Mn(II), Mn(III), Co(II), Co(III), and Fe(III), but has no effect on the chelate of Ni(II). The effect of 1,10-phenanthroline, which is composed of two pyridine units, is much greater than that of pyridine. The polymerization rate of methyl methacrylate by the bis(benzoylacetonato)Cu(II)-1,10-phenanthroline system may be represented as follows:

$$R_p \propto [\text{MMA}]\{[\text{Cu(II)}][\text{1,10-phenanthroline}]\}^{1/2}$$

The initiation reaction is assumed to be by a ligand-exchange reaction of bis(benzoylacetonato)Cu(II) with 1,10-phenanthroline, where a benzoylacetonyl ligand is displaced by 1,10-phenanthroline and Cu(II) is simultaneously reduced to Cu(I).

In has been reported that many additives accelerate vinyl polymerization by metallic chelates of β-diketone. Some additives, such as pyridine[1] and carbonyl compounds,[2] have been shown to coordinate to the central metal of chelate compounds through the lone-pair electrons and to increase the initiation rate of vinyl polymerization by tris(acetylacetonato)Mn(III) ($Mn(acac)_3$, where acac represents an acetylacetonyl ligand). This implies that the greater the ability for coordination to metal, the greater the effect. The chelating agents form a class of compounds which have the greatest ability for coordination. Recently, Bamford and Ferrar have briefly mentioned that ethylene and propylene diamines have a remarkable effect on polymerization by $Mn(acac)_3$. It has been found that 1,10-phenanthroline (phen) has much greater effects on the polymerization of methyl methacrylate (MMA) by metallic chelates of β-diketone than pyridine does. Phen is a chelating agent which is composed of two pyridine units. The effect of phen on bis(benzoylacetonato)Cu(II) ($Cu(ba)_2$, where ba denotes a benzoylacetonyl ligand) is studied in some detail.

Experimental

Reagent. The pyridine, MMA, and solvents were dried over **3A** molecular sieves and were distilled under reduced pressure just before use. The chelate compounds were commercially obtained and were used without further purification. The metallic chelates of acetylacetone were manufactured by the Dojindo Co., Ltd. The $Cu(ba)_2$ was supplied by Eastman Organic Chemicals. The recrystallization of phen was carried out from a benzene solution (mp 94°C). The dipyridyl was recrystallized from an ethanol-water system(mp 69°C).

Procedure. The chelate, the chelating agent, MMA, and benzene were mixed under atmospheric conditions. After the mixture had been placed in a glass tube and degassed by repeated freezing, evacuating, and thawing, it was sealed off. Polymerization was then carried out in the dark. The temperature was controlled within ±0.1°C. The polymer thus produced was precipitated in methanol containing a small amount of hydroquinone and hydrogen chloride, filtered, and dried *in vacuo* to a constant weighs. Conversions were then calculated on the weight of the polymer.

Results and Discussion

1. *Effect of Chelating Agent.* The effects of phen and dipyridyl are compared with those of pyridine in Table 1. Phen has an accelerative effect on the polymerization of MMA by all the chelates of β-diketone examined other than $Ni(acac)_2$. Dipyridyl has an effect on $Mn(acac)_2$, $Mn(acac)_3$, $Cu(ba)_2$, $Co(acac)_2$, and $Co(acac)_3$, but has no effect on $Fe(acac)_3$ and $Ni(acac)_2$. Pyridine accelerates the polymerization of MMA by $Mn(acac)_2$, $Mn(acac)_3$, $Co(acac)_2$, and $Co(acac)_3$, but has no effect on $Cu(ba)_2$, $Fe(acac)_3$, and $Ni(acac)_2$. Pyridine, however, has greater effects on the chelates of Mn and Co than dipyridyl does.

TABLE 1. EFFECTS OF CHELATING AGENT

Chelate		Conversion (%)			
type	concentration $\times 10^2$ mol/l	no additive	phen 2×10^{-2} mol/l	dipyridyl 2×10^{-2} mol/l	pyridine 4×10^{-2} mol/l

$Ni(acac)_2$	3.11	trace	trace	0	0

[MMA]=2.82 mol/l; solvent: benzene; at 60°C for 8 hr

It has been described that the effect of ketones is dependent on the nucleophilicity.[2] The effects of pyridine homologs on the polymerization of styrene decreases in this order: pyperidine>pyridine>2,6-lutidine.[1] This order is consistent with the ability of coordination to the central metal. In the present case also, it is reasonable to assume that the effects of pyridine homologs are dependent on the ability of coordi-

nation to the central metal, as can be anticipated from the viewpoint of nucleophilicity and steric hindrance. The average pK values for pyridine, dipyridyl, and phen are 5.21, 4.36, and 4.87 respectively.[4] Pyridine is the most nucleophilic. Steric hindrance of coordination to the central metal of chelate compounds probably decreases in this order: phen>dipyridyl>pyridine. Nevertheless, phen is the most effective. Pyridine has smaller effects than phen. The noticeable effect of phen, which has two coordination sites in a molecule, is attributable to the chelating effect of phen.

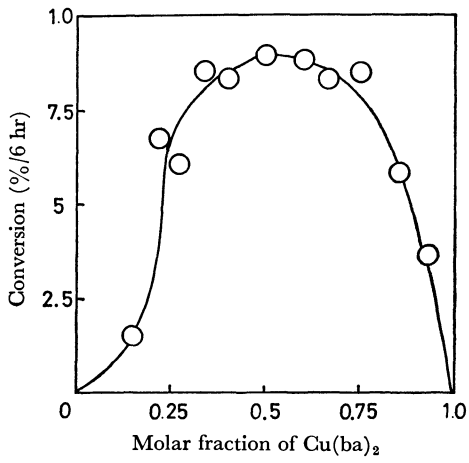

Fig. 1. Dependence of conversion on molar fraction of chelate.
[Cu(ba)$_2$]+[phen]=2.1×10^{-2} mol/l
[MMA]=2.82 mol/l; at 60°C in benzene

2. *Dependence on Molar Fraction of Cu(ba)$_2$.* Conversions at a constant polymerization time are shown as a function of the molar fraction of Cu(ba)$_2$ in Fig. 1. It is apparent from the figure that the binary system is very active in the initiation of MMA polymerization, although neither component shows any appreciable effect. In the case of the Mn(acac)$_3$-phen system,[5] a clear peak is observed at the molar fraction of 0.5. In the present combination, no sharp peak appears, but a wide plateau can be seen in the range of the molar fractions from 0.33 to 0.75.

3. *Dependence on Initiator Concentration.* The dependence of the polymer yield on the polymerization time is shown at different concentrations of the initiator in Fig. 2. No linear relation between the yield and the time can be observed even in the initial stage of polymerization. Therefore, according to the Aoki-Matsumura-Otsu method,[6] the rate of polymerization was estimated approximately from the ratio of the polymer yield and the time at a 5% polymer yield.

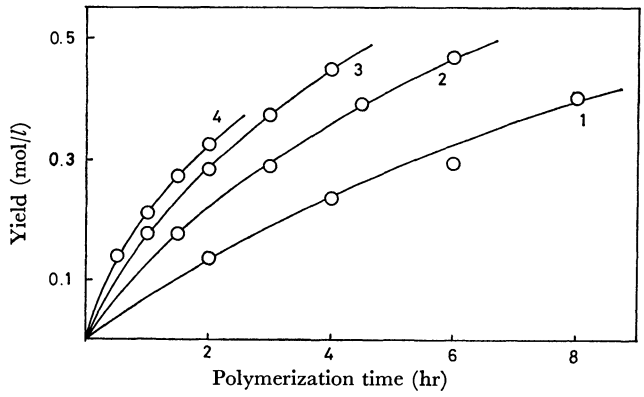

Fig. 2. Dependence of yield on polymerization time.
[MMA]=3.57 mol/l; at 70°C in benzene
{[Cu(ba)$_2$][phen]}$^{1/2}$
1. 3.89×10^{-3} mol/l 2. 7.77×10^{-3} mol/l
3. 11.7×10^{-3} mol/l 4. 15.5×10^{-3} mol/l

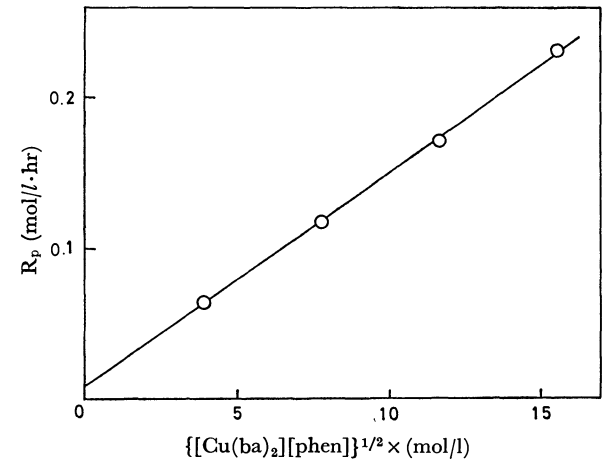

Fig. 3. Dependence of polymerization rate on initiator concentration.
[MMA]=3.57 mol/l; at 70°C in benzene

The rate of polymerization thus obtained is shown as a function of the concentrations of Cu(ba)$_2$ and phen in Fig. 3. The molar concentration of Cu(ba)$_2$ is equal to that of phen in each run. The rate of polymerization is linearly dependent on the square root of [Cu(ba)$_2$][phen]. This suggests that termination is not by a reaction of a polymer radical with the chelate, but by a bimolecular reaction of polymer radicals. This conclusion is also supported by the experimental evidence that Cu(ba)$_2$ has no effect on the polymerization of MMA initiated by azo-bis-isobutyronitrile.

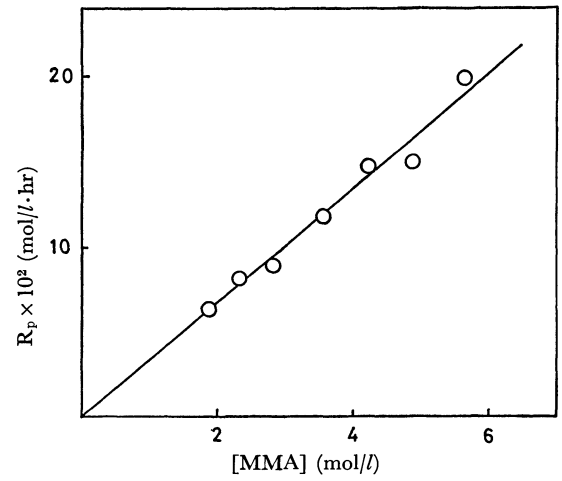

Fig. 4. Dependence of polymerization rate on concentration of MMA.
[Cu(ba)$_2$]=[phen]=7.77×10^{-3} mol/l at 70°C in benzene

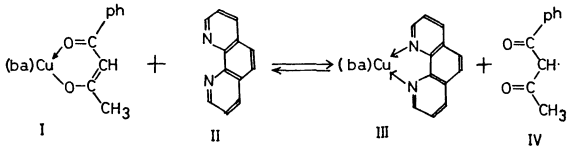
6) S. Aoki, S. Matsumura, and T. Otsu, This Bulletin, **42**, 2574 (1969).

The line does not pass through the point of origin. This deviation is probably attributable to the fact that the rate is not strictly determined at the initial stage of polymerization from the linear relation between the time and conversion.

4. *Dependence on the Monomer Concentration.* The dependence of the polymerization rate on the MMA concentration is shown in Fig. 4. It is apparent that the rate of polymerization is linearly proportional to the concentration of MMA. The monomer does not participate in the initiation reaction at all. This is the first case, in which MMA does not participate in the initiation reaction of the polymerization by metallic chelates of β-diketones.

5. *Initiation Reaction.* It has been reported by many workers that the initiation reaction of vinyl polymerization by metallic chelates of β-diketone proceeds by means of the elimination of a ligand from the chelate, which accompanies the reduction of the central metal.[1,2,7,8] Electron-donating additives coordinate to the metal of the chelate and accelerate the elimination of the β-diketonyl radical from the chelate.[1-3] This increases the initiation rate of polymerization. Phen also coordinates to Cu and accelerates the polymerization of MMA. Phen is a chelating agent and coordinates at two sites. The initiation reaction can be represented as follows:



I II III IV

where ph represents a phenyl group. The reaction is a ligand-exchange reaction between the benzoylacetonyl group and phen, and Cu(II) is simultaneously reduced to Cu(I). Radical polymerization is initiated by the benzoylacetonyl radical thus produced. This exchange reaction reasonably explains why phen has a greater effect on $Cu(ba)_2$ than pyridine. It also supports the initiation reaction that the carbonyl group can be detected by IR spectroscopy in polystyrene produced by the initiator system. One of the driving forces for the formation of the radical is the precipitation of III from the polymerizing mixture, which shifts the equilibrium toward the right side.

The authors are grateful to Dr. M. Suzuki, Dr. A. Okada, and Mr. Y. Shimura for their interest and encouragement during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3101—3106 (1971)

The Photoreactions of Phenazines *via* a Semiquinone Radical. The Photoreductive Deacylation of 1- or 2-Acyloxyphenazine[1)]

Hiroo INOUE, Tadao OCHIAI, Akira SUGIMOTO, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received April 19, 1971)

The Photo-irradiation of a solution of 1- or 2-benzoyloxyphenazine in 2-propanol, followed by aeration, affords 1- or 2-hydroxyphenazine, benzaldehyde, isopropyl benzoate, and/or benzoic acid as the reaction products. The spectral change of the solution in the reaction process gives evidence of the fission of the acyl-to-oxygen bond. The addition of ferric chloride or dimethyl sulfate to the reaction system containing 1-benzoyloxyphenazine in 2-propanol leads to the formation of isopropyl benzoate. When methanol instead of 2-propanol is used as the solvent, methyl benzoate is produced mainly. In cyclohexene as a hydrogen-donating solvent, benzaldehyde and an oxetane are obtained. The irradiation of a solution of 1-benzoyloxyphenazine in *t*-butyl alcohol or benzene gives no product, and the starting material is recovered in a 90—100% yield. 1-Benzoyloxyphenazhydrin, a photo-reduction intermediate, does not contribute to the formation of benzaldehyde. The intermediary formation of a semiquinoid form during irradiation brings about the fission of the acyl-to-oxygen bond, thus affording the corresponding aldehyde.

The oxidation-reduction through a semiquinone radical is the subject of considerable interest in relation to that in a biological system, particularly in flavoprotein catalysis, and in oxidation-reduction by dehydrogenases involving pyridine nucleotides.[2)]

The photo-reduction of phenazine in alcoholic media produces the semiquinone radical (I) or molecular complexes (II) of phenazine and 5,10-dihydrophenazine of varying stoichiometry.[3,4)] We attempted to investigate a reaction which proceeds through the intermediary

formation of the semiquinone radical about phenazines with a substituent. The present paper will indicate that the irradiation of a solution of 1- or 2-acyloxyphenazine in 2-propanol, followed by aeration, leads to the fission of the acyl-to-oxygen bond, thus affording 1- or 2-hydroxyphenazine (IV), and that in the case of 1- or 2-benzoyloxyphenazine (III), the benzoyl group is converted to benzaldehyde, isopropyl benzoate, and/or benzoic acid.

$+ C_6H_5COOCH(CH_3)_2 + C_6H_5COOH$

Experimental

Materials. 1- or 2-Hydroxyphenazine was synthesized by the method described in the literature.[5-7] 1-Hydroxyphenazine, mp 157—158°C. 2-Hydroxyphenazine, mp 253—254°C. The acyloxyphenazines were prepared by the reaction of acetic anhydride or benzoyl chloride with 1- or 2-hydroxyphenazine in pyridine, followed by recrystallization from ethanol.[8] 1-Acetoxyphenazine, mp 119—120°C. 2-Acetoxyphenazine, mp 151—152°C. 1-Benzoyloxyphenazine, mp 172—173°C.

Found: C, 75.95; H, 3.94; N, 9.61%. Calcd for $C_{19}H_{12}N_2O_2$: C, 75.99; H, 4.03; N, 9.33% 2-Benzoyloxyphenazine, mp 144—145°C.

Found: C, 75.95; H, 4.01; N, 9.05%. Calcd for $C_{19}H_{12}N_2O_2$: C, 75.99; H, 4.03; N, 9.33%.

The benzaldehyde, isopropyl benzoate, methyl benzoate, anhydrous ferric chloride, and dimethyl sulfate were purchased from commercial sources. The methanol, 2-propanol, *t*-butyl alcohol and cyclohexene used as solvents were purified by distilling them two times on anhydrous cupric sulfate, calcium oxide, calcium oxide and sodium respectively.

General Procedure of Photoreaction. Spectral Change: The reactions were carried out in a quartz spectrophotometer cell which was irradiated with light from a 100-W high-pressure mercury arc lamp at a distance of 6 cm and at room temperature. The lamp characteristics, and the procedure for carrying out the reactions, were the same as have been described in detail in a previous paper.[9] At the concentration of 1- or 2-acetoxyphenazine of $(1—1.5)\times10^{-4}$ mol/*l*, the change in the visible absorption spectra corresponding to substrate-disappearance or product-appearance was followed with the period of irradiation. After the reaction, oxygen was admitted into the reaction system, and the spectra of the resulting solution were measured.

Photoreaction: The photoreactions were carried out by the methods described in a previous paper.[10] A dispersed solution of $(3—5)\times10^{-5}$ mol of 1- or 2-benzoyloxyphenazine in 10 m*l* of 2-propanol, unless otherwise stated, was placed in a quartz or Pyrex tube with an inside diameter of 15—20 mm and a wall thickness of 1 mm, and was cooled with liquid nitrogen; the air was removed under the reduced pressure of 1 mmHg, and then the tube was filled with nitrogen gas. The procedure of the replacement by nitrogen gas was repeated 4—5 times. The tube was then sealed and irradiated with a 100-W high-pressure mercury arc lamp in a distance of 4 cm and at room temperature. In order to isolate the reaction products, another procedure was attempted on a large scale by using a cylinderical, 300-m*l* reaction vessel.

Analyses of Products. After the reaction, the visible absorption spectrum of the reaction mixture was measured. The amount of 1- or 2-hydroxyphenazine produced was determined from the optical density of the absorption at 440 mμ, where the starting material has no absorption. After measuring the spectrum, the solution was concentrated to about one-tenth of the original volume in order to analyze the products. The benzaldehyde and isopropyl benzoate were identified by a comparison of their retention times in gas chromatography with those of authentic materials. The amounts of these compounds were determined by means of gas chromatography (gc), using a Yanagimoto 5 DH gas chromatograph; a column containing polyethylene glycol-20M and/or silicone grease-30 was used. Helium gas was used as the carrier gas. Benzoic acid was converted to methyl benzoate by introducing diazomethane into a part of the concentrated solution,[11] after measuring the amounts of benzaldehyde and isopropyl benzoate, and was determined by measuring the amount of methyl benzoate by gc analysis.

Isolation of 1-Hydroxyphenazine. A dispersed solution of 0.4 g of 1-benzoyloxyphenazine in 250 m*l* of 2-propanol, containing partially the crystal of 1-benzoyloxyphenazine, was placed in a cylinderical, 300-m*l* reaction vessel, and then the vessel was irradiated with a 100-W high-pressure mercury arc lamp for 100 hr after nitrogen gas had been bubbled into the solution. The resulting solution was concentrated up to a half volume *in vacuo* at room temperature, and the concentrated solution was poured into about 500 m*l* of water. A white precipitate deposited (0.15 g) was collected with filtration; subsequent recrystallization from ethanol afforded 1-hydroxyphenazine (mp 152—154°C), the IR spectrum of which was identical with that of the authentic meterial.

1-Benzoyloxy-5,10-dihydrophenazine (VI) and Its Phenazhydrin (V). An aqueous saturated solution of sodium hydrosulfite was added to a solution of 30 mg of 1-benzoyloxyphenazine in ethanol. A white powder precipitated. The precipitate (VI) (25 mg) was filtered off, washed repeatedly with water, and dried *in vacuo*. Immediately after the powder had been dried, it was submitted to the reaction, for it was unstable in air. The IR spectrum of the powder (KBr) is shown in Fig. 4. When the powder stood for 2—3 days, it changed to a greenish powder (V), the IR spectrum of which

had the absorptions at 3300 and 3400 cm^{-1} characteristic of phenazhydrin.[12]

Results and Discussion

Spectral Aspects. 1-Acetoxyphenazine was used for the measurement of the spectral change under irradiation with ultraviolet light, since it is more easily soluble in 2-propanol than 1-benzoyloxyphenazine. A solution of 1-acetoxyphenazine in 2-propanol, which had been placed in a quartz cell, was irradiated with light after degassing under the reduced pressure of 10^{-5} mmHg. As is shown in Fig. 1, the absorption of 1-acetoxyphenazine at 363 mμ disappeared rapidly and a new broad band appeared in the 490—500 mμ region. The new broad band also disappeared gradually. Immediately after irradiating for 5 min, oxygen gas was admitted to the system. The visible absorption spectrum of the resulting solution had absorptions at 368 and 420—430 mμ, which agreed with those of 1-hydroxyphenazine, as is shown in Fig. 1. The results show that 1-hydroxyphenazine is obtained quantitatively. This means that the acetyl group is cleaved, but does not rearrange on the phenazine ring during the photo-reduction or the oxidation process. Furthermore, the absorption in the 490—500 mμ region may be attributed to that of a phenazhydrin-type compound, such as a molecular complex between 1-hydroxyphenazine or its keto form and 1-hydroxy-5,10-dihydrophenazine. The irradiation of 1-acetoxyphenazine in methanol also showed a spectral change similar to that in the case of 2-propanol.

The spectral change of 2-acetoxyphenazine in 2-propanol by irradiation with ultraviolet light was similar to that of 1-acetoxyphenazine. However, the absorption in the 490—500 mμ region in the case of 2-acetoxyphenazine became larger than that of 1-acetoxyphenazine, indicating the easier formation of a

phenazhydrin-type compound, as is shown in Fig. 2. Immediately after the large peak appeared, the introduction of oxygen resulted in an absorption spectrum represented by the sum of the spectra of 2-acetoxyphenazine and 2-hydroxyphenazine. For example, the introduction of oxygen after irradiating for 11 min, resulted in the molar ratio of 2-acetoxyphenazine to 2-hydroxyphenazine of 3/7. This must mean that the phenazhydrin-type compound contains either 2-acetoxyphenazine or its dihydrophenazine. The difference between the optical densities at 490—500 mμ in the spectral changes of 1- and 2-acetoxyphenazine may be caused by the difference in the ease of the formation of their phenazhydrin-type compounds. The oxidation after the absorption at 490—500 mμ region disappeared completely resulted in the generation of the absorption spectrum of the keto form of 2-hydroxyphenazine, which has been reported by Badger, Pearce and Pettit,[13] as is shown in Fig. 2. Thus, also in the case of 2-acetoxyphenazine, it was confirmed that the fission of the acyl-to-oxygen bond occurs during irradiation with ultraviolet light. However, the acetyl group of 1-acetoxyphenazine was removed more readily than that of 2-acetoxyphenazine. This was caused by the greater difficulty of reducing a semiquinone radical of 1-acetoxyphenazine to its dihydrophenazine as compared with the case of 2-acetoxyphenazine because of the steric retardation of the acetoxy group of 1-acetoxyphenazine.

Photo-reduction of 1-Benzoyloxyphenazine. The benzoyl group was selected as the acyl group in order to make easier analyses of the photoreaction products. A dispersed solution of 1-benzoyloxyphenazine in 2-propanol was degassed in a Pyrex vessel, irradiated with light at room temperature, and then aerated. The yields of the reaction products are shown in Table 1.

Table 1. Photo-reduction of 1-benzoyloxyphenazine in alcohols and subsequent oxidation[a)]

ROH	Irradiated time, hr	Yield of product (%)			
		1-HOPh[b)]	C_6H_5-CHO	C_6H_5-COOR	C_6H_5-COOH
$(CH_3)_3COH$	160	10	0	0	0
$(CH_3)_2CHOH$	260	72	14	9	20—30
CH_3OH	140	55	0	40	5—10

a) The amount of 1-benzoyloxyphenazine was $(4.4—4.6)\times10^{-5}$ mol in 10 ml of alcohols. Irradiated distance: 4 cm. Reaction vessel: Pyrex glass.
b) 1-HOPh means 1-hydroxyphenazine.

The spectral change in 1-benzoyloxyphenazine was similar to the results obtained by directly irradiating a solution of 1-acetoxyphenazine in 2-propanol with ultraviolet light for a short time, as has been described above. The spectral yield of 1-hydroxyphenazine, as calculated from the optical density of the absorption at 440 mμ, was 72%; the analytical yields of benzaldehyde, isopropyl benzoate, and benzoic acid by gc analysis were 14, 9, and 20—30% respectively. The generation of gas was not observed. In addition to these products, the presence of pinacol and acetone was confirmed by gc. The formation of pinacol and acetone indicates the occurence of the photo-reduction of 1-benzoyloxyphenazine. Furthermore, 1-hydroxyphenazine was isolated from the residue after distilling out the resulting solution, and was identified by a comparison with the IR spectrum of the authentic material. The formation of bezaldehyde means that the homolytic fission of the acyl-to-oxygen bond occurs in the photo-reduction process.

The yields of benzaldehyde and benzoate changed depending on the kinds of alcohols used as the solvents, as Table 1 shows. When methanol was used as the solvent, methyl benzoate was obtained as the main product. On the irradiation of 1-benzoyloxyphenazine in *t*-butyl alcohol for 160 hr, benzaldehyde and *t*-butyl benzoate were not obtained, but 1-benzoyloxyphenazine was recovered in a 90—100% yield. That is, the requirement for the formation of benzaldehyde is that the solvent is a hydrogen donor. Furthermore, a protic solvent tended to decrease the yield of benzaldehyde and, contrarily, to increase that of the corresponding ester.

When 1-benzoyloxyphenazine in cyclohexene with a hydrogen-donating property was irradiated with light, an oxetane (8-phenyl-7-oxabicyclo[4.2.0]octane),[14] benzaldehyde, bicyclohexenyl, and 1-hydroxyphenazine were confirmed by gc analysis, though the amount of the oxetane could not be analyzed quantitatively because it is unstable to heat. The results are shown in Fig. 3. The formation of the oxetane supports the idea that benzaldehyde is produced during the irradiation of 1-benzoyloxyphenazine in a hydrogen-donating solvent.

The reduction of 1-benzoyloxyphenazine with aqueous sodium hydrosulfite did not result in the fission of the acyl-to-oxygen bond. That is, 1-benzoyloxyphenazine was reduced to 1-benzoyloxy-5,10-dihydrophenazine (VI) by an aqueous sodium hydrosulfite solution, and then the resulting solution was heated at about 80°C

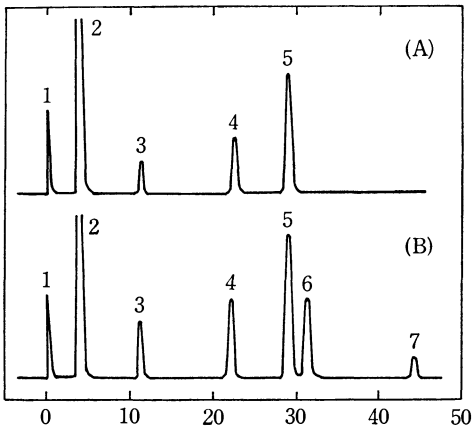

Fig. 3. Gas chromatogram of the products in the photoreaction of 1-benzoyloxyphenazine(A) or benzaldehyde(B) in cyclohexene: Conditions; absorbent, 150 cm, high-vacuum silicone grease-30; carrier gas, helium gas; programmed temperature rate, 6°C/min and temperature range, 80—320°C.
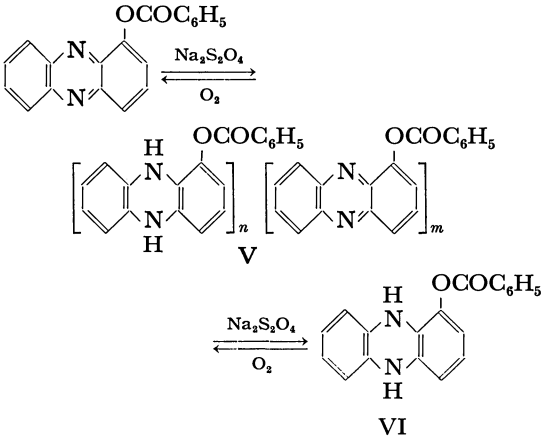
1 air, 2 cyclohexene, 3 benzaldehyde, 4 bicyclohexenyl, 5 8-phenyl-7-oxabicyclo[4.2.0]octane, 6 cyclohexenylphenylcarbinol, and 7 1,2-diphenyl-1,2-ethanediol.

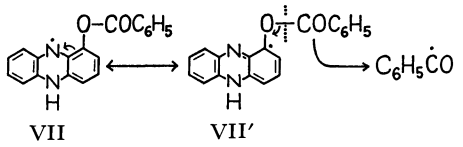
under a nitrogen atmosphere for 6 hr. The color of the solution changed from yellow to greenish-black. The oxidation of the solution with oxygen resulted in the recovery of 1-benzoyloxyphenazine. Furthermore, 1-benzoyloxyphenazhydrin (V) was prepared by the reduction of 1-benzoyloxyphenazine with an aqueous sodium hydrosulfite solution,[12] and was characterized by its IR spectrum (Fig. 4), which has the absorptions of the –NH– group at 3300 and 3400 cm^{-1} and of the –CO–O– group at 1725 and 1740 cm^{-1}. The oxidation of V in 2-propanol with oxygen did not give benzaldehyde and isopropyl benzoate, but resulted in the quantitative recovery of 1-benzoyloxyphenazine. On the



other hand, the irradiation of 1-benzoyloxyphenazine in the presence of 5,10-dihydrophenazine in 2-propanol for 140 hr gave 1-hydroxyphenazine and isopropyl benzoate in 35 and 5% yields respectively. A considerable amount of 1-benzoyloxyphenazine remained, although the amount was not obvious because of the contamination of phenazine. Thus, the formation of a phenazhydrin- or dihydrophenazine-type compound (V or VI), which is considered to be one of the photo-reduction

14) J. S. Bradshaw, *J. Org. Chem.*, **31**, 237 (1966).

products of 1-benzoyloxyphenazine, was ineffective in the fission of the acyl-to-oxygen bond. Therefore, the intermediary formation of a semiquinone radical during the photo-reduction must exert a profound effect on the fission of the acyl-to-oxygen bond. That is, the formation of benzaldehyde can be explained by a homolytic β-fission of the acyl-to-oxygen bond from a canonical structure (VII') of the semiquinone (VII):



VII VII'

The mechanism of the formation of the benzoate ester is not yet clear. However, the possibility of the formation of isopropyl benzoate from benzaldehyde diisopropyl acetal (VIII)[15] can be ruled out, since benzaldehyde and VIII in 2-propanol do not change to isopropyl benzoate under similar conditions. The mechanism of the formation of benzoic acid will be reported later.

$$C_6H_5CHO \longrightarrow \underset{\text{VIII}}{C_6H_5CH(OCH(CH_3)_2)_2} \xrightarrow{h\nu} C_6H_5COOCH(CH_3)_2$$

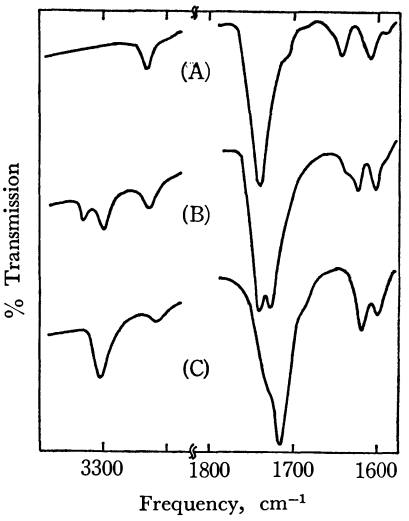


Fig. 4. Infrared spectra of 1-benzoyloxyphenazine (A), 1-benzoyloxyphenazhydrin (B), and 1-benzoyloxy-5,10-dihydrophenazine (C).

Effects of Ferric Chloride and Dimethyl Sulfate. When a solution of 1-acetoxyphenazine in 2-propanol containing ferric chloride with the molar ratio of 1: 1 was irradiated, the absorption of 1-acetoxyphenazine at 363 mμ disappeared rapidly; after irradiation for 2—3 min, a broad new peak appeared at 440 mμ similar to that of the semiquinoid form of pyocyanine.[16] This new band also disappeared upon further irradiation, leading to the appearance of the absorption at 480—490 mμ. After the absorption in the visible region had disappeared completely, oxidation was accomplished by oxygen and resulted in the appearance of a major peak at 368 mμ, as well as a tail up to about 660 mμ, which corresponds to the absorption of the mixture of 1-hydroxyphenazine and ferric chloride. However, there was no spectral change without irradiation of light. Thus, the occurence of the fission of the acyl-to-oxygen bond was established by investigating the spectral change of the reaction system. Also, in the case of dimethyl sulfate, the abosrption at 440 mμ was observed during the photo-reduction, and oxidation by oxygen resulted in the appearance of an absorption spectrum having absorptions at 368 and 430 mμ, absorptions which corresponded to those of 1-hydroxyphenazine, as is shown in Fig. 5.

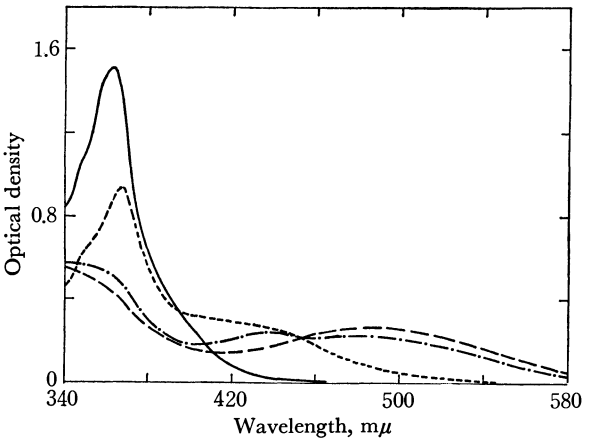

Fig. 5. Spectral change of 1-acetoxyphenazine in the presence of dimethyl sulfate under irradiation of ultraviolet light: Concentration of 1-acetoxyphenazine and dimethyl sulfate; 1.02×10^{-4} mol/*l* and 1.4×10^{-4} mol/*l*.
—— Before irradiation, —·— after 2 min, —— 3 min of irradiation, and ------ after 1 hr of oxidation after irradiating for 3 min.

The photo-irradiation of a solution of 1-benzoyloxyphenazine in 2-propanol, which has been placed in a Pyrex vessel, resulted in the formation of isopropyl benzoate, as is shown in Table 2. The spectral change in the reaction mixture was similar to the results in the case of 1-acetoxyphenazine described above. Although the irradiation of 1-benzoyloxyphenazine in *t*-butyl alcohol did not result in the fission of the acyl-to-oxygen bond, the addition of dimethyl sulfate to the reaction system

Table 2. Effect of the added compounds on the photoreaction of 1-benzoyloxyphenazine in 2-propanol[a]

Added compound	Irradiated time, hr	Yield of product (%)			
		1-HOPh	C_6H_5-CHO	C_6H_5-COOCH-$(CH_3)_2$	C_6H_5-COOH
None	260	72	14	9	20—30
$(CH_3)_2SO_4$	120	—	0	30	—
$FeCl_3$	95	—	0	45	—
Ph-H_2[b]	140	35	0	5	—

a) The starting amounts of 1-benzoyloxyphenazine, dimethyl sulfate, ferric chloride and 5,10-dihydrophenazine were $(4.3—4.6)\times10^{-5}$, 4.9×10^{-4}, 4.9×10^{-5}, and 1.3×10^{-4} mol, respectively. The volume of 2-propanol was 10 m*l*. Irradiated distance: 4 cm. Reaction vessel: Pyrex glass.
b) Ph-H_2 means 5,10-dihydrophenazine.

15) D. Elad and R. D. Youssefyeh, *Tetrahedron Lett.*, **1963**, 2189.
16) W. S. Zaugg, *J. Biol. Chem.*, **239**, 3964 (1964).

gave 1-hydroxy- phenazine and *t*-butyl benzoate as the products. The yield of 1-hydroxyphenazine was 70%. The amount of *t*-butyl benzoate could not be measured because it decomposed so readily in gc analysis.

Photo-reduction of 2-Benzoyloxyphenazine. A solution of 2-benzoyloxyphenazine in 2-propanol was irradiated with light for 50 hr according to the procedure used in the case of 1-benzoyloxyphenazine. 2-Hydroxyphenazine, benzaldehyde, and isopropyl benzoate were obtained in 66, 6, and 2% yields respectively. No other products derived from the benzoyl group could be detected by gc analysis in spite of recording up to about 300°C. Furthermore, the photochemical Fries rearrangement[17] of the benzoyl group to the phenazine ring was not observed. The benzoyl group would be converted to the dark brown polymeric material by a secondary photochemical reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3106—3108 (1971)

The Conversion of Some Alkylxanthates to the Corresponding Trithiocarbonates. The Nucleophilic Reaction of $^{-}$SCSSR

Hiroshi YOSHIDA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received April 19, 1971)

The reaction of *O*-methyl-, ethyl-, and benzylxanthates with a catalytic amount of triethylamine in the presence of excess carbon disulfide gave the corresponding trithiocarbonate in good yields. The products were formed by the nucleophilic reaction of $^{-}$SCSSR with xanthates. The kinetic study showed the following order of nucleophilicity toward xanthates in DMF:

$$^{-}SCOSMe > {}^{-}SCSSMe > Me_3N$$

Dialkyl trithiocarbonates are generally prepared from mercaptans and thiophosgene[1]:

$$RSH + ClCSSR' \longrightarrow RSCSSR'$$

$$RSH + CS_2 \longrightarrow KSCSSR \longrightarrow RSCSSR'$$

$$2RSH + CSCl_2 \longrightarrow RSCSSR$$

In the course of the studies of the reaction of xanthates with tertiary amines,[2] the present authors have found a convenient route for the preparation of trithiocarbonates from xanthates.

In a previous paper,[2] the authors reported that xanthates reacted with tertiary amines to give quaternary ammonium salts at room temperature, and dithiolcarbonates at elevated temperatures. It was then shown that these reaction products were formed by the following paths. As an example, the reaction of methyl methylxanthate and triethylamine will be shown:

$$MeOCSSMe + Et_3N \longrightarrow \underset{\underset{Me}{|}}{Et_3N^+} {}^{-}SCOSMe$$

$$MeOCSSMe + {}^{-}SCOSMe \longrightarrow MeSCOSMe + {}^{-}SCOSMe$$

The salt thus formed reacted easily with carbon disulfide to yield the corresponding trithiocarbonate salt:[3]

$$\underset{\underset{Me}{|}}{Et_3N^+} {}^{-}SCOSMe + CS_2 \longrightarrow \underset{\underset{Me}{|}}{Et_3N^+} {}^{-}SCSSMe + COS$$

Results and Discussion

When O-alkylxanthates was treated with triethylamine in the presence of carbon disulfide at higher temperatures, the corresponding trithiocarbonate was obtained in a good yield (Table 1) and gaseous carbon oxysulfide was detected by vpc. Moreover, when methyl methylxanthate was reacted with triethylamine in carbon disulfide at room temperature, diemethyl trithiocarbonate and a small amount of triethylmethylammonium methyltrithiocarbonate were found. These observations seem to show that $^{-}$SCSSR reacts with xanthate to yield trithiocarbonate.

Table 1. The reaction of xanthates with triethylamine in the presence of carbon disulfide[a]

Xanthate	Reaction condition		Yield of trithiocarbonate(%)
	°C	hr	
MeOCSSMe	100	0.7	94
MeOCSSEt	100	0.7	93
MeOCSS*n*-Pr	100	0.7	81

MeOCSSMe	130	1	93		
EtOCSSMe	130	15	26	47	22
n-PrOCSSMe	130	20	25	49	20
i-PrOCSSMe	130	240	28	41	13
EtSCSSMe	130	20	27	49	23

a) Mol ratio, xanthate: CS_2: KSCSSMe=1: 2: 0.2. DMF was added as a homogeneous solvent by about 20 wt %.

tion at 130°C, while heating for about 4 hours gave trithiocarbonates in a good yield. The results are summarized in Table 2. The order of reactivity of xanthates (Me>Et>*n*-Pr≫*i*-Pr) seems to show the reaction proceeds *via* the nucleophilic attack of $^-$SCSSMe on the *O*-alkyl group of xanthates.

When ethyl methyl trithiocarbonate was heated at 130°C with KSCSSMe, crossed products, dimethyl and diethyl trithiocarbonates, were found (Table 2, the bottom line). Without KSCSSMe, however, no crossed product was found under similar reaction conditions. Thus, the crossed products were supposed to be yielded by the transesterification catalysed by the mercaptide ion,[2)] which was itself formed by the thermal decomposition of $^-$SCSSMe.

Thus, the reaction of xanthate with triethylamine in the presence of carbon disulfide may be simplified as follows:

$$ROCSSR' + Et_3N \longrightarrow Et_3\overset{\overset{Me}{|}}{N}{}^+ \ ^-SCOSR' \quad (1)$$

$$^-SCOSR' + CS_2 \longrightarrow {}^-SCSSR' + COS \quad (2)$$

$$ROCSSR' + {}^-SCSSR' \longrightarrow RSCSSR' + {}^-SCOSR' \quad (3)$$

$$ROCSSR' + {}^-SCOSR' \longrightarrow RSCOSR' + {}^-SCOSR' \quad (4)$$

The first reaction is the alkylation of triethylamine with xanthate to yield a quaternary ammonium salt, which was then changed to the corresponding trithiocarbonate salt (reaction (2)). The reactions (3) and (4) are the nucleophilic attack of $^-$SCSSR' and $^-$SCOSR' on xanthate to yield trithio- and dithiolcarbonate respectively. Since no dithiolcarbonate was detected in the reaction, the reaction (2) may be said to proceed faster than the reactions (3) and (4).

In order to clarify the mechanism, the reaction of $^-$SCSSMe with xanthate was investigated kinetically in DMF. The rate constant was first-order with xanthate and was independent of the concentration of carbon disulfide. These results show that the reaction (2) proceeds much faster than the reactions (3) and (4). As Fig. 1 shows, the apparent first-order rate consttants (k_1') are proportional to the concentration of $^-$SCSSMe. The slope of the line gives a second-order rate constant, k_2. The data are summarised in Table 3.

It is well known that thiolate anions have strong nucleophilicities toward tetrahedral carbons in protic solvents.[4)] Although the nucleophilicities of some thiolate anions have been investigated in DMF,[5)] no work on the thiocarbonate ion has been presented.

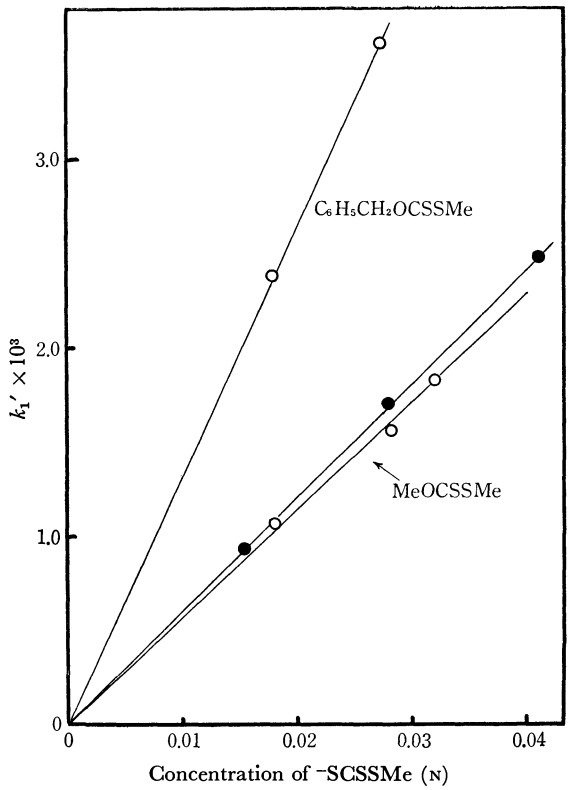

Fig. 1. The relation between the apparent first-order rate constant (k_1') and the concentration of $^-$SCSSMe for the reaction (3).
○ $Me_4NSCSSMe$ ● KSCSSMe

Table 3. Second-order rate constants for the reaction of xanthates with nucleophiles
(30°C k: l/mol·min)

Xanthate	Nucleophile	in DMF	in C_6H_6
MeOCSSMe	Me_3N[a)]	0.036	0.0012
	Et_3N[a)]		0.000097
	$Me_4NSCOSMe$[a)]	0.186	
	$Me_4NSCSSMe$	0.0573	
	KSCSSMe	0.0601	
$C_6H_5CH_2OCSSMe$	Me_3N[a)]		0.0028
	$Me_4NSCSSMe$	0.132	

a) Taken from Ref. 2.

Table 3 shows that $^-$SCSSMe and $^-$SCOSMe have larger nucleophilicities toward xanthate than trimethylamine and obviously than triethylamine has in DMF. The smaller reactivity of $^-$SCSSMe than that of $^-$SCOSMe may be attributed to the resonance stabilization of the ion.

The greater reactivity of benzylxanthate than that of methylxanthate supports the S_N2 mechanism. Once the reaction (1) proceeds, the reactions (2) and (3) recurr to give trithiocarbonate.

Experimental

All the reactions were carried out in stoppered test tubes. The reaction mixture was treated with cold aqueous hy-

drochloride and then extracted with carbon disulfide. The carbon disulfide extract was dried over calcium chloride, and was analyzed by vpc and NMR.

Materials. $Me_4NSCSSMe$ was prepared according to the previously described method.[3] KSCSSMe was prepared from methylmercaptan and carbon disulfide in a cold aqueous potassium hydroxide solution. After drying, the salt was recrystallized from acetone - ether. The purity was determined by acid-base titration.

Kinetic Run. A DMF solution containing ^-SCSSMe (0.015—0.04N), xanthate (0.05—0.08N), and carbon disulfide (0.1—0.4N) was allowd to stand in a constant-temperature bath. The rate was followed at suitable time intervals by analyzing the NMR spectrum of the S-Me groups.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3108—3112 (1971)

The Properties and Assignment of Isomers of 2,4-Dinitrophenylhydrazones of Some Aliphatic α-Keto Acids

Hirohiko KATSUKI, Tsuya YOSHIDA,* Jun NAGAI, and Shozo TANAKA**
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto
(Received April 19, 1971)

Visible and infrared spectra and some other properties of *cis* and *trans* isomers of 2,4-dinitrophenylhydrazones of some aliphatic α-keto acids have been studied. It was observed that absorption maximum of the *cis* isomer in visible region occurred at a longer wavelength than that of the *trans* isomer in ethyl acetate as well as in bicarbonate solution and *vice versa* in sodium hydroxide solution. In infrared region, N–H and C=O stretching bands of the *cis* isomer were found at longer wavelengths than the corresponding bands of the *trans* isomer. It was concluded that a hydrogen bond is formed between C=O and N–H groups in the *cis* isomer. Further evidence which supports the above conclusion was given by the difference between both isomers in the nickel complex forming reaction, sodium carbonate reaction and in the properties of sodium salt. Instability of the *trans* isomer appeared to increase as the number of carbon atoms in the keto acid molecule increased. 2,4-Dinitrophenylhydrazones of some other α-keto acids were found to give polymorphs but not geometrical isomers.

2,4-Dinitrophenylhydrazine has been widely used as a reagent for the analysis of carbonyl compounds. A number of studies have been made on physical and chemical properties of the hydrazone derivatives. With α-keto acids, some of which are important metabolites in intermediary metabolism of organisms, investigations on the separation of geometrical isomers of the hydrazones were first carried out by us[1] and others[2–4] in 1955—6. We pointed out the importance of studies on both the isomerization between the *cis* and *trans* isomers of α-keto acid hydrazones and their properties for analysis, and a method for photometric determination of pyruvic acid irrespective of the existence of their isomers was reported.[5]

However, separation of the isomers of hydrazones of other α-keto acids other than those reported was not always possible because of lack of knowledge concerning isomerization between both isomers. The isomerization reaction was investigated and the first large scale separation became feasible by combining the salting-out method with isomerization treatment.[6]

In general, there should exist geometrical isomers in most condensation products of carbonyl compounds with carbonyl reagents including 2,4-dinitrophenylhydrazine. Spectroscopic studies in visible region have been reported since 1913 on the assignment of geometrical isomers of semicarbazones,[7] oximes,[8] and substituted[9,10] or non-substituted[11] phenylhydrazones of carbonyl compounds.

Studies on the infrared spectra were also made with the isomers of various hydrazone derivatives of α-keto acids.[1–4,12] The results indicated that a hydrogen bond was formed between C=O and N–H groups in the *cis* isomer but not in the *trans* isomer.

Proton nuclear magnetic resonance has also been applied successfully to the elucidation of structural isomerism involving restricted rotation. Karabatsos *et al.* studied NMR spectra of phenylhydrazones, semicarba-

zones, of aldehydes and ketones.[13-16]

It was reported that 2,4-dinitrophenylhydrazones of some α-keto acids such as glyoxylic (I), pyruvic (II), α-ketobutyric (III), α-ketovaleric (IV), α-ketocaproic (V), and α-ketoisocaproic acid (VI) could be separated into two isomers by utilizing the solubility differences in 1N sodium carbonate.[6] These hydrazones were tentatively classified into group A. The hydrazones of α-ketoisovaleric (VII), α-keto-β-methylvaleric (VIII) and α-keto-β-dimethylbutyric acid (IX) could not be separated into two isomers by the above method and gave *x*- and *y*-forms by recrystallization from nonpolar and polar solvent, respectively. These hydrazones were classified into group B.

The present communication describes visible and infrared spectra and some properties of these isomers and forms, and deals with the assignment of the compounds. The study was successfully applied to the characterization,[17] determination[18,19] of α-keto acids which appear in biological materials by 2,4-dinitrophenylhydrazine method.

Experimental

Separation and Purification of Isomers and Forms of the Hydrazones. These were described previously.[6]

Sodium Salts of the Hydrazones. The *cis* hydrazones of keto acids which belong to group A or the hydrazones of keto acids of group B were converted into their sodium salts by treating them with an excess amount of 1N sodium carbonate. The sodium salts of the hydrazones, scarcely soluble in 1N sodium carbonate, were filtered and washed twice with 1N sodium carbonate and twice with a small amount of water. They were recrystallized from 50% aqueous acetone.

Some kinds of *trans* hydrazones of keto acids of group A, such as I and II, were dissolved in 1N sodium carbonate, and the solution was saturated with sodium chloride. The precipitated sodium salts were filtered and washed twice with a small amount of 1N sodium carbonate saturated with sodium chloride, and once with a small amount of water.

The *trans* hydrazones of III, IV, V, and VI were dissolved in a small amount of absolute ethanol. An excess amount of 1N sodium carbonate was added to it. Sodium salts, thus precipitated, were washed with 1N sodium carbonate and water, then recrystallized in the same way as for the *cis* isomers of the hydrazones.

Absorption Spectra in Visible Region. The hydrazones were dissolved in 0.1N sodium bicarbonate or ethyl acetate. The spectra were taken with fresh solutions with the use of a Beckman Spectrophotometer, Model DU, and a Hitachi Recording Spectrophotometer, Model EPS. The spectra of the hydrazones in alkali were taken as follows: to the bicarbonate solution of the hydrazone, an equal volume of 2.0N sodium hydroxide was added and the mixture was shaken thoroughly. After the mixture was left to stand for 10 min at 30°C, the spectra were taken within 10 min. The spectra showed no noticeable change during this period.

Infrared Spectra. Infrared spectra of the hydrazones were taken with a Nihonbunko Infrared Spectrophotometer, Model Koken DS 301 by the Nujol mull method, and also by the potassium chloride disc method in the case of the keto acid hydrazones which belong to group B.

Results and Discussion

Absorption Spectra in Visible Region. In Table 1 are shown the wavelengths at which absorption maxima were observed and the molecular extinction coefficients of the hydrazones at those wavelengths in ethyl acetate, 0.1N sodium bicarbonate and 1N sodium hydroxide containing 0.05N sodium bicarbonate.

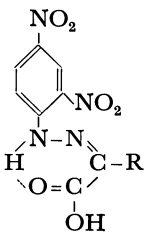
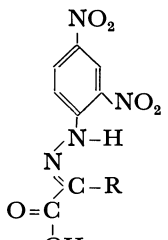
a) Containing 0.05M sodium bicarbonate.
b) Contaminated with trace amounts of the *cis* isomer.

It is evident from the spectra of the free hydrazone and the sodium salt (taken in ethyl acetate and sodium bicarbonate solution, respectively) that absorption maximum of the *cis* isomer is at a longer wavelength than that of *trans* isomer, and that the molecular extinction coefficient of the *cis* isomer is greater than that of the *trans* isomer. This holds in all isomeric pairs of the hydrazons tested. These results would be expected from the stable six-membered ring structure of the *cis* isomer as follows:[1-4]



(*cis* isomer)



(*trans* isomer)

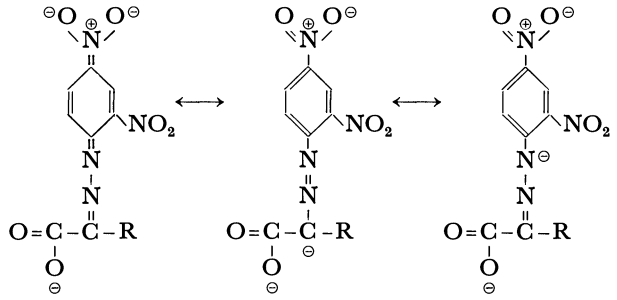
19) H. Katsuki, T. Yoshida, C. Tanegashima, and S. Tanaka, *ibid.*, (1971) in press.

It seems reasonable to assume that in sodium bicarbonate solution, only carboxyl group of the hydrazone of keto acid is dissociated, whereas both carboxyl and N–H groups are ionized in strong alkaline solution, giving red coloration. The fact that the addition of alkali to *N*-methyl-phenylhydrazones does not produce a red color[20] seems to support this assumption. The red coloration of alkaline solution is due to the formation of an unstable intermediate or intermediates. Some typical one are assumed to be as follows:



The *trans* isomer would be expected to give a deeper red than the *cis* isomer in alkaline solution since the hydrogen atom of N–H group of the latter is involved in a hydrogen bond formation and not easily ionizable. As a support of this hypothesis the results of spectral analyses of sodium hydroxide solution might be presented. The absorption maximum of the *trans* isomer was found to be at a longer wavelength than that of the *cis* isomer without exception and the molecular extinction coefficient of the *trans* isomer was greater than that of the *cis* isomer.

From the structure described above, a *cis-trans* interconversion would be expected to occur in alkaline solution. The observation that the red coloration produced in the *cis* isomer deepened as the concentration of sodium hydroxide was increased is in agreement with such a prediction.[21] Thus it is suggested that gradual breakage of the hydrogen bond in the *cis* isomer leads to conversion of the *cis* isomer into the *trans* isomer through the intermediate(s) described above.

In order to prove the interconversion of the two isomers in alkaline solution, as suggested by the development of red coloration under such conditions, the isomers were isolated as free hydrazone by the addition of hydrochloric acid to the alkaline solution. Further separation of the isomers was achieved by paper chromatography. Two spots corresponding to the *cis* and *trans* isomers were detected besides one spot presumably representing a decomposition product.

Two forms of the hydrazones of keto acids which belong to group B behaved differently in a solid state, but their solubilities, R_f values and partition coefficients were identical.[6] These two forms showed the same absorption spectra. Thus, they apparently behaved as the same substance in solution. From the spectral data in three different solvents, the form in solution seems to have the *cis* structure.[22]

Reaction with Sodium Carbonate. Although the spectra of the hydrazones in visible region in sodium carbonate solution and of those in sodium bicarbonate solution were nearly the same, the molecular extinction coefficient in the longer wave length region had slightly higher values in sodium carbonate than in sodium bicarbonate. It is difficult to differentiate the *cis* isomers from the corresponding *trans* isomers by visual inspection of the colored solution without comparing the spectra of isomeric pairs. However, a remarkable difference between the *cis* and *trans* isomers was found when the hydrazones reacted with sodium carbonate in ethanol. On the basis of this fact, a test for assigning the *cis* and *trans* isomers of α-keto acid hydrazones was devised as follows: A few milligrams of the hydrazone is dissolved in several drops of ethanol and to this solution is added one drop of 1N sodium carbonate. The *trans* isomer produces red coloration, and the *cis* isomer none.

As shown in Table 2, the *trans* isomers gave a positive reaction and the *cis* isomers a negative reaction with one exception. Although all the hydrazones of the keto acids of group B were expected to give a negative reaction, those of IX gave a positive reaction.

Nickel Complex Formation. The nickel complex forming test[23] was applied to the series of isomers of

TABLE 2. SOME REACTIONS AND PROPERTIES OF THE HYDRAZONES

Hydrazones of keto acids		Sodium carbonate reaction	Nickel complex formation	Color of dehydrated sodium salt
I	*trans*	+	−	black brown (decomp.)
	cis	(−)[a]	+	orange
II	*trans*	+	−	dirty brown
	cis	−	+	red
III	*trans*	+	−	yellow

20) F. Bohlmann, *Chem. Ber.*, **84**, 490 (1951).
21) H. B. Stewart, *Biochem. J.*, **55**, xxvi (1953).
22) A shift of the absorption maximum of VII with increasing water content in ethanol solution had been attributed to isomerization. *Cf.* H. Katsuki, K. Sumizu. T. Moriwaki, and S. Tanaka, This Bulletin, **31**, 665 (1958). However, it appears that shift is due to a non-specific solvent effect, since such a phenomenon was also observed with the *cis*- as well as the *trans* hydrazone of II. The absorption maximum of the *cis* hydrazone of II shifted from 363 mμ to 378 mμ and that of the *trans* isomer from 348 mμ to 365 mμ under these conditions.
23) H. Katsuki, K. Sumizu, T. Moriwaki, and S. Tanaka, *Nature*, **181**, 639 (1958).

hydrazones mentioned above. As shown in Table 2, the *cis* hydrazones of keto acids of group A and both forms of the hydrazones of keto acids of group B showed a positive reaction without exception, whereas the *trans* hydrazones of keto acids which belong to group A showed a negative reaction. The results of the nickel complex forming test were in line with the proposed structures of the isomers of keto acid hydrazones.

Properties of Sodium Salt. The characteristic properties of sodium salt of the *cis* hydrazone of II were reported.[1] The hydrated form of its sodium salt had a yellow color, but its color changed to red when dehydrated by standing *in vacuo* or by heating. The dehydrated form was extremely hygroscopic. It turned yellow as soon as it was exposed to air. The dehydrated sodium salt of the *trans* isomer had a dirty brown color and was not hygroscopic. These characteristic properties were also observed with sodium salt of the hydrazone of VII, which had a few molecules of water of crystallization and the dehydrated form showed an orange-red color. According to Hayashi,[24] sodium salt of *cis* isomer of phenylglyoxylic acid 2,4-dinitrophenylhydrazone also showed a similar behavior. In that case the hydrated form was orange, but the dehydrated form had a deep red color.

The characteristic color formation would be expected upon dehydration for the sodium salts of all of the *cis* isomers mentioned above. Inspection of Table 2 reveals that most keto acid hydrazones fulfilled this requirement. Exceptions were sodium salt of the *cis* hydrazone of IV, which was yellow, and that of IX, which decomposed when dehydrated.

Infrared Spectra. As N–H stretching band, each *trans* hydrazone of I, V, and VI showed a single absorption band and that of II, III, and IV showed two bands in the region 3500—3200 cm^{-1}, whereas each of all the *cis* hydrazones of these keto acids showed a single N–H stretching band which occurred at a longer wavelength than the corresponding band of the *trans* isomer. These results are shown in Figs. 1, 2, and 3.

We see that infrared spectra of most hydrazones showed a single stretching band for C=O group 1664—1750 cm^{-1}) except for the case of the *trans* hydrazones of III and IV, for which two and three bands were observed, respectively. The band for the *cis* isomer was seen at a longer wavelength than the corresponding band of the *trans* isomer. The difference in the positions of the stretching bands for C=O group between *cis* and *trans* isomers of the hydrazones of group A was the smallest for VI.

In the case of the hydrazones of keto acids which belong to group B, both *x* and *y* forms seemed to be polymorphic to each other because they showed identical spectra in Nujol mull (Fig. 4) as well as in potassium chloride disc except for those of VII. Both of the two forms of VIII hydrazones showed *cis* type N–H and C=O stretching bands. Absorption spectra in visible region and other properties of the two forms of VIII

by Nujol mull method.

hydrazones supported their *cis* structure. Thus, it was concluded that the two hydrazones of VIII have *cis* structure in solid state as well as in solution.

In the case of IX, it was not possible to assign the hydrazone in solid state, since it showed an abnormal N–H band. Judging from the position of absorption maximum in visible region, the hydrazones of IX in solution seem to have *cis* structure but the result of the sodium carbonate reaction which is normally specific for the *trans* structure does not seem to be in line with it. No explanation could be given for this inconsistency.

The two forms of VII hydrazones, which showed quite different infrared spectra from each other, seem to be *trans* and *cis* isomers, respectively, but not polymorphs, because they showed similar stretching bands for C=O group to those of *cis* and *trans* hydrazones of VI, respectively. However, in solution, they behaved as the same substance to each other and they had the characteristics of *cis* type in all respects. If we assume that the *x* form (*trans* isomer) is stable only in solid state and isomerizes to the *y* form (*cis* isomer) as soon as it is dissolved in solution as reported by Abramovitch and Spenser for pyruvamide phenylhydrazone,[25] the behavior of VII hydrazones might be explained. Judging from its behavior in solid state, VII could be considered a member of group A, though it was classified as belonging to group B according to its behavior in solution.

It appears that the structures of the *cis* and *trans* isomers are stable with the hydrazones of lower keto acids. With the hydrazones of higher keto acids, however, the structure of the *trans* isomer seems to be less stable.

This seems to be supported also by the results of the isomerization of the hydrazones in solution as well as in melting state.[6]

The authors wish to thank Prof. Toru Takenaka, Institute for Chemical Research, Kyoto University, for his useful suggestion and Dr. Chizuko Tanegashima, Mukogawa Women's University, for her technical assistance.

Free-Radical Chlorination of Alkylsilanes. VI.* The Hydrogen Abstraction from α-Substituted Hydrosilanes by Chlorinated Methyl Radicals

Yoichiro NAGAI, Hideyuki MATSUMOTO, Masaki HAYASHI, Eiji TAJIMA, and Hamao WATANABE

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received April 23, 1971)

Relative rates of hydrogen abstraction from Si-H bonds of α-substituted hydrosilanes by the trichloromethyl or the dichloromethyl radical were determined by allowing the hydrosilanes to compete in pairs for a chlorocarbon compound, carbon tetrachloride or chloroform, at 80°C in the presence of benzoyl peroxide. Results show that relative rates of the investigated hydrosilanes toward the trichloromethyl and the dichloromethyl radicals are satisfactorily correlated with the summation of Taft σ* values for the substituent on the central silicon atom, giving ρ* values of −0.11 and −0.08, respectively. Linear correlations are also found to exist between the relative rates and the ^{29}Si-H coupling constants.

Previously,[1-3] it has been shown that a chain reaction occurs when a hydrosilane is allowed to react with an aliphatic halide in the presence of a radical generator, *e.g.* benzoyl peroxide. The chain carrying steps[1-6] are likely to be:

$$\equiv Si\cdot + \equiv CX \longrightarrow \equiv SiX + \equiv C\cdot \quad (1)$$

$$\equiv C\cdot + \equiv SiH \longrightarrow \equiv CH + \equiv Si\cdot \quad (2)$$

(X=Cl or Br)

The reaction makes it feasible to measure both the relative rates of halogen atom abstraction from C-Hal bonds by silyl radicals[2,5-9] and those of hydrogen abstraction from Si–H bonds by carbon radicals.

The present investigation deals with the latter reaction employing several α-substituted hydrosilanes in connection with our earlier work[10] on reactions of nuclear substituted phenylsilanes with carbon tetrachloride under free radical conditions. It was hoped that some correlation would emerge between the relative rates for reactions of the α-substituted hydrosilanes with carbon tetrachloride or with chloroform and structural variables in the substrates or in the attacking carbon radicals.

Results and Discussion

In the present study, triethylsilane, phenyldimethylsilane, diethylchlorosilane, ethyldichlorosilane and trichlorosilane were selected for the α-substituted hydrosilanes. The counter reactant was carbon tetrachloride or chloroform, so that the trichloromethyl or the dichloromethyl radical was to be generated in the system being considered. The investigated hydrosilanes were allowed to compete in pairs at 80°C toward an appropriate chlorinated methane, benzoyl peroxide being used as catalyst. The relative rates of reactions (2) were conveniently calculated by the Ingold-Shaw equation[11]

$$\frac{k_A}{k_B} = \frac{\log [A]_i/[A]_f}{\log [B]_i/[B]_f}$$

where $[A]_i$, $[B]_i$ represent the initial concentrations of two hydrosilanes, $[A]_f$, $[B]_f$ the final concentrations and k_A/k_B the ratio of rate constants for the attack of the abstracting reagent on the two species.

Table 1 summarizes the results of the analysis of the various competitive reaction mixtures. Included in the tabulation are the initial, $[A]_i$ and $[B]_i$, and final, $[A]_f$ and $[B]_f$, amounts of the hydrosilanes competing for the chlorinating reagent. The latter quantities were determined by means of vapor phase chromatography. Figure 1 indicates summaries of all the competitive experiments of Table 1 in which probable errors are included. Examination of Fig. 1 shows the results of the cross-checks on the relative rate constants for reactions of the α-substituted silanes investigated both with carbon tetrachloride and with chloroform to be satisfactory. For example, the relative rate for trichlorosilane relative to triethylsilane can be calculated *via* three possible pathways involving different compounds and the agreement between the values so calculated appears to be reasonable. The averages of the k_A/k_{Et_3SiH} values are summarized in Table 2, in which the experimental uncertainties are not included because the cross-check experiments make it difficult to estimate these quantities.

It is seen from Table 2 that the successive introduction of electron-withdrawing groups on the central silicon atom decreases the reactivity of the Si-H bonds

toward either the trichloromethyl or the dichloromethyl radical. This trend is in keeping with electron-seeking character of the presumed attacking radical, the trichloromethyl or the dichloromethyl radical, serving as an electron acceptor from the hydride hydrogen atom.

TABLE 2. RELATIVE RATES FOR REACTIONS OF α-SUBSTITUTED HYDROSILANES (80°C)

a) The summation of Taft σ^* values for three substituents on silicon. The value for Cl is calculated from multiplying the value for CH_2Cl by 2.8.

$$[\equiv Si{:}H{\cdot}C\equiv] \longleftrightarrow [\equiv Si^{+}\ H{:}C^{-}\equiv] \longleftrightarrow [\equiv Si{\cdot}H{:}C\equiv]$$

Kinetic data listed in Table 2 are plotted in Fig. 2 against the summation of Taft σ^* values[12] for three substituents on silicon. As will be shown in Fig. 2, the plots for reactions with carbon tetrachloride afford an excellent correlation with a slope of −0.11 and a correlation coefficient of 0.992. A linear correlation is also found to exist for reactions with chloroform with a slope of −0.08 and a correlation coefficient of 0.995. The observed linear correlations may imply that, within this class of substrates, polar factor is of primary importance in determining the rate for the Si-H hydrogen abstraction and that steric or other contributions for a set of the intermediate silyl radicals are nearly constant or vary linearly with changes in electronic effects of the substituents. The reaction constant (in

12) R.W. Taft, Jr., "Steric Effects in Organic Chemistry," ed. by M. S. Newman, John Wiley and Sons, New York, 1956, p. 556.

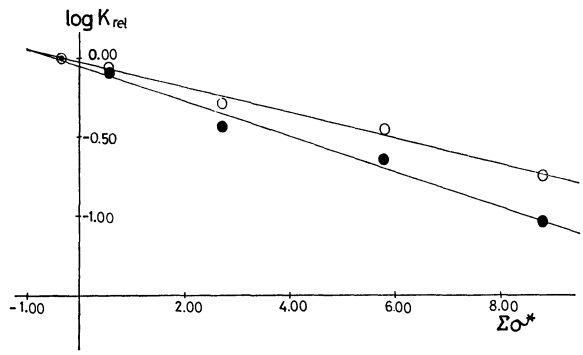

Fig. 2. Plots of relative rates *versus* $\sum\sigma^*$. Open circles represent reactions of carbon tetrachloride and solid circles those of chloroform.

absolute magnitude) is slightly larger for reactions with the trichloromethyl radical than for those with the dichloromethyl radical. Although such a comparison of the ρ^* values may be valid only if allowance is made as to the different solvents in which results have been obtained, the trend found in this study is expected from the polarity of the attacking radicals.

Importance of polar effects in the reaction of hydrosilanes with radicals can be seen in other instances.[13,14] For example, Morris and Thynne[14] reported that trimethylsilane is more reactive toward attack of the trifluoromethyl radical than is trichlorosilane by a factor of about 5 (at 164°C).

It is noteworthy that points for phenyldimethylsilane fall on the straight lines and from this fact the conjugation between the reaction site and phenyl substituent in the transition state is considered to be of only minor importance. This conclusion is reasonable since $3p_\pi$(Si)—$2p_\pi$(C) orbital overlap seems to be ineffective.[15]

It has recently been quoted that linear correlations emerge between the ^{13}C–H coupling constants and CH reactivities toward the abstracting reagents such as the chlorine atom[16,17] or the methyl radical.[18] By analogy, it might be expected that similar correlations would exist between the ^{29}Si-H coupling constants and SiH reactivities toward the attacking radicals employed in the present investigation (See Fig. 3). Although the factors governing the magnitude of $J(^{29}\text{Si-H})$ values are not yet fully understood,[19] the observed correlations are of interest and may imply correlations between change in the fraction of *s* character employed by silicon in a Si-H bond reflecting change in the electron density around the hydrogen and the ease of removal of the hydrogen by the abstracting radical.

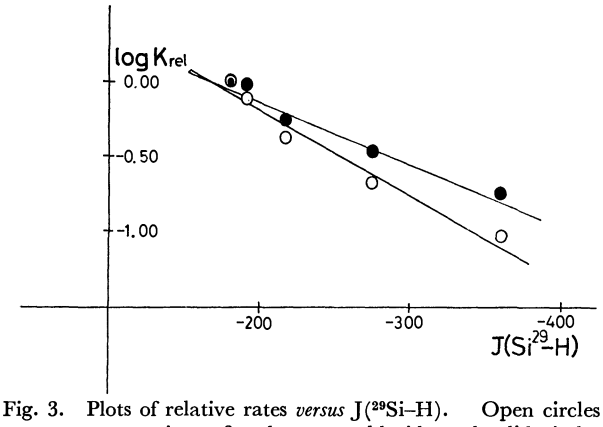

Fig. 3. Plots of relative rates *versus* $J(^{29}\text{Si–H})$. Open circles represent reactions of carbon tetrachloride and solid circles those of chloroform.

Experimental

Starting Materials. Triethylsilane (bp 106.0—106.5°C, lit.[20] 107°C/733 mm.), phenyldimethylsilane (bp 155.0—155.3°C, lit.[21] 158°C), diethylchlorosilane (bp 96—98°C, lit.[22] 99.2°C), ethyldichlorosilane (bp 73.5—74.0°C, lit.[22] 74.2°C) and trichlorosilane (bp 30.5°C, lit.[20] 31.5—32.0°C/729 mmHg) were prepared as described in the literature. Carbon tetrachloride and chloroform were purified according to the standard procedures.[23] VPC analysis of these materials showed negligible impurities. Benzoyl peroxide was commercially obtained as a special grade.

Products. Among the samples necessary for identification of the reaction products, triethylchlorosilane (bp 147°C, lit.[20] 147°C/729 mmHg), phenyldimethylchlorosilane (bp 190—191°C, lit.[21] 192—194°C), diethyldichlorosilane (bp 130°C, lit.[24] 131°C/740 mmHg) and ethyltrichlorosilane (bp 96.5—97.0°C, lit.[25] 97.9°C) were prepared according to the literature. Silicon tetrachloride and dichloromethane were commercially available.

Structures of reaction products were confirmed by comparing infrared spectrum of the respective sample which had been collected by preparative VPC from a reaction mixture with that of the corresponding authentic sample.

Procedure for Kinetic Runs. A solution of two different hydrosilanes was mixed in approximately 3—5 fold excess of an appropriate chloromethane with a catalytic amount of benzoyl peroxide and the resulting solution introduced into a tube which was sealed after the mixture was degassed several times. Then, the reaction tube was maintained at 80°C in a constant temperature bath for 3—5 h. It was found that about 15—90% of the hydrosilanes had reacted during the period of time. The reaction mixtures were subjected to VPC analysis, using column materials such as Silicone DC 550, 710 and so on. It was found by VPC analysis that with all the competitive experiments polydechlorination of carbon tetrachloride or of chloroform had occurred to

negligible extent. Corrections were made for the thermal conductivity of the various components. The relative rates were calculated from original data with equation (3).

NMR Spectra. $J(^{29}Si\text{-}H)$ data were determined from spectra obtained on a Varian Model A-60D high resolution nuclear magnetic resonance spectrometer. NMR spectra were studied in the pure liquid phase. The coupling constants were evaluated from the satelite bands produced by the ^{29}Si in natural abundance which are symmetrically disposed about the main Si-H proton signals. The numerical values obtained are shown in Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3116—3120 (1971)

The Constituents of Hops. VI[1] Studies of the Volatile Composition of *Humulus lupulus* L. during Ripening

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, Dojimanaka 2-43, Kita-ku, Osaka

(Received April 23, 1971)

Evidence is presented for the volatile constituents of hops, not only in the resin glands, the so-called lupulin, but also in the stalk with leaves and in the three crops of cones during ripening. Lupulin shows a specific accumulation of myrcene, and the amount of the volatile constituents increases from fifty times to eight hundred times that in any other part of the plant in the course of ripening. While ripe cones contain neither any germacratrienes, the precursors of several sesquiterpenes, nor any aliphatic aldehydes, the stalk with leaves and the young cones have quite high concentrations of them respectively. Observation suggests that some of the volatile constituents are formed at an early stage of growth, whilst others are formed later.

The steam-volatile constituents of the cultivated Japanese hop, "Shinshu-wase" (*Humulus lupulus* L.), have previously been studied.[2-6] In the present paper, the isolation and the identification of volatile compounds from different plant tissues during ripening will be reported.

The part with the highest concentration of volatile components is well-known to be the "lupulin" glands of the cones, whilst the other parts of plant have also been found to include the major constituents to some extent. Germacrene D,[7] which is a key intermediate of cadinene-group compounds, and nonanal are found to be formed at an early stage of growth, whilst myrcene is formed in a remarkable amount at a later stage of growth. This observation suggests the compartmentalization effect of biogenesis in the plant tissue on the accumulation of volatile compounds. However, such a technique of the direct volatilization of individual plant tissue for GLC analysis[8] as will avoid numerous ill effects that the experimental samples will suffer after harvest is required before further detailed study can be done. The positive correlation with the size of the cones, or the formation of lupulin, and the quantity of aroma compounds are shown to be in agreement with the results of the recent study of Hautke *et al.*[9]

Experimental

The seedless Shinshu-wase used for the experiment was all cultivated in the same hop yard in Iwate Prefecture. The experimental samples were twice harvested on July 25th and again on August 31st when the cones were their final size, after dried in an oast below 50°C for several hrs, they were tansported by air each time. The analytical samples of various plant parts at different periods and the contents of the neutral volatile components are listed in Table 1. Lupulin for the sample VI was separated from the other cone parts by grinding in liquid nitrogen.

Each of the six samples was extracted with ether, the extract was then steam-distilled to obtain the essential oil for analysis. The distillate was extracted with ether, and the oil thus obtained was separated into the hydrocarbons and the fraction of the oxygenated constituents by selective adsorption on neutral alumina. The proportions of these two fractions from the six samples examined are also shown

VI	Lupulin only	31/Aug.	41.4	94.1	5.9

in Table 1. Analysis was carried out by a combination of adsorption chromatography (silica gel), preparative GLC (Carbowax 20M), and the temperature-programmed capillary GC–MS method. The identification of the compounds was verified by the agreement of the mass spectra as well as by that of the retention time on GLC with those of authentic samples or of published standard references. Furthermore, the major constituents were isolated using the combined method described above, and the identity of the constituents was confirmed by comparing their IR spectra with those of authentic samples.

Apparatus and Operating Conditions. The preparative GLC conditions, using a model 90-P Varian Aerograph fitted with a thermal conductivity detector, were as follows: a 10-ft. × 3/8 in. aluminum column containing 20% Carbowax 20M on 60—80 mesh Diasolid-L. Helium was used as the carrier gas, and the column temperature was set at 100—220°C.

For the analytical GLC, a Hitachi Model K-53 apparatus equipped with a flame ionization detector was used. The capillary column used for the analysis was 45m × 0.25 mm, made of stainless steel and coated with HB 2000; the column temperature was programmed non-linearly from 100 to 150°C. The helium-carrier gas-inlet pressure was set at 1 kg/cm² for initiation and at 2.5 kg/cm² at the end.

The GC–MS were measured with the direct combination of GLC fitted with a Golay column (45m × 0.5 mm, HB 2000) and mass spectrometry using a Hitachi Model RMU-6 Mass Spectrometer; the operating conditions were as follows: ionization energy, 80 eV; acceleration voltage, 2000 V. The column temperature was programmed non-linearly at 60—150°C under a gas-inlet pressure of 0.6—2.0 kg/cm².

Results and Discussion

The identified constituents of the examined oils of "Shinshu-wase" are listed in Table 2, together with the peak number on the programmed GLC (Fig. 1—6).

Significant differences in the composition during the course of ripening may be seen in the gas chromatograms (Fig. 1—6) and in Table 2. The proportion of the oxygenated constituents to hydrocarbons is approximately 1: 1—2 in the samples I—III, whilst in the samples IV—VI it appears to be 1: 15—29 (Table 1). In the sample IV, the common major hydrocarbons, *i.e.*, caryophyllene, α- and β-humulenes, α- and β-selinenes, δ-cadinene, and myrcene, increase in almost the same ratio (Table 3), while the amount of myrcene in the samples V and VI increases almost 20 times more than in the other samples. It is very interesting to note that the annual plant *H. japonicus*[1] which has

no lupulin, contains only a little amount of myrcene although in other respects it is similar to the volatile constituents of *H. lupulus* previously reported. Therefore, myrcene might be a characteristic compound in the lupulin of fully-ripened hops. Thus, the size of the cones is naturally correlated to the quantity of aroma compounds. The most predominant sesquiterpenic hydrocarbon is humulene, and the next is caryophyllene, in all the examined samples (I—VI), in the ratio of 2: 1. These two hydrocarbons are characteristic of the whole hop plant and are not connected with the differences in the plant tissue and the course of ripening.

A considerable amount of germacrene-D is detected in the sample I at an earlier stage of growth, and a little of it in the samples II and III, but none of it is detected in the samples IV—VI. The contents of selinenes and cadinenes increase considerably at later stages of growth. These compounds are known also to be produced chemically[7] through the germacratrienes. In addition, β-elemene produced by a Cope rearrangement of germacrene-A[10] is found a notable amount in the sample I. The above evidence strongly suggests that the labile germacrene-A, the precursor of β-elemene, α-, and β-selinenes, is present at an earlier stage of growth.

Aliphatic aldehydes, particularly nonanal are specifically accumulated in young cones (the sample III). It is interesting to consider the biological meaning of this compound at that stage of growth. It might be a repellent against insects, with its homologues the stink substances of *Pentatomidae* and *Coreidae*.[11]

Studies on the Baudisch Reaction. IV. The Reaction Mechanism[1)]

Kazuhiro MARUYAMA* and Iwao TANIMOTO**

*Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Sakyo-ku, Kyoto

**Faculty of Home Economics, Kyoto Women's University, Higashiyama-ku, Kyoto

(Received April 28, 1971)

Mechanism of the Baudisch reaction was investigated using semicarbazide hydrochloride in lieu of hydroxylamine hydrochloride which is one of the reacting components. It was suggested that pyrocatechol-copper-hydroxylamine complex formed as a reaction intermediate is oxidized to *o*-benzoquinone-copper complex by hydrogen peroxide and one of the carbonyl groups of *o*-benzoquinone reacts with hydroxylamine hydrochloride to give *o*-benzoquinone monooxime, *i.e.* 2-nitrosophenol.

The Baudisch reaction is of interest with respect to the direct production of *o*-nitrosophenols from the corresponding hydrocarbons by the reaction with hydroxylamine hydrochloride, hydrogen peroxide and copper(II) salt.[2,3)] We found that the copper-hydroxylamine complex combined with the phenol formed at the first stage of reaction played a key role in the reaction.[1a,b)] In our recent studies,[1c)] it was demonstrated that *p*-cresol gave 5-methyl-2-nitrosophenol and 3,5-dimethylphenol gave 4,6-dimethyl-2-nitrosophenol; the hydroxy group of *p*-cresol or 3,5-dimethylphenol was replaced by nitroso group and a new hydroxy group was introduced into the position *ortho* to this nitroso group. Furthermore, 2-nitroso-1-naphthol which is the product starting from 1-naphthol was also produced exclusively in the Baudisch reaction of 2-naphthol. These results suggest the essential contribution of pyrocatechol-copper(II) complex (Fig. 1) as a reaction intermediate. For the sake of confirmation we examined whether pyrocatechols, in lieu of phenol, give *o*-nitrosophenols under the same conditions of the Baudisch reaction or not. It was found that pyro-

catechols rapidly change into *o*-nitrosophenol-copper (II) complexes. All the mechanisms so far postulated[2c,d,3,4] failed to give an explanation. In this paper we would like to discuss the route by which *o*-nitrosophenol was produced from the pyrocatechol-copper(II) complex and try to elucidate the whole mechanism of the Baudisch reaction.

Results and Discussion

Pyrocatechol did not react with semicarbazide hydrochloride as well as hydroxylamine hydrochloride at pH 2.50 even in the presence of copper(II) ion. The reaction was started, however, by the addition of hydrogen peroxide. After the reaction was completed, the red solution was acidified and the product was extracted with a solvent. The elemental analysis of the purified products coincided with the calculated value for 2-hydroxyphenylazoformamide, *i.e.* semicarbazone of *o*-benzoquinone. The semicarbazone formed a characteristic reddish violet complex with copper(II) ion in water. Electronic spectra of the semicarbazone and of its copper(II) complex are shown in Fig. 2. The absorption peak of semicarbazone at 325 nm is ascribed to the azo group conjugating with aromatic ring, and the peak observed in copper salt at 527 nm seems to indicate the formation of an *o*-hydroxyazo copper chelate. By a similar procedure semicarbazones of substituted *o*-benzoquinones were obtained from the corresponding pyrocatechols. The results are summarized in Table 1. As one of the two hydroxy groups is apparently substituted by an azoformamide group, two isomeric products may result from substituted pyrocatechols. As an example, 4-methyl-2-hydroxyphenylazoformamide and 3-methyl-6-hydroxyphenylazoformamide can be produced from 4-methyl pyrocatechol. However, since the reduction of the product by tin(II) chloride gave only 6-amino-*m*-cresol, it can be deduced that 4-methyl-2-hydroxyphenylazoformamide was produced exclusively. Table 1 shows that in every case the hydroxy group replaced by the azoformamide group was the same as the one which was replaced by the nitroso group in the Baudisch reaction. These results imply that hydroxylamine hydrochloride or semicarbazide hydrochloride reacts with pyrocatechol in a similar manner.

– – –: Cu^{2+} salt of 2-hydroxyphenylazoformamide in water

According to Horner and Drückheimer,[5] *o*-benzoquinonediazides are obtained by the reaction between *o*-benzoquinones and *p*-toluenesulfonyl hydrazide. Reduction of quinonediazides by hypophosphorus acid gives a mixture of isomeric phenols. Utilizing this reaction, one can determine which carbonyl group of substituted *o*-quinone was preferentially attacked. As an example, 4-chloro-*o*-benzoquinone gives 3-chlorophenol (91%) and 4-chlorophenol (8%); the carbonyl group *para* to chlorine atom is preferentially attacked by hydrazine.[5] Thus, we recognize that the position of the carbonyl group attacked by hydrazide in Horner and Drückheimer's reaction corresponds to the position of the hydroxy group replaced by nitroso or azoformamide group in our reaction. The results seem to indicate the following possible reaction sequence. Pyrocatechol-copper complex is oxidized to *o*-benzoquinone-copper complex and then one of the carbonyl groups of *o*-benzoquinone is attacked by hydroxylamine (or semicarbazide). In line with the above consideration, *o*-benzoquinones gave *o*-nitrosophenols under Baudisch reaction conditions, and no reaction of pyrocatechols with hydroxylamine(or semicarbazide) hydrochloride started until addition of hydrogen peroxide even in the

presence of copper(II) ion. Examination of the electron density using simple HMO method gave no fruitful guide for the preferential attack of Schiff bases(hydroxylamine, semicarbazide or *p*-toluenesulfonyl hydrazide) to one of two carbonyl groups of *o*-quinones.

On the other hand, the Baudisch reaction in methanol does not take place when no hydroxy group exists in a molecule,[1a] and the reaction of benzene, for example, might proceed *via* phenol formation. Thus, we examined the effect of copper(I) ion on the Baudisch reaction. A mixture of copper(I) and copper(II) in various molar ratio was used in the reaction, the total molar quantity of both ions being kept constant. The result is shown in Fig. 3. *o*-Nitrosophenol formation

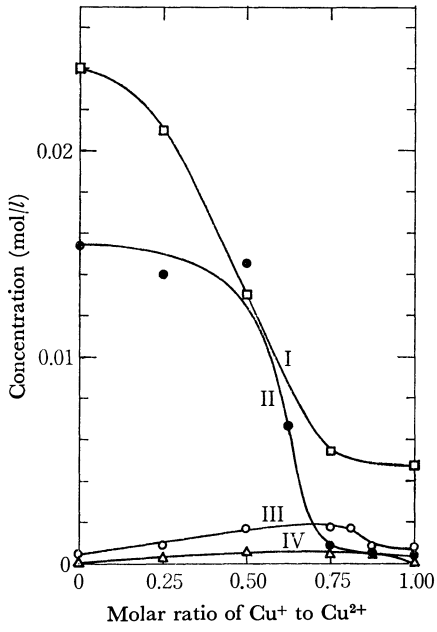

Fig. 3. Effect of copper(I) on the production of *o*-nitrosophenols from phenols or benzenes.
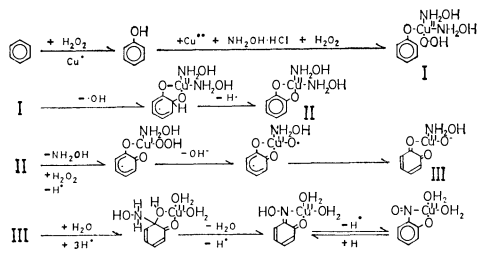
I: *p*-chlorophenol, II: phenol, III: benzene
IV: chlorobenzene

from the phenols decreased gradually with the increase of molar ratio of copper(I) ion. However, in the case of aromatic hydrocarbons the amounts of *o*-nitrosophenols produced was somewhat increased with the increase of the relative molar ratio of copper(I). This is conceivable by considering that copper(I) ion is essential for the decomposition of hydrogen peroxide to form hydroxy radical which attacks aromatic hydrocarbons to afford phenols.

The whole sequence of the Baudisch reaction can be summarized as follows.



A part of copper(II) ion is reduced at first to copper(I) by hydroxylamine and copper(I) reacts with hydrogen peroxide to produce hydroxy radical. Complex I is then formed from phenol, copper(II), hydroxylamine and hydrogen peroxide, and the complex produces pyrocatechol-copper complex II. In the next stage, complex II may be oxidized to *o*-benzoquinone-copper complex III. In this stage, hydrogen peroxide will substitute the hydroxylamine ligand of complex II and then successive oxidation proceeds. As copper species can easily change their oxidation states,[6] electron of pyrocatechol can be transferred with no difficulty to peroxide through copper atom.[7] Finally, complex III might be oximated to *o*-nitrosophenol-copper(II) complex.

Experimental

Materials. 4-Chlorocatechol was prepared by the chlorination of pyrocatechol.[8] Copper(I) chloride was prepared by the reduction of copper(II) sulfate.[9] After being washed with glacial acetic acid, the crystal was dried and used. Other reagents were the same as described previously.[1a,b,c]

Formation of Hydroxyphenylazoformamide. A typical example is the following: In a 1*l* three-necked flask, equipped with a stirrer, were placed copper(II) nitrate (8 g, 0.033 mol), 4-methyl pyrocatechol (3.7 g, 0.030 mol), semicarbazide hydrochloride (5.6 g, 0.05 mol) and 500 m*l* of hydrochloric acid-sodium acetate buffer (pH 2.5). To this mixture was added 5 m*l* of 30% hydrogen peroxide solution diluted with 200 m*l* of water in 2 hr. The solution was stirred for 2.5 hr at 20°C. The reaction mixture was acidified after the filtration of the residue, and extracted with ethyl ether. The red product in ethyl ether was extracted as a copper salt of the product with an aqueous solution of copper(II) acetate. After the reddish violet aqueous solution was extracted repeatedly with ethyl ether and chloroform, the solution was acidified and extracted with chloroform. The extract was evaporated under a reduced pressure and orange red crude crystals, 4-methyl-2-hydroxyphenylazoformamide, were obtained (*ca.* 800 mg). After being eluted with acetone-ethanol (1:1) on an alumina column, the pure product was obtained, mp 152—153.5°C. The result of elemental analysis is shown in Table 1.

The product was confirmed as follows. The hydroxyphenylazoformamide was dissolved in an acidic tin(II) chloride solution. After the color of the solution had almost faded away, the solution was refluxed for 30 min. After being cooled and extracted with ethyl ether, the solution was made alkaline with aquous 6N NaOH solution. *O,N*-Dibenzoyl derivative of 5-methyl-2-aminophenol, mp 144.5—145.5°C, was obtained. No melting point depression was observed in admixture with an authentic sample.[10]

The Effect of Copper(I) on the Production of o-*Nitrosophenols.*

6) R. G. R. Bacon and H. A. O. Hill, *Quart. Rev.* (London), **19**, 95 (1965).

7) In the Baudisch reaction, copper(II) ion forms a stable complex with *o*-nitrosophenol or monooxime of *o*-benzoquinone. The complex can protect the product against further oxidation or oximation. This might be another important role of copper(II) ion in the Baudisch reaction.

8) R. Willstätter and H. E. Müller, *Ber.*, **44**, 2182 (1911).

9) C. S. Marvel and S. M. McElvain, *Org. Syn.*, *Coll. Vol.*, **1**, 170 (1941).

10) The melting point of this compound (162°C) was reported by K. V. Auwers *et al.* (*Ber.*, **54**, 1314 (1921)), but their report should be corrected.

A mixture of copper(I) chloride and copper(II) chloride was used. The total amount of copper ions was kept 0.005 mol. This mixture and hydroxylamine hydrochloride (0.695 g, 0.01 mol) were dissolved in 100 m*l* of a Walpole buffer (pH 2.55). To the solution, benzene (0.5 m*l*) or chlorobenzene (1.0 m*l*) dissolved in 20 m*l* of *n*-hexane was added. After the addition of 30% hydrogen peroxide (1 m*l*), the mixture was stirred at 30°C for 20 min under a nitrogen atmosphere. Aliquot of the mixture (20 or 50 m*l*) was removed and was acidified with 3 m*l* of 6N HCl. The determination of *o*-nitrosophenol produced was described previously.[18]

Spectrophotometry. The electronic spectra of hydroxyphenylazoformamide in chloroform and its copper(II) salt in water were measured. The aqueous solution of hydroxyphenylazoformamide-copper(II) was obtained by shaking an ethereal solution of hydroxyphenylazoformamide with an aqueous copper(II) sulfate solution.

This work was supported in part by a Research Grant from Kyoto Women's University.

Carboxylation of Phenol Derivatives. XX. Syntheses of Phenolpolycarboxylic Acids by the Carboxylation of Alkali Phenoxide in the Presence of Alkali Alkyl Carbonate[1]

Taketoshi KITO and Ichiro HIRAO

Laboratory of Industrial Chemistry, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

(Received April 30, 1971)

Phenolpolycarboxylic acids, especially hydroxytrimesic acid, were obtained in good yields by heating alkali phenoxide under a carbon dioxide pressure in the presence of alkali alkyl carbonate. Hydroxytrimesic acid was obtained in the best yield by the reaction of potassium phenoxide and potassium alkyl carbonate. In this reaction, neither a superatmospheric pressure nor a high reaction temperature was needed. The formation processes of phenolcarboxylic acids are also discussed.

Phenolcarboxylic acids are usually prepared by heating alkali phenoxide under a carbon dioxide pressure. In this reaction, salicylic acid (SA) is produced mainly from the sodium salt, and *p*-hydroxybenzoic acid (POB) mainly from potassium salt, while 4-hydroxyisophthalic acid (4-OIP) is formed only as a minor product from both the salts.[2]

Although phenolcarboxylic acids are also obtained from the reaction of alkali phenoxide and alkali alkyl carbonate in an atmosphere of nitrogen or carbon dioxide, 4-OIP is similarly a minor product.[3,4]

On the other hand, the methods to produce 4-OIP and hydroxytrimesic acid (OT) have been reported.[5,6] For example, 4-OIP is obtained when dipotassium salicylate or dipotassium salt of POB is heated under a superatmospheric pressure of carbon dioxide at temperatures from 300° to 500°C, and OT is obtained when phenol, SA, POB, 4-OIP, or 2-hydroxyisophthalic acid (2-OIP) or alkali salts of these compounds are heated at carbon dioxide pressures greater than 100 atm at temperatures higher than 250°C in the presence of potassium carbonate. By these methods, phenolpolycarboxylic acids are obtained in good yields, but a high pressure and a high temperature are needed.

However, it has now been found that when the carboxylation of alkali phenoxide is carried out in the presence of an excess of alkali alkyl carbonate, phenolpolycarboxylic acids, such as 4-OIP and OT, are obtained in good yields under mild conditions. The present investigation deals with this newer method for preparing phenolpolycarboxylic acids, especially OT.

Experimental

Alkali Alkyl Carbonate. Carbon dioxide was vigorously introduced into a solution of alkali alcoholate, derived from pure aliphatic alcohol and alkali metal. From the resulting mixture, the excess alcohol was distilled off in a vacuum at a temperature lower than 120°C.

Reaction of Alkali Phenoxide and Alkali Alkyl Carbonate. In a 300-m*l* autoclave, equipped with an electromagnetic stirrer, we placed 0.02 mol of alkali phenoxide, the prescribed amount of alkali alkyl carbonate, and 100 m*l* of a light oil (bp>250°C). After the air had been replaced by carbon dioxide (unless otherwise mentioned, the carbon dioxide pressure means the starting pressure), the autoclave was heated to the prescribed temperature. This took about 30 min. When the reaction was carried out in a flask, a 300-m*l* three-necked flask, equipped with a mechanical stirrer, a thermometer, a gas inlet-tube, and a 10-cm glass tube whose top was connected to a gas-flow meter, was used in place of an autoclave. The flow rate of carbon dioxide was regulated at about 25 *l*/h. After reaction had been stopped, 200 m*l* of water was added and a light oil was separated from the aqueous solution. The aqueous solution was

adjusted to pH 7 with hydrochloric acid and washed with ether. Then, phenolcarboxylic acids were acidified with hydrochloric acid and extracted with ether. After the removal of the ether, SA, POB, 4-OIP, 2-OIP, and OT were found to be present in the residue.

Analysis of the Products by the Ultraviolet Technique. After the removal of the SA by washing with chloroform, the residue was dissolved in water; the solution was then buffered at pH 11 with disodium hydrogen phosphate and sodium hydroxide and at pH 2.8 with disodium hydrogen citrate and sodium hydroxide. The absorptivities of the components are given in Table 1. By using the four key wavelengths the amounts of POB, 4-OIP, 2-OIP, and OT may be determined. The SA can also be determined by the ultraviolet technique after the evaporation of the chloroform from the chloroform solution.

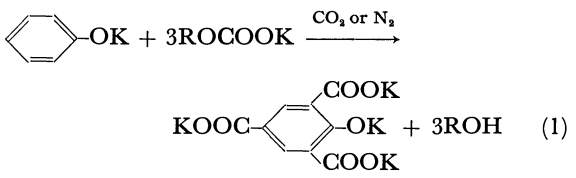
Results and Discussion

Phenolcarboxylic acids are formed by heating potassium phenoxide and an equimolar quantity of potassium alkyl carbonate in an atmosphere of nitrogen or carbon dioxide, but the main product is always POB or SA.

We have further investigated this reaction in the presence of an excess amount of potassium aklyl carbonate. The results are summarized in Table 2. In this reaction, one of the most remarkable features is that considerable amounts of OT and 4-OIP are obtained under mild conditions. Although the latter compound is also obtained from the reaction of potassium phenoxide and carbon dioxide or an equimolar quantity of potassium alkyl carbonate, it is always a minor product. However, by the reaction of potassium phenoxide and potassium 1-pentyl carbonate in a 1 : 3 molar ratio at 220°C for 2 hr, 4-OIP was formed in a 36% yield even at an atmospheric pressure. The total yield of phenolcarboxylic acids (POB+SA+4-OIP+2-OIP+OT) was nearly independent of the reaction temperature and the molar ratio of potassium alkyl carbonate to potassium phenoxide, that is, the carbonate ratio. On the contrary, the carboxylation yield, which is defined as the mole per cent of carbon dioxide introduced into a phenyl nucleus, increased with a rise in the reaction temperature or with an increase in the carbonate ratio. If the reaction proceeds according to Eq. (1), the theoretical values of the carbonate ratio



(1)

and of the carboxylation yield must be 3 and 300% respectively. However, the maximum carboxylation yield was only 198% (66% of the theoretical value), even at a carbonate ratio of 5 : 1 and at 240°C.

The reaction was again examined in an autoclave under carbon dioxide pressure. The results are summarized in Table 3. From the results shown in Tables 2 and 3, it is evident that the reaction temperature, the carbonate ratio, and the carbon dioxide pressure have a great effect on both the composition of phenolcarboxylic acids and the carboxylation yield. For example, the carboxylation yield amounted to 284% in the reaction of potassium phenoxide and three times as much potassium 1-pentyl carbonate at 260°C and 5 kg/cm² of carbon dioxide; in other words, OT was nearly the only product. Although other kinds of potassium alkyl carbonates, such as potassium ethyl-, *n*-butyl-, and *n*-octyl carbonate, were used in place of potassium 1-pentyl carbonate (Table 3), no remarkable effects of the alkyl group on the yield of OT was observed. Moreover, the superatmospheric pressure of carbon dioxide was not needed in this reaction.

The effect of the atmosphere was also examined (Table 4). It has been reported that potassium alkyl carbonate reacts with potassium phenoxide to yield phenolcarboxylic acids, especially POB, in good yields. In this reaction, the carbonate is regarded as a car-

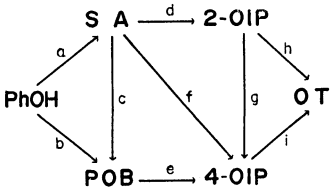
boxylating agent. The results listed in Table 4 are consistent with the above idea. However, it must be a weak carboxylating agent. In other words, the first carboxy group is easily introduced into the *ortho* or *para* position to the hydroxy group, but it is difficult to introduce the third one. Although the best-known carboxylating agent is carbon dioxide, the asterisked result in Table 2 is somewhat analogous to the asterisked one in Table 4. Therefore, carbon dioxide is also a weak carboxylating agent, but the yield of OT increased considerably when the carboxylation reaction was carried out under a carbon dioxide pressure. Consequently, in the reactions under a carbon dioxide pressure potassium alkyl carbonate may act as an alkali supplying agent rather than as a carboxylating agent to the carboxy groups introduced.



Scheme 1

There are nine routes that are considered to be possible formation processes of the five kinds of acids (Scheme 1). Potassium phenoxide, on being heated for 2 hr in the presence of an equimolar quantity of potassium 1-pentyl carbonate in a stream of carbon dioxide, gave 31% of POB and 48% of SA at 180°C, together with minor amounts of 4-OIP, but it gave 57% of POB, 11% of SA, and 12% of 4-OIP at 220°C. The increase in the amount of POB at 220°C must be due to the rearrangement of the dipotassium salicylate to the dipotassium salt of POB, which is known to be an important process in producing POB. The rearrangement of the tripotassium salt of 2-OIP to the tripotassium salt of 4-OIP may similarly occur at high temperatures. Then, the tripotassium salt of 2-OIP was heated at 180°C or 240°C for 2 hr in an atmosphere of nitrogen; the resulting solid was analysed by the ultraviolet spectral technique, whereas 4-OIP was not obtained even at 240°C. Consequently, the (g) route can be disregarded.

There are three routes, that is, (d)—(h), (e)—(i), and (f)—(i), for yielding OT. Therefore, the dipotassium salt of POB or dipotassium salicylate was heated with twice as much potassium ethyl carbonate at 200° or 240°C for 2 hr in an autoclave at 5 kg/cm² of carbon dioxide. The results were as follows; 1 mol of dipotassium salt of POB gave, at 240°C, 0.89 mol of OT and 0.01 mol of POB, and at 200°C, 0.76 mol of POB, 0.20 mol of 4-OIP, and 0.02 mol of OT, while 1 mol of dipotassium salicylate gave, at 240°C, 0.81 mol of OT and 0.09 mol of SA, and at 200°C, 0.53 mol of SA, 0.28 mol of 4-OIP, and 0.14 mol of 2-OIP. From these results, it was found that neither the dipotassium salt of POB nor dipotassium salicylate give OT at temperatures lower than 200°C, although they give OT as the main product in a good yield at high temperatures. In these reactions, OT must be formed predominantly *via* Route (i), because dipotassium salt of POB can not give 2-OIP and dipotassium salicylate rearranges to dipotassium salt of POB or is carboxylated mainly at the position *para* to the hydroxy group rather than at

TABLE 5. REACTIONS IN THE VARIOUS COMBINATIONS OF ALKALI SALTS

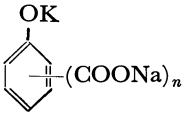
the position *ortho*. Then, it became clear that both the dipotassium salt of POB and dipotassium salicylate give 4-OIP, which is further carboxylated to OT at high temperatures.

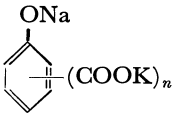
SA gives 4-OIP *via* two routes. It is known that dipotassium salicylate rearranges to the dipotassium salt of POB,[7] but the rearrangement is influenced by the presence of carbon dioxide. For example, although dipotassium salicylate, on being heated at 240°C and 5 kg/cm^2 of carbon dioxide, rearranges to give 24% of POB and 28% of 4-OIP, 46% of the starting material, dipotassium salicylate, remains unreacted. Therefore, Route (f) is also of importance as the process for yielding 4-OPI. On the other hand, both the tripotassium salt of 2-OIP and that of 4-OIP, on being heated at 240°C and 5 kg/cm^2 of carbon dioxide in the presence of twice as much potassium ethyl carbonate, gives OT in a good yield, but 2-OIP was a minor product in any of the reactions listed in Tables 2, 3, and 4.

On the basis of these data, it seems that the main processes for 4-OIP are the (a)—(c)—(e), (a)—(f), and (b)—(e) routes and that the main process for OT is Route (i).

Sodium salt was used in place of potassium phenoxide or potassium 1-pentyl carbonate. The results are summarized in Table 5. OT was obtained in the best yield when both M_1 and M_2 were potassium. The yield of OT was lowered when either M_1 or M_2 was replaced by sodium, but better results were obtained in the reactions using sodium phenoxide (M_1=sodium). The structures of the products are designated (I) when potassium phenoxide is used and (II) when sodium phenoxide.



(I)



(II)

The reactivity of potassium phenoxide is generally greater than that of sodium phenoxide in the carboxylation of alkali phenoxide. On the other hand, as the COONa group is a more powerful electron attractor than the COOK group, the former makes the phenyl nucleus inactive to a greater extent than the latter. Consequently, the carboxylation yields in the reactions using sodium 1-pentyl carbonate are lower than that in the reactions using the potassium salt of the corresponding carbonate.

Thanks are due to Mr. Y. Hokamura for his assistance in the experimental work.

The Copolymerization of 2-Chloroacrylaldehyde with Styrene[1]

Yoshio MATSUBARA, Parimal R. KAVI, Masakuni YOSHIHARA, and Toshihisa MAESHIMA

Department of Applied Chemistry, Faculty of Science and Engineering, Kinki University, Kowakae, Higashi-Osaka

(Received May 4, 1971)

The copolymerization of α-chloroacrolein (M_1) with styrene (M_2) has been investigated. An alternating copolymer was obtained without an initiator in dimethyl sulfoxide at 60°C. The formation of a charge-transfer complex between the respective monomers was observed by the continuous-variation method, and it was found that this complex plays an important role in the polymerization. Meanwhile, in the case of the BF_3OEt_2-catalyzed system, it was observed that the polymerization temperature strongly affected the copolymerizability and the structure of the copolymer.

In the course of our research on the polymerization of acrolein and its derivatives,[2-4] the copolymerization of α-chloroacrolein (CAL) with styrene (St) was investigated. Our work on the copolymerization CAL with pyridazinone derivatives[5] has already been reported.

Recently, Elias *et al.*[6] investigated the radical polymerizations of CAL, α-chloroacrolein diacetate, and α-chloroacrolein dimethyl acetal, and also reported the radical copolymerizations of CAL with St and vinyl chloride. It was also indicated by these workers that α-chloroacrolein dimethyl acetal formed a 1:2 complex with boron trifluoride etherate at −60°C *via* the acetal oxygen atoms, which then gave oligomers at 25° to 30°C through cationic mechanism. However, this work did not contain any data on the cationic copolymerization.

In the present paper, we intend to discuss the formation and the polymerization of the 1:1 charge transfer complex due to some donor-acceptor-type interaction between CAL and St both in the absence of and in the presence of boron trifluoride etherate.

Experimental

Materials. The CAL was synthesized from acrolein according to Moureu's method[7] and purified by vacuum distillation (bp 29°C/17 mmHg, d_{25} 1.193, n_D^{25} 1.458).

The St was purified by distillation under a vacuum before use. The boron trifluoride etherate was purified by distillation in the usual manner.

Copolymerization Procedure. The copolymerization was carried out under the dry nitrogen atmosphere in a glass ampoule. Given amounts of the monomer and the solvent were placed in an ampoule, a catalyst solution was added at required temperature, and the ampoule was sealed. After the reaction, the resulting mixture was poured into a large amount of methanol to precipitate the copolymer.

Characterization of the Copolymer. The composition of the copolymer was determined by elemental analysis. The nuclear magnetic resonance (NMR) spectra of the copolymer were measured in carbon tetrachloride with a HITACHI R-20 spectrometer. The infrared(IR) spectra reported in this paper were taken with a YANAGIMOTO LSG-25 infrared spectrometer. The X-ray diffraction spectra of the copolymer were obtained by using nickel-filtered Cu*Kα* radiation with a RIGAKU DENKI geiger flex. The viscosity measurements were carried out with an Ostwald viscometer using toluene as the solvent and at 25°C. The number-average molecular weight of the copolymer was determined by vapour-pressure osmometry using benzene as a solvent at 40.5°C with HITACHI PERKIN ELMER MODEL 105 apparatus. The continuous-variation method[8] applied to the CAL-St system was carried out in dimethyl sulfoxide or toluene using a quartz cell with a path length of 10 mm and at room temperature.

Results and Discussion

Copolymerization without a Catalyst. The results of the copolymerization of CAL with St in the absence of a catalyst are summarized in Table 1. The copolymer obtained was a white powder, soluble in toluene, pyridine, and tetrahydrofuran, and insoluble in methanol and diethyl ether. Figure 1 shows that the maximum values of both the copolymerization rate and the limiting viscosity number of the copolymer were observed at the CAL mole fraction with a monomer-feed com-

position of 0.5, indicating that there may be some interaction between CAL and St. Meanwhile, the initial copolymerization rate was proportional to the 1.88 order of the monomer concentration, suggesting that the initiation takes place as a result of the interaction between the two monomers.[9] In order to estimate the over-all activation energy for the copolymerization of CAL with St, the polymerization was carried out at 60, 70, and 80°C in the monomer-feed composition of 0.5. Plots of the logarithm of the copolymerization rate against the reciprocal of the absolute temperature gave a linear relation, and from its slope the activation energy was given as 11.37 kcal/mol. This value of the activation energy is much lower than that obtained for usual radical polymerization. The Fineman-Ross plot gave monomer reactivity ratios of r_1=0.18 and r_2=0.06 for the non-catalyzed copolymerization of CAL (M_1) with St (M_2). These values of r_1 and r_2 are less than those for the radical copolymerization reported by Elias (r_1=0.18, r_2=0.078).[6]

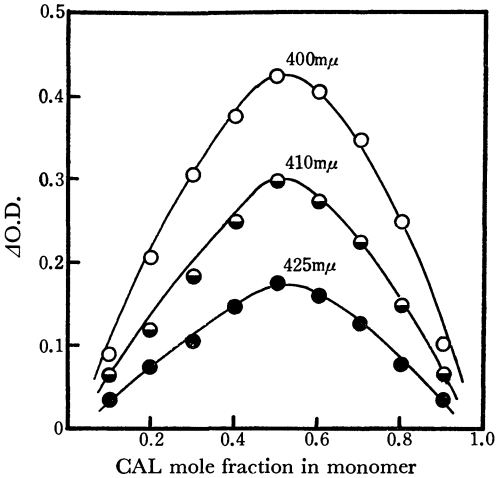

Fig. 2. Continuous variation method in CAL and St system. [CAL]+[St]=0.1 mol/l in DMSO at room temperature

All these results indicate that this copolymerization might take place through a charge-transfer complex. This theory is critically supported by the fact that electronic spectra obtained by means of the continuous variation method gave a maximum value in the optical density when an equimolar mixture was employed (Fig. 2).

Copolymerization in the Presence of Boron Trifluoride Etherate. CAL was copolymerized with St, using boron trifluoride etherate as the catalyst and toluene as the solvent, at −78, 0, 30, and 60°C.

The results of the copolymerization at −78°C are as shown in Table 2. The copolymer obtained as a white powder had a molecular weight in the range of 2300—2800 and was soluble in most organic solvents, such as acetone, carbon tetrachloride, benzene, tetrahydrofuran, and dimethylformamide. Figure 3 shows that an in-

crease the CAL mole fraction of the monomer-feed composition clearly decreases both the copolymerization rate and the number-average molecular weight of the copolymer. These facts are well in accord with the reluctance of CAL to homopolymerize in the presence of BF_3OEt_2.

A colour change from colourless to reddish-brown during polymerization in this system was observed in every case except at −78°C, and the colour became darker with an increase in the time and the temperature. This appearance of the colour at room temperature was recorded by electronic absorption spectra at suitable time intervals; the results are shown in Fig. 4. The A spectrum, obtained without a catalyst, had a shoulder at 400 mμ, while, the B spectra, obtained when BF_3OEt_2 was added, showed a new peak at 486 mμ, the intensity of which tended to be enhanced as time passed. Moreover, it was found that the continuous-variation method gave a maximum peak for the CAL-St ratio of 1:1 (Fig. 5). However, the optical density in this case was quite large as compared to that of the CAL-St system. These observations imply that the strong appearance of a colour in the presence of BF_3OEt_2 might be caused by the formation of a coordina-

tion bond between BF_3OEt_2 and the aldehyde group of CAL, this would decrease the electron density of its vinyl group, and, hence, the charge-transfer complex would be intensified. A few investigations have shown that such an interaction appeared in the reaction of a carbonyl compound with an inorganic metallic compound.[10-13] It is noted that the peak due to the complex disappeared when water or alcohol was added to the system.

Figure 6 shows monomer-copolymer composition curves obtained at various temperatures, and Table 3 tabulates the monomer-reactivity ratios obtained from the Fineman Ross plots. One of the most interesting manifestations in Table 3 is the fact that the value of $r_1 \cdot r_2$ gradually decreased with a rise in the polymerization temperature. This observation suggests that a radical polymerization through the charge-transfer complex takes place in some portion at higher temperatures. The same phenomenon has been observed by Sumitomo *et al.*[14] in the formation of the charge-transfer complex between α-cyanomethyl acrolein and zinc chloride, whose copolymerization with styrene gave an alternating copolymer.

It is interesting to note that the copolymerization rate reached its maximum value at about 0°C (Fig. 7). It is also indicated in Fig. 7 that the molecular weight of the copolymer decreased with a rise in the temperature, but increased after reaching a minimum value at about 30°C. This also suggests that a change in the temperature caused a different type of polymerization process to occur as has been described above.

Structure of the Copolymer. The IR, NMR, and X-ray diffraction spectra of the copolymer obtained with a CAL mole fraction of 0.5 in the monomer-feed composition are shown in Figs. 8, 9, and 10 respectively. The spectra of the copolymer obtained from a non-catalyzed system are marked A, whereas those obtained from a catalyzed system at 60, 30, 0, and −78°C are marked B, C, D, and E respectively.

The IR spectra, remarkably, contained the characteristic peaks of both CAL and St. A and B were

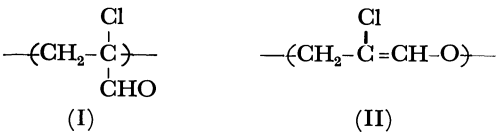
found to contain very similar absorption peaks. However, in the spectra obtained from a BF_3OEt_2-catalyzed system, namely, B, C, D, and E, the intensities of the peaks due to the C=O of the aldehyde groups decreased as the temperature decreased. On the other hand, the decrease in the temperature was found to increase the intensities of the peaks at 1670 cm^{-1} due to C=C and those at 1170 cm^{-1} due to the C–O of C=C–O in the order of B, C, D, and E.

This fact is in good agreement with the results of the NMR spectra. The peak at 4.2 and 5.7 ppm in the D and E spectra might be caused by the methylene proton signals, c and d respectively, as Fig. 9 shows.

In the X-ray diffraction spectra (Fig. 10), the intensities of the peaks were found to decrease in the order of B, C, D, and E. However the A and B spectra had similar peaks.

All these results lead to the conclusion that the BF_3OEt_2-catalyzed system gave a crystalline copolymer with Structure II at lower temperatures, while a noncrystalline polymer with Structure I was obtained at higher temperatures. This may be explained by taking account of the stability of the terminal CAL cation with the counter anion, as is indicated below.



(I) (II)

Thus, when the polymerization occurs *via* the polymer cation A, the higher the temperature, the easier it will be for the reaction to proceed *via* vinyl polymerization, B, than *via* carbonyl Polymerization, C, the carbonyl cation may be destabilized at higher temperatures.[15]

(Received May 4, 1971)

A few synthetic methods of *N*-substituted-carbamimidoylformic acid (**6**) were examined. Among them, condensation of ethyl 1-carbethoxyformimidate or ethyl thiooxamidate with amines and followed by partial hydrolysis gave unsuccessful results, except of the case of benzylamine in the latter reaction. Direct substitution of potassium thiooxamidate (**9**) with alkylamines in water gave **6**, potassium and/or alkylammonium *N*-substituted-thiooxamidate in fairly good yield, depending on conditions used. The presence of heavy metal ions in the reaction system caused an extensive decomposition of **9**, however, the substitution proceeded smoothly by treatment of alkyl- and aryl-ammonium *N*-unsubstituted- or *N*-substituted-thiooxamidate in methanol with mercuric oxide or lead oxide to give in a good yield **6** or *N,N*-disubstituted-carbamimidoylformic acid, respectively.

N-Substituted-carbamimidoylformic acid which is known only as a partial structure of kasugamycin[1-3] is unique as regards a carboxyl group attaches directly to the carbon atom of formamidine, and kasugamycin has been synthesized in *ca.* 10% yield by condensation of kasuganobiosamine with diethyl ester of oxalimidic acid and followed by partial hydrolysis.[4] However, such a partial hydrolysis was considered to proceed non-selectively, and consequently, to be not profitable for a synthesis of *N*-substituted- or *N,N'*-disubstituted-carbamimidoylformic acid.

In this paper, the authors examined the condensation of ethyl 1-carbethoxyformimidate or ethyl thiooxamidate with amines and successive partial hydrolysis, and direct substitution of potassium thiooxamidate or its free acid with amines.

Results and Discussion

Reaction of Ethyl 1-Carbethoxyformimidate or Ethyl Thiooxamidate with Amines. Although the formation of 1-carbethoxyformamidine hydrobromide from ethyl 1-carbethoxyformimidate (**1**) and ammonium bromide is

known,[5] condensation of **1** with amine hydrochlorides at room temperature was unsuccessful, excepting that the reaction of **1** and 2-amino-2-deoxy-D-glucose (**8**) hydrochloride in methanol at elevated temperature gave 2-carbomethoxy-4-(D-*arabino*-1′,2′,3′,4′-tetrahydroxybutyl)-imidazole (**2**) in 10% yield, together with 3, 6-diethoxy-2,5-dihydro-2,5-dioxo-pyrazine (**3**) as a by-product. Condensation of **1** and free amines (*p*-toluidine and **8**) gave complicated products, however, the presence of *N*-substituted-1-carbethoxyformamidine (**4**) was proved by different ways. In the case of **8**, the reaction mixture in methanol was refluxed in the presence of catalytic amount of hydrogen chloride to give **2**, and moreover, decomposition of it with water yielded 2-deoxy-2-oxalylamino-D-glucose methyl ester (**5a**: RNH_2=**8**) which was converted to the corresponding amide by treatment with methanolic ammonia. However, direct partial hydrolysis of the reaction mixture in 0.1 *N*-hydrochloric acid at room temperature gave only a intractable sirup. In the case of *p*-toluidine, direct partial hydrolysis of reaction mixture gave unknown white crystals in 39% yield, $C_{10}H_{10}O_3N_2$, and an attempted ester-exchange reaction with acetic or formic acid gave methyl *N*-*p*-tolyl-oxamidate (**5b**: R=*p*-tolyl) and *N*,*N*′-di-*p*-tolyl-carbamimidoylform-*p*-toluidide.

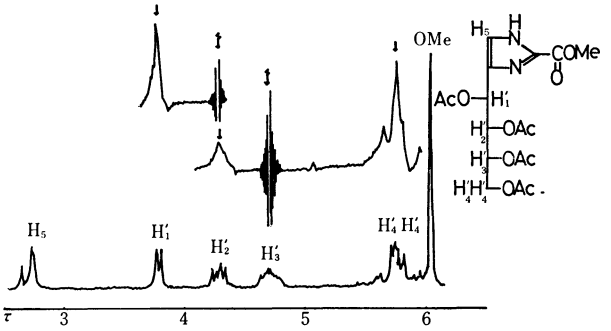

Fig. 1. NMR spectrum of 2-carbomethoxy-4-(D-*arabino*-1′,2′,3′,4′-tetraacetoxybutyl)-imidazole (100 MHz, $CDCl_3$).

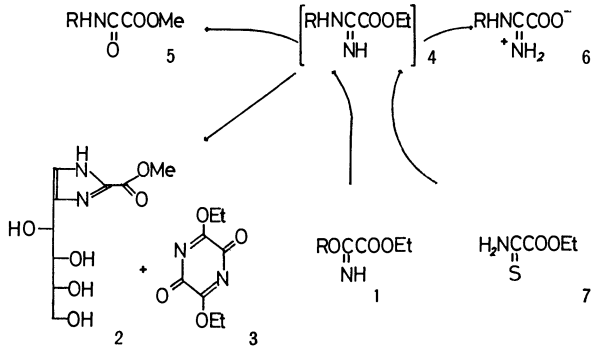
The structure of **2** was determined from the following facts: it shows λ_{max}^{MeOH} 267 nm (ε 1.25×10^4), consumes 3.08 equimolar amount of sodium periodate, and gave the corresponding tetraacetate by a usual acetylation, whose NMR spectrum was shown in Fig. 1. In the NMR spectrum, signals at τ 2.74 (*s*, 1H), 3.78 (*d*, 1H), 4.28 (*q*, 1H), 4.71 (*m*, 1H), and 5.6—6.0 (*m*, 2H) were assigned by the double-resonance technique to H_5, H_1', H_2', H_3', and H_4', respectively. The lower chemical shift of H_5 than usual ring protons in sugar moiety indicates the presence of imidazole ring, and the change of chemical shifts of H_5 and H_1' to τ 2.54 and 3.67 by addition of trifluoroacetic acid supports this deduction. Recently, Fischer and Lewis[6] reported that the reaction of **8** and ethyl iminoacetate hydrochloride in dimethylformamide gave D-glucopyrano[1′,2′: 4,5]-2-methylimidazoline which had a lactol ring in the sugar portion. The reason for the difference between these facts is now under studying.



Scheme 1

On the other hand, it has been known that the reaction of thioamides and amines give amidines[7] and the presence of metal salts such as mercuric chloride assists in driving the reaction to completion, owing to the formation of insoluble metal sulfides.[8] Direct substitution of equimolar amount of ethyl thiooxamidate (**7**) and benzylamine in ethanol at room temperature for an hour gave only *N*,*N*′-dibenzyl-thiooxamidic acid amide as precipitates, however, a solution of equimolar amount of **7** and mercuric chloride in methanol showed a strong acidity, indicating a chelate formation, and further addition of two mol of amine induced the precipitation of the sulfide. Thus, the partial hydrolysis of the product in *N*-hydrochloric acid liberated *N*-benzylcarbamimidoylformic acid (**6j**: R=benzyl) in 32% yield. Similar treatment of the chelate solution with **8** gave again **2** in 8% yield, but, other usual amines could not be condensed successfully. From these results presented in Scheme 1, it is concluded that the two methods mentioned above are not recommendable, because the formation of **4** is accompanied with side reaction and is not realized in the case of usual amines.

Substitution of Potassium Thiooxamidate or Its Free Acid with Amines. Thiooxamidic acid is stable in a salt state, but potassium salt decomposes by refluxing in dioxane with liberation of hydrogen sulfide, and the free acid decomposes gradually in acidic solution to carbon dioxide, hydrogen sulfide and hydrogen cyanide. Moreover, it was found that potassium thiooxamidate (**9**)[9] decomposed extensively by addition of Ag^+, Hg^{2+}, or Pb^{2+} ion with liberation of the corresponding metal sulfide, and formed corresponding chelate compounds by addition of Cu^{2+}, Fe^{3+}, or Zn^{2+} ion. Consequently, the substitutions were examined in the absence or presence of metal ion, and metal oxides such as mercuric oxide and lead oxide were found to be the best accelerator on the substitutions.

Direct substitution of **9** with four equivalent of ammonia in absolute methanol under vigorous stirring at room temperature gave carbamimidoylformic acid (**6a**: R=H) in 90% yield, whose structure was supported by characteristic IR absorptions of amidine (3350, 3310, and 3020 cm^{-1}) and intramolecular carboxylate (1640 cm^{-1}), and by its hydrolysis to oxalic acid in alkaline conditions. However, other amines

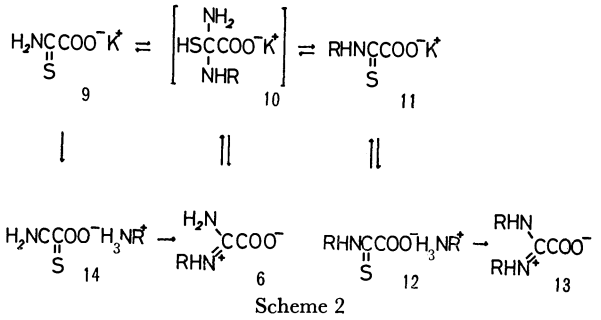
did not react in the same conditions, probably due to the greater insolubility of **9** than products in methanol. The same substitution with alkylamines in water proceed much faster than in methanol, and gave **6**, potassium *N*-substituted-thiooxamidate (**11**) and/or the corresponding alkylamine salt (**12**) in fairly good yield, respectively, depending on conditions used (Method A). The formation of each product could be controlled by adjustment of the amount of water and amine, reaction period, and pH of the reaction mixture. And the mixture of the products was sometimes separated by crystallization.

In general, **6** is formed at first, the use of large amount of water accumulate **11**, and deposition of **12** is accelerated by use of large amount of amine and by neutralization of potassium ion. For example, the reaction of each 50 mmol of **9** and benzylamine in minimum amount of water (25 m*l*) for 15 min at room temperature deposited **6j** in 61% yield, then standing the filtrate overnight gave **11a** (R=benzyl) in 9% yield, and further neutralization of the filtrate caused the deposition of **12a** (R=benzyl) in 10% yield. A similar phenomenon was also observed in the case of cyclohexylamine.

The existence of an equilibrium in this reaction[10] was ascertained by the following experiment; *i. e.*, reaction of **11a** with seven equivalents of ammonia gave **6a**, **6j**, and **12a** in 22, 37, and 11% yield, respectively. From this result, it is obvious that α-alkylamino-α-amino-α-mercaptoacetic acid (**10**) should be exist as an intermediate in the equilibrium between **6**, **9**, and **11**, as shown in Scheme 2. Such a tetrahedral intermediate was deduced in the hydrolysis of thioimidate esters,[11] and also in the hydrolysis of amidines to amides from a kinetic study.[12]

As an attempted acceleration with a metal ion, Zn^{2+} was examined. Addition of zinc chloride to a suspended solution of **9** in methanol made a homogeneous brown solution. However, addition of amines to this brown solution caused the precipitation of a white chelate composed of **9** and zinc (1: 1), which did not show the tendency of reaction with large excess amount of amines under stirring for a week at room temperature. A homogeneous mixture of equimolar amount of **9**, cylcohexylamine or benzylamine, and zinc cyanide or equimolar mixture of zinc chloride and sodium methoxide gave **6i** (R=cyclohexyl) or **6j** in 18 and 17% yield, respectively, under stirring for ten days. These facts indicate that the affinity of zinc to sulfur is very weak in the systems used.



Scheme 2

On the other hand, the structure of **12** was at first deduced to be α,α-bisalkylamino-α-mercaptoacetic acid, from the facts that **12b** (R=cyclohexyl) showed a intense peak *m/e* 187 ($C_8H_{13}NO_2S$) in the mass spectrum which indicates the presence of C–S bond, and the treatment of **12b** with mercuric oxide in methanol gave *N*,*N*′-dicyclohexyl-carbamimidoylformic acid (**13b**: R=cyclohexyl) in 85% yield. However, the deduction was discarded by the facts that it showed $\lambda_{max}^{H_2O}$ 270 nm (ε 8.04×10^3) instead of an end-absorption in usual amidine, and electrophoresis of **12a** at pH 8 showed two ninhydrin-positive spots, where benzylamine moved to the direction of the cathode and **11a** to the

anode. Successful conversion of **12** to **13** indicated the possibility of a synthesis of **6** by treatment of alkylammonium thiooxamidate (**14**) with metal oxides in methanol. In fact, **14** obtained from **9** and amine hydrochlorides or free thiooxamidic acid[13] and amines were smoothly converted to **6** by stirring at room temperature with mercuric oxide or lead oxide in methanol. This method (Method B) was successfully applied to alkyl- and arylamines, and also amino-sugars, as was summarized in Table 1. Among them, benzyl and cyclohexyl 2-amino-2-deoxy-α-D-glucopyranoside were newly prepared from the corresponding 2-acetamido derivatives by an improved method of Gross and Jeanloz.[14]

Contrary to common amidines, exchange-reaction of *N*-substituent in **6** or **13** was generally unsuccessful. For example, reaction of *N*-(*n*-butyl)-carbamimidoylformic acid (**6e**: R=*n*-butyl) and benzylamine at 200°C gave a decarboxylated product: *N,N'*-dibenzylformamidine in 64% yield, and reaction of **6j** and benzylamine in ethanol by refluxing for 5 hr gave *N*-benzylformamide in 37% yield. Direct condensation of **6a** and large excess amount of benzylamine at room temperature for 2 days gave **6j** in 2.8% yield.

Application of the new method mentioned here to the preparation of unsymmetric *N,N'*-disubstituted-carbamimidoylformic acid is now undertaking.

Experimental

All the melting points are uncorrected. The solutions were evaporated under diminished pressure at a bath temperarure not exceeding 45°C. Optical rotations were measured in a 0.5-dm tube at 578 and 546 nm with Carl-Zeiss Polarimeter. The infrared spectra were measured in KBr discs, and the NMR spectra were determined at 100 MHz with a JNM-100H spectrometer, using TMS as an internal reference. The mass spectra were obtained on a Hitachi RMU6E mass spectrometer, using a direct inlet and an ionization energy of 70 eV.

Reaction of Ethyl 1-Carbethoxyformimidate (1) and 2-Amino-2-deoxy-D-glucose (8) Hydrochloride. A suspended solution of 2-amino-2-deoxy-D-glucose hydrochloride (7 g, 33 mmol) and ethyl 1-carbethoxyformimidate (5 g, 34 mmol) in methanol (200 m*l*) was refluxed for 5 hr, and the hydrochloride unchanged was filtered off. Addition of two-fold of ether to the filtrate gave a white crystals, 2-carbomethoxy-4-(D-*arabino*-1',2',3',4'-tetrahydroxybutyl)-imidazole (**2**) which was recrystallized from methanol, in 10% yield (0.8 g). Mp 177.5—176°C; $[\alpha]_D^{23}$ −32° (*c* 1.0, water); UV (nm): λ_{max}^{MeOH} 267 (ε 1.25×10^4); IR (cm^{-1}): 1725 (C=O).

Found: C, 43.46; H, 5.58; N, 11.64%. Calcd for $C_9H_{14}N_2O_6$: C, 43.90; H, 5.73; N, 11.38%.

Concentration of the mother liquor gave a small amount of 3,6-diethoxy-2,5-dihydro-2,5-dioxo-pyrazine (**3**) which was recrystallized from methanol. Mp 167.5—168.2°C; NMR (τ): 5.37 (*q*, 2H, *J*=7.4 Hz), 8.50 (*t*, 3H); IR (cm^{-1}): 1725 (C=O).

Found: C, 49.18; H, 5.13; N, 14.32%. Calcd for $C_8H_{10}N_2O_4$: C, 48.48; H, 5.09; N, 14.14%.

The compound **2** showed negative Fehling test, and the structure was determined as described before. Among them, the periodate oxidation was performed by the method of Fleury and Lange[15], using methyl α-D-glucopyranoside as a reference. The compound **2** consumed 3.23 mol of periodate at room temperature for 15 hr and 3.08 mol at 2.5°C for 18 hr, and the reference 2.30 and 1.94 mol, respectively.

2-Carbomethoxy-4-(D-arabino-1',2',3',4'-tetraacetoxybutyl)-imidazole. To a solution of acetic anhydride (1.74 g, 17 mmol) and pyridine (30 m*l*) was added **2** (0.7 g, 2.8 mmol) with shaking at room temperature, and the reaction mixture was concentrated, after standing for 3 hr. Crystallization of the residual precipitate from methanol gave 0.7 g (60.5%) of white crystals. Mp 171°C; $[\alpha]_D^{23}$ −9° (*c* 1.0, methanol); UV (nm): λ_{max}^{MeOH} 260 (ε 1.05×10^4); IR (cm^{-1}): 3250 (NH), 1745, and 1715 (C=O).

Found: C, 49.20; H, 5.33; N, 6.86%. Calcd for $C_{17}H_{22}N_2O_{10}$: C, 49.27; H, 5.36; N, 6.76%.

2-Oxalylamino-2-deoxy-D-glucose Methylester (5a). To a cooled solution of **1** (3.4 g, 23 mmol) in methanol (20 m*l*) was added dropwise a solution of **8** (5 g, 28 mmol) in methanol (200 m*l*), and the mixture was allowed to stand at room temperature for one day. To the resulted pale yellow solution was added half a volume of ether to give a yellow sirup which could not be crystallized. After a treatment of the sirup once with water, a part of it was crystallized from methanol-ether. Yield, 0.9 g (15%). Mp 188.5—189°C (dec.); $[\alpha]_D^{23}$ +49°→+22° (*c* 1.0, water, 24 hr).

Found: C, 40.99; H, 5.91; N, 5.86%. Calcd for $C_9H_{15}NO_8$: C, 40.75; H, 5.70; N, 5.28%.

2-Oxamidoylamino-2-deoxy-D-glucose. To a cooled solution of **5a** (0.1 g, 3.8 mmol) in methanol (50 m*l*) was passed an excess amount of ammonia, and the solution was evaporated to give a white powder which was crystallized from water-ethanol. Yield, 0.08 g (84%). Mp 190°C (dec.); $[\alpha]_D^{25}$ +24°→+21° (*c* 1.0, water, 45 hr).

Found: C, 38.51; H, 5.50; N, 10.96%. Calcd for $C_8H_{14}N_2O_7$: C, 38.40; H, 5.64; N, 11.20%.

Reaction of p-Toluidine and 2. A solution of *p*-toluidine (2.14 g, 20 mmol) and **1** (2.9 g, 20 mmol) in methanol (40 m*l*) was stood at room temperature for one hr, and then concentrated. The sirup obtained could not be crystallized. A solution of the sirup in N-hydrochloric acid was heated for 1.5 hr at 65°C, neutralized to pH 4.6, and concentrated to about half volume to give a white powder which was crystallized from water. The product melts at 158°C (dec.), and the structure could not be characterized. Yield, 1.6 g (39%). IR (cm^{-1}): 3270, 3160, 1655.

Found: C, 58.46; G, 5.35; N, 13.97%. Calcd for $C_{10}H_{10}N_2O_3$: C, 58.25; H, 4.89; N, 13.58%.

On the other hand, treatment of the sirup with acetic or formic acid and evaporation were repeated twice to give a small amount of *N,N'*-di-(*p*-tolyl)-carbamimidoyl-*p*-toluidide. Mp 178—178.5°C (lit.[16] mp 182°C).

Found: C, 76.82; H, 6.46; N, 10.84%. Calcd for $C_{23}H_{23}N_3O$: C, 77.28; H, 6.49; N, 11.76%. From the mother liquor, a small amount of methyl *N*-(*p*-tolyl)-oxamidate (**5b**), mp 144.5—145.5°C (lit.[17], mp 145°C) was obtained.

Found: C, 62.34; H, 5.62; N, 7.38%. Calcd for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25%.

When the above ester-exchange was performed in the presence of hydrochloride, a small amount of *N,N'*-di-*p*-tolyloxamide was obtained. Mp 264°C (lit.[18], mp 269°C).

Found: C, 71.69; H, 5.89; N, 9.75%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.10; N, 10.44%.

N-Benzylcarbamimidoylformic Acid from Ethyl Thiooxamidate and Benzylamine. To an ice-cooled solution of mercuric chloride (13.5 g, 50 mmol) in ethanol (100 ml) was added ethyl thiooxamidate[9] (6.7 g, 50 mmol) to give white precipitates, and then further addition of benzylamine (10.7 g, 0.1 mol) in ethanol (10 ml) caused the precipitation of mercuric sulfide. The reaction mixture was filtered, and the filtrate was concentrated after addition of concentrated hydrochloric acid (5 ml) and water (100 ml), to give a sirup. After standing this sirup at room temperature for one day, it was dissolved in water and the solution was neutralized to pH 7.0 with N-sodium hydroxide to give white crystals. Yield, 3.0 g (32%), mp 170—171°C (dec.).

Found: C, 57.52; H, 6.03; N, 14.88%. Calcd for $C_9H_{10}N_2O_2 \cdot 1/2H_2O$: C, 57.74; H, 5.92; N, 14.97%.

When a solution of **7** (6.7 g, 50 mmol) and benzylamine (5.4 g, 50 mmol) in ethanol (100 ml) was stood at room temperature in the absence of metal oxide, a small amount of yellow crystals (*N,N'*-dibenzyl-thiooxamic acid amide) were precipitated, which was recrystallized from ethanol. Yield, 0.9 g (12%), mp 118—121°C. IR (cm^{-1}): 3260 (N-H), 1665 (C=O).

Found: C, 67.70; H, 5.55; N, 9.95%. Calcd for $C_{16}H_{16}N_2OS$: C, 67.59; H, 5.67; N, 9.85%.

General Preparation of N-Substituted-carbamimidoylformic Acid (6) by Substitution of Potassium Thiooxamidate (9) with Amines in Water (Method A). Addition of equimolar amount of amines to **9** in the minimum amount of water caused the deposition of **6** within 15 min–1 hr. If the product is soluble in water, **Method B** must be used, because the enforcement of deposition of **6** by neutralization of the reaction mixture yielded sometimes **12**, which was isolated in the case of benzylamine and cyclohexylamine. Results obtained were summarized in Table 1.

Potassium N-Benzyl-thiooxamidate (11a). To a solution of **9** (7.2 g, 50 mmol) in water (200 ml) was added benzylamine (5.4 g, 50 mmol) in water (100 ml), and then concentrated after standing for half an hour to give yellow crystals which was recrystallized in ethanol-water. (2:1 v/v). Yield, 10.0 g (86%), mp 235—238°C.

Found: C, 46.61; H, 3.60; N, 6.04%. Calcd for $C_9H_8KNO_2S$: C, 46.33; H, 3.46; N, 6.02%.

Alkylammonium N-Substituted-thiooxamidate (12). *a) Benzylammonium N-Benzylthiooxamidate (12a)*: A solution of **9** (4.3 g, 30 mmol) and benzylamine (4.3 g, 40 mmol) in water (50 ml) was stood for one day to deposit yellow crystals. Yield, 2.7 g (30%), mp 166—167°C (dec.).

Found: C, 63.32; H, 5.76; N, 9.56; S, 10.68%. Calcd for $C_{16}H_{18}N_2O_2S$: C, 63.56; H, 6.00; N, 9.27; S, 10.59%.

b) Cyclohexylammonium N-Cyclohexylthiooxamidate (12b): A solution of **9** (14.3 g, 0.1 mol) and cyclohexylamine (25 g, 0.25 mol) in water (100 ml) was stood at room temperature for 15 hr, and neutralized to pH 5.0 with N-hydrochloric acid. The pale yellow crystal separated was purified from ethanol. Yield, 9.2 g (32.2%), mp 181—182°C (dec.). MS (*m/e*): 187 ($C_8H_{13}NO_2S$), 141 ($C_7H_{11}NS$), 112, 106, 99 ($C_6H_{13}N$; cyclohexylamine).

Found: C, 59.04; H, 9.05; N, 9.69; S, 11.25%. Calcd for $C_{14}H_{26}N_2O_2S$: C, 58.72; H, 9.15; N, 9.78; S, 11.18%.

The structure of **12** was determined as described before. Among which, electrophoresis was carried out on Toyo Filterpaper No. 51 at pH 8 and 20 Volt/cm for 2 hr with phosphate buffer. In the case of **12a**, *N*-benzylthiooxamidic acid moved 9.7 cm to anode and benzylamine 4.6 cm to cathode, whereas reference substances moved as the same distance.

N,N'-Disubstituted-carbamimidoylformic Acid (13). *a) Benzyl Derivative (13a)*: A suspended solution of **12a** (6 g, 20 mmol) and mercuric oxide (4.8 g, 22 mmol) was stirred for 15 hr at room temperature, and filtered. Concentration of the filtrate gave white crystals which was purified from water-methanol (1:1). Yield, 3.2 g (60%), mp 143—144°C.

Found: C, 71.89; H, 5.94; N, 10.31%. Calcd for $C_{16}H_{16}N_2O_2$: C, 71.62; H, 6.01; N, 10.44%.

b) Cyclohexylamine Derivative (13b): A similar treatment of **12b** with mercuric oxide gave **13b** in 85% yield, which was purified from ethanol. Mp 139°C.

Found: C, 66.40; H, 9.77; N, 10.93%. Calcd for $C_{14}H_{24}N_2O_2$: C, 66.63; H, 9.59; N, 11.10%.

General Preparation of 6 by Treatment of 14 with Lead Oxide (Method B). A mixture of **14**, which was prepared from equimolar amount of **9** and amine hydrochlorides or free thiooxamidic acid[13] and amines, and about four equimolar amount of lead oxide in suitable amount of methanol was shaked at room temperature for 3 to 7 hr, and lead sulfide was filtered off. Concentration of the filtrate gave *N*-monosubstituted-carbamimidoylformic acids usually in 50—80% yield, as shown in Table 1.

Benzyl 2-Amino-2-deoxy-α-D-glucopyranoside Hydrochloride. A solution of benzyl 2-acetamido-2-deoxy-α-D-glucopyranoside (31 g, 0.1 mol) and potassium hydroxide (60 g, 1.1 mol) in ethanol (150 ml) was refluxed in an oil-bath for 5 hr at 120—125°C, neutralized with concentrated hydrochloric acid (95 ml) under cooling, and potassium chloride precipitated was then filtered off. Evaporation of the filtrate gave crystals in 85% yield, which was recrystallized from methanol. Mp 235—236°C (dec.); $[\alpha]_D^{23}$ +122° (*c* 1.0, water).

Found: C, 50.84; H, 6.43; N, 4.97%. Calcd for $C_{13}H_{19}NO_6HCl$: C, 51.06; H, 6.59; N, 4.58%.

Cyclohexyl 2-Amino-2-deoxy-α-D-glucopyranoside Hydrochloride. A similar treatment of cyclohexyl 2-acetamido-2-deoxy-α-D-glucopyranoside, which was prepared from 2-acetamido-2-deoxy-D-glucose by the method of the authors[19] in 60% yield (Mp 184—186°C; $[\alpha]_D^{23}$ +126° (*c* 1.0, water); Found: C, 55.39; H, 8.03; N, 4.78%. Calcd for $C_{14}H_{25}NO_6$: C, 55.43; H, 8.31; N, 4.62%), with potassium hydroxide gave crystals in 35% yield, which was recrystallized from methanol. Mp 250°C (dec.); $[\alpha]_D^{23}$ +120° (*c* 1.0, water).

Found: C, 48.28; H, 8.34; N, 4.62%. Calcd for $C_{12}H_{23}NO_5HCl$: C, 48.39; H, 8.13; N, 4.70%.

Attempted Substitutions of 6 with Amines. a) A suspended solution of **6a** (0.88 g, 10 mmol) in benzylamine (30 ml) was stirred for two days to give pale yellow homogeneous solution. This solution was neutralized with acetic acid, and mixed with a small amount of water. Filtration of the insoluble material gave **6j** in 2.8% yield. Mp 170°C.

b) A mixture of **6e** (1.4 g, 10 mmol) and benzylamine (2.1 g, 20 mmol) was heated at 200°C for 1 hour, and crystals appeared after cooling was filtered and recrystallized from ligroin. This crystals was determined to be *N,N'*-dibenzylformamidine from elemental analysis and mp. Yield, 1.4 g, (63.5%). Mp 76—77°C (lit.[20] mp 79°C) (Found: C, 80.59; H, 7.10; N, 12.51%. Calcd for $C_{15}H_{16}N_2$: C, 80.32; H, 7.19; N, 12.49%).

c) A solution of **6j** (1.8 g, 10 mmol) and benzylamine (1.1 g, 10 mmol) in the ethanol was refluxed for 5 hr, and concentrated. The residue was dissolved in ether, and insoluble materials (**6j**, 0.8 g) was filtered off. Concentration of the filtrate gave *N*-benzylformamide, which was recrystallized from ligroin - ether. Yield, 0.5 g (37%). Mp 61—62°C

Studies of the Synthesis of Furan Compounds. XXV.[1] 2-[2-(5-Nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazoles and -1,3,4-thiadiazoles[2]

Ichiro HIRAO and Yasuhiko KATO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu

(Received May 10, 1971)

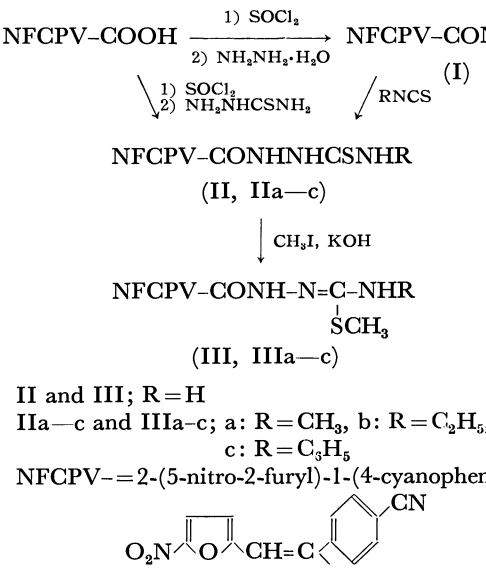
5-Amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazoles and -1,3,4-thiadiazoles have been synthesized from 3-(5-nitro-2-furyl)-2-(4-cyanophenyl)acrylic acid according to a procedure previously described.[3] All of these compounds exhibit strong antibacterial activity against *Staphylococcus aureus*, but they exhibit a weak activity, or almost no activity, against the other microorganisms tested.

2-[2-(5-Nitro-2-furyl)-1-substituted]vinyl-1,3,4-oxadiazole derivatives have been synthesized in order to investigate the influence of β-substituents at a –C=C– side chain of the furan ring upon the antibacterial activity. In the course of the investigation, the present authors have previously reported compounds whose β-carbon at a –C=C– side chain of the furan ring were bound to hydrogen,[4] methyl,[5] phenyl,[6] 2-furyl,[7] and 4-nitrophenyl[3] groups. This paper will deal with the introduction of a 4-cyanophenyl group into that position.

Results and Discussion

3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloylhydrazine (I) was prepared from the chloride of 3-(5-nitro-2-furyl)-2-(4-cyanophenyl)acrylic acid[8] with hydrazine hydrate by the use of methylene chloride as the solvent and without the formation of 1,2-bis[3-(5-nitro-2-furyl)-2-(4-cyanophenyl)acryloyl]hydrazine as a by-product.

1-[3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloyl]-thiosemicarbazide (II) and its 4-substituted derivatives (IIa: R=CH_3, IIb: R=C_2H_5, and IIc: R=C_6H_5) were obtained respectively, by the treatment of the corresponding acid chloride with thiosemicarbazide and by the reaction of I with the corresponding isothiocyanates. The treatment of II and IIa—IIc with methyl iodide afforded the corresponding *S*-methylisothiosemicarbazide (III) and its 4-substituted derivatives (IIIa—c).



II and III; R=H

IIa—c and IIIa-c; a: R=CH_3, b: R=C_2H_5, c: R=C_3H_5

NFCPV-=2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl;

The introduction of phosgene into a solution of I in dioxane-water produced 2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazolone (IV) in a good yield. This compound was confirmed to have the keto-structure from the infrared absorption bands[9] at 3350 (N–H) and 1772 cm^{-1} (C=O). The treatment of IV with a large excess of acid anhydrides or with 2—3

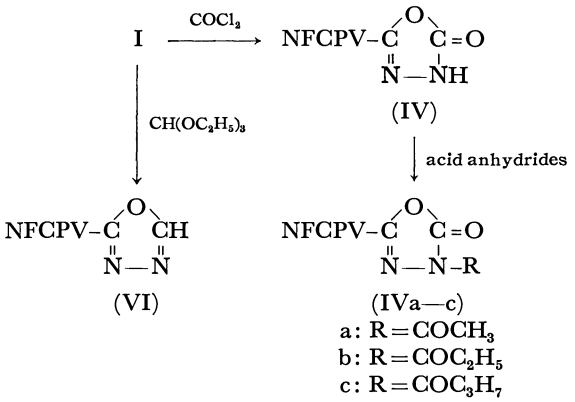
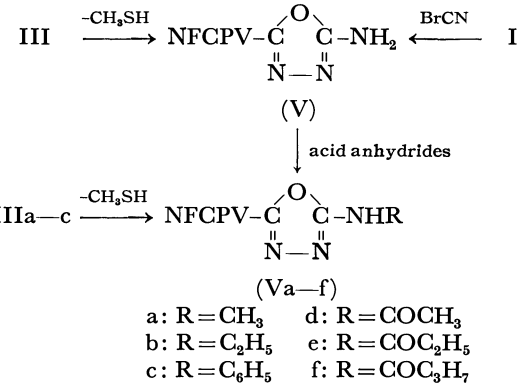
9) The infrared absorption spectra in this experiments were obtained with a Shimadzu IR-27S spectrophotometer with KBr method.

equimolar acid anhydrides in dioxane gave the corresponding monoacyl derivatives (IVa: R=$COCH_3$, IVb: R=COC_2H_5, and IVc: R=COC_3H_7). These compounds seems to be the *N*-acyl compounds, since the IR spectra contained two C=O absorptions, one near 1770 and the other near 1790 cm^{-1}, thus eliminating the posibility of *O*-acylation.



When heated in ethanol, III was cyclized to 5-amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazole (V) in a good yield. Compound V was also produced from I and cyanogen bromide. Similar treatment of IIIa—IIIc in refluxing ethanol afforded 5-substituted amino-derivatives (Va: R=CH_3, Vb: R=C_2H_5, and Vc: R=C_6H_5). 5-Acylamino derivatives (Vd: R=$COCH_3$, Ve: R=COC_2H_5, Vf: R=COC_3H_7) were similarly prepared by the heating of V with acid anhydrides. 2-[2-(5-Nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazole (VI) was obtained by refluxing I in ethyl orthoformate.

5-Amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)-vinyl]-1,3,4-thiadiazole (VII) was obtained by the dehydration-cyclization of II with surplus phosphoryl



chloride. 5-Alkyl and 5-phenyl-amino-1,3,4-thiadiazoles (VIIa: R=CH_3, VIIb: R=C_2H_5, and VIIc: R=C_6H_5) were prepared by the similar treatment of IIa—IIc with phosphoryl chloride, while the treatment of VII with acid anhydrides afforded 5-acylamino derivatives (VIId: R=$COCH_3$, VIIe: R=COC_2H_5, and VIIf: R=COC_3H_7). All of these compounds are listed in Tables 1 and 2.

a) 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic amide was used in the test.

Microbiological Assays.[10] The antibacterial activities of the compounds toward ten microorganisms were examined. The minimum amount of each compound necessary for the complete inhibition of growth was determined by dilution method, using the usual bouillon agar medium (pH 6.8—7.0); some of the results are shown in Table 3. The antibacterial activity of this type of compound showed a behavior similar to that of the compounds possessing a 4-nitrophenyl group[3] previously reported on. All of the compounds tested exhibited a strong activity against *Staphylococcus aureus*, but showed only a weak antibacterial activity at best against the other microorganisms employed. In conclusion, the introduction of a 4-cyanophenyl group into the β-carbon of the –C=C– side chain did not increase the activity.

Experimental[11]

3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloyl Chloride A mixture of 3-(5-nitro-2-furyl)-2-(4-cyanophenyl)acrylic acid[8] (19.9g, 0.07 mol), thionyl chloride (12 g, 0.1 mol), *N,N*-dimethylformamide (1 g), and chlorobenzene (300 m*l*) was stirred at 65—70°C for 1 hr. The resulting solution was cooled with an ice-salt bath, and the acid chloride was separated as yellow crystals, filtrered, washed with dry ether, and used in the following experiments without further purification.

3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloylhydrazine (I). To a stirred, cooled (—5—0°C) mixture of 80% hydrazine hydrate (10.1 g, 0.2 mol), water (10 m*l*), and methylene chloride (90 m*l*), we added, drop by drop a solution of the acid chloride (15.2 g, 0.05 mol) in 350 m*l* of methylene chloride in 30 min. After the addition, the temperature was allowed to rise to room temperature, after which stirring was continued for an additional hr. The resulting suspension was filtered, and the residue was washed with aqueous methanol and then dried to afford 11.4 g (76.5%) of a yellow product melting with decomposition at 217—218°C. Recrystallization from methanol gave yellow leaflets; mp 219°C dec. The yield was 9.7 g (65.1%).

Found: C, 56.21; H, 3.21; N, 18.77%. Calcd for $C_{14}H_{10}N_4O_4$: C, 56.38; H, 3.36; N, 18.79%.

1-[3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloyl]thiosemicarbazide (II). A solution of the acid chloride (9.1 g, 0.03 mol) in dry dioxane (700 m*l*) was stirred slowly into a suspension of thiosemicarbazide (3.28 g, 0.036 mol) and sodium bicarbonate (10 g, 0.12 mol) in 70 m*l* of dioxane. The suspension was stirred for 1 hr at room temperature and then heated at 80°C for 3 hr. After cooling, yellow precipitates were filtered out and poured into aqueous hydrochloric acid. The insoluble product was collected on a filter, washed with water, and then dried. In this way was obtained 8.4 g (77.6%) of a crude product melting with decomposition at 196—197°C. Crystallization from *N,N*-dimethylformamide-water (5: 3, vol/vol) gave yellow prisms (Table 1).

4-Substituted 1-[3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloyl]-thiosemicarbazides (IIa-c). A mixture of I (2 g, 6.7 mmol), alkyl (or phenyl) isothiocyanate (10 mmol), and methanol (100 m*l*) was refluxed for 2—3 hr. The resulting solution was cooled or concentrated, and the precipitated product was collected by filtration. Recrystallization from methanol gave a pure product, as is shown in Table 1.

1-[3-(5-Nitro-2-furyl)-2-(4-cyanophenyl)acryloyl]-S-methylisothiosemicarbazide (III) and Its 4-Substituted Derivatives (IIIa–c). To a stirred mixture of 5 mmol of II (or IIa-c), methyl iodide (15 mmol), and ethanol (30—45 m*l*) was added, drop by drop, a solution of potassium hydroxide (5 mmol) in 40 m*l* of ethanol. After the addition, stirring was continued for 10—12 hr at room temperature. The resulting suspension was filtered, and the residue was washed with a small amount of cold ethanol and dried. When the products were heated in solvents, decomposition occurred with the evolution of methyl mercaptan, but these products were pure enough, as is shown by the results of elemental analyses (Table 1).

2-[2-(5-Nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazol-5-one (IV). To a stirred solution of I (5.96 g, 20 mmol) in 400 m*l* of dioxane-water (3:2, vol/vol), phosgene was introduced under cooling at 15—17°C. After 2 hr, the precipitated product was collected and washed with water to give 6.4 g (quantitative) of crude IV; mp 182—184°C. Recrystallization was then carried out (Table 2).

4-Acyl-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazol-5-ones (IVa–c). A mixture of IV (0.32 g, 1 mmol) and 5 m*l* of acid anhydride (or 0.4 g of acid anhydride and 5 m*l* of dioxane) was heated on a steam bath for 1—2 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with water, dried, and recrystallized. The yields and mps of the products are given in Table 2.

2-[2-(5-Nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazole (VI). A suspension of I (2.98 g, 10 mmol) in ethyl orthoformate (70 m*l*) was heated at 100—105°C for 8—10 hr. The resulting solution was concentrated *in vacuo*, and the product was filtered and washed with cold ethanol. Recrystallization from methanol gave VI as ochreous prisms; mp 225—226°C dec. The yield was 2.68 g (87.2%).

Found: C, 58.23; H, 2.42; N, 17.80%. Calcd for $C_{15}H_8N_4O_4$: C, 58.44; H, 2.60; N, 18.18%.

5-Amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazole (V). *Procedure A*: A suspension of III (3.71 g, 10 mmol) in ethanol (80 m*l*) was refluxed until the evolution of methyl mercaptan had ceased (*ca.* 4.5 hr). The resulting solution was taken to dryness *in vacuo*, and the residue was crystallized from methanol to give 2.76 g (85.4%) of V as yellow prisms.

Procedure B: A mixture of I (1.49 g, 5 mmol), cyanogen bromide (0.85 g, 8 mmol), and 100 m*l* of methanol was heated under reflux for 2 hr. Cooling then provided 1.46 g (90%) of yellow crystals, mp 167—169°C dec. Recrystallization from methanol raised the melting point to 246—247°C dec; this melting point was undepressed on admixture with a sample prepared by *Procedure A* as above for V.

5-Substituted Amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-oxadiazoles (Va–c). These were prepared in the same way as V above (*Procedure A*) using 5 mmol of 4-substituted *S*-methylisothiosemicarbazide derivatives (IIIa–c).

5-Amino-2-[2-(5-nitro-2-furyl)-1-(4-cyanophenyl)vinyl]-1,3,4-thiadiazole (VII) and 5-Substituted Amino Derivatives (VIIa–c). A mixture of 5 mmoles of II (or IIa-c) and phosphoryl chloride (10 m*l*) was heated under refiux for 2–3 hr. The solution was then poured onto crushed ice, and the solidified product was filtered, washed with water, and dried. Two or three recrystallizations gave a pure product (Table 2).

5-Acylamino Derivatives of V and VII. Compound V (or VII) (2 mmol) was covered with the acid anhydride (7 m*l*) and heated on a steam bath for 2—3 hr. Water (30 m*l*) was then added to the resulting solution to decompose the excess acid anhydride. The product was collected, washed with water, and dried. In this way, the corresponding acyl products were obtained; recrystallizations were achieved from solvents or solvent pairs, as is shown in Table 2.

11) All the melting and decomposition points are uncorrected. The elemental analyses were performed on a Yanagimoto CHN Corder MT-2 type.

Retardation Effect Induced by Pyridine in the Radical Copolymerization of Styrene and Liquid Sulfur Dioxide

Tsutomu ENOMOTO,* Masashi IINO, Minoru MATSUDA, and Niichiro TOKURA*

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received May 12, 1971)

We have found that the radical copolymerization of styrene and liquid sulfur dioxide (liq. SO_2) is retarded when a basic solvent such as pyridine is used; we also investigated the mechanism of the retardation induced by pyridine. The polymerization in pyridine was most strongly retarded when the styrene mole fraction in the feed, $[St]_0/([St]_0+[SO_2]_0)$, was small (below about 0.2) and when the pyridine mole fraction in pyridine-liq.SO_2, $[Py]_0/([Py]_0+[SO_2]_0$, was 0.4—0.5. Moreover, from the results in the reaction of the phenylsulfonyl radical (the model radical for the propagating sulfonyl radical) in pyridine or in a pyridine - liq. SO_2 mixture, it may be concluded that the end unit of the polymer has the pyridinium sulfonate structure ($-SO_3^-HPy^+$) and that the retardation may occur by means of the reaction of the propagating sulfonyl radical with the pyridine-SO_2 complex.

We have been investigating the solvent effect on the compositions of copolymers obtained by the radical copolymerization of styrene and liquid sulfur dioxide (liq. SO_2). The following results have so far been obtained; the copolymer compositions depend on the total monomer concentration and on the nature of the solvent, but hardly on feed composition; that is, the styrene content in the copolymer increases with an increase in the volume fraction of the solvent and by the addition of a basic solvent such as pyridine.[1)]

Furthermore, we have found that this polymerization is retarded when a basic solvent such as pyridine, triethylamine, or furan is used.

In this paper, we will dicsuss the mechanism of the retardation induced by pyridine.

Results and Discussion

Retardation of the Radical Copolymerization of Styrene and Liq. SO_2 by Pyridine. In Table 1 the qualitative results are summarized. Table 1 shows that; (1) the polysulfone (methanol-insoluble polymer) is not obtained in pyridine, but is obtained in dichloromethane under the same experimental condition (runs 1 and 2); (2) by increasing the styrene mole fraction in the feed or the azobisisobutyronitrile (AIBN) concentration, polysulfone is obtained, even in pyridine (runs 3, 4, 5, and 6); (3) retardation is also observed in the radical copolymerization of hexene-1 and liq. SO_2 (runs 7 and 8); (4) by the evaporation of the methanol solutions of runs 1, 4, and 5, methanol-soluble (low-molecular weight) styrene polysulfone is obtained.

These results suggest that retardation may occur by the deactivation of the propagating sulfonyl radical (by degradative chain transfer or addition reaction which forms an inactive radical).

Next, we have investigated the rate of copolymerization in pyridine with AIBN under the experimental conditions in which methanol-insoluble polymer was obtained. The styrene mole fraction in the feed and the total concentration of pyridine and liq.SO_2 were kept constant at 0.2 and 12.0 mol/*l* respectively, while the mole fraction of liq.SO_2 in pyridine-liq.SO_2, $[SO_2]_0/([SO_2]_0+[Py]_0)$, was varied from 0.2 to 0.8, using cyclohexane as an inert solvent.[1)] The polymerization rates (mol conv./hr) were calculated using both the initial slope of the time-conversion curves and the copolymer compositions, as is shown in Table 2. Rates relative to the rate of run 7 (Table 2) are plotted against $[SO_2]_0/([SO_2]_0+[Py]_0)$ in Fig. 1. From Fig. 1 it is clear that polymerization was most strongly retarded when comparable amounts of pyridine and

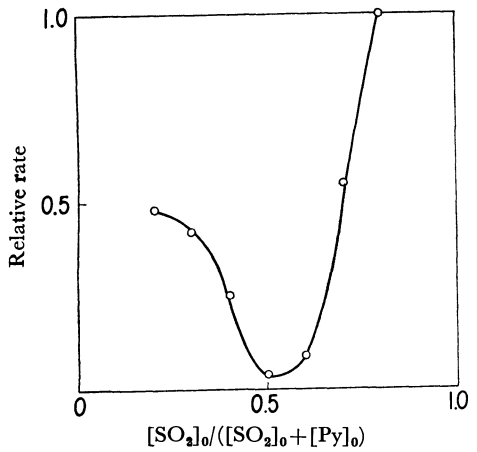

Fig. 1. The plot of relative rate (Table 2) of copolymerization in pyridine against liq. SO_2 mole fraction in liq. SO_2-pyridine, $[SO_2]_0/([SO_2]_0+[Py]_0)$.

liq.SO_2 were present ($[SO_2]_0/([SO_2]_0+[Py]_0)\approx0.5$—$0.6$) and was less retarded when there was an excess of pyridine.

From this fact we can speculate that retardation may occur as a result of the reaction of the propagating sulfonyl radical and the pyridine-SO_2 complex. It is well known that SO_2 behaves as an electron acceptor and forms charge-transfer complexes with pyridine and various amines. Although it has been reported[2] that SO_2 forms a 1:1 (mole) complex with pyridine, our finding,[3] obtained by the continuous-variation method in UV spectra, has shown that the complex consists of one mole of pyridine and two moles of SO_2.

Thermal and Photochemical Decompositions of Phenyl Phenylsulfonyl Diimide (PPD) in Pyridine or in a Pyridine-Liq.SO_2 Mixture. To make clear the retardation mechanism speculated as above, we have carried out a model reaction using the phenylsulfonyl radical.

The α-phenylethanesulfonyl radical is better than the phenylsulfonyl radical as a model radical for the propagating sulfonyl radical in the copolymerization of styrene and liq.SO_2, but attempts to prepare it in a solution containing pyridine were unsuccessful.

As the source of the phenylsulfonyl radical, we have used phenyl phenylsulfonyl diimide (PPD), which has been reported by Rosenthal and Overberger[4] to form this radical by thermal decomposition. Phenylsulfonyl halide was inadequate because of its ionic reaction with pyridine.

The results obtained are summarized in Table 3. Table 3 shows that pyridinium benzenesulfonate ($PhSO_3^-HPy^+$,PBS) was obtained in a good yield in the reaction in the pyridine-liq.SO_2 mixture; on the other hand, in pyridine this product was not obtained. PBS is water-soluble and was obtained from the water-soluble part of the reaction mixture, as will be described in the Experimental section. From the ether-soluble part, we obtained azobenzene; its yield was best in the reaction in pyridine. We could not identify

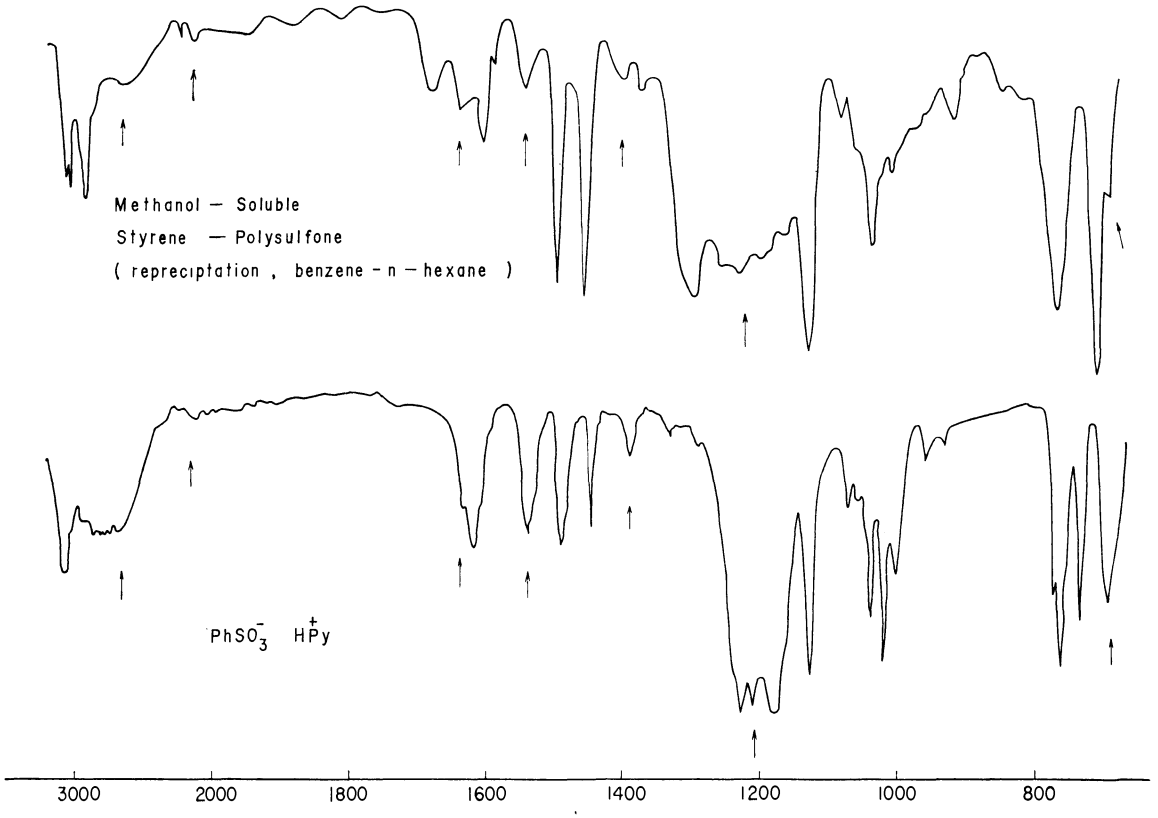

Fig. 2. IR spectra of methanol-soluble styrene-polysulfone obtained by copolymerization in pyridine and $PhSO_3^-$ HPy^+.

any product other than azobenzene from the ether-soluble part.

Table 4 shows that the photolysis of PPD at room temperature in the pyridine-liq.SO_2 mixture gave PBS, while in the dark the reaction did not occur. It is well known that an azo-compound such as PPD is subject to homolysis by light and forms two radicals and nitrogen. Therefore, the results in Table 3 indicate that PBS arises from the phenylsulfonyl radical.

The infrared spectra of methanol-soluble styrene polysulfone described in the preceeding section and PBS are shown in Fig. 2. The arrow in the spectra of polysulfone indicates a peak which does not exist in ordinary styrene polysulfone obtained in bulk or in a non-basic solvent. It is clear that these peaks arise from the end unit of this polymer, formed by termination. The peak at 2200 cm^{-1} indicates the presence of the moiety of the initiator (AIBN) as another end unit of this polymer. All the peaks denoted by arrows also exist in the spectra of PBS. This fact indicates that the end unit of this polymer has a structure similar to that of PBS, namely, $-SO_3^-HPy^+$. In fact, the aqueous solution of this polymer (it is dissolved for the most part in water) is acidic, as is PBS. From the above results, it seems certain that retardation occurs by the deactivation of the propagating sulfonyl radical and that pyridinium sulfonate is formed ultimately. Moreover, the fact that PBS is obtained in a pyridine-liq.SO_2 mixture, but not in pyridine, suggests that the propagating sulfonyl radical is deactivated by the reaction with the pyridine-SO_2 complex.

The results in the thermal decompositions of phenyl *p*-methylphenylsulfonyl diimide (*p*-methylPPD) and phenyl *p*-chlorophenylsulfonyl diimide (*p*-chloroPPD) are summarized in Table 5. In *p*-methylPPD, though the yield was low, pyridinium *p*-toluenesulfonate (*p*-methylPBS) was obtained in the reaction in pyridine. Its formation may be considered to be due to the reaction of pyridine and *p*-toluenesulfinic acid, which is itself formed by the following hydrogen abstraction reaction, because *p*-methylPPD has very reactive hydrogen atoms (a methyl group attached to a phenyl group) toward abstraction, while PPD and *p*-chloroPPD, in which no pyridinium sulfonates were obtained in pyridine, have no such hydrogen atoms;

$$CH_3C_6H_4SO_2\cdot + CH_3C_6H_4SO_2N_2C_6H_5 \longrightarrow CH_3C_6H_4SO_2H + \cdot CH_2C_6H_4SO_2N_2C_6H_5$$

a) 70°C, 24 hr. b) SO_2 mole fraction in pyridine-liq.SO_2.
c) It includes a small amount of PBS (from its NMR spectra). d) Based on diimide.

In fact, we have carried out the reaction of benzene sulfinic acid with pyridine and obtained PBS, as will be described in the Experimental section. In *p*-chloro-PPD, pyridinium *p*-chlorobenzenesulfonate (*p*-chloro-PBS) and PBS were obtained in the pyridine-liq.SO_2 mixture, but not in pyridine. PBS probably arises from the phenylsulfonyl radical formed by the addition reaction of the phenyl radical and SO_2. These results also support the idea that the sulfonyl radical is deactivated by the reaction with the pyridine-SO_2 complex.

We can suggest the following two mechanisms as possible for the deactivation of the sulfonyl radical;

(1) $\sim SO_2\cdot$ + complex $\longrightarrow$
$\sim SO_2H$ + inactive radical $\xrightarrow{+Py}$
$\sim SO_3^-HPy^+$

(2) $\sim SO_2\cdot$ + complex $\longrightarrow$
$\sim SO_2$ − complex·(inactive radical) $\longrightarrow$
$\sim SO_3^-HPy^+$

It is well known that when a radical attacks an aromatic ring, an addition reaction (mechanism 2) usually occurs, but not hydrogen abstraction reaction (substitution reaction on hydrogen, mechanism 1).[5] Accordingly, it seems reasonable to consider that retardation occurs by the addition reaction of the sulfonyl radical to the complex and the formation of an inactive (stable) radical (mechanism 2).

Experimental

Materials. Styrene, AIBN, pyridine, dichloromethane, and cyclohexane were purified by the usual method. Liq. SO_2 was dehydrated by phosphorus pentoxide and distilled *in vacuo*. PPD was prepared[6] from sodium benzenesulfinate and benzenediazonium chloride and was recrystallized from ethanol (mp 74—76°C; lit,[6] 78°C). *p*-MethylPPD and *p*-chloroPPD were prepared using the same method (*p*-methyl PPD: mp 93—95°C; lit,[7] 95°C, *p*-chloroPPD: mp 102—103°C; lit,[6] 106°C).

Copolymerization of Styrene and Liq.SO_2. Polymerization was carried out using a method previously reported.[8] The polymerization rates were measured by the gravimetric method, and the copolymer compositions were determined from the elementary analyses of carbon.

Thermal Decomposition of PPD in Pyridine or in a Pyridine-Liq.SO_2 Mixture. 9.84 g (0.04 mol) of PPD were reacted at 70°C for 24 hr in pyridine (50 or 80 ml) or in a pyridine-liq.SO_2 mixture. The mole fraction of liq.SO_2 in the pyridine-liq.SO_2 mixture was varied from 0.2 to 0.8 (pyridine +liq.SO_2=60 ml; Table 3). After the reaction the liq.SO_2 was evaporated and the pyridine was distilled off under reduced pressure (1—2 mmHg). The residue thus obtained was extracted with water and ether. In the case of the reaction in the pyridine-liq.SO_2 mixture, the evaporation of the water of the water layer and recrystallization from acetone gave PBS (2.9—5.5 g; Table 3): hygroscopic, mp 129.5—132°C; lit,[9] 125—130°C. Its IR and NMR spectra coincided with those of an authentic sample prepared from benzene sulfonic acid and pyridine. PBS could also be obtained by extraction with dehydrated acetone instead of water. This fact indicates that PBS is not formed by the addition of water. On the other hand, in the case of the reaction in pyridine, the evaporation of the water from the water layer gave no PBS, but did give an unidentified product in only a small yield (0.8 g): nonhygroscopic, mp 200—202°C. In either pyridine-liq.SO_2 or pyridine systems, the ether layer was chromatographed on a silica gel column; subsequent elution with a petroleum ether-benzene mixture gave azobenzene in a yield such as is shown in Table 3: mp 65—68°C, identified by comparison with an authentic sample.

In *p*-methylPPD, *p*-methylPBS was identified by comparison with an authentic sample: hygroscopic, mp 117—123°C (recrystallized from acetone); lit,[10] 119—121°C. In the case of *p*-chloroPPD, the IR spectrum of the product shows, when compares with that of authentic *p*-chloroPBS, that a mixture of *p*-chloroPBS and PBS was obtained.

Photo-decomposition of PPD. The reactants in a quartz-reaction vessel were irradiated at room temperature by means of a high-pressure mercury lamp about 5 cm from the vessel.

The Reaction of Benzenesulfinic Acid with Pyridine. 5.26 g (0.03 mol) of benzenesulfinic acid and pyridine (30 ml) were reacted at 70°C for 24 hr. By the same procedure as in the case of PPD, 1.38 g (19.3%) of PBS were thus obtained. 0.3 g of PBS was also obtained in the reaction in the pyridine −liq.SO_2 mixture (mole ratio 1:1) instaed of in pyridine.

Measurement of the Nitrogen Volume Evolved. The volume of the nitrogen evolved was measured from the difference in the volumes at 20°C and 1 atm before and after the reaction, using a mercury manometer. The reaction vessel was filled with nitrogen at 1 atm and 20°C prior to the reaction. In the measurement, the reaction vessel was cooled by liquid nitrogen to prevent any effect of the liq.SO_2.

Conformations of the Esters. II.[1] The Conformation of Alkyl Acetates

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 13, 1971)

Alkyl acetates which carry secondary and tertiary alkyl groups have been found to have bifurcated bands in the carbonyl region of the infrared spectra. The origin of the bifurcated bands has been studied carefully, and it has been concluded that the Fermi resonance is the most probable origin of the phenomenon.

The conformation of the ester group has long been believed to be *s-trans*. The conformation of acetates is not an exception; it has been reported that alkyl acetates take the *s-trans* conformation, judging from the results of dipole-moment measurements,[2] electron diffraction,[3] and infrared spectroscopy.[4] The only exception is the report by Monaham[5] which postulates that the *s-cis* conformer exists in poly(*t*-butyl acrylate) and *t*-butyl acetate after irradiation by light, as revealed by the temperature dependence of the infrared spectra in the lower-frequency region. In the light of the fact that the *s-cis* conformer can exist together with the *s-trans* in some esters of formic acid which carry a bulky alkyl group,[1] it seems that it would be interesting to reinverstigate the situation of the acetate esters. Since it is believed that the *s-cis* conformation can exist in formates, because hydrogen is the smallest alkyl group in *n*-alkanoic acids and the steric repulsion between the alkyl group of an alcoholic part and hydrogen must be the least, the methyl group in acetates serves as a critical example in diagnosing the conformations of the ester group derived from the higher alkanoic acids: if no *s-cis* conformation exist in acetates, other higher alkanoic acid esters can not possibly show signs of the existence of the stable *s-cis* conformer. Thus, the infrared and nuclear magnetic resonance spectra of acetates have been reexamined. The purpose of this paper is to report the results of this investigation.

Fig. 1. Two conformers of acetate.

Experimental

Materials. Various alkyl acetates were prepared according to the standard method. The purity of the samples was checked by means of their physical constants, infrared spectra, nuclear magnetic resonance spectra, and results of gas chromatography. *t*-Butyl acetate-d_3 (CD_3CO_2t-Bu) was prepared from *t*-butyl alcohol and acetyl-d_3 chloride in the presence of pyridine.

Spectra. The infrared spectra were measured by using a Hitachi EPI-G2 grating infrared spectrophotometer (4000——400 cm^{-1}) and a Perkin Elmer 112G single-beam grating spectrophotometer (3600—3300 cm^{-1}, 1800—1700 cm^{-1}). The latter instrument is more precise; the error is estimated to be 0.4 cm^{-1} at 1750 cm^{-1}. The absorption curves due to the carbonyl stretching of alkyl acetates were graphically separated, and it was confirmed that almost all the peaks were in good agreement with the calculated Lorenzian curves. The nuclear magnetic resonance spectra were recorded on a JNM-4H-100 spectrometer.

Results and Discussion

As has previously been described,[1] the chief factors governing the preference of the conformations of the ester group can be considered to include the following three: 1) the dipole-dipole interaction between C=O and O–R bonds, 2) the repulsion between lone-pair electrons of two oxygen atoms, and 3) the steric repulsion between either C=O and R or CH_3 and R (Fig. 2).

As to the first two factors, the *s-trans* conformer is favored over the *s-cis*. However, the third factor, which makes the existence of the *s-cis* conformer in *t*-butyl formate possible, may also operate in acetates so that the *s-cis* conformer exists. Although, of course, the repulsion between methyl and R groups cannot be overcome by that between R and carbonyl oxygen in a usual sense, there is a possibility that the ester group becomes non-planar because of the severe repulsion in

the planar conformation and that, in such a conformation, the *s-cis* becomes relatively favored.

Infrared Spectra. From the results obtained with formates[1] it is expected that the *s-cis* and *s-trans* conformations of acetates are reflected in the carbonyl stretching vibration absorptions. Many authors have reported on the infrared C=O stretching spectra of acetates,[7,8] but none has discussed the shapes of the absorptions, most of the attention being devoted to the frequencies and intensities of the bands. The results obtained in this study are shown in Table 1. It can be pointed out immediately that methyl and ethyl acetates give only one absorption (which is sharp and symmetrical) in the solvents studied, whereas isopropyl and *t*-butyl acetates give rise to two absorptions. Clearly those acetates which are derived from primary alcohols give only one absorption, while those derived from secondary and tertiary alcohols give two absorption peaks.

The solvent effect (see Fig. 3) on these absorptions is remarkable. With only one exception (cyclohexyl acetate), the absorption at the higher frequency, which is the stronger one in such nonpolar solvents as carbon tetrachloride and carbon disulfide, becomes the minor absorption in such polar solvents as acetonitrile and dimethyl sulfoxide. In order to make the situation clearer, the solvent effect on the carbonyl-stretching absorption of acetates was studied by changing the mixing ratio of carbon tetrachloride to acetonitrile.

The results obtained with *t*-butyl acetate are shown in Fig. 4 and Table 2. Apparently, as the polarity of the mixed solvent increases, the absorption at higher wave number diminishes, whereas the absorption at lower wave number increases, in intensity.

The bifurcation of the carbonyl bands of the acetates which carry secondary or tertiary alkyl groups could be explained as resulting from any one of the following causes: 1) solute-solvent interaction, 2) solute-solute interaction, 3) equilibrium between *s-cis* and *s-trans* conformational isomers, and 4) Fermi resonance (including a fairly strong overtone or combination tone).

The first two possibilities may be ruled out for the following reasons: 1) The bifurcation of the carbonyl band in nonpolar solvents because, in these solvents, solute-solvent interactions are negligibly samll. 2) It is very difficult to explain, from the intermolecular interaction, why methyl and ethyl acetates show only one band, whereas secondary and tertiary alkyl acetates show two bands. 3) The concentration of the solution is so low that the intermolecular solute-solute interaction is hardly possible. 4) *t*-Butyl acetate gives essentially the same absorption curves at 0.5, 5, and 50 mmol/l concentration.

If the populations of the rotational isomers change according to the polarity of the solvents, this change must be reflected in the skeletal vibrations. Thus, the infrared spectra of *t*-butyl acetate at lower frequencies (1100—400 cm^{-1}) were recorded in the range of 23°C and −150°C, the three phases being covered by this technique. The results are shown in Figs. 5 and 6. No clear change in the absorptions could be found.

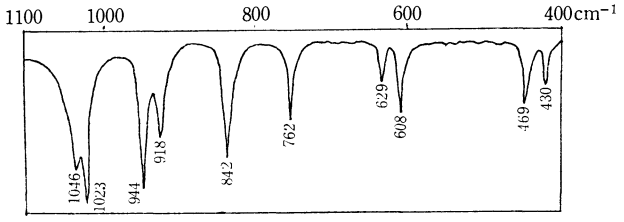

Fig. 5. Infrared spectra of *t*-butyl acetate in the range of 1100—400 cm^{-1} in liquid state.

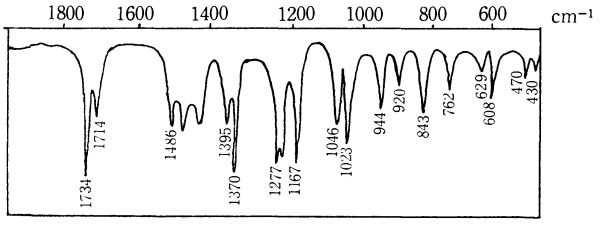

Fig. 6. Infrared spectra of solid state *t*-butyl acetate at lower temperature.

The *s-cis* conformer of the ester is considered to be more polar than the *s-trans*, because the arrangement of bond dipoles implies the more polar nature and because the calculated dipole moments, calculated using the usual C–O and C=O bond dipoles, are 3.40 and 1.53D for the *s-cis* and *s-trans* conformers respectively. These considerations necessarily mean that the population of the *s-cis* conformer will become denser in a polar solvent relative to a non-polar solvent. Thus, the infrared spectra in 1100—400 cm^{-1} region were again scanned with solutions made by dissolving *t*-butyl acetate in solvents of various polarities (CS_2, $CHCl_3$, CH_3CN, DMSO, and $HCONMe_2$). The results showed essentially no change in the spectra, the one exception being a band at 918 cm^{-1} which became stronger in polar solvents.

Since the *s-cis* conformer of the formates is known to give an absorption at a higher frequency than the *s-trans* in the carbonyl-stretching absorption region, and since this arrangement agrees with the consideration of intramolecular dipolar interactions, it is natural to assume that it is the *s-cis* conformer of the acetate which gives rise to an absorption at a higher frequency. However, this consideration leads to a conclusion which is the reverse of actuality: namely, the absorption band which is enhanced in polar solvents is the one located at the lower frequency (see Fig. 4).

All these discussions favor the absence of the *s-cis* conformer of the acetates.[9] Thus, the third possibility may be disregarded also.

Further support for ruling out the possibility of conformational heterogeneity as being the reason for the bifurcation of the carbonyl band could be obtained by studying the overtone region of the carbonyl stretching. Thus, the infrared spectrum of *t*-butyl acetate in the region of 3600—3400 cm^{-1} was carefully recorded. It was made clear that *t*-butyl acetate has only one symmetrical sbsorption, at 3447.6 cm^{-1} (ε=4.00), in carbon tetrachloride at the low concentration of 0.01 mol/l. This result suggests that the most probable cause of the

Fig. 7. Infrared spectra of ν_{CO} of *t*-butyl acetate and *t*-butyl acetate-d_3.
—— line: CH_3CO_2t-Bu
---- line: CD_3CO_2t-Bu

9) Morgan and Unwin[8] recently suggested that the *s-cis* conformer might be present in isopropyl and *t*-butyl acatetes, judging from the abnormal solvent effect on the carbonyl-stretching vibration in the infrared spectra. However, since their discussion assumed that these compounds show only one carbonyl absorption, their results must be reinvestigated in the light of the fact reported above.

s=strong, m=medium, w=weak

bifurcation of the carbonyl band is not the confromational heterogeneity, but the overtone or combination tone, which is enhanced by Fermi resonance.

After establishing the origin of the bifurcation of the carbonyl band of some acetates, it seemed that it would be interesting to know what kind of vibration is responsible for the Fermi resonance. Thus, the deuteration of the acetyl methyl of *t*-butyl acetate was carried out and the infrared spectra were measured. The reason for this deuteration was the fact that there are numerous examples of carbonyl compounds which show Fermi resonance in the carbonyl region attributed to the resonance between the carbonyl fundamental and the overtone of the α C–H deformations.[10-14] The results with *t*-butyl acetate-d_3 are shown in Fig. 7, together with the curves of undeuterated samples for the sake of comparison. As may be seen in Fig. 7 and also in Table 1, *t*-butyl acetate-d_3 also has two absorptions in the carbonyl region in both polar and nonpolar solvents, this behavior being similar to that of the nondeuterated specimen; the only difference between the deuterated and nondeuterated compounds is the fact that the former always give a somewhat stronger band on the higher-frequency side. Thus, it is unlikely that any of the vibrational modes involving hydrogen is responsible for the Fermi resonance.

The infrared spectra of some acetates in carbon disulfide at the lower frequencies are given in Table 3. The skeletal vibrations are expected to be sensitive to the mass of R in CH_3CO_2R; the results shown in Table 3 conform with this expectation. Nevertheless, all the secondary and tertiary alkyl acetates studied so far give rise to a bifurcated band. Thus, we prefer that a common band at 1280—1240 cm^{-1}, which may be assigned to the antisymmetric stretching mode of the C–O–C of the esters, be chosen as one of the origins for the bifurcation in the carbonyl region. Then another band which is responsible for this phenomenon should be found at *ca.* 460 cm^{-1}. Indeed, we can see that those substances which give two bands in the carbonyl region have a fairly strong absorption at 505—430 cm^{-1}, although the assignment of these bands is still obscure. Thus, it can tentatively be concluded that the bifurcation of the carbonyl bands of some acetates can be attributed to the Fermi resonance between the carbonyl fundamental and a combination tone arising from the antisymmetric C–O–C stretching mode and an unknown mode of vibration which gives absorption at 505—430 cm^{-1}.

Nuclear Magnetic Resonance Spectra. The proton magnetic resonance spectra of *t*-butyl acetate in a mixed solvent of carbon disulfide and dichloromethane were measured at various temperatures. The *t*-butyl and acetyl methyl signals appear at 1.40 and 3.07 ppm downward from TMS at room temperature. The chemical shifts are almost the same at −50, −70, and −95°C. No sign of a decrease in the peak heights of these peaks is found as the temperature is lowered.[15] Thus, the results conform with those obtained by the infrared spectral study in that the conformational heterogeneity is not observed with *t*-butyl acetate.

The authors wish to express their hearty thanks to Professor T. Shimanouchi and S. Ichikawa for their helpful discussions.

Conformations of the Esters. IV. The Conformations of Carbamates

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 13, 1971)

It has been confirmed from an infrared spectral study of the C=O, N–H, and N–D stretching regions that primary, secondary, and tertiary carbamates take the *s-cis* and *s-trans* conformations with respect to the ester group. The nuclear magnetic resonance spectra and the results of dipole-moment studies support this conclusion.

The conformation of the ester has long been claimed to be *s-trans*, and the conformation of carbamates has been reported to be no exception (Fig. 1). Van der

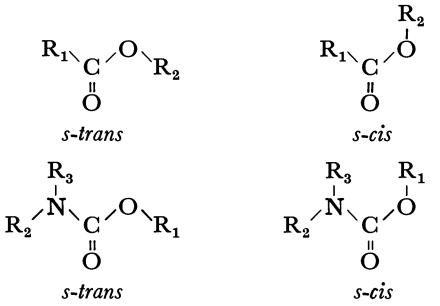

Fig. 1. The conformations of ester and carbamate.

Werf reported[1] two conformations of the ester group in methyl *N*-methyl-*N*-alkylsulfonylcarbamates, but this conclusion has since been proved by NMR study to be not the case.[2] Since we have recently shown that the *s-cis* conformation can exist in some formates,[3] the search for the *s-cis* conformation in carbamates has been undertaken as an extention. The purpose of this paper is to present the results of such a study using infrared and nuclear magnetic resonance spectral techniques and dipole-moment measurements.

Experimental

Materials. The simple carbamates were prepared by the reaction of methyl chloroformate or ethyl chloroformate with aqueous or neat amine with cooling. Methyl *N*-phenylcarbamate was prepared by refluxing a mixture of aniline and methyl chlorofomate in chloroform for an hour. Methyl *N*-deuterio-*N*-methylcarbamate ($MeNDCO_2Me$) was prepared by mixing methyl *N*-methylcarbamate with thirty molar deuterium oxide overnight at room temperature and by subsequent distilling under nitrogen. The physical constants of the compounds used in this study agree with those previously reported in the literature. The purity of the compounds was checked by studying their infrared and nuclear magnetic resonance spectra.

Apparatus. The infrared spectra were measured by using a Perkin Elmer 112G single-beam grating spectrometer (3600—3300 cm^{-1}, 2700—2400 cm^{-1}, 1800—1650 cm^{-1}) and a Hitachi EPI-G2 grating infrared spectrophotometer (4000—400 cm^{-1}). The nuclear magnetic resonance spectra were recorded on a JNM-4H-100 spectrometer. The dipole moment was obtained by the solution method, using benzene as the solvent. The dielectric constant (ε) was measured by the heterodyne-beat method. The electronic polarizations (P_E) were computed from the table of bond refraction, and the atomic polarization (P_A) was taken as 5% of the electronic polarization. The values of the observed dipole moment include an inaccuracy of ± 0.02D.

Results and Discussion

In disussing the conformations of carbamates, two conformers (*s-cis* and *s-trans*) may be considered when the nitrogen atom carries two identical substituents (Ia, Ib, IIIa, and IIIb in Fig. 2), whereas it is necessary to take four conformations into account when the nitrogen of the carbamate carries non-identical substituents, as is exemplified by the secondary amides, IIa, IIb, IIc, and IId, in Fig. 2.

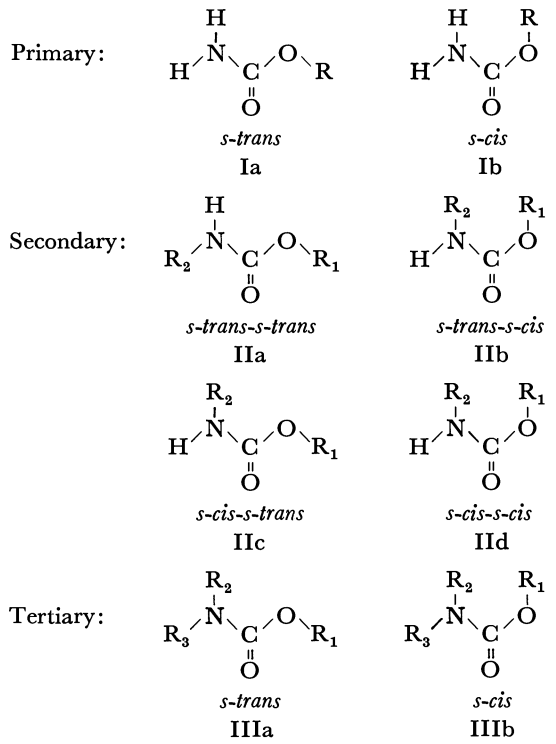

Fig. 2. The conformations of carbamate.

It is well known that the *s-trans* conformation is more stable than the *s-cis* in ordinary secondary amide. LaPlanche reported[4] that *N*-methylformamide (HCONHMe) has only an 8% *s-cis* conformer, and even *N*-*t*-butylformamide (HCONH*t*-Bu) has only a 12% *s-cis* conformer, although in the latter compound the

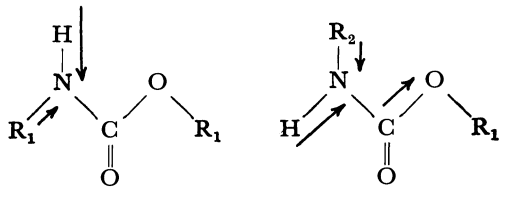
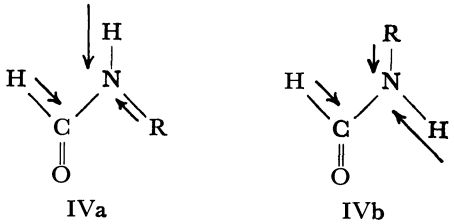
4) L. A. LaPlanche and M. T. Rogers, *J. Amer. Chem. Soc.*, **86**, 337 (1964).

Fig. 3. The conformations of secondary amide.

R_1 is hydrogen, which is sterically small, and the steric repulsion between H and the *t*-butyl group in the *s-cis* conformer is considered to be smaller than that between C=O and the *t*-butyl group in the *s-trans* (Fig. 3) (thus, the *s-cis* conformer is expected to form the majority).

On the other hand, *N*-methyl acetamide (MeCONHMe) exists as the *s-trans* conformer only,[5] probably because the repulsion between two methyl groups in the *s-cis* conformer is too large for the *s-cis* conformer to exist. Comparing the situation of the carbamate with that of the amide, the alkoxy group in carbamate is larger than the hydrogen of the formyl group in formamide. Therefore, the repulsion between R_2 and OR_1 in IIc and IId (Fig. 2) must be larger than that between formyl hydrogen and R_2 in formamide (Fig. 3. IVb, R=H). The dipole-dipole interaction between H–N and the C–OR_1 bond is more favorable for IIa than that for IIc as far as the conformations of the amide part are concerned (see below). These considerations lead to the conclusion that the ratio of the population of the *s-trans* conformer with respect to the amide part of this carbamate (IIa and IIb) to that of the *s-cis* conformers (IIc and IId) is probably larger in carbamates than in ordinary amides. Therefore, it may be expected that the existence of the IIc and IId conformers at least can be neglected.





If both the *s-trans* and *s-cis* conformers of the amide group of carbamates should exist, two methyl peaks will appear in the NMR spectra of methyl *N*-methylcarbamate when the temperature of the measurement is lowered enough, because the rotation of the N–CO bond of the amide group has been reported to be slow enough for the NMR time scale.[6,7] For example, methyl *N,N*-dimethylcarbamate (Me_2NCO_2Me) has been reported to have two *N*-methyl peaks in the NMR spectra at temperatures lower than −13°C.[8] On the other hand, methyl *N*-methylcarbamate ($MeNHCO_2Me$) shows only one *N*-methyl peak from 23°C to −100°C at 2.86 ppm from TMS in the CS_2–CH_2Cl_2 solvent at 100 MHz. This fact may be taken as suggesting that the exchange between conformers is not taking place on the NMR time scale. From the standpoint of steric considerations, it may be assumed that the IIa conformation is the most stable. Therefore, the IIa conformation is most probably the one which exists as a sole isomer. It may be argued that the chemical shift between *N*-methyls of IIa and IIb is too small to be resolved at present. However, from the above considerations, together with the discussion of the infrared spectral data to be given below, such a case can be considered rare.

Table 1. Carbonyl absorptions of carbamates

Infrared Spectra of Carbonyl-stretching Vibration. It is natural to anticipate that the *s-trans* and *s-cis* conformers of carbamates will have different carbonyl absorptions in their infrared spectra. Some authors have reported,[9–12] on the carbonyl absorption of carbamates, but no one has reported the observation of two carbonyl absorptions. Using a high-resolution infrared spectrophotometer, the carbonyl absorptions of

several methyl and ethyl carbamates were measured in carbon tetrachloride and acetonitrile. The results are shown in Table 1. It is apparent that almost all the primary (I, II), secondary (III—VIII), and tertiary (IX, X) carbamates have two carbonyl absorptions in both nonpolar and polar solvents. Since the concentrations of the measurement are dilute enough to exclude the solute association, this bifurcation of the absorptions can be said not to be due to the association effect. The intensity of the higher frequency absorption is stronger than that of the lower one in these two solvents with most compounds; compounds III, VII, and IX are exceptions. It is well known[13] that, in may cases of Fermi resonance, the intensities of bifurcated carbonyl absorption bands change dramatically when the polarity of the solvent is changed. In this case, however, the solvent effect is not so strong (except for III, VII, and IX). Therefore, Fermi resonance may not be the origin of the bifuraction of the carbonyl absorptions in the carbamates. Thus, it is most probable to assume that the existence of conformational isomers is the real origin of this bifurcation of carbonyl absorptions. As the calculated dipole moment values (as will be described later) of the *s-cis* conformer, IIb, are larger than those of the *s-trans* conformer, IIa, the population ratio of IIb to IIa can be expected to increase in polar solvents such as acetonitrile in comparison with in nonpolar carbon tetrachloride, as is the case of formates.[2] However, the solvent effect has been found to be very small in reality on the carbonyl absorptions of carbamates. The higher wave number band can be assigned to the *s-cis* conformer (Ib, IIb, and IIIb) and the lower one, to the *s-trans*, because the direction of the two dipoles of C=O and O–R is parallel in the *s-cis* conformer and is roughly antiparallel in the *s-trans* (Fig. 4); the latter necessitates less energy for stretching the carbonyl bond. Table 1 shows that the higher wave number band is stronger than the lower one in primary and secondary carbamates. This may be taken as evidence for the concept that, in these compounds, the *s-cis* conformer of carbamates with respect to the ester group is more stable than the *s-trans*.

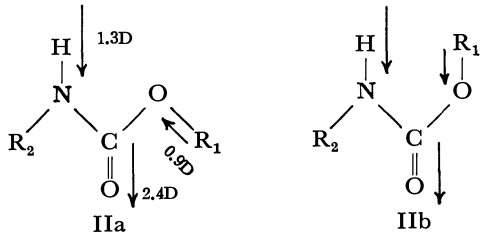

Fig. 4. The directions of the bond dipoles of carbamates.

Infrared Spectra of the N–H and N–D Stretching Vibrations and the First Overtone Band of the Carbonyl Absorption.

In order to obtain more information about the conformations of carbamates, the N–H stretching vibration absorptions in the infrared spectra were measured. The results are shown in Table 2. It is well known that

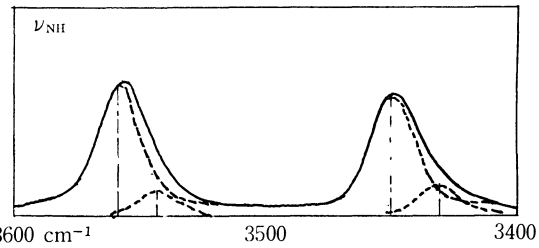

Fig. 5. Infrared spectra of ν_{NH} of methyl carbamate(H_2NCO_2-Me).

the primary amide has two N–H stretching vibration absorptions, an antisymmetrical stretching mode at about 3550 cm^{-1} and a symmetrical one at about 3450 cm^{-1}. Compounds I and II have four bands; both anitsymmetric and symmetric N–H stretching vibration bands are bifurcated. Secondary carbamates (III—VIII) have two N–H stretching vibration bands. In this region of 3600—3400 cm^{-1}, the first overtone of the carbonyl stretching vibration may appear. Therefore, the values of 2 ν_{CO} are listed in the last column of Table 2. Indeed, for example, the first overtone of the fundamental carbonyl absorptions of compound VIII appear at 3459 cm^{-1} (ε=4.2) and 3487 cm^{-1} (ε=5.1), but the intensity is much weaker than that of the fundamental tones. Generally speaking, the molecular extinction coefficient of the first overtone of carbonyl bands of carbamates is less than *ca.* 7. Since the intensities of the weaker bands in compounds I—VIII lie in the range of 41—17 (ε), the possibility of these weaker bands being the first overtones of carbonyl stretching absorptions is very small.

Further support for this assignment may be obtained by avoiding the influence of the overtone of carbonyl absorptions. Thus, the infrared spectra of the N–D stretching vibration were measured. Methyl *N*-deuterio-*N*-methylcarbamate ($MeNDCO_2Me$) shows also

two absorptions, at 2571 cm^{-1} (ε=16) and 2578 cm^{-1} (ε=71), at the low concentration of c=0.0007 mol/l in carbon tetrachloride. This fact can most easily be explained assuming the existence of two conformational isomers.

In Table 2 the difference in the location between the higher and the lower N–H stretching absorptions in wave numbers is about 10 cm^{-1}. On the other hand, it has been reported[14] that the difference in the N–H stretching vibration of the *s-trans* and *s-cis* conformers of amide is about 30—40 cm^{-1}. Therefore, this small difference in the locations of the two absorptions may be taken as indicating that, in secondary carbamates, the conformers with respect to the amide group (IIc and IId) do not exist; this conclusion is in agreement with the NMR results. These small wave-number differences may be attributed to several factors, including the dipole-dipole interaction between H–N and R_1–O bonds through a somewhat long distance (*cf.* Fig. 4). By analogy with the considerations used in the assignment of the carbonyl absorptions, the directions of the two dipoles (H–N, R_1–O) in the *s-cis* conformer (Ib or IIb) probably give rise to the absorption of the N–H stretching at the higher wave number; therefore, the lower one must be assigned to the *s-trans* conformer (Ia or IIa). The intensity of the higher band is stronger than the lower band (Table 2); from these N–H stretching band studies, also, it is confirmed that the *s-cis* conformer (Ib or IIb) is more stable than the *s-trans* conformer (Ia or IIa). The results of the infrared study of N–H and N–D stretching vibration absorptions apparently shows that compound III has two conformations and that the *s-cis* conformer is more stable than the *s-trans*. The abnormality of the carbonyl bands of this compound, that is, the fact that it gives a stronger absorption at lower wave number, may be attributed to the Fermi resonance. The same may also be said about compound VII.

As to the tertiary carbamates, IX, X, and XI, the carbonyl absorptions are complicated. The intensity ratio of the two bands is reversed in compounds IX and X, and compound XI has only one symmetrical band in these two solvents. In order to know more about the conformation of tertiary carbamates, the first overtone spectra of compounds IX and X were measured. Compound IX has only one peak, at 3407.1 cm^{-1} (ε=8.18), and compound X has two peaks, at 3360 cm^{-1} (ε=0.23) and at 3393 cm^{-1} (ε=3.42), at the concentration of 0.013 mol/l in carbon tetrachloride. These results may mean that the Fermi resonance is one of the factors causing the complication of the spectra at the carbonyl region, but it is impossible to draw a solid conclusion without reservation at the present time.

Dipole Moment. The dipole-moment values of methyl *N,N*-dimethylcarbamate (IX) are found to be 2.55D at 16°C and 2.59D at 31°C in a benzene solution. The calculated dipole moment values are 1.38D for the *s-trans* with respect to the ester group and 3.48D for the *s-cis* (bond moment: C=O: 2.4D,C–H: 0.4D, C–N:0.4D, C–O: 0.9D). This calculation was made assuming that these conformations are all on one plane, but the O–Me group may be considered to be out of the plane of the amide group because of the steric repulsion between *N*-methyl and *O*-methyl groups. Since the error is estimated to be ±0.02D, these results may be taken as indicating that the *s-cis* conformer is more stable than the *s-trans* conformer in this compound.

Nuclear Magnetic Resonance Spectra. To obtain information about the conformations of carbamates, the nuclear magnetic resonance spectra of methyl *N*-methylcabamate ($MeNHCO_2Me$) were measured from 23°C to −100°C in the CS_2–CH_2Cl_2 solvent. Only at about −100°C the peak of the methoxy methyl group began to broaden, while the peak of the *N*-methyl group was almost unchanged throughout this temperature range. These phenomena may be taken as further evidence for the existence of the conformational equilibrium of the ester group in this carbamate.

From the infrared and nuclear magnetic resonance spectra and the dipole-moment study, it can be concluded that, in primary and secondary carbamates, two conformers with respect to the ester group exist and the *s-cis* conformer is more stable than the *s-trans*, and that the same may be true in tertiary carbamates. Judging from the steric effect, this fact is very surprising, particularly in connection with the tertiary carbamate, for in these compounds the steric repulsion between *N*-alkyl and *O*-alkyl groups is expected to be large. This phenomenon may be explained partially by two factors; the first is the stabilization of the *s-cis* conformation due to C–N and O–R_1 bond dipolar interaction, and the second is the destabilization of the *s-trans* conformation due to the repulsion between the lone-pair electrons of ether-oxygen and nitrogen (the so-called "Rabbit Ear"; *cf.* E. L. Eliel (Fig. 6)[15] in heterocyclic compounds.).

Aromatic Arylation with Aryl Radicals. III. Gomberg Reaction in Dimethyl Sulfoxide

Nobumasa KAMIGATA, Teruyoshi KURIHARA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received May 18, 1971)

Benzenediazonium tetrafluoroborate in dimethyl sulfoxide decomposed instantaneously with evolution of nitrogen upon addition of a dimethyl sulfoxide solution of choline or tetramethylammonium hydroxide. Orientations and partial rate factors for the phenylation of substituted benzenes indicated that the phenylating agent is not phenyl cation but phenyl radical. Hammett's plots of partial rate factors for *meta* and *para* substitutions were good straight lines with $\rho_m=0.34$, $\rho_p=1.63$ (in choline) and $\rho_m=0.48$, $\rho_p=1.69$ (in tetramethylammonium hydroxide solutions). Decomposition of benzenediazonium tetrafluoroborate by tetramethylammonium hydroxide in aqueous solution was also studied, and the orientation and partial rate factors for the phenylation of substituted benzenes were determined.

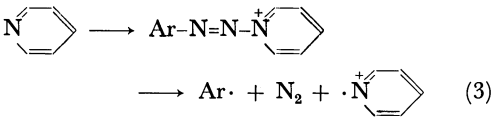
Arenediazonium salts decompose with evolution of nitrogen in aprotic polar solvents, and phenyl cation is considered to be the intermediate on the basis of the kinetic studies[1] and the partial rate factors for the competitive arylation of benzene and substituted benzenes.[2]

$$ArN_2^+ \longrightarrow Ar^+ + N_2 \quad (1)$$

However, it has been reproted that arenediazonium salts undergo homolytic decomposition in methanol[3] or pyridine.[4]

$$ArN_2^+ + CH_3O^- \longrightarrow Ar\text{-}N{=}N\text{-}OCH_3 \longrightarrow Ar\cdot + N_2 + \cdot OCH_3 \quad (2)$$

or



When an arenediazonium solution was added to a dimethyl sulfoxide solution of sodium nitrite, the diazonium salt decomposed instantaneously with evolution of nitrogen, and a homolytic decomposition mechanism was proposed.[5]

$$ArN_2^+ + NO_2^- \longrightarrow Ar\text{-}N{=}N\text{-}O\text{-}N{=}O \longrightarrow Ar\cdot + N_2 + NO_2 \quad (4)$$

or

$$2Ar\text{-}N{=}N\text{-}O\text{-}N{=}O \longrightarrow Ar\text{-}N{=}N\text{-}O\text{-}N{=}N\text{-}Ar + N_2O_3 \longrightarrow Ar\cdot + N_2 + Ar\text{-}N{=}N\text{-}O\cdot \quad (5)$$

As a continuation of our investigations on the decomposition of arenediazonium salts in aprotic polar solvents, addition of quaternary ammonium hydroxide to diazonium salts has been studied. It has been found that a reaction similar to the Gomberg reaction has taken place. With quaternary ammonium hydroxides the medium is homogeneous, whereas the ordinary Gomberg reactions are carried out in heterogeneous mixtures of water and aromatics.

In this paper, the results of this investigation will be described, and the evidence for the homolytic decomposition will be presented.

Experimental

Materials. Dimethyl sulfoxide was purified according to the method described in a previous paper.[1b] Benzene, ethylbenzene, and chlorobenzene were washed with concentrated sulfuric acid and water successively, dried over calcium chloride, and distilled. Boiling points were 80, 135.7, and 131°C, respectively. Anisole was washed with an aqueous sodium hydroxide solution and water, dried over calcium chloride, and distilled; bp 153°C. Benzonitrile was purified by steam distillation. The distillate was washed with sodium carbonate solution and water, dried over calcium chloride, and distilled under reduced pressure; bp 123.4°C/100 mmHg. Nitrobenzene was washed repeatedly with a potassium dichromate solution, dried over calcium chloride, and distilled; bp 95.5°C/18 mmHg. Choline of Tokyo Kasei Limited was used without further purification. A 20% methanolic solution of tetramethylammonium hydroxide obtained from Aldrich Chemical Co., Inc. was evaporated under reduced pressure, and the residue was used.

Benzenediazonium tetrafluoroborate was prepared according to the directions described previously.[6]

Isomeric ethylbiphenyls, methoxybiphenyls, chlorobiphenyls, cyanobiphenyls, and nitrobiphenyls were prepared as the reference compounds by the methods described in the literature.[7] They were purified by elution chromatography, distillation or recrystallization, and their melting points and boiling points agreed with the values in the literature.

Phenylation of Monosubstituted Benzenes in DMSO. Under a nitrogen atmosphere a solution of 2.00 g of benzenediazonium tetrafluoroborate in 20 g of DMSO was added

drop by drop at 20°C into a vigorously stirred solution of choline or tetramethylammonium hydroxide (3 mol/mol of PhN_2BF_4) and equimolar mixture of benzene and a substituted benzene (total aromatics, 50 mol/mol of PhN_2BF_4) in 60 g of DMSO. Evolution of nitrogen was instantaneous upon addition of each drop of the diazonium salt solution, and the addition was completed in about ten minutes. Ether was added to the solution, and the mixture was washed with water in order to remove DMSO and excess quaternary ammonium hydroxide. After it was dried over anhydrous magnesium sulfate, ether and about 70% of the aromatic solvents were evaporated, and biphenyl isomers in the residue were analyzed by gas chromatography with a Hitachi Gas Chromatograph K-53. Biphenyl isomers were identified by comparison of the retention times with those of the authentic samples on a 1 m to 6 m column (depending upon the ease of separation) packed with Chromosorb W (10% Apiezon L). Quantitative determinations were made by use of calibration curves.

Not benzene but chlorobenzene was used as the standard for the competitive phenylation, since unsubstituted biphenyl easily sublimes during the evaporation of substituted benzenes. The reactivity of each position of substituted benzenes was calculated relative to the reactivity of the *ortho* position of chlorobenzene. The partial rate factor of the *ortho* position of chlorobenzene was determined by a competitive phenylation of benzene and chlorobenzene without evaporation of the unchanged aromatics. The partial rate factors of various substituted benzenes were calculated by the following equation.

$$k_x/k = (k_x/k_{o\text{-Cl}}) \times (k_{o\ Cl}/k)$$

where,

k_x/k: partial rate factor for phenylation of PhX at the x (*o*-, *m*-, or *p*-) position

$k_x/k_{o\text{-Cl}}$: relative rate of phenylation at the x position of PhX against that of the *ortho* position of chlorobenzene

$k_{o\text{-Cl}}/k$: partial rate factor for phenylation at the *ortho* position of chlorobenzene

Phenylation of Monosubstituted Benzenes in Water. Under a nitrogen atmosphere a solution of 2.20 g of benzenediazonium tetrafluoroborate in 35 g of water was added drop by drop at 20°C into a vigorously stirred solution of tetramethylammonium hydroxide (3 mol/mol of PhN_2BF_4) and equimolar mixture of benzene and a substituted benzene (total aromatics, 50 mol/mol of PhN_2BF_4) in 35 g of water. The reaction mixture was treated in a manner similar to that described above for the experiments in DMSO, and the product isomers were analyzed.

Results and Discussion

Benzenediazonium tetrafluoroborate in dimethyl sulfoxide (DMSO) decomposed instantaneously with evolution of nitrogen upon addition of a DMSO solution of choline ($HOCH_2CH_2(CH_3)_3N^+OH^-$) or tetramethylammonium hydroxide. Although the diazonium salts slowly decomposes even in the absence of these quaternary ammonium hydroxide, the rates of the first order decomposition yielding phenyl cation[2b] is much smaller than those observed in the presence of quaternary ammonium hydroxides. Therefore the mechanism of this rapid decomposition must be different from that involving phenyl cation. The difference of the mechanisms is also suggested by the absence of 1,3-benzoxathian in the products, which was always produced when phenyl cation was generated in DMSO.[2b]

Table 1 shows the orientations and partial rate factors for the phenylation of substituted benzenes with benzenediazonium tetrafluoroborate and choline or tetramethylammonium hydroxide in DMSO. All the substituents behaved as *o,p*-directors, and the partial rate factors were always larger than 1. These data are similar to those of phenylation with phenyl radical produced from benzoyl peroxide[8] or *N*-nitrosoacetanilide[9] and quite different from those of phenylation with phenyl cation.[2,10] These findings indicate that the benzenediazonium salt reacts with quaternary ammonium hydroxide to produce phenyl radical.

It is likely that the following mechanism proposed by Rüchardt and Merz[11] for the Gomberg reaction is also

applicable to the homogeneous reaction between PhN_2^+-BF_4^- and $R_4N^+OH^-$ in DMSO.

Although the Gomberg reaction has been used extensively for synthetic purposes, the partial rate factors for phenylation of substituted benzenes by the Gomberg reaction have not been determined yet. Therefore, the partial rate factors and orientation were determined under the ordinary Gomberg reaction conditions (*i. e.*, heterogeneous mixtures of aromatics and water) using tetramethylammonium hydroxide as a strong base instead of sodium hydroxide commonly used. The results are shown in Table 2.

Figures 1 and 2 are the Hammett's plots of the partial rate factors of the *meta* and *para* positions. Satisfactory V-shape relationships are observed for *meta* and *para* data with ρ_m=0.34, ρ_p=1.63 (with choline, in DMSO), ρ_m=0.48, ρ_p=1.69 (with tetramethylammonium hydroxide, in DMSO) and ρ_m=0.46, ρ_p=1.38 (with tetramethylammonium hydroxide, in H_2O). The ρ values were calculated from the right half of the V-shape which contained larger number of experimental data than the left half.

Table 3 summarized the ρ_p values for the phenylation under various reaction conditions. It is interesting to compare the ρ_p values in Table 3. In PhN_2BF_4–$NaNO_2$, -Choline, and -Me_4NOH in DMSO, the ρ_p values are in the range of 1.63–1.69. The smaller ρ value (1.38) observed in PhN_2BF_4—Me_4NOH in H_2O may be ascribed to the change in solvents. In these four systems, the hydrogen abstractor is probably the same, *i.e.*, Ph–N=N–O·.

In three other systems listed in Table 3, the ρ_p values are much smaller. If the hydrogen abstractor in *N*-nitrosoacetanilide is Ph–N=N–O·, the smaller ρ_p value (1.27) compared with those in Expt. 1—3, must be ascribed to the difference in solvents. However, if the hydrogen abstractor in this system is Ph–N(–$COCH_3$)–O· as Chalfont and Perkins proposed,[12] the smaller ρ value can be ascribed to the difference in solvents and hydrogen abstractors.

In benzoyl peroxide and phenylazotriphenylmethane the temperatures are higher (80 and 60°C), and it is likely that reactions are less selective and ρ values are smaller at higher temperatures. The hydrogen abstractor in these systems are also different from those in Expts. 1—4.

Clear interpretation of these different ρ values, however, can be made only after more detailed studies are carried out.

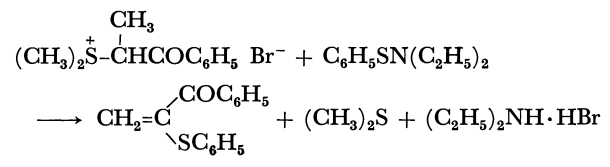
Syntheses and Reactions of 2-Ethylthio- or 2-Phenylthio-2-cycloalkenones

Teruaki MUKAIYAMA, Takeshi ADACHI, and Takanobu KUMAMOTO
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received May 25, 1971)

2-Ethylthio- or 2-phenylthio-2-cycloalkenones (five-, six-, or seven-membered ring) were obtained in high yields by the reactions of alicyclic β-ketosulfonium salts with sulfenamides. It was found that dihydrofuran derivatives were obtained in good yields from the sulfonium salts of the cycloalkenones and active methylene compounds.

Recently we found that α-phenylthioacrylophenone was obtained in quantitative yield by the reaction of dimethyl-α-methylphenacyl sulfonium bromide with *N*, *N*-diethylbenzenesulfenamide.[1]

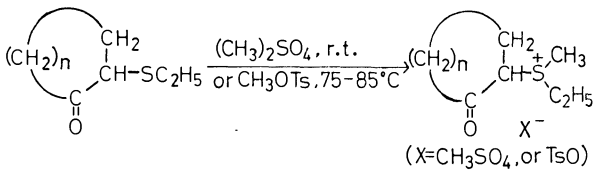


Scheme 1

This indicates that 2-alkylthio- or 2-arylthio-2-cycloalkenones, valuable synthetic intermediates, would be produced from alicyclic β-ketosulfonium salts and sulfenamides.

The preparation of alicyclic β-ketosulfonium salts and the reactions of the salts with sulfenamides were investigated. It is well-known that sulfonium salts are prepared by the reactions of alkyl halides with dimethyl sulfide. However, it was found that the reaction of 2-bromocycloalkanones such as 2-bromocyclohexanone with dimethyl sulfide afforded no corresponding sulfonium salts, except when the reaction was carried out in the presence of silver tetrafluoroborate.[2] Thus, the preparation of the sulfonium salts was attempted by the reactions of β-keto-sulfides with dimethyl sulfate or methyl *p*-tosylate.

When 2-ethylthiocyclohexanone was treated with dimethyl sulfate at room temperature for 1—2 days or with methyl tosylate at 75—85°C for 7—8 hr, the corresponding sulfonium salts were obtained in almost quantitative yields as viscous oil. In a similar way, cyclopentanone and cycloheptanone analogs were prepared in high yields.



Scheme 2

The reactions of sulfonium salts (IIa—c) thus obtained with several sulfenamides were examined. When methylethyl-2-oxocyclohexylsulfonium tosylate (IIb′) was treated with *N*-phenylthiopyrrolidine[3] (sulfenamides of type *A* in Scheme III) in dichloromethane at room temperature for a day, 2-phenylthio-2-cyclohexenone (IVc) was obtained in 54% yield along with diphenyl disulfide (31%).

The result can be explained as follows. Sulfonium salt (IIb′) reacts with *N*-phenylthiopyrrolidine to afford α-sulfenylated intermediate (III) and pyrrolidine. III is in turn converted to IVc with the elimination of β-hydrogen atom and methyl ethyl sulfide by the influence of pyrrolidine produced at the same time. It was established that IVc was obtained in 78% yield by the reaction of IIb′ with *N*-phenylthiophthalimide (sulfenamides of type *B* in Scheme III) in the presence of triethylamine. These results indicate that sulfenamides of type *B* are preferable to those of type *A* for the synthesis of 2-alkylthio- or 2-arylthio-2-cycloalkenone. In a similar way, reactions of the five- or the seven-membered sulfonium salt with *N*-phenylthio- or *N*-ethylthiophthalimide gave the corresponding 2-phenylthio- or 2-ethylthio-2-cycloalkenones (IVa—f) in good yields (Tabel 1).

TABLE 1. SYNTHESES OF 2-ETHYLTHIO- OR 2-PHENYLTHIO-2-CYCLOALKENONES

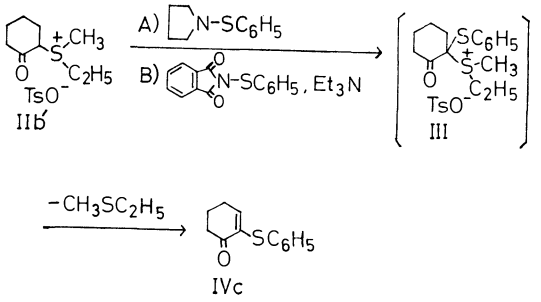
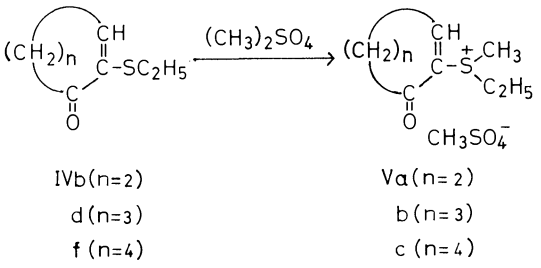
2) T. Mukaiyama and M. Higo, *Tetrahedron Lett.*, **1970**, 5297.
3) T. Mukaiyama, S. Kobayashi, and T. Kumamoto, *ibid.*, **1970**, 5115.



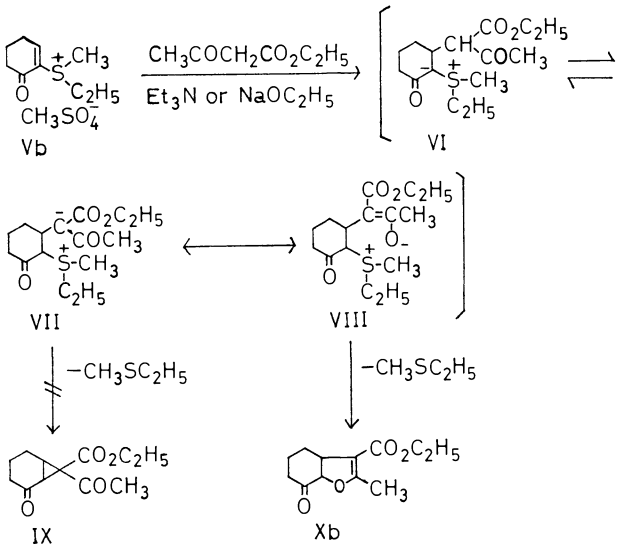
Scheme 3

Reactions of the sulfonium salts (Va—c) of the cycloalkenones with active methylene compounds, such as ethyl acetoacetate or acetylacetone, were attempted. When 2-ethylthio-2-cyclohexenone (IVd) or 2-ethylthio-2-cycloheptenone (IVf) was treated with dimethyl sulfate at 40—50°C for 5 hr, the corresponding sulfonium salts were obtained in almost quantitative yields. In the case of the five-membered analog, the yield of the sulfonium salt (Va) was low.



Scheme 4

It was found that when the sulfonium salt (Vb) was treated with ethyl acetoacetate in the presence of triethylamine or sodium ethoxide under ice-cooling for 5 hr, the compound, mp 58—59°C, $C_{12}H_{16}O_4$, was obtained along with methyl ethyl sulfide. Its IR spectrum showed the presence of ester group at 1725 cm^{-1}, carbonyl group of cyclohexane ring at 1695 cm^{-1} and the C=C stretching of enol ether at 1640 cm^{-1}, but not a band for acetyl group. The NMR spectrum (60 MHz) exhibited characteristic peaks of two angular hydrogens at 6.1—6.6 τ (1*H*, multiplet) and at 5.4 τ (1*H*, doublet, J=10 Hz), and the UV spectrum in ethanol showed absorption maximum at 255 mμ (ε=12200). Thus, the structure is assigned to the dihydrofuran derivative, 9-ethoxycarbonyl-8-methyl-7-oxabicyclo[4.3.0]-8-nonen-5-one (Xb).



Scheme 5

This result may be explained as follows. First, the intermediate ylide (VI) is produced from the sulfonium salt (Vb) and ethyl acetoacetate by the Michael addition. The ylide (VI) is in turn changed to the betaine form (VII or VIII) by the proton transfer. Subsequent intramolecular nucleophilic attack of enolate anion (VIII) at the α-carbon of sulfonium group affords Xb with the elimination of methyl ethyl sulfide. There is an alternative route for a possible formation of the cyclopropane derivative (IX) involving an attack of the carbanion (VII) at the α-carbon.[4] However, no

such compound could be isolated from the reaction mixture.

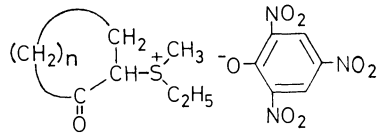
Similarly, dihydrofuran derivatives (Xa—f) were obtained from the sulfonium salts of cyclopentenone or cycloheptenone analog and active methylene compounds as shown in Table 2.

Experimental

Materials. 2-Ethylthiocyclopentanone (Ia, bp 57—59°C/4 mmHg) and 2-ethylthiocycloheptanone (Ic, bp 96.5—97.5°C/5 mmHg) were prepared according to the method of Mousseron.[5]

Preparation of Methylethyl-2-oxocycloalkylsulfonium Salts (II). A mixture of 2-ethylthiocyclohexanone (Ib)[5] (1.58 g, 0.01 mol) and freshly-distilled dimethyl sulfate (1.39 g, 0.011 mol) was stirred at room temperature. After stirring for 1—2 days, methylethyl-2-oxocyclohexylsulfonium methylsulfate (IIb) was obtained in almost quantitative yield as a slightly yellowish viscous oil. Similarly, methylethyl-2-oxocyclopentylsulfonium methylsulfate (IIa) and methylethyl-2-oxocycloheptylsulfonium methylsulfate (IIc) were obtained in good yields. Methylethyl-2-oxocyclohexylsulfonium tosylate (IIb′) was prepared by the treatment of Ib (4.75 g, 0.03 mol) with methyl tosylate (6.15 g, 0.033 mol) at 75—85°C for 7—8 hr as a slightly brownish viscous oil. All of these oily salts were used for the reaction with sulfenamides without further purification, and identified by transformation into their picrates.

Table 3. Methylethyl-2-oxocycloalkyl-sulfomium picrates



n	Mp °C (dec.)	Analyses, Found (Calcd) (%) C	H	N	S
2	109—110	43.90 (43.41)	4.41 (4.42)	10.80 (10.58)	8.14 (8.28)
3	158	45.17 (44.89)	4.61 (4.77)	10.72 (10.47)	8.29 (7.99)
4	129.5	46.51 (46.26)	5.25 (5.10)	10.28 (10.12)	7.68 (7.77)

Preparation of 2-Phenylthio-2-cyclohexenone (IVc). (A) The Reaction of IIb′ with N-Phenylthiopyrrolidine: A solution of *N*-phenylthiopyrrolidine (5.37 g, 0.03 mol) in dichloromethane (5 m*l*) was added dropwise to a solution of IIb′ (10.9 g, 0.03 mol) in dichloromethane (10 m*l*) under ice-cooling. The reaction mixture was stirred continuously at room temperature for a day. After removal of the solvent, the resulting dark brown syrup was extracted with ether and the ether layer was chromatogaphed on silica gel. Elution with petroleum ether gave diphenyl disulfide 1.0 g (31%) and that with benzene gave slightly yellowish-green crystals, mp 52—54°C, 3.3 g (54%), which were crystallized from isopropyl alcohol to afford colorless needles (IVc), mp 57—58°C.

(B) The Reaction of IIb′ with N-Phenylthiophthalimide: Into a mixture of IIb′ (7.26 g, 0.02 mol) and *N*-phenylthiophthalimide (5.1 g, 0.02 mol)[6] in dichloromethane (25 m*l*), a solution of triethylamine (2.02 g, 0.02 mol) in dichloromethane (2 m*l*) was added dropwise with stirring under ice-cooling. After additional stirring at room temperature for a day, the precipitate of phthalimide (2.11 g, 72%) was filtered off. The filtrate was concentrated under reduced pressure and the resulting oil was chromatographed on silica gel. Elution with benzene gave slightly brownish crystals, mp 52—55°C, 3.2 g (78%). Recrystallization from isopropyl alcohol gave colorless needles (IVc), mp 57—58°C. In a similar manner, 2-phenylthio-2-cyclopentenone (IVa) or 2-phenythio-2-cycloheptenone (IVe) was obtained by the reaction of the corresponding sulfonium salt (IIa or IIc respectively) with *N*-phenylthiophthalimide as shown in Table 2.

Preparation of 2-Ethylthio-2-cyclohexenone. Into a mixture of IIb (29.7 g, 0.1 mol) and *N*-ethylthiophthalimide (20.7 g, 0.1 mol)[6] in dichloromethane (60 m*l*), a solution of triethylamine (10.1 g, 0.1 mol) in dichloromethane (10 m*l*) was added dropwise under ice-cooling. After additional stirring at room temperature for a day, the white precipitate of phthalimide (14 g) was filtered off and the filtrate was concentrated. The residue was extracted with ether and ether layer was washed with 10% sodium hydroxide, 10% hydrochloric acid and water, and dried over sodium sulfate. After removal of the solvent, the residual liquid was distilled to afford a slightly yellowish-green liquid (IVd), bp 110—112°C/4 mmHg, 12.5 g (80%). Similarly, 2-ethylthio-2-cyclopentenone (IVb) or 2-ethylthio-2-cycloheptenone was obtained. The results are listed in Table 1.

Preparation of the Sulfonium Salt of 2-Ethylthio-2-cycloalkenone. A mixture of 2-ethylthio-2-cycloalkenone and dimethyl sulfate (1:1.1 molar ratio) was stirred at 40—50°C for 5 hr or at room temperature for 3—4 days. The corresponding sulfonium salt was obtained as a viscous oil, which turned crystalline on transformation into its 2,4,6-trinitrobenzenesulfonate or picrate.

Table 4. Sulfonium salts of alicyclic β-ketosulfides

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3158—3160 (1971)

A Dianthr[14]annulene

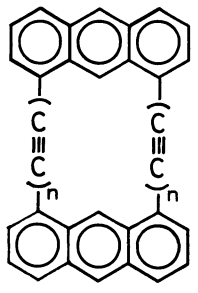
Shuzo AKIYAMA and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka

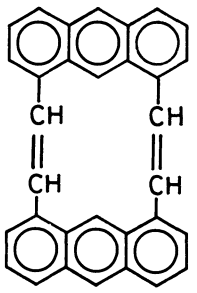
(Received May 28, 1971)

1,2,3,4,5:8,9,10,11,12-Di(1′,8′-anthr)[14]annulene (III) has been synthesized by the Wittig reaction of 1,8-diformylanthracene (IV) and the bis-ylide (VIII) derived from 1,8-bis(bromomethyl)anthracene (VI).

We previously reported the syntheses and properties of dianthratetradehydro[18]- and dianthroctadehydro-[26]annulenes (I and II).[1,2] It seemed to be of interest to synthesize dianthrannulene and compare its properties with those of dianthradehydroannulenes (I and II). On inspection of a molecular model of the dianthr[14]annulene (III), we realized that the molecule should be twisted owing to the steric repulsion between the hydrogen atoms at 9′-positions of the aromatic nuclei and those of the ethylenic bonds. Thus, a comparison of the electronic spectra of III and related compounds seemed to be of considerable interest. We wish to report the synthesis of the dianthr[14]annulene (III), a lower analogue of I and II.



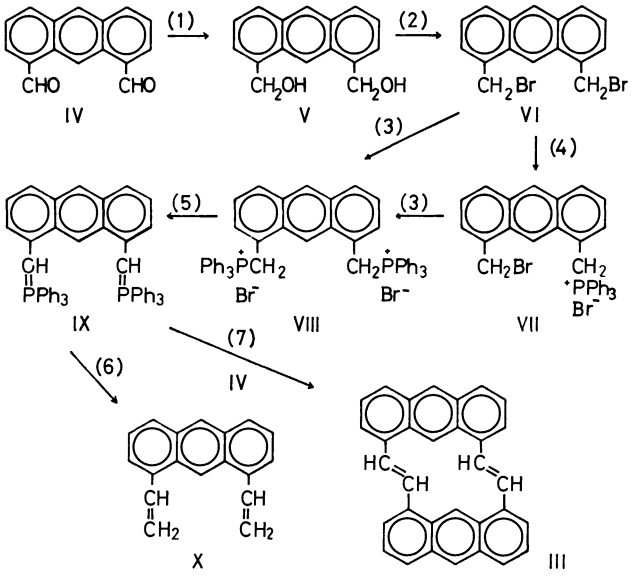
I n=2, II n=4



III

Synthesis. Preparation of III was performed according to an analogous sequence of the reaction used in the synthesis of 1,2,3:6,7,8-di(1′,8′-naphth)[10]-annulene.[3]

1,8-Diformylanthracene (IV)[2] was reduced by means of sodium borohydride to give 1,8-bis(hydroxymethyl)-anthracene (V). Glycol (V) was converted quantitatively to bis-bromomethyl derivative (VI). Bis-triphenylphosphonium salt (VIII) was obtained in a high



Scheme. Synthesis of dianthr[14]annulene and 1,8-divinylanthracene.

yield by treatment of VI with 3 molar equivalents of triphenylphosphine in dimethylformamide at *ca.* 100°C. The reaction of the phosphine in benzene gave exclusively monophosphonium salt (VII) which could be converted to VIII in a good yield by further treatment with the phosphine in dimethylformamide. Phenyllithium in toluene transformed VIII to bis-ylide (IX). The Wittig reaction of 1,8-diformylanthracene IV and bis-ylide IX in toluene afforded dianthr[14]annulene III as bright yellow needles in a moderate yield. The crystals of III exhibit light green fluorescence. III gave satisfactory results of elemental analysis and the mass spectrum of III gave a molecular ion peak (M^+=404) exactly corresponding to the molecular weight of III.

1,8-Divinylanthracene (X), a reference substance of III, was prepared by the reaction of bis-ylide (XI) with an excess of paraformaldehyde in toluene.

Properties. Dianthr[14]annulene III thus prepared was found to be an extremely stable compound. It decomposed above 360°C. Annulene III is sparingly soluble in common organic solvents. The solubility in chlorobenzene was found to be 20 mg per 100 m*l* at room temperature. The configuration of ethylenic bonds in III was confirmed to be *trans*, because, as is shown in Fig. 1, the infrared spectrum of III exhibits a band at 975 cm^{-1} which is characteristic of *trans*-ethylene linkage.

The electronic spectrum of III is recorded in Fig. 2 together with those of the related compounds. The spectra of 1,8-diethynyl-[1] and 1,8-divinylanthracenes

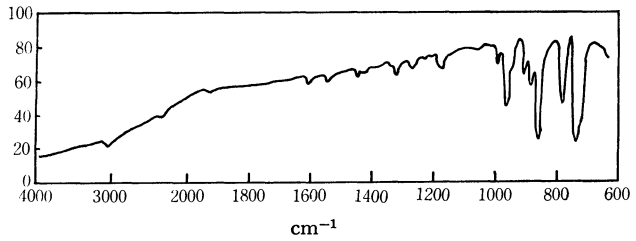

Fig. 1. The infrared spectrum of dianthr[14]annulene.

exhibit distinct vibrational fine structure characteristic of anthracene derivatives. However, disappearance of the fine structure and broadening of both absorption bands (250 nm and 340—450 nm regions) were observed in the spectrum of III. Broadening of the fine structure in the spectrum of X as compared with that of 1,8-diethynylanthracene can reasonably be attributed to the steric hindrance between the hydrogen atoms at 2- and/or 9-positions of anthracene nucleus and those of olefinic linkage. The same trend has been observed in the spectrum of 1,2-di-1′-anthrylethylene,[4] *i.e.*, the ethylene exhibits a broad spectrum in contrast to that of 1,1′-dianthrylacetylene[5] which shows a well-defined fine structure. The electronic spectrum of I also exhibits a sharp fine structure,[1] and vibrational sub-peaks are still observed in the broad and intense absorption bands of II.[2] Thus, the broadening and disappearance of the fine structure in the spectrum of III seem to be attributed mainly to the non-planar geometry of the annelated[14]annulene (III).

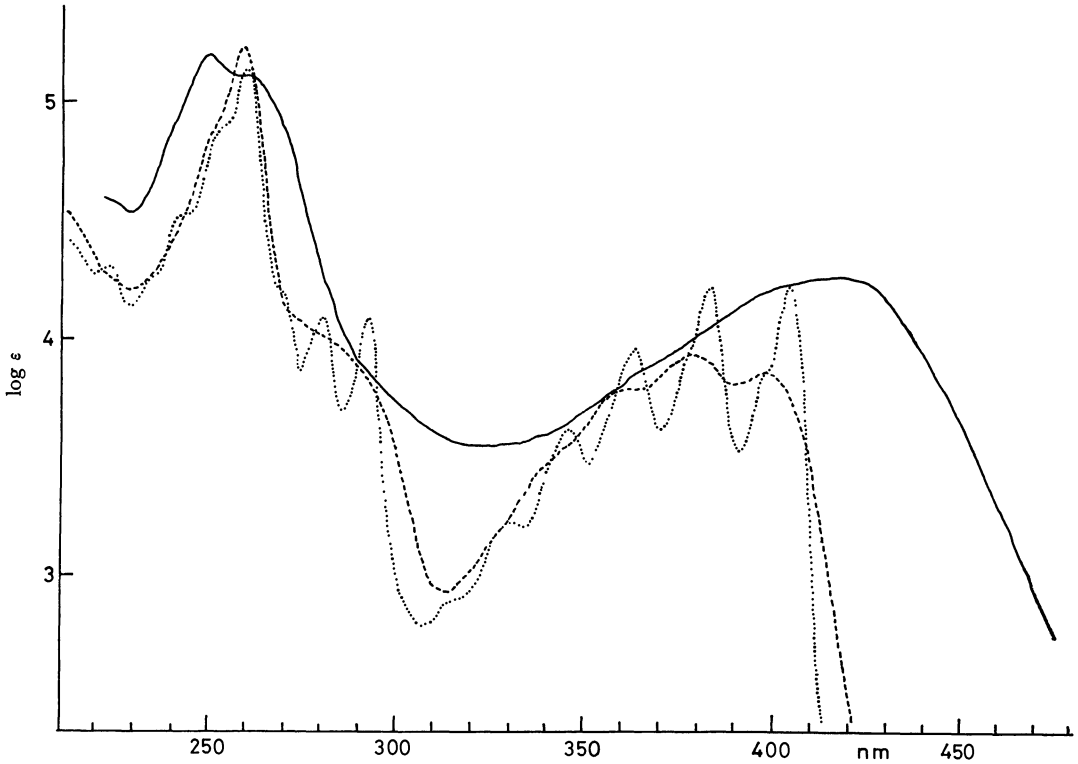

Fig. 2. The electronic spectra of dianthr[14]annulene (III, ——), 1,8-divinylanthracene (X, ——), and 1,8-diethynylanthracene (------).

4) Unpublished result.

5) S. Akiyama, K. Nakasuji, and M. Nakagawa, This Bulletin, **44**, 2231 (1971).

The NMR spectrum of III could not be measured owing to the poor solubility of III in various NMR solvents.

Experimental

All melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T spectrophotometer. The infrared and the mass spectra were measured on a Hitachi EPI-2 spectrophotometer and a Hitachi RMU-6D mass spectrometer, respectively.

1,8-Bis(hydroxymethyl)anthracene (V). The dialdehyde[2] (IV, 11.72 g, 0.05 mol) was reduced by means of sodium borohydride (1.90 g, 0.05 mol) in tetrahydrofuran (150 m*l*) employing a Soxhlet technique. Reflux was continued for 4 hr. Water was then added to deposit yellow crystals in a quantitative yield. Glycol V thus prepared was found to be identical with the specimen previously prepared.[2]

1,8-Bis(bromomethyl)anthracene (VI). To a stirred mixture of the diol (V, 2.38 g, 0.01 mol), pyridine (0.40 g, 5 mmol) and tetrahydrofuran (50 m*l*), was added a solution of phosphorus tribromide (4.07 g, 0.015 mol) in tetrahydrofuran (10 m*l*) over a period of 20 min. After stirring for further 2 hr at room temperature, cracked ice was added to the reaction mixture. The organic layer was separated, and worked up according to the usual procedure. The solvent was evaporated under reduced pressure. The residue was collected by filtration, and washed successively with an aqueous solution of sodium hydrogen carbonate and water. The yellow crystals obtained in a quantitative yield were recrystallized from benzene to afford yellow needles, mp 230—232°C (dec.). Found: C, 52.94; H, 3.31; Br, 43.69%. Calcd for $C_{16}H_{12}Br_2$: C, 52.78; H, 3.32; Br, 43.90%.

1-Bromomethyl-8-triphenylphosphoniomethylanthracene Bromide (VII). A solution of dibromide (VI, 3.64 g, 0.01 mol) and triphenylphosphine (3.90 g, 0.015 mol) in dry benzene (120 m*l*) was refluxed for 3 hr. The precipitate formed was collected, washed with benzene, and then dried to yield VII, mp 260—265°C (dec.), 6.05 g (97%). Found: C, 66.20; H, 4.34%. Calcd for $C_{34}H_{27}Br_2P$: C, 65.20; H, 4.34%. Unsatisfactory results in the analysis of carbon might be due to contamination with a small amount of bis-phosphonium salt VIII.

1,8-Bis(triphenylphosphoniomethyl)anthracene Dibromide (VIII).
1) From the Monophosphonium Salt (VII): A mixture of VII (2.10 g, 3.35 mmol), triphenylphosphine (1.30 g, 5 mmol) and dimethylformamide (15 m*l*) was refluxed for 30 min. The precipitate formed by the addition of benzene (10 m*l*) was collected and then washed with a small amount of benzene, resulting in yellow fine cubes, 2.48 g (84%). The second crop (0.17 g, 6%) was obtained from the mother liquor. Decomposition of VIII was observed above 360°C.

2) From the Dibromide (VI): A solution of VI (0.364 g, 1 mmol) and triphenylphosphine (0.786 g, 3 mmol) in dimethylformamide (2 m*l*) was heated on a boiling water-bath for 2 hr. The precipitate formed on cooling the reaction mixture in an ice-water bath was collected by filtration and washed with a small amount of benzene. Bis-phosphonium bromide VIII, thus prepared, showed an identical IR spectrum with that of VIII derived from VII and decomposed also above 360°C. Found: C, 70.04; H, 4.78; Br, 17.49%. Calcd for $C_{52}H_{42}Br_2P_2$: C, 70.28; H, 4.76; Br, 17.98%.

1,2,3,4,5:8,9,10,11,12-Di(1',8'-anthr)[14]annulene (III). To a suspension of the bis-phosphonium salt (VIII, 5.334 g, 6 mmol) in toluene (200 m*l*), was added an ethereal solution of phenyllithium (0.85 N, 14.1 m*l*, 12 mmol) at 80°C over a period of 15 min under nitrogen atmosphere. After the mixture had been stirred for 15 min at 80°C, a solution of the dialdehyde (IV, 1.404 g, 6 mmol) in toluene (210 m*l*) was added, and stirred for 2 hr at the same temperature. The insoluble material was collected by filtration, and washed with water and alcohol successively to remove triphenylphosphine oxide. The residue was then digested repeatedly with boiling chlorobenzene (total 1.2 *l*). A brown resinous powder insoluble in chlorobenzene (*ca.* 0.7 g) remained. The hot extract was passed through a column of alumina (60 g) to give yellow filtrate with green fluorescence. The solvent was removed under reduced pressure to afford yellow needles, 0.412 g (17%). The original filtrate of the reaction mixture was passed through a thin layer of alumina (10 g), and the filtrate was concentrated *in vacuo* to afford the second drop of III (0.101 g, 4%). The slightly crude crystals of III thus obtained were dissolved in chlorobenzene and passed through a short column of alumina, affording pure III as bright yellow fine needles with green fluorescence. III was found to decompose above 360°C. Found: C, 94.78; H, 5.00%. Calcd for $C_{32}H_{20}$: C, 95.02; H, 4.98%. IR: 975 cm^{-1} (*trans* double bond). Mass: 404 (M^+), Calcd 404.5. The ratio of $M^+/M^+ + 1$ was found to be consistent with the theoretical value (obs. 0.331. theor. 0.349). UV: $\lambda_{max}^{tetrahydrofuran}$ (ε) 249 (157900), 257 (131300), and 418 (18300) nm.

1,8-Divinylanthracene (X). To a stirred solution of the bis-ylide IX [from VIII, 1.778 g, 2 mmol and phenyllithium, 4 mmol in toluene (50 m*l*)], was added a large excess of paraformaldehyde [dried over phosphorus pentoxide for 3 days] at 70°C. Rapid disappearance of the characteristic red color of the ylide solution was observed. After stirring for 2 hr the solvent was evaporated under reduced pressure and extracted with cyclohexane (150 m*l*). The extract was percolated through a thin layer of alumina (3 g), affording a faint yellow solution with blue-violet fluorescence. Concentration of the solvent under reduced pressure resulted in pale yellow plates, 0.270 g (57%), mp 68—70°C. The material was recrystallized twice from methanol to give analytical specimen, mp 70—71.5°C. Found: C, 93.66; H, 6.06%. Calcd for $C_{18}H_{14}$: C, 93.87; H, 6.13%. IR: 1240, 910 ($=CH_2$), 990 ($=C\langle_H$) cm^{-1}. Mass: 230 (M^+), Calcd 230. UV: $\lambda_{max}^{n\text{-hexane}}$ (ε) 256 (165600), 360 (6100), 378 (8700), and 398 (7300) nm.

The Reduction of *gem*-Dibromocyclopropanes by Means of Chromium(II) Acetate or Potassium Pentacyanocobaltate

Tamio SHIRAFUJI, Koichiro OSHIMA, Yasusi YAMAMOTO, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yosida, Kyoto

(Received May 28, 1971)

The reduction of *gem*-dibromocyclopropane(I) with Cr^{II} acetate in DMSO gives monobromocyclopropanes (II and III) exclusively, whereas the same components in aq DMF afford cyclopropyl acetates(IV and V) as the major products in addition to II and III. A similar substitution on cyclopropane carbon is observed in the reduction of I with $K_3Co(CN)_5$ in DMSO, furnishing cyclopropyl cyanides (IX and X) mainly. The stereochemistry of II, III, IV, and V is determined by the NMR coupling constants and chemical shifts, and that of IX and X, by transformation to the corresponding cyclopropyl methyl ketones derived from cyclopropanecarboxylic acids of known configurations. The reaction of II or III with $K_3Co(CN)_5$ is also described.

The reduction of *gem*-dibromocyclopropanes (I) with chromium(II) (Cr^{II}) sulfate produces *endo*-monobromocyclopropanes (II), along with allenes and completely reduced cyclopropanes (Scheme 1, route A).[1] We now wish to report on the behavior of I toward Cr^{II} acetate or potassium pentacyanocobaltate ($K_3Co(CN)_5$) in polar solvents (Scheme 1, route B or C). The reaction of these reductants with organic halides is not without precedent,[2] but the observed semireduction of I and the accompanying substitution reaction on cyclopropane carbon appear to be novel. The semireduction to monobromocyclopropanes[3] has been effected by means of Cr^{II} acetate in DMSO (system B), whereas substitution products such as cyclopropyl acetates or cyclopropyl cyanides have been obtained as major products in the reaction of I with Cr^{II} acetate in aqueous DMF (system C) and in that of I with $K_3Co(CN)_5$ in DMSO respectively. Such behavior is in remarkable contrast with that of Cr^{II} sulfate in aqueous DMF (system A[1]).

Table 1 summarizes the yields of the isomeric monobromocyclopropanes obtained in the reaction of I with the system B, which proceeded smoothly to afford only

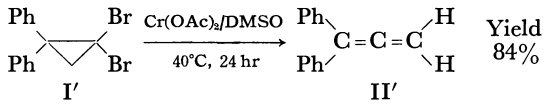
3) a) D. Seyferth, H. Yamazaki, and D. L. Alleston, *J. Org. Chem.*, **28**, 703 (1963); b) D. Seyferth and B. Prokai, *ibid.*, **31**, 1702 (1966); c) T. Ando, H. Yamanaka, F. Namigata, and W. Funasaka, *J. Amer. Chem. Soc.*, **89**, 5719 (1967).

negligible amounts of byproducts, such as allenes and cyclopropanes. The isomer distribution followed the same lines as were observed with other reductants[3]; that is, the predominance of *endo* (or *cis*) products, II, over the stereoisomers, III, holds with the exception of the case of Ic. Unexpectedly, the treatment of 1,1-dibromo-2,2-diphenylcyclopropane (I') with Cr^{II} acetate in DMSO gave 1,1-diphenylallene (II') as the sole isolable product. This is the only case where an allene is obtained.



I' II'

The reaction of I with Cr^{II} salts would probably proceed according to Scheme 1, but several remarkable points of difference have been observed between the two systems, A and B. (1) A more rigorous preference of II over III is observed with the system A. (2) Better yields of allenes are obtained in the system A with the exception of the above-mentioned case of 1, 1-dibromo-2,2-diphenylcyclopropane. (3) Totally-reduced cyclopropanes are obtained only in the system A. Rapidly flipping radicals (VI) may be responsible, in part at least, for the formation of II and III in the system B, whereas organochromium intermediates (VII) probably account for the exclusive formation of II in the system A. Allenes and cyclopropanes may originate from the postulated inverse ylides (VIII), which can not be important in the system B.

Unexpectedly, the treatment of I with the system C gave cyclopropyl acetates (IV and V) in addition to monobromocyclopropanes (II and III), as is shown in Table 2.[4] The stereochemistry of IV and V was determined by means of the NMR chemical shifts and coupling constants of the acetoxy methyl protons and the acetoxy-substituted methine protons.[5]

Table 3 summarizes the reactions of I with $K_3Co(CN)_5$ in DMSO.[6] The stereochemistry of the resulting cyclopropyl cyanides (IX and X) was determined by transformation to the corresponding cyclopropyl methyl ketones (XI and XII), as is shown in Table 4.[5] The authentic samples were obtained by the reaction of methyllithium with cyclopropanecarboxylic acids (XIII and XIV) of know configurations (Table 5).[7]

The *endo*/*exo* ratios of monobromocyclopropanes given in Tables 2 and 3 are nearly the same as those obtained in the reduction of I with the system B and are consistently larger than one. Reversely, the *endo*/*exo* or *cis*/*trans* ratios of the substitution products, V/IV and X/IX, were smaller than one. The attempted reaction of two isolated monobromocyclopropanes, II and III, with Cr^{II} or Cr^{III} acetate in DMSO or in aqueous DMF afforded no cyclopropyl acetates, IV and V, but only complex mixtures, which could not be investigated

b) Yields were based on the consumed amount of II or III.

further. We are tempted to assume that IV and V originate from chromium carbenoids (VII) or from chromium inverse ylides (VIII).

The reaction of Ib with $K_3Co(CN)_5$ in DMSO was monitored by means of glc. The results, shown in Fig. 1, indicated the initial formation of IIb and IIIb from Ib followed by the subsequent conversion of IIb and IIIb to cyclopropyl cyanides, IXb and Xb. In fact, the treatment of isolated II or III with $K_3Co(CN)_5$ in DMSO afforded a mixture of IX and X, as is shown in Table 6. The observed formation of a mixture, IX and X, from either II or III possibly involves an S_N-type reaction on a cyclopropane ring, accompanied by no ring-cleavage.[8] We may point out that the isomer ratios in this kind of S_N reactions are largely controlled thermodynamically, but a full explanation must await further investigations in the future.

Experimental

All the boiling points are uncorrected. Glc analyses and separations were performed using a 2-*m* column of HVSG (30%) and He as the carrier gas. The NMR spectra were obtained on a 60 MHz instrument (JEOL C-60-H spectrometer), and the chemical shifts are given in ppm from a TMS internal standard. The mass spectra were obtained on a Hitachi RMU 6D spectrometer. The microanalyses were performed by Mrs. K. Fujimoto at Prof. Sisido's Laboratory and by the Elemental Analyses Center of Kyoto University. The $K_3Co(CN)_5$[2b] and anhydrous Cr^{II} acetate[11] were prepared by the recorded methods.

General Procedure of the Reactions of gem*-Dibromocyclopropane Derivatives with Cr^{II} Acetate or $K_3Co(CN)_5$ in DMSO or Aqueous DMF.* In a nitrogen atmosphere, Cr^{II} acetate (or KCN and Co^{II} chloride) was dissolved in freshly-distilled (over CaH_2) DMSO or in aqueous DMF (1: 1) so as to give *ca.* a 0.3M solution by heating with stirring at 60—70°C for 30 min; then, the solution was maintained at an appropriate reaction temperature (20—80°C). To this we added, drop by drop, a solution (*ca.* 1.5M) of *gem*-dibromocyclopropanes in the same solvent. The atomic ratio of bromine: Cr^{II} (or Co^{II}) was taken to be 1: 1.5—2.0 unless otherwise stated. Heating and stirring were continued until the reddish-brown solution (or blue solution) turned green (or colorless). The mixture was then treated with water and extracted with *n*-hexane, ether, or benzene. The extract was washed with water, dried (Na_2SO_4), and concentrated *in vacuo*. The products were separated and identified as usual. The following description is concerned with cases which are not sufficiently covered by Tables 1, 2, and, 3. Incidentally, the reactions of monobromocyclopropanes with $K_3Co(CN)_5$ in DMSO shown in Table 6 were also performed by this procedure.

*Reaction of 1,1-Dibromo-2-*n*-hexylcyclopropane (Ic) in DMSO.* Dibromide Ic (0.10 g, 0.35 mmol) was treated with a solution of Cr^{II} acetate (0.25 g, 1.5 mmol) in DMSO (30 ml) at 50°C for 17 hr. The glc separation of the reaction mixture gave *cis*-1-bromo-2-*n*-hexylcyclopropane (0.02 g, 27%) and a *trans* isomer 0.035 g, 46%). The *cis*-bromide formed an oil; bp 75°C/18 mmHg (bath temp.), IR (neat): 1248 cm^{-1}, NMR $\delta(CCl_4$, 10%): 2.99 (*m*, 1H, >C<u>H</u>Br, J_{cis}=6.6 Hz), 1.37 (*m*, 10H, methylenes), 0.89 (*m*, 4H, methyl and methine), and 0.44 (*m*, 2H, -C<u>H</u>$_2$CHBr-).

Found: C, 52.9; H, 8.2%. Calcd for $C_9H_{17}Br$: C, 52.7; H, 8.4%. The *trans*-bromide also formed an oil; bp 70°C/18 mmHg (bath temp.), IR (neat): 1234 cm^{-1}, NMR $\delta(CCl_4$, 20%): 2.48 (*m*, 1H, >C<u>H</u>Br, J_{trans}=3.3 Hz), 1.32 (*m*, 11H, methylenes and methine), and 0.87 (*m*, 5H, methyl and -C<u>H</u>$_2$CHBr-).

Found: C, 52.7; H, 8.3%. Calcd for $C_9H_{17}Br$: C, 52.7; H, 8.4%.

Identification of Substitution Products (IV, V, IX, and X). The substitution products, IV, V, IX, and X, were unstable, so that the isolation of each stereoisomer was hard to accomplish. Each mixture of IV and V, or of IX and X, was obtained in an analytically-pure form by preparative tlc; the results of the analyses are shown in Table 7. High-sensitivity glc analyses of the mixtures gave the isomer ratio, which was in accord with the NMR analyses of the mixtures (Table 7). The ratios have been given above in Tables 2, 3, and 6. The attempted isolation of stereoisomers by preparative glc did not give satisfactory results.

Transformation of Cyclopropyl Cyanides (IX and X) to the Corresponding Cyclopropyl Methyl Ketones (XI and XII). A mixture of IX and X was treated with excess amounts of methylmagnesium iodide in ether under gentle refluxing. The reaction mixture was then worked up as usual. A

8) S_N-type reactions of vinylic halides with $K_4Ni_2(CN)_6$ in methanol have been recorded to give α,β-unsaturated nitriles in good yields. See Ref. 9. The S_N-type reaction of *endo*-rich cyclopropyl halides with Ag^I nitrate in methanol gave almost equimolar mixtures of *exo*-rich methoxycyclopropanes and ring-opened methanolysates See Ref. 10.

mixture of XI and XII was obtained in an analytically-pure form by preparative glc. The physical properties are shown in Table 8. High-sensitivity glc analyses of the mixture gave the isomer ratio, which was in accord with the NMR analyses of the mixture (Table 8). The ratios have been given above in Tables 4 and 5.

Transformation of Cyclopropanecarboxylic Acids (XIII and XIV) to the Corresponding Cyclopropyl Methyl Ketones (XI and XII). A mixture of XIII and XIV was treated with excess amounts of methyllithium in ether under gentle refluxing. The reaction mixture was then worked up as usual. A mixture of XI and XII was obtained in an analytically-pure form by preparative glc. The analytical data are shown in Table 8.

The authors are grateful to Professor Keiiti Sisido for his generous help. The financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is also acknowledged with pleasure.

The Structure of Petasitolone, a New Constituent of *Petasites japonicus* Maxim[1]

Keizo NAYA, Fumio YOSHIMURA, and Ichiro TAKAGI

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo

(Received May 29, 1971)

Petasitolone(I), a new sesquiterpene isolated from *Petasites japonicus* Maxim. has been shown to be 8-oxo-11-hydroxy-$\Delta^{6(7)}$-eremophilene by a physico-chemical method, and synthesized from the known fukinone(VI).

The constituents of flower stalks of *Petasites japonicus* Maxim. have been studied.[2-4] We reported the isolation of fukinone (VI) from the methanolic extract of a cultivated variety "Aichiwasebuki" of this plant. We also isolated a new sesquiterpene named petasitolone from the extract.

Petasitolone (I), $C_{15}H_{24}O_2$, bp 92°C/0.15 mmHg, $[\alpha]_D^{24}+16.7°$, a colorless oil, was obtained by steam and vacuum distillation, and chromatography on silica gel. The two oxygen atoms and one double bond were readily characterized by spectroscopic data: IR bands (Fig. 1) at 3480, 1170 (OH), 1665 cm^{-1} and an UV

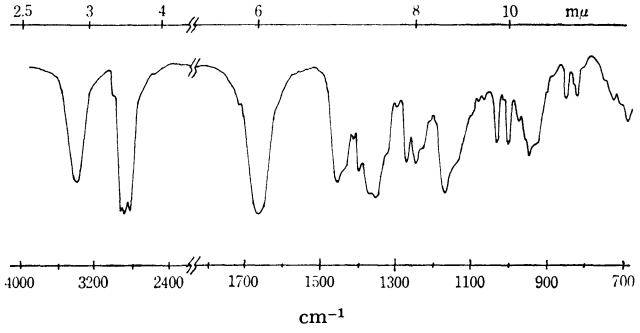

Fig. 1. IR spectrum of petasitolone.

maximum at 237.5 mμ (α,β-unsaturated C=O). Its NMR spectrum indicates one isolated olefinic proton at 6.6[5] due to a β-hydrogen of an α,β-unsaturated ketone, one hydroxyl proton at 3.52, two methyls attached to a carbon bearing a hydroxyl at 1.30, one tertiary methyl at 1.11 and one secondary methyl at 0.93 (d, J=7 Hz). Petasitolone I failed to yield a semicarbazone but afforded a mixture of two 2,4-dinitrophenylhydrazones, $C_{21}H_{28}O_5N_4$, mp 159—160°C and $C_{21}H_{26}O_4N_4$, mp 173—174°C, by Brady's method. The latter $C_{21}H_{26}O_4N_4$ shows no OH band in its IR spectrum and was found to be identical with anhydropetasitolone (II) by mixed melting point determination.

From the above results, petasitolone is strongly presumed to be a bicyclic sesquiterpene containing an α,β-unsaturated carbonyl and a dimethylcarbinol group. The conclusion concerning the structure was confirmed by the following reactions.

Petasitolone was dehydrated with phosphorus oxychloride-pyridine in the cold to yield anhydropetasitolone (II), $C_{15}H_{22}O$, which exhibits an IR band at 1675 cm^{-1} and an UV maximum at 254 mμ (α,β-unsaturated C=O). Its NMR spectrum shows new signals: *i.e.*, a slightly split singlet at 1.86 for a vinyl methyl and two signals at 5.02 and 4.88, respectively for an end-methylene group.

Catalytic hydrogenation of petasitolone with platinum oxide-acetic acid yielded a mixture of dihydropetasitolone (III), $C_{15}H_{26}O_2$ and desoxydihydropetasitolone (IV), $C_{15}H_{26}O$ in the approximate ratio of 2: 3. Upon hydrogenation with palladium charcoal in ethanol, petasitolone furnished predominantly dihydropetasitolone III. Hydrogenolysis to the desoxydihydro compound IV implies that the hydroxyl group of petasitolone can be assumed to be located in the allylic position to the double bond. The desoxydihydro compound IV was found to be identical with the known dihydrofukinone (IV)[3] by comparison of IR spectra and ORD (-Cotton effect) curves, and mixed melting point determination of the two 2,4-dinitrophenylhydrazones.

Thus, from the above evidence the structure of petasitolone, dihydropetasitolone and desoxydihydro compound can be assigned as shown in stereoformulas I, III, and IV.

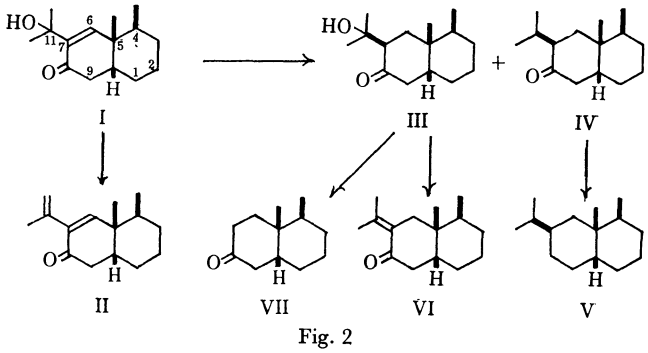

Fig. 2

Along with the above work, the following reactions were examined.

The desoxydihydro compound IV was converted into the known 7β-eremophilane (V)[3,6] *via* ethylene thioketal followed by desulfurization with Raney nickel. On the other hand, when dihydropetasitolone III was subjected to preparative glc for purification, it gave a de-

composition product $C_{12}H_{20}O$ with loss of the dimethylcarbinol unit. The product was identical with desisopropylidenefukinone (VII) obtained previously by base catalyzed retro-aldol reaction from fukinone VI. Dehydration of dihydropetasitolone III with phosphorus oxychloride-pyridine yielded the known fukinone VI as expected.

Synthesis of Petasitolone (I). We postulated that naturally occurring intermediate for petasitolone I is fukinone VI which is converted in the plant to petasitolone I by photochemical oxidation. Little is known about the photosensitized addition of oxygen to an α,β-unsaturated carbonyl system. In fact, the mode of addition to the double bond conjugated with the carbonyl group was found to be similar to that found by Schenck in simple olefinic systems.[7]

When fukinone was irradiated in the presence of rose bengal in atmospheric oxygen followed by reduction with sodium sulfite, petasitolone I was obtained as the main product (45%). The details of the oxidation products will be reported later.

Experimental

All the melting and boiling points are uncorrected. Mass spectra were measured with a Hitachi RMU-6 mass spectrometer; ion source temperature 250°C; evaporation temperature 150°C. IR spectra were recorded with a JASCO DS-402G spectrophotometer and UV spectra were obtained with a Cary Model 14 spectrophotometer. ORD curves were measured with a JASCO spectropolarimeter Model ORD-5. NMR spectra were determined with a Japan Electron Optics JNM-C-60 spectrometer, using TMS as an internal standard ($\delta=0$) and $CDCl_3$ as solvent. Analytical and preparative glc were performed with a Shimadzu GC-1C apparatus on a stainless steel column ($\phi=3$ mm). Tlc were run on silica gel (Merck Kieselgel G). Microanalyses were carried out in the microanalytical section of Shionogi Research Laboratory, Shionogi and Co., Ltd.

Isolation of Petasitolone (I). The dried flower stalks of *P. japonicus* Maxim. (4.5 kg) cultivated in Osaka Prefecture were extracted with methanol at room temperature for 2 weeks. The extract was evaporated *in vacuo* and the residue was extracted with ether to give a dark brown oil (100 g). The oil was chromatographed on silica gel (1 kg). Elution with benzene gave crude fukinone (VI) (40 g) and further elution with methanol afforded an oil (50 g) which was subjected to steam distillation. The distillate was extracted with ether to give an oil (10 g) which contained petasitolone (I) as a major component. The crude petasitolone was purified by silica gel column chromatography using light petroleum-acetone (50: 1) as eluent and by vacuum distillation to give an almost pure sample (1 g) as a colorless oil, bp 92°C/0.15 mmHg; MS: M$^+$ion *m/e* 236, base peak *m/e* 43; IR (film): 3480, 1665, 1170 cm^{-1}; UV: λ_{max}^{MeOH} 237.5 mμ (ε, 8279); $[\alpha]_D^{24}$ +16.7° (*c*, 0.99, MeOH); NMR: 0.93 (d, $J=7$ Hz, 3H), 1.11 (s, 3H), 1.30 (s, 6H), 3.52 (br s, 1H), 6.6 (s, 1H).

Petasitolone (I) was recovered unchanged on both attemted acetylation and Jones' oxidation. The crude product obtained from petasitolone and 2,4-dinitrophenylhydrazine by Brady's method was chromatographed on silica gel and eluted with light petroleum-ether (50: 1) to afford II- and then I-2,4-dinitrophenylhydrazones.

Anhydropetasitolone (II) 2,4-dinitrophenylhydrazone, red needles, mp 173—174°C.

Found: C, 63.30; H, 6.52; N, 13.85%. Calcd for $C_{21}H_{26}O_4N_4$: C, 63.30; H, 6.58; N, 14.06%.

Petasitolone (I) 2,4-dinitrophenylhydrazone, red needles, mp 159—160°C.

Found: C, 60.40; H, 6.85; N, 13.47%. Calcd for $C_{21}H_{28}O_5N_4$: C, 60.56; H, 6.78; N, 13.45%.

Preparation of Anhydropetasitolone (II). Phosphorus oxychloride (3 m*l*) was added slowly to a solution of petasitolone (470 mg) in pyridine (4 m*l*). After being kept standing for 2 days the reaction mixture was added dropwise into ice water, extracted with ether, washed with water and dried over anhydrous sodium sulfate. The solvent was then evaporated. The residue was chromatographed on silica gel (10 g) with light petroleum-ether (50: 1) as eluent to give pure anhydropetasitolone (II) (140 mg) ; MS: M$^+$ion *m/e* 218, base peak *m/e* 147; UV: λ_{max}^{hexane} 254 mμ (ε, 4110); IR (film): 1675, 895 cm^{-1}; NMR: 1.86 (s, 3H), 5.02 and 4.88 (2H). Anhydropetasitolone 2,4-dinitrophenylhydrazone, $C_{21}H_{26}O_4N_4$, mp 173—174°C.

Found: C, 63.62; H, 6.71; N, 13.99%. Calcd for $C_{21}H_{26}O_4N_4$: C, 63.30; H, 6.58; N, 14.06%.

Catalytic Hydrogenation of Petasitolone. a) Platinum Oxide as Catalyst: Petasitolone I (1 g) in acetic acid (10 m*l*) was hydrogenated over Adams' catalyst (80 mg) at room temperature and atmospheric pressure to yield dihydropetasitolone (III) (300 mg) and a desoxydihydro compound (IV) (450 mg). Dihydropetasitolone III : a colorless oil, IR (film): 3340, 1690 cm^{-1}. IR spectrum and glc retention time of compound IV were identical with those of dihydrofukinone obtained from fukinone.[3] ORD in MeOH (*c*, 0.125): $[\phi]_{311}$ −904, $[\phi]_{272}$+1848, $a=-27.5$; 2,4-Dinitrophenylhydrazone, mp 170.5—171°C (authentic sample, [3] mp 171—171.5°C, mixed mp 170.5—171°C).

b) Palladium Charcoal as Catalyst: Petasitolone (600 mg) in ethanol (10 m*l*) was hydrogenated over 10% palladium charcoal (150 mg) at room temperature and atmospheric pressure for 16 hr. About 70 m*l* of hydrogen was absorbed and crude dihydropetasitolone III (560 mg) was obtained as the main product.

Conversion of Desoxydihydro Compound (IV) into 7β-Eremophilane(V). A mixture of IV (25 mg), ethanedithiol (2 m*l*), and BF_3-etherate (4 drops) was allowed to stand for 1 hr, and extracted with ether affording crude thioketal (40 mg). The crude thioketal in ethanol (2m*l*) was refluxed with Raney nickel (1 g) to give 7β-eremophilane (24 mg), which is identical with the authentic sample[3] by glc (PEG-20M, 2.6 m; 30 m*l*/min H_2, column temperature 180°C; retention time 6 min 20 sec).

Conversion of Dihydropetasitolone (III) into Desisopropylidenefukinone (VII) in Glc Column. Dihydropetasitolone III was passed through a glc column (PEG-20M; column temperature 180°C) to give desisopropylidenefukinone (VII), identical with the authentic sample[3] by comparison of IR spectra and glc.

Conversion of Dihydropetasitolone (III) into Fukinone (VI). Dihydropetasitolone III (250 mg) and phosphorus oxychloride (1 m*l*) was dissolved in pyridine (2 m*l*). After being kept standing for a week, the reaction mixutre was poured into ice-water and extracted with ether affording crude fukinone VI (200mg), which was purified by preparative glc (SPE, 2.6 m; 86 m*l*/min H_2; column temperature 190°C; retention time 8 min 20 sec).

Preparation of Petasitolone from Fukinone by Photosensitized Oxidation. A mixture of fukinone (2 g) and rose bengal (50 mg) dissolved in absolute methanol (250 m*l*) was irradiated with a fluorescent lamp (30 watt) under bubbling

7) G. O. Schenck, K. Gollnick, G. Buchwald, S. Schroeter, and G. Ohloff, *Ann. Chem.*, **674**, 93 (1964).

of air for 4 days, when all fukinone was consumed (on tlc analysis). A solution of sodium sulfite (4 g) and water (60 m*l*) was added to the reaction mixture and stirred for 10 hr. The solvent was evaporated *in vacuo*, and the residue was extracted with ether to give a crude oil (1.75 g). The crude oil was chromatographed repeatedly over silica gel eluted with benzene or light petroleum-ether (10 : 1) to afford pure petasitolone (0.9 g) which was identical with the natural specimen by comparison of IR and glc (SE-30, 2.6 m; 60-*ml*/min H_2; column temperature 130°C; retention time 8 min).

The authors wish to thank the staff of Shionogi Research Laboratory, Shionogi and Co., Ltd., for microanalysis and the Institute of Food Chemistry for the measurements of MS and NMR spectra.

Photolytic and Thermal Decompositions of 5-Substituted 1,2,3,4-Thiatriazoles in the Presence of Olefins. Reactions of Sulfur Atoms

Renji OKAZAKI, Kazumi OKAWA, Seiji WAJIKI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 15, 1971)

Photochemical decompositions of 5-phenyl- and 5-amino-1,2,3,4-thiatriazoles in the presence of cyclohexene or tetramethylethylene led to the formation of the corresponding episulfide, the production of which has been explained in terms of sulfur atom reactions with the olefins. Kinetic measurements revealed the limitation of the reactions as a synthetic method of an episulfide from an olefin. Mechanism of the episulfide formation was briefly discussed. Thermal decompositions of these thiatriazoles in the presence of olefins gave rise to no episulfides.

Reactions of sulfur atoms have been extensively studied by Strausz and Gunning[1-3] using the photolysis of carbonyl sulfide. Almost all the reactions, however, have been carried out in gas phase and the precursor of sulfur atoms has been restricted only to carbonyl sulfide. Although carbonyl sulfide is probably the most useful source of sulfur atoms for mechanistic studies, the gaseous sulfide is an inconvenient precursor for synthetic studies. There are a few data on reactivities of sulfur atoms in solution,[4,5] and very recently Leppin and Gollnick reported direct photolysis of carbonyl sulfide in diverse organic solvents and reactions of sulfur atoms, thus formed, in solution.[6-8]

This paper describes the reactions of sulfur atoms generated from 5-substituted 1,2,3,4-thiatriazoles in organic solvents and their applicability as a synthetic method of episulfides from olefins.

Results and Discussion

5-Phenyl-1,2,3,4-thiatriazole (I) has been reported to decompose thermally into nitrogen, benzonitrile, and sulfur, and photochemically into the above three compounds and phenyl isothiocyanate.[9]

We found that photolysis of I in the presence of cyclohexene yielded cyclohexene episulfide (II). Results are summarized in Table 1. Identification and yield determination of the reaction products were carried out by means of gas chromatography (g.l.c.). Episulfide (II) was a sole product derived from reactions of sulfur atoms with cyclohexene, no cyclohexene thiols, insertion products, being formed.

Irradiation with high pressure or low pressure mercury lamp (HP or LP lamp) gave rise to II in a similar yield. Irradiation time was chosen so that the amount of II monitored by glc became approximately maximum, since II was found to decompose partially under these reaction conditions. Decomposition rates of I (rate constant k_1) were determined spectrophotometrically by following the decrease in the absorption ($\lambda_{max}^{CH_2Cl_2}$ 283 nm, ε 12000) and the decomposition was found to obey good first-order kinetics (see Table 1 for k_1 values).

Episulfide (II) was found to decompose also according to the first-order kinetics with rate constants (k_2) of 0.218 hr^{-1} (LP lamp) and 0.0848 hr^{-1} (HP lamp). Using these rate constants (k_1 and k_2) and assuming that k_3 and k_3' (rate constants of formation of II and

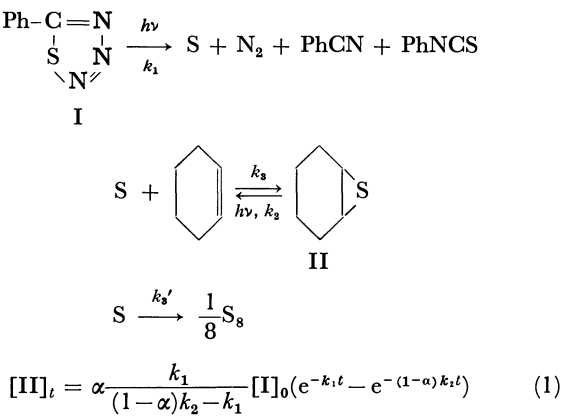
	2	11	87	11	—[c]	0	0.148	0.35
HP	1	8	44	4	30	—[c]	0.0395	0.26
	2	8(12)[d]	39(55)	5(7)	33(46)	29	0.0428	0.25

a) For definition, see Text.
b) HP and LP denote high pressure and low pressure mercury lamps, respectively.
c) Not determined.
d) Yield in parenthese based on I decomposed.

molecular sulfur, respectively) are much larger than k_1 and k_2, we can derive equation (1) on the basis of the following scheme and accordingly can estimate a hypothetical mole ratio (α) of II formed to I decomposed[10] when II is assumed not to photodecompose.



$$[\mathrm{II}]_t = \alpha\frac{k_1}{(1-\alpha)k_2-k_1}[\mathrm{I}]_0(e^{-k_1 t}-e^{-(1-\alpha)k_2 t}) \qquad (1)$$

where $[I]_0$ and $[II]_t$ stand for the concentration of I before irradiation and that of II at time t, respectively. The α values thus obtained (Table 1) indicate that, even if II were stable under these photochemical conditions, the yields might not exceed 35% and 26% under irradiation conditions with LP lamp and HP lamp, respectively. The low values of α seem to reveal the limitation in using sulfur atoms in solution as a reagent for episulfide syntheses.

Comparison of the present data with those of triplet sulfur atom reactions in gas phase deserves some mention. A triplet sulfur atom in gas phase has been reported to react with cyclopentene, structurally similar to cyclohexene, forming cyclopentene episulfide in 54% yield. In the case of other olefins such as ethylene, propylene and butene, the corresponding episulfides have been obtained in more than 80% yield.[11] The great difference in the yield of episulfides is probably attributable to the fact that sulfur atoms generated in solution become less reactive due to deactivation by collision with solvent molecules and readily polymerize into molecular sulfur instead of reacting with cyclohexene.

In this connection, the following two observations are noteworthy. First, the thermal decomposition of I in the presence of an olefin gave no episulfide. This is probably explicable in terms of low excess kinetic(translational) energy of sulfur atoms generated in the thermal reaction. Second, no thiols were formed in the photochemical reactions with cyclohexene. This suggests that the reactive species formed in the photodecomposition of I is a triplet sulfur atom.[1,8] According to Leppin and Gollnick, a singlet sulfur atom generated from carbonyl sulfide is effectively deactivated into a triplet species in alcohol, alkyl cyanide and aromatic hydrocarbon solvents.[6] It is reasonable that dichloromethane, used as solvent in the present study, might be also a solvent favorable for the intersystem-crossing because of heavy atom effect of the chlorine atoms.

Table 2. Quenching of photodecomposition of thiatriazole (I) with naphthalene or piperylene in dichloromethane-cyclohexene (3:1)

Quencher	Products (%)			Recovered I (%)
	$C_6H_{10}S$	PhCN	PhNCS	
Naphthalene[a]	12	80	6	0
Piperylene[b]	5[c]	74[c]	6[c]	20[c]

a) With LP lamp. See Experimental.
b) With HP lamp. See Experimental.
c) Yield based on I decomposed.

Quenching experiments were carried out with naphthalene and piperylene which are known as efficient quenchers for a triplet species. Comparison of the results listed in Table 2[12] with those in Table 1 leads to the conclusion that the reactions were not affected by the quenchers and accordingly the triplet state of I would not be involved in the photoreactions, though the possibility that a short-lived triplet state might be involved cannot be excluded completely.

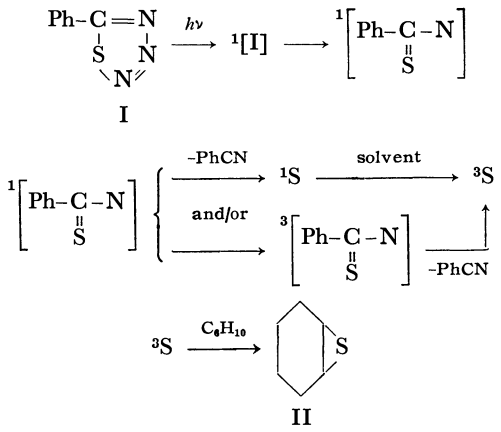
On the basis of the observations described so far, the

10) Since a small amount of phenyl isothiocyanate was actually formed, the exact value is equal to $\alpha/(1-P/100)$, where P is a percentage yield of phenyl isothiocyanate based on I decomposed. However, here we use the approximate value of α for simplicity.

11) E. M. Lown, E. L. Dedio, O. P. Strausz, and H. E. Gunning, *J. Amer. Chem. Soc.*, **89**, 1056 (1967).

12) Although the yield of II in the reaction with piperylene as quencher is lower than that in one without the quencher, this can be readily explained from the fact that a diene also reacts with sulfur atoms.[1]

following scheme is plausible for formation of II.[13]



Difference in α values (0.35 and 0.26) caused by change of irradiation conditions can be accounted for probably by the difference in energy content of sulfur atoms; the triplet sulfur atom generated under irradiation with LP lamp might have much more energy than that generated under irradiation with HP lamp.

Table 3. Effect of cyclohexene concentration upon the yield of cyclohexene episulfide[a]

150/50	20	63	9	51

a) I used, 5.00 g (30.7 mmol); light source, LP lamp; reaction time, 10 hr; reaction temperature, 20°C.
b) Yield based on I decomposed.
c) Not determined.

Attempts were made to increase the α value and consequently the yield of II by increasing the concentration of cyclohexene in the reaction solution. Results are given in Table 3. In 75% (v/v) cyclohexene solution the yield of II amounted to 20%. This value, though not satisfactory for synthetic purpose, is larger than other ones reported for episulfide formation with sulfur atoms in liquid phase; in the presence of cyclohexene, photodecomposition of ethyl isothiocyanate,[4] thermal decomposition of diethyl tetrasulfide,[14] and photodecomposition of carbonyl sulfide[8] have been reported to give the episulfide (II) in 7, 8, and 2% yields, respectively.

Table 4. Yields of episulfide in photodecompositions of thiatriazoles (I and III) in the presence of olefin

Thiatriazole	Light source	Olefin[c] (ml)	Solvent (ml)	Reac. time (hr)	Episulfide (%)
I[a]	HP	C(50)	150	18	6
I[a]	LP	C(80)	110	5	7
I[a]	HP	T(10)	190	16	1
I[a]	LP	T(10)	190	12	6
III[b]	HP	C(50)	150	10	0.4
III[b]	LP	C(50)	150	6	7
III[b]	HP	T(20)	140	19	0.5
III[b]	LP	T(20)	140	9	6

a) 5.00 g (30.7 mmol) in benzene.
b) 2.70 g (26.5 mmol) in methanol.
c) C and T stand for cyclohexene and tetramethylethylene, respectively.

13) Attempts to trap Ph–C(=S)–N fragment with maleic anhydride were unsuccessful.

When the photodecomposition of I was carried out in the presence of cyclohexene or tetramethylethylene with benzene as solvent, similar results were obtained though the yields of the episulfide were somewhat low (Table 4). The reason for the low value in the reaction with tetramethylethylene is not clear.

5-Amino-1,2,3,4-thiatriazole (III) (λ_{max}^{MeOH} 267 nm, ε 4600), which is quite easily accessible from semicarbazide, could be employed as sulfur atom precursor (Table 4). In this case again, however, the yields of the episulfide were low, especially when irradiated with HP lamp.

Experimental

5-Phenyl-[15] and 5-amino-1,2,3,4-thiatriazoles,[16] cyclohexene episulfide,[17] and tetramethylethylene episulfide[18] were prepared by the methods described in literature. Gas chromatographic analyses were carried out using diethylene glycol polysuccinate column at 100°C.

Photodecomposition of 5-Phenyl-1,2,3,4-thiatriazole (I) in Dichloromethane. A General Procedure: Dichloromethane solution of the thiatriazole (5.00 g, 30.7 mmol) and cyclohexene was irradiated with high pressure (HP lamp) (Rikosha, 100 W) or low pressure mercury lamp(LP lamp) (Rikosha, 160 W). All the reactions were carried out under nitrogen atmosphere at 20°C. Rate measurements were performed spectrophotometrically by following the decrease of absorption at 283 nm (ε 12000). Product analyses were made as follows. The residue obtained after evaporation of the excess olefin and the solvent was dissolved again in dichloromethane. The insoluble part was sulfur. The soluble part was decanted into a volumetric flask and subjected to gas chromatographic analyses.

Photodecompositions of 5-Phenyl- (I) or 5-Amino-1,2,3,4-thiatriazole (III) in Benzene or Methanol. The reactions were carried out in a similar manner to that in the reactions in dichloromethane. Product analyses were not made except for episulfide (II).

Photodecomposition of Cyclohexene Episulfide (II). The episulfide (1.04 g) dissolved in a mixture of dichloromethane (150 ml) and cyclohexene (50 ml) was irradiated with LP or HP lamp. The decomposition rate was determined by following the decrease of II using glc.

Quenching Experiments. a) Quenching with Piperylene: The thiatriazole (I) (2.00 g, 12.3 mmol), cyclohexene (20 ml), and piperylene (6.8 g, 100 mmol) were dissolved in dichloro-

methane (60 m*l*), and the solution was irradiated with HP lamp for 18 hr. After similar work-up to that in the other experiments for (I), product analyses were made by glc.

b) Quenching with Naphthalene: The thiatriazole (I) (5.00 g, 30.7 mmol), cyclohexene (50 m*l*), and naphthalene (3.85 g, 30.1 mmol) were dissolved in dichloromethane (150 m*l*) and the solution was irradiated with LP lamp for 10 hr. Product analyses were performed similarly.

Thermal Decomposition of the Thiatriazole (I) or (III) in the Presence of Cyclohexene. The thiatriazole (I) (5.00 g, 30.7 mmol) in a cyclohexene(90 m*l*)-toluene(100 m*l*) mixture was heated at about 100°C for 20 hr. After usual work-up, no cyclohexene episulfide was formed. The thiatriazole (III) (2.70 g, 26.5 mmol) and cyclohexene (50 m*l*) were dissolved in methanol (150 m*l*), and the solution was refluxed for 7 hr. No formation of II was observed.

Adsorptive Properties of Decationated Zeolite for Some Aromatic Hydrocarbons as Observed by Gas Chromatography

Hiroshige MATSUMOTO,* Hideo FUTAMI,** Fumiyoshi KATO, and Yoshiro MORITA

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Nishiokubo, Shinjuku-ku, Tokyo

(Received March 20, 1971)

The adsorptive properties of decationated zeolite for simple aromatic hydrocarbons, such as benzene, toluene, ethylbenzene, and xylenes were investigated by means of gas chromatography at 270—330°C. The specific retention volumes of these alkylbenzenes increased with the increase in the sodium ion content and the rise in the pretreatment temperature of zeolite. The adsorption heat was substantially independent of the sodium content, but slightly increased with the rise in pretreatment temperature above 550°C. A linear relationship was found between the decrease in the ionization potential of aromatic hydrocarbons and the increase in the heat of adsorption. For comparison, the adsorption of ethylene was also examined. With the rise of pretreatment temperature of zeolite, the retention volume of ethylene decreased. On introduction of water to the system, the retention volume of ethylene reversibly increased, whereas that of aromatic hydrocarbons decreased. In accordance with the decationation process of zeolite proposed by Hall *et al.*, these aromatic hydrocarbons are adsorbed preferably on tricoordinated aluminum site as well as on sodium ion to form the charge transfer complex, while ethylene interacts with hydroxyl group to form the carbonium ion or hydrogen-bonded complex.

In spite of the widespread use of decationated zeolite as a catalyst for the reactions of aromatic hydrocarbons, its adsorptive properties are still open to question. Adsorption measurement at an elevated temperature is improtant in elucidating the kinetics and mechanisms of catalysis. Little information, however, is available on high temperature adsorption of aromatic hydrocarbons on decationated zeolite. Difficulty in experiment seems to arise from the decomposition and poor volatility of the adsorbate. Gas chromatography might be of use to overcome this difficulty.[1,2] In this work, the apparent adsorption constant and apparent adsorption heat of several aromatic hydrocarbons on decationated zeolite were determined using a simple gas chromatographic technique.

Significant advance has been made in understanding the acid property of decationated zeolite by spectroscopic observations, particularly by infrared absorption. Most investigators agree that the acidic sites on this solid consist of the Brönsted and Lewis acids and that the former can be converted into the latter by thermal treatment. The adsorptive properties of decationated zeolite for some aromatic hydrocarbons was discussed in accordance with this concept.

Experimental

Materials. Sodium zeolite used in this work was Linde Y Molecular Sieve (SK-40). The ammonium form was prepared by the ion exchange of sodium zeolite with 0.05—0.5N solution of ammonium acetate at 50°C. The exchange levels of ammonium zeolite, defined as the percentage of the original sodium ion replaced, were determined to be 14, 25, 37, 59, and 67. The zeolite was preliminary dried at 110°C for 4 hr, pelletized, and ground to the size 48—60 mesh. X-ray examination revealed good crystallinity in these materials. Aromatic hydrocarbons (commercial guaranteed grades) were dehydrated with metallic sodium, distilled and passed through a silica gel column before use.

Apparatus and Procedure. The apparatus was similar to that of the usual gas chromatogragh reported by Everly.[1] The unit consisted of a pulse injection system connected in series to a gas chromatographic column packed with 0.2 g of zeolite and a thermal conductivity cell. The column made from stainless steel was settled in an iron block to keep the temperature constant. The maximum temperature variation over the column was less than 1°C. The carrier gas (hydrogen) was passed through a purification train of Pd and 5A Molecular Sieve. No appreciable change in peak width and retention volume of aromatic hydrocarbons was observed with carrier gas (helium, agron, and nitrogen), its flow rate, and

particle size of zeolite.

The weight change of zeolite with thermal treatment was measred by a micro-thermobalance under the condition similar to those in gas chromatography. The effect of water vapor on the retention volume were examined by using a sideline in which the carrier gas passed through a saturator system, consisting of three bubble-vessels filled with water.

Prior to each measurement, fresh zeolite was treated at the desired temperature for 2 hr in a stream of carrier gas. A small amount of argon, as a non-adsorbable gas, was added into a pulse in order to determine the net retention volume of hydrocarbons. The corrected specific retention volume V_r was calculated by means of the equation[3]

$$V_r = (t-t_0)\frac{T}{298}\cdot\frac{3}{2}\cdot\frac{(P_i/P_0)^2-1}{(P_i/P_0)^3-1}\cdot\frac{F}{W}$$

where t and t_0 are the retention times (min) of a hydrocarbon and inert gas, respectively, T is the column temperature (°K), P_i and P_0 are the pressures at the column inlet and outlet, respectively, F is the flow rate of carrier gas (ml/min), and W is the weight of zeolite packed (g).

When a linear isotherm is expected, the apparent equilibrium constant of adsorption K can be obtained by

$$K = \frac{V_r}{RT}$$

where R represents the gas constant.[4] Linearity of an isotherm may be indirectly confirmed by the fact that the specific retention volume is independent of the partial pressure of adsorbate. The result is shown in Fig. 1, in terms of the relation between V_r and the pulse volume of hydrocarbon.

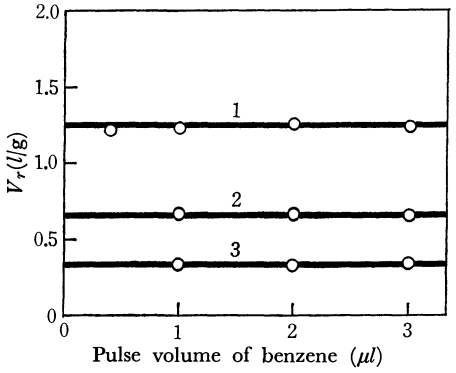

Fig. 1. Effect of injected pulse volume on the specific retention volume.

Results

Effect of Sodium Ion. Zeolite cation plays an important role for the adsorptive property of zeolite. In the adsorption of aromatic hydrocarbon on decationated zeolite with various degree of ion exchange, the retention volume markedly decreased with the increase of exchange level. The logarithms of V_r/RT for benzene and *o*-xylene are plotted against the reciprocal of the absolute temperature in Figs. 2 and 3, respectively. The data show linear relationships which

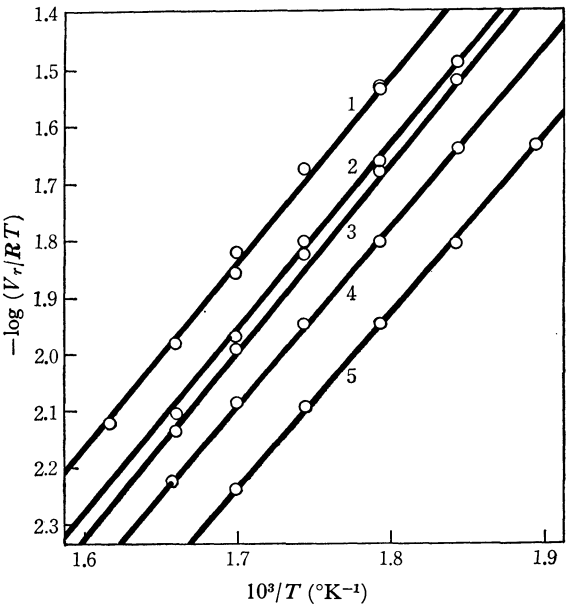

Fig. 2. Temperature dependence of the retention volume of benzene on the zeolites with various degrees of ion exchange.
Pretreatment temperature; 500°C
Ion exchange level: 1, 0 and 14%; 2, 25%; 3, 44%; 4, 59%; 5, 67%

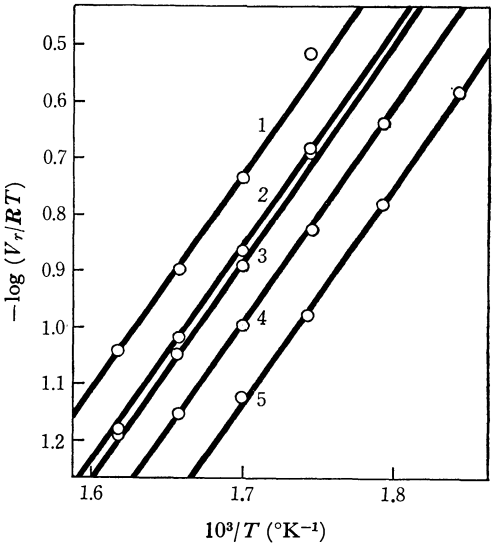

Fig. 3. Temperature dependence of the retention volume of *o*-xylene on the zeolites with various degrees of ion exchange.
Pretreatment temperature: 500°C
Ion exchange level: 1, 0 and 14%; 2, 25%; 3, 44%; 4, 59%; 5, 67%

have practically the same slopes. The apparent heats of adsorption are derived from the tangent of these plots. We see that the apparent adsorption heats of benzene and *o*-xylene are independent of the sodium ion content in the zeolite treated at 500°C, being estimated to be 14.9 and 18.3 kcal/mol, respectively. The former value is rather small in comparison with 15.5 kcal/mol for sodium X zeolite.[1] In similar examinations of other hydrocarbons such as toluene, ethylbenzene and *m*- and *p*-xylene, no appreciable change in the adsorption heat was observed with the change in ex-

4) J. J. Yan Deemter, F. J. Zwiderweg, and A. Klinkenberg, *Chem. Eng. Sci.*, **5**, 271 (1956).

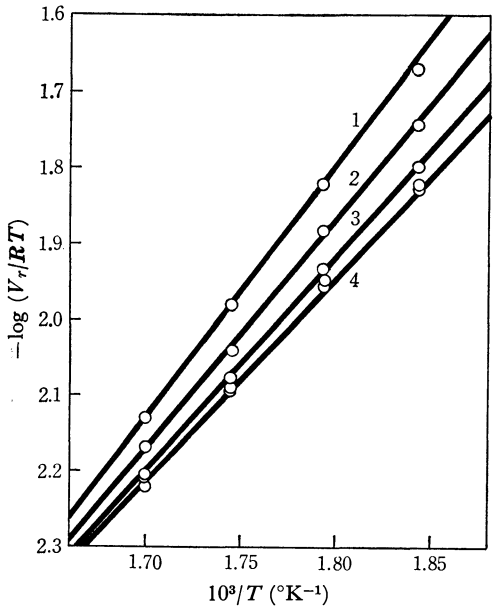

Fig. 4. Temperature dependence of the retention volume of benzene on the zeolite treated at various temperatures.
Ion exchange level: 67%
Pretreatment temperature: 1, 650°C; 2, 600°C; 3, 550°C; 4, 500, 450, 400, and 350°C

change level of zeolite. Thus, it might be expected that ion exchange influences not the strength but the number of the adsorptive sites on zeolite surface.

Effect of Thermal Treatment. Thermal treatment also influences adsorptive properties of decationated zeolite. Figure 4 shows the temperature dependence of benzene adsorption on 67% exchanged zeolite treated at various temperatures. Hardly any variation was observed in adsorptive properties of the zeolite subjected to the treatment at 350—500°C. In the higher temperature range of the treatment, both the specific retention volume and the apparent adsorption heat increased with the rise in the pretreatment temperature.

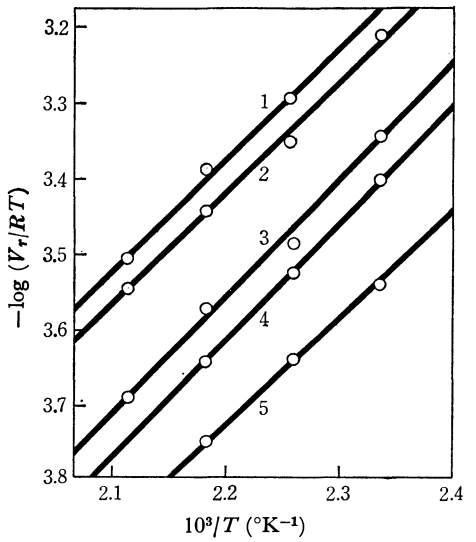

Fig. 5. Temperature dependence of the retention volume of ethylene on the zeolite treated at various temperatures.
Ion exchange level: 67%
Pretreatment temperature: 1, 400°C; 2, 350°C; 3, 450°C; 4, 500°C; 5, 600°C

This might indicate that the thermal treatment at a higher temperature changes the adsorption sites on decationated zeolite.

For comparison, similar examinations were carried out for ethylene adsorption. The results are shown in Fig. 5. There is a marked difference between the adsorption of ethylene and that of benzene. With the rise of temperature of heat treatment, the specific retention volume of ethylene decreased, whereas that of benzene increased. The apparent adsorption heat of ethylene is amlost independent of the pretreatment temperature, while that of benzene depends on the pretreatment temperature above 550°C. It seems that benzene and ethylene are adsorbed on different sites.

TABLE 1. EFFECT OF WATER ADDITION ON THE RETENTION VOLUME OF BENZENE AND ETHYLENE

Condition	V_r of benzene at 225°C (l/g)	V_r of ethylene at 155°C (ml/g)
After calcination at 600°C[a)]	3.41	9.80
On introduction of water	2.22[b)]	14.4[c)]
After calcination at 600°C	3.45	9.00
On reintroduction of water	2.08[b)]	12.0[c)]

a) 67% exchanged zeolite
b) 18.9 mmHg of water pressure
c) 4.6 mmHg of water pressure

Effect of Water Vapor. The effect of thermal treatment on adsorptive properties is presumably due to the water content in zeolite, since a major portion of ammonia seems to evolve below 300°C.[5] The effect of water was examined by introducing water vapor to the system. The results are shown in Table 1. For 67% exchanged zeolite calcined at 600°C, the specific retention volumes of benzene and ethylene are 3.41 l/g at 225°C and 9.8 ml/g at 155°C, respectively. On introduction of water to the system, the retention volume of benzene decreased and reached the stationary value of 2.22 l/g under 18.9 mmHg of water pressure, whereas that of ethylene increased to the level of 14.4 ml/g under 4.6 mmHg of water pressure. When addition

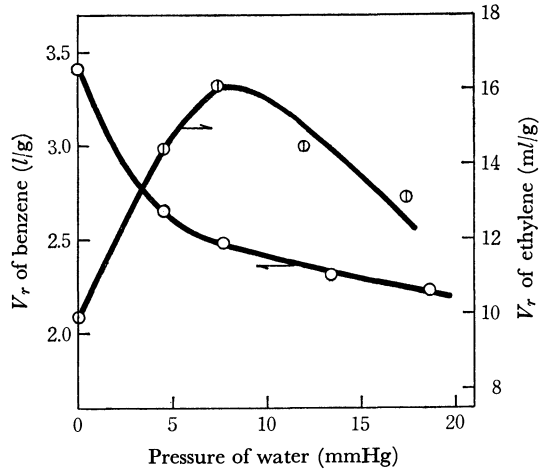

Fig. 6. Retention volume of benzene and ethylene under various pressures of water.

5) J. W. Ward, *J. Catal.*, **9**, 225 (1967).

of water was stopped and the zeolite was treated at 600°C, the original levels of the retention volumes were restored. Again on further introduction of the same pressure of water, each retention volume showed almost the same value as that on the first introduction.

For the adsorption of benzene and ethylene, poisoning and promotive effects of water vapor increased with the increase of its vapor pressure in carrier gas as shown in Fig. 6. A low retention volume of ethylene under a high pressure of water seems to be due to poisoning by the adsorption of excessive water on the surface.

Table 2. The retention volume and the adsorption heat of several aromatic hydrocarbons

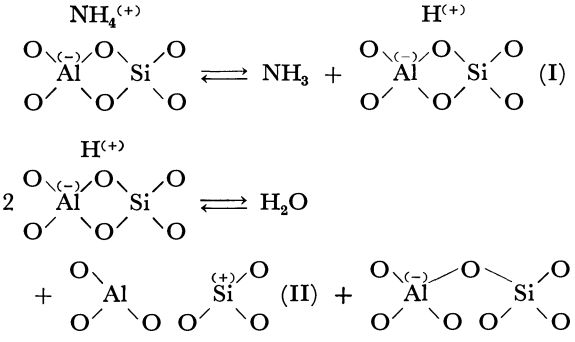
Hydrocarbons	V_r at 330°C (l/g)	Q (kcal/mol)
Benzene	0.267	14.9
Toluene	0.947	16.1
Ethylbenzene	2.40	17.4
o-Xylene	3.74	19.1
m-Xylene	2.47	17.8
p-Xylene	2.80	19.2

Sample: 67% exchanged zeolite treated at 600°C

Effect of Alkyl Substituent. Similar measurements were carried out for several alkylbenzenes such as toluene, ethylbenzene, and xylenes in order to confirm the influence of alkyl groups. No chemical reaction of these compounds occurred. The specific retention volume and apparent heat of these hydrocarbons are shown in Table 2. The retention volume increased with the number of alkyl substituents. It can be seen that the larger the retention volume, the larger the heat of adsorption. In the case of cumene and higher alkylbenzene, dealkylation and disproportionation occurred under similar conditions. Adsorption of these alkylbenzenes was not examined, since sorption mechanism might be influenced by the adsorption of reaction products.

Discussion

In the adsorption of π-base such as aromatic hydrocarbons, there is no doubt that the adsorptive sites of decationated zeolite are acidic. It is, however, still obscure whether such sites are the Brönsted acid or Lewis acid. Following Uytterhoeven, Christner, and Hall,[6] decationation process of zeolite can be visualized as follows



6) J. B. Uytterhoeven, J. B. Christner, and W. K. Hall, *J. Phys. Chem.*, **69**, 2117 (1965).

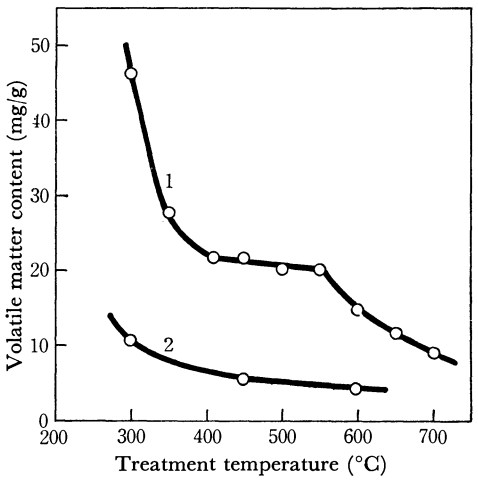


Fig. 7. Weight changes of decationated and sodium zeolite as a function of temperature.
1, Decationated zeolite (67% exchanged)
2, Sodium zeolite

The Brönsted acid site is given by I and the Lewis acid site by II.

Figure 7 shows weight changes of 67% decationated and the original sodium zeolite as a function of the temperature of heat treatment. The results are expressed in terms of the amount of volatile component (water and ammonia) of the samples after each calcination, assuming that the zeolite treated at 1000°C contains no volatile matter. For the decationated zeolite, a marked weight loss takes place below 400 and above 550°C. Effluent gas analysis shows that the initial weight decrease is due to the evolution of ammonia and of water (probably physically adsorbed water). Although the evolution is still continued little by little until 550°C, only that of water is observed above 550°C. It might be that below 400°C the greater part of ammonium ions has been decomposed to ammonia and proton to produce the Brönsted acid sites, and that the removal of the protons as water to generate the Lewis acid sites starts around 550°C. On the other hand, no appreciable weight change of sodium zeolite is detected above 400°C.

It might be considered that aromatic hydrocarbon is adsorbed more preferably on the Lewis acid site than on the Brönsted acid site, since the specific retention volume markedly increased by the treatment above 550°C (Fig. 8). The retention volume of ethylene decreased with the rise of temperature of heat treatment of decationated zeolite. This trend is similar to that of catalytic activity in the reactions *via* carbonium ion intermediate.[7,8] Ethylene seems to be adsorbed on the Brönsted acid site to form carbonium ion or strong hydrogen-bonded complex as a precursor to carbonium ion.[6] Ward[5] and Hattori *et al.*[9] have recognized in infrared measurements of adsorbed pyridine on decationated zeolite that the strong Lewis acid site can be

converted into the Brönsted acid site by the addition of water. We see in Table 1 and Fig. 6 that the specific retention volume of ethylene increased and that of benzene decreased by the introduction of water. Thus, the adsorptive sites of decationated zeolite available for ethylene and benzene seem to be the Brönsted acid and the Lewis acid, respectively.

Alkylbenzene are probably adsorbed not only on tricoordinated aluminum atoms (the Lewis acid) but also on sodium cations, since the sodium ions on the zeolite are almost exposed by heat treatment above 400°C (Fig. 7) and the specific retention volume increases with the increase in the sodium ion content (Figs. 2 and 3). The apparent adsorption heat of benzene is practically independent of the sodium ion content. The adsorptive strength of sodium sites, therefore, does not appear to be affected by a change in the concentration. On the other hand, the adsorption heat of benzene increased with the rise of the temperature of heat treatment above 550°C. This probably indicates that tricoordinated aluminum sites are stronger than sodium sites for the adsorption of benzene.

The interaction between π-base and electrophilic site would be due to charge transfer. It can be seen that both the retention volume and the adsorption heat of benzene derivatives increased with the extent of alkyl substitution (Table 2). The electron-releasing alkyl groups increase the electron density of aromatic ring, making it more susceptible to interact with tricoordinated aluminum atom or sodium ion. This might be confirmed quantitatively with the ionization potential sequence of adsorbates. Figures 9 and 10 show the linear correlations of logarithmic adsorption constant and adsorption heat, respectively, with the ionization

potential of aromatic hydrocarbons. The values of the ionization potential (measured by the electron impacting method) are taken from literature,[10] thick lines indicating the variations of these values. It can be seen that the higher the ionization potential, the smaller the adsorption constant and adsorption heat. These correlations suggest the charge transfer interaction between aromatic hydrocarbon and decationated zeolite.

The NMR Chemical Shifts of Aromatic Ring Protons. II. The Substituent Chemical Shift of the Ring Protons of 1-Substituted Naphthalenes

Yasuhide YUKAWA, Yuho TSUNO, and Nobujiro SHIMIZU

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, Osaka

(Received September 25, 1970)

We have shown, in the preceding paper, that the chemical shift of *o*-, *m*-, and *p*-ring protons of a number of monosubstituted benzenes could be determined without any difficulty and that they could be assigned without ambiguity by means of the statistically-distributed deuterium substitution method.[1] In the present paper, we will report the application of the same technique to the naphthalene-series, for which few systematic studies seem to have been reported.[2]

Ring hydrogens of naphthalene were about 85% statistically replaced by deuteriums through the hydrogen-deuterium exchange reaction of naphthalene in the presence of a small amount of aluminum trichloride as a catalyst. The extent of the substitution was checked by IR analysis at appropriate intervals. The NMR spectrum of the deuterated naphthalene showed only two singlets corresponding to α and β protons; the intensities of both signals were nearly the same. Since there is little possibility that more than two hydrogens remain at vicinal positions, the spectra are very much simplified to give only two signals, without any splitting of the signals caused by spin-spin interactions. Although the direct assignment of two peaks from the spectrum was impossible, it was made possible by changing chemically their relative intensities up to *ca.* 3: 2, as is shown in Fig. 1-A. This modification was done by heating the above deuterio-naphthalene under reflux with trifluoroacetic acid. As the dedeuteration occurs much more rapidly at the α-position than at the β-position in trifluoroacetic acid, the more intense signal must be assigned to α-protons, and the less intense one, to β-protons. A series of 1-substituted naphthalenes (X in 1-X-Naph-d_6; NO_2, CN, Br, COOH, H, OH, NH_2) were prepared from this partially-deuterated naphthalene. The NMR spectra of Naph-X are generally made up of seven singlets, four of which are little smaller in their intensities than the other three singals, as is shown in Fig. 1-B and 1-C. From this difference in intensity, the smaller four signals can be assigned to β-protons, or 2, 3, 6, and 7-protons, and the rest, to α-protons, or 4, 5, and 8-protons. In some cases, more than two signals overlapped, but it was still possible to analyse the spectra rather precisely by considering the ratio of the intensities of the signals in detail. All the measurements were carried out with a Hitachi R-20 NMR spectrometer at 60 MHz. The chemical shifts were measured at 5 mol% in a *N*,*N*-dimethylacetamide solution from the internal standard TMS. The chemical shifts of each signal can be determined precisely, within ±0.5 Hz in most cases, but the accuracy may fall as much as to ±1.5 Hz in the worst case. The equal intensities of the four signals belonging to the β-protons unfortunately provided us with a serious disadvantage in making further unambiguous assignments of the individual signals, and the same is also true for the three signals corresponding to the α-protons. Nevertheless, plausible assignments can be done by comparison with the data for mono-substituted benzenes and also with their solvent effects.

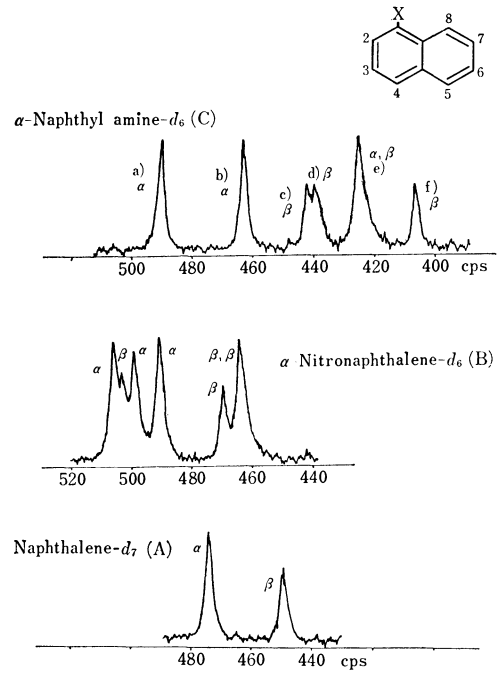

Fig. 1. NMR spectra of deuterated naphthalenes.

In the case of α-naphthylamine in a *N*,*N*-dimethylacetamide solution, for instance, the individual signals could be assigned as follows; one (signal *a*) of the three signals belonging to the α-protons is more deshielded than that of unsubstituted naphthalene ($\Delta = -15.8$ Hz). Since the amino group has a large shielding effect in the benzene series, the *a* signal must be assigned to the 8-proton, of the other two, *e* (two signals overlapped) at a high field ought to be assigned to the 4-proton, and *b*, to the 5-proton. The *f* and *e* signals referred to β-protons can be assigned to 2- and 3-protons respectively by analogy with the relative chemical shifts of the aniline protons. It should also be possible to assign the *d* signal to the proton at the conjugate 7-

NH_2	41.2	22.9	47.7	11.4	7.6	9.6	−15.8

Relative values of 2,3,6, and 7-protons were determined from the chemical shift of the β-proton of naphthalene and those of 4, 5, and 8-protons from that of α-proton.

position, and *c*, to the 6-proton, considering the fact that the resonance effect is mostly responsible for the determination of the chemical shifts. The assignments for the other compounds were obtained in a similar manner. In most cases, the resulting assignment for the protons on the substituted ring is believed to be highly reliable, because of the rigorous agreement of the relative variations of the substituent chemical shifts between the corresponding protons of benzene and naphthalene. However, for the β-protons on the other ring, certain ambiguities might unfortunately be involved in the tentative assignment. The relative chemical shifts are listed in Table 1.

The substituent effects in the substituted ring of the naphthalene serise are linearly correlated with those of the corresponding protons in the benzene series; $\Delta\Delta\delta^2 = 1.09\,\Delta\Delta\delta^0$, $\Delta\Delta\delta^3 = 0.98\,\Delta\Delta\delta^m$, and $\Delta\Delta\delta^4 = 0.89\,\Delta\Delta\delta^p$. This may indicate that there is not much difference in the substituent effect on the ring proton chemical shift between the benzene and naphthalene series. The substituent effects on the respective protons are expressed in terms of the σ_p^0 and $\Delta\bar{\sigma}_R^+$ in just the same way as for the benzene series;

$$\Delta\Delta\delta^3 = -27.7(\sigma_p^0 + 0.29\Delta\bar{\sigma}_R^+)$$
$$\Delta\Delta\delta^4 = -38.7(\sigma_p^0 + 0.87\Delta\bar{\sigma}_R^+)$$
$$\Delta\Delta\delta^5 = -22.7(\sigma_p^0 + 0.13\Delta\bar{\sigma}_R^+)$$
$$\Delta\Delta\delta^6 = -19.1(\sigma_p^0)$$
$$\Delta\Delta\delta^7 = -19.7(\sigma_p^0 + 0.17\Delta\bar{\sigma}_R^+)$$

In these treatments, σ_p^0 is used as a conventional measure of the unexalted polar effect throughout the series, since no σ^0 values for the respective naphthalene position are available. Perhaps, in view of the analogy to the benzene system, $\Delta\Delta\delta^3$ should be described in terms of the σ_m^0 parameter. This results in the correlation;

$$\Delta\Delta\delta^3 = -32.1(\sigma_m^0 + 0.45\Delta\bar{\sigma}_R^+)$$

Similarly, the chemical shifts of the non-conjugate 6-proton are given by;

$$\Delta\Delta\delta^6 = -21.0(\sigma_m^0 + 0.23\Delta\bar{\sigma}_R^+)$$

It is evident from these correlations that the protons on the substituted ring are more susceptible to both the polar and resonance effects of substituents than those on the other ring. The same treatment cannot be applied to the chemical shifts of the 8-proton. As the ordinary electronic effects of substituents could not be transmitted so effectively to this position, the behavior of this proton may give many valuable information about the particular interactions with substituents at the closest position.[3]

From the theoretical point of view, it should be more reasonable to treat these results in terms of the inductive σ_i and π-electronic σ_π parameters.[4] The results of this treatment and a comparison with recent results obtained by means of Taft and Dewar treatments[5] will be the subjects of a forthcoming paper.

The Observation of Surface Hydroxyl Groups on Metal Oxides by Means of Infrared Reflectance Spectroscopy

Nobutsune TAKEZAWA*

Research Institute for Catalysis, Hokkaido University, Sapporo

(Received January 16, 1971)

Much work has been carried out applying the transmission method to the infrared spectral study of adsorption.[1-3] In most cases, the catalyst used as an adsorbent has been supported on a carrier which transmitted the infrared radiation, and has been pressed into a disc. However, since the activity of the catalyst is occasionally affected by the presence of the carrier[1] and the pressure applied on the disc,[4] we cannot simply compare the results with those obtained on a powdered catalyst without a carrier.

Recently, it has been shown, however, that the diffuse reflectance method can be applied to the study of the powdered bulk compounds without using any carrier such as KBr or nujol mull.[5] In this respect, we attempted to study the adsorption on metal oxides in powder form. There have already been a few reports studying the adsorption.[6,7]

Experimental

A Nippon Bunko (Japan Spectroscopic Co. Ltd.) Model DR-1 reflectance apparatus was modified so that the catalyst could be prepared in a cell at an elevated temperature without exposing it to air. The optical system was similar to that used by Mamiya,[7] but the cell could be placed horizontally.

The catalysts used were magnesium oxide (J. T. Baker Chem. Co.), silica (Aerosil, Degussa Co.), stannic oxide (Koso Chemical Co.), zinc oxide (Kanto Chemical Co.), germanium oxide (Nakarai Chem., Ltd.), and titanium oxide (E. Merck A. G.). They were placed in a cell (2 mm in depth and 7 mm in diameter) in the form of a powder without using the disc technique. The average particle size of each sample was as follows: silica ($<1\ \mu$), stannic oxide ($8\ \mu$), zinc oxide ($25\ \mu$), germanium oxide ($7\ \mu$), and titanium oxide ($20\ \mu$).

The spectra during the dehydration and the adsorption of water or deuterium oxide were recorded with a Nippon Bunko Model IR-G infrared spectrophotometer. The dehydration was carried out at temperatures ranging from 50 to 310°C in a stream of prepurified nitrogen. Prior to the experiments, it was determined that the reflectivity of the catalysts was unaffected by the amount of the catalysts.[8]

Water or deuterium oxide vapor saturated at room temperature was carried with the nitrogen stream into the cell during the adsorption experiments.

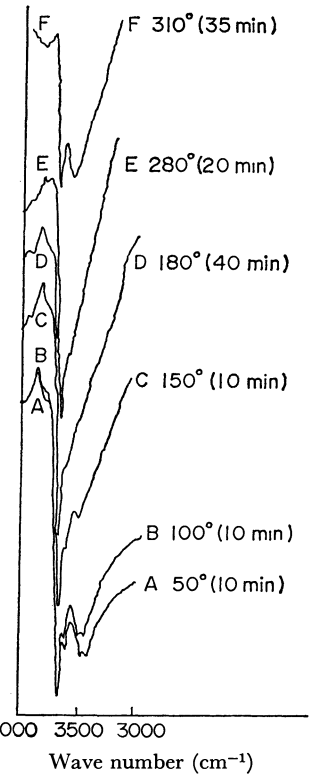

Fig. 1. Dehydration of magnesium oxide at various temperatures.
In brackets in the figure, the time for the dehydration is indicated. (The ordinates are displaced to avoid overlapping of traces.)

Results and Discussion

Figure 1 illustrates the spectra during the dehydration of magnesium oxide at various temperatures. The absorption bands were observed near 3700, 3630, 3500, 3450, and 1630 cm^{-1} at 50°C.[9] When the catalyst was heated at 150°C, the 3450 and 1630 cm^{-1} bands disappeared simultaneously. Since the bands occurred at 3445 and 1627 cm^{-1} in liquid water[10]

Nuclear Magnetic Resonance Studies of Nitrosonaphthols

Toshiyuki SHONO, Yoshikatsu HAYASHI, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka

(Received February 17, 1971)

In solution, nitrosophenols are in tautomeric equilibrium[1-5] with quinone monoximes. Fischer *et al.*,[6] using nuclear magnetic resonance and infrared spectra, found that 4-nitrosophenol exists in the phenolic form in a dilute dimethyl sulfoxide solution. On the basis of nuclear magnetic resonance spectra, supported by UV and IR data, Norris and Sternhell[7] suggested that 4-nitrosophenol exists predominantly in the quinone monoxime form in an organic solvent. Jaffé[8] has calculated, by the molecular orbital method, that the oxime form of 4-nitrosophenol should be the more stable. As for nitrosonaphthols, Buraway[1] and his associates, on the basis of electronic spectra, have shown that 1-nitroso-2-naphthol exists in the oxime form only.

Hadži[9] investigated the monoximes of *p*-benzoquinone and 1,2-naphthoquinone (1-oxime and 2-oxime) by means of their infrared spectra. It has been found that the oxime formulation correctly represents the structure of these compounds in the solid state, and that this structure predominates also in their chloroform solutions. However, 2-nitroso-1-naphthol (1,2-naphthoquinone 2-oxime) seems to exist in the chelated nitroso form in solution in carbon tetrachloride. With the exception of a brief mention of the nuclear magnetic resonance spectrum of 4-nitroso-1-naphthol, the literature contains no reference to nuclear magnetic resonance investigation of the tautomeric nitrosonaphthols; this has prompted us to examine 1- and 2-nitrosonaphthols and their derivatives.

Experimental

Compounds. The 1-nitroso-2-naphthol which has been taken as the sample was a commercial product, mp 109—110°C, recrystallized from ligroin. The 2-nitroso-1-naphthol, mp 153—154°C, was synthesized by the method of Henriques.[10] 1-Methyloximino-2-naphthoquinone,[11] mp of 74—75°C. Found: C, 70.57; H, 4.79; N, 7.45%. Calcd for $C_{11}H_9O_2N$: C, 70.58; H, 4.81; N, 7.48%. 2-Methyloximino-1-naphthoquinone;[12] mp 89—90°C. Found: C, 70.60; H, 4.85; N, 7.51%. Calcd for $C_{11}H_9O_2N$: C, 70.58; H, 4.81; N, 7.48%. Both were prepared by the reaction of nitrosonaphthol with methyl iodide and were recrystallized from ligroin.

Nuclear Magnetic Resonance Spectra. The proton magnetic resonance spectra (PMR) of the compounds were measured by means of a JNM-3H-60 spectrometer; the results are summarized in Table 1.

Infrared Spectra. A Hitachi model EPI-S2 infrared recording spectrophotometer was used.

Results and Discussion

If detectable amounts of both isomeric forms, I and

II or III and IV, were present, the spectral pattern would be either a superposition of both forms, or be composed of an independent pattern for each one, depending upon the rate of exchange between the two isomers. If there was any difference between the chemical shifts of the two hydroxyl protons (phenol and oxime) of each tautomer, it should be possible to establish the equilibrium isomer ratio from the signal area. Unfortunately, as is shown in Table 1, the hydroxyl proton gave only one broad peak. The PMR spectrum of both the methyl ethers of nitrosonaphthol, V and VI, are shown in Fig. 1. The difference in the spectra of V and VI is remarkable, particularly at the chemical shifts of the (3) and (4) protons. This difference may be attributed to the existence of the conjugation between the double bond and the carbonyl group. Both compounds, V and VI, seem to exist in the same quinoid form, for the wave numbers of the C=O bands (1670, 1660 cm^{-1} respectively) of V and VI in solution are not much different from those for quinones[13] (benzoquinone 1667, 1,2-naphthoquinone 1678 and 1,4-naphthoquinone 1675 cm^{-1}), and no nitroso group was detected by the Liebermann reaction.

13) M. Josien, N. Fuson, J. Lebas, and T. Gregory, *J. Chem. Phys.*, **21**, 331 (1953).

in Fig. 2. As has been mentioned above, Buraway[1] and Hadźi[9] have shown that 1-nitroso-2-naphthol exists in the oxime form on the basis of only the electronic and infrared spectra. The chemical shift of the aromatic proton at (3) appeared in a very high field, (τ=3.48—3.72). These facts show that the oxime formulation (II) correctly represents the structure of 1-nitroso-2-naphthol. On the contrary, in 2-nitroso-1-naphthol the aromatic protons at (3) and (4) show a mixture of the AB ($J_{3,4}$=9.8 Hz) and AX ($J_{3,4}$=10 Hz) patterns depending upon the solvent, as is shown in Fig. 3.

This fact shows that detectable amounts of the two forms, III and IV, are both present. From the singal area, the equilibrium isomer ratio is determined to be as is shown in Table 1. In assigning the aromatic protons at (3) and (4) of nitrosonaphthols and their methyl ethers, we have decided that the downfield signal is a (4) proton by analogy with the results obtained with α,β-unsaturated cyclic carbonyl compounds. In a planar cycloalk-2-en-1-one with efficient conjugation between the double bond and carbonyl group, the C-3 proton is strongly deshielded relative to the C-2 proton by mesomeric electron withdrawal.[14]

It is worth noting that the chemical shift of the aromatic proton at (8) appeared in a very low field as a broad line. This seems to be a deshielding effect of the carbonyl and oxime groups of the α-position.

Carbon Products Prepared from Variant Pitch Materials. VI. Pitch Carbon Prepared from Naphtha Cracking Pitch

Sugio Ōtani and Asao Ōya

Faculty of Technology, Gunma University, Kiryu Gunma

(Received February 23, 1971)

It was previously reported that a carbon rod or tablet could be prepared from specific variant pitch materials alone instead of from coke powder and a pitch binder.[1-5] The carbon-shaped articles prepared by this method were referred to as Pitch Carbon, and coal-tar pitch was used as the raw pitch material in the previous experiments. In this case, some special, very trouble some pre-treatments[1-3,5] were required in preparating the pitch carbon in order to elevate the softening point of the raw coal-tar pitch and/or to increase its reactivity in the heating process.

This work was undertaken in order to search for better raw pitch materials for the preparation of pitch carbon, it was found that the pitch produced in the naphtha cracking process is an interesting raw material for pitch carbon.

Experimental

The raw pitch material used here was naphtha cracking pitch (Ligare-N) supplied by the Kureha Chemical Ind. Co., this pitch had a softening point of 193—196°C and had the elemental composition shown in Table 1. The raw pitch was crushed to under 100 mesh and then pressed with 400 kg/cm^2 into tablets of 20 mm in diameter and about 4 mm thick. The tablets were pre-heated in air up to 300°C over a 7-hr period. When the heating rate of this process was too fast, the tablets fused or blistered. Consequently, in the range of temperatures from 180° to 230°C, the heating rate was controlled to 0.3°C/min. The resulting tablets were heated under a stream of N_2 gas at the desired temperatures below 2600°C for 10 min. The heating rate was 5°C/min up to 1000°C and 50°C/min at temperatures higher than 1000°C. The measurement of the properties of the resulting pitch carbon was carried out according to the procedures previously described.[2]

Table 1. Changes in elemental compositions of naphtha cracking pitch and coal-tar pitch by heating in air

Kind of pitch		C(%)	H(%)	diff.(%)[b]
Naphtha	Raw	94.3	4.5	1.2
	After pre-heating	79.4	3.8	16.8
Coal	Raw	91.5	4.6	3.9
	After pre-treatment[a]	92.0	3.9	4.1

a) Raw pitch was distilled at 400°C for 80 min by bubbling air, powdered after cooling, and then heated in air up to 200°C.[3]

b) diff. (%)=100 −C(%) −H(%)

Results

Four characteristic phenomena were observed in the present experiments compared with the case of using coal-tar pitch.

(1) The pre-treatment on the raw pitch material as reported in the previous papers[2-3,5] could be eliminated from the process of preparing pitch carbon without any trouble.

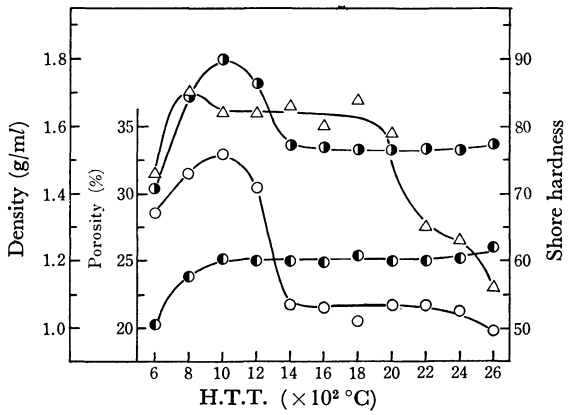

Fig. 1. Changes of density, porosity, and hardness with H.T.T. (—○— Apparent porosity, —◐— Bulk density, —◑— Apparent density, —△— Shore hardness)

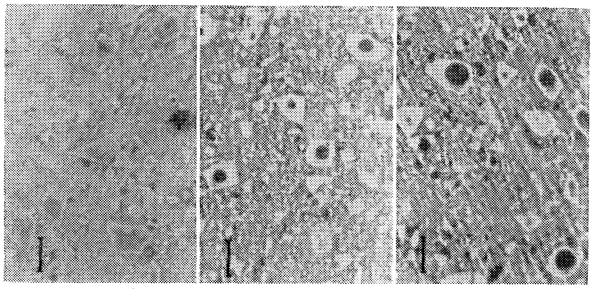
(2) As is shown in Fig. 1, the most characteristic feature of the pitch carbon obtained here was its much greater hardness for its low-bulk density as compared with that of the pitch carbon prepared from coal-tar pitch[2-3] or conventional artificial graphite.[6] The pitch carbon finally obtained was non-graphitizable.

(3) Considerable amounts of oxygen were incorporated into the pitch by pre-heating up to 300°C. This phenomenon was not observed at all in the case of coal-tar pitch, as is shown in Table 1. From its infrared spectra and elemental analysis, it was found that the oxygen incorporated is in the form of C=O (1700 cm^{-1}) and C–O (1200 cm^{-1}) and is eliminated during the further heating process under a N_2 gas atmosphere.

(4) In the tablets heated above 600°C, the closed pores formed in most of the larger particles, as is shown in Fig. 2.



(a) After heating up to 300°C in air (b) 800°C (c) 1600°C

Fig. 2. The microscopic textures of the pitch carbon. (|——| 100μ)

Discussion

The fact described in (3) indicates that the naphtha cracking pitch has a higher reactivity to oxygen in air than does coal-tar pitch. This reactivity accelerates to sinter or bridge among the pitch particles and/or molecules. The high softening point and this reactivity of the pitch may it possible to eliminate the pre-treatment required in the case of coal-tar pitch. It seems that the rigid layers from at the surface of the particle at an early stage of heating and result in the closed pores in the large particles during the subsequent carbonization process. The characteristic feature pointed at in (2) is probably due to those closed pores.

The Cyclization of Polyenes.[1] VII. The Cyclization of Labda-13-ene-8,12,15-triol

Tadahiro KATO, Susumu KANNO, Mitsuru TANEMURA, Akira KUROZUMI, and Yoshio KITAHARA[2]

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received March 18, 1971)

12α-Hydroxy epimanoyl oxide[3] (I), a labdane-type diterpene, was isolated by Giles *et al.* from Turkish tobacco, which also produces diterpene lactones, α- and β-levantenolides[4] (II, III).

As we have already reported the synthesis of II and III on the basis of biogenetical consideration,[5] it does not seem absurd to expect the conversion of triol (IV) to I or its stereoisomers. This paper will describe the acid-catalyzed cyclization of IV.

The reduction of synthesized α-levantenolide (II) with lithium aluminum hydride afforded the relatively unstable triol (IV), which was then treated with several Lewis acids, such as iodine, *p*-toluenesulfonic, sulfuric, and camphorsulfonic acids, and stannic chloride under various conditions. The reactions were followed by silica-gel thin-layer chromatography using natural 12α-hydroxyepimanoyl oxide (I) as a reference. The treatment of IV with stannic chloride gave, among the examined acids, the simplest mixture, from this mixture an oily compound (V) was isolated in a 37% yield by silica-gel chromatography.

5) a) T. Kato, M. Tanemura, T. Suzuki, and Y. Kitahara, *Chem. Commun.*, **1970**, 28. b) M. Tanemura, T. Suzuki, T. Kato, and Y. Kitahara, *Tetrahedron Lett.*, **1970**. 1463.

The gross structure of the product (V) was determined on the basis of the following observations. The NMR spectrum[6] of V exhibits signals of a doublet and a triplet at 4.05 and 5.48 ppm, with $J=7.2$ Hz due to C_{15}- and C_{14}-protons, a sharp singlet at 1.15 (C_8–Me), and broad multiplet at 4.77 (C_{12}–H). The hydroxyl group of V was easily oxidized with manganese dioxide to give the corresponding unsaturated aldehyde (VI), which showed a conjugated carbonyl group at 1672 cm^{-1} in the IR spectrum. The NMR spectrum of VI shows two kinds of formyl groups in *ca.* a 3: 1 ratio, indicating that VI is a mixture of either C_{12}-epimers or double-bond isomers at C_{13}–C_{14}. The former is more probable, since the 13-methyl group appears at 1.95 ppm, showing the *trans* relation of the methyl group with respect to the formyl group.[7] The destruction of the asymmetry at the 12 position of IV might occur prior to the ring formation.[8] Our objective, I, could not be isolated, although the formation, in quite a small amount, of a substance having the same R_f value on thin-layer chromatography with natural I was observed.

Experimental

Reduction of dl-α-*Levantenolide.* To a stirred, absolute ether solution (10 m*l*) of α-levantenolide (200 mg), we added lithium aluminum hydride (30 mg) under ice cooling. After stirring for an hour at 0°C, the reaction mixture was further stirred at room temperature for another hour and then poured onto ice water. Ether extracts from the reaction mixture were washed with cold hydrochloric acid and water, and then dried over magnesium sulfate in a refrigerator. Triol (IV) (200 mg) was thus obtained from the ether solution. Although the triol (IV), which should be stored in a refrigerator, could not be purified because of its unstability, the physical evidence supported the structure of the reduction product. NMR (δ) of the crude triol (IV) (D_2O was added) 1.13 (C_8–Me), 1.74 (C_{13}–Me), 4.05 (C_{15}-protons), 4.77 (C_{12}-proton), and 5.40 (C_{14}-proton). IR (film) 3400 cm^{-1} (strong), no absorption in the carbonyl region.

Cyclization of Triol (IV). Stannic chloride (0.1 m*l*) was added to a chloroform solution (10 m*l*) of the triol (200 mg) at −40——−60°C and the mixture was kept for an hour at the same temperature. The temperature of the reaction mixture was gradually raised to 25°C by removing the cooling bath. It took about an hour. After being diluted with ether, the ether solution was washed with aqueous sodium bicarbonate and then water, dried over magnesium sulfate, and then evaporated. The residued oil thus obtained was chromatographed on silica gel with a mixed solvent of benzene - isopropyl ether (8:1) to give V (70 mg). Found, C, 77.86; H, 10.85%. Calcd for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18%.

Although four methyl groups at C_4, C_8, and C_{10} were observed as a sharp singlet in the NMR spectrum of V, the signals due to C_{12}-, C_{14}-, and C_{15}-protons appeared broadly, suggesting that the alcohol (V) is an epimeric mixture. NMR (δ), 0.85 (tert Me×2), 0.87 (tert Me), 1.15 (sharp s, C_8–Me), 1.73 (C_{13}–Me), 3.12 (bs, OH, disappeared on the addition of D_2O), 4.05 (bd, $J=7.2$ Hz, C_{15}–H_2), 4.77 (m, C_{12}–H), and 5.48 (br. t, $J=7.2$ Hz, C_{14}–H). IR (film), 3375 (OH), 1653 (C=C) cm^{-1}.

Oxidation of V. Active manganese dioxide (500 mg) was added to an ether solution (5 m*l*) of V (60 mg) and the reaction mixture was stirred for two hr at room temperature. The subsequent filtration and washing of the solid and evaporation of the combined ether afforded unsaturated aldehyde (VI).

The pair of doublets at 10.23 and 10.20 ppm, which appear in the ratio of 3: 1, corresponds to one formyl proton in the NMR spectrum of VI. The appearance of two kinds of formyl protons may be due to the presence of an epimeric mixture, which could not be separated by usual chromatography. VI; NMR (δ), 1.20 (s, C_8–Me), 1.95 (C_{13}–Me), 5.83 (bd, $J=7$ Hz, C_{14}–H), 10.23 (d, $J=7$ Hz), and 10.20 (d, $J=7$ Hz). IR (film) 1672 (conjugated formyl) cm^{-1}.

The authors wish to thank to Dr. J. A. Giles (12α-hydroxyepimanoly oxide) and the Takasago Perfumery Co. (β-ionone) for their generous gifts of valuable materials.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3184 (1971)

Syntheses of Aromatic Dicarbamates and Their *N,N'*-Dihydroxymethyl Derivatives

Shigeya TAKEUCHI and Eisaku NINAGAWA

Department of Chemistry, Faculty of Education, Toyama University, Gofuku, Toyama

(Received March 18, 1971)

In previous papers,[1-3] aromatic monocarbamates, their *N*-monohydroxymethyl carbamates, and *N,N'*-methylenebis(carbamates) were synthesized. This paper will deal with the syntheses of aromatic dicarbamates and their *N,N'*-dihydroxymethyl derivatives.

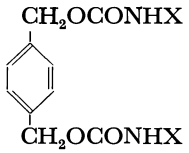
p-Xylylene dicarbamate (Ia) and 4,6-dimethyl-*m*-xylylene dicarbamate (IIIa) were synthesized by the method of Kraft[4]:

$$R\text{-}(CH_2OH)_2 + 2C_2H_5OCONH_2 \xrightarrow{Al(OC_3H_7)_3} R\text{-}(CH_2OCONH_2)_2 + 2C_2H_5OH$$
(Ia, IIa)

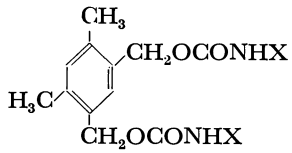
These dicarbamates (Ia, IIa) react with 2 mol of formaldehyde, in the presence of potassium hydroxide as a catalyst, to form *N,N'*-dihydroxymethyl derivatives (Ib, IIb):

$$R\text{-}(CH_2OCONH_2)_2 + 2CH_2O \xrightarrow{OH^-} R\text{-}(CH_2OCONHCH_2OH)_2$$
(Ia, IIa) (Ib, IIb)

From the analytical data, the structures of these products were determined to be as follows:



Ia (X=H)
Ib (X=CH_2OH)



IIa (X=H)
IIb (X=CH_2OH)

Experimental

The melting points are uncorrected. The IR spectra were recorded with a KBr disk on a JASCO Model IR-S infrared spectrometer. The NMR spectra were recorded on a Japan Electron Optics 60 MHz spectrometer in d_6-DMSO (*ca.* 10%); the δ values (ppm) were given against tetramethylsilane as an internal standard.

Preparation of p-*Xylylene Dicarbamate (Ia).* To 53.5 g (0.60 mol) of ethyl carbamate (recrystallized from benzene) in a 300 m*l* four-necked flask fitted with a stirrer, a thermometer, a condenser, and a 30 cm asbestoslagged column, we added 34.5 g (0.25 mol) of *p*-xylylene glycol (mp 115—116°C, from methanol) and 160 m*l* of ethylbenzene. The reaction mixture was heated at 110°C in an oil bath to remove any water in the reagents and was then cooled to 100°C. Subsequently, aluminum isopropoxide (about 10 g) was added and the reaction temperature was held at 134—137°C. The reaction mixture was subsequently stirred for 15 hr. The ethanol-ethylbenzene azeotropic mixture was removed through the column. The crude product thus obtained was recrystallized from DMF to give 28.3 g (50.5%) of a white powder melting at 211—213°C. IR (cm^{-1}): 3430—3230 ($\nu(NH_2)$, *etc.*), 1700 (ν(C=O)), 1620 ($\delta(NH_2)$). NMR (ppm): 7.27 (s, 4H, C_6H_4–), 6.5 (s, 4H, $-NH_2$), 4.93 (s, 4H, $-CH_2$–). Found: C, 53.70; H, 5.53; N, 12.36%. Calcd for $C_{10}H_{12}N_2O_4$: C, 53.56; H, 5.4; N, 12.5%.

*Preparation of 4,6-Dimethyl-*m*-xylylene Dicarbamate (IIa).* To 49.0 g (0.55 mol) of ethyl carbamate we added 33.2 g (0.20 mol) of 4,6-dimethyl-*m*-xylylene glycol and 160 m*l* of ethylbenzene. The reatcion mixture was stirred for 11 hr at 135°C and then treated as has been described above. Mp 199—200°C. Yield, 14.0 g (27.7%). IR (cm^{-1}): 3427—3207 ($\nu(NH_2)$, *etc.*), 1687 (ν(C=O)), 1605 ($\delta(NH_2)$). NMR (ppm): 7.22 and 7.02 (s, each one proton, C_6H_2–), 6.5 (s, 4H, $-NH_2$), 4.93 (s, 4H, $-CH_2$–), 2.23 (s, 6H, $-CH_3$). Found: C, 57.38; H, 6.40; N, 11.12%. Calcd for $C_{12}H_{16}N_2O_4$: C, 57.12; H, 6.41; N, 11.10%.

Reaction Product of Ia with Formaldehyde. A mixture of Ia (5.6 g, 0.025 mol), paraformaldehyde (2.0 g, 0.067 mol), dioxane (30 m*l*), and water (15 m*l*) was stirred at 74°C and pH 11.4 for 80 min, and then to the reaction mixture we added 200 m*l* of water. The solid thus formed was filtered and recrystallized from methanol-water to afford Ib as a white powder; 2.9 g (40.8%); mp 172—173°C. A test with a Tollens reagent was positive. IR (cm^{-1}): 3317 (ν(NH), ν(OH)), 1695 (ν(C=O)), 1530 (ν(CN)+δ(NH)). NMR (ppm): 7.8 (t, 2H, –OH), 7.29 (s, 4H, C_6H_4–), 5.5 (t, 2H, –NH–), 5.0 (s, 4H, $-CH_2OC$–), 4.43 (t, 4H, $-N-CH_2O$–). Found: C, 50.94; H, 5.84; N, 9.66%. Calcd for $C_{12}H_{16}N_2O_6$: C, 50.69; H, 5.68; N, 9.86%.

Reaction Product of IIa with Formaldehyde. A mixture of IIa (2.1 g, 0.008 mol), paraformaldehyde (0.8 g, 0.025 mol), dioxane (30 m*l*), and water (15 m*l*) was stirred at 70°C and pH 13.2 for 30 min and then treated as has been described above. Mp 145—147°C. Yield, 0.57 g (18.3%). A test with a Tollens reagent was positive. IR (cm^{-1}): 3250 (ν(NH), ν(OH)), 1690 (ν(C=O)), 1530 (ν(CN)+δ(NH)). NMR (ppm): 7.8 (t, 2H, –OH), 7.23 and 7.0 (s, each one proton, C_6H_2–), 5.5 (t, 2H, –NH–), 4.97 (s, 4H, $-CH_2OC$–), 4.45 (t, 2H, $-N-CH_2O$–), 2.24 (s, 6H, $-CH_3$). Found: C, 53.67; H, 6.68; N, 8.82%. Calcd for $C_{14}H_{20}N_2O_6$: C, 53.85; H, 6.47; N, 8.97%.

The authors wish to express their thanks to Professor Minoru Imoto of Kansai University for his kind direction, to Professor Masayoshi Kinoshita of Osaka City University for his valuable suggestions and continuous encouragement, and to Dr. Chingyun Huang of the Kobunshi Laboratory of the Nihon Gas Co. for his helpful guidance.

Single-Photon Ionization in the Flash Photolysis of *N,N,N',N'*-Tetramethyl-*p*-phenylenediamine in Solution

Takeshi IMURA, *Naoto YAMAMOTO, *Hiroshi TSUBOMURA, and Kazuo KAWABE

Department of Electrical Engineering, Faculty of Engineering, Osaka University, Suita, Osaka
**Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

(Received March 25, 1971)

The photo-ionization of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in solution was reported to take place by double-photon process through the triplet state.[1,2] Recently, it was reported that the formation of TMPD cation passing through no triplet state also takes place,[3,4] and that no evidence of double-photon process was obtained in other experiments using the method of laser photolysis.[5]

As a result of our investigation of the effect of light intensity on the photocurrent induced by the ionic species and caused by the flash photolysis of TMPD in acetonitrile at a room temperature, we obtained evidence of ionization by the single-photon rather than the double-photon process.

Experimental details were given previously.[6] Light intensity was regulated by setting the brass wire-gauzes of various transmittances. The photocurrent was measured at the initial maximum peak.

Figure 1 (A) shows the photocurrent *vs.* relative light intensity logarithmically. The linear relation in the formation of ionic species is obvious. The lower curve(b) was obtained when only the light with wavelengths greater than 3100 Å was irradiated with a cut-off filter.

The initial concentration of the generated ionic species should be proportional to the initial value (i_0) of the photocurrent as measured at the maximum peak, and should depend only on the total light intensity (L), since the decay of the photocurrent ($>10^{-2}$ sec) was extremely slow compared with the duration of a flash ($<10^{-5}$ sec). The recombination of the ionic species and the other decay processes may be practically neglected during the flash firing. Therefore, the relation $i_0 \propto L^n$ will hold directly, where $n=1$ and 2 according to the ionization for the single- and the double-photon process, respectively. The experimental results indicate that $n=1$.

When the whole body of the sample including the electrodes was uniformly irradiated by removing the slit, the linear curves in Fig. 1 (B) were again obtained notwithstanding the fact that the exchange of charges between the electrodes and excited TMPD, or the additional generation of the ionic species near the electrodes, can easily take place.

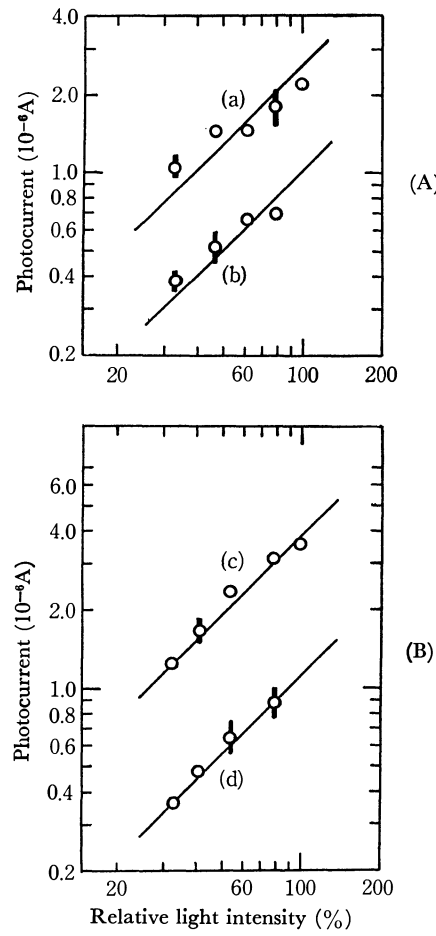

Fig. 1. Effect of light intensity on the photocurrent of TMPD in acetonitrile.
Solid lines correspond to the slope 1.0.
Cut-off filter ($\lambda>3100$ Å) was used in (b) and (d).
(A) Slit was used. Flash input: 275 J.
(a) 3.7×10^{-3}M, (b) 3.8×10^{-3}M.
(B) No slit was used. Flash input: 210 J, 2.7×10^{-4}M.

A sort of semi-ionized state (I) having the CT character can be considered for the ionization.

$$\text{TMPD} \xrightarrow{h\nu} \text{TMPD}^* \longrightarrow [\text{TMPD}^{\delta+} \cdots (\text{CH}_3\text{CN})_m{}^{\delta-}]^* \quad (m \geqq 1)$$

I

It seems that TMPD cation and the counter-anionic species[7] are liberated so spontaneously from state I that no more photon is needed. Examples of the fragmen-

tation into cation and anion from the excited CT state are found.[6,8] As acetonitrile easily accepts electrons from Na metal (ionization potential of Na atom=5.138 eV), the same kind of reaction can be expected by the transfer of electron from TMPD in the excited state (ionization potential of TMPD(gas phase)≒6 eV[9]) to acetonitrile through CT interaction.

Photoconductive measurements were also tried in ethanol solution, where the ionization through a double-photon process was demonstrated by the effect of light intensity on the optical density of generated TMPD cation,[1] but the photocurrent could hardly be detected.[5,6]

Vinyl Polymerization. 272. Synthesis and Polymerization of 9-*O*-Methacryloylquinine

Kiyoshi YAMAUCHI, Masayoshi KINOSHITA, and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 25, 1971)

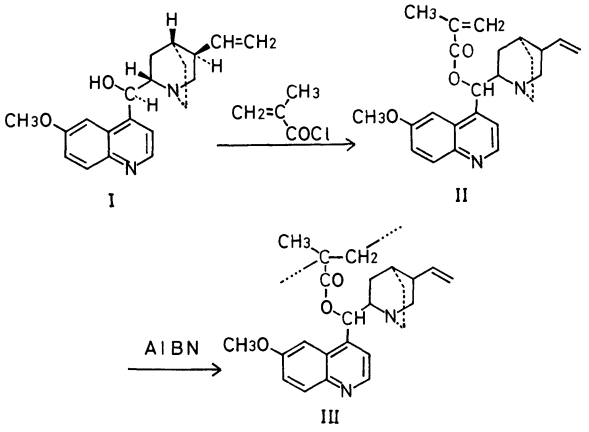
There have been various studies aimed at incorporating drugs into polymeric materials.[1] The most challenging aspect of the problem has been the search for systems, in which the polymer might receive advantages, such as increased pharmacological activities and reduced undesirable side effects.

The present study was undertaken for the synthesis and the polymerization of 9-*O*-methacryloylquinine (II) with the hope that the polymer (III) derived from II might show an increased effectiveness against the usual quinine (I) formulations, such as antifebrile and antimalarial activities.[2]

Further, III would be useful as an optically active resin, since quinine holds four asymmetric carbons. Grubhofer and Schleith[3] performed a resolution of manderic acid, using the reaction product of Amberlite XE 64 reisn with thionyl chloride and then with I (16% content of I). The polymer (III), which we wish to discuss in this paper, might be attractive in this field, too, since it contains one resolving agent per monomer unit.

The synthesis of II was performed by the reaction of I with methacryloyl chloride; it was obtained in a 70% yield. The stereospecific configuration of the quinine part was not altered during the esterification, since an alkaline hydrolysis of II reproduced I in a good yield.

The ester (II) could be converted into a water-soluble dihydrochloride quantitatively, during which time a racemization and a fission of the ester bond of II had not taken place. The compound (II) was also optically stable toward heating in benzene. On the basis of these chemical properties of II, the polymerization was carried out in benzene at 80°C, using AIBN as an initiator. The polymer (A) obtained in the lower concentration of II was soluble in chloroform, benzene, and pyridine, whereas the polymer (B) produced in the higher concentration was insoluble in most organic solvents, but swelled in DMF and DMSO. The difficulty in solubility may be caused by cross-linking through the participation of the vinyl group on the quinuclidinyl ring, and a coupling of radicals produced by chain-transfer reactions.



For the studies of the pharmacological activities of the polymer, it would be desirable to modify the polymer into a water-soluble one. This was performed by converting III to its hydrochloride. The introduction of dry hydrogen chloride gas into a benzene solution of polymer (A) generated a hygroscopic salt, and it became very soluble in water, as expected. On the other hand, the salt formation of polymer (B) was difficult because of the lack of appropriate solvents.

The use of the polymer as a high-molecular-weight drug and as an optical-active resin is now being studied; the studies will be described later.

Solvent: a, chloroform; b, benzene; c, water.
* Hygroscopic properties of samples were taken into account for calculation of analytical data.

Experimental

The melting points were uncorrected. The infrared spectra (IR) were run on a Jasco Model IR-G Spectrometer. The ultraviolet absorption spectra (UV) were measured with a Hitachi Recording Spectrometer, Model EPS-3T. The optical rotations were recorded with a Yanagimoto Photo-Magnetic Polarimeter, Model OR-10. The molecular weight was determined using a Hitachi Vapor Pressure Osmometer, Model 115. The physical constants and analytical data of the compounds are listed in Table 1.

9-O-Methacryloylquinine (II). A mixture of quinine monohydrochloride dihydrate (13.0 g, 0.032 mol) and chloroform (60 ml) was treated with 4N sodium hydroxide to transfer quinine into the chloroform layer, which, after dring with anhydrous sodium sulfate, was mixed with methacryloyl chloride (3.3 g, 0.032 mol) and triethylamine (3.2 g, 0.032 mol). After the reaction mixture had been kept at room temperature for one day, it was washed with 10% sodium bicarbonate and dried over anhydrous sodium sulfate. The organic solution was concentrated and then chromatographed on alumina (2 cm × 70 cm, 300 mesh, neutral). Elution with ethyl acetate gave 9.2 g of crystalline 9-*O*-methacryloylquinine, which was recrystallized from ether to afford 9.0 g (70%) of the pure product.

IR (KBr); 2960, 1710, 1620, 1590, 1500, 1225, and 1150 cm^{-1}.

The optical rotation of II was not changed after heating at 80°C for ten hours in benzene; $[\alpha]_D^{19}$+30.4° (*c* 10, benzene).

Hydrolysis of II. A mixture of II (0.39 g, 1 mmol), methanol (10 ml), and 4N potassium hydroxide (10 ml) was allowed to stand for two hours at room temperature. Subsequent extraction with chloroform and evaporation of the solvent gave 0.27 g (76%) of a white solid, the optical ratation of which showed $[\alpha]_D^{19}$−104° (*c* 1.5, chloroform). An authentic sample had $[\alpha]_D^{19}$−108° (*c* 1.5, chloroform). The solid gave only one spot in thin layer chromatography in several solvent systems. IR, UV, and NMR spectra were all identical with those of quinine (I); mp 176°C (lit,[2] 177°C).

Polymerization of II. *Polymer (A):* The ester (II) (2.00 g, 5.1×10^{-3} mol), AIBN (4.5×10^{-3} g, 2.8×10^{-5} mol), and benzene (12 ml) were placed in a glass tube, which was then degassed and sealed. The tube was immersed in a waterbath thermostatted at 80°C and shaken for eight hours, after which it was opened; the reaction mixture was then poured into diethyl ether to precipitate a white polymer, 0.98 g (49%).

The polymer is soluble in chloroform, benzene, DMF, DMSO, and conc. hydrochloric acid, and insoluble in water, methanol, and acetone. Mw=4380 (benzene, 30°C).

Polymer (B): A mixture of II (0.84 g, 2.1×10^{-3} mol), AIBN (2.1×10^{-3} g, 1.3×10^{-5} mol), and benzene (1.6 ml) was treated in a manner similar to that used for polymer (A), producing 0.78 g (93%) of a yellow solid which had an identical IR spectrum with that of polymer (A).

The polymer did not dissolve in any organic solvents and concentrated hydrochloric acid, but swelled in DMF and DMSO.

Preparation of Hydrochloride. II-HCl: Dry hydrogen chloride gas was passed through a benzene solution of II (0.69 g) to produce 0.63 g (70%) of the white hydrochloride. The salt is hygroscopic, and is soluble in water, methanol, and pyridine, but insoluble in tetrahydrofuran and ether.

IR (KBr): 3400, 2500, 1723, 1615, 1500, 1250, and 1135 cm^{-1}.

The ester (II) was recovered from II-HCl (0.30 g) by mixing it with 10% sodium bicarbonate and extracting it with chloroform; 0.21 g (83%), $[\alpha]_D^{19}$+29.7° (*c* 9.0, chloroform), mp 125—126°C.

Polymer (A)-HCl: The introduction of hydrogen chloride gas into a mixture of polymer (A) (0.10 g) and benzene yielded 0.11 g (85%) of the salt. The product is hygroscopic and is soluble in water and methanol, but insoluble in ether, chloroform, and acetic acid.

IR (KBr): 3400, 2600, 1735, 1620, 1600, 1500, 1250, 1140, and 1110 cm^{-1}.

Polymer (B)-HCl: Polymer (B) (0.1 g) in benzene afforded 0.1 g (83%) of the hygroscopic hydrochloride, which was insoluble in any organic solvents and water. Its IR spectrum was similar as that of polymer (A)-HCl.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3188 (1971)

Magnetic Properties of Organic Stable Radicals. III. Diphenyl Nitric Oxide

Osamu TAKIZAWA,* Jun YAMAUCHI,** Hiroaki OHYA-NISHIGUCHI,* and Yasuo DEGUCHI*

*Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

**The Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received March 26, 1971)

We have already reported on the magnetic property of 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (TANOL), which can be explained fairly well by theoretical calculations based on the one-dimensional Heisenberg model.[1] On the other hand, from the findings on the temperature dependence of the susceptibility of the porphyrexide radical, it has been proposed that this radical forms an Ising-type antiferromagnetic chain.[2] The difference between the magnetic properties of TANOL and porphyrexide is considered to be due to their different molecular structures; the former has a nonplanar molecular framework and a localized spin distribution, while the latter is somewhat planar and has a small delocalized spin distribution over the whole molecular frame. In order to examine the effect of the delocalization of spin on the magnetic exchange interaction, another organic stable radical with a more delocalized spin in the π-orbital has been chosen as the next sample. In the present paper we shall report the results of our susceptibility measurements of the diphenyl nitric oxide (DPNO) radical. In this radical the unpaired spin is delocalized in the conjugated π-electron system spreading over the whole molecule,[3] and the molecule is presumed to have a planar framework similar to those of benzophenone and di-*p*-anisyl-nitric-oxide.[4] Cambi has reported the magnetic susceptibility data of DPNO at room temperature only.[5] In the present paper, the magnetic measurements were extended to the temperature range between 1.5°K and 293°K.

A DPNO radical prepared by the method of Wieland and Roth[6] was recrystallized from ether, the melting point being 59.5—60.5°C. Its radical concentration was determined to be 96% by comparing it with the calculated value, using the Curie-Weiss law and the Weiss constant of $\theta = -3.5$°K at 77°K. The measurements were carried out by means of a magnetic torsion balance[7] in the magnetic field about 8 kOe. The diamagnetic correction was made employing -1.21×10^{-4} emu/mol. The results, shown in Fig. 1, obeyed the Curie-Weiss law in the temperature range above 30°K. After deviating from the Curie-Weiss law when the temperature was lowered, the magnetic susceptibility reached a broad maximum at 6.2°K. Thereafter, it decreased successively toward a finite value of 140×10^{-4} emu/mol. The broad maximum in the susceptibility can be attributed to the short-range magnetic ordering, for no intrinsic anisotropy of magnetic susceptibility could be found from the measurement of a single crystal of DPNO. In order to clarify the magnetic property of DPNO, it was compared with the theoretical results of the one-dimensional Heisenberg model ($T_m = 6.2$°K) calculated by Bonner and Fisher,[8] which are also shown in Fig. 1. The theoretical results agree quite well with the present experimental results in the available temperature region.

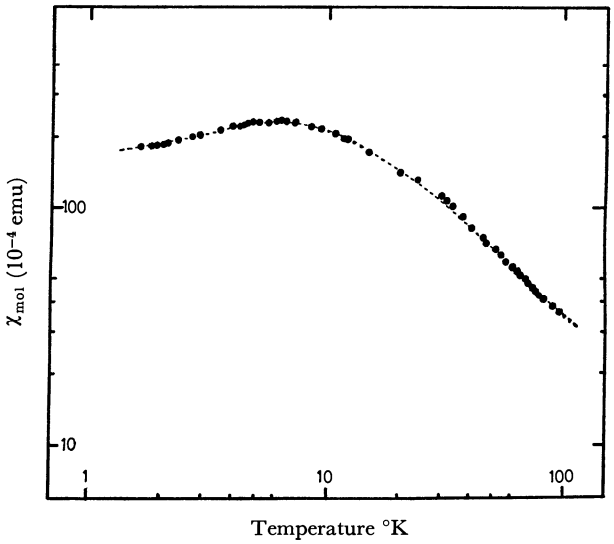

Fig. 1. Magnetic susceptibility of DPNO radical.
●: observed values, ------: calculated values of one-dimensional Heisenberg model

Recently, the magnetic properties of di-*p*-anisyl nitric oxide (DANO) have been shown to be consistent with the nearest-neighbor antiferromagnetic Heisenberg model of a quadratic layer lattice proposed by Duffy, Strandburg and Deck.[9] However, one of the present authors has discussed in detail the magnetic properties of some organic free radicals.[10] In his paper, it was concluded that the neutral organic free radicals with one unpaired electron in a molecule have a one-dimensional antiferromagnetic spin array with a Heisenberg-type isotropic interaction, and was suggested that the DANO radical is a one-dimensional Heisenberg-type antiferromagnet. The present results on the DPNO radical are also consistent with the aforementioned conclusion regarding the neutral organic free radicals.

The Characteristics of Defect Lead Titanate

Shin-ichi SHIRASAKI, Kooichiro TAKAHASHI, and Kazuo MANABE*

National Institute for Research in Inorganic Materials, Honkomagome, Bunkyo-ku, Tokyo

** Tokyo College of Photography, Atsugi, Kanagawa*

(Received April 3, 1971)

$PbTiO_3$ and $BaTiO_3$ have been known as typical ferroelectric materials with perovskite-type structures, the former being characterized by a fairly high Curie temperature (490°C) and by the largest tetragonal lattice strain (0.063) among known perovskite-type ferroelectrics. On the other hand, although many sorts of barium titanate, such as $BaTi_3O_7$, $BaTi_2O_5$, and Ba_2TiO_4, besides the well-studied $BaTiO_3$, have been known, no phase other than $PbTiO_3$ has so far been found in the system of Pb–Ti–O. This means that, during the course of the solid-solid reaction between PbO and TiO_2 at elevated temperatures, one of the reactants present in an excess remains unreacted without forming any compounds other than a single product of $PbTiO_3$. Furthermore, neither an oxygen-excess nor an oxygen-deficient state in $PbTiO_3$ has been found. The present communication will discuss the basic chracterization of the defect lead titanate newly found.

Experimental

All the ceramic samples of defect lead titanate proposed here were prepared by firing noncrystalline lead titanate. The noncrystalline bodies were prepared by adding a titanium tetrachloride aqueous solution to a strongly basic aqueous solution (with the aid of NaOH) of lead acetate under following conditions: with an equimolar ratio of Ti^{4+} and Pb^{2+} quantities (sample A′), with Pb^{2+} in twice the molar quantity of Ti^{4+} (sample B′), and with the latter solution in a large excess (sample C′). All the precipitates thus obtained were thoroughly washed with water until they were free from Na^+. A portion of as-precipitated sample C′ was immersed into a basic aqueous solution of lead acetate for 10 hr and then washed with water (sample D′); the solution was formed by the dissolution of lead acetate into a slightly basic aqueous solution adjusted with the aid of acetic acid and ammonia water. Finally, the noncrystalline samples, A′, B′, C′, and D′ were all fired at 800°C for 1 hr in order to convert them satisfactorily into polycrystalline samples, A, B, C, and D respectively.

Results and Discussion

The results of the chemical analysis of these polycrystalline samples indicated that they all more or less possessed Pb- and oxygen-deficiencies; they can be characterized by the general formula of $(PbO)_x \cdot TiO_2$. Here, it was confirmed that no phases other than the perovskite one were observed, at least on X-ray powder patterns of the samples. The defective structures, however, should be understood as being metastable even if they are stable up to 800°C. A piece of experimental evidence to support the above statement was that all the samples of defect lead titanate, when heated at a considerably higher temperatures (for example, at 950°C) were changed to those with less deficiencies by successively isolating TiO_2 from the original samples.

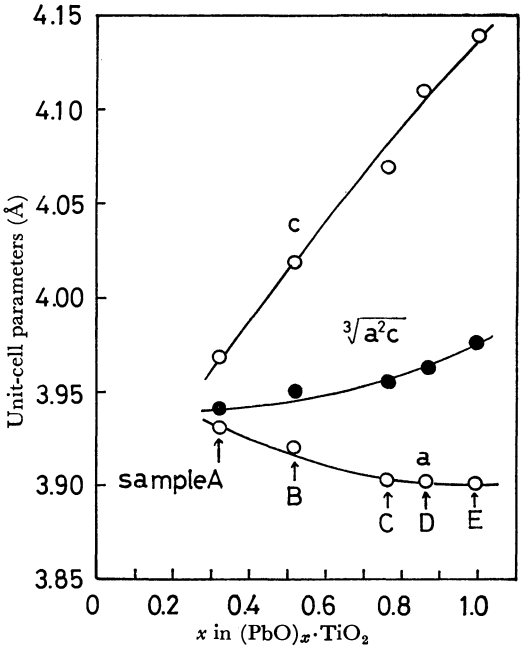

Fig. 1. Unit-cell parameters (a,c and $\sqrt[3]{a^2c}$) as a function of the value x in $(PbO)_x \cdot TiO_2$.

On the other hand, the unit-cell parameters (a,c and $\sqrt[3]{a^2c}$) of each tetragonal lattice varied from one sample to others, depending on the history of the preparation of the samples. The dependence of these parameters on the x value in $(PbO)_x \cdot TiO_2$ is obvious; Fig. 1 depicts this along with the data on a standard sample, E, which was prepared by the solid-solid reaction of an equimolar mixture of PbO and TiO_2 at 1000°C for 1 hr. As may be seen in Fig. 1, with an increase in the degree of the nonstoichiometry between constituent cations, a reducing tendency of $\sqrt[3]{a^2c}$ value is evident. In other words, this fact may be the same as saying that a contraction of the unit-cell volume of the defect lead titanate takes place as a result of the introduction Pb- and/or oxygen-vacancies into the $PbTiO_3$ crystal. It is surprising that considerable amounts of the deficiencies can be introduced into the $PbTiO_3$ crystal while maintaining the perovskite-type structure. At any rate, the present ceramic samples of defect lead titanate may be successfully taken as a new type of ferroelectric material, because they all more or less possess tetragonal lattice strains, $1-c/a$.

Further study was undetaken in order to determine whether or not the defect structures are uniform over the bulk. For this purpose, the degree of the fluctua-

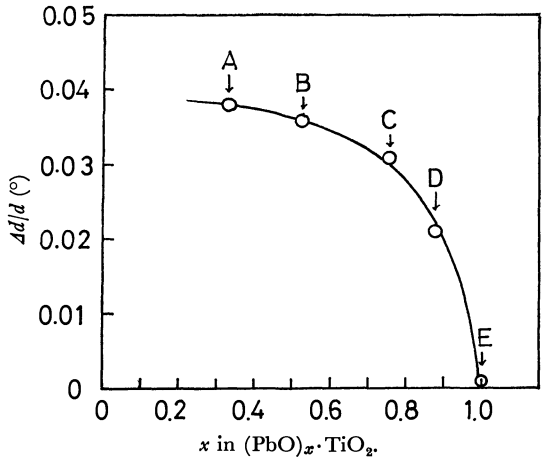

Fig. 2. The fluctuation of interplaner spacings in defect lead titanate.

tion of interplanar spacings, $\Delta d/d$, of each cubic lattice, which appeared when the substance was intentionally held at a temperature (550°C) above the Curie point of the samples, was calculated by observing the reflection angles, θ, and the pure X-ray diffraction broadening, β, with the aid of the relationship:[1,2]

$$\beta = -\frac{\Delta d}{d} \cdot \frac{\sin\theta}{\cos\theta}$$

Practically, when plotting $\beta \cdot \cos\theta$ against $\sin\theta$, the $\Delta d/d$ value was determined from the slope of the straight line obtained. The dependence of the $\Delta d/d$ ratio on the x value is evident, as is illustrated in Fig. 2. Here, from the fact of the presently-observed dependence on x of $\sqrt[3]{a^2c}$ at room temperature, one may expect a further dependence of $\sqrt[3]{a^3}$ or a at 550°C on x. If so, it seems resonable to believe that the fluctuation of interplanar spacings occurs mainly due to a fluctuation of the x value, *i.e.* due to a microscopic inhomogeneity of the defect structures.

In summary, the present lead titanate prepared through the wet process can be characterized by both Pb- and oxygen-deficient structures, and by their inhomogeneities, the degree of which increase with an increase in the over-all degree of the deficiencies.

The Effects of the Exciting Energy on the Atomic and Molecular Detachments of Hydrogen in the Photolysis of Simple Molecules

Kinichi Obi, Yuji Ogata, and Ikuzo Tanaka

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received April 16, 1971)

Photochemical studies of simple molecules have been mainly concerned with understanding the primary processes, together with their relative yields.[1)]

In this note we wish to report on certain interesting features of the variation in the percentage of the molecular and atomic detachment processes of hydrogen in the photolyses of ethane, ethylene, water, and ammonia with the change in the excitation energy. The experimental data are qualitatively interpreted by a simple theoretical treatment of the RRKM theory.

The primary processes of ethane, ethylene, water, and ammonia are summarized in Table 1. The photolysis of ethylene at 1634 and 1849 Å was carried out using a bromine lamp and a low-pressure mercury lamp respectively. The results of our study of the photolysis of ethylene will be published elsewhere.[2)] In these primary processes, we were most interested in the effect of the exciting energy on the hydrogen elimination primary processes. Figure 1 shows the percentage of the atomic detachment of hydrogen as a function of the excess photon energy, which is the energy difference between the photon energy and the heat of reaction for the atomic elimination. In the case of ethane, the total yield of Reactions (1) and (2) is taken as 100%.

It can clearly be seen in Fig. 1 that there are two kinds of energy dependency in these molecules; one increases its atomic percentage with an excess of energy, such as the cases of ethane and ethylene, while the other shows the oposite trend, such as the cases of water and ammonia. As is shown in Table 1, in the

case of the former the heat of reaction for molecular detachment is much smaller than that for atomic detachment, whereas in the case of the latter the difference between the heats of reaction between the two kinds of detachment is small.

The percentage of the atomic detachment was calculated from the relative rates of the molecular and atomic detachments, which were themselves estimated by the application of the simple RRKM theory to the excited state of the reactant. According to the RRKM theory, the unilmoecular rate constant is expressed as follows:[3]

$$k_E = A\frac{(E-E_a+a^+E_z^+)^{s-1}}{(E+aE_z)^{s-1}} \quad (1)$$

where E is the excess energy of the electronic excited state ($E=E(h\nu)-E_0$, E_0 is the energy of the electronic excited state), E_a is the activation energy, and E_z and E_z^+ are the zero-point energies of the energized molecule and the activated complex respectively. The a and a^+ quantities are empirical correction factors for the energized molecule and the activated complex respectively. The index, s, is the number of the vibrational mode, and A is a constant evaluated from the properties of the species in question.

In this treatment the molecular and atomic detachments are assumed to be competitive processes from the excited state. Thus, the percentage of atomic detachment is given by $\alpha(A)=100\ k_E(A)/(k_E(A)+k_E(M))$, where $k_E(A)$ and $k_E(M)$ represent the rate constants for the atomic and molecular detachment process es respectively. Using Eq. (1), $\alpha(A)$ is expressed as follows:

$$\alpha(A) = \frac{100}{1+A'\left(1+\frac{\Delta E_a-\lambda}{E'-E_a(A)}\right)^{s-1}} \quad (2)$$

3) D. W. Setser and B. S. Rabinovitch, *Can. J. Chem.*, **40**, 1425 (1962).

where $A'=A(M)/A(A)$, $E'=E+a^+(A)E_z^+(A)$, $\Delta E_a=E_a(A)-E_a(M)$, and $\lambda=a^+(A)E_z^+(A)-a^+(M)E_z^+(M)$.

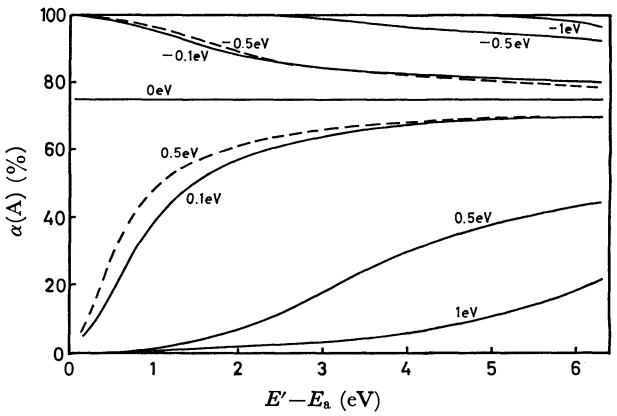

Fig. 2. Dependency of calculated percentage of atomic detachment on excess energy ($E'-E_a$) for various $\Delta E_a-\lambda$ values. ——: $s=18$, – – –: $s=3$.

Assuming $A'=1/3$, at which the percentage of atomic detachment is 75% for a large excess energy, the percentage of atomic detachment was calculated for several values of $\Delta E_a-\lambda$ and s as a function of $E'-E_a$. The results are shown in Fig. 2 for the case of ethane ($s=18$) and also for water ($s=3$), but for the latter only the results for $\Delta E_a-\lambda=\pm 0.5$ eV are shown. As may be seen in Fig. 2, if $\Delta E_a-\lambda$ is positive, the molecular detachment percentage decreases, while if it is negative, it increases with an increase in $E'-E_a$, that is, the photon energy. Comparing these calculated results with the experimental one in Fig. 1, it can be predicted that ethane and ethylene have positive values of $\Delta E_a-\lambda$, while water and ammonia have negative values.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3192 (1971)

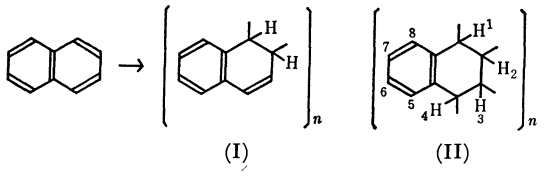
The Proton Magnetic Resonance Spectrum of 1,2,3,4-Tetrahydronaphthalene Polymer

Tadashi YONEMITSU, Yasuhiko MATSUKUMA, Kunihiro FURUKAWA, and Genjiro HAZATO

Department of Industrial Chemistry, Faculty of Engineering, Kyushu Sangyo University, Kashii, Fukuoka

(Received April 5, 1971)

The polymerization of naphthalene has been reported by Minato *et al.*[1] The naphthalene polymer was obtained easily by the reaction with anhydrous aluminum chloride. This polymer was estimated to be a 1,2-dihydronaphthalene oligomer. According to the procedure of Minato *et al.*, we also synthesized the naphthalene polymer. The polymer obtained by us was a brown, powdered crystal. This crystal softened and darkened at 50—60°C, melted at about 150°C, and finally carbonized at about 200°C. The molecular weight of the polymer was found to be 1025 by the cryoscopic method. As the molecular weight of $(C_{10}H_8)_8$ is 1024, the average degree of polymerization is 8. Figure 1 shows two structures of the polynaphthalene. The (II) structure seems to be more favorable in both stability and the progress of the reaction. The proton magnetic resonance spectrum of the polymer was obtained on a JNM-MH-100 spectrometer.



(I) (II)

Fig. 1. The structures of the polynaphthalene and the numbering.

The peaks at 1.84, 2.83, and 7—9 ppm are ascribed to the hydrogens of the 2,3-, 1,4-, and 5,6,7,8-positions respectively. The sharp peak at 7.19 ppm is suspected to be due to $CHCl_3$ in the solvent, $CDCl_3$.

On the other hand, in the NMR spectrum of 1,2-dihydronaphthalene, two peaks have been found, at 5.82 and 6.33 ppm, corresponding to the 3- and 4-positions.[2] Therefore, if the 1,2-dihydro-structure predominates in the polymer, two peaks corresponding to the 3- and 4-positions should appear in the range of 5—7 ppm. Moreover, of course, no peak has been found in that range in tetralin.[3] Therefore, it seems that the polymer we have obtained has the 1,2,3,4-tetrahydro-structure predominantly.

The authors wish to thank Dr. Goto and his coworkers in Japan Electron Optics Laboratory Co., Ltd., for the measurement of the NMR spectrum.

Alkoxysilanes. VIII. The Preparation of Alkoxysiloxy Derivatives of Aluminum and Boron

Ichiro KIJIMA, Takeshi YAMAMOTO, and Yoshimoto ABE*

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 26, 1971)

In order to obtain a polymer containing a heterosiloxane linkage in the molecular main chain, we have already reported on the preparation of alkoxysiloxy derivatives of metals (Sb,[1] Ti,[2] Zr,[3] Sn). In the present experimental work, the preparation of the derivatives of aluminum and boron was attempted.

The reaction of triiso-propoxyaluminum or tri-*n*-butyl borate with tri-*t*-butoxysilanol was investigated; it was difficult to isolate the reaction product in 1:1 molar ratio of the silanol to triisopropoxyaluminum by recrystallization and distillation because of its high solubility in solvents or because of its decomposition. The reaction in the 3: 1 molar ratio caused decomposition during the removal of the solvent from the reaction mixture and led to the formation of a gel insoluble in organic solvents. The gas evolved during the decomposition was identified as isobutylene by means of gas chromatography. Therefore, it was considered that, in this reaction, the rupture of the alkoxy group attached to silicon occurred along with alcohol exchange. This reaction is very different from that of the metal alkoxides with the silanol. The difference may be attributed to the property as Lewis acids of aluminum compounds. In the 2:1 molar ratio, however, bis(tri-*t*-butoxysiloxy)-isopropoxyaluminum (I) was isolated by recrystallization (mp 75—76°C). The results of the molecular-weight determination indicated that it was associated. On the other hand, tri-*t*-butoxydi-*n*-butoxy (II) and bis(tri-*t*-butoxysiloxy)*n*-butoxysiloxyboron (III) were easily obtained as viscous liquids, however, it seems difficult to replace the last *n*-butoxy group attached to boron by the butoxysiloxy group because of its steric hindrance.

$$M(OR)_3 + n(Bu^tO)_3SiOH \longrightarrow [(Bu^tO)_3SiO]_nM(OR)_{3-n} + nROH$$

where M=Al, R=Pr^i, and n=2 (I); M=B, R=Bu^n and n=1 (II) or 2 (III)

The reaction of acetylacetonatodiisopropoxyaluminum with the silanol gave bis(tri-*t*-butoxysiloxy)acetylacetonatoaluminum (IV), as in the case of titanium, zirconium, and tin. Bis(tri-*t*-butoxysiloxy)isopropoxyaluminum is associated, while this compound is monomeric (Table 1). The difference seems to be ascribed to the coordination of the carbonyl group in the acetylacetonato to aluminum.[4] These compounds were identified by means of elemental analysis, as is shown in Table 1, and by studying the IR spectra, which were essentially identical and which showed the IR absorption peaks at 1050—1075 (ν_{Si-O-C} and $\nu_{Si-O-Al}$[5]) and 1320 (ν_{B-O-C}), 1500—1600(AcAc) cm^{-1}. The reaction products from bis(acetylacetonato)isopropoxyaluminum, however, were almost all tri(acetylacetonato)-aluminum. In this case, therfore, disproportionation

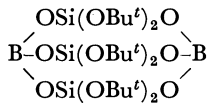
may occur:

$$(AcAc)Al(OPr^i)_2 + 2(Bu^tO)_3SiOH \longrightarrow [(Bu^tO)_3SiO]_2Al(AcAc) + 2Pr^iOH$$
(IV)

$$3(AcAc)_2Al(OPr^i) + 2(Bu^tO)_3SiOH \longrightarrow 2Al(AcAc)_3 + [(Bu^tO)_3SiO]_2Al(OPr^i) + 2Pr^iOH$$

In order to obtain a polymeric substance, the reaction of acetylacetonatodiisopropoxyaluminum or tri-*n*-butyl borate with di-*t*-butoxy and bis(tri-*t*-butoxysiloxy)silanediol was carried out: with di-*t*-butoxysilanediol, a little tri(acetylacetonato)aluminum and a powder (decomposed at 200°C) soluble in organic solvents were formed, whereas with bis(tri-*t*-butoxysiloxy)silanediol, needle crystals (decomposed at 280°C) almost insoluble in solvents were obtained (V). It was shown, by means of studying the IR spectra and by the elemental analysis, that these substances contained the Si–O–Al bond together with the acetyl-acetonato groups, and that the former had an atom ratio of C: H: Si equal to 6: 13: 1 and that the latter has a unit structure of $[-Al(AcAc)-O-Si[OSi(OBu^t)_3]_2-O-]_n$, although the structures were not confirmed. On the other hand, it was difficult to isolate the products formed by the reaction of tri-*n*-butyl borate with the diols by recrystallization or distillation, however, the results of the study of the IR spectra, the elemental analysis, and the molecular weight determination showed that the raw material obtained by the reaction of the alkoxide with di-*t*-butoxysilanediol was in accordance with the following formula:



(VI)[6]

Experimental

Materials. The alkoxysilanols were prepared by the method already described.[2,7] Commercially-available aluminum triisopropoxide was redistilled before use. The tri-*n*-butyl borate was obtained by the reaction of boric anhydride with *n*-butyl alcohol according to the procedure of Walton and Rosenbaum;[8] bp 107—109°C/1 mmHg, n_D^{20} 1.4089. The acetylacetonatodiisopropoxyaluminum was afforded by Thomas method;[4] bp 147—148°C/2 mmHg.

Preparation of Compounds (I) and (II). A mixture of metal alkoxide or acetylacetonato chelate, silanol, and benzene was refluxed for 1 hr. The solvent was then removed, and the residue was fractionally distilled *in vacuo* or recrystallized from *n*-hexane or benzene. The results are shown in Table 1.

Reaction of Acetylacetonatodiisopropoxyaluminum with Silanediols. A mixture of 3.5 g (0.014 mol) of the acetylacetonato chelate, 8.4 g (0.014 mol) of bis(tri-*t*-butoxysiloxy)silanediol, and 30 m*l* of benzene was heated. White needle crystals appeared at 70°C; then the mixture was further heated for 30 min. The crystals were filtered and washed with benzene (yield 8.1 g). The analytical data are shown in Table 1.

In another run, a mixture of 4.0 g (0.016 mol) of the chelate, 3.4 g (0.016 mol) of di-*t*-butoxysilanediol, and 30 m*l* of toluene was refluxed for 1 hr. The solvent was then removed, and the residue was recrystallized from *n*-hexane, giving 0.5 g of needle crystals; mp 187—190°C. Found: C, 54.42; H, 6.38; Al, 8.41% (tris(acetylacetonato)aluminum). The filtrate gave a yellow powder (3.7 g) after the removal of the solvent; mp about 200°C (decomposed).

Analysis. The silicon was determined by a method already described. The aluminum was determined to be aluminum oxide after a weighed sample had been decomposed by an aqueous alcohol solution.

Nicotinonitrile Derivative from 2-Cyano-3-mercapto-3-methylthioacrylamide

Masataka YOKOYAMA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba

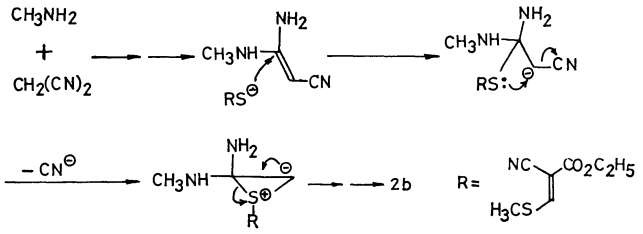
(Received May 11, 1971)

The reaction of 2-cyano-3-mercapto-3-methylthioacrylamide (**1a**) with carbonyl compounds has been reported.[1] This paper deals with the reaction of **1a** with a cyano compound.

It has been found that 2-imino-4-methylthio-6-methylamino-1,2-dihydronicotinonitrile (**3**) can be isolated in 71% yield by the reaction of **1a** with malononitrile and an aqueous solution of methylamine (30%).

The structure of **3** was established on the basis of spectroscopic evidence and the results of elementary analysis. The NMR spectrum (acetone-d_6) showed a broad NH signal at δ 5.80, a singlet peak for one proton of C(5)–H at δ 5.50, a doublet methyl singal at δ 2.85 (J=5 Hz), and a singlet methyl signal at δ 2.43. On addition of deuterium oxide, the NMR peak of NH disappeared and the doublet methyl signal changed to a singlet. This indicates the presence of the $NHCH_3$ group. The NH stretching bands appeared at 3440, 3400, and 3310 cm^{-1}, and a conjugated CN group occurred at 2200 cm^{-1}. The features of the UV spectrum of **3** were similar to those of 2-aminopyridine,[2] but quite different from those of ethyl 3(2-amino-2-methylaminoethenylthio)-2-cyano-3-methylthioacrylate (**2b**) (see Experimental). Compound **3** might better be written in a pyridone type form to accomodate C(5)–H to δ 5.50.

A plausible mechanism for the formation of **3** is illustrated in Scheme 1 by assuming **2a** as an intermediate. Compound **2b**, corresponding to **2a**, could be isolated by the reaction of ethyl 2-cyano-3-mercapto-3-methylthioacrylate with malononitrile and the aqueous solution of methylamine (30%). Formation of **2b** can be accounted for in the following way:



Compound **3** can be formed by the cyclization reaction of **2a**, followed by the loss of an atom of sulfur. A similar desulfuration reaction has been reported on the behavior of a cyclic polysulfide.[3]

Compound **3** was also obtained by refluxing **2b** in alcohol-aqueous ammonia (28%), sulfur being simultaneously eliminated. In the reaction of **1a** with malononitrile and the aqueous solution of methylamine, a small amount of sulfur was detected, while no cyano ion eliminated from malononitrile could be detected by spot test.[4]

Desulfuration of **3** afforded 2-imino-6-methylamino-1,2-dihydronicotinonitrile (**4**). The NMR spectrum (DMSO-d_6) of 4 showed a doublet peak of C(5)–H which caused coupling with that of C(4)–H at δ 5.90

4) A dark brown solution containing cuprous sulfate and ammonium sulfide changes to a colorless one by addition of a cyanide ion.

(J=8 Hz), and no peak at δ 2.43 for the methylthio group. Formation of **4** also supports the structure of **3**.

Experimental

Compound **1a** was prepared according to the procedure given in a previous report.[1] The NMR spectra were recorded with a JNM-4H-100 MHz Spectrometer using tetramethylsilane as an internal standard. The IR, UV, and mass spectra were recorded with a Nihon Densi 403G, Hitachi EPS-3T, and Hitachi Double Focus RMU-6E, respectively. Microanalyses were performed at the Institute of Physical and Chemical Research.

Preparation of 2-Imino-4-methylthio-6-methylamino-1,2-dihydronicotinonitrile (3). To a mixture of an aqueous solution of methylamine (30%, 30 m*l*) and **1a** (5 g, 0.03 mol) was gradually added malononitrile (20 g, 0.3 mol) with stirring at room temperature. The reaction mixture immediately started to boil. After 5 min, a colorless crystalline material started to precipitate gradually. After 1 hr, it was filtered, washed with ethanol, and dried. Recrystallization from methanol gave 4 g of colorless needles: yield 71%; mp 223—224°C; $UV_{max}^{99\%EtOH}$ 236.5 mμ (log ε =4.59), 255 (sh, 4.39), 288 (4.10).

Found: C, 49.22; H, 5.14; N, 29.02; S, 16.47%; mol wt, 194 (mass spectrum). Calcd for $C_8H_{10}N_4S$: C, 49.48; H, 5.19; N, 28.85; S, 16.48%; mol wt, 194.19.

A small amount of sulfur was detected from the above filtrate.

Desulfuration of 3. A Raney nickel (Ni: 48%) was activated in the usual way.[5] Compound **3** (3 g, 0.02 mol) was refluxed with the activated Raney nickel (25 g) in ethanol (50 m*l*) for 6 hr. The decolorized reaction mixture was separated from nickel by decantation and centrifugation. The nickel was washed with ethanol and the washings were also centrifuged. The combined alcoholic solution was concentrated to *ca.* 20 m*l* under diminished pressure. The resulting solution was left to stand for 2 weeks. After a small amount of the unreacted **3** was filtered off, the filtrate was allowed to stand for an additional 2 weeks. The second crystalline material (colorless needles) was collected and washed with ethanol: yield 0.1 g; mp 180—181°C; NMR (DMSO-d_6) δ 6.30 (br, 3, NH) δ 5.90 (d, 1, C(4)-H, J=8 Hz) δ 5.50 (d, 1, C(5)-H, J=8 Hz) δ 2.65 (d, 3, CH_3, J=7 Hz); IR (KBr) 3450, 3360, 3130 (s, NH), 2950 (m, CH), 2220 cm^{-1} (s, conj. CN); $UV_{max}^{99\%EtOH}$ 237.5 mμ (logε =4.76), 257 (sh, 4.51), 290 (4.11).

Found: C, 56.69; H, 5.41; N, 37.96%; mol wt, 148 (mass spectrum). Calcd for $C_7H_8N_4$: C, 56.74; H, 5.44; N, 37.82%; mol wt, 148.17.

The NMR absorption of NH disappeared and the doublet methyl signal at δ 2.65 changed to a singlet by addition of deuterium oxide. The structure of the product was thus assigned to 2-imino-6-methylamino-1,2-dihydronicotinonitrile.

Preparation of Ethyl 3(2-Amino-2-methylaminoethenylthio)-2-cyano-3-methylthioacrylate (2b). To a mixture of **1b** (8 g, 0.046 mol) and the aqueous solution of methylamine (30%, 15 m*l*) was slowly added malononitrile (15 g, 0.15 mol) at room temperature. After 30 min, a colorless crystalline material started to precipitate. After 3 hr, the precipitate was collected and washed with ethanol. Recrystallization from methanol gave 3.6 g of colorless plates: yield 29%; mp 177—178°C; NMR (acetone-d_6) δ 5.58 (d, 1, NH, J=4 Hz) δ 4.08 (q, 2, CH_2, J=8 Hz) δ 3.48 (s, 2, NH_2) δ 3.30 (s, 1, CH) δ 2.60 (d, 3, CH_3, J=4 Hz) δ 1.20 (t, 3, CH_3, J=8 Hz); IR (KBr) 3440, 3420, 3180, 3120 (s, NH_2, NH), 2200 (vs, conj. CN), 1660 cm^{-1} (vs, CO); $UV_{max}^{99\%EtOH}$ 228.5 mμ (logε=4.05), 289 (3.58), 345 (4.38).

Found: C, 43.92; H, 5.63; N, 15.30; S, 23.12%; mol wt, 265 (vapor-pressure osmometer, in acetone). Calcd for $C_{10}H_{15}N_3S_2O_2$: C, 43.95; H, 5.53; N, 15.38; S, 23.44%; mol wt, 273.24.

With the addition of deuterium oxide, the NMR absorptions of NH_2 and NH disappeared and the doublet methyl signal at δ 2.60 changed to a singlet.

The author wishes to thank Propessor Dr. Tatsuo Takeshima and Dr. Hiroshi Midorikawa for their kind advice.

Conformations of the Esters. III. The Infrared Carbonyl Absorptions and Conformations of Propionates, Isobutyrates, and Pivalates

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 13, 1971)

In a previous paper,[1] it has been proved that alkyl acetates take only the *s-trans* conformation within their ester group, and it has been suggested that the higher homologs of the esters also have such a conformation. However, in the homologs of carboxylic acids, a conformational heterogeneity will arise if the alkyl chain is properly substituted. The conformational heterogeneity has been reported with mono and dihaloacetates,[2,3] methoxy- and phenoxyacetates,[4,5] α-methoxypropionates, and α-methoxyisobutyrates.[5] However, few authors[6,7] have reported on the conformational heterogeneity of the esters, whose α-carbon is replaced by another carbon group (alkylacetates). The purpose of this note is to present the results of a study of the infrared spectra in the carbonyl region of alkylacetates, and to relate the crabonyl-stretching frequencies with the conformations derived by rotation about the C_{CO}–C_{α} bond.

Experimental

Materials. The required esters were prepared according to the published procedures. The purities of the samples were checked by means of their physical constants, gas-chromatographic results, NMR spectra and infrared spectra.

Apparatus. The infrared spectra were recorded on a Perkin-Elmer 112G single-beam grating spectrometer (3500—3300 cm^{-1}, 1800—1700 cm^{-1}) and a Hitachi EPI-G2 grating infrared spectrophotometer (4000—400 cm^{-1}). The measurement of the spectra and the separation of the bands of esters were carried out as has been described previously.[1]

Results and Discussion

As the model compounds of alkylacetates, some propionates, isobutyrates, and pivalates were chosen. These esters have been reported to have only one carbonyl absorption,[2,3,5,8,9] and no authors have reported the unsymmetric nature of the carbonyl bands of these esters. We measured the carbonyl absorption shapes carefully with a infrared spectrometer of a high resolution. The results are given in Table 1. Clearly, propionates and isobutyrates give bifurcated band in the carbonyl region except for only one case (compound III). These results may be taken as indicating the presence of two conformers if they are proved to be really carbonyl bands. The bifurcation can be attributed neither to the solute-solute interaction nor to the solute-solvent interaction, because the spectra were measured with a solution of a very low concentration and two-peaked absorptions are observed even in carbon tetrachloride. The origin of the bifurcation is also difficult to explain from the standpoint of Fermi resonance for the following two reasons. The solvent effects on the band shapes of the almost all the propionates and isobutyrates are hardly affected at all by solvent polarity. The independency of the relative intensity of the solvent polarity can be attributed to the small difference in the polarities of the conformers. On the other hand, it is well known that in the case of the Fermi resonance, the intensities of the two peaked absorptions of the carbonyl region are dramatically affected by the solvent polarity; in fact, a reversal of the intensity ratio is often observed[10] (see also the case of methyl pivalate). Methyl propionate (I) has car-

bonyl overtone absorptions of almost the same shape at 3454 cm^{-1} (ε=0.45) and 3472 cm^{-1} (ε=3.56). These two facts rule out the possibility of the bifurcation of the carbonyl bands being due to the Fermi resonance.

Thus, it is most likely that the bifurcation comes from the presence of at least two conformations. Three stable conformations can arise corresponding to the rotation about the C–O bond in the alcohol part. However, if this is the only cause of the bifurcation, it is difficult to explain why the methyl and *t*-butyl propionates give two absorptions in this region. This consideration leads to the conclusion that the presence of the two bands is most probably attributable to the rotational isomers about the C_{CO}–C_{α} bond, as is shown in Fig. 1.

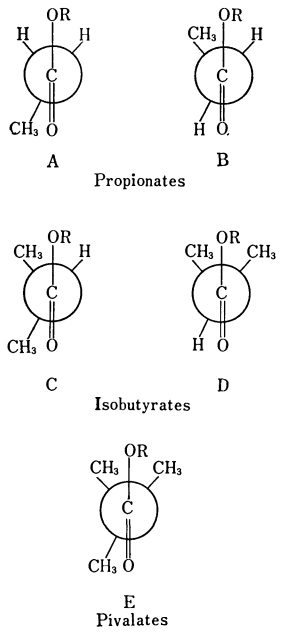

Fig. 1. Possible conformations of alkyl propionate, isobutyrate, and pivalate.

According to the above considerations, pivalate esters should give only one C=O band, because they have only one conformation, E, due to the symmetry of the *t*-butyl group. The results with ethyl and *t*-butyl pivalates conform to this expectation, but methyl pivalate unexpectedly gives a two-peaked band. In order to test the possibility of a Fermi resonance, the C=O absorption spectrum of methyl-d_3 pivalate (XI) was measured. It gives only one symmetrical peak. This necessarily means that the mode of C–H vibration is responsible for the bifurcation of the carbonyl band and strongly suggests that the phenomenon is caused by the Fermi resonance. Auxiliary support for this explanation has been obtained by the dramatic solvent effect on the carbonyl absorptions. Now it is clear that the bifurcation of the carbonyl bands of some simple esters reflects the heterogeneity of the conformations.

There then remains the problem of assigning the two bands to each conformation. Comparing the wave number where the carbonyl absorptions of acetates and pivalates occur, the higher frequency band may be assigned to the C–H and C=O eclipsed forms, B and D. Then it may be taken that these B and D conformers are more stable than the A and C conformers, judging from the integrated intensities of the respective bands. However, it is well known that, for unknown reasons, the C–H and C=O eclipsed conformers are less stable than the C–CH_3 and C=O eclipsed conformers. Therefore, these two contradictory arguments must be settled before establishing the assignments. We do not dare to assign the bands at present, but would like simply to point out the need of further work.

The authors wish to express their hearty thanks to Professor T. Shimanouchi of The University of Tokyo for his helpful discussions.

Synthetic Studies of the Flavone Derivatives. XXIII.[1] The Synthesis of Eupatilin

Tokunaru HORIE, Masao TSUKAYAMA, Mitsuo MASUMURA, Kenji FUKUI,* and Mitsuru NAKAYAMA*

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima
**Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima*

(Received May 14, 1971)

Eupatilin, isolated from *Eupatorium semiserratum* D C., has been identified as 5,7-dihydroxy-6,3′,4′-trimethoxyflavone (I) on the bases of its spectral data and degradative studies.[2] The present paper will describe the synthesis of I from 2,4-dibenzyloxy-6-hydroxy-3-methoxyacetophenone (II).

The esterification of II with 3,4-dimethoxybenzoyl chloride (III) yielded 2,4-dibenzyloxy-3-methoxy-6-(3,4-dimethoxybenzoyloxy)acetophenone (IV). The IV ester was converted into 2,4-dibenzyloxy-6-hydroxy-3-methoxy-ω-(3,4-dimethoxybenzoyl)acetophenone (V) by the Baker-Venkataraman transformation. The cy-

IX R=H, R′=Et

clodehydration of V with sodium acetate afforded 7-benzyloxy-5-hydroxy-6,3′,4′-trimethoxyflavone (VI). The catalytic hydrogenolysis of VI gave the desired flavone I, which was then easily converted into the diacetate (VII), the diethyl ether (VIII), and the monoethyl ether (IX). The flavone I was shown to be identical with the natural pigment[3] by a mixed-melting-point determination and by IR and UV spectral comparisons.

Experimental[4]

2,4-Dibenzyloxy-3-methoxy-6-(3,4-dimethoxybenzoyloxy)acetophenone (IV). A mixture of the crude II[5] (2.3 g) and III (2.3 g) in anhydrous pyridine (10 m*l*) was heated at 120°C for 2 hr. The cooled reaction mixture was poured into diluted hydrochloric acid, and then extracted with ether. The ether layer was allowed to stand overnight in a refrigerator. The separated crystals were recrystallized from ethyl acetate to give IV; mp 155—157°C (colorless prisms); yield, 800 mg (24%).

Found: C, 70.83; H, 5.53%. Calcd for $C_{32}H_{30}O_8$: C, 70.83; H, 5.57%.

2,4-Dibenzyloxy-6-hydroxy-3-methoxy-ω-(3,4-dimethoxybenzoyl)-acetophenone (V). A mixture of IV (0.9 g), powdered potassium hydroxide (1 g), and anhydrous pyridine (15 m*l*) was heated at 60°C for 4 hr with stirring. The reaction mixture was acidified with diluted hydrochloric acid, and then extracted with ether. The ether layer was allowed to stand overnight in a refrigerator. The separated crystals were recrystallized from ethyl acetate to give V; mp 131—132°C (yellow needles); yield, 450 mg (50%).

Found: C, 70.85; H, 5.33%. Calcd for $C_{32}H_{30}O_8$: C, 70.83; H, 5.57%.

7-Benzyloxy-5-hydroxy-6,3′,4′-trimethoxyflavone (VI). A mixture of V (370 mg), sodium acetate (1 g), and acetic acid (10 m*l*) was heated at 140°C for 4 hr. The reaction mixture was diluted with water, and then extracted with ether. The product was recrystallized from ethyl acetate to give VI; mp 175—177°C (pale yellow plates); yield, 210 mg (71%). UV: λ_{max}^{EtOH} mμ (log ε); 244(4.26), 251.5(4.23), 278 (4.25), 344 (4.39). NMR:[6] ($CDCl_3$) 12.82_s (5-OH).

Found: C, 69.18; H, 5.19%. Calcd for $C_{25}H_{22}O_7$: C, 69.11; H, 5.10%.

5,7-Dihydroxy-6,3′,4′-trimethoxyflavone (Eupatilin) (I). A mixture of VI (150 mg) and palladium charcoal (Pd: 10%; 75 mg) in a mixed solvent of ethyl acetate and methanol (1:1; 80 m*l*) was shaken in an atmosphere of hydrogen for 3 hr. The product was recrystallized from ethyl acetate to give I; mp 241—242°C (yellow prisms); yield, 92 mg (77%). UV: λ_{max} mμ (log ε); (EtOH) 242(4.30), 277(4.29), 345 (4.38); (EtOH–AcONa) 278(4.45), 316(4.20), 376(4.26); (EtOH–$AlCl_3$) 254(4.18), 290(4.24), 352(4.39). NMR: (DMSO) 3.76_s, 3.84_s, 3.87_s (3×MeO); 6.60_s, 6.90_s, 7.09_d (J=9), 7.53_d(J=2), 7.65_q(J=9, 2) (5×Arom.H); 10.5_b, 13.07_s (2×OH) (Natural Pigment:[7] mp 240—241.5°C).

Found: C, 62.51; H, 4.47%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

Diacetate (VII): mp 154—155°C (colorless needles from methanol). UV: λ_{max}^{EtOH} mμ (log ε); 249(4.35), 265_{sh}(4.16),[8] 338(4.40). NMR: ($CDCl_3$) 2.37_s, 2.47_s (2×MeCO); 3.83_s, 3.92_s (6H) (3×MeO); 6.56_s, 6.96_d(J=9), 7.29_s, 7.30_d(J=2.5), 7.49_q(J=9, 2.5) (5×Arom.H).

Found: C, 61.68; H, 4.63%. Calcd for $C_{22}H_{20}O_9$: C, 61.68; H, 4.71%.

Diethyl Ether (VIII): mp 165.5—166.5°C (colorless needles from ethanol). UV: λ_{max}^{EtOH} mμ (log ε); 240(4.34), 266 (4.15), 327(4.42). NMR: ($CDCl_3$) 1.46_t, 1.50_t, 4.14_q (J=7) (2×EtO); 3.87_s, 3.91_s(6H) (3×MeO); 6.51_s, 6.73_s, 6.91_d (J=9), 7.27_d(J=2.5), 7.46_q(J=9, 2.5) (5×Arom. H) (lit,[2] mp 164—166°C).

Found: C, 66.24; H, 6.26%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%.

Monoethyl Ether (IX): mp 176—177°C (pale yellow needles from ethanol). UV: λ_{max}^{EtOH} mμ (log ε); 244(4.29), 253_{sh} (4.25), 278.5(4.27), 344(4.45). NMR: ($CDCl_3$) 12.80_s(5-OH).

Found: C, 64.80; H, 5.40%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

Acetate of IX: mp 176—177°C (colorless needles from methanol). UV: λ_{max}^{EtOH} mμ (log ε); 240(4.30), 260_i(4.06),[9] 330(4.35).

Effects of AC Pretreatment on the Formation of Anodic Titanium Oxide Films

Masaki YAMAZAKI,* Mitumoto NAKAGAWA,** and Hiroshi NOZAKI*

*Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

**Department of Applied Chemistry, Faculty of Engineering, Tokai University, Shibuya-ku, Tokyo

(Received May 20, 1971)

Recently, we have reported the formation of electrolytic titanium oxide films in an aqueous solution of barium hydroxide.[1] In this formation, the pretreatment of titanium was done by applying an AC current to titanium in an aqueous solution of sulphuric acid. It has been found that the AC pretreatment is effective in increasing the bath voltage in the anodization of titanium; this pretreatment is also useful in producing good insulating films on the surface of titanium. It would be of interest to know whether a good dielectric film could be formed on titanium by using the AC pretreatment in connection with electrolytic capacitors. Thus, in this work we will report the effects of the AC pretreatment of titanium on the formation of anodic oxide films in an aqueous solution of phosphoric acid.

Two titanium electrodes, 50 mm × 20 mm × 1 mm, were prepared from ST-40 titanium (H, <0.015%; O, <0.20%; N, <0.05%; Fe, <0.20%). One of the electrodes was mechanically polished, while the other was pretreated in a 16 wt% H_2SO_4 solution at 25°C, using AC (50 Hz) at 50 mA/cm², for 2 hr.[1] After these procedures, the surfaces of both electrodes were examined with an optical microscope. The microphotographs obtained are shown in Fig. 1A for the mechanically-polished electrode and in Fig. 1B for the AC-pretreated electrode. Figure 1 shows that the electrode is partially dissolved in the H_2SO_4 solution by the AC pretreatment. This fact was also confirmed by measuring the weight decrease in the titanium electrode during the AC pretreatment.

The anodizations of both the electrodes mentioned above were carried out under the same conditions; the electrodes were anodized in a 13 wt% aqueous solution of phosphoric acid at 25°C with a constnat current density of 3 mA/cm². In these anodizations, the growth of the voltage with the time was examined. The results obtained are shown in Fig. 2. It is obvious from Fig. 2 that the voltage for the AC-pretreated electrode increases rapidly with the time up to 180 V, while the voltage for the mechanically-polished electrode hardly increases at an over 50 V. These results indicate that the AC pretreatment is useful in producing anodic titanium oxide films which have good insulating properties.

Fermentation without Multiplication of Cells Using Microcapsules That Contain Zymase Complex and Muscle Enzyme Extract

Masao KITAJIMA and Asaji KONDO

Central Research Laboratories, Fuji Photo Film Co., Ltd., Asaka-shi, Saitama

(Received May 20, 1971)

In an earlier article, the present authors described that such enzymes as catalase, urease, lipase, and hemoglobin could be microencapsulated into sphere particles from 10 to 1000 μ in diameter by the use of some synthetic polymers, without much loss of enzymatic activity.[1] An enzyme solution was enveloped with a semi-permeable inactive polymer membrane which protected the enzymes, macromolecular protein, from leaking out, but which did not affect the permeation of substrates and products of a low molecular weight.

These enzyme-containing microcapsules are regarded as a kind of immobilized enzymes,[2] but they are essentially different from the others in that the enzymes themselves are intact and retain their normal properties. One of the merits of the encapsulation in comparison to other methods of chemical or physical immobilization is expected to lie in its applicability to multi-enzyme systems.

More than one enzyme of any kind, with reagents if necessary, can be microencapsulated at the same time in a capsule. In this paper we will discuss the microencapsulation of enzyme extracts obtained from yeast (zymase complex) and the muscle of a rabbit, and will investigate alcoholic and lactic fermentation using these microcapsules.

Experimental

Enzyme Extracts. *Zymase Complex*: A freshly-fermented yeast solution (supplied by the Toyo Jozo Co., Ltd.) was treated with a refrigerated cell fractionator (Sorvall-Ribi, RF-1) to destroy the cells. The homogenated solution was centrifuged at 2000 rpm for 30 min, and then the supernatant was filtered with a filter paper to remove the cell wall and the undestroyed cells. The filtrate was turbid and contained plasmic granules.

The Muscle Enzyme Extract. About 100 g of leg muscle of a rabbit was cut into one-centimeter blocks, and then it was homogenated by a homoblender for 15 min while 200 m*l* of a 0.05M pH 7.0 phosphate buffer solution was added. After the fibrous materials had been taken off, the solution was centrifuged at 9000 rpm for 20 min. The supernatant, the enzyme extract, was clear and colorless. All these treatments were carried out at temperatures below 10°C.

Microencapsulation. 3.0 g of an enzyme extract were emulsified in 15 m*l* of a 5% benzene solution of a ladder polymer of sesqui phenylsiloxane (supplied by the Shinetsu Kagaku Co., Ltd.) by the use of a homoblender for 3 min. This W/O-type emulsion was added quickly to 150 m*l* of a 3% gelatine solution phosphate-buffered at pH 7.0 under brisk agitation at 20°C. At this stage, a (W/O)/W-type complex emulsion was formed. The temperature was gradually raised to 37°C over a 1-hr period, after which the agitation was continued for an additional 1.5 hr at the same temperature. The benzene was evaporated gradually during the process so that a hard, solid capsule wall of the silicone was formed around a droplet of the enzyme extract. The microcapsules thus formed were recovered by centrifugation and were washed with the buffer solution three times.

In all the experiments, the amount of the capsules was weighed after incubation and drying in order to minimize the denaturation of the enzymes.

Incubation and Determination of the Reaction Product. *Alcoholic Fermentation*: In a 50 m*l* flask we placed microcapsules containing the zymase complex and 30 m*l* of a 400 mM glucose solution. Then it was put in an air incubator kept at 30°C.

The concentration of the reaction product, ethyl alcohol, was determined by gas chromatography using a Hitachi-Perkin Elmer Model F6-D gas chromatograph. The calibration curve was obtained by the use of an alchohol-water mixture as the standard solution.

Lactic Fermentation: In a test tube we placed about 150 mg of microcapsules containing the muscle enzyme extract, 1 m*l* of 100 mM glucose, 1 m*l* of 1 mM NAD, 1 m*l* of 10 mM ATP, and 2 m*l* of the 50 mM pH 7.0 tris-HCl buffer solution. Then it was incubated in a water bath kept at 39°C.

At the end of the incubation, the microcapsules were removed by filtration, then, to the filtrate obtained above, we added 5 m*l* of a 10% trichloroacetic acid solution. (No preciptitation was observed upon this addition, as there was no free enzyme in the filtrate). After filtration, the amount of the reaction product, lactic acid, was determined according to the Barker and Summerson method.[3] The optical density was measured at 560 nm using a Hitachi Type 139 spectrophotometer. The control solution was prepared by removing the microcapsules from the incubation solution. The calibration curve was prepared by the use of lithium lactate as the standard material.

Results and Discussion

Figure 1 shows a photomicrograph of the microcapsules that contain the zymase complex. Each looks like a ping-pong ball containing the enzyme solution.

Table 1 gives the results for alcoholic fermentation using the microcapsules containing the zymase complex. About 1% of alcohol was produced in 10 days. The reaction rate is calculated as 10—50 μmol of alcohol per gram of capsule per hour. We could not observe any multiplication of yeast cells outside the capsules in any of the experiments.

Table 2 gives the results for the lactic fermentation using microcapsules containing the muscle-enzyme ex-

tract. In these cases, ATP and NAD were added to facilitate the reaction. It is calculated from the results that about 1 μmol of lactic acid is procuced in an hour. The reaction time was chosen according to the sensitivity of the analysis for the products.

As was indicated by Emden, Mielhof, and Parnas, 13 enzymes are necessary to convert glucose into alcohol or into lactic acid. If any one of these enzymes is lost or denatures during the microencapsulation process, the reaction cycle cannot be completed and the final products can not be obtained. Although many encapsulation methods have been reported,[4)] most of them are unsuitable for enzymes. The method described above is believed to be the most suitable one for the encapsulation of enzymes, since no reactive reagent is necessary and the reaction conditions are quite mild throughout the process.

The present authors previously reported that modified red cells that have a reinforced membrane with normal hemoglobin and enzymes in it were obtained by treating red cells with some isocyanates.[5)] These modified cells can also be used as an immobilized multi-enzyme system, since they exibit many complicated enzymatic activities.

The microcapsules obtained here will be useful for the industrial and medical use of enzymes, since they are easy to recover and handle, and can be used in continuous-column reactions that are more complicated than that made possible by the immobilized monofunctional enzymes. It is expected that the enzymes are aligned close to each other in these capsules, so multi-stage reactions can proceed effectively, as in natural cells. It is also expected that they can be used as model samples in studying cellular reactions or membranes.

The authors wish to thank Mr. M. Morishita of the Toyo Jozo Co., Ltd., for kindly supplying the enzyme extracts, and Mr. F. Arai of our research laboratories for the technical assistance.

Photosensitive Systems Involving Photoconduction and Photochromism

Takao NAKAYAMA, Isamu SHIMIZU, Hiroshi KOKADO, and Eiichi INOUE
Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received May 21, 1971)

The photoreversible color changes (photochromism) of spirans are well known. The spectral sensitizing effect of the colored species of spirans upon the photoconduction of zinc oxide has also been observed.[1)]

In this paper, we will discuss some photosensitive systems which show both photochromism and spectral sensitization for photoconduction.

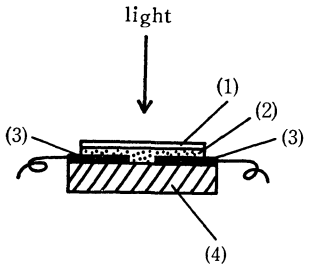

Fig. 1. Experimental arrangement for sp 3 zinc oxide bilayer.
(1) sp 3 evaporated film, (2) zinc oxide powder layer
(3) chromium electrode, (4) glass base

The photosensitive element was formed as is shown in Fig. 1. The photoconductive layer (Fig. 1-(2)) was coated with ZnO powder(0.3 $\mu\phi$)-alcoholic paste on a glass substratum with a pair of Cr-electrodes. After the solvent had been dried from the layer, a photochromic layer (Fig. 1-(1)) was settled upon the layer (Fig. 1-(2)) by the vacuum evaporation of spiran (1,3,3-trimethylspiro[5-chlor-indoline-2,2'-(6'-nitro)benzopyran]).

The photoconductive response of the element was hardly observed in the visible light region, its color was faint yellowish white. An intense color appeared when the element was irradiated with ultraviolet light (365 nm).

The photoconductive response of the photo-colored element was also observed in the visible light region. The spectrum of the photoconduction corresponded to the absorption spectrum of the UV-light-photo-generated colored species of spiran (Curves II and III of Fig. 2). The photocurrent and reflection spectral curves of the element after irradiation with UV light are shown in Fig. 2.

The color of the element was bleached by irradiation with visible light. The photo-bleached element did not show any photocurrent in the visible region. The change between the coloration accompanying spectrally-sensitized photoconduction by UV irradiation and the bleaching of the color by visible light irradiation was repeated several times.

This kind of photochromic and photoconductive element are promising for use with memorized imaging systems.

The Isomeric Sulfites of Dihydrofukinolidol

Keizo NAYA, Ichiro TAKAGI,* and Tsuneo KASAI

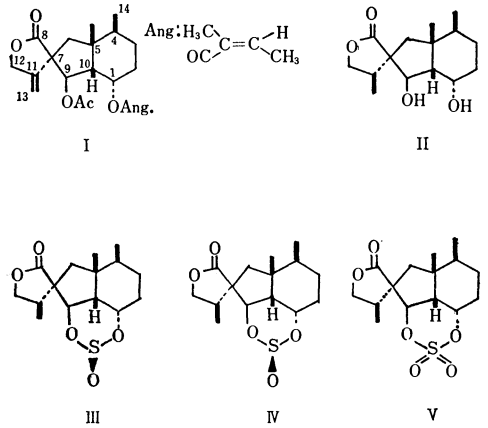
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo

(Received May 24, 1971)

We have already elucidated the structure of fukinolide (I) isolated from *Petasites japonicus* Maxim. In this structural study, dihydrofukinolidol (II) was obtained by the hydrogenation of fukinolide I with platinum oxide-acetic acid, followed by alkaline hydrolysis;[1] it was tentatively assigned to the stereoformula II with a 13-β methyl group, considering the approach of the catalyst from the back of the attached site of the ester groups in the hydrogenation process.

This paper will deal with the configurational assignment of the two isomeric sulfites prepared from dihydrofukinolidol II. The isomeric cyclic sulfites derived from the 1,3-diol system have recently been much investigated in order to provide decisive information for the conformational assignment, especially with regard to the correct orientation of the S–O group.[2]

For the purpose of clarifying the 1,3-relationship, including the configurations between the two hydroxyl groups in dihydrofukinolidol II, the compound II, $C_{15}H_{24}O_4$, mp 190—191°C, was treated with thionyl chloride-pyridine to afford a mixture of two isomeric sulfites. The crude product was separated by column chromatography with silica gel-benzene. The faster-running product (III) formed colorless prisms, mp 190.5—191.5°C (dec.), $[\alpha]_D^{22}$ −80° and the slower one (IV), colorless needles, mp 187.5—188.5°C (dec.), $[\alpha]_D^{22}$ −145°. Though the mixed melting point of III and IV showed a slight depression (mp 186.5—187.0°C dec.), both the products were found to possess the same molecular formula, $C_{15}H_{22}O_5S$; both regenerated dihydrofukinolidol II by alkaline hydrolysis, and were converted to the same sulfate by oxidation with perbenzoic acid.



I II III IV V

Fig. 1. Stereoformulas of Fukinolide I, Dihydrofukinolide II, Sulfites III and IV, Sulfate V.

It was suggested that these isomers were derived from the different configurations of the sulfite S=O groups. In addition, the higher melting product III was less soluble in methanol and chloroform. In view of the *cis-trans* isomerism,[3] the compounds III and IV were supposed to have *trans*- and *cis*-characters respectively, according to the above properties (mp, solubility, and adsorption).

Table 1. Comparison of chemical shifts (ppm as δ-values) in the NMR spectra[a] of fukinolidol (I), dihydrofukinolidol (II), sulfites (III) and (IV)

Proton assignment	Compounds I	II	III	IV
1-H	5.10m	4.10m	4.75q (J=6)	5.00m
6-H	1.90d (J=15)	1.50d (J=14)	1.56d (J=14)	1.55d (J=14)
	2.55d (J=15)	2.00d (J=14)	2.04d (J=14)	2.04d (J=14)
9-H	5.77d (J=12)	4.61d (J=11)	5.26d (J=12)	4.45d (J=12)
10-H	2.82dd (J=6, 12)	2.55dd (J=6, 12)	2.95dd (J=7, 13)	3.65dd (J=7, 13)
12-H		4.23t (J=8)	4.35t (J=7.7)	4.35t (J=7.7)
		4.10q (J=8.5, 10)	3.90q (J=8.5, 10)	3.90q (J=8.5, 10)
13-Me		1.15d (J=7)	1.20d (J=7)	1.20d (J=7)
14-Me	0.90d (J=7.5)	0.78d (J=4)	0.88d (J=7)	0.90d (J=7)
15-Me	1.12s	1.00s	1.12s	1.18s

a) NMR spectra were taken in $CDCl_3$ at 60 MHz with TMS standard.

The configurational difference between the two sulfites was well defined by a comparison of the NMR spectra (Table 1 and Fig. 2). The most remarkable difference between the NMR spectra of the two isomers, III and IV, is the strong deshielding of 9-H in III, and of 10-H and 1-H in IV. This contrast may be expected to occur under the influence of the axially-oriented S=O groups in the chair and boat conformations. Furthermore, the compounds III and IV exhibited the IR absorptions of the axial S=O groups[4] at 1190 and 1200 cm^{-1} respectively.

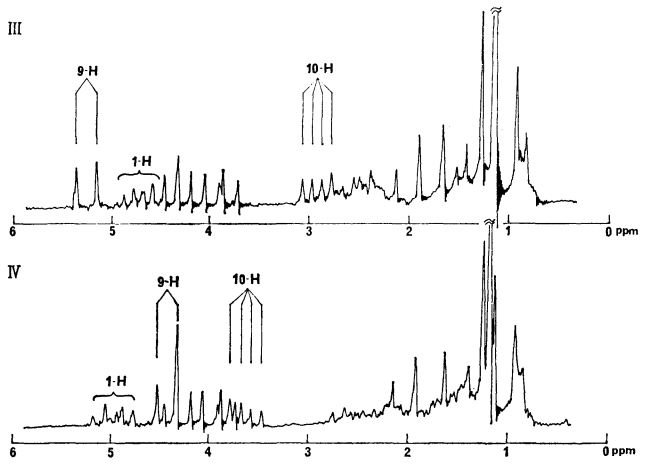

Fig. 2. NMR spectra of sulfites III and IV.

As the absolute configuration of dihydrofukinolidol had been completely established except for the 13β-methyl of the formula II,[5] the above evidence makes possible the assignment of the stereoformula A for III and that of B for IV among the possilbe configurations (A—D, Fig. 3).[6]

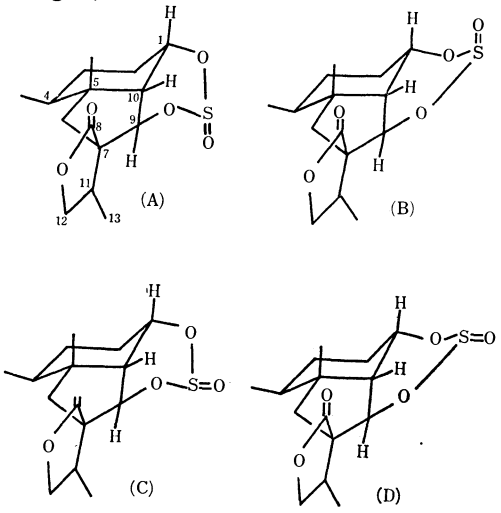

Fig. 3. Possible stereoformulas of sulfites III and IV.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a JASCO DS-402G spectrophotometer, while the UV spectra were obtained with a Cary Model 14 spectrophotometer. The optical rotations were measured with a Hitachi EPU-2A spectrophotometer. The NMR spectra were determined with a Hitachi R-20A spectrometer, using TMS as the internal standard (δ=0) and $CDCl_3$ as the solvent.

Preparation of Isomeric Sulfites of Dihydrofukinolidol (II). A solution of dihydrofukinolidol[1] (870 mg, mp 190—191°C) in dry pyridine (16 m*l*) was stirred, drop by drop, into a mixture of thionyl chloride (3.4 m*l*) and dry pyridine (16 m*l*) at −35——45°C over a 2 hr period; after the mixture had then been stirred at room temperature for additional 2 hr, the solvent was removed *in vacuo*. The residue was poured into water and extracted with ether. The extract was washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the residual solid (1.04 g) was chromatographed over silica gel (20 g); subsequent elution with benzene afforded III (320 mg) as colorless prisms, mp 190.5—191.5°C (dec.) (from ethyl acetate-light petroleum), $[\alpha]_D^{22}$−80° (*c*, 1.0, chloroform); IR (KBr): 1764, 1190 cm^{-1}; tlc (Merck Kieselgel G): R_f, 0.67 (benzene-ethyl acetate, 5: 1).

Found: C, 57.48; H, 6.99; S, 10.41%. Calcd for $C_{15}H_{22}O_5S$: C, 57.30; H, 7.05; S, 10.20%.

Further elution with the same solvent gave IV (240 mg) as colorless needles, mp 187.5—188.5°C (dec.) (from ethyl acetate-light petroleum), $[\alpha]_D^{22}$−145° (*c*, 1.0, chloroform); IR (KBr): 1765, 1200 cm^{-1}; tlc: R_f, 0.48 (benzene-ethyl acetate, 5: 1).

Found: C, 57.57; H, 6.97; S, 10.50%. Calcd for $C_{15}H_{22}O_5S$: C, 57.30; H, 7.05; S, 10.20%. A mixed-melting-point determination with III and IV showed a slight depression (mixed mp 186.5—187.0°C dec.).

Hydrolysis of the Sulfites (III) and (IV). a) The cyclic sulfite III (28 mg) in ethanol (5 m*l*) was added to a 10% potassium hydroxide-methanol solution (3 m*l*), left at room temperature for 2 days, and then warmed at 40—50°C for 10 hr. After acidification with dilute sulfuric acid, the mixture was diluted with water and extracted with ether, washed with a saturated sodium hydrogen carbonate solution and water, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave II (21 mg) as colorless needles, mp 189—191°C (from ethyl acetate-light petroleum), IR (KBr): 3550, 3460, 1760 cm^{-1}; tlc: R_f, 0.48 (benzene-ethyl acetate, 1: 1).

b) The cyclic sulfite IV (35 mg) was treated as above to give II (22 mg), mp 188—189.5°C (from ethyl acetate-light petroleum). The products from a) and b) showed no melting point depression on admixture with dihydrofukinolidol II, mp 190—191°C.

Oxidation of Cyclic Sulfites with Perbenzoic Acid. a) To a solution of III (20 mg) in chloroform (0.5 m*l*), a solution of 0.117N perbenzoic acid-chloroform (1.6 m*l*) was added; the mixture was then left at room temperature for 16 days. The mixture was extracted with ether, and the extract was washed with a saturated sodium hydrogen carbonate solution and with water. The dried extract was concentrated to afford a solid (19 mg). Chromatography over silica gel (3 g) by means of elution with benzene gave the starting material (8 mg) and an oxidation product V (5 mg); mp 135—138°C (from ethyl acetate-light pertoleum); tlc: R_f, 0.55 (benzene-ethyl acetate, 5: 1).

b) A solution of 0.117N perbenzoic acid-chloroform (3.2 m*l*) was added to a solution of IV (42 mg) in chloroform (1 m*l*), after which the mixture was left at room temperature for 6 days. Working-up as above gave a crude product (71 mg) which was chromatographed on silica gel (5 g) by elution with benzene to furnish crystalline V as colorless leaflets; mp 141.5—142°C (dec.) (from ethyl acetate-light petroleum); tlc: R_f, 0.55 (benzene-ethyl acetate, 5: 1).

Found: C, 54.67; H, 6.63; S, 9.57%. Calcd for $C_{15}H_{22}O_6S$: C, 54.53; H, 6.71; S, 9.67%. The mixed melting point of the two products from a) and b) showed no depression (mixed mp 136—138°C).

The authors wish to thank the Shionogi Research Laboratory, Shionogi & Co., Ltd., for the microanalysis, and the Institute of Food Chemistry for the measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3206 (1971)

1,8-Dimethylanthracene

Shuzo AKIYAMA and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 28, 1971)

It has been reported by Lavaux[1] that the Friedel-Crafts reaction of toluene with dichloromethane in the presence of aluminum chloride afforded three compounds with mp 240, 244.5, and 86°C. The last compound has been tentatively assigned to 1,8-dimethylanthracene by Clar.[2]

During the course of synthetic studies of various anthracene derivatives,[3,4] we have prepared 1,8-dimethylanthracene by the reduction of 1,8-bis(bromomethyl)anthracene[4] by means of lithium aluminum hydride in tetrahydrofuran. The resulting hydrocarbon showed mp 128—129°C, and gave satisfactory elemental analysis, infrared, ultraviolet (Fig. 1) and mass spectra. In view of the method of preparation, the hydrocarbon thus obtained should be unequivocally 1,8-dimethylanthracene. Consequently, the hydrocarbon of mp 86°C prepared by Lavaux evidently concerns another dimethylanthracene.

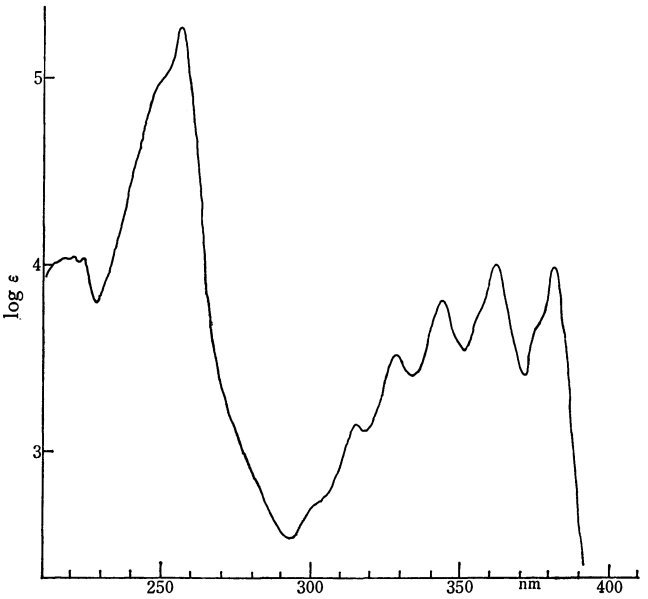

Fig. 1. The electronic spectrum of 1,8-dimethylanthracene.

Experimental

1,8-Dimethylanthracene. A mixture of 1,8-bis(bromomethyl)anthracene[4] (0.728 g, 2 mmol), an excess of lithium aluminum hydride (0.076 g) and tetrahydrofuran (40 m*l*) was stirred at room temperature for 1 hr and then refluxed for 2 hr. The reaction mixture was decomposed by addition of cracked ice and 6N hydrochloric acid (10 m*l*). The organic layer was worked up according to the usual procedure. Removal of the solvent *in vacuo* resulted in a crude material which was re-dissolved in benzene (10 m*l*). The benzene solution was passed through a thin layer of alumina (4 g). Evaporation of the solvent under reduced pressure afforded faint yellow crystals (0.321 g, 78%). Recrystallization twice from ethanol gave colorless plates with blue fluorescence, mp 128—129°C. Found: C, 93.02; H, 6.81%. Calcd for $C_{16}H_{14}$: C, 93.16; H, 6.84%. Mass: 206 (M^+), 191 (M^+-CH_3). Mol. Wt. 206. UV: $\lambda_{max}^{n\text{-hexane}}$ (ε) 220.5 (1100), 223.5 (1100), 256 (18200), 314 (1300), 328.5 (3300), 344.5 (6600), 362 (10300), and 381 nm (9800). IR: 2850—3100, 1520, 1620, 1440, 1380, 900, 876, 780, 740 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3207 (1971)

An Empirical Formula for the Optimum Concentration for Hydrothermal Precipitation

Tominosuke KATSURAI

Department of Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 6, 1971)

By means of visual autoclaving, *viz.*, visual studies on autoclaving processes with sealed glass tubes, we can easily observe the relation between the concentration of electrolyte solution and the temperature at which onset of turbidity takes place in the solution. It was found that if we plot temperature *vs.* concentration, we obtain a curve concave upward. This means that the incipient stage of hydrothermal precipitation takes place most easily at a certain concentration,[1,2] or that there is an optimum concentration for hydrothermal precipitation.

A simple formula fitting the curve can be obtained if we utilize the distance between solute particles as a unit of concentration. For this purpose let us take the case in which 6.02×10^{23} (Avogadro's number) particles are distributed in equal distance of 12 Å in a 1 *l* volume. The distance corresponds to 1 M solution.

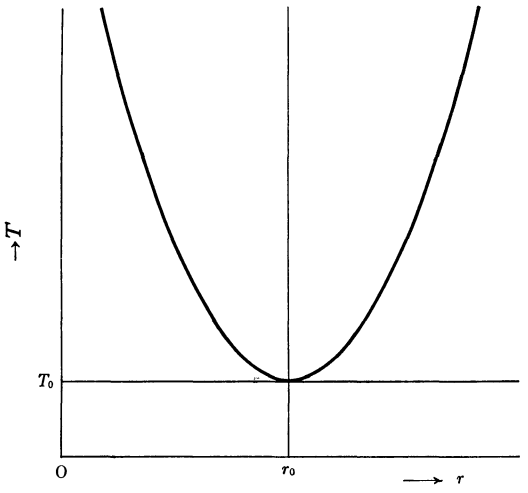

Fig. 1. Relation between inter-solute distance (concentration) and the temperature at which onset of turbidity takes place.

In the usual hydrothermal experiments, concentration is given in terms of mol per liter. The relation between the molar concentration c and the corresponding distance r is given by

$$r = \frac{12}{\sqrt[3]{c}}. \tag{1}$$

By means of this relation, we find that the data of visual autoclaving can be represented by

$$T = T_0 + \alpha(r-r_0)^2, \tag{2}$$

where T=temperature at which onset of turbidity takes place,
T_0 =the lowest temperature at which onset of turbidity takes place,
r =distance between solute particles,
r_0 =the value of r corresponding to T_0,
α =constant.

This is the equation of a parabola with its apex at (r_0, T_0) as shown in Fig. 1. For the sake of illustration, examples are given for aqueous solutions of some compounds.

Compound	T_0 in °C	r_0 in Å	α in Å^{-2}
$AlCl_3$	166	72	0.028
$Ce(NH_4)_2\cdot(NO_3)_6$	107	35	0.069
$ThCl_4$	158	48	0.028
$Th(NO_3)_4$	151	54	0.028

So far there seems to be no theory on hydrothermal precipitation to afford an explicit formula for the relation between r and T. In the meantime, Eq. (2) might be utilized for its simplicity for grasping the process of hydrothermal precipitation.

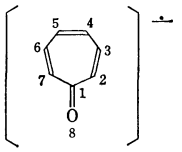
An SCF MO Treatment of Tropone Radical Anion

N. TRINAJSTIĆ
Institute "Rudjer Bošković," Zagreb, Croatia, Yugoslavia

(Received November 18, 1970)

Ikegami and Seto[1] reported on the ESR spectrum of tropone radical anion.



We would like to report our calculations for tropone radical anion using "half-electron" SCF MO method of Dewar *et al.*[2] We also give a comparison between tropone radical anion and the parent compound. Calculations for tropone were performed using Dewar's variant[3] of the original Pople's SCF MO method.[4] Calculated charge densities for tropone and its radical anion and calculated spin densities for tropone radical anion together with spin densities obtained from the observed hyperfine splitting constants[5] are given in Table 1. The

TABLE 1. CALCULATED CHARGE DENSITIES FOR TROPONE AND TROPONE RADICAL ANION, AND CALCULATED AND OBSERVED SPIN DENSITIES FOR TROPONE RADICAL ANION

Ring position	Charge density		Spin density of tropone radical anion	
	Tropone	Tropone radical anion	Calculated	Experimental[a]
1	0.6462	0.5879	0.00	—
2,7	1.0092	1.2585	0.35	0.36
3,6	0.9464	0.9588	0.04	0.004
4,5	0.9854	1.1695	0.21	0.21
8	1.4720	1.6383	0.00	—

a) Y. Ikegami and S. Seto, This Bulletin, **41**, 2225 (1968).

results suggest that spin densities on the stoms 1 and 8 are small or zero, since the highest occupied MO of tropone radical is an antisymmetric orbital. A similar conclusion is reached by HMO calculations[1], but McLachlan's procedure predicted[1] negative spin densities on these atoms even bigger in magnitude than the spin densities on the atoms 3 and 6. This was not tested by ESR study because neither atom 1 nor 8 carries a hydrogen atom. However, both sets of calculations (HMO and McLachlan's procedure)[1] reproduce qualitatively the experimental spin densities, but the quantitative agreement is not so good. If we compare, for example, the ratios of the spin densities on the atoms 2 or 7 and 4 or 5, we obtain the following results.

ρ 2,7/ρ 4,5	Method of calculation
1.56	HMO
2.02	McLachlan's procedure
1.67	our calculations
1.69	experimental value

We would like to add that our calculations included the bond length variations (variable β).[6] This was found[7] recently to be very important in the spin density calculations of the conjugated anion radicals.

In Table 2 is given π-electron charge distribution on the oxygen atom of tropone calculated by various authors, who all agree that a certain amount of π-electron charge is donated to the oxygen. The unpaired electron in the tropone radical ion, which occupies the π-molecular orbital contributes a certain amount of the charge to the total π-electronic charge densities of each ring carbon atom except for C_1, and to the charge density of the oxygen atoms. Such a charge density distribution may indicate that the polar character of the carbonyl group C_1–O is increased in tropone radical ion.

We have also calculated bond lengths of tropone and its radical anion. The results are given in Table 3. Our calculation of bond lengths of tropone predicts

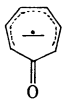
the bond alternation within the seven-membered ring. The results of earlier structural studies on tropone agree with the value of 1.26 ± 0.02 Å for the length of C=O bond, but CC bonds were predicted to be of an equal length (average value being 1.405 ± 0.02 Å).[8] On the other hand, a recent structure determination of 4,5-benzotropone[9] indicated that polyenoid-type bond alternation is present in the tropone moiety. An alternation was found in the tropone ring and experimental bond lengths agree fairly well with our calculated values (Table 3).[10] Apparently tropone is a cyclic polyenoid molecule and it can be regarded as a non-aromatic compound. This was confirmed experimentally[11] and theoretically.[12] Calculated bond lengths (as well as calculated charge densities) of tropone radical anion support representation of its structure as shown below.



The C=O bond and CC bonds 1,2 and 1,7 are fixed as double and single bonds, respectively, while the remaining CC bonds are aromatic with an average bond length 1.4 Å. This is quite a different structure from that of tropone.

12) Aromatic stabilization (A_s) of tropone is calculated to be only 0.8 kcal/mol. Benzene, for example, has $A_s=20.0$ kcal/mol. Aromatic stabilization was calculated in the manner described by M. J. S. Dewar, A. J. Harget, and N. Trinajstić, *J. Amer. Chem. Soc.*, **91**, 6321 (1969).

SHORT COMMUNICATIONS

The Oxyphenylation of Olefins

Hiroshi Horino and Naoto Inoue
College of General Education, Tohoku University, Kawauchi, Sendai
(Received May 21, 1971)

A number of papers on the aromatic substitution of olefins by the reaction of palladium compounds have been published in recent years.[1-3] In the course of our studies of the aromatic substitution of olefins according to Heck's arylation, a new addition reaction was found in which a phenyl group and an anion part of the protic solvents were added simultaneously to reactant olefins.

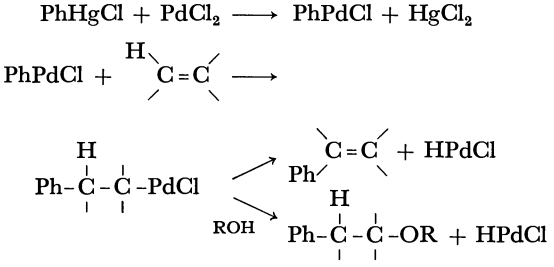
IV	Dioxane–H_2O(1:1)	V(16)[5]	VIa(72)[6]
IV	CH_3CO_2H	V(40)	VIb(14)[6]
IV	CH_3OH	V(16)	VIc(47)[c]

a) Mp 81—82°C, IR(KBr); ν_{OH}=3300—3150 cm^{-1}, NMR(CCl_4); τ 4.95(1H, d, J=6 Hz)
b) Bp 162—165°C/1 mmHg, IR(Neat); $\nu_{C=O}$=1740 cm^{-1}, NMR(CCl_4); τ 8.0(3H), 3.75(1H, d, J=5 Hz).
c) Bp 133—136°C/1 mmHg, IR(Neat); ν_{C-O}=1080 cm^{-1}, NMR(CCl_4); τ 6.88(3H), 5.6(2H, d, J=8 Hz).

The general procedure of the reaction is as follows. A solution of indene (I) (1.2 mmol) or 1,2-dihydronaphthalene (IV) (1.2 mmol), lithium palladium chloride (1 mmol),[2] and phenylmercuric chloride (1 mmol) in the solvents listed in Table 1 was stirred for more than five hours at room temperature.

The reaction products were then separated by chromatography on a silica-gel column. Compound II (or V) was eluted with *n*-hexane, and III (or VI) was eluted with benzene or a mixture of *n*-hexane and benzene (1:1). The isolated products were identified by elementary analysis and by mixed-melting-point tests with authentic samples.[4-7] The addition of sodium acetate (1 or 2 mmol) to a solution of I (1.2 mmol), lithium palladium chloride (1 mmol), and phenylmercuric chloride (1 mmol) in a mixture of acetone and water gave IIIa in a 50 to 60% yield, as is shown in Table 1. The treatment of II or V with a solution of lithium palladium chloride and mercuric chloride in methanol, or with a solution of hydrochloric acid in a mixture of acetone and water, gave only the starting material. The reaction of IIIa or VIa with lithium palladium chloride and mercuric chloride afforded the starting substance. Therefore, it is clear that the oxy compound (III or VI) was not derived from the arylated olefin (II or V), and that II or V was not formed from III or VI.

According to Heck's mechanism,[2] we suggest the following scheme to illustrate the formation of the oxy compounds as well as the arylated olefins.



The configurations of the isolated oxy compounds, IIIa, b, and VIa, b, c, were determined to be *trans*.[7]

The extension of this reaction to other simple olefins is now under investigation.

7) The hydroboration and oxidation of 2-phenylindene (II)[4] and 2-phenyl-3,4-dihydronaphthalene (V)[5] gave IIIa and VIa[6] respectively, those substances were then acetylated to IIIb and VIb[6] with acetic anhydride and pyridine. The treatment of VIa with sodium hydride and subsequently with methyl iodide afforded VIc.

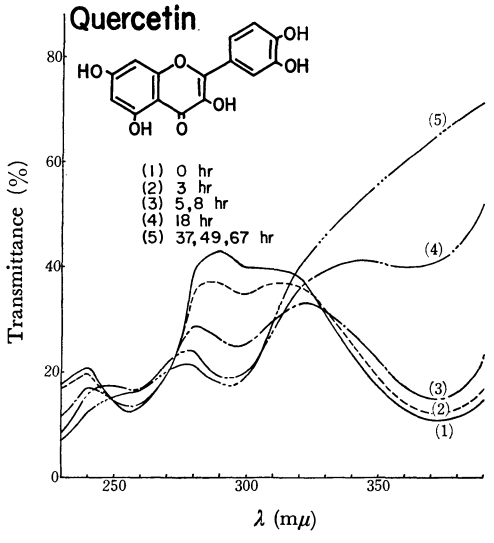
The Light Resistance of the Flavones and the Flavonols

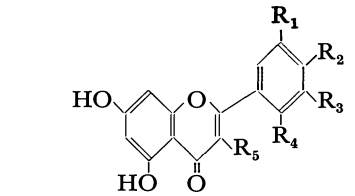
Makoto KANETA and Noboru SUGIYAMA*
Fukushima Technical College, Fukushima
**Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo*
(Received May 21, 1971)

The plants of *Reseda luteola* (luteolin), *Arthraxon hispidus* (luteolin, arthraxin),[1-3] *Miscanthus tinctorius* (luteolin, arthraxin),[3] *Miscanthus sinensis* (tricin),[3] *Phragmites communis* (tricin),[3] *Allium Cepa* (quercetin), *Myrica rubra* (myricetin), *Sophora japonica* (quercetin), and *Morus bombycis* (morin) have traditionally been used as sources of a natural flavonoid dyestuff, the constituents of which are shown in the respective parentheses above.

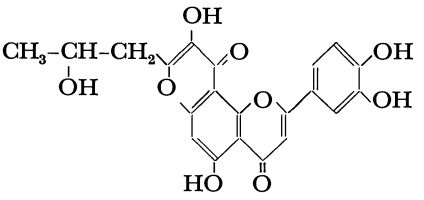
Cloth dyed with *Reseda luteola*, *Arthraxon hispidus*, and *Miscanthus tinctorius* has been said to show a high resistance to the light. However, the causes of this have been unknown. The photooxygenation of 3-hydroxyflavones[4] and the photooxidative cyclization of the quercetin derivatives[5] have recently been reported. Since these results seem to suggest that the molecular structure of flavones influences the resistance to the light, the light resistances have been examined by mean of the UV spectra on the following flavones: quercetin (**1**), morin (**2**), arthraxin (**3**), luteolin (**4**), 8-acetyl-5,7-dihydroxy-3′,4′-dimethoxyflavone (**5**),[1] and tricin (**6**). Because of the similarity in the molecular structures of these substances, their molecular extinction coefficients will be considered to be approximately equal.

The ethanol solution of the sample was irradiated with a 200-W high pressure mercury lamp through a Pyrex, water-cooled jacket under bubbling air. The UV spectrum of an aliquot's portion was then recorded at intervals of 3, 5, 8, 18, 37, 49, and 67 hr. The





1 R_1,R_2,R_5=OH R_3,R_4=H
2 R_2,R_4,R_5=OH R_1,R_3=H
4 R_1,R_2=OH R_3,R_4,R_5=H
6 R_2=OH R_1,R_3=OMe R_4,R_5=H



3

resistance to the light was measured in terms of the time required for the disappearance of Band I with the high absorption intensity in the 320—380 nm-region.

As a result, Band I of the UV spectra of **1** and **2** disappeared within 18 to 37 hr, whereas the bands of **4**, **5**, and **6** did so only after 67 hr. Among the bands of **3**, **4**, **5**, and **6**, the band of **3** disappeared in the shortest time. This result seems to indicate that the hydroxyheterocyclic ring attached to the flavone nucleus of **3** is easily decomposed by irradiation, like the pyrone ring of flavonols.

It is thus clear that flavones, in contrast with 3-hydroxyflavones, show a high power of resistance to the light when air is bubbled into its ethanol solution. This agrees with the fact that the dyestuff materials in *Reseda luteola*, *Arthraxon hispidus*, and *Miscanthus tinctorius* are superior to those in the other grasses in point of the resistance to the light.

Proton Knight Shift in Lithium-Methylamine Solutions

Yoshio NAKAMURA, Mikio YAMAMOTO, Shigezō SHIMOKAWA,* and Mitsuo SHIMOJI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

**Department of Chemistry, Faculty of Engineering, Hokkaido University, Sapporo*

(Received June 28, 1971)

Alkali-metals can be dissolved in liquid methylamine (CH_3NH_2) as in liquid ammonia. We have reported[1,2] that the volume expansion and viscosity of the Li–CH_3NH_2 system can be interpreted by the presence of anion-like solvated electrons trapped by 'cavities', as in alkali metal-ammonia solutions.[3] In this communication we describe the experimental results on the proton Knight shift in the Li–CH_3NH_2 system over a wide range of Li concentration.

The method of preparation of Li–CH_3NH_2 solutions has been described.[1] Solutions were sealed in measuring cells in a vacuum. Nuclear resonance was observed with a JEOL-3H-60 external lock NMR spectrometer in a magnetic field in the vicinity of 14,092G. The Knight shift k is defined[4] as $k=(H_r-H_s)/H_r$, where H_r is the magnetic field for which resonance occurs in the reference solution, and H_s is the magnetic field in sample solution at a fixed frequency. The Knight shift of protons in CH_3- and NH_2-group in CH_3NH_2 was measured as a function of Li concentration. The pure solvent was taken as a reference. Measurements were carried out at 21°C.

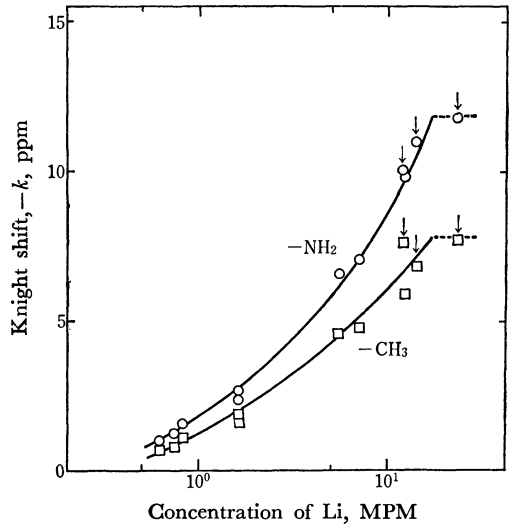

Fig. 1. Proton Knight shift for Li solutions in CH_3NH_2 at 21°C.

The results are shown in Fig. 1. The concentration of the metal is expressed by MPM or mol percentage of metal. The observed Knight shift increases with increasing metal concentration, as for proton and nitrogen in alkali metal-ammonia solutions.[4-6] The shifts are larger for the NH_2-group than for the CH_3-group, which may indicate that the CH_3NH_2 molecules are oriented at the edge of a cavity so that an ammonia-like trap is produced.[7] The values of k for the NH_2-group are of the same order of magnitude as those found in liquid ammonia.[5] It is interesting to see that the observed curve is continuous from low concentration (electrolytic region) to high concentration (metallic region) exhibiting no anomalies at the transition region, which is also in accordance with the observations in ammonia solutions.[5] The broken lines in the figure indicate the saturated solution range determined previously by electrical conductivity measurements.[2] Linewidths were generally around 15 Hz.

It should be noted that the resonance peaks both for CH_3- and NH_2-groups split into unsymmetrical doublets for three samples with high Li concentration, as indicated by arrows in Fig. 1. The width of the split was 8 Hz for the 12.0 MPM solution and almost independent of the metal concentration. Whether this corresponds to two different states of the solvated electrons[3] will be the subject of further investigation. It is also noted that at lower concentrations the sign of k seems to be inverted, though it is negative for the concentration range studied. A supplementary measurement with a saturated solution of the K metal ($\sim 4.7\times10^{-2}$ MPM) shows a positive value of k, +0.07 ppm, for protons in NH_2. A similar result has been observed for the Na-saturated solution, the concentration being about 2×10^{-2} MPM.

The Reactions of Hot Deuterium Atoms with Ethylene

Yasuhisa SANO and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 30, 1971)

The reactions of hot hydrogen atoms with hydrocarbons have been extensively investigated, using recoil tritium from the nuclear reaction.[1,2] The energy with which hydrogen atoms efficiently react with the substrate is not certain, however. Consequently, the photolysis of hydrogen halides and hydrogen sulfide has received renewed attention as the source of hot hydrogen atoms.[3-5]

We have recently studied the 2288 Å photolysis of DI–C_2H_4 mixtures. The excess energy of the D atoms produced ranges from 1.4 to 2.3 eV.[6,7] Since ethylene is a well-known scavenger for thermal hydrogen atoms, it may be one of the most suitable substrates for investigating the hot hydrogen atom-reactions. Nevertheless, very few measurements with this compound have been reported.

The deuterium iodide used was synthesized by heating a mixture of deuterium and iodine on platinized asbestos in a Pyrex tube at 400°C for two days. During the storage of DI gas in the bulb covered with Al-foil, the HI content gradually increased, probably because of the proton-exchange reaction between DI and water in glass or in grease. The initial content of HI was less than 5%; when the content reached over 15%, the DI gas was renewed. The amounts of the products were measured volumetrically with a Toepler pump, and their analyses were made by mass spectrometry.

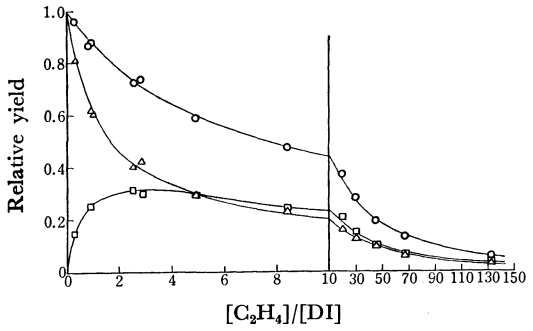

Fig. 1. The relative yields of total hydrogen (○), D_2 (△), and HD (□) as a function of the $[C_2H_4]/[DI]$ ratio. The yield of D_2 in the photolysis of pure DI was taken as unity. Initial DI pressure is 5 Torr and the irradiation time 6 min.

Figure 1 shows the relative yields of total hydrogen, D_2, and HD as a function of the $[C_2H_4]/[DI]$ ratio. The values are corrected for the HI contamination, the isotope effect being disregarded. Every run was sandwiched by the photolysis of pure DI so that the relative yield could be calculated accurately.

The HD formation may be explained in terms of such reactions of hot D atoms with ethylene as:

$$D^* + C_2H_4 \longrightarrow C_2H_3 + HD \quad (1)$$

and/or:

$$D^* + C_2H_4 \longrightarrow C_2H_3D + H \quad (2)$$

followed respectively by:

$$C_2H_3 + DI \longrightarrow C_2H_3D + I \quad (3)$$

and/or:

$$H + DI \longrightarrow HD + I \quad (4)$$

Mass-spectrometric analysis showed that the C_2 fraction in the product contained neither ethane nor acetylene, but C_2H_3D. Table 1 shows the $[C_2H_3D]/[HD]$ ratio as a function of the initial $[C_2H_4]/[DI]$ ratio, the values of which have already been corrected both for the HI contamination and for the C-13 natural abundance.

TABLE 1. THE $[C_2H_3D]/[HD]$ RATIO AS A FUNCTION OF THE INITIAL $[C_2H_4]/[DI]$ RATIO

The irradiation time is 6 min, the estimated conversion of DI being 25%.

$[C_2H_4]/[DI]$	0.27	0.83	2.51	8.35
$[C_2H_3D]/[HD]$	1.5	2.0	1.8	2.0

These results seem to substantiate the occurrence of the hot atom reactions described above. Moreover, the fact that the $[C_2H_3D]/[HD]$ ratio is more than unity suggests that Reaction (2) cannot be ignored in this system. If only Reaction (1) is responsible for the formation of HD, the $[C_2H_3D]/[HD]$ ratio should be less than unity, because a part of the C_2H_3 radicals formed react with the I_2 which is eventually formed in this system and produce no C_2H_3D. On the other hand, if Reaction (2) is more predominant than Reaction (1), the ratio should be more than unity, because a part of the H atoms produced in Reaction (2) react with I_2 and do not contribute to the formation of HD. I_2 molecules are an inevitable product in this system, and the rate constant of the $H+I_2 \rightarrow HI+I$ reaction is known to be more than ten times that of the $H+HI \rightarrow H_2+I$ reaction for the thermalized H atoms.[8]

A Ternary Rare Earth Boride with a $ThCr_2Si_2$-type Structure

Koichi NIIHARA, Toetu SHISHIDO, and Seishi YAJIMA
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai
(Received July 3, 1971)

In the study of the phase diagram in the yttrium-cobalt-boron system, a ternary compound with a tetragonal unit cell was found to have a composition of 19.8%Y, 40.5%Co, and 39.7%B (by atomic). The stoichiometric composition of YCo_2B_2 is proposed. This is the first compound found in the Y–Co–B system.

The samples were prepared by arc-melting from stoichiometric amounts of Y, Co, and B under purified argon. The purities of the Y, Co, and B used were 99.9%, 99.99%, and 99.9% (by weight) respectively. For homogenizing, the samples were wrapped with tantalum foil, sealed in quartz capsules under a vacuum, and annealed for 150 hr at 800°C. After these heat treatments, the samples were ground in an agate mortar under an inert atmosphere to prevent oxidation and then examined by chemical and X-ray analyses.

n. obs.=not observed.

The X-ray patterns were taken using Fe radiation with a Debye-Scherrer camera and a diffractometer equipped with an X-ray monochromator. The observed intensities were measured with a Geiger-Müller counter.

The YCo_2B_2 pattern was indexed as tetragonal. As is shown in Table 1, there is a good agreement between the observed and calculated interplanar spacings. The tetragonal unit cell of the YCo_2B_2 structure has the dimensions of $a=3.561\pm0.003$ Å, $c=9.358\pm0.005$ Å, and $c/a=2.628$, and it contains two YCo_2B_2 formula units. Pycnometric-density measurements were also carried out. The experimental and theoretical densities are 6.30 g/cm³ and 6.39 g/cm³ respectively.

The relative intensities were computed assuming that YCo_2B_2 crystallizes isostructurally to the $ThCr_2Si_2$ type,[1-4] which is an ordered ternary version of the $BaAl_4$ type, the two nonequivalent sites of the Al atoms being occupied by different kinds of atoms. The reliability factor, $R=\sum|I_{ob}-I_{cal}|/\sum I_{ob}$, is 0.16. This good agreement between the observed and calculated intensities (Table 1) shows that this is the most probable structure. The space group is number 139, $I4/mmm(D_{4h}^{17})$. The atom locations and the projection of the YCo_2B_2 structure on (010) are shown in Table 2 and in Fig. 1 respectively.

Reaction of Thioboronite. A Convenient Method for the Preparation of β-Hydroxyalkanethioates

Teruaki MUKAIYAMA and Katsuhiko INOMATA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

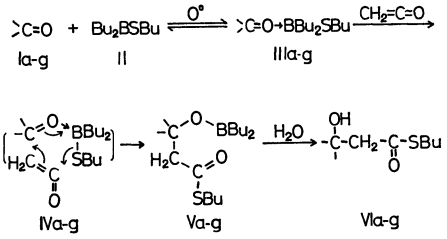
(Received July 17, 1971)

As a part of our study on the reactions of thioboronites, a new and convenient method for the preparation of β-hydroxyalkanethioates by the reaction of carbonyl compounds with ketene was established.

It was reported that nitriles react with thioboronites to form co-ordination complexes, which react with isocyanates or diphenyl ketene to give the corresponding acetamidine or acetaldimine derivatives in fairly good yields.[1,2]

Based on these facts, the analogous reaction of thioboronite with carbonyl compounds and ketene were examined. As an example, equimolar amounts of *n*-butyl di-*n*-butyl thioboronite (1.09 g, 5.1 mmol) and benzaldehyde (0.54 g, 5.1 mmol) in 15 m*l* dry ether were treated with ketene[3] at 0°C for 2 hr. After removal of ether, the oily substance was treated with H_2O–MeOH–H_2O_2 at room temperature. The solution was allowed to stand overnight and MeOH was removed *in vacuo*. The resulting mixture was extracted with ether and the ether layer was washed with 5% solution of sodium bicarbonate and dried over anhydrous sodium sulfate. Ether was evaporated to afford 1.09 g (90%) of *S*-*n*-butyl β-hydroxyhydrocinnamethioate (VIb).

A possible reaction path is outlined in Scheme 1. Initially, an intermediate (III), co-ordination complex,



Scheme 1

might be formed from carbonyl compound (I) and thioboronite (II). Ketene will react with the complex to form V through the cyclic transition state (IV). Formation of V was confirmed by the infrared spectrum and hydrolysis to β-hydroxyalkanethioate (VI).

Paetzold and Kosma reported that α,β-unsaturated carboxylic acid chlorides are obtained by a similar reaction of boron chloride with ketene and carbonyl compounds except in the case of benzophenone.[4]

TABLE 1. YIELDS AND PROPERTIES OF β-HYDROXYALKANETHIOATES[a]

	Ia—g	Product	Bp °C (mmHg)	Isolated Yield, %

a) In ether at 0°C for 2 hr.
b) Mp 75.5—76.5°C

The present β-hydroxyalkanethioate synthesis using thioboronite affords the corresponding β-hydroxyalkanethioates in excellent yields from aliphatic, aromatic, and α,β-unsaturated aldehydes and aliphatic, cyclic, and aromatic ketones (including benzophenone, see Table 1). In addition, this reaction has another synthetic utility, since β-hydroxyalkanethioate can be used as an active synthetic intermediate. As an example, the thiol ester can be reduced to aldehyde by unactivated Raney nickel, which indicates the different characteristics of the compound from β-hydroxyalkanoate obtained by Reformatsky reaction.[5]

A New Catalyst System for Ammonia Synthesis

Atsumu Ozaki, Ken-ichi Aika, and Humio Hori

Tokyo Institute of Technology, Research Laboratory of Resources Utilization, Ookayama, Meguro-ku, Tokyo

(Received July 20, 1971)

The well-known doubly-promoted iron catalyst (Fe–Al_2O_3–K_2O) has been industrially adopted for ammonia synthesis since the discovery by Mittasch *et al.* in 1910.[1,2] We have studied the role of potash promoter in this catalyst.[3-6] The reaction has been elucidated in terms of adsorbed species as estimated by kinetics and isotope effect and isotopic exchange in nitrogen. The results led to the conclusion that the potash promoter gives rise to a drastic change in the main adsorbed species over iron during the course of ammonia synthesis, from nitrogen atom over pure iron or alumina promoted iron to imino group over the doubly promoted iron, thus enhancing the rate of ammonia synthesis.[3,4] Another effect of the potash promoter is enhancement of the rate of isotopic mixing in nitrogen over iron in the presence of hydrogen.[5,6] These effects of the potash promoter have been interpreted on the basis of its electron-donating nature. If the observed effects by potash are produced by an electron donation to iron, metallic potassium would be more effective owing to its much lower ionization potential. This prediction has been tested and extended to other transition metals.

Catalysts were prepared by impregnating coconut carbon with transition metal chlorides from aqueous solutions, followed by reduction in hydrogen stream at 400°C and by adsorption of potassium vapor at about 400°C. The content of transition metal was 2.5 or 5% wt. of the carbon support. The rate of ammonia synthesis was determined in a closed circulating system equipped with a liquid nitrogen trap using a stoichiometric mixture of hydrogen and nitrogen under 600 mmHg. The reaction temperature ranged from 100 to 400°C.

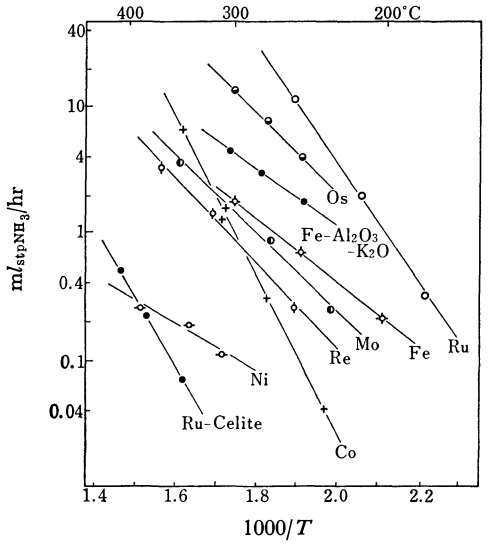

Fig. 1. Arrhenius plots of synthesis rates at a flow rate of 4.5 *l*/hr under 600 mmHg over catalysts of 2.5 g each except Fe–Al_2O_3–K_2O (0.77 g) and Ru-Celite (1.5 g). Os catalyst was prepared from OsO_4.

The results are summarized in Fig. 1 where Arrhenius plots of the rate of ammonia synthesis are shown for several transiton metals, together with previous data on ruthenium celite[7] and the doubly promoted iron.[8] None of these metals, when supported on the coconut carbon without potassium added, showed any activity even at 400°C for the ammonia synthesis, whereas pure iron or ruthenium on Celite can produce ammonia at a measurable rate.[3,7] On the other hand, potassium metal adsorbed on the coconut carbon not impregnated with a transition metal also showed no activity at 400°C, while potassium metal adsorbed on reduced iron remarkably enhanced the rate of ammonia formation. It is thus concluded that potassium metal added enhances the rate of ammonia synthesis on the transition metal.

Figure 1 shows that Ru and Os rank high among the transition metals tested. Fe, Co, Re, and Mo are moderately active, and Ni is much less active. Very little or no activity was detected on Ti, Mn, Rh, and Pd even with adsorbed potassium. The results show that the active catalysts are formed by the metals known to catalyze ammonia synthesis without a promoter such as potassium.[2] In this respect, the effect of potassium is not so specific for the kind of transition metal. But Ru–C–K catalyst has outstanding activity and is able to form ammonia with a rate of 0.037 *ml*·STP NH_3/hr 2.5 g at 146°C and 600 mmHg. This catalyst seems promising for low temperature synthesis of ammonia.

In view of rather low specificity in the effect of potassium, the basic pathway of ammonia formation would be unchanged by the addition of potassium, although the rate determining step might change. The remarkable effect of potassium can be understood if a nitrogen molecule is activated to an anionic intermediate by incorporation of a free electron in a transition metal, simply because an electron transfer from alkali to the transition metal takes place on addition of alkali metal. In agreement with this, sodium, which has a higher ionization potential than potassium, gives a much lower activity than potassium.

Codimerization of Ethylene and Styrene Catalyzed by Bis(triphenylphosphine)σ-aryl Nickel(II) Halide-Trifluoroboron Etherate

Noboru KAWATA, Ken-ichi MARUYA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 31, 1971)

Bis(triphenylphosphine)σ-aryl nickel(II) halide (RNi-$(P\phi_3)_2X$, R=*o*-tolyl, 1-naphthyl, mesityl; X=halide ion; $\phi=C_6H_5$) has been reported to dimerize ethylene selectively, when trifluoroboron etherate coexists with the nickel complex.[1] It has been found that this catalyst system has also a high catalytic activity for the selective codimerization of ethylene and styrene. Rhodium(III) chloride[2] and palladium(II) chloride[3] have been reported to catalyze the codimerization of ethylene and styrene. The former gives 2-phenyl-2-butenes under a high pressure of ethylene and the latter 1-phenyl-butenes. The present catalyst system, however, gives 3-phenyl-1-butene selectively without accompanying 1-phenyl-butenes as is shown in the table. No activity for the codimerization was observed in the absence of trifluoroboron etherate, nor when bis(triphenylphosphine)nickel(II) dibromide was used in place of the σ-aryl nickel complex. The selectivity of codimerization into 3-phenyl-1-butene depends considerably on the σ-aryl ligand of the nickel complex, although catalytic activity seems to be independent of it. When most of styrene was consumed, 3-phenyl-1-butene initially formed was gradually isomerized into *cis*- and *trans*-2-phenyl-2-butenes, and they further reacted with ethylene to form 3-methyl-3-phenyl-1-pentene, causing decrease in the selectivity of the codimerization, while only trace amounts of the isomerized products of 3-phenyl-1-butene were observed in the products obtained under the reaction conditions given in Table 1. The results can be understood by assuming the formation of a nickel hydride, with which π-coordinated styrene is transformed into α-ethylbenzene-nickel intermediate followed by insertion of ethylene to give 3-phenyl-1-butene. The hydrogen source of the nickel hydride was elucidated by means of the dimerization of deutero ethylene.[4]

Table 1. Codimerization of ethylene and styrene

R-Ni$(P\phi_3)_2$Br	Styrene consumed (mmol)	3-Phenyl-1-butene obtained (mmol)	Selectivity[a] (%)
R=*o*-Tolyl	12.7	7.2	58
R=1-Naphthyl	12.9	10.3	80
R=Mesityl	12.7	11.6	91

Nickel complex, 1.0 mmol; $BF_3\cdot O(C_2H_5)_2$, 1.0 mmol; Styrene, 17.4 mmol; CH_2Cl_2, 30 m*l*; temp. 0°C; React. time, 15 min.

a) Based on the styrene consumed. The other products were styrene dimers, *etc.*

The experimental procedure is illustrated by the following ethylene-styrene codimerization. To a solution of bis(triphenylphosphine)-1-naphthyl nickel(II) bromide (1 mmol) in dry methylene chloride (30 m*l*) under nitrogen in a 50 m*l* flask were added trifluoroboron etherate (1 mmol) and styrene (17.4 mmol). The nitrogen gas in the flask had been evacuated at the temperature of liquid nitrogen before ethylene gas (700 mmHg) was introduced at 0°C with vigorous stirring. The temperature of the flask was kept at 0°C for 15 min with continuous supply of ethylene. The reaction was then terminated by adding aqueous sodium hydroxide solution (5 m*l*). Most of the volatile substances such as ethylene, butenes and the solvent were transferred into another flask by means of a liquid nitrogen trap before non-volatile materials were extracted with *n*-hexane. The amounts of non-volatile materials were quantitatively determined by gas chromatography. The results are shown in the table. 3-phenyl-1-butene (phenyl, 2.75 τ(m); CH_2=CH–, 4.0 τ (m), 4.97 τ(d); –CH(–), 6.67 τ(m); $-CH_3$, 8.7 τ(d)) and its isomers isolated by a fractional gas chromatography were identified by NMR spectroscopy, and were also checked by hydrogenation into 2-phenyl-butane with Raney nickel catalyst.

A Remark on the Unsuitable Use of Nitrobenzene as a Standard Substrate for Homolytic Aromatic Substitution

Hiroyuki OHTA and Katsumi TOKUMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

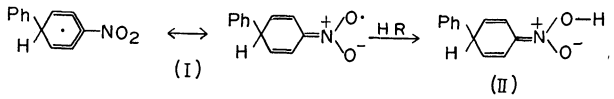
(Received August 2, 1971)

In homolytic aromatic substitution,[1] reactivities of various aromatic substrates are often determined relative to nitrobenzene[1a,1b,2] or benzene[3] as a standard substrate. We now wish to report that the apparent reactivity of nitrobenzene towards phenyl radicals appreciably changes in the presence of substances carrying transferrable hydrogen atoms such as toluene, ethylbenzene or cyclohexane, showing that nitrobenzene cannot be generally used as a standard substrate for homolytic substitution.

In a mixture of substrates, either phenylhydrazine was treated with nickel peroxide at room temperature[4] or benzoyl peroxide was decomposed at 80°C under nitrogen to generate phenyl radicals and the resulting biaryls were determined by gas chromatography. Whereas the reaction employing phenylhydrazine in nitrobenzene or in toluene gave *o*-, *m*-, and *p*-nitrobiphenyl in a distribution of 58, 7, and 35% or *o*-, *m*-, and *p*-methylbiphenyl in 68, 19, and 13%, respectively,[4] the reaction in a mixture of nitrobenzene and toluene led to a variation in distribution of *o*-, *m*-, and *p*-nitrobiphenyl to 73, 9, and 18% without affecting the distribution of methylbiphenyl isomers. The apparent relative reactivity of toluene to nitrobenzene, k_{PhMe}/k_{PhNO_2}, is 0.69. This is higher than the expected value of 0.33 estimated from the ratio of the reactivities, relative to benzene,[3] of toluene (k_{PhMe}/k_{PhH}, 1.68) and nitrobenzene (k_{PhNO_2}/k_{PhH}, 5.02). The use of benzoyl peroxide as a phenylating source similarly changed the reactivity of nitrobenzene. The value of k_{PhMe}/k_{PhNO_2} is 1.1, distribution of *o*-, *m*-, and *p*-nitrobiphenyl being 71, 11, and 18%, respectively, and that of *o*-, *m*-, and *p*-methylbiphenyl, 63, 22, and 15%, respectively. Likewise, the reactivity of nitrobenzene changed in its mixture with ethylbenzene or cyclohexane.[5]

In order to determine the apparent reactivity, relative to benzene, of nitrobenzene in the presence of toluene, phenylation employing phenylhydrazine was carried out in a ternary mixture of nitrobenzene, toluene, and benzene to show, for nitrobenzene, k_{PhNO_2}/k_{PhH} to be 2.1_1 and partial rate factors, f_o, f_m, and f_p to be 5.1_6, 0.30, and 1.7_5, respectively, and, for toluene, k_{PhMe}/k_{PhH}, f_o, f_m, and f_p to be 1.5_3, 3.0_4, 0.86, and 1.3_6, respectively. On the other hand, phenylation of a binary mixture of nitrobenzene or toluene with benzene was reported to give, concerning nitrobenzene, 5.02, 9.32, 1.16, and 9.05 for k_{PhNO_2}/k_{PhH}, f_o, f_m, and f_p and, concerning toluene, 1.68, 3.30, 1.09, and 1.27 for k_{PhMe}/k_{PhH}, f_o, f_m, and f_p, respectively.[3,6] These results clearly indicate that the presence of toluene, without variation of its reactivity, lowered the apparent reactivity of nitrobenzene, the depression of the partial rate factor of which was the most remarkable for para-position of the nitro group and the least for the ortho-position.

The anomalous behaviour of nitrobenzene could be understood by assuming that nitrophenylcyclohexadienyl radicals resulting from the addition of phenyl radicals to nitrobenzene would, at the expense of transferring their hydrogen atoms to give nitrobiphenyl, abstract hydrogen atoms from a hydrogen donor on their nitro group, as proposed for photo-excited nitrobenzene.[7] Then a precursory radical of *p*-nitrobiphenyl (I) would undergo abstraction to give II more easily than an isomeric radical precursory of *o*-nitrobiphenyl, in which the reactive center might be sterically hindered by the adjacent phenyl group, leading to higher reduction in the yield of *p*-nitrobiphenyl than



o-isomer. The resulting compound, II or its isomer, subsequently might undergo either dehydration to give nitroso compound which can scavange free radicals[8] without finally producing nitrobiphenyl, or dehydrogenation to nitrobiphenyl or other reactions.

1) As a general reference for homolytic aromatic substitution, see, for example: a) G. H. Williams, "Homolytic Aromatic Substitution," Pergamon Press, Oxford (1960). b) D. H. Hey, in G. H. Williams, ed., "Advances in Free-radical Chemistry," Vol. II, Logos Press, London (1967), p. 47. c) O. Simamura, T. Migita, N. Inamoto, and K. Tokumaru, "Yuriki Hanno," Tokyo Kagaku Dozin, Tokyo (1969), Chapter 11.

2) For example, D. H. Hey, S. Orman, and G. H. Williams, *J. Chem. Soc.*, **1961**, 565.

3) R. Ito, T. Migita, N. Morikawa, and O. Simamura, *Tetrahedron*, **21**, 955 (1965).

4) H. Ohta and K. Tokumaru, This Bulletin, in press.

5) It is to be noticed that decomposition of benzoyl peroxide in a mixture of equal volumes of nitrobenzene and cyclohexane gave cyclohexanol (3% based on the peroxide) and cyclohexanone (1%), both of which were not formed from decomposition in cyclohexane carried out alone in a degassed ampoule. It is also worth mentioning that Prof. T. Migita and his coworkers showed that decomposition of *t*-butyl peroxide in a mixture of toluene and nitrobenzene gave benzoic acid and *t*-butanol in a remarkable yield (private communication).

6) Phenylation using phenylhydrazine and nickel peroxide was found to give similar values to those obtained from phenylation using *N*-nitrosoacetanilide at 20°C.[3]

Lewis Acid Complexes of Diphenylcyclopropenone

Zen-ichi Yoshida and Hideki Miyahara
Department of Synthetic Chemistry, Kyoto University, Yoshida, Kyoto
(Received August 3, 1971)

Condensation reactions of diphenylcyclopropenone (**1**) with active methylene compounds are known to be catalysed by boron trifluoride etherate.[1] Cyclopropenone-Lewis acid complexes could be intermediates, in view of the well known tendency of forming Lewis acid complexes of ketones[2] and the activation of (**1**) by hydrogen chloride[3] or triethyloxonium tetrafluoroborate.[4] In the latter the corresponding intermediates are obviously cyclopropenium cation derivatives.

We wish to report the isolation and the spectral features of 1:1 diphenylcyclopropenone-Lewis acid complexes[5] such as BF_3-complex (**2**), mp 166—167°C and $SbCl_5$-complex (**3**), 216—217°C prepared quantitatively by adding $BF_3 \cdot OEt^2$ to **1** in acetic acid and $SbCl_5$ to **1** in dry methylene dichloride both at room temperature. Both complexes were stable and non-hygroscopic. The structures were determined by analytical (satisfactory for C and H) and spectroscopic (pmr and IR) data and chemical reactions. Hydrolysis of both **2** and **3** liberated diphenylcyclopropenone water complex (**4**) quantitatively. **2** was also obtained from diphenylethoxycyclopropenium tetrafluoroborate after standing for a long time.

Table 1. Phenyl proton chemical shifts (τ in ppm) in $AsCl_3$[a]

Species	ortho[b]	para+meta[b]	(para+meta) −ortho
1	1.83	2.22	0.39
	2.00[c]	2.39[c]	0.39
2	1.70	2.18	0.48
3	1.80	2.14	0.34
4[d]	1.83	2.22	0.39
	2.00[c]	2.39[c]	0.39

a) Taken with a Jeolco C-60-H at room temperature in the concentration range 1.25—5% in $AsCl_3$, except otherwise stated.
b) The center of the corresponding multiplets of AB_2C_2-systems.[7]
c) In $CDCl_3$
d) Water complex prepared according to literature.[8]

Neither concentration effect nor appreciable dissociation of the complexes were observed on the NMR for several hours.

To ascertain the structures of complexes **2** and **3**, the spectra were compared with those of the related species **1** and **4** (Table 1). By complexation with water the IR spectrum changes but not the pmr spectrum (phenyl protons) of **1**. Appreciable lower shifts of 1850 (broad) and 1640 cm^{-1} bands in **1** to 1840 (broad) and 1600 (broad) cm^{-1} bands were observed. It seems likely[9] that 1885 (broad) and 1528 cm^{-1} bands in **2** as well as 1860 (sharp) and 1502 cm^{-1} bands in **3** correspond to 1850 and 1640 cm^{-1} bands in **1**, respectively. This shift may be explained by the order of acidity of Lewis acids ($SbCl_5 > BF_3$).[2] The O–B and O–Sb bonds in the complexes (**2**,**3**) are presumably the electron pair (σ) bond, because even water complex **4** should be formed by energy greater than 8.1 kcal/mol.[11] This is supported by the existence of the strong ν(B–F) 1100 cm^{-1} band[12] due to non-planar BF_3 in **2** and the strong ν(Sb–Cl) 360 cm^{-1} band[13] in **3**. The downfield shifts of (para+meta) protons of the complexes **2** and **3** from those of **1** are 2.4 Hz and 4.8 Hz, respectively, which are comparable with the change between those of 1-phenylcyclohexyl and 1-phenylcyclopentyl cation.[7] The corresponding values for ortho protons of **2** and **3** are 6.0 Hz and 1.8 Hz, respectively. From a comparison of both data it is suggested that an anomalous shielding-effect acts on the ortho-protons in $SbCl_5$ complex. The greater shifts of ortho proton in BF_3 complex than that of (para+meta) might be characteristic influence of strained carbonium ions[7] on phenyl-proton chemical shift. These spectral features might be interpreted in terms of the structure as shown in Fig. 1.

The Retentive Solvolysis of 1-Phenylethyl Chloride in Binary Mixtures of the Carboxylic Acid with Nitromethane or the Nitrile

Kunio Okamoto, Issei Nitta, Masahiro Dohi, and Haruo Shingu
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received July 23, 1971)

It has been previously demonstrated that a nucleophilic co-solvent, such as di-*n*-butyl ether[1] or acetone,[2] intervenes in the acetolysis of 1-butyl-1-*d* *p*-nitrobenzenesulfonate[1] or the methanolysis of 2-octyl *p*-bromobenzenesulfonate,[2] thus affording a by-product derived from the co-solvent and the substrate for the respective solvolyses. We wish now to report on some novel examples which clearly indicate that such intervention leads the S_N1 solvolysis, otherwise inversive, to become a retentive solvolysis.

When the butyrolysis was conducted on optically active 1-phenylethyl chloride (0.10M) in the presence of sodium butyrate (0.100N) at 100°C, in accord with a standard tendency in the S_N1 solvolysis of this system, 1-phenylethyl butyrate with a net (3.5%) inversion of configuration was obtained in an 82% yield, along with styrene in a 14% yield.

In contrast to this, in a binary mixture of butyric acid with acetonitrile (80.0 mol%) the butyrolysis yielded 1-phenylethyl butyrate with a 2.9% *retention* of configuration, accompanied by a predominant (97%) racemization. In addition, a by-product, *N*-1-phenylethylacetamide, isolated from the reaction mixture, when worked-up with water, had a net (3.2%) inverted configuration; this amide may stem from the net-inverted *N*-1-phenylethylacetimidoyl chloride, which was a product of the S_N2-like reaction of the ion-pair intermediate with acetonitrile. These results can be explained by the following reaction scheme, which includes a back-side shielding[3] of the ion-pair intermediate by the C≡N group of acetonitrile and also a subsequent front-side attack of butyric acid on the shielded intermediate:

$$\text{(R)-RCl} \longrightarrow [\text{MeCN}\cdot\overset{+}{\text{R}}\cdot\overset{-}{\text{Cl}}] \xrightarrow{\text{PrCO}_2\text{H}} \text{(R)-RO}_2\text{CPr}$$

$$\downarrow$$

$$\text{(S)-RN=CMe} \xrightarrow{(\text{H}_2\text{O})} \text{(S)-RNHCOMe}$$

$$\text{Cl}$$

Similarly, a net retention of configuration was observed in the propionolysis and in the valerolysis in the binary mixtures of the respective carboxylic acids with acetonitrile. Nitromethane, as a co-solvent, also exhibited a similar retentive function in the butyrolysis. These results are presented in Table 1, along with the first-order solvolysis rate constant for each run.

The nitriles other than acetonitrile (*viz.*, fumaronitrile, malononitrile, and acrylonitrile) were also found to be effective co-solvents in changing the steric course of the butyrolysis from a net inversion to a net retention. In Fig. 1 the extents of the retention (or inversion) of 1-phenylethyl butyrate are plotted against the concentrations of the added nitriles. There is a decided trend towards higher retentions in solvents with higher nitrile concentrations, but there is no simple correlation between the structure of the nitrile and the extent of retention. However, compared with acetonitrile or malononitrile, acrylonitrile and fumaronitrile show no specific effectiveness for the retention; this indicates that their C=C groups are scarcely responsible for the back-side shielding of the ion-pair intermediate.

Table 1. The net steric course and the rates in the solvolysis of 1-phenylethyl chloride (100°C)[a]

Solvent acid	Net steric course for $R'CO_2R$[b]	Net steric course for RNHCOMe[c]	10^5k_1 (sec^{-1})
Acetic	2.94% inv.	—	58.1

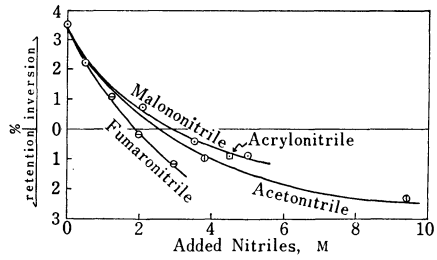

Fig. 1. Extents of retention (or inversion) of 1-phenylethyl butyrate (100°C).

In view of these results, the retentive S_N1 hydrolysis of some aralkyl *p*-nitrobenzoates in the aqueous acetone solvent, found by Goering and his collaborators,[4] may be attributed to the back-side shielding by acetone. Furthermore, our previous observation[5] that the hydrolysis of 1-phenylethyl chloride in aqueous acrylonitrile (97 wt%) affords 1-phenylethyl alcohol with a net (6.3%) retained configuration can be interpreted as involving back-side shielding by acrylonitrile.

Quenching Cross-Sections of the Metastable Mercury Atom (6^3P_0)

Hiroyuki HORIGUCHI and Soji TSUCHIYA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo

(Received July 9, 1971)

Recently, Callear and McGurk[1] reported that the cross-sections for the deactivation of $Hg(6^3P_0)$ atoms were larger by an order of magnitude than their former data[2] which showed a considerablly less reactivity of $Hg(6^3P_0)$ atoms compared to that of $Hg(6^3P_1)$ atoms. Cambell *et al.*[3] measured the absorption of $Hg(6^3P_0)$ in the gaseous mixture of N_2, quencher and mercury which was excited by the 2537 Å radiation. Their data support the larger cross-sections for quenching $Hg(6^3P_0)$ atoms. We proposed a method[4] to determine the cross-section for each process, $6^3P_1 \rightarrow 6^3P_0$, $6^3P_1 \rightarrow 6^1S_0$, and $6^3P_0 \rightarrow 6^1S_0$, and found that the cross-sections for $6^3P_0 \rightarrow 6^1S_0$ were not so small as Callear and William's results.[2] Recently, we measured the time-history of the 4047 Å absorption of $Hg(6^3P_0)$ after the flash irradiation of the 2537 Å radiation, and observed the cross-section of a reactive molecule for quenching $Hg(6^3P_0)$ atoms. The results are shown in Table 1.

The cross-sections for quenching the 6^3P_0 state are in agreement with the new data of Callear and McGurk[5] within a factor of 5. It is seen from Table 1 that the ratio of the quenching corss-section for the process $6^3P_1 \rightarrow 6^1S_0$ to that for $6^3P_0 \rightarrow 6^1S_0$ is close to 3 except for the case of quenching by N_2, CH_4, or CO_2, which has a larger ratio. Recent results of Vikis and Moser[6] by a chemical method show that the reactivity of $Hg(6^3P_0)$ is much less than that of $Hg(6^3P_1)$, but this is not consistent with the present experiment. Kang Yang[7] proposed that from the conservation of angular momentum, the cross-section of H_2 for quenching $Hg(6^3P_0)$ may be smaller than that of alkane. However, our results differ as has been pointed out by Vikis and Moser.[6] The present results suggest the conclusion that if a molecule has a large cross-section ($\gtrsim 1$ Å^2) for the process $6^3P_1 \rightarrow 6^1S_0$, the corresponding 6^3P_0 cross-section is of the same order of magnitude, and that a molecule with a very small cross-section ($\lesssim 0.1$ Å^2) for quenching the 6^3P_1 state has a much smaller cross-section to deactivate the 6^3P_0 state. If the former case corresponds to the strong coupling between the excited Hg atom and a quenching molecule. the quenching rate of $Hg(6^3P_1)$ would be the same order of magnitude as that of $Hg(6^3P_0)$, because the degeneracy of $^3P_1$ state is removed by a collisional perturbation of a quenching molecule (Q),[8] and the mixing of two states $Hg(6^3P_1)+Q$ and $Hg(6^3P_0)+Q$ occurs in the course of non-adiabatic transition to $Hg(6^1S_0)+Q$. This seems to explain qualitatively the present results for CO, NO, H_2, and D_2.

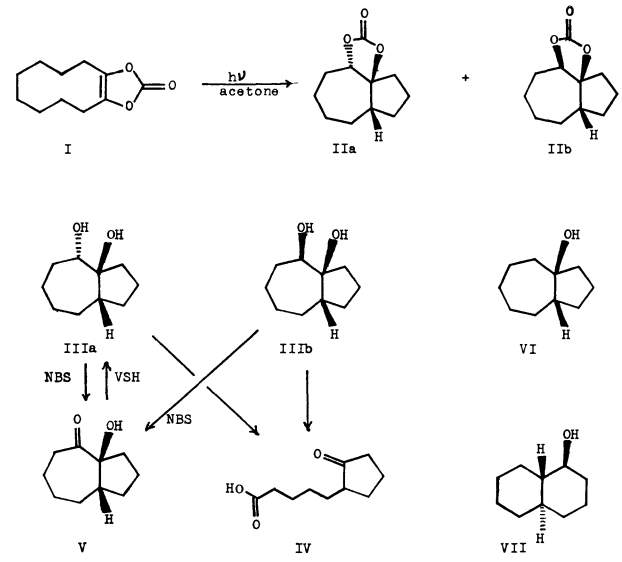
Photoinduced Transannular Reaction of 4,5-Octamethylene-1,3-dioxolen-2-one

Tamejiro HIYAMA, Shinsaku FUJITA, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yosida, Sakyo-ku, Kyoto
(Received August 25, 1971)

Recently, 1,3-dioxolen-2-one (vinylene carbonate) has been reported to undergo dimerization[1] or cycloaddition[2] on UV irradiation. However, the photoreaction of compound I[3,4] given in the title proceeded in quite a different way as described below.

A 0.2M solution of I in acetone was irradiated under N_2 with a 200 W high-pressure Hg lamp. The photolysate was distilled to give a mixture of stereoisomers[4] (IIa and IIb, 71% yield) which were isomeric with I as established by means of MS (M^+ *m/e* 196) and elemental analysis. The mixture exhibited an IR band at 1795 cm^{-1} characteristic of a 1,3-dioxolan-2-one system. The NMR signal of the methine proton adjacent to oxygen appeared at δ 4.65—4.75. As separation of IIa and IIb was unsuccessful, the mixture was converted into the corresponding *vicinal* diols (IIIa: IIIb= 5.7: 1). The structure and stereochemistry of IIIa[4] (mp 82—83°C, M^+ *m/e* 170, IR 3400 cm^{-1}) and IIIb[4] (M^+ *m/e* 170, IR 3480 cm^{-1}) were determined as follows. (1) Since the glycol cleavage of IIIa and IIIb with $NaIO_4$ and $KMnO_4$ yielded the same keto acid IV (1735, 1710 cm^{-1}, oxime mp 121—124°C (lit,[5] 124—125.5°C), semicarbazone mp 192—193°C (lit,[5] 195—196°C)), both IIIa and IIIb should have a bicyclo[5.3.0]decane structure. (2) As the oxidation of IIIa and IIIb with *N*-bromosuccimide (NBS)[6] afforded the same ketol V[4] (IR 3460, 1700 cm^{-1}), they shoud have the same mode of ring fusion. (3) The reduction of V with $NaH_2Al(OCH_2CH_2OMe)_2$ (VSH) gave IIIa exclusively: the *trans*-configuration of the *vicinal* hydroxyl groups of IIIa was established on the basis of Cram's rule. (4) The half tosylation of the mixture of IIIa and IIIb followed by reduction with $LiAlH_4$



in ether or $NaBH_4$ in dimethyl sulfoxide, afforded *cis*-bicyclo[5.3.0]decan-1-ol (VI)[7] along with *trans*, *trans*-α-decalol (VII).[8] In conclusion, IIIa and IIIb were characterized as *cis*-bicyclo[5.3.0]decane-*trans*-1, 2-diol and its *cis*-diol isomer, respectively.

The transannular reaction of I proceeded as well upon benzene-sensitization. Intramolecular hydrogen-abstraction by the excited olefinic bond in its triplet state and the subsequent recombination of the resulting diradical may account for the new photoreaction.[9] In contrast to the mother compound, the derivative I underwent no cycloaddition to ethylene or acetylene on attempted acetone-sensitized reaction. The intramolecular reaction predominated even in 2-propanol containing benzene sensitizer.

Ultrasonic Study on Aqueous Solutions of Amino Acids

Katsutaka SASAKI and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received October 3, 1970)

Ultrasonic experiments for aqueous solutions of amino acids (glycine, *l*-alanine, *l*-valine, and *l*-leucine) were carried out by means of pulse technique in order to study the nature of solute-solvent interactions. The sound velocity and absorption coefficient were determined for aqueous solutions in the frequency range 15–45 MHz, at temperatures 10–30°C. No relaxation frequency was observed in all the solutions. The absorption coefficient for glycine solutions at low concentrations is nearly equal to that for pure water. The result is consistent with the idea that glycine molecules behave as a structure breaker within water. Concerning the concentration dependency of sound velocity and absorption, no appreciable difference is observed in various solutions of amino acids in spite of difference in the size of hydrocarbon side chains in solute molecules. It is concluded that the behavior of *l*-alanine and its higher homologues in water dose not differ from that of glycine.

Recently, a number of studies have been made on the solute-solvent interactions in aqueous solutions.[1,2] Holtzer and Emerson[3] discussed the changes in the structure of water induced by nonelectrolytic solute molecules, based on a simple two state model.[4]

We pointed out from ultrasonic measurements that denaturing agents such as urea, guanidine hydrochloride *etc.* have a "cooperative breaking effect" on the "open-packed structure" or ice-like structure" in water.[5] The cooperative breaking effect of denaturing agents arises from the cooperative nature of structure formation and breaking in water.[6,7]

Since the proposition stated by Frank and Evans,[8] hydrocarbon molecules in water are believed to reinforce the structure (icebergs) around the molecules within water. We showed that 1,3-diethylurea molecules behave as a structure former due to the structure-forming ability of ethyl groups which is in sharp contrast to the behavior of urea and 1,3-dimethylurea molecules as a structure breaker.[9] Hydrophobic bonds which result from the structure-forming ability of hydrocarbon groups in water have been studied by many workers, since it is believed to be an important factor governing the conformation of protein molecules in water.[10,11]

There have been some ambiguities about the behavior of amino acids in water.[12] Tyrell and Zamann[13] reported that there is no appreciable difference between the behavior of glycine and that of *dl*-alanine in water.

On the contrary, Robinson,[14] Tanford[15], and Ellerton *et al.*[16] stated that in aqueous solutions of *l*-alanine and its higher homologues the behaviors of solutes definitely differ from that in glycine solutions.

We have investigated the influences of serveral neutral amino acids upon the structure of water by means of an ultrasonic pulse technique.

Experimental

An ultrasonic pulse method was used for the measurement of absorption coefficient and sound velocity. The apparatus and the procedures were described previously.[17] The sound velocity and absorption coefficient were measured at 5 MHz and in the frequency range 15–45 MHz at temperatures 10–30°C. The data of absorption coefficient were reproducible within ±2% and sound velocity data ±1 m/sec. Samples of glycine, *l*-alanine, *l*-valine, and *l*-leucine were obtained from Nakarai Chemicals Ltd. The shear viscosity in aqueous solutions of these amino acids were measured by means of a capillary viscometer of Ostwald type.

Results

Sound Velocity. The sound velocity data at 5 MHz measured for the aqueous solutions of glycine and *l*-alanine are plotted against temperature in Figs. 1 (a) and (b), respectively, together with the velocity data for pure water by Greenspan and Tschiegg.[18] The velocity *vs.* concentration curves obtained for aqueous solutions of glycine, *l*-alanine, *l*-valine, and *l*-leucine are plotted in Fig. 2 at various temperatures. Concentrations are given in volume %. The concentrations are calculated from the density and weight

vs. concentration relations for various amino acid solutions forms a single curve at various temperatures. The situation is quite similar to the case of sound velocity shown in Fig. 2. In order to obtain the magnitude of structural absorption $(\alpha/f^2)_{struct.}$ from the data given in Fig. 5, determination of the classical absorption is necessary. The classical absorption is given by

$$(\alpha/f^2)_{shear} = \frac{8\pi^2\eta}{3\rho V^3} \quad (1)$$

where ρ is density, V sound velocity, and η shear viscosity. The values of η were measured for all solutions and given in Fig. 6. Thus, the structural absorption is given in the equation

$$(\alpha/f^2)_{struct.} = (\alpha/f^2)_{obs.} - (\alpha/f^2)_{shear}. \quad (2)$$

The result obtained is shown in Fig. 7.

Discussion

The Effect of Glycine upon the Structure of Water. Robinson *et al.*[20] pointed out from thermodynamical data that glycine behaves as a structure breaker in water while *l*-alanine and higher homologues behave as a structure former. Longsworth[21] supported this view. As for the behaviors of glycine in water, a number of workers have reached the same conclusion that glycine acts as a structure breaker.[13–16,20,21] As seen in Fig. 4 (a), the magnitude of absorption coefficient in an aqueous solution of glycine increases slowly with concentration. The tendency is similar to the case of 1,3-dimethylurea solution, in which the solute molecules behave as a structure breaker.[9] Thus, it might be said that the behavior of glycine in water is essentially similar to that of 1,3-dimethylurea. It seems that glycine molecules break the structure of water though the ability is supposed to be weaker than that of ordinary denaturing agents, such as urea.

The Effect of Side Chain of Amino Acids upon the Structure of Water. It is generally believed that the structure-forming ability of solute molecules in liquid water increases with the size of hydrocarbon side chain.[22,23] However, there has been some controversy concerning the behavior of *l*-alanine and higher homologues of amino acids in water.

Tanford and his collaborators[15,24] pointed out that *l*-alanine and higher homologues behave as a structure former while glycine behaves as a structure breaker. Recently, Spink and Auker[25] supported the view of Robinson, Tanford, and others, based on their thermodynamical data. Kay and Evans[26] also stated that the effect of hydrocarbon side chains of *l*-alanine and higher homologues on the structure in water differs from that of glycine.

On the contrary, Tyrell and Zamann[13] reported on the basis of thermodynamical data that there is no appreciable difference between the behavior of glycine and that of *dl*-alanine in water. This view is supported by the recent study of Kauzmann *et al.*[12]

The results in the present study clearly support the conclusion of Tyrell & Zamann and Kauzmann *et al.* As seen in Figs. 2,5, and 7, the ultrasonic data of sound velocity and absorption form a single curve at each temperature irrespective of the different size of side chains. Thus, it is concluded that the behavior of these four amino acids in water are similar essentially, and the structure-forming effect due to alkyl groups in amino acid molecules are cancelled out by the strong structure-breaking effect due to the dipolar field by zwitter ions ($NH_3^+CHRCOO^-$).

It can therefore be said that amino acids cannot be regarded as good models for studying hydrophobic bonding.[12]

Concluding Remarks

The following conclusion are obtained.

1) The effects of four amino acids on the ice-like structure in water are essentially similar to each other. l-Alanine and its higher homologues do not always behave as a structure former in water.

2) Glycine molecules behave as a weak structure breaker for the ice-like structure in water.

An ESR Study of NO_2 Adsorbed on Silica Gel Surfaces[1]

Masamoto IWAIZUMI, Shozo KUBOTA, and Taro ISOBE
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai
(Received January 22, 1971)

NO_2 adsorbed on silica-gel surfaces shows temperature-dependent ESR spectra, which can be explained by assuming a restricted rotation of the NO_2 molecule, where the preferred axis is the O–O direction. It is concluded from this observation that a hydrogen-bond force between the oxygen of NO_2 and OH groups on the silica-gel surfaces plays a part in the NO_2-silica-gel interaction. It is also estimated, from the observed hyperfine tensor, that the ONO angle may become slightly smaller when NO_2 is adsorbed onto the silica-gel surface from the gas phase.

It is considered that the adsorption of radicals on solid surfaces changes the nature of their motion from that in the gas phase, in solution, or in solid matrices. In many cases of studies of free radicals in adsorbed states, a restricted motion of the molecules has been detected through line-width-broadening effects in the ESR spectra.[2] However, there have been few cases where detailed information about the motion of the radicals or about the nature of the radical-surface interaction has been obtained.

In the present work we examined NO_2 adsorbed on the silica-gel surface by ESR with the aim of getting information about the adsorbed state. We found that NO_2 shows temperature-dependent ESR spectra, which can be explained by the restricted rotation of the molecule, where the preferred axis is the O–O direction. On the basis of this observation, it can be estimated that the NO_2 molecule interacts with the silica-gel surface through a hydrogen bond with OH groups on the silica-gel surface. The change in the molecular structure by adsorption is not large. However it is estimated that the ONO angle may become smaller when NO_2 is adsorbed on the silica-gel surface from the gas phase.

Experimental

The samples for ESR measurements were prepared by letting NO_2 gas be adsorbed on silica-gel surfaces in a vacuum line. The NO_2 used was obtained commercially (The Matheson Co., Inc.) and was dried with P_2O_5. Prior to treatment with NO_2, the silica gel (a Kanto Chemical Co. product for chromatography, 60—80 mesh) was heated for 6 hr at 500—550°C and at 10^{-6} Torr. The silica gel was then exposed to NO_2 gas at about 1 atm at room temperature. After exposing the silica gel to NO_2 for a few minutes, the excess NO_2 was removed by leading the gas into a trap cooled by liquid nitrogen. The ESR spectra were measured by a Hitachi model MES 4001 X-band ESR spectrometer at various temperatures ranging from room temperature to 77°K. The sample was cooled with a gas-flow cooler or with a liquid nitrogen dewar with an unsilvered lower section. The temperature of the sample was monitored by a copper-constantan thermocouple placed just below the sample tube in the cavity.

Results and Discussion

Hindered Rotation of NO_2 on Silica Gel. Figure 1 shows the ESR spectra of NO_2 adsorbed on the silica-gel surface at various temperatures. As Fig. 1 shows, the spectra are temperature dependent. The changes in the spectra were completely reversible upon changes in the temperature. The ESR spectra of NO_2 trapped in various solid matrices have been reported by a number of authors,[3–10] and it has been shown that they can be interpreted in terms of anisotropic hyperfine interaction with the nitrogen nucleus and anisotropic g factors, with the principal axes parallel to the molecular axes. In most of the cases treated in the solid matrices, the hyperfine and g tensors are unsymmetrical, as is to be expected from the molecular geometry. In the present case, however, the ESR spectrum observed at 77°K is interpreted by g and hyperfine tensors which are approximately axially symmetric. This indicates that the radical is rotating about this symmetry axis sufficiently rapidly to give a rotational average about the axis at this temperature. The experimental parameters obtained here are compared in Table 1 with those found in solid matrices. It may be seen from the table that the axis of the rotation is the y axis, *i.e.*, the O–O direction, and that the parameters of the x and z axes are averaged by the rapid rotation of the molecule. As the temperature increases, the absorption peak associated with the y axis disappears and the spectrum tends to become a triplet splitting with equal intensities, indicating that the rotation around the x and z axes becomes important.

According to theoretical calculations of the electro-

Field increases from left to right.

nic structure of the NO_2 molecule,[13-17] it can be considered that a large net negative charge exists in the two oxygen atoms in the molecule. In view of the fact that NO_2 prefers to rotate about the O–O direction on the silica-gel surface, it is reasonable to consider that a hydrogen bond formed between the oxygen of the NO_2 molecule and OH groups on the silica-gel surface may play an important role in the interaction

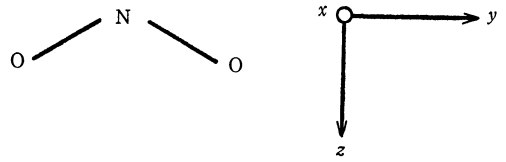

Fig. 2. Coordinate system for NO_2.

of the NO_2 molecule and the silica-gel surface. This model permits the rotation of the NO_2 molecule around the O–O direction. Previously Rozenberg *et al.*[18] pointed out, on the basis of experiments on the adsorption capacity of the silica gel as a function of the dehydration temperature, that the hydrogen-bond force may participate in the adsorption of NO_2 on the silica-gel surface. Our conclusion from the ESR experiments agrees with their result.

Recently, a study of NO_2 adsorbed in synthetic zeolites was reported by Pietrazah *et al.*[19] They observed temperature-dependent ESR spectra and explained them in terms of a hindered rotation of the molecule. However, it has been shown that there was no prefered axis of the rotational freedom for NO_2 adsorbed in synthetic zeolites. It is interesting that the silica-gel system shows a distinct contrast to their results in that, on the silica-gel surface, NO_2 is preferred to rotate about the O–O direction.

Structure of NO_2 on Silica Gel. In the NO_2 molecule, the odd electron is considered mainly to occupy a $4a_1$ molecular orbital constructed from nitrogen $2s$ and $2p_z$, and oxygen $2p_y$ and $2p_z$ atomic orbitals, having the form[5,13-17];

$$\Psi(4a_1) = a_N(2s)\Psi_N(2s) - a_N(2p_z)\Psi_N(2p_z) + a_O(2s)\{\Psi_{O1}(2s) + \Psi_{O2}(2s)\} + a_O(2p_y)\{\Psi_{O1}(2p_y) - \Psi_{O2}(2p_y)\} + a_O(2p_z)\{\Psi_{O1}(2p_z) + \Psi_{O2}(2p_z)\}. \quad (1)$$

The contribution of the nitrogen $2s$ orbital to the $4a_1$ orbital can be estimated from the observed isotropic part of the nitrogen hyperfine splitting constants by the following expression:

$$A_{Iso} = a_N^2(2s)(8\pi/3)g\beta g_N\beta_N\Psi_{N(2s)}(0)^2 \quad (2)$$

with:

$$\Psi_{N(2s)}(0)^2 = 34.0\times 10^{24}\,cm^{-3}.$$

On the other hand, the anisotropic part in the hyperfine interaction of an odd electron in the $2p_z$ component of the $4a_1$ orbital with the nitrogen nucleus can be expressed by the diagonal tensor, A_1, axially symmetric:

$$A_1 = \begin{pmatrix} -\alpha & & \\ & -\alpha & \\ & & 2\alpha \end{pmatrix} = (2/5)a_N^2(2p_z)g\beta g_N\beta_N\langle r^{-3}\rangle \begin{pmatrix} -1 & & \\ & -1 & \\ & & +2 \end{pmatrix}. \quad (3)$$

However, the experimental anisotropic hyperfine tensors obtained for the immobile NO_2 molecules in the solid matrices are usually not axially symmetric but are resolved into two axially symmetric tensors, A_1 and A_2 (symmetric about the x axis). Thus:

$$A_2 + A_1 = (2/5)g\beta g_N\beta_N\langle r^{-3}\rangle \times \left\{a_N^2(2p_x)\begin{pmatrix} +2 & & \\ & -1 & \\ & & -1 \end{pmatrix} + a_N^2(2p_z)\begin{pmatrix} -1 & & \\ & -1 & \\ & & +2 \end{pmatrix}\right\}. \quad (4)$$

A_2 has been explained as arising from the configuration interaction of the ground state with an excited state involving $2b_1 \leftarrow 1b_1$ excitation. When Dousmanis's value[20] for $\langle r^{-3}\rangle_{2p} = 22.5\times 10^{24}\,cm^{-3}$ is used, one can calculate the contribution of the nitrogen $2s$ and $2p_z$ orbitals to the $4a_1$ orbital. From the estimated $a_N(2s)$ and $a_N(2p_z)$, the ONO angle may be calculated, assuming the usual relationship:[21]

$$\angle ONO = 2\cos^{-1}(k^2+2)^{-1/2}, \quad (5)$$

where:

$$k^2 = a_N^2(2p_z)/a_N^2(2s).$$

The experimental hyperfine splitting constants being used, the ONO angle of the NO_2 molecule in the gas phase can be calculated to be 135.5°. In the case of the adsorbed state of the NO_2 molecule treated here, however, we cannot make such a calculation, since the x, y, and z components of the anisotropic hyperfine interaction cannot be obtained separately. However, if we compare the experimental hyperfine coupling constants with the data for NO_2 in the gas phase in Table 1, it is apparent that the magnitude of the isotropic part of the nitrogen hyperfine interaction is larger in the adsorbed state than in the gas phase, while the anisotropic part in the adsorbed state is smaller than those in the gas phase. This suggests that the contribution of the nitrogen $2s$ orbital to the $4a_1$ orbital decreases, and that the nitrogen $2p_z$ contribution may increase by adsorption from the gas phase. It is estimated, therefore, that the ONO angle may decrease by adsorption on the silica gel from the gas phase, although the change in the angle is small, *i. e.*, about 4–5°.

Conclusion

It has been found that NO_2 adsorbed on the silica-gel surface shows temperature-dependent ESR spectra. The low-temperature spectra can be explained as arising from the NO_2 molecule rotating around the O–O direction. As the temperature increases, the spectra indicate that the rotation around the other two axes become important. It is estimated from the observation that a hydrogen-bond force between the oxygen of NO_2 and OH groups on the silica-gel surface plays a part in the NO_2-silica-gel interaction. It has also been shown that the ONO angle might become smaller when NO_2 is adsorbed on the silica-gel surface from the gas phase.

The authors wish to thank Dr. Hiroshi Utsugi for his helpful discussions.

On the Factors Determining the Molecular Arrangement in Crystalline Ethylene

Masao HASHIMOTO, Michiko HASHIMOTO, and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solution, Tohoku University, Sendai

(Received March 30, 1971)

The orientation-dependent potential energy of the ethylene crystal was calculated using a somewhat modified expression for the dispersion energy in the case of non-axially symmetric molecules. It was concluded that the main force which determines the angle between the *bc* plane and the C=C bond axis in the ethylene crystal is the dispersion; on the other hand, it is the quadrupole-quadrupole interaction which determines the angle between the *ab* plane and the C=C bond axis. The expected molecular arrangement in the crystalline ethylene belongs to the space group $P2_1/n$, this is consistent with the conclusion obtained from the spectroscopic data.

Kihara[1-4] has suggested, in his brilliant models, that the molecular arrangement in some molecular crystals depends upon the electrostatic multipole interactions. On the other hand, Craig *et al.*[5,6] concluded that, in the benzene and the naphthalene crystals, the molecular arrangement depends upon a minimization of intermolecular hydrogen-hydrogen repulsions rather than upon the quadrupole-quadrupole and the dispersion energies.

In a previous paper[7] (designated I henceforth), we have found that the electrostatic multipole, the intermolecular hydrogen-hydrogen repulsion, and even the dispersion interaction energies seem to play an important role in determining the molecular arrangement. There remain some ambiguities in determining the factor effective for the molecular arrangement in molecular crystals. Therefore, it is necessary to investigate other molecular crystals from this point of view.

In the present investigation we have studied the refinement of the crystal structure of ethylene, of which both spectroscopic[8-13] and theoretical investigations using the non-bonded atom-atom pair potentials[14] have already been made. We have calculated the orientation dependence of the lattice energy of the crystalline ethylene by means of the same method as before (see I).

It was concluded that the main force which determines the angle between the *bc* plane and the C=C bond axis in the ethylene crystal is the dispersion interaction; on the other hand, it is the quadrupole-quadrupole interaction which determines the angle between the *ab* plane and the C=C bond axis. These results obtained were then compared with the results obtained by the use of the Lennard-Jones-type non-bonded atom-atom interaction potential. All the numerical calculations were made at Computer Center of Tohoku University.

Theoretical

Dispersion Energy. Since the ethylene molecule has a non-axial symmetry, the expression (1) of the dispersion energy for axially-symmetric molecules must be modified:

$$W_{\mathrm{disp}} = -[(A-2B+C)\{\sin\theta\sin\theta'\cos(\phi-\phi') - 2\cos\theta\cos\theta'\}^2 + 3(B-C)(\cos^2\theta+\cos^2\theta') + 2(B+2C)]/R^6, \quad (1)^{15}$$

where $A=e^2\alpha_{\parallel}(QM)_{\parallel}/4$, $B=e^2\alpha_{\parallel}\alpha_{\perp}(QM)_{\parallel}(QM)_{\perp}/2\alpha_{\parallel}(QM)_{\perp}+\alpha_{\perp}(QM)_{\parallel}$, and $C=e^2\alpha_{\perp}(QM)_{\perp}/4$. $(QM)_{\parallel}$ and $(QM)_{\perp}$ are the quantum mechanically-calculable averages (see 1).

In the non-axially symmetrical ethylene molecule, the three components of the molecular polarizability are written in terms of α_x, α_y, and α_z in the cartesian coordinate, where α_z is along the C=C bond; α_y, along the molecular plane, and α_x, along the axis perpendicular to it. $\alpha_{\parallel}$ and $\alpha_{\perp}$ may be expressed as follows:

$$\alpha_{\parallel}=\alpha_z;\ \alpha_{\perp}=(\alpha_x\cos\beta+\alpha_y\sin\beta)/2. \quad (2)$$

β is the angle of the rotation of the molecular plane around the C=C bond axis. In the same way, the modified (QM)'s may be written as follows:

$$(QM)_{\parallel}=(QM)_z;\quad (QM)_{\perp}=\{(QM)_x\cos\beta+(QM)_y\sin\beta\}/2 \quad (3)$$

Then, A, B, and C in Eq. (1) are replaced by new α's and (QM)'s. Thus, Eq. (1) has ben modified to be applicable to the case of non-axial symmetry.

Other Interactions. Quadrupole-quadrupole, the non-additive three body, and the overlap repulsion interactions are treated in exactly the same way as in I. The quadrupole moment of the ethylene molecule used in the present work is $\pm1\times10^{-26}$ e.s.u., which was determined approximately by Smith.[16,17]

The Axilrod and Teller expression for three-body interaction must be modified before it can be applied

to the anisotropic molecule. This was done by Stogryn,[18] but the numerically-calculable form was not given there. This will be published elsewhere by the present authors in this series of investigations. At this time, therefore, we will content ourselves with discussing its order of magnitude.

Numerical Calculation

In Table 1, the calculated values of the (QM)'s and α's are indicated. The (QM)'s were calculated as usual (see I), while the α's were calculated by using bond polarizabilities[19].

Table 1. The anisotropies of quantum mechanically calculable average and polarizability of ethylene molecule. The C=C bond axis is along the z-axis

	(QM) a.u.	α cm^3
x	23.882	39.6×10^{-25}
y	18.560	33.8×10^{-25}
z	26.270	54.4×10^{-25}

We start from the structure determined by Bunn.[20] Consider three kinds of molecular rotation. The first is the deflection of the C=C bond axis from the *ab* plane, the second is the deflection of the molecular plane from the *bc* plane, and the last is the rotation of the molecular plane around C=C bond axis. These angles of rotations are indicated in terms of δ, γ, and β respectively (see Fig. 1). In Fig. 1, there are indicated the twelve first neighbour molecules. They are between 4.5 and 6.5 Å away from the central molecule, O. The second neighbours are between 7.4 and 12.9; the third, between 11.1 and 19.4; the fourth, between 15.0 and 25.8, and the fifth, between 19.1 and 32.3 Å, away from the O molecule. We calculated the dispersion and quadrupole-quadrupole interaction energy for the molecules up to fifth neighbours, but the repulsion energy for the first neighbours only.

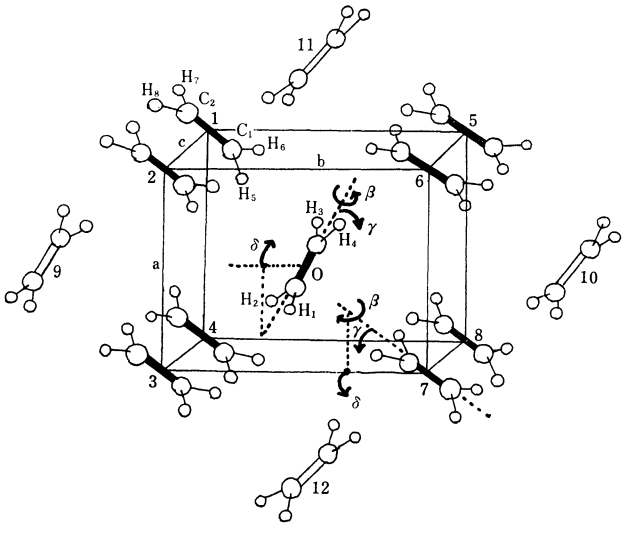

Fig. 1. The starting positions of carbon and hydrogen atoms in crystalline ethylene.
○···carbon atoms; o···hydrogens. a=4.89Å, b=6.46Å, and c=4.14Å.

Results and Discussion

Figure 2 indicates the β-dependency of the interaction energies when δ and γ are fixed at the values of Bunn's structure. The arrows show the values of β, which correspond to Bunn's structure and the spectroscopic structure.[13] From Fig. 2 it may be concluded that the factor determining the molecular orientation around the C=C bond axis is mainly the minimization of the dispersion energy. This confirms the non-axial symmetry of the polarizability of the ethylene molecule about the C=C bond axis.

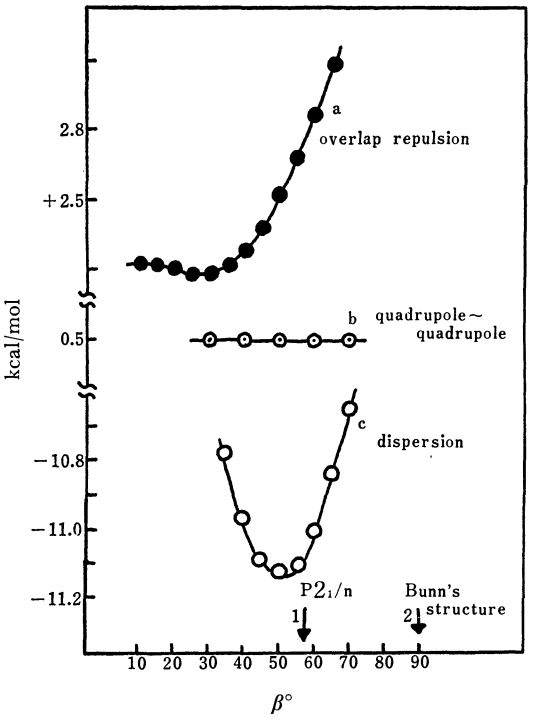

Fig. 2. Variations of interaction energies with the angle of rotation around the C=C bond axis.
a: overlap repulsion; b: quadrupole-quadrupole; c: dispersion interaction.
The arrows 1 and 2 indicate the values correspond to the spectroscopic and Bunn's structures, respectively.

Fixing the β value at the value indicated in Fig. 2, we calculated the δ- and γ-dependencies. The results are indicated in Fig. 3 and 4 respectively. The arrows in these figures also have the same meaning as in Fig. 2. It may be concluded from Fig. 3 that the dispersion interaction mainly determines the angle between the molecular plane and the *bc* plane. We have concluded from Fig. 4 that the angle between the C=C bond axis and the *ab* plane is mainly determined by the quadrupole-quadrupole interactions.

The above conclusions are also confirmed from another point of view. If we approximate the mo-

lecular interaction by the non-bonded atom-atom interaction of the type of Lennard-Jones,

$$v(r) = \sum_j (b_j/r_j^{12} - a_j/r_j^6), \quad (4)$$

where the parameters, a_j and b_j, have been chosen[21] so as to give the best fit with second virial coefficient data of methane. The j summation is extended to all pairs of atoms in the two molecules. Equation (4) is further summed up to fifth neighbours in the crystal.

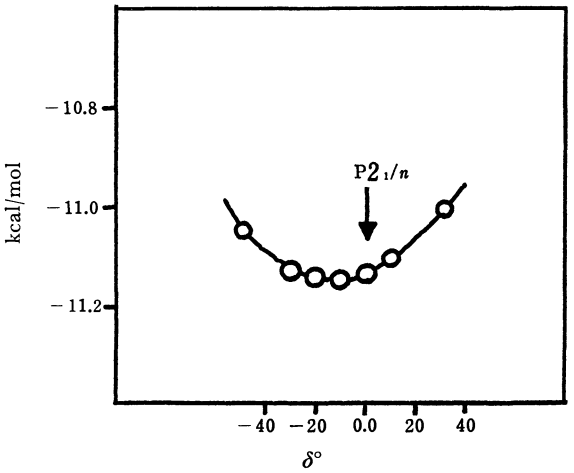

Fig. 5. Variation of Lennard-Jones interaction energy with the angle of deflection from *ab* plane.

Figure 5 indicates the δ-dependency of the $v(r)$. Since the deviation of δ from the experimental value is found to be about 10°, the interaction expressed by Eq. (4) can not explain the experimental δ value. Therefore, quadrupole-quadrupole interaction is necessary to explain the experimental δ value.

It can be concluded from the above results that the main force which determines the angle between the *bc* plane and the C=C bond axis in the ethylene crystal is the dispersion interaction; on the other hand, it is the quadrupole-quadrupole interaction which determines the angle between the *ab* plane and the C=C bond axis. It can also be concluded that the molecular orientation around the C=C bond axis is mainly determined by the dispersion interaction and that the angle of rotation around the C=C axis is nearly equal to the experimental one. This structure belongs to the $P2_1/n$ space group.

The role of the three-body interaction, which is estimated to be of the order of 0.2 kcal/mol if the ethylene molecule has spherical symmetry and which is too large to be neglected, may be important, since it is perhaps strongly orientation-dependent in such anisotropic molecules as ethylene. However, a good estimate of the accuracy of three-body interaction for asymmetric molecules is difficult to make at the present time and must remain a problem for the future.

The authors wish to thank Dr. Masamoto Iwaizumi for his helpful discussions.

The Ultraviolet Absorption Spectra of Olefins Adsorbed on the Platinum Catalyst

Yuko SOMA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 12, 1971)

The ultraviolet absorption spectra of olefins adsorbed on the platinum catalyst supported on silica were studied. By comparing the absorption bands of olefins adsorbed on the platinum catalyst with the chrage-transfer bands of platinum-olefin complexes, the observed bands could be interpreted as being due to the electronic transition from filled platinum 5*d* orbitals to the empty π^* orbital of adsorbed olefins.

The adsorption of olefins on platinum catalysts in relation to hydrogenation has been studied by many workers with various techniques. The structure of adsorbed species on metal catalysts has thus far been elucidated mostly using infrared spectroscopy. Sheppard and his co-workers investigated the adsorption of olefins on a platinum, nickel, or palladium catalyst by infrared spectroscopy, and concluded that the CH_2M–CH_2M type was the structure of the main chemisorbed species on the metal catalysts.[1] By low-energy electron–diffraction studies of ethylene adsorption on the platinum single crystal, Somorjai concluded that ethylene was adsorbed with a C_2H_4 structure on Pt(111) and (100), while Merill explained the adsorbed species on Pt(111) as C_2H_2+2H.[2,3]

Those investigations were concerned with the structure of adsorbed species on the catalyst, knowledge of which was essential to elucidate the reaction mechanism on the catalyst. In addition to this, the understanding of the bonding nature or the electronic interaction between the catalyst and the adsorbed species is very important in the study of the detailed nature of the catalytic reactions.

In the present work, the electronic spectra of olefins adsorbed on the platinum catalyst were studied in an attempt to clarify the bonding nature between adsorbed olefins and the catalyst. The spectra were interpreted as charge-transfer bands due to the electronic transition from platinum to adsorbed olefins; to the author's knowledge, those are the first examples of charge-transfer bands between adsorbed species and the catalyst observed. Thus far, the investigation of the electronic spectra of chemisorbed species has been restricted mostly to the intramolecular transitions and to chemisorbed species on metal oxides.

The ultraviolet absorption spectra of olefins adsorbed on silica-alumina have been studied by Webb and other groups, who have explained them in terms of the carbonium ions on oxides.[4] In this paper, it will be reported that, on a metal catalyst, the situation is different from that on oxides, and that the spectra of adsorbed olefins on a platinum catalyst are closely related to those of platinum-olefin complexes, as is the case with the infrared spectra of adsorbed species on metal catalysts; special reference has been made to the metal complexes including identical species among those chemisorbed.

Experimental

The platinum catalyst was prepared from chloroplatinic acid. Chloroplatinic acid (H_2PtCl_6) containing more than 37% of Pt was supplied by Wako Pure Chemical Industries, Ltd., while the supporting oxide, silica, was obtained from the Degussa Co., Ltd.; their surface areas were 360 m^2/g. Silica was dispersed in an acetone solution of chloroplatinic acid, which was then left standing at room temperature until the solvent had evaporated. The resulting powder (metal content of 1.5% by weight) was pressed to form a disk which was cut in a square platelet (12×20 mm, *ca.* 0.1 mm thick). The platelet was placed in a quartz optical cell connected to a vacuum system, as is shown in Fig. 1.

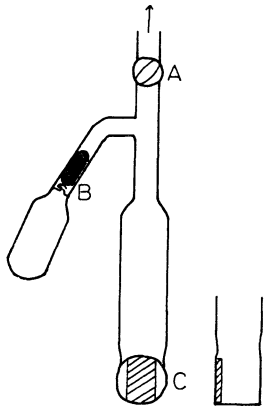

Fig. 1. Optical cell.
A. greaseless cock, B. breakable seal, C. quartz window

The disk was reduced by heat treatment at 350°C in a stream of about 30 cmHg of hydrogen gas for 6 hr and then outgassed at 10^{-6} mmHg at the same temperature for 1 hr to form the catalyst. A silica-supported platinum has been known to reduce the polymerization of olefins as compared with evaporated platinum films. Measured amounts of reaction gases were sealed under a vacuum in a separate compartment attached to the cell through a breakable seal.

The spectra of adsorbed species were recorded in the wavelength range of 250—500 nm with a Hitachi EPS spectrometer by placing a silica disk in the reference beam. At wavelength shorter than 250 nm, the transmission was too small to measure the spectra because of the increased scattering by silica. The spectra of the disks of silica and silica-supported platinum used in these experiments are shown in Fig. 2, the transmission spectra of evaporated platinum film is also shown for comparison.

An ethylene complex of zero-valent platinum, $Pt(PPh_3)_2(C_2H_4)$, was synthesized according to Cook's method.[5] The spectra of this complex were measured in ethylene-saturated cyclohexane, benzene, or an ethyl alcohol solution.

Results

Figures 3–6 show the spectra of adsorbed species in which the back-grounds due to the original catalysts have been subtracted.

When olefins were brought into contact with the platinum catalyst at room temperature, absorption bands immediatly appeared at about 270 and 300 nm, as is shown in Fig. 3 (Curve 1) and Table 1. These bands were stable at least one day if hydrogen was not introduced. After evacuation for 30 sec, the bands changed little. Upon the admission of hydrogen, however, the above bands gradually decreases, and a weak broad band appeared in 340–360 nm (Fig. 3-3). The pressures of olefins and hydrogen were 2–3 cmHg and 5–8 cmHg respectively. The removal of the bands is more rapid for higher olefins; in the case of 1-butene, the bands at 290 and 310 nm disappeared completely 20 min after the admission of hydrogen, whereas in the case of ethylene the bands at 270 and 300 nm remained for 24 hr.

When acetylene was introduced to the catalyst, no bands were observed. On the addition of hydrogen in the cell, spectra similar to those of adsorbed ethylene were observed. As is shown in Fig. 4, the intenisity of the band at 320 nm relative to that of 270 nm was stronger than in the case of ethylene adsorption. These bands decreased slowly on standing, while the weak band in 340–360 nm appeared, as was the case in the olefin hydrogenation.

Table 1. Ultraviolet absorption bands of olefins adsorbed on bare platinum surfaces

C_2H_4	270 nm	300 nm
C_3H_6	285	310
$n\text{-}C_4H_8$	290	310
$1\text{-}C_6H_{12}$	295	310

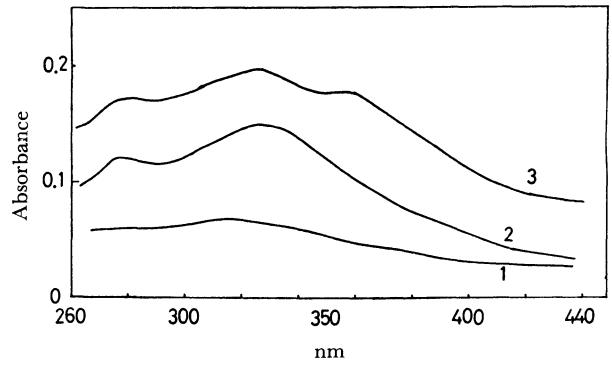

Fig. 4. Spectra of acetylene adsorbed on $Pt\text{-}SiO_2$
1. initial adsorption, C_2H_2 3.77 cmHg
2. addition of 7.60 cmHg of H_2 after evacuating for 30 sec
3. after overnight hydrogenation

When hydrogen was initially adsorbed on a Pt catalyst, a very strong band which was considered to be the absorption due to chemisorbed hydrogen appeared. The band maximum was hidden below 250 nm, and its tail extended to 400 nm, as is shown in Fig. 5. On evacuation for 30 sec and the admission of olefin to the cell at room temperature, the intensity of the absorption bands due to hydrogen remained almost unchanged and weak bands due to olefins around 270 and 300 nm appeared. On standing for a long period, the weak 350 nm band appeared as the intensity of the 270 and 300 nm bands decreased.

At a higher temperature, 90°C, the broad band which might be caused by polymerization of olefins appeared at wavelengths longer than 340 nm.

The spectrum of $Pt(PPh_3)_2(C_2H_4)$ in the ethylene-saturated benzene solution and that of $Pt(PPh_3)_2O_2$ in the benzene solution are shown in Fig. 6. The bands at 276 and 288 nm in the benzene solution appeared at 267 and 288 nm in the cyclohexane solution. The band at a longer wavelength, 288 nm,

B. $Pt(PPh_3)_2O_2$ in benzene solution

decreased quickly for a few minutes when ethylene had not been saturated in the solution. On the other hand, the band at 276 nm did not change on standing. From the results of the substitution reaction reported by Halpern,[6] it was revealed that the ethylene molecule of $Pt(PPh_3)_2(C_2H_4)$ was quickly replaced by oxygen in solution. Besides, free triphenylphosphine has an absorption band at 260 nm ($\varepsilon=2000$). In connection with these facts, it may be concluded that the band at 288 nm in the benzene solution is a charge-transfer band between platinum and ethylene of $Pt(PPh_3)_2(C_2H_4)$.

Discussion

The spectra of olefin complexes of platinum in the ultraviolet region have scarcely been studied except for those of Zeise's salt, $K^+[PtCl_3(C_2H_4)]^-$. For Zeise's salt, the bands at 299, 267, and 246 nm were assinged to charge-transfer transitions between filled platinum 5*d* orbitals and the empty olefin π^* (antibonding) orbital. The extinction coefficients of the two latter bands, $\varepsilon=3000\ cm^{-1}M^{-1}$, are considerably larger than that of the first one.[7]

In the case of the zero-valent platinum complex, $Pt(PPh_3)_2(C_2H_4)$, a charge-transfer band between platinum 5*d* and the ethylene π^* orbital was observed at 288 nm in the ethylene-saturated cyclohexane solution. Other charge-transfer bands might exist below 250 nm.

The above experimental results of olefin adsorption on platinum suggest that the bands at 270 and 310 nm are due to the absorption related to the adsorbed olefins. The reasons for this are: i) on the admission of olefins, these bands appeared, while they were removed by hydrogenation, and ii) on the admission of acetylene, no absorption bands was observed until hydrogen was introduced. The existence of the olefin structure on the Pt catalyst have been revealed by experiments using infrared spectroscopy or low-energy electron diffraction, as has been indicated in the Introduction.

The infrared spectra of olefin adsorbed on the platinum catalyst have been studied by Sheppard and his collaborators, and a $CH_2M\text{–}CH_2M$-type structure has been proposed as the structure of the main chemisorbed species because the frequencies of the CH stretching vibrations (2920, 2880, 2795 cm^{-1}) are very close to those of saturated hydrocarbons.[1] In the case of ethylene adsorption, this species ($CH_2\text{-}M\text{–}CH_2M$) disappeared after the addition of hydrogen at 20°C, and no spectrum of adsorbed species were detected, but at higher temperatures (95°C) the spectra of the chemisorbed species which was attributed to the existence of the *n*-butyl group persisted after the addition of hydrogen. The spectra of the residual surface species after hydrogenation at room temperature were detected in the case of higher olefins. Thus, the behavior of the ultraviolet spectra observed and the assignments were consistent with those of the infrared spectra of adsorbed olefins.

A comparison of the absorption bands of olefin adsorbed on the Pt catalyst with the charge-transfer bands of olefin complexes of platinum indicates that the bands at 270 and 300 nm are due to the transition between platinum 5*d* and the olefin π^* orbital. The intensities of these bands in the chemisorbed species which correspond to ε of several hundreds

7) R. G. Denning, F. R. Hartley, and L. M. Venazi, *J. Chem. Soc., A*, **1967**, 1322.

8) The number of platinum atoms available in the reaction was estimated using the adsorption data of CO on the Pt-impregenated silica catalyst reported by Hughes,[9] that is, the ratio of the number of CO molecules adsorbed to the number of platinum atoms increased smoothly with the support surface, reaching about 0.6 when the surface area of silica was 360 m^2/g. Assuming that olefin adsorbs on the same sites as CO on platinum, the number of platinum atoms available in the olefin adsorption was reduced to about 10^{18} atoms for a platelet. The extinction coefficients of absorption bands due to adsorbed species were then calculated from the above value.

9) T. R. Hughes, R. J. Houston, and R. P. Sieg, *Ind. Eng. Chem. Process Design Devel.*, **1**, 96 (1962).

of $cm^{-1}M^{-1}$, assuming that all the platinum atoms are involved in the adsorption, are roughly consistent with those of the complexes.[8] The band at 270 nm, which appears at a longer wavelength for the higher olefins, is attributed to the similar transition in ethylene-platinum complexes. The weak band at 350 nm might be due to the occurence of polymerization.

The CH stretching bands of the Pt(0) complex, $Pt(PPh_3)_2(C_2H_4)$, which appear at 3004 and 2964 cm^{-1}, are considerably lower in their frequencies than those of free ethylene, as are those of ethylene adsorbed on the supported platinum catalyst. These experimental facts are consistent with the results of the ultraviolet spectra, suggesting a similarity between the chemisorbed species and the ethylene-Pt complexes.

The fact that the adsorbed species are similar to both the zero-valent and divalent Pt-olefin complexes is not unreasonable, for no clear-cut differences in the bonding between olefin and platinum in the two kinds of salts have yet been revealed to exist.[10,11]

The currently-accepted explanation of the nature of the bonding in metal-olefin complexes is given by the molecular orbital treatment, in which a σ-bond (olefin to metal) and a π-bond (metal-to-olefin back donation) are involved.[11,12] About the relative strengths of the σ and π components of the metal-olefin bond, the work so far suggested that the π-component of the platinum-olefin bond is stronger than the σ-component. The back donation from the central metal atom to the ligand π^* orbital in metal-olefin or metal-acetylene complexes usually reduces the bond order of the π-bonding of the ligand, thence reducing the carbon-carbon stretching frequency. As has been described above, the position of the CH stretching bands of ethylene adsorbed on the supported platinum catalyst and those of ethylene in the Pt(0) complex shift towards those of free ethane, indicating a reduced C=C bond order of ethylene in the chemisorbed species or the complex. A similar reduction in bond order has been reported for the C=C bond of acetylene upon chemisorption on supported platinum or upon the formation of complexes of the $Pt(PPh_3)_2$-(RC=CR′) type.[13,14] Consequently, it may be suggested that the back donation of an electron from platinum to chemisorbed olefins or acetylene plays a fairly important role in the bonding between the metal and the adsorbate.

The author wishes to thank Professor Masaru Nishikawa and Takaharu Onishi for their encouragement and helpful discussions.

The Catalytic Activity and Selectivity of Acidic Metal Salt Catalysts for *n*-Butene Isomerization

Makoto MISONO and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received April 20, 1971)

Double-bond isomerization of *n*-butenes over several supported acidic metal salts such as metal sulfates, perchlorates and phosphates including free acids has been investigated at 60°C with the butene pressure of 14 cmHg. The activity and the selectivity of *cis-trans* isomerization over double-bond migration increased monotonously, as the acid strength of catalysts increased. Acid strength, activity and selectivity of metal salt catalysts increased with the electronegativity of metal ion where free acids were the most strongly acidic and active catalysts ($H^+ > Al^{3+} > Ni^{2+} > Mg^{2+} > Na^+$), and for a given metal ion they increased with the acid strength of the conjugated acid ($ClO_4^- > SO_4^{2-} > PO_4^{3-} > CH_3COO^-$). The activity and selectivity were explained on the basis of a *sec*-butyl carbonium ion mechanism which appears more concerted over weak acids. The active sites for the reaction were suggested to be protonic acid sites closely connected to acid radical.

The simplest and most elementary steps involved in acid catalyzed reactions may be a proton addition to a substrate and its elimination from the protonated complex. It has been established fairly well that the double-bond isomerization of *n*-butenes over most acidic solid catalysts proceeds *via* proton addition to butene followed by its release.[1-3] The *cis-trans* isomerization and the double-bond migration of olefins are referred to as double-bond isomerization, where the hydrocarbon skeleton remains unchanged. Ac-

cording to the presumed mechanism, a proton transfers to butene from the surface of catalyst forming *sec*-butyl carbonium ion, and then a proton goes back to the surface from the ion leaving isomerized or unisomerized butene. The stereoselectivity in the isomerization of 1-butene to 2-butenes over acidic, basic and metal catalysts have been a subject of many investigations,[4,5] but we have found that the selectivity of *cis-trans* isomerization over double-bond migration of 2-butenes was markedly dependent on the acid strength of catalyst.[6] As the acid strength of metal sulfate increased from $MgSO_4$ to $Al_2(SO_4)_3$ and H_2SO_4–SiO_2, the rate of isomerization and the selectivity of *cis-trans* isomerization gradually increased by a factor of 10—10^2. Furthermore, it was demonstrated that the selectivity of each metal sulfate remained almost constant upon changing the preheating temperature, indicating that the nature of metal ion is the predominant factor determining the acid strength of proton on the surface. It was, therefore, possible to estimate the acid strength of the surface of metal sulfate from the electronegativity of metal ion.[7] The estimated acid strength which was qualitatively confirmed using Hammett's indicators showed linear correlations with the catalytic activity and the selectivity of *cis-trans* isomerization.

All these facts prompted us to study further this system in order to find general relationships which connect each other; the nature of the constituent elements of catalyst, the chemical properties of the catalyst surface, the reaction mechanism and the catalytic activity and selectivity. For this purpose, an investigation using a series of catalysts whose chemical nature varies gradually seems useful.

The purposes of the present paper are i) a more precise investigation of the nature of acid sites developing on the surface of the silica-supported metal sulfates and of the relationship between the selectivity and the kinetics of butene isomerization and ii) the extension of the general rules found for metal sulfates to other metal salts.

Experimental

Catalyst Preparation. Silica-supported metal salts were prepared according to the method described before.[6] Silica gel obtained by the hydrolysis of tetraethoxysilane (*ca* 500 m^2/g) was used as support in most cases. Metal sulfates supported on SiO_2 are abbreviated hereafter as Al–S for Al_2SO_4–SiO_2 and Mg–S for $MgSO_4$–SiO_2, *etc.* Unless stated otherwise, the amount of supported metal salts was about 5 wt%.

Butenes, Reaction procedure, Analysis and Acid strength measurement. They were the same as before,[6] except that the circulation systems with the volumes of 124 and 300 m*l* were used in the present work. The catalysts were evacuated for 1 hr at 100°C in reactors preceding the reaction, unless stated otherwise.

Results

Butene isomerization over Al–S and Mg–S. Figure 1 shows the progress of the reaction of *cis*-2-butene over Mg–S (typical weak acid) and Al–S (typical strong acid) plotted according to the first-order equation

$$\ln (x_e - x) = -kt + \ln x_e$$

where x and x_e are the conversion at time t and at equilibrium, respectively. This equation does not hold in rigorous sense, because the averaged rate constant of back reaction from 1-butene and *trans*-2-butene depends on the composition of the products which may vary during the course of reaction (see

Fig. 2). However, this effect is usually small, so that a linear plot is obtained up to a considerably high conversion, if the reaction is of first order for back and forward directions.[2]

It is seen in Fig. 1 that over Mg–S the reaction follows this equation, except an initial small but rapid deactivation. This plot is very similar to the one obtained by Hightower and Hall over deactivated silica-alumina.[2,8] Repeated runs resulted in little change in the reaction rate over Mg–S. Over Al–S, on the other hand, a rapid and large deactivation occurred at first and it decreased gradually showing a slow time-dependent poisoning, until a nearly constant rate constant was reached after a long period of reaction. The rate at the apparently stationary stage was about half to one-third the initial one.

These trends in deactivation and their contrast between a weak acid and a strong acid catalyst have been observed in the oligomerization of propylene over differently Na-exchanged silica-alumina and Al–S at the temperature range of 100—300°C.[9]

Figure 2 shows the changes in the product composition (given by the *trans*-2-butene/1-butene ratio, *trans*/1) during the course of reaction. The *trans*/1 ratio extrapolated to zero conversion, which was nearly equal to the *cis*/1 ratio obtained from *trans*-2-butene for each catalyst, was high for strong acid catalyst and low for weak acid catalyst, as reported before.[6] The large *trans*/1 ratio for Al–S decreased by the repeated runs as the result of deactivation, while the repeated runs over Mg–S fell on the same line. The end point in Fig. 2 gives the equilibrium ratio of 1:*trans* : *cis*=6 : 66 : 28 (at 80°C). The apparent energies of activation were about 7 kcal/mol for Al–S and about 11 kcal/mol for Mg–S.

Polymerization or coke formation always accompanies the acid catalyzed reaction of olefins.[1,2] Hightower and Hall[2,8] and Brouwer[10] used silica-alumina deactivated by coke formation to obtain reproducible data on the kinetics of butene isomerization. In order to examine the effect of polymerization of butenes (besides the deactivation, there is a possibility of the preferential coke formation of 1-butene which may cause a high *trans*/1 ratio as pointed out by Hightower and Hall[8]), the rates of polymerization of butenes over Al–S and Mg–S were measured by the pressure decrease. Results are summarized as follows: i) pressure decreased more rapidly over Al–S than over Mg–S, reflecting the difference in the extent of deactivation, ii) there was little difference for each catalyst in the rates of pressure decrease among three butene isomers, and iii) the rate of polymerization was less than 10% of the rate of isomerization.

The results of *cis*-2-butene isomerization over silica-supported aluminum sulfate with various aluminum sulfate contents are shown in Fig. 3. The activity increased almost linearly with the aluminum sulfate content up to~3 wt% and then showed saturation at higher content of aluminum sulfate. The selectivity (*trans*/1 ratio), on the other hand, remained almost constant over the whole range of the aluminum sulfate content studied. The acid strength of these catalysts also seems to be constant, as seen from the observed colors of the Hammett indicators over these catalysts

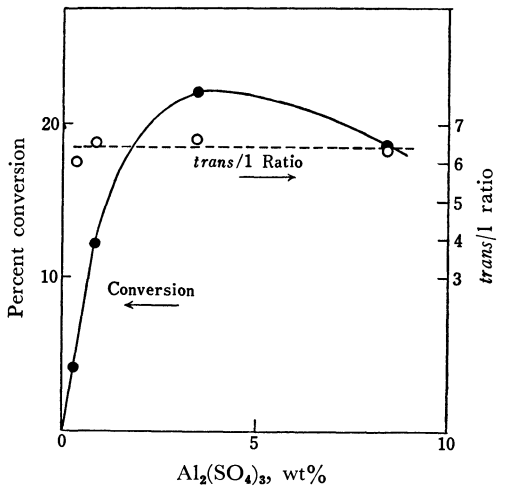

Fig. 3. Effect of amount of supported aluminum sulfate upon catalytic activity and selectivity of *cis*-2-butene isomerization over Al–S at 60°C.

Table 1. The color changes of Hammett's indicators[a]

Catalyst	pK_a of indicator			*trans*/1 ratio

as given in Table 1. These facts again support that the selectivity is determined by the acid strength, while the activity by both the acid strength and acid content. Table 2 shows the changes in the activity and the selectivity upon the extraction of aluminum sulfate by water from Al–S. Both of them decreased rapidly upon the repeated washing. This result is in contrast to the fact given in Fig. 3 that the selectivity remained nearly constant upon the variation of the amount of supported aluminum sulfate.

Isomerization of cis-2-*Butene over Silica-supported Metal Salts Other than Metal Sulfate.* The rates of *cis*-2-butene isomerization and the *trans*/1 ratios over silica-supported metal salt catalysts are summarized in Table 3. The rates are given by the conversion at 10 min over 100 mg of catalyst to show the relative activity. Following trends may be remarked in this table: i) For perchlorate salts, the *trans*/1 ratio and the activity increased with the electronegativity of metal ion and the free acid gave the highest values, as observed for metal sulfate catalysts[6] ($H^+ > Ni^{2+} > Mg^{2+} > Na^+$).

Table 3. Isomerization of *cis*-2-butene over various silica-gel supported metal salts at 60°C

Catalyst		Activity[a]	*trans*/1 ratio
Metal sulfate			
Al^{3+}		40	6.5—7.0
Ni^{2+}		10	2.3
Mg^{2+}		2	1.2
Na^+		no reaction	—
Metal perchlorate			
Ni^{2+}	(100)[b]	20	11
	(200)[b]	4	9
	(300)[b]	0.4	8
Mg^{2+}		5	7
Na^+		very low	2
Free acid			
$HClO_4$	(60)[b]	30	16—20
H_2SO_4		40	10
H_3PO_4	(120)[b]	very low	2.5
	(200)[b]	0.1	3
Metal chloride			
Ni^{2+}		very low	1.2
Mg^{2+}		no reaction	—
Metal acetate			
Mg^{2+}		no reaction	—

Ion exchange resin (Dowex 50W)		—	8—10[c]
p-toluene sulfonic acid		—	8—20[d]

a) % conversion after 10 min over 100 mg of catalyst.
b) Evacution temperature. Others were evacuated at 100°C.
c) Ref. 4.
d) Ref. 6.

ii) For the salts of a given metal ion, they were in the order of the acid strength of the conjugated acid ($ClO_4^- > SO_4^{2-} > PO_4^{3-} > CH_3COO^-$).

iii) As for free acids, both activity and *trans*/1 ratio decreased as $HClO_4 > H_2SO_4 > H_3PO_4$. Over $HClO_4$–SiO_2, *cis*/1 from *trans*-2-butene was ~14 and *cis*/*trans* ratio from 1-butene ~0.7. It is clearly seen that not only the *cis*/1 ratio but also the *trans*/1 ratio exceeded the equilibrium ratio (Fig. 4), although the data rather scattered.[11]

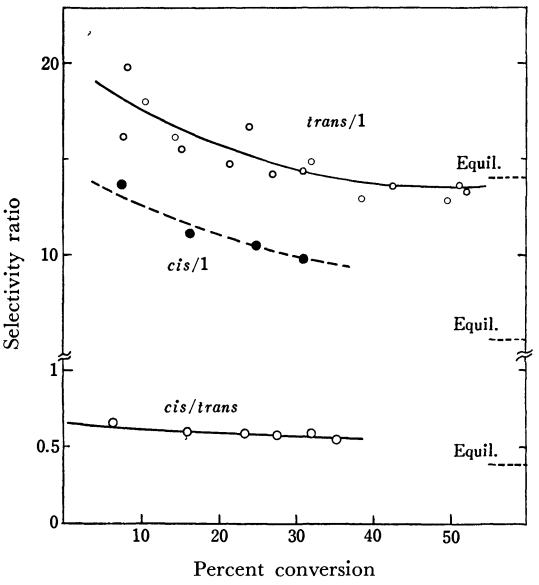

Fig. 4. Composition *vs.* conversion plots of isomerization of butenes over silica-supported perchloric acid at 60°C. *trans*/1 ratio decreased once below the equilibrium ratio due to rapid deactivation and then recovered to the equilibrium one.

iv) Metal chloride and acetate catalysts gave very low or no activity for this reaction.

The acid strength measured by indicators (Table 1) well explains the activity and *trans*/1 ratios as was done in the previous work for metal sulfates.[6] For example, the *trans*/1 ratio increased from 1.2 for Mg–S to 7.0 for $Mg(ClO_4)_2$–SiO_2, where the acid strength of Mg–S was comparable with that of benzeneazodiphenylamine ($pK_A = 1.5$) and $Mg(ClO_4)_2$–SiO_2 was more strongly acidic than anthraquinone ($pK_A = -8.2$).

Finally, the effect of different silica gels as support may be mentioned. Little effect on the activity and the selectivity was observed for the active catalysts such as Al–S. However, there was a little increase in activity in the case of the catalysts having very low activity such as Mg–S and $NiCl_2$–SiO_2 when more acidic silica gel was used as support, although the activities of the supports alone were always much lower than $NiCl_2$–SiO_2.

Discussion

Essential parts of the results obtained previously about the double-bond isomerization of butenes over metal sulfate catalysts were as follows.[6]

i) The acid strength of metal sulfate catalyst was primarily determined by the electronegativity of the

11) Results of several experiments were plotted for *cis*-2-butene isomerization. The scattering of data was due to the rapid deactivation of catalyst, and there existed systematic trend in scattering which will be fully discussed in the forthcoming paper.

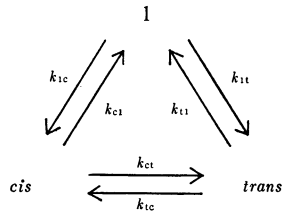
constituent metal ion.

ii) The acid strength controls the selectivity of *cis-trans* isomerization over double-bond migration. The activity is determined by both acid strength and content.

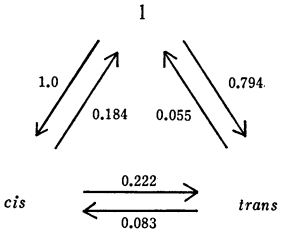
iii) The selectivity change was interpreted by the change in the relative rates of proton addition to butene and proton elimination. These rates are expected to vary with acid strength.

The results obtained in the present work for the supported metal perchlorates, sulfates and phosphate (including free acids) (Tables 1 and 3) demonstrate that the acid strength of metal salt catalysts, at least salts of oxy acids, can be controlled not only by changing the metal ion but also by changing the anion. The *trans*/1 ratios and the acid strength given in those tables follow, in general, the expected order of the "intrinsic" acid strength of metal salts. The "intrinsic" acid strength is referred to as the acid strength related directly to the properties of the constituent atoms or groups of the substance. This might be expressed, for example, by the pH of aqueous solution of the metal salts, if one can neglect the leveling effect. If the general trend between the acid strength and the selectivity is applicable to silica-alumina, the *trans*/1 or *cis*/1 ratio over silica-alumina should be as high as those for Al–S and H_2SO_4–SiO_2, since its acid strength is as strong as that of Al–S.[9,12] Reported *trans*/1 or *cis*/1 ratio for silica-alumina ranges from 1 to 7.[1,2,5,8,10] However, it may be noted that Hightower and Hall[8] reported that the *trans*/1 ratio over fresh silica-alumina was about 7, which diminished rapidly down to almost unity by the repeated runs and that most of the previous data were obtained over more or less deactivated catalysts.

Acid Strength and Reaction Mechanism. The selectivity ratio (*trans*/1 or *cis*/1) increased from Mg–S to Al–S with the increase in the catalytic activity. As the equilibrium favors 2-butene formation, secondary isomerization from 1-butene to 2-butene could have effected the high selectivity ratio for active catalysts. However, this possibility can be rejected, since the selectivity ratios higher than the equilibrium ones were found; *e.g.*, *cis*/1 ratios were 14, 10, and 6 for $HClO_4$–SiO_2, H_2SO_4–SiO_2 and Al–S, respectively, where the equilibrium ratio is 5.4, and the *trans*/1 over $HClO_4$–SiO_2 was 16—20, as compared with the equilibrium ratio of 14.4 (Table 3 and Fig. 4). The preferential polymerization of 1-butene as the reason of high *trans*/1 or *cis*/1 ratio suggested by Hightower and Hall[8] is also denied, because this side reaction was less than 10% of the isomerization and little difference was observed among the rates of pressure decrease of three butene isomers. Therefore, the observed selectivity ratio may safely be considered as the ratio of the rates of two paths from a butene isomer. Further, the relationships found among three selectivity ratios for each catalyst, that is, (*trans*/1) (1/*cis*) (*cis*/*trans*)= 1,[4,6] indicate that the reaction orders of isomerizations were nearly identical for each catalyst, so that the observed ratios may be considered as the ratios of the rate constants; *viz.*, *trans*/1, *etc.* are k_{ct}/k_c, *etc.* in the following reaction scheme.



The relative rate constants can be calculated utilizing equilibrium and selectivity ratios as an example for Mg–S at 60°C as follows[4,8]



Suppose a simple reaction catalyzed by acid, consisting of a proton addition and elimination,

$$A + H^+ \rightarrow (M) \quad (1)$$

$$(M) \rightarrow B + H^+ \quad (2)$$

where A, B, and M are reactant, product and protonated reaction intermediate, respectively. In step (1), a catalyst acts as an acid and in the next step as a base. As the acid strength increases, the rate will increase initially by the acceleration of step (1) and then diminish upon further increase in the acid strength due to the slow rate of step (2), showing a volcano-type activity pattern.[13,14] This concept may be applied in the present case, since it seems generally accepted that double-bond isomerization of butenes catalyzed by solid acids such as silica-alumina and metal sulfate proceeds through proton addition to form a *sec*-butyl carbonium ion (step(1)) and elimination of proton from the complex (step(2)).[1,2,6,8,10] If one accepts this mechanism, one may expect that over a strong acid the proton addition occurs readily and the carbonium ion is stable. This step would be slow and the ion is unstable over a weak acid. Considering a *sec*-butyl carbonium ion, the proton release from C–H_a would tend to result into *cis*-2-butene formation, from C–H_b into *trans*-2-butene and from one of C–H_c into 1-butene.[8] Since two C_3–H bonds of methylene may be energetically similar and differs from those of methyl (C_1–H_c), it is under-

14) O. A. Leffler and E. Grunwald, "Rates and Equilibria of Organic Reactions," John-Wiley and Sons, New York (1963), p. 163.

standable that among various catalysts the *trans*/1 and *cis*/1 ratios were always nearly identical and were different from the *cis*/*trans* ratio which was almost unity.[6]

The changes in 2-/1-butene ratios (*trans*/1 and *cis*/1) may be explained by the variation in the transition state and the relative rates of proton addition and elimination as follows. According to Hammond[15] and Leffler and Grunwald,[14] the transition state of a reaction step more nearly resembles the reactant as the step becomes more exothermic. This postulate calls for, in other words, the transition state of a bond rupture step to involve relatively less bond breakings when the bond is easily broken and relatively more when it is difficult to break. If one applies this postulate to the proton elimination from carbonium ion, the transition state is expected to reflect more the final state, butene, as the ion becomes more stable as over a strong acid. The formation of stable 2-butenes is, therefore, favored over a strong acid. If the carbonium ion is less stable as over a weak acid, the transition state resembles the initial state, the ion, reflecting to a less degree the product, or butene, so that the 2-/1-butene ratio approaches unity. Furthermore, as the acid strength decreases, proton addition would become more difficult and tend to occur almost simultaneously with proton elimination. Then the isomerization reaction will appear more concerted over a weak acid: double-bond migration will increase, relative to *cis-trans* isomerization.

A similar interpretation can be found in the elimination reaction *via* carbonium ion (El mechanism).[16] As the acid strength of a solvent, a nucleophilic reagent or a catalyst decreases, the reaction mechanism changes from El to E2 like mechanism:

$$\text{(El mechanism)}\quad RX + A \rightarrow R^+ + XA$$
$$R^+ \rightarrow \quad R' + H^+$$

By the El mechanism, *sec*-butyl bromide or tosylate gave the butene mixture in the composition of 1 : *trans* : *cis*=5∼7 : 41∼46 : 47∼54 (high 2-/1-butene ratio), while it was 23 : 18 : 59 by E2 mechanism (low 2-/1-butene ratio).[17] When a very unstable carbonium ion is formed as in the elimination of amino group from *sec*-butylamine catalyzed by HNO_2, the composition of butenes was 22 : 25 : 53.[17]

Active Acid Sites for the Double-Bond Isomerization of Butenes. Since 2-/1-butene ratio reflects the acid strength,[6] little variation in the *trans*/1 ratio found upon changing the amount of supported aluminum sulfate (Fig. 3) and the preheating temperature,[6] suggests that a certain and definite interaction between silica gel surface and aluminum sulfate developed the acid sites active for the isomerization. These sites must be protonic (Brönsted type) from the following reasons, although the electronegativity of metal ion which expresses the acid strength of a metal ion as Lewis acid[7] linearly correlated with the selectivity and the catalytic activity.[6]

i) Deuteration of isomerized butenes took place during the reaction over deuterated $NiSO_4$–SiO_2,[1] *p*-toluene sulfonic acid[3] and silica-alumina.[2]

ii) Supported free acids were the most active catalysts and gave the highest *trans*/1 ratios among the series of metal salts of a given acid (Table 3).

iii) $NiCl_2$–SiO_2 and $MgCl_2$–SiO_2 were much less active or inactive as compared to Ni–S or Mg–S. One might be allowed to expect some activity for the formers, if the metal ions themselves are active.

iv) The rate of isomerization decreased upon deuteration of the catalysts (catalyst isotope effect).[18]

This protonic site active for the isomerization is not likely to be a proton in silanol group which may exist and whose acid strength may vary by the metal ion. But it seems to be a proton closely connected to sulfate or perchlorate ion, since 1) the activity and *trans*/1 ratio, as well as the acid strength, strongly depended on the acid strength of anion (Tables 1 and 3), 2) metal chloride catalysts were not active, even though Me–O–Si–OH were reported to exist for these catalysts,[19] and 3) an ion exchange resin (sulfonic acid type)[6] and *p*-toluene sulfonic acid[3] whose acid sites must be SO_3H gave the *trans*/1 ratio and activity as high as H_2SO_4–SiO_2 and $HClO_4$–SiO_2. As the electronegativity represents the power of atom or an ion to attract electron, the role of metal ion may be lowering the electron density of oxygen of –OH, promoting the tendency of the proton to dissociate. The effects of the electronegative group on the acidity was postulated for fluorine treated silanol group.[20] The rapid decrease in the *trans*/1 ratio and the activity upon washing out of aluminum sulfate (Table 2) indicates that the structure of active acid sites is very soluble in water and is, therefore, different from the one reported by Burne et al.[21]

Polymerization on the Surface as the Origin of Deactivation. The pressure decrease observed during isomerization was rapid initially and then the rate reached nearly constant. This process was fast over strong acids and was slow and small over weak acids. These trends closely resemble those found in the case of propylene oligomerization over silica-aluminas with various acid strengths.[9] As in propylene oligomerization and butene isomerization over silica-alumina,[2,8] the polymerization or coke formation from butene is likely to be the primary origin of deactivation in the present case and the acid strength decreased by the deactivation.

Dependence of ζ-Potential upon Particle Size and Capillary Radius at Streaming Potential Study in Nonaqueous Media[1]

Ayao KITAHARA, Tadashi FUJII, and Seiji KATANO

Science University of Tokyo, Kagurazaka, Shinjiku-ku, Tokyo

(Received April 23, 1971)

The effect of particle size and capillary radius on electrokinetic potential(ζ-potential) was studied in order to check the influence of overlapping of the electrical double layer and radius effect on the measured ζ-potential by the streaming potential method. The streaming potential was measured with varying particle size and capillary radius of glass in the benzene solution of $(C_4H_9)_4NI$. The measurement was carried out over the range where the laminar flow and the Quincke's law hold. The surface conductance was corrected experimentally. ζ-Potential increased with increase of the particle size in the glass column. It was unsuccessful to obtain the ζ-potential independent of the reduced radius of the capillary pore with the Oldham's treatment. ζ-Potential increased with increase of the capillary radius. The increase was elucidated by the Wood's method using the appropriate constants, and the constant ζ-potential which was not affected by the capillary radius was obtained. The value was still different from that obtained by the electrophoretic method, but the difference was considerably small as compared with the previous data.

Electrokinetic potential (ζ-potential) is important as the quantity used in place of surface potential which is necessary to discuss the stability of dispersion or the properties of the electrical double layer, but it is difficult to measure or estimate the ζ-potential on the insulator or the semiconductor. ζ-Potential is usually measured by the electrophoretic method or the streaming potential method. However, the retardation effect and the relaxation effect must be corrected for the former method.[2] The surface conductance and the overlapping of the double layer must be taken into consideration for the latter in order to obtain the proper value. Both values should agree with each other, provided that all proper corrections have been made.

The same system has to be investigated by both methods for comparison, but such study is rare except a few,[3] although the comparison between the streaming potential and the electro-osmosis was done and the coincidence was recognized[4] because of their similar packing column system.

The necessary corrections have to be done for each method to obtain the reliable value of ζ-potential. The correction for the surface conductance was studied for aqueous systems both theoretically and experimentally by Ghosh *et al.*[5] Oldham *et al.* proposed the theory of correcting capillary radius and the surface conductance which was applied successfully to the aqueous and nonaqueous data obtained by other authors.[6] The effect of pore orientation on the cell constant in the pore system of fiber was studied by Mason *et al.* for the streaming potential.[7]

In our laboratory, ζ-potential of the same sample system (barium sulfate powder dispersed in cyclohexane solutions of Aerosol OT) was measured with both the electrophoresis and the streaming potential methods. Both values were widely different.[8] Effects of the surface conductance and the overlapping of the double layer for the streaming potential, which were not corrected, would cause the difference. Fortunately, the thick double layer present in the nonaqueous system makes it easy to study the overlapping.

In this paper, the effect of the overlapping of the double layer was studied experimentally for the nonaqueous system of the particle column and the capillary of glass and data obtained were checked by the present theories. The surface conductance was also corrected experimentally.

Experimental

Samples. A series of spherical glass particles were purchased from the Sugito Seimitsu Glass Co. and further classified with the standard sieves. The diameter range of the samples was tabulated in the 2nd column of Table 1. Glass capillaries of different radii shown in Table 2 were used.

Glass particles were cleaned with mixture of nitric and sulfuric acids and digested on a water bath for 10 hr. After cooling, they were washed repeatedly with de-ionized water until the specific conductivity of the washings was nearly equal to that of the de-ionized water. The particles were dried in an oven at 120°C and extracted with acetone and benzene in turn for 3 hr. They were reheated for 2 hr at 200°C under 10^{-2} mmHg immediately before use. Capillaries were cleaned, washed and dried similarly to the case of particles. After cooling in a desiccator, they were immersed in purified benzene for a while before use.

Benzene used as a solvent was purified and dried from GR grade reagent as usual and finally treated with Molecular Sieves 4A to remove a trace of water, Tetra-*n*-butyl amonium iodide $(C_4H_9)_4NI$ used as an electrolyte in benzene

P-3	88—105	12.3
P-4	44—62	7.9
P-5	26—44	5.8

Table 2. Radius of glass capillary

Sample No.	Radius (mm)
C-1	1.45, 1.46, 1.55
C-2	0.95, 1.00, 1.05
C-3	0.44, 0.45
C-4	0.18

was GR grade reagent. The content of water in the benzene solution was below 100 ppm throughout this study.

Apparatus. The streaming potential was measured with an essentially similar apparatus to that used by Dodd *et al.*[9] The cell of the particle system was made of Teflon or glass coated by silicone to prevent surface leakage. Electrodes in the system were perforated stainless steel plates coated by silver. The particle column of 2 $cm^2 \times 0.5$ cm was made by filling about 1.5 g glass particles between both electrodes. The capillary of the length of 25 cm was used as the cell of the capillary system. Platinum wires were placed very closely to both ends of the capillary as electrodes.

Methods. The occurring streaming potential was measured with a vibron voltmeter (DC amplifier of the Takeda Riken Ind. Type TR-85). The electric resistance of the column or capillary filled with the electrolyte benzene solution was measured with a high-resistance measuring apparatus (Modell II-3 of the Hitachi Manufacturing Co.) which can measure up to 10^{15} ohm.

The cell constant of the column or the capillary was determined from the measurement of the conductivity of 0.1 N KCl aq. solution. The measurement was carried out for the same column or capillary after the benzene solution had been thoroughly discharged and washed to avoid the effect of polarization of electrodes. The orientation effect proposed by Mason was not considered because of the sphere particle system.

Results and Discussion

Assurance of Laminar Flow. To ascertain the laminar flow of the solution in the column or capillary, the Darcy's law was examined with the streaming potential apparatus. The law says that

$$V = KP \tag{1}$$

where V is the volume rate of the flowing solution under a driving pressure P and K is the permeability. If the height of the solution column acting as pressure P is h,

$$P = kh (k\text{: constant}), \text{ and } V = -\mathrm{d}h/\mathrm{d}t \ (t\text{: time}) \tag{2}$$

Then Eq. (3) is reduced as follows:

$$\log h = -K't/2.3 + \log h_0, \tag{3}$$

where $K' = kK$ and h_0 is the extrapolated initial height of the solution column. Equation (3) was experimentally confirmed both for the particle column and capillary systems. The relation held over the range of the lower height for the capillary system. The measurement of the streaming potential was carried out within this range. Reynolds number was below 0.1.

Quincke's Law and Time Dependence of Streaming Potential. Next, the applicability of the lineality between the streaming potential (E) and pressure (P) was checked. The Quincke's law was applicable within the pressure range over which the laminar flow was ascertained. The slope of the potential-pressure curve varied with repeated measurements and approached an equilibrium value after 20—24 hr (about 8 measurements), although the constant K' was almost invariable over 24 hr. The time dependence of E/P may be due to cleansing of the wall of the cell and particles or capillary surface and the ion-exchange of particles or capillary. The capillary used once did not show the same streaming potential in repeated experiments. The equilibrium values of E/P were used for the calculation of ζ-potential.

Correction of Surface Conductance. The Helmholtz-Smolchouski's equation taking into consideration of the surface conductance for the capillary radius r is described as follows:

$$\zeta = \frac{4\pi\eta}{D}\frac{E}{P}\left(\kappa_b + \frac{2\kappa_s}{r}\right), \tag{4}$$

where κ_b and κ_s are the bulk and the surface specific conductivity, respectively, and η and D are the viscosity and the dielectric constant of the double layer which are usually substituted by the bulk values. $\kappa_b + \frac{2\kappa_s}{r} = \kappa_c$ for the present nonaqueous system was calculated from the conductivity ($1/R$) of the column or the capillary system filled with the benzene solution of the electrolyte and the cell constant (k_c) whose measurements were described in the experimental part, that is, $\kappa_c = k_c/R$. In the present system, κ_s was much larger than κ_b which had been measured separately in another cell.

Reduced Capillary Radius of Column. The mean reduced capillary radius of the particle column (r) was determined as follows: Poiseuille's law says that

$$V = \frac{n\pi r^4 P}{8\eta l}, \tag{5}$$

where n and l are the number and the length of the capillary, respectively. Ohm's law is expressed as follows:

$$R = \frac{l}{\kappa_b n\pi r^2}. \tag{6}$$

From Eqs. (5) and (6), $r = \sqrt{\frac{8\kappa_b\eta VR}{P}} = \sqrt{8\kappa_b\eta RK}$. (7)

The measurement of r with use of Eq. (7) was carried out with 0.1 N KCl aq. solution. The result was listed on the 3rd column in Table 1.

ζ-Potential of Column System. The change of ζ-potential of the column system with particle size was shown in Fig. 1 for 10^{-5} and 10^{-4} mol/l solutions of $(C_4H_9)_4NI$ in benzene. ζ-potential increased with increase of particle size and appears to approach the saturation value.

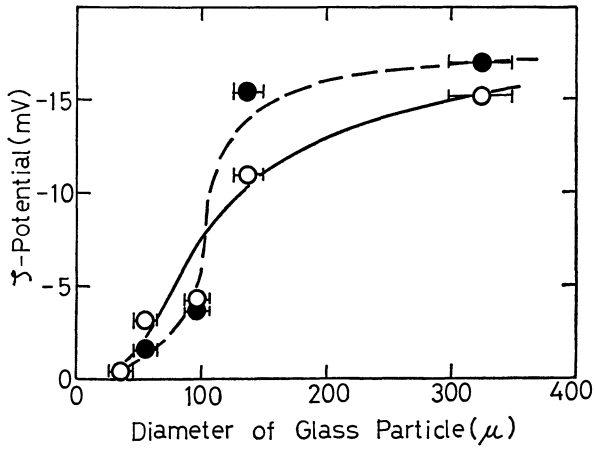

Fig. 1. Change of ζ-potential with particle size of glass in solution of $(C_4H_9)_4NI$ in benzene.
—○—: 10^{-4} mol/l, --●--: 10^{-5} mol/l

The theory proposed by Oldham *et al.*[6] was applied to obtain the ζ-potential independent of particle size. The thickness of the double layer ($1/\kappa$: Debye length) which is necessary for the study was calculated from the data of the specific conductivity.[10] The values were 3.3 μ and 10 μ for 10^{-4} and 10^{-5} mol/l solution system, respectively. The constant ζ-potential independent of the particle size could not be obtained by the Oldham's method. Insufficient reliability of the values of reduced radius for the quantitative calculation and the heterogeneity of pore radius, the contribution of which was investigated by Overbeek *et al.*[11] and by Rutgers *et al.*[12] may be considered as reasons of the failure. Therefore, the measurement for the capillary system was carried out to study the effect of the capillary radius more critically.

ζ-Potential of Capillary System. The contribution of the surface conductance to the total conductance in this system was much larger than that of the bulk conductance similarly to the case of the column system. Hence, the correction by Rutgers *et al.*[13] was improper and inaccurate to do.

ζ-potential calculated from Eq. (4) was depicted against the capillary radius (a) in Fig. 2 for the 10^{-4} mol/l solution of $(C_4H_9)_4NI$ in benzene. It is seen from the figure that ζ-potential depends markedly on the radius, though the data scatter to some extent. Since the value of κa ranges over 55—450 for the capillary system used, the correction of the overlapping of the double layer by the method of Oldham[5] was virtually ineffective to obtain the value independent of the radius.

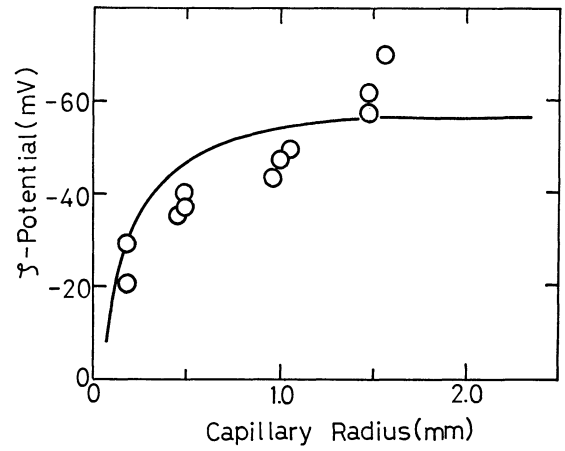

Fig. 2. Change of ζ-potential with capillary radius.
○: Observed values
——: Line by Eq. (9) as $\zeta = -62$ mV, $A = -8.8$ mm

Wood discussed the radius effect over the wide range considering the distribution of charge.[14] The following equation can be obtained from the combination of Eqs. (15), (16), and (22) in the original paper of Wood:

$$\zeta_0 - \frac{2\pi}{Da}\sum_i d_i \Delta M_i = \zeta_{obs}, \tag{8}$$

where ζ_0 and ζ_{obs} are the corrected and observed ζ-potential, respectively, d_i is the distance of the element i from the wall and ΔM_i is the moment of the element. Over the range in which the overlapping of the double layer that should be corrected by the Oldham's method is absent, d_i and ΔM_i have their finite values and they are constant for a fixed concentration of the electrolyte. Then Eq. (8) reduces to Eq. (9):

$$\zeta_0 = \zeta_{obs} + \frac{A}{a}, \tag{9}$$

where A is a constant. This equation was checked with the experimental values in Fig. 3. The linearity between ζ_{obs} and $1/a$ can be approximately recognized. $\zeta_0 = -62$ mV as the corrected ζ-potential and $A = -8.8$ mm were obtained from the least saquares method by the computor. The allowance range of ζ_0 was -62 ± 10 mV from the figure.

Alternatively, the microelectrophoresis of fine glass powders dispersed in the 10^{-4} mol/l solution of $(C_4H_9)_4NI$ in benzene gave -120 mV as the ζ-potential.

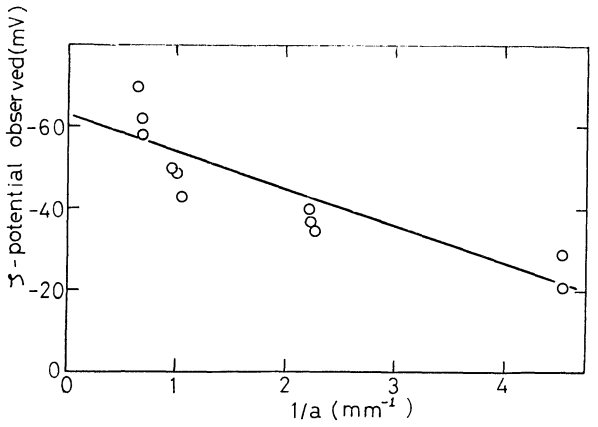

Fig. 3. The relation between ζ-potential observed (ζ_{obs}) and the reciprocal of radius ($1/a$) for the capillary system. The solid line was drawn with use of $\zeta_0 = -62$ mV and $A = -8.8$ mm.

The difference is still present between the value (−120 mV) from the electrophoresis and the one (−62 mV) from the streaming potential. However, difference has been considerably smaller as compared with the large difference of the preceding paper.[8] That is, ζ-potential from the electrophoresis and the streaming potential of barium sulfate powders dispersed in Aerosol OT solution in cyclohexane was +100 mV and +2 mV, respectively. The remaining difference may be elucidated from following reasons. (a) There is minor difference in composition of glass samples used for two methods, causing probable difference in the surface state. (b) There is difference in the washing extent of the surface, because enough washing is done in the process of the streaming potential measurement. (c) The double layer in the nonaqueous system may be distorted by the large local field strength resulting from the high applied potential (40—60 V/cm).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3245—3250 (1971)

Acidity Constants of Phenanthrylamines in the Ground, Excited Singlet, and Triplet States

Kinzo Tsutsumi*, Kazuko Aoki, Haruo Shizuka, and Toshifumi Morita

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received May 4, 1971)

Measurements of the acidity constants in the ground ($pK_a(S_0)$), the lowest excited singlet ($pK_a(S_1)$), and triplet states ($pK_a(T_1)$) for 2-, 3-, 4-, and 9-phenanthrylamines have been carried out by spectrophotometry. The pK_a values obtained were in the order of $pK_a(S_0) > pK_a(T_1) > pK_a(S_1)$. The absorption and emission spectra of the phenanthrylamines were compared with the results of the calculations by means of the semi-empirical SCF-MO-CI method. A linear relationship between the pK_a values and the net charge (or charge densities) in the ground and excited states was obtained both experimentally and theoretically.

The basic properties of aromatic compounds have been extensively studied especially for the ground states (S_0). The pK_a values determined experimentally have been satisfactorily explained in terms of the π-electronic energy change accompanied by protonation, and also in terms of the charge density on the atom which attacked by the proton. On the basis of the simple Hückel molecular orbital theory,[1] Coulson and Longuet-Higgins[2] pointed out a linear relation between the pK_a values and the charge densities for the ground states. Does the same thing hold when the self-consistent field molecular orbital theory is used?

Experimental studies on the acid-base properties in the excited states were carried out originally by Förster[3] and developed by Weller,[4] who extended the kinetic method to obtain the acidity constants and who succeeded, with substituted aromatic hydrocarbons, in obtaining the same values as those determined by the Förster cycle. Several workers[3–11] have studied the subject of the acidity constants in the

ground and excited states. Summarize those results, the pK_a values in the lowest excited singlet states (S_1) are very much lower than those in S_o, while the pK_a (T_1) values are a little smaller or similar to those in S_1.

In order to explain these results, several discussions have appeared. Jackson and Porter[5] have explained this tendency of pK_a values as resulting from the differences among the electronic structures: the S_0, S_1, and T_1 states have normal, ionic, and radical structures respectively. The pK_a value in the S_1 state was elucidated by the resonance theory.[6-7] An explanation was also made considering the solvation effect on the pK_a values.[8] On the other hand, some theoretical calculations have been reported: they have suggested that the pK_a values in the excited states correlate with the electron-density distribution in the excited states.[9]

These explanations give us interesting suggestions concerning the basic properties in the excited states. No pK_a values of phenanthrylamines, except for those in S_0,[12] have been reported. Little attention has yet been paid to the theoretical consideration concerning these compounds. The purpose of the present paper is to measure these pK_a values for phenanthrylamines and to see if there exists a quantitative correlation between the charge distributions calculated theoretically by the SCF-MO-CI method and the experimental pK_a values in the ground and excited states.

Experimental

Materials. The 2-, 3-, 4-, and 9-phenanthrylamines used were given by Dr. Etsuro Ohta (Gunma University); these compounds were recrystallized twice from benzene. The cyclohexane was purified by passing it through a silica-gel column and by distillation. The methanol and ethanol were Kanto Chemical Co., Ltd., G. R.-grade products and were used without further purification. The buffer solutions used were adjusted using hydrochloric acid and sodium acetate.[13]

Apparatus. The UV absorption spectra were measured by means of a Hitachi 139 spectrophotometer. The fluorescence and phosphorescence spectra were taken with a Hitachi MPF 2A fluorescence spectrophotometer.

The Determination of pK_a Values. The pK_a values in the ground states (S_0) were measured by spectrophotometry at 20°C. The pK_a (S_1) and pK_a (T_1) values were estimated by means of the Förster cycle[3] as in the following relation:

$$pK_a(S_0) - pK_a^* = (\Delta E_{HA} - \Delta E_A)/(2.303RT)$$

where ΔE_{HA} and ΔE_A are the energy differences between the ground and excited states of the protonated and unprotonated molecules respectively. The $pK_a(S_0)$ and pK_a^* ($pK_a(S_1)$ or $pK_a(T_1)$) denote the pK_a values in S_0 and the excited state (S_1 or T_1) respectively. R and T are the gas constant and the absolute temperature respectively. In the present work, the energy difference between the S_0 and S_1 states was evaluated by means of the absorption and fluorescence spectra; the difference corresponds to the O–O transition energy. The energy difference between S_0 and T_1 was estimated by means of the phosphorescence spectra. If the $pK_a(S_0)$ is known, the pK_a^* can then be obtained.

Calculation

The π-electronic structures of some phenanthrylamines were studied by the use of the semi-empirical self-consistent field molecular orbital theory[14,15] combined with the singly excited configuration-interaction calculation. The CI calculation was made by taking 30 configurations of lower energies. The two-center Coulomb repulsion integrals, γ_{ij}, were calculated according to the Mataga-Nishimoto approximation.[16] The one-center Coulomb repulsion integrals, γ_{ii}, were estimated from the corresponding valence-state ionization potentials, (I_i), and electron affinities, (A_i), by the Pariser-Parr method,[14] I_i and A_i being determined from the spectroscopic data using the promotion energies of Hinze and Jaffé.[17] The two-center core resonance integrals, β_{ij}, were evaluated with the Nishimoto-Forster approximation.[18]

Some choices have been made concerning the appropriate I_i value for the nitrogen atom of an amino group. We used three types of parameter values (energies in eV) for the nitrogen atom:

(I) $I_N=28.709$, $\gamma_{NN}=16.757$, core charge=2,[17]

(II) $I_N=27.904$, $\gamma_{NN}=16.428$, core charge (N)=1.957, $I_{C'}=11.5516$, $\gamma_{C'C'}=11.3236$, core charge (C')=1.035.

Here, C' denotes the carbon atom next to the nitrogen atom. These parameter values are taken them Dewar and Morita,[19] who took the sigma polarization effect into account.

(III) $I_N=24.71$, $\gamma_{NN}=13.75$, core charge=2.

These parameter values were determined by Hirota and Nagakura[20] based on doubly-excited configuration interaction calculations.

In the SCF calculations, the variable-β,γ procedure developed by Dewar and Schmeising[21] and later by Nishimoto and Forster[18] was employed. The geometry was assumed to be as follows. All the C–C bond lengths and all the bond angles were taken to be equal to 1.39 Å and 120° respectively. The C–N bond length was assumed to be 1.38 Å. The actual calculation was carried out by an electronic computer, HITAC 5020 E, located at the Computer Center, The University of Tokyo.

Results

Electronic Absorption Spectra. The absorption spectra of the four phenanthrylamines were measured in cyclohexane at room temperature. Figure 1 shows those absorption spectra. By the substitution of an amino group, the π-electronic structure of phenanthrene was perturbed. The experimental and calculated values for the transition energies and oscillator strengths are listed in Table 1. Table 1 shows that the calculated values are in accordances with those obtained experimentally. No significant effect of the variation of parameters on the transition energies was observed.

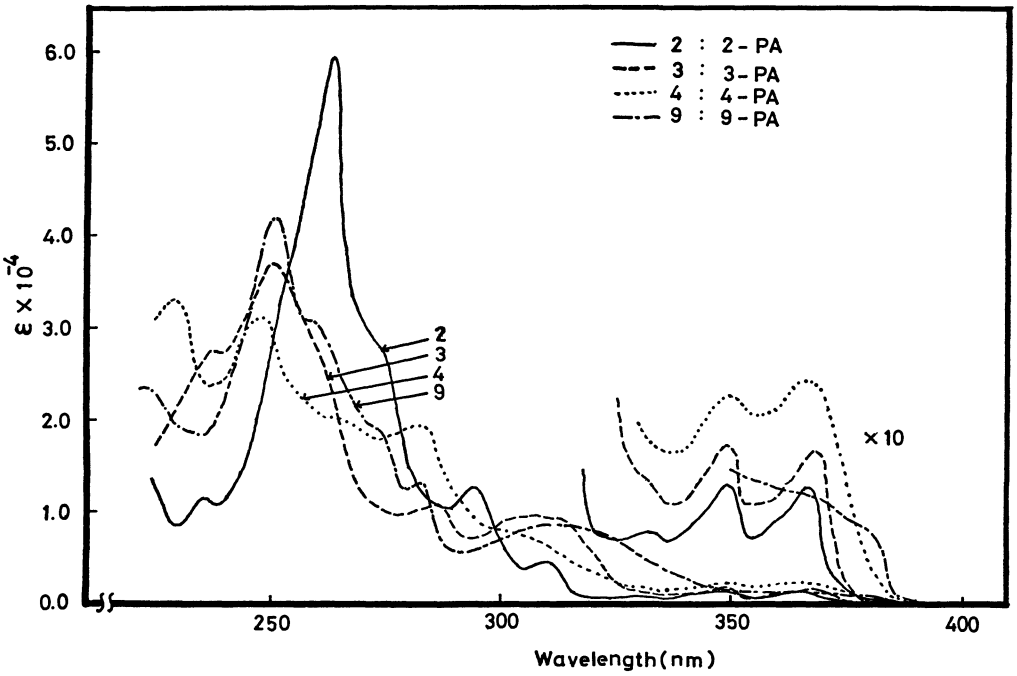

Fig. 1. UV absorption spectra of phenanthrylamines in cyclohexane at 20°C.

ΔE and f denote the transition energy in units of eV and the oscillator strength respectively. I, II, and III are explained in the text, and PA denotes phenanthrylamine.

Ground-state Acidity Constants, $pK_a(S_0)$. Eliot and Mason[12] have reported the pK_a (S_0) values of phenanthrylamines measured by the potentiometric method. In the present work, the $pK_a(S_0)$ values were determined spectrophotometrically using the buffer solutions. These results are summarized in Table 2.

Table 2. Ground-state acidity constants

Substance	$pK_a(S_0)$		
	(1)[a]	(2)[b]	ΔH[c]

a) This work.
b) *Cf.* Reference 12.
c) ΔH denotes the enthalpy change in the dissociation of the conjugate acid of the phenanthrylamine in units of kcal/mol. *Cf.* Ref. 12.

The $pK_a(S_0)$ values obtained in the present work are somewhat high ($pK_a \approx 0.36$) in comparison with those reported by Eliot and Mason[12].

Excited Singlet-state Acidity Constants. The absorptions and fluorescence spectra of the four phenanthrylamines(RNH_2) and of their conjugate acids were measured at 20°C in an aqueous methanol solution (5 vol. percent methanol solution) for the parent molecules and in an aqueous methanol solution with sulfuric acid added for the protonated molecules (RNH_3^+). The absorptions and fluorescence spectra of the parent molecules appeared in various regions perturbed by the substituent amino group. However, the spectra of the protonated molecules are similar to that of phenanthrene. For example, the transition energies of the conjugate acid of 2-phenanthrylamine correspond to those of phenanthrene (Table 3) Similar results were obtained for 3-, 4-, and 9-phenanthrylamines. Therefore, the 345 nm (3.5_9 eV) absorption bands of the conjugate acids were assigned to the $^1L_b \leftarrow {}^1A$ transition of the phenanthrene molecule[22] with a maximum at 344 nm(3.6_0 eV). Little effect of the substituent NH_3^+ group on the phenanthryl group was found.

Table 3. Transition energies for the conjugate acid of 2-phenanthrylamine

S_4	4.5_4	4.5_2	4.74

a) Experimental data for the conjugate acid of 2-phenanthrylamine.
b) Experimental data of phenanthrene in cyclohexane.
c) Calculated values of phenanthrene in the present work.

The $pK_a(S_1)$ values estimated by the Förster cycle are listed in Table 4.

Triplet-state Acidity Constants. The phosphorescence spectra of the four phenanthrylamines were measured in the rigid methanol-ethanol (1 : 1 mixture in volume) matrices[23] at 77°K. These data are summarized in Table 5. The conjugate acids had the same $T_1 \rightarrow S_0$ transition energies as those of phenanthrene. These results show that the features of the lowest triplet states of the conjugate acids are very similar to those of phenanthrene. The $pK_a(T_1)$ values of protonated PA (RNH_3^+) were also determined by the Förster cycle, as is shown in Table 5. In the present work, the order of the pK_a values of protonated PA is $pK_a(S_0) > pK_a(T_1) > pK_a(S_1)$, as is shown in Tables 2, 4, and 5.

Charge Densities. The charge densities on the nitrogen atom in phenanthrylamines have been estimated by the semi-empirical SCF-MO-CI calculations using the parameters described above. Table 6 shows the calculated charge densities.

Discussion

The lone-pair electron on the amino-nitrogen atom would migrate to the phenanthryl ring much more intensely in the excited singlet state than in the ground state and a little more intensely in the triplet than in the ground state. The calculated results show this is true, as may be seen in Table 6. Accordingly, the basicities would be the largest for the ground state, medium for the lowest triplet state and the least for the lowest excited singlet state. The experimental

Phenanthrene	450			

a) Estimated from the relation:
$\Delta H(T_1)=\Delta H(S_0)-(\Delta E_{AH}(T_1)-\Delta E_A(T_1))$.

results indicate this very tendency. Furthermore, as is shown in Table 4, the dissociation of protonated phenanthrylamines in the lowest excited singlet state is an exothermic reaction.

If the chemical non-crossing rule[2] could be applied for the excited states, the linear relation between the charge densities and the excited state pK_a values might be anticipated. Figure 2(a) shows the plot of the pK_a values against the charge densities: a good linear fit is seen for the excited singlet states. Points corresponding to the ground-state pK_a values also

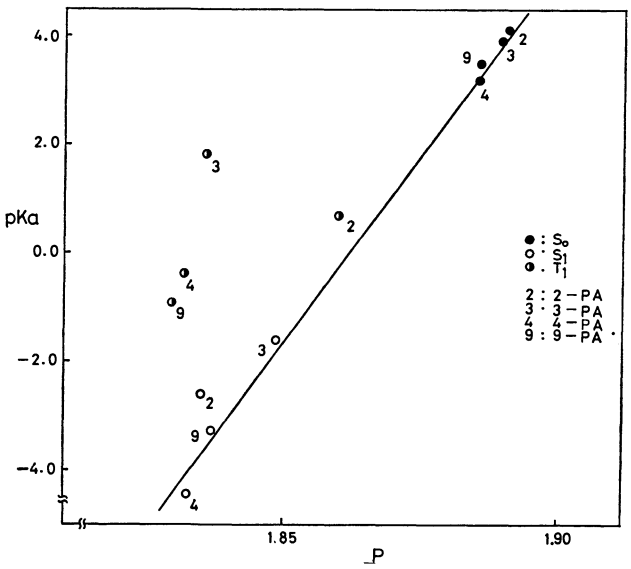

Fig. 2(a). Plot of the pK_a values *vs.* the charge densities. The S_0, S_1, and T_1 denote the ground, the lowest excited singlet, and the triplet states respectively.

lie on the same straight line. Treatment by the least-squares method gives the following equation:

$$pK_a = 133.46P - 248.34 \quad (1.83<P<1.90) \tag{1}$$

for this linear correlation. The slope of the line and the correlation coefficient, except for the plot for the triplet state, are 133.46 and 0.992 respectively. In this plot, we used charge densities calculated using the (II) parameter set, which is based on the consideration of the sigma polarization effect, because the charge densities computed by the (II) parameter set gave a somewhat better linear correlation than those calculated by the (I) and (III) parameter sets.

The enthalpy change (ΔH) in the dissociation of RNH_3^+ (Eq. 2) can be estimated approximately as follows:

$$RNH_3^+ \overset{K_a}{\rightleftharpoons} RNH_2 + H^+ \tag{2}$$

where K_a denotes the equilibrium constant. The enthalpy change can be written as:

$$\Delta H = -RT \ln K_a = (2.303\,RT)pK_a \tag{3}$$

The value of ΔH is approximated by the following equation:

$$\Delta H = I_N - A + C \tag{3'}$$

where I_N is the valence-state ionization potential of the nitrogen atom as determined by the method of Dewar and Morita[19] (see Eqs. (5) and (6); A is the electron affinity of a proton, and C is a constant). Equation (4) is derived from Eqs. (3) and (3'):

$$pK_a^{theo} = \frac{1}{2,303\,RT}(I_N - A + C) \tag{4}$$

$$= \frac{1}{2.303\,RT} I_N + \text{const.}$$

According to Eq. (4), the theoretical pK_a values should be proportional to the valence-state ionization potential of the nitrogen atom.

The estimations of the I_N values were carried out using the following relation[19]:

$$I_N = a + bq + cq^2 \tag{5}$$

where q denotes the total valence-shell electron density, and for the trigonal nitrogen, a, b, and c are equal to −89.402, 24.6265 and −1.4515 respectively. Equation (5) can be also given in the form of Eq. (6):

$$I_N = -10.1622\,Q_\pi - 2.1130\ \text{eV} \tag{6}$$

where Q_π is the net charge on the nitrogen atom; the term of $(Q_\pi)^2$ is disregarded since the $(Q_\pi)^2$ values are very small.

Table 6. Charge densities in the S_0, S_1, and T_1 states

	$P(S_0)$[a]			$P(S_1)$[a]			$P(T_1)$[a]		
	(I)[b]	(II)	(III)	(I)	(II)	(III)	(I)	(II)	(III)
2-PA	1.899	1.891	1.873	1.858	1.835	1.790	1.861	1.860	1.837
2-PA	1.898	1.890	1.872	1.865	1.849	1.810	1.852	1.836	1.796
4-PA	1.894	1.886	1.867	1.849	1.833	1.786	1.847	1.832	1.789
9-PA	1.894	1.886	1.867	1.852	1.837	1.796	1.846	1.830	1.784

a) $P(S_0)$, $P(S_1)$, and $P(T_1)$ denote the charge densities in S_0, S_1, and T_1 states.
b) Meanings of (I), (II), and (III) are described in the text.

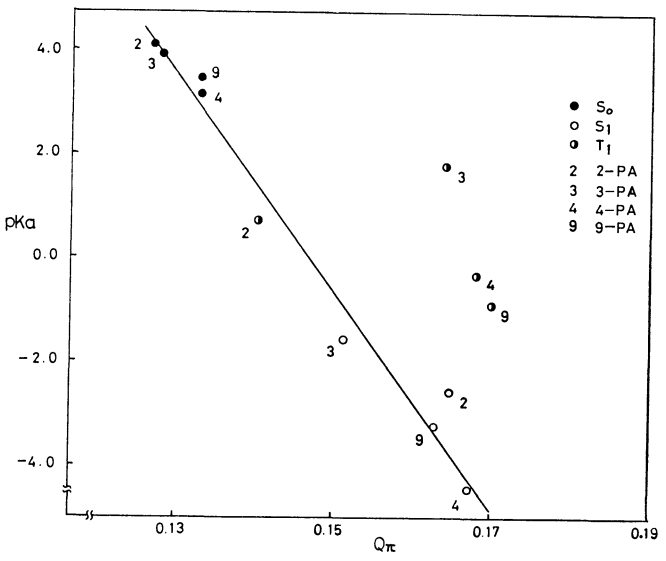

Fig. 2(b). Plot of the pK_a values *vs.* the net charges. The S_0, S_1, and T_1 denote the ground, the lowest excited singlet, and the triplet states respectively.

From the substitution of Eq. (6) into Eq. (4), Eq. (7) is given by:

$$pK_a^{theo} = -\frac{1}{2.303\,RT}(10.1622\,Q_\pi + 2.1130 + A - C) \quad (7)$$

$$= -1.748\times10^2\,Q_\pi + \text{const.}$$

where T equals 293°K.

Therefore, the linear relationship between the pK_a^{theo} values and the net charge Q_π can be derived; the slope of this relationship equals -1.748×10^2, as is described in Eq. (7). Figure 2(b) shows the plot of the experimental pK_a values *vs.* the net charge, Q_π; a good linear relationship is obtained. The following equation is given by the least-squares method:

$$pK_a = -2.05\times10^2\,Q_\pi + 30.322 \quad (8)$$

The slope of the line and the correlation coefficient, except for the plot for the triplet state, are -2.05×10^2 and 0.999 respectively. The slope of the line obtained experimentally is almost the same as that derived by the theoretical method, as is shown in Eqs. (7) and (8).

The pK_a values for the 1-phenanthrylamine can be estimated from the linear relationship in Figs. 2(a) and (b), if the charge densities are known. The estimated pK_a values are shown in Table 7.

Table 7. Estimated pK_a values for the 1-phenanthrylamine

	State	
	S_0	S_1
$P^{a)}$	1.886	1.837
pK_a	3.3_7	-3.1_7

a) P denotes the charge density calculated using the (II) parameter set, as has been described in the text.

The triplet-state pK_a values deviated from linearity. This must be due to some factors such as:

(1) In the present treatment, entropy changes in the dissociation of the conjugate acids are assumed to be constant for the three states of this series of compounds.

(2) The measured pK_a values are for the phosphorescent states. The charge densities to be used in plotting, therefore, should be calculated for the same states. The charge densities in the triplet state calculated by the present method are not precisely equal to those for the phosphorescent state, since the excited molecular orbitals are determined on the basis of the ground-state energy minimization. In order to improve this situation, we tried computations using Roothaan's open-shell procedure based on the minimization of the triplet-state energy.[24] Unfortunately, we were not successful in using it. In the large molecules such as we treated here, the MO energies were very close to each other, and at each stage of iteration an exchange of the MO levels occurred, resulting in no convergence of the charge densities.

Finally, it can be said that a linear relationship between the pK_a values and the net charge (or charge densities) is obtained both experimentally and theoretically in the ground and excited states.

The authors wish to thank Dr. Etsuro Ohta of Gunma University for giving them the phenanthrylamines.

Radiotracer Studies on Adsorption of Surface Active Substance at Aqueous Surface. IV. Direct Measurement of Adsorption of Tritiated Nonionic Surfactant

Kazuo TAJIMA, Makio IWAHASHI, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received May 13, 1971)

The radio- and surface-chemically pure nonionic surfactant, $C_{10}H_{21}(CHT)_2O(C_2H_4O)_6H$, was synthesized, and surface tension and adsorbed amount of its aqueous solution were measured directly at the air-solution interface at 30°C. Surface tension was measured by the drop-volume and Wilhelmy plate methods, while adsorbed amount was measured by the radiotracer method. The adsorption isotherm showed saturation values of 2.73×10^{-10} mol/cm^2 above the concentration of about 1/5 of the critical micelle concentration. The observed amount of adsorption was in good agreement with the values calculated from surface tension data measured by the Wilhelmy plate method by applying the Gibbs adsorption isotherm for a single solute system. The time dependence of surface tension of surfactant solution was further discussed, and the inherent time dependence was shown for pure surfactant solution.

Although the surface and bulk properties of the aqueous solution of nonionic surfactant have been studied by many investigators,[1-3] most of them have referred to surfactants of wide homologous distribution. As has been pointed out in a previous paper on adsorption of ionic surfactant,[4] the exact knowledge of adsorption is very important for understanding various phenomena at the air-solution interface. If the radiotracer method using tritiated nonionic surfactant is adopted, the adsorption on aqueous surface can be measured with high accuracy as in the case of ionic surfactant.[5]

In the present paper, tritiated hexaoxyethylenedodecyl ether (3,6,9,12,15,18-hexaoxa-1-triacontanol-19,20-^3H,^3H,; TD(EO)$_6$) was synthesized, and the adsorbed amounts were measured directly at the surface of its aqueous solution by the radiotracer method. The time dependence of the surface tension of this solution was further measured, and the drop-volume and Wilhelmy plate methods were compared with regard to the reliable surface tension value applicable for the Gibbs adsorption isotherm.

Experimental

Materials. TD(EO)$_6$ was synthesized according to the following schema, the details of which will be reported elsewhere.[6] First, tritiated dodecanol (I) was synthesized by the tritiation of dodecenol,[7] and its chemical and radiochemical purities were checked. By the bromination of (I) with hydrogen bromide, tritiated dodecyl bromide was obtained. The product was condensed with trioxyethylene monoalcoholate (II) in the nitrogen atmosphere at about 200°C. The condensation product was extracted with ether and the extract was distilled at 187°C/2 mmHg to give tritiated trioxyethylenedodecyl monoether (III). After chlorination of (III) with thionyl chloride, the product was again reacted with (II) to form TD(EO)$_6$. The crude TD(EO)$_6$ was purified by distillation to remove as completely as possible the lower boiling substances up to about 200°C/2 mmHg. Then the residue was recrystallized repeatedly from absolute hexane at 5—7°C and finally by the chromatography on neutral alumina using mixed solvent of acetone : benzene : methanol in 25 : 24 : 1 volume ratio. Both melting point (25.1°C) and refractive index (n_D^{40} 1.4480) agreed with the published values of 24.9°C and 1.4479, respectively.[8] The surface chemical purity of TD(EO)$_6$ obtained was confirmed by the critical micelle concentration (CMC) determined from a sharp break point of the surface tension *vs.* concentration curve being in agreement with literature value.[9] Water was triply distillated using borosilicate glass apparatus, after being refluxed overnight with the mixture of sulfuric acid and potassium permanganate.

Method and Procedures. The method and apparatus for the measurements of adsorption by a radiotracer technique were previously described in details.[5] The total radioactivity, A_1, on the surface of TD(EO)$_6$ solution which had attained the surface tension equilibrium, and the bulk radioactivity from the interrior of solution, A_2, were measured by a sheet scintillation counter. Radioactivity due to the adsorbed molecules, A_1-A_2, was multiplied by a conversion factor to obtain the amount of adsorption.[5] The surface tension of solution was measured by the drop-volume and Wilhelmy plate methods. In the former method, time required to form each drop was about 5 min. In the latter method, the change of surface tension was automatically recorded up to 24 hr. All measurements were carried out in the atmosphere of saturated humidities in order to prevent the evaporation from the surface of solution. The surface tension of pure water remained constant within the error of ±0.5 dyn/cm for 24 hr. The temperature was maintained at 30 ± 0.2°C.

Results and Discussion

Stability of Aqueous Solution of TD(EO)$_6$. It is well known[10] that the ionic surfactant, for instance

sodium tetradecyl sulfate (STS), is readily hydrolyzed in aqueous solution, which has been stocked over 24 hr at room temperature. On the contrary, it is expected that the nonionic surfactants such as polyoxyethylene (EO) alkyl ether consisting of ether bonds, might be more stable in aqueous solution than surfactants having ester bonding like STS. We examined the stability of the aqueous solution of these substances by tracing the time dependence of the surface tension. The results are shown in Fig. 1. The measurements were made for four aqueous solutions of STS and $TD(EO)_6$, successively taken from the respective stock solutions at proper time intervals. In the case of STS, surface tension exhibited a nearly same initial value, and it gradually decreased during the period of 24 hr tending to run along a common broken line, showing no tendency to arrive at equilibrium. The slow decrease of surface tension expressed by the broken line is the indication of hydrolysis taking place in the bulk of the stock solution. On the contrary, surface tension of $TD(EO)_6$ solutions reached to the identical final value after about 24 hr, and the value remained constant even after 17 days. The molecules of $TD(EO)_6$ are chemically stable in aqueous solution which may be stored unchanged for about two weeks at least.

Surface Tension Measurements. Figure 2 shows the typical examples of a time dependence of surface tension for $TD(EO)_6$ solution, where γ shows the equilibrium surface tension. Equilibrium surface tension thus obtained is plotted against the concentration in Fig. 3. The values measured by the drop-volume method are also shown in the same figure for comparison. The surface tension data obtained by the drop-volume method are considerably higher than those by the Wilhelmy plate method. This is due to the slow decrease of surface tension with time, which is pronounced in the dilute solutions. This time dependence also makes the measurement of equilibrium surface tension difficult especially by the drop-volume method. The critical micelle concentration measured by the drop-volume method, CMC′= 8.3×10^{-5} mol/l, is shifted to the higher concentration than that by the Wilhelmy plate method, CMC= 5.2×10^{-5} mol/l. Since the CMC value obtained by the Wilhelmy plate method is more reliable, above discrepancy indicates the fact that the relaxation of surface tension up to about 1 hr is observed even above the CMC up to the concentration of 8.3×10^{-5} mol/l. Since $TD(EO)_6$ exhibits considerable surface activity and considerably lower CMC than STS, a marked time dependence can be expected not only for the solution below the CMC, but also for the solution slightly above the CMC. The latter case may be due to the adsorbing surfactant molecules not being supplied instantaneously from the micelles.

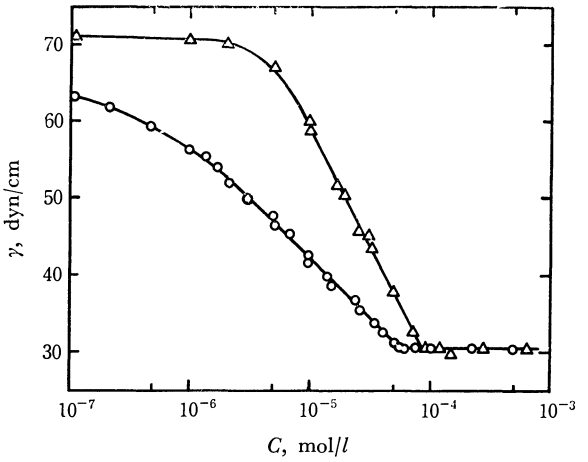

Fig. 3. Surface tension *vs.* concentration of $TD(EO)_6$ solution at 30°C.
○: Wilhelmy plate method
△: drop-volume method

Adsorption Measurement. The adsorption isotherm obtained is shown in Fig. 4. It is found that there is a range of constant adsorption $(2.73\times10^{-10}$ mol/cm^2) above the concentration of about 1/5 of the

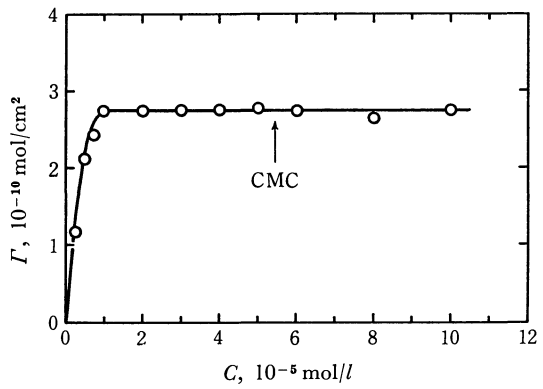

Fig. 4. Adsorption isotherm of $TD(EO)_6$ solution at the air-solution interface at 30°C.

CMC similar to the adsorption isotherm of ionic surfactant with[11] and without[5] salt.

The cross-sectional area per molecule is 60.8 Å^2 in a region of saturated adsorption as shown in Fig. 4. From this value, it is possible to deduce some knowledge concerning the hydrophilic group in the state of adsorption. If the EO groups of the surfactant are in the state of random coil, the relation between the cross-sectional area, S, and the number of EO groups, n, of the molecule is expressed by $S=\pi a^2 n^{2/3}$, where a is a radius of an EO group coil, assumed to be spherical. From the values of $S=60.8$ Å^2 and $n=6$, a cross-sectional area, πa^2, of ethylene glycol group of dodecyl ether is calculated as 18.4 Å^2. This value is very close to the limiting area per molecule, 19.5 Å^2, of ethylene glycol monooctadecyl ether spread at the air-water interface.[12] This confirms the view that the hydophilic groups of polyoxyethylenedodecyl ether are practically in the form of random spherical coils in the adsorbed state. From the measurements of hydration for nonionic surfactant possessing long polyoxyethylene groups, Schott[13] also considered them to be in the form of random coils surrounding the hydrocarbon core of the micelle. Thus, it seems that the EO groups are in a similar state of random coil of close mutual contact both in the state of micelle in the solution and in the state of saturated adsorption at the air-solution interface.

Gibbs Adsorption Isotherm. The experimental confirmation of the Gibbs adsorption isotherm has already been made for aqueous solution of ionic surfactant.[4,5,11] However, in applying the Gibbs isotherm to the solution of ionic surfactant, we have made some non-thermodynamical assumptions such as no hydrolysis in the bulk and surface phases, and the electrical neutrality at the surface for adsorbed species. However, since the aqueous solution of nonionic surfactant does not require such non-thermodynamical assumptions, it seems a most favorable system for applying the Gibbs adsorption isotherm.

The Gibbs adsorption isotherm, for a solution of single solute without any bulk hydrolyses, is expressed as follows;

$$-d\gamma = \Gamma RT\, d\ln C \qquad (1)$$

where γ denotes the equilibrium surface tension, Γ, surface excess and C, concentration of solute. Since the concentration of surfactant used is less than 10^{-4} mol/l, the term of activity coefficient may safely be considered as unity. The adsorbed amounts, calculated from the data of Fig. 3 by applying Eq. (1), are shown by solid lines A and B in Fig. 5. The results calculated from data of surface tension (drop-volume method) *vs.* concentration, measured with the same surfactant by Corkill *et al.*[9] were also shown in the same figure, for comparison. It was seen that the values observed by a radiotracer method are in good agreement with those calculated from the data of the Wilhelmy plate method and not with those from the drop-volume method. Although the values of C and D, which were calculated from the carefully measured data of Corkill *et al.*, are closer to the observed value than that of A, still they are distinctly higher than the observed value. The mean value of C and D, 3.25×10^{-10} mol/cm^2, considered as the value at 30°C, is about 20% higher than the observed value. Therefore, disagreement of the values obtained from the drop-volume method can be ascribed to the application of non-equilibrium surface tension to the Gibbs adsorption isotherm. The deviation of calculated (Wilhelmy) and observed values in concentration below 1×10^{-5} mol/l in Fig. 5, although slight, may be due to the uncertainties for the measurements, of surface tension in extremely low concentration, even for a prolonged measurement of time dependence of surface tension by the Wilhelmy plate method.

A satisfactory agreement between calculated and observed values indicates the validity of the Gibbs adsorption isotherm in the case of ionic surfactant solution.[4,5,11] However, it is important to apply sur-

face tension values completely in equilibrium, which should be appreciated especially when the time dependence is marked as in the case of polymer surfactant. Also, it should be emphasized that surface tension often deviates largely from the equilibrium value according to the method of measurement as shown in Fig. 3.

Time Dependence of Surface Tension of Surfactant Solution. Corkill *et al.*[9] reported that, with the solution of same surfactant as in the present studies, the equilibrium surface tension is reached almost instantaneously at concentration below the CMC. Razouk and Mysels,[14] in the experiments on film elasticity and surface relaxation, noted reduced increases in the equilibrium surface tension after extensive purification of sodium dodecyl sulfate by foaming, but could not eliminate observed relaxation times of up to 10 min duration. They considered that the relaxation suggested the last traces of impurity not being removed from the system even after the purification by foaming.

In contrast to these statements, slow decrease of the surface tension of pure aqueous surfactant solution has been reported with regard to the solution of hexaoxyethylenedecyl ether,[15] or hexaoxyethylenehexadecyl ether.[16] Also, in the present study, a remarkable time dependence was observed as shown in Fig. 2. Now, there are many reasons to believe that the surface relaxation or the surface tension aging of surfactant solution appears not only in the surfactant solution containing the surface-active impurity, but also in the solution of pure surfactant.

According to the Gibbs adsorption isotherm applied for the solution containing several independent solutes, Eq. (1) gives the total amounts of adsorption of these solutes.[17] Therefore, the calculated amount of adsorption shown as solid line B in Fig. 5 indicates a sum of the amount of adsorption of $TD(EO)_6$ and that of impurities if any. Then, the coincidence of these values with the observed amount of adsorption which corresponds exclusively to radiometrically determined tritium labelled species of $TD(EO)_6$ may be taken as the experimental evidence of the absence of the adsorption of any surface-active impurities. The surface tension decrease with time as shown in Fig. 2 cannot be explained merely by the presence of surface-active impurities as Mysels stated.[18] Further, if the surface relaxation is produced only by the presence of impurity, then the equilibrium surface tension of the solution may not be equal to that of pure surfactant. The "true" surface tension, which the solution of pure surfactant might show, can be obtained by adding the surface tension decrease produced by the impurity to the steady value of surface tension attained after long time, provided that the effect of impurity on the surface tension is additive as Mysels postulated.[18] The surface tension value thus obtained which is practically equal to the surface tension extrapolated to time zero in Fig. 2, is applied to Eq. (1), but adsorbed amount obtained deviated even more largely from the observed value than that calculated from the value of drop-volume method. Therefore, additive effect of impurity on the surface tension is not sufficient to elucidate the time effect.

The explanation of relaxation of surface tension by the existance of impurity cannot exclude the possibility of an inherent time effect attributable to the pure aqueous surfactant solution. In fact, we cannot find any report which distinctly shows the surface tension of aqueous surfactant completely independent of time for all concentrations. On the contrary, many investigators rather believe the inherent relaxation in surface tension of aqueous surfactant solutions, and have proposed several empirical formula expressing surface tension *vs.* time relation or giving equilibrium surface tension by the extrapolation of time to infinity.[19]

Thus, it is certain that aging of surface tension does occur even in aqueous surfactant solution of sufficient purity to show a negligible amount of impurity adsorption.

Infrared Spectra and Lattice Vibrations of $Li_2SO_4 \cdot H_2O$[1]

Shunsuke MESHITSUKA, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo

(Received May 19, 1971)

Infrared spectra of $Li_2SO_4 \cdot H_2O$ and $Li_2SO_4 \cdot D_2O$ have been measured from 4000 to 30 cm^{-1} at room temperature and liquid-nitrogen temperature. Librational bands of the water of crystallization have been observed and the modes of libration are discussed. The normal coordinate analysis of the crystal as a whole has been performed and the observed bands are interpreted. Translational bands of H_2O and librational bands of SO_4 are also discussed.

The present report deals with a study by infrared spectroscopy and the normal coordinate calculation concerning the vibrations of $Li_2SO_4 \cdot H_2O$ and $Li_2SO_4 \cdot D_2O$ crystals. The investigation was undertaken because of interesting features of the crystals. NMR spectra suggest that the water of crystallization performs a flipping motion around the molecular symmetry axis. There are two different positions for Li ions in a unit cell, one being located close to the water of crystallization and the other tetrahedrally surrounded by the oxygen atoms of the sulfate ions. Some changes in the infrared spectra might take place by variation of temperature on account of this flipping motion of the water of crystallization, and the effect of the environmental difference of the two Li ions might be observed in the infrared spectra.

By the use of X-ray diffraction,[2-4] neutron diffraction[5,6] and NMR spectroscopy,[7-10] several investigators have studied the crystal structure of $Li_2SO_4 \cdot H_2O$ and $Li_2SO_4 \cdot D_2O$, with particular attention to the orientation of the water molecule. Ketudat and Pound concluded from the quadrupole splitting of the deuterium resonance of $Li_2SO_4 \cdot D_2O$ that at room temperature, the water molecule undergoes hindered rotation about the bisector of the D–O–D angle with frequency greater than that of quadrupole interaction.[11] The same conclusion has been reached by other investigators.[12-14] This view is consistent with the large root mean square amplitude of the vibration of the hydrogen atoms observed in the recent neutron diffraction study.[6]

There are only a few works on the infrared[15,16] or Raman spectra[17] of these compounds. The intramolecular vibrations of the SO_4 ion and also the librations of the water molecule have been analyzed to some extent. However, because of the lack of measurements at low temperature the analysis remains still uncertain. There has been no study on the far infrared spectra below 350 cm^{-1}.

Neutron inelastic scattering studies of these compounds have been made by several workers.[18,19] Bajorek *et al.* have observed librational frequencies as well as translational lattice vibrations of the water molecule.[20]

Experimental and Observed Spectra

$Li_2SO_4 \cdot H_2O$ of a special grade (Wako Pure Chemical Industries, Ltd.) was used without further purification.

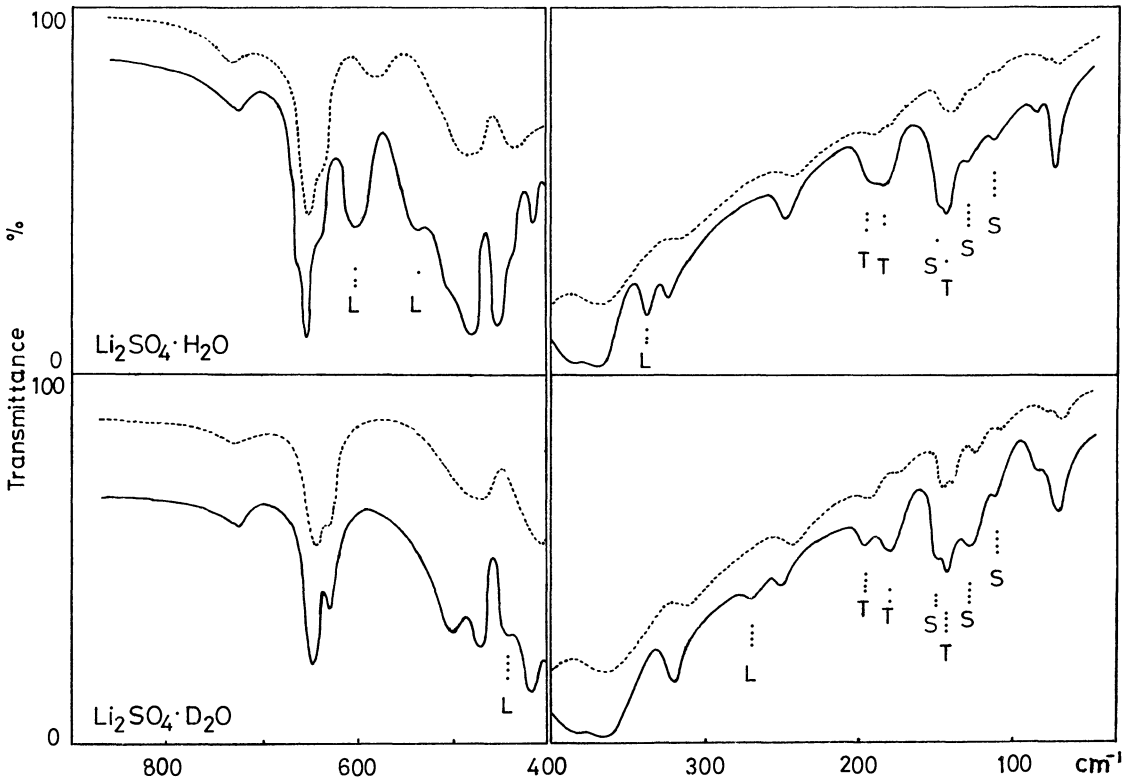

Fig. 2. Infrared spectra of $Li_2SO_4 \cdot H_2O$ and $Li_2SO_4 \cdot D_2O$ in Nujol, ····· 300°K, —— 110°K.
L, T, and S denote a librational band of H_2O, a translational band of H_2O and a librational band of SO_4 respectively.

An infrared spectrophotometer Hitachi EPI-G3 (4000—400 cm^{-1}) and a far infrared spectrophotometer Hitachi FIS-3 (400—30 cm^{-1}) were used. Each measurement was carried out at room temperature and also at liquid nitrogen temperature. The deuterated samples were prepared by gradual recrystallization from a heavy water solution of the anhydrous compound. Although a small amount of light water still remained in the deuterated sample, the heavy water content was sufficiently large for the assignment of infrared bands of $Li_2SO_4 \cdot D_2O$. The observed infrared spectra are shown in Figs. 1-3. By lowering the temperature, all the bands become sharp and intense. At the same time, the bands except for those due to intra-molecular vibrations shift to higher frequencies.

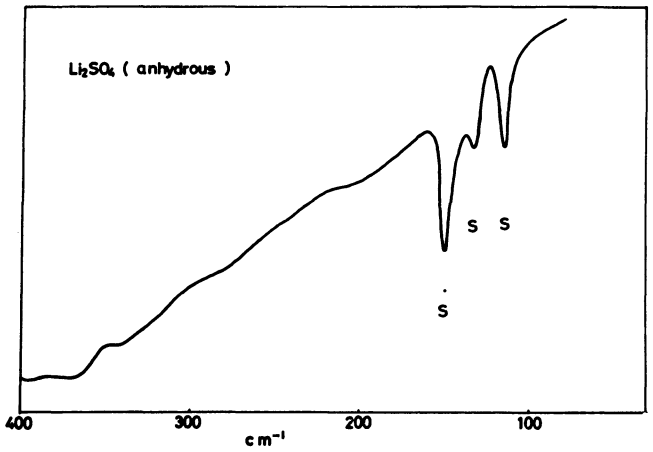

Fig. 3. Infrared spectrum of anhydrous Li_2SO_4 in Nujol at room temperature.
S denotes a librational band of SO_4.

Normal Coordinate Analysis

The crystal structure of $Li_2SO_4 \cdot H_2O$ is $P2_1$–C_2^2 and the crystal parameters are a=5.4537 Å, b=4.8570 Å, c=8.1734 Å, and β=107°22′.[6] A Bravais unit cell contains two $Li_2SO_4 \cdot H_2O$ unit. The optically active lattice vibrations as well as the intra-molecular vibrations were calculated according to the method developed by Shimanouchi *et al.*[21]

A Urey-Bradley type force field was applied to the H_2O molecule and SO_4 ion, and a valence force type potential was used for the interactions within a distance of 3.0 Å between H_2O molecule and SO_4 and Li ions. The bound state of the crystalline water in $Li_2SO_4 \cdot H_2O$ has some characteristic features. The hydrogen atoms of H_2O molecule make hydrogen bondings: one with another water and the other with the oxygen atom of the sulfate ion. One of the lone pairs of the oxygen atom of the water molecule directs toward the Li ion. The other is in the direction toward a hydrogen atom of another H_2O molecule to make a hydrogen bonding. Thus the H_2O molecules constitute a zigzag chain in the crystal by hydrogen bondings.

The potential around the H_2O molecule was assumed to be as shown in Fig. 5 by analogy with the H_2O molecule in ice.[22] In the course of the calculation the interaction coordinates around the H_2O

22) Y. Kyogoku, *Nippon Kagaku Zasshi*, **81**, 1648(1960).

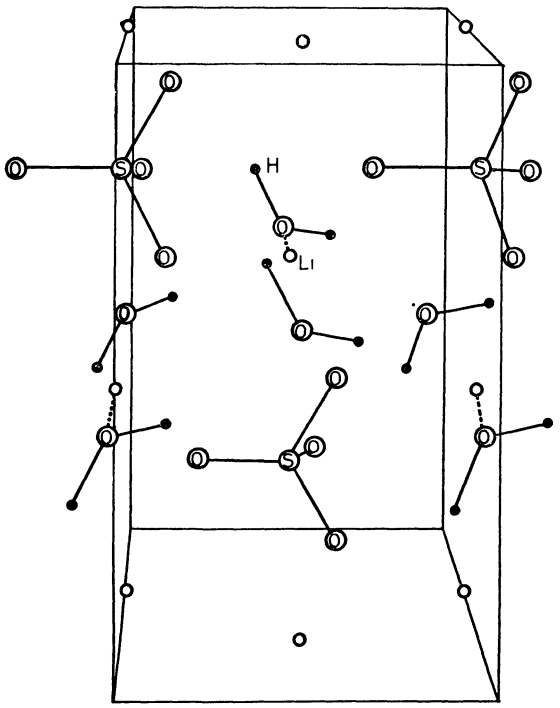

Fig. 4. Crystal structure of $Li_2SO_4 \cdot H_2O$.

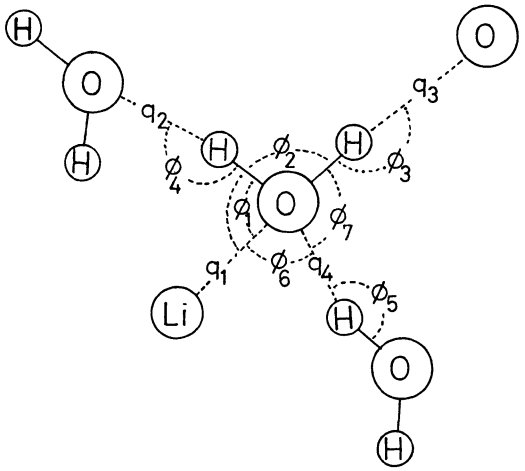

Fig. 5. Coordinates around a H_2O molecule.

molecule are simplified, and Δq(Li···O), Δq(O···H), $\Delta\phi$(Li···O–H), $\Delta\phi$(O–H···O), and $\Delta\phi$(O···Li···O) are used from the following consideration. The coordinate $\Delta\phi$(H–O···H), which is the interaction between the two H_2O molecules in a unit cell, serves to enlarge the frequency splittings between A and B symmetry species. The A and B species, however, are not observed separately so this coordinate is excluded. Further, the coordinate $\Delta\phi$(Li···O···H) is omitted, because this has little effect on the librational frequencies and on the other lattice vibrations. Consequently the potential function in the crystal is expressed as

$$V = V_{intra} + \tfrac{1}{2}\sum_{ij} K_i^1(\Delta q_{ij}(\text{Li}\cdots\text{O}))^2 + \tfrac{1}{2}\sum_{ij} K_i^2(\Delta q_{ij}(\text{O}\cdots\text{H}))^2 + \tfrac{1}{2}\sum_{ij} H_i^1(\Delta\phi_{ij}(\text{Li}\cdots\text{O–H}))^2 + \tfrac{1}{2}\sum_{ij} H_i^2(\Delta\phi_{ij}(\text{O–H}\cdots\text{O}))^2 + \tfrac{1}{2}\sum_{ij} H_i^3(\Delta\phi_{ij}(\text{O}\cdots\text{Li}\cdots\text{O}))^2$$

where V_{intra} denotes the intra-molecular potentials of SO_4 ion and H_2O molecule. K_i^1, K_i^2, H_i^1, H_i^2, and H_i^3 represent the force constants corresponding to the coordinates Δq(Li···O), Δq(O···H), $\Delta\phi$···(Li···O–H), $\Delta\phi$(O–H···O) and $\Delta\phi$(O···Li···O), respectively. The sum was taken over all kinds of internal coordinates i, and all the internal coordinates j for each kind of i in a Bravais unit cell.

Results and Discussion

Intra-molecular Vibrations. Since the site symmetry of sulfate ion in the crystal is C_1, ν_1 becomes infrared active, ν_2 splits into two bands, and ν_3 and ν_4 both split into three bands.[23] The observed spectra are in good agreement with the predictions: ν_1 (1010 cm^{-1}), ν_2 (513 and 478 cm^{-1}), ν_3 (1170, 1155, and 1110 cm^{-1}) and ν_4 (656, 647, and 637 cm^{-1}) at a low temperature. This assignment is also in line with the fact that the frequencies show no frequency shifts on deuteration and little temperature dependence. It is interesting that the splittings of ν_2 and ν_4 become greater on deuteration. The bands at around 1170, 1155, and 1110 cm^{-1} are as strong as other sulfates, and so broad that the positions of the peaks are difficult to determine. Although these bands are considered to be due to the splitting of the stretching mode of the sulfate ion belonging to the F_2 symmetry species, such large splittings have not been obtained by the normal coordinate calculation.

H_2O Librational Modes. The behavior of the water in the crystalline lattice is observed directly by the librational bands which have three characteristic features.

1) The bands are observed in the region between 1100 and 200 cm^{-1}.

2) These frequencies become approximately $1/\sqrt{2}$ on deuteration.

3) The intensities of the bands are very sensitive to temperature change.

Thus the three bands at 600, 533, and 338 cm^{-1} at low temperature are assigned to the librational bands of the water of crystallization in $Li_2SO_4 \cdot H_2O$ crystal. The bands at 600 and 338 cm^{-1} shift respectively to 440 and 269 cm^{-1} on deuteration. The deuterated band corresponding to 533 cm^{-1}, however, seems to be buried under the strong and broad bands at 387 and 372 cm^{-1} of the Li ion. The frequency ratios are 1.35 and 1.26 respectively. Janik *et al.* have observed a band at 835 cm^{-1} and assigned it to a libration of the water molecule.[16] However, we have observed no bands near that frequency.

The librational bands of water of crystallization have been observed in many compounds, but it is difficult to determine the modes of the librational motions experimentally. A normal coordinate analysis is useful for elucidating the behavior of the water molecule in a crystalline lattice.[24-26] The eigen vector (***Lx***) matrix set up by the Cartesian coordinate method shows the displacements of the atoms which correspond to each normal mode. It is seen from this ***Lx*** matrix that the band at 600 cm^{-1} is the rocking mode and the other two bands are mixtures of the wagging and twisting modes. As the values of ***Lx*** depend on the potential field around the water molecule, the interaction coordinates around the water molecule are chosen as thoroughly as possible. The bands at 533 and 338 cm^{-1} can not be observed distinctly until the sample is cooled to liquid nitrogen temperature. This suggests that the bands corresponding to the wagging and twisting motions become diffuse at ordinary temperature as a result of the 180° flipping motion of the water molecule.

H_2O Translational Modes. As the intensities of the bands at 196, 180, and 143 cm^{-1} are very sensitive to temperature change and the frequency shifts are small on deuteration, the bands are assigned to translational lattice vibrations in which water mole-

	143	141	164

cule moves dominantly. Corresponding to these bands, 235, 186, and 164 cm^{-1} were observed by neutron inelastic scattering.[20]

Bands due to Li Ion. The nature of the metal $\cdots OH_2$ bonds in aquo-complexes has been studied by Nakagawa, and it is proposed that both ionic and covalent characters are involved in the bonds.[24] In this study the band at 432 cm^{-1} is assigned to the $Li\cdots OH_2$ stretching because the frequency shift is small on deuteration and is as sensitive as other lattice vibrations to temperature change. The $Li\cdots OH_2$ stretching force constant (0.40 mdyn/Å) together with the distance (1.91 Å) indicates that this bond may have a considerable covalent character.

The broad and intense bands at 387 and 372 cm^{-1} and the weak bands at 325 and 249 cm^{-1} were assigned to bands due to the Li ion for the following reasons. These bands do not change on deuteration and are less dependent upon temperature than those due to H_2O lattice vibrations. It is strange that the bands at 325 and 249 cm^{-1} are much weaker than those at 387 and 372 cm^{-1}. However, they cannot be explained by combination bands or difference bands. Thus they are assumed to be $O\cdots Li\cdots O$ bending.

SO_4 Librational Modes. The spectrum of the anhydrous sample shows that the bands at 150, 133, and 105 cm^{-1} are markedly sharp and the frequencies correspond to 147, 138, and 113 cm^{-1} respectively in the spectrum of the hydrate. The bands have therefore been assigned to the librational modes of the sulfate ion. It is worthy of notice that the librational frequencies of the sulfate ion have little dependence on the existence of the water of crystallization. The same phenomena have been observed in other compounds in our laboratory. From these considerations the assignment of the vibrations of $Li_2SO_4 \cdot H_2O$ and $Li_2SO_4 \cdot D_2O$ crystals were made as shown in Tables 2 and 3.

The authors wish to express their gratitude to the members of Shimanouchi Laboratory, the University of Tokyo, for use of the computer programs. Thanks are also due to Professor I. Nakagawa, the University of Tokyo, for his helpful suggestions.

Adsorption and Decomposition of Formic Acid Adsorbed on Pyrolyzed Polyacrylonitrile

Yutaka KUBOKAWA, Hisashi MIYATA, and Yoshihiko UEGAKI*

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka

(Received May 21, 1971)

Infrared spectra of various pyrolyzed polyacrylonitrile and of deuterated formic acids (HCOOD, DCOOH, and DCOOD) adsorbed on it were investigated. The effect of pyrolysis temperature upon the decomposition products of formic acid adsorbed on the polymer was studied. It was found that parallelism exists between the concentration of the conjugated nitrile group and the percentage of the decomposition of formic acid adsorbed, leading to the conclusion that the active sites for the decomposition reaction are associated with the conjugated nitrile group in the case of polyacrylonitrile pyrolyzed below 300°C. On the other hand, there was a close correlation between the activity for decomposition and the number of free spins in the polymer pyrolyzed above 350°C.

Since various polymers are used as organic semiconductors, their catalytic activities have been investigated by a number of workers. Manassen and his co-workers[1,2] studied the dehydrogenation reactions catalyzed by pyrolyzed polyacrylonitrile and other polymers with defined structures, and concluded that the quinoid rings in the polymer structure are essential for the dehydrogenation reaction.

However, no detailed study has been carried out on the interaction of the reactants with the polymer under the reaction condition. Information on such interaction seems to be necessary in order to clarify the mechanism of the catalytic reactions on the poly-

* Present address: Industrial Products Research Institute, Shimomaruko, Otaku, Tokyo.

mer. In the present work, therefore, infrared spectra of formic acid adsorbed on pyrolyzed polyacrylonitrile and also the spectral changes during the decomposition of formic acid have been investigated. From the results, the catalytic activity of pyrolyzed polyacrylonitrile has been discussed.

Experimental

Materials. Freshly distilled acrylonitrile was dissolved in water and stirred vigorously at 65°C under nitrogen while azobisisobutyronitrile was added. The white polymer thus formed was dissolved in dimethylformamide. By flowing the solution and vaporizing the solvent, a thin film was obtained. The film was cut down to 15×20 mm (about 20 mg), placed in a flame of Pyrex glass and pyrolyzed at 100–400°C in an infrared cell under evacuation. For the catalysts used in the study of the adsorption and decomposition of formic acid, the white polymer was pyrolyzed under evacuation for 3 hr at 150–500°C, the resulting polymer being powdered in a mortar.

Formic acid (Nihon Shiyaku Co. G. R.) was dehydrated by crystallization and vacuum-distilled in the presence of anhydrous copper sulfate. DCOOD (Merck) was used without further purification. DCOOH and HCOOD were prepared by the exchange of DCOOD with H_2O, and of HCOOH with D_2O, respectively.

Apparatus and Procedure. For studies of adsorption and decomposition a conventional constant volume apparatus was used. After the adsorption of formic acid vapor at room temperature, the trap attached to the reaction vessel was immersed in a dry ice-acetone mixture. Decomposition of formic acid adsorbed on the polymer was investigated by measuring the pressure increase due to decomposition. The decomposition products were hydrogen, carbon dioxide and carbon monoxide, being uncondensable at −78°C. After the experiment at room temperature, the temperature of the catalyst was raised in steps, and similar experiments were carried out. Activation energies of decomposition were determined[3,4] by comparison of the rates of decomposition at different temperatures corresponding to the same amount adsorbed. The amount of formic acid desorbed during the decomposition reaction was determined by the pressure increase which took place when the cold trap was warmed to room temperature after the reaction. Analysis of the decomposition products was carried out by gas chromatography using a 2 m silica gel column at 65°C. The isotopic abundance of H_2, HD, and D_2 was determined by a Hitachi RMU-5 mass spectrometer.

The cell used for the infrared spectroscopy of adsorption layer is similar to that used by Peri[5]. All spectra were recorded on a Hitachi EPI-S2 spectrophotometer with a NaCl prism.

Pyrolyzed polyacrylonitrile (about 10 mg) was placed in a quartz tube, evacuated at 100°C, sealed off, and the spectra were recorded on a Nihon Denshi ESR spectrometer 3BX.

Results and Discussion

Pyrolysis of Polyacrylonitrile. Figure 1 shows the infrared spectra of polyacrylonitrile pyrolyzed at various temperatures. On pyrolysis at 150°C in the region above 1800 cm^{-1}, two sharp bands appeared at about 3000 and 2235 cm^{-1}. With the rise of pyrolysis temperature the band at 3000 cm^{-1} bacame broad and increased in intensity, while the band at 2235 cm^{-1} decreased in intensity. Simultaneously, a sharp band at 2195 cm^{-1} appeared at 200°C, but disappeared completely on raising the temperature up to 350°C. Above the pyrolysis temperature 250°C, the spectrum was opaque in the region below 1600 cm^{-1}. The change in the intensities of the bands at 2235 and 2195 cm^{-1} with pyrolysis temperature is shown in Fig. 2.

As regards the pyrolysis of polyacrylonitrile a number of investigations have been carried out. According to Grassie and Hay,[6] Burlant and Parsons,[7]

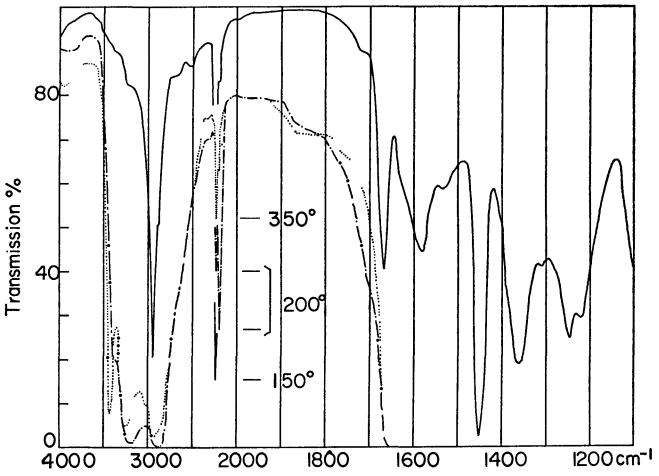

Fig. 1. Infrared spectra of polyacrylonitrile pyrolyzed at 150 (——), 200 (—·—·—), and 350°C (·····).

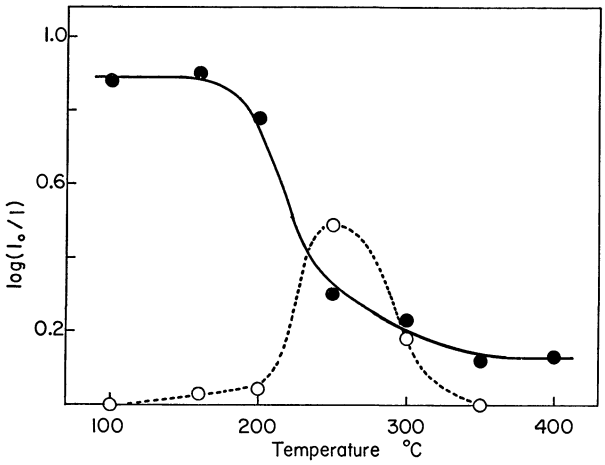

Fig. 2. Change in the band intensities at 2235 (—●—●—) and 2195 cm^{-1} (--○--○--) with pyrolysis temperature.

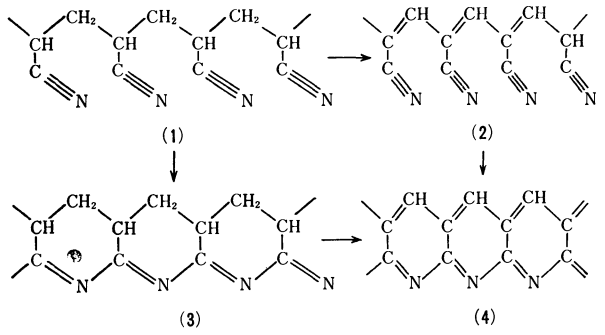
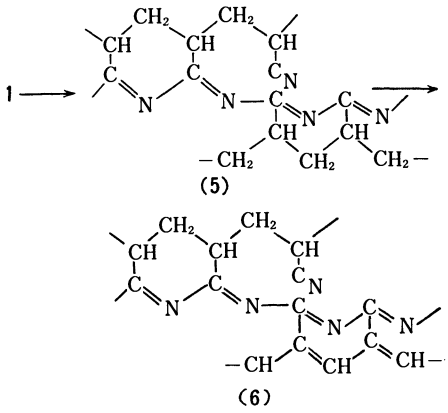
6) N. Grassie and J. N. Hay, *J. Polym. Sci.*, **56**, 189 (1962).

7) W. J. Burlant and J. L. Parsons, *ibid.*, **22**, 249 (1956).

and Conley and Bieron,[8] the pyrolysis proceeds as follows.



Aromatization of polyacrylonitrile occurs through two parallel processes; **1→2→4** and **1→3→4**. Burlant and Parsons[7] have assigned the bands at 2235 and 2195 cm^{-1} to the alkyl nitrile and to the conjugated nitrile groups, respectively. It follows that the variation in the intensities of both bands with pyrolysis temperature corresponds to the change in the concentration of both nitrile groups. In other words, on pyrolysis of polyacrylonitrile the conjugated nitrile group appears at 200°C. Its concentration passes through a maximum at 250°C and then decreases to almost zero above 350°C. On the other hand, the concentration of the alkyl nitrile group decreases monotonously with increasing pyrolysis temperature. It is seen in Fig. 2 that even above 400°C a small amount of the alkyl nitrile group still remains. Such behavior might be explained by taking into acount the occurrence of the following crosslinking reaction.[6]



Infrared Study of Interaction of Formic Acid with Pyrolyzed Polyacrylonitrile. It was found that formic acid was not adsorbed on polyacrylonitrile pyrolyzed below 150°C, where there was no band at 2195 cm^{-1} attributable to the conjugated nitrile group. After the adsorption of formic acid the transmission of the polymer decreased in the range from 3400 to 1000 cm^{-1} and the band at 2195 cm^{-1} decreased in intensity.

In order to characterize the interaction of formic acid with pyrolyzed polyacrylonitrile completely, deuterated formic acids were used in infrared measurements. The results obtained with DCOOH are shown

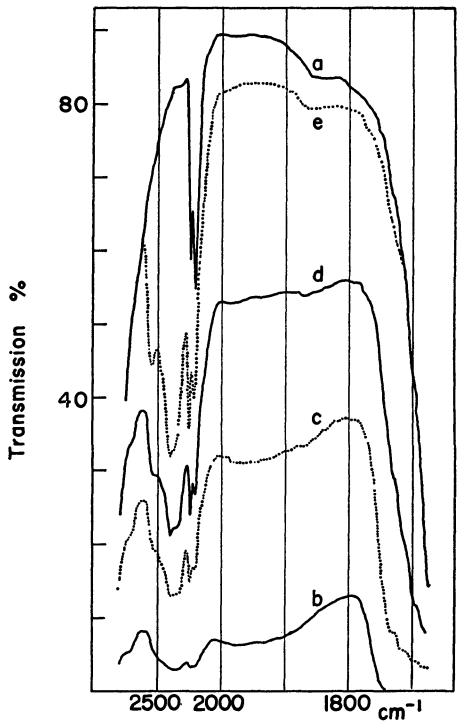

Fig. 4. Infrared spectra of HCOOD adsorbed on polyacrylonitrile pyrolyzed at 240°C.
(a) before adsorption; (b) after adsorption of 9 mmHg HCOOD at 25°C for 2 hr, and removal of gas phase; (c) after evacuation at 120°C for 30 min; (d) at 120°C for 2 hr; (e) at 180°C for 1 hr.

in Fig. 3. We see that a weak band appears at 2100 cm^{-1}. On raising the temperature of the polymer to 120°C, this band shifted to 2070 cm^{-1}, and increased in intensity. It still remained after evacuation for 3 hr at 120°C, and finally disappeared by evacuation at 200°C.

Figure 4 shows the results obtained with the adsorption of HCOOD. The band at 2070 cm^{-1} was not observed. Raising the temperature up to 120°C resulted in a new band at 2380 cm^{-1} having a small shoulder at 2320 cm^{-1} not removed by evacuation at 120°C for 2.5 hr. Even after evacuation at 180°C it still remained, in contrast to the band at 2070 cm^{-1}.

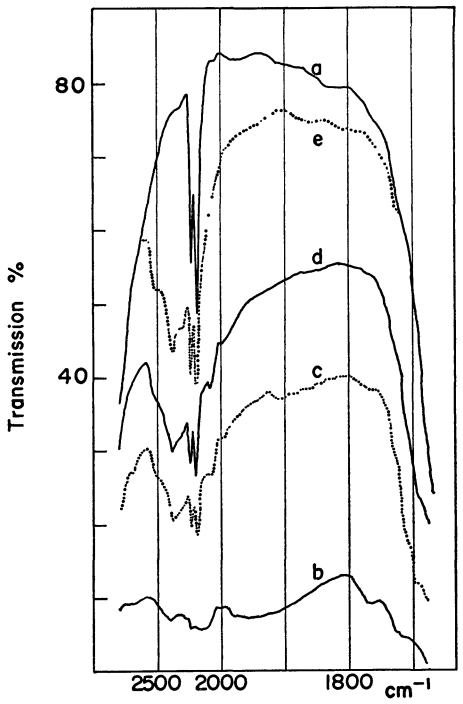

Fig. 5. Infrared spectra of DCOOD adsorbed on polyacrylonitrile pyrolyzed at 240°C.
(a) before adsorption; (b) after adsorption of 6 mmHg DCOOD at 25°C for 2 hr, and removal of gas phase; (c) after evacuation at 120°C for 30 min; (d) at 120°C for 2 hr; (e) at 180°C for 1 hr.

When DCOOD was observed, both bands at 2380 and 2070 cm^{-1} were observed as in Fig. 5. Neither band was removed by evacuation at 120°C, but at 180°C only the band at 2070 cm^{-1} was removed. Such behavior would be expected from the results obtained with DCOOH and HCOOD. Since the bands at 2070 and 2380 cm^{-1} are not observed with undeuterated formic acid, they arise from the interaction of CD and OD groups with the polymer. Considering the fact that pyrolyzed polyacrylonitrile is an efficient hydrogen acceptor as pointed out by Manassen,[1] it is concluded that such an interaction of CD and OD groups involves the D atom transfer to the polymer. Since the frequency of 2070 cm^{-1} belongs to the range of the C–D absorption, it appears that the band at 2070 cm^{-1} originates from the D atom transfer to the C atom in the polymer. Thus, another band at 2380 cm^{-1} can be assigned to the N–D vibration, which was formed by the D atom transfer to the N atom in the polymer.

Decomposition of Formic Acid adsorbed on Polyacrylonitrile pyrolyzed. The temperature of the polymer which had adsorbed a definite amount of formic acid was raised up in steps, at each of which the decomposition of formic acid adsorbed was investigated in the manner described above. Table 1 shows the amounts of formic acid desorbed and those of the decomposition products at various reaction temperatures. It is seen that at lower temperatures the decomposition products consist of carbon dioxide, hydrogen and carbon monoxide, the proportion of carbon dioxide being very large. With the rise of reaction temperature the proportion of hydrogen increases. Such a behavior suggests that at lower temperatures dehydrogenation reaction occurs predominantly, and the hydrogen formed is retained by the polymer. A similar behavior was observed by Manassen in the dehydrogenation of isopropyl alcohol.[1]

The results were obtained with polyacrylonitrile pyrolyzed at 250 and 500°C. The effect of pyrolysis temperature upon the activity of the polymer is shown in Fig. 6. It is seen that decomposition is observed

Table 1. Decomposition of formic acid adsorbed on polyacrylonitrile pyrolyzed at 250 and 500°C

Reaction temp. °C	Amount of HCOOH desorbed ccSTP/g	Activation energy kcal/mol	Total amount of the products ccSTP/g	Distribution of the products (%)		
				CO_2	CO	H_2
(a) pyrolyzed at 250°C						
70	11.5	21.5	1.46	90	1.4	8.6
120	14.7	24.6	5.76	86	2.6	11.4
180	0.58	23.7	4.63	68	2.0	30.0
240	0.00		0.57	70	13.6	17.4

260	1.63		4.76	58	13	29
350	0.00		0.98	6	30	64

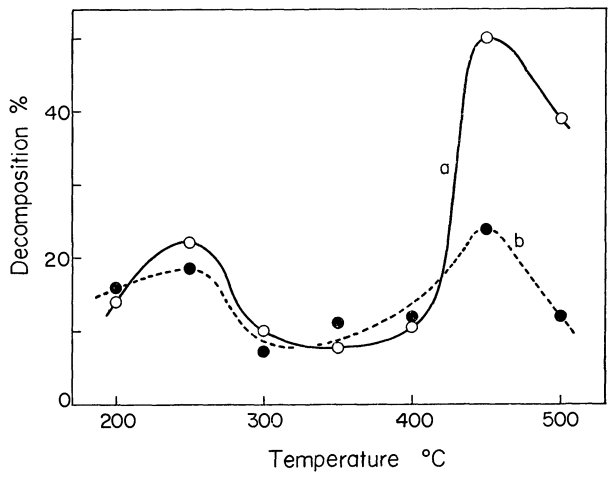

Fig. 6. Effect of pyrolysis temperature upon the activity of the polymer.
(a) 1st experiment (—○—○—), (b) 2nd experiment (--●--●--).

with only polyacrylonitrile pyrolyzed above 200°C. With increasing pyrolysis temperature, the decomposition percent of formic acid increases, showing two maxima at 250 and 450°C. The hydrogen formed during decomposition is retained by the polymer. Its effect upon the activity of the polymer was investigated by repeating the decomposition of formic acid on the same polymer. The results are shown in Fig. 6. The activity is affected slightly or not at all by the retention of hydrogen except for the measurements on the polymer pyrolyzed at higher temperatures.

The results were obtained under conditions where a definite amount (about 40 cc STP/g) of formic acid was introduced and almost all of it was adsorbed on the polymer. Table 2 shows the results for the case where the amount of formic acid introduced was so large that an appreciable amount of formic acid remained in the gas phase (formic acid pressure *ca.* 17 mmHg). It is seen that distributions of the products are almost the same in both cases, although at a reaction temperature above 350°C, the extent to which formation of carbon monoxide occurs is higher in the case when the amount of formic acid adsorbed was 151 cc.

Table 2. Decomposition on formic acid adsorbed in the case of the initial amount of formic acid adsorbed 151.0 ccSTP/g[a)]

Reaction temp. °C	Amount of HCOOH desorbed ccSTP/g	Total amount of the products ccSTP/g	Distribution of the products (%)		
			CO_2	CO	H_2
72	87.9	4.9	95	5	0
130	4.0	14.9	94	6	0
172	5.2	19.1	78	22	0
245	0.1	5.6	42	47	11
340	9.4	6.0	14	58	28

a) Polyacrylonitrile pyrolyzed at 350°C was used.

Hydrogenation and Dehydrogenation of Polyacrylonitrile During the Decomposition of Formic Acid. A comparison of the results in Figs. 2 and 6 shows that there is a parallelism between the concentration of the conjugated nitrile group and the percentage of the decomposition of formic acid adsorbed. Considering that adsorption and decomposition of formic acid take place only on the polyacrylonitrile with the conjugated nitrile group, it is concluded that the active sites for the decomposition of formic acid are associated with the conjugated nitrile group in the case of polyacrylonitrile pyrolyzed below 350°C.

It is concluded that the adsorption of formic acid involves an interaction between the hydroxyl group of formic acid and the conjugated nitrile group in the polymer, leading to the formation of the N–H bond in the temperature range above 120°C.

In addition to the N–H bond formation, the C–H bond formation occurs during the decomposition of formic acid. At present details of the C–H bond formation are not clear. As seen in Table 1, the hydrogen content in the decomposition products increases with increasing reaction temperature, suggesting that the desorption of hydrogen from the polymer takes place. In other words, the polymer hydrogenated during the decomposition of formic acid is dehydrogenated in the higher temperature range. In order to obtain information on the mechanism of dehydrogenation, the decomposition of deuterated formic acid was investigated. On polyacrylonitrile pyrolyzed at 250°C, the isotopic distribution of hydrogen is shown in Table 3. It is seen that considerable quantities of H_2 are produced in the case of DCOOD decomposition. This suggests that some portion of hydrogen desorbed does not originate from formic acid. However, taking into account the fact that the most abundant species is H_2 in the case of HCOOD, while HD in the cases of DCOOH and DCOOD, it may be concluded that a substantial fraction of hydrogen desorbed results from the combination of two hydrogen atoms, one from the CH group of formic acid and the other from the polymer.

Table 3. Isotopic distribution of hydrogen

Reaction temp. °C		Distribution of isotopic hydrogen (%)		
		HCOOD	DCOOD	DCOOH
180	H_2	84	32	9
	HD	16	59	84
	D_2	0	9	7
240	H_2	87	10	19
	HD	13	78	75
	D_2	0	12	6

The activity of the polymer for the decomposition of formic acid should decrease after the reaction, since the nitrile group in the polymer is converted into the NH group after the decomposition reaction. As shown in Fig. 6, however, such a decrease in activity is hardly observed. Such behavior may be explained by assuming that the number of nitrile groups consumed by the reaction is very small compared to the total

TABLE 4. INITIAL RATE OF DECOMPOSITION OF FORMIC ACID

Deuterated formic acid	Initial rate at 120°C (CO_2 formation) mm Hg/min	Ratio
HCOOD	0.482	4.1
DCOOH	0.326	2.8
DCOOD	0.117	1.0

number of nitrile groups available for the reaction. In fact, the amount of formic acid adsorbed on the polymer, 40 ccSTP/g, is very large compared to the amount adsorbed expected from the surface area, (6.1 m^2/g), suggesting that the total number of nitrile groups is accessible to the molecule of formic acid. For example, if all the nitrile groups are available for the reaction, then only 5% of them is consumed by performing the decomposition reaction. Little or no decrease in the activity seems to be explicable.

It seems clear that during the decomposition of formic acid cleavage of the O–H bond as well as of the C–H bond occurs, although details of the latter process remain unknown. In order to obtain information on the rate-determining step for the decomposition reaction, the kinetic isotopic effect of deuterated formic acid was investigated with polyacrylonitrile pyrolyzed at 250°C. As seen in Table 4, the reaction rates decrease in the order HCOOD>DCOOH>DCOOD. It appears, therefore, that cleavage of neither the C–D bond nor the O–D bond is the rate-determining factor in the decomposition reaction.

Relation between the Number of Free Spins of Pyrolyzed Polyacrylonitrile and its Catalytic Activity. As seen in Fig. 6, the polymer pyrolyzed above 350°C exhibits a remarkable activity for the decomposition reaction. Since there are few or no conjugated nitrile groups in such a polymer, its activity is not attributable to the presence of conjugated nitrile groups. It is well-known that the polymer pyrolyzed above 350°C has the quinoid structure,[8,9] which shows the activity for hydrogen acceptor as pointed out by Manassen.[1] It appears, therefore, that the activity for the decomposition reaction arises from the presence of the quinoid structure.

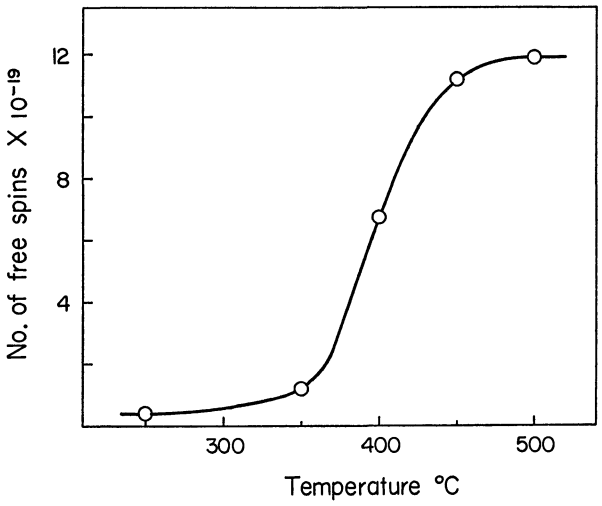

Fig. 7. Number of free spins of polyacrylonitrile pyrolyzed at various temperatures.

The number of free spins of polymer pyrolyzed at various temperatures was measured by ESR. The results are shown in Fig. 7. It is seen that the number increased markedly at temperatures above 350°C, reaching a saturated value around 450°C. A comparison of the results shown in Figs. 6 and 7 suggests that there is a close correlation between the activity for the decomposition and the number of free spins in the polymer. Although the true nature of such a correlation is not clear at present, a similar behavior has been found by Manassen,[1] and Gallard *et al.*[10]

Measurements of Optical Absorption Spectra under ^{60}Co-γ Irradiation. Aqueous Methylene Blue Solutions Containing Oxygen

Shin-ichi OHNO, Akihisa SAKUMOTO, Teikichi SASAKI, Kiyoshi KAWATSURA, and Katsutoshi FURUKAWA

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken

(Received May 24, 1971)

Aerated aqueous solutions of methylene blue (MB^+; 3×10^{-7} M) were subjected to ^{60}Co-γ rays in the presence of added methanol, ethanol, or D-glucose at dose rates up to 4×10^{15} eV $g^{-1}s^{-1}$, and the change in the optical absorption spectrum in the 300—700 nm region was studied using a rapid-scan spectrophotometer (scanning speed: 30 ms/100 nm). In the presence of high concentrations ($>10^{-2}$ M) of organic substances, it was found that radiation caused a decrease in the absorption due to MB^+ at 650 nm (the magnitude of the decrease was proportional to the radiation intensity), and that, on the removal of the radiation source, the original absorption spectrum was restored. This was interpreted as meaning that the radiation-produced leuco-form of methylene blue (MBH) was rapidly oxidized by oxygen. The rate constant, $k(MBH+O_2)$, was estimated to be $(0.6\pm0.2)\times10^4$ $M^{-1}s^{-1}$ at neutral pH. In the absence of added organic substances, the permanent decoloration of MB^+ took place; this was interpreted as being due to the reaction of MB^+ with OH-radicals. From the competition kinetic study using 10^{-4} M methanol, the rate constant, $k(OH+MB^+)$, was estimated to be 1.1×10^{10} $M^{-1}s^{-1}$.

Short-lived species in radiation-induced reactions have been studied by pulse-radiolysis techniques,[1] which, in most cases, employ an electron accelerator. On the other hand, much less effort has been made to study the short-lived species during continuous ^{60}Co-γ irradiations. Some reasons for this are: (1) The radiation from available Co-60 sources is, very often, not intense enough to produce measurable concentration of the species to be studied. (2) One must eliminate the radiation effects on the measuring systems, which is more difficult in γ-radiolysis than in electron-beam radiolysis.

We have now constructed an apparatus which can be adopted to a commercially-available spectrophotometer, *e.g.*, a Hitachi rapid-scanning spectrophotometer RSP-2, and which makes it possible to obtain an optical absorption spectrum in the 300-700 nm range of the liquid sample during irradiation up to 4×10^{15} eV $g^{-1}s^{-1}$. The details of the apparatus will be described elsewhere.[2] Here we wish to report the results of such measurements in the case of aerated aqueous solutions of methylene blue.

It is well known that methylene blue in air-free solutions containing various added organic substances loses its color upon irradiation, and that this decoloration can be reversed by the admission of air.[3,4] It is of interest, therefore, to measure the steady-state concentration of methylene blue in aerated solutions during the γ-radiolysis.

Experimental

The radiation source, 15 kCi ^{60}Co, was of a cylindrical type (40 cm in height, 13.4 cm in outer diameter). It was hung on a hoist which could be operated so as to move horizontally at a constant speed (3.3 cm s^{-1}).

The intensity of the radiation energy absorbed by a dilute aqueous solution at a horizontal distance of D cm from the center of the present source is expressed by Eq. (1), on the basis of the Fricke-dosimetry:[5]

$$I\ (\text{eV g}^{-1}\text{s}^{-1}) = 15.6\times10^{17}/D^2 \qquad (1)$$

where $D \geq 20$ cm

The reaction vessel was a 20-cm quartz tube 4.0 cm in internal diameter. The optically-flat windows were attached to the tube ends. The vessel was completely filled with the sample solution through the side arms attached to the vessel.

The reaction vessel was subjected to radiations at a fixed position (see Fig. 1) and at an ambient temperature *ca.* 25°C. The absorption spectra in the range from 330 to 700 nm were obtained using a Hitachi rapid-scanning spectrophotometer RSP-2 (scanning speed: 30 ms/100 nm) and were recorded on an oscilloscope (Hitachi V-018). Variations in the optical density at selected wavelengths could also be recorded as a function of the time.

5) Measurements made by the ^{60}Co-source operating group of the Institute.

All the reagents were of an Analar grade and were used without further purification. The concentration of methylene blue were calculated using an extinction coefficient reported in the literature, *i.e.*, 0.77×10^5 M^{-1}cm^{-1} at 665 nm.[6] The optical path-length of the reaction vessel employed was 40 cm.

Results

Methylene Blue+Ethanol. Figure 2a shows the radiation effects on an optical absorption spectrum of an aerated solution of 3×10^{-7} M methylene blue in the presence of 0.1 M ethanol. Radiation (3.9×10^{15} eV g^{-1}s^{-1}) decreased the absorption at 650 nm by about 30%. However, this bleaching during the irradiation was found to be almost completely reversible, and, on the removal of the radiation source, the original absorption spectrum was restored.

Similar results were obtained when lower concentrations of ethanol (10^{-2} or 10^{-3} M) were used, though the recovery after the removal of the source was 90% when 10^{-3} M ethanol was employed.

Methylene Blue+D-glucose. Aerated aqueous solutions of 3×10^{-7} M methylene blue and 0.1 M D-glucose at various pH values (neutral, 0.1 N H_2SO_4, and 0.01 N NaOH) were examined. All these results were similar to those in the case of 0.1 M ethanol mentioned in the previous section. Both the decrease in absorption during irradiation and the subsequent recovery on removing the source could be repeated several times. The variation in the optical density at 650 nm with the time in the case of methylene blue in aerated 0.01 N NaOH containing 0.1 M D-glucose is shown in Fig. 2b. The radiation source was first brought near the sample (thus causing the decrease in absorption) and then removed from the sample at a constant speed of 3.3 cm s^{-1}.

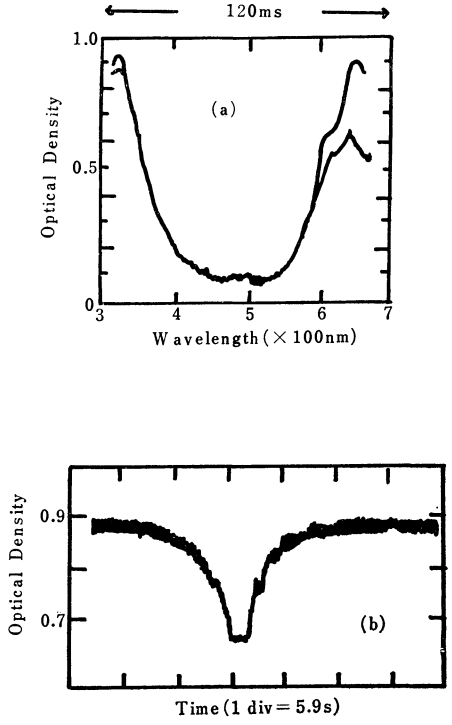

Fig. 2. Radiation effects on absorption spectra of aerated aqueous solutions of 3×10^{-7} M MB$^+$.
(a) 0.1 M ethanol present; Spectrum before irradiation (upper curve) and during the irradiation at dose rate of 3.9×10^{15} eV g^{-1} s^{-1} (lower curve); (b) Decrease in absorption and its recovery accompanying the transfer of the source (see text).

Irreversible Bleaching of Methylene Blue. A permanent decoloration of methylene blue occured when it was irradiated in an aerated, or in an argon-saturated, solution containing a low concentration (10^{-4} M) of methanol. The absorption spectra were recorded (*cf.* Fig. 3a) at various intervals after the source was placed at the fixed position (3.9×10^{15} eV g^{-1}s^{-1}). From the results shown in Fig. 3a, one may plot the decrease in the methylene blue concentration with the irradiation time, as in Fig. 3b. This bleaching was found to be irreversible. The initial yield for bleaching was 0.05 molecules per 100 eV of absorbed energy.

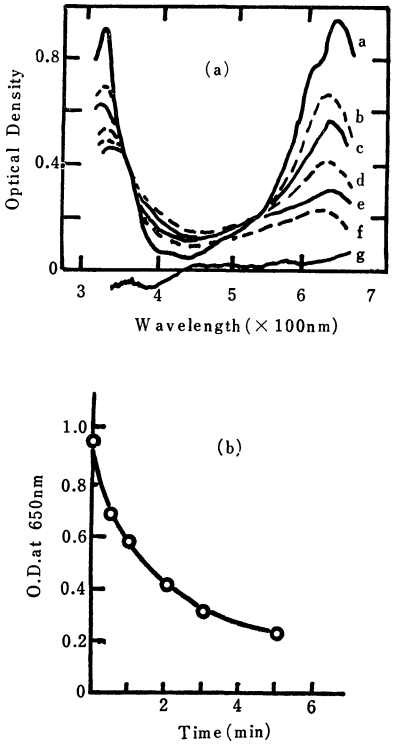

Fig. 3. Spectral change of an aerated solution of (3×10^{-7} M MB$^+$ + 10^{-4} M CH_3OH) with irradiation time at dose rate of 3.9×10^{15} eV g^{-1} s^{-1}.
(a) Spectrum before irradiation(a), and after 0.5(b), 1(c), 2(d), 3(e), and 5(f) min irradiation; Reference solution(g);
(b) Plot of optical density at 650 nm from the above results.

Discussion

When an aerated solution of methylene blue (MB$^+$; see Fig. 4) and high concentrations of organic substances are subjected to irradiation, the reactions which must be considered are very complex. Radiation decomposes water to give H, H_2, e_{aq}^-, H_3O^+,

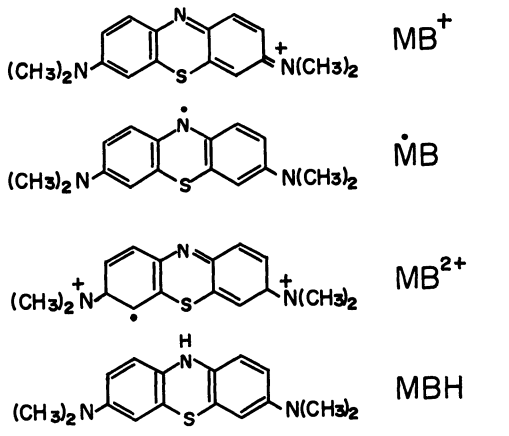

Fig. 4. MB^+ (methylene blue), $\dot{M}B$(semiquinone-form), MB^{2+} (half-oxidized form), and MBH(leuco-form).

OH, and H_2O_2. In aerated solutions where the concentration of oxygen is $\sim 4\times10^{-4}$ M,[7] H and e_{aq}^- will predominantly react with O_2 to yield HO_2 or O_2^-. If the ratio of the concentration of the organic substance to that of MB^+ is high enough, all the OH-radicals react according to:

$$OH + RCH_2OH \rightarrow \dot{R}CHOH + H_2O \quad (2)$$

where RCH_2OH represents ethanol, D-glucose, *etc.* The organic radicals are reducing agents:[3,4]

$$\dot{R}CHOH + MB^+ \rightarrow RCHO + \dot{M}B + H^+ \quad (3)$$

where $\dot{M}B$ represents the half-reduced semi-quinone form of the dye. Such species as $\dot{R}CHOH$ and $\dot{M}B$ may react with themselves (*e.g.*, disproportionation) or with O_2, H_2O_2, O_2^-, or HO_2. These reactions have not yet been fully studied. However, one may assume that reactions involving these radicals are fast. Some relevant rate constants available from the literature are included in Table 1. The present study has failed to observe an absorption due to MB-semiquinone (λ_{max}: 420 nm, $\varepsilon=10{,}400$ $M^{-1}cm^{-1}$),[6] as may be seen from Fig. 2a. This may be because $\dot{M}B$ is too short-lived to attain measurable steady-state concentrations under our experimental conditions. Therefore, it may be concluded that the reversible change in absorption at 650 nm during irradiation is related to the formation of the colorless leuco-base (MBH), which is the fully reduced form of the dye and which is well known to be rapidly oxidized by O_2 to MB^+.[3,4]

Table 1. Some relevant rate constants

Reaction	$k(M^{-1}s^{-1})$	Ref.
$MB^+ + \dot{R}CHOH$ (D-glucose)	2×10^9	12
$MB^+ + e^-_{aq}$	2.5×10^{10}	6
$\dot{M}B + \dot{M}B$ (pH 7)	3.0×10^9	6
$MB^+ + OH$	1×10^{10}	11
$CH_3\dot{C}HOH + O_2$	4.6×10^9	13
$\dot{R}CHOH$ (D-glucose) $+ O_2$	1.6×10^9	13

Rate Constant for ($MBH+O_2$) Reaction. The radiation-induced chemical reactions which finally yield leuco-MB in the present system may be very complicated. However, they all occur in a very short time compared with the time required for the re-oxidation of MBH by O_2. Thus, the reaction sequence forming MBH may be simply expressed as:

$$MB^+ \xrightarrow{G_4 I} MBH \quad (4)$$

where G_4 denotes the 100 eV-yield of MBH in the bulk of the solution, and I, the intensity of the radiation energy absorbed. The re-oxidation of MBH by O_2 may be:

$$MBH + O_2 \xrightarrow{k_{5a}} MB^+ + HO_2^- \quad (5a)$$

Alternatively, it may be:

$$MBH + O_2 \xrightarrow{k_{5b}} \dot{M}B + HO_2 \quad (5b)$$

followed by a further oxidation of $\dot{M}B$, which can be assumed to be much faster than Reaction (5b). In either case, the rate of the disappearance of MBH may be expressed as $k_5[MBH][O_2]$. Thus, for the steady-state concentration of MBH (designated as $[MBH]_s$):

$$d[MBH]/dt = 0 = G_4 I - k_5[MBH]_s[O_2] \quad (6)$$

We also obtain the relation:

$$[MB^+]_0 = [MB^+]_s + [MBH]_s \quad (7)$$

where $[MB^+]_0$ is the initially-added MB^+ concentration, and $[MB^+]_s$, the steady-state MB^+ concentration observed during irradiation. Equation (6) will hold as long as a sufficient amount of the solutes (O_2, organic substance) remains in the solution under the irradiation. This condition will be fulfilled while the total absorbed dose does not exceed 10^{19} eV g^{-1} in the present case (4×10^{-4} M O_2 will be consumed at this dose if it disappears with $G=3$).

The G(MBH) values for deaerated solutions in the presence of sufficient amounts of organic substances have been reported to be 3.3,[8] 2.75,[9] and 2.9.[9] Thus, we may take a value of 3 for the value of G_4 in Eq. (6). The value of $[O_2]$ is 3.7×10^{-4} M for aerated aqueous solutions at 25°C.[7] Thus, one obtains:

$$[MBH]_s = \left(\frac{0.81\times10^4}{k_5}\right)\times I \quad (8)$$

Figure 5 plots the $[MBH]_s$-values *vs.* I. These have been calculated using Eq. (7) and from the measurements of $[MB^+]_s$ at various I values (by varying the distance between the reaction cell and the radiation source) in the (3.7×10^{-7} M MB^++0.1 M ethanol) system. The reasonable fit of the data to a straight line demonstrates the validity of the above scheme. From the slope of the line, one obtains:

$$k_5 = (0.6\pm0.2)\times10^4\ M^{-1}s^{-1} \text{ at neutal pH.}$$

Thus, the half-life of the leuco-form in the present

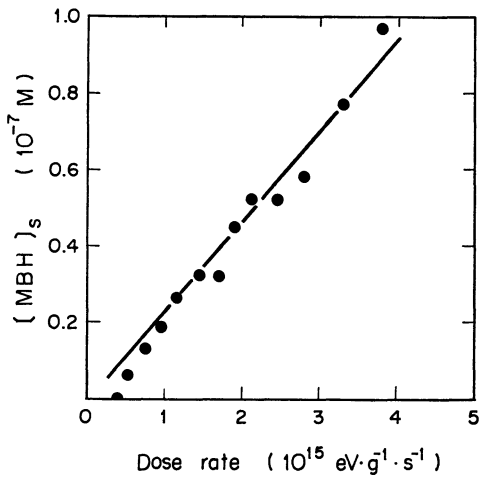

Fig. 5. Steady-state concentrations of leuco-form, $[MBH]_s$, as a function of dose rate, I.

system may be calculated to be $\ln 2/k_5[O_2]=0.3$ s.

Irreversible Decoloration of MB^+. It is generally accepted that the irreversible bleaching of MB^+ occurs by the attack of OH-radicals and that about three OH-radicals are required for one molecule of MB^+ bleached:[3]

$$MB^+ + OH \rightarrow MB^{2+} + OH^- \quad (9)$$

Thus, competition between Reactions (2) and (9) in the (3×10^{-7} M $MB^+ + 10^{-4}$ M CH_3OH) system would lead to the expression:

$$G(-MB^+)_{irrev.} = \frac{G_{OH}}{3}\left(\frac{k_9[MB^+]}{k_9[MB^+] + k_2[CH_3OH]}\right) \quad (10)$$

One may use a value of 0.05 for $G(-MB^+)_{irrev}$ from Fig. 3b, a value of 2.5 for G_{OH},[1] and a value of 5×10^8 $M^{-1}s^{-1}$ for k_2.[10] The value of k_9 is then calculated to be 1.1×10^{10} $M^{-1}s^{-1}$, which is in fair agreement with the value obtained by Hutchinson.[11]

Applicability of the Present Method. The apparatus used in this work may be used to observe the change due to irradiation in the optical absorption spectrum of any transparent material. An optical density change of 0.01 is detectable with the present apparatus. This means that the smallest concentration change which is detectable is approximately 10^{-8} M if a light absorbing species has an extinction coefficient of 10^4 $M^{-1}cm^{-1}$ (optical path-length of the cell: 40 cm). The presence of transient species during a continuous irradiation will be observed if the intensity of radiation is sufficient to produce a steady-state concentration higher than 10^{-8} M. The conditions required for this are determined by means of an equation similar to Eq. (6);

$$GI\times(\text{half-life}) \approx [\text{transient}] \quad (11)$$

With numerical values appropriate to our present work ($G=3$, $I=3.9\times10^{15}$ $eVg^{-1}s^{-1}$, [transient]$=10^{-8}$ M), it may be concluded that optically-absorbing species with a half-life of 0.06 s or longer will be detected and their steady state concentration determined. Provided that the G-value, the rate of generation, is known from other methods (*e.g.*, chemical analyses), information on the rate constant for reactions of the transient and, thus, its lifetime in various media may be obtained.

This method does not utilize kinetic spectroscopy and can be readily used at laboratories with no electron accelerator. However, since the measurable species must have a lifetime of at least 0.06 s, the widespread application of the method cannot be expected at the present moment (*cf.*, the lifetime of the hydrated electron in water, ≈1 ms). Considerable refinement of this method would be possible by, for example, (1) improving the sensitivity of the detection system or (2) employing a larger radiation source. Of these two possibilities, the former one is of more practical interest. One may readily improve the sensitivity by employing a longer optical path-length of the cell. Alternatively, one may employ a highly sensitive detection technique, for example, a lock-in amplifier in conjunction with analyzing light choppers. Attempts to study shorter-lived species by the use of the present spectrophotometer method with some modifications are now in progress in our laboratory.

Thermoelectric Power of the Iodine Complexes of Aromatic Diamines and Thiazines

Mizuka SANO*, Koichi OHNO**, and Hideo AKAMATU***

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received May 24, 1971)

The thermoelectric power of *N,N'*-diphenyl-*p*-phenylenediamine·I_2, *N,N'*-di-β-naphthyl-*p*-phenylenediamine·$I_{3.5}$, phenothiazine·I_3, and *N*-methylphenothiazine·I_3 was measured in the temperature range from −35 to 140°C. The observed power for each complex was explained by means of the mechanism of mixed conduction of electrons with holes, and the ratio of electron-conduction to hole-conduction was estimated as a function of temperature. In the iodine complexes of the substituted *p*-phenylenediamines the conductivity due to electrons is found to be larger than that due to holes, while in phenothiazine·I_3 holes contribute more to the conductivity. In *N*-methylphenothiazine·I_3, the hole-conduction is predominant in the higher temperature region and the electron-conduction in the lower temperature region.

Solid electron-donor-acceptor complexes, particularly those involving appreciable contribution from the dative structures, exhibit interesting electric and magnetic properties. *N,N'*-diphenyl-*p*-phenylenediamine (DPPD),[1,2] *N,N'*-di-β-naphthyl-*p*-phenylenediamine (DNPD),[1] phenothiazine (PT),[3], and *N*-methylphenothiazine (MPT)[3] have been reported to form stable iodine complexes. The crystal structure analysis of the iodine complex of DPPD has shown that the iodine atoms are stacked in columns perpendicular to the *ac* plane, and the donor molecules are arranged in layers 3.77 Å apart.[4] The iodine columns are coordinated to NH groups of the donor. The infrared spectrum of phenothiazine-iodine complex has been reported to be identical with that of semiquinoid phenazathionium bromide, indicating that the ground state of the solid complex is dative.[3]

The magnetic properties of these iodine complexes have been reported.[1] They are either diamagnetic or weakly paramagnetic at room temperature. After corrections are made for the diamagnetic contribution and for the paramagnetic one due to paramagnetic impurities, the intrinsic paramagnetic susceptibility is found to decrease slightly with the decrease in temperature. The exchange coupling constant J between ionradicals in a solid has values of 0.05 eV for DPPD·I_2, 0.08 for DNPD·$I_{3,5}$, 0.04 for MPT·I_3, and over 0.1 for PT·I_3.

These complexes show high electrical conductivity but neither photoconductivity nor Hall voltage, so that only the measurement of thermoelectric power seems to be a reliable means of determining the type of conduction. In this paper we present the results on the thermoelectric power measurement of the complexes and an estimation of the ratio of electron-conduction to hole-conduction in the solid.

Experimental

DPPD·I_2, dark green crystals with metallic lustre were obtained by mixing benzene solutions of the diamine and iodine in the stoichiometric ratio. (Found: C, 42.86; H, 3.40; N, 5.70%. Calcd for $C_{18}H_{16}N_2I_2$: C, 42.05; H, 3.14; N, 5.45%).

DNPD·$I_{3.5}$, dark brownish black crystalline powder precipitated on addition of a benzene solution of iodine to a benzene solution of the diamine (Found: C, 38.97; H, 2.17; N, 3.46%. Calcd for $C_{26}H_{20}N_2I_{3,5}$: C, 38.81; H, 2.51; N, 3.48%).

PT·I_3 was prepared by mixing benzene solutions of the components in the stoichiometric ratio.[3] MPT·I_3 was prepared from an ether solution.

A sample powder was sandwiched in a Teflon holder between small disks of platinum supported by two copper cylinders. Each platinum disk was insulated electrically from the copper cylinder with a piece of Teflon sheet. The powder was pressed under the pressure of 100 kg/cm² with an aid of a lever. Thickness of the sample was adjusted to 0.2—0.5 cm. The junctions of copper-constantan thermocouples were soldered to the platinum disks.

Cylindrical electric heaters attached to the upper and lower portions of the copper cylinders were controlled to provide temperature gradient in a sample. For measurements below room temperature the copper cylinders were cooled with dry ice cubes. By this arrangement the temperature dependence of thermoelectric power could be measured in the range from −35 to 140°C. Reference junctions connected to the thermocouples were insulated electrically from one another and placed in an ice-water bath maintained at 0°C.

The thermo-electromotive force (emf) of a sample observed through the copper leads of the thermocouples and that of each thermocouple were measured potentiometrically by use of suitable switching systems. The thermoelectric power Q is calculated by the relation.

$$Q = \Delta V/\Delta T, \quad (1)$$

where ΔV represents the thermo-emf generated in the sample-platinum-copper circuit by the temperature difference ΔT between the sample-platinum junctions. The average temperature of the junctions is taken to be the temperature of sample.

The electrical conductivity of the same sample specimen packed in the Teflon holder was measured by the *DC* method as a function of temperature. The temperature of the specimen was controlled with the aid of a third electric heater in conjunction with a dry ice cooling bath.

Results

All the complexes showed high absorption coefficients in the visible and near-infrared spectral regions. The absorption peaks, though broad and poorly defined, were found around 2.2, 1.7, and 1.1 μ for PT·I_3, MPT·I_3, and DPPD·I_2, respectively. The peaks in the near-infrared region are characteristic of solid ionradical salts with strong exchange coupling between ionradical components.[5]

The complexes gave rise to thermo-emf in the order of 10^{-3} V between the platinum electrodes for a temperature difference of about 10°. The absolute thermoelectric power of the complexes was obtained by correcting for the value for copper.[6] The power of each complex was found to be constant at a fixed sample temperature, being independent of the amount of provided temperature gradient around 10° and of the thickness of the sample. Good reproducibility of power was obtained by the rise and fall of temperature within the temperature range. The iodine complex of 4,4′-bis(dimethylamino)-diphenylamine (DADA), however, showed no reproducible power when it was heated up to 40°C.

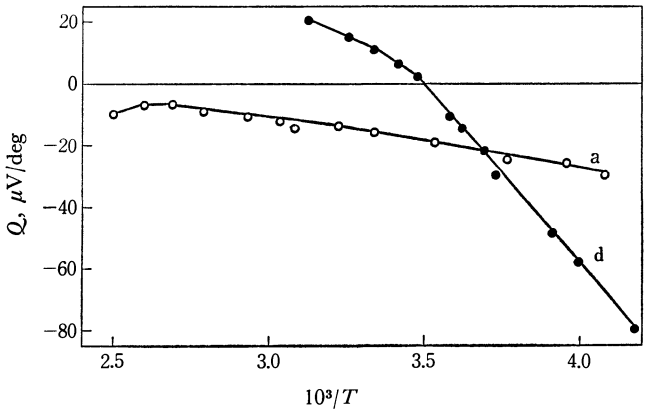

Fig. 1. Thermoelectric powers for (a) DPPD·I_2 and (d) MPT·I_3.

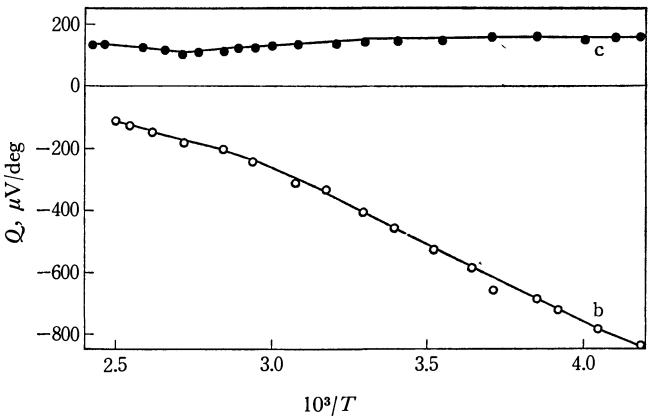

Fig. 2. Thermoelectric powers for (b) DNPD·$I_{3.5}$ and (c) PT·I_3.

Values for the power at 15°C are summarized in Table 1. The sign of power refers to the sign of developed emf at the cold junction. The power for DPPD·I_2, DNPD·$I_{3.5}$, and MPT·I_3 was found to decrease with falling temperature, while that for PT·I_3 changed little with temperature change. The temperature dependence of power is shown in Figs. 1 and 2.

The logarithm of conductivity σ was found to be proportional to the reciprocal of temperature $1/T$ in the entire temperature region, and the activation energy for conduction E_a could be calculated by the formula

$$\sigma = \sigma_0 \exp\left(-\frac{E_a}{kT}\right). \tag{2}$$

The activation energy and specific resistivity ρ at 15°C are summarized in Table 1.

Table 1. Thermoelectric power and specific resistivities at 15°C, and activation energies for conduction

	Q (μV/deg)	ρ (Ω·cm)	E_a (eV)
DPPD·I_2	−20	3.5×10	0.095
DNPD·$I_{3.5}$	−540	5×10^4	0.37
DADA·I	−860	1.3×10^5	—
PT·I_3	+150	1.7×10	0.164
MPT·I_3	+3	2.3×10^2	0.14

Discussion

Johnson and Lark-Horovitz derived the following formula (Eq. (24) in Ref. 7) as a general expression for thermoelectric power of a band-model semiconductor.[7]

$$Q = -\frac{k}{e(n_1c+n_2)}\left[A(n_1c-n_2) - n_1c\ln\left\{\frac{n_1h^3}{2(2\pi m_1kT)^{3/2}}\right\} + n_2\ln\left\{\frac{n_2h^3}{2(2\pi m_2kT)^{3/2}}\right\}\right], \tag{3}$$

where n_1 and n_2 are the densities and m_1 and m_2 the effective masses of conduction electron and hole, respectively. c denotes the mobility ratio μ_1/μ_2, and A the scattering parameter. The parameter comes from the energy of transferring average carrier, and varies somewhat with the scattering process. Scattering theory predicts this quantity varies from 2 for neutral scattering centers to 4 for ionic centers.[8]

In the case where only one type of carrier is present, the expression for the power is obtained from Eq. (3) by dropping the terms pertaining to another type of carrier. Thus we get for electrons

$$Q = -\frac{k}{e}\left[A - \ln\left\{\frac{n_1h^3}{2(2\pi m_1kT)^{3/2}}\right\}\right]. \tag{4}$$

8) T. A. Kontorova, *J. Tech. Phys. Moscow*, **24**, 1291, 1687, 2217 (1954).

Within the limitation of the Boltzmann distribution, the carrier density n_1 can be related to the Fermi level ζ by the equation

$$n_1 = \frac{2(2\pi m_1 kT)^{3/2}}{h^3} \exp\left(-\frac{\varepsilon_1{}^0-\zeta}{kT}\right), \quad (5)$$

where $\varepsilon_1{}^0$ is the energy at the bottom of the conduction band. Substituting Eq. (5) into Eq. (4), we obtain

$$Q = -\frac{k}{e}\left[\frac{\varepsilon_1{}^0-\zeta}{kT}+A\right]. \quad (6)$$

The expression for the power only by holes is given by

$$Q = +\frac{k}{e}\left[\frac{\zeta-\varepsilon_2{}^0}{kT}+A\right], \quad (7)$$

where $\varepsilon_2{}^0$ is the energy at the top of the valence band.

Substitution of both densities of electron and hole into Eq. (3) gives the following expression for mixed conduction of electrons with holes.

$$Q = -\frac{k}{e}\left[\frac{(x-1)}{(x+1)}\left(\frac{E_g}{2kT}+A\right)+\frac{(\varepsilon_1{}^0-\zeta)-(\zeta-\varepsilon_2{}^0)}{2kT}\right], \quad (8)$$

where x denotes the conductivity ratio $n_1\mu_1/n_2\mu_2$, and E_g the forbidden band width.

Explanation of the experimentally obtained curve of the power for each complex was undertaken by means of the formula for the carriers of only one type, on the assumption that the energy difference between the Fermi level and the conduction band $\varepsilon_1{}^0-\zeta$ or the valence band $\zeta-\varepsilon_2{}^0$ is equal to the observed activation energy of conduction E_a. Only the formula including the value of A with negative sign is found to represent the observed power. Theory does not allow a negative A value, so that this type of conduction is ruled out.

In a triethylammonium(TCNQ)$_2$ single crystal the sign of the majority of carriers has been reported to be negative along the c-crystal axis and positive along the a-axis.[9] The result suggests a mixed contribution from both types of carriers to the conductivity in ionradical crystals.

Comparing the expression for mixed conduction

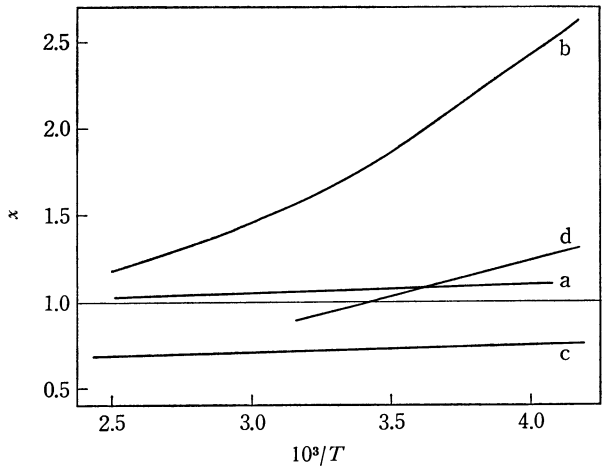

Fig. 3. Conductivity ratios for (a) DPPD·I_2, (b) DNPD·$I_{3.5}$, (c) PT·I_3, and (d) MPT·I_3.

Eq. (8) with the experimentally obtained curve on the assumption that for an ionradical solid the value of A equals 4, as found for ionic scattering centers in ionic crystals, and that the last term in Eq. (8) is negligibly small compared with the first one, one can estimate the conductivity ratio x, and thus determine the type of conduction. In this analysis twice the value for E_a is used for E_g. The conductivity ratio thus obtained is shown in Fig. 3 as a function of temperature. If the electron density n_1 is taken to be equal to the hole density n_2, the value for x corresponds to the mobility ratio μ_1/μ_2. This condition, however, does not seem to hold in the entire range of temperature.

The x values for DPPD·I_2 and DNPD·$I_{3.5}$ are greater than unity, indicating that the conductivity due to electrons is larger than that due to holes. The x-value smaller than unity for PT·I_3 indicates that holes contribute more to the conductivity in the complex. In MPT·I_3, on the other hand, the hole-conduction is predominant in the higher temperature region and the electron-conduction in the lower temperature region. The change of x-value with temperature seems to arise mainly from the different dependence of electron and hole mobilities on temperature.

Solvent Effect on the Vibrational Structures of the Fluorescence and Absorption Spectra of Pyrene

Akira NAKAJIMA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received May 24, 1971)

The anomalously large Ham effect observed in pyrene has been studied in various solvents at room temperature by measuring the fluorescence and absorption spectra. As in the case of benzene, the Ham bands of pyrene were assigned to the 0–0 and a_g-vibration bands. This was confirmed by fluorescence polarization measurement. The correlation of the intensities of the fluorescence and absorption bands to solvent polarities is discussed.

Despite much work on the solvent shifts[1-8] of electronic spectra, comparatively few studies of the solvent effect on their vibrational structures have been carried out. In general the vibrational components in the fine structure of a weak electronic transition are expected to show different intensity behaviors under the action of solvent perturbation.[9] Such a structural change in an electronic band system can be observed remarkably in an electronically forbidden transition containing both vibrationally-induced and forbidden components. However, the phenomenon can rarely be observed in the spectrum of an electronically allowed transition.[9]

Recently the author noticed that the vibrational structures of the fluorescence and absorption spectra of pyrene are markedly altered in various fluid solvents and this effect can be ascribed to the same phenomenon as that known as the Ham effect[10-15] well investigated on benzene. Extensive studies[9,13-18] of the Ham bands in the 2600 Å region of the benzene absorption revealed that the effect is taken to be the appearance of the symmetry forbidden 0–0 progression in the $^1B_{2u}$—$^1A_{1g}$ band system[19,20] affected by dispersion forces between benzene and solvent molecules. As has been demonstrated by Durocher and Sandorfy,[9] and also by Koyanagi,[18] this phenomenon is not restricted to benzene, but can be observed with many benzene derivatives,[9,16,17] naphthalene,[9,16] phenanthrene,[9] *p*-benzoquinone,[18] and perhaps a number of other aromatic molecules.

Most studies on the Ham effect have been performed mainly by the measurements of absorption spectra by adding some amount of highly polarizable substances at relatively low temperatures.[9,10,13,14,16,17] This work was carried out by observing both the fluorescence and the absorption spectra of pyrene in pure solvents at room temperature. When the first absorption band under consideration overlaps the neighboring strong band as in the case of pyrene, the studies by means of fluorescence spectra are advantageous, unless the solvent quenching of fluorescence occurs appreciably.

How the observed effect is to be associated with the solvent properties is a difficult problem of the work.

Experimental

Pyrene was purified by recrystallization, chromatography, zone-refining, and sublimation.

Spectroscopic grade (Dotite Spectrosol) *n*-hexane, cyclohexane, benzene, carbon tetrachloride, acetonitrile, *N,N*-dimethylformamide, and dimethylsulfoxide were obtained from Wako Pure Chemical Industries, Ltd. Spectroscopic grade ethyl ether and tetrahydrofuran were obtained from Kishida Kagaku Co., Ltd. GR grade methanol, ethanol, chloroform, 1,2-dichloroethane, toluene, *p*-dioxane, acetone, and ethyl acetate were purchased from Wako Pure Chemical Industries, Ltd. All these solvents were used without further purification. Isopentane and methylcyclohexane were purified by chromatographic adsorption on silica gel and subsequent fractional distillation. Chlorobenzene of Wako EP grade was dried and fractionally distilled.

The absorption spectra were measured with a Hitachi EPS-3 recording spectrophotometer. The fluorescence spectra were obtained using a Hitachi MPF-2A spectrofluorimeter with sensitivity corrections.[21] The fluorescence polarization spectrum was measured at 77°K in a mixture of methylcyclohexane and isopentane (1 : 1) by use of an apparatus constructed with a Hitachi G-3 grating monochromator and

a Hitachi EPU-2A prism monochromator.

All the solvents used were confirmed to emit no luminescence having any essential influence on the fluorescence spectra with excitation at about 330 mμ. The concentration of pyrene for fluorescence measurements were of the order of 10^{-5} mol/l. The gas-phase fluorescence was measured with a non-fluorescent square quartz cell containing a small amount of pyrene, evacuated and sealed, in a regulated electric furnace.

Results and Discussion

The spectral changes of pyrene fluorescence in various solvents at room temperature are shown in Figs. 1 and 2. The characteristic bands are named *a*, *b*, *c*, *d*, *e* in the decreasing order of wave number. All the fluorescence spectra were normalized for convenience at 26200 cm^{-1} (band *c*). The vapor-phase spectrum is somewhat diffuse because of the high temperature (180°C) at which it was measured. The bands are observed as shoulders. The relative intensities of the bands *a*, *b*, and *e* increase markedly with the increase of the apparent solvent polarity in going from the gaseous state or a nonpolar solvent such as *n*-hexane to a highly polar solvent such as acetonitrile, while the frequency shifts of these bands are very small and nearly comparable to the experimental error. The slight solvent shifts are in striking contrast to the pronounced solvent enhancement.

The absorption spectra in the region of the first singlet-singlet transition are also shown in Fig. 2. Since no spectral change can be expected to occur, the absorption spectra were not measured in the regions of higher strongly allowed transitions. We see that the fluorescence spectra bear a general mirror-image relationship to the absorption spectra, taking account of the absorption tail of the second intense transition. The first and second absorption bands (corresponding to the fluorescence bands *a* and *b*, respectively) also increase similarly with increasing solvent polarity. It can therefore be accepted that the Ham effect for pyrene takes place

to almost the same extent in the absorption and the fluorescence spectra.[22]

As has been suggested,[9] the Ham effect proves to be a helpful tool in vibrational analysis. In analogy with benzene, the solvent-enhanced components can be assigned to the 0–0 band, the a_g-vibration bands and their progressions.[9,14,17,20] From the other vibrationally-induced bands much less influenced by the solvent, information on the mechanism of intensity borrowing due to vibronic coupling[20,23] can be deduced. As given in Table 1, the assignment of the vibrational bands of the fluorescence spectrum was made in reference to the reliable work by Klimova.[24] The band *c*, though strong, could not be assigned.

Based on the presence of the b_{1g}-vibration bands and other evidences,[25–27] Klimova concluded that the first excited singlet electronic state of pyrene (belonging to the point group D_{2h}) has B_{3u} symmetry and the second, B_{2u}.[24] The first singlet transition $^1B_{3u} \leftarrow {}^1A_{1g}$ is, like that of naphthalene,[9] not symmetry forbidden[25] but the contributions to the transition moment cancel each other in a good approximation.

For the sake of confirmation the fluorescence polarization of pyrene[27–29] was measured by the usual photoselection technique.[30] The polarization spectrum together with the low-temperature fluorescence spectrum is illustrated in Fig. 3. It is seen that the weak components are intensified with the increased solvent polarity by cooling and by the additional crystal forces in the rigid matrix.[17,31] The polarization of the main part of the band system is shown to be weakly parallel to the direction of the moment of the second electronic transition. At the wave numbers for the b_{1g}-vibration bands (the *d* band and some bands at lower energies) the polarizations are positive, indicating that the intensity is derived from the neighboring second electronic state with B_{2u} symmetry through coupling with the b_{1g} vibrations.[27] On the other hand, the 0–0 band (*a*) and a_g-vibration bands (*b*, *e*) are negatively polarized against

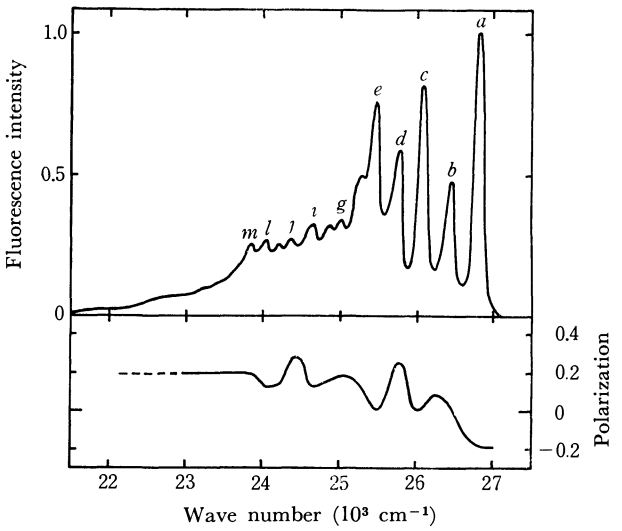

Fig. 3. Polarization and fluorescence spectra of pyrene at 77°K in a methylcyclohexane-isopentane (1 : 1) mixture.
Above: Fluorescence spectrum,
Below: Polarization as a function of wave number with excitation at 30300 cm^{-1}.

22) Since the relative intensities of the fluorescence bands *I* are given as the ratios of their observed intensity to that of the *c* band, the intensity variation of the *c* band in various solvents may be disregarded. However, it can be regarded as small, because the intensity of the third absorption band being a mirror image of the *c* band changes within 20% in the solvents used and most part of this change is affected by the solvent-broadened absorption tail of the second strong transition.

the background of positive polarization, in harmony with the assignment of the first excited singlet π state to B_{3u} symmetry.[24,27]

Care should be taken to make a correct symmetry assignment of an electronic state with several different vibrational components by polarization measurements.[27,29] In this sense the solvent-enhanced 0–0 band can play a very significant role.

Considering the relation between the intensities of the Ham bands and the properties of the solvent molecules, the Ham effect might be due to the reduction of molecular symmetry in the field of surrounding solvent molecules or to the distortion of the π electron cloud by the environmental perturbation.[9,12,14,17,18] Confirmation of the cause of the effect is, however, very difficult.

In the study of the Ham bands of benzene, Koyanagi[17,18] showed a correlation between the apparent molar extinction coefficient of the origin band and the square of the relative quantity relating to dispersion energy $(\bar{\alpha}_s/\bar{r}^6)^2$, where $\bar{\alpha}$ denotes the mean polarizability of the solvent[32] and $\bar{r}$ the mean intermolecular distance between the solute and the solvent molecules.[33,34] Following his theory,[18] the effect of dispersion forces[35] was examined by a similar plot of the molar extinction coefficient ε_1 of the 0–0 band for absorption or the relative intensity I_a of the a band for fluorescence against $(\bar{\alpha}_s/\bar{r}^6)^2$ shown in Fig. 4(a). No perceptible trend can be found among these scattered points. Taking further into account not only the dispersion term[35] including the ionization potentials of the solute and the solvent but also the induction term arising from the interaction between the solvent permanent dipole and the solute induced dipole, the following factor[17,18] was introduced in Fig. 4(b).

$$f = \left\{\left(\frac{3}{2}\cdot\frac{I_p\cdot I_s}{I_p+I_s}\cdot\bar{\alpha}_s + \bar{\mu}^2\right)\Big/\bar{r}^6\right\}^2$$

where I_p and I_s are the ionization potentials[36] of pyrene and the solvent, respectively, and $\bar{\mu}^2$ is the mean square of the solvent dipole moment.[34] The situation, however, is not as improved as might be expected. The errors inherent in the evaluation of the inverse twelfth power of $\bar{r}$ might become serious, but it should be kept in mind that $\bar{r}$ is the proper quantity to be uniquely determined from the molar volumes of the solute and solvent.[37] One possible explanation is that the molecular size of pyrene is several times larger than that of benzene, implying some local interaction between pyrene and the solvent molecules. It is likely that the approximation[18] of a polarizable rigid sphere to a solvent molecule would not be justified in the present system.

Some other attempts have been made to find a correlation. Since it appears that the dielectric constant D of the solvent is of major importance in the enhancement of the bands, it is instructive to plot ε_1 or I_a *vs.* the dielectric factor $(D-1)/(2D+1)$ for the

32) $\bar{\alpha}_s$ was calculated from the refractive index and the molar volume of the solvent.[33,34]

solvent as shown in Fig. 5. This reveals that there is an appreciably clear relation between them.[38] Moreover, an explicit relationship between the relative fluorescence intensities I_a and Kosower's Z-values[39] can be seen from Fig. 6 for the non-alcoholic polar solvents.

Recently, W. Liptay *et al.*[40] studied the solvent effects on the wave numbers and intensities of the absorption bands of fluorenone and showed the validity of their theoretical relation expressed by means of the ground- and excited-state dipole moments of the solute.[41] In the present case, however, their relation cannot be employed,[42] since pyrene has no dipole in either the excited or ground state.

Accordingly, in view of the appreciable dependence on the solvent dielectric constant, the following quantity was tentatively defined with an adjustable parameter χ:

$$f' = \left(\frac{D-1}{2D+1} - \chi \cdot \frac{n^2-1}{2n^2+1}\right),$$

where n denotes the refractive index of the solvent.[33,34] The case where $\chi=0$ was examined previously. As shown in Fig. 7, assuming that $\chi=0.5$, a rather good correlation was obtained between ε_1 or I_a and f', except for benzene and dioxane which are also known to give an anomalous effect on the frequency shifts of electronic spectra.[40] Other χ-values (*e.g.*, $\chi=1$) and other similar factors appearing in the ordinary solvent shift theories[1-8] have been found to give no better results. Applicability of the quantity given above in the original sense[1-3,8] to the molecule without dipole may, of course, be doubtful. The dielectric nature of solute-solvent interaction in the present system seems to be of significance. No correlation could be found with the energy parameters $\gamma\varepsilon^*$[43] employed in the solution theory[44] based on the cell method.[43] It is only inferred at present that both the dispersive and the inductive interactions involving more complex or microscopic solution structures might be of considerable importance.

pyrene in carbon tetrachloride[47] are observed to be relatively large, the contribution by Robinson's mechanism[45] seems to be a smaller fraction of the observed effect.

Extention of this fluorescence study to aromatic molecules other than pyrene is of interest. Experiments in various mixed solvents provide some useful information regarding solvent-solute and, in certain cases, solvent-solvent interactions, in which connection, knowledge of the recent solution theory[44] is helpful. It might be interesting to investigate from similar viewpoints the vibrational structures of phosphorescence spectra[14,48] as well for a variety of compounds in different media.

The author wishes to thank Dr. O. Kiyohara and Prof. K. Arakawa for invaluable discussions. He is also indebted to Messrs. M. Aoi and K. Yamamoto for the instrumental calibrations. Grateful acknowledgements are due to the referee for his kind remarks.

47) Pyrene fluorescence was considerably quenched and a chemical reaction was observed in carbon tetrachloride. A specific interaction seems to take place.

Anharmonic Potential Functions of Simple Molecules. I. Direct Numerical Diagonalization of Vibrational Hamiltonian Matrix and Its Application to CO and HCl

Isao SUZUKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received May 27, 1971)

The vibrational energy levels of diatomic molecules are related with the harmonic and anharmonic force constants by solving the vibrational Hamiltonian matrix numerically. The associated rotational levels are computed by two different methods; (1) perturbation treatment which utilizes the wave functions obtained, and (2) direct numerical diagonalization of the vibration-rotation submatrices. This approach, combined with the least-squares procedure, is applied to the determination of anharmonic force constants for CO and HCl molecules. Special attention is paid to the truncation effect of potential functions upon the calculated energy levels. Limitations in the usual perturbation method as well as the applicability of the present method to triatomic molecules are discussed.

The least-squares determination of the harmonic and anharmonic force constants from available spectroscopic data has been attempted for a few simple polyatomic molecules such as CO_2, HCN, OCS, N_2O, H_2O, and HCCH.[1-9] In the above determination, the potential function is expressed in terms of an appropriate coordinate system and is expanded in a power series, the terms quadratic through quartic being retained. The relationships between these force constants and the vibration and vibration-rotation energies are rather complicated; the perturbation technique is usually employed, and the vibration-rotation Hamiltonian of a polyatomic molecule is solved by the successive application of the contact transformations.[10,11] This may be an only approach to finding analytical expressions relating these force constants with energy levels, but some problems concerning its direct use in the least-squares determination of anharmonic force constants remain unsolved: (a) validity of the approximation used, (b) the truncation effect upon the higher order terms, and (c) treatment of anharmonic resonances, especially the handling of weak resonances. If, on the other hand, a proper set of basis wave functions (usually harmonic oscillator wave functions) is chosen, the vibrational Hamiltonian can readily be written down in matrix form, and the vibrational energy levels are obtained through numerical diagonalization. In addition, an orthogonal and normalized wave function can be obtained for each vibrational state as a linear combination of the original basis functions. The components of the eigen vector correspond to the coefficients of the linear combination, from which the rotational energy levels in a given vibrational state are derived by the standard pertur-

bation method. With the use of high speed computers, this second method may yield a more reliable set of harmonic and anharmonic force constants, particularly when it is combined with the least squares procedure.

This line of approach was motivated from the study of the anharmonic potential function for the water molecule, which is expected to have large cubic and quartic cross terms. The direct diagonalization method is, however, first applied to and tested in diatomic molecules, the simplest molecular system with only one vibrational freedom. The vibration-rotation energy levels of a diatomic molecule are given in the form of a double power series,

$$E_{v,J} = \sum_{i,j} Y_{ij}(v+1/2)^i[J(J+1)]^j \quad (1)$$

Dunham[12] derived the relationships between the term values Y_{ij}'s and the force constants (known as the Dunham constants a_i's). The force constants derived from Dunham's equations are compared with those obtained from the present method. Diatomic molecules are probably only molecules, for which force constants higher than quartic can be determined from the presently available data. The least-squares fit to the spectroscopic data has been made with the five parameter potential function (FPPF, quadratic through hexic) as well as the three parameter potential function (TPPF, quadratic through quartic). The truncation effect upon the values of force constants is discussed. The seven parameter potential function (SPPF, quadratic through octic) is also considered in some cases. Two diatomic molecules, CO and $H^{35}Cl$, whose vibrational levels and associated rotational constants have been known precisely up to sufficiently high levels ($v=5$ or $v=6$), are subjected to a detailed investigation. The direct diagonalization method is also attractive in handling polyatomic molecules, since no special treatment is required for the anharmonic resonances.

Hamiltonian

The vibration-rotation Hamiltonian for a diatomic molecule is given as[12]

$$\mathbf{H} = \mathbf{H}_{\mathrm{VIB}} + \mathbf{H}_{\mathrm{ROT}}, \quad (2)$$

$$\mathbf{H}_{\mathrm{VIB}} = (1/2)\omega_e(q^2+p^2) + k_3q^3 + k_4q^4 + k_5q^5 + \cdots \quad (3)$$

$$\mathbf{H}_{\mathrm{ROT}} = B_e(J_x^2+J_y^2)(1-2\gamma^{1/2}q+3\gamma q^2-4\gamma^{3/2}q^3+)\cdots = B_e(J_x^2+J_y^2)\sum_{k=0} R_kq^k . \quad (4)$$

The Hamiltonians as well as all constants are expressed in cm^{-1} units and the operators are dimensionless: $p=\hbar^{-1}(\partial T/\partial q)$, $J_x=\hbar^{-1}P_x$, and $J_y=\hbar^{-1}P_y$. B_e is an equilibrium rotational constant, w_e is a harmonic frequency, and k_i's are anharmonic force constants.[13] The quantity $\gamma=(2B_e/\omega_e)$ represents 'smallness' in perturbation treatment and $R_k=(-1)^k\gamma^{(k/2)}\times(k+1)$ reflects the effect of normal vibration upon the rotational Hamiltonian.

Pure Vibrational Problem. Non-vanishing matrix elements of $(p^2+q^2)/2$, q^3, q^4, q^5, q^6, q^7, and q^8 in the harmonic oscillator wave functions are given in Table A–1 in the Appendix. The contribution of each force constant to the vibrational Hamiltonian matrix $\mathbf{H}_{\mathrm{VIB}}$ might be represented in matrix form, $\mathbf{A}^{(i)}$. The first few nonvanishing elements in each A-matrix are also given in Table A–2 in the Appendix. The final $\mathbf{H}_{\mathrm{VIB}}$ is given as matrix sum

$$\mathbf{H}_{\mathrm{VIB}} = \sum_{i=2} k_i\mathbf{A}^{(i)}, \quad (5)$$

where $k_2=\omega_e$. When n basis functions are chosen, an n by n secular equation in the form of

$$\mathbf{H}_{\mathrm{VIB}}\mathbf{L}_i = \mathbf{L}_i\nu_i \quad (6)$$

is solved for eigen vector L_i and eigen value ν_i. The eigen vectors are normalized to unity: $\mathbf{L}\,\tilde{\mathbf{L}}=\tilde{\mathbf{L}}\,\mathbf{L}=\mathbf{E}$, where $\mathbf{E}$ is a unit matrix.[14]

Vibration-Rotation Energy. The rotational-energy for the vth vibrational state is expressed as

$$E_{v,J} = B_vJ(J+1) - D_vJ^2(J+1)^2, \quad (7)$$

where J is a rotational quantum number. The spacings for rotational energy levels are much narrower than those for vibrational levels, and use of the ordinary perturbation method is justified. Therefore, $\mathbf{H}_{\mathrm{ROT}}$ in Eq. (4) is treated as a perturbing term, and the first-order vibration-rotation energy $E_{v,J}^{(1)}$ is given as

$$E_{v,J}^{(1)} = B_e\langle J|J_x^2+J_y^2|J\rangle\sum_{k=0} R_k\langle v|q^k|v\rangle = B_eJ(J+1)\sum_{k=0} R_k\langle v|q^k|v\rangle . \quad (8)$$

The 'true' wave function for the vth vibrational level is represented as a linear combination of the harmonic oscillator basis functions φ_n's:

$$|v\rangle = \sum_{n=0} a_{vn}|n\rangle \quad (9)$$

Throughout this paper, the indices n and m are used to indicate the harmonic oscillator wave functions $\varphi_n{}^0(q)$ and $\varphi_m{}^0(q)$, and v and v' refer to the true (perturbed) vibrational states. The coefficients a_{vn} are the components of the vth eigen vector. Since φ^0's are normalized and orthogonal, B_v is computed as

$$B_v = B_e\sum_{k=0} R_k\langle v|q^k|v\rangle = B_e[1+\sum_{k=1} R_k\sum_{n,m} a_{vn}a_{vm}\langle n|q^k|m\rangle]. \quad (10)$$

Similarly, the centrifugal distortion constant D_v in Eq. (7) can be obtained by applying the second-order perturbation treatment: $E_{v,J}^{(2)}=\sum_{v\neq v'} H_{vv'}{}^{(1)}H_{v'v}{}^{(1)}/(E_v^{(0)}-E_{v'}{}^{(0)})$.

The alternative method for obtaining the vibration-rotation energy levels is more direct. Since the rotational Hamiltonian $\mathbf{H}_{\mathrm{ROT}}$ for a diatomic molecule is diagonal with respect to the rotational quantum number J, the entire vibration-rotation Hamiltonian matrix is factored into a number of subma-

12) J. L. Dunham, *Phys. Rev.*, **41**, 721 (1932).

13) The force constants k_n's in Eq. (3) are related with the Dunham constants a_m's in the following equation,
$2k_{n+2}=\omega_e\gamma^{n/2}a_n\cdot(n=1,2,3,\cdots)$

14) A similar treatment was carried out by Heilbronner *et al.*[15] but they used a very limited number of basis functions.

15) E. Heilbronner, Hs. H. Guntherd, and R. Gerdil, *Helv. chim. Acta*, **39**, 1171 (1956).

trices, each of which is constituted from the states with identical J values. For non-zero J-values, the terms originated from $\mathbf{H}_{\mathrm{ROT}}$ are treated as effective potential constants which modify the values of k_i in Eq. (3). The values of B_v and D_v are obtained from a direct calculation of vibration-rotation energies. $E_{v,J}$. The B_v values computed from the perturbation method, Eq. (10), are in excellent agreement with those obtained directly. The perturbation method, which is much quicker, is usually used in the present study. The direct method, however, excels the perturbation method when the vibration-rotation wave functions are to be computed. When various vibration-rotation dipole moment matrix elements $R_{v,J}{}^{v',J'}$ are evaluated for CO and HCl, the direct method is used.

Numerical Analysis

The numerical computations have been carried out on a HITAC 5020 E digital computer of the Computation Centre in the University of Tokyo. In order to preserve the desired number of significant figures, double precision arithmetic (64 bits) was used. For most practical purposes, however, the single precision is adequate. The vibrational energy levels and associated rotational constants are taken from the recent high resolution measurements on the vibration-rotation bands of CO and $H^{35}Cl$.[16,17] Their values are listed in Table 1 along with the term values Y_{ij}'s and the potential constants a_n's derived by these authors.

Preliminary Calculation. a) *Number of Basis Functions*: The vibrational energy levels ($v\leqq6$ for CO and $v\leqq5$ for HCl) are calculated from a trial set of the FPPF for both CO and HCl.[18] The number of basis functions is varied from 7 to 50. Convergence of eigen values is appreciably slower in HCl but is completed for the above levels when 30 basis functions are used. Similar results are obtained for the TPPF. Thus, 30 basis functions are used throughout this work, and errors resulting from the truncation of the Hamiltonian matrix are expected to be negligible. A reasonable convergence is obtained for the fundamentals and the first overtones of both CO and HCl and the second overtone of CO with ten basis functions. This implies that the present method is applicable to triatomic molecules. b) *Frequencies*: As shown in Table 1, Rank *et al.* derived the values of the first five force constants from the observed frequencies and rotational constants. The vibrational energy levels for CO and HCl are calculated from these force constants by three different methods, and they are given in Columns (i)–(iii) of Table 2. These energy levels are obtained (i) by direct diagonalization of a 30 by 30 vibrational Hamiltonian matrix, (ii) by the usual second order approximation, where x_e and α_e are given as

$$x_e = (3B_e/2)(5a_1{}^2/4-a_2) = (3/2)(5k_3{}^2/2\omega_e-k_4) \tag{11}$$

and

$$\alpha_e = -(6B_e{}^2/\omega_e)(1+a_1) = -(6B_e{}^2/\omega_e)[1+k_3(2/\omega_eB_e)], \tag{12}$$

and (iii) by using Dunham's formulae[19] (Eq. (15)

a) Without hexic off-diagonal matrix elements.

in Ref. 12). The differences (i)–(ii) and (i)–(iii) are given, respectively, in Columns (v) and (vi). They show that these approximation methods break down rapidly in higher vibrational levels. The discrepancies are much larger in HCl, and it is alarming that even for the first overtone of HCl, the calculated frequencies in (ii) and (iii) are off from the exact solution by about 11 and 7 cm^{-1}, respectively.

c) *Rotational Constants.* As given in Eq. (4), the rotational Hamiltonian of a diatomic molecule is expressed as a power series expansion of the dimensionless normal coordinate q, and the terms $k=0$ through $k=6$ are first retained in the present calculation. The calculated values for the rotational constants are given in Columns (i)–(iv) of Table 2. The rotational constants, B_v, may be regarded as the sum of terms $B_v(k)=B_e\cdot R_k\langle v|q^k|v\rangle$. The contribution of each $B_v(k)$ term is listed in Table 3 for the $v=0$, $v=1$, and $v=5$ levels of CO and HCl. The convergence is satisfactory for the low vibrational levels of CO and still good for the $v=5$ level.[20] For HCl, it is satisfactory only for the $v=0$ and $v=1$ levels. It becomes slower in higher vibrational levels. When the least-squares adjustment of force constants is attempted for the HCl molecule, the rotational Hamiltonian is expanded further to the $k=8$ term. Contributions from $B_v(7)$ and $B_v(8)$ are added in Table 3-b.[21]

d) Effect of Off-diagonal Matrix Elements. In the second order perturbation treatment in polyatomic molecules, where harmonic, cubic, and quartic force constants are retained, the off-diagonal contributions of the quartic force constants to the energies are neglected. Only exceptions are the cases in which second order anharmonic resonances are apparent. In the same sense, the off-diagonal contributions of the hexic force constant can be neglected in the fourth order approximation, and the diagonalized results without hexic off-diagonal terms are

20) To estimate the maximum error due to the neglect of higher terms, $B_5(7)+B_5(8)$ is calculated later, which gives 9×10^{-6} cm^{-1}.

21) Even though the terms up to $k=8$ are retained, convergence is slow and unsatisfactory for the higher levels. This forces us to put lighter weights (usually 0.01) on these rotational constants, when the least-squares adjustment is made.

TABLE 3. CONVERGENCE OF ROTATIONAL CONSTANT EXPANSION: $B_v(k)$ VALUES ARE LISTED FOR THE $v=0$, $v=1$, $v=2$, AND $v=5$ LEVELS (in cm^{-1})

$B_5(7)+B_5(8)=-0.000009\ cm^{-1}$ for CO.

given in Column (iv) of Table 2. Deviations (i)-(iv) in Column (vii) resemble those in column (v) in the case of CO, and are especially small for the low vibrational levels. As for HCl, the neglect of hexic off-diagonal terms drastically lowered the calculated frequencies. This can be interpreted that the terms like $k_7q^7+k_8q^8$ are necessary to account for the vibrational frequencies of HCl, and the SPPF is also tested in HCl.

Least-Squares Adjustment of Force Constants

Method of Least-Squares. The least-squares corrections to the initial values of force constants are found by solving well-known simultaneous linear equations

$$(\tilde{\mathbf{J}}\mathbf{P}\mathbf{J})\Delta\mathbf{K}=\tilde{\mathbf{J}}\mathbf{P}\Delta\boldsymbol{\nu}. \tag{13}$$

J, **P**, $\Delta\mathbf{K}$, and $\Delta\boldsymbol{\nu}$ have their usual meaning. In the anharmonic potential problem, a finite difference method has been used to evaluate the elements of Jacobian matrix **J**.[1] One advantage in the numerical diagonalization method is that we can use the techniques developed for normal coordinate analysis. From the first order perturbation method,[22] the Jacobian matrix element for the frequency ν_h with a change in the values of k_i is given by

$$\delta\nu_h/\delta k_i=(\tilde{\mathbf{L}}\mathbf{A}^{(i)}\mathbf{L})_{hh}, \tag{14}$$

where $\mathbf{A}^{(i)}$ and **L** are given in Eqs. (5) and (6). The elements for the rotational constant B_v are slightly more complex, Nakagawa and Shimanouchi[23] and Mills[24] evaluated the changes in eigen vectors due to a small change in a force constant k_i. Applying their results to the present case, we have

$$\Psi_v=\Psi_v{}^0+\sum_{v'\neq v}P_{vv'}\Psi_{v'}{}^0, \tag{15}$$

where $P_{v,v'}=\Delta k_i(\tilde{\mathbf{L}}\mathbf{A}^{(i)}\mathbf{L})_{vv'}/(\nu_v{}^0-\nu_{v'}{}^0)$ and $\Psi_{v'}{}^0$'s are the wave functions with $\Delta k_i=0$. As given in Eq. (10), $B_v{}^0$ for $\Delta k=0$ is expressed as

$$B_v{}^0=B_e\sum_{k=0}R_k\langle v|q^k|v\rangle$$

and

$$B_v\approx B_e\sum_{k=0}R_k\langle v|q^k|v\rangle+2\sum_{v'\neq v}P_{vv'}\langle v|q^k|v'\rangle, \tag{16}$$

$$\delta B_v/\delta k_i\approx 2B_e\sum_{k=0}(\delta P_{vv'}/\delta k_i)\langle v|q^k|v'\rangle$$

$$=2B_e\sum_{k=0}R_k\sum_{v'\neq v}(\tilde{L}_0A^{(i)}L_0)_{vv'}\langle v|q^k|v'\rangle/(\nu_v{}^0-\nu_v{}^0) \tag{17}$$

Application to CO and HCl. The least-squares adjustment of force constants has been made for the FPPF as well as the TPPF. The calculation has been made for the latter to see the truncation effect upon the harmonic, cubic, and quartic force constants. The vibrational frequencies and the rotational constants, are used as observational data. The results for CO and HCl are given separately in Tables 4—7. Only a minimum number of data is used to obtain Sets 1 and 2, *i.e.* ν_1, ν_2, B_0, and B_1. Six frequencies ν_1—ν_6 and five rotational constants B_0—B_4 are used in Sets 5 and 6. Sets 3 and 4 are intermediate cases. Sets 1,3, and 5 are obtained by solving a full Hamiltonian, while the quartic off-diagonal matrix elements are ignored in obtaining Sets 2,4, and 6. Similarly, in the FPPF, the hexic off-matrix ele-

ments are ignored in Set 8, while a full Hamiltonian is solved for Sets 7 and 9. In Set 9, the equilibrium rotational constant B_e is treated as an adjustable parameter, in other sets its value is fixed (1.931274 cm^{-1} for CO and 10.593553 cm^{-1} for HCl). The relative weights of the rotational constants and vibrational frequencies might affect the outcome. In the present calculation, $B_v\times 10^2$ is usually entered as input data.[25] In Sets 7′–9′ of CO, $B_v\times 10^3$ is used to see the effect due to the change in the relative weight. From the consideration of accuracy in evaluating rotational constants, less weights have to be given to B_3 and B_4 of HCl, usually $B_v\times 10$ being used as data.

Agreement between the calculated and experimental values in HCl is less satisfactory, and the seven parameter potential function (SPPF) is also tested. The results are included in Sets 10 and 11 of Tables 6 and 7. B_e is treated as a variable in Set 11.

Table 8. The calculated and observed frequencies and rotational constants (in cm^{-1}) for isotopic CO and HCl

	B_1	5.2673	5.2642
	B_2	5.1537	5.1535

Isotopic Species. Only a limited number of data is available for the isotopic species of CO and HCl,[26-28] and no least-squares fit of force constants has been attempted. Within the limit of Born-Oppenheimer approximation, however, the force constants $k_j^{(i)}$ for the isotopic species are related with those in the parent species k_j by means of

$$k_j^{(i)} = k_j(\mu/\mu^{(i)})^{j/4}, \quad (j=2,3,4,\cdots) \tag{18}$$

where μ and $\mu^{(i)}$ are the reduced masses of the parent and isotopic species, respectively. $B_e^{(i)}$ is given as $B_e^{(i)}=(\mu/\mu^{(i)})B_e$.[29] The results are summarized in Table 8, where no significant discrepancies are detected between the calculated and observed frequencies and rotational constants.

Discussion

Force Constants. In CO, the values of the five parameter force constants are not so sensitive to the change of the relative weights, but the effect may be seen in Table 5, where the differences between the observed and calculated frequencies and rota-

24) I. M. Mills, *J. Mol. Spectry.*, **5**, 334 (1960).

25) This is equivalent to weighting the rotational constants a hundred times heavier than the frequencies The frequencies are known with the accuracy of a few thousandths of a wave number. The accuracies of the rotational constants for the low vibrational levels are estimated in the order of 10^{-5} cm^{-1}

29) Note that $q=\gamma^{-1/2}\Delta r/r_e=(\Delta r/r_e)(\omega_e/2B_e)^{1/2}$, $B_e=\hbar/(4\pi r_e^2 c\mu)$, and $\omega_e=(1/2\pi)(K_e/\mu)^{1/2}$.

tional constants are listed. Regardless of the choice in the weighting systems, the first three force constants, *i.e.* ω_e, k_3, and k_4 of the FPPF converge to almost the same values. The values of k_5 and k_6 are more sensitive to the handling of data and to the method of calculation. The force constant k_6 converges to a larger value in Set 8. In the perturbation treatment, the off-diagonal contribution of hexic force constant is discarded, since its contribution to the vibrational energy is expected to be small and is of the same order as the diagonal contribution from the neglected higher order terms. As seen from Column (vii) of Table 2, however, the above statement is not adequate for CO and the discrepancy as large as 18 cm^{-1} is found for the $v=6$ level, while the diagonal contribution from k_8 is expected to be less than 1 cm^{-1}. A trial calculation is carried out by using the force constants in Set 9 plus $k_7=-0.001$ cm^{-1} and $k_8=0.0001$ cm^{-1}.[30] The calculated frequencies for the $v=5$ and $v=6$ levels decrease only by 2 and 4 cm^{-1}, respectively. The truncation errors for k_5 and k_6 are much smaller in Set 9, and it is regarded as the best set so far obtained.

From the calculation of the FPPF, we were able to determine the precise values of the first three parameters. ω_e, k_3, and k_4. However, in the potential functions of triatomic molecules from which the present study was initiated, we can hardly expand the potential function beyond quartic terms for parctical reasons. The least-squares adjustment of the TPPF is therefore attempted to seek the most appropriate method and the handling of data to obtain the reasonable values for these three constants. It is clearly seen from Table 4 that the force constants in Sets 1 and 2 are much closer to the values found in the FPPF. The deviations of these force constants from the 'true' values are almost the same in both sets but differing in sign. The average values of the force constants in Sets 1 and 2, $\omega_e=2169.09$, $k_3=-122.48$, and $k_4=8.8126$ cm^{-1}, are much close to the values found in Set 9. These results might be useful when the anharmonic potential functions of polyatomic molecules are dealt with.

The conclusion analogous to the case of CO may be drawn on the converged values of force constants for HCl: the first three force constants in the FPPF, especially those in Sets 7 and 9 converge to almost the same values. As for the TPPF, Sets 1 and 2, in which the minimum number of data is used, yield force constants closer to those in the FPPF. Much closer fit is also obtained when the average values of force constants in Sets 1 and 2 are taken: $\omega_e=2988.76$, $k_3=-291.42$, and $k_4=37.46$ cm^{-1}. However, the values of the first three force constants in Set 8 deviate from those in Sets 7 and 9 by 2—10%. They are much larger than the corresponding deviations found in CO. The overall fit of the calculated frequencies and rotational constants to the experimental values are poorer in HCl. The value $\gamma=(2B_e/\omega_e)$, which is a measure of smallness in perturbation treatment, is 0.007 for HCl in contrast to 0.0017 for CO. The ratio of k_{n+1}/k_n is about 0.01 for CO but close to 0.1 for HCl. This, in conjunction with the relatively large value of γ, makes the convergence much slower. Thus the SPPF where the potential function is expanded to the $k=8$ term was also tested. The results are included in Tables 6 and 7. Since the higher order force constants are considered, the converged values for k_5 and k_6 in Sets 10 and 11 are most reliable, and they are found closer to those found in Sets 7 and 9. This confirms the conclusion drawn earlier on HCl and CO. As far as the FPPF is concerned, the solution of the full vibrational Hamiltonian is preferable.

When the equilibrium rotational constant is treated as an adjustable parameter, a slight increase in the value of B_e serves for the improvement in the least-squares fit. The change in the B_e value is larger in HCl, but the corresponding decrease in the internuclear distance is in the order of 0.0001 Å. Table 9 summarizes the force constants obtained by the ordinary perturbation formulas and by the present method. As far as the general pattern of potential function in diatomic molecule is concerned, the force constants calculated from Dunham's equations, Eq. (15) in Ref. 12, or from the much simpler second-

TABLE 9. THE FIRST THREE FORCE CONSTANTS (in cm^{-1}) OF CO AND HCl DERIVED BY VARIOUS METHODS

(a) CO

	2nd-Order	4th Order	Direct (Set 7)	Direct (Set 9)

order equations, Eqs (16) and (17), have sufficient accuracies, and errors are probably within a few percent. More careful considerations seem to be necessary for more quantitative arguments, such as spectroscopic detection on the deviations from the Born-Oppenheimer behavior. Dunham's equations are sometimes insufficient for attaining the required accuracy, and the relationship between the spectroscopic term value Y_{ij} and the force constants must be examined carefully. Herman and Ashgarrian[31] tried to explain the discrepancy between the observed and theoretically predicted $Y_{02}(\approx D_e)$ values of HCl from the deviations of Born-Oppenheimer oscillators. Their failure obviously stems from neglect of contributions of the higher order force constants to Y_{02}. A more careful treatment such as given recently by Bunker[32] seems necessary.

As already stated, we have triatomic molecules in mind, and CO may serve as a model for CO_2, and HCl for H_2O. The parameter $\gamma=2B_e/\omega_e$ of CO_2 is less than one third of the corresponding value of CO (0.00058 as compared with 0.00178 of CO), and the least-squares determinatation based on Nielsen's second order perturbation treatment for this molecule[1,2] seems to be adequate. A preliminary calculation shows that the calculated values given in Ref. 2 do not differ significantly from those obtained from the diagonalization method. From the results of HCl, overall difficulties are anticipated for the treatment of anharmonic potential of H_2O. Inclusion of higher order force constants seems to be necessary at least for those related with the hydrogen stretching coordinates. However, some values may be estimated from the lower order force constants by assuming a suitable model potential. The Morse function[33] with two adjustable parameters A and a,

$$V(q) = A[1-\exp(-aq)]^2 \tag{19}$$

is probably the simplest potential for the bond-stretch. These constants can be determined from w_e and k_3 by $a=-2k_3/\omega_e$ and $A=\omega_e^3/8k_3^2$, and higher force constants evaluated from Eq. (19). This is done for CO and HCl, and the results, given in Table 10, show that the bond stretching potential qualitatively follows the pattern of the Morse function[1-3,6] Quantitatively, however, the prediction of the simple Morse function is not very satisfactory. In HCl the k_4 value is about 25% off from the converged one. In order to increase the freedom, the expanded Morse function[34] is also considered;

$$V(q) = \sum_{i=1}^{2} A_i[1-\exp(aq)]^{i+1} \tag{20}$$

The constants A_1, A_2, and a can be determined from ω_3, k_3, and k_4 from the relations

$$\omega_e = 2A_1a^2 \tag{21}$$

$$k_3 = (A_2-A_1)a^3 \tag{22}$$

$$k_4 = (3/2)(7A_1/18) - A_2a^4 \tag{23}$$

which leads to the quadratic equation for a

$$F(a) = a^2 + (36k_3/11\omega_e)a + (24k_4/11\omega_e) = 0. \tag{24}$$

The remaining higher order force constants can be obtained,

$$k_5 = -(1/4)[(A_1-5A_2)]a^5, \tag{25}$$

$$k_6 = (3/4)[(31A_1/270)-A_2]a^6. \tag{26}$$

In the cases for CO and HCl, rigorous solutions for Eq. (24) give imaginary roots for a. However, if we use the value of a which makes the above $F(a)$ minimum $a=-(18k_3/11w_e)$, we have much improved results which are given in the third column of Table 10.

In conclusion, the following remarks can be made. (1) The truncation effect upon the highest order force constant retained in the potential function is in the order of 10—20%, but larger deviations must be tolerated for the hydrogen containing molecules. In the latter, it is preferable to use the FPPF, since the effects of the quintic and hexic force constants to low vibrational levels are not negligible. (2) In order to calculate the rotational constants with accuracies comparable to those attained experimentally, the terms up to $k=6$ should be retained in the rotational Hamiltonian. More terms are necessary for the HCl

molecule. (3) In the TPPF, use of the minimum number of data seems preferable. When the least-squares fit is carried out, solutions with and without the quartic off-diagonal elements must be considered. The results indicate the error limits for these force constants.

The author wishes to express his sincere gratitude to Prof. Takehiko Shimanouchi for his helpful discussion and continuous interest in this work.

Appendix

The non-vanishing matrix elements in the harmonic oscillator representation $\langle n|q^k|n-m\rangle$ are listed in Table A-1. The terms from $k=1$ to $k=8$ are included in the table. The matrix element $\langle n|q^k|n+m\rangle$ can be obtained from the corresponding expression for $\langle n|q^k|n-m\rangle$ by replacing n with $n+m$. Note also that $\langle n|q^2+p^2|n\rangle=2n+1$ and $\langle n|q^2+p^2|n+2\rangle=0$.

In Table A-2, non-vanishing matrix elements of $A_{nm}^{(i)}$ ($n\leq 10$, $m\leq 10$, and $i\leq 8$) are shown.

Time-Resolved Fluorescence Studies on Charge Transfer Interactions in 1,2,4,5-Tetracyanobenzene-Toluene Complex[1]

Keiichi EGAWA, Nobuaki NAKASHIMA, Noboru MATAGA,[2] and Chiyoe YAMANAKA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

**Department of Electrical Engineering, Faculty of Engineering, Osaka University, Suita, Osaka*

(Received May 28, 1971)

Time-resolved CT (charge transfer) fluorescence spectra and the fluorescence rise and decay curves at various wavelengths of the CT fluorescence band have been measured for the 1,2,4,5-tetracyanobenzene (TCNB)-toluene system at various temperatures. The results and detailed studies of the effect of solvent polarity on the fluorescene wavenumbers have demonstrated that the relaxation process is due to the change of structure including the surrounding solvent molecules from the Franck-Condon (F.C.) state to the equilibrium (e.q.) state of the excited complex. This relaxation process causes a large Stokes shift of the CT fluorescence.

Although there are numerous investigations on the electron donor-acceptor (EDA) complexes by the absorption spectral measurements, few studies have been carried out on the excited complexes by fluorescence spectral measurements, except for rigid solvents at lower temperatures, because of the fact that the fluorescence yield of the EDA complex in solution at room temperature is extremely small in general.[3] However, somewhat detailed fluorescence studies are possible in the case of TCNB-aromatic hydrocarbon EDA complexes since they are strongly fluorescent in solution at room temperature when the solvent dielectric constant is not large.

It has been observed for the TCNB-toluene EDA complex that the fluorescence lifetime at room temperature is more than 100 nsec which is much longer than the radiative lifetime (~50 nsec) calculated from the intensity of the CT absorption band.[4] Contrary to this, the fluorescence lifetime observed in a rigid state at 77°K is nearly equal to the calculated radiative lifetime.[4] This clearly indicates a considerable change in the structure of the complex during the fluorescence lifetime, where the molecular rearrangement motions including the surrounding solvent molecules occur easily at room temperature but with difficulty at 77°K. The rearrangement relaxation from the F. C. excited state to the e.q. fluorescent state, which can be ascribed to the strong interaction between the excited complex and the surrounding solvent molecules, brings out an extraordinary large Stokes shift of *ca.* 12000 cm^{-1} at room temperature.[4]

In order to elucidate the structure of the excited complex and the dynamical processes of its rearrangement motions we have carried out detailed studies on the effect of temperature and solvent polarity on the fluorescence wave-numbers. We have measured the time resolved fluorescence spectra and the fluorescence rise and decay curves at various fixed wavelengths of the CT fluorescence band of the complex at various temperatures. The results of the time-resolved fluorescence studies gave a direct demonstration of the extensive F.C.→e.q. relaxation process assumed previously.[4]

Experimental

A 337 nm light pulse of nitrogen gas laser was used for the excitation of the complex. The light pulse has a peak output power of 10 kW and duration of 3 nsec. Its repetition rate was *ca.* 50 Hz. Fluorescence emission was observed with a travelling wave-pulsed photomultiplier according to Bennett.[5] The outputs from the photomultiplier with delay line were displayed on an X-Y recorder. Thus, we obtained the time-resolved spectrum at a fixed delay time

or the time variation of luminescence intensity at a fixed wavelength. Our apparatus was calibrated to obtain correct luminescence quantum spectrum. For the measurement of ordinary luminescence spectrum, an Aminco-Bowman spectrophotofluorometer calibrated to obtain the correct luminescence quantum spectrum was used. The measurement of temperature effect on the fluorescence was conducted by, using a metal dewar with quartz windows. The temperature of the solution in a quartz cuvette placed in the dewar was controlled by a constant flow of cold nitrogen gas. The flow of the gas was controlled by heating liquid nitrogen and the temperature of the solution was measured with a thermocouple. The measurement at 77°K was carried out with a quartz dewar containing a solution in a cuvette immersed in liquid nitrogen. Differential thermal analysis on the phase transition of toluene was made with an apparatus constructed by Prof. S. Seki and his coworkers of this university.

TCNB sample was the same as used before.[4] It was recrystallized from ethanol before use. Benzene and toluene were shaken with sulfuric acid, dried over calcium chloride and after passing through a column of activated alumina, distilled fractionally. *o*- and *m*-xylene were distilled. Cyclohexane and *n*-hexane were passed through a column of activated silica gel, dried over sodium metal and distilled. *o*-Dichlorobenzene and monochlorobenzene were dried over calcium chloride and distilled. Trichloroethylene was distilled. Merck spectrograde tetrachloroethylene was used without further purification. All solutions were deaerated by freeze-pump-thaw cycles.

Results and Discussion

The luminescence spectra of TCNB–toluene system at several temperatures are given in Fig. 1.

When the temperature of the solution is lowered from room temperature to 193°K, the wavelength of the fluorescence band maximum (λ_F^m) shifts from 510 nm to 530 nm. A slight decrease of fluorescence intensity as well as decay time occurs. In the temperature range 183—153°K, where the system is in a supercooled liquid state, the λ_F^m value is approximately constant (~530 nm). A remarkable spectral shift from 530 nm to 450 nm occurs in the temperature range 150—138°K, as indicated partly in Fig. 2. At *ca.* 138°K, the phosphorescence band appears at about 500 nm. It seems probable that, at some temperature around 138°K, the phase transition from the supercooled liquid to the glassy state occurs when the temperature is lowered. At about 146—148°K, the solution is in a quite viscous supercooled liquid state and the fluorescence band with maximum at 490 nm is very broad (with half-value width of *ca.* 6000 cm^{-1}). At lower temperatures (136—77°K) fluorescence band shows further blue shift (λ_F^m=435 nm at 133°K and 420 nm at 77°K).

When the temperature is raised from 77°K, the fluorescence band maximum shows a red shift. An abrupt change in the spectrum as well as in the temperature of the system occurs at 137°K where the phosphorescence intensity becomes much stronger than the fluorescence intensity. We have confirmed by means of differential thermal analysis that this spectral change can be ascribed to the phase change of solution from glassy to crystalline states. The luminescence spectrum of the complex in the crystalline state is shown in Fig. 1. We have confirmed that this luminescence band can be ascribed to the phosphorescence of the complex by means of phosphorescence measurement. The observed phosphorescence decay time was about 2 sec. Thus, the spectra in the crystalline state differ from those in the glassy

state. In the temperature range 182—188°K, the phosphorescence band with peaks at 475 nm and 500 nm disappears and the fluorescence band appears at 425 nm as shown in Fig. 3. This change corresponds to the melting of the crystal. It should be noted that we can recognize an iso-emissive point at *ca.* 470 nm. At higher temperatures the fluorescence band shows a red shift and λ_F^m value at 243°K is *ca.* 530 nm. When the temperature is raised further, the spectrum shows a blue shift to λ_F^m value of 510 nm at room temperature.

At room temperature, the fluorescence spectra at various delay times from the exciting laser pulse were practically the same, and the fluorescence decay times at various wavelengths of the band were all equal to *ca.* 100 nsec. Analogous results can be observed also in the case of the glassy state at low temperatures (137°—77°K), where the fluorescence decay times at various wavelengths were all equal to *ca.* 50 nsec.

The results indicate that the excited F.C.→e.q. relaxation process of the complex including the surrounding solvent molecules at room temperature is much faster than the time resolving ability (a few nsec) of the apparatus. In the case of the glassy state at low temperatures, however, the observed results seem to indicate that it is impossible for the above relaxation process to occur during the fluorescence lifetime in the rigid state.

If the excited F.C.→e.q. relaxation time becomes comparable to the fluorescence lifetime somewhere between room temperature and the temperature of the glassy state, the fluorescence of the complex should show a time-dependent spectral shift and wavelength-dependent fluorescence rise and decay times. We have actually observed such results in the case of the supercooled liquid state at about 147°K.

As indicated in Fig. 4, the fluorescence decay times at 147°K and at 145°K show remarkable wavelength-dependences and the decay times at long wavelength part of the fluorescence band are much longer than those at short wavelength part of the band. In Fig. 5, we show fluorescence rise and decay curves at 147°K for several different wavelengths. We see

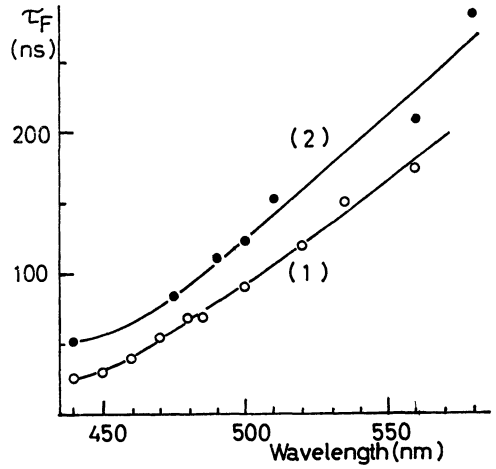

Fig. 4. Wavelength-dependence of the fluorescence decay time in the supercooled liquid state.

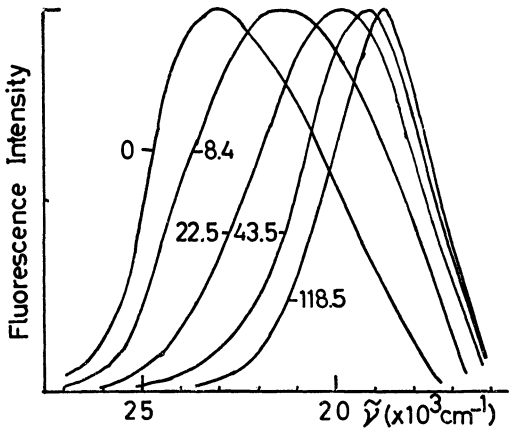

Fig. 6. Time-resolved CT fluorescence spectra of TCNB-toluene system in the supercooled liquid state at 147°K. Times indicated are in nsec after the rise of the laser pulse.

that both the fluorescence rise and decay times are longer at longer wavelengths. Furthermore, as shown in Fig. 6, time-resolved spectra (different spectra at delay times differing from the exciting pulse) have been clearly observed at 147°K.

The above results clearly show that the excited F.C.→e.q. relaxation process in the highly viscous environment at 147°K is much slower than that at room temperature. At 147°K, the relaxation time can be comparable to the decay time of the excited state. Thus, the relaxation process involving the surrounding solvent molecules has been demonstrated.

In Fig. 6, the band shape at the early stage of the fluorescence emission appears to differ considerably from that at the later stage of emission. This might be ascribed to the change in the structure of the complex during the relaxation process. However, it does not seem conclusive since the experimental error is larger at smaller delay times because of the time jitter ($\leq$2 nsec) due to the discharge trigger of the laser tube and smaller emission intensities. At any rate, the change of the structure of the complex should occur somewhere in the course of the excited F.C.→ e.q. relaxation since the radiative lifetime calculated from the absorption intensity is much smaller than the observed decay time.

Recently, the excited singlet-singlet (S_n-S_1) absorption spectra of TCN–Bbenzene and TCNB–toluene complexes have been measured by laser photolysis and by analyzing the reabsorption effect of the CT fluorescence by the excited singlet complexes.[6,7] Since the observed S_n–S_1 absorption spectra are very similar to those of TCNB anion, the electronic structure of the complex in the fluorescent e.q. state has been concluded to be a contact ion-pair.[6,7] Quantum chemical calculations on the TCNB–toluene complex show that the local excitation of TCNB and CT configuration contribute equally to the excited F.C. state while the fluorescent e.q. state has been found to have 99% CT character.[6b] Theoretical calculations have indicated clearly that the complex has the structure given in Fig. 7a in the ground e.q. as well as the excited F.C. states where the intermolecular overlap integral is considerable, while it has a symmetrical overlapping structure (Fig. 7b) in the excited e.q. and ground F.C. states where the intermolecular overlap integral is very small.[6b] Thus the F.C.→e.q. relaxation observed directly in the present work presumably involves a considerable structural change of complex in addition to rearrangements of the surrounding solvent molecules, and the contact ion-pair state seems to have a much longer radiative lifetime than that calculated from absorption intensity.

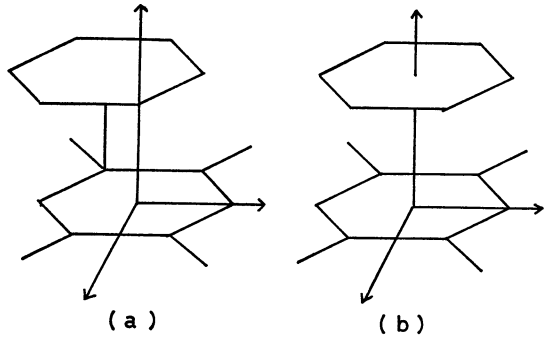

Fig. 7. Possible geometrical configurations of the complex.
a. Ground e. q. and excited F. C. states.
b. Fluorescence e. q. and ground F. C. state.

Since the structural change in the course of the excited F.C.→e.q. relaxation is quite large and the dipole moment of the excited e.q. state seems to be much larger than those in the excited F.C. and ground states, the effect of the solvent polarity on the wavenumbers of the fluorescence band maxima of the complex may be similar to the case of heteroexcimers. Using the theory of dielectric polarization, we can easily show that the wavenumber difference between the absorption and fluorescence band maxima can be given by[8]

$$hc(\tilde{\nu}_a-\tilde{\nu}_f) \cong 2(\Delta f/a^3)(\vec{\mu}_a^2-\vec{\mu}_a\cdot\vec{\mu}_g^{FC}-\vec{\mu}_g\cdot\vec{\mu}_a^{FC}+\vec{\mu}_g^2) - (\Delta f_n/a^3)(\vec{\mu}_a^2-\vec{\mu}_g^{2FC}-\vec{\mu}_a^{2FC}+\vec{\mu}_g^2), \quad (1)$$

$$\Delta f=\frac{\varepsilon-1}{2\varepsilon+1}-\frac{n^2-1}{2n^2+1},\quad \Delta f_n=\frac{n^2-1}{2n^2-1}$$

where a is the cavity radius in Onsager's theory of reaction field, ε and n are the solvent dielectric constant and refractive index, respectively, $\vec{\mu}_a$ and $\vec{\mu}_g$ represent dipole-moments in the excited e.q. and ground e.q. states, respectively, $\vec{\mu}_a^{FC}$ and $\vec{\mu}_g^{FC}$ are dipolemoments in the excited F.C. and ground F.C. states. In the present, the terms with $\vec{\mu}_a^2$ might be much larger than the others in the rhs of Eq. (1). Thus, we have

$$hc(\tilde{\nu}_a-\tilde{\nu}_f) \approx 2(\vec{\mu}_a^2/a^3)\left(\Delta f+\frac{1}{2}\Delta f_n\right). \quad (2)$$

As shown in Fig. 8, Eq. (2) can reproduce experimental results of TCNB–toluene complex in various solvents very well. Since $\tilde{\nu}_a$ value is approximately constant in these systems, the following is valid.

$$hc\tilde{\nu}_f \approx -2(\vec{\mu}_a^2/a^3)\left(\Delta f+\frac{1}{2}\Delta f_n\right) \quad (3)$$

This is the same equation as that applied to the solvent shift of the heteroexcimer fluorescence.

It should be noted that the $(\tilde{\nu}_a-\tilde{\nu}_f)$ value in toluene *i.e.* the value for the TCNB–toluene two component system is included in Fig. 8. We have discussed the possibility of 1 : n ($n\geq2$) complex formation during the lifetime of the fluorescent state in the case of TCNB–benzene and TCNB–toluene systems, in view of the very large Stokes shift.[4] The results in Fig. 8, show that the 1 : n ($n\geq2$) complex formation is improbable, since the observed shift of the fluorescence band can be well explained as due to the electrostatic interaction between the 1 : 1 complex and the solvent molecules.

The results in Fig. 6 can be further analyzed by means of Bakhshiev's equation.[9] The fluorescence intensity at the wavenumber ν and at the delay time t can be written as

$$I(\tilde{\nu}, t) = n(0)B(t) \exp\left[-\int_0^t B(t)dt\right] \cdot \gamma(t) f(\tilde{\nu}, t) \qquad (4)$$

where $n(0)$ is the number of excited molecules at $t=0$, $B(t)$ is the sum of radiative and radiationless transition probabilities, and $\gamma(t)$ is the fluorescence quantum yield. $B(t)$ and $\gamma(t)$ are functions of t in general because of time-dependent structural changes of the system. $f(\tilde{\nu}, t)$ represents the effect of the time-dependent spectral shift on the observed fluorescence rise and decay processes.

If the transition probability and the fluorescence quantum yield is time-independent, *i.e.* the excited F.C.→e.q. relaxation process does not involve the structural change of the complex itself but is caused by the reorientation motions of the surrounding solvent molecules, Eq. (4) can be rewritten as,

$$I(\tilde{\nu}, t) \approx n(0)\frac{1}{\tau_F} \cdot \gamma \exp\left[-t/\tau_F\right] \cdot f(\tilde{\nu}, t)$$
$$= Const \cdot \exp\left(-t/\tau_F\right) \cdot f(\tilde{\nu}, t) \qquad (5)$$

If the change of the structure of the complex occurs at some time in the early stage of the excited F.C.→ e.q. relaxation, the time variation of the fluorescence intensity after that time can be expressed by Eq. (5). $f(\tilde{\nu}, t)$ can be evaluated from the normalized time-resolved spectra as indicated in Fig. 6. The decay time associated with $I(\tilde{\nu}, t)$ can be calculated by means of Eq. (5) assuming an appropriate value for τ_F. In Table 1, the calculated values at various wavelengths taking $\tau_F = 120$ nsec are compared with the observed values. Agreement between the observed and calculated values is rather satisfactory. Almost all parts of the structural change might be completed immediately after the excitation.

Table 1. Observed and calculated fluorescence decay times for TCNB-toluene system at 147°K

Wavelength (nm)	$\tau_{F,obs}$(nsec)	$\tau_{F,calc}$(nsec)
440	25	30
460	40	50
480	60	60
500	90	90
520	120	105
535	140	130
560	170	135

No relaxation process occurs during the excited state lifetime in the case of the glassy state of TCNB-toluene system. However, we have found out that we can observe a slight time variation of fluorescence spectra in the case of the crystalline state. The crystalline state was formed at 137°K when temperature was raised from 77°K in the glassy state. After the phase transition occurred at 137°K, the temperature was lowered to 77°K or raised to 171°K and the wavelength dependence of the decay times as well as the time-resolved spectra were measured. The results are given in Figs. 9 and 10.

We see that the extent of the wavelength dependent variations of the decay time and the red shift in the time-resolved spectra at 171°K are larger compared to those at 77°K. In general, the extent and the rate of the time-dependent spectral changes in the crystalline state are much smaller than those in the supercooled liquid state at 147°K. This may be due to the fact that the molecular motions responsible for the excited F.C.→e.q. relaxation are much slower in the crystalline state than in the supercooled liquid state at 147°K.

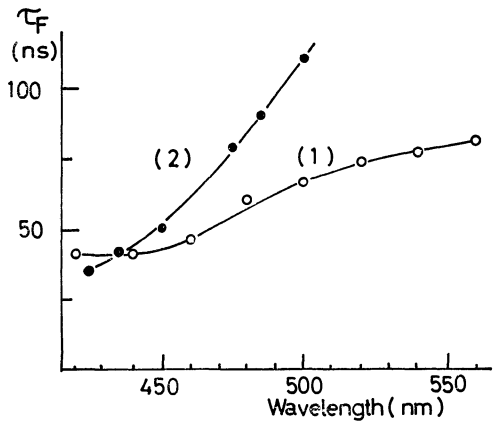

Fig. 9. Wavelength-dependence of the fluorescence decay time in the crystalline state.
1, 77°K; 2, 171°K

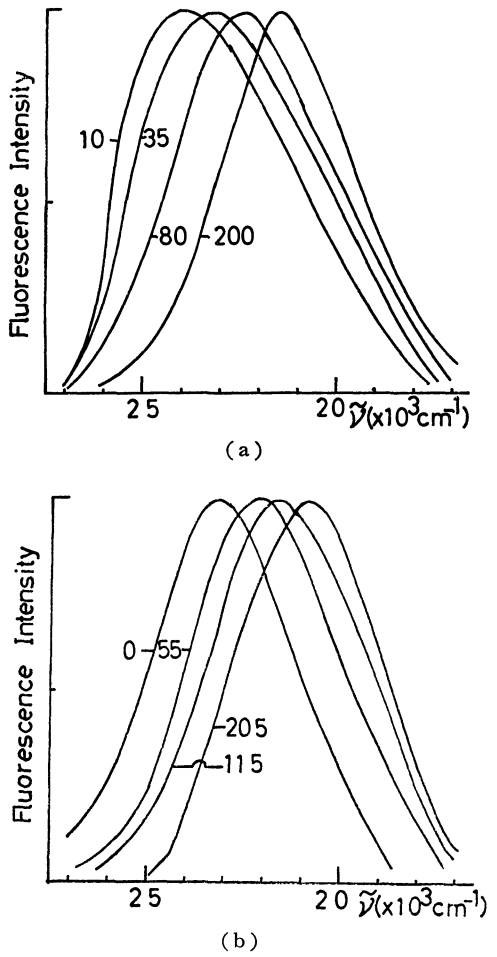

Fig. 10. Time-resolved fluorescence spectra of TCNB-toluene system in the crystalline state. Times indicated are in nsec after the rise of the laser pulse.
a, 77°K; b, 171°K

It seems rather peculiar that the time-dependent spectral changes were not observed in the glassy state, in contrast to the results of the crystalline state. However, since the crystalline state of the TCNB-toluene system was produced by the phase transition from the glassy state at a fairly high temperature, it might be rather soft and contain many defects, which would allow some molecular motions during the excited state lifetime. In the case of TCNB-benzene, TCNB-*o*-xylene and TCNB-*m*-xylene systems, the crystalline state is formed simply by the phase transition from the liquid state when the temperature is lowered. We were not able to observe any wavelength dependence of the fluorescence decay time for these systems in the crystalline state at 77°K. This seems to indicate that the crystals of these systems contain a much smaller amount of defects than the TCNB-toluene system, and it is very difficult for the molecular motions to rise during the excited state lifetime.

Table 2. Observed and calculated fluorescence decay times for TCNB-toluene system in the crystalline state

(A) at 77°K taking $\tau_F = 65$ nsec

Wavelength (nm)	$\tau_{F,obs}$(nsec)	$\tau_{F,calc}$(nsec)
420	40	40
440	40	50
450	45	55
480	60	65
500	65	65
540	75	70

(B) at 171°K taking $\tau_F = 70$ nsec

Wavelength (nm)	$\tau_{F,obs}$(nsec)	$\tau_{F,calc}$(nsec)
425	35	50
450	55	60
475	80	75
500	110	100

We have analyzed the experimental results of Fig. 10 according to Eq. (5), and the results of calculations are shown in Table 2A and 2B. Agreement between the observed and calculated τ_F values is fairly satisfactory. Thus, the model assumed for Eq. (5) appears to be valid approximately in these cases as in the case of relaxation process at 147°K. Probably, a slight structural change in the complex occurs immediately after the excitation even in the crystalline state and only a slight reorientation relaxation of the surrounding solvent molecules occurs during the excited state lifetime.

Concluding Remarks

The extensive relaxation process of excited F.C.→ e.q. in the TCNB-toluene system including the surrounding solvent molecules has been demonstrated by the measurement of the time-resolved fluorescence spectra. The extensive relaxation seems to be initiated by the structural change of the complex due to excitation. Analysis of the time-resolved spectra has indicated that almost all parts of the structure change in the complex occurs immediately after the excitation even in the quite viscous medium at 147°K.

The Electrolytic Conductances of Bis(halogenoacetato)bis-(ethylenediamine)cobalt(III) Ions in Water

Masatoki Yokoi and Kashiro Kuroda*

Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto, Nagano

**Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime*

(Received May 31, 1971)

The electrolytic conductances of bis(halogenoacetato)bis(ethylenediamine)cobalt(III) perchlorate, $[Co(halac)_2(en)_2]ClO_4$ where Hhalac=CH_3CO_2H, CH_2ClCO_2H, $CHCl_2CO_2H$, CCl_3CO_2H, and CF_3CO_2H were measured in water at 25°C. The equivalent conductances of the solutions ($c=10^{-3}$—10^{-4} mol/l) were obtained from the conductance kinetic runs by extrapolating conductances to time zero. The ionic equivalent conductances of the complex ions were 21.5—17.2 $ohm^{-1}cm^2eq.^{-1}$, and decreased with the increase of the chlorine content in the chloroacetato ligands. Little differences in the ionic equivalent conductances were observed between a pair of cis and trans isomers. The rate constants of the first order aquation of the complexes were estimated.

The electrolytic conductance of a complex ion has often been measured in order to determine (1) the electric charge of the ion, (2) the velocity of substitution reaction such as aquation, and (3) the equilibrium constant of the complex formation or the association constant with a counter ion.

Although many data are available in literature[1], we can hardly find any systematic research which directs out attention to the elucidation of the relation between the conductivity and the structure of complexes. In order to grasp the relation, this study deals with the conductance of bis(halogenoacetato) bis(ethylenediamine)cobalt(III) perchlorate, $[Co(halac)_2(en)_2]ClO_4$, in aqueous solution at 25°C, where Hhalac=CH_3CO_2H, CH_2ClCO_2H, $CHCl_2CO_2H$, CCl_3CO_2H, and CF_3CO_2H.[2] The group of complexes has the following benefits to elucidate the dependence of conductivity on the structure of complexes. They are uni-univalent electrolytes which are the easiest type of electrolyte for theoretical consideration. The *cis*- and *trans*-isomers for various halac have been identified.[3] The size of the complexes increases steadily with the increase of the number of halogene atom in the halac ligands. The counter ion - perchlorate - has little tendency to associate with the complex ions in the range of concentration which were measured ($c=10^{-3}\sim10^{-4}$ mol/l). Their aquation velocities are relatively slow, despite the fact that they belong to the diacido-complex which generally aquates quickly.[4] Thus it is possible to obtain reliable values for equivalent conductance at infinite dilution.

Experimental

Materials. The complexes were prepared by the procedures described previously.[3] They were recrystallized at least twice and washed with absolute ethanol many times in order to remove completely the perchloric acid or sodium perchlorate which were used to precipitate the complexes in recrystallization. They were then dried in a vacuum desiccator over silica gel until the weight of the materials did not change any more. The specific conductance of the water was in a range 6×10^{-7}—7×10^{-7} ohm^{-1} cm^{-1}.

Apparatus and Measurement. A Jones-type bridge was used for the measurements and an alternative current of 10 kc frequency was applied to the bridge. A weighed sample in a small polyethylene dish was dissolved by magnetic stirring in one of two flask-type conductivity cells which had been placed in an oil-thermostat and contained a definite amount of conductivity water (~400 g). The cell constants of the cells were 0.23308 and 0.05355. Immediately after the dissolution, the resistance was measured at definite time intervals. A few complexes were measured in both of the cells, and the agreement of the results was satisfactory. As an example of the measurements, Fig. 1 shows the time-dependence of the specific conductance L of *cis*-$[Co(dclac)_2(en)_2]ClO_4$. We see that the specific conduc-

tance of all the complexes increased linearly with time in the region 40—100 min. The values obtained within 20 min sometime deviated slightly from the straight line. This can be attributed to the non-homogeneity of the solution, even though all the solid sample dissolved completely in a few minutes. The specific conductance at time zero was extrapolated from the straight line, and the equivalent conductance was calculated.

For each of the complex salts, the measurement was carried out with at least three different concentrations. The equivalent conductances thus obtained are given in Table 1.

Discussion

Dependence on Concentration. The concentration dependence of the equivalent conductance Λ of all the complex salts agreed with the Onsager limiting conductance equation for the uni-univalent salts

$$\Lambda = \Lambda_0 - (\alpha\Lambda_0 + \beta)\sqrt{c}. \quad (1)$$

Thus, from this equation, it is possible to estimate the equivalent conductance at infinite dilution Λ and the ionic equivalent conductance λ_0^+ by subtracting λ_0^-(67.4 for perchlorate and 40.9 for acetate[5]) from Λ_0. These values are summarized in Table 2. The effective ionic radii R^+ are also indicated which are calculated from the following equation,[6] assuming the Stokes law holds in the ionic transportation:

$$R^+ = Fe/1800\pi\eta\lambda_0^+ \quad (2)$$

where F is the Faraday charge, e the electronic charge, and η the viscosity coefficient of water.

a) acetate

We see that the ionic equivalent conductance decreases and the effective ionic radii increases with increase of the chlorine content in the halac ligand, and that there hardly exists a difference in conductivity between a pair of *cis*- and *trans*-isomers. These results are worthy of discussing.

In a dilute solution, the equivalent conductance of ions depends on the volume or the ionic radii and not on the mass, when the charge of the ions are identical. If actual conductivity of a group of ions is not parallel to the radii of the ions, as in the case of the alkali ions, the cause is attributed to the different degree of the solvent association of ions. Thus, the effective volume of an ion in a solution can be estimated from the conductivity measurement. In the present *cis*- and *trans*-series of the complexes, the association of water molecule (if any) is considered to be identical except at the site of the methyl and the chloromethyl radicals. As the radicals are not hydrophilic, the association at this site would be negligible. Thus, in each series of the complexes, it can be reasonably accepted that the effect of the solvent association does not affect the order of the conductivity of the complexes. Actually, the experimental results showed the normal order expected from the size of the complexes. In the tables, the values of *cis*- and *trans*-$[Co(mclac)_2(NH_3)_4]ClO_4$ are shown for comparison. It is seen that the tetraammine-complexes have a higher conductivity than the corresponding bis(ethylenediamine)-complexes.

Rate of Aquation. The conductivity of the complexes increases with time. This can be undoubtedly attributed to the aquation

5) R. A. Robinson and R. H. Stokes, "Electrolyte Solutions," 2nd ed. Butterworths, London (1959), p. 463.

6) R. M. Fuoss and F. Accascina, "Electrolyte Conductance," Interscience Publishers Inc., New York, N. Y. (1959), p. 60.

$$[Co(halac)_2(en)_2]^+ + H_2O \rightarrow [Co(halac)(H_2O)(en)_2]^{2+} + halac^-.$$

If the conductivity of the resulting halogenoacetatoaquo complexes were known, it would be possible to evaluate accurately the rate of aquation from the time dependence of conductivity. However, the halogenoacetatoaquobis(ethylenediamine)cobalt(III) salts have not been isolated, and the conductivity of the ions are unknown. Thus, an assumption is necessary for the calculation of the rate constant.

The size of the ions which determines the conductivity of this group of complexes can be approximately equal in a reactant bis(halogenoacetato)-complex and the resulting halogenoacetatoaquo-complex, because the replacement of a halogenoacetato ligand by a water molecule does not considerably change the total size of the ion. The resultant ions are divalent. Therefore, it is reasonable to assume that the conductivity of the resultant complex ion is twice as large as that of the corresponding reactant complex ion. The variation of the conductivity with time was examined on this assumption and with λ_0^-'s of the halogenoacetate ions.[7] The plots of log $(L_\infty - L)$ of *cis*-$[Co(ac)_2(en)_2]ClO_4$ *versus* time are shown

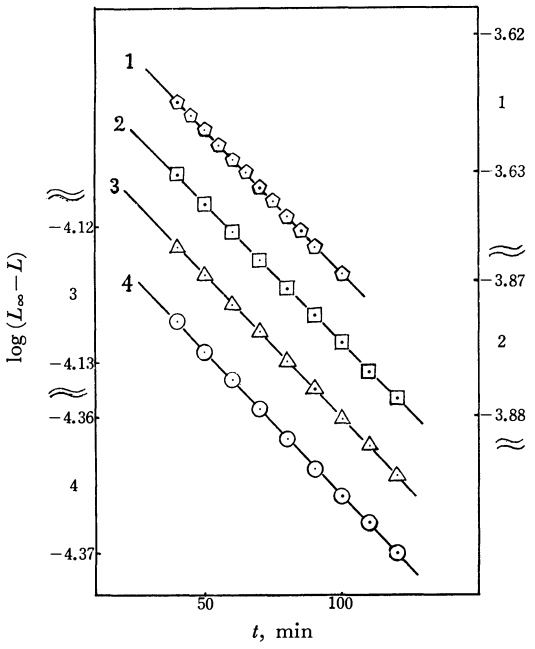

Fig. 2. The plots of log $(L_\infty - L)$ *vs.* time of *cis*-$[Co(ac)_2(en)_2]ClO_4$.
1, $c=2.498\times10^{-3}$, 2, $c=1.458\times10^{-3}$, 3, $c=8.130\times10^{-4}$, 4, $c=4.648\times10^{-4}$.

7) The values of λ_0^- of dichloroacetate and trichloroacetate ions used in the calculation were 37.4 and 35.2, respectively. These values were obtained by the extrapolation of the conductivity data of potassium dichloroacetate and sodium trichloroacetate in aqueous solution at 25°C obtained by one of the authors (M.Y.).

Table 3. First order rate constants of aquation $[Co(halac)_2(en)_2]^+$

	k_1 min^{-1}	k_1 min^{-1}
	$[Co(halac)_2(en)_2]ClO_4$	
	cis	*trans*
ac	4.8×10^{-4}	—
mclac	5.5×10^{-4}	1.2×10^{-4}
dclac	4.9×10^{-4}	1×10^{-5}
tclac	5.2×10^{-4}	1.7×10^{-4}
tfac	5.6×10^{-4}	1.7×10^{-4}
	$[Co(halac)_2(NH_3)_4]ClO_4$	
	cis	*trans*
mclac	4.9×10^{-3}	0.9×10^{-4}

in Fig. 2 as an illustration. The plots are linear. This means that the aquation is a first order reaction similar to the acid-hydrolyses of many analogous complex ions. The first order rate constants obtained by the above procedure are summarized in Table 3. It is interesting to note that the rate constants do not differ considerably among the complexes under the present conditions, *viz.* in the severe neutral solution, although a deviation is observable in *trans*-$[Co(dclac)_2(en)_2]^+$. On the other hand, it has been observed quantitatively in $[Co(halac)(NH_3)_5]^{2+}$ [8] or in the related complexes such as $[Co(aminoacid)(NH_3)_5]^{2+}$ [9] that aquation is accelerated with hydrogen ion depending on the basicity of the halac ligands. A similar behavior was noted qualitatively with this series of complexes (the acidic solution of a complex of the series changes its absorption spectrum faster than the neutral solution). Thus, the aquation (acid hydrolysis) is an acid-catalyzed reaction and the reaction has been supposed to proceed *via* the following path,[8] the larger the basicity of the ligand, the greater being the acceleration of the reaction rate by hydrogen ion.

$$Co\text{-}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}R + H^+ + H_2O \rightarrow Co\text{-}O\text{-}\overset{\overset{OH}{|}}{C}\text{-}R + H_2O$$

$$\rightarrow Co\text{-}OH_2 + O{=}\overset{\overset{OH}{|}}{C}\text{-}R$$

In neutral solution or at a negligible hydrogen ion concentration, the reaction takes place as

$$Co\text{-}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}R + H_2O \rightarrow Co\text{-}OH_2 + {}^-O\text{-}\overset{\overset{O}{\|}}{C}\text{-}R$$

and the rate of the reaction is almost independent of R.

Two Types of Complexes of *o*-Phenylenediamine with Tetracyanoquinodimethane

Masatake OHMASA*, Minoru KINOSHITA, and Hideo AKAMATU**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 3, 1971)

o-Phenylenediamine and tetracyano-*p*-quinodimethane (TCNQ) were shown to form two types of solid complexes with compositions of 1 : 1 and 2 : 1. The 2 : 1 complex is essentially of ionic type, while the 1 : 1 complex is characterized as of non-bonding type from the analysis of its infrared absorption spectrum. It was shown that the difference in type is reflected on the magnetic and electrical properties of these complexes. The ESR absorption or the spin concentration of the 1 : 1 complex changed irreversibly with grinding or heat-treatment (70°C), while no appreciable change was observed in the 2 : 1 complex with these treatments. The electrical resistivity is lower for the 1 : 1 complex than the 2 : 1 complex by a factor of 10^2. From these observations, it is considered that the ground state electronic structure of the 1 : 1 complex is in a similar situation to those of diaminopyrene-chloranil and benzidine-TCNQ complexes.

In a previous paper,[1] the electronic properties of the 2 : 1 complex of *o*-phenylenediamine (*o*-PD) with 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) have been discussed as a complex of ionic type. Since then, it was found that the complex of 1 : 1 composition can also be obtained. The ground state character for the 1 : 1 complex was found to be primarily of non-bonding type in contrast to the 2 : 1 complex.

It is of interest to examine and compare the electronic properties of these complexes, since both types can be obtained from the same donor and acceptor. The magnetic and electrical properties of the two complexes were found to differ a great deal from each other.

Experimental

Complex Preparation. *The 2 : 1 Complex*: To a saturated solution of TCNQ in 15 m*l* of dichloromethane was added a solution of 400 mg of *o*-PD in 10 m*l* of dichloromethane at room temperature, and the resulting purple precipitate was collected.

The 1 : 1 Complex: A solution of 610 mg of *o*-PD in 15 m*l* of dichloromethane was added to a solution of 107 mg of TCNQ in 50 m*l* of dichloromethane, and the mixture was cooled to −10°C. Black crystals thus formed were collected.

Measurements. The absorption spectra in the visible and infrared regions, the ESR absorption spectra and the electrical resistivity were measured in a similar manner to that in previous reports[1,2] in which purification of the chemicals was also described.

Results and Discussion

Composition of the Complexes. The chemical composition (donor to acceptor ratio) of the complex was determined from the analysis of the absorption spectra in the UV and visible regions. The results obtained are given in Table 1, the assigned stoichiometric ratios being also listed.

TABLE 1. THE CHEMICAL COMPOSITION OF THE *o*-PD·TCNQ COMPLEXES

Complex	Composition (Donor : Acceptor)	
	Spectral analysis	Assigned stoichiometry
o-PD·TCNQ(1 : 1)	1 : 0.97	1 : 1
o-PD·TCNQ(2 : 1)	1 : 0.47	2 : 1

Characterization of the Complexes. The infrared absorption spectra of both 2 : 1 and 1 : 1 complexes of *o*-PD with TCNQ are shown in Fig. 1, together with the spectra of *o*-PD, TCNQ,[3,4] and lithium salt of TCNQ.

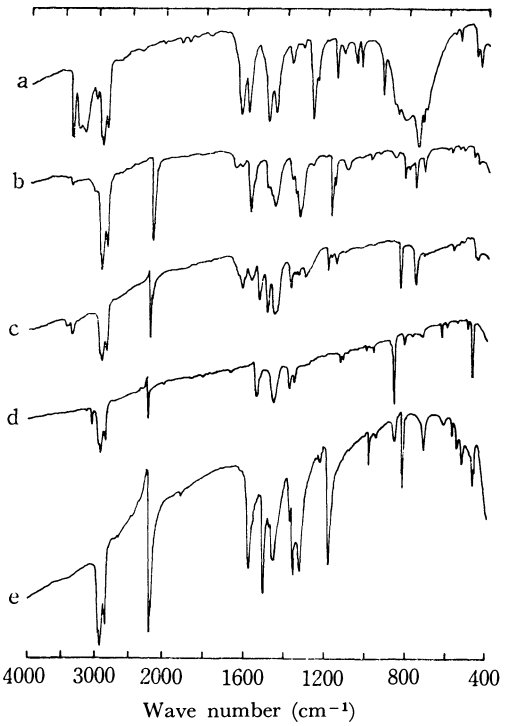

Fig. 1. Infrared absorption spectra of *o*-PD·TCNQ complex and related compounds.

The infrared absorption spectrum of the 2 : 1 complex indicates ionic character of the complex. As seen in Fig. 1, the C≡N stretching vibration located at 2223 cm^{-1} in neutral TCNQ is broadened and shifted to 2180 cm^{-1} in the complex. The ring C=C stretching vibration at 1540 cm^{-1} in neutral TCNQ disappears and a new band appears at 1580 cm^{-1}. Another new band is also observed at 1180 cm^{-1}. These features are identical with those of lithium salt of TCNQ, and confirm that the 2 : 1 complex is of ionic type.

Absorption bands of the donor in the 2 : 1 complex also suggest ionic character. An intense band at 1275 cm^{-1} in the spectrum of neutral *o*-PD is assigned to the ring stretching mode involving considerable C–N stretching, because its position and shape are very similar to the corresponding band of aniline.[5] This mode is shifted to 1336 cm^{-1} in the complex and the shift is in the same direction for the same vibrational mode of the *N,N*-dimethyl-*p*-phenylenediamine-TCNQ complex.[1] It is therefore concluded that the 2 : 1 complex is of ionic type. The amine part can be considered to have the form of $(o\text{-PD})_2^+$, because of the neutrality requirement.

In the 1 : 1 complex, the C≡N stretching vibration band is narrow and is located at 2210 cm^{-1}, and the ring stretching mode of TCNQ was observed at 1535 cm^{-1}. The location and the shape of these bands are similar to those of the corresponding bands of neutral TCNQ. The peaks at 1620, 1570, and 1492 cm^{-1} of the complex are identified with those at 1628, 1592, and 1492 cm^{-1} of neutral *o*-PD, respectively. This indicates that the 1 : 1 complex is characterized primarily as of non-bonding type.

The band at 1275 cm^{-1} of neutral *o*-PD, however, was shifted to 1305 cm^{-1} upon complex formation of the 1 : 1 composition. This suggests that the dative structure contributes considerably to the ground electronic state of the complex. In fact, the magnetic and electrical properties of the 1 : 1 complex also seem to reflect this contribution.

The difference in the electronic character can evidently be ascribed to the difference in composition, namely to the difference in the manner of molecular stacking in the crystals. The formation of an ionic complex is governed by the energy needed to charge the component molecules and by the electrostatic energy of the charged lattice. The former is determined by the ionization energy of the donor and the electron affinity of the acceptor, while the latter by Madelung's energy and polarization effects, both of which depend upon the crystal structure of the complex. In our complexes, since the ionization potential of the donor and the electron affinity of the acceptor are the same for both complexes, the electrostatic energy for salt formation seems to favour the crystal structure of the 2 : 1 complex rather than that of the 1 : 1 complex.

It is also of interest to discuss the difference in character of the 1 : 1 complex of *o*-PD·TCNQ and that of the 1 : 1 complex of *p*-phenylenediamine-TCNQ (*p*-PD·TCNQ), since the latter was found to be ionic in contrast to the former.[1] Matsunaga studied the electronic character of a number of complexes and arranged them in a diagram to correlate the character with the relative ionization potentials of donors and the relative electron affinities of acceptors.[6] The complex of *p*-PD·TCNQ is situated in the region of the complexes of non-bonding type, but very near the border line dividing the complexes having non-bonding ground states and those having dative or ionic ground states. The tendency of *p*-PD to form the complexes of dative ground states is suggested to be an exception to his diagram which reflects the effect of the size and shape of the component molecules on the electronic character. Since the ionization potentials of *o*- and *p*-PD are nearly the same,[7] the 1 : 1 complex of *o*-PD·TCNQ is also expected to situate around the border line, but in the region of the non-bonding group. The fact that the *o*-PD·TCNQ complex is found to be actually of non-bonding type verifies, therefore, the validity of the suggestion on the size and shape effects for *p*-PD complexes.

Magnetic and Electrical Properties. The magnetic and electrical properties of the complexes are summarized in Table 2, and the plots of the ESR absorption intensity against temperature are shown in Fig. 2. For both complexes, the intensity increased exponentially with temperature in a higher temperature region. The absorption intensity (I) was analysed in a similar manner to that described for the case of the *p*-PD·TCNQ complex.[1,8,9] The values of the activation energy δ, obtained from the plots of $\ln(IT)$ *vs.* $1/T$

Table 2. Magnetic and electrical properties of the *o*-PD·TCNQ complexes

Complex	Spin concentration[a]	δ (eV)	*g*-Value	$\rho_{15°C}$ (ohm·cm)	*E* (eV)
1 : 1	1×10^{22}	0.11	2.0026	1.0×10^{5}	0.28
2 : 1	7×10^{21}	0.07	2.0028	1.4×10^{7}	0.45

a) Number of electrons contributing to the paramagnetism per one mole of the complex at room temperature, 296°K.

3) T. Takenaka, Preprints of the Symposium on Molecular and Electronic Structure, October, 1969, Fukuoka, Japan.
4) B. Lunelli and C. Pecile, *J. Chem. Phys.*, **52**, 2375 (1970).
5) J. C. Evans, *Spectrochim. Acta*, **16**, 428 (1960).
6) Y. Matsunaga, This Bulletin, **42**, 2490 (1969).
7) The ionization potential of *o*-PD is considered to be larger by about 0.1 eV than that of *p*-PD, because the complexes of *o*-PD with *p*-bromanil and *p*-PD with *p*-bromanil show the charge-transfer band maxima at 646 and 672 mμ, respectively, in carbon tetrachloride.[1]
8) The notation of δ is used here instead of J in Ref. 1.
9) A correction was made for the intensities in the higher temperature region of the 1 : 1 complex by subtracting the intensities obtained by an extrapolation from the lower temperature side to the higher temperature side.

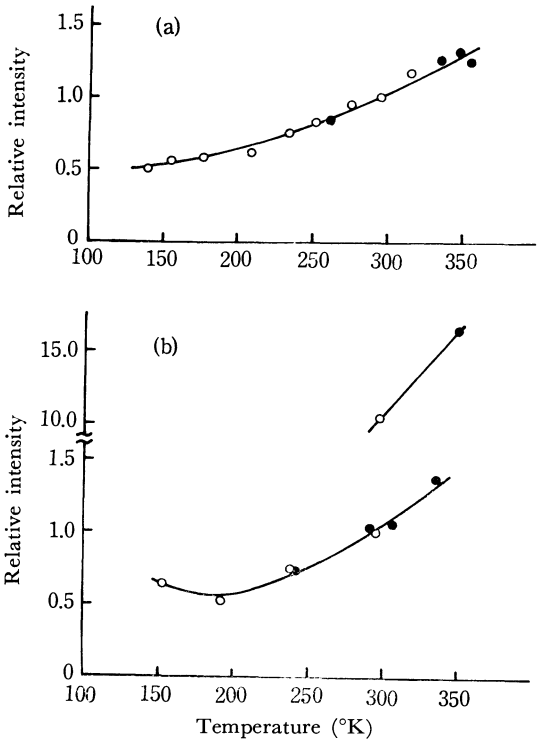

Fig. 2. Variations of ESR absorption intensities with temperature for *o*-PD·TCNQ complexes. Open circles are the points measured when the temperature was lowered, while shaded circles are the points measured when the temperature was raised.
(a) The 2 : 1 complex. The intensity changed reversibly.
(b) The 1 : 1 complex. When the temperature was raised up to 70°C, the intensity increased abruptly. However, when the temperature was lowered from 70°C, the intensity changed with the δ value coincident with that of the lower temperature region.

are given in Table 2.

When the 1 : 1 complex was warmed to 70°C in a vacuum for about 15 minutes, the ESR absorption intensity increased by a factor of 12. This phenomenon was found to be irreversible. However, the value of δ of the sample after heat treatment seems to coincide with that before the heat treatment. The nature of the paramagnetic sites does not seem to change with heat treatment.

The ESR absorption intensity of the 1 : 1 complex increased also by grinding. When the polycrystalline sample was ground in an agatemortar, the line width became slightly broadened and the intensity increased by a factor of about 5. The unpaired electrons observed in the 1 : 1 complex are, therefore, considered to be produced by an electron-transfer from the donor to the acceptor at lattice-defects and/or at the surfaces. The electron-transfer is likely enhanced by such treatments as grinding and heating.

As is seen in Table 2, the value of δ and the spin concentration of the 2 : 1 complex were found to be of the same order as those of the 1 : 1 complex. However, the spin concentration of the former was not affected when the sample was heated up to 82°C. The ESR absorption intensity changed reversibly with temperature as shown in Fig. 2.

The electrical resistivities of these complexes changed with temperature according to the equation $\rho=\rho_0 \times \exp(E/\boldsymbol{k}T)$. The values of the activation energy (E) and the specific resitivity (ρ) at 15°C are given in Table 2. Both $\rho_{15°C}$ and E are higher for the 2 : 1 complex than for the 1 : 1 complex.

The electrical conductivity of the 1 : 1 complex is rather high among the complexes of non-bonding type.[10,11] The complex of 1,6-diaminopyrene with *p*-chloranil[10,12] and the complex of benzidine with TCNQ containing solvent molecules[2,13] also exhibit relatively high conductivity, although they are not ionic in character. These three complexes, have the following common properties. (i) Although they are formed between strong donors and strong acceptors, their ground electronic character is not ionic but non-bonding. (ii) The ESR absorption intensity increases greatly when the crystals are ground into fine powder.[2] (iii) They exhibit relatively high electrical conductivity. These features differ greatly from typical ionic or non-ionic complexes, and seem to indicate that the ground electronic structures of these complexes are in a similar situation to each other. In fact, Matsunaga[6] has pointed out that the complex of 1,6-diaminopyrene with chloranil is located near the border line on his diagram, and such a complex exhibits relatively high conductivity. Our 1 : 1 complex is also located near the border line, and is considered to fall into such a class of complexes.

Magnetic Properties of Diisothiocyanatobis(thiourea)nickel(II) and Related Complexes

Shuji EMORI, Motomichi INOUE, and Masaji KUBO
Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received June 5, 1971)

The magnetic susceptibilities of diisothiocyanatobis(thiourea)nickel(II), diisothiocyanatobis(*N,N'*-dimethylthiourea)nickel(II), diisothiocyanatobis(2-thioimidazolidinone)nickel(II), diisothiocyanatobis(2-thiopyrrolidone)nickel(II), and diisothiocyanatobis(thioacetamide)nickel(II) were observed between the liquid-helium temperature and room temperature. Except for the second complex, antiferromagnetic interaction operates between one-dimensional nickel chains, within each of which ferromagnetic spin coupling exists. The exchange integrals, J within a chain and J' between chains, were evaluated on the basis of the coupled-double-chain model and the molecular-field model. The absence of interaction between chains in the crystals of the second complex can be accounted for by the presence of bulky *N,N'*-dimethylthiourea molecules between chains. The antiferromagnetic interactions between chains in the crystals of other complexes are attributable to the presence of bridging arrangements between chains, as is indicated by X-ray analysis.

The X-ray crystal analysis of diisothiocyanatobis(thiourea)nickel(II), $Ni(tu)_2(NCS)_2$, was carried out by Nardelli *et al.*,[1,2] who found that nickel ions are bridged by sulfur atoms belonging to thiourea to form linear chains in the crystal, as is shown in Fig. 1. Belova *et al.*[3] determined the magnetic susceptibility of this compound in a range between the liquid-nitrogen temperature and room temperature and suggested the presence of ferromagnetic spin interaction between nickel ions. The compound attracted attention as a model compound for one-dimesional ferromagnets. Flint and Goodgame[4] performed similar studies on a series of compounds with the general formula of $M(tu)_2(NCS)_2$ (M=Mn, Fe, Co, Ni), which had been confirmed by Nardelli *et al.*[5] to be isomorphous with the nickel complex. With decreasing temperature, the observed susceptibilities were found to deviate from the Curie-Weiss law, the deviations being inexplicable by an Ising model with spins $S=1$. However, because of the lack of low-temperature data, no further conclusions could be drawn. On the other hand, the X-ray crystal analyses[6,7] and infrared absorptions[8,9] of $Ni(tim)_2(NCS)_2$ (tim=2-thioimida-

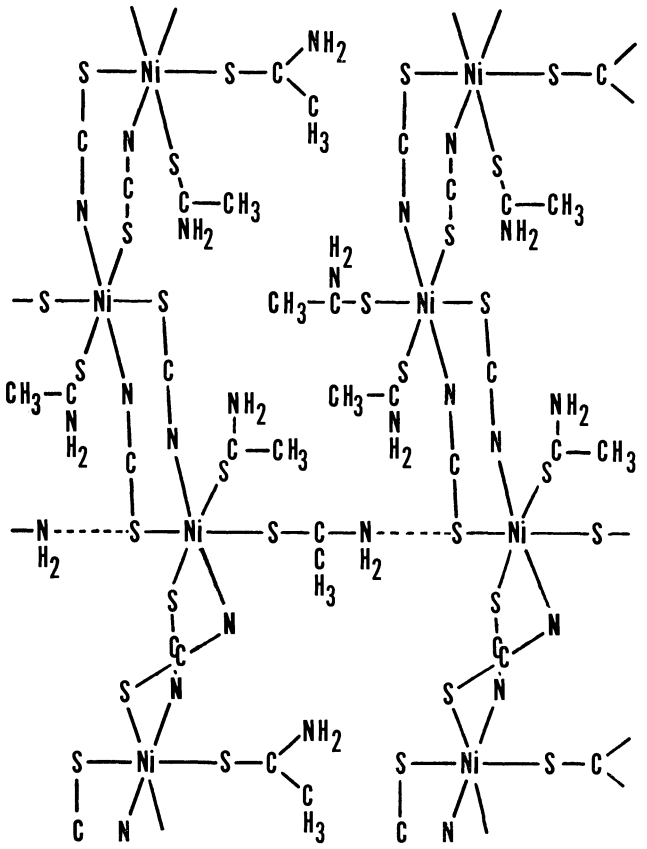

Fig. 3. Structure of $Ni(tam)_2(NCS)_2$.

zolidinone) and $Ni(tam)_2(NCS)_2$ (tam=thioacetamide) indicated that they form crystals with different chain structures, as is shown in Figs. 2 and 3, presumably due to the difference in the donor character of the ligands and the formation of intermolecular hydrogen bonds. These findings suggest that the chain structure of nickel atoms in these compounds do not represent simple one-dimensional ferromagnets, but involve magnetic interactions between chains. The present investigation has been undertaken in order to discuss magnetic interaction within a chain and between chains in these nickel complexes on the basis of the magnetic susceptibilities observed between the liquid-helium temperature and room temperature.

Experimental

Preparation of Materials. The crystals of $Ni(tu)_2(NCS)_2$, $Ni(tim)_2(NCS)_2$, and $Ni(tam)_2(NCS)_2$ were prepared by methods proposed by Nardelli *et al.*[1,10,11] Commercial preparations of thiourea and 2-thioimidazolidinone were allowed to react with nickel(II) thiocyanate. The resulting complexes were recrystallized from water and a 1 : 1 mixture of ethanol and water, respectively. In preparing $Ni(tam)_2(NCS)_2$ in a similar manner, nickel(II) sulfide precipitated during recrystallization. Therefore, a commercial preparation of thioacetamide was purified in advance by recrystallization from benzene, and then allowed to react with nickel(II) thiocyanate. The X-ray powder patterns of these compounds agreed with the data reported in the literature.[1,2,6,7] Found: Ni, 17.84%. Calcd for $Ni(tu)_2(NCS)_2$: Ni, 17.95%. Found: Ni, 15.42%. Calcd for $Ni(tim)_2(NCS)_2$: Ni, 15.48%. Found: Ni, 17.94%. Calcd for $Ni(tam)_2(NCS)_2$: Ni, 18.05%. The crystals of $Ni(dmt)_2(NCS)_2$ (dmt=*N,N'*-dimethylthiourea) were obtained in the same manner as for $Ni(tu)_2(NCS)_2$, using *N,N'*-dimethylthiourea in place of thiourea. Found: Ni, 15.11; C, 25.27; N, 21.77; H, 4.41%. Calcd for $Ni(dmt)_2(NCS)_2$: Ni, 15.32; C, 25.07; N, 21.93; H, 4.22%. For the preparation of $Ni(tpl)_2(NCS)_2$ (tpl=2-thiopyrrolidone), thiopyrrolidone was synthesized by a method reported by Mecke and Mecke[12] and was recrystallized from xylene (fractionated isomeric mixture). A calculated quantity of this starting material was added to a solution of nickel(II) thiocyanate in a 1 : 1 mixture of ethanol and water. The system was heated to dissolve the solid and then filtered. The filtrate was evaporated until crystals separated. Found: Ni, 15.60; C, 32.15; N,14.67 ; H, 3.73%. Calcd for $Ni(tpl)_2(NCS)_2$: Ni, 15.56; C, 31.84; N, 14.86; H, 3.75%.

Magnetic Measurements. Above the liquid-nitrogen temperature, the magnetic susceptibility was determined[13] by the Gouy method, using an Ainsworth recording semimicrobalance, the magnetic field strength amounting to about 3000 Oe. The temperature was determined by means of a copper-constantan thermocouple. In a temperature range of 4.2—80°K, the Faraday method was employed by the use of a torsion balance. The accuracy was estimated to be about ±1.5%. The temperature was measured within an accuracy of ±0.1°K by using an Allen-Bradley carbon thermometer below about 10°K and an Au/Co–Pt thermocouple between 10 and 80°K.

The observed molar susceptibilities have been corrected for diamagnetic contributions from ligands (in 10^{-6} emu/mol): nickel ions, −12;[14] thiocyanate ions, −35;[14] thiourea, −42;[15] *N,N'*-dimethylthiourea, −65;[15] 2-thioimidazolidinone, −61;[14] thiopyrrolidone, −61;[14] and thioacetamide, −42.[16] The temperature-independent paramagnetism was assumed to be equal to 193×10^{-6} emu/mol.[17]

Results

The observed magnetic susceptibilities corrected for diamagnetic contributions and the temperature-independent paramagnetism obey the Curie-Weiss law at high temperatures. The reciprocal susceptibility, $1/\chi$, is plotted in Figs. 4—8 against the temperature, emphasis being laid on data in the low-temperature region, where deviations from the Curie-Weiss law are rather marked. The Weiss constants and

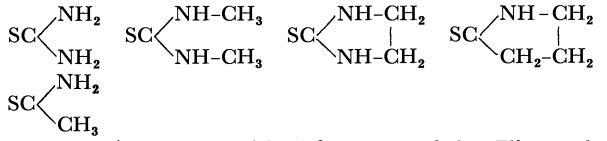
$Ni(tpl)_2(NCS)_2$[d]	3.10	10.3	2.17	8.4
$Ni(tam)_2(NCS)_2$[e]	3.13	16.2	2.18	—[g]

a) tu: Thiourea. b) dmt: *N,N'*-Dimethylthiourea. c) tim: Thioimidazolidinone. d) tpl: 2-Thiopyrrolidone. e) tam: Thioacetamide.



f) The value agrees with 40°K reported by Flint and Goodgame.[4] g) T_m was not observed.

the g-values evaluated from the Curie constants are listed in Table 1. The Weiss constants are positive, indicating that ferromagnetic interaction is predominant.

Discussion

The crystal structure of diisothiocyanatobis(thiourea)nickel(II), $Ni(tu)_2(NCS)_2$, shown in Fig. 1 suggests that the predominant ferromagnetic interaction arises from magnetic interaction through Ni–S–Ni bonds within a one-dimensional nickel chain.

Suzuki *et al.*[18] calculated the parallel susceptibility, χ, of a one-dimensional lattice consisting of Ising spins of $S=1$.

$$\frac{kT\chi}{Ng^2\beta^2}=\frac{1}{2a^2(a+2)}\left[1+\frac{4a^3+5a^2-a+1}{a[(a+a^{-1}-1)^2+8]^{1/2}}\right] \quad (1)$$

where $a=\exp(-2J/kT)$, J is the exchange integral between the nearest neighboring spins in the one-dimensional lattice, T is the absolute temperature, g is the g-value, and β is the Bohr magneton.

Using $g=2.18$, as evaluated from the Curie constant, and assuming $J/k=17$°K, the parallel susceptibility was calculated to be as is shown by a broken curve in Fig. 4. Although the curve well reproduces the experimental data above about 70°K, agreement is poor below this temperature. In addition, the curve of the observed susceptibility shows a maximum at 11.0°K. Accordingly, it is concluded that a weak lateral antiferromagnetic interaction operates between linear chains.

For one-dimensional lattices consisting of spins $S=1/2$, the magnetic susceptibility has been calculated with the Heisenberg model.[19] However, because of the mathematical difficulties involved, rigorous calculations have not been performed for spins greater than 1/2. The series expansion method developed by Rushbrooke and Wood[20] gives a rather poor agreement with the experimental data, because the series converges slowly except at temperatures well above the Néel temperature. Therefore, the following analysis is developed on the basis of the Ising model.

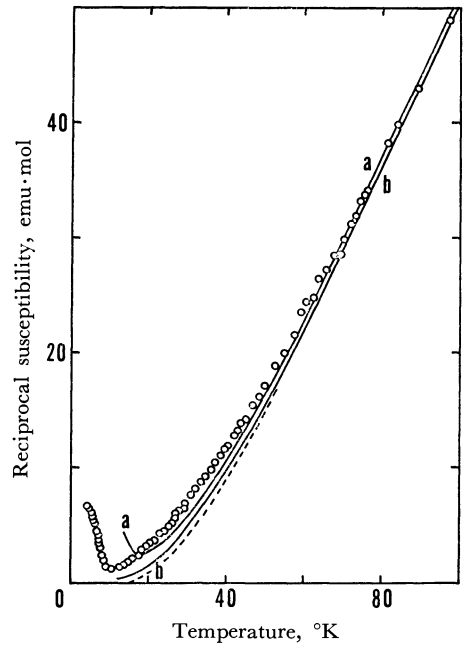


Fig. 4. Reciprocal susceptibility of $Ni(tu)_2(NCS)_2$ as a function of temperature.
Broken curve: Ising model (Eqs. (1) and (2)). Solid curve a: Coupled-double-chain model (Eq. (11)). Solid curve b: Molecular-field model (Eq. (14)).

Although Eq. (1) is rigorous for an isolated one-dimensional lattice, it is difficult to incorporate the effect of interaction between chains into the equation. Therefore, the following alternative method was used. Flint and Goodgame[4] analyzed the susceptibility of $Ni(tu)_2(NCS)_2$ by extending the theoretical equation for the linear Ising model with $S=1/2$ to $S\geq 1$.

$$\chi=\frac{Ng^2\beta^2S(S+1)}{3kT}\exp(j/kT) \quad (2)$$

This equation is based on "reduced" spin magnetic moments capable of orienting only in parallel and antiparallel directions defined as

$$\mu=\frac{1}{2}\left[\frac{S(S+1)}{3/4}\right]^{1/2}g\beta \quad (3)$$

The parameter, j, is related to the exchange integral, J, by[21]

$$j=\frac{S(S+1)}{3/4}J \quad (4)$$

As was pointed out by Flint and Goodgame,[4] Eq. (2) well reproduces the observed susceptibility of

Table 2. Exchange integrals, J within a chain and J' between chains, in the crystals of some nickel(II) complexes evaluated by the Ising model (Eq. (1)), the coupled-double-chain model (Eq. (11)), and the molecular-field model (Eq. (14))

	Ising model	Coupled-double-chain model		Molecular-field model	
	J/k (°K)	J/k (°K)	$-J'/J$	J/k (°K)	$-J'/J$
$Ni(tu)_2(NCS)_2$	17	19	0.02_0	19	0.002
$Ni(dmt)_2(NCS)_2$	20	21	0	21	0
$Ni(tim)_2(NCS)_2$	3.0	3.6	0.2_0	3.6	0.27
$Ni(tpl)_2(NCS)_2$	3.0	3.6	0.2_0	3.6	0.28
$Ni(tam)_2(NCS)_2$	4.5	4.6	0.03_3	4.6	—[a]

a) Because T_m was not observed, J' cannot be estimated.

$Ni(tu)_2(NCS)_2$ at high temperatures, but gives poor agreement with it at low temperatures because of the presence of interaction between chains.

For mutually interacting one-dimensional lattices of spins $S=1/2$, theoretical equations have been derived on the basis of a coupled-double-chain model[22,23] as well as a molecular-field model.[24] In the former model, a pair of interacting chains is considered to obtain the magnetic susceptibility given by[23]

$$\frac{kT\chi}{Ng^2\beta^2} = \frac{e^{2K}(e^{K'}R-\sinh^2 K)}{4(R-e^{K'}\sinh 2K)(\cosh^2 K'\cosh^2 2K-\sinh^2 2K)^{1/2}} \tag{5}$$

In this expression,

$$R = \cosh K'\cosh 2K+(\cosh^2 K'\cosh^2 2K-\sinh^2 2K)^{1/2} \tag{6}$$

$$K = j/2kT \tag{7}$$

$$K' = zj'/2kT \tag{8}$$

where j is the exchange integral within a chain, j' is that between chains, and z is the number of nearest chains. In the latter model, antiferromagnetic interaction between Ising chains lying in a plane in parallel to one another is approximated by a molecular field to yield the parallel susceptibility given by[24]

$$\frac{k\chi}{Ng^2\beta^2} = \frac{1}{4}e^{j/kT}\left\{T+T_c\exp\left[\frac{j}{k}\left(\frac{1}{T}-\frac{1}{T_c}\right)\right]\right\}^{-1} \tag{9}$$

where the parameter, T_c, expressing the interaction between chains is equal to the temperature, T_m, of the maximum susceptibility and is related to the exchange integral, j', between chains by

$$j' = -T_c\exp(-j/kT_c) \tag{10}$$

where the first minus sign on the right-hand side takes into account the antiferromagnetic interaction between chains ($j'<0$). Needless to say, Eq. (5) and Eq. (9) lead to Eq. (2) when $K'=0$ and $T_c=0$, respectively.

Equations (5) and (9), which are valid for $S=1/2$, were extended to $S=1$ using the reduced spin model. The former equation leads to

$$\frac{kT\chi}{Ng^2\beta^2} = \frac{2e^{2K}(e^{K'}R-\sinh 2K)}{3(R-e^{K'}\sinh 2K)(\cosh^2 K'\cosh^2 2K-\sinh^2 2K)^{1/2}} \tag{11}$$

where, in accordance with Eqs. (4), (7), and (8), K and K' are given by

$$K = 4J/3kT \tag{12}$$

$$K' = 4zJ'/3kT \tag{13}$$

On the other hand, Eq. (9) is extended to

$$\frac{k\chi}{Ng^2\beta^2} = \frac{2}{3}e^{8J/3kT}\left\{T+T_c\exp\left[\frac{8J}{3k}\left(\frac{1}{T}-\frac{1}{T_c}\right)\right]\right\}^{-1} \tag{14}$$

where T_c is related to the exchange integral, J', between chains by (see Eqs. 4 and 10)

$$J' = -\frac{3}{8}T_c\exp(-8J/3kT_c) \tag{15}$$

As is shown in Fig. 4, the susceptibility of $Ni(tu)_2(NCS)_2$ can be expressed by Eq. (2) above about 70°K with the parameter, j/k, equal to 51°K. This, along with Eq. (4), yields the exchange integral within a chain given by $J/k=19$°K. Using this value for J, and assuming that $J'/J=-0.02$ (Table 2), theoretical calculation was performed on the basis of the coupled-double-chain model (Eq. (11), $z=2$). The result is shown by a solid curve in Fig. 4. The agreement with the experimental data is excellent except for the region near the temperature of the maximum susceptibility.

The susceptibility was calculated theoretically by means of the molecular-field model also (Eq. (14)). As has been mentioned above, the parameter, J, can be evaluated from the data in the high-temperature region as $J/k=19$°K. From this, along with the observed temperature of the maximum susceptibility, T_m ($=T_c=11$°K), J' can be calculated by means of Eq. (15) as $J'/k=0.04$°K. The solid curve b in Fig. 4 shows the results of calculation by means of Eq. (14) using these parameters. The agreement of the theoretical curve with the experimental data is satisfactory. Thus, the ratio, $-J'/J$, of the exchange integral between chains to that within a chain is estimated to be of the order of 0.002—0.02.

The observed positive value for J implies that ferromagnetic interaction exists within a chain. This is anticipated because two orthogonal sp^2 orbitals of a sulfur atom are involved in magnetic interaction through a Ni–S–Ni linkage.

23) M. Inoue and M. Kubo, *J. Magn. Resonance*, **4**, 175 (1971).
24) J. W. Stout and R. C. Chisholm, *J. Chem. Phys.*, **36**, 979 (1962).

On the other hand, the negative value for J' indicates that antiferromagnetic interaction predominates between chains through Ni–NCS···SCN–Ni linkages. In fact, the distance between the nearest sulfur atoms belonging to neighboring chains amounts to 3.45 Å, which is smaller than the sum (3.70 Å) of van der Waals radii.[1,2]

The observed susceptibility of diisothiocyanatobis-(*N*,*N'*-dimethylthiourea)nickel(II), $Ni(dmt)_2(NCS)_2$, shows no maximum in the temperature range investigated (see Fig. 5) and can be reproduced by Eq. (1) with $g=2.12$, as evaluated from the Curie constant and $J/k=20$°K. The exchange integral is not much different from that of $Ni(tu)_2(NCS)_2$ (see Table 2). In addition, the X-ray powder patterns bear a close resemblance to those of $Ni(tu)_2(NCS)_2$, the crystal of which belongs to the triclinic system and yields a very complicated powder spectrum. Accordingly, it is concluded that this compound has one-dimensional nickel chains similar to those in $Ni(tu)_2(NCS)_2$. However, the substitution of thiourea with bulky *N*,*N'*-dimethylthiourea molecules leads to an increase in the distance between chains leading to a decrease in lateral magnetic interaction, and hence to the absence of any maximum in the susceptibility *versus* temperature curve.

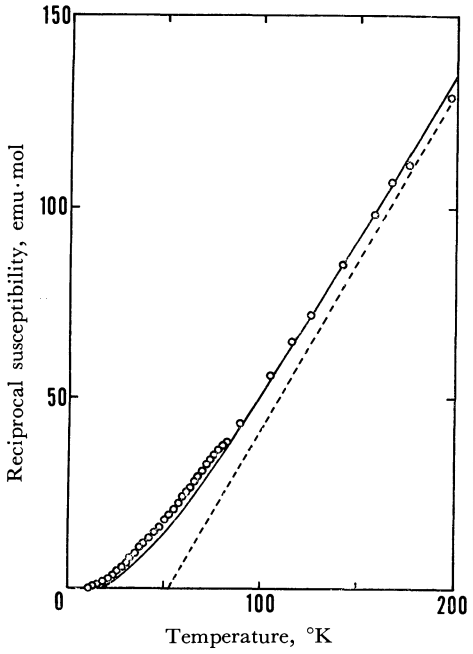

Fig. 5. Reciprocal susceptibility of $Ni(dmt)_2(NCS)_2$ as a function of temperature.
Broken curve: The Curie-Weiss law. Solid curve: Ising model.

The theoretical equation (2) ($j=8J/3$,$J/k=21$°K) based on reduced moments also fits experimental data, as is shown by the solid curve in Fig. 5, which is indistinguishable from the curve of Eq. (1). This indicates that both Eq. (1) and Eq. (2) are good approximations to the susceptibility of linear Ising ferromagnets free from lateral interactions.

Diisothiocyanatobis(2-thioimidazolidinone)nickel(II), $Ni(tim)_2(NCS)_2$, forms one-dimensional lattices of nickel

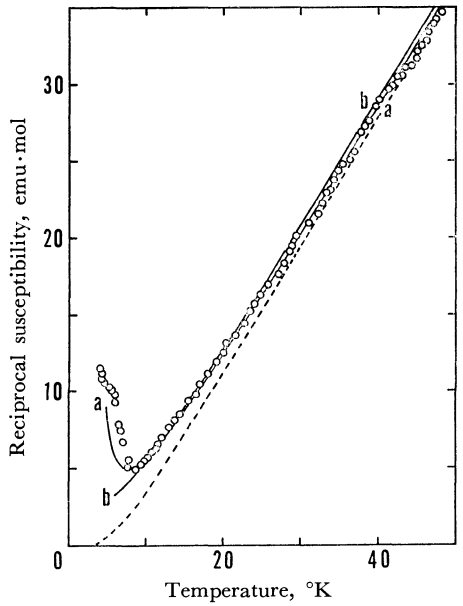

Fig. 6. Reciprocal susceptibility of $Ni(tim)_2(NCS)_2$ as a function of temperature.
Broken curve: Ising model. Solid curve a: Coupled-double-chain model. Solid curve b: Molecular-field model.

atoms through bridging by thiocyanate ions, as is shown in Fig. 2.[6] Although the Weiss constant is positive (Table 1), the susceptibility assumes a maximum value at 8.3°K, below which antiferromagnetic behavior appears. Theoretical calculations (Eq. (1) with $J/k=3.0$°K and Eq. 2 with $J/k=3.6$°K) for isolated Ising chains give broken curves in agreement with each other (*cf.* Fig. 6), but in poor agreement with the experimental data. This indicates that, in addition to ferromagnetic interaction within a chain, antiferromagnetic interaction exists between chains and gives rise to deviations from theoretical calculations for the Ising model, especially at low temperatures. The only conceivable interaction within a chain is superexchange interaction through Ni–N–C–S–Ni linkages, whereas that between chains is an antiferromagnetic superexchange interaction through Ni–S–C–NH···S–Ni linkages lying on a $(0\bar{1}1)$ plane. This is because NH··· S hydrogen bonds exist in the crystals,[6] no other paths being conceivable. From this structure, it can be concluded that $z=2$ in Eq. (15). Theoretical calculations were carried out with Eqs. (11) and (14). Curves calculated with the J'/J ratios listed in Table 2 are shown in Fig. 6. The agreement with the experimental data is excellent.

The temperature dependence of the susceptibility of diisothiocyanatobis(2-thiopyrrolidone)nickel(II), $Ni(tpl)_2(NCS)_2$, bears a striking resemblance to that of $Ni(tim)_2(NCS)_2$, as is shown in Fig. 7. Theoretical calculations analogous to those employed for the latter compound yield the exchange integrals listed in Table 2. The exchange integrals are also close to the corresponding ones of the latter compound. Accordingly, it is concluded that this compound forms crystals similar to those of $Ni(tim)_2(NCS)_2$ shown in Fig. 2. The X-ray powder patterns of the two compounds resemble each other in agreement with the

prediction from magnetic measurements.

The crystal structure[7] of diisothiocyanatobis(thioacetamide)nickel(II), $Ni(tam)_2(NCS)_2$, reveals that nickel atoms are bridged by thiocyanate ions to form one-dimensional chains, as is shown in Fig. 3. However, unlike the case with $Ni(tim)_2(NCS)_2$, two thiocarbonyl groups are coordinated on the *cis* positions of the coordination octahedron of a nickel atom. The one-dimensional chain has a threefold screw axis, and the crystal belongs to the rhombohedral system.

At high temperatures, the observed magnetic susceptibility can be explained by both Eq. (1) and Eq. (2), which coincide with each other, as is shown in Fig. 8. Below 40°K, deviations appear from the theoretical curve. However, no maximum susceptibility was observed in the temperature range investigated. Accordingly, calculations are infeasible with the molecular-field model. With the coupled-double-chain model (Eq. (11) with $z=6$), the exchange integrals, J within a chain and J' between chains, were calculated to be as shown in Table 2. The latter amounts to about 3% of the former. If a single chain is replaced by a resultant spin moment, interactions between chains can be represented by those among such resultant moments in two-dimensional triangular lattice. It has been shown theoretically that antiferromagnetic ordering can never be realized in two-dimensional triangular lattices.[25] This seems to be the reason why no transition to an antiferromagnetic state was observed for this compound.

The Catalytic Dehydrohalogenation of Haloethanes on Solid Acids and Bases

Isao MOCHIDA, Yasuhide ANJU, Hiroko YAMAMOTO, Akio KATO, and Tetsuro SEIYAMA

Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka

(Received June 7, 1971)

The elimination reactions of haloethanes and halopropanes on solid acids and bases, including a series of metal sulfates supported by silica gel, were studied at 300°C by means of the pulse technique in order to clarify the mechanism of the catalytic dehydrohalogenation. The *trans*-1,2-dichloroethylene/*cis*-1,2-dichloroethylene (*trans*-1,2/*cis*-1,2) selectivities from 1,1,2-trichloroethanes as well as the activities of the metal sulfates supported by silica gel were well correlated with the electronegativities of the metal ions. Generally speaking, the rates of the dehydrochlorination from chloroalkanes were nearly equal to those of the dehydrobromination from bromoalkanes on the solid acids, but the latter were larger than the former on solid bases. The reactivities of the alkylhalides on solid acids and bases were examined from the electronic view-point, and we tried to correlate them with some reactivity indexes. A kinetic isotope effect with regard to hydrogen was observed on solid bases, but not on solid acids, in the dehydrobromination of 1,2-dibromoethane. From these facts, it was concluded that the dehydrohalogenation proceeds through a carbonium-ion mechanism on solid acids and *via* an E2 step-by-step mechanism on solid bases.

It has been reported in previous papers[1] that the dehydrochlorination of 1,1,2-trichloroethane proceeds with different selectivities on solid bases, solid acids, ion-exchanged molecular sieves, chromia, and metal sulfates. The reaction mechanism was discussed on the basis of the linear-free-energy-relationships (LFER) approach, regarding five chloroethanes as well as the *trans*-1,2/*cis*-1,2 selectivities. The selectivity of *trans*-1,2/*cis*-1,2 on the metal sulfate was found not to be related with the electronegativity of the metal ion,[1b] which has been thought to represent the acid strength of the metal sulfate,[2] but to depend on the geometries of the catalysts. The effect of the geometries can be diminished among a series of metal sulfates by using the silica gel as the catalyst support.[3,4]

In the present study, the correlation of the catalytic activities and selectivities with the activities of a series of metal sulfates mounted on silica gel was investigated. At the same time, the reactivities of several haloethanes and halopropanes were measured on typical solid acids, solid bases, and the intermediate in order to obtain more information about the effects of substituents and leaving halogens on the elimination reactivity. The kinetic isotope effect of HBr (DBr) elimination from 1,2-dibromoethane was also measured in order to determine whether or not the C–H bond cleavage was the rate-determining step. A more probable mechanism of the elimination of hydrogen halide may be deduced from these results.

Noller *et al.* have reported that, for dehydrohalogenations over metal salts, the ionic contribution (El-character) increased with the increasing acidity of the cation.[5] They also examined the substituent effect on the reactivity over metal salts.[6] However their studies seem to be lacing in the consideration of the acid-base interaction between catalysts and reagents.

Experimental

Reagents. All the reagents used in this work were obtained from Tokyo Kasei except for 1,2-dibromo-tetradeuteroethane, which was obtained from Merck. They were all of G. R. or E. P. grade and were not purified further.

Catalysts. The catalysts of metal sulfates supported by silica gel were obtained by impregnating silica gel (Wako) with 0.3 meq/g of each metal sulfate (G. R. from the Hayashi Co.), and then dried at 120°C in the atmosphere.[3] The other catalysts were described in the previous papers.[1]

Apparatus and Procedures. The reaction rates and selectivities were measured at 300°C by the pulse technique, as has been described in the previous papers.[1] The catalysts were pretreated in a helium-gas flow for 3 hr at 300°C. The calcination temperature between 300 and 500°C had little effect on either the activity or the selectivity of nickel sulfates on silica gel in the HCl elimination from 1,1,2-trichloroethane, although distinct effects were observed in other reactions.[3,7] The elimination reaction was of nearly first order under the experimental conditions, and the conversion was verified to be a linear function of the reciprocal space velocity (RSV) at low conversions. Thus, the slope of the conversion/RSV gives the apparent rate constant, k (ml/g·min). The details of the experiments were described in the previous papers.[1]

Results

Dehydrochlorination of 1,1,2-Trichloroethane on Metal Sulfates Supported by Silica Gel. The dechlorination and exchange of chlorine with hydrogen took place in addition to the dehydrochlorination on the metal sulfates supported by silica gel in manners similar to those observed on the unsupported metal sulfate.[1b] The dehydrochlorination was of principal concern in the present study because all the other reactions were minor except for the dechlorinations

on cupric and ferric sulfates.

1) The Catalytic Activity: The products of the dehydrochlorination from 1,1,2-trichloroethane were *trans*-1,2-dichloroethylene, *cis*-1,2-dichloroethylene, and 1,1-dichloroethylene. The catalytic activity varied very much among metal sulfates. The catalytic activities of various supported metal sulfates are shown in Fig. 1 as the function of the electronegativities of the metal ions, the values of which were taken from the literature.[2] Here, the catalytic activity was expressed by the total reaction rate of dehydrochlorination. The logarithms of the reaction rates have a reverse-volcano relationship with the electronegativities of the metal ions except for the thallium ion, although only a few observations were made on the basic side of the catalysts. The minimum activity was found at the silver ion, whose electronegativity was 5.6.

2) The Stereoselectivity: The *trans*-1,2/*cis*-1,2 ratios on the catalysts, the stereoselectivities of this dehydrochlorination, are shown in Fig. 2 as the function of the electronegativities of the metal ions. The logarithms of the ratios are linearly correlated with electronegativities over one and a half orders of magnitude in the ratios. The ratio of 1,1-dichloroethylene/1,2-dichloroethylene (1,1/1,2) was another selectivity of this elimination, although 1,1-dichloroethylene could not be detected on the metal sulfates of high electronegativity. This selectivity was linearly correlated with the *trans*-1,2/*cis*-1,2 selectivity on the same catalyst, as is shown in Fig. 3, where the solid line was that obtained using typical solid acids and bases such as silica-alumina and strontium oxide in a previous paper.[1a] A linear relation was observed in this case, too.

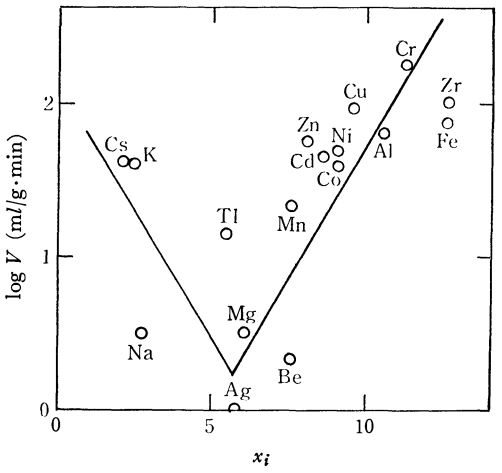

Fig. 1. Catalytic activities of metal sulfates supported by silica gel for the dehydrochlorination of 1,1,2-trichloroethane were plotted against the electronegativities of the corresponding metal ions.
The values of electronegativities, x_i, are taken from Ref. 2.

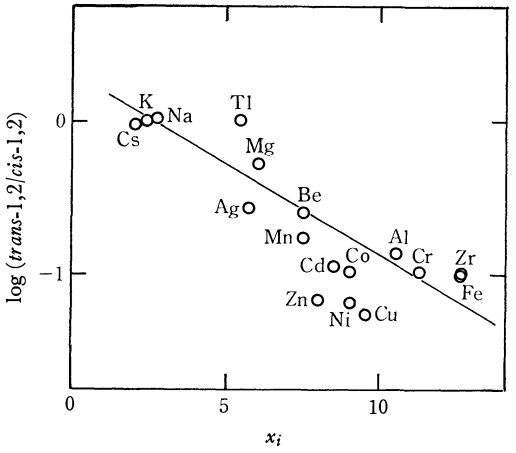

Fig. 2. The *trans*-1,2/*cis*-1,2 selectivities of metal sulfates supported by silica gel were correlated with the electronegativities of the corresponding metal ions.
The values of electronegativities, x_i, are taken from Ref. 2.

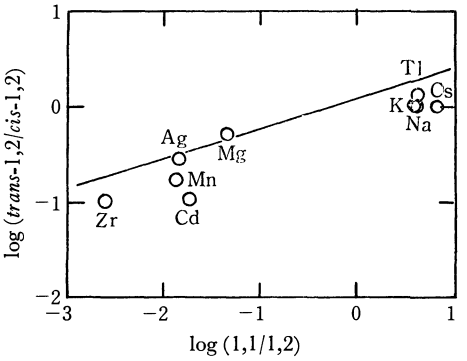

Fig. 3. A correlation between *trans*-1,2/*cis*-1,2 and 1,1/1,2 selectivities from 1,1,2-trichloroethane on metal sulfates supported by silica gel.

3) Reactivity Orders of the Five Chloroethanes: The reactivity orders of the five chloroethanes were 1,1,1-trichloroethane (1,1,1) > 1,1-dichloroethane (1,1) > 1,1,2-trichloroethane into 1,2-dichloroethylene (1,1,2 into 1,2) > 1,1,2,2-tetrachloroethane (1,1,2,2) > 1,2-dichloroethane (1,2) > 1,1,2-trichloroethane into 1,1-dichloroethylene (1,1,2 into 1,1) on nickel, cupric cadmium, and ferric sulfates supported by silica gel, whereas they were 1,1,1>1,1,2,2>1,1,2 into 1,1>

Table 1. Reactivity order of five chloroethanes in dehydrochlorination

a) On sulfates of a high electronegativity.

Reactant / Catalyst	1,1,1	1,1	1,1,2 into 1,2	1,1,2,2	1,2	1,1,2 into 1,1
$NiSO_4$-SiO_2	1910	214	48	2	1.3	0
$CuSO_4$-SiO_2	2575	198	90	6.4	0.5	0
$Fe_2(SO_4)_3$-SiO_2	2490	237	73	6.9	2.7	0
$CdSO_4$-SiO_2	2870	432	45	3.5	1.2	0

b) On sulfates of a low electronegativity.

1,1>1,1,2 into 1,2>1,2 on potassium and thallium sulfates, as is shown in Table 1. The former reactivity order and the large difference among the reactivities of chloroethanes observed on a metal sulfate of a high electronegativity were like those on a solid acid such as silica-alumina.[1a] On the other hand, the latter reactivity order on a metal sulfate of a low electronegativity was similar to that observed on a basic catalyst such as strontium oxide,[1a] except for the high reactivities of 1,1,1 and 1,1 on such metal sulfates. The reactivity difference between the most and the least reactive chloroethanes on potassium sulfate was only one and a half orders of magnitude. Such a small difference has been observed on the molecular sieve 13X, which was considered to be neutral in the Hammett indicator test.[1a]

Dehydrohalogenation of Haloethanes and Halopropanes on Solid Acids and Bases. *1) Comparison between Dehydrochlorination and Dehydrobromination*: The reactivities of the dehydrohalogenation of several dihaloethanes and monohalopropanes on solid acids and bases are shown in Figs. 4 and 5, where the rates of dehydrochlorination are shown in the abscissa, and those of dehydrobromination, by the ordinate. The dotted lines in both figures show the equal reactivities of the two reactants. The structures of the halides had a considerable effect on the rates over the solid acids. In contrast, only a small effect was observed on the solid bases. The difference was more than five hundred on solid acids, whereas it was less than one hundred on solid bases.

On solid acids, the rates of dehydrochlorination and those of dehydrobromination were nearly equal, as is shown in Fig. 4. The dehydrobromination was two times faster than the dehydrochlorination on solid bases, as is shown in Fig. 5. In any case, it seems from these linear correlations that both dehydrohalogenations, —HCl and —HBr, can be discussed on the common basis of the reaction

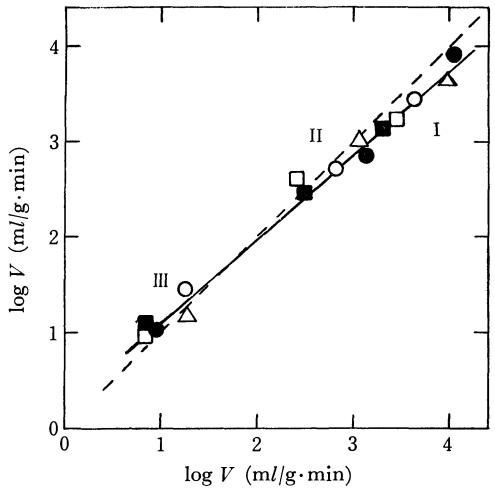

Fig. 4. The reactivities of dehydrochlorination and dehydrobromination on solid acids, ● for silica-alumina, △ for alumina-boria, ■ for nickel sulfate, □ for $NiSO_4$-SiO_2 and ○ for alumina. Group I corresponds to the reactivity regarding iso-PrX, II to *n*-PrX and III to $BrCH_2CH_2X$, where X is chlorine in the case of dehydrochlorination and that is bromine in the case of dehydrobromination.

The symbols of Br, Cl, *n*-Pr, and *iso*-Pr, represent the reactivities of dehydrohalogenation of $BrCH_2CH_2X$, $ClCH_2CH_2X$, *n*-PrX, and *iso*-PrX, respectively. (X is Cl or Br)

mechanism, although a discrimination between acidic and basic catalysts is essential.

2) Substituent Effects: The reactivities of *iso*-PrBr, *n*-PrBr, EtBr, 1,2-dibromoethane, and 1-bromochloroethane for dehydrobromination on solid acids are plotted against the Taft's σ^* of the R group in RBr in Fig. 6. The σ^* is thought to represent the electronic effect of the substituent in the saturated compounds.[8] The reactivity decreased monotonously with the increasing σ^*. The correlation seems to consist of two straight lines. The slope of the line through *iso*-, and *n*-propyl bromides and ethyl bromide might indicate the carbonium-ion

mechanism, because many reactions which are thought to proceed through the carbonium ion give slopes of such a degree.[9] The reactivities of dihaloethanes are too large if the reaction proceeds through the same carbonium-ion mechanism. In reaction of 1-bromo-2-chloroethane, a considerable amount of 1,2-dibromoethane and 1,2-dichloroethane, the products of the halogen exchange reaction, were detected on solid acids. These rather complicated results should be taken into account in the discussion of the reaction mechanism of the elimination.

The NMR chemical shifts were thought to represent the static electron density of the hydrogen. The reactivities on solid bases are compared with the chemical shift of hydrogen to be eliminated in Fig. 7. Except for isopropyl halide, a certain relation can be considered to exist between the reactivity and the chemical shift of the proton, although more adequate reactivity indices should be considered. It may be a dynamic one.[11]

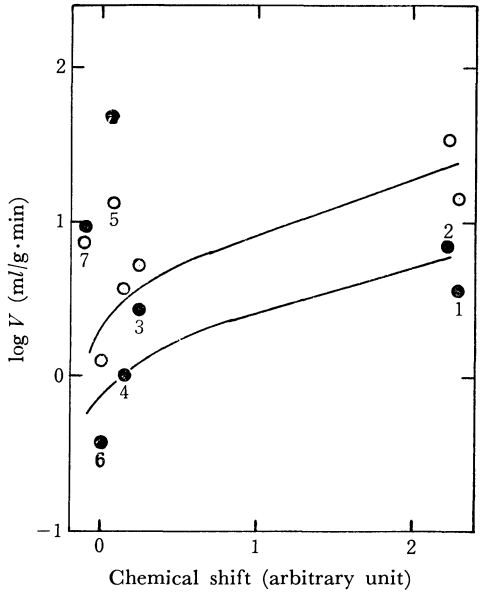

Fig. 7. The reactivities of dehydrohalogenation divided by the symmetry number, the number of its equivalent hydrogen atom, as a function of the NMR chemical shift of hydrogen to be eliminated, ○ for $KOH-SiO_2$ and ● for $K_2SO_4-SiO_2$. Kinetic Isotope Effect. The kinetic isotope effect in dehydrobromination from 1,2-dibromoethane was measured on solid acids and bases. The rates of dehydrobromination (k_H), those of dedeuterobromination (k_D), and the values of k_H/k_D are shown in Table 2. The maximum theoretical value of k_H/k_D at 300°C is 2.7.[12] The k_H/k_D values on all solid bases except magnesium oxide were greater than 1.5, whereas those on solid acids were nearly unity. Sodium-poisoned alumina had a value of k_H/k_D intermediate between solid acids and bases. This fact may correspond to the amphoteric character of this catalyst.

Table 2. Kinetic isotope effect in dehydrobromination of 1,2-dibromoethane

Catalyst	k_H[1]	k_D[2]	k_H/k_D
SrO	8.6 ±0.2	4.0 ±0.1	2.15±0.11
CaO	0.56±0.04	0.34±0.08	1.65±0.66

Discussion

Correlation of Catalytic Activity and Selectivity with the Acid-base Character of Catalysts and a Gradual Change in the Dehydrohalogenation Mechanism. The availability of the electronegativities of the metal ions has been established in many acid-catalyzed reactions.[2-4] The HCl-elimination from 1,1,2-trichloroethane may be included as one such example. The electronegativity of the metal ion was excepted to express the acid strength of the metal sulfate.[2] At higher *Xi* values, the ratio of *trans*-1,2/*cis*-1,2 from 1,1,2-trichloroethane was as small as 0.1, as is shown in Fig. 2, the reactivity order of chloroethanes was also similar to that on typical solid acids. At lower *Xi* values, on the other hand, the ratios are unity, and their plots in Fig. 3 are close to those on typical solid bases, furthermore, the reactivity order is similar to that on solid bases. These facts indicate that the gradual change in the reaction mechanism previously concluded[1] can be applied to this series of catalysts, also.

It is interesting that the catalytic activities *vs. Xi* plots are shaped in a reverse-volcano, with a minimum at the silver ion. 1,2-dichloroethylene was primarily formed on the metal sulfates with the high *Xi* values as is shown in Fig. 1. This product may be explained by the abstraction of 1-chlorine,[13] which

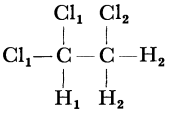
13)

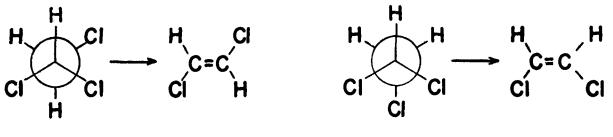


seems to be easily eliminated as an anion by the acidic sites. On the other hand, 1,1-dichloroethylene, that would be produced by the abstraction of the 1-hydrogen[13] easily eliminated as a proton is formed from 1,1,2-trichloroethane on the sulfates with the low *Xi* values. Thus, the gradual change in the reaction mechanism may explain the change in the selectivity according to the acid-base character of the catalyst.

The Mechanism of Dehydrohalogenation on Solid Acids. The fact that no kinetic isotope effect in the dehydrobromination from 1,2-dibromoethane was observed on solid acids indicates that the cleavage of the C–H bond is not involved at or before the rate-determining step. The negative slopes of the lines in Fig. 6 indicate that the reaction intermediate is positively charged. These facts suggest that the active site on solid acids may abstract halogen as an anion. An E2 concerted mechanism has been previously proposed for the HCl elimination on solid acids based on the distribution of the products from 1,1,2-trichloroethane.[1a] The substitution effect shown in Fig. 6 can not be explained by the stabilities of a hypothetical intermediate in an E2 concerted mechanism ($CH_3\overset{-}{C}H\overset{+}{C}H_2$ from $CH_3CH_2CH_2Br$ < $\overset{-}{C}HBr\overset{+}{C}H_2$ from CH_2BrCH_2Br, for example). This fact as well as the absence of any isotope effect rules out the E2 concerted mechanism.

The reactivity order of five chloroethanes on metal sulfates with high *Xi* can be understood on the consideration that the carbonium ion is stabilized by the α-substituted chlorine atom but is unstabilized by the β-substituted chlorine atom.[1a] The equal reactivity between dehydrochlorination and dehydrobromination can also easily be explained by the small free energy differences in $RCl+H^+ \rightarrow R^+ + HCl$ and $RBr+H^+ \rightarrow R^+ + HBr$.[14]

Between two conformations of 1,1,2-trichloroethane, the *trans* form I is more stable than the *cis* one II in a vapor phase,[15] whereas II may be predominant due to strong interaction between electronegative halogen and the acidic surface of solid acids.[3] Whether the *cis* or *trans* elimination is assumed, the stereoselective formation of *cis*-1,2-dichloroethylene can be explained as follows:



I II

As a explanation of the preferential *cis*-1,2-dichloroethylene formations, which, in some catalysts, are far over the equilibrium value (*cis*-1,2/*trans*-1,2=30,[1b] equilib. one=1.55[16]), this carbonium-ion mechanism containing an electrostatic interaction between acid sites and chlorine atoms may be more adequte than an E2 one.

Alumina has less catalytic activities as to *iso*-Pr and *n*-Pr, but more as to other reactants, than does silica-alumina. Alumina is generally thought to be less active for the carbonium-ion formation, but strikingly more active for some reactions, than is silica-alumina.[17] Therefore, regarding the less reactive reagents, another mechanism should be considered. A homolytic C–Cl cleavage may take to some extent. A considerable exchange of the halogens of 1-bromo-2-chloroethane and the markedly small slope in Fig. 6 may be understood in terms of this additional mechanism.

The Mechanism of Dehydrogenation on Solid Bases. The values of k_H/k_D over unity on solid bases in the elimination of HBr from 1,2-dibromoethane indicate that the C–H bonds were cleaved at or before the rate-determining step. There are three possible mechanisms: that is an E2 concerted, an E2 step-by-step (proton abstraction), or a carbanion mechanism. The dehydrohalogenation selectivity of the preferential elimination of hydrogen bromide from 1-bromo-2-chloroethane on solid bases can be explained in terms of neither the stability of the intermediate in a carbanion mechanism, which is expected from the stabilizing effect of bromine and chlorine on the carbanion ($Br\overset{-}{C}HCH_2Cl > Cl\overset{-}{C}HCH_2Br$), nor the stability of a hypothetical intermediate in an E2 concerted mechanism ($Br\overset{-}{C}H\overset{+}{C}H_2 > Cl\overset{-}{C}H\overset{+}{C}H_2$). Taking account of the higher reactivity of chlorine in comparison with that of bromine, as deduced from the preferential HCl-elimination of 1-bromo-2-chloroethane on solid acids, the selective HBr-elimination on the basic catalyst cannot be explained by an E2 concerted mechanism, either. Thus, both mechanisms must be abandoned. If an E2 step-by-step mechanism with the determining step of the proton abstraction is assumed, the preferential dehydrobromination from 1-bromo-2-chloroethane can be explained in terms of the effect of halogen in the α- and β-positions.[1b] The preferential stereoselectivity of *trans*-1,2 formation from 1,1,2-trichloroethane and the reactivity order of the five chloroethanes on solid bases can also be well explained by the E2 step-by-step mechanism.[1a] The higher reactivity for dehydrobromination than dehydrochlorination on solid bases can be explained from the effect of the halogen of the β-position, and the greater reactivity for the dehydrohalogenation of dihaloethanes may be due to the inductive effect of the halogen of the α-position. All these results may support the idea that the dehydrohalogenation on

14) For example, in the case of R=*n*–Pr, the free energies of formation for compounds are as follows: *n*-PrCl, 8.54 kcal/mol; *n*-PrBr, 14.85; HCl, −23.41; HBr, −13.76 at 300°C. (D. R. Stull, E. F. Westrum, and G. C. Sinke, "The Chemical Thermodynamics of Organic Compounds," Wiley, New York (1968), p. 518).

solid bases proceeds through an E2 step-by-step mechanism, although the reactivity of the haloethane can not yet be quantitatively explained.

The peculiarly high reactivities of *iso*-PrBr and *iso*-PrCl on solid bases cannot be explained by this mechanism. In the dehydrohalogenation of these secondary halides, a carbonium-ion character may increase, because the secondary carbonium ion is easily formed. Noller *et al.* have reported that the dehydrohalogenation of 2-chlorobutane proceeded through a two-step mechanism with a carbonium ion intermediate.[18] This mechanism may be valid in the case of isopropyl halides.

A quantitative explanation of the reactivity must be made next. The MO approach will be useful if its accuracy can be increased.

Dynamic Behaviors of the Electron Donor-Acceptor Complex in its Lowest Excited Singlet State

Hiroshi MASUHARA, Motoo SHIMADA, Nobuyuki TSUJINO, and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 7, 1971)

Dynamic behaviors of the weak electron donor-acceptor (EDA) complex in its lowest excited singlet state have been investigated by the nsec flash photolysis method and measurements of fluorescence and transient photocurrent. In polar solvents the weak EDA complex in its lowest excited singlet state dissociates spontaneously into ions. The dynamic behaviors of *s*-tetracyanobenzene(TCNB)-benzene and TCNB-toluene complexes were studied in some solvents and the existence of the direct radiationless process at the excited Franck-Condon (FC) state as well as in the course of relaxation process from the excited FC state to the fluorescent state has been confirmed in the case of 1,2-dichloroethane solution. The nature of the intra-complex radiationless processes was discussed on the basis of this result. It has been pointed out that the lifetime of excited states is of crucial importance for understanding the dynamic behaviors of excited weak EDA complexes.

EDA complexes which are fluorescent in solution at room temperature are rather scarce. However, one can observe at room temperature the fluorescence of complexes of some acceptors such as TCNB, tetrachlorophthalic anhydride (TCPA) and pyromelitic dianhydride (PMDA) with hydrocarbon donors.[1-6] From the study of solvent effects on the fluorescence of these complexes, it has been shown that the low fluorescence yield in nonpolar solvents can be ascribed to a small value of radiative rate constant k_f while, in polar solvents, it can be attributed to a large value of radiationless rate constant k_n.[2,3,6] In order to understand the results, the effect of solvent and temperature on fluorescence spectra, fluorescence quantum yield and fluorescence decay times of TCNB complexes were investigated. A small value of k_f was ascribed to the large difference in electronic structure between the fluorescent and ground states.[2] The important role of surrounding environments in the relaxation process, through which the fluorescent state is produced from the excited FC state, was made clear.[2,7,8]

Recently, we have shown that the ionic dissociation of TCNB-toluene complex in the lowest excited singlet state occurs in acetonitrile.[9] Detailed studies on the ionic dissociation of excited EDA complexes may provide useful information for understanding radiationless transitions as well as primary processes of photochemical reactions of EDA complexes. It is well-known that the ionic dissociation of heteroexcimer or the electron transfer in the encounter collision in the excited state can occur easily in polar solvents.[10] However, there are only a few studies on ionic dissociation of the excited EDA complexes which are stable in the ground state.[11,12] In these

studies, the absorption spectra of produced ion radicals were measured by only the conventional flash photolysis method and no direct observation on the primary process of the production of ion radicals in nsec time region was performed. However, the study on the primary processes of ionic photodissociation of EDA complexes is indispensable in order to obtain a correct picture of the dynamic behaviors of excited complexes.

In the present paper the results of our studies on the ionic photodissociation of various weak EDA complexes in various solvents will be described, and the mechanisms of the ionic photodissociation as well as other radiationless processes in these complexes will be discussed in detail.

Experimental

We used a Q-switched ruby laser (Japan Electron Optics, JLR-02A) with out put of *ca.* 1.5 J. The exciting light pulse of 347 nm was produced through ADP frequency doubler with conversion efficiency of *ca.* 8%. The output of an exciting pulse was measured with a ballistic thermopile TRG model 100 (HADRON). The light pulse has a duration of 15—20 nsec. The absorption spectra of ions produced by exciting the complex at the charge-transfer (CT) absorption band were measured photographically by using laser-breakdown sparks in O_2 and Xe gases as spectroflashes.[13] The rise and decay curves of ions were observed by the nsec flash photolysis method we developed. Since a 50 Ω resistor is equipped to photomultiplier to obtain nsec time resolution, a monitoring light intensity falling onto the photomultiplier must be far greater than that of a conventional flash photolysis.[14] We used a Xe flash lamp as monitoring light, the duration of which was adjusted to *ca.* 300 μsec. A block diagram of the present nsec flash photolysis apparatus is shown in Fig. 1. The timing circuit using a cathode-coupled multivibrator makes the adjustment of an exciting pulse to the peak intensity of the monitoring flash lamp easy and linear.[15]

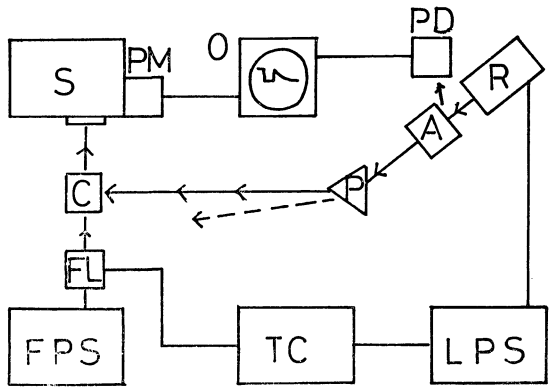

Fig. 1. A block diagram of nsec flash photolysis apparatus. R, ruby; A, ADP frequency doubler; P, separating prism; C, sample cell; LPS, laser power supply; TC, timing circuit; FPS, flash power supply; FL, monitoring flash lamp; S, Nalumi R21 spectrograph; PM, RCA 1P28 or Hamamatsu TV R406 photomultiplier; PD, Hewlet-Packard 5082—4220 photodiode; O, Tektronix 585A synchroscope.

The ion radicals produced were also observed by measuring the photocurrent induced by laser excitation. Although the details of the measurement of the photocurrent will be reported by Taniguchi and Mataga,[16] some fundamental points are given here. Direct irradiation on the electrodes was avoided by focusing the 347 nm pulse. The electrodes were Ni plates of 9 mm × 10 mm set 7 mm apart from each other. To obtain nsec time resolution a 50 Ω resistor was used and the supplied DC voltage between electrodes was adjusted from 90 V to 540 V. The time constant of the electronic circuit is less than 5 nsec. The DC dark current was omitted by using the ac coupling of the input of a Tektronix 585 A synchroscope. For examining the effect of the excitation light intensity on the photocurrent, the normal laser pulse was reduced by using neutral filters composed of wire gauzes. The filters reduced the light intensity to 0.3%, 13%, 32%, and 68%. Some weaker signals of photocurrent were measured by using an Iwatsu cascade amplifier CA-2.

The fluorescence spectra and relative quantum yields of the fluorescence were measured with an Aminco-Bowman spectrophotofluorometer.

The temperature effect on ionic dissociation was studied by measuring the laser-induced photocurrent at various temperatures. The cell for the measurements of photocurrent was fitted into a copper-cellholder, which was coupled to a tank filled with liquid N_2. The whole system was contained in a quartz dewar, the bottom of which is unsilvered to permit photoexcitation. The temperature was measured with a Cu-constantan thermopile and a micro volt meter model AM 1001 (Ohkura Electric Co.).

Acetonitrile, mesitylene, and α-methylstyrene were purified by distillation. Benzene, toluene, and ethyl ether (Merk spectrograde), and ethyl alcohol, isopropyl alcohol, acetone and 1,2-dichloroethane (Nakarai Chemicals, spectrograde) were used without further purification. TCNB, TCPA, and hexamethylbenzene (HMB) were the same as used before.[2] PMDA was purified by repeated recrystallization from ethyl acetate. All the solutions were carefully degassed by the usual method.

Results and Discussion

Absorption Spectra of the Transient Acceptor Anion Produced by Laser Photolysis. The spectra obtained by exciting TCNB-toluene complex to its lowest excited singlet state in acetonitrile solution are shown in Fig. 2. Since the observed transient absorption spectra are identical with those of TCNB anion,[17] it has been proved that the excitation of this complex by light absorption at the CT band leads to the ionic dissociation in acetonitrile solution. This anion decays rather slowly in the course of tens of μsec. Some parts of the produced anions are quite stable and observable even by a usual spectrophotometer. It was not possible to identify the transient spectra of

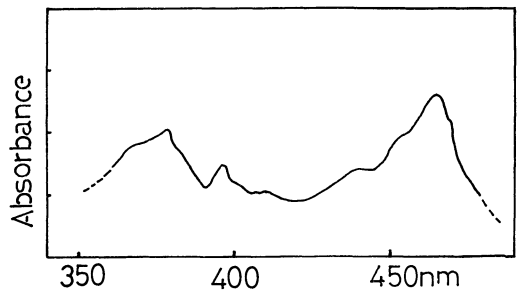

Fig. 2. The transient absorption spectra of the TCNB-toluene-acetonitrile system. Concentration of TCNB, 6×10^{-3} M. Volume ratio of toluene *vs.* acetonitrile, 1 : 2.

toluene cation, which may be ascribed to the fact that the absorption band of cation which lies at *ca.* 460 nm[18] may be hidden behind the strong band of TCNB anion.

We have also made some investigations in other polar solvents, fixing volume ratio of donor solvent *vs.* polar solvent to 1 : 2. The transient spectra due to TCNB anion produced by exciting the TCNB-toluene complex at the CT band were observed also in acetone, isopropyl alcohol and ethyl alcohol. We examined the ionic dissociation of other TCNB complexes by means of the laser photolysis method and observed the absorption spectra of TCNB anion in acetonitrile solution in the cases of TCNB-benzene and TCNB-mesitylene complexes. In the case of the latter, the spectra were also taken by using the fluorescence of cyclohexane solution of tetraphenylbutadiene as a flash light, a technique used by Porter and Topp.[13] Since the fluorescence lifetime of tetraphenylbutadiene is short, the fluorescence light pulse has the same shape in time as an exciting laser pulse. Accordingly, this technique is convenient for observing the species produced rapidly. The acceptor anion was detected also in the cases of TCNB-α-methylstyrene and PMDA-mesitylene complexes with nsec flash photolysis. Thus, the ionic dissociation caused by exciting the CT band in polar solvents has been observed commonly for various weak EDA complexes.

Kinetic Analyses by the Measurements of Fluorescence, Absorption and Photocurrent in Nsec Time Region. The rise and decay curves of acceptor anion were obtained by nsec flash photolysis technique developed in the present work. The oscillograms showing rapid production of acceptor ions in the systems of TCNB-α-methylstyrene-acetonitrile, PMDA-mesitylene-acetonitrile and TCNB-toluene-acetonitrile, are given in Figs. 3, 4 and 5(a), respectively. Such a rapid production of acceptor anion was also observed in the case of TCNB-toluene-acetone. The S_n–S_1 spectra of TCNB-toluene and TCNB-benzene complexes recently reported[7,19,20] are similar to the spectra of TCNB anion. We cannot distinguish the solvated anion from the excited singlet EDA complex having

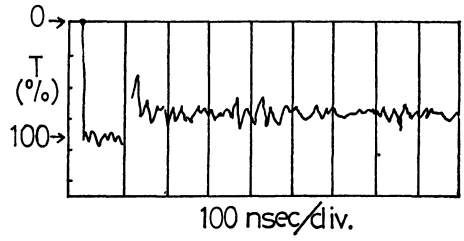

Fig. 3. The rise of TCNB anion produced by exciting the TCNB-α-methylstyrene-acetonitrile system. Observed at 465 nm.

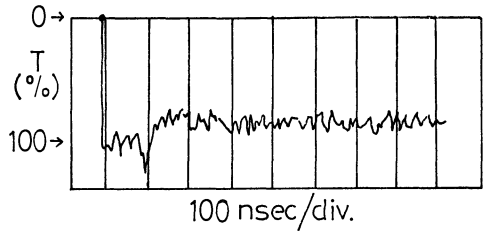

Fig. 4. The rise of PMDA anion produced by exciting the PMDA-mesitylene-acetonitrile system. Observed at 665 nm.

the structure of "contact ion-pair"[7,19] by measuring and comparing only the shape of the absorption spectra, although behavior of this anion, *e.g.* the decay processes is different from that of the excited singlet EDA complex.

We have measured the photocurrent induced by laser excitation of weak EDA complexes in various solvents since this may be another useful and important method for examining ionic photodissociation. It has been shown that the obtained photocurrent is due to the dissociated ions, by comparing the rise and decay curves of the photocurrent with those of absorption of acceptor anion. The kinetic relation between transient photocurrent and transient absorption are given in Fig. 5. The rise curve and earlier stage of decay of the photocurrent are almost the same as those of absorption of TCNB anion.[21]

21) A difference in photocurrent and absorption arises in the later stage of decay. This might be due to secondary reactions as well as the dark current caused by the dark reaction occurring at electrodes because of high applied electric field. The observed photocurrent induced by laser excitation can be ascribed to the dissociated ion radicals.

The rise curve of photocurrent in the case of TCNB-toluene-acetonitrile system and an excitation laser pulse are given in Fig. 6. The shape of the rise curve is the same as that of a time-integrated function of a 347 nm pulse. We have obtained the same results for all the complexes in various solvents at room temperature.

We can observe both the CT fluorescence of TCNB-benzene and the photocurrent due to dissociated ions in the case of 1,2-dichloroethane solution. As indicated in Fig. 7, the fluorescence decay is rather fast corresponding to the rapid production of ions in this solution.

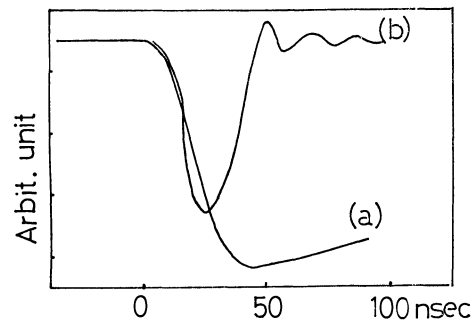

Fig. 6. The rise and decay of photocurrent in the case of the TCNB-toluene-acetonitrile system.
(a) transient photocurrent (b) shape of an exciting pulse.

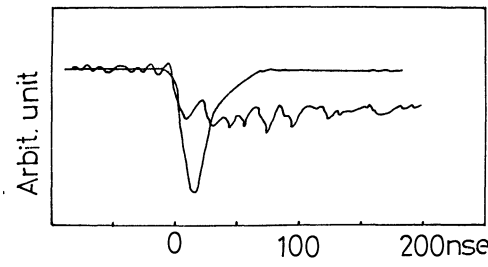

Fig. 7. The kinetic relation between photocurrent and CT fluorescence in the case of the TCNB-benzene-1,2-dichloroethane system.

The photocurrent of aerated TCNB-toluene-acetonitrile system was also measured. It was found that production of TCNB anion in the aerated system was almost the same as that in the degassed system. The decay of ions in aerated solution is, of course, faster than that in degassed solution.

Ionic Dissociation of Weak EDA Complexes in Their Lowest Excited Singlet States. All the results seem to show that ionic dissociation of these complexes occurs in the lowest excited singlet state. However, a two-step process with an excited state as an intermediate and a collision process between excited EDA complexes followed by ionic dissociation should be examined to elucidate the primary process of the dissociation, since a laser pulse is an intense exciting light. First the effect of excitation light intensity on the photocurrent was examined.

In general, the photocurrent density is given by[22]

$$i(t) = \sum_j Z_j e n_j(t) \mu_j E \qquad (1)$$

where Z_j, μ_j, and $n_j(t)$ represent electric charge, mobility, and number of the carrier j in unit volume, respectively. E is an applied electric field. In the present system of weak EDA complexes, the charge carriers are acceptor anions and donor cations, and the equation is reduced to

$$i(t) = en(t)(\mu_{\text{anion}} + \mu_{\text{cation}})E. \qquad (2)$$

Since both ions are simultaneously produced by laser excitation and disappear by recombination reaction, we have

$$\frac{dn}{dt} = aI - bn^2, \qquad (3)$$

where a and b represent rate constants of production and disappearance of ions, respectively. I is an intensity of the exciting pulse.

In the case of EDA complexes in various solvents at room temperature, the dissociation into ion radicals occurs quite rapidly in nsec time region while they decay slowly during time more than ten μsec. Thus the peak photocurrent obtained immediately after excitation is proportional to the concentration of the dissociated ions. The effect of excitation light intensity on the peak photocurrent of TCNB-toluene-acetonitrile system is given in Fig. 8. The linear relation shows that this ionic dissociation is a one-photon process.[23]

The effect of the excitation light intensity on the production of ions has been studied also by means of nsec flash photolysis and measurement of the transient absorption band. The observed results on the TCNB-toluene-acetone system, also indicating a one-photon process, are given in Fig. 9.

We have investigated the temperature effect on ionic dissociation in the case of TCNB-toluene-ethyl alcohol system. The volume ratio of toluene *vs.* ethyl alcohol was set to 1 : 10, in which case a rigid

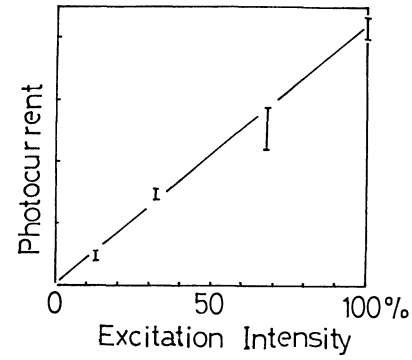

Fig. 8. The effect of exciting light intensity on the peak photocurrent of the TCNB-toluene-acetonitrile system. Optical density at 347 nm is *ca.* 0.1.

22) G. E. Johnson and A. C. Albrecht, *J. Chem. Phys.*, **44**, 3179 (1966); H. S. Pilloff and A. C. Albrecht, *ibid.*, **49**, 4891 (1968); T. Imura, N. Yamamoto, and H. Tsubomura, This Bulletin, **43**, 1670 (1970).

23) The effect of excitation light intensity on ionic dissociation was examined under rather low solute concentration. In the case of high concentration (O. D. at 347 nm ~1.0), a saturation effect of photocurrent was caused by high intensity laser excitation.

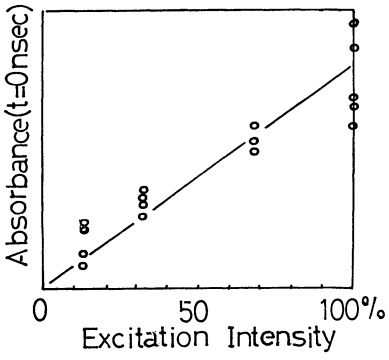

Fig. 9. The effect of exciting light intensity on the transient absorption of TCNB anion produced by irradiating the TCNB-toluene-acetone system. Observed at 462 nm. Optical density at 347 nm is *ca.* 1.0.

glass was formed at liquid nitrogen temperature. Mobility μ and dielectric constant ε of solvent undergo changes with change of temperature. It is well known that mobility μ is proportional to diffusion-controlled rate constant k, which is approximately proportional to T/η,[24] where η and T represent viscosity coefficient and temperature, respectively. Moreover, the relation $\log \eta \sim 1/T$ holds in the case of the glass-forming solvent mixtures.[25] Thus, $\log (i/T)$, where i is the peak photocurrent, should be proportional to $1/T$. It is necessary, however, to correct the peak photocurrent with respect to the dielectric constant of mixed solvent. In the present work, we have neglected the contribution of toluene to dielectric constant of mixed solvent and taken into consideration only the change of dielectric constant of ethylalcohol due to the change of temperature. The results are given in Fig. 10, which shows a linear relation between $\log (i/T)$ and $(1/T)$. This can be ascribed to the fact that the quantum yield of dissociation is constant, independent of temperature, indicating spontaneous dissociation (without activation energy) of this complex in ethyl alcohol.

From the results it can be concluded that the weak EDA complexes (which are stable in the ground state) dissociate spontaneously into ions in their excited CT singlet states in polar solvents.

Dynamic Behaviors of TCNB-Benzene and TCNB-Toluene Complexes in Various Solvents. The dynamic behaviors of excited TCNB-benzene and TCNB-toluene complexes in various solvents were studied in detail, fixing the volume ratio of the donor solvent *vs.* another solvent to 1 : 2. The lifetime and relative quantum yield of fluorescence, exciting the CT band at 347 nm, were measured by the usual method.[2] The relative quantum yields of ionic dissociation were obtained by correcting photocurrent with respect to the strength of applied electric field, the distribution and number of exciting photons, viscosity and dielectric constant of mixed solvents and by comparing the peak photocurrent. Viscosity η and dielectric constant ε of a mixed solvent were

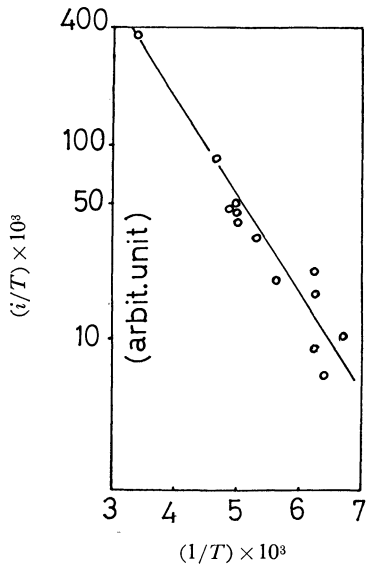

Fig. 10. $\log (i/T)$ *vs.* $(1/T)$ relation observed for the TCNB-toluene-ethanol system.

calculated approximately by equations $\eta=\sum_i v_i\eta_i$ and $\varepsilon=\sum_i v_i\varepsilon_i$, where η_i, ε_i, and v_i represent viscosity, dielectric constant, and volume fraction of the solvent i, respectively.

Estimation of the order of magnitude of the absolute quantum yield of dissociation for the systems of TCNB benzene-acetonitrile and TCNB-α-methylstyrene-acetonitrile was made as follows. (1) The distribution of exciting photons was assumed to be uniform in the effective irradiation spot on the front face of the cell, which was determined from a burned spot on a color sheet produced by a 347 nm pulse. (2) The distribution of the produced TCNB anion in the monitoring portion of the sample cell was averaged. (3) The concentration of the produced anion was calculated, using an optical density of TCNB anion obtained immediately after the excitation (Fig. 5 (a)) and assuming molecular extinction coefficient at 465 nm to be *ca.* 10^4. (4) The quantum yield was put equal to the number of anions divided by the number of exciting photons which were measured to be 1.7×10^{17} per pulse by the TRG 100 thermopile. All the results on TCNB-benzene and TCNB-toluene complexes are listed in Tables 1 and 2.

We see that the decrease of φ_f from benzene to 1,2-dichloroethane solutions is larger than that of τ_f. This result can be explained on the basis of the following two alternative models. (a) The radiative transition probability of fluorescence k_f decreases and the radiationless transition probability increases with the increase of the solvent polarity, due to the strong interaction between the complex and solvent. (b) The direct radiationless process arises from the excited FC state as well as in the course of the relaxation process from the excited FC state to the fluorescent state. This radiationless process as well as the usual one from the fluorescent state increase as the solvent polarity is increased, while the k_f value

TABLE 1. DYNAMIC BEHAVIORS OF TCNB-BENZENE COMPLEX IN ITS LOWEST EXCITED SINGLET STATE

Solvent	ε_{mix}[a]	Fluorescence lifetime	φ_f[b]	φ_{ion}[b]	φ_{nf}[b,c]
Benzene	2.3	~100 nsec	0.009 (1.0)[e]	0	0.91
Ethyl ether	3.7		0.02 (0.23)	0	0.98
1,2-Dichloroethane	7.7	20[d]	0.004 (0.04)	0.001 (0.0015)	0.995
Acetone	14.6			0.035 (0.35)	0.965
Acetonitrile	25.8			0.1 (1.0)	0.9

a) Calculated dielectric constants.
b) φ_f, φ_{ion}, and φ_{nf} represent absolute quantum yields of fluorescence, ionic dissociation, and intra-complex radiationless transition, respectively.
c) φ_{nf} does not contain ionic dissociation and was estimated by the relation $\varphi_{nf}=1-\varphi_f-\varphi_{ion}$.
d) The fluorescence decay curve was observed by exciting the complex with N_2 gas laser. The N_2 laser was the same as that described in Ref. 8.
e) The values in parentheses are relative quantum yields.

TABLE 2. IONIC DISSOCIATION OF TCNB-TOLUENE COMPLEX IN ITS LOWEST EXCITED SINGLET STATE

Solvent	ε_{mix}	Relative quantum yield of ionic dissociation	Appearance of absorption band of TCNB anion
Toluene	2.4	~0	Not observed
Ethyl ether	3.7	~0	Not observed
1,2-Dichloroethane	7.7	0.01	Not observed
Isopropyl alcohol	13.0	0.29	Observed
Ethyl alcohol	17.0		Observed
Acetonitrile	25.8	1.00	Observed

is not affected by the solvent polarity.

On the other hand, the difference in Stokes shift of fluorescence between TCNB-benzene and TCNB-benzene-1,2-dichloroethane systems can be explained by the usual dielectric theory of the solvent shift of fluorescence spectra.[8] This means that the electronic structure of the excited TCNB-benzene complex is independent of the solvent polarity and a constant value of k_f can be expected. Therefore, at the present stage of investigation the larger decrease of φ_f with the increase of solvent polarity from benzene to 1,2-dichloroethane solutions, compared with the decrease of τ_f, may be ascribed to the existence of the direct radiationless process (b).

From Table 1, we can see the increase of φ_{nf} with the increase of solvent polarity from benzene to 1,2-dichloroethane and the increase of φ_{ion} as well as the decrease of φ_{nf} when the solvent is changed from 1,2-dichloroethane to acetonitrile. These results show that solvent polarity plays an important role not only for ionic dissociation but also for intra-complex radiationless transition.

Ionic Dissociation of Various Weak EDA Complexes. We have studied the ionic photodissociation of various EDA complexes in acetonitrile solution. In the case of liquid donors the volume ratio of the donor *vs.* acetonitrile was fixed to 1 : 2. All the results are listed in Table 3, together with the values of the fluorescence lifetime and the result of S_n–S_1 spectral measurement in nonpolar solvents. The yield of ionic dissociation in acetonitrile solution of TCNB complexes with methyl-substituted benzene decreases from benzene to HMB donors. Together with this decrease arises difficulty to observe S_n–S_1 absorption spectra in nonpolar solvents. The S_n–S_1 spectra of TCNB-HMB complex in methylmethacrylate and TCNB-α-methylstyrene systems have not been observed. However, the S_n–S_1 spectra of TCNB-benzene and TCNB-toluene complexes have been observed easily by analyzing the re-absorption of CT fluorescence[7,19,26] and those of TCNB-mesitylene[27] and PMDA-mesitylene complexes by the nsec flash photolysis method. On the other hand, the electronic structure of excited equilibrium state of TCNB complexes has been shown to depend little upon the donor according to our theoretical consideration.[7] Thus, the above results of decreasing dissociation of TCNB complexes with increasing strength of donor appear to contradict the theoretical consideration. The contradiction can be removed by considering the fluorescence lifetimes of these complexes. Those of TCNB-α-methylstyrene and TCNB-HMB complexes in nonpolar solvents seem to be short, since fluorescence decay function is almost the same in shape as an exciting laser pulse. It seems to be difficult to observe the S_n–S_1 spectra of TCNB-α-methylstyrene and TCNB-HMB complexes because of these short lifetimes, and the dissociation yields of these complexes in polar solvents might be low. Short lifetimes may be due to the large value of intra-complex radiationless transition rate constant. This consideration in terms of short lifetime is, of course, related to that given in the above section.

Related and Future Problems. The present results on the process k_f of TCNB-benzene complex in

polar solvents might be related to the CT and electron-transfer mechanism of the fluorescence quenching of aromatic hydrocarbons. One of the authors (N. M.) reported that the stronger decrease of φ_f of the heteroexcimer (HE), formed by an aromatic hydrocarbon and an aromatic amine, compared to the decay time with the increase of solvent polarity may be ascribed to the decrease of k_f and increase of radiationless process as the solvent polarity is increased.[2,10,28] On the other hand, Weller and his co-workers assumed the existence of non-fluorescent solvated ion-pair state as well as the fluorescent HE state and the competition between two processes of formation of these states.[10,29] According to this interpretation, the low value of φ_f of HE in polar solvents is due to the larger probability of the process leading to the non-fluorescent solvated ion-pair state. Our recent study on HE indicates that the assumption of the existence of the non-fluorescent ion-pair state in a solvent, which is not very polar, is fairly reasonable.[16] Although such a non-fluorescent solvated ion-pair state was not assumed explicitly on TCNB-benzene and TCNB-toluene complexes, it may be related to the direct radiationless processes from the excited FC state as well as in the course of the relaxation process from the excited FC state to the fluorescent state.

We have concluded that short lifetimes of rather stronger complexes may be due to the large value of intra-complex radiationless transition rate constant. In this case there might be also a radiationless process due to the degradation from the excited FC state of the complex in addition to the radiationless processes from the fluorescent state. If this degradation process from the excited FC state exists at all, it will be an interesting subject for investigation.

In contrast to our present results where the dissociation of weak EDA complexes occurs in their lowest excited singlet states, the spontaneous dissociation in the lowest CT triplet state of PMDA-mesitylene complex in ether-isopentane solution at low temperature has been reported.[12] The difference may be ascribed to the difference in solvent and temperature, although atomistic mechanism which determines the different way of dissociation is not very clear. We have confirmed that TCNB-α-methylstyrene complex shows a behavior similar to that of other complexes, *i.e.*, it dissociates in the lowest excited singlet state, although its fluorescence behavior is quite peculiar, giving two fluorescence bands in nonpolar solvents.[30] On the other hand, we have recently found a rather slow rise of the laser-induced photocurrent differing from the present results, in the case of PMDA-2-methyltetrahydrofuran complex.[31]

The authors wish to express their thanks to Mr. T. Okada and Mr. Y. Taniguchi for their helpful discussions.

Vibration Spectra and Molecular Structures of *n*-Butyronitrile, β-Chloropropiononitrile, and β-Bromopropiononitrile

Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo, Hongo, Tokyo

(Received June 15, 1971)

Infrared and Raman spectra of XCH_2CH_2CN-type molecules (X=CH_3, Cl, and Br) are studied. From the spectral analysis, it is concluded that *trans* and *gauche* isomers coexist in the liquid phase, the *gauche* being more stable. It is also shown that these molecule take *gauche* configurations in the crystalline phase.

In a previous report, the vibration spectra and the molecular structure of succinonitrile were discussed from the point of view of a normal coordinate treatment and the molecular structure.[1] The spectra of succinonitrile in the solid state showed that *trans* and *gauche* forms coexist above −50°C, while only the *gauche* form remains below −50°C. These results are quite different from those of ordinary disubstituted ethanes, such as *n*-butane, 1,2-dichloroethane, and 1,2-dibromoethane, where the stable configuration in the crystalline phase is the *trans* form.[2] In order to ascertain whether this is a phenomenon characteristic of the molecules having cyanide groups, the infrared and Raman spectra of XCH_2CH_2CN-type molecules (X=CH_3, Cl, and Br) were studied.

An empirical rule was proposed by the present author for the relationship between the skeletal deformation vibrations and the molecular configurations of rotational isomers.[3] The validity of this rule was also tested in the present work.

Experimental

Samples. *n*-Butyronitrile was prepared from *n*-butyric acid by the standard method. The product was purified by redistillation; bp 117°C/760 mmHg. The purity was tested by means of gas chromatography.

β-Chloropropiononitrile was synthesised from ethylene cyanohydrin. Thionylchloride was mixed with ethylene cyanohydrin and kept at room temperature for several hours. The mixture was washed with a $NaCO_3$-H_2O solution, dried over calcium chloride, and then distilled; bp 175°C/760 mmHg.

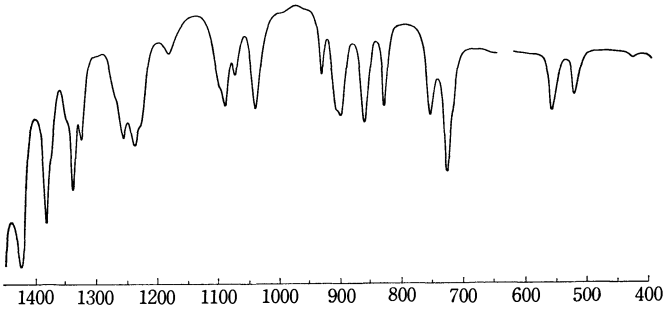

Fig. 1. Infrared spectra of liquid *n*-butyronitrile (room temperature).

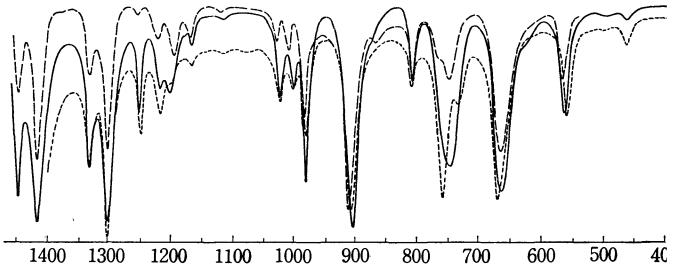

Fig. 2. Infrared spectra of β-chloropropiononitrile (——: liquid, room temperature, ———: glass, −196°C, ----: CS_2 solution).

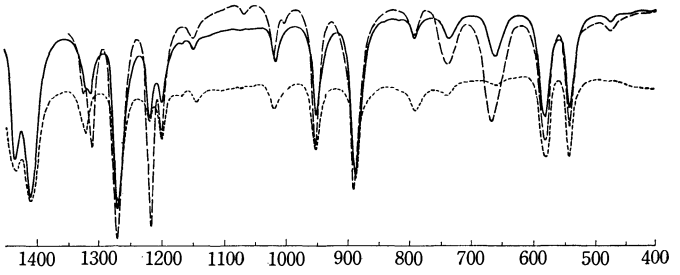

Fig. 3. Infrared spectra of β-bromopropionitrile (——: liquid, room temperature, ----: glass, −196°C, ----: CS_2 solution).

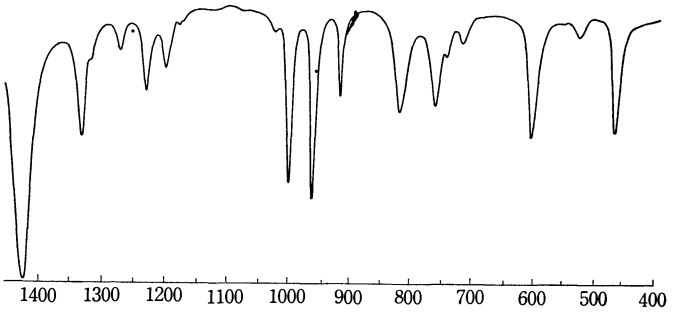

Fig. 4. Infrared spectra of succinonitrile (room temperature).

β-Bromopropiononitrile was also made from ethylene cyanohydrin. Ethylene cyanohydrin was mixed with phosphorous tribromide in ether on an iced-bath and was then kept for 24 hr. The mixture was washed with a $NaCO_3$-H_2O solution, dried over calcium chloride, and distilled; bp 63–65°C/5 mmHg. As the product was rather unstable in the air, freshly-distilled samples were used for the measurements.

Vibration Spectra. The infrared spectra in the NaCl and KBr regions (4000–500 cm^{-1}) were recorded by a Japan Spectroscopic Company 402G grating infrared spec-

trometer. A Hitachi FIS-1 far-infrared spectrometer was used for the measurement of the infrared spectra in the lower-frequency region. The Raman spectra were recorded by means of a laser Raman spectrometer which had been designed and constructed in our laboratory.[4] The spectrometer was operated under a resolution of 5–10 cm^{-1}.

The observed frequencies for the liquid sample are summarised in Table 1. The observed infrared spectra of the XCH_2CH_2CN-type molecules in the region of 1400–400 cm^{-1} are shown in Figs. 1–3. For the cases of β-chloropropiononitrile and β-bromopropiononitrile, the spectral changes observed at a low temperature (liquid nitrogen) and in a CS_2 solution are also included. The infrared spectra of succinonitrile observed at room temperature is given in Fig. 4 for comparison. It is important to emphasise that the infrared spectra at low temperatures do not correspond to those of the crystalline phase, although the liquid-nitrogen temperature is lower than the melting points of the samples. The infrared spectra were obtained from films deposited on a cooled (−196°C) potassium chloride window in a conventional low-temperature cell. The deposited film was transparent and the samples were assumed to be in the glassy state. An attempt to obtain the crystalline sample by annealing was unsuccessful.

The Raman spectra for the liquid XCH_2CH_2CN-type molecules in the region of 100–1400 cm^{-1} are shown in Figs. 5–9. The Raman spectra for the crystalline samples are shown in Figs. 6–10. In the case of Raman spectroscopy, annealing is much easier.

Normal Coordinate Treatment

For confirming the vibrational assignment, the normal frequencies of the XCH_2CH_2CN-type molecules were calculated by using the force constants obtained for a series of alkanonitriles[5] and alkylharides.[6] The method of calculation has been described in other papers.[1,7] In the present report, the results of the calculation will not, then, discussed in detail.[8]

Vibrational Assignment and Discussion

Solvent Effect. The *trans* isomer of β-chloropropiononitrile or β-bromopropiononitrile is stabilised more than the *gauche* isomer when the molecule is dissolved in a medium with a small dielectric constant, such as carbon disulfide, because the dipole moment of the *gauche* isomer is larger than that of the *trans* isomer. Thus, the solvent effect on the spectrum is very good experimental evidence for the identification of vibration bands related with rotational isomers.

Two types of absorption bands are found in Figs. 2 and 3. Their relative intensities in a CS_2 solution increase in one type and decrease in the other type. The absorption bands belonging to the former type are assigned to the *trans* isomer, and the other bands, to the *gauche* isomer. In Table 1, the *trans* and the *gauche* bands are indicated by "*t*" and "*g*" respectively.

Low-temperature Spectra. When the infrared spectra of β-chloropropiononitrile and β-bromopropiononitrile at the temperature of liquid nitrogen are compared with those at room temperature, an increase in the relative intensities is observed for the *gauche* bands, while the *trans* bands lose some of their intensities (see Figs. 2 and 3). The Raman spectra of the crystalline samples (see Figs. 6, 8, and 10) definitely determine the location of vibration bands corresponding to either the *trans or gauche* isomer.

Skeletal Deformation Vibrations. Skeletal deformation vibrations and torsional vibrations are expected to occur in the region of 100–700 cm^{-1}. The skeletal deformation vibrations of alkanonitriles can be conveniently classified into three groups.[3] We call them the A, B, and C groups. The B group is composed of pure C–C≡N bending vibrations which occur in the region of 300–400 cm^{-1} with strong intensities. The frequencies related to this vibrational mode are hardly affected by the change in the geometry of the rotational isomers. The A and C groups are composed of the coupled vibrations of C–C≡N bending and C–C–C (or C–C–X) deformation modes, which are localized in the regions of 500—600 cm^{-1} and 100—200 cm^{-1} respectively. The A-type deformation vibrations are good characteristic frequencies with respect to the rotational isomerism. In this group, the vibration of a *trans* isomer has a lower frequency than that of a *gauche* isomer. On the other hand, the C-type deformation-vibration frequencies exhibit rather irregular behaviour because of their coupling with torsional vibrations. In the Raman spectra of Figs. 5—10, we see the bands corresponding to the skeletal deformation vibrations of the A, B, and C types. For example, the Raman bands at 563 and 533 cm^{-1} of *n*-butyronitrile correspond to the A-type deformation vibrations, while the bands at 380 and 362 cm^{-1} and the bands at 185 cm^{-1} correspond, respectively, to the B- and the C-type deformation vibrations.

The spectral changes in the skeletal deformation vibrations on passing from the liquid to the crystalline phase give most reliable experimental evidence for the assignment of the vibration frequencies to the rotational isomers. In the cases of β-chloro- and β-bromopropiononitriles, *trans* and *gauche* bands can easily be identified by referring to the empirical rule of a stretching-vibration frequency of a carbon-halogen bond.[9] A comparison of the spectra in Figs. 6 and 8 shows that the C–Cl stretching vibration at 758 cm^{-1} and the skeletal deformation vibration at 502 cm^{-1} of β-chloropropiononitrile belong to one rotational isomer, while the band at 669 cm^{-1} (the C–Cl stretching) and the band at 563 cm^{-1} (the skeletal deformation) belong to the other rotational isomer. As the C–Cl stretching vibration at 758 cm^{-1} originates from the *trans* isomer, the band at 502 cm^{-1} is assigned to the A-type skeletal deformation vibra-

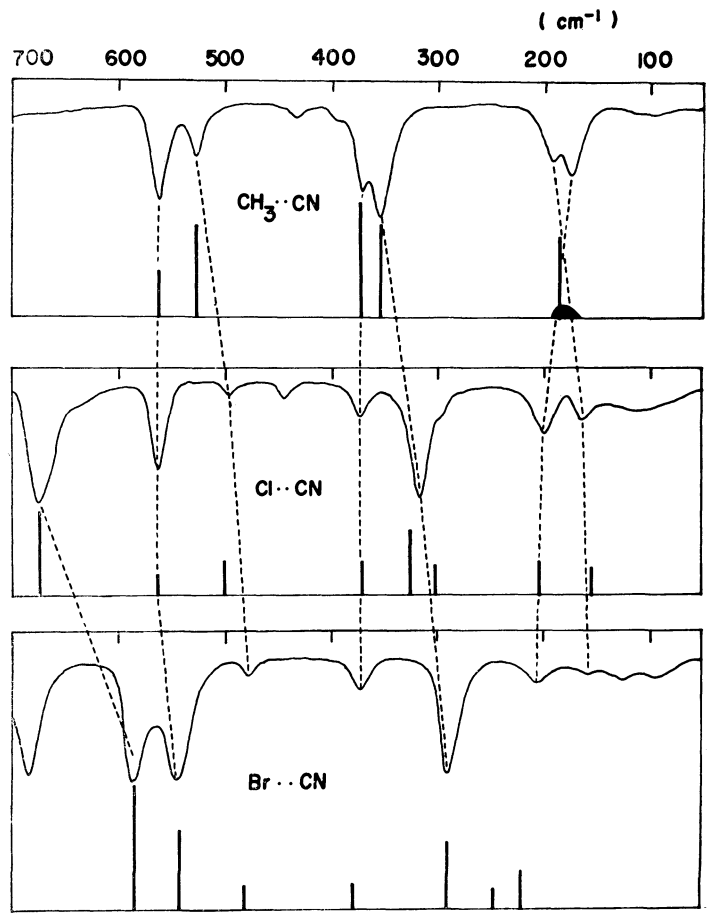

Fig. 11. Comparison of skeletal deformation vibrations of XCH_2CH_2CN (upper curve: infrared, lower bar: Raman).

tion of the *trans* isomer. In the same way, the band at 563 cm^{-1} corresponds to the A-type deformation vibration of the *gauche* isomer, because the 669 cm^{-1} band can definitely be assigned to the C–Cl stretching vibration of the *gauche* isomer. The same situation holds for the bands at 685 and 481 cm^{-1} and for the bands at 584 and 546 cm^{-1} in the case of β-bromopropiononitrile (see Figs. 7 and 10). In the same way, the bands due to the skeletal deformation vibrations can easily be classified for each rotational isomer. The results are summarised in Table 1.

In the case of *n*-butyronitrile, the frequency assignments are based upon the results of normal coordinate treatment and the results of the vibrational assignment for β-chloro- and β-bromopropiononitriles. Two A-type skeletal deformation bands are found, at 533 and at 563 cm^{-1} (see Fig.5). The vibration frequencies are calculated to be 562 cm^{-1} for the *gauche* isomer and 513 cm^{-1} for the *trans* isomer. Thus, the observed frequenciy of 563 cm^{-1} is assigned to the *gauche* isomer, while that of 533 cm^{-1} is assigned to the *trans* isomer. These assignments correspond to those of β-chloro- and β-bromopropiononitrile very well.

The relative intensities of the A-type bands present another confirmation of the assignment. In Fig.11, the infrared and Raman spectra of the XCH_2CH_2CN-type molecules are compared. The relative intensity of the A-type molecules are compared. The intensity of the A-type band of the *gauche* isomer is stronger than that of the *trans* isomer in the infrared spectra, while the *gauche* band decreases in relative intensity in the Raman spectra. This may correspond to the situation that an A-type band of a *trans*-isomer is infrared-inactive if a molecule is of the XCH_2-CH_2X type.

Other Vibrations. The assignments of the other vibrations, namely, the CH_2 deformation vibrations, the C–C stretching vibrations, and the C–CN stretching vibrations, are rather straightforward with the help of the well-established frequency assignments for 1,2-disubstituted ethanes and the results of the calculated normal frequencies. The results are summarised in Table 1. As for *n*-butyronitrile, the identification of the *trans* and *gauche* bands were not definite in this region and, therefore, the observed frequencies were not assigned.

Rotational Isomer. For the three molecules studied, it is ascertained that the *trans* and the *gauche* isomers coexist in the liquid phase. The energy differences between the two rotational isomers in the liquid phase were observed to be about 640, 500, and 420 cal/mol for β-bromopropiononitrile, β-chloropropiononitrile, and *n*-butyronitrile respectively, the *gauche* isomers being more stable. The values of the energy difference are preliminary; a detailed discussion will be reported elsewhere.

The Raman spectra of the crystalline samples show that the *gauche* isomers remain in the crystalline state at the temperature of liquid-nitrogen. The conclusion for *n*-butyronitrile contradicts that of Reference.[10] There was no spectral evidence for the coexistence of the *trans* and *gauche* isomers in the solid state.

Theoretical and Experimental Considerations of the Direct Photo-Isomerization and Chemistry of 1,3-Pentadiene

Kozo INUZUKA* and Ralph S. BECKER

Department of Chemistry, University of Houston, Houston, Texas 77004, U. S. A.

(Received June 24, 1971)

Potential energy curves as a function of the angle of twist around single and double bonds have been calculated for piperylene (1,3-pentadiene). Also, direct-excitation *cis*→*trans* photoisomerization and *trans*→methylcyclobutene photochemistry have been investigated as a function of the temperature. The theoretical analysis strongly indicates that the cyclobutene is formed photochemically from the *trans-s-cis* isomer which is created thermally from the *trans*-isomer in the ground state (not by photoisomerization). The temperature-dependency data support this conclusion. The theoretical data also indicate that there is a small barrier to photoisomerization around the double bond in the first excited singlet (and triplet) state. The temperature-dependency data also support this conclusion. The potential energy curves are in harmony with the known emission (none exists), photoisomerization, and internal-conversion data for the *cis*- and *trans*-piperylenes. The emission properties of model cyclic diene steroids are compared with those expected from linear dienes, and the emission results of the former are interpreted within the theoretical framework developed.

The direct photoirradiation of a cyclohexane solution of piperylene at 2537 Å results in the formation of 3-methylcyclobutene and *cis-trans* isomerization as the main reactions.[1] On the other hand, the sensitized photoisomerization of piperylene has also been studied in detail using a variety of sensitizers.[2-5] The experimental data show that there is a photostationary equilibrium between *cis*- and *trans*-piperylene, and also that other photoproducts are produced.[3] The concentration ratio of *cis*- and *trans*-isomers depends on the lowest triplet energy of the sensitizer.[2,5] The theoretical consideration of the photochemical mechanisms appropriate to piperylene are more difficult than in the case of butadiene. The introduction of the methyl group in the terminal carbon atom brings about a steric effect in piperylene, and also the methyl group may have some inductive and resonance effects on the π-electron system of the molecule. In this investigation we made the general assumption that the substitution of a methyl group into the terminal methylene of butadiene does not produce any significant effect on the π-electron structure of butadiene. Therefore, calculated results of the potential energy curves of butadiene can be used to explain the mechanism of the *cis-trans* isomerization of piperylene. However, we have specifically included the non-bonded interaction effect between the methyl group and the other atoms of piperylene at the *cis*-side, at the *trans*-side, and for the form twisted by 90 around the double bond (*vide infra*).

Methods of Calculation

The following numerical values[6] were used for the skeletal structure of *trans*-1,3-butadiene: 1.339 Å for the carbon double bond and 1.480 Å for the central single bond. The value of 123° was assigned to the bond angle, $\angle$CCC. The skeletal structure only was taken into account. All the calculations were carried out within the framework of the general semiempirical SCF-MO-CI method, and the Pariser-Parr approximation was used for the electron repulsion integrals. The resonance integral for the nearest neighbor carbon atom, β_{CC} was treated as a parameter and adjusted to fit the calculated lowest π,π^* state

energy to the experimental value. The β_{CC} for the twisted bond was obtained from the following equation:

$$\beta(\theta) = \beta_{CC} \cos\theta \quad (1)$$

where θ is the angle of twist. All the penetration terms were neglected. In the present paper, calculations concerning the single-bond twist and the terminal double-bond twist were carried out.

In the case of double-bond twisting, the effect of the bond twist upon the electron repulsion integrals was taken into account (*vide infra*). In the case of single-bond twisting, the foregoing concern was neglected because such neglect did not have any significant effect upon the final result. We calculated the state energies of the molecule as it is twisted about the single or double bond using the SCF–MO's obtained. All singly-excited configuration interactions were taken into account (complete single excited-state configurational interaction). Furthermore, in the case of the double-bond twist, all doubly-excited configuration interactions were also taken into account (complete single and double excited-state configurational interaction). The total π-electron energy, E, in the ground state is obtained by:

$$E = E_\pi + E_n \quad (2)$$

where E_π is the energy of the π electrons and where E_n is an effective nuclear interaction term given by Pople:[8]

$$E_n = \sum_{\mu<\nu} Z_\mu Z_\nu / R_{\mu\nu} \quad (3)$$

Z_μ is the effective charge of the atom, μ; unity is used for Z_μ in the present calculation. The potential energy curves for the ground state are obtained by the calculation of the total π electron energy, E, as a function of the angle of twist. The potential energy curves of the excited states, as a function of the angle of twist, are obtained by superimposing the state energies upon the potential curve of the ground state.

Before the calculation of the twisting around the double bond of 1,3-butadiene was carried out, the general SCF–MO–CI method was used to calculate the shape of the potential energy curves for twisted ethylene in order to verify its utility. The calculated potential energy curve of the triplet state[9,10] is in harmony with the experimental results on the photoisomerization of *cis* and *trans*-1,2-dichloroethylene. To produce such potential minima in the excited states of ethylene at 90° (within the framework of the semiempirical SCF–MO–CI with zero differential overlap using the point charge atomic repulsion integral), the following function was used for the atomic repulsion integral of the atoms of the terminal double bond:[12]

$$\gamma_{C=C}(\theta) = \gamma_{C=C}(0) + A(1 - \cos\theta) \quad (4)$$

where the first term corresponds to the planar atomic repulsion integral value, where θ is the angle of twist, and where A is a parameter. All the other atomic repulsion integrals were calculated by the Pariser-Parr equation without any correction. In addition, the twisting around any bond will result in the introduction of $2p\sigma$ components into the atomic repulsion integrals between the *non-nearest* neighbor atoms.[12] This effect will make an atomic repulsion integral value larger than the one with only a pure $2p\pi$ component corresponding to the same bond distance. To take this effect into account, an off-center position was assumed for the location of the center of the atoms involved. As the simplest method, the off-center positions were taken on the same side of the $2p\pi$ orbitals and by some small distance off the center of the atom along the $2p\pi$ atomic-orbital axis. This off-center distance was looked upon as the parameter. The calculation was carried out over the angles from 0° (planar form) to 85° (the nearperpendicular form).

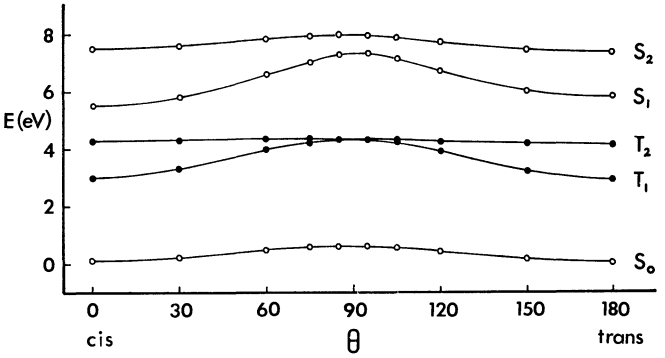

Fig. 1. Potential energy curves for ground and excited states of 1,3-butadiene as a function of angle of twist around the single bond using Eq. (1) ($\beta_{C=C} = -2.70$ eV and $\beta_{C-C} = -2.00$ eV) and including all singly excited configurations.

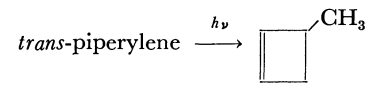
The results calculated using these approaches are shown in Figs. 1 and 2.

Results and Discussion

The potential energy curves of 1,3-butadiene twisted around the central bond are shown in Fig. 1.

The potential energy curves resulting from twisting around the double bond are shown in Fig. 2, where these potential energy curves are shown to be symmetric with respect to the twisting angle, 90° since all effects of the hydrogen atoms are neglected. These potential energy curves show that the energies of the T_1, S_1, and S_2 states decrease with an increase in the twisting angle around the double bond. The potential curve for T_1 is almost degenerate with the ground state at 90°. The potential energy curve, T_2, has a maximum at 90°, and it crosses the two potential curves S_1 and S_2 near 80°. The introduction of a methyl group in the position of the terminal hydrogen atom of butadiene will make the potential energy curves of butadiene asymmetric with respect to 90°. The spectroscopic data for the S_1 and T_1 of *cis*- and *trans*-piperylene were used to make a rough estimation of the shape of the potential energy curves of piperylene on the *cis*- and *trans*-sides. The absorption spectra of *cis*- and *trans*-piperylene[13] in an *n*-heptane solution have the $S_0 \rightarrow S_1$ band maxima at 225 nm for the *cis*-form and at 222 nm for the *trans*-form. The difference between the band maximum of the isomers is about 0.1 eV. From the S–T absorption data,[14] the $S_0 \rightarrow T_1$ transition energy of the *trans*-form may be seen to be higher than that of the *cis*-form by about 0.1 eV. The non-bonding interaction energies between the methyl hydrogen atoms and the other atoms of the residual part at the twisting angle, 0, 90, and 180°, using 180° (*trans*) as a reference, were calculated by using Bartell's equations.[15] These values reached their maxima at the *cis*-side (0°) and their minima at 90°. These calculated results show that the non-bonding interaction energy between the methyl group and the residual part of the molecule is negligible for the *trans* (180°) and perpendicular (90°) forms. The non-bonding energy value gave, at most, an energy increase of 0.2 eV for the *cis*-form. As these calculated values correspond to the maximum interaction energy value for each form, the actual non-bonding interaction energy value may be smaller than the value calculated. This calculated value, 0.2 eV, can be superimposed on the calculated ground-state and excited-state potential energy curves of butadiene at 0° (*cis*-form). A consideration of the spectroscopic differences for the $S_0 \rightarrow S_1$ (0.1 eV) and $S_0 \rightarrow T_1$ (0.1 eV) transitions and the non-bonding interaction energy suggests that the lowest excited singlet and triplet states of piperlylene are higher by $\leq$0.1 eV on the *cis*-side than on the *trans*-side (Fig. 2). Therefore, the potential energy curves will be asymmetric around 90° and isomerization should be easier from the *cis*-side than from the *trans*-side (*vide infra*).

The direct irradiation of a mixture of *cis*- and *trans*-piperylene[1] initially gives rise to an increase in the *cis*-piperylene, while the *trans*-piperylene decreases. The 3-methylcyclobutene originates primarily from the *trans* isomer[1] as:



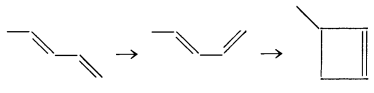
(5)

The following reaction[1] also occurs concurrently:

(6)

The irradiation of 1,3-butadiene is known to give rise to cyclobutene.[1,16] This process apparently occurs from the excited singlet state of 1,3-butadiene.[16] This suggestion may also be applicable to the process of the cyclization of piperylene, because the structure of piperylene is parallel to that of 1,3-butadiene. Figure 2 shows that, in the ground-state, twisting around the terminal double bond has a very high potential barrier near 90°. This suggests that the twisting around the terminal double bond of butadiene is very difficult because of the high activation energy. However, the potential curves for the lowest excited singlet and triplet states show that there is a shallow minimum at 30–50° and a small barrier (~0.03 eV) beyond 60° in S_1, and that there is a shallow minimum at 35–60° and a low barrier (~0.1 eV) near 90° in T_1 (Fig. 2). The numerical values for the potential minimum and the barrier height in S_0, S_1, and T_1, and the other states depend on the choice of the parameters; that is, the off-center values, A in Eq. (4) and the approximation used for the electron repulsion integral, *etc.* However, within our present procedure, changes in the magnitude of the parameters for the off-center value and the A value in Eq. (4) result in potential energy curves similar in shape to those in Fig. 2. Those results suggest that a twisted form around the terminal double bond is more stable than the planar forms in S_1 and T_1. Also, Fig. 2 shows that the potential energy curve of T_1 is almost degenerate with that of the ground state, at 90°.[17] This situation in butadiene is very similar to that of piperylene with a slight modification resulting from a slight asymmetry around 90° (*vide supra*). Srinivasan[1] proposed that 3-methylcyclobutene (III) comes primarily from *trans*-piperylene (I). The production of 3-methylcyclobutene from *trans*-piperylene could arise as follows:

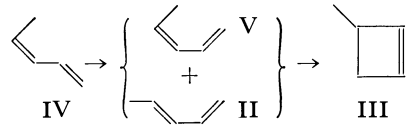
13) L. E. Jacobs and J. R. Platt, *J. Chem. Phys.*, **16**, 1137 (1948).
14) R. E. Kellogg and W. T. Simpson, *J. Amer. Chem. Soc.*, **87**, 4230 (1965).
15) L. S. Bartell, *J. Chem. Phys.*, **32**, 827 (1960).
16) R. Srinivasan, *J. Amer. Chem. Soc.*, **85**, 4045 (1963).
17) The calculation was carried out through 0 to 85°. The potential energy curves of both states, S_0 and T_1 are not perfectly degenerated at 85°. Recently Eleveth [*Chem. Phys. Lett.*, **3**, 122 (1969)] carried out the calculation of the state energies of *trans*-butadiene at two twisted angles, 0 and 90°, using the different approach. His result shows that the both states, S_0 and T_1 are nearly degenerate at 90° but they are not perfectly degenerate.



(7)

I II III

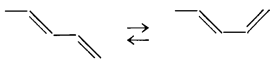
The very small production of 3-methylcyclobutene (III) originating from *cis*-piperylene (IV) could occur by the following process:



(8)

IV II III

We will now examine the nature of the steps in the reaction (7). Figure 1 suggests that *s-cis*↔*s-trans* isomerization around a single bond of butadiene in the lowest excited states, S_1 and T_1 is difficult. Although there is a potential barrier for *s-cis*↔*s-trans* isomerization in the ground state, its height is quite low relative to those in S_1 and T_1. Figure 1 will be, in principle, also correct for the *s-cis*↔*s-trans* isomerization of piperylene around its single bond. These results thus clearly suggest that (1) the *trans-s-cis* piperylene (II) is not produced from *trans*-piperylene in an excited state, but in the ground state and, (2) that 3-methylcyclobutene is produced from II (*versus* I) photochemically. Furthermore, other recent theoretical research[18] suggests that the concentration of *s-cis*-butadiene in *s-trans* is about 3.2% at room temperature and that its concentration decreases on a decrease in the temperature. Therefore, *trans-s-trans*-piperylene in the ground state will be considered to be in thermodynamic equilibrium with the *trans-s-cis*-piperylene (II).



(9)

I II

If *cis*-piperylene were to be the reactant, then reaction (8) would be the appropriate one to consider. The *trans-s-cis*-piperylene (II) is not expected to be produced from IV in the ground state because of the high energy requirement for double-bond isomerization. The *cis-s-cis*-piperylene (V) is not expected to be formed from IV in an excited state for reasons parallel to those given above concerning single-bond isomerization. Furthermore, because of the methyl-hydrogen steric interaction, the equilibrium concentration of the *cis-s-cis*-piperylene (V) produced from IV in the ground state is expected to be very small. Therefore, V will be of very little consequence in the production of the cyclobutene compound. It is potentially possible that (II) could be produced in the excited state of *cis*-piperylene, although the barrier to single-bond isomerization is present. This would involve excited-state double-bond isomerization, followed by a particular coupling, if internal conversion occurred (hot ground state *s-cis*↔*s-trans*); however, this reaction is not expected to occur with any appreciable efficiency. Thus, the formation of 3-methylcyclobutene from *cis*-piperylene is relatively unlikely, and the principal reactant is probably *trans*-piperylene *via* the intermediate (II). The relative importance of the *cis* and *trans* isomers in terms of the quantity of cyclobutene produced from them is in agreement with very recent quantitative findings[1b] published after this investigation was completed. The quantum yield of cyclobutene from the *trans* isomer is ~10 times that from the *cis* isomer.

Further verification exists for the source and mechanism proposed above for the production of the cyclobutene. According to our potential energy curves (Fig. 1), a *s-cis*↔*s-trans* equilibrium in the ground state would depend upon the temperature. That is, the concentration of *trans-s-cis*-piperylene (II) would decrease at low temperatures. Accordingly, the formation of the 3-methylcyclobutene photochemically produced should also *decrease at low temperatures*. The results of the direct irradiation of *cis*- and *trans*-piperylene[19] at different temperatures are shown in Table 1. In this experiment, the formation of 3-methylbutene is found from *trans*-piperylene, but essentially none is observed from *cis*-piperylene. The

Table 1. The photochemistry of piperylenes as a function of temperature

Compound irradiated[a]	Temperature	Irradiation time	% conc.	3-methylcyclobutene
cis-piperylene	21°C	180 min	8.1 (trans)	essentially none observed
	−76°C	180 min	4.0 (trans)	essentially none observed
	21°C[d]	120 min	3.8 (trans)	essentially none observed
	−76°C[d]	120 min	2.1 (trans)	essentially none observed
trans-piperylene	21°C	100 min	—[b]	4.6×[c]
	−76°C	100 min	—[b]	1.5×[c]

a) In *trans*-1,2-dimethylcyclohexane by 200 W mercury arc lamp with Corning 9—54 filter (~220 nm cut-off, >70% transmission 254 nm).

b) It was not possible to determine the quantity of the *cis*-isomer produced. Quantities of *cis* and *trans* isomer determined by gas chromatography.

c) Numbers indicate quantity cyclobutene produced times that of a standard reference signal as determined by gas chromatography.

d) This represents a duplicate run under different experimental arrangements such that the absolute percent concentrations are different. However, note that ratio of the percent concentrations at the two temperatures is the same as that for the preceding set of data.

experiment shows that the formation of 3-methylcyclobutene does *decrease with a decrease in the temperature.* Recently, van der Lugt and Oosterhoff[20] performed theoretical calculations concerning the cyclization of *s-cis*-butadiene using a Valence Bond Procedure. Judging from their results,[20] the photocyclization of *s-cis*-butadiene can occur relatively easily from the *s-cis* form in the excited singlet state. According to our experimental and theoretical data (those of others[18,20]), the rate-determining step for the production of the cyclobutene from the *trans* isomer could well involve the formation of II from the *ground state* of *trans*-piperylene (Eqs. (7) and (9)). Also, it is possible that a barrier could exist in the excited state similar to that found for butadiene.[20] An explanation for the difference in the amount of the cyclobutene from the *cis* and *trans* isomers was given earlier.

On the basis of the above discussion and reaction (9), it can be said that, when II is excited and the cyclobutene (III) is produced, the equilibrium between *trans-s-trans-* (I) and *trans-s-cis*-piperylene (II) should be reestablished. Thus, except for minor side reactions, eventually all of the *trans-s-trans*-piperylene (I) should be converted into (II) and the (II) into the cyclobutene (III). This is in agreement with the trend seen experimentally.[1]

In the direct photoisomerization of the piperylene double bond, *cis-trans* isomerization is another important process. The *cis*↔*trans* isomerization of piperylene corresponds to the twisting around the terminal double bond (of butadiene). Figure 2 shows that the twisting of the double bond of butadiene can occur in the lowest singlet state. However, shallow potential energy minima exist at 30–50 and 150–120°, and small potential barriers are present at more highly twisted angles (*cf.* Fig. 2 and above). In the case of butadiene, the potential energy curves are symmetric with respect to 90° if the non-bonding interaction of all the H atoms is neglected. However, in the case of piperylene the effect of the methyl group should make the potential energy curve asymmetric with respect to 90° (*cf.* above and Fig. 2). Thus, we would predict *a temperature dependence for photoisomerization.* Our experimental results (Table 1) show that the *cis*-piperylene→*trans*-piperylene photoisomerization does occur *and that it is temperature-dependent.* Also, the photoisomerization of *trans*-piperylene→*cis*-piperylene can be expected, though it is 20% less than in the *cis*→*trans* process.[1b] These facts suggest that the *cis*-piperylene→*trans*-piperylene isomerization is slightly dominant over the reverse reaction. Therefore, the potential energy curve of the lowest singlet state of piperylene could be slightly asymmetric with respect to 90°. Our potential energy curves do show an asymmetry that would be in agreement with the experimental results (*cf.* above and Fig. 2).

In addition to the formation of the cyclobutene (III), small quantities of 1,3-dimethylcyclopropene have been observed.[1b] However, the quantity is very small compared with the amount of isomerization or even the amount of cyclobutene that results, particularly in the case of the *trans*-piperylene. It has been proposed that cyclopropylmethylene biradical intermediates are important in explaining the formation of the cyclopropene.[1b] Also, it has been proposed that these same intermediates are important,[1b] or are perhaps important,[21] in the photoisomerization of 1,3-dienes. It is salient to point out that, in one case,[1b] the difference in the photochemical reactivity of the *cis* and *trans* piperylenes was based on the fact that no barrier existed between the planar forms and the 90°-twisted forms in the excited singlet state. However, our experimental data (Table 1) strongly suggest that this is not true, at least for the *cis* isomer. Furthermore, our theoretical results indicate that a small barrier exists for twisting in the excited singlet state for both the *cis* and *trans* isomers (*vide supra*). In addition, some asymmetry appears to exist in the potential energy curves (*vide supra*). Finally, very recently serious doubt has been cast on the proposals that cyclopropylmethylene biradical intermediates are important in the photo *cis-trans* isomerization.[22] This doubt has been based on the differences in the concentration dependences for the isomerizations and for the production of the cyclopropenes.[1b]

There are four kinds of processes for the conversion of S_1 to S_0: fluorescence, internal conversion, intersystem crossing (with accompanying emission, internal conversion and photochemistry in triplet states), and photochemistry in S_1. No one has observed emission from a linear 1,3-diene at room temperature; this situation is very similar to that of acrolein, where the total quantum yield of emission is ~0.01[12] (this point will be discussed more later). The total photochemical yields in solution are only about 0.10.[1b] Further, there is a strong indication that ϕ_{IS} is less than 0.1.[21] Thus, in piperylene, internal conversion directly from S_1 to S_0 must have a high quantum yield (~0.80). Figure 2 suggests that fluorescence is unlikely since torsional twisting has essentially no barrier and this latter process is expected to be fast (faster than fluorescence). The spin-orbit coupling is expected to be small in the carbon-hydrogen system except in special cases.[23] Finally, Fig. 2 shows that, as the angle of twist increases, the energy separation between S_1 and S_0 decreases. Thus, the probability of internal conversion *via* vibronic coupling increases as the angle of twist increases from 0 toward 90°. Therefore, the foregoing considerations provide a good qualitative understanding of the experimental results obtained for piperylene. Pertinent to the discussion above, if internal conversion and photochemistry could be restricted, then fluorescence and/or phosphorescence should be observable. Although acrolein exhibits very little emission,[12] model conjugated keto steroids show ϕ_p values of 0.2—0.3.[24]

This has been interpreted in terms of the inability of such molecules to isomerize and to torsionally dissipate all of the energy; furthermore, spin-orbit coupling exists as well as vibronic coupling between the $T_{n,\pi}^*$ and $T_{\pi,\pi}^*$ states.[12] Furthermore, ergosterol and lumisterol$_2$ show fluorescence at 80°K.[25] Each of these molecules contain saturated ring systems fused to a cyclohexadiene ring. In these latter two cases, isomerization around a double bond in the excited singlet state should be prohibited and the rigidly bonded steroidal framework should prevent any noticeable torsional dissipation of energy. Thus, a potential energy minimum should exist at some small finite angle and fluorescence should occur. This is in agreement with the experimental results.[25] However, it should be noted that temperature and/or viscosity effects appear to be important since the foregoing steroids apparently do not emit at room temperature[25] even though the quantum yield of photochemistry is less than 1. Studies concerning these steroids and other polyenes are in progress.

Summary

Potential energy curves as a function of the angle of twist around single and double bonds have been calculated for 1,3-butadiene. In addition, these have been modified to apply to piperylene (1,3-pentadiene) by taking into account non-bonding interactions involving the methyl group. The results indicate that substantially higher barriers exist for twisting a single bond in the first excited singlet and triplet states than in the ground state. On the other hand, substantially lower barriers exist in the first excited singlet and triplet states for double-bond twisting compared to that in the ground state. On the basis of these and other considerations, we predicted that (1) cyclobutene should be photochemically produced from the *trans*-piperylene *via* the *trans-s-cis* isomer, (2) a temperature dependence should exist for cyclobutene production from the *trans* isomer because of a barrier to *s-cis-trans* isomerization in the ground state, and a possible barrier in the excited state and (3) very little cyclobutene should be produced from the *cis*-piperylene. All of these predictions are in harmony with the experimental results.

On the basis of the shape of the potential energy curves in the excited singlet (and triplet) states, we predicted that a barrier should exist for the inter photoisomerization of *cis* and *trans* piperylenes. This is verified, at least in part, by the existence of a temperature dependence for the photo *cis*→*trans* process.

On the basis of several pieces of evidence, it does not appear to be necessary to invoke cyclopropylmethylene biradicals as intermediates in the photo *cis-trans* isomerizations of 1,3-dienes.

Charge-Transfer and Proton-Transfer in the Formation of Molecular Complexes. I. The Complex Isomerization of Some Anilinium Picrates by Melting

Gunzi SAITO and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 3, 1971)

o-Chloroaniline, *m*-nitroaniline, 3-nitro-4-methylaniline, and *N,N*-dimethylamino-*p*-benzaldehyde form true phenolates with picric acid. However, their electronic and vibrational spectra were found to be drastically modified by melting. The appearance of a new electronic absorption located near the place where the corresponding *s*-trinitrobenzene complex exhibits the charge-transfer band is noted above the melting point. At the same time, the vibrational bands due to the anilinium ion observed at room temperature are replaced by those due to the aniline. On the basis of these observations, it was concluded that complex isomerization from a true phenolate to a charge-transfer complex takes place by melting in these cases. On the other hand, the spectra of *N,N*-diethylanilinium and *m*-chloroanilinium picrates were shown to remain the same below and above the melting points.

Many years ago, Pfeiffer suggested that the interaction between the two components in a molecular complex could be considered as an interaction between particular force fields to be assigned to some regions of the molecules.[1] If each of the component molecules had more than one type of force field, isomeric molecular complexes could be obtained, depending upon which pair of force fields predominated in the interaction. For example, when an aromatic amine is combined with a polynitrophenol, one type of force field produces an acid-base interaction, and the other, an electron donor-acceptor interaction. The former interaction leads to the formation of true phenolate by proton-transfer, and the latter, to a true molecular compound by charge-transfer (CT). The papers in the present series will deal with the phenomena characteristic of the molecular complexes composed of such bifunctional component molecules.

Hertel has assumed that the progressive weakening

1) P. Pfeiffer, "Organische Molekülverbindungen," 2 Aufl., Verlag von F. Enke, Stuttgart (1927), 341—346.

of the acid-base interaction and strengthening of the donor-acceptor interaction should produce molecular complexes which range in type from true phenolates at one end of the series to true molecular compounds at the other.[2] One may expect the presence of intermediate situations where the same components form either phenolates or CT complexes, depending upon ambient conditions. In fact, several combinations of the components giving such polymorphs were discovered by Hertel. This phenomenon was named "complex isomerism" by this author. The polymorphs differ distinctly from each other in their colors, melting points, molar volumes, phase diagrams, and X-ray diffraction patterns.[2-5] For example, the combination of 1-bromo-2-naphthylamine and picric acid gives a yellow-colored salt at room temperature. The color turns violet-red at 114°C, and then the complex melts at 178°C. The latter temperature is not far from the melting point of the corresponding brilliant red *s*-trinitrobenzene (TNB) complex, 195°C. Further evidence for the change in the type of interaction accompanying the transition has been provided by spectroscopic studies of the polymorphic phases of the two picrates carried out by Briegleb and Delle.[6,7] The infrared spectra of 1-bromo-2-naphthylamine- and 1,6-dibromo-2-naphthylamine-picric acid at room temperature have been shown to have the pattern assigned to NH_3^+ vibrations. When the complexes are heated to 140°C, which is well above the transition points, the intensities of this pattern are markedly diminished and the bands due to the NH_2 group are newly observed. The deep coloration at high temperatures has been attributed to the appearance of CT absorptions. The crystal and molecular structures of the red-colored form of the 1-bromo-2-naphthylamine complex are known.[8]

In principle, the melt of an anilinium picrate is an equilibrium mixture of not only the cation, the anion, and the ion-pair, but also the CT complex and the component molecules. When the equilibrium is favorable to the CT complex and its components, a marked deepening of the color may be observed at the melting point, as if the transition point were elevated to this temperature. A close examination of twenty-four anilinium picrates has revealed that a new phenomenon, complex isomerization by melting, can be observed if the amines are appropriately chosen.

Experimental

Materials. The picric acid and all the aromatic amines used in this work were commercially obtained. The sodium picrate mono hydrate was prepared by the neutralization of the acid with sodium carbonate. The amine hydrochlorides were made by means of a reaction between hydrochloric acid and the amines. They were washed with a small amount of water and then with ether. The anilinium picrates were precipitated by mixing the component compounds separately dissolved in benzene.

Measurements. To measure the reflectance spectra of molten samples, we employed the device proposed by J. Aihara of our laboratory.[9] A powdered sample sandwiched between two quartz plates was mounted on powdered sodium chloride embedded in a brass block. The reflectance given by this arrangement was recorded on a Beckman DK 2A spectroreflectometer. The temperature at the boundary between the quartz plate and the sodium chloride, which is somewhat higher than that of the sample, was regulated as has been described earlier.[10] The measurements are rather qualitative because of the change in the sample thickness and also because of the shift of the baseline caused by heating.

The vibrational spectra of the powdered or molten sample sandwiched between two rock salt plates were examined in the region from 2000 to 4000 cm^{-1} using a Jasco IR-G infrared spectrophotometer equipped with a heating attachment. The temperature near the sample holder was monitored by means of a copper-constantan thermocouple and was kept constant using a Chino temperature-indicating controller, type E 500.

Results and Discussion

A preliminary survey was made by the visual examination of the color change at the melting point. *o*-Bromoanilinium and *o*-iodoanilinium picrates have been known to exhibit complex isomerism; therefore, the anilines having basicities close to or less than those of these two seemed to be the most hopeful component compounds. They are *o*-chloroaniline, *m*-nitroaniline, 3-nitro-4-methylaniline, *N,N*-dimethylamino-*p*-benzaldehyde, and *m*-chloroaniline (see Fig. 11). As expected, all these anilines except the last one were found to form picrates which show a marked color change upon melting. None of the other anilines gave picrates with such behavior.

The o-*Chloroaniline Complex* (*Figs. 1 and 2*). The complex precipitated from a red-colored benzene solution is a pale yellow powder which melts at 138—139°C (134°C by Hertel[2]). The color turns light red upon melting and then returns to yellow upon solidification. As is shown in Fig. 1, the reflectance spectrum at room temperature has a strong absorption below 450 mμ. Upon heating, a red-shift of this band is noted, as is indicated by curve b. Upon melting, a broad band covering the range from 450 to 600 mμ appears. Following the procedure employed by Briegleb and Delle,[7] the CT absorption of an imaginary complex formed between *o*-chloroaniline and picric acid was assumed to be approximated by that of the TNB complex, because the acceptor-strength of picric acid is comparable with that of TNB. The solid TNB complex is red and gives the spectrum shown by curve d. The close similarity

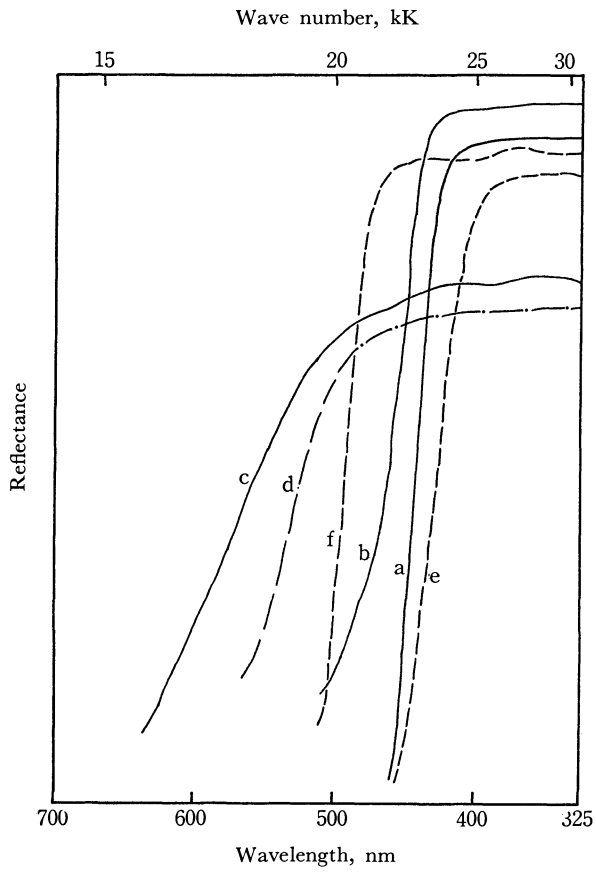

Fig. 1. Reflectance spectra, a) the *o*-chloroaniline-picric acid at room temperature, b) the same a little below the melting point, c) the same in the molten state, d) the TNB complex at room temperature, e) picric acid, and f) sodium picrate.

between curves c and d clearly indicates that the broad band appearing upon the melting of the complex arises from the CT interaction.

In the case of the *N*,*N*-dimethylaniline-TNB complex reported earlier, it was found that the spectrum in the molten state is different from the solid-state spectrum, but much like the one in the dissolved state.[9] Consequently, we attempted to compare the high-temperature spectrum, curve c in Fig. 1, with the spectrum of the corresponding TNB complex in a chloroform solution. Unfortunately, the CT absorption of the *o*-chloroaniline-TNB complex in chloroform was not observable. Nevertheless, the location of its maximum may be estimated by the following method. In our previous work, the energy of the CT absorption maximum of a TNB complex was shown to be larger by 6 kK than that of the corresponding *p*-chloranil complex.[11] Since the CT band of the *o*-chloroaniline-*p*-chloranil complex in a chloroform solution is found at 19.1 kK, the required value may be about 25 kK. This value seems to be a little too high to be compared with curves c and d. Thus, the present results are not in accordance with the observations for the dimethylaniline-TNB complex.

Since *o*-chloroaniline is a weak electron donor and picric acid is a weak acceptor, the resulting CT complex may be expected to be non-ionic. Therefore, the vibrational bands due to the NH_3^+ group must be replaced by those due to the NH_2 group of the amine by melting if complex isomerization occurs. This change will drastically modify the spectrum in the region from 2000 to 4000 cm^{-1}. In Fig. 2, the vibrational spectra of the *o*-chloroaniline complex at room temperature and above the melting point are compared with those of the free amine, its hydrochloride, the free acid, and its sodium salt. All the bands but the one at 3150 cm^{-1} in the complex at room temperature are well approximated by a summation of the bands in the anilinium hydrochloride and those in the sodium picrate. The strong bands appearing near 3600 cm^{-1} in the sodium picrate are not observed in the *o*-chloroaniline complex. They may be assigned to the hydrated water.[12] It is easy to see that the broad bands located at 2040, 2550, and 2820 cm^{-1} in the complex at room temperature constitute the pattern characteristic of the anilinium ion. Although there is no band in the hydrochloride corresponding to the one at 3150 cm^{-1}, Mariella *et al.* have reported that the band appearing in the range from 3150 to 3310 cm^{-1} is characteristic

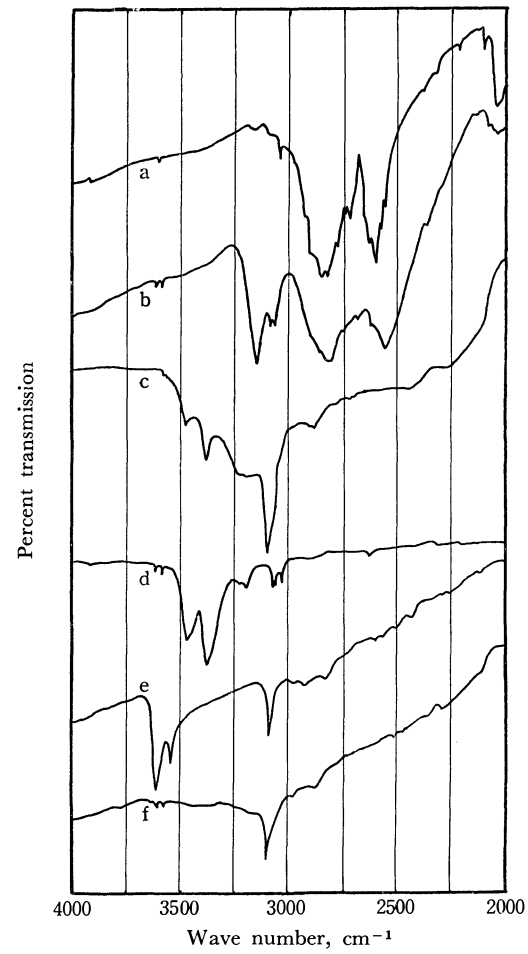

Fig. 2. Vibrational spectra, a) *o*-chloroaniline hydrochloride, b) the *o*-chloroaniline-picric acid at room temperature, c) the same above the melting point, d) *o*-chloroaniline, e) sodium picrate, and f) picric acid.

of the picrates of primary amines. This band has been assigned to a NH_3^+ stretching frequency.[13] The bands in the room-temperature spectrum are not visible in the molten state. The rather weak bands now observable at 3215, 3380, and 3475 cm^{-1} can be ascribed to the amine, and the strong one at 3095 cm^{-1}, to the acid. The weakness of the former bands relative to the latter may be attributed, at least in part, to the vaporization of the amine during the heating. When the anilinium picrate dissociates into its neutral component molecules, the change in the vibrational spectrum may be expected to be the same as that observed. However, the presence of a strong CT band in the melt excludes such an explanation.

It must be noted that the melting point of the *o*-chloroanilinium picrate is essentially the same as that of the corresponding TNB complex—134°C *vs.* the 134.5°C reported by Hertel.[2] Such a coincidence is rather unusual because most anilinium picrates have been known to melt at temperatures higher by 30—70°C than the TNB complexes. Considering the possibility that the picrate isomerizes into the CT complex a little below the melting point, we examined this anilinium picrate by means of a differential scanning calorimeter. At the melting point, two overlapping endothermic peaks were recorded on the thermogram.

The m-*Nitroaniline Complex* (*Figs. 3 and 4*). A red benzene solution is obtained when the yellow component compounds are dissolved together. The complex crystallizes as yellow needles with a melting point of 149–150°C. With this complex, a reversible color change from yellow to red is observed. The reflectance spectrum at room temperature, curve a in Fig. 3, shows that this is an anilinium picrate formed by proton-transfer from the acid to the amine. Upon melting, a broad, strong band with its maximum around 500 mμ or 20 kK appears. As *m*-nitroaniline is rather strongly colored, the spectrum of its melt is presented by curve c for the sake of comparison. The newly-appeared band cannot be attributed to either the amine or the acid. The solid TNB complex gives the spectrum shown by curve d. When curves b and d are compared, it seems to be acceptable that the broad band appearing in the molten complex is a CT absorption. The energy of the CT band in the TNB complex in a chloroform solution is estimated to be 22.7 kK. The band observed with the melt is apparently shifted to the long-wavelength side. The above-mentioned estimation was made on the basis of the energy of the CT band in the *m*-nitroaniline-tetracyanoethylene (TCNE) complex, 14.2 kK, and the average difference in the energy of the CT absorption between TNB complexes and TCNE complexes, 8.5 kK.[11]

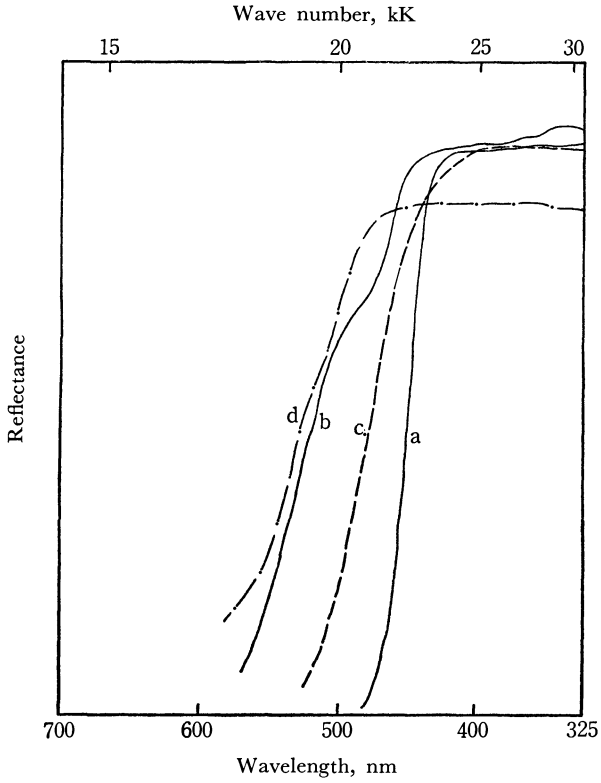

Fig. 3. Reflectance spectra, a) the *m*-nitroaniline-picric acid at room temperature, b) the same above the melting point, c) *m*-nitroaniline in the molten state, and d) the solid TNB complex.

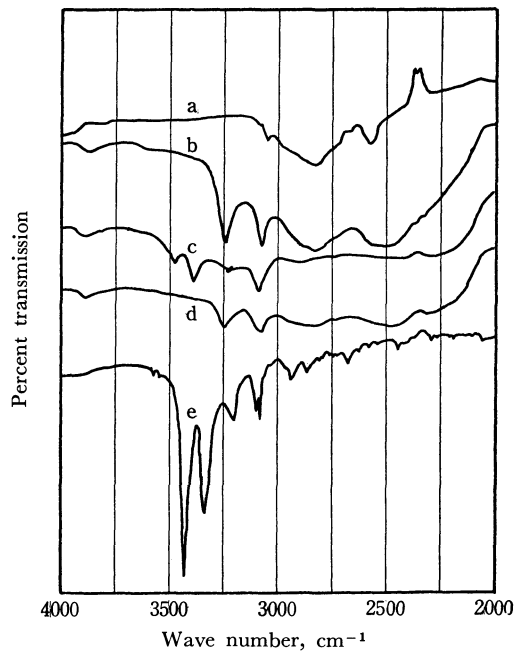

Fig. 4. Vibrational spectra, a) *m*-nitroaniline hydrochloride, b) the *m*-nitroaniline-picric acid at room temperature, c) the same above the melting point, d) the same after solidification, and e) *m*-nitroaniline.

The solid complex exhibits a vibrational spectrum containing two broad bands, located at 2500 and 2850 cm^{-1}, which are characteristic of the anilinium ion (see Fig. 4). The relatively sharp bands appearing at 3388 and 3475 cm^{-1} upon melting correspond well to those in the spectrum of the free amine. The band at 3247 cm^{-1} has no corresponding band in the spectrum of the hydrochloride; however, it is in the range reported by Mariella *et al.* for the picrates of primary amines. The spectrum recorded after

13) R. P. Mariella, M. J. Gruber, and J. W. Elder, *J. Org. Chem.*, **26**, 3217(1961).

solidification is included in Fig. 4 to show how reversible the change is. The hypothesis that this anilinium picrate transforms essentially into a CT complex at the melting point is firmly supported by these pieces of spectroscopic evidence. Finally, we may add that the present complex melts at a temperature about 50°C higher than the TNB complex, which has been reported to melt at 98°C by Sudborough and Beard.[14]

The 3-Nitro-4-methylaniline Complex (Figs. 5 and 6). When the red-colored amine is combined with yellow-colored picric acid, the complex is obtained in the form of yellow needles. The color turns red reversibly upon melting at 156–157°C. The reflectance spectrum was measured a little below and above the melting point. As is shown by curve c in Fig. 5, the molten amine absorbs strongly in the region from 350 to 500 mμ. Therefore, the absorption band characteristic of the complex in the molten state is observed as a shoulder around 525 mμ or 19 kK. This value should be compared with that of 21.1 kK estimated for the energy of the CT absorption of the complex in a chloroform solution. In the room-temperature spectrum of the TNB complex, the CT absorption covers the range from 530 to 600 mμ. The intensity of this band is markedly diminished by melting, as is indicated by curve e. This change

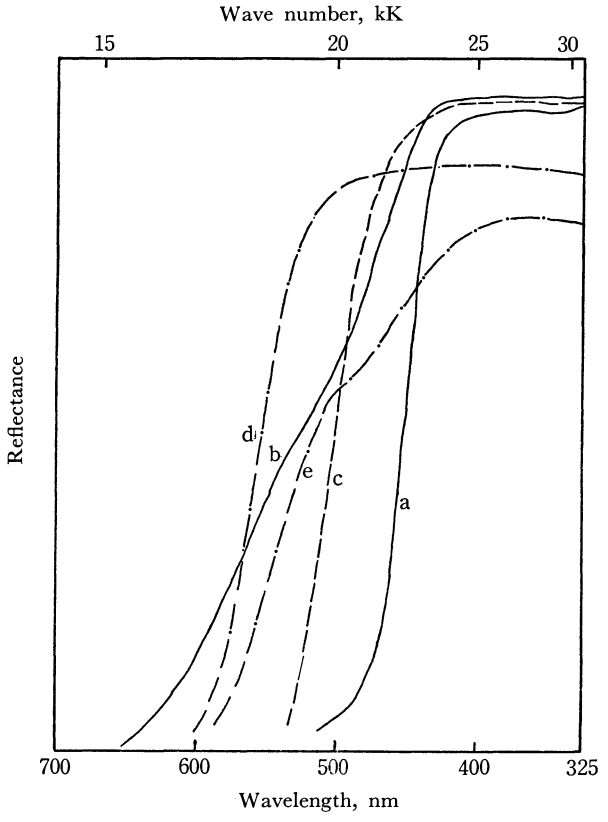

Fig. 5. Reflectance spectra, a) the 3-nitro-4-methylaniline-picric acid a little below the melting point, b) the same above the melting point, c) the amine in the molten state, d) the solid TNB complex, and e) the molten TNB complex.

14) J. J. Sudborough and S. H. Beard, *J. Chem. Soc.*, **97**, 773 (1910).

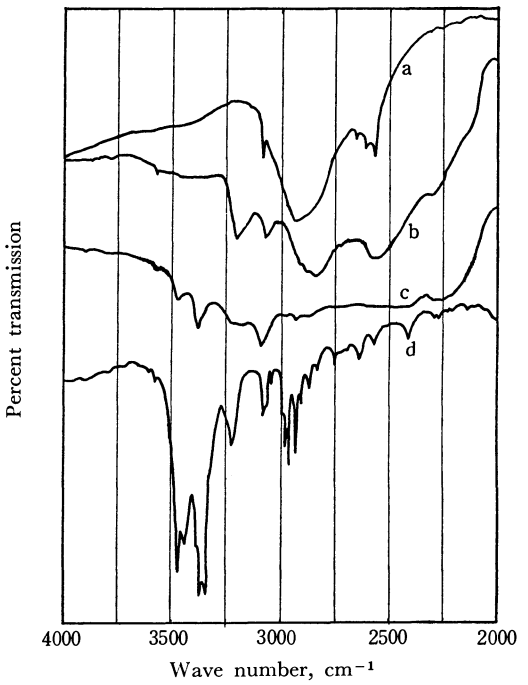

Fig. 6. Vibrational spectra, a) 3-nitro-4-methylaniline hydrochloride, b) the solid 3-nitro-4-methylaniline-picric acid, c) the same in the molten state, and d) the amine.

is possibly to be attributed to the partial dissociation of the molecular complex in the molten state. The resultant spectrum bears a resemblance to curve b.

The vibrational spectrum of the complex is drastically modified by the change in the state, as is shown in Fig. 6. Below the melting point, the two broad bands at 2570 and 2850 cm^{-1} attributable to the anilinium ion dominate. When melted, they are replaced by those at 3390 and 3478 cm^{-1} attributable to the amine. Thus, the spectroscopic observations indicate that the acid-base interaction predominates in the solid complex, and the electron donor-acceptor interaction, in the molten complex. The band near 3100 cm^{-1} remains through the phase change and is to be assigned to picric acid or picrate anion. The absorption characteristic of the picrates of primary amines is observed at 3210 cm^{-1}. The melting point of the TNB complex is found to be 82°C.

The N,N-Dimethylamino-p-benzaldehyde Complex (Figs. 7 and 8). When this white amine and picric acid are dissolved together in benzene, a dark red color develops. Bright yellow prisms crystallize from it. This complex melts at 98—99°C, and it turns red. Upon solidification, the complex turns yellow again. The reflectance spectrum recorded below the melting point, curve a in Fig. 7, is similar to that of sodium picrate; therefore, this complex is considered to be a true phenolate in the solid state. As is shown by curve b, a very pronounced absorption appears upon melting. The maximum seems to be shifted to the long-wavelength side compared with the estimated value for the CT band of the TNB complex in a chloroform solution, 22.0 kK. The spectrum of the reddish brown solid TNB complex is shown by curve c, and that of the melt, by curve d. The larger decrease in

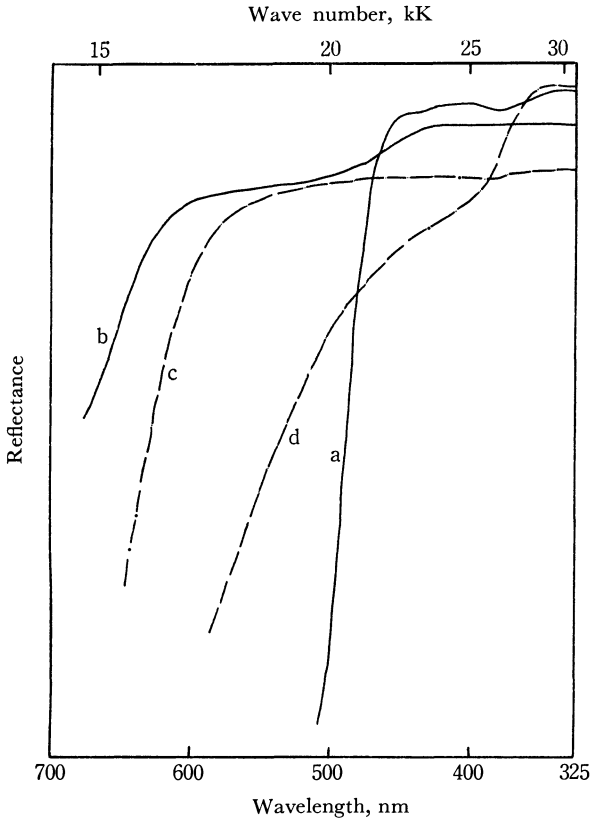

Fig. 7. Reflectance spectra, a) the dimethylamino-*p*-benzaldehyde-picric acid, b) the same in the molten state, c) the solid TNB complex, and d) the same in the molten state.

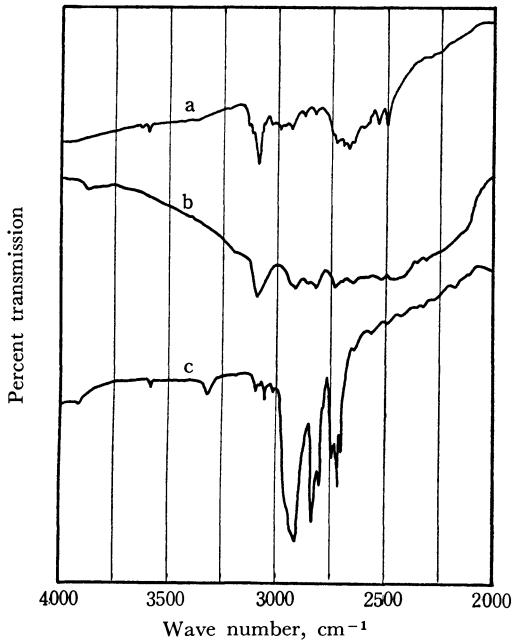

Fig. 8. Vibrational spectra, a) the dimethylamino-*p*-benzaldehyde-picric acid at room temperature, b) the same above the melting point, and c) the amine.

the intensity of the CT band of the TNB complex suggests that this complex dissociates appreciably into its components in the molten state. The similarity between curves b and c is considered to be evidence that the complex in the molten state is of the electron donor-acceptor type.

The vibrational spectra of the solid and molten complexes are presented in Fig. 8. As the amine hydrochloride is not available, the room-temperature spectrum has no reference. According to Mariella *et al.*, tertiary amine picrates have characteristic bands in the range from 2500 to 2670 cm^{-1}.[13] The spectroscopic feature observed at room temperature seems to be of the acid-base interaction. The bands at 2740, 2825, and 2920 cm^{-1} in the melt can be well compared with the strong bands observed in the free amine. Hence, an interaction of the electron donor-acceptor type apparently dominates in the molten complex. The TNB complex melts at 66°C. As is found in many other cases, the melting point of the picrate is definitely higher than this temperature.

The N,N-*Diethylaniline and* m-*Chloroaniline Complexes (Figs. 9 and 10).* For comparison with the complexes mentioned above, we will describe here the spectral behavior of two complexes which do not isomerize at their melting points. *N,N*-Diethylaniline has been chosen as an example because it is one of the strongest bases and also one of the strongest electron donors among the derivatives of aniline. The other example, *m*-chloroaniline, is a base only a little bit stronger than *o*-chloroaniline. Moreover, the electron-donor strengths of these two position isomers are almost equal to each other. Both the diethylaniline and *m*-chloroaniline complexes are yellow in the solid and molten states. The reflectance spectrum of the former complex is shown in Fig. 9. Only a slight shift to the long-wavelength side is observed

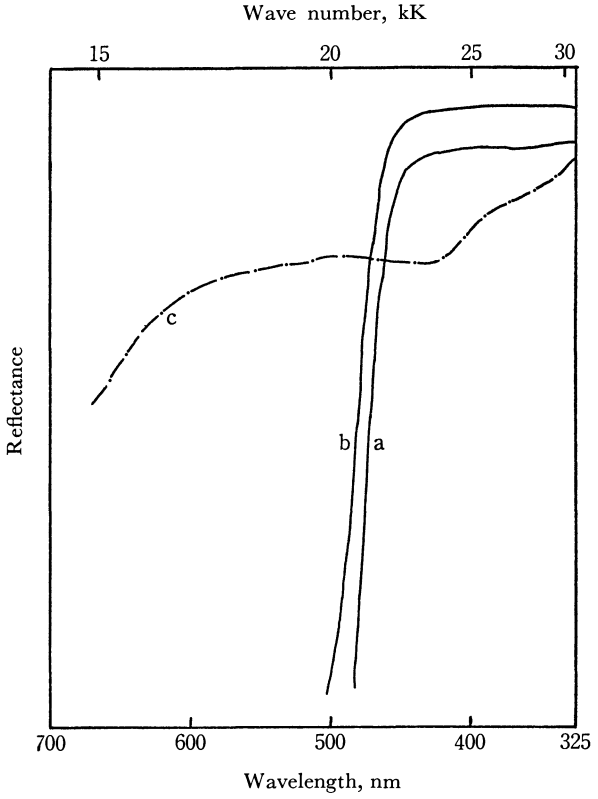

Fig. 9. Reflectance spectra, a) the *N,N*-diethylaniline-picric acid at room temperature, b) the same in the molten state, and c) the TNB complex at room temperature.

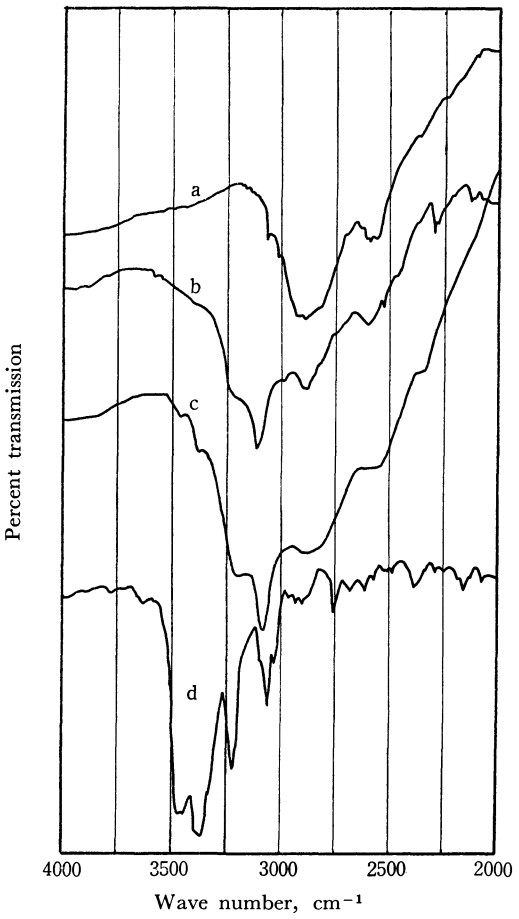

Fig. 10. Vibrational spectra, a) *m*-chloroaniline hydrochloride, b) the *m*-chloroaniline-picric acid at room temperature, c) the same in the molten state, and d) the amine.

when the complex is heated. The spectrum is quite different from that of the corresponding TNB complex. The latter shows a CT absorption covering nearly all the visible region (see curve c).

Figure 10 presents the vibrational spectra of the *m*-chloroaniline complex at room temperature and above the melting point. Both the spectra have two broad strong bands, located at 2575 and 2875 cm^{-1}, which can be compared with those in the amine hydrochloride. The band common to the picrates of primary amines appears at about 3160 cm^{-1}, and the one to be assigned to the picrate ion, at about 3100 cm^{-1}. However, two weak bands visible in the molten complex at 3360 and 3450 cm^{-1} suggest the presence of a small amount of the amine. Nevertheless, it is unquestionable that these complexes are largely of the acid-base type, even in the molten state. The diethylaniline and *m*-chloroaniline complexes melt at 133°C and 173°C (177°C was the value reported by Hertel[2]) respectively. The latter temperature is appreciably higher than the melting point of the corresponding TNB complex, 114.5°C, which is taken from the work by Sudborough and Beard.[14]

General Remarks. When a strong acid is combined with a strong base, the acid-base interaction is expected to predominate. The strength of the former component is expressed by the pK_a, and that of the latter, by the pK_b. As the acid is picric acid throughout the present work, only the pK_b of the amines will be taken into consideration here. On the other hand, the quantity to be considered in the electron donor-acceptor interaction is the ionization potential, I_P, of the amines. As proposed in our previous works,[11,15] the energy of the CT band in the complexes with a common acceptor observed in a chloroform solution will be taken as a measure of I_P. In this work, *p*-chloranil is selected for this purpose. This energy, $h\nu_{CT}$, is approximately given by the $I_P - E_A$ — constant, where E_A is the electron affinity of *p*-chloranil. In Fig. 11, the amines are arranged, with $14 - pK_b = \log[R_1R_2R_3NH^+]/[R_1R_2R_3N][H^+]$ placed on the ordinate, and $h\nu_{CT}$ on the abscissa.[16] We see here that an amine with a high $(14 - pK_b)$ value, that is, a strong base, tends to have a low $h\nu_{CT}$ value, that is, a strong electron donor. As a result, there seems to be a linear relationship between these two quantities, especially among the amines with $(14 - pK_b)$ values higher than 3. The only exception is *N,N*-dimethyl-*o*-toluidine, in which the conjugation between the dimethylamino group and

Fig. 11. the benzene nucleus may be supposed to be sterically hindered. In their complexes with picric acid, the acid-base interaction is found to predominate in both the solid and molten states. The amines to form such complexes are indicated by open circles. On the other hand, the amines which were found to form CT complexes above the transition or melting points are those with $(14-pK_b)$ values less than 3. In Fig. 11, they are indicated by shaded circles. Furthermore, it must be noted that many of these amines do not fit the relationship mentioned above and tend to be electron donors better than would be expected from the relationship. The results summarized in Fig. 11 reinforce Hertel's view.

In conclusion, it must be pointed out that the possibility of finding monotropic phases, where the four amines studied here and picric acid form CT complexes, still remains. When the red-colored melts are solidified, a part of the solid was often observed to be transitorily red-colored.

The Electron Spin Resonance of Binuclear Vanadyl Tartrates

Akinori HASEGAWA, Yoshio YAMADA, and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received July 9, 1971)

The ESR spectra of aqueous solutions of binuclear vanadyl tartrates remarkably varied with their pH values. This variation was found to be directly correlated with the change in the form of the carboxyl group, *i.e.* whether it was dissociated or acidic. Thus, the frozen solution spectra were observed in water-ethylene glycol at 77°K and analyzed in terms of several magnetic parameters containing the parameter of magnetic dipolar interaction, *D*. From these *D* values, the intramolecular V···V distances were estimated to be *ca.* 4.2, 5.2, and 6.5Å in the solutions at pH 9, 4.8, and 2.8 respectively. Such a remarkable change in the V···V distances as interpreted to be caused by the dissociation of the coordinate bonds between the vanadium atom and the carboxyl oxygen atom and the change in the molecular structure of the tartrates, brought about the change in the form of the carboxyl groups.

The aqueous solutions of vanadyl tartrates give ESR spectra characteristic of a dimeric structure with two unpaired electrons coupled with a spin-exchange interaction.[1] Although the dimeric structure in an aqueous solution had been doubted because of the specific ESR linewidth variation,[2] it has been confirmed by the observations of pairs of satellite lines caused by singlet-triplet transitions, which were allowed because of the mixing of the singlet and the triplet levels.[3-5]

The ESR spectrum of the aqueous vanadyl tartrate solution changes according to the change in the pH value. As to the aqueous solution of vanadyl *dl*-tartrate, fifteen triplet lines were observed, but no satellite lines appeared above pH 6.[1] Two kinds of considerably complicated triplet-state spectra accompanied by satellite lines were observed in the pH ranges from 5 to 3 and from 3 to 2. The values of the spin exchange interaction, J, have been determined to be 1.071×10^{-1} and 5.62×10^{-2} cm^{-1} on the basis of the analysis of the satellite lines for the dimeric species in the pH 3—5 and 2—3 ranges respectively.[4,5] In these two pH ranges, no difference was observed between the aqueous-solution spectrum of vanadyl *dl*-tartrate and that of vanadyl *dd*-tartrate, but a remarkable difference appeared between them above pH 6.[3]

Frozen-solution spectra of vanadyl *dl*- and *dd*-tartrates were observed at pH 7 in a water-ethylene glycol mixture.[6] Their spectra consist of the lines attributable to $\Delta M_s=\pm1$ transitions at $g\approx2$ and to $\Delta M_s=\pm2$ transitions at $g\approx4$, and they are interpreted in terms of the parameter of the magnetic dipolar interaction, D, and the anisotropies of the g value and the hyperfine coupling constant.

However, no interpretation has been given to the structural change of the complex caused by the change in pH. In the present paper, therefore, we attempted to investigate the structural change in these dimeric species by means of ESR, IR, pH titration, and a molecular model.

Experimental

Vanadyl *dl*-tartrate ($Na_4[(VO)_2(d\text{-tart}),(l\text{-tart})]\cdot11H_2O$) and vanadyl *dd*-tartrate ($Na_4[(VO)_2(d\text{-tart})_2]\cdot6H_2O$) were prepared by the method of Tapscott and Belford.[1] pH titrations of the aqueous solutions of these vanadyl tartrates, the pH value of which had been previously adjusted to 2.7 with HCl, were carried out by addition of the aqueous solution of NaOH. The ESR spectra of the solutions of vanadyl *dl*- and *dd*-tartrates at different pH values were measured in the frozen and liquid solution states; the frozen spectra

were obtained at 77°K in water-ethylene glycol (1 : 1 in volume), and the aqueous solution spectra, at room temperature. The specimens submitted to IR measurements were prepared by freeze-drying the aqueous solutions, the pH values of which had been adjusted to 9, 4.8, and 2.8. The ESR spectra were measured by a spectrometer described elsewhere,[7] and the IR spectra, by the KBr disk method, using a Hitachi EPI-G3 IR spectrometer.

Results and Discussion

The ESR spectra of aqueous vanadyl tartrate solutions depend remarkably upon their pH values, as has been pointed out by several authors.[2-5] Thus, pH titrations of the aqueous solutions were carried out; two inflection points appeared at pH 4.8 and 9, in the pH titration curve of vanadyl *dl*-tartrate, as can be seen in Fig. 1. The same result was also obtained in the case of vanadyl *dd*-tartrate. The amount of NaOH consumed between these two inflection points corresponded to just twice the number of moles of vanadyl tartrate used. All of the four carboxyl groups in a vanadyl tartrate molecule are known to dissociate at pH 9.[1] These facts suggest that, at pH 4.8, two of the carboxyl groups have the acidic form, and the other two have the dissociated form. In the same manner, all of the groups are suggested to have the acidic form at pH 2.8. The change in the ESR spectrum of the aqueous solution was found to be closely correlated with the change in the form of the carboxyl group; different kinds of spectra were observed at pH 2.8, 4.8, and 9, and each of them turned to another upon the pH change in exactly the same manner as was to be expected from the pH titration curve.

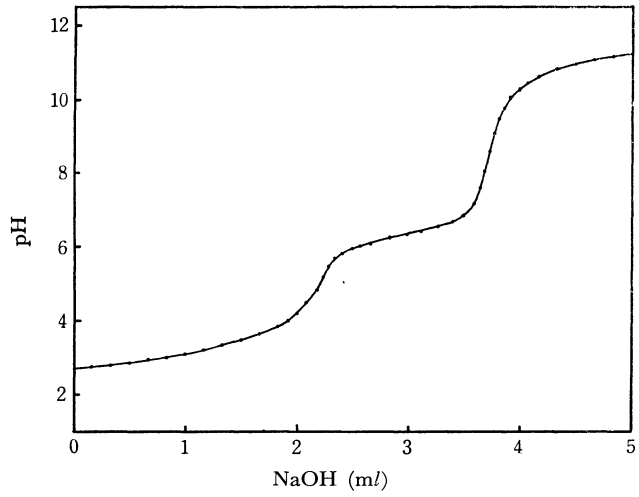

Fig. 1. pH titration curve of 0.085 g vanadyl *dl*-tartrate with aqueous solution of 0.15 N NaOH.

The ESR spectra of the aqueous solutions at pH 2.8, 4.8, and 9 have been well investigated by several authors.[2-5] However, the ESR spectra of the frozen solutions have been studied only at pH 7,[6] where most of carboxyl groups take the dissociated form. Thus, the ESR frozen solution spectra of vanadyl *dl*- and *dd*-tartrates were observed in water-ethylene glycol at pH 9, 4.8, and 2.8; the results are shown in Figs. 2(a)—(d). A difference between the ESR spectrum of vanadyl *dl*-tartrate and that of vanadyl *dd*-tartrate was found in the frozen solution state only at pH 9, as in the case of the aqueous solution state. The spectrum at pH 2.8 is complicated by the presence of hyperfine lines both from the complex corresponding to that obtained at pH 4.8 and from a complex containing a single vanadium nucleus,

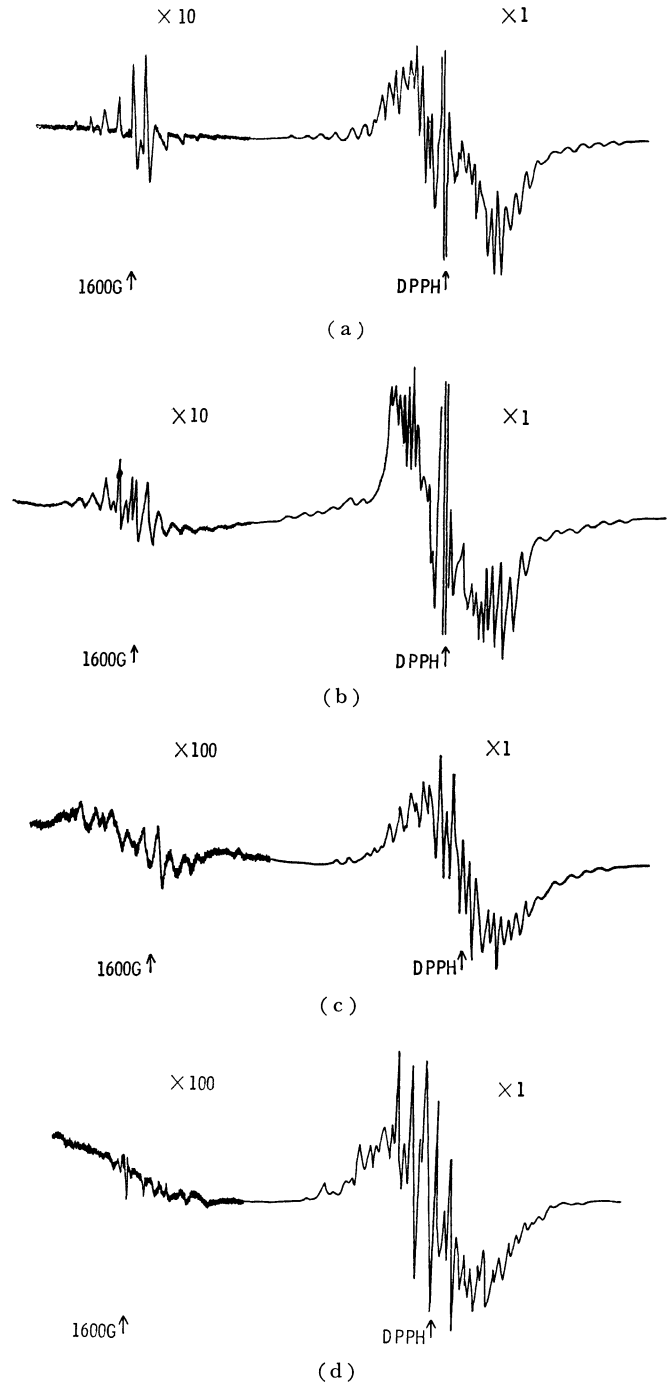

Fig. 2. ESR spectra of frozen solution of vanadyl *dl*-tartrate at (a) pH 9, (c) pH 4.8, and (d) pH 2.8 and of vanadyl *dd*-tartrate at (b) pH 9. Spectra of vanadyl *dd*-tartrate at lower pH values are respectively the same as those of vanadyl *dl*-tartrate.

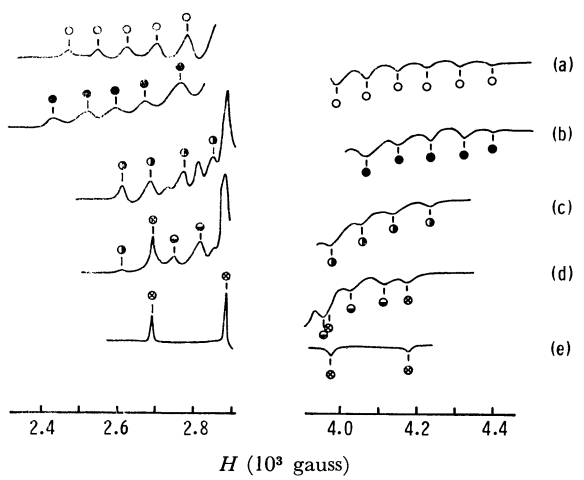

Fig. 3. Expanded view of ESR spectral lines near the both sides of the $\Delta M_s = \pm 1$ transitions of vanadyl *dl*-tartrate at (a) pH 9, (c) pH 4.8, (d) pH 2.8, and (e) pH 1.5 and of vanadyl *dd*-tartrate at (b) pH 9. Letters, (a)~(d), in the following figures have the same meaning as those in this figure. Several symbols in this figure are used to show the assignment of the spectral lines.

which is produced at pH values lower than 2. The ESR spectrum of the frozen solution at pH 1.5 was, therefore, measured in order to subtract it from the spectrum at pH 2.8. Except for the spectrum at pH 1.5, each of these spectra consists of the transition lines of $\Delta M_s = \pm 1$ at $g \approx 2$ and of $\Delta M_s = \pm 2$ at $g \approx 4$. If it is assumed that the ligand field around the vanadium atoms is axially symmetrical and that the two V=O axes in a complex molecule are parallel to each other, these ESR spectra of binuclear complexes can be described by the following spin Hamiltonian:[8,9]

$$\begin{aligned}\mathscr{H} = &\sum_{i=1}^{2} \beta\{g_{\parallel} \boldsymbol{H}_z \cdot \boldsymbol{S}_z^{(i)} + g_{\perp}(\boldsymbol{H}_x \cdot \boldsymbol{S}_x^{(i)} + \boldsymbol{H}_y \cdot \boldsymbol{S}_y^{(i)})\} \\ &+ \sum_{i=1}^{2} \{A_{\parallel} \boldsymbol{I}_z^{(i)} \cdot \boldsymbol{S}_z^{(i)} + A_{\perp}(\boldsymbol{I}_x^{(i)} \cdot \boldsymbol{S}_x^{(i)} + \boldsymbol{I}_y^{(i)} \cdot \boldsymbol{S}_y^{(i)})\} \\ &+ J\boldsymbol{S}^{(1)} \cdot \boldsymbol{S}^{(2)} + \frac{2}{3} D\Big\{\boldsymbol{S}_{z'}^{(1)} \cdot \boldsymbol{S}_{z'}^{(2)} - \frac{1}{4}(\boldsymbol{S}_+^{(1)} \cdot \boldsymbol{S}_-^{(2)} \\ &+ \boldsymbol{S}_-^{(1)} \cdot \boldsymbol{S}_+^{(2)})\Big\} \end{aligned} \quad (1)$$

where the distinction between z and z' originates from the fact that the V=O axis is not necessarily parallel to the V···V axis and where D is a parameter of the magnetic dipolar interaction.

The resonance condition of the $\Delta M_s = \pm 1$ transition between triplet states is given approximately from this spin Hamiltonian, by modifying the relation derived by Glarum and Marshall[9] with anisotropies of the g value and the hyperfine coupling:[8]

$$\begin{aligned} h\nu = g\beta H + K(M^{(1)} + M^{(2)}) \pm \frac{1}{2}\left(J + \frac{2}{3}\gamma D\right) \\ \mp \left\{K^2(\Delta M)^2 + \frac{1}{4}\left(2J - \frac{2}{3}\gamma D\right)^2\right\}^{1/2} \end{aligned} \quad (2)$$

where $$g^2 = g_{\parallel}^2 \cos^2\theta + g_{\perp}^2 \sin^2\theta \quad (3)$$

8) B. Bleaney, *Phil. Mag.*, **42**, 441 (1951).
9) S. H. Glarum and J. H. Marshall, *J. Chem. Phys.*, **47**, 1374 (1967).

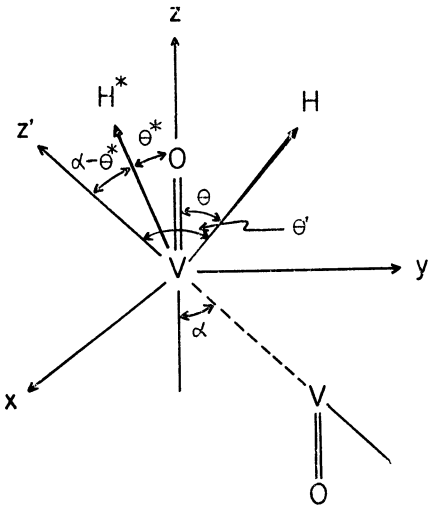

Fig. 4. The relation between two molecular axes and two orientations of the external magnetic field: H is the external magnetic field in a general orientation satisfying Eqs. (2)~(6), and H^*, in the plane containing z and z' axes, is that in the specific orientation giving the maximum resultant splitting satisfying Eqs. (9), (10), and (12).

$$gK = \sqrt{\frac{1}{4}A_{\parallel}^2 g_{\parallel}^2 \cos^2\theta + \frac{1}{4}A_{\perp}^2 g_{\perp}^2 \sin^2\theta} \quad (4)$$

$$\gamma = 3\left(\frac{g_{\parallel}^2 \cos^2\alpha + g_{\perp}^2 \sin^2\alpha}{g^2}\right)\cos^2\theta' - 1 \quad (5)$$

$$\Delta M = |M^{(1)} - M^{(2)}|, \quad (6)$$

where the angles, θ, θ', and α are defined as is shown in Fig. 4. The external magnetic field is, therefore, oriented at the angle of θ to the symmetrical axis with regard to the g value and the hyperfine coupling, *i.e.*, the V=O direction, and at the angle of θ' to the direction at which the maximum magnetic dipolar splitting can be expected, *i.e.*, the V···V direction.

If the assumption,

$$K^2(\Delta M)^2 \ll \left(J - \frac{1}{3}\gamma D\right)^2 \quad (7)$$

is satisfied, Eq. (2) can be simplified as:

$$h\nu = g\beta H + K(M^{(1)} + M^{(2)}) + \gamma D\left(M_s - \frac{1}{2}\right) \quad (8)$$

where $M_s = 1$ or 0. The assumption is satisfied for the frozen solution spectrum at pH 9 because of a large value of J; the J value can be deduced to be about 2×10^{-1} cm^{-1} from the analysis of the linewidth of the triplet spectrum, though the value has not been determined explicitly as yet. The application of Eq. (8) to the spectra at lower pH values is, however, subject to restriction because the J value decreases with the decrease in pH value;[4,5] the derivation of Eq. (8) from Eq. (2) can not be allowed for the transitions corresponding to the large value of $(\Delta M)^2$. Fortunately, even for the spectrum at pH 2.8, the resonance lines due to small values of ΔM, which can be observed near both sides of the $\Delta M_s = \pm 1$ transition spectrum, satisfy the condition of Eq. (7), and the deviation arising from Eq. (8) does not exceed the limits of experimental error. The outermost lines were assigned to the lines of $M^{(1)} = M^{(2)} = \pm 7/2$ with

a maximum resultant splitting due to hyperfine and magnetic dipolar interaction, where the anisotropy of the g value is assumed to be negligible as compared with the anisotropy of the hyperfine coupling constant and with the angular dependency of the magnetic dipolar splitting. The external magnetic field which gives the outermost lines is defined as being oriented at the angles of θ^* to the direction of V=O and $\alpha-\theta^*$ to the direction of the V···V direction, in the plane containing V=O and V···V directions, as can be seen in Fig. 4. The hyperfine coupling constant and magnetic dipolar splitting at this magnetic field direction can be determined approximately from Eq. (8) and from the spectral lines near both the sides of the $\Delta M_s = \pm 1$ transition spectrum, which are shown, with their assignments, in Fig. 3. They are, therefore, shown, neglecting the anisotropy of the g value, by:

$$\frac{1}{2}A_{\parallel}^* = \frac{1}{2}\sqrt{A_{\parallel}^2\cos^2\theta^* + A_{\perp}^2\sin^2\theta^*} \tag{9}$$

and

$$2D^* = D\{3\cos^2(\theta^*-\alpha)\} - 1\} \tag{10}$$

Hereupon, the isotropic coupling constant, $a_0/2$, obtained from the liquid-solution spectrum is connected with the values of $A_{\parallel}$ and $A_{\perp}$ by a well-known relation:

$$\frac{1}{2}a_0 = \frac{1}{3}\left(\frac{1}{2}A_{\parallel} + A_{\perp}\right) \tag{11}$$

On the other hand, the θ^* angle must satisfy the following condition, as can be expected from the maximum resultant splitting:

$$\frac{\partial}{\partial\theta^*}\left[14\times\frac{1}{2}\sqrt{A_{\parallel}^2\cos^2\theta^* + A_{\perp}^2\sin^2\theta^*} + D\{3\cos^2(\theta^*-\alpha)-1\}\right] = 0 \tag{12}$$

As the values of $A_{\parallel}^*/2$ and $2D^*$ can be evaluated from the frozen-solution spectrum, and the value of $a_0/2$, from the liquid-solution spectrum, the θ^* value satisfying Eqs. (9)—(12) can be determined unequivocally provided that the value of α is assumed. Thus, the relation between α and θ^* was calculated from the parameters given in Table 1 by using a computer; the results are shown in Fig. 5. From the value of θ^*,

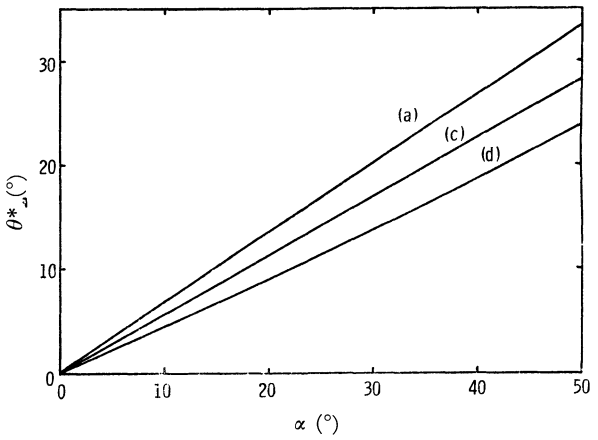

Fig. 5. The relation between α and θ^* for vanadyl *dl*-tartrate. The line for (b) is located slightly higher than that of (a), but almost superimposed with (a) in this figure.

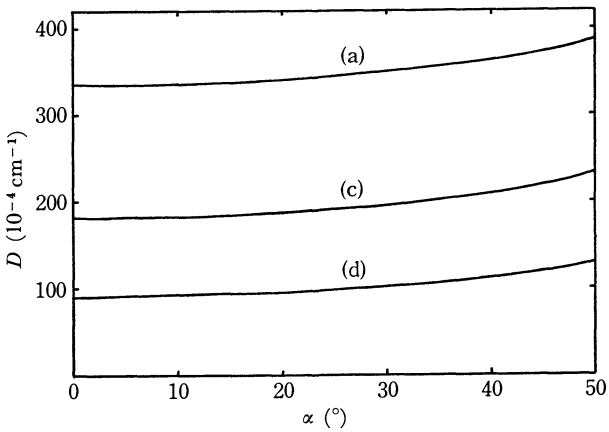

Fig. 6. The relation between α and D for vanadyl *dl*-tartrate. The line for (b) is also located slighly higher than that of (a), but almost superimposed with (a).

in turn, the values of $A_{\parallel}$, $A_{\perp}$, and D were obtained for each value of α. The relation between D and α is shown in Fig. 6.

According to the results of X-ray diffraction,[10] the value of α is 28° for the crystal of vanadyl *dl*-tartrate obtained from the solution at pH 8. When this value is adopted for the complex in the solution of vanadyl *dl*-tartrate at pH 9, the value of θ^* is determined to be 18°58′ from Fig. 5. Thus, the values of $A_{\parallel}/2$, $A_{\perp}/2$, and D determined on the basis of $\alpha=28°$ are given in Table 2. The values of α for other complexes are not yet known but they may be deduced to be not so large.

The intensity ratio of the transition of $\Delta M_s=\pm2$ to that of $\Delta M_s=\pm1$ is proportional to the square of the D value:[11]

$$I_{\Delta M_s=\pm2}/I_{\Delta M_s=\pm1}=\frac{1}{8}\left(\frac{D\sin 2\theta'}{H}\right)^2 \tag{15}$$

It can, therefore, be checked in terms of this relation whether or not the evaluated D value is reasonable. As the intensities of all the $\Delta M_s=\pm1$ transitions are roughly equal in Figs. 2 (a)—(c), the intensities of the $\Delta M_s=\pm2$ transition in these figures may be supposed to be proportional to the square of each D value. The change in the D value evaluated above with the decrease in pH value reasonably explains the observed change in the intensity of the $\Delta M_s=\pm2$ transition, though the D value is an approximate one because of the uncertainty of the α value.

The splitting due to the magnetic dipolar interaction is also approximately shown by:[12]

$$D=\frac{3}{4}g^2\beta^2\frac{\langle 1-3\cos^2\theta'\rangle_{\max}}{R^3} \tag{16}$$

where R is the V···V distance, the θ', the angle between V···V and the magnetic field directions. The value of D (in cm^{-1}) is, therefore, correlated with the V···V distance, R (in Å), by:[6]

$$D=\frac{0.650}{R^3}g^2 \tag{17}$$

When the $D=348\times10^{-4}\,cm^{-1}$ obtained for $\alpha=28°$ was substituted into Eq. (17), the intramolecular V···V distance for the vanadyl *dl*-tartrate at pH 9 was evaluated to be 4.16 Å, where the g value was assumed to be 1.953 (Table 1) as an approximation. The estimated value is very close to the V···V distance determined by means of X-ray diffraction-4.08 Å.[6,10] Although some question is involved in the comparison between the V···V distance in the solution state and that in the crystalline state, the comparison may be significant because a complex molecule is surrounded by eleven water molecules even in the crystalline state.[1] Thus the validity of the procedure for the estimation of the magnetic parameter was confirmed. It is also interesting to compare these results with those which were determined by Belford *et al.* directly from the spectrum observed without such a procedure.[6] The latter values are, by nature, in agreement with those in Table 1. The values of $A_{\parallel}$ and D which were obtained through this procedure, and which are given in Table 2, are larger than those obtained directly from the spectrum.

The relation between R and α was obtained from Fig. 6 and Eq. (16) by the use of the g values in Table 1. The relation depends remarkably upon the value of pH, as can be seen in Fig. 7. The intramolecular V···V distance, which is an approximate value because of the undetermined value of α, changes step by step from *ca.* 4.2 through *ca.* 5.2 to *ca.* 6.5 Å, being closely correlated with the decrease in the pH value, that is, with the change in the form of the carboxyl group.

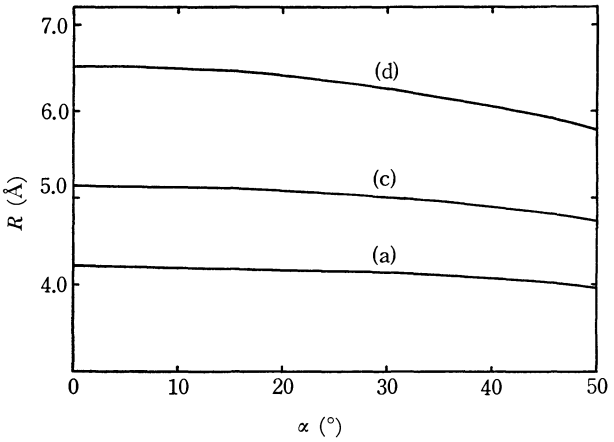

Fig. 7. The relation between α and R for vanadyl *dl*-tartrate. The line for (b) is located a slightly lower than that of (a), but almost superimposed with (a).

When the IR spectra were measured for the complexes in solid forms prepared from solutions of different pH values, the frequency of the absorption due to V=O stretching changed with the change in the pH value; for the vanadyl *dl*-tartrate, 958, 978, and 988 cm^{-1} respectively at pH 9, 4.8, and 2.8, and for vanadyl *dd*-tartrate, 949 cm^{-1} at pH 9, and those at lower pH values were the same as those for vanadyl *dl*-tartrate. Such an increase in the V=O stretching frequency suggests a decrease in the coordination ability of equatorial ligands to the vanadium atom.[13]

It is of great interest to interpret these results in connection with the structural change in these complexes brought about by the change in pH. Such a structural change may be successfully discussed by means of a model of the complex molecule. According to the results of the X-ray diffraction of vanadyl *dl*-tartrate prepared at pH 8,[10] each of two vanadium ions in a molecule of the complex is coordinated with four oxygen atoms, other than the doubly-bonded oxygen atom forming part of the vanadyl ion, two of which are the carboxyl oxygen atom and the alcoholic oxygen atom in a tartrate molecule, and the

other two of which are those in the other tartrate molecule, as can be seen in Fig. 8. The two quadrilaterals, which are made by combining these four oxygen atoms coordinating to a vanadium atom, slide with one another, resulting in the angle of 28° between V=O and V···V directions and in the distance of 4.08 Å between these vanadium atoms.[6] The molecular model also supports such a structure. For vanadyl *dd*-tartrate at pH 9, the molecular model suggests that the V=O direction is almost parallel to the V···V direction that the V···V distance is approximately equal to that for the vanadyl *dl*-tartrate. With the decrease in the pH value, the carboxyl group in tartrate takes an acidic form and the coordination of the oxygen atoms in this group is weakened. The change in V···V distance, 4.2, 5.2, and 6.5 Å, estimated from the ESR spectrum must be interpreted in terms of a drastic change in the molecular structure. However, there is no molecular model which allows such a change in the V···V distance if four oxygen atoms of tartrates are kept coordinating to each vanadium atom.

Finally, the following structural changes may be suggested for the interpretation of the change in the V···V distance with the pH. The coordinate bond between a vanadium atom and an oxygen atom of a carboxyl group breaks down with the change in the form of the carboxyl group from a dissociated to an acidic one, and the water molecules of the solvent, in turn, participate in the coordination with the vanadium atom. At the same time, the bond between the second and the third carbon atoms in the tartrate molecule rotates, and the rotation about the C–O bond, in which the second or the third carbon atom participates, is also allowed. Furthermore, the length of the coordinate bond remaining may also increase. Thus, at pH 4.8, the dissociation of the two coordinate bonds in a vanadyl tartrate binuclear complex brings about the enlargement of the V···V distance to *ca.* 5.2 Å, and at pH 2.8 the following dissociation of the two coordinate bonds to *ca.* 6.5 Å. This separation of 6.5 Å is possible only for the following structure: the two vanadium atoms are coordinated with oxygen atoms bound to the second and the third carbon atoms in tartrates and are extremely remote from one another, two carboxyl groups in each tartrate molecule are projected out and free from the coordination to the vanadium atom, and two hydrogen atoms are bound to carbon atoms orient to the rather inner part, as can be seen in Fig. 9. The value of α is expected to be small for this complex.

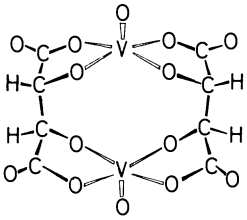

Fig. 8. The structure of the vanadyl *dl*-tartrate in the aqueous solution at pH 9.[1,10]

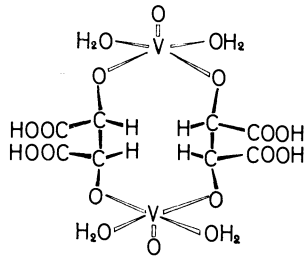

Fig. 9. Proposed structure of the vanadyl *dl*-tartrate in the aqueous solution at pH 2.8.

In such a structure at pH 2.8, two tartrate molecules coordinate to the vanadium atom in the relation of *cis* for vanadyl *dl*-tartrate and of *trans* for vanadyl *dd*-tartrate, as can be expected from the molecular model proposed by Tapscott and Belford.[1,9] If the effect of the difference between the *cis* and *trans* forms on the ESR spectrum is assumed to be weakened by the coordination of the solvent molecules, it can be tentatively accounted for why the ESR spectrum of vanadyl *dl*-tartrate is in close agreement with that of vanadyl *dd*-tartrate at pH 4.8 and 2.8.

In conclusion, the remarkable change in the ESR spectrum of the binuclear vanadyl tartrate complex with the pH has been interpreted in terms of the change in the molecular structure of the complex accompanied by the dissociation of coordinate bonds and the change in the structure of the tartrate molecule.

The authors would like to express their deep gratitude to Professor Junkichi Sohma and Assistant Professor Keiichi Ohno of Hokkaido University for their useful discussions.

The Flow Properties of Hydrophilic Latexes Thickened with Alkali

Yoshio Ito and Shunsuke Shishido
Department of Chemistry, Faculty of Science, Niigata University, Niigata
(Received July 10, 1971)

This paper has aimed at the revelation of the thickening mechanism of a latex on the addition of alkali. Experiments have been made on two kinds of latexes dialyzed thoroughly, *i.e.*, the butadiene-methyl methacrylate copolymer latex and the butadiene-methyl methacrylate-methacrylic acid copolymer latex. The degree of the swelling of the latex particles on the addition of alkali has been correctly obtained and has been connected with the thickenability of the latex. The results provide a more rigorous description than Wesslau's suggestion that the thickening of a latex on the addition of alkali is ascribed to the swelling of the latex particles alone. The reason why NH_4OH is a proper thickener is presented, and the most suitable amount of alkali for the thickening of a latex is discussed.

A hydrophillic polymer latex can be thickened by the addition of alkali. Wesslau[1] has suggested that the increase in the particle size in a latex thickened with NH_3 is responsible for the increase in the viscosity of the latex; however, this suggestion is correct only qualitatively. Therefore, influences of other factors on the viscosity of a latex should be examined, as has been pointed out by several investigators.[2-6]

The present investigation has aimed at the revelation of the flow properties of latexes thickened with alkali.

Experimental and Results

Latexes. A butadiene–methyl methacrylate (B–M) copolymer latex and a butadiene–methyl methacrylate–methacrylic acid (B–M–A) copolymer latex were obtained from the Nihon Gas Chemical Co., Ltd.

Both the latexes used were thoroughly dialyzed with deionized water until their surface tensions were equal or almost equal to that of water. Figure 1 shows the infrared spectra of the copolymer films made from the dialyzed latexes (full line), and from those adjusted to pH 11 with carbonate free sodium hydroxide (dotted line). Table 1 lists the designations of the latexes and the compositions of the copolymers as mol% of the monomers. The particle-size distributions of the latexes used were determined by the measurement of the sizes of about 2000 particles by means

Table 1. Compositions of copolymers of latexes[a]

Latex designation	Mol% of monomers		
	Butadiene	Methyl methacrylate	Methacrylic acid
B-M	55	45	0
B-M-A	50	46.5	3.5

a) The values listed were determined on the basis of the IR-spectral data of Fig. 1.[7]

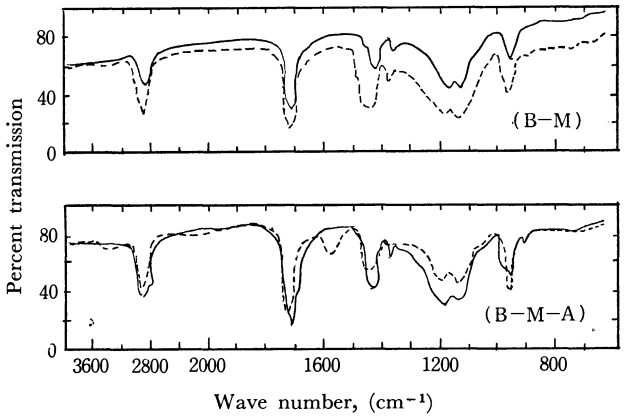

Fig. 1. Infrared spectra of copolymer films. Designations, B-M and B-M-A, are described in Table 1. The full lines and the dotted lines represent the spectra of the films to be made from the dialyzed latexes and those ionized with sodium, respectively.

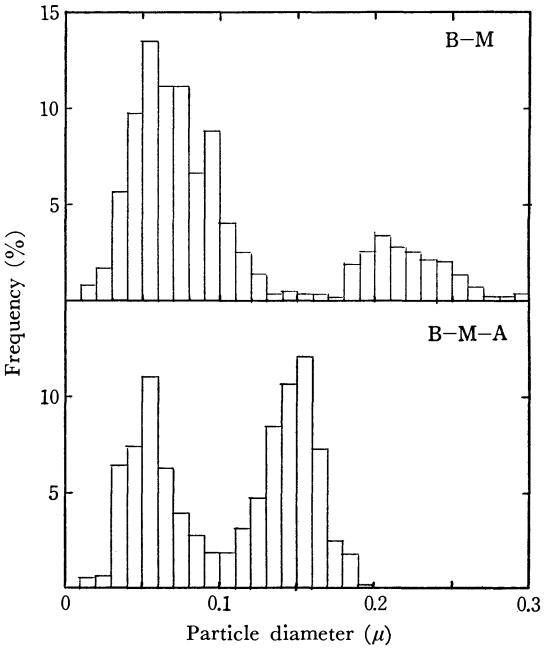

Fig. 2. Particle-size distribution determined with electron microscopy.
The particle frequency is described as a function of diameters.

of the electron microscopy[7,8]; they are shown in Fig. 2.

Viscosity. A colloidal suspension such as a latex is generally a non-Newtonian fluid.[9-12] However, when the concentrations of the latexes used were less than 35 wt% on solids, the flow behavior was Newtonian at rates of shear below 8×10^2 sec^{-1}. Consequently, the concentrations in this investigation were limited to 35 wt% on solids as an initial step toward revealing the intricate flow behavior of latexes.

The viscosities were measured with a Ubbelohde-type viscometer for the latexes dialyzed and for those thickened with NH_4OH and NaOH. Figure 3 shows the relations between the specific viscosity (η_{sp}) and the dried-polymer content (wt%) of the latexes. The B–M latex was hardly thickened by the addition of NH_4OH; on the other hand, the B–M–A latex was remarkably thickened with aqueous solutions of NH_4OH and dilute aqueous solutions of NaOH, but hardly thickened with concentrated aqueous solutions of NaOH.

Swelling and Volume Fraction of Latex Particles. The flow properties of suspensions are generally discussed on the basis of the relation between η_{sp} and vol%(ϕ) on solids. However, when the particles of a latex are swollen, the discussion[1] is based on the data of the wt% on the dried polymer because of the difficulty of determining the volume fraction exactly.

Above concentrations (N) of NH_4OH and NaOH indicate those in the serum of the latexes. All viscosities were measured at 35.00±0.01°C.

In this investigation, the difficulty was overcome with the determination of the degree of swelling for the latex-film instead of that for the latex-particles.

Making of Latex-films. When a polymer latex is evaporated above the glass temperature of the polymer, it becomes a non-porous film.[13,14] Latex-films of about 0.5 mm in thickness were made by means of the evaporation of the latexes on mercury at 60°C.

Swelling of Latex-films. The degree of swelling may be defined as the ratio of the swollen volume of a polymer film to its volume dried.

The films of the latexes used could be swollen in deionized water or in aqueous solutions of alkali, and then again contracted by drying. It was confirmed that the degrees of swelling were reproducible within ±1% by repetition of the swelling and the contraction; this held for different samples too. From these facts, it was presumed that the degree of swelling of a latex-film is equal to that of the latex particles.

In this investigation, the volume of the film was measured with a Beckman-Toshiba air comparison pycnometer, model 930.

Figure 4 shows the dependence of the degrees of swelling of the latex-films immersed in aqueous solutions of alkali on the alkali content of the solution.

The B–M latex-film was hardly swollen with an increase in the NH_4OH concentrations; the degree of swelling of the B–M–A latex-film was suddenly increased at a moderate concentration of NH_4OH and then slightly decreased with a further increase in the concentration. In the case of the swelling in solu-

tions of NaOH, the swelling behavior of the B–M film was similar to that in the case of NH_4OH; the degree of swelling of the B–M–A film was suddenly increased at a moderate concentration and then remarkably decreased with a further increase in the concentration.

It is worth noting that the carboxyl groups in the B–M–A film immersed were equivalent to the alkali content in the solution at the maximum point of swelling.

Discussion

Although the B–M–A latex is more similar to the samples used by Muroi *et al.*[2-4] than to those used by Wesslau[1] in view of the presence of carboxyl groups in the copolymer, this latex, which is unsoluble even in a concentrated NaOH solution, is a suitable sample for an investigation of the flow behavior of a thickened latex, as was proposed by Wesslau.

Equation of Viscosity. The wt% in Fig. 3 may be rewritten as in Fig. 5 in terms of the vol% on the basis of the presumption that when a film and latex-particles of an equal content on solids are thickened with an alkali solution of an identical concentration, the degrees of swelling of both samples are equal.

In Fig. 5, the plots for the B–M latex and the B–M–A latex at 50°C are added.

All the plots were on a curve represented by a full line in this figure and expressed in terms of an empirical formula (1):

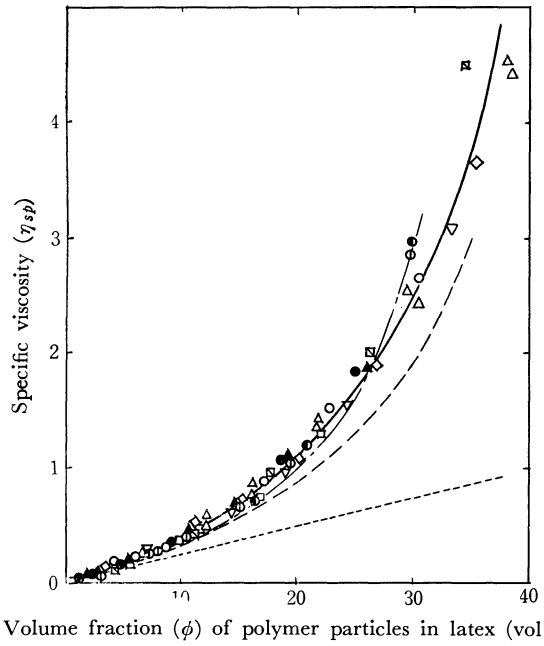

Fig. 5. Relations of η_{sp} and ϕ(vol%) for dialyzed latexes and those thickened.
It is the same with the symbols in Fig. 3 except those of the dialyzed latexes at 50°C, B-M ◐: H_2O and B-M-A ⓘ: H_2O.
——— Einstein's theoretical equation (2)
– – – – Hermans' theoretical equation (3)
------ Einstein's equation at very high dilution (4)

$$\eta_{sp} = (\eta/\eta_0) - 1 = 2.5\phi + 9.6\phi^2 + 31.6\phi^3, \quad (1)$$

where η and η_0 are the viscosities of the latex and its serum, *i.e.*, the dispersing medium, respectively. The broken line represents Einstein's theoretical equation[15] (2), the chain line is Hermans' theoretical equation[16] (3), and the dotted line is Einstein's equation (4) at a very high dilution:

$$\eta/\eta_0 = (1+\tfrac{1}{2}\phi)/(1-2\phi) = 1 + 2.5\phi + 5\phi^2 + 10\phi^3 + 20\phi^4 + \cdots, \quad (2)$$

$$\eta/\eta_0 = 1/(1-2.5\phi) = 1 + 2.5\phi + 6.3\phi^2 + 15.6\phi^3 + 39.0\phi^4 + \cdots, \quad (3)$$

$$\eta/\eta_0 = 1 + 2.5\phi. \quad (4)$$

The (1) empirical formula resembled both the theoretical equations, (2) and (3), and was half-way between Guth-Simha's[17] (5) and Vand's empirical formulae[18] (6), which have often been used:

$$\eta/\eta_0 = 1 + 2.5\phi + 14.1\phi^2 + \cdots, \quad (5)$$

$$\eta/\eta_0 = 1 + 2.5\phi + 7.35\phi^2 + \cdots. \quad (6)$$

The activation energies of flow for both latexes were independent of the concentration and were the same as that for water.

These results suggest that the viscosity of the latex is dependent on that of its dispersing medium and the volume fraction of its particles, and is independent of other factors for the first approximation.

Thickening of Latex with Alkali. As a comparison between the thickenability of the B–M–A latex with alkali in Fig. 3 and the degree of swelling in Fig. 4 shows, the results of the experiment support Wesslau's suggestion.[1] The fact that Eq. (1) was applicable to all the series in Fig. 5 provides a more rigorous description than Wesslau's, though; that is, an increase in the viscosity of a latex on the addition of alkali can be ascribed only to the swelling of the latex-particles.

This conclusion needs to be compared with Muroi's suggestion[2-4] that the dissolution of the surface layers of latex particles containing carboxyl groups and swelling of their cores on the addition of alkali cause the thickening of the latex. The dissolution of the surface layers in his investigation was ascribed to the larger number of carboxyl groups concentrated in the particle surface layers than in the present investigation. Accordingly, the conclusion in the present report does not contradict Muroi's suggestion.

Selection of Alkali for Thickening. It is usually said that the best alkaline thickener is one giving a thickening curve such as B in Fig. 6, and that NH_4OH is the best reagent. These facts can easily be illustrated by a comparison between the curve of the swelling of the B–M–A film with NH_4OH in Fig. 4 and the B-curve in Fig. 6. On the other hand, a

concentrated aqueous solution of NaOH can not be regarded as a good thickener, as is shown in Fig. 3; the D-curve in Fig. 6 is a schematic illustration of this, and it can also be expected from Fig. 4.

The alkali concentration at the maximum value of the degree of swelling, as is shown in Fig. 4, provides information about the most suitable amount of alkali for the thickening of a latex because of the equivalence in the amounts of the carboxyl groups and the alkali ions, as has been described previously.

Particle Size and Its Distribution. Although both the latexes used differed considerably in their particle-size distributions, as is shown in Fig. 2, the $\eta_{sp}\sim\phi$ relations, Eq. (1), were nearly akin to Einstein's relation, Eq. (2), for suspensions of spheres of uniform size. These results suggest that a latex possessing such a size distribution may be regarded as a mono-dispersed system in view of fluid mechanics.

The viscosity of a latex containing a surface-active agent is dependent on the particle size and its distribution.[19] When such latexes are thickened, their flow properties become complex, as has been reported by several investigators.[5,6]

The simpler results obtained in the present investigation may be supposed to be caused by the complete dialysis of the latex.

This research was supported in part by a grant-in-aid for Fundamental Scientific Research from the Ministry of Education, for which the authors are grateful.

The Semiconductive Property and the Phase Transition of the $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^{-\cdot}$ Anion Radical Salt. The Entropy Change Due to Electrons and Holes

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 16, 1971)

The semiconductive organic crystal of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ is known to undergo a first-order phase transition at 315.7°K. The discontinuity in the temperature dependence of the electrical conductivity takes place at the transition temperature, above which the populations of the electrons and the holes in the electrical conductivity increase abruptly. A theoretical consideration of the system of conduction carriers in an intrinsic semiconductor was developed in order to evaluate the entropy change of the electrons and holes at the phase transition. For $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, this kind of entropy change was found to be much less than the total entropy change determined from the heat-capacity measurements by Kosaki *et al.* In view of these results, it was concluded that the anomaly in the electrical conductivity was induced by the change in the crystal structure.

There are a few organic semiconductors that are known to undergo phase transitions.[1,2] The phase transitions of such organic semiconductors are particularly interesting, since the anomalies in their electrical conductivities are associated with their phase transitions.

Much attention has been paid to the solid anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) because of their high electrical conductivities.[1-4] The phase transition of the TCNQ anion radical salt of methyltriphenylphosphonium, $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, is known to take place at 315.7°K.[1,5-7] Heat-capacity measurements of this phase transition have been made by Kosaki *et al.*[7] The transition has thus been found to be of the first order. The enthalpy and the total entropy change associated with the phase transition were experimen-

tally determined to be 485.18 cal/mol and 1.7206 cal/deg·mol respectively.

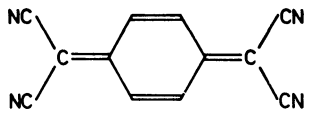

Fig. 1. 7,7,8,8-Tetracyanoquinodimethane (TCNQ).

On the other hand, the discontinuity in the temperature dependence of the electrical conductivity of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ was observed at the transition temperature, where the electrical conductivity increased abruptly by a factor of about 3.5 in the higher temperature range.[1] This change was found to be reversible. If this anion radical salt belongs to an intrinsic semiconductor, the temperature dependence of the electrical conductivity, σ, below or above the transition temperature can be expressed by:

$$\sigma = \sigma_0 \exp(-E_g/2kT), \tag{1}$$

where E_g is the energy gap between the conduction band and the valence band. The energy gap in the low-temperature phase, E_g, was experimentally determined to be 0.82±0.04 eV, while that in the high-temperature phase, E_g', was thus determined to be 0.60±0.04 eV.[1] An appreciable decrease in the energy gap by about 0.22 eV in the high-temperature phase was found to be caused by the phase transition. Therefore, at the transition temperature, the abrupt increase in the electrical conductivity in the higher temperature range can be understood mostly in terms of the increase in the population of conduction carriers in the high-temperature phase. At this time, the abrupt increase in the electrons and the holes should cause some entropy creation at the phase transition.

The purpose of the present paper is to examine to what extent this kind of entropy change contributes to the total entropy change as determined by the heat-capacity measurements. For this purpose, a general statistical theory for the system of electrons and holes in an intrinsic semiconductor will be developed in the Theoretical section. The entropy change due to the electrons and holes was evaluated when a first-order phase transition takes place in the semiconductor. By applying this theory to the phase transition of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, we shall investigate the mechanism of the phase transition of this anion radical salt.

Theoretical

Let us consider, in general, the system of an intrinsic semiconductor, where the energy gap between the conduction band and the valence band is assumed to be E_g. In the case of a usual organic semiconductor, the band widths of both the conduction band and the valence band are narrow enough in comparison with the energy gap.[8,9] The carriers for the electrical conduction are excited electrons in the conduction band and holes in the valence band. For an intrinsic semiconductor, the number of the electrons is equal to that of the holes.

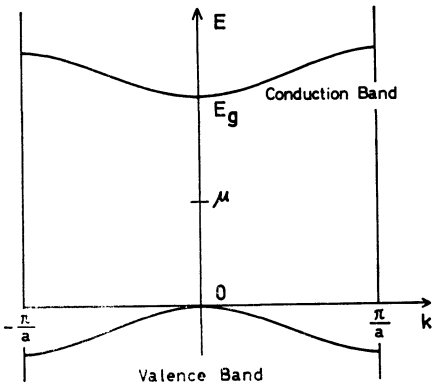

Fig. 2. A schematic representation of the band structure of an intrinsic semiconductor. The zero energy level is taken at the top of the valence band. E_g is the energy gap between the conduction band and the valence band, and μ is the level of the Fermi energy.

Electrons in Conduction Band. First, let us proceed to consider the electrons in the conduction band. It is convenient to describe this system as a grand canonical ensemble.[10] The grand partition function, Z_G, at the temperature T is represented by:

$$Z_G = \sum_{n_i} \exp(-\beta \sum_i \varepsilon_i n_i), \tag{2}$$

$$\varepsilon_i = E_i - \mu, \qquad \beta = \frac{1}{kT}, \tag{3}$$

where the sum with i runs over all the conceived quantum states. In the i th quantum state, E_i is the energy of an electron and n_i represents the number of electrons. μ is the chemical potential (*i.e.*, the Fermi energy). For the Fermi-Dirac statistics, since $n_i=0$ or 1,

$$Z_G = \prod_i (1 + e^{-\beta\varepsilon_i}). \tag{4}$$

The entropy of the system of the electrons in the conduction band, S(electron), can be derived from:

$$S(\text{electron}) = \frac{\partial}{\partial T}\left(\frac{1}{\beta}\ln Z_G\right)_{V,\mu} = k\sum_i \ln(1+e^{-\beta\varepsilon_i}) + T^{-1}\sum_i (e^{\beta\varepsilon_i}+1)^{-1}\varepsilon_i. \tag{5}$$

By using the form of the Fermi-Dirac distribution function of $f_i=1/(e^{\beta\varepsilon_i}+1)$, S(electron) is expressed as:

$$S(\text{electron}) = -k\sum_i [f_i \ln f_i + (1-f_i)\ln(1-f_i)]. \tag{6}$$

The first Brillouin zone in the conduction band is composed of N conduction levels, each of which includes α and β spin states. Then,

$$S(\text{electron}) = -2k\sum_{i=1}^{N} [f_i \ln f_i + (1-f_i)\ln(1-f_i)]. \tag{7}$$

In Eq. (3), the energy of the electron in the conduction band, E_i, and the Fermi energy of the intrinsic semiconductor, μ, are;

9) O. H. LeBlanc, *J. Chem. Phys.*, **35**, 1275 (1961); R. Silbey, J. Jortner, S. A. Rice, and M. T. Vala, Jr., *ibid.*, **42**, 733 (1965).
10) C. Kittel, "Elementary Statistical Physics," John Wiley & Sons, New York (1958).

$$E_i = E_g + \frac{\hbar^2 k_i^2}{2m_e}, \tag{8}$$

$$\mu = \frac{1}{2}E_g + \frac{3}{4}kT\ln\frac{m_h}{m_e}, \tag{9}$$

where $\hbar^2 k_i^2/2m_e$ is the kinetic energy of the electron and is related to the conduction band structure, and where m_e or m_h is the effective mass of the electron or the hole respectively. In the case of usual organic semiconductors, although it is very difficult to determine the precise band structures, the band widths of both the conduction band and the valence band are of the order of kT.[8,9] Since E_g is much larger than kT, one can neglect, in Eq. (8), $\hbar^2 k_i^2/2m_e$ in comparison with E_g, and μ is very nearly equal to $\frac{1}{2}E_g$. By the use of these approximations, the Fermi-Dirac distribution function of f_i is replaced by:

$$f = f_i \approx \frac{1}{\exp(E_g/2kT)+1}, \quad (i=1,2,\cdots, N). \tag{10}$$

Therefore, from Eq. (7), we have:

$$S(\text{electron}) = -2Nk[f\ln f + (1-f)\ln(1-f)]. \tag{11}$$

Holes in Valence Band. The holes in the valence band can be treated in a way similar to that of the electrons in the conduction band. In the case of the holes in the valence band, the Fermi-Dirac distribution function is:

$$f_i = \frac{1}{e^{-(E_i-\mu)/kT}+1}. \tag{12}$$

Here, the energy of a hole, E_i, in the valence band is:

$$E_i = -\frac{\hbar^2 k_i^2}{2m_h}. \tag{13}$$

If we assume that E_g is much larger than $\hbar^2 k_i^2/2m_h$,

$$f = f_i \approx \frac{1}{\exp(E_g/2kT)+1}, \quad (i=1,2,\cdots, N). \tag{14}$$

In this case, the entropy of the system of the holes in the valence band, S(hole), is found to be identical with that of the electrons in Eq. (11).

Entropy Change Associated with a First-order Phase Transition. By summing S(electron) and S(hole), the entropy per mol for the system of the conduction carriers in an intrinsic semiconductor, S(carrier), is then expressed as:

$$\begin{aligned} S(\text{carrier}) &= S(\text{electron}) + S(\text{hole}) \\ &= -4R[f\ln f + (1-f)\ln(1-f)]. \end{aligned} \tag{15}$$

Let us now consider the case when a first-order phase transition takes place in the intrinsic semiconductor at the temperature, T_c. The energy gaps for the low-temperature phase and the high-temperature phase are assumed to be E_g and E_g' respectively. At the transition temperature, the Fermi-Dirac distribution function, f, and the entropy for the system of the conduction carriers, S(carrier), in the low-temperature phase can be derived from the T_c and E_g values by means of Eqs. (10) and (15), while those in the high-temperature phase, f' and S'(carrier), can be derived from the T_c and E_g' values. Therefore, for the system of the conduction carriers, the entropy change, ΔS(carrier), at the phase transition is estimated to be:

$$\Delta S(\text{carrier}) = S'(\text{carrier}) - S(\text{carrier}). \tag{16}$$

Application of the Theory to the Phase Transition of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$

In this section, the above-mentioned theory will be applied to the phase transition of the anion radical salt of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ at $T_c=315.7$°K. For this anion radical salt, as has been described in the Introduction, the energy gap between the conduction band and the valence band in the low-temperature phase, E_g, is 0.82 ± 0.04 eV, while that in the high-temperature phase, E_g', is 0.60 ± 0.04 eV.[1] Therefore, these values well fulfill the condition that both E_g and E_g' should be considerably larger than kT_c. The notations described in the preceding section will be used for f, S(carrier), f', and S'(carrier). From Eq. (10), f and f' at the transition temperature are evaluated approximately by:

$$f \approx \exp(-E_g/2kT_c), \tag{17}$$

$$f' \approx \exp(-E_g'/2kT_c). \tag{18}$$

Putting the values of f and f' into Eq. (15), we have;

$$S(\text{carrier}) = 3.7\times10^{-5}\ \text{cal/deg·mol}, \tag{19}$$

$$S'(\text{carrier}) = 1.5\times10^{-3}\ \text{cal/deg·mol}. \tag{20}$$

Therefore, for the phase transition of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, the molar entropy change due to the electrons and holes for the electrical conduction is estimated to be:

$$\Delta S(\text{carrier}) = 1.5\times10^{-3}\ \text{cal/deg·mol}. \tag{21}$$

Discussion

The above-mentioned results clearly indicate that, in the phase transition of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, the magnitude of $\Delta S(\text{carrier})=1.5\times10^{-3}$ cal/deg·mol is negligibly small in comparison with that of the total entropy change, $\Delta S(\text{obs})=1.7206$ cal/deg·mol, as determined from the heat-capacity measurements.[7] This means that it is quite hopeless to consider the system of the electrons and the holes in the electrical conduction as the main source of entropy creation at the transition. Therefore, most of the total entropy change was found to arise from other sources.

Let us examine the entropy change in the magnetic spins associated with the unpaired electrons on the TCNQ anion radicals. Obviously, the $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ anion radical salt is composed of the diamagnetic counter cations, TCNQ anion radicals, and formally neutral TCNQ molecules.[3-5] The magnetic spins ($S=1/2$) on the TCNQ anion radicals are known to be paired up by an exchange interaction.[5] This system contains a singlet ground state and a triplet exciton state. However, Kepler found a sharp discontinuity in the temperature dependence of the paramagnetic susceptibility of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ at the transition temperature.[5] Chesnut showed that a certain type of order-disorder transition with respect to the triplet exciton density does occur if one includes in the inter-

action a term which is quadratic in the triplet exciton density, ρ.[11] In this case, the spin entropy change, ΔS(spin), associated with the phase transition is:

$$\Delta S(\text{spin}) = \tfrac{1}{2}R\Delta\rho \ln 3, \quad (22)$$

where $\Delta\rho$ is the change in the triplet exciton density at the transition. In a previous paper,[12] the present author estimated the value of ΔS(spin) for the phase transition of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ to be 0.13 cal/deg·mol by the use of $\Delta\rho=0.12$, which was calculated from Kepler's data on the discontinuity in the paramagnetic susceptibility at the transition temperature.[5] Although the value of ΔS(spin) is appreciably larger than that of ΔS(carrier), the value of ΔS(spin) is again much less than that of ΔS(obs).

The above-mentioned investigations indicate that the rest of the entropy change, $\Delta S(\text{obs})-\Delta S(\text{carrier})-\Delta S(\text{spin})=1.59$ cal/deg·mol, should be ascribed to the entropy change due to the change in the crystal structure. It is important to note that the magnitude of this residual entropy change amounts to 92.4% of the total entropy change of ΔS(obs). In view of these results, we may conclude that the phase transition of the anion radical salt of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ at 315.7°K comes mostly from some structural changes. The anomalies in the electrical conductivity and in the paramagnetic susceptibility are probably induced by the change in the crystal structures.

Concluding Remarks

For such semiconductors as $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, where the energy gap is considerably larger than kT, the magnitude of the entropy for the system of the electrons and holes in the electrical conduction is negligibly small, since the distributions of the electrons in the conduction band and of the holes in the valence band are quite limited at the temperature T.

On the other hand, however, the carrier population is very much increased for semiconductors in which the energy gap is comparable to kT. In this case, the magnitude of the entropy for the system of the electrons and holes becomes appreciably large. If these semiconductors undergo phase transitions, this kind of entropy should make a significant contribution to the mechanism of the phase transitions. In addition to the increase in the carrier population, the level of the Fermi energy in Eq. (9) is not located at the center between the conduction band and the valence band. Therefore, Eq. (14) for the holes in the valence band is no longer identical with Eq. (10) for the electrons in the conduction band. Since one cannot neglect the term of $\hbar^2k_i^2/2m_e$ in Eq. (8) or that of $\hbar^2k_i^2/2m_h$ in Eq. (13) in comparison with that of E_g, exact knowledge concerning the band structures of both the conduction band and the valence band will be required in order to evaluate the entropy due to the electrons and the holes.

The author would like to express his appreciation to Professor Akiko Ohno for her helpful discussions.

Stability and Extractability of Zinc(II) Thiocyanate Complexes in Several Solvent Extraction Systems

Hiromitsu MORIYA and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 18, 1971)

The formation and extraction equilibria of zinc(II) complexes with thiocyanate ions have been determined at 25°C. Zinc(II) ions in 1 M sodium perchlorate constant ionic media containing thiocyanate ions at various concentrations have been extracted into chloroform containing β-isopropyltropolone (IPT), into hexane containing trioctylphosphine oxide (TOPO), or into methyl isobutyl ketone (MIBK). The stability constants of the zinc(II) thiocyanate complexes in the aqueous phase were first determined from the decrease in the IPT chelate extraction, and then the distribution constants for the zinc(II) thiocyanate complexes into the latter two solvents were determined. The results were explained by saying that (i) zinc(II) forms the first ($\log \beta_1 = 0.56$), second($\log \beta_2 = 1.32$), and the third($\log \beta_3 = 1.18$) complexes in the above aqueous phase, (ii) TOPO in hexane extracts the second complex as an adduct in the $Zn(SCN)_2(TOPO)_2$ form, (iii) MIBK extracts both the second and the third complexes, and (iv) the addition of sodium perchlorate causes a salting-in effect in the lower-ligand-concentration region. Some discussion was made of the dissociation of ion-pairs in the organic phase.

Since Bock[1] reported a comprehensive study of the solvent extraction of metal ions as thiocyanate complexes, it has been recognized that thiocyanate extraction is an effective method for the separation of various metal ions. The solvent extraction of zinc(II) thiocyanate complexes has been studied both from the analytical and thermodynamical standpoints, and quantitative information about the chemical equilibria has been reported by several authors. Among them, Bock[1] first assumed that both the Zn-

1) R. Bock, *Z. anal. Chem.*, **133**, 110 (1951).

$(SCN)_2$ and $(NH_4)_2Zn(SCN)_4$ complexes are extracted into diethyl ether. Later on, Tribalat and Dutheil[2] determined the distribution of zinc(II) between methyl isobutyl ketone(MIBK) and aqueous 1 M sodium perchlorate constant ionic solutions containing various amounts of thiocyanate ions. They concluded, from an analysis of the distribution data, that all of the first, second, third, and fourth zinc(II) thiocyanate complexes are formed in the aqueous phase and that the $Zn(SCN)_2$ species is extracted into MIBK. The complex formation of zinc(II) in aqueous solutions with thiocyanate ions has been determined by various methods, and the stability constants have been reported.[3]

In the present investigation, the authors have also studied the complex formation of zinc(II) with thiocyanate ions and the extraction of them with trioctylphosphine oxide(TOPO) in hexane or with MIBK. They have determined the stability constants of the thiocyanate complexes in 1 M sodium perchlorate constant ionic media from the changes in the extraction of the divalent zinc ions with the chelating extractant, β-isopropyltropolone(IPT), in chloroform as a function of the thiocyanate concentration in the aqueous phase. Then they measured the extraction of zinc(II) thiocyanate complexes in these aqueous solutions into the two organic solvents, and the complex species in the organic phase were assigned from the distribution data. Some discussion was made of the extraction behavior in these systems and the extractability of each complex.

Experimental

Reagents. A radioactive tracer, zinc-65, was used in order to determine the distribution ratio of zinc(II). It was obtained from the New England Nuclear Co. as a hydrochloric acid solution. The tracer was diluted with a large amount of a 1 M sodium perchlorate solution and stored as the stock solution. The TOPO was obtained from the Dojindo Co. The IPT was obtained from the Takasago Koryo Co. The MIBK was obtained from the Tokyo Kasei Co.; it was washed with dilute perchloric acid, water, and a dilute sodium hydroxide solution respectively, and then several times with water. Sodium perchlorate was prepared from sodium carbonate and perchloric acid and recrystallized three times from water. The other reagents were of an analytical grade and were used without further purification. The concentration of the extractants in the organic solvents was calculated from the amount dissolved in the solvent, while that of the sodium perchlorate or thiocyanate solution was calculated from the weight of the residue left after a certain amount of the solution has been evaporated up in an air-bath at 120°C. The concentration of the thiocyanate solution was also determined by argentimetry.

Procedures. All of the procedures were carried out in a thermostated room at 25±0.5°C. Stoppered glass tubes (volume 20 m*l*) were used for the agitation of the two phases. A certain amount of the sodium thiocyanate solution, the tracer and an acetate buffer (the initial concentration in the aqueous phase was 0.01 M) and the sodium perchlorate solution were added to glass tubes, and then the organic solution was added. The initial concentration of zinc in the aqueous phase was 1×10^{-6} M. The hydrogen-ion concentration for the extraction with IPT was $10^{-3.3}$ to $10^{-5.3}$ M while for the extraction of the thiocyanate complexes, it was 10^{-4} to 10^{-5} M. The initial volume of the two phases was always 5.0 m*l*, and the ionic concentration in the aqueous phase was 1 M unless otherwise noted. The two phases in the tubes were agitated mechanically for about two hours and then centrifuged. A 2 m*l* portion was pipetted from each phase and transferred into small test tubes. The γ-radioactivity of the samples was measured with a well-type(NaI) scintillation counter. A small portion was also taken from the aqueous phase, and the hydrogen-ion concentration was measured potentiometrically by using a solution containing 1.00×10^{-2} M perchloric acid and 9.9×10^{-1} M sodium perchlorate as the standard of $-\log[H^+]$ 2.00 in the 1 M ionic medium.

Statistical

The formation and the stability constant for the "*n*th" zinc(II) complex with thiocyanate ions may be described as follows:

$$Zn^{2+} + nSCN^- \rightleftharpoons Zn(SCN)_n^{2-n}$$

$$\beta_n = \frac{[Zn(SCN)_n^{2-n}]}{[Zn^{2+}][SCN^-]^n} \quad (1)$$

The total concentration of zinc(II) in aqueous solutions containing thiocyanate ions can be described as;

$$[Zn(II)]_{total} = [Zn^{2+}] + [ZnSCN^+] + [Zn(SCN)_2] + [Zn(SCN)_3^-] + \cdots$$
$$= [Zn^{2+}](1 + \sum\beta_n[SCN^-]^n) \quad (2)$$

In the present paper, the subscript "*org*" denotes a chemical species in the organic phase, while the lack of any subscript denotes that in the aqueous phase.

(1) Extraction of Zinc(II) as Chelate Complexes. As was described in a previous paper,[4] the distribution ratios of zinc(II) from an aqueous phase containing no ligand, D_0, and that from an aqueous phase containing a ligand, L^-, can be described as follows if the concentration of the chelating extractant in the organic phase is the same;

$$D[H^+]^2/K_0 = (1+\sum\beta_n[SCN^-]^n)^{-1} \quad (3)$$

where $K_0=D_0[H^+]^2$.

As has been reported, the extracted zinc(II) complex with IPT in the organic phase is described as $ZnA_2(HA)$.[5] However, when the IPT concentration in the organic phase is kept constant, this K_0 should be constant as long as no IPT complexes are formed in the aqueous phase.[4,5] Thus, when the value of K_0 is determined in the absence of the ligand, the stability constants can be determined from this and the distribution ratio measured as a function of the ligand concentration by using Eq. 3.

4) T. Sekine, M. Sakairi, F. Shimada, and Y. Hasegawa, This Bulletin, **38**, 847 (1965).

5) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 1463 (1964).

(2) Extraction of Zinc(II) as Thiocyanate Complexes. (a) Extraction of Uncharged Thiocyanate Complex: When the uncharged complex in the aqueous phase is extracted with a neutral extractant, E, in the organic phase, it is described as;

$$Zn(SCN)_2 + eE(org)_2 \rightleftarrows Zn(SCN)_2E_e(org)$$

$$Kex_e' = \frac{[Zn(SCN)_2E_e]_{org}}{[Zn(SCN)_2][E]^e_{org}} \quad (4)$$

The distribution ratio of zinc(II) in such a system can be described as;

$$D = \frac{[Zn(SCN)_2]_{org} + [Zn(SCN)_2E]_{org} + [Zn(SCN)_2E_2]_{org} + \cdots}{[Zn^{2+}] + [ZnSCN^+] + [Zn(SCN)_2] + [Zn(SCN)_3^-] + \cdots} \quad (5)$$

By introducing Eqs. (2) and (4) into Eq. (5), we obtain;

$$D = \frac{(1 + \sum^{1+E} Kex_e'[E]^e_{org})\beta_2[SCN^-]^2}{1 + \sum\beta_n[SCN^-]^n} \quad (6)$$

When the concentration of the extractant, E, is kept at b M, the following constant can be defined;

$$K_{DM2} = 1 + \sum Kex_e'b^e = \frac{[Zn(SCN)_2]_{org.total}}{[Zn(SCN)_2]} \quad (7)$$

Then Eq. (6) can be described as;

$$D = \frac{K_{DM2}\beta_2[SCN^-]^2}{1 + \sum\beta_n[SCN^-]^n} \quad (8)$$

(b) Extraction of Both Uncharged Complex and Ion-pairs of Anionic Complexes with Sodium Ions: When the organic solvent is a solvating polar one and extracts the neutral complex, the extraction equilibrium can be described as;

$$Zn(SCN)_2 \rightleftharpoons Zn(SCN)_2(org) \quad (9)$$

The extraction constant for this may also be described by Eq. (7) except that the solvation number of the complex cannot be defined.

The extraction of anionic complexes with sodium ions may also occur. The extraction of the third complex may be described as;

$$Zn(SCN)_3^- + Na^+ \rightleftharpoons NaZn(SCN)_3(org)$$

$$Kex_3'' = \frac{[NaZn(SCN)_3]_{org}}{[Zn(SCN)_3^-][Na^+]} \quad (10)$$

The ion-pair could dissociate in the organic phase;

$$NaZn(SCN)_3(org) \rightleftharpoons Na^+(org) + Zn(SCN)_3^-(org)$$

$$Kdiss(org) = \frac{[Na^+]_{org}[Zn(SCN)_3^-]_{org}}{[NaZn(SCN)_3]_{org}} \quad (11)$$

The concentration ratio of the third complex in the two phases can be described from Eqs. (10) and (11) as;

$$\frac{[NaZn(SCN)_3]_{org} + [Zn(SCN)_3^-]_{org}}{[Zn(SCN)_3^-]} = Kex_3''[Na^+]\left(1 + \frac{Kdiss(org)}{[Na^+]_{org}}\right) \quad (12)$$

In the present study, however, the sodium-ion concentration is kept at 1 M; moreover, as will be described later, that in the organic phase could also be regarded as constant in the lower-ligand-concentration region. Thus, from Eq. (12), an extraction constant can be defined as;

$$K_{DM3} = \frac{[NaZn(SCN)_3]_{org} + [Zn(SCN)_3^-]_{org}}{[Zn(SCN)_3^-]} \quad (13)$$

When both the second and the third complexes are extracted, the distribution ratio may be described as;

$$D = \frac{[Zn(SCN)_2]_{org} + [NaZn(SCN)_3]_{org} + [Zn(SCN)_3^-]_{org}}{[Zn^{2+}] + [ZnSCN^+] + [Zn(SCN)_2] + [Zn(SCN)_3^-] + \cdots} \quad (14)$$

By introducing Eqs. (2), (7), and (13), Eq. (14) can be described as;

$$D = \frac{K_{DM2}\beta_2[SCN^-]^2 + K_{DM3}\beta_3[SCN^-]^3}{1 + \sum\beta_n[SCN^-]^n} \quad (15)$$

(3) Graphic Analysis of the Distribution Data. The zinc(II) IPT chelate distribution data obtained as a function of the thiocyanate concentration and given by a $\log D[H^+]^2K_0^{-1}$ *vs.* $\log[SCN^-]$ plot (*cf.* Eq. (3)) may be treated by a curve-fitting method.[6,7]

When the stability constants for the thiocyanate complexes in the aqueous phase are thus obtained, the extraction data of the zinc(II) thiocyanate complexes with TOPO or MIBK can be determined by using these stability constants as follows.

When only the $Zn(SCN)_2$ complex is extracted into the organic phase, (*cf.* Eq. (8)), the distribution constant can be determined from;

$$K_{DM2} = D(1 + \sum\beta_n[SCN^-]^n)/\beta_2[SCN^-]^2 \quad (16)$$

When both the $Zn(SCN)_2$ and $Zn(SCN)_3^-$ complexes are extracted (*cf.* Eq. (15)), the distribution data can be described as;

$$Y = \log \frac{D(1 + \sum\beta_n[SCN^-]^n)}{[SCN^-]^2} = \log(K_{DM2}\beta_2 + K_{DM3}\beta_3[SCN^-]) \quad (17)$$

When the data are plotted as Y *vs.* $\log[SCN^-]$, they may be fitted by the standard curve[5-7];

$$Y = \log(1 + v), \quad X = \log v \quad (18)$$

and the constants, K_{DM2} and K_{DM3}, can be determined from the curve-fitting and from the β_2 and β_3 values which have already been obtained from the IPT extraction.

Results

The extraction of zinc(II) in a 1 M sodium perchlorate solution into chloroform containing 0.1 M IPT was determined as a function of the hydrogen-ion concentration. The value of the constant, K_0, in Eq. (3) was obtained from the results as;

$$\log K_0 = -8.38$$

It was found that the K_0 value is independent of the hydrogen-ion concentration in the range of $-\log[H^+]$ 3.5 to 5.0 when the IPT concentration in the organic phase is 0.1 M.

Figure 1 shows the decrease in the zinc(II) extrac-

tion with IPT as a function of the thiocyanate concentration in the aqueous phase. This plot was analyzed graphically by using Eq. (3), and the best-fit was obtained when the formation of the first, second, and third complexes was assumed. The stability constants obtained are given in Table 1. The solid curve in Fig. 1 was drawn by using these constants.

Figure 2 gives the distribution ratio of zinc(II) between 1 M Na(SCN, ClO_4) ($-\log[H^+]$ was 4 to 5) and MIBK(closed circles) or hexane containing 1.0×10^{-3} M TOPO(open circles) as a function of the thiocyanate concentration. From these data and the stability constants of thiocyanate complexes in Table 1, the value of Y in Eq. (17) was determined for each plot, these values are given in Fig. 3. It may be seen from Fig. 3 that the values of Y for the TOPO extraction are almost constant in the thiocyanate concentration region from 8×10^{-3} M to 3×10^{-1} M; in other words, the values of K_{DM2} in Eq. (16) are not dependent on the thiocyanate concentration, and thus the only zinc(II) species in the organic phase should be the $Zn(SCN)_2$ complex. It was found that

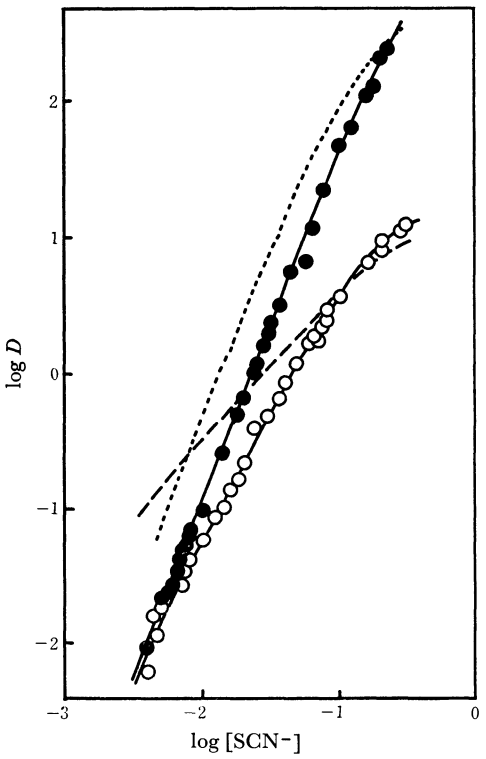

Fig. 2. Extraction of Zn(II) thiocyanate complexes as a function of the aqueous thiocyanate concentration. Org. phase; ○ hexane containing 1.0×10^{-3} M TOPO, ● MIBK, Aq. phase; 1M Na(SCN, ClO_4). The solid curves are;

$\log D=\log(5.2\times10^2[SCN^-]^2+6.4\times10^4[SCN^-]^3)/(1+3.7[SCN^-]+21[SCN^-]^2+15[SCN^-]^3)$: ●
The broken line and the dotted line show the extraction into hexane containing 1.0×10^{-3} M TOPO or MIBK, respectively, when the aqueous phase is sodium thiocyanate solution containing no sodium perchlorate.

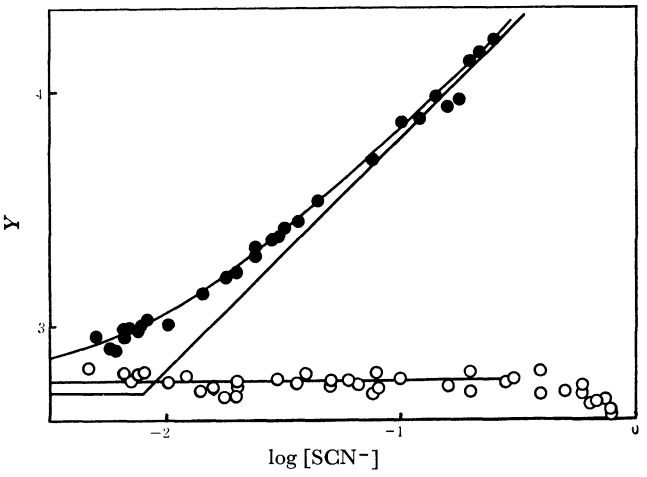

Fig. 3. Graphic analysis of the extraction data (○: TOPO, ●: MIBK).
The ordinate is; $Y=\log D(1+3.7[SCN^-]+21[SCN^-]^2+15[SCN^-]^3)/[SCN^-]^2$
The solid lines are; $Y=2.77$: ○, $Y=\log(5.2\times10^2+6.4\times10^4[SCN^-])$: ●

the distribution ratio between an aqueous phase containing 0.3 M thiocyanate ion and organic phases containing various amounts of TOPO is proportional to

the square of the TOPO concentration in the range of the TOPO concentrations from 2×10^{-4} M to 3×10^{-3} M; thus, the extraction equilibrium can be given by;

$$Zn(SCN)_2 + 2TOPO(org) \rightleftharpoons Zn(SCN)_2(TOPO)_2(org) \quad (19)$$

The distribution constant defined by Eq. (4) ($[Zn(SCN)_2(TOPO)_2]_{org}/[Zn(SCN)_2][TOPO]_{org}$) was obtained as $10^{7.45}$, and that defined by Eq. (7), was $10^{1.45}$ (at 1.0×10^{-3} M TOPO). The solid curve for the TOPO plot in Fig. 2 is a curve calculated by using Eq. (8) and the stability and the distribution constants obtained.

The slope of the extraction curve into MIBK in Fig. 2 is higher than that into hexane containing TOPO; this may be supposed to be due to the extraction of the higher thiocyanate complexes. The value of Y in Eq. (17) was calculated for each plot and plotted against log[SCN$^-$], as is shown in Fig. 3. The plot in Fig. 3 was fitted with the standard curve in Eq. (18). The best-fit curve is shown by the solid curve in Fig. 3. From the parameters of the best-fit curve, the distribution constants in Eqs. (7) and (13) were determined on the basis of Eq. (17). The solid curve for the MIBK plot in Fig. 2 is the curve calculated by using Eq. (15) and the stability and the distribution constants obtained.

Figure 4 shows the percentage distribution of the concentrations of zinc(II) species in the aqueous phase, and those in the hexane phase containing TOPO and in MIBK phase in an equilibrium with the aqueous phase.

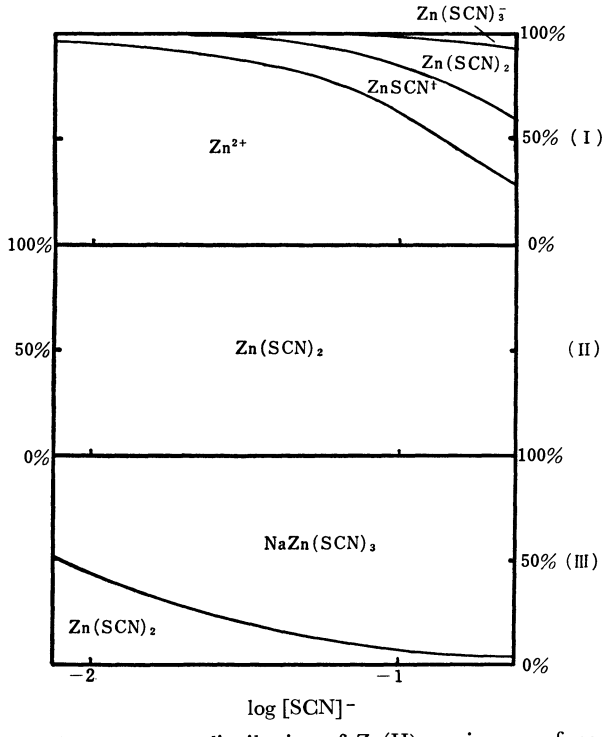

Fig. 4. Percentage distribution of Zn(II) species as a function of the thiocyanate concentration calculated from the constants in Table 1.
(I) 1 M Na(SCN, ClO_4). (II) hexane containing 1.0×10^{-3}M TOPO which is in an equilibrium with (I). (III) MIBK which is in an equilibrium with (I).

The above extractions were always made from the 1 M constant ionic medium. In order to ascertain the effect of the coexisting sodium perchlorate, extraction was also made from sodium thiocyanate solutions containing no sodium perchlorate.

The broken line and the dotted line in Fig. 2 give the extraction curve from these aqueous phases, in which the ionic concentration was not kept constant.

The results described above may be summarized as follows: (i) The extraction curve of zinc(II) in the 1 M Na(SCN, ClO_4) solutions with IPT was explained in terms of the formation of the first, second, and third complexes. The stability of the third complex is not high ($K_3=[Zn(SCN)_3^-]/[Zn(SCN)_2]$ [SCN$^-$] $=10^{-0.14}$). The stability constants given in Table 1 seem to be reasonable because they can explain the zinc(II) thiocyanate extraction with TOPO or MIBK. (ii) The extraction of zinc(II) into hexane containing TOPO was explained in terms of the extraction of the second complex species with two molecules of TOPO. (iii) The extraction of zinc(II) into MIBK was explained in terms of the extraction of the second and the third complexes. (iv) When the aqueous phase contains only sodium thiocyanate, the extraction becomes somewhat higher than that from the constant ionic medium in the region where the thiocyanate concentration is lower than 0.1 M.

Discussion

The extracted ion-pairs, $Na^+Zn(SCN)_3^-$, could dissociate in MIBK. When the dissociation occurs, the extraction of the third complex should be dependent on the sodium concentration in the organic phase, as may be seen from Eq. (12) (the sodium ion concentration in the aqueous phase is kept constant). When the other charged species, such as protons and hydroxide ions, are negligible, the following equation can be written on the basis of the electrical neutrality in the organic phase;

$$[Na^+]_{org} = [ClO_4^-]_{org} + [SCN^-]_{org} + [Zn(SCN)_3^-]_{org} \quad (20)$$

In the present study, the concentration of zinc(II) in the initial aqueous phase is 1×10^{-6} M; this is much lower than the concentration of sodium perchlorate in MIBK (that was estimated to be 1×10^{-2} M[8]). Although no information is availabe about the dissociation of sodium perchlorate and that of the extracted $NaZn(SCN)_3$ ion-pairs, it is most probable that the sodium-ion concentration in the organic phase is constant. Because the concentrations of zinc(II) and sodium thiocyanate in the aqueous phase are much smaller than that of sodium perchlorate under the experimental conditions used in the present study, Eq. (20) can be regarded as $[Na^+]_{org}\simeq[ClO_4^-]_{org}$. Thus the K_{DM3} defined by Eq. (13) could be regarded as a constant in this study.

The stability constants obtained in the present study indicate that they are not very stable. The

8) Y. Hasegawa, T. Ishii, and T. Sekine, This Bulletin, **44**, 275 (1971).

values of the stability constants in the literature[3] are rather scattered. The constants reported in the same ionic medium as in the present study by Tribalat and Dutheil[2] in Table 1 are also somewhat different from the present results; their constant for the first, second, and third complexes are lower than those in the present study, and they estimated a formation of a fourth complex in the same medium which was not found by the present authors.

The extraction curve of zinc(II) from the 1 M Na (SCN, ClO_4) solution into MIBK reported by Tribalat and Dutheil (Fig. 1 in Ref. 2) almost agrees with the results shown in Fig. 2. They analyzed the data by assuming that only the uncharged complex, $Zn(SCN)_2$, is extractable among the four complexes. In the present study, however, it was concluded that both the uncharged complex and the uninegative charged third complex are extracted into the MIBK phase. This assumption seems to be well supported by the extraction data with TOPO in hexane. It may be seen in Fig. 2 that the slope of the plot of the TOPO extraction becomes smaller in the highest-ligand concentration region than that of the MIBK extraction, and the calculated curves from the stability constants obtained by the IPT extraction, shown in Fig. 2 or in Fig. 3, fit the experimental results well.

This seems to agree with the results expected from the nature of the solvents. Hexane containing a small amount (1×10^{-3} M) of TOPO can be regarded as a nonpolar solvent to which the extraction of a polar species such as ion-pairs is unfavorable(although it is possible to extract ion-pairs into a hexane solution of TOPO, especially when the TOPO concentration is high[9]). On the other hand, as has been reported for many MIBK extraction systems,[9-12] the extraction of negatively-charged metal thiocyanate complexes as ion-pairs with cations in the background salt or that of pairs of the sodium ion and the perchlorate ion[8] seems to be very common into this polar and relatively high-dielectric-constant ($\varepsilon=12$) solvent, which also has a great ability of solvation on metal species.

It is remarkable that the log D *vs.* log[SCN^-] plot of the MIBK extraction in Fig. 2 is nearly a straight line with a slope of +2.5. As can be seen from the figures and Eq. (17), this apparent tendency for the log D *vs.* log[SCN^-] plot to be almost a straight line is probably due to the fact that, although the extraction of the uncharged complex does not increase any more in the highest concentration (this is the reason why the slope of the extraction curve with TOPO in Fig. 2 approaches zero), the extraction of the third complex, which increases in the highest region, will still enhance the distribution ratio. When the log D *vs.* log[SCN^-] plot is practically a straight line, in other words, when $\log D=n\log[SCN^-]=c$ where n or c is a constant, it seems to be usually difficult to determine the equilibrium constants, β_n and k_{DMn}, in Eq. (15) simultaneously from the extraction data due to the experimental errors. In the present study, the stability constants, β_n, had already been determined by separate experiments, and, as these constants were available, only the determination of K_{DMn} in Eq. (15) was necessary for the analysis of the equilibrium.

As may be seen in Fig. 2, the extraction curve is different when the aqueous phase is a constant ionic medium and when it contains only sodium thiocyanate. This is probably due in part to the changes in the activity coefficients of the chemical species by the change in the ligand concentration (and, consequently, by the change in the ionic strength); at the same time, it is probable also due to the lower concentration of sodium in the aqueous phase in the MIBK system, as can be seen from Eqs. (10) and (12).

The extraction in analytical work are usually carried out with no control of the activity or in the presence of various other electrolytes in the aqueous phase; in order to make a quantitative analysis of the extraction curves obtained under such conditions, a correction for these factors is indispensable. However, such a correction of the activity (not only of the ligand and metal ions, but also of all the other chemical species connected with the extraction, such as the complexes or the coexisting salts) is usually very difficult; thus, the information available from usual analytical data on the chemical equilibria involved in the systems is of limited use.

The authors are grateful to Mr. Naohiko Ihara of the present laboratory for his experimental aid and invaluable discussions during the work. Part of this work has been carried out in the Laboratory of Analytical and Nuclear Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of the laboratory.

Metal Complexes with Amino Acid Amides. III. Geometrical Structures and Electronic Spectra of Bis(α-amino-acid-amidato)palladium(II), -nickel(II) and -copper(II)

Takashi KOMORITA, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 25, 1971)

Square planar complexes of $[ML_2]$ type were synthesized, where M=Pd^{2+} and Ni^{2+} for L=L-valine-, L-phenylalanine- and L-proline-amidate anions, and M=Pd^{2+}, Ni^{2+} and Cu^{2+} for L=L-leucinemethylamidate anion and for L_2=trimethylenediamine-*N*,*N*′-diisobutyric acid amidate dianion; the last ligand is a tetradentate one and gives exclusively *cis* type complexes. *Cis* and *trans* isomers were isolated and identified for each of the L-valinamidato and the L-prolinamidato palladium complexes. All the other complexes were inferred to be *trans* isomers from examination of the electronic absorption and circular dichroism spectra. Common solvent effects of the ligand field bands were clearly observed between the *trans* palladium and *trans* nickel complexes. A similar empirical relationship was also found between the ligand field bands of the *trans* palladium complexes and those of the corresponding *cis* isomers. The spectral behavior of the bis(L-amino-acid-amidato)-copper(II) complexes was not so easily related to that of the corresponding nickel or palladium complexes. The ligand field bands of the palladium, nickel, and copper complexes were tentatively assigned.

In the previous papers of this series,[1,2] square planar bis-chelate complexes of palladium(II), nickel(II) and copper(II) with several α-amino acid amidate ligands were reported. A pair of isomers were prepared for each of bis(L-alaninamidato)- and bis(L-leucinamidato)-palladium(II), but only one isomer was isolated for every nickel(II) and copper(II) complex examined. It has been concluded from the electronic, IR, and NMR spectra that all the complexes cited are of square planar $[M(N)_4]$ type, and that the pairs of palladium(II) complexes are of *cis* and *trans* isomers. The nickel(II) and copper(II) complexes have been considered to be mostly *trans* in solid state or in solution with a few exceptions.

The most interesting fact found in the study of the electronic absorption (AB) and circular dichroism(CD) spectra of these complexes is the similarity of the ligand field bands of the *trans* nickel complexes to those of the corresponding palladium complexes.[1,3] We believe that a comparative study of CD spectra will useful for the elucidation of the electronic structure of square planar complexes. With this view in mind we decided to extend our work to the complexes with additional ligands.

The purpose of the present study is to confirm the previous conclusion concerning the geometrical structures of the bis(α-amino-acid-amidato) complexes, and to investigate their AB and CD spectra more extensively. Bis(α-amino-acid-amidato) type complexes of palladium(II), nickel(II), and copper(II) were prepared with some optically active L-α-amino-acid amides and with a tetradentate ligand which gives *cis* type complexes exclusively.

Experimental

Materials. *1) Ligands*:[4] *Trimethylenediamine*-N,N′-*diisobutyric Acid Amide*: *tndbaH*$_2$: When trimethylenediamine dihydrochloride was used in place of the ethylenediamine analog in Schlesinger's method for ethylenediamine-*N*,*N*′-diisobutyronitrile,[5] trimethylenediamine-*N*,*N*′-diisobutylonitrile was obtained from the ether layer as rhombic plates in good yield. This compound is soluble in ether; mp 90—92°C (uncorr.).

Found: C, 63.68; H, 9.81; N, 26.86%. Calcd for $C_{11}H_{20}N_4$: C, 63.43; H, 9.68; N, 26.90%.

The dinitrile (17.7 g) was suspended in 75 m*l* of concentrated hydrochloric acid under ice cooling and the mixture was allowed to stand overnight at room temperature. The dinitrile was then dissolved. When necessary, hydrogen chloride gas was bubbled into the mixture in order to complete the dissolution. The dihydrochloride salt of the desired compound was obtained as white crystals from the solution by diluting with equivolume of water and cooling in an ice bath. The crystals were filtered off and washed with methanol and then ether. Recrystallization was carried out by concentrating the aqueous solution *in vacuo*. The yield was good.

Found: C, 41.44; H, 8.36; N, 17.37%. Calcd for $C_{11}H_{26}N_4O_2Cl_2$: C, 41.64; H, 8.26; N, 17.66%.

The desired amide $tndbaH_2$ was derived from the dihydrochloride by ion exchange chromatography with Amberlite IRA-410 (OH^--type). This was recrystallized from chloroform and dried at 60°C *in vacuo*. Elongated rectangular plates; mp 140.5—141.5°C (uncorr.).

Found: C, 54.03; H, 9.98; N, 22.88%. Calcd for $C_{11}H_{24}N_4O_2$: C, 54.07; H, 9.90; N, 22.93%.

Other Ligands: L-Valinamide, L-Phenylalaninamide and L-prolinamide were prepared as described elsewhere.[2] L-Leucinemethylamide was prepared according to literature;[6] bp 97—106°C/2 mmHg.

2) $[Pd(tndba)]\cdot 5H_2O$: Forty milliliters of aqueous solution containing 0.75 g of lithium tetrachloropalladate-

1) Part I: T. Komorita, J. Hidaka, and Y. Shimura, This Bulletin, **41**, 854 (1968).

2) Part II: T. Komorita, J. Hidaka, and Y. Shimura, *ibid.*, **42**, 168 (1969).

3) T. Komorita, J. Hidaka, and Y. Shimura, *ibid.*, **42**, 1782 (1969).

4) The following abbreviations are used for ligands: alaaH=alaninamide, leuaH=leucinamide, valaH=valinamide, phalaaH=phenylalaninamide, proaH=prolinamide, leumaH=leucinemethylamide and $tndbaH_2$=trimethylenediamine-*N*,*N*′-diisobutyric acid amide.

5) N. Schlesinger, *Ber.*, **44**, 1135 (1911).

6) A. Rosenberg, *Acta Chem. Scand.*, **11**, 1390 (1957).

(II)[7] was added to a solution of 0.76 g of tndbaH_2 in 35 m*l* of water with stirring. When a clear solution was obtained after stirring for several minutes, the brownish yellow solution was carefully neutralized under pH adjustment with 1 N lithium hydroxide. It took about 100 min for neutralization. The end point was detected when it was observed that the pH was retained at 7.3 for 30 min without further addition of alkali. A crude complex was obtained from the pale yellow solution by concentrating it to near dryness and adding a small amount of ethanol and a large amount of acetone. Purification was performed by ion exchange chromatography with the required amount of 1 : 2 mixture (by volume) of Amberlite IR-120B (H^+-type) and IRA-410 (OH^--type). The eluate was concentrated *in vacuo* below 35°C until the complex began to crystallize and allowed to stand under ice cooling. The pale yellow needles were filtered off, washed with a small volume of cold water twice and dried in air.

Found: C, 30.12; H, 7.34; N, 12.59%. Calcd for $C_{11}H_{32}N_4O_7Pd$: C, 30.11; H, 7.35; N, 12.77%.

3) trans-[*Pd*(L-*vala*)$_2$] *and* cis-[*Pd*(L-*vala*)$_2$]·*0.5*H_2O: Twenty milliliters of aqueous solution containing 1.48 g of lithium tetrachloropalladate(II)[7] was added to a solution of 1.44 g of L-valaH in 20 m*l* of water with stirring. The resulting brown solution was treated with 0.5 N lithium hydroxide in a similar way to that for 2). The pale yellow solution was concentrated *in vacuo* until it became a syrup. Most of the lithium chloride was removed from the syrup by dissolving it in a few m*l* of ethanol and then by extracting it three times with 30 m*l* of ether each time. The same purification procedure was repeated once more. The residual viscous syrup was dissolved in 50 m*l* of 99% ethanol. To this solution, 450 m*l* of ether was added little by little, and the mixture was kept in a refrigerator overnight. After the supernatant solution was removed by decantation, the precipitate was dissolved in 50 m*l* of 99% ethanol again, and reprecipitated carefully from this solution by adding 500 m*l* of ether. At this stage, the crude complex (a *cis-trans* mixture) was obtained as a fine powder, which was washed with ether and dried *in vacuo*. The mixture was fractionally recrystallized by addition of acetone to the concentrated aqueous solution. All fractions of the fibrous crystals, which were washed with a (1 : 10) water-acetone mixture and then with acetone, were collected (1.23 g). Then the contaminated lithium chloride was completely eliminated with an ion exchange column as described in 2). The eluate was concentrated by a rotary evaporator, and then diluted to about one fifth of the saturated concentration. Isolation of the *cis* and *trans* isomers from this solution was performed by fractional crystallization with acetone. Purity of the isomers was checked by the uniformity of the crystals as well as by the reproducibility of the CD spectrum. The *trans* isomer was isolated as glistening fine plates, which had been suspended in the solution at the beginning of crystallization and grew rather slowly. On the other hand, the cis isomer grew more rapidly from the wall of a beaker as prisms, and its aqueous solution was inclined to be supersaturated.

The *trans* isomer: dried over calcium chloride.

Found: C, 35.50; H, 6.24; N, 16.49%. Calcd for $C_{10}H_{22}N_4O_2Pd$: C, 35.67; H, 6.59; N, 16.64%.

The *cis* isomer: dried in the atmosphere.

Found: C, 34.78; H, 6.74; N, 16.15%. Calcd for $C_{10}H_{23}N_4O_{2.5}Pd$: C, 34.74; H, 6.71; N, 16.21%.

7) In practice, lithium chloride and palladium(II) chloride were dissolved in water.

Both isomers are pale yellow, and soluble in water, methanol, ethanol, and *N,N*-dimethylformamide (DMF).

4) trans-[*Pd*(L-*phalaa*)$_2$]: A solution of 1.50 g of L-phalaaH in 25 m*l* of water was slowly added to 60 m*l* of an aqueous solution containing 1.10 g of lithium tetrachloropalladate(II).[7] Together with the brownish precipitate, the whole mixture was subjected to a similar neutralization procedure as in 2). The color of both the precipitate and the supernatant solution then changed to pale yellow. The mixture was continuously stirred for 2 additional hr. Yield of the precipitate, or the desired complex in a crude state, was 1.48 g (82%). This could be recrystallized from a (1 : 2) water-methanol mixture; dried *in vacuo* over phosphorus pentoxide; pale yellow plates; soluble in methanol and ethanol, and slightly soluble in DMF.

Found: C, 50.09; H, 5.17; N, 12.86%. Calcd for $C_{18}H_{22}N_4O_2Pd$: C, 49.95; H, 5.12; N, 12.95%.

5) trans-[*Pd*(L-*proa*)$_2$]·*0.5*H_2O *and* trans-[*Pd*(L-*proa*)$_2$]·CH_3OH: To a solution containing 1.41 g of L-proaH in 40 m*l* of water was added 1.00 g of a powdered palladium(II) chloride, and the suspension was continuously stirred until most of the palladium(II) chloride was dissolved. This took about 40 min. The mixture was then neutralized with an anion exchange resin, Dowex 1×8 (50—100 mesh) of OH^--type. The resin was added little by little with mechanical stirring so that the pH of the mixture was kept under 8. A precipitate was produced at the beginning of the neutralization procedure, but it disappeared as the reaction proceeded. The end point of the neutralization was determined in the same way as in 2). The whole procedure took about 5 hr, and about twice the calculated amount of anion exchange resin was needed. The resin and the residual starting material were discarded by filtration. From the resulting yellow solution, the desired *trans* complex was isolated as a hemihydrate or a methanol adduct. The total yield of the *trans* complexes was 47%, but we could not isolate the *cis* isomer in this procedure.

Hemihydrate: The yellow solution prepared as above was concentrated *in vacuo*. An appropriate amount of acetone was added to the solution and the mixture was cooled in an ice bath. The yellow microcrystals were collected on a glass filter, washed with (1 : 10) water-acetone mixture and acetone, and dried over calcium chloride. Very long plates.

Found: C, 35.62; H, 5.59; N, 16.15%. Calcd for $C_{10}H_{19}N_4O_{2.5}Pd$: C, 35.15; H, 5.60; N, 16.40%.

Methanol Adduct: The yellow solution prepared as above was concentrated to dryness *in vacuo*. The residuals were dissolved in methanol and the methanol solution was concentrated *in vacuo*. The yellow prisms were washed with a small amount of methanol, acetone, and ether, and dried over phosphorus pentoxide *in vacuo*.

Found: C, 35.85; H, 6.00; N, 15.54%. Calcd for $C_{11}H_{22}N_4O_3Pd$: C, 36.23; H, 6.08; N, 15.36%.

Both the hemihydrate and the methanol adduct are soluble in water, methanol, and ethanol.

6) cis-[*Pd*(L-*proa*)$_2$]·*3.5*H_2O: A solution containing 1.48 g of lithium tetrachloropalladate(II)[7] in 60 m*l* of water was mixed with a solution of 1.41 g of L-proaH in 20 m*l* of water. The mixture was neutralized with 0.5 N lithium hydroxide in the same way as that in 2). The yellow solution was concentrated to one fifth of its original volume *in vacuo* and treated with an ion exchange column as in 2), where about twice the calculated amount of resin was used. The first fraction of crystalline products was deposited when the eluate was concentrated to a few m*l*. From the mother liquor two additional fractions were obtained by fractional addition of acetone. Each fraction consisted mainly of

needle crystals and was contaminated by a small amount of plates, or the *trans* isomer. The first two fractions, rich in *cis* isomer, were combined and fractionally recrystallized from the aqueous solution by addition of acetone. The pure *cis* complex consisted of fine yellow needles. Its purity was checked by the CD spectrum as it was difficult to distinguish it from the *trans* complex by their crystal forms only. The sample for elemental analyses was dried in air.

Found: C, 30.28; H, 6.34; N, 14.06%. Calcd for $C_{10}H_{25}N_4O_{5.5}Pd$: C, 30.35; H, 6.37; N, 14.16%.

This complex is soluble in water, methanol, ethanol and DMF. Total yield of the crude complex, contaminated with a small amount of the *trans* isomer, was rather low, 0.71 g (*ca.* 32%). It should be added that considerable amounts of both isomers were separated from the column used in the above preparation when eluted with a concentrated sodium chloride solution.

7) trans-[*Pd(*L-*leuma)*$_2$]: A solution containing 1.32 g of lithium tetrachloropalladate(II)[7] in 70 m*l* of water was added to 80 m*l* of an aqueous solution containing 1.58 g of L-leumaH with stirring. The brown solution was neutralized as in 2) by use of 0.5 N lithium hydroxide. When the resulting solution was concentrated *in vacuo*, the desired complex was deposited as yellow hexagonal plates; yield, 1.85 g (94%). It was recrystallized by concentrating the aqueous solution *in vacuo*. The pure crystals were washed with water and then dried over calcium chloride.

Found: C, 42.53; H, 7.78; N, 14.08%. Calcd for $C_{14}H_{30}N_4O_2Pd$: C, 42.81; H, 7.70; N, 14.26%.

This complex is soluble in water, methanol, ethanol, and DMF.

8) Nickel(II) Complexes: The preparation procedure for these complexes is similar to that for *trans*-bis(L-alaninamidato)nickel(II);[1] an aqueous solution of the ligand (2.2 equivalent amount[8]) and then 1 N sodium hydroxide (2 equiv.) were added to an aqueous solution of nickel(II) acetate (1 equiv.). The desired complex was obtained from the resulting orange colored solution.

[*Ni(tndba)*]·H_2O: The orange yellow solution was concentrated to a small volume (*ca.* 5 m*l*/1 g of the ligand used) and then diluted with a large amount (about 8 times) of ethanol. Sodium acetate and the desired complex were fractionally precipitated from the solution by adding ether gradually. The complex was recrystallized by adding ether to a 95% ethanol solution, the concentration of which had been adjusted to about half as saturated. The sample for elemental analyses was dried over calcium chloride overnight. Deep yellow pillars.

Found: C, 41.43; H, 7.56; N, 16.94%. Calcd for $C_{11}H_{24}N_4O_3Ni$: C, 41.41; H, 7.58; N, 17.56%.

trans-[*Ni(*L-*vala)*$_2$]·$2H_2O$: The complex was obtained by adding methanol and then ether to the concentrated mother solution; dried in air as orange prisms; soluble in water (not very stable), methanol, ethanol, and DMF.

Found: C, 36.95; H, 7.72; N, 16.98%. Calcd for $C_{10}H_{26}N_4O_4Ni$: C, 36.95; H, 8.06; N, 17.24%.

trans-[*Ni(*L-*phalaa)*$_2$]: Recrystallized from a methanol solution by vacuum evaporation; dried *in vacuo* over phosphorus pentoxide; orange plates; soluble in methanol, ethanol and DMF.

Found: C, 56.16; H, 5.85; N, 14.30%. Calcd for $C_{18}H_{22}N_4O_2Ni$: C, 56.14; H, 5.76; N, 14.55%.

trans-[*Ni(*L-*proa)*$_2$]·$2H_2O$: Recrystallized from an aqueous solution by vacuum evaporation; dried over phosphorus pentoxide; orange pillars; soluble in water, methanol, ethanol, and DMF.

Found: C, 37.56; H, 6.96; N, 17.30%. Calcd for $C_{10}H_{22}N_4O_4Ni$: C, 37.42; H, 6.91; N, 17.45%.

trans-[*Ni(*L-*leuma)*$_2$]·H_2O: Recrystallized by adding ether to an ethanol solution; dried over phosphorus pentoxide; orange plates; soluble in methanol, ethanol and DMF, but rapidly decomposed in water.

Found: C, 46.58; H, 8.72; N, 15.45%. Calcd for $C_{14}H_{32}N_4O_3Ni$: C, 46.30; H, 8.88; N, 15.43%.

9) Cu(tndba)·$1.5H_2O$: Copper(II) hydroxide, freshly prepared from 0.93 g of copper(II) sulfate pentahydrate, was added to a solution containing 0.91 g of tndbaH_2 in 15 m*l* of water. The mixture was continuously stirred until a homogeneous red solution was obtained; it took about 100 min. It was filtered and concentrated *in vacuo* until it became a viscous syrup. The syrup was mixed with 2 m*l* of absolute ethanol and then with 150 m*l* of acetone, and allowed to stand in a refrigerator after scratching the vessel with a glass rod. Crystallization proceeded very slowly. Brick-red crystals. The sample for elemental analyses was dried over calcium chloride overnight.

Found: C, 40.19; H, 7.71; N, 16.78%. Calcd for $C_{11}H_{25}N_4O_{3.5}Cu$: C, 39.69; H, 7.57; N, 16.83%.

*10) Cu(*L-*leuma)*$_2$: Copper(II) hydroxide freshly prepared from 0.87 g of copper(II) sulfate pentahydrate was added to a solution of 1.00 g of L-leumaH in 20 m*l* of water. The mixture was stirred for 30 min. The residual copper(II) hydroxide was then filtered off. The violet solution was concentrated *in vacuo* below 35°C until the brick-red crystals of the desired complex began to separate out. The whole mixture was then dissolved in 40 m*l* of ethanol. The complex was precipitated from the solution by slow addition of ether, and recrystallized from its 99% ethanol solution by addition of ether. The crystals were dried over calcium chloride and then over phosphorus pentoxide *in vacuo*. Yield, 0.73 g (60%).

Found: C, 47.64; H, 8.64; N, 15.61%. Calcd for $C_{14}H_{30}N_4O_2Cu$: C, 48.05; H, 8.64; N, 16.01%.

This complex is soluble in water, methanol, ethanol, and DMF.

Measurements. The instruments and solvents employed for measurements of AB and CD spectra were the same as those reported,[2] except for the Shimadzu MPS-50L spectrophotometer used for AB measurements in Nujol mulls. All the measurements were carried out at room temperature.

Both the hemihydrate and the methanol adduct of *trans*-bis(L-prolinamidato)palladium(II) hardly dissolved into DMF, but the AB and CD spectra of the complex in this solvent could be obtained with material prepared by a method analogous to that for *trans*-bis(L-alaninamidato)-palladium(II).[1] The material dissolved somewhat easily in DMF. It was confirmed from its AB and CD spectra in the aqueous and alcoholic solutions and elemental analysis that it is composed of *trans*-[Pd(L-proa)$_2$] and sodium chloride at a mole ratio of about 3 : 1 (Found: C, 34.24; H, 5.30; N, 15.73; Cl, 2.63%.).

Results and Discussion

Spectral data for the complexes newly prepared are given in Tables 1, 2, and 4—7, and in Figs. 1—7 and 9—14. Supplementary data which were obtained for several complexes previously reported are also included in Tables 1, 2 and 4—7. Discussion in this section will be made in reference to the data given in the previous papers for the bis(L-α-amino-

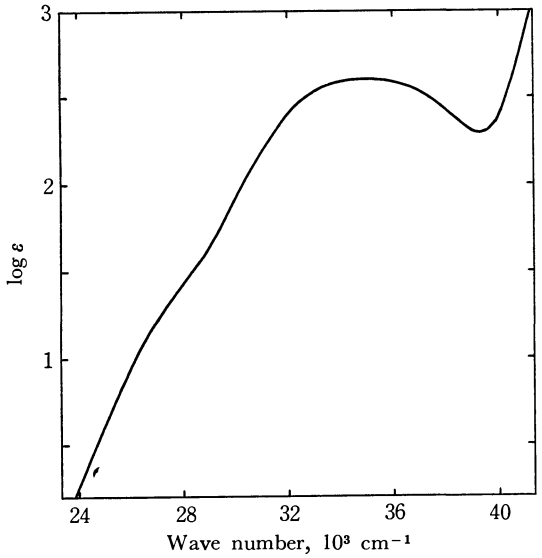

Fig. 1. AB spectrum of [Pd(tndba)] in water.

acid-amidato) complexes. Several AB and CD curves are reproduced in Figs. 5 and 14.

Cis-Trans *Isomerism and Spectral Behavior.* *1) Palladium(II) Complexes*: The absorption spectrum of [Pd(tndba)] given in Fig. 1 and Table 1 is analogous to the spectra of the bis(amino-acid-amidato)palladium(II) complexes, which have been classified into group (B) in Part I.[1] This indicates definitely that the latter complexes have *cis* structures, because the two amino groups of the tndba moiety must be *cis* to each other in the former complex. This is just the conclusion drawn in Part I.[1]

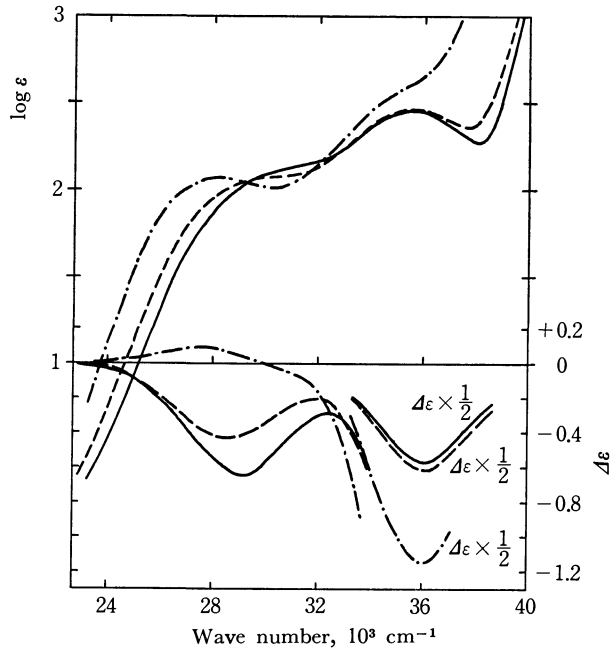

Fig. 2. AB and CD spectra of *trans*-[Pd(L-vala)$_2$] in water (——), in ethanol (----), and in DMF (—·—·).

It was well confirmed by the CD spectra in Table 2, Fig. 4 and Fig. 2 of Ref. 3 that the *trans*-bis(α-amino-acid-amidato)palladium(II) complexes generally have three bands in the ligand field band region: at 26.8—29.2, 31.4—32.3 and 35.5—36.4 kK (kK= 10^3 cm^{-1}). These bands (as well as the corresponding components of AB band) will be called tI, tII and tIII, respectively, in this paper.

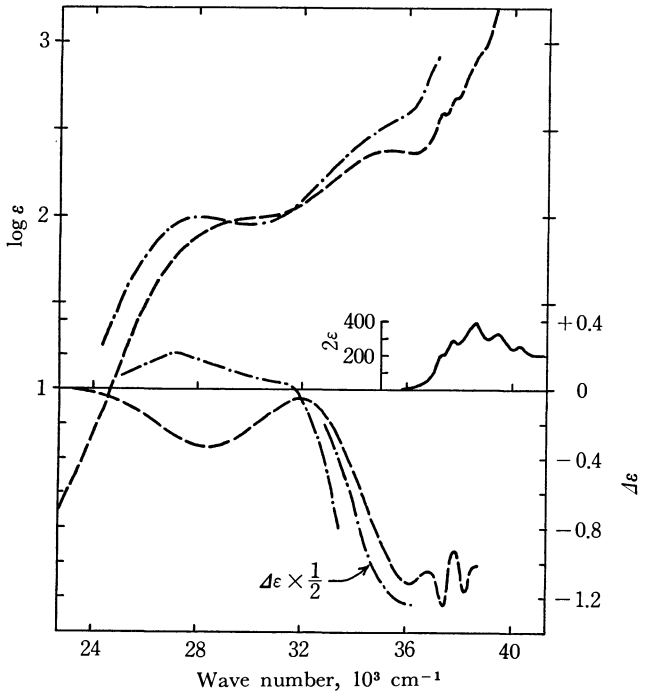

Fig. 3. AB and CD spectra of *trans*-[Pd(L-phalaa)$_2$] in ethanol (———) and in DMF (—·—·), and AB spectrum of L-phalaaH in ethanol (——).

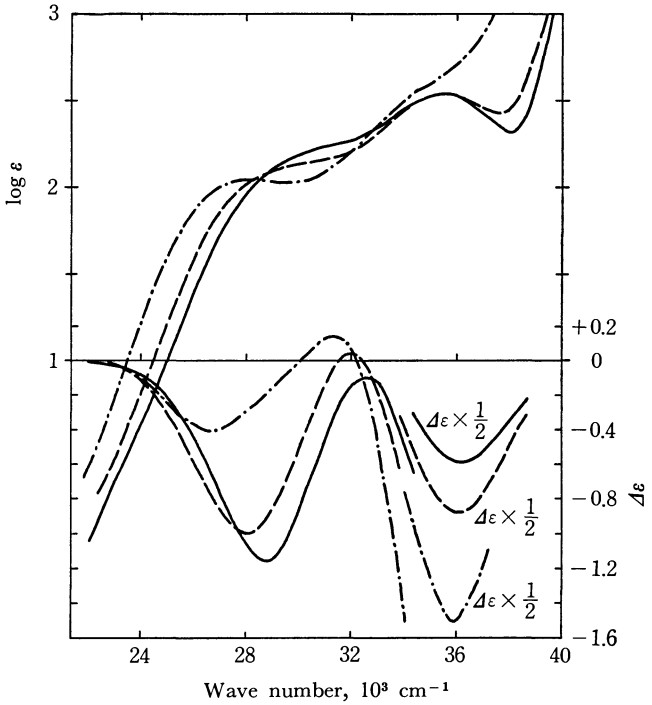

Fig. 4. AB and CD spectra of *trans*-[Pd(L-proa)$_2$] in water (——), in ethanol (———) and in DMF (—·—·).

With respect to the *cis* complexes, four kinds of CD band were observed; these (and the corresponding components of AB band) are labeled c0, cI, cII and cIII as shown in Table 2. Since the situation of the four bands would not differ much among the complexes (Figs. 5—7, and Fig. 2 of Ref. 1), it is conceivable that cII bands are hidden in the CD spectra of all of the *cis* complexes other than the leua complex.

No reliable method for AB and CD band analyses

has so far been established, especially for the bands which contain three or more components with comparable intensities. The results of band analyses given in Table 3 are accordingly somewhat arbitrary, but probable at the present stage since they were obtained from the data for a series of closely related complexes. The molar extinction coefficients estimated for cII and tII are the most unreliable of the numerical values in Table 3 but nevertheless seem to be comparable to those for cI and tI, respectively.

Figure 8 illustrates the general CD behavior exhibited by the palladium complexes as the solvent was changed from water, ethanol to DMF; only a significant deviation from the general CD behavior was found in the cIII band of the proa complex (See Fig. 7).

Two important facts found in Table 3 and Fig. 8 are that characteristics of tI, tII and tIII bands show a close resemblance to those of cI, cII and cIII, respectively, and that the sign inversion for a single CD band is actually caused in the tI and the cIII bands

of a few complexes by change of only the solvent.

2) Nickel(II) Complexes: The CD band with the lowest wave number of the bis(L-amino-acid-amidato)nickel(II) with vala, phalaa or leuma was negative in the alcoholic solution and positive in DMF (Table 5, Figs. 9 and 10, and Fig. 1 of Ref. 3). This is analogous to the behavior exhibited by the tI bands of the *trans* palladium complexes with those ligands (Figs. 2 and 3, and Fig. 2 of Ref. 3). There is a close correspondence between the whole ligand field (AB and CD) spectra of these nickel complexes (Tables 4 and 5) and those of the corresponding *trans* palladium ones. Thus, the three nickel complexes are inferred to be *trans* isomers both in solution and in solid state. It is strongly suggested therefore that the CD band at 24.0 kK corresponds to tIII (Table 5), and the small positive band at 20.8 kK, detected for *trans*-[Ni(L-alaa)$_2$] in methanol,[1] to tII. It may be noted in this connection that the tI CD extrema of the nickel complexes appear to correspond to the AB shoulder (or peak) at about 20.0 kK but that the tIII situates at considerably higher wave number than the AB peak (Tables 4 and 5, Figs. 9—11, Fig. 1 of Ref. 3 and Fig. 4 of Ref. 1).

The CD behavior of the proa complex seems to be an intermediate of the behaviors of the correspond-

ing *cis* and *trans* palladium complexes, in the respective solvents (Fig. 11). The wave numbers of the CD extrema, however, do not differ much from those for the other nickel complexes inferred to be *trans* (Table 5). Moreover, the AB spectrum of the proa complex is very similar to spectra of the *trans* complexes and significantly differs from that of the tndba complex, the structure of which is restricted to *cis*-type (Fig. 12). On the whole, it is concluded that the proa complex is also a *trans* isomer. Thus, no *cis* isomer of bis(amino-acid-amidato)nickel(II) has been found so far.

3) Copper(II) Complexes: The six bis(α-amino-acid-amidato)copper(II) complexes showed a broad ligand field band at 18.7—19.5 kK (log ε= 1.67—1.76, except for the proa complex) in aqueous solution.[2] These complexes are considered to be *trans* or to be predominantly so in aqueous and alcoholic solutions. This conclusion is supported to some extent by the following observations; Cu(tndba) is slightly higher either in its intensity or in the wave number than the bis(amino-acid-amidato) complexes. The former has no vague shoulder at its lower wave number side in contrast to the latter (Fig. 13 and Table 6). The spectral difference between the tndba and the bis(amino-acid-amidato) complexes seems to be analogous to that between *cis* and *trans* complexes of palladium(II) or of nickel(II).

The above and the previous[2] discussion concerning the geometrical structure can be applied also to the copper complex with L-leuma in the aqueous, ethanol, and DMF solutions as well as to all the bis(α-amino-acid-amidato)copper(II) complexes dissolved in DMF. Though the leuma complex exhibits the ligand field band at considerably lower wave numbers than the other bis(L-amino-acid-amidato)copper(II) complexes in respective solvents (Table 6), the red shift can be attributed to an effect of the methyl group attached to the amido nitrogen. Actually, similar shifts were also observed in the corresponding *trans* complexes of palladium and nickel (Tables 1 and 4).

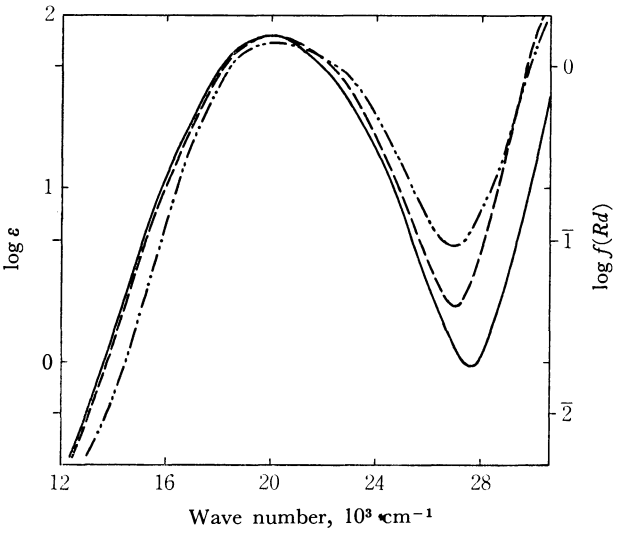

Fig. 13. AB spectrum of Cu(tndba): in water (——), in ethanol (— — —), and in solid state (reflectance, —··—··).

The CD behavior of the bis(L-amino-acid-amidato)-copper(II) complexes is apparently very complicated (Table 7, Fig. 14, and Table 4 of Ref. 2 and Fig. 2 of Ref. 2) in contrast to that of the corresponding nickel or palladium complexes. On the other hand, the shapes and the solvent dependencies of the AB bands of the copper complexes do not differ much from each other (Fig. 14, Fig. 2 of Ref. 2, and Fig. 3 of Ref. 2). It can be accepted that the relative ordering of the components of the band is independent of the kind of ligand. It seems reasonable from an examination of the CD data that the ordering is also independent of the kind of solvent. It is inferred from these considerations that the ligand field band

of the bis(α-amino-acid-amidato)copper(II) complexes generally consists of at least three components which are roughly at 17, 19, and 21—22 kK; these are labeled A, B and C, respectively. Only the leuma complex seems to exhibit each of the three components at lower wave numbers by 0.5—1 kK than the other complexes (Fig. 14b).

A very small positive CD band which is seriously eclipsed by large negative ones was observed at about 14 kK for the copper complexes with L-vala, L-phalaa and L-proa (Figs. 14a and 14c, and Fig. 2 of Ref. 2). The reflectance spectrum of $Cu(L\text{-proa})_2\cdot 2H_2O$ reveals a weak but distinct shoulder at about 13 kK.[2,9] Similar CD bands have been found for bis(L-aminoacidato)copper(II) complexes.[10]

The CD behavior of the proa complex is somewhat specific as discussed in Part II[2] but more or less resembles that of the leuma or of the phalaa complex as demonstrated in Fig. 14.

Nature of the Ligand Field Band. The *trans* palladium as well as the *trans* nickel complexes have three components in the ligand field band; each of the components exhibits a behavior common to both palladium and nickel complexes. Thus, each band labeled tI, tII or tIII for both complexes should be assigned to a common *d–d* transition. Such was the case in the tentative assignment made in Part I.[1] On the other hand, a new kind of CD band, cII, was found in this work for the *cis* palladium complexes other than those previously reported. This requires us to reconsider the band assignment for both *cis* and *trans* palladium complexes.

Three of the possible assignments are listed as the preferable ones in Table 8; the bands labeled with the same Roman numeral are assigned to the transitions derived from a certain transition in D_{4h} symmetry, in each possible assignment of the three, because those bands show a very similar behavior to

9) If the AB and CD bands at 13—14 kK were neither of A, Bnor C, it should be assigned to ν_1; see footnote 11 and the following discussion.

10) T. Yasui, This Bulletin, **38**, 1746 (1965); T. Yasui, J. Hidaka, and Y. Shimura, *J. Amer. Chem. Soc.*, **87**, 2762 (1965).

each other. The assignment for the *trans* complexes in Part I[1] is revived in assignment (1), whereas that for *cis* complexes in (2) apart from cII. However, another possibility (3) is not so easily omitted. The c0 band is assigned to a spin-forbidden transition in every case for the following reasons (*cf.* Ref. 1). First, it has a significantly lower absorption coefficient than the other bands (Table 3). Secondly, it is very unlikely that the band is assigned to ν_1',[11] because it scarcely ever shifts by change of the solvent. Thirdly, it seems that the three bands of the *trans* complexes are reasonably assigned to ν_2, ν_3, and ν_4. From this it follows that ν_2', ν_3', and ν_4', are to be assigned to the three bands other than c0 in the *cis* complexes.

Table 8. Possible band assignments for the palladium and the nickel complexes

Band	Possible assignments[a,b]		
	(1)	(2)	(3)
tI	ν_3	ν_2	ν_2
tII	ν_2	ν_1	ν_3
tIII	ν_4	ν_3, ν_4	ν_4
c0	sf	sf	sf
cI	ν_3'	ν_2'	ν_2'
cII	ν_2'	ν_1'	ν_3'
cIII	ν_4'	ν_3', ν_4'	ν_4'

a) For the definition of the transitions, see footnote 11.
b) sf=a spin forbidden transition.

Let us examine the validity of each of the three assignments. If assignment (2) were valid, the spectral data would indicate that ν_1 is more slightly shifted than ν_2 as the solvent is changed. This is unlikely under a simple ligand field theory. Moreover, the three bands of the *trans* complexes seem to be reasonably assigned to ν_2, ν_3, and ν_4 since only ν_1 is magnetic dipole forbidden.[12] Thus assignment (2) seems unreasonable. Next, assignment (3) is in conflict with the theoretical expectation that the splitting energies would be influenced most seriously between (xz) and (yz) orbitals by the *cis-trans* isomerism. In conclusion, assignment (1) is the most preferable, but still does not seem unambiguous. A similar assignment has been given for bis(β-ketoenolato) copper(II) complexes.[13]

It can be roughly estimated that contributions of interelectronic repulsion energy are less by 3B to ν_3 and ν_4 than to ν_2, where B is Racah's parameter. If assignment (1) is valid, the energy difference $\nu_2-\nu_3$ can be estimated from the experimental results to be some 1000 cm^{-1} for the nickel complexes; this may be smaller than 3B.[14] It is therefore likely that the contributions of ligand field energy to respective transitions are in the order $\nu_2<\nu_3<\nu_4$ for the nickel complexes. The energy order is expected to be realized in the electronic spectra of the corresponding copper complexes as it is, because there is no contribution of interelectronic repulsion energy to any transition in the d^9 chromophore. With respects to the copper complexes, all the A, B and C bands seem to be magnetic dipole allowed. Actually, the largest CD band is A or C in the complexes with phalaa, proa and leuma (Fig. 14), whereas B in those with alaa, leua and vala. Thus three bands A, B, and C may be tentatively assigned, to ν_2, ν_3, and ν_4, respectively.[9] Definitive assignment of ligand field bands has not been given in the CD studies of the copper(II) complexes with optical active amino acids and peptides.[10,15]

The Benzenoid Absorption. A typical band series of phenyl groups was observed in 38000 cm^{-1} (260 mμ) region in both AB and CD spectra of *trans*-bis(L-phenylalaninamidato)palladium(II) in ethanol. These spectra are given in Fig. 3, together with the AB spectrum of L-phenylalaninamide in ethanol (10 mM), and the numerical data in Table 1 and 2. Measurements of the CD spectra were carefully repeated both for the complex and for the ligand, but for the latter $|\Delta\varepsilon|$ was too small ($\lesssim$0.03) in this region to give reliable results. The AB and CD spectra were also measured in an ethanol solution containing the ligand (10 mM) and sodium ethoxide (10 mF). The results, however, were indistinguishable from those without alkali. Though the benzenoid absorption of the complex is overlapped by the other absorption, it seems to be scarcely affected by the complex formation. We conclude from this observation that there is no first order interaction between the phenyl π and the metal d orbitals in the complex. Thus, we exclude the possibility that apical coordination of the phenyl groups exists and causes the about ten times enhanced CD of the benzenoid absorption in the complex.

The 32000 cm^{-1} Band of [Ni(tndba)]. The electronic spectrum of [Ni(tndba)] shows another weak band at about 32000 cm^{-1} (Fig. 12). This band shifted to lower wave numbers when the solvent was changed from water to ethanol. It became slightly more intense when the ethanol solution was diluted (Fig. 12b). Its peak is at a wave number about 9000 cm^{-1} higher than that of the main ligand field band maximum. These characteristics are very similar to those of Band II of bis(α-amino-acid-amidato)copper(II) complexes described in Part II,[2] and hence these two kinds of band seem to have a common origin. However, the following facts appear

11) ν_1, ν_2, ν_3, and ν_4 mean transitions from (z^2), (xy), (xz) and (yz) to (x^2-y^2), and ν_1', ν_2', ν_3' and ν_4' mean those from (z^2), (x^2-y^2), (xz) and (yz) to (xy), respectively, where (k) means a molecular orbital composed mainly of d_k-orbital. The x axis is fixed to be nearly colinear with metal-N(amido) linkage in the *trans* complex, but to bisect N-metal-N angle within each chelate ring in the *cis* complex. The y axis is fixed also within coordination square in both *trans* and *cis* complexes.

12) ν_1 can become magnetic dipole allowed by configuration interaction or mixing of p-orbitals under C_2 symmetry.

13) F. A. Cotton and J. J. Wise, *Inorg. Chem.*, **6**, 917 (1967).

14) The value of B in gaseous Ni^{2+} ion is 1041 cm^{-1}, C. K. Jørgensen, "Absorption Spectra and Chemical Bonding in Complexes," Pergamon Press, Oxford (1962), p. 137.

15) J. M. Tsangaris and R. B. Martin, *J. Amer. Chem. Soc.*, **92**, 4255 (1970).

to be somewhat in conflict with this conclusion: Such a kind of band has not been observed in either the *trans*-bis(α-amino-acid-amidato)nickel(II) complexes or in Cu(tndba), and the intensity of the band of [Ni(tndba)] was not so seriously dependent on concentration and on the kind of solvent (including solid state) as in Band II of the copper complexes.

The authors thank Dr. Seiko Komorita for measurements of the AB spectra in Nujol mulls.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3363—3366 (1971)

The Solvent Effect on the Electron-Transfer Reactions of Cobalt(III) Complexes. The Reduction of the *cis*-Chloro-2-aminoethanolbis(ethylenediamine)cobalt(III) Ion by Iron(II) in Aqueous Solutions of Organic Solvents

Kousaburo Ohashi, Katsumi Yamamoto, Toshio Suzuki, and Yoshimi Kurimura*

Department of Chemistry, Ibaraki University, Mito, Ibaraki

**College of General Education, Ibaraki University, Mito, Ibaraki*

(Received April 7, 1971)

The solvent effect on the reduction of the *cis*-chloro-2-aminoethanolbis(ethylenediamine)cobalt(III) ion by iron(II) was investigated in aqueous solutions of dimethylsulfoxide (DMSO), dimethylformamide (DMF), ethanol, and acetone. The second-order rate constants for the reduction are 4.4×10^{-5} M^{-1}sec^{-1} in the absence of an organic solvent, 1.4×10^{-3} M^{-1}sec^{-1} in 0.20 M_f DMSO, 7.3×10^{-4} M^{-1}sec^{-1} in 0.20 M_f DMF, 1.1×10^{-4} M^{-1}sec^{-1} in 0.20 M_f ethanol, and 1.0×10^{-4} M^{-1}sec^{-1} in 0.20 M_f acetone, at 25°C and at 0.16 M $HClO_4$ and $\sum[ClO_4^-]=0.60$ M (M_f=mol fraction of organic solvent). From the kinetic and spectral data, it is suggested that the increase in the rate upon the addition of an organic solvent may be mainly due to a change in the solvation sphere of the reductant by replacing the water molecules by the organic molecules.

Systematic kinetic investigations of the reductions of the cobalt(III) complexes in the organic solvents and in the organic solvent-water mixtures would provide important information regarding the mechanism of the electron-transfer reactions. Relatively few papers have been reported, however, on the effect of a solvent on the electron-transfer reactions of the metal complexes.

The exchange reactions between $Co(phen)_3^{2+}$ and $Co(phen)_3^{3+}$ in acetone-water[1] and that between iron(II) and iron(III) in isopropanol-water,[2] acetone-water,[3] methanol-water,[3] ethanol-water,[3] 1-propanol-water,[3] and dimethylsulfoxide-water[4] have been investigated. The rates of all these reactions decrease with an increase in the concentrations of the organic solvents.

In some organic solvent-water mixtures, it was found by the present authors that the rates of the reductions of some Co(III)-chloro complexes by iron(II) increase with an increase in the concentration of the nonaqueous solvent, such as dimethylsulfoxide (DMSO), dimethylformamide (DMF), ethanol, and acetone.

In this connection, a rate study of the reduction of the *cis*-chloro-2-aminoethanolbis(ethylenediamine)-cobalt(III) ion by iron(II) was done in organic solvent-water mixtures so as to obtain some information about the effect of the solvent on the electron-transfer reactions.

Experimental

Preparation of Complex. The *cis*-chloro-2-aminoethanolbis(ethylenediamine)cobalt(III) chloride used as the oxidant was prepared in a manner previously reported.[5] The identity and purity of the complex were confirmed analytically and spectrophotometrically. Found: C, 20.68; H, 6.51; N, 20.91. Calcd for $[Co(en)_2(NH_2CH_2CH_2OH]-Cl]Cl_2$: C, 20.79; H, 6.68; N, 20.21.

Materials. Dimethylsulfoxide and dimethylformamide of a spectroscopic grade (Tokyo Kasei) were distilled under reduced pressure. Ethanol and acetone of G. R. grade (Tokyo Kasei) were distilled two times before use.

The preparation of the iron(II) solution and the determinations of the concentrations of hydrogen and perchlorate ions in this solution were carried out by a method similar to that described previously.[6] All the other chemicals used were of a G. R. grade and were used without further purification. The ionic strengths of the solutions were adjusted by the addition of sodium perchlorate solution.

Kinetic Runs. Erlenmeyer flasks containing appropriate amounts of redistilled water, the iron(II) solution, an organic solvent, and a dry complex respectively were kept in a thermostat. The desired volumes of redistilled water and organic solvent were added to the flask containing the dry complex, and the resulting solution was kept in a thermostat for about 30 min. Then, appropriate amounts of the iron(II) solution were added to this solution. A por-

tion of the reaction mixture was transferred rapidly into a 1-cm optical cell placed in a thermostated cell compartment of a Hitachi Model 124 spectrophotometer. The variation in the absorbance of the reaction mixture was recorded automatically in the vicinity of the first absorption maximum of the cobalt(III) complex. The wavelength used for the rate determination was 534 nm.

In all the experiments, the reactions were followed under pseudo-first-order conditions, in which the iron(II) concentration was in great excess with respect to that of the cobalt(III) complex. The pseudo-first-order rate constants, k_p, were calculated from the slope of the log (A_t-A_∞) *vs.* time plots, where A_t and A_∞ are the absorbances at time t and after all the cobalt(III) is reduced to cobalt(II) respectively.

Results

Reduction of cis-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ *in an Aqueous Solution.* The pseudo-first-order plots for the iron(II) reduction are shown in Fig. 1. The second-order rate constant, k, for the reaction can be obtained from the slope of the log (A_t-A_∞) *vs.* time plot and a known value of the iron(II) concentration, which is essentially constant under the conditions employed.

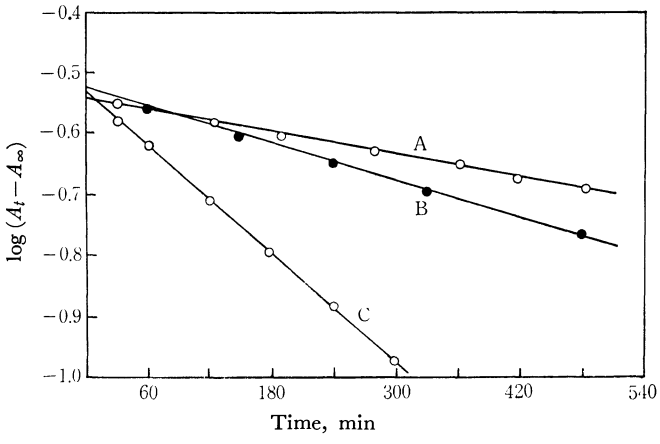

Fig. 1. The pseudo-first-order plots for the reactions of *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ with iron(II) in ethanol-water mixtures.
$[Fe(II)]=0.210$ M, $\sum[ClO_4^-]=0.60$ M, $[HClO_4]=0.16$ M, 25 ± 0.1°C.
A : aqueous solution, $[Co(III)]=4.30\times10^{-3}$ M.
B : 0.20 mol fraction of ethanol, $[Co(III)]=4.62\times10^{-3}$ M.
C : 0.56 mol fraction of ethanol, $[Co(III)]=4.48\times10^{-3}$ M.

Figure 2 shows the dependence of the k_p value on the concentration of iron(II) in aqueous solutions. The linear behavior shown in Figs. 1 and 2 indicates that the rate equation can be expressed by:

$$-\frac{d[Co(III)]}{dt}=k[Co(III)][Fe(II)] \quad (1)$$

The effect of the hydrogen-ion concentration on the rate was examined at a given ionic strength of 0.60 in aqueous solutions. The results indicate that the second-order rate constant is independent of the hydrogen-ion in the concentration region between 0.14 M to 0.43 M.

The effect of the ionic strength on the rate was also examined at a given hydrogen-ion concentration.

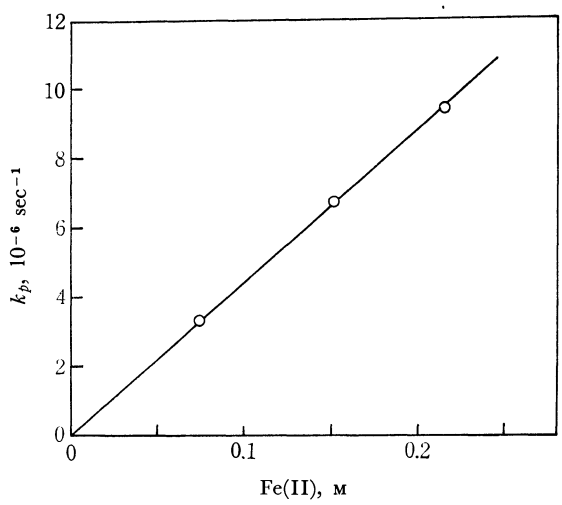

Fig. 2. The dependence of the pseudo-first-order rate constant for the reduction of *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ in aqueous solutions upon iron(II) concentration.
$[Co(III)]=4.30\times10^{-3}$ M, $\sum[ClO_4^-]=0.60$ M, $[HClO_4]=0.16$ M, 25 ± 0.1°C.

Table 1. Effect of ionic strength on the second-order rate constants for the reduction of *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ by iron(II) in aqueous solutions

$\sum[ClO_4^-]$	Rate constant[a] M^{-1} sec^{-1}
0.60	4.38×10^{-5}
1.0	5.07×10^{-5}
2.0	5.78×10^{-5}

a) $[Co(III)]=5.40\times10^{-3}$ M, $[Fe(II)]=0.18$ M, $[HClO_4]=0.20$ M, 25 ± 0.1°C.

A relatively small increase in the rate with an increase in the ionic strength was observed in the hydrogen-ion concentration region investigated. The results are shown in Table 1.

The rate constants and activation parameters for the reduction in an aqueous solution are represented in Table 2, along with the values obtained in an ethanol-water mixture.

Reduction of cis-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ *in Some Organic Solvent-Water Mixtures.* The reduction of the Co(III) complex in DMSO-water, DMF-water, ethanol-water, and acetone-water mixtures also obeys the rate expression (1) under the experimental conditions employed.

The second-order rate constants and activation parameters for the reduction at various mol fractions of ethanol are listed in Table 2. With the addition of ethanol to an aqueous solution, the values of the rate constants, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ increase gradually. Such a trend in the rate constants and activation parameters was also observed in the other organic solvent-water mixtures investigated.

The variations in the rate constants with the mol fraction of the organic solvent are illustrated in Fig. 3. In all cases, especially in the cases of DMSO-water and DMF-water, a marked increase in the rates with an increase in the mol fraction of organic

Table 2. The rate constants and activation parameters for the reduction of *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ in ethanol-water mixtures at 25±0.1°C

0.074	7.19×10^{-5}	14.6	23.2	−33.8
0.20	1.12×10^{-4}	15.5	22.8	−30.6
0.32	1.65×10^{-4}	17.8	22.6	−25.6
0.56	3.72×10^{-4}	21.2	22.1	−17.8

a) $[Co(III)]=4.01\times10^{-3}$ M, $[Fe(II)]=0.21$ M, $\sum[ClO_4^-]=0.60$ M, $[HClO_4]=0.16$ M.

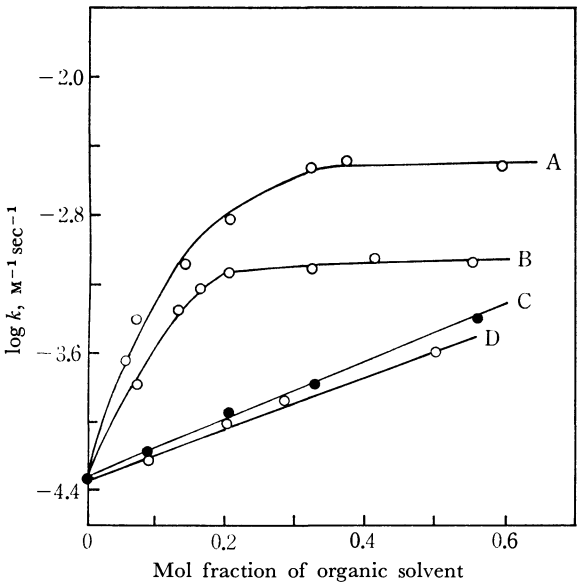

Fig. 3. The plots of logarithmic second-order rate constant *vs.* mol fraction of organic solvent.
$[Co(III)]=4.30\times10^{-3}$ M, $[Fe(II)]=0.086$—0.210 M, $\sum[ClO_4^-]=0.60$ M, $[HClO_4]=0.16$ M, 25±0.1°C
A : dimethylsulfoxide—water
B : dimethylformamide—water
C : ethanol—water
D : acetone—water

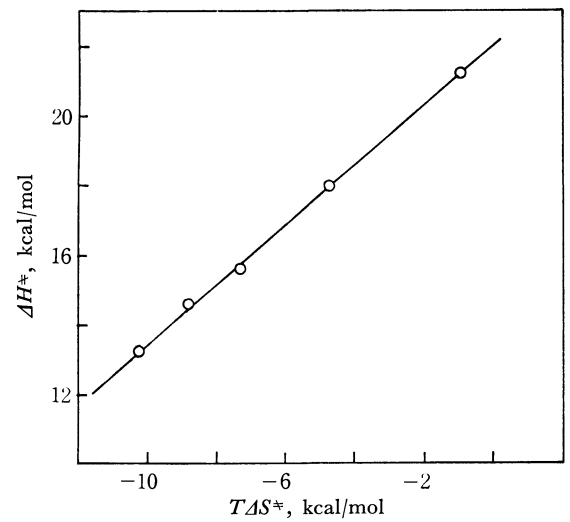

Fig. 4. A plot of $\Delta H^{\neq}$ *vs.* $T\Delta S^{\neq}$ for the iron(II) reduction of *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ in aqueous solution of ethanol.
$\sum[ClO_4^-]=0.60$ M, $[HClO_4]=0.16$ M, 25°C.

solvent is to be seen in this figure. A plot of $\Delta H^{\neq}$ *vs.* $T\Delta S^{\neq}$ at 25°C for the reaction in the ethanol-water mixture gives a straight line with a slope of about 0.85 (Fig. 4). This seems to indicate that there is a certain degree of compensation effect between $\Delta H^{\neq}$ and $T\Delta S^{\neq}$.

Absorption spectra of Ferric Perchlorate in Several Organic Solvent-Water Mixtures. In Fig. 5, the absorption spectra of ferric perchlorate in DMSO-water mixtures are represented. The absorbances of the ferric perchlorate solutions in the mixtures of DMSO, DMF, ethanol, and acetone with water in 0.20 M perchloric acid solutions are plotted as a function of the mol fraction of the organic solvent (Fig. 6). It is apparent from these curves that the addition of DMSO, DMF, ethanol, or acetone to an aqueous solution of ferric perchlorate increases the absorbance of the solution

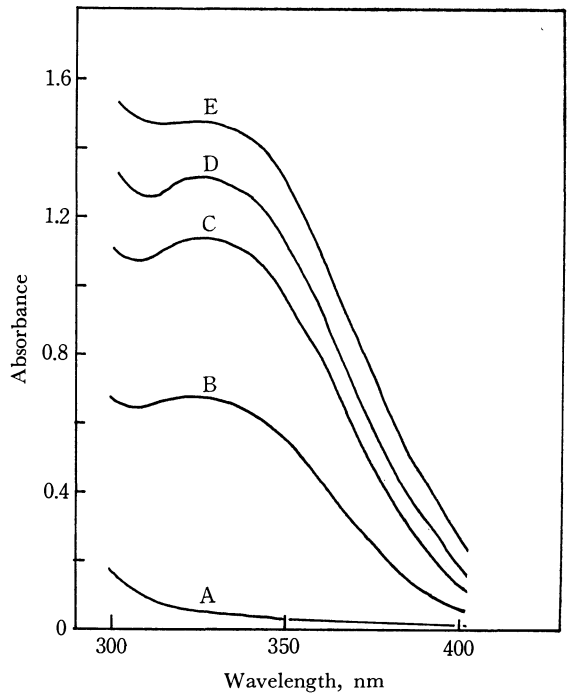

Fig. 5. Absorption spectra of ferric perchlorate in aqueous solution of dimethylsulfoxide.
$[Fe(III)]=1.60\times10^{-5}$ M, $\sum[ClO_4^-]=0.20$ M, $[HClO_4]=0.20$ M, 25°C.
A : aqueous solution.
B : 0.06 mol fraction of dimethylsulfoxide.

at wavelengths in the vicinity of 350 nm. Such increases in absorbance were also observed previously upon the addition of some alcohols to an aqueous solution of ferric perchlorate.[2,7]

Discussion

The facts that the rate of iron(II) reduction of the *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ is essentially independent of the hydrogen-ion concentration and that the rate is only slightly dependent upon the ionic strength of the solution seem to indicate that the marked increase in the rates with an increase in the concentration of the organic solvent in the organic solvent-water mixtures can not be due mainly to an alternation of the effective hydrogen ion concentration or that of the ionic strength in the media by the addition of organic solvents to aqueous solutions.

The ferrous-ferric exchange reaction proceed about 10^8 times slower in isopropyl alcohol than in water.[2] No specific explanation can be given for this results, however, it has been suggested that the predominant ferrous and ferric species may be quite different in the two solvents.[2] If the reactions have larger differences in configuration in isopropyl alcohol than in water, the reorganization energy may be much greater in alcohol.[2]

Because the coulombic repulsion free energy and outer-sphere reorganization free energy would be increased by a decrease in the macroscopic dielectric constant, and because the macroscopic dielectric constant is decreased with an increase in the organic solvent content, it may be supposed that the rate of the electron-transfer reaction between metal complexes is generally slower in organic solvents than in water, assuming that the same ionic species are present in the two solvents.[8]

In the present system, the anomalous increase in the rate upon the addition of an organic solvent to aqueous solution could not be explained by the effects of coulombic and outer-solvation-sphere reorganization free energy. The addition of an organic solvent to an aqueous solution of ferric perchlorate increases the absorbance of the solution. This increase is similar to that observed on the addition of other alcohols to aqueous solutions of ferric perchlorate.[7] This seems to suggest that some of the water molecules in the coordination-sphere of the ferric ion are replaced by organic solvent molecules. It may be supposed as was mentioned by Sutin,[2] that if the ionization potentials of the organic solvents used here are less than that of water, it would be easier to remove an electron from the solvation shell if the shell contains such organic molecules. This would shift the absorption band of the ferric perchlorate solution toward a longer wavelength and increase the absorbance in the vicinity of 350 nm.[2] Such a replacement of the water molecules by the organic molecules may also be expected in the case of the ferrous perchlorate solution by the addition of an organic solvent to the aqueous solution. In fact, it was suggested that, in a DMSO-water mixture at a higher water concentration, the mixed-ligand complexes, $Fe(DMSO)_{6-n}(H_2O)_n^{2+,3+}$,[4] and in pure DMSO, the DMSO complexes, $Fe(DMSO)_6^{2+,3+}$,[9] are important. On the other hand, the replacement of the ligands in the *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ by the organic molecules during the reaction may be ignored because of the inertness of this complex. The increase in the rate for the present reaction in the organic solvent-water mixtures seems to be contrary in trend to the cases of the electron-exchanges reactions between $Co(phen)_3^{2+}$ and $Co(phen)_3^{3+}$ [1] and iron(II) and iron(III).[4] However, the change in the coordination sphere in the ferrous ions would be one of the most important reasons for the increase in the reactivity upon the addition of organic solvent to the aqueous solutions.

In acidified organic solvent-water mixtures, the main species of iron(II) may be present in the $Fe(OH_2)_{6-a}(OS)_a^{2+}$ form, where OS is the organic solvent molecule. The overall reaction may be given by:

$$cis\text{-}Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+} + Fe(OH_2)_{6-a}(OS)_a^{2+} \rightarrow Co^{2+} + 2en + NH_2CH_2CH_2OH + Cl^- + Fe(III) \quad (2)$$

Although the electron-transfer reaction between *cis*-$Co(en)_2(NH_2CH_2CH_2OH)Cl^{2+}$ and iron(II) would proceed *via* a chloride-bridged activated complex in aqueous solutions,[10] the mechanism for reaction (2) in the organic solvent-water mixtures would not necessarily be same as that for the reaction in aqueous solution.

Electron-Transfer Reactions of Multidentate-ligand Cobalt(III) Complexes. III. The Reductions of Several Chloro- and Bromo(nitrilopolycarboxylato)-cobaltate(III) Ions by Iron(II)

Yoshimi KURIMURA, Ikuko MEGURO,* and Kousaburo OHASHI*

College of General Education, Ibaraki University, Mito

**Department of Chemistry, Ibaraki University, Mito*

(Received April 16, 1971)

The reductions of chloro- and bromo(ethylenediaminetriacetatoacetic acid)cobaltate(III), chloro- and bromo(*N*-hydroxyethylethylenediamine-*N*,*N*′,*N*′-triacetato)cobaltate(III), and dichloro(ethylenediaminediacetato)cobaltate(III) ions by iron(II) in perchloric acid solutions obey the second-order rate expression: $-\mathrm{d}[\mathrm{Co(III)}]/\mathrm{d}t = k_c[\mathrm{Co(III)}][\mathrm{Fe^{2+}}]$. The second-order rate constants, k_c, and activation parameters for these reactions were determined spectrophotometrically. For the cases of all the Co(III) complexes investigated, an increase in the rate constant with the hydrogen-ion concentration at a constant ionic strength is expressed by: $\log k_c = \log k_0 + A[\mathrm{H^+}]$, where k_0 and A are constants for the given complex at a constant ionic strength and temperature. The hydrogen-ion dependence can be explained by the difference in the degree of stabilization of the Co(III) anion between that by hydrogen ions and that by sodium ions.

In previous papers, the results of kinetic studies of the electron-transfer reactions of the cobalt(III) complexes of the $CoN_4Cl_2^+$, $CoN_4OH_2Cl^{2+}$ [1] ($N_4=(NH_3)_4$, $(en)_2$, and trien[2]) and CoN_5Cl^{2+} [3] ($N_5=(NH_3)_5$ and tetren[4]) types have been reported. In these studies, the effect of nonbridging ligands on the electron-transfer process were of major interest.

Haim and Sutin[5] found that iron(II) reductions of $Co(HY)Cl^-$ (Y^{4-}=ethylenediaminetetraacetate) proceeds by means of a chloride-bridged inner-sphere mechanism. The behavior of the reaction of $Co(HY)Cl^-$ with iron(II) has also been investigated by Pidcock and Higginson.[6] No kinetic studies of the other monohalogeno- and dihalogeno(nitrilopolycarboxylato)cobaltate(III) complexes have been published, however; the present work on the reaction kinetics was undertaken in order to establish the features of the reaction mechanism.

Experimental

Materials. The stock solution of iron(II) perchlorate was prepared by dissolving iron wire (Mallinckrodt Co. Anala R quality) in a dilute perchloric acid solution. The concentrations of the iron(II), perchrolate, and hydrogen ions were determined by methods similar to those previously reported.[1] All the other reagents used for the preparation of the stock solutions were of a guaranteed reagent quality. Redistilled water was used for the preparation of the reaction mixture.

Preparations of Cobalt(III) Complexes. Sodium chloro- and bromo(ethylenediaminetriacetatoacetic acid)cobaltate(III) (Na[Co(H·EDTA)Cl][7] and Na[Co(H·EDTA)Br][8]), sodium chloro- and bromo(*N*-hydroxyethylethylenediamine *N*,*N*′,*N*′-triacetato)cobaltate(III) (Na[Co(EDTAOH)Cl],[7] and Na[Co(EDTAOH)Br][8]) were prepared by methods similar to those described in the references cited.

Found: C, 28.76; H, 3.82; N, 6.36%. Calcd for Na[Co(H·EDTA)Cl]·0.5H_2O: C, 28.90; H, 3.40; N, 6.74%.

Found: C, 25.29; H, 3.57; N, 5.83%. Calcd for Na[Co(H·EDTA)Br]·H_2O: C, 25.61; H, 3.22; N, 5.97%.

Found: C, 28.59; H, 4.41; N, 6.46%. Calcd for Na[Co(EDTAOH)Cl]·1.5H_2O: C, 28.62; H, 4.32; N, 6.68%.

Found: C, 27.74; H, 4.35; N, 6.29%. Calcd for Na[Co(EDTAOH)Br]·H_2O: C, 26.39; H, 3.77; N, 6.16%.

Sodium dichloro(ethylenediaminediacetato)cobaltate(III). $CoCl_2\cdot 6H_2O$ (4.6 g) and ethylenediaminediacetic acid (3.6 g) were dissolved in 100 m*l* of water. A sodium hydroxide solution (1.6 g in 50 m*l* of water) was then added to the solution, and the Co(II) was oxidized by the addition of 20 m*l* of a 30% hydrogen peroxide solution. Dark blue crystals were obtained after the addition of 100 m*l* of concentrated hydrochloric acid; they were recrystallized from alcohol-water.

Found: C, 22.31; H, 3.49; N, 8.97%. Calcd for Na[Co(EDDA)Cl_2]: C, 22.04; H, 3.08; N, 8.57%.

The electronic spectral data for the complexes are included in Table 1.

Table 1. Spectral data for cobalt(III) complexes

Na[Co(EDDA)Cl_2]	599	246

a) First absorption maximum.

Kinetic Measurements. The cobalt(III) and iron(II) solutions, both of which contained the necessary amounts of perchloric acid and sodium perchlorate, were kept in a thermostat. The desired volume of the iron(II) solution was then added to the cobalt(III) solution, the solution was transferred to a 1-cm cell which had been placed in a thermostated cell compartment of a Hitachi Model 125 Recording Spectrophotometer, and the absorbance of the reaction mixture in the vicinity of the absorption maximum for the cobalt(III) complex was recorded as a function of the time. Most of the experiments were carried out under second-order conditions. The second-order rate constants,

k_c, for each run were evaluated from the slopes of the usual second-order plots. Some of the Co(EDTAOH)Br$^-$ kinetic runs were carried out under pseudo-first-order conditions. The pseudo-first-order rate constants, k_n, were evaluated from the slopes of the log (A_t-A_∞) *vs.* time plots, where A is the absorbance at time t, and A_∞, the absorbance after all the Co(III) has been reduced to Co(II). The second-order rate constant, k_c, was calculated from the equation $k_c=k_n/[Fe^{2+}]$. For the cases of all the cobalt(III) complexes, the rates of the aquations of the complexes could be neglected as compared to those of the reductions.

Results

Rate Studies at a Given Hydrogen Ion Concentration. In all the cases investigated, the reductions of the Co(III) complexes by iron(II) followed the rate law of $-d[Co(III)]/dt=k_c[Co(III)][Fe^{2+}]$, good second-order plots being obtained in up to 80—95% of the reactions. In addition, all the values of k_c were essentially constants for he given cobalt(III) complex in the region of initial concentrations of iron(II) from 0.0462 to 0.0982 M at a particular hydrogen ion concentration and ionic strength. The second-order rate constants at $[H^+]=0.10$ M and $\Sigma[ClO_4^-]=1.0$ M and at 25°C are summarized in Table 2, along with the activation parameters, which were obtained from temperature dependence of the k_c.

TABLE 2. SECOND-ORDER RATE CONSTANTS[a] AND ACTIVATION PARAMETERS[a] FOR THE REDUCTIONS OF CoZCl$^-$ [b] BY Fe^{2+}

Complex	k_c $M^{-1}sec^{-1}$	$\Delta H^{\neq}$ kcal mol^{-1}	$\Delta S^{\neq}$, eu
Co(H·EDTA)Cl$^-$	1.52[c]	7.8	−31
Co(H·EDTA)Br$^-$	1.23	7.0	−35
Co(EDTAOH)Cl$^-$	1.65	7.5	−33
Co(EDTAOH)Br$^-$	0.73	6.3	−38
Co(EDDA)Cl_2^-	2.36	11	−20

a) Evaluated at $[H^+]=0.10$ M and $\Sigma[ClO_4^-]=1.0$ M and at 25°±0.1°C in $HClO_4$-$NaClO_4$ mediums.
b) Z=H·EDTA^{3-}, EDTAOH^{3-} and EDDACl^{3-}.
c) Rate constant obtained by A. Haim and N. Sutin[5] is 1.9 ± 0.2 $M^{-1}sec^{-1}$ at 25°C, $\Sigma[HClO_4]=2.2$—2.8 M and ionic strength of 3.0 M.

Dependence of the Rate Constant on the Hydrogen-ion Concentration. The hydrogen-ion dependence of the rate constant was examined in the $HClO_4$–$NaClO_4$ medium, in which the ionic strength was maintained at 1.0 M. The values of k_c are slightly increased with an increase in the hydrogen-ion concentration in all cases. The values of the second-order rate constants were found to vary with the hydrogen-ion concentration according to the equation:

$$\log k_c = \log k_0 + A[H^+] \quad (1)$$

where k_0 and A are constants for a given complex and at a constant ionic strength and temperature. The values of log k_c are plotted as a function of the hydrogen-ion concentration in Fig. 1. The k_0 and A values could be obtained from the intercept and slope of the log k_c *vs.* $[H^+]$ plot respectively. These values are summarized in Table 3.

Discussion

It has been demonstrated from a direct observation of the transient species of the primary product that the reaction of Co(H·EDTA)Cl$^-$ with Fe^{2+} proceeds *via* a chloride-bridged transition state.[5] Therefore, it is reasonable to assume that the reactions of CoZCl$^-$ (Z=H·EDTA^{3-}, EDTAOH^{3-}, and EDDACl^{3-}) and perhaps CoZBr$^-$ with iron(II) proceed *via* the chloride- and bromide-bridged mechanisms respectively. Such an inner-sphere reaction may be regarded as proceeding through the formation of a bridged activated complex such as $[Co^{III}Z\cdots Cl\cdots Fe^{II}]$.[5] The initial products of the Co(II) and Fe(III) may be the Co(II)-aminopolycarboxylic acid complex and $FeCl^{2+}$ [5] respectively; these substances are unstable and rapidly form Co^{2+} and the Fe(III)-aminopolycarboxylic acid complex respectively under the conditions employed.

The similar effectiveness for the Co(H·EDTA)Cl$^-$ and Co(EDTAOH)Cl$^-$ complexes, and also that for the Co(H·EDTA)Br$^-$ and Co(EDTAOH)Br$^-$ complexes, seem to suggest that there is no appreciable change in the relative effectiveness by replacing the protonated carboxyl group in the Co(H·EDTA)X$^-$ (X=Cl$^-$ and Br$^-$) complex by a $-CH_2OH$ group. The Co(H·EDTA)Br$^-$ and Co(EDTAOH)Br$^-$ complexes are less reactive than the respective corresponding chloride complexes. The smaller effectiveness for the Co(III)-bromo complex compared with that of the corresponding Co(III)-chloro complex has been known in the reduc-

tions of the Co(III) complexes by low reactive reducing agents, such as Fe(II)[9,10] and Eu(II).[11,12] The bridging efficiency seems to depend primarily upon the nature of the reducing agent. This may indicate that the stabilization of the transition state by bond making to the reductants may be of greater importance than bond breaking for the reductants in the reactions investigated.[12]

The higher reactivity for the $Co(EDDA)Cl_2^-$ complex relative to the other complexes investigated may be due to existence of two chloride ions in this complex.

A rate dependence on the hydrogen-ion concentration similar to that expressed by Eq. (1) has been proposed by Pidcock and Higginson,[6] and also there is much experimental evidence for such hydrogen-ion dependence.[6] They ascribed the relatively small increase in the rate constant with an increase in the hydrogen-ion concentration at a constant ionic strength in the iron(II) reduction of $Co(H\cdot EDTA)Cl^-$ to a specific salt effect due to interaction between ions of opposite charges, rather than to a catalysis involving a reaction path in which a proton enters into the transition complex.[6] It was suggested that the increase in the second-order rate constant for the reactions of the $Co(HY)Cl^-$ complex with iron(II) could be ascribed to a greater stabilization of the $Co(HY)Cl^-$ complex by sodium ions than by hydrogen ions.[6]

This explanation seems to applicable to the iron(II) reductions of the $Co(H\cdot EDTA)Br^-$, $Co(EDTAOH)Cl^-$, $Co(EDTAOH)Br^-$, and $Co(EDDA)Cl_2^-$ complexes since all the k_c values for these complexes followed Equation (1) rather than the first-order dependence of the hydrogen ion.

Since the uncoordinated carboxyl group in the $Co(H\cdot EDTA)X^-$ complex are almost all protonated under the conditions employed, and since there is no uncoordinated carboxyl group in the $Co(EDTAOH)X^-$ and $Co(EDDA)Cl_2^-$ complexes, it could hardly be supposed that the reactions of these complexes proceed through a reaction path in which a proton enters into the transition state. On the other hand, there can be no rate dependence upon the hydrogen-ion concentration in the iron(II) reductions of the Co(III) complexes with positive charges, such as CoN_5Cl^{2+} and $CoN_4Cl_2^+$ ($N_5=(NH_3)_5$, $(en)_2NH_3$, and tetren and $N_4=(NH_3)_4$, $(en)_2$, and trien[13]), in the $HClO_4$–$NaClO_4$ medium under conditions of a constant ionic strength and a relatively high hydrogen-ion concentration, because no change in the interactions between the ions of opposite charges, the Co(III) ion and the perchlorate ion, would result from replacing the sodium ions by hydrogen ions.

The values of A, which may be a measure of the difference in the interactions between the cations (H^+ and Na^+) and the reactant Co(III) anion, are almost the same in the cases of the $Co(H\cdot EDTA)Cl^-$, $Co(H\cdot EDTA)Br^-$, $Co(EDTAOH)Cl^-$ and $Co(EDTAOH)Br^-$ complexes, but it is slightly larger for the case of $Co(EDDA)Cl_2^-$. This seems to be ascribable to the greater difference between the degree of the stabilization of this complex by sodium ions and that by hydrogen ions as compared to those of the other Co(III) complexes investigated. The relatively higher values of k_0, ΔH^*, ΔS^*, and A for the $Co(EDDA)Cl_2^-$ may suggest a somewhat different reaction pattern relative to that of the other complexes, for instance, a reaction path including a double chloride-bridged activated complex.

Selenium (IV) reacts with 4-nitro-*o*-phenylenediamine to form 5-nitropiaselenol, which is detected by means of a gas chromatograph equipped with an electron-capture detector. By this highly sensitive method, the selenium in pure tellurium metal (99.9—99.999%) can easily be determined. Aqua regia oxidizes both selenium and tellurium to the quadrivalent state, and no loss of selenium is found upon this treatment. This method requires only 10—30 mg of a tellurium sample, and the presence of foreign ions does not interfere. It was found that pure tellurium, commercially available, always contains 10^{-3}—10^{-4}% selenium.

Spectrophotometric[1,2] and fluorimetric[3,4] procedures are convenient analytical methods for the determination of traces of selenium. Many organic reagents have been suggested for this purpose, 3,3′-diaminobenzidine[5,6] being widely used. The present author and a coworker[7] have recently proposed a far more sensitive method for detecting selenium in pure sulfuric acid by means of a gas-chromatograph equipped with an electron-capture detector and using 4-nitro-*o*-phenylenediamine. The present paper will describe a gas-chromatographic determination of selenium in pure tellurium. As even about 0.01 μg of selenium can be determined, only a few milligrams of tellurium are needed as the sample. By the oxidation of the pure tellurium with aqua regia, the selenium and the tellurium were converted to the respective quadrivalent states. The selenium in the solution was determined by the gas-chromatographic method using 4-nitro-*o*-phenylenediamine.

Experimental

Reagents. *4-Nitro-o-phenylenediamine Hydrochloride Solution*: This was a 1% acidic solution so stable that the solution could be used after standing for more than 1 week at room temperature.

Stock Selenium(IV) Solution: 351.3 mg of selenium dioxide were dissolved in 250 m*l* of distilled water (1 mg of Se in 1 m*l*). Working solutions were prepared by diluting the stock solution.

Stock Selenium(O) Solution: 3.06 mg of elemental selenium were dissolved in 50 m*l* of carbon disulfide (61.2 μg of Se in 1 m*l*). Working solutions were prepared by diluting the stock solution with carbon disulfide.

Stock Aqua Regia Solution: Concentrated hydrochloric acid and nitric acid were mixed in the volume ratio of three to one. The working solution was the doubly diluted stock solution.

The other reagents were of an analytical reagent grade.

Apparatus. A Shimadzu Model GC-3AE gas chromatograph equipped with an electron-capture detector was used. The glass column (1 m long, 4 mm bore) was packed with 15% SE—30 on 60—80 mesh Chromosorb W. The column and the detector temperature were maintained at 200°C. The nitrogen flow-rate was 48 m*l*/min. A Shimadzu Model 250A recorder was used, and the chart speed was 5 mm/min.

General Procedure. 30 mg of grained pure tellurium was put into a 100-m*l* beaker, and 6 m*l* of aqua regia which has been doubly diluted was added; the solution was then heated in a boiling water bath for 10 min. After cooling, a 3 m*l* portion of concentrated hydrochloric acid was added and the content was transferred to a 100-m*l* separatory funnel and the beaker was rinsed with 10-m*l* of distilled water into the funnel. When the selenium content was too large, an aliquot containing 0.01—0.1 μg of Se was used. Two milliliters of a 1% 4-nitro-*o*-phenylenediamine solution were added and the solution was allowed to stand for 2 hrs. Then, the 5-nitro-piaselenol formed was extracted into 1 m*l* of toluene by shaking for 5 min and the toluene extract was washed with 5 m*l* of 0.2 N sodium hydroxide. Five microliters of the toluene extract were injected into the gas-chromatograph and the peak height was measured.

Results and Discussion

Preparation of the Tellurium Sample. Selenium in the tellurium metal is not present in the form of selenium(IV), but in the elemental form, since the selenium compounds are more readily reduced and less easily oxidized than the corresponding tellurium compounds. Therefore, any selenium in the tellurium must be converted into the 4^+ oxidation state.

In order to dissolve and oxidize both tellurium and selenium to the quadrivalent form, nitric acid, aqua regia or a mixed acid of perchloric acid and nitric acid is usually used. Aqua regia is the most convenient oxidizing reagent, for, unless a considerable excess of nitric acid is used, the basic nitrate and tellurium dioxide are likely to be precipitated. The perchloric acid also lowers the peak height slightly, but the reason is not known. The gas-chromatogram which is obtained with 30 mg of tellurium dissolved in 6 m*l* of aqua regia diluted to two times is shown in Fig. 1. The retention time of 5-nitropiaselenol is four minutes.

Oxidation with Aqua Regia. Usually, when the oxidation of selenium is performed in the presence of hydrochloric acid, a volatile chloride, $SeCl_4$ is formed. This chloride must be responsible for the loss of sele-

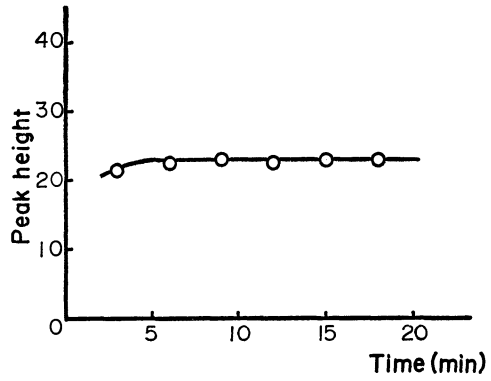

Fig. 3. Effect of the oxidation time (100°C) (30 mg Te).
Range 0.2 V

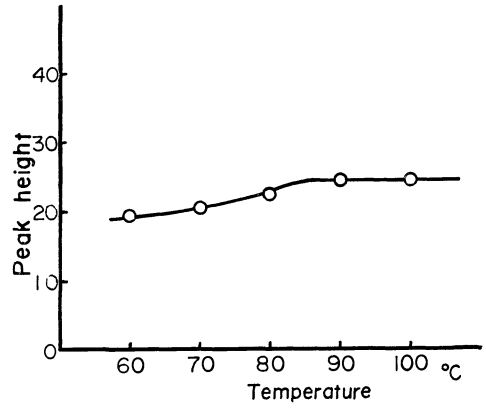

Fig. 4. Effect of the oxidation temperature (30 mg Te).
Range 0.2 V

First of all, the effect of the concentration of aqua regia is studied. It is desirable that the concentration of aqua regia required to oxidize both selenium and tellurium be as low as possible. However, if the volume of the solution is too small, the loss of selenium may occur during oxidation in a boiling water bath. Therefore, doubly-diluted aqua regia is used for the oxidation procedure. The results are shown in Fig. 2. Complete oxidation is performed from 5 to 10 m*l* of aqua regia. Therefore, 6 m*l* of aqua regia, diluted to two times, are used in the following experiments. Next, the oxidation time is measured by heating in a boiling water bath (Fig. 3). As the oxidation is complete from 6 to 18 min, a sufficient oxidation time is 10 min. Lastly, Figure 4 shows the effect of the oxidation temperature. When the oxidation is performed at more than 90°C, the peak height shows the maximum and constant value.

Washing the Toluene Extract with Sodium Hydroxide. When the toluene extract is injected directly, without washing with sodium hydroxide, into the gas-chromatograph, an unknown peak appears overlapping the 5-nitropiaselenol. However, it can easily be removed by washing with a sodium hydroxide solution. Though, usually, the nitro compound is readily dis-

Table 1. Effect of the foreign ions

$\left(\frac{[X]}{[Se]} = 10^4\right)$

Foreign ion (X)	Se recovery Se(0) in CS_2 (μg)	Se recovery in 30 mg Te (μg)
none	0.067 0.062	0.056 0.053

solved in an alkaline solution, as long as the toluene extract is washed with at least 5 m*l* of a 10^{-3}—1 M sodium hydroxide solution, the unknown acidic substance is removed and no back extraction of 5-nitropiaselenol can be found.

Effect of Foreign Ions. Although the amounts of foreign metals in pure tellurium would be comparable to that of selenium, the effect of a large amount of various ions is examined. No effect is found, even if 10^4 times as many of foreign ions are present, as is shown in Table 1.

Calibration Curve. The calibration curves are made from both a known amount of selenous acid in a hydrochloric acid solution and the elemental selenium dissolved in CS_2 by the above-mentioned procedure. These two curves are parallel to each other (Fig. 5). This results also shows that the oxidation is complete.

Determination of Selenium in Tellurium. Selenium in 30 mg of commercial pure tellurium was determined by the above-mentioned procedure; the same sample containing a standard addition of elemental selenium was also used for the determination. As its standard addition is always obtained by deducing the former values from the latter values, this method is proved to be suitable and correct for the determination of selenium in pure tellurium metal. The results are shown in Table 2.

TABLE 2. SELENIUM CONTENT IN TELLURIUM

Company	Selenium content in tellurium	
	Analytical reagent grade $\times 10^{-4}$%	Extra pure reagent $\times 10^{-4}$%
A	1.8±0.1	
B	30.0±0.1	22.5±0.2
C	13.5±0.2	7.5±0.1
D	4.0±0.1	31.5±0.2

The mean value of four times mesurement

As the sensitivity of an electron-capture detector tends to vary during operations, a series of experiments should be carried out successively and an unknown content of selenium should be determined along with standard samples which contain similar amounts of selenium. The procedure's outstanding features are that it is simple, highly sensitive, and rapid, and that no special skill is necessary to perform it.

The author is grateful to Professor Kyoji Tôei for his helpful discussions and encouragement.

Spectroscopic Studies of Polynuclear Complexes. III.[1] Characteristics of Some μ-Peroxoammine Cobalt(III) Complexes.

Yoichi SASAKI, Junnosuke FUJITA, and Kazuo SAITO
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received May 20, 1971)

The spectroscopic and chemical properties of various μ-peroxo and μ-superoxo cobalt(III) complexes containing several kinds of polyamine including optically active *l*-propylenediamine (*l*-pn) have been studied. The single bridged μ-peroxo complexes have strong absorption peaks at *ca.* 300 nm, whereas the double-bridged μ-peroxo-μ-amido and μ-peroxo-μ-hydroxo complexes have peaks at *ca.* 350 nm. The μ-superoxo complexes have two absorption peaks in the visible region at *ca.* 700 and 480 nm. The former is remarkably stronger for single-bridged species, but both are of almost equal strength for double bridged species. The complexes $[LNH_3Co(\mu\text{-}O_2^{(2-)})CoNH_3L]^{4+}$ (L; 2en (ethylenediamine), 2*l*-pn, and trien(triethylenetetramine)) are spontaneously converted into $[LCo(\mu\text{-}O_2^{(2-)}, OH)CoL]^{3+}$ in water at room temperature. The en ligands in $[(dien)(en)Co(\mu\text{-}O_2^{(2-)})Co(en)(dien)]^{4+}$ (dien; diethylenetriamine) are replaced by *l*-pn in a few days in aqueous solutions containing an excess of *l*-pn. The absolute configuration of $[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-pn})_2]^{3+}$ is assigned to be $\Delta\Delta$ on the basis of circular dichroism spectrum.

As an extention of our preparative and spectroscopic studies of binuclear cobalt complexes bridged by peroxo or superoxo anions,[1,2] this paper deals with spectroscopic and chemical properties of some binuclear cobalt ammine complexes bridged by peroxo anions. Such complexes have been synthesized by many authors in various ways.[3] Fremy[4] passed air through an ammoniacal solution of cobalt(II) salt and obtained μ-peroxo-decaamminedicobalt(III) ions, $[(NH_3)_5Co(\mu\text{-}O_2^{(2-)})Co(NH_3)_5]^{4+}$, identified by Werner.[5] This compound is readily decomposed to cobalt(II) salt in a neutral solution with evolution of oxygen. Werner[6] prepared a double bridged dicobalt complex $[(NH_3)_4Co(\mu\text{-}O_2^{(2-)},NH_2)Co(NH_3)_4]^{3+}$ from well-known Vortmann's sulfate obtained by passing air through a warm ammoniacal solution of cobalt(II) salt and neutralizing with sulfuric acid. Mori *et al.*[7] obtained the same complex more conveniently and with better yield by warming Fremy's μ-peroxo complex[3] in aqueous ammonia. Recently Gainsford and House, and Duffy *et al.*[8] prepared polyamine derivative of Fremy's μ-peroxo complex,[4] *e.g.* $[(en)_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(en)_2]^{4+}$ and $[(trien)(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(trien)]^{4+}$ [9] by adding en or trien to an aqueous solution of $[(NH_3)_5Co(\mu\text{-}O_2^{(2-)})Co(NH_3)_5]^{4+}$ at room temperature. Foong *et al.*[10] obtained a double bridged dicobalt complex $[(en)_2Co(\mu\text{-}O_2^{(2-)},OH)Co(en)_2]^{3+}$ by passing air through an aqueous ethanol solution of cobalt(II) salt and en.

We prepared such binuclear complexes with aims of comparing the ultraviolet and visible absorption spectra with other binuclear complexes given previously,[1,2] and found that some of House's complexes with μ-peroxo bridges undergo rapid spectral change in aqueous solutions even at room temperature. The change seems to be related to an unusual lability of amine type ligands of binuclear complexes with μ-peroxo bridges.

Absorption Spectra of the Complexes. House *et al.*[8] prepared several binuclear complexes of cobalt containing polyamines with peroxo single bridge, including $[(tetren)Co(\mu\text{-}O_2^{(2-)}Co(tetren)]^{4+}$, $[(dien)(en)Co-$

prepared solutions. However, the complexes containing ammonia *i.e.* $[(en)_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(en)_2]^{4+}$, $[(trien)(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(trien)]^{4+}$ and $[(l\text{-pn})_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(l\text{-pn})_2]^{4+}$ underwent rapid spectral change and the absorption maxima shifted to *ca.* 350 nm. The absorption pattern of the other three complexes remained unchanged as shown in Fig. 1.

The double bridged complexes with peroxo and hydroxo bridges, $[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-pn})_2]^{3+}$ and $[(en)_2Co(\mu\text{-}O_2^{(2-)}, OH)\ Co(en)_2]^{3+}$ were prepared according to the method of Foong *et al.*[10] and the absorption spectra were recorded in water. They remained unchanged for more than 24 hr with maxima at *ca.* 350 nm, as seen in Figs. 1 and 2.

s, shoulder. a) from Ref. 2a. (in water)

The spectral data of peroxo bridged complexes are summarized in Table 1. It is seen that the absorption peaks in the ultraviolet region depend on the structure of the bridging part. The single bridged μ-peroxo complexes have absorption maxima at *ca.* 300 nm, whereas the double bridged complexes, μ-peroxo-μ-hydroxo and μ-peroxo-μ-amido, at *ca.* 350 nm.

The absorption spectra of the μ-superoxo complexes corresponding to the μ-peroxo complexes are also shown in Fig. 3 and the data summarized in Table 1. Single bridged μ-superoxo complexes were isolated by the method of House *et al.* Double bridged μ-superoxo-μ-hydroxo complexes were not isolated and their approximate absorption spectra in the visible region were recorded by use of aqueous solutions of the corresponding μ-peroxo-μ-hydroxo complexes in the presence of excessive free chlorine.

The spectral pattern of these μ-superoxo complexes seems to be dependent also on the structure of the bridging part. Single bridged complexes have a distinctive absorption peak at *ca.* 300 nm. They also give absorptions at *ca.* 700 nm (log ε *ca.* 3) and *ca.* 480 nm (log ε, 2.8), the former being stronger. On the other hand, double bridged complexes give absorption peaks at *ca.* 700 and *ca.* 480 nm and their intensities are almost equal (log ε, 2.5). The absorption pattern at *ca.* 300 nm is not clear because of the presence of chlorine.

So far as the complexes given in Table 1 are concerned, the pattern of absorption spectra appears useful for discriminating the structure of the bridging part for both μ-peroxo and μ-superoxo complexes.

Lability of Coordinated Ammines and Amines. As stated previously, the absorption spectrum of $[(en)_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(en)_2]^{4+}$ in water changed rapidly and became identical with that of $[(en)_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(en)_2]^{3+}$ prepared by the method of Foong *et al.* within 20 min at room temperature. Such a change indicates that the coordinated ammonia molecules in the single bridged μ-peroxo complexes are easily replaced by water molecules to give double bridged complexes. A similar spectral change was also observed with the corresponding *l*-pn complex. The absorption spectrum of $[(trien)(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(trien)]^{4+}$ in water converges to a pattern with a band at 350 nm with an ε value 5760 (per one complex ion) within *ca.* 40 min, and shows an approximate isosbestic point as seen in Fig. 4. Fallab,[11] Miller and Wilkins[12] reported that $[(trien)Co(\mu\text{-}O_2^{(2-)}, OH)Co(trien)]^{3+}$ showed a band at *ca.* 350 nm, although they did not isolate such species. We also examined the absorption spectrum of this double bridged complex by passing oxygen into an aqueous solution containing trien and cobalt(II) in various molar ratios. The apparent ε values at 350 nm increased with increase in the molar ratio, and approached a constant value 6800, when the ratio was more than 2. Thus it seems that $[(trien)(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(trien)]^{3+}$ also liberates

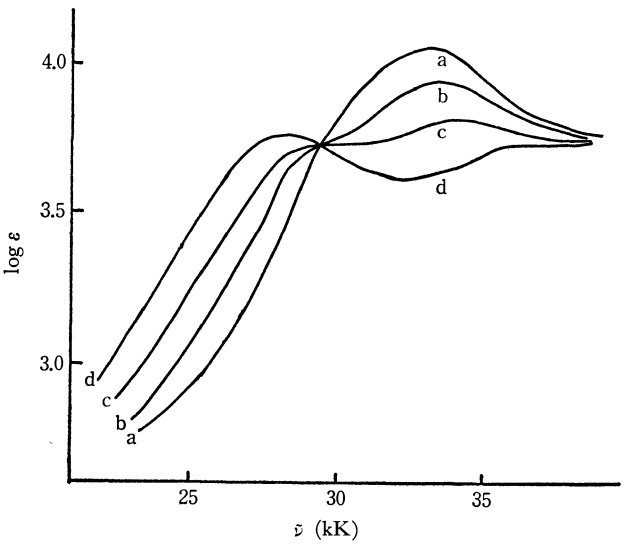

Fig. 4. Change in absorption spectrum of an aqueous solution of $[(trien)(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(trien)]^{4+}$ at room temperature.
a : immediately b : after 5 min

ammonia to form $[(trien)Co(\mu\text{-}O_2^{(2-)}, OH)Co(trien)]^{3+}$ in water at room temperature. All these complexes have various geometrical isomers, but they cannot be distinguished by conventional absorption spectrum measurement.

When a large excess of *l*-pn was added to an aqueous solution of $[(dien)(en)Co(\mu\text{-}O_2^{(2-)})Co(en)(dien)]^{4+}$ at room temperature, circular dichroism

—— after 3 hr ---- after 2 days —·—· after 5 days

11) S. Fallab, *Chimia*, **23**, 177 (1969); **24**, 76 (1970).
12) F. Miller and R. G. Wilkins, *J. Amer. Chem. Soc.*, **92**, 2687 (1970).

(CD) appeared as shown in Fig. 5. The CD curve became constant after ten days, while the absorption spectrum remained almost unchanged. When an aqueous solution of synthesized $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(2-)})Co(l\text{-pn})(dien)]^{4+}$ was treated with a large excess of en, the CD peak decreased gradually and eventually no CD was observable. These reactions are understood to be ligand substitutions of bidentate en or *l*-pn.

When *l*-pn was added to an aqueous solution of $[(en)_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(en)_2]^{4+}$, the absorption and the CD spectrum changed rapidly at room temperature and became identical with those of $[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-pn})_2]^{3+}$ synthesized by modified Foong *et al.*[10] within 20 min. The reaction is much faster than that of the substitution of bidentate ligands mentioned above. On the other hand, substitution of *l*-pn for en in the double bridged complex $[(en)_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(en)_2]^{3+}$ proceeds much slower than that in single bridged μ-peroxo complexes.

Ammonia and amines in uninuclear cobalt(III) complexes are generally believed to be substitution inert.[13] Hence all the observations mentioned above would be understood by considering that the ammonia and amines in the binuclear complexes are unusually labile. Such a lability is not significant in double bridged μ-peroxo-μ-hydroxo complexes and seems to be characteristic of single bridged μ-peroxo complexes. Such a change in lability is more marked for ammonia than for multidentate amines.

Recently Taylor and Sykes[14] reported that $[(NH_3)_4Co(\mu\text{-}OH, NH_2)Co(NH_3)_4]^{4+}$ liberates ammonia in an aqueous solution at a rate 0.46×10^{-4} sec^{-1} (half time 250 min) at 35°C. It was found that the binuclear chromium(III) complex $[(NH_3)_5Cr(\mu\text{-}O)Cr(NH_3)_5]^{4+}$ (rhodochromic salt) liberates one of its ammonia molecules very rapidly at room temperature,[15] and this fact was interpreted as an effect of π-bonding character of chromium oxygen bond.

A more detailed discussion on such an unusual change in lability cannot be made because of insufficient kinetic data. However, some of the properties of binuclear μ-peroxo complexes given in literature[5,8] would be understood by considering the ligand labilising effect in μ-peroxo complexes.

Other Properties of the μ-Peroxo Complexes. All the binuclear μ-peroxo complexes can be oxidized almost quantitatively to the corresponding μ-superoxo complexes by treatment with a slightly acidic aqueous solution containing chlorine. The single bridged μ-superoxo complexes were isolated as perchlorates,[8b] but the double bridged μ-superoxo-μ-hydroxo complexes were not isolated. μ-Peroxo complexes are also oxidized with nitric acid to the corresponding μ-superoxo complexes, but the yield is low.

The μ-peroxo complexes decomposed to cobalt(II) salts in perchloric and sulfuric acid, but always gave small amounts of the μ-superoxo complexes (*ca.* 10% at most). The yield was determined by measuring the intensity of absorption bands at *ca.* 700 nm, which are characteristic of μ-superoxo complexes. When single bridged μ-peroxo complexes were treated with concentrated hydrochloric acid, uninuclear chloropentaamine type complexes were formed.[8,16] On the other hand, μ-peroxo-μ-hydroxo double bridged complexes produced *trans*-dichlorotetraammine type complexes by a similar treatment.

Optical Activity of the Complexes Containing l-Propylenediamine. The absorption and the CD spectra of $[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-pn})_2]^{3+}$ synthesized by a modified Foong *et al.* method[10] and of $\Delta\Delta$-$[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, NH_2)Co(l\text{-pn})_2]^{3+}$ [2a] are shown in Fig. 2. From a comparison of their well-coinciding CD curves, the μ-peroxo-μ-hydroxo complex seems to have an asymmetric center around both cobalt ions and its absolute configuration can be determined to be $\Delta\Delta$. Hence the $\Delta\Delta$-$[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-pn})_2]^{3+}$ seems to be formed stereospecifically under the given conditions. The CD curve of this complex produced by the hydrolysis of $[(l\text{-pn})_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(l\text{-pn})_2]^{4+}$ also suggests a similar stereospecific formation. Further, the $\Delta\Delta$-configuration of this complex is supported by the CD spectrum of its μ-superoxo derivative which was obtained in a slightly acidic solution containing chlorine. We discussed such a stereospecificity of $[(l\text{-pn})_2Co(\mu\text{-}O_2^{(2-)}, NH_2)Co(l\text{-pn})_2]^{3+}$ in a previous paper.[2a] The same steric regulation appears to operate in the formation of μ-peroxo-μ-hydroxo complex.

The complex $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(2-)})Co(l\text{-pn})(dien)]^{4+}$ prepared by the method of House *et al.* gives a CD spectrum in water as shown in Fig. 6. The CD changes as indicated and becomes constant

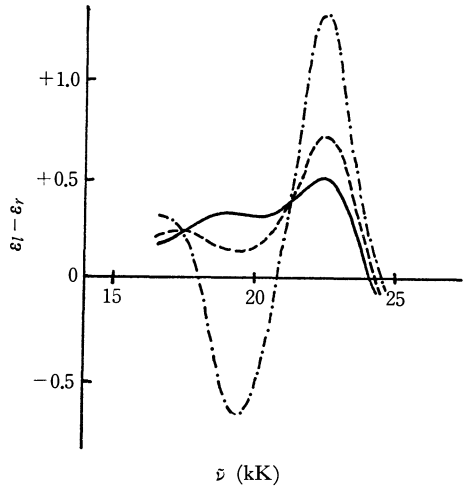

Fig. 6. Change in CD spectrum of an aqueous solution of $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(2-)})Co(l\text{-pn})(dien)]^{4+}$ (see text)

after *ca.* 2 days at room temperature. The final spectrum is identical with the final pattern (broken line with dot) in Fig. 5, which was formed by the reaction of *l*-pn with $[(dien)(en)Co(\mu\text{-}O_2^{(2-)})Co(en)(dien)]^{4+}$. This μ-peroxo complex can have various geometrical and diastereomeric isomers according to varying chelation of the bi- and terdentate ligand. They have all N_5O type coordination, and change in absorption spectra is not always expected among the isomers. No change in absorption pattern does not deny isomeric change of the complex. It appears, however, that the crystalline $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(2-)})Co(l\text{-pn})(dien)]^{4+}$ obtained (see Experimental) has different isomeric composition from its most stable form in aqueous solution, and the CD change in Fig. 6 can be understood as due to some kind of rearrangement in the binuclear complex.

The intensity of CD is of the order of $\Delta\varepsilon = ca. +1.3$ which can be accounted for by either vicinal effect coming from *l*-pn, or by asymmetric configuration in this complex. Apparently the CD indicates some kind of inversion with lapse of time, and this fact may support stereoselective coordination of the ligand. However, the band assignment in this complex still remains uncertain, and nothing decisive as to whether the optically active ligand exhibits stereoselectivity in such a single bridged complex or not can be stated at the present stage.

Experimental

Preparation of the Complexes. The preparation methods of all the complexes are essentially the same as those given in literature.[8,10] The results of elementary analysis are summarized in Table 2.

1) $[(en)_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(en)_2](ClO_4)_4$ and $[(trien)(NH_3)Co(\mu\text{-}O_2^{2-})Co(NH_3)(trien)](ClO_4)_4$:
These complexes were prepared by the method of House *et al.*[8] involving substitution of en and trien for ammonias of $[(NH_3)_5Co(\mu\text{-}O_2^{(2-)})Co(NH_3)_5]^{4+}$. They were also prepared directly as follows; cobalt(II) nitrate hexahydrate (2.9 g) and sodium perchlorate (10 g) were dissolved in water (10 m*l*), mixed with ethylenediamine hydrate (2 g) or trien (2 g) in concentrated aqueous ammonia solution (30 m*l*) and bubbled with air for *ca.* 30 min. The brown precipitate was washed with ethanol and ether and air dried (yield *ca.* 3 and 2.5 g, respectively).

2) $[(l\text{-pn})(dien)Co(\mu\text{-}O_2^{(2-)})Co(dien)(l\text{-pn})](ClO_4)_4$:
Cobalt(II) nitrate hexahydrate (2.9 g) and sodium perchlorate (10 g) were dissolved in water (10 m*l*), treated with dihydrochloride of *l*-pn (3 g), dien (1 g) and sodium hydroxide (1.6 g) in water (20 m*l*), and bubbled with air for *ca.* 30 min. The brown precipitate was similarly washed and dried (yield *ca.* 3 g).

3) $[(l\text{-pn})_2(NH_3)Co(\mu\text{-}O_2^{(2-)})Co(NH_3)(l\text{-pn})](ClO_4)_4$:
$[(NH_3)_5Co(\mu\text{-}O_2^{(2-)})Co(NH_3)_5](NO_3)_4\cdot 2H_2O$[5] (1.3 g) was added to a solution of dihydrochloride of *l*-pn (1.5 g), sodium hydroxide (0.8 g) and sodium perchlorate (1.5 g) in water (7.5 m*l*) under constant passage of air. A brown precipitate was formed after 30 min, which was washed and dried in a similar way (yield 0.9 g).

4) $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(-)})Co(l\text{-pn})(dien)](ClO_4)_5$:
Crude $[(dien)(l\text{-pn})Co(\mu\text{-}O_2^{(2-)})Co(l\text{-pn})(dien)](NO_3)_4$ was prepared by a similar method to the perchlorate[6] without sodium perchlorate. The brown nitrate was collected after 5 days. This salt (0.6 g) was added to a solution of concentrated hydrochloric acid (1.5 m*l*) and zinc chloride dihydrate (2.5 g) in water (3 m*l*), warmed at 80°C for 30

min and cooled to room temperature. It appears that the peroxo bridge was oxidized to superoxo in the hydrochloric acid solution by the nitrate and precipitated as tetrachlorozincate. The green powder was washed with ethanol, dissolved in a small amount of water containing a trace of nitric acid, and treated with a saturated sodium perchlorate solution. The green crystals were washed with ethanol and ether and air dried (yield 0.4 g).

5) $[(l\text{-}pn)_2Co(\mu\text{-}O_2^{(2-)}, OH)Co(l\text{-}pn)_2](ClO_4)_3$: Cobalt(II) perchlorate (2.4 g) was dissolved in water (10 m*l*) and mixed with *l*-pn (1.5 g) in ethanol (10 m*l*) and water (30 m*l*). Oxygen was passed through this solution for *ca.* 30 min. Yellow crystals precipitated initially dissolved during the course of bubbling. The solution was filtered and kept in a refrigerator for a day. The dark brown crystals were washed with ethanol and ether and air dried (yield *ca.* 1 g).

Propylenediamine was resolved by Dwyer's method.[17]

Measurements. The absorption and the circular dichroism spectra were recorded with a Hitachi 124 double beam recording spectrophotometer and Jasco ORD/UV-5 spectrophotometer with appropriate accessories, respectively.

We are grateful to the Ministry of Education for a Grant-in-aid for our studies on optically active complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3378—3382 (1971)

The Stereochemistry of Nucleophilic Addition. II.[1] The Reformatsky Reaction of Methyl (+)-α-Bromopropionate, 2-Phenylpropanal, and 3-Phenyl-2-butanone

Takashi MATSUMOTO, Isao TANAKA, and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received December 31, 1970)

The Reformatsky reaction of methyl (+)-α-bromopropionate with benzaldehyde was carried out in order to study the reaction mechanism, and two epimeric methyl 3-hydroxy-2-methyl-3-phenylpropionates (IIa and IIb) were obtained in a 59 : 41 ratio. From a comparison of the optical activity of IIb with that of pure (−)-IIb, it was estimated that IIb consists only seven percent of an optically-active compound; this results supports the hypothesis of the enolate anion mechanism. Subsequently, the stereochemistry of this reaction with 2-phenylpropanal (IV) and 3-phenyl-2-butanone (VIII) was studied. The condensation of IV with methyl bromoacetate gave a mixture of the epimeric methyl 3-hydroxy-4-phenylvalerates (Va and Vb), which were separated in a 26 : 74 ratio by means of column chromatography on silica gel. Similarly, VIII was also condensed with methyl bromoacetate to give the epimeric methyl 3-hydroxy-3-methyl-4-phenylvalerates (IXa and IXb) in a 31 : 69 ratio. The configurations of these esters were assigned by correlation with the products of the Grignard reaction, the stereochemistry of which is well known. From the present study, it is clear that the Reformatsky and the Grignard reactions of the carbonyl compound having an asymmetric α-carbon atom proceed in a similar fashion; that is, the entering group predominantly approaches the carbonyl group from the least-hindered side. Therefore, Cram's rule of asymmetric induction can be applied in the stereochemistry of the Reformatsky reaction.

The Reformatsky reaction[2] has long been recognized as a convenient method for preparing β-hydroxy esters, and the stereochemistry of this reaction, as well as that of the Ivanov reaction, has been explained by the hypothesis of an enolate anion mechanism[3-6] involving a cyclic transition state. If the reaction proceeds through the enolate anion intermediate, the condensation of the optically-active α-haloester possessing an asymmetric α-carbon atom, with a carbonyl compound which has no asymmetric carbon atom might be expected to yield a racemate of the corresponding β-hydroxy ester. To obtain further information on this reaction mechanism, we have now studied the condensation of benzaldehyde with methyl (+)-α-bromopropionate (I) in a benzene solution in the presence of zinc. The product (methyl 3-hydroxy-2-methyl-3-phenylpropionate) was separated by means of column chromatography on silica gel to give two epimeric esters; IIa (liquid), $[\alpha]_D^{25}+1.5°$ ($CHCl_3$) and IIb (mp 50.5—51.5°C), $[\alpha]_D^{25}-3.9°$ ($CHCl_3$), in a 59 : 41 ratio. The configurations of the racemates of these major (IIa) and minor (IIb) products had already been identified by Zimmerman and English[7] and Canceill *et al.*[8] as *erythro*- and *threo*-compounds respectively. In order to compare them with the above IIb, optically-pure (−)-IIb was prepared from (±)-*threo*-3-hydroxy-2-methyl-3-phenylpropionic

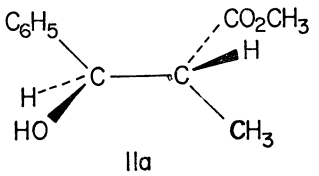
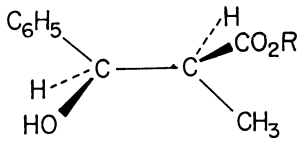
acid (IIIb), mp 97—98°C, in the following manner. (±)-IIIb was resolved by means of cinchonidine, and one of the diastereomeric salts, mp 170—172°C; $[\alpha]_D^{25}$ −87.6° (EtOH), was decomposed with dilute sulfuric acid to give (−)-IIIb, mp 106—107°C; $[\alpha]_D^{25}$ −19.7° (EtOH), which was then further converted by diazomethane to (−)-IIb ($[\alpha]_D^{25}$ −57.1° ($CHCl_3$)). Since (+)-I was recovered with an unchanged specific rotation after it had been refluxed in dry benzene with zinc for 2 hr (the time required for the reaction), it was estimated that a ninety-three-percent racemization occurred in the above condensation. In view of this racemization and the ratio, which was not 50 : 50 in the *erythro*- and *threo*-isomers, the main reaction seems to proceed through the enolate anion mechanism. However, since only a small degree of the optical activity is observed in the products, it is apparent that the reaction partially proceeds by a different reaction mechanism, such as the carbanion mechanism.



IIa



IIb R=CH_3

IIIb R=H

Subsequently, we turned our attention to the study of the stereochemistry of the Reformatsky reaction with carbonyl compounds possessing an asymmetric α-carbon atom, because this type of reaction has been little studied.[9-11] In a previous paper[11] we reported on the stereochemistry of the Reformatsky reaction with 2-alkylcyclohexanones. In this paper we wish to extend the scope of it to non-cyclic carbonyl compounds.

The condensation of 2-phenylpropanal (IV) with methyl bromoacetate in dry benzene in the presence of zinc gave a mixture of epimeric methyl 3-hydroxy-4-phenylvalerates, which were separated by column chromatography to give two oily esters (Va and Vb) in a 26 : 74 ratio. The configurations of these minor (Va) and major (Vb) products were assigned by correlation with the products of the Grignard reaction, the stereochemistry of which is well known. The reduction of Va and Vb with $LiAlH_4$ in ether afforded the corresponding diols, VIa and VIb, respectively. Subsequently, VIa and VIb were subjected to the tosylation with *p*-toluenesulfonyl chloride in pyridine, followed by the reduction of the resulting monotosylates with $LiAlH_4$ in tetrahydrofuran, to give the epimeric 2-phenyl-3-pentanols, VIIa (liquid) and VIIb (mp 39—40°C) respectively. Since Cram and Elhafez[12] had reported the preparation of *threo*- and *erythro*-2-phenyl-3-pentanols by the Grignard reaction of IV with ethylmagnesium bromide or by the reduction of 2-phenyl-3-pentanone with $LiAlH_4$, the condensation of IV with ethylmagnesium iodide was carried out for purposes of direct comparison; the mixture of epimers thus obtained was successfully separated by column chromatography[13] into the *threo* and *erythro* isomers in a 19 : 81 ratio. The alcohols, VIIa and VIIb, were shown to be identical with the authentic *threo* (minor) and *erythro* (major) isomers respectively by comparisons of their IR and NMR spectra.

12) D. J. Cram and F. A. Abd Elhafez, *J. Amer. Chem. Soc.*, **74**, 5828 (1952).

13) The diastereomers were separated by Cram and Elhafez[12] through the use of the phthalic acid ester for the *threo* isomer and the 3-nitrophthalic acid ester of the *erythro* isomer.

Similarly, 3-phenyl-2-butanone (VIII)[14] was also condensed with methyl bromoacetate to give the epimeric methyl 3-hydroxy-3-methyl-4-phenylvalerates (IXa and IXb) in a 31 : 69 ratio. The reduction of the minor (IXa) and major (IXb) esters with $LiAlH_4$ gave the corresponding diols (Xa, mp 76.5—77.5°C and Xb, mp 76—76.5°C), which were

then further converted to the corresponding 2-phenyl-3-methyl-3-pentanols (XIa and XIb) *via* monotosylates. The Grignard reaction of VIII with ethylmagnesium iodide gave the epimeric alcohols in a 20 : 80 ratio, these minor and major alcohols were also shown by the spectral comparison to be identical with the above XIa and XIb respectively. The six models of transition states for the addition to the carbonyl group directly bonded to asymmetric carbon atom are shown in Fig. 1. The A, B, and C conformations should be more stable than the corresponding A′, B′, and C′ conformations. Of the three (A, B, and C), A is the most stable, while the second most stable conformation is B, as has been reported by Karabatsos.[15] Thus, A and B, where the incoming group, R′, is closest to the smallest group, hydrogen, lead to the major and minor products respectively, as is shown in Fig. 2.

From the present study, it is clear that the Reformatsky and the Grignard reactions with the carbonyl compound possessing an asymmetric α-carbon atom proceed in a similar fashion. Therefore, it may be suggested that Cram's rule[12,15] of asymmetric induction can be applied in the stereochemistry of the Reformatsky reaction. The stereoselectivity of the Reformatsky reaction observed is slightly less than that of the Grignard reaction.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, t: triplet, qa: quartet, qi: quintet, m: multiplet. The column chromatography was performed on Merck silica gel (0.08 mm).

Methyl (+)-α-Bromopropionate (I). (+)-I (bp 55–56°C/31 mmHg, $[\alpha]_D^{25}$ +68.8° (neat)) was prepared from (+)-lactic acid (30% aqueous solution) by the method of Cowdrey *et al.*[16] The reported physical properties[16] of (+)- and (−)-I are bp 46°C/14 mmHg, $[\alpha]_D$ +19.17°[17] and bp 44°C/12 mmHg, $[\alpha]_D$ −68.57°, respectively.

The Reformatsky Reaction of Benzaldehyde with Methyl (+)-α-Bromopropionate. This reaction was carried out by a method similar to that used with ethyl (±)-α-bromopropionate by Zimmerman and English.[7] The crude product (1.123 g) was directly purified by means of column chromatography on silica gel (80 g). Elution with benzene containing 7% and then 15% ether gave two fractions. The first fraction gave methyl *erythro*-3-hydroxy-2-methyl-3-phenylpropionate (IIa: 503 mg), $[\alpha]_D^{25}$ +1.5° (*c* 0.152, $CHCl_3$) as a colorless oil. NMR in $CDCl_3$: 1.10 (d, J= 7 Hz, $-\overset{|}{C}HCH_3$), 2.74 (m, $-\overset{|}{C}HCH_3$), 3.21 (d, J=4 Hz, $-OH$), 3.52 (s, $-CO_2CH_3$), 4.93 (dd, J=4 and 5.5 Hz, $-\overset{|}{C}HOH$), 7.18 (s, $-C_6H_5$).

Found: C, 68.11; H, 7.20%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

The second fraction gave the *threo*-isomer (IIb: 356 mg), $[\alpha]_D^{25}$ −3.9° (*c* 0.198, $CHCl_3$) as a colorless solid. This was recrystallized from ether containing *n*-pentane to give colorless crystals, mp 50.5—51.5°C, which were shown to be identical with authentic (±)-IIb by a mixed-melting-point determination and by a comparison of their IR spectra. NMR in $CDCl_3$: 0.92 (d, J=7 Hz, $-\overset{|}{C}HCH_3$), 2.74 (qi, J=7 Hz, $-\overset{|}{C}HCH_3$), 3.35 (s, $-OH$), 3.60 (s, $-CO_2CH_3$), 4.61 (d, J=8 Hz, $-\overset{|}{C}HOH$), 7.18 (s, $-C_6H_5$).

Found: C, 68.20; H, 7.33%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

The Resolution of (±)-threo-3-Hydroxy-2-methyl-3-phenylpropionic Acid (IIIb) with Cinchonidine. A solution of (±)-IIIb (1.20 g), mp 97—98°C (lit,[7] mp 96.5—97.5°C) in ethyl acetate was added to a hot solution of cinchonidine (1.96 g) in ethyl acetate (100 m*l*), and then the solution was concentrated to *ca.* 40 m*l*. After the solution had stood at room temperature, the precipitates were collected and then recrystallized from ethyl acetate to give cinchonidine salt as colorless crystals; mp 170—172°C, $[\alpha]_D^{25}$ −87.6° (*c* 0.083, EtOH); yield, 1.22 g.

Found: C, 73.66; H, 7.28; N, 5.80%. Calcd for $C_{29}H_{34}O_4N_2$: C, 73.39; H, 7.22; N, 5.90%.

The cinchonidine salt (1.36 g) was decomposed with dilute sulfuric acid (5%: 20 m*l*) and extracted with ether, and the extract was washed with a saturated sodium chloride solution. After it had been dried over sodium sulfate and the ether had been removed, the residue (425 mg) was recrystallized from benzene to give (−)-IIIb as colorless crystals; mp 106—107°C; $[\alpha]_D^{25}$ −19.7° (*c* 0.094, EtOH).

Found: C, 66.87; H, 6.65%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

The acid, (−)-IIIb, was methylated with ethereal diazomethane to give (−)-IIb, $[\alpha]_D^{25}$ −57.1° (*c* 0.123, $CHCl_3$) or −41.6° (*c* 0.114, EtOH). The IR spectrum was identical with that of authentic (±)-IIb.

The Reformatsky Reaction of 2-Phenylpropanal (IV) with Methyl Bromoacetate. A few drops of a solution of IV (3.22 g) and methyl bromoacetate (5.47 g) in dry benzene (10 m*l*) were stirred, at 80°C, into a mixture of purified zinc powder (2.35 g) and dry benzene (3.0 m*l*). When the exothermic reaction started, the heating bath was removed; the liquid reactants were then added at a rate to maintain the refluxing without further external heating. The total addition required 15 min. The mixture was refluxed for an additional 90 min, cooled, decomposed with a mixture of ice and dilute hydrochloric acid, and then extracted with benzene. The extract was successively washed with aqueous sodium hydrogen carbonate and water, dried over sodium sulfate, and then evaporated. The residue was distilled under a vacuum to give a mixture of epimeric β-hydroxy esters as a colorless oil; bp 147—151°C/10 mmHg; yield, 3.90 g.

The above ester (2.027 g) was chromatographed on silica gel (200 g); subsequently elution with benzene containing 7% and then 10% ether was carried out to give two fractions. The first fraction gave Va (459 mg).

Found: C, 69.15; H, 7.80%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The second fraction gave Vb (1301 mg).

Found: C, 69.25; H, 7.86%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

Reduction of Va and Vb with $LiAlH_4$. *a)* A solution of Vb (1.300 g) in dry ether (10 m*l*) was added, drop by drop over a 20-min period, to a suspension of $LiAlH_4$ (490 mg)

17) It seems that the low specific rotation value for (+)-I is due to the contamination of racemate.

in dry ether (5.0 ml). The mixture was refluxed for 2 hr, cooled, poured into a mixture of ice (*ca.* 50 g) and dilute hydrochloric acid (5%: 30 ml), and then extracted with ether. The extract was washed with a saturated sodium chloride solution, dried over sodium sulfate, and then evaporated to give VIb (1.106 g) as an oil which showed no carbonyl absorption band in its IR spectrum and which could be used for the next step without purification. For analysis this was chromatographed on silica gel; elution with benzene containing 50% ether was then carried out.

Found: C, 73.48; H, 9.14%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

b) A solution of Va (343 mg) in dry ether (6.0 ml) was reduced with $LiAlH_4$ (130 mg) by a method similar to that used for VIb; a diol (VIa: 274 mg) was thus obtained as an oil.

Found: C, 73.02; H, 9.22%. Calcd for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

threo- *and* erythro-*2-Phenyl-3-pentanols (VIIa and VIIb).* *a) By the Grignard Reaction*: The Grignard reaction of IV with ethylmagnesium iodide was carried out by a method similar to that of Cram and Elhafez.[12] The crude product (1.054 g: bp 88—107°C/8 mmHg) was purified by means of column chromatography on silica gel (200 g), after which elution was carried out with benzene containing 4% ether to give two fractions. The first fraction gave *threo*-2-phenyl-3-pentanol (VIIa) as an oil (110 mg).

Found: C, 80.31; H, 9.68%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

The second fraction gave a solid (457 mg) which was then recrystallized from petroleum ether to give the *erythro*-isomer (VIIb) as colorless crystals; mp 39—40°C.

Found: C, 80.20; H, 9.93%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

b) From VIa and VIb: A mixture of VIb (0.977 g), *p*-toluenesulfonyl chloride (1.034 g), and dry pyridine (10 ml) was allowed to stand at room temperature for 24 hr and was then poured into a mixture of ice and dilute hydrochloric acid (10%: 50 ml). The mixture was extracted with ether, and the extract was washed successively with dilute hydrochloric acid and a saturated sodium chloride solution. After the extract had been dried over sodium sulfate and the ether had been removed, the crude product (0.778 g) was purified by column chromatography on silica gel (60 g) to give monotosylate as an oil; yield, 0.388 g. NMR in $CDCl_3$: 1.28 (3H, d, J=7 Hz, $-\overset{|}{C}HC\underline{H}_3$), 2.42 (3H, s, $-C_6H_4C\underline{H}_3$), 7.22 (5H, s, $-C_6\underline{H}_5$), 7.28 and 7.76 (each 2H, d, J=8.5 Hz, $-C_6\underline{H}_4CH_3$).

Found: C, 64.46; H, 6.66%. Calcd for $C_{18}H_{22}O_4S$: C, 64.65; H, 6.63%.

A solution of the above tosylate (350 mg) in dry tetrahydrofuran (5.0 ml) was stirred, drop by drop over a 20-min period, into a suspension of $LiAlH_4$ (171 mg) in dry tetrahydrofuran (5.0 ml). The mixture was then refluxed for 3 hr, poured into a mixture of ice and dilute hydrochloric acid (5%: 30 ml), and extracted with ether. The extract was washed with a saturated sodium chloride solution, dried, and then evaporated to give an oil (275 mg) which was chromatographed on silica gel (30 g). Elution with benzene containing 3% ether was subsequently carried out to give a solid (138 mg) which was shown to be identical with the above authentic *erythro*-isomer (VIIb) by an IR spectral comparison.

Similarly, the diol VIa was also converted to the *threo*-isomer (VIIa).

The Reformatsky Reaction of 3-Phenyl-2-butanone (VIII) with Methyl Bromoacetate. A ketone (VIII: 4.05 g) was condensed with methyl bromoacetate (4.10 g) in dry benzene in the presence of zinc (1.77 g) by a method similar to that used for V. The product was distilled under a vacuum to give an oil; bp 148—151°C/9 mmHg; yield, 3.37 g.

A portion (2.604 g) of the above product was chromatographed on silica gel (230 g) and separated into two epimeric β-hydroxy esters (IXa: 694 mg and IXb: 1524 mg).

IXa; Found: C, 70.49; H, 8.31%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

IXb; Found: C, 70.45; H, 8.21%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

Reduction of IXa and IXb with $LiAlH_4$. *a)* IXa (1.00 g) was reduced with $LiAlH_4$ by a method similar to that used for VIb. The crude product was recrystallized from *n*-hexane to give Xa as colorless crystals; mp 76.5—77.5°C; yield, 700 mg. NMR in $CDCl_3$: 1.17 (s, $-\overset{|}{\underset{|}{C}}C\underline{H}_3$), 1.32 (d, J=7 Hz, $-\overset{|}{C}HC\underline{H}_3$), 1.78 (qa, J=5 Hz, $-C\underline{H}_2-CH_2OH$), 2.64 (s, $-O\underline{H}$), 2.91 (qa, J=7 Hz, $-\overset{|}{C}\underline{H}CH_3$), 3.86 (t, J=5 Hz, $-C\underline{H}_2OH$), 7.32 (s, $-C_6\underline{H}_5$).

Found: C, 74.29; H, 9.45%. Calcd for $C_{11}H_{14}O_3$: C, 74.19; H, 9.34%.

b) IXb was also reduced with $LiAlH_4$ to give Xb as colorless crystals; mp 76—76.5°C (after crystallization from *n*-hexane). The mixed melting point with Xa (mp 76.5—77.5°C) was 59—61°C. NMR in $CDCl_3$: 1.18 (s, $-\overset{|}{\underset{|}{C}}C\underline{H}_3$), 1.33 (d, J=7 Hz, $-\overset{|}{C}HC\underline{H}_3$), *ca.* 1.70 (m, $-C\underline{H}_2CH_2OH$), 2.55 (bs, -OH), 2.81 (qa, J=7 Hz, $-\overset{|}{C}\underline{H}CH_3$), 3.77 (m, $-C\underline{H}_2OH$), 7.15 (s, $-C_6\underline{H}_5$).

Found: C, 74.40; H, 9.44%. Calcd for $C_{11}H_{14}O_3$: C, 74.19; H, 9.34%.

2-Phenyl-3-methyl-3-pentanols (XIa and XIb). *a) By the Grignard Reaction*: A solution of VIII (9.00 g) in dry ether (20 ml) was added, drop by drop at 0—5°C over a 30-min period, to a Grignard reagent, prepared from magnesium (1.48 g) and ethyl iodide (9.48 g) in dry ether (30 ml). The mixture was stirred at room temperature for 30 min and was then refluxed for 1 hr. After a usual work-up, the product was distilled under a vacuum to give an oil; bp 103—113°C/7 mmHg; yield, 7.92 g. A portion (2.051 g) of the above oil was chromatographed on silica gel (200 g). The elution was carried out with benzene containing 1% and then 5% ether to give the epimeric alcohols (XIa, 225 mg and XIb, 908 mg).

XIa: Found: C, 80.89; H, 10.38%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

XIb: Found: C, 80.60; H, 10.41%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

b) From Xa and Xb: By a method similar to that used for VIIb, the two diols (Xa and Xb) were converted to XIa, and XIb respectively, which later substances were shown by a spectral comparison to be identical with the above epimeric alcohols of the Grignard reaction.

Stereochemical Studies in Friedel-Crafts Reactions. I. The Reactions of *cis*- and *trans*-4-Tetrahydrophthalic Acid and Its Dimethyl Ester with Benzene

Kaichiro SUGITA and Shuzi TAMURA

Department of Chemistry, Ritsumeikan University, Kita-ku, Kyoto

(Received January 11, 1971)

The aluminum chloride-catalyzed reactions of *cis*-Δ^4-tetrahydrophthalic acid (**1A**) and its dimethyl ester (**3A**) with benzene gave, stereoselectively, *t*-4-phenyl-*cis*-hexahydrophthalic acid (**2A**) and its dimethyl ester (**12**) respectively. Similarly, the reactions of *trans*-Δ^4-tetrahydrophthalic acid (**1B**) and its dimethyl ester (**3B**) with benzene gave, stereoselectively, *c*-4-phenyl-*trans*-hexahydrophthalic acid (**2B**) and its dimethyl ester respectively, accompanied by a small amount of the *c*-4,*t*-2,*r*-1-isomer. The mechanism can be explained by presuming the interaction of the lone-pair electrons of carbonyl oxygen in the axial carboxyl group with a vacant *p*-orbital of the carbonium ion, which is produced by protonation to the double bond of the cyclohexenes (**1A**, **1B**, **3A**, **3B**).

A number of expensive studies of the directive effect of various remote substituents in hydroboration,[1] oxymercuration,[2] and epoxydation[3] have been reported, but little has been reported on the Friedel-Crafts reaction. Therefore, we have studied the directive effect on the Friedel-Crafts reactions of benzene to the double bond of 4-mono- and 4,5-disubstituted cyclohexenes catalyzed by aluminum chloride. Recently, it was reported[4] that the reaction of *cis*-Δ^4-tetrahydrophthalic acid (**1A**) with benzene catalyzed by aluminum chloride gave quantitatively, 4-phenylhexahydrophthalic acid (**2A**). The stereochemistry of the **2A** acid was not described, however. The present paper will deal with some reactions of benzene with the double bond of such 4,5-disubstituted cyclohexenes as the **1A** acid and its dimethyl ester (**3A**), *trans*-Δ^4-tetrahydrophthalic acid (**1B**), and its dimethyl ester (**3B**).

Results and Discussion

*Configuration of 4-Phenylhexahydrophthalic Acid (**2A**).* The configuration of the acid, **2A**, obtained by the reaction of **1A** with benzene was established on the basis of ring closure, epimerization, and the reaction of 4-phenylhexahydrophthalic acid anhydride (**4A**)[5] with benzene. When the **2A** acid was treated with acetic anhydride or acetyl chloride, the corresponding acid anhydride, **4A**, was obtained in a quantitative yield. Conversely, the hydrolysis of **4A** led to **2A**. The dimethyl ester **12** was converted to a new acid, **2C**, upon treatment with sodium ethoxide, followed by acidification. The **2C** acid is *t*-4,*t*-2,*r*-1-acid with a tri-equatorial structure, which is thermodynamically stable. On the basis of these results, the structure of **2A** was reasonably assumed to be as is shown in Scheme 1.[6]

In order to confirm this *t*-4,*c*-2,*r*-1 configuration of the **2A** acid, the reaction of the **4A** anhydride with benzene was carried out in the presence of aluminum chloride. This reaction gave a mixture of two isomeric keto acids, **5A** and **6A**, both of which were isolated upon fractional recrystallization. The Hunsdiecker reaction of **5A**, followed by treatment with potassium hydroxide in alcohol, gave 4-benzoylbiphenyl.[7] Therefore, the keto acid, **5A**, is 5-phenyl-2-benzoylcyclohexane-1-carboxylic acid. The treatment of **6A** with platinum-black gave 4-phenyl-2-benzylbenzoic acid (**7**). The IR spectrum of **7** shows a strong carbonyl absorption at 1685 cm^{-1}. Its structure was further confirmed by the IR and NMR spectra of the methyl ester, **8**, obtained from **7** and diazomethane. The isomeric keto acid, **5A**, was treated much as **6A** had been to afford the methyl ester **10**. The NMR spectra of the resulting esters exhibited a doublet (J=9.0 Hz[8]) at 8.0 for **8** and a doublet (J=3.0 Hz) at 8.10 ppm for **10**, which were ascribed to Ha in **8** and to Ha′ in **10** respectively.

The bromination of **6A** gave the mono-bromo ketone **11** (γ_{CO} 1680 cm^{-1}), which, on treatment with hydroiodic acid, afforded **6A**. Under similar conditions, **5A** was recovered unchanged. Since the ease of bromination depends on the respective rate of enolization,[9] the difference in behavior of **5A** and **6A** should be attributed to the presence of the axial benzoyl group in **6A** and the equatorial one in **5A**. The methyl ester of **5A** gave a mixture of the **5B** isomeric acid upon epimerization with sodium ethoxide, followed by acid hydrolysis. The recrystallization

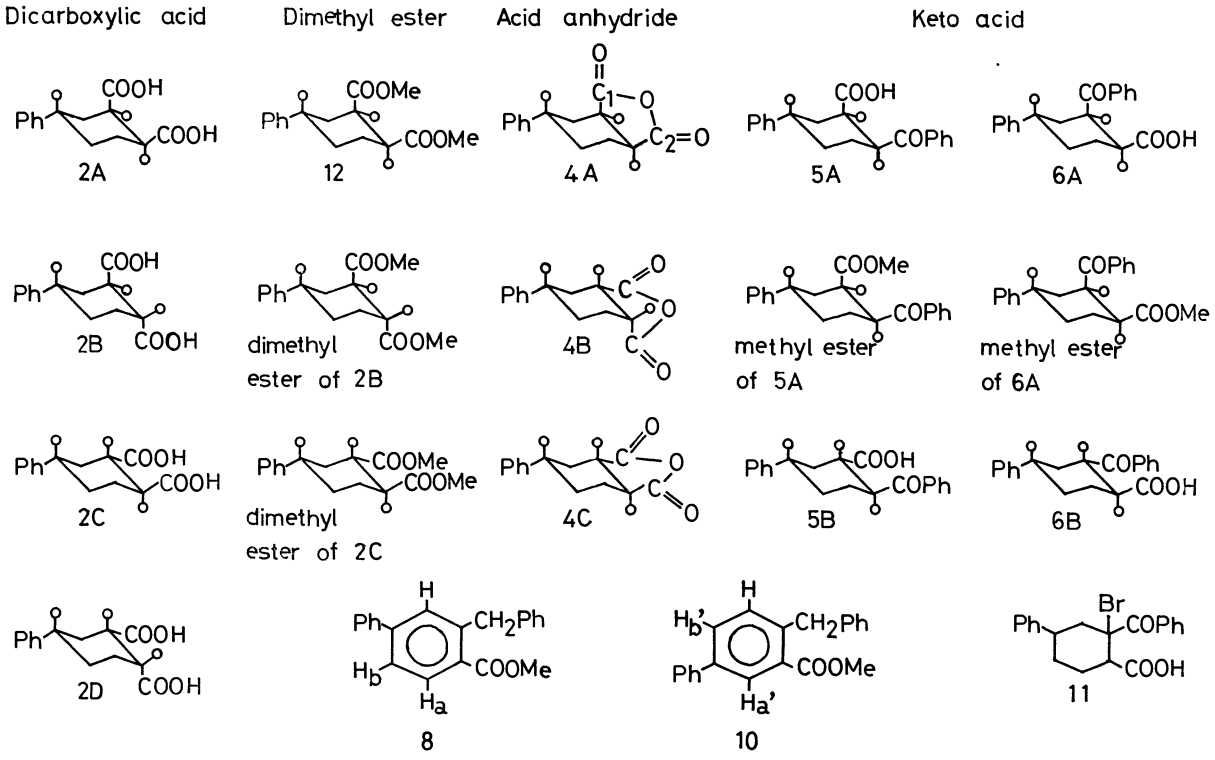

Scheme 1.

of this mixture gave a new acid, **5B**, in a 40% yield. The epimerization of the methyl ester of **6A** similarly gave another new acid, **6B**. These results support the **5A** and **6A** structures shown. Furthermore, the all-equatorial isomers, that is, the **5B** and **6B** keto acids are considered to be *t*-2-benzoyl-*c*-5-phenyl-*r*-1-cyclohexanecarboxylic acid and *t*-2-benzoyl-*t*-4-phenyl-*r*-1-cyclohexanecarboxylic acid respectively.

As is shown in Scheme 1, **6A** was obtained as a result of the attack by benzene an C–1 in **4A**, while **5A** was formed by the reaction of benzene at C–2. When **5A** or **6A** was treated with aluminum chloride in benzene under reflux, both were recovered unchanged. On the basis of the observed reaction of the acid anhydride **4A** with benzene, the configuration of **4A** can reasonably be assumed to be *c*–2, *t*–4, *r*–1 and the alternative structure, **4B**, can be excluded. As the hydrolysis of the acid anhydride **4A** gives the **2A** acid, the configuration of **2A** must be the same as **4A**.

The Reaction of Cyclohexenes with Benzene. The aluminum chloride-catalyzed reaction of various 4,5-disubstituted cyclohexenes with benzene was carried out. The results are shown in Table 1.

The reaction of dimethyl *cis*-Δ^4-tetrahydrophthalate (**3A**) with benzene gave a viscous oil in an 82% yield. The oil proved to be homogeneous on gas-chromatographic analysis and was identified as the dimethyl ester of **2A** by a comparison of the IR spectra. Therefore, the reaction gave, stereoselectively, dimethyl *t*-4-phenyl-*cis*-hexahydrophthalate (**12**) or the dimethyl ester of **2A**. The reaction of *trans*-Δ^4-tetra-

Table 1. Aluminum chloride-catalyzed addition reaction of benzene with 4,5-disubstituted cyclohexene

Cyclohexene	Product	Bp (Mp)	Yield (%)	Product distribution[a] (min)
1B	Crystalline solid[b]	(149—154°C)	90	b)
3A	**12**[c]	153—154°C/3 mmHg (53— 54°C)	82	single peak (69)
3B	Viscous oil[d]	154—155°C/3 mmHg	80	80 (60) : 20 (65)

a) By gas-chromatographic analysis. The ratio was calculated from the peak areas. (retention).

b) Fractional recrystallization from 40% acetic acid gave **2B** (70%), mp 162—164°C, and *t*-4, *t*-2, *r*-1-acid (**2C**) (8%), mp 215—217°C. IR of **2B**: (KBr) 2700—2400 (-OH), 1690 (carboxyl) and 1600 cm^{-1} (aromatic). Found: C, 67.08; H, 6.39%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%. The dimethyl ester of **2B** was obtained by the treatment of **2B** with diazomethane in ether. IR: (neat) 1730 (ester) and 1605 cm^{-1} (aromatic. NMR: δ ($CDCl_3$) 2.30—1.60 (m, 6, $3CH_2$), 2.95—2.55 (m, 1, CH), 3.45—3.00 (m, 2, 2CH), 3.75 (s, 6, $2CH_3$) and 7.22 ppm (s, 5, aromatic). The *t*-4, *t*-2, *r*-1-acid (**2C**) was identified by a mixed-melting-point determination and by a comparison of its IR spectrum with those of an authentic sample.

c) The product crystallized on cooling. Found: C, 69.74; H, 7.45%. Calcd for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30%.

d) IR: (neat) 1730 (ester) and 1605 cm^{-1} (aromatic). Found: C, 69.75; H, 7.38%. Cald for $C_{16}H_{20}O_4$: C, 69.54; H, 7.30%.

hydrophthalic acid (**1B**) and benzene gave a mixture of acids in a 90% yield, from which **2B** was isolated in a 70% yield and *t*-4-phenyl-*trans*-hexahydrophthalic acid (**2C**) in an 8% yield. Finally, the reaction of dimethyl *trans*-Δ^4-tetrahydrophthalate (**3B**) gave, in an 80% yield, a viscous oil which showed two peaks (area ratio 4 : 1) on gas-chromatography. The GC retention time indicated that the major component was the dimethyl ester of **2B**, and the minor one, the dimethyl ester of **2C**. In short, *trans*-4,-5disusbstituted cyclohexene (**1B**, **3B**) reacted with benzene to give **2B** and the dimethyl ester of **2B** contaminated with the *t*-4,*t*-2,*r*-1-isomer (**2C**, dimethyl ester of **2C**); this is in contrast to the behavior of the *cis*-4,5-disubstituted cyclohexene isomers (**1A**, **3A**). The configuration of the **2B** acid was established on the basis of the analogous epimerization and ring closure described above. The dimethyl ester of **2B** was converted to *t*-4,*t*-2,*r*-1-acid (**2C**) with sodium ethoxide, followed by acidification. This indicated that the **2B** and **2C** acids are stereoisomeric with each other. The **2B** acid was converted to **4A** in a quantitative yield with acetic anhydride, while **2B** was recovered unchanged upon treatment with acetyl chloride. The **2C** acid gave **4A** in a quantitative yield upon treatment with acetic anhydride and gave a new acid anhydride (**4C**) in quantitative yield when treated with acetyl chloride. In spite of the stereochemical differences in these acids (**2A**, **2B**, **2C**) in ring closure, the same product (**4A**) was obtained. In view of these facts, **2B** was identified as *c*-4-phenyl-*trans*-hexahydrophthalic acid having both carboxyl groups in an anti-axial conformation; this should explain the unsuccessful dehydration to anhydride.

Mechanism. It is generally known[10] that the alkylation of aromatics with olefins catalyzed by Lewis acids is initiated by the protonation of the double bond, thus forming a carbonium ion which then reacts with the aromatic rings.

In the presence of a trace amount of water, the protonation of the double bond of *cis*-4,5-disubstituted cyclohexene (**1A**, **3A**) gives a carbonium ion[11] which may be in either one of the two conformations (**13**, **14**) shown in Scheme 2. The conformation of **13** seems to be more stable than **14** since **13** is stabilized by the interaction of the lone-pair electorons of carbonyl oxygen in the axial carboxyl group with the vacant *p*-orbital. On the other hand, **14** does not have an axial carboxyl which might serve to stabilize the carbonium ion. The above explanation may be acceptable in view of the fact that a 1,3-interaction of this type has previously been established.[12,13] Thus, the stereoselective formation of **2A** and **12** can presumably be explained by a route which involves the **15** transition state. Scheme 3 summarizes the reac-

Scheme 3.

10) S. H. Patinkin and B. S. Friedman, "Friedel-Crafts and Related Reaction," vol. 2, Part 1, ed. by G. A. Olah, John Wiley, New York (1964), p. 3.

11) The ester carbonyl can be coordinated by aluminum chloride:

$$R\text{-}O\diagdown\!\!\diagup C{=}O\cdots AlCl_3 \longleftrightarrow R\text{-}O\diagdown\!\!\diagup C{=}\overset{\oplus}{O}\ \overset{\ominus}{AlCl_3}$$

This coordination may antagonize the above-mentioned carbonium-ion stabilization by *n*-electrons on carbonyl oxygen. Possibly, the stereochemistry involved in the present work suggests that such a coordination is not important in the product-determining step of the Friedel-Carfts reaction.

12) N. Baggett, J. S. Brimacombo, A. B. Foster, M. Stacey, and D. H. Whiffen, *J. Chem. Soc.*, **1960**, 2574.

13) a) B Dobinson and A. B. Foster, *ibid.*, **1961**, 2338; b) N. Baggett, M. A. Bukhari, A. B. Foster, J. Lehamann, and J. M. Webber, *ibid.*, **1963**, 4157.

tion of *trans*-4,5-disubstituted cyclohexenes (**1B**, **3B**). The intermediary carbonium ions can be either bridged, **16**, stabilized by an axial carboxyl group or a usual carbonium ion, **17**. The reaction of benzene with the carbonium ion **16** proceeds in a manner similar to that described in the case of **13** to give the *c*-4,*t*-2,*r*-1 configuration (**2B**, the dimethyl ester of **2B**) stereoselectively. The equatorial attack of benzene and the carbonium ion, **17**, proceeds *via* the most favorable transition state, **19**, in which the two substituents and benzene all occupy equatorial positions, so that the *t*-4,*t*-2,*r*-1 configuration (**2C**, the dimethyl ester of **2C**) is formed.

Experimental[14]

Materials. Commercially-avalilable *cis*-Δ^4-tetrahydrophthalic acid (**1A**) was used. Dimethyl *cis*-Δ^4-tetrahydrophthalate (**3A**) was prepared by the procedure reported by Nazarov and Kucherov;[15] bp 107—109°C/5 mmHg (lit,[15] bp 110—111°C/5mmHg). *trans*-Δ^4-Tetrahydrophthalic acid (**1B**) was prepared by the procedure reported by Nazarov and Kucherov;[15] mp 169—170°C (lit,[15] mp 170—171°C). Dimethyl *trans*-Δ^4-tetrahydrophthalate (**3B**) was prepared by the procedure reported by Nazarov and Kucherov;[15] bp 110—111°C/5mmHg (lit,[15] bp 137°C/20mmHg).

t-*4-Phenyl*-cis-*hexahydrophthalic Acid (**2A**).* This was prepared by the procedure reported by Schefczik;[4] mp 190—191°C (lit,[4] 194°C).

*Reaction of **4A** with Benzene.* Into a solution of **4A** (21.5 g) in dry benzene (87 m*l*), we stirred aluminum chloride (33 g) over a five-minute period below 10°C. Stirring was continued for one hour without further cooling and then for 20 additional minutes under reflux. Then the reaction mixture was poured onto icewater. The evaporation of solvent gave a mixture of carboxylic acids (27 g, 93%), mp 160—186°C. Fractional recrystallization from 95% alcohol gave **5A** (3 g, 11%) and **6A** (18 g, 67%). The recrystallization of **5A** from 85% alcohol gave colorless prisms; mp 182—183°C. IR: (KBr) 2700—2400 (-OH), 1700 (carboxyl), 1680 (Ketone) and 1600 cm^{-1} (aromatic). Found: C, 77.61; H, 6.66%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%. The recrystallization of **6A** from 95% alcohol gave colorless prisms; mp 202—203°C. IR: (KBr) 2700—2400 (−OH), 1700 (carboxyl), 1680 (ketone) and 1600 cm^{-1} (aromatic). Found: C, 77.82; H, 6.43%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

*The Methyl Esters of **5A** and **6A*** were obtained by the treatment of **5A** and **6A** with diazomethane in ether.

4-Benzoylbiphenyl was prepared by the procedure reported by Long and Henze;[7] mp 100—101°C (lit,[7] 103—104°C).

*4-Benzoylbiphenyl from **5A**.* To a solution of sodium hydroxide (3 g) in water (70 m*l*), **5A** was added (20 g). The mixture was heated to reflux until a clear solution was observed. The solution was cooled to room temperature and filtered. Nitric acid was added, drop by drop, to this filtrate until it reached incipient turbidity. Then a few drops of aqueous sodium hydroxide were added just to clear the solution up again. The slow stirring in of a solution of silver nitrate (13 g) in water (30 m*l*) produced a copious precipitate of the silver salt, which was then collected, washed with water, and carefully dried in a vacuum desiccator. The silver salt was obtained quantitatively. To a suspension of the dry silver salt (20 g) in dry chloroform (100 m*l*), a solution of bromine (9.6 g) in dry chloroform (20 m*l*) was added at room temperature. After this mixture had been refluxed for three hours, a suspension was obtained. After cooling, the suspension was filtered, and the silver bromide in the filter was washed with chloroform. The combined filtrate was washed with an aqueous sodium thiosulfate solution, an aqueous sodium hydroxide solution, water, and brine. Then the solution was dried over anhydrous magnesium sulfate and concentrated under reduced pressure. The distillation of the reaction residue gave an oily product (4 g), bp 220—245°C/2 mmHg. This oil was added to a solution of potassium hydroxide (3 g) in ethyl alcohol (60 m*l*) and refluxed for two hours. Subsequent recrystallization from alcohol gave 4-benzoylbiphenyl (2.5 g, 16%), mp 99—101°C. The structure was confirmed by a mixed-melting-point determination and by a comparison of the IR spectra with those of an authentic sample.[7]

*4-Phenyl-2-benzylbenzoic Acid (**7**).* A mixture of **6A** (1.6 g) and platinum-black (0.5 g) was heated under nitrogen at 305—310°C for four hours. The reaction mixture was then separated and the ether was extracted. The ether layer was treated with 5% sodium hydrogencarbonate and then acid. Recrystallization from alcohol gave **7** (1.0 g, 67%); mp 170—171°C. IR: (KBr) 2700—2400 (-OH), 1685 (carboxyl) and 1600 cm^{-1} (aromatic). Found: C, 84.20; H, 5.52%. Calcd for $C_{20}H_{20}O_2$: C, 84.48; H, 5.67%.

*Methyl Ester of **7** (**8**).* This was obtained by the treatment of **7** with diazomethane in ether. NMR: $\delta(CDCl_3)$ 3.85 (3H, s, CH_3), 4.48 (2H, s, CH_2), 7.20 (5H, s, aromatic), 7.60—7.30 (7H, m, aromatic) and 8.00 ppm (H, d, J= 9 Hz, CH).

*5-Phenyl-2-benzylbenzoic Acid (**9**).* A mixture of **5A** (1.6 g) and platinum-black (0.5 g) was worked up similarly. Recrystallization from alcohol gave **9** (0.8 g, 52%); mp 156—157°C. IR: (KBr) 2700—2400 (-OH), 1695 (carboxyl) and 1600 cm^{-1} (aromatic). Found: C, 84,34; H, 5.77%. Calcd for $C_{20}H_{16}O_2$: C, 84.48; H, 5.67%.

*Methyl Ester of **9** (**10**).* This was obtained by the treatment of **9** with diazomethane in ether. NMR: δ $(CDCl_3)$ 3.80 (3H, s, CH_3), 4.40 (2H, s, CH_2), 7.20 (5H, s, aromatic), 7.70—7.30 (7H, m, aromatic) and 8.10 ppm (H, d, J=3 Hz, CH).

*4-Phenyl-2-benzoyl-2-bromocyclohexane-1-carboxylic Acid (**11**).* To a solution of **6A** (1.0 g) in acetic acid (160 m*l*), bromine (0.8 g) was added at room temperature. The solution was kept at 80°C for 10 min and then cooled. It was poured onto cracked ice and filtered. The precipitate was washed with water and dried. It gave a yellow product (1.1 g); mp 169—175°C. Recrystallization from 80% alcohol gave **11** as colorless prisms (0.9 g, 70%); mp 184—185°C. The melting point of the product was depressed by mixing with **6A**. IR: (KBr) 2700—2400 (-OH), 1700 (carboxyl), 1680 (benzoyl) and 1600 cm^{-1} (aromatic). Found: C, 62.16; H, 4.80%. Calcd for $C_{20}H_{19}OBr$: C, 62.02; H, 4.95%.

*Bromination of **5A**.* The treatment of **5A** with bromine was carried out in a manner similar to that used in the experiment described above except for the condition of acetic acid (50 m*l*). A crystalline material was thus ob-

14) All the melting points and boiling points are uncorrected. The IR spectra were taken on a Hitachi EPI-S spectrometer. The NMR spectra were obtained on a Japan Electron Optics C-60-H spectrometer. The glpc analyses were carried out with a Shimazu GC-4AP appratus using Silicon Grease as the stationary phase.

15) I. N. Nazarov and V. F. Kucherov, *Otdel. Khim. Nauk*, 1954, 329; *cf. Chem. Abstr.*, 49, 5328 (1955).

tained quantitatively; mp 176—180°C. The melting point of the product, without any purification, was identical with that of **5A**. The IR spectra of the product were identical with that of **5A**.

*Debromination of **11** with 47% Hydroiodic Acid.* To a solution of **11** (50 mg) in acetone (3 m*l*), 47% hydroiodic acid (0.1 m*l*) was added. The solution was then kept at about 50°C for three minutes. After the iodine had been destroyed by the addition of a small quantity of sodium thiosulfate, 5 m*l* of water was added to give a precipitate. The precipitate was collected by filtration with water and dried. It gave a white product (35 mg, 88%); mp 197—199°C. The structure of the product, without any purification, was confirmed by a mixed-melting-point determination and by a comparison of the IR spectra with those of **6A**.

*Treatment of **5A** and **6A** with Aluminum Chloride.* This was done similarly except that the reaction time was one hour. In the case of **5A**: **5A** (3.1 g), aluminum chloride (1.5 g) and benzene (10 m*l*). A crystalline material (2.7 g, 87%) was obtained (mp 176—180°C). The recrystallization of the product from 85% alcohol gave colorless prisms, mp 180—181°C. The melting point of the product was not depressed by mixing with **5A**. The IR spectra of the product were identical with those of **5A**. In the case of **6A**: **6A** (3.1 g), aluminum chloride (1.5 g) and benzene (10 m*l*), a crystalline material (2.6 g, 84%) was obtained (mp 194—198°C). The recrystallization of the product from 95% alcohol gave colorless prisms, mp 201—202°C. The melting point of the product was not depressed by mixing with **6A**. The IR spectra of the product were identical with those of **6A**.

Table 2. Epimerization of trisubstituted cyclohexane

Sample[a)]	Product	Mp	Yield (%)
Dimethyl ester of **2A**	**2C**[b)]	220—221°C	400 mg (89)
Dimethyl ester of **2B**	**2C**[b)]	218—219°C	400 mg (89)

Methyl ester of **5A**	**5B**[d)]	179—180°C	200 mg (40)
6A	**6B**[e)]	241—242°C	450 mg (90)
Methyl ester of **6A**	**6B**[e)]	240—242°C	400 mg (80)

a) The corresponding methyl ester was obtained by the treatment of diazomethane in ether.

b) Recrystallization from 60% acetic acid gave **2C** of colorless prisms. IR: (KBr) 2700—2400 (-OH), 1705 (carboxyl) and 1600 cm^{-1} (aromatic). Found: C, 67.82; H, 6.41%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%. The dimethyl ester of **2C** was obtained by the treatment of **2C** with diazomethane in ether. IR: (neat) 1730 (ester) and 1600 cm^{-1} (aromatic). NMR: $\delta(CDCl_3)$ 2.95—1.15 (m, 9, 3CH and $3CH_2$), 3.70 (d, 6, $2CH_3$) and 7.22 (s, 5, aromatic).

c) The structure of the product was confirmed by a mixed-melting-point determination and by a comparison of its IR spectra with those of an authentic sample.

d) It gave a white product (430 mg, 90%); mp 160—174°C. Found: C, 78.03; H, 6.68%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%. Recrystallization from 80% alcohol gave 5B of white prisms. IR: (KBr) 2800—2500 (-OH), 1700 (carboxyl), 1680 (ketone) and 1600 cm^{-1} (aromatic). Found: C, 77.20; H, 6.68%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

e) Recrystallization from 90% alcohol gave **6B** of colorless prims. IR: (KBr) 2700—2400 (-OH), 1700 (carboxyl), 1680 (ketone) and 1600^{-1} (aromatic). The melting point of **6B** was depressed by mixing with **6A**. The IR spectra of **6B** and **6A** were different in the fingerprint region. Found: C, 77.79; H, 6.62%. Calcd for $C_{20}H_{20}O_3$: C, 77.90; H, 6.54%.

*Aluminum Chloride-catalyzed Reaction of 4,5-Disubstituted Cyclohexene (**1B**, **3A**, **3B**) with Benzene. General Procedure*: Into a solution of 4,5-disubstituted cyclohexene (0.03 M) in dry benzene (0.3 M) we stirred aluminum chloride (0.06 M) over a five-minute period below 10°C. Stirring was continued for one hour without further cooling, and for two additional hours under reflux. Then the reaction mixture was poured onto icewater. The benzene solution was dried over anhydrous magnesium sulfate and evaporated. The product was purified by recrystallization or distillation. The results are given in Table 1.

General Epimerization Procedure: To a sodium ethoxide solution prepared from absolute ethanol (50 m*l*) and sodium ((200 mg) for the dimethyl ester of **2A** (**12**) and the dimethyl ester of **2B**, (100 mg) for **5A**, the methyl ester of **5A**, **6A**, and the methyl ester of **6A**), we added the sample (500 mg). The solution was refluxed for five hours and cooled. After the addition of water (100 m*l*) to the reaction mixture, the resulting mixture was acidified and filtered. The results are shown in Table 2.

*Ring Closure of 4-Phenylhydrophthalic Acid (**2A**, **2B**, **2C**) with Acetic Anhydride or Acetyl Chloride. General Procedure*: A mixture of 4-phenylhexahydrophthalic acid (9.5 g) and acetic anhydride (40 m*l*) or acetyl chloride (40 m*l*) was refluxed for three hours. After the acetic anhydride (25 m*l*) or acetyl chloride (25 m*l*) had been removed from the reaction mixture, the solution was cooled in an ice-box for three days. We thus obtained a crystalline solid. The crystalline solid was washed with light petroleum ether (bp 30—70°C) and purified by recrystallization. The results are shown in Table 3.

Table 3. Ring closure of 4-Phenylhexahydrophthalic acid

Sample	Reagent	Product	Mp	Yield
2A	Acetic anhydride	**4A**[a)]	105—106°C[b)]	quant.
2A	Acetyl chloride	**4A**[a)]	106—107°C[b)]	8.4 g 89%
2B	Acetic anhydride	**4A**[a)]	106—107°C[b)]	quant.
2B	Acetyl chloride	**2B**[c)]	154—159°C[d)]	8.4 g 89%
2C	Acetic anhydride	**4A**[a)]	105—106°C[b)]	quant.

c) The structure of the product was confirmed by a mixed-melting-point determination and by a comparison of its IR spectra with those of an authentic sample.

d) Crude product.

e) IR: (Nujol) 1865, 1785 and 1600 cm^{-1}. The melting point of **4C** was depressed upon mixing with **4A**. The IR spectra of **4A** and **4C** were different in the fingerprint region. Found: C, 73.09; H, 6.13%. Calcd for $C_{14}H_{14}O_3$: C, 72.74; H, 6.44%.

The authors are very grateful to Professor K. Sisido, Dr. K. Uchimoto, and Mr. T. Imagawa of Kyoto University for their many helpful discussion and suggestions during this work. The authors are also grateful to Dr H. Takahashi, Government Industrial Research Institute, Osaka, for supplying the butadiene, to the Nozaki Laboratory of Kyoto University for the measurement of the NMR spectra, and to Mrs. K. Fujimoto of the Sisido Laboratory for her elemental analyses.

Stereochemical Studies in Friedel-Crafts Reactions. II. The Reactions of 4-Substituted Cyclohexenes with Benzene

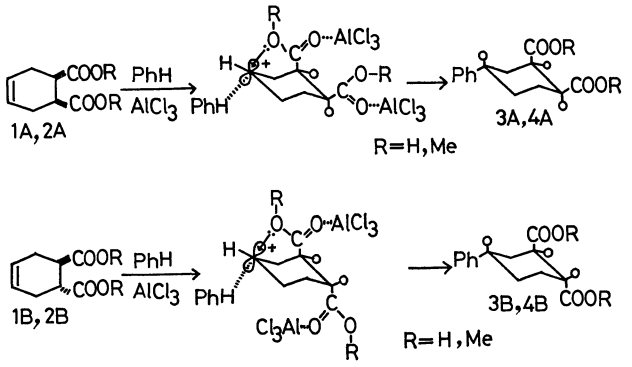
Kaichiro SUGITA and Shuzi TAMURA

Department of Chemistry, Ritsumeikan University, Kita-ku, Kyoto

(Received January 11, 1971)

The addition reactions of benzene to the double bonds of 4-substituted cyclohexenes, such as 4-benzoylcyclohexene (**5**), 4-acetylcyclohexene (**6**), methyl 4-cyclohexenecarboxylate (**7**), and 4-cyclohexenecarboxylic acid (**8**) have been studied in the presence of aluminum chloride. In all cases, the reactions gave mainly 1,4-disubstituted cyclohexane with the *trans* configuration stereoselectively. A possible mechanism for this reaction is suggested.

This paper will be concerned with a useful synthetic method for introducing the phenyl group exclusively at the 4-position of the monosubstituted cyclohexene ring by means of the Friedel–Crafts reaction. In the preceding paper[1] of this series, we reported that *cis*- and *trans*-Δ^4-tetrahydrophthalic acid and their dimethyl esters react with benzene in the presence of aluminum chloride to produce the corresponding 1,2,4-trisubstituted cyclohexanes. Thus, *cis*-Δ^4-tetrahydrophthalic acid (**1A**) or its dimethyl ester (**2A**) gives, stereoselectively, *trans*-4-phenyl-*cis*-hexahydrophthalic acid (**3A**) or its dimethyl ester (**4A**) respectively. Meanwhile, *trans*-Δ^4-tetrahydrophthalic acid (**1B**) or its dimethyl ester (**2B**) gives, stereoselectively, *cis*-4-phenyl-*trans*-hexahydrophthalic acid (**3B**) or its dimethyl ester (**4B**).



Scheme 1

This finding prompted us to explore the reaction of benzene with carbonium ions which are derived from 4-negatively substituted cyclohexenes. The present paper will describe some addition reactions of benzene to 4-benzoylcyclohexene (**5**), 4-acetylcyclohexene (**6**), methyl 4-cyclohexenecarboxylate (**7**), and 4-cyclohexenecarboxylic acid (**8**) in the presence of aluminum chloride.

Results and Discussion

The results of the reactions of various 4-substituted cyclohexenes with benzene have been summarized in Table 1. The products obtained from 4-substituted cyclohexenes and benzene were found by gas-chromatographic analysis to be composed of two components in all cases. The major components were *trans*-1,4-disubstituted cyclohexanes, whereas the minor components were the *cis*-1,4-disubstituted isomers. All the *trans*-products were identified by a comparison of the spectral and physical data with those of an authentic sample.[2] No 1,3-disubstituted product could be detected.[3]

The semi-crystalline solid obtained from the reaction of 4-benzoylcyclohexene (**5**) and benzene was found to be a mixture of *trans*-4-benzoyl-1-phenyl[4] cyclohexane (**9A**)(96%) and its *cis*-isomer (**9B**)(4%). Since no epimerization of **9A** by sodium ethoxide occurred, the phenyl and benzoyl groups must be diequatorial, *i.e.*, in the *trans* position[5] with respect to each other. On the other hand, the mother-liquid obtained from the reaction of **5** with benzene was converted to pure **9A** by the action of sodium ethoxide. This indicates that **9B** must be the *cis*-isomer. An oily product obtained from the reaction of 4-acetylcyclohexene (**6**) and benzene was found to be a mixture of *trans*-4-acetyl-1-phenylcyclohexane (**10A**) (95%) and its *cis*-isomer (**10B**)(5%). Likewise, methyl 4-cyclohexenecarboxylate (**7**) and benzene were found to be methyl *trans*-4-phenylcyclohexane-1-carboxylate (**11A**)(85%) and its *cis*-isomer (**11B**) (15%).

Thus, the above-mentioned reaction provides a useful method of preparing **9A**, **10A**, and **11A** in good yields. For example, the Friedel-Crafts reaction of **5**, followed by epimerization, gives **9A** in a 90% overall yield.

The reaction of 4-cyclohexenecarboxylic acid (**8**) with benzene gave a mixture of crystalline carboxylic acids in a 94% yield. The mixture of methyl esters obtained by treatment with diazomethane in ether consisted of the *trans* ester (**11A**)(67%) and its *cis*-isomer (**11B**)(33%). When the epimerization of

2) W. S. Johnson and R. D. Offenhauer, *J. Amer. Chem. Soc.*, **67**, 1045 (1945).

3) The results obtained in subsequent experiments suggest that the carbonium ion is formed at the 4-position. Therefore, the carbonium ion is not formed at the 3-position.

4) Since it has been reported[a,b] that the phenyl group has a substantially greater A value than the benzoyl, acetyl, and methoxycarbonyl groups, it is supposed that the phenyl group in this paper has an equatorial conformation. a) E. L. Eliel, N. L. Allinger, S. T. Angyal, and G. A. Morrison, "Conformational Analysis," Interscience Publishers, New York, N. Y. (1965), p. 236. b) E. W. Grabish, Jr., and D. B. Patterson, *J. Amer. (**7**)		118—121°C/5 mmHg	79	85 (27) : 15 (23)
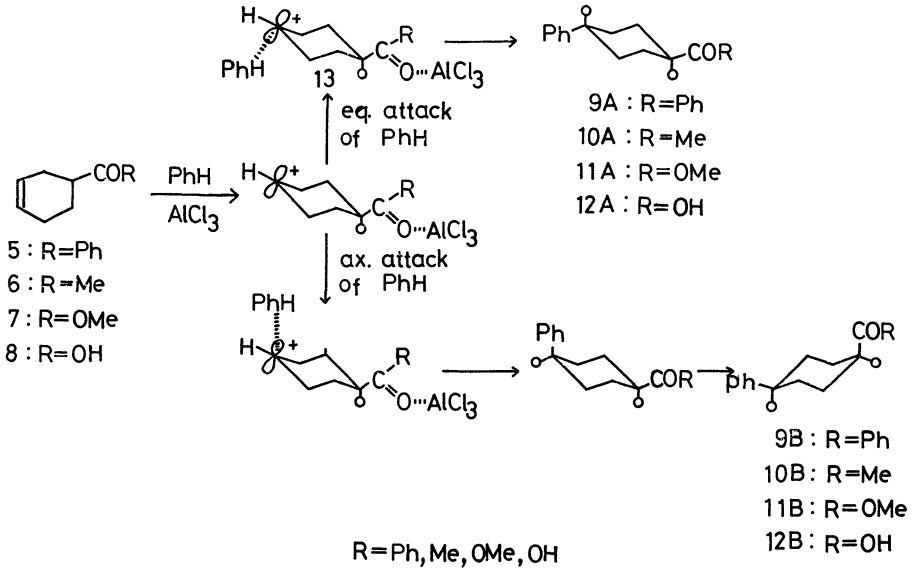
(**8**)		b)	94[c]	67 (26.5) : 33 (24.5)

a) By gas chromatographic analysis. The product ratio was calculated from the peak areas. Dimethyl *cis*-Δ^4-tetrahydrophthalate[1] was used as an internal standard for determination of yields.
b) Semi-crystalline solid.
c) The ratio of the acid was determined as the corresponding methyl ester.
d) Retention time (min).



Scheme 2.

the methyl ester was carried out in a manner similar to that described above, the **12A** acid was obtained. The **12A** acid was identified as being in a *trans*-isomer.

Thus, the addition of benzene to the double bond of 4-substituted cyclohexenes (**5**, **6**, **7**, **8**) in the presence of aluminum chloride selectively occurred at the 4-position to the substituent, as is shown in Table 1. These results indicate that the carbonium ion must be produced at the 4-position in these reactions. The equatorial attack of benzene on the carbonium ion should be more favorable than an axial attack, since it leads to a more favorable transition state (**13**) in which the substituent and attacking benzene are both equatorial. Thus, these reactions give rise to predominantly *trans*-1,4-disubstituted products.[6]

6) It may be considered that the result obtained in the present work support the mechanism.

Experimental[7]

Materials. 4-Acetylcyclohexene (**6**) was prepared by the procedure reported by Petrov.[8] Methyl 4-cyclohexenecarboxylate (**7**) and 4-cyclohexenecarboxylic acid (**8**) were prepared by the procedure reported by Klein, Dunkelblum, and Avrahami.[9]

4-Benzoylcyclohexene (5). This was obtained as follows. To a mixture of β-Chloropropiophenone (34 g),

7) All the melting points and boiling points are uncorrected. The IR spectra were taken on a Hitachi EPI-S spectrometer. The NMR spectra were obtained on a Japan Electron Optics C-60-H spectrometer. potassium acetate (30 g), and toluene (30 ml), butadiene (34 ml) was added in an autoclave. The solution was heated with stirring at 90—92°C for 24 hr. Then the inorganic salt was filtered off after adding toluene. The toluene solution was washed with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. The distillation of the reaction residue gave **5**; bp 125—126°C/5 mmHg (24 g, 63% yield). IR: (neat) 1670 (benzoyl) and 1645 cm^{-1} (olefin). NMR: $\delta(CDCl_3)$ 2.45—1.50 (m, 6, $3CH_2$), 3.50—3.00 (m, 1, CH), 5.80 (t, 2, CH=CH), 7.50—7.25 (m, 3, aromatic), and 8.10—7.75 ppm (m, 2, aromatic). Found: C, 84.45; H, 7.69%. Calcd for $C_{13}H_{14}O$: C, 83.83; H, 7.58%.

4-Acetyl-1-phenylcyclohexane. This was prepared by the procedure reported by Johnson and Offenhauer;[2] mp 55—56°C (lit,[2] 55.1—55.6°C). IR: (Nujol) 1700 (Ketone) and 1600 cm^{-1} (aromatic). NMR: $\delta(CDCl_3)$ 2.05—1.25 (m, 8, $4CH_2$), 2.18 (s, 3, CH_3), 2.75—2.25 (m, 2, 2CH) and 7.20 ppm (s, 5, aromatic).

Methyl 4-Phenylcyclohexane-1-carboxylate. This was prepared by the procedure reported by Johnson and Offenhauer;[2] mp 28—30°C (lit,[2] 29—30°C). IR: (Nujol) 1730 (ester) and 1600 cm^{-1} (aromatic). NMR: $\delta(CDCl_3)$ 2.90—1.20 (m, 10, $4CH_2$ and 2CH), 3.68 (t, 3, CH_3) and 7.22 ppm (s, 5, phenyl).

4-Phenylcyclohexane-1-carboxylic Acid. This was prepared by the procedure reported by Johnson and Offenhauer;[2] mp 200—201°C (lit,[2] 203—204°C).

4-Benzoyl-1-phenylcyclohexane from 4-Phenylcyclohexane-1-carboxylic Acid. A mixture of 4-phenylcyclohexane-1-carboxylic acid (3.3 g) and thionyl chloride (3.5 g) was refluxed for 2 hr and then cooled. The excess thionyl chloride in the reaction mixture was removed under an atmosphere of nitrogen at 30—40°C under reduced pressure. 4-Phenyl-1-chloroformylcyclohexane as a liquid was obtained quantitatively and was used directly, without distillation. To a suspension of aluminum chloride (2.5 g) in dry benzene (17 ml), we vigorously stirred in 4-phenyl-1-chloroformylcyclohexane (3.8 g), drop by drop, below 10°C. Stirring was continued for one hour without further cooling, and then for two more hours under reflux. Then the reaction mixture was poured onto icewater. The benzene solution was separated, washed with water, 5% sodium hydrogencarbonate, and water, dried over anhydrous magnesium sulfate, and evaporated to dryness. A semi-crystalline solid was dissolved in hot *n*-hexane. The solvent was then removed to give *trans*-4-benzoyl-1-phenylcyclohexane (1.0 g, 23% yield); mp 73—79°C. Recrystallization from *n*-hexane gave colorless prisms (0.7 g, 16% yield); mp 95—96°C. IR: (Nujol) 1670 (benzoyl) and 1600 cm^{-1} (aromatic). NMR: $\delta(CDCl_3)$ 2.25—1.40 (m, 8, $4CH_2$), 2.75—2.35 (m, 1, CH), 3.60—3.05 (m, 1, CH), 7.22 (s, 5, aromatic), 7.60—7.35 (m, 3, aromatic), and 8.15—7.80 ppm (m, 2, aromatic). Found: C, 86.33; H, 7.68%. Calcd for $C_{19}H_{20}O$: C, 86.32; H, 7.63%.

Aluminum Chloride-catalyzed Reaction of 4-Substituted Cyclohexene with Benzene. General Procedure: Into a solution of 4-substituted cyclohexene (0.05 mol) in dry benzene (0.5 mol) we stirred aluminum chloride (0.06 mol) over a five-minute period below 10°C. Stirring was continued for one hour without further cooling, and then for two additional hours under reflux. Then the reaction mixture was poured onto icewater. The benzene solution was separated, dried over anhydrous magnesium sulfate, and evaporated to dryness. The product was purified by recrystallization or distillation.

trans-*4-Benzoyl-1-phenylcyclohexane* (***9A***) *from 4-Benzoylcyclohexene* (***5***). The reaction product was recrystallized from *n*-hexane to give **9A** as colorless prisms; mp 96—98°C, 74% yield. The mother liquid was used as the epimerization sample. **9A** was identified · as 4-benzoyl-1-phenylcyclohexane by a mixed-melting-point determination and by a comparison of its IR and NMR spectra with those of an authentic sample.

trans-*4-Acetyl-1-phenylcyclohexane* (***10A***) *from 4-Acetylcyclohexene* (***6***). The product was kept standing in an ice-box for 10 days to separate a crystalline solid (**10A**) (62% yield) from the mother liquid. The mother liquid was used as the epimerization sample. The recrystallization of **10A** from light petroleum ether (bp 30—70°C) gave colorless prisms; mp 54—55°C. **10A** was identified as 4-acetyl-1-phenylcyclohexane by a mixed-melting-point determination and by a comparison of its IR and NMR spectra with those of an authentic sample (Found: C, 82.96; H, 9.12%).

Methyl trans-*4-Phenylcyclohexane-1-carboxylate* (***11A***) *from Methyl 4-Cyclohexenecarboxylate* (***7***). The product was kept standing in an ice-box for 10 days to separate a crystalline solid (**11A**) (27% yield) from the mother liquid (52% yield). The mother liquid was used as the epimerization sample. The recrystallization of **11A** from *n*-hexane gave colorless prisms; mp 29—30°C. **11A** was identified as methyl 4-phenylcyclohexane-1-carboxylate by a mixed-melting-point determination and by a comparison of its IR and NMR spectra with those of an authentic sample (Found: C, 77.20; H, 8.29%).

trans-*4-Phenylcyclohexane-1-carboxylic Acid* (***12A***) *from 4-Cyclohexenecarboxylic Acid* (***8***). The reaction product was recrystallized from 60% aqueous acetic acid to give a crystalline solid; mp 79—124°C. The recrystallization of the crystalline solid from 60% acetic acid gave colorless needles (**12A**) (3% yield); mp 199—200°C. **12A** was identified as 4-phenylcyclohexane-1-carboxylic acid by a mixed-melting-point determination and by a comparison of its IR and NMR spectra with those of an authentic sample. IR: (KBr) 2400—2700 (-OH), 1685 (carboxyl) and

TABLE 2. EPIMERIZATION OF 1,4-DISUBSTITUTED CYCLOHEXANE

Sample	Product	Mp(°C)	Yield	
			mg[f]	%
9A	9A	94— 98	450	90
Mother liquid[a]	9A	92— 96	400	80
10A	10A	51— 55	450	90
Mother liquid[b]	10A[e]	54— 55	400	80
11A	12A	197—200	400	90
Mother liquid[c]	12A	198—201	400	90
d)	12A	195—199	350	80

In all cases, the product obtained was identified by mixed melting point and by comparison of IR spectra with that of authentic sample.

a) From the reaction of **5** with benzene.
b) From the reaction of **6** with benzene.
c) From the reaction of **7** with benzene.
d) Crude product obtained from the reaction of **8** with benzene was converted into its methyl ester by esterification of diazomethane.
e) The product obtained crystallized upon standing in an ice-box. Recrystallization from petroleum ether (bp 30—70°C) gave colorless prisms.
f) Yield from 500 mg of the sample.

1600 cm^{-1} (aromatic) (Found: C, 76.33; H, 7.82%).

General Epimerization Procedure. To a sodium ethoxide solution prepared from absolute ethanol (50 m*l*) and sodium (100 mg), we added the sample (500 mg). The solution was refluxed for five hours and then cooled. After the addition of water (100 m*l*) to the reaction mixture, the resulting mixture was acidified and filtered. The results are shown in Table 2.

The authors are very grateful to Professor K. Sisido, Dr. K. Uchimoto, and Mr. T. Imagawa of Kyoto University for their many helpful discussions and suggestions during this work. The authors are also grateful to Dr. H. Takahashi, Government Industrial Research Institute, Osaka, for supplying the butadiene, to the Nozaki Laboratory of Kyoto University for the measurement of the NMR spectra, and to Mrs. K. Fujimoto of the Sisido Laboratory for elemental analyses.

Studies on Separation of Amino Acids and Related Compounds. V. A Racemization Test in Peptide Synthesis by the Use of an Amino Acid Analyzer[1,2]

Nobuo IZUMIYA, Masako MURAOKA, and Haruhiko AOYAGI

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received March 16, 1971)

Several tripeptides, H-Gly-DL-Ala-B-OH, in which B residues are DL-alanine, L-valine, L-leucine, L-phenylalanine, L-proline, and L-serine have been synthesized and the separation of each glycyltripeptide diastereomers by an amino acid analyzer have been studied. Among six peptides studied, diastereomeric mixtures of H-Gly-DL-Ala-L-Val-OH and H-Gly-DL-Ala-L-Leu-OH were separated completely. A procedure to determine the amounts of LL and DL diastereomer of H-Gly-Ala-Leu-OH by the use of the analyzer was developed, and this procedure was applied to examine the influence of coupling reagents for racemization during coupling of benzyloxycarbonyl-glycyl-L-alanine and L-leucine benzyl ester by several reagents.

To determine the extent of racemization during peptide bond formation several methods have been reported in the literatures.[3] We have attempted to find a convenient racemization test with the application of an automatic amino acid analyzer though Bodanszky and Conklin already reported the use of the analyzer for such purpose.[4] They applied the analyzer for amino acid analysis of acid hydrolysate of a coupling product derived from Ac-L-Ile-OH[5] and H-Gly-OEt, and determined the amounts of L-isoleucine and D-alloisoleucine. Manning and Moore reported the use of the analyzer in the system involving the coupling of *N*-carboxyanhydride of L-leucine and a DL-amino acid.[6]

In this paper we report an accurate procedure to determine the degree of racemization by an amino acid analyzer and the results of the influence of several coupling reagents on the extent of racemization during peptide synthesis.

The proposed scheme for racenization test is shown in Fig. 1. The crude Z-tripeptide-OBz 1 is subjected to hydrogenolysis, the hydrogenated material is submitted to the analyzer, and the amounts of the LL and DL diastereomers are determined.

$$\text{Z-Gly-L-A-OH} + \text{H-L-B-OBzl} \xrightarrow[\text{of A residue)}]{\text{(with partial racemization}} \text{Z-Gly-A-B-OBzl (LL plus DL)} \xrightarrow{H_2\text{-Pd}} \text{H-Gly-A-B-OH (LL plus DL)}$$

Fig. 1. Proposed sequence of synthesis of a diastereomeric mixture.

It was tried previously to discover a convenient system of glycyltripeptide diastereomers for separation by the analyzer.[1] We synthesized the LL and DL isomer of H-Gly-Lys-Glu-OH and similar several tripeptides, with the surmise that a diastereomeric mixture of a polyfunctional neutral tripeptide might be efficiently separated under appropriate conditions. It was observed, however, that all mixtures gave incomplete separation.[1] In the present investigation, we selected rather simple systems involving H-Gly-Ala-B-OH tripeptides in which B could be Ala, Val, Leu, Phe, Pro, and Ser residues.

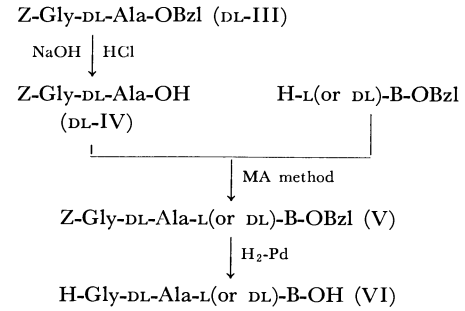

Fig. 2. Synthesis of a crude tripeptide consisting of diastereomers. B; DL-Ala, L-Val, L-Leu, L-Phe, L-Pro or L-Ser residue.

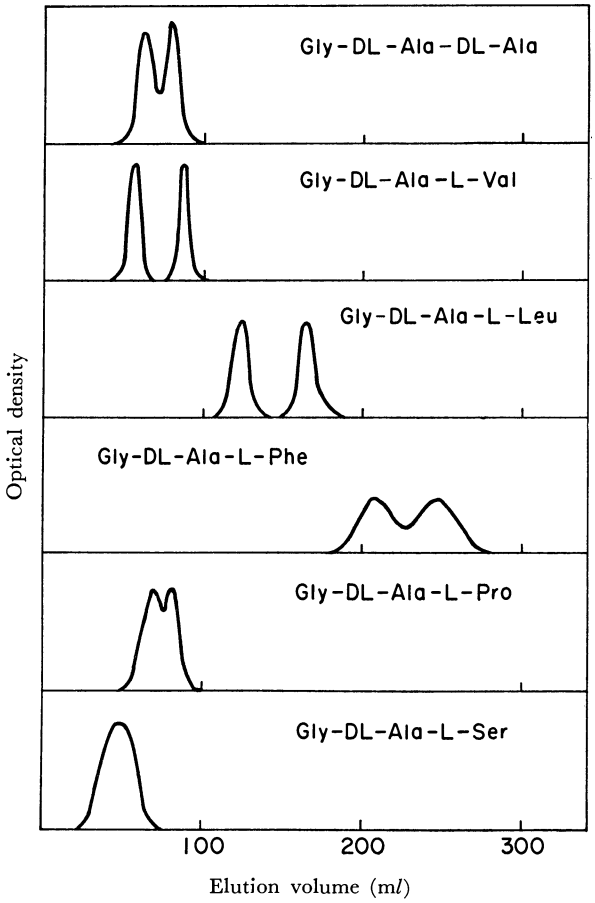

Fig. 3. Elution pattern of H-Gly-DL-Ala-B-OH (VI).

In the previous paper, each pure diastereomer of a tripeptide such as H-Gly-Lys-Glu-OH was prepared, and an artificial mixture of the diastereomers was subjected to separation experiment.[1] In this investigation, a crude tripeptide (VI) consisting of diastereomers was synthesized as shown in Fig. 2 instead of preparation of a pair of pure diastereomers. As shown in Fig. 3, the diastereomeric mixture containing Val or Leu residue as B component was found to be separated completely by the analyzer, and the other mixture containing Ala, Phe, Pro, or Ser separated incompletely.

A diastereomeric mixture of H-Gly-Ala-Leu-OH (IX) was the preferred system for the racemization test (see, Fig. 4) because two peaks of IX were not overlapped with either leucine or H-Gly-Ala-OH

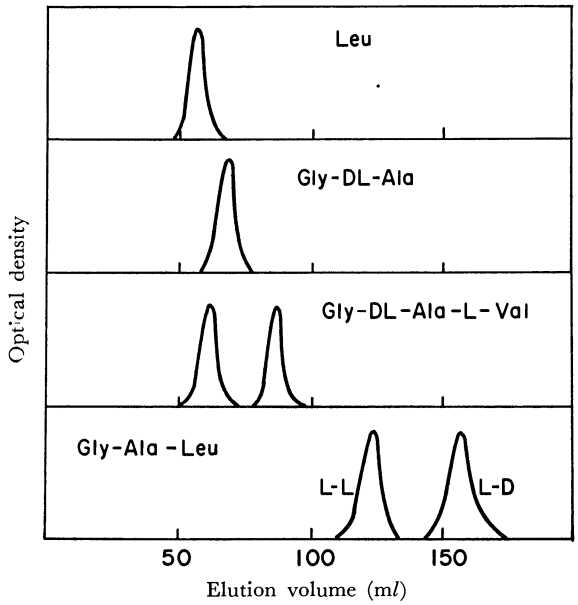

Fig. 4. Elution pattern of amino acid and peptides.

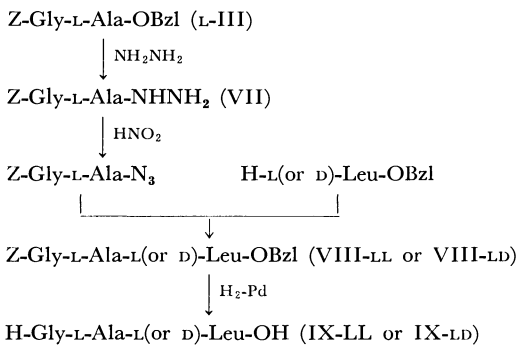

Fig. 5. Synthesis of a pure tripeptide.

which might be contaminated in a final crude tripeptide (see, Fig. 1).[7] A pair of pure diastereomers of IX was prepared as shown in Fig. 5 to be used for identification of two peaks in Fig. 3; the LL isomer was eluted faster than the corresponding LD isomer (Fig. 4).

The limit of detection of the LD contaminated in the LL isomer was studied with an artificial mixture of both isomers. Even when a mixture of the LL isomer (5 μmol) and DL (0.005 μmol) was analyzed, a small peak of the DL could still be recognized. It will be evident that the present method is more sensitive in detecting the slight occurrence of racemization than the Anderson test which has been used widely nowadays.[3]

The present method was applied in the detection of a possible racemization in azide procedure. A crude Z-Gly-Ala-Leu-OBzl obtained from pure Z-Gly-L-Ala-N_3 and H-L-Leu-OBzl was directly hydrogenated, and a part of the filtrate from a hydrogenated mixture was submitted to the analyzer. The material in the filtrate showed only single peak by the LL isomer,

7) Several related amino acids and peptides were subjected to the analyzer; glycine was eluted at 32 ml of effluent volume, alanine at 36 ml, LD isomer of H–Ala–Leu–OH at 126 ml, and its LL isomer at 138 ml.

Table 1. Extent of racemization during peptide bond formation[a)]

No.	Coupling reagent	Additional component	Solvent	Tertiary amine	Reaction time, hr	Reaction temp., °C	Yield of tripeptide (IX-LL plus IX-DL), %	Extent of racemization
1[b)]	Isobutyl chloroformate		THF	TEA	15	25	87	9.5
2	Isobutyl chloroformate		THF	NMM	15	25	91	2.4
3[c)]	Isobutyl chloroformate	HOSu	THF	TEA	2	25	55	1.1
4[c)]	Isobutyl chloroformate	HOSu	THF	NMM	2	25	63	0.2
5	DCC		THF	TEA	48	0	73	22
6	DCC		THF	NMM	48	0	77	21
7[d)]	DCC	HOSu	THF	TEA	48	0	98	0.0
8[c)]	NEPIS		CH_3CN	TEA	24	25	95	1.8
9	NEPIS		CH_3CN	NMM	24	25	72	1.7
10[c)]	EEDQ		THF	TEA	7	25	97	0.2
11	EEDQ		THF	NMM	7	25	91	0.2

a) All components (Z-Gly-L-Ala-OH, H-L-Leu-OBzl, coupling reagent, HOSu and tertiary amine) in the coupling were of equivalent weight.
b) The procedure following that in the literature[10] was noted in detail in the experimental part.
c) The procedure was similar to that described in the literatures: MA,[11] NEPIS,[15] and EEDQ.[16]
d) The procedure reported[12] was slightly modified; the components were of equivalent weight and the temperature was 0°C during the entire reaction.

using a load of up to 6 μmol. The result agreed with the fact that the azide procedure has been considered to be safe to avoid racemization.[3,8]

This procedure was employed to examine the influence of various coupling reagents to racemization, the experiments being summarized in Table 1. In a typical mixed anhydride (MA) method, the coupling yield of Z-Gly-L-Ala-OH and H-L-Leu-OBzl was approximately 87%[9] and the extent of racemization,[4] which is defined as {100[DL isomer]}/{[LL isomer]+[DL isomer]}, was calculated as 9.5. Anderson and his colleagues reported that the extent of racemization was 9 using fractional crystallization in case of the coupling of Z–Gly–L–Phe–OH and H–Gly–OEt.[10] The use of NMM instead of TEA decreased the recemization as 2.4 in this experiment, but Anderson *et al.* reported no isolation of a DL-tripeptide in their experiment.[10] The difference of these results may be due to the differences of the detection method for racemization and of the compounds investigated. The addition of HOSu to the MA system with TEA or NMM decreased the degree of racemization considerably; the results confirm the observation of Anderson and Callahan on the role of HOSu in the MA method.[11]

In the DCC method, the extents of racemization were calculated as 22 and 21 respectively when TEA and NMM were used (Table 1). It was reported previously that the extent of racemization was 9.4 in case of the coupling of Z–L–Leu–L–Phe–OH and H–L–Val–OBu^t,[12] and 9.1—10.6 in case of Z–Gly–L–Phe–OH and H–Gly–OEt.[13] No explanation for the higher degree of racemization observed in our experiment can be offered at the present time. On the contrary the coupling using HOSu and DCC gave no racemate; Weygand *et al.*[12] also reported the occurrence of less than 1% racemization under the similar conditions.

The extent of racemization were calculated as 1.7—1.8 and 0.2 in the applications of NEPIS[14,15] and EEDQ[16] respectively. These results showed similar levels of racemizations observed previously; 3.2 with NEPIS[17] and no detection of a recemate with EEDQ[16] were reported.

A simple and straightforward procedure described in this paper will be a useful test to detect possible

8) The occurrence of racemization have been reported recently even in the case of the azide procedure when unusual reaction condition was applied: G. W. Anderson, J. E. Zimmerman, and F. M. Callahan, *J. Amer. Chem. Soc.*, **88**, 1338 (1966); H. Determann, "Peptides," ed. by H. C. Beyerman, A. Van de Linde, and W. Maassen van den Brink, North-Holland Pub. Co., Amsterdam (1967), p. 73.

9) Yield of 87% was derived from an analysis of H–Gly–Ala–Leu–OH (LL plus DL isomer) by an amino acid analyzer. We assume that the yield of free tripeptide corresponds to approximately that of Z–Gly–Ala–Leu–OBzl (VIII) because the hydrogenation of VIII will proceed quantitatively.

racemization when a new coupling method is developed in future.

Experimental

R_f of thin-layer chromatography with Merck silica gel G refers to *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, vol) system. Benzyl ester toluenesulfonates of L-valine,[18] L-[18] and D-leucine,[19] L-phenylalanine,[18] and L-serine,[20] and H-Gly-DL-Ala-OH[21] were prepared following the literatures.

H-DL-Ala-OBzl·TsOH (I). This was prepared according to the procedure for the L isomer.[18] Yield, 82%, mp 109°C; R_f 0.74 (Found: C, 57.97; H, 6.13; N, 4.13%).

H-L-Pro-OBzl·TsOH (II). A mixture of L-proline, benzyl alcohol, toluenesulfonic acid, and benzene was treated following the general procedure.[18] Yield of II as an oil, 98%; R_f 0.69.

Z-Gly-DL-Ala-OBzl (DL-III). To a chilled solution (−10°C) of Z-Gly-OH (2.1 g) and TEA (1.4 m*l*) in THF (20 m*l*), isobutyl chloroformate (1.31 m*l*) was added. After 10 min, a mixture of I (3.52 g), TEA (1.4 m*l*) and chloroform (20 m*l*) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated to dryness. After the residual oil was dissolved in ethyl acetate, the solution was washed with 2% hydrochloric acid and 4% sodium bicarbonate, and dried over sodium sulfate. The filtrate was evaporated and the residue was crystallized by addition of petroleum ether. It was recrystallized from ethyl acetate-petroleum ether; yield, 2.54 g (69%); mp 91°C (Found: C, 64.94; H, 5.96; N, 7.52%). Wieland and Heinke prepared this compound by MA method with phosphorus oxychloride; mp 91—92°C.[22]

Z-Gly-L-Ala-OBzl (L-III). This was obtained from Z-Gly-OH and H-L-Ala-OBzl·TsOH as described above. Yield, 62%; mp 77°C; $[\alpha]_D^{25}$ −14.0° (*c* 1, ethyl acetate) (Found: C, 65.07; H, 6.01; N, 7.56%). Gante prepared this compound by a coupling of Z-Gly-OH and N-2,4-dinitrophenyloxycarbonyl-L-Ala-OBzl; mp 77—78°C.[23]

Z-Gly-DL-Ala-OH (DL-IV). To a solution of DL-III (3.7 g, 10 mmol) in methanol (30 m*l*), N sodium hydroxide (12 m*l*) was added. After 2 hr, N hydrochloric acid (12 m*l*) was added and the solution was evaporated. The resulting crystals were collected by aid of cold water. It was recrystallized from ethanol-ether; yield, 1.99 g (71%); mp 182°C (Found: C, 55.56; H, 5.84; N, 9.76%). Clayton *et al.* prepared this compound by a coupling of DL-alanine and a mixed anhydride derived from Z-Gly-OH; mp 183°C.[24]

Z-Gly-L-Ala-OH (L-IV). This was obtained from L-III as described above. Yield, 82%; mp 133°C; $[\alpha]_D^{20}$ −9.8° (*c* 4.4, ethanol) (Found: C, 55.58; H, 5.73; N, 9.81%). This was prepared previously by a coupling of L-alanine and Z-Gly-OH mixed anhydride,[24] and by saponification of Z-Gly-L-Ala-OEt[25]; mp 133°C,[24] 119.5°C;[25] $[\alpha]_D$ −9.5°,[24] −10.2° (ethanol).[25]

Z-Gly-DL-Ala-B-OBzl (B=DL-Ala, L-Val, L-Leu, L-Phe, L-Pro or L-Ser) (V). This compound was prepared from DL-IV (0.28 g, 1 mmol) and a benzyl ester (1 mmol) of an amino acid B as described for the preparation of DL-III. Ethyl acetate solution was dried, and evaporated to yield an oily product (0.3—0.4 g). It contained a compound V indicating R_f 0.94—0.96, and was used for the next step without purification.

H-Gly-DL-Ala-B-OH (VI). A solution of each V (0.3—0.4 g) in 90% acetic acid (5 m*l*) was treated with hydrogen in the presence of palladium black. After several hr, the material with R_f 0.94—0.96 disappeared and a material with R_f 0.21—0.46 appeared; a material in the solution showed R_f 0.21 (H-Gly-DL-Ala-B-OH in which B is L-Ser), 0.31 (DL-Ala), 0.34 (L-Pro), 0.43 (L-Val), 0.44 (L-Phe), and 0.46 (L-Leu). The filtrate from the catalyst was evaporated to dryness. The residual hygroscopic solid was used as such in an experiment with an amino acid analyzer as described later.

Z-Gly-L-Ala-NHNH$_2$ (VII). A solution of L-III (3.7 g) and hydrazine hydrate (2.4 m*l*) in methanol (10 m*l*) was allowed to stand at room temperature for 2 days. It was evaporated and the residual solid was recrystallized from acetone-ether; yield, 2.7 g (92%); mp 134°C; $[\alpha]_D^{25}$ −30.0° (*c* 1, methanol). This was prepared previously from Z-Gly-L-Ala-OEt; mp 133°C,[26] mp 158—160°C.[27]

Z-Gly-L-Ala-L-Leu-OBzl (VIII-LL). To a chilled solution of VII (2.36 g) in acetic acid (50 m*l*) and 2 N hydrochloric acid (10 m*l*), an aqueous solution (5 m*l*) containing sodium nitrite (0.64 g) was added. After 5 min at −5°C, the azide was extracted with ethyl acetate (50 m*l*×3). An organic layer was washed with 10% sodium bicarbonate and dried over sodium sulfate. The filtrate was added to a mixture of H-L-Leu-OBzl·TsOH (3.2 g) and TEA (1.12 m*l*) in DMF (40 m*l*). After 3 days at 0°C, the reaction mixture was evaporated and the residue was dissolved in ethyl acetate. Ethyl acetate solution was washed with 2% hydrochloric acid and 4% sodium bicarbonate, dried, and evaporated. The residual solid was recrystallized from ether-petroleum ether; yield, 2.72 g (70%); mp 102°C; $[\alpha]_D^{25}$ −31.6° (*c*, 1, ethyl acetate).

Found: C, 64.29; H, 7.00; N, 8.47%. Calcd for $C_{26}H_{33}O_6N_3$: C, 64.58; H, 6.88; N, 8.69%.

Z-Gly-L-Ala-D-Leu-OBzl (VIII-LD). Reaction of VII (2.36 g) and H-D-Leu-OBzl·TsOH (3.2 g) as described above yielded 2.48 g (64%) of VIII-LD; mp 125°C; $[\alpha]_D^{25}$ −1.0° (*c* 1, ethyl acetate).

Found: 64.80; H, 6.93; N, 8.49%. Calcd for $C_{26}H_{33}O_6N_3$: C, 64.58; H, 6.88; N, 8.69%.

H-Gly-L-Ala-L-Leu-OH (IX-LL). VIII-LL (1.93 g) was hydrogenated as described for the preparation of VI. The filtrate was evaporated and the resulting crystals were collected by aid of ethanol. It was recrystallized from water-methanol; yield of an air-dried material, 0.93 g (88%); mp 242—245°C (decomp); R_f 0.59; $[\alpha]_D^{25}$ −84.0° (*c* 1, water) (for $C_{11}H_{21}O_4N_3 \cdot 1/4\,H_2O$. Found: C, 50.31; H, 8.22; N, 15.80%; H_2O, 1.65%). The same compound without water of crystallization was prepared previously from Z-Gly-L-Ala-L-Leu-OMe; $[\alpha]_D^{23}$ −87° (water).[27]

H-Gly-L-Ala-D-Leu-OH (*IX*-LD). This was prepared from VIII-LD; yield of an air-dried material, 86%; mp 243—245°C (decomp); R_f 0.57; $[\alpha]_D^{25}$ −29.6° (*c* 0.4, water).

Found: C, 49.20; H, 8.29; N, 15.75%. Calcd for $C_{11}H_{21}O_4N_3 \cdot 1/2H_2O$: C, 49.24; H, 8.27; N, 15.66%. The air-dried sample lost 3.03% of its weight after being dried for 3 hr at 80°C *in vacuo*. Calcd for $1/2H_2O$: 3.35%.

Chromatography of Amino Acids and Peptides by Amino Acid Analyzer. A diastereomeric mixture (VI; approximately 1 μmol) of tripeptide was analyzed by a Hitachi amino acid analyzer, model KLA-3B, under the following conditions: length of column with spherical resin, 0.9×50 cm; solvent, a standard 0.2 M citrate buffer at pH 4.25; flow rate, 60 m*l*/hr; jacket temperature, 55°C. The patterns obtained are shown in Fig. 3. Similarly, amino acids (0.5 μmol), dipeptides (0.5 μmol), and an artificial mixture (1 μmol) of the LL and LD isomer of H-Gly-Ala-Leu-OH (IX) were analyzed; some of the patterns are shown in Fig. 4. It was observed that leucine was eluted at 58 m*l* of effluent volume, H-Gly-DL-Ala-OH at 73 m*l*, IX-LL at 129 m*l*, and IX-LD at 159 m*l*.

Detection of Racemization. *(a) Possible Racemization in Azide Method*: The azide derived from Z-Gly-L-Ala-$NHNH_2$ (VII) was condensed with H-L-Leu-OBzl as described in the preparation of VIII-LL. Ethyl acetate solution was evaporated, the crude Z-Gly-Ala-Leu-OBzl was hydrogenated, the filtrate from the catalyst was evaporated, and a part (6 μmol) of the residue was submitted to the analyzer. The product showed only single peak of IX-LL.

(b) Racemization in MA Method: Similar conditions (temperatures and reaction times) for coupling of Z-Gly-L-Phe-OH and H-Gly-OEt by MA method[9] were applied for the present experiment. To Z-Gly-L-Ala-OH (L-III) (1 mmol) in THF (5 m*l*) was added isobutyl chloroformate. After 12 min at −15°C, a mixture of H-L-Leu-OBzl·TsOH and TEA in THF (5 m*l*) was added, and the reaction mixture was left at 25°C for 15 hr. The mixture was treated as described in the preparation of DL-III, and the ethyl acetate solution was evaporated; yield of a crude solid (VIII), 474 mg. A part (47.4 mg) of VIII was hydrogenated in 90% acetic acid, and the filtrate was evaporated. The residue was dissolved in 0.2 M citrate buffer at pH 4.25 (10 m*l*), and a part (0.7 m*l*) of it was submitted to the analyzer; the yield of H-Gly-Ala-Leu-OH (LL plus DL) from L-III was calculated as 87%, and the extent of racemization was calculated as 9.5. Similar experiment with NMM instead of TEA was carried out, and the yield of the tripeptide and the extent of racemization were calculated (see, Table 1).

(c) Racemization in other Methods: Z-Gly-L-Ala-OH was condensed with H-L-Leu-OBzl by a method using the reagent of DCC, NEPIS or EEDQ. An isolation of crude Z-Gly-Ala-Leu-OBzl (VIII), the hydrogenation of VIII, and an analysis of the hydrogenated material were identical with the procedures described above. The results are summarized in Table 1.

We wish to express our thanks to Dr. K. Noda of this laboratory for his help with an amino acid analyzer and to Professor B. Belleau for the generous gift of EEDQ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3395—3399 (1971)

Syntheses of (3S, 4R, 15S)-4,15-Dimethyl-1,5-dioxa-3-(3′-formamidosalicylamido)-cyclopentadecane-2,6-dione and Its (15R)-Epimer, New Antimycin Analogs[1]

Mitsuhiro KINOSHITA, Keitaro ISHII, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received April 16, 1971)

A new type of antimycin analogs, (3S, 4R, 15S)-4,15-dimethyl-1,5-dioxa-3-(3′-formamidosalicylamido)-cyclopentadecane-2,6-dione (**10a**) and its (15R)-epimer (**10b**) have been synthesized. The epimeric fifteen-membered amino-dilactone moieties in **10a** and **10b** were synthesized from a masked L-threonine and *t*-butyl DL-10-hydroxyundecanoate. Each of the separated epimeric amino-dilactones was *N*-acylated with *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester. Hydrogenation followed by *N*-formylation afforded the antifungal substances, **10a** and **10b**. The 10-*C*-configurations of **10a** and **10b** were determined as "S" and "R", respectively. The (15S)-epimer (**10a**) showed apparently stronger antifungal activity against *Piricularia oryzae* than that of the (15R)-epimer (**10b**).

Recently the total syntheses of dehexyl-deisovaleryl-oxy-antimycin A_1 as a prototype of antimycin A and of antimycin A_3 in a form of the diastereoisomeric mixture have been reported from our laboratory.[2,3]

The most striking characteristic of the structure of antimycin A is its nine-membered dilactone ring linked *via* an amide linkage to 3-formamidosalicylic acid.[4] We now wish to report the syntheses of a new type of antimycin analogs (**10a**) and its epimer (**10b**) which have a fifteen-membered dilactone ring instead of nine-membered ring in antimycin A.

t-Butyl 10-oxoundecanoate (**2**) was prepared from 10-oxoundecanoic acid (**1**)[5] and isobutene by the

same method as previously reported[2] in an 83% yield. Sodium borohydride reduction of **2** in tetrahydrofuran afforded *t*-butyl DL-10-hydroxyundecanoate (**3**) in a 95.8% yield. Catalytic hydrogenation of **2** with Raney Ni W-5 in ethanol also gave 3, however, the yield in this process was low (57.1%).

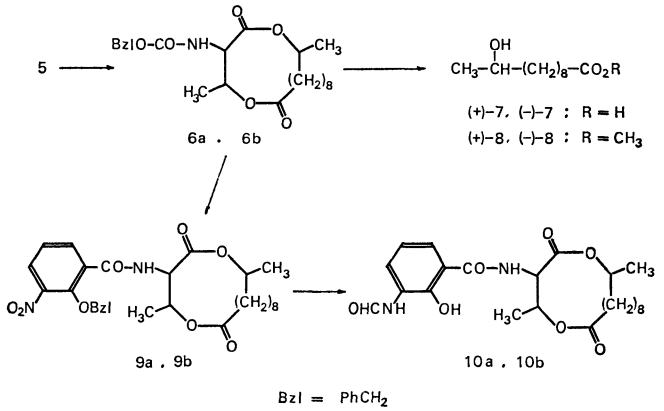
5: R=H

The racemic *t*-butyl 10-hydroxyundecanoate (**3**) was allowed to react with excess amount of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine[6] in the presence of *N*,*N*′-dicyclohexylcarbodiimide (DCCI) and pyridine in ether. The condensation product was purified by silica gel column chromatography with a petroleum ether - diisopropyl ether (2 : 1) system to afford *t*-butyl 10-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonyloxy)undecanoate (**4**) as a diastereomeric mixture in a 63.5% yield.

De-*t*-butylation of **4** with trifluoroacetic acid gave a free linear ester acid (**5**) which was cyclized in 0.04 M benzene solution by adding 2 moles of trifluoroacetic anhydride at 70°C for 23 hr. The reaction mixture was concentrated and chromatographed on silica gel with a benzene-butanone (30 : 1) system to give from the first and second peaks crystalline cyclization products, **6a** and **6b** in 18.2 and 17.5%, respectively. The products, **6a** and **6b** were found to be the diastereomeric intramolecular cyclization products, namely, the single 15-*C*-epimers of (3S, 4R)-3-(benzyloxycarboxamido)-4,15-dimethyl-1,5-dioxacyclopentadecane-2,6-dione on the basis of elemental analyses, NMR, IR spectra, and molecular weight determinations by mass spectra.



6) E. Schröder, *Ann. Chem.*, **670**, 127 (1963).

The absolute configurations of 15-C-atoms in the epimeric dilactone compounds, **6a** and **6b** were determined as "S" and "R", respectively, by application of Horeau's method[7] to the optical active methyl 10-hydroxyundecanoate, (+)-**8** and (−)-**8**, which were obtained by diazomethane treatment of the crystalline enantiomers, 10-hydroxyundecanoic acids, (+)-**7** and (−)-**7**, derived from **6a** and **6b**, respectively, by the hydrolysis with methanolic sodium hydroxide solution.

The benzyloxycarbonyl groups of **6a** and **6b** were removed by catalytic hydrogenolysis over palladium black in methanol to give the corresponding free amino-dilactones, which were directly *N*-acylated with an active ester, *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester[2] in tetrahydrofuran.

The crude *N*-acylation products were purified through silica gel columns with a *n*-hexane-ethyl acetate (2 : 1) system to afford the corresponding (3S,4R,15S)-4,15-dimethyl-1,5-dioxa-3-(*O*-benzyl-3′-nitrosalicylamido)-cyclopentadecane-2,6-dione (**9a**) and its (15R) epimer (**9b**) as glassy solids in 89.2 and 86.1% yield, respectively. The structures of **9a** and **9b** were confirmed by their NMR spectra (Table 1).

The compounds, **9a** and **9b** were then hydrogenolyzed over palladium black in methanol to yield the corresponding *N*-(3′-aminosalicyloyl)amidodilactones, which were immediately *N*-formylated with 98% formic acid and DCCI. The crude products were purified by preparative thin-layer chromatography with a *n*-hexane-ethyl acetate (2 : 1) system to afford the title compounds, (3S, 4R, 15S)-4,15-dimethyl-1,5-dioxa-3-(3′-formamidosalicylamido)-cyclopentadecane-2,6-dione (**10a**)(as a crystal) and its (15R)-epimer (**10b**)(as a glassy solid), in 44.7 and 50.7% yield, respectively.

The UV-absorptions of **10a** and **10b** were very similar to those of natural antimycin A and dehexyldeisovaleryloxy-antimycin A_1. The IR-spectra were also similar to those of the natural product and the analog in respect to the characteristic absorptions assignable to ester carbonyl, formamido and aromatic amido groups.

The structures of **10a** and **10b** were further confirmed by the inspection of their NMR spectra (Table 1).

The coupling constants ($J_{3,4}$=2.0) observed in the NMR spectra of the dilactone compounds, **6a**, **6b**, **9a**, **9b**, **10a**, and **10b** (Table 1) are consistent with the partial conformation in which the vicinal threonine-protons, 3–H and 4–H of the fifteen-membered dilactone ring are *gauche*-related. It has recently been reported that in neoantimycin,[8] the vicinal threonine-protons of the fifteen-membered tetralactone ring have a small coupling constant (J=2.5 Hz), similar to that of the dilactone compounds as described above.

Bioassay. The synthetic new antimycin analogs, **10a** and **10b** showed strong inhibition against certain fungi. Minimal inhibitory concentrations

a) d., doublet; dd., doublet-doublet; m., multiplet; s., singlet; dq., doublet-quartet; t., triplet; tq., triplet-quartet.
b) Internal standard TMS in *ca.* 10% deuteriochloroform solution.
c) In parentheses.

(mcg/ml) of **10a** and **10b** against *Piricularia orizae* were 1.2×10^{-2} and 12.5, respectively.

It is noteworthy that the configurational or conformational difference between the epimeric dilactone structures of **10a** and **10b** may apparently reflect on the striking difference between their antifungal activities.

Experimental

Melting points were determined on a micro hot stage and were uncorrected. Thin-layer chromatography (TLC) was conducted by the use of WAKOGEL B-5 (Wako Pure Chemical Industries, Ltd.). Silica gel column chromatography was carried out by using WAKOGEL C-200 which was activated at 110°C for 1 hr. IR-spectra were recorded on a Hitachi IPI-2 spectrometer, UV-spectra were taken in a Hitachi Perkin-Elmer UV-VIS spectrometer 139. NMR spectra were recorded on a Varian-A-60D spectrometer (TMS as an internal standard) in *ca.* 5—10% (W/V) solution in deuteriochloroform. Optical rotations were measured with a Zeiss Photoelectric Precision Polarimeter 0.005° employing a 0.5 decimeter tube. In general, all concentrations were carried out in a rotary evaporator at reduced pressure below 40°C.

t-*Butyl 10-Oxoundecanoate (2).* To a solution of 10-oxoundecanoic acid (**1**) (11.4 g, mp 55.8—57.0°C) in a mixture of dichloromethane (34 m*l*) and conc. sulfuric acid (0.33 m*l*) was added liquid isobutene (33.4 m*l*) under cooling at −30°C. The stoppered flask was allowed to stand at room temperature for 70 hr. The reaction mixture was processed by the same method as described in the previous paper[2] to give **2** as colorless liquid boiling at 129.5—131°C under 4 mmHg: Yield, 14.6 g (82.8%); n_D^{20} 1.4383; ν_{max}^{liq} 1727 cm^{-1} (C=O and ester).

Found: C, 70.60; H, 11.13%. Calcd for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01%.

t-*Butyl 10-Hydroxyundecanoate (3).* Sodium borohydride (343 mg, 9.08 mmol) was added to a solution of *t*-butyl 10-oxoundecanoate (**2**) (582 mg, 2.27 mmol) in dry tetrahydrofuran (19.3 m*l*) and stirred for 3 hr at room temperature. The reaction mixture was neutralized with 20% H_2SO_4 (1.0 m*l*) and extracted with ether. The combined extracts were washed with $NaHCO_3$ and saturated NaCl solution. After evaporation of the solvent, the residue was distilled under reduced pressure. The fraction boiling at 114—116.5°C/0.03 mmHg was collected: yield, 568 mg (95.8%); n_D^{20} 1.4428; ν_{max}^{liq} 3440 (OH) and 1735 cm^{-1} (ester).

Found: C, 69.40; H, 11.75%. Calcd for $C_{15}H_{30}O_3$: C, 69.72; H, 11.70%.

t-*Butyl 10-*(N-*Benzyloxycarbonyl*-O-t-*butyl*-L-*threonyloxy*)*undecanoate (4).* A solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine (6.00 g, 19.4 mmol) in dry ether (13.1 m*l*) was added dropwise during 40 min to a stirred solution of *t*-butyl 10-hydroxyundecanoate (**3**)(5.00 g, 19.4 mmol), DCCI (4.41 g, 21.4 mmol) and dry pyridine (1.65 m*l*, 19.4 mmol) in dry ether (20 m*l*) cooled to 0°C. Stirring at 0°C was continued for a further 4 hr. After standing at 0°C for 20 hr, to the reaction mixture, DCCI(2.2 g) and dry pyridine(0.83 ml) and then a solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine (3.00 g) in dry ether (6 m*l*) was dropped under stirring at 0°C. Further additions of the threonine derivative (1.0 g×2), DCCI (1.10 g ×2) and dry pyridine (0.413 m*l*×2) in two portions were undertaken in the same procedure as in the preceding additions in 24-hr intervals. After standing at 0°C for 20 hr the precipitate of *N*,*N*'-dicyclohexylurea (5.16 g, 53.7%) was filtered off and the filtrate was treated with acetic acid (1.5 m*l*) under stirring at 0°C for 2 hr. An additional

urea was removed by filtration and the filtrate was washed with 5% $NaHCO_3$ solution, 5% citric acid and saturated NaCl solution, dried over Na_2SO_4, and concentrated to dryness. The syrupy residue (17.31 g) was chromatographed on a silica gel column (1.78 kg, 8.2×65 cm). Elution with a petroleum ether-diisopropyl ether (2 : 1) system gave a straw-colored syrup (6.77 g, 63.5%) as a first fraction which behaved as a homogeneous compound on the tlc using the same solvent system as in the column chromatography: $[\alpha]_D^{23.5}$ −2.5° (*c* 1.63, chloroform); ν_{max}^{liq} 3460, 3360 (NH), 1730 (ester and amide I) and 1505 cm^{-1} (amide II).

Found: C, 68.07; H, 9.40; N, 2.70%. Calcd for $C_{31}H_{51}O_7N$: C, 67.73; H, 9.35; N, 2.55%.

*10-(N-Benzyloxycarbonyl-L-threonyloxy)undecanoic Acid (**5**).* A mixture of **4** (1.72 g) and trifluoroacetic acid (19 ml) was kept at room temperature with occasional swirling for 5 min, after which the reaction mixture was evaporated below 10°C. The residual syrup was then dissolved in ether and again evaporated. This procedure was repeated three times to remove trifluoroacetic acid. The final residue was dried over sodium hydroxide under reduced pressure to afford **5** (1.37 g).

*(3S,4R,15S)-3-Benzyloxycarboxamido-4,15-dimethyl-1,5-dioxacyclopentadecane-2,6-dione (**6a**) and (3S,4R,15R)-3-Benzyloxycarboxamido-4,15-dimethyl-1,5-dioxacyclopentadecane-2,6-dione (**6b**).* A mixture of **5** (1.37 g, 3.13 mmol), dry benzene (78 m*l*) and trifluoroacetic anhydride (0.436 m*l*, 3.13 mmol) was heated at 70°C for 14 hr, after which additional trifluoroacetic anhydride (0.436 m*l*) was added and again heated at the same temperature for 9 hr. The reaction mixture was evaporated and the residue was then dissolved in ether and again evaporated. This procedure was repeated three times to remove trifluoroacetic acid. The final residue was dried over sodium hydroxide in a vacuum to yield a crystalline mass (1.65 g). The product was chromatographed on a silica gel column (400 g, 4.7×53 cm) with benzene-butanone (30 : 1) system to give two fractions corresponding to the first and second elution peaks of the chromatogram. The first fraction gave a crystalline cyclization product **6a** (238 mg, 18.2%); mp 69.7—71.2°C (from ethyl acetate-petroleum ether); $[\alpha]_D^{22}$ +7.1° (*c* 1.7, chloroform); ν_{max}^{KBr} 3440 (NH), 1743 (ester), 1725 (amide I) and 1517 cm^{-1} (amide II).

Found: C, 65.68; H, 7.67; N, 3.44%; M (mass spectrometry), 419.2256; M+1, 420.2311. Calcd for $C_{23}H_{33}O_6N$: C, 65.85; H, 7.93; N, 3.34%; M, 419.2308; M+1, 420.2386.

The second fraction afforded a crystalline cyclization product **6b** (229 mg, 17.5%); mp 135.0—136.0°C (from ethyl acetate-petroleum ether); $[\alpha]_D^{22}$ −33.8° (*c* 1.8, chloroform); ν_{max}^{KBr} 3350 (NH), 1740 (ester), 1715 (amide I), and 1535 cm^{-1} (amide II).

Found: C, 66.16; H, 8.31; N, 3.49%. M (mass spectrometry), 419.2313; M+1, 420.2381. Calcd for $C_{23}H_{33}O_6N$: C, 65.85; H, 7.93; N, 3.34%. M, 419.2308; M+1, 420.2386.

*(+)-10-Hydroxyundecanoic Acid [(+)-**7**].* To a solution of **6a** (100 mg, 0.238 mmol) in methanol (0.48 m*l*) was added 10% aq. NaOH (0.24 m*l*, 0.594 mmol) under ice-cooling and stirred for 4.5 hr at room temperature. The mixture was concentrated, diluted with water and extracted ten times with 1 m*l*-portions of ethyl acetate. The aqueous layer was acidified (pH 4) with 10% H_2SO_4 and extracted with ethyl acetate (1.5 m*l*×4). The dried ethyl acetate layer was evaporated to give a crystalline mass (93.2 mg), which was dissolved in methanol and hydrogenolysed over palladium black.[9] The reduction product was chromatographed on silica gel (6 g) with *n*-hexane-ethyl acetate-acetic acid (20 : 10 : 1) system to afford (+)-**7** (40.9 mg, 85.3%); mp 61.5—63.7°C (from ethyl acetate-petroleum ether); $[\alpha]_D^{21}$ +6.2° (*c* 1.9, chloroform); ν_{max}^{KBr} 3360 (OH), 1712 cm^{-1} (COOH).

Found: C, 65.67; H, 11.12%. Calcd for $C_{11}H_{22}O_3$: C, 65.31; H, 10.96%.

*(−)-10-Hydroxyundecanoic Acid [(−)-**7**].* Saponification of **6b** with 10% aq. NaOH by the same procedure as that used to obtain (+)-**7** from **6a** afforded (−)-**7**; mp 62.0—63.0°C; $[\alpha]_D^{21.2}$ −7.0° (*c* 2.5, chloroform); IR-spectrum of (−)-**7** was identical with that of its enantiomer (+)-**7**.

Found: C, 65.48; H, 11.15%. Calcd for $C_{11}H_{22}O_3$: C, 65.31; H, 10.96%.

*Methyl (+)-19-Hydroxyundecanoate [(+)-**7**].* To a solution of (+)-**7** (18.5 mg) in dry ether (0.6 m*l*) was added excess distilled diazomethane in ether. After 15 min the solution was filtered and the filtrate was evaporated to dryness leaving (+)-**8** as a colorless oil (17.8 mg, 90%). tlc [benzene-acetone (15 : 1)] showed a single spot: $[\alpha]_D^{25}$ +5.6° (*c* 1.8, methanol).

*Methyl (−)-10-Hydroxyundecanoate [(−)-**8**].* The diazomethane treatment of (−)-**7**, similar to that of (+)-**7** gave the enantiomeric methyl ester (−)-**8**: $[\alpha]_D^{25}$ −5.8° (*c* 2.5, methanol).

*Determinations of Absolute Configurations of (+)-**8** and (−)-**8** by Horeau Procedure.* a) α-Phenylbutyric anhydride[10] (50.3 mg, 0.165 mmol) was added to (+)-**8** (18.7 mg, 0.083 mmol) in pyridine (0.5 m*l*). After standing for 18 hr at room temperature, water and benzene were added and the mixture was extracted several times with 0.2 N aq. Na_2CO_3. The extracts were washed with ether, acidified with 6 N HCl and extracted with benzene. The benzene extract was washed with water, dried over Na_2SO_4 and concentrated to dryness. The residue (39.2 mg) had IR and NMR spectra identical with those of racemic α-phenylbutyric acid: $[\alpha]_D^{20}$ −5.0°; $[\alpha]_{546}^{20}$ −6.0°; $[\alpha]_{436}^{20}$ −10.5°; $[\alpha]_{365}^{20}$ −17.7° (*c* 1.96, benzene). Since the recovered α-phenylbutyric acid was levorotatory, the hydroxy ester (+)-**8** has the "S" configuration at its asymmetric center. b) By the same procedure as described in a), the reaction of (−)-**8** (25.2mg, 0.117 mmol) with α-phenylbutyric anhydride (71.2 mg, 0.234 mmol) in pyridine gave a recovered sample (41.5 mg) of α-phenylbutyric acid: $[\alpha]_D^{20.5}$ +4.0°; $[\alpha]_{546}^{20.5}$ +5.3°; $[\alpha]_{436}^{20.5}$ +10.4°; $[\alpha]_{365}^{20.5}$ +18.0° (*c* 2.08, benzene). The configuration at carbinol carbon of (−)-**8**, therefore, is estimated as "R".

*(3S,4R,15S)-4,15-Dimethyl-1,5-dioxa-3-(O-benzyl-3'-nitrosalicylamido)cyclopentadecane-2,6-dione (**9a**).* A solution of **6a** (100 mg, 0.239 mmol) in methanol (3.5 m*l*) was stirred with palladium black (*ca.* 9 mg) for 25 min under bubbling with hydrogen. The filtered reduction mixture was evaporated to yield the free amino-dilactone (65 mg) which showed a single ninhydrin positive spot on tlc with a benzene-acetone (20 : 1) system. The free amino-dilactone (65 mg) was dissolved in dry tetrahydrofuran (1.2 m*l*) and *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester (88.3 mg, 0.239 mmol) was added. The mixture (pH 6) was kept for 4 hr at room temperature, after which it (pH 5) was allowed to stand for 16 hr at 37°C in an incubator. The reaction mixture (pH 4) was adjusted to pH 6 by the addition of triethylamine and again kept at 37°C for 3 hr. The resulting solution was evaporated to afford a yellow syrup (200 mg)

9) By this hydrogenation process the another saponification product of **6a**, namely *N*-benzyloxycarbonyl-L-threonine, was converted to L-threonine which was easily removed from the title compound by a silica gel column.

10) H. Falk and K. Schlog, *Monatsch. Chem.*, **96**, 276 (1965).

which was purified through a silica gel column (20 g, 1.3×43 cm). Elution with a *n*-hexane - ethyl acetate (2 : 1) system gave the title compound **9a** as a yellow glassy solid: yield 115 mg (89.2%); $[\alpha]_D^{23}$ −16.9° (*c* 1.7, chloroform); $\nu_{max}^{CCl_4}$ 3400 (NH), 1746 (ester), and 1680 cm^{-1} (amide I).

Found: C, 64.64; H, 7.16; N, 4.86%. Calcd for $C_{29}H_{36}O_8N_2$: C, 64.43; H, 6.71; N, 5.18%.

*(3S,4R,15R)-4,15-Dimethyl-1,5-dioxa-3-(O-benzyl-3'-nitrosalicylamido)cyclopentadecane-2,6-dione (**9b**).* The title compound (**9b**) was prepared from **6b** by the same procedure as described for the preparation of the epimer (**9a**) as a yellow glassy solid: yield 86.1%; $[\alpha]_D^{22}$ +35.7° (*c* 1.4, chloroform); $\nu_{max}^{CCl_4}$ 3410 (NH), 1748 (ester), and 1680 cm^{-1} (amide I).

Found: C, 64.69; H, 6.77; N, 5.60%. Calcd for $C_{29}H_{36}O_8N_2$: C, 64.43; H, 6.71; N, 5.18%.

*(3S,4R,15S)-4,15-Dimethyl-1,5-dioxa-3-(3'-formamidosalicylamido)cyclopentadecane-2,6-dione(**10a**).* A solution of **9a** (59.6 mg, 0.109 mmol) in methanol (8 m*l*) was stirred with palladium black under bubbling with hydrogen gas for 30 min. The filtered yellow-green reduction mixture was evaporated to give an orange-red glassy solid (43 mg, 93.9%). The product (43 mg, 0.103 mmol) was dissolved in tetrahydrofuran (1.6 m*l*) and to the solution was added DCCI (22.4 mg, 0.109 mmol) and 98% formic acid (5.4 mg) under ice-cooling. After standing for 23 hr in a refrigerator, the reaction mixture was filtered to remove *N,N'*-dicyclohexylurea (14.7 mg, 60.3%). The orange-red filtrate was evaporated and the crude product (64.8 mg) was purified by preparative thin-layer chromatography (three 20×20 cm-plates) with *n*-hexane - ethyl acetate (2 : 1). The strongest fluorescent band was collected and extracted with ether to afford orange crystals which were recrystallized from ether-petroleum ether (30—40°C) to yield colorless needles of **10a**: yield 21.5 mg (44.2%); mp 124—127.6°C; $[\alpha]_D^{21}$ +49° (*c* 1.1, chloroform); λ_{max}^{MeOH} mμ (log ε), 227 (4.55) and 319 (3.78); $\nu_{max}^{CHCl_3}$ 3430, 3390 (NH), 1740 (ester), 1703 (NHCHO), 1647 (ArCONH), 1613, 1593 (Ar–H) and 1532 cm^{-1} (ArCONH).

Found: C, 61.67; H, 7.23; N, 6.34%. Calcd for $C_{23}H_{32}O_7N_2$: C, 61.59; H, 7.19; N, 6.25%.

*(3S,4R,14R)-4,15-Dimethyl-1,5-dioxa-3-(3'-formamidosalicylamido)cyclopentadecane-2,6-dione (**19b**).* By the same procedure as described for the preparation of **10a**, the title compound (**10b**) was prepared from **9b** as a glassy solid: yield 50.7%; $[\alpha]_D^{22}$+14° (*c* 1.8, chloroform); λ_{max}^{MeOH} mμ (log ε), 227 (4.46) and 319 (3.77); $\nu_{max}^{CHCl_3}$ 3408, 3465 (NH), 1740 (ester), 1707 (NHCHO), 1647 (ArCONH), 1613, 1596 (Ar–H) and 1536 cm^{-1} (ArCONH).

Found: C, 61.32; H, 7.24; N, 5.86%. Calcd for $C_{23}H_{32}O_7N_2$: C, 61.59; H, 7.19; N, 6.25%.

We wish to thank Mr. S. Nakada for the elemental analyses and Mr. M. Wada and Mr. S. Aburagi for their technical assistance. We also wish to thank Professor S. Zen of Kitasato University for the measurement of mass spectra, and Mr. I. Takagi for his microbiological tests.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3399—3405 (1971)

Studies on Aminosugars. XXIX. Syntheses of Nucleosides of 3-Amino-3-deoxy-3-*C*-hydroxymethyl-β-D-ribofuranose[1]

Hiroaki YANAGISAWA, Mitsuhiro KINOSHITA, and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 21, 1971)

Reduction of 3-acetamido-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose-γ-lactone (**1**) with lithium aluminum hydride or sodium borohydride followed by acetylation gave 3-acetamido-3-*C*-acetoxymethyl-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**2**). Hyrdolysis of **2** followed by *N*-phthaloylation and *O*-acetylation gave 3-*C*-acetoxymethyl-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-phthalimido-α-D-ribofuranose (**7**), which was acetolyzed and chlorinated to give acylglycosyl chloride (**9**). Condensation of **9** with 6-benzamidopurine followed by aminolysis afforded 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)adenine (**11**). 6-dimethylaminopurine, guanine, cytosine and uracil derivatives were similarly synthesized.

In a previous paper[2] we reported the syntheses of branched aminonucleosides which have a new branched amino sugar moiety, 3-amino-3-*C*-carboxy-3-deoxy-D-ribose. As an extension of this work, the syntheses of 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)adenine (**11**), 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)-6-dimethylaminopurine (**14**), 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)guanine (**16**), 1-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)cytosine (**18**) and 1-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)uracil (**20**) are described in the present paper.

It has been found that substitution of 3′-hydroxy group or 3′-hydrogen atom of the sugar moiety of ribonucleosides with some substituents often gives rise to biological activities, *i.e.*, 3′-deoxyadenosine (cordycepin),[3] 9-(3′-amino-3′-deoxy-β-D-ribofuranosyl)-6-dimethylaminopurine[4] and 3′-amino-3′-de-

1) Part XLII of "Studies on Antibiotics and Related Substances" by Sumio Umezawa. A part of this paper was read at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970. (Abstracts of Papers of the Meeting, Vol. III, p. 1572).

oxyadenosine[5] have antitumor activities and 3′-*C*-methyladenosine and 3′-*C*-methylcytosine[6] show antiviral activities. In this connection we were interested in transforming the 3′-*C*-carboxyl group of 3′-amino-3′-*C*-carboxy-3′-deoxy-D-ribose moiety in the aminonucleosides[2] to other substituents. We carried out the reduction of the 3′-*C*-carboxyl group to 3′-*C*-hydroxymethyl group.

Synthesis of Sugar Moiety. 3-Acetamido-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose-γ-lactone[2] (**1**) was reduced in tetrahydrofuran with lithium aluminum hydride and the reduction product was acetylated with acetic anhydride-pyridine to afford 3-acetamido-3-*C*-acetoxymethyl-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**2**). It has recently been reported that α-amino and α-acylamino esters were reduced with sodium borohydride to afford the corresponding α-amino and α-acylamino alcohols, respectively, in good yields.[7] The reduction of **1** with sodium borohydride also gave **2** in a good yield.

Compound **2** was treated with a mixture of concentrated sulfuric acid, acetic anhydride and acetic acid in order to obtain the corresponding acetyl sugar which was required for the preparation of nucleoside. The product, whose tlc showed a single spot, had an IR-absorption at 1669 cm^{-1} (amide I), but no absorp tion at 3300—3500 (NH) and 1500—1600 cm^{-1} (amide II). The NMR spectrum of the product showed the presence of four acetyl groups and the absence of N–H proton. These observations and the result of elemental analysis suggested that the structure of the product is 1,2,5-tri-*O*-acetyl-3-deoxy-α-D-ribofuranose-3-spiro-2′-(*N*-acetylaziridine) (**3**). The assignment was also supported by the following reaction. Product **3** was treated with acetic acid as a nucleophile[8] to afford 3-acetamido-1,2,5-tri-*O*-acetyl-3-*C*-acetoxymethyl-3-deoxy-α-D-ribofuranose (**4**) whose structure was confirmed by elemental analysis, IR spectrum [3380 (NH), 1680 (amide I) and 1545 cm^{-1} (amide II)] and NMR spectrum [N–H proton (τ 3.54) and five acetyl groups]. Aziridine formation between 3-amino and 3-*C*-hydroxymethyl groups was also observed on the acetolysis of 3-acetamido-5-*O*-benzyl-3-*C*-benzyloxymethyl-3-deoxy-1,2-*O*-isopropyridene-α-D-ribofuranose (**5**) derived from **2**. The product was assigned as 1,2-di-*O*-acetyl-5-*O*-benzyl-3-deoxy-α-D-ribofuranose-3-*C*-spiro-2′-(*N*-acetylaziridine) (**6**) on the basis of elemental analysis, IR spectrum [1667 cm^{-1} (amide I), no absorption of N–H stretching and amide II] and NMR spectrum (single benzyl group and no N–H proton).

Since the amide-hydrogen in 3-acetamido group of **2** was very reactive in acidic media as described above, the acetamido group of **2** should be favorable for replacement by phthalimido group in order to prevent aziridine formation. Deacetylation of **2** with barium hydroxide followed by phthaloylation with phthalic anhydride-pyridine and *O*-acetylation afforded 3-*C*-acetoxymethyl-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-phthalimido-α-D-ribofuranose (**7**). The NMR spectrum of **7** revealed the presence of two conformers which might be caused by a steric interaction between the bulky phthalimido group, isopropylidene group and acetoxymethyl group. Acetolysis of **7** afforded 3-*C*-acetoxymethyl-1,2,5-tri-*O*-acetyl-3-phthalimido-D-ribofuranose (**8**). Treatment of **8** with hydrogen chloride in ether gave 3-*C*-acetoxymethyl-2,5-di-*O*-acetyl-1-chloro-3-deoxy-D-ribofuranose (**9**), which was immediately used in the next condensation reaction without purification because of its instability.

Synthesis of Nucleosides. Condensation of **9** with benzamidopurine was carried out in the presence of mercuric cyanide and Drierite in nitromethane[9] to afford 6-benzamido-9-(3′-*C*-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-D-ribofuranosyl)adenine (**10**).[10] By a similar procedure **9** was condensed with 6-chloropurine, N^2-acetylguanine,[11] and N^4-acetylcytosine[12] to afford 9-(3′-*C*-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-D-ribofuranosyl)-6-chloropurine (**12**),[10] 9-(3′-*C*-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-β-D-ribofuranosyl)-N^2-acetylguanine (**15**) and N^4-acetyl-1-(3′-*C*-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-β-D-ribofuranosyl)-cytosine (**17**), respectively. Although the condensation of **9** with uracil by the mercuric cyanide-nitromethane method and Hilbert-Johnson method[13] was unsuccessful, the desired condensation product, 1-(3′-*C*-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-phthalimido-β-D-ribofuranosyl)uracil (**19**) was obtained with the use of trimethylsilyl method[14] in which 2,4-*O*-bis-(trimethylsilyl)-uracil[15] was used as an activated base.

Positions of the base-sugar linkages in the blocked nucleosides **10**, **12**, **15**, **17**, and **19** were determined by UV spectrometry. The condensation reaction of N^2-acetylguanine with **9** gave predominantly N-9 substituted product.[16] The NMR spectra of the condensation products showed that they were anomeric mixtures except in the case of **19**. The blocked nucleoside of uracil was shown to be the β-anomer

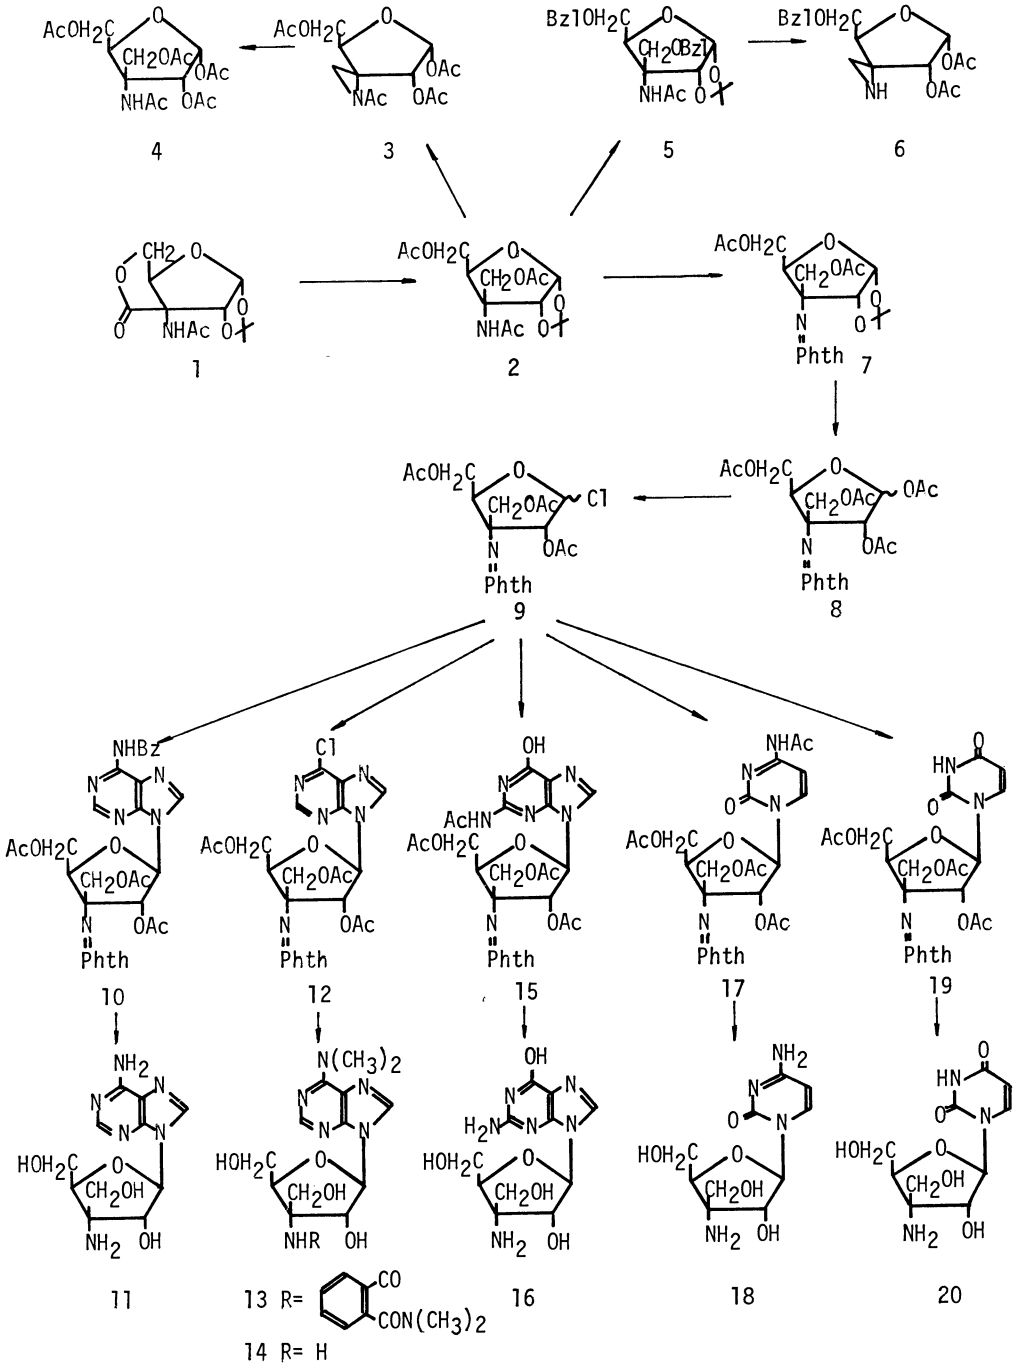

Fig. 1

(**19**). β-Anomer (**15**) was isolated from the anomeric mixture by preparative layer chromatography and β-anomer (**17**) by recrystallization. The blocked nucleoside (**10**)[10] was deacetylated and dephthaloylated with *n*-butylamine-methanol[17] to afford an anomeric mixture of 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-D-ribofuranosyl)adenine, from which β-anomer (**11**) was isolated. Other blocked nucleosides **15**, **17**, and **19** were similarly deblocked to afford 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl) guanine (**16**) and 1-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)cytosine (**18**) and 1-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-β-D-ribofuranosyl)uracil (**20**), respectively. The blocked nucleoside (**12**)[10] was treated with dimethylamine-methanol to afford 9-[3′-deoxy-3′-(*o*-*N*,*N*-dimethylcarbamoyl) benzamido-3′-*C*-hydroxymethyl-D-ribofuranosyl]-6-dimethylaminopurine (**13**).[10] The product (**13**)[10] was then dephthaloylated with *n*-butylamine-methanol to afford an anomeric mixture of 9-(3′-amino-3′-deoxy-3′-*C*-hydroxymethyl-D-ribofuranosyl)-6-dimethylaminopurine, from which β-anomer (**14**) was isolated by recrystallization.

The NMR spectra of the amino nucleosides **11**, **14**, **16**, **18**, and **20** showed that they contain no anomer.

17) L. Goodman and J. W. Marsico, *J. Med. Chem.*, **6**, 413 (1963).

Their anomeric configurations were determined to be β on the basis of their ORD curves. In general, pyrimidine β-D-nucleosides show positive and purine β-D-nucleosides negative Cotton effects.[18] The ORD curves of the purine nucleosides **11**, **14** and **16** showed negative Cotton effects and those of the pyrimidine nucleosides **18** and **20** showed positive ones. This indicates that all the synthetic branched aminonucleosides have β-configurations.

Examination of the antiviral activity of the branched aminonucleosides (**11**, **14**, **16**, **18** and **20**) is in progress. Compound **11**, namely the 3'-amino-3'-hydroxymethyl derivative of adenosine, has been found to exhibit weak inhibition against *vaccinia Dairen*.

Experimental

Thin layer chromatography (tlc) and preparative layer chromatography (plc) were carried out with the use of silica gel (Daiichi Pure Chemicals Co., Inc.). The prepared plates were activated at 110°C for 1 hr. The spray reagent was 10% sulfuric acid. Silica gel column chromatography was carried out with the use of WAKO-GEL C-200 (Wako Pure Chemical Industries, Ltd.). NMR spectra were taken with a Varian A-60D spectrometer at a frequency of 60 MHz in deuteriochloroform, deuteriodimethyl sulfoxide and deuterium oxide with tetramethylsilane and sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. Melting point determination was carried out on a micro hot stage and not corrected.

*3-Acetamido-3-C-acetoxymethyl-5-O-acetyl-3-deoxy-1,2-O-isopropylidene-α-D-ribofuranose (**2**).* *a) Reduction of **1** with Lithium Aluminum Hydride*: A solution of **1** (2.55 g) in tetrahydrofuran (20 m*l*) was added dropwise to a suspension of lithium aluminum hydride (0.99 g) in tetrahydrofuran (24 m*l*) under ice-cooling and stirring for 15 min. The mixture was then stirred in an ice bath for 3 hr and at room temperature for 3 hr. To the reaction mixture was added ethyl acetate (20 m*l*) and 20% aqueous isopropanol (20 m*l*) under ice-cooling and the mixture was stirred at room temperature for 30 min. Isopropanol (150 m*l*) was added to the reaction mixture and the precipitates were separated by centrifuging and washed with isopropanol (80 m*l*×4). The supernatant layer and washings were evaporated to dryness. To the residue was added pyridine (45 m*l*) and acetic anhydride (30 m*l*) and the mixture was kept at room temperature for 15 hr. The reaction mixture was evaporated with toluene, the residue being dissolved in 1 N hydrochloric acid (40 m*l*) and ethyl acetate (80 m*l*). The organic layer was separated, washed with water (20 m*l*) and aqueous sodium bicarbonate solution (20 m*l*) successively, dried over sodium sulfate and evaporated. Trituration of the syrupy residue with diisopropyl ether afforded **2** as a colorless crystal; yield 2.06 g (61.5%). The analytical sample was purified by recrystallization from ethyl acetate-diisopropyl ether: mp 135—136°C; $[\alpha]_D^{23}$+74° (*c* 1.7, ethanol); ν_{max}^{Nujol} 3350, 1743, and 1683 cm^{-1}; τ^{CDCl_3} 3.87 (s, N–H), 4.09 (d, H-1, $J_{1,2}$=4.0 Hz), 7.90 (s, two $OCOCH_3$), 7.98(s, $NCOCH_3$), 8.43 and 8.62 [=$C(CH_3)_2$].

Found: C, 52.37; H, 6.93; N, 4.26%. Calcd for $C_{15}H_{23}NO_8$: C, 52.17; H, 6.71; N, 4.06%.

*b) Reduction of **1** with Sodium Borohydride*: A solution of sodium borohydride (8.9 g) in 50% aqueous ethanol (110 m*l*) was added to a solution of **1**(14.1 g) in ethanol(83 m*l*) and the mixture was refluxed for 15 hr. The reaction mixture was evaporated with toluene to remove a trace of water. Pyridine (120 m*l*) and acetic anhydride (90 m*l*) was added to the residue and the mixture was stirred vigorously at room temperature for 3 hr. The reaction mixture was evaporated and the residue was partitioned between ethyl acetate (200 m*l*) and water (200 m*l*). The organic layer was successively washed with water, aqueous potassium bisulfate solution and aqueous sodium bicarbonate solution. The dried organic layer was evaporated and the residue was triturated with diisopropyl ether to afford **2**: yield 12.5 g (67.5%); mp 135—136°C (from ethyl acetate-diisopropyl ether).

*1,2,5-Tri-O-acetyl-3-deoxy-α-D-ribofuranose-3-C-spiro-2'-(N-acetylaziridine) (**3**).* To a solution of **2** (1.15 g) in a mixture of acetic acid (8 m*l*) and acetic anhydride (8 m*l*) was added dropwise concentrated sulfuric acid (0.8 m*l*) and the mixture was allowed to stand at room temperature for 12 hr. The reaction mixture was shaken with 10% aqueous sodium acetate (40 m*l*) and dichloroethane (20 m*l*). The aqueous layer was further extracted with dichloroethane (10 m*l*×3). The combined extracts were washed with aqueous potassium bicarbonate solution (20 m*l*), dried over sodium sulfate and evaporated to give **3** as a syrup; yield 710 mg (65%). The analytical sample was purified by silica gel column chromatography (ethyl acetate-benzene 1 : 1); $[\alpha]_D^{23}$+61° (*c* 2.1, ethanol); ν_{max}^{Film} 1743, 1669 cm^{-1}; τ^{CDCl_3} 4.43 (d, H-1, $J_{1,2}$=3.2 Hz), 4.64 (d, H-2), 7.86, 7.88, 7.89 and 7.99 (s, $COCH_3$).

Found: C, 50.93; H, 5.77; N, 4.45%. Calcd for $C_{14}H_{19}NO_8$: C, 51.06; H, 5.82; N, 4.25%.

*3-Acetamido-1,2,5-tri-O-acetyl-3-C-acetoxymethyl-3-deoxy-α-D-ribofuranose (**4**).* A solution of **3** (60 mg) in acetic acid (1.5 m*l*) was heated at 55°C for 5 hr, and then evaporated with toluene. The residual syrup was purified through a silica gel column (10 g, 24×1 cm). Elution with ether acetate-benzene (1 : 1 and 3 : 1) afforded **4** as a glass: yield 55 mg (78%); $[\alpha]_D^{22}$ +13° (*c* 2.3, ethanol); ν_{max}^{KBr} 3380, 1753, 1680, and 1545 cm^{-1}; τ^{CDCl_3} 3.54 (s, N–H), 3.86 (d, H-1, $J_{1,2}$=2.7 Hz), 4.46 (d, H-2), 7.83, 7.87, 7.88, 7.93 and 7.97 (s, $COCH_3$).

Found: C, 49.78; H, 5.91; N, 3.64%. Calcd for $C_{16}H_{23}NO_{10}$: C, 49.35; H, 5.95; N, 3.60%.

*3-Acetamido-5-O-benzyl-3-C-benzyloxymethyl-3-deoxy-1,2-O-isopropylidene-α-D-ribofuranose (**5**).* To a solution of sodium (110 mg) dissolved in methanol (6 m*l*) was added **2** (505 mg) and the resulting solution was refluxed for 30 min. After addition of a small amount of ethyl acetate, the solution was evaporated to dryness. The residue was dissolved in anhydrous dimethylformamide (8 m*l*) and to the solution was added freshly dried barium oxide (2.04 g), barium hydroxide octahydrate (0.87 g) and benzyl bromide (2.8 m*l*) under ice-cooling. The mixture was stirred in an ice-bath for 2 hr and then at room temperature for 18 hr. After addition of dichloroethane (20 m*l*) to the reaction mixture, the precipitates were filtered off with a hyflo super cell pad. The filtrate was concentrated to 3—4 m*l* and was diluted with ethyl acetate (15 m*l*). The resulting slurry was warmed, and the precipitates were again filtered off and washed with ethyl acetate. The filtrate and washings were evaporated and the residue was placed on a silica gel column (20 g, 1.8×18 cm) and eluted with benzene-ethyl acetate (3 : 1),

18) J. T. Yang, and T. Samejima, *J. Amer. Chem. Soc.*, **85**, 4039 (1963); T. L. V. Ulbricht, J. P. Jennings, P. M. Scopes, and W. Klyne, *Tetrahedron Lett.*, **1964**, 695; T. Nishimura, B. Shimizu, and I. Iwai, *Biochim. Biophys. Acta*, **157**, 221 (1968).

The eluent containing **5** was evaporated to dryness: a syrup, yield 570 mg (88%); $[\alpha]_D^{17}$ +42° (*c* 3.2, ethanol); ν_{max}^{Film} 3285 and 1654 cm^{-1}; τ^{CDCl_3} 2.70 (s, two C_6H_5), 3.84 (s, N–H), 4.23 (d, H-1, $J_{1,2}$=3.6 Hz), 5.19 (d, H-2), 5.51 (s, two benzyl CH_2), 8.10 (s, N–$COCH_3$), 8.48 and 8.68 [s, =$C(CH_3)_2$].

Found: C, 67.81; H, 6.81; N, 3.34%. Calcd for $C_{25}H_{31}NO_6$: C, 68.00; H, 7.08; N, 3.17%.

*1,2-Di-*O*-acetyl-5-*O*-benzyl-3-deoxy-α-*D*-ribofuranose-3-*C*-spiro-2′-(*N*-acetylaziridine) (**6**).* To a solution of **5** (384 mg) in a mixture of acetic acid (3 m*l*) and acetic anhydride (3 m*l*) was added dropwise concentrated sulfuric acid (0.29 m*l*) and the mixture was kept at room temperature for 12 hr. After addition of 10% sodium acetate solution (20 m*l*), the mixture was extracted with dichloroethane (20 m*l*, 5 m*l*×2) and the extracts were washed with water and aqueous potassium bicarbonate solution and dried over sodium sulfate. After evaporation of the solvent, the residue was purified by silica gel column (10 g, 20×1 cm). Elution with benzene-ethyl acetate (1 : 3 and 1 : 1) gave **6** asasyrup; yield 66 mg (20%); $[\alpha]_D^{17}$ +91° (*c* 1.8, ethanol); ν_{max}^{Film} 1746 and 1667 cm^{-1}; τ^{CDCl_3} 2.66 (s, C_6H_5), 4.47 (d, H-1, $J_{1,2}$= 3.4 Hz), 4.70 (d, H-2), 7.94, 7.98 and 8.04 (s, $COCH_3$).

Found: C, 60.91; H, 6.56; N, 3.81%. Calcd for $C_{19}H_{23}NO_7$: C, 60.47; H, 6.14; N, 3.71%.

*3-C-Acetoxymethyl-5-*O*-acetyl-3-deoxy-1,2-*O*-isopropylidene-3-phthalimido-α-*D*-ribofuranose (**7**).* A mixture of **2** (3.81 g) and barium hydroxide octahydrate (7.62 g) in water (29 m*l*) was refluxed under stirring for 2 hr. Carbon dioxide was passed through the reaction mixture for neutralization. Precipitates were separated by centrifuging and washed with ethanol. The supernatant and washings were evaporated to give a syrup containing colorless crystals. To this was added ethanol (40 m*l*) and the crystals were filtered off and washed with ethanol (10 m*l*). The filtrate and washings were evaporated to afford a syrup (3.01 g). To a solution of the syrup in pyridine (25 m*l*) was added phthalic anhydride (2.46 g) and the mixture was warmed at 50°C for 30 min. Acetic anhydride (25 m*l*) was added and the mixture was further warmed at 50°C for 30 min. The resulting mixture was evaporated and the residue was dissolved in a small amount of benzene and chromatographed on a silical gel column (40 g, 2.8×15 cm). Elution with benzene and benzene-ethyl acetate (10 : 1 and 6 : 1) afforded **7** as a glass: yield 3.34 g (70%). The NMR spectrum of **7** showed that it was a mixture of two conformers (7 : 3) : τ^{CDCl_3} (major) 2.16 (s, C_6H_5), 4.11 (d, H-1, $J_{1,2}$=4.0 Hz), 7.87, 8.01 (s, $COCH_3$), 8.57 and 8.70 [s, –$C(CH_3)_2$]; (minor) 4.07 (d, H-1, $J_{1,2}$=3.9 Hz), 7.87, 7.95 (s, $COCH_3$), 8.57 and 8.67 [s, –$C(CH_3)_2$]; $\nu_{max}^{CHCl_3}$ 1747 and 1725 cm^{-1}; $[\alpha]_D^{17}$+120° (*c* 1.2, ethanol).

Found: C, 58.63; H, 5.66; N, 3.44%. Calcd for $C_{21}H_{23}NO_9$: C, 58.19; H, 5.35; N, 3.23%.

*3-C-Acetoxymethyl-1,2,5-tri-*O*-acetyl-3-deoxy-3-phthalimido-*D*-ribofuranose (**8**).* To an ice-cooled solution of **7** (3.34 g) in a mixture of acetic acid (23 m*l*) and acetic anhydride (23 m*l*) was added concentrated sulfuric acid (1.76 m*l*) under stirring and the mixture was kept at room temperature for 12 hr. The reaction mixture was mixed with powdered sodium acetate trihydrate (18 g) and the resulting slurry was stirred for 30 min. After evaporation at 35°C, the residue was partitioned between water (100 m*l*) and ethyl acetate (70 m*l*). The aqueous layer was further extracted with ethyl acetate (20 m*l*×2). The combined organic layers were washed with aqueous potassium bicarbonate solution (50 m*l*×3) and dried over sodium sulfate. Removal of ethyl acetate and a trace of acetic acid by co-distillation with toluene gave **8** as a glass: yield 2.14 g (58%). An analytical sample was purified by silica gel chromatography with a solvent system, benzene-ethyl acetate (10 : 1) : $[\alpha]_D^{17}$+82° (*c* 2.1, ethanol); $\nu_{max}^{CHCl_3}$ 1750 and 1726 cm^{-1}; τ^{CDCl_3} 2.15 (s, C_6H_4), 3.83 (s, H-1), 4.15 (s, H-2), 7.85, 7.90, 8.06 and 8.08 (s, $COCH_3$).

Found: C, 54.71; H, 4.96; N, 3.04%. Calcd for $C_{22}H_{23}NO_{11}$: C, 55.34; H, 4.86; N, 2.93%.

*3-C-Acetoxymethyl-2,5-di-*O*-acetyl-1-chloro-3-deoxy-*D*-ribofuranose (**9**).* Through a mixture of **8** (2.14 g) and Drierite (2.14 g) in dry ether (100 m*l*) was passed dry hydrogen chloride under ice-salt cooling for 2 hr and the mixture was allowed to stand for 19 hr in a refrigerator. The reaction mixture was evaporated below 30°C and the residual hydrogen chloride was removed by co-distillation with benzene. The TLC of the residue showed that the product **9** (R_f 0.79 with benzene-ethyl acetate 1 : 1) was unstable and a new spot (R_f 0.63) appeared during evaporation. The residue, therefore, was used immediately for the next condensation reaction.

*6-Benzamido-9-(3′-C-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-*D*-ribofuranosyl)adenine (**10**).* A solution of **9** [prepared from **8** (2.14 g)] in a small amount of nitromethane was added to a mixture of benzamidopurine (1.07 g), mercuric cyanide (1.14 g) and Drierite (7.00 g) in nitromethane (50 m*l*). After the mixture was refluxed under stirring for 4 hr, the precipitates were filtered off and washed with ethyl acetate. The filtrate and washings were mixed with silica gel (7 g) and evaporated to dryness. The powered residue was placed on a silica gel column (70 g, 2.8×28 cm) and eluted with benzene and benzene-ethyl acetate (1 : 1, 1 : 2 and 1 : 5). The eluent containing **10** was evaporated to afford **10** as an amorphous powder; yield 1.13 g (38%). An analytical sample was obtained by PLC technique with a solvent system, benzene-ethyl acetate (1 : 4) : $[\alpha]_D^{17}$ –31° (*c* 1.39, ethanol); $\nu_{max}^{CHCl_3}$ 1748, 1724, 1610 and 1587 cm^{-1}; λ_{max}^{MeOH} 280 mμ (ε 22300).

Found: C, 58.56; H, 4.70; N, 13.13%. Calcd for $C_{32}H_{28}N_6O_{10}$: C, 58.53; H, 4.30; N, 12.81%.

*9-(3′-Amino-3′-deoxy-3′-C-hydroxymethyl-β-*D*-ribofuranosyl)adenine (**11**).* A solution of **10** (1.13 g) in a mixture of methanol (30 m*l*) and *n*-butylamine (10 m*l*) was refluxed for 19 hr. After evaporation of the resulting solution to dryness, ethyl acetate (50 m*l*) was added to the residue and the mixture was allowed to stand overnight in a refrigerator. The colorless precipitates (440 mg) were separated by filtration and recrystallized from 10% aqueous methanol (20 m*l*): yield 140 mg (27%); mp 230°C; $[\alpha]_D^{14}$ –60° (*c* 1.1, water); RD[19] (c 0.015, water) at 20°C; $[\Phi]_{300}$ –800°, $[\Phi]_{278}$ –1900° (tr); $\lambda_{max}^{H_2O}$ 259mμ (ε 17100), $\lambda_{max}^{0.1NHCl}$ 257 mμ (ε 16100), $\lambda_{max}^{0.1NNaOH}$ 260 mμ (ε 16700); τ^{D_2O} 1.89, 2.17 (s, H-2 and H-8), 4.12 (d, H-1′, $J_{1',2'}$=7.2 Hz) and 5.39 (d, H-2′).

Found: C, 44.91; H, 5.65; N, 28.29%. Calcd for $C_{11}H_{16}N_6O_4$: C, 44.59; H, 5.44; N, 28.37%.

*6-Chloro-9-(3′-C-acetoxymethyl-2′,5′-di-*O*-acetyl-3′-deoxy-3′-phthalimido-*D*-ribofuranosyl)purine (**12**).* A solution of **9** [prepared from **8** (3.46 g)] in a small amount of nitromethane was added to a mixture of 6-chloropurine (1.12 g), mercuric cyanide (1.84 g) and Drierite (10 g) in nitromethane (90 m*l*) under refluxing and stirring. The nitromethane (20 g) was distilled off and the residue was refluxed under stirring for 2 hr. The precipitates were filtered off and washed with ethyl acetate. The filtrate and washings were evaporated with silica gel (7 g) to dryness. The pow-

19) ORD were determined on a JASCO ORD/UV-5 recording spectropolarimeter.

dered residue was placed on a silica gel column (150 g, 3.3×30 cm) and eluted with benzene and benzene-ethyl acetate (10 : 1, 3 : 1, 2 : 1 and 1 : 1), successively. The eluent containing **12** was evaporated to afford a glass; yield 1.92 g (46.3%); λ_{max}^{MeOH} 242 and 266 mμ.

*6-Dimethylamino-9-[3'-deoxy-3'-(o-N,N-dimethylcarbamoyl)-benzamido-3'-C-hydroxymethyl-D-ribofuranosyl]purine (**13**).*[10] A solution of **12** (1.92 g) in 20% dimethylamine-methanol (20 ml) was refluxed for 3.5 hr. The reaction mixture was evaporated to dryness with silica gel (4 g). The powdered residue was placed on a silica gel column (90 g, 2.5×33 cm) and eluted with ethyl acetate and ethyl acetate-ethanol (4 : 1), successively. The eluent containing **13**[10] was evaporated to afford a glass (**13**)[10]; yield 1.18 g (70%). Further purification of the product (200 mg) was carried out by PLC (5 sheets of 0.5 mm×20×20 cm plate) to afford an analytical sample (130 mg): $[\alpha]_D^{20}$ −34° (*c* 3.0, methanol); ν_{max}^{KBr} 3350 and 1596 cm^{-1}; λ_{max}^{MeOH} 275 mμ (ε 20000). The NMR spectrum showed that **13** was an anomeric mixture (β/α=3.5/1): τ^{CD_3OD} (β anomer) 1.73, 1.77 (s, H-2 and H-8), 3.93 (d, H-1', $J_{1',2'}$=7.6 Hz), 4.94 (d, H-2'), 6.50 [s, purine N(CH$_3$)$_2$], 6.85, 7.07 [s, phthaloyl N(CH$_3$)$_2$]; τ^{CD_3OD} (α anomer) 4.08 (d, H-1', $J_{1',2'}$=4.3 Hz), 6.52 [s, purine N(CH$_3$)$_2$], 6.92, 7.17 [s, phthaloyl N(CH$_3$)$_2$].

Found: C, 54.03; H, 6.45; N, 18.94%. Calcd for $C_{23}H_{29}N_7O_6\cdot 1/2\ H_2O$: C, 54.33; H, 5.93; N, 19.27%.

*6-Dimethylamino-9-(3'-amino-3'-deoxy-3'-C-hydroxymethyl-β-D-ribofuranosyl)purine (**14**).* A solution of **13** (200 mg) in 50% *n*-butylamine-methanol (12 ml) was refluxed for 2 days. After evaporation, the residue was partitioned between water (10 ml) and ethyl acetate (10 ml). The aqueous layer was separated, washed with ethyl acetate (10 ml×7) and evaporated to dryness. The NMR spectrum of the glassy residue revealed that it was an anomeric mixture (β/α=3.5/1). The β-anomer (**14**) was separated as crystals from the methanolic solution of the anomeric mixture; yield 62 mg (48%). An analytical sample was obtained by further recrystallization from methanol: mp 172—174°C; $[\alpha]_D^{23}$ −68° (c 2.0, water); RD (*c* 0.017, water) at 20°C, $[\Phi]_{310}$ −800° $[\Phi]_{296}$ −1700° (tr); ν_{max}^{KBr} 3340 and 1600 cm^{-1}; $\lambda_{max}^{H_2O}$ 275.5 mμ (ε 20100), $\lambda_{max}^{0.1NHCl}$ 268 mμ (ε 20000) and $\lambda_{max}^{0.1NNaOH}$ 276 mμ (ε 19600); τ^{D_2O} 1.89, 2.13 (s, H-2 and H-8), 4.06 (d, H-1', $J_{1',2'}$=7.6 Hz), 5.34 (d, H-2') and 6.87 [s, purine N(CH$_3$)$_2$].

Found: C, 47.85; H, 6.45; N, 25.48%. Calcd for $C_{13}H_{20}N_6O_4$: C, 48.14; H, 6.22; N, 25.91%.

*N^2-Acetyl-9-(3'-C-acetoxymethyl-2',5'-di-O-acetyl-3'-deoxy-3'-phthalimido-β-D-ribofuranosyl)guanine (**15**).* To a mixture of N^2-acetylguanine (866 mg), mercuric cyanide (1.14 g) and Drierite (10 g) in nitromethane (100 ml) was added a solution of **9** [prepared from **8** (2.15 g)] in a small amount of nitromethane under refluxing and stirring. After nitromethane (10 ml) was distilled off, the mixture was refluxed for 2 hr under stirring. The precipitates were filtered off and washed with ethyl acetate and the filtrate and washings were evaporated with silica gel (2 g). The residue was placed on a silica gel column (70 g, 3.5×16 cm) and eluted with benzene, benzene-ethyl acetate (10 : 1, 5 : 1, 2 : 1 and 1 : 2), ethyl acetate and ethyl acetate-isopropanol (10 : 1), successively. Evaporation of the eluent containing **15** afforded the anomeric mixtue of **15** as a glass; yield 1.29 g (47%). The product (473 mg) was subjected to PLC (10 sheets of 0.5 mm×20×20 cm plate) with a solvent system, ethyl acetate-isopropanol (10 : 1). The upper bands with R_f value of 0.43 were collected under UV light (365 mμ) and extracted with ethyl acetate-isopropanol (1 : 1) to afford the β-anomer (**15**) as a glass: yield 211 mg (21%); $[\alpha]_D^{25}$ −5° (*c* 4.2, methanol); ν_{max}^{KBr} 3420, 1755, 1726, 1695 (sh), 1610 and 1562 cm^{-1}; λ_{max}^{MeOH} mμ (ε) 242(19800), 255 (18300), 260(18400) and 282 (14000); τ^{CD_3OD} 1.89 (s, H-8), 2.06 (s, phthaloyl C_6H_4), 4.00 (s, H-1' and H-2'), 7.68, 7.90, 7.96 and 8.14 (s, COCH$_3$).

Found: C, 53.08; H, 4.52; N, 13.42%. Calcd for $C_{27}H_{26}N_6O_{11}$: C, 53.11; H, 4.29; N, 13.71%.

The lower bands on PLC afforded a mixture of anomers (α/β=2/1): yield 97 mg (9.6%); τ^{CD_3OD} (α-anomer) 2.71 (s, H-8), 3.37 (d, H-1', $J_{1',2'}$=5.1 Hz) and 3.95 (d, H-2').

*9-(3'-Amino-3'-deoxy-3'-C-hydroxymethyl-β-D-ribofuranosyl)-guanine (**16**).* A solution of **15** (β anomer, 177 mg) in 50% *n*-butylamine-methanol (10 ml) was refluxed for 20 hr. The product (**16**) was deposited as solid in the reaction mixture, separated by centrifuging and washed with methanol; yield 55 mg. Recrystallization from water gave an analytical sample; mp 230°C (colored) but not fused below 300°C; $[\alpha]_D^{23}$ −25° (*c* 1.6, 0.1 N HCl), RD (*c* 0.025, water) at 20°C, $[\Phi]_{320}$ −500°, $[\Phi]_{310}$ −650°(tr); ν_{max}^{KBr} 3380, 3150, 1690, 1653, and 1595 cm^{-1}; $\lambda_{max}^{H_2O}$ 251 mμ (ε 11900) and 274 mμ (ε 8600)(sh), $\lambda_{max}^{0.1NHCl}$ 256.5 mμ (ε 11400) and 275 mμ (ε 8400)(sh), $\lambda_{max}^{0.1NNaOH}$ 258 mμ (ε 9300) and 269 mμ (ε 9500).

Found: C, 40.31; H, 5.60; N, 25.38%. Calcd for $C_{11}H_{16}N_6O_5\cdot H_2O$: C, 40.00; H, 5.49; N, 25.45%.

*N^4-Acetyl-1-(3'-C-acetoxymethyl-2',5'-di-O-acetyl-3'-deoxy-3'-limido-β-D-ribofuranosyl)cytosine (**17**).* A mixture of *N*^{4}-acetylcytosine (0.875 g), mercuric cyanide (1.45 g) and Drierite (10 g) in nitromethane (120 ml) was heated and nitromethane (20 ml) was distilled off at atmospheric pressure. To the resulting mixture was added a solution of **9** [prepared from **8** (2.74 g)] in a small amount of nitromethane under refluxing and stirring. After the second distillation of nitromethane (10 ml), the reaction mixture was refluxed for 2.5 hr under stirring. The precipitates were filtered off and washed with ethyl acetate. Silica gel (2 g) was added to the combined filtrate and washings and evaporated. The residual powders were placed on a silica gel column (50 g, 3.8×17 cm) and eluted with benzene, benzene-ethyl acetate (2 : 1 and 1 : 2), ethyl acetate and ethyl acetate-isopropanol (10 : 1), successively. The eluent containing **17** was evaporated to afford a crystalline solid (1.46 g, 45%). Pure β-anomer (**17**) was obtained by recrystallization of the crystals from ethanol, the first crop 398 mg and the second 252 mg. Total yield 650 mg (45% from the anomeric mixture); mp 268—273.5°C (sintered); $[\alpha]_D^{20}$ +28° (*c* 2.0, dimethyl sulfoxide); ν_{max}^{KBr} 3420, 3140, 1754, 1725, 1662, 1624 and 1560 cm^{-1}; λ_{max}^{MeOH} 242 mμ (ε 22400) and 299 mμ (ε 9000); τ^{DMSO-d_6} 1.75 (d, H-6, $J_{5,6}$=7.6 Hz), 2.77 (d, H-5), 3.65 (d, H-1', $J_{1',2'}$=5.2 Hz), 4.06 (d, H-2'), 7.82, 7.86, 7.88 and 8.26 (s, COCH$_3$).

Found: C, 55.00; H, 4.53; N, 9.68%. Calcd for $C_{26}H_{26}N_4O_{11}$: C, 54.73; H, 4.59; N, 9.82%.

*1-(3'-Amino-3'-deoxy-3'-C-hydroxymethyl-β-D-ribofuranosyl)cytosine (**18**).* A solution of **17** (277 mg) in 50% *n*-butylamine-methanol (10 ml) was refluxed for 15 hr and then evaporated to dryness. The residue was dissolved in ethyl acetate (10 ml) and kept in a refrigerator. The colorless precipitates were collected by filtration and partitioned between water (10 ml) and ethyl acetate (10 ml). The aqueous layer was washed with ethyl acetate (10 ml×5) and evaporated to dryness; yield 123 mg (96%). An analytical sample was obtained reprecipitation from methanol-ethyl acetate; mp 117—120°C; $[\alpha]_D^{27}$ +29° (*c* 3.6, water); RD (*c* 0.029, water) at 20°C, $[\Phi]_{300}$+2700°, $[\Phi]_{289}$+4800 (pk); ν_{max}^{KBr} 3310, 3180 (sh), 1655, 1636 and 1600 (sh)cm^{-1}; $\lambda_{max}^{H_2O}$ 230 mμ (ε 7900) and 270 mμ (ε 8500), $\lambda_{max}^{0.1NHCl}$ 278.5

mμ (ε 11000), $\lambda_{max}^{0.1NNaOH}$ 231 mμ (ε 6900) and 272 mμ (ε 7800); τ^{D_2O} 2.10 (d, H-6, $J_{5,6}$=7.6 Hz), 3.91 (d, H-5), 4.02 d, H-1′, $J_{1',2'}$=6.0 Hz), 5.69 (d, H-2′).

Found: C, 43.65; H, 6.57; N, 18.55%. Calcd for $C_{10}H_{16}N_4O_5 \cdot CH_3OH$: C, 43.41; H, 6.63; N, 18.41%.

*1-(3′-C-Acetoxymethyl-2′,5′-di-O-acetyl-3′-deoxy-3′-phthalimido-β-D-ribofuranosyl)uracil (**19**).* To a solution of **9** [prepared from **8** (3.31 g)] in benzene (10 ml) was added 2,4-di-*O*-trimethylsilyluracil (5.0 g). The mixture was refluxed for 1 hr under stirring and 2,4-di-*O*-trimethylsilyluracil (3.0 g) was then added to this. After the mixture was refluxed for 2 days under stirring, ethanol (40 ml) was added and the resulting slurry was stirred for 30 min. The precipitates were removed by filtration. Silica gel (3 g) was added to the filtrate and evaporated. The residue was placed on a silica gel column (50 g, 3.8×17 cm) and eluted with benzene, benzene-ethyl acetate (5 : 1, 1 : 1, 1 : 2), successively. Evaporation of the eluent containing **19** afforded a pure sample of **19** as a glass; yield 846 mg (23%); $[\alpha]_D^{26}$ +27° (*c* 3.5, methanol); ν_{max}^{KBr} 3410, 1750 (sh), 1720 and 1635 (sh) cm^{-1}; λ_{max}^{MeOH} 242 mμ (ε 13900) and 257 mμ (ε 11600); τ^{CD_3OD} 2.09 (s, phthaloyl C_6H_4), 2.33 (d, H-6, $J_{5,6}$=7.9 Hz), 4.18 (d, H-1′, $J_{1',2'}$=4.4 Hz), 4.21 (d, H-5), 4.40 (d, H-2′), 7.90, 8.07 and 8.18 (s, $COCH_3$).

Found: C, 54.26; H, 4.77; N, 7.43%. Calcd for $C_{24}H_{23}N_3O_{11}$: C, 54.44; H, 4.38; N, 7.93%.

*1-(3′-Amino-3′-deoxy-3′-C-hydroxymethyl-β-D-ribofuranosyl)uracil (**20**).* A solution of **19** (116 mg) in 50% *n*-butylamine-methanol (10 ml) was refluxed for 18 hr. After evaporation the residue was partitioned between water (6 ml) and ethyl acetate (6 ml). The aqueous layer was washed with ethyl acetate (6 ml×7) and evaporated to afford a crystalline solid. To the residue was added isopropanol (6 ml) and the crystals of **20** were collected by centrifuging; yield 27 mg (45.1%). An analytical sample was obtained by recrystallization from water: mp 257.5°C (sintered), 261.5—262°C (decomp.); $[\alpha]_D^{20}$ +13° (*c* 1.0, 0.1 N HCl): RD (*c* 0.025, water) at 20°C, $[\Phi]_{300}$ +800°, $[\Phi]_{278}$ +2900° (pk); ν_{max}^{KBr} 3440, 3365, 1720 and 1680 cm^{-1}; $\lambda_{max}^{H_2O}$ 261.5 mμ (ε 10300), $\lambda_{max}^{0.1NHCl}$ 261 mμ (ε 10500), $\lambda_{max}^{0.1NNaOH}$ 263 mμ (ε 7600); τ^{D_2O} 2.06 (d, H-6, $J_{5,6}$=8.1 Hz), 4.00 (d, H-1′, $J_{1',2'}$=6.5 Hz), 4.04 (d, H-5), 5.69 (d, H-2′) and 6.31 (s, 3′ $-CH_2$).

Found: C, 44.01; H, 5.66; N, 15.13%. Calcd for $C_{10}H_{15}N_3O_6$: C, 43.95; H, 5.53; N, 15.38%.

(Received May 4, 1971)

The carboxylation reaction of propene catalyzed by nickel carbonyl was studied undeer various conditions. Iso- and *n*-butyric acids were obtained in good yields under mild conditions in the presence of a large amount of an organic acid. The catalytic carboxylation area was examined in detail. The carboxylation reaction proceeded smoothly in tetrahydrofuran, acetic acid, and dioxane. The proportion of isobutyric acid was largest in acetic acid (72.5–77.5%). Triphenylphosphine (TPP) had a great effect on the reaction rate, the catalytic reaction area, and the product distribution. On the reaction mechanism, an active species (HNi(CO)(TPP)X) was taken to account for the experimental results.

The preparation of carboxylic acids or their derivatives from unsaturated compounds and carbon monoxide in the presence of metal carbonyls is an important synthetic reaction known well as the carboxylation reaction. Numerous reports have been published on this reaction[2] besides the original works of Reppe *et al.* In our previous studies it was found that the carboxylation of propylne[3] and propadiene[4] in the presence of nickel carbonyl and organic acids takes place smoothly under a low carbon monoxide pressure.

It is said that the carboxylation of olefins except such reactive ones as bicyclo[2,2,1]heptene derivatives needs more stringent reaction conditions than does that of acetylenes.[2] Concerning the carboxylation reaction of olefins catalyzed by nickel catalysts, few detailed investigations have been published; all of them have used much more severe conditions than those for propyne and propadiene reported by us. In this report, the carboxylation of propene using a

nickel carbonyl catalyst has been investigated in detail with the aim of synthesizing butyric acid under milder conditions than those used in the literature.[5]

$$CH_3CH{=}CH_2 + CO + H_2O \xrightarrow{Ni(CO)_4} CH_3CH_2CH_2CO_2H + (CH_3)_2CHCO_2H$$

The effects on the reaction processes of the reaction temperature, the carbon monoxide pressure, the solvent, and the addition of triphenylphosphine (TPP) were examined. As was seen in the case of the oxo reaction, two isomers were obtained. The nickel carbonyl catalyst and a catalyst system composed of nickel carbonyl and TPP both initiated the reaction smoothly under mild conditions and gave excellent yields of butyric acid. The presence of TPP in the reaction system contributed to obtaining a stable catalytic reaction and had a large influence on the product distribution.

Experimental

Materials. The propene, carbon monoxide, nickel carbonyl, TPP, and other compounds employed in this study were commercial products which were proved to be sufficiently pure by gas chromatography and/or elemental analysis.

Apparatus and Procedures of Carboxylation. A 200-m*l* rotational stirring-type stainless-steel autoclave (used at about 800 rpm) was charged under nitrogen with the solvent, an organic acid, hydroquinone, and a catalyst. The vessel was then cooled to about −40°C and the air was replaced completely by nitrogen. After evacuation, carbon monoxide was introduced until the specified pressure was reached. Then, propene was injected by an injection pump. Two reaction processes, the batch process (A) and the constant pressure process (B), were employed. The (A) process was used to search for the catalytic reaction conditions. The vessel was heated to the specified temperature with stirring, and the fall in the pressure was observed at that temperature. The (B) process was used to collect the kinetic data of the reaction. In this case, the pressure of the vessel was kept constant during the reaction by continuously supplying carbon monoxide from a gas storage tank. The relative reaction rate was calculated roughly from the absorption curve of carbon monoxide in the initial reaction period. The supply of carbon monoxide was stopped during the reaction, after which the vessel was cooled to room temperature. Then, the remaining gas was discharged through a mixture consisting of carbon tetrachloride, bromine, and water to decompose the nickel carbonyl and capture the residual propene.

Analytical Procedures. The reaction products, isobutyric acid and *n*-butyric acid, were determined by gas chromatography using a 2.5-m column of 21% dioctyl sebacate and 4% sebacic acid at 125°C. Acetophenone was used as the internal standard substance. The amount of residual propene trapped as 1,2-dibromopropane was determined gas-chromatographically by a 2.5-m column of 30% dioctyl phthalate at 120°C, using anisole as the internal standard substance. The amount of nickel carbonyl remaining after the reaction was determined by the nickel dimethylglyoxime method.

Results and Discussion

Carboxylation in the Presence of Nickel Carbonyl. At the beginning of this study, some attempts were made to determine the favorable conditions. The results are shown in Table 1. Under the same conditions as those used for the carboxylation of propyne,[3] propene was unreactive and most of the propene and the nickel carbonyl were recovered (Run 1). The reaction under the carbon monoxide pressure using stoichiometric amounts of nickel carbonyl and an organic acid to propene (Run 2) showed a rapid pressure drop at 260°C; this drop indicated that the reaction was under way. In the next run (Run 3), where the amount of nickel carbonyl was reduced to a catalytic amount, the reaction started smoothly. When the amount of organic acid was reduced to a catalytic amount (Run 4), however, virtually no reaction was observed. It became apparent that a large amount of organic acid favored the carboxylation of propene. Therefore, subsequent experiments were carried out in the presence of a large amount of isobutyric acid or acetic acid.

Catalytic Reaction Area: The catalytic carboxylation using nickel carbonyl was influenced by the reaction temperature and the carbon monoxide pressure. In other words, there is an area of smooth catalytic reaction (afterwards abbreviated as CRA) on the carbon monoxide pressure *versus* reaction temperature diagram. The CRA was examined for the reaction of propene in the presence of a large amount of isobutyric acid: the results are shown in Fig. 1.[6] For a given carbon monoxide pressure, no fall in pressure was observed at temperatures outside of the specified area. That is, all the nickel carbonyl and propene charged were recovered at temperatures below this area; on the other hand, at temperatures above this area, the propene was recovered unchanged, and the nickel carbonyl was decomposed completely. In this region, the catalytic reaction occurred after a short induction period, and almost all the charged nickel carbonyl was recovered after the reaction.

Effect of the Temperature and the Carbon Monoxide Pressure on the Reaction Rate: Several runs were made varying the temperature and the carbon monoxide pressure. The results are shown in Table 2. For the same carbon monoxide pressure, the carboxylation reaction proceeded faster at higher temperatures within CRA. For example, raising the temperature from 160°C to 170°C increased the initial carbon monoxide absorption rate by a factor of 2 (Runs 6 and 7). On the other hand, decreasing the carbon monoxide pressure also accelerated the reaction so much that the rate at 10.5 atm was about two times that at 15 atm (Runs 5 and 7). From these values, it was roughly estimated that the rate is reversely proportional to about a square of the carbon monoxide pressure, as was observed in the case of propyne.[3]

Effect of the Solvent on the Reaction Rate: Six solvents which give a homogeneous solution were ex-

amined. The results are listed in Table 3. The initial carbon monoxide absorption rates were faster in tetrahydrofuran, acetic acid, and dioxane than those in diglyme, dimethyl cellosolve, and methyl ethyl ketone. For synthetic purposes, acetic acid was the most suitable solvent from the viewpoints of the recovery of nickel carbonyl (high catalytic level), and the yield, and also from the viewpoint of the selectivity of the products, as will be described later.

Product Distribution: Two isomeric butyric acids were obtained by the carboxylation of propene. In Tables 2 and 3, isobutyric acid is shown to have been formed predominantly in every case. Decreasing the temperature tended to increase the proportion of isobutyric acid (Run 6). The solvent also had a considerable effect on the distribution of the two isomers. In acetic acid, the ratio of isobutyric acid to *n*-butyric acid (i/n) was highest. The reported ratios in the literature are i/n=1 by nickel carbonyl,[5] 1/3 by dicobalt octacarbonyl,[7] 2/1 by palladium catalysts,[8] and 1/3 by platinum chloride.[9] The high values obtained here, 2/1—3/1, are thus worthy of note.

Carboxylation in the Presence of Nickel Carbonyl and TPP. A catalyst system composed of nickel carbonyl and TPP was examined, and the results obtained were compared with those obtained using nickel carbonyl alone in order to determine the effect of TPP. The results are summarized in Table 4.

Effect of TPP on CRA: As has been described already, the catalytic carboxylation of propene in the presence of the nickel carbonyl catalyst was possible under the restricted conditions of Fig. 1. The presence of TPP made it possible to perform catalytic carboxylation smoothly under the conditions at which the carboxylation with nickel carbonyl alone did not occur because of the decomposition of the catalyst itself. For example, at 170°C and a carbon monoxide pressure of 7.5 atm, which lies outside the CRA for nickel carbonyl, the catalytic reaction proceeded smoothly in the presence of TPP (Runs 9 and 17). A smooth catalytic reaction was also obtained even at a carbon monoxide pressure of 4 atm (Run 16). This stability of the catalyst system is advantageous from the synthetic point of view.

Effect of TPP on the Reaction Rate: Although the presence of TPP acted to broaden the CRA, it did not accelerate the reaction. At 160°C and a carbon monoxide pressure of 8 atm, the presence of 2 mole equivalents of TPP to nickel carbonyl served to slow down the initial reaction rate to roughly one-fourth that in the absence of TPP (Runs 8 and 20). At 170°C and a carbon monoxide pressure of 15 atm, however, the above two catalyst systems showed approximately equal rates (Runs 5 and 18). Increasing the amount of TPP from 1 to 3 mole equivalents to nickel carbonyl raised the relative rate from 1 to 3.5 (Runs 15, 17, and 19).

Effect of the Carbon Monoxide Pressure on the Reaction Rate: In the presence of 2 mole equivalents of TPP to nickel carbonyl, the decrease in the carbon monoxide pressure raised the reaction rate. This tendency, however, is not so remarkable as that in the absence of TPP. The relative initial rates at carbon monoxide pressures of 15, 7.5, and 4 atm in the presence of 2 mole equivalents of TPP to nickel carbonyl were 1.0, 1.4, and 2.0 respectively (Runs 18, 17, and 16), while in the absence of TPP the initial reaction rate at a carbon monoxide pressure of 10.5 atm was about 2 times that at a carbon monoxide pressure of 15 atm (Runs 5 and 7).

Effect of TPP on the Product Distribution: The presence of TPP had a great influence on the distribution of two isomers. Increasing the ratio of TPP to nickel carbonyl (P/Ni) raised the proportion of *n*-butyric acid, as is shown in Table 4. In connection with such results, it was reported recently that, in the hydroformylation reaction using cobalt[10] or rhodium[11] carbonyl complexes, the presence of phos-

phorus compounds gives linear carboxylation products selectively. In the presence of 2 mole equivalents of TPP to nickel carbonyl, the isobutyric acid ratio seemed to increase slightly with an increase in the carbon monoxide pressure (Runs 16, 17, and 18), but the difference in the carbon monoxide pressure initially charged does not fully reflect the total isomer distribution, for the partial pressure of carbon monoxide is not constant during the reaction.

Carboxylation Reaction Path. The active species of catalyst for the carboxylation using nickel carbonyl is speculated to be $HNi(CO)_nX$ (I) (n; maybe 2), which is probably formed by the addition to nickel carbonyl of an active hydrogen compounds (HX) such as hydrogen halide, organic acid, and water. The reaction path is believed to be as follows:[3,12]

$$Ni(CO)_4 + HX \rightleftharpoons HNi(CO)_nX + (4-n)\ CO$$

$$CH_3CH{=}CH_2 + HNi(CO)_nX \rightleftharpoons CH_3\underset{H}{\underset{|}{C}}H\text{-}\underset{Ni(CO)_nX}{\underset{|}{C}}H_2$$

$$CH_3\underset{X(CO)_nNi}{\underset{|}{C}}H\text{-}\underset{H}{\underset{|}{C}}H_2 \quad \overset{CO}{\rightleftharpoons} \quad CH_3CH_2CH_2CONi(CO)_nX$$

$$(CH_3)_2CHCONi(CO)_nX \quad \xrightarrow{H_2O} \quad CH_3CH_2CH_2CO_2H + HNi(CO)_nX$$

$$(CH_3)_2CHCO_2H + HNi(CO)_nX$$

In the presence of TPP, nickel carbonyl would exist as its TPP derivatives formed by replacing some carbon monoxide by TPP, depending on the reaction conditions. The results of the rate and the product distrubution suggest that the active species, different from that in the absence of TPP, also works in the reaction. As recent articles have reported the existence of $HNi[P(C_6H_{11})_3]_2Cl$[13] and $HNi[P(C_6H_{11})_3]_2(OAc)$,[14] it would be reasonable to consider the $HNi(CO)(TPP)X$ (II) species as corresponding to the $HNi(CO)_2X$ (I) of the nickel carbonyl catalyst. Concerning the formation of II, the following scheme may be considered:

$$\begin{array}{ccc} & Ni(CO)_{4-n}(TPP)_n & \\ {\scriptstyle CO \text{ or } TPP}\ \swarrow\!\!\nearrow\ {\scriptstyle HX} & & {\scriptstyle CO \text{ or } TPP}\ \nwarrow\!\!\searrow\ {\scriptstyle HX} \\ HNi(CO)_2X & \overset{\overset{TPP}{\rightleftharpoons}}{\underset{CO}{}} & HNi(CO)(TPP)X \\ (I) & & (II) \end{array}$$

It has been reported that TPP has a strong field-stabilizing power as a ligand.[15] Therefore, both the active species, II, and the Ni-alkyl complexes derived from II would have higher thermal stability than I and its alkyl derivatives. This is in accordance with the finding that, in the presence of TPP, the catalytic carboxylation proceeds under a low carbon monoxide pressure at a high temperature. As for the results of the reaction rate in the presence of TPP, a clear explanation is difficult at the present time. The rate of carboxylation reaction is probably determined by the step of the reaction between propene and the active species, such as I and II.[3] The rate is, then, determined by the reactivity and the concentration of active species. However, their dependence on the reaction conditions is very complicated because of the presence of the many equilibrium steps described in the above scheme. The increase in the proportion of n-butyric acid is caused mainly by two factors, both of which are in good accordance with the effect of TPP on the product distribution. One is the increase in the hydride character of Ni–H,[16] which facilitates the anti-Markownikoff addition to olefin. The other is the steric bulkiness of TPP, which facilitates the formation of the n-alkyl complex rather than that of the more crowded iso-alkyl complex.

Studies on Hetero-Cage Compounds. II.[1] pK_a Studies on the 3,10-Diazabicyclo[4.3.1]decane System

Tadashi Sasaki, Shoji Eguchi, and Tsutomu Kiriyama

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received May 4, 1971)

The pK_a values of pseudopelletierine (**1**), 10-methyl-3,10-diazabicyclo[4.3.1]decan-4-one (**2**), 10-methyl-3,10-diazabicyclo[4.3.1]decane (**3**), 6,8-*exo*-ethanopseudopelloetierine (**4**), 7,9-*exo*-ethano derivatives **5** and **6** of **2** and **3** were measured potentiometrically in water-methyl cellosolve (20 : 80 v/v) at 20°C. The conformational problems in the 3,10-diazabicyclo[4.3.1]decane system were discussed based on the observed pK_a' (pK_{mcs}) values. The characteristic conformational behavior of the monocation (**7**) of **3** was suggested by the higher value of its pK_{mcs} than of **6**.

In a previous publication,[1] we described the synthesis of 10-methyl-3,10-diazabicyclo[4,3.1]decane (**3**) and its 7,9-*exo*-ethano derivative (**6**) by lithium aluminum hydride reduction of 10-methyl-3,10-diazabicyclo[4.3.1]decan-4-one (**2**) and its 7,9-*exo*-ethano derivative (**5**) respectively, both of which were obtained by the Schmidt reaction of pseudopelletierine (**1**) and 6,8-*exo*-ethanopseudopelletierine (**4**), respectively. From the chemical behavior toward methyl iodide and from the NMR spectra, it was shown that the *N*-methyl pyramidal inversion[2] in **3** is allowed, while that in **6** is prohibited by the steric hindrance due to the 7,9-*exo*-ethano bridge, and the *N*-methyl group is forced to take an *anti*-orientation.[3] In this paper, we wish to describe the results of the pK_a studies on these systems.

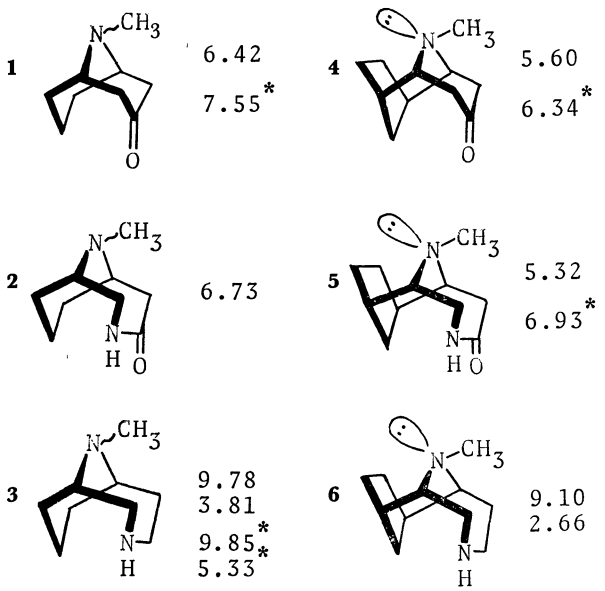

Fig. 1. pK_{mcs} of **1**—**6** (* in water) at 20°C.

The apparent pK_a values of the amines **1**—**6** were measured potentiometrically in water - methyl cellosolve (20 : 80 v/v) at 20°C. The obtained values (pK_{mcs}) are summarized in Fig. 1, in which the values in water (pK_a) are also shown for **1**, **3**, **4**, and **5**.

The pK_{mcs} value of pseudopelletierine was 6.42 which is larger than the value (5.60) of its *exo*-ethano derivative (**4**). The pK_{mcs} value (6.73) of the lactam **2** was also larger than that (5.32) of the corresponding *exo*-ethano lactam **5**. This suggests that the basicity of the *t*-amine is reduced as much as 0.82—1.41 pK unit by the presence of the ethano bridge. This can be ascribed to the more crowdedness in the conjugate acids of **4** and **5** than in those of **1** and **2**. A somewhat similar effect of the steric demand on the amine basicity was also recognized by other workers.[4]

The pK_{mcs} value of **2** was 0.31 larger than that of the ketone **1**, while the value of the ethano-lactam **5** was 0.28 smaller than that of the ethano ketone **4**. This suggests a contradictory effect of the lactam group on the *tert*-amine basicity in **1**—**2** and **4**—**5** series. However, examination of the values of **4** and **5** in water indicates that **5** is a stronger base than **4**. Thus, the basicity of the *t*-amines **2** and **5** might be strengthened by the presence of the lactam group instead of the carbonyl group in **1** and **4**.[5,6]

The tricyclic diamine **6** had two pK_{mcs} values (9.10 and 2.66). In the NMR data of mono salt (**10**)

1) Part I: T. Sasaki, S. Eguchi and T. Kiriyama, *J. Org. Chem.*, **36**, 2061 (1971).

2) For recent reviews on the pyramidal inversion, see a) H. Kessler, *Angew. Chem.*, **82**, 237 (1970); b) A. Lauk, L. C. Allen, and K. Mislow, *ibid.*, **82**, 453 (1970).

3) The prefix *anti* refers to direction with respect to the ethano bridge.

4) For example, see a) H. O. House, P. P. Wickham, and H. C. Müller, *J. Amer. Chem. Soc.*, **84**, 3139 (1962); b) L. A. Paquette and J. W. Heimaster, *ibid.*, **88**, 763 (1966).

5) The basicity promoting effect of the lactam group could be explained by inductive and field effects as well as the ring-size effect. *Cf.* The pK_a value of acetamide (−1.40, 18°C) and cyclohexanone (−6.8, 25°C); J. T. Edward, S. C. R. Meacock, *J. Chem. Soc.*, **1957**, 2000; H. J. Campbell and J. T. Edward, *Can. J. Chem.*, **38**, 2109(1960). For a review on the electronic effects, see C. K. Ingold,"Structure and Mechanism in Organic Chemistry," 2nd Ed., Cornell University Press (1969), Chapter II.

6) The fact that the pK_{mcs} value of **5** is smaller than that of **4** could be explained by the steric hindrance in the solvation. For a similar effect of a carbonyl group on acetolysis rates of 2,6-bridged bicyclo[2.2.1]heptyl and bicyclo[2.2.2]octyl tosylates strengthened by the steric hindrance of the solvation, see R. M. Moriarty, C. R. Romain, and T. O. Lovett, *J. Amer. Chem. Soc.*, **89**, 3927 (1967).

of **6** with trifluoroacetic acid, the chemical shifts of C_2- and C_4-methylene protons adjacent to the *s*-amino group were more deshielded compared to C_1- and C_6-methine protons adjacent to the *t*-amino group.[1] This indicates that the first equivalent of the acid is neutralized by the *s*-amino group in **6** rather than by the *t*-amino group. Hence, the value 9.10 is assigned to pK_{mcs} of the *s*-amino group in **6**, and 2.66 to that of the *t*-amino group. The much smaller value (2.66) of the *t*-amino group in **6** than the values 5.32 and 5.60 of the *t*-amino group in **4** and **5** is apparently explained by the strong inductive- and field-effects of the $-NH_2^+$ group.[5] The assignments are compatible with the fact that the pK_a values of *t*-amines are smaller than those of the corresponding *s*-amines in several monocyclic amines such as pyrrolidine, *N*-methylpyrrolidine, piperidine, *N*-methylpiperidine, morpholine, and *N*-methylmorpholine as summarized in Fig. 2.[7]

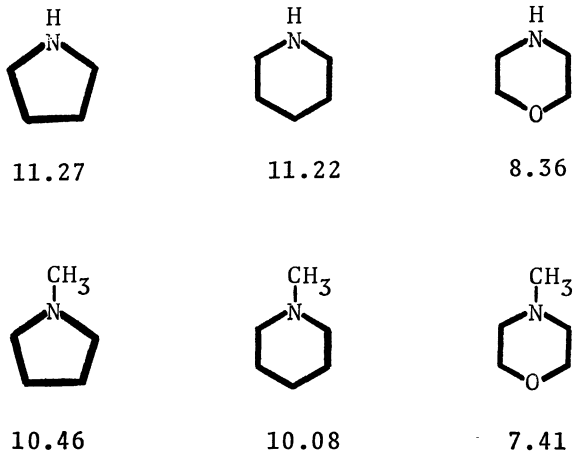

Fig. 2. pK_a of cyclic amines (in water at 25°C).

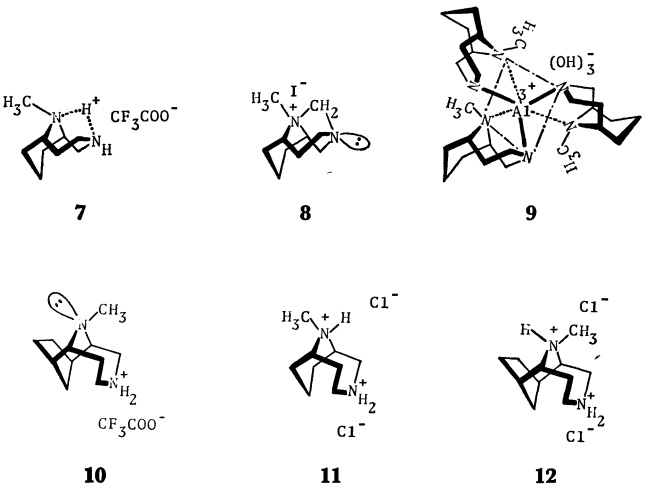
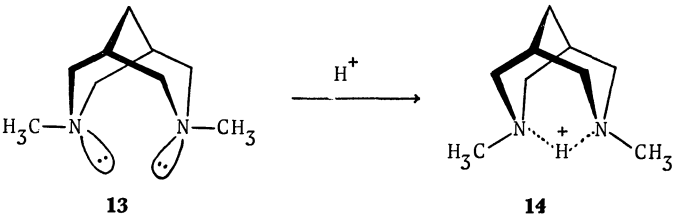
On the other hand, bicyclodiamine **3** had two pK_{mcs} values (9.78 and 3.81), in which a larger one could be assigned to the *s*-amino group and a smaller one to the *t*-amino group analogously to **6** and other monocyclic *s*- and *t*-amines. The larger pK_{mcs} value of the *s*-amino group in **3** than that in **6**, and the greatly decreased value of the *t*-amino group in **3** compared to **1** and **2** suggest that the monocation of **3** should be more stable than that of **6** for some steric reasons. An inversion of the homopiperazine ring to a boat form is possible in **3**, while in **6**, the presence of the 8,9-*exo*-ethano bridge fixes the N–CH_3 group in *anti*-direction, the inversion of the homopiperazine ring thus, being prohibited. Hence, the monocation of **3** can exist in such a conformation as **7** where the piperazine ring takes the chair-form and the homopiperazine ring takes the boat-form as evidenced by the NMR data of compounds **7** and **9**.[1] A similar



but more drastic conformational effect on the amine basicity has been reported on the bispidine system.[8] *N,N*-Dimethylbispidine (**13**) has a very large pK_a value such as 11.88. This is 1.8 pK unit larger than *N*-methylpiperidine. The stabilizing factors of the monocation might be involved in a very stable adamantane-like conformation such as **14.**



In the bicyclodiamine **3**, the stabilizing effect of the monocation by the *t*-amino group can be fulfilled only by inverting its chair-homopiperazine ring to a boat-homopiperazine ring leading to a strained 1,5-diazabicyclo[3.2.1]octane ring structure instead of a strain-free adamantane form[9] in bispidine **13**. Hence, the increase in the pK_{mcs} value from 9.10 of **6** to 9.78 of **3** is reasonably moderate compared to that of *N*-methylpiperidine to bispidine. Furthermore, the decrease in the second pK_{mcs} value (3.81) or the difference between the two pK_{mcs} values (9.78 and 3.81) seems smaller than that in **13**,[10] but larger than that in piperazine whose pK_a values are reported to be 9.82 and 5.68 at 20°C.[11,12] The abnormally smaller value (2.66) of the *t*-amino group in **6**, how-

9) Strictly speaking, adamantane is not strain-free, *cf*, P. v. R. Schleyer, J. E. Williams, and K. R. Blanchard, *J. Amer. Chem. Soc.*, **92**, 2377 (1970).

10) The second pK_a value is not reported but even the disalt formation is described to be difficult; Ref. 8.

11) The pK_a value of homopiperazine does not seem to have been reported.

12) G. Schwarzenbach, B. Maissen, and H. Ackermann, *Helv. Chim. Acta*, **35**, 2333 (1952).

ever, is explained by both the electronic effects of $-NH_2^+$ group and the above described steric hindrance of the *exo*-ethano bridge.

A homopiperazine ring seems to be one of the smallest membered ring of diazacyclic compounds that can afford a stable monocation form with one equivalent of acid. Investigation[13] on the proton exchange rate and the *N*-pyramidal inversion rate in *N,N*-dimethylpiperazine monohydrochloride discloses no intermediate formation of a 1,4-diazabicyclo[2.2.1]heptane type monocation in the conversion of *trans*- to *trans**-*N,N*-dimethylpiperazine monohydrochloride, though an organometallic complex formation of bicyclo[2.2.1]heptane skeleton is reported on *N,N*-dimethylpiperazine.[14]

Finally, the stereochemistry of the quaternization in **3** might be discussed briefly.[15] The fact that the basicity of the *s*-amino group is stronger than that of the *t*-amino group in **3**, and the formation of tricyclic diazaundecanium iodide (**8**) from **3** and methylene iodide is facile[1] supports the view that an approach of a proton or methylene iodide from an upper side of the homopiperazine ring in **3** (Fig. 3, A) is more favored to that from a lower side (Fig. 3, B), even if the homopiperazine ring takes a pseudo-chair (a flattened-chair) form due to the steric repulsion between C_8-methylene and $-NH-CH_2-$ groups.[16]

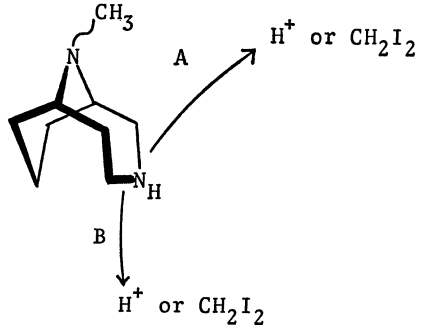

Fig. 3.

Experimental

pK_a measurements were carried out by titrating potentiometrically in an 80% methyl cellosolve-hydrochloric acid solution of each amine ith 0.1 N potassium hydroxide at 20°C. Titration was performed on a Radiometer Model TTl. The 80% methyl cellosolve solution consisted of 4.0 m*l* of methyl cellosolve, 0.6 m*l* of 0.1 N hydrochloric acid, 0.4 m*l* of water, and *ca.* 1.2 mg of each amine.

All the amines used had reported physical constants: pseudopelletierine (**1**), mp 63—65°C (sealed tube) (lit,[17] 63—64°C); 10-methyl-3,10-diazabicyclo[4.3.1]decan-4-one (**2**), mp 164—166°C (lit,[18] 164—166°C); 10-methyl-3,10-diazabicyclo[4.3.1]decane (**3**), mp 43—46°C (sealed tube) (lit,[1] 43—46°C); 6,8-*exo*-ethanopseudopelletierine (**4**), mp 100—102°C (lit,[4b] 103—104°C); 7,9-*exo*-ethano-10-methyl-3,10-diazabicyclo[4.3.1]decan-4-one (**5**), mp 154°C (lit,[1] 154°C); 7,9-*exo*-ethano-10-methyl-3,10-diazabicyclo[4.3.1]-decane (**6**), mp 66—69°C (sealed tube) (lit,[1] 66—69°C).

The authors express their appreciation to Prof. T. Goto and Dr. Y. Kishi for the pK_a measurements.

The Reaction of Nitriles under High Pressure. I. The Formation of Triphenyl-1,3,5-triazine *via* the Equilibrium among Benzonitrile, Alcohols, and Benziminoethers[1]

Masahiro KURABAYASHI, Koshin YANAGIYA, and Masahiko YASUMOTO

The Government Chemical Industrial Research Institute, Tokyo, 6th Div., Mita, Meguro-ku, Tokyo

(Received May 13, 1971)

Benziminoethers were formed from benzonitrile and alcohols to the equilibrium extent, and then 3 mol of benziminoethers were reacted with each other to afford triphenyl-1,3,5-triazine at 2—10 kbar and 100—120°C. The equilibrium shifted toward benziminoether with an increase in the pressure. The equilibrium constant decreased progressively in the order of methanol>ethanol≈*n*-propanol≈*n*-butanol> isopropanol≈*sec*-butanol, which accords with the increasing number of substituents on the α-position of the alcohols. The formation of triphenyl-1,3,5-triazine obeyed the second-order reaction mechanism and was also retarded in the same order. The reaction was found to proceed in the following manner: Benziminoethers produced by the addition of alcohols to benzonitrile dimerize through a rate-determining step and then trimerized into triphenyl-1,3,5-triazine. The apparent activation volume of the formation of triphenyl-1,3,5-triazine amounted to -31 cm^3 mol^{-1} at 110°C when methanol was used as the alcohol. The accelerating effect of the pressure on the formation of triphenyl-1,3,5-triazine is concluded to be mainly caused by the shift of equilibrium toward benziminoether. Three isomers of cyanopyridine were converted in good yields into the corresponding triazines under high pressure.

It is known that nitriles with active hydrogen on the α-position trimerize into trisubstituted-*s*-triazines *via* iminoethers (IE)[2] or amidines.[3] In 1950, Cairns[4] treated many kinds of nitriles with lower alcohols at 70—150°C and 3—8 kbar and thus obtained *s*-triazines in yields of 10—80%. He showed also that the lower the alcohol used the greater the promoting effect. In spite of these interesting findings, he did not describe the mechanism of the reaction nor the role of alcohols, although it had been known that the formation of IE from several alcohols and nitriles is reversible in the presence of alcoxide under atmospheric pressure.[5]

In our first attempt to investigate the reaction of nitriles under high pressure, benzonitrile was chosen as a representative nitrile. The equilibrium constants among benzonitrile, several alcohols, and their iminoethers were determined under high pressure, and the mechanism of the formation of triphenyl-*s*-triazine (TPT) was examined.

Results and Discussion

When the initial ratio of methanol to benzonitrile was widely varied (see Table 1), the plot of the concentration[6] of methylbenziminoether (MBI) against the benzonitrile concentration × methanol concentration gave straight lines (see Fig. 1). This fact indicates the existence of an equilibrium among benzonitrile, methanol, and MBI such as is described beolw;

$$C_6H_5CN + ROH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C_6H_5C(NH)OR \qquad (1)$$

$$K = k_1/k_2 = [IE]/[C_6H_5CN][ROH], \qquad (2)$$

where k_1 and k_2 are the rate constants for the forward and reverse reactions respectively. The equilibrium constant, K, was determined from Fig. 1 as 0.097 and 0.043 mol^{-1} l at 100°C with methanol under pressures of 7850 and 6000 kg/cm^2 respectively. Figure 2 shows that this equilibrium was established less than ten hours after the initiation of the run with methanol at 100°C and at about 8000 kg/cm^2 and not affected by the progress of the formation of TPT.

The experimental results with several lower alcohols are listed in Table 2. Fairly good agreements are seen between the K values in the right and left small columns, illustrating that the equilibria of Eq. (1) were established with these lower alcohols as well as with methanol under the reaction conditions noted in the table. Though Eq. (1) is a quasi-equilibrium reaction succeeded by the trimerization of IE (mentioned later), it is thought that the K values referred to in this paper agree, within the limits of experimental error, with those of the ideal equilibrium state influenced by no other reaction. K decreased conspicuously when methanol was replaced by ethanol, or when *n*-propanol was replaced by isopropanol. However, the replacement of ethanol by *n*-propanol or *n*-butanol or the replacement of isopropanol by *sec*-butanol did not change the constant appreciably. No IE was produced with *t*-butanol. This fact can easily be understood if one asumes that the forward reaction in Eq. (1) is more strongly retarded by the increasing substitution (either methanol or primary or secondary or tertiary) at the α-position of alcohol than is the reverse reaction.

The natural logarithms of the values of K listed in Tables 2 and 3 are plotted against the pressure and are

6) For the calculation of the concentrations, the volume of the reaction medium was assumed to be the sum of the apparent volume of benzonitrile, alcohol, and IE, which were calculated by dividing their quantities as determined in the reaction medium by their specific gravities at 20°C. Under atmospheric pressure, the additivity in volume was found to be nearly constant for mixtures of benzonitrile, methanol, and MBI.

shown in Fig. 3. The change in the volume (ΔV) in Eq. (1) is given by the thermodynamic equation for the liquid phase, $\partial \ln K/\partial P = -\Delta V/RT$, and was found, by applying the tangential method to the curves in Fig. 3, to be -17.9 ml mol^{-1} at 120°C and 1 atm. This value is approximately equal to the calculated volume difference, -16.5 ml mol^{-1}, which is the difference between the sums of the molar volumes of the reactants (left side) and the product (right side) of Eq. (1) at 120°C.

The apparent rate of the formation of TPT, v_m (in mol l^{-1} hr^{-1}) is given by:

$$v_m = x/tV_m, \qquad (3)$$

where x is the amount of TPT (in mol) produced in the reaction time, t (in hr), and where V_m is the mean volume of the reaction medium (in l), that is, the arithmetic mean of the initial volume[7] and the volume at time t.[6] The curve with open circles in Fig. 4 shows the $\ln v_m$ values plotted against the reaction pressure; it indicates a marked positive effect of the pressure on the production of TPT. From the thermodynamic equa-

7) The initial volume was obtained by summing the volumes of the components at the initial point, which were calculated from the experimentally-obtained value of K and the starting amounts of the reactants.

TABLE 2. EFFECT OF ALCOHOLS ON THE EQUILIBRIUM CONSTANT, $K=[IE]/[C_6H_5CN][ROH]$[a]

The K value in the left small column of each alcohol in the large column indicates the equiriblium constant obtained for a mixture of alcohol and benzonitrile, and the K value in the right small column indicates the constant obtained for a mixture of the same alcohol and its benziminoether (IE).

a) Reaction conditions: 110°C, 10 hr, C_6H_5CN:CH_3OH=1:3.2 (in mol).
b) The reaction was carried on for 96 hr in a glass syringe.

tion, $\partial \ln k/\partial P = -\Delta V^*/RT$, the apparent activation volume for the formation of TPT from benzonitrile in the presence of methanol was calculated to be −31.0 ml mol^{-1} at 110°C and 3000—5000 kg/cm². The value of v_m decreased with an increase in the number of substitution on the α-position of the alcohol added, and decreased with an increase in the number of the carbon atoms in the alkyl substituents.

The yield of TPT prepared from a mixture of an alcohol and the benziminoether of the alcohol was larger than that prepared from a mixture of the alcohol and benzonitrile (see Table 2). This fact indicates that IE plays an important role in the formation of TPT. At lower initial mixing ratios of benzonitrile to methanol, a linear relation was obtained between v_m and $[IE]_m$[2 8] as shown in Fig. 5, indicating that

8) $[IE]_m$ is the average value of the concentration of IE at the initial point[7] and after the reaction time t[6].

the formation of TPT is a second-order reaction with respect to the IE concentration. It can be inferred from these results that TPT is formed through a relatively slow dimerization of IE, followed by the cyclization of the dimer with another molecule of IE. The reaction mechanism is given by:

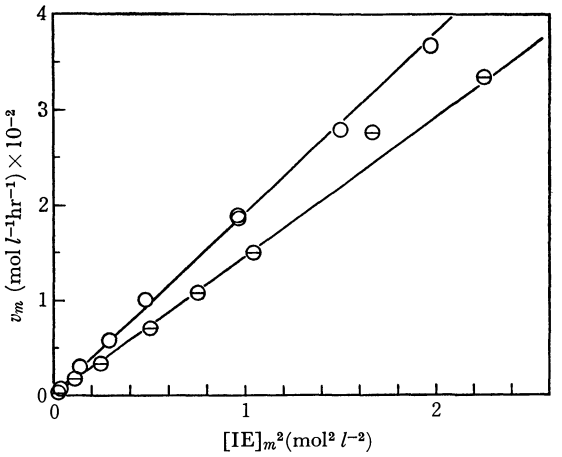

Fig. 5. Relation between the mean rate of the formation of TPT, v_m, and the mean concentration of MBI, $[IE]_m$, in the various initial ratio of C_6H_5CN:CH_3OH at 120°C.
○, 7850 kg/cm²; ⊖, 6000 kg/cm²

The initial concentrations of MBI, $[IE]_i$, was calculated from the data in Table 1 and listed in the following table together with the observed concentrations of it, $[IE]_{obs}$, at ten hours after the initiation of the runs.

$$2C_6H_5C(NH)OR \xrightarrow[\text{slow}]{k_3} C_6H_5C(OR)=N-C(NH)C_6H_5 + ROH \quad (4)$$

$$C_6H_5C(OR)=N-C(NH)C_6H_5 + C_6H_5C(NH)OR \xrightarrow[\text{fast}]{k_4} \text{(2-phenyl-4,5-diphenylimidazole)} + 2ROH \quad (5)$$

Here, we propose alkoxybenzimidoylbenzamidine[9] as the structure of the dimer.

If Eq. (4) is the rate-determining step in the formation of TPT, the rate of the formation of TPT is given as:

$$d[TPT]/dt = k_3[IE]^2, \quad (6)$$

9) Yakubovich had obtained a dimer of perfluoroadipo(or glutaro-)iminoether hydrochloride which has a similar structure.[10]

10) A. Ya. Yakubovich, E. L. Zaitseva, R. M. Gitina, U. P. Bazov, I. M. Filatova, and G. I. Braz, *J. General Chem. U. S. S. R.*, **36**, 878 (1966).

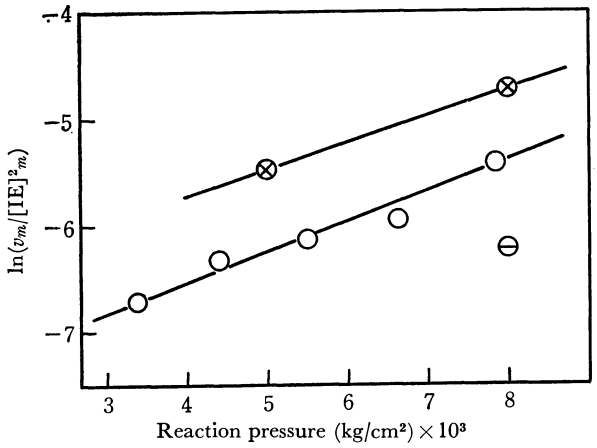

Fig. 6. Plots of $v_m/[IE]_m^2$, which is the rate of Eq. (4) expressed by Eq. (8), *vs.* reaction pressure at 100—120°C for 10 hr in the initial ratio of C_6H_5CN:CH_3OH=1: 3.2.
⊖, 100°C; ○, 110°C; ⊗, 120°C

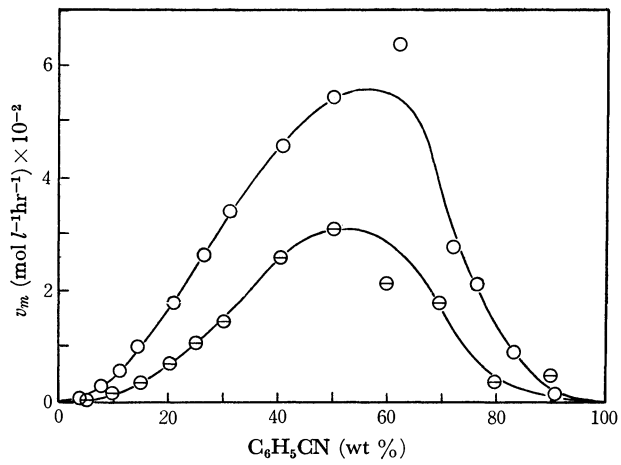

Fig. 7. Relation between the mean rate of the formation of TPT and the initial ratio of C_6H_5CN: CH_3OH at 120°C for 10 hr.
○, 7850 kg/cm² ⊖, 6000 kg/cm²

where k_3 is the rate constant of Eq. (4). From Eq. (3), v_m can be expressed as:

$$v_m \approx d[TPT]/dt \quad (7)$$

and:

$$k_3 \approx v_m/[IE]_m^2 \quad (8)$$

By plotting the natural logarithm of $v_m/[IE]_m^2$ against the reaction pressure (Fig. 6), the activation volume (ΔV^*) of Eq. (4) was determined to be 9 m*l* mol^{-1} in the range of 3000—8000 kg/cm². This indicates that the effect of the pressure on this rate-determining step is relatively small. The marked effect of the pressure on the formation of TPT can, therefore, be mainly ascribed to the fact that pressure shifts the equilibrium of Eq. (1) toward the right.

Figure 7 shows that the value of v_m is at its maximum when the mixing ratio of benzonitrile to methanol is in the range of from 1: 3/2 to 1: 2/3 in weight or from 1: 3 to 1: 2 in molar ratio. The presences of these maxima are expected from Eqs (6) and (2), which mean that the rate of the formation of TPT is proportional to the square of the concentration of IE, *i.e.*, to those of the concentration of benzonitrile and methanol respectively; those facts are important for the effective use of the capacity of the pressure vessel.

As is shown in Table 4, the addition of a small amount of acids stopped the formation of both MBI and TPT, while the addition of bases had little effect on their formation. These results obtained under high pressure differ from those of the commonly-employed synthetic methods, in which a large amount of strong

a) Reaction conditions: 6600 kg/cm², 100°C 10 hr.
b) $v_m/[IE]_m^2$ are recalculated by taking the value of the run, in which no solvent was added, as unity.
c) Dielectric constants of C_6H_5CN and CH_3OH are 25.2 and 33 respectively, at 25°C.

acids[11-13] or bases[14] are necessary for the direct formation of *s*-triazines from nitriles (having no α-hydrogen). Weakly acidic conditions are also required for the trimerization of IE.[2,10] When a part of the methanol in the initial mixture was replaced by some aprotic solvent, the $v_m/[IE]_m^2$ ratio decreased in the decreasing order of the dielectric constant (see Table 5). These results suggest that the solvation of IE or its dimer, which is expected to be of a considerably polar nature, causes the rate of Eq. (4) to increase.

The procedure mentioned above may be a useful method of preparing various types of IE and trisubstituted-*s*-triazines, because it requires no chemically-reactive catalyst. For example, the three isomers of cyanopyridine were trimerized into the corresponding tripyridyl-*s*-triazines in an almost quantitative yield in the presence of methanol.

Experimental

Materials. Benzonitrile and the six alcohols, all of an EP grade, were carefully dried and distilled. Their water contents were determined by the Karl-Fisher method and were found to be less than 0.02%. The hydrochloride of IE was obtained by Pinner's method by introducing hydrogen chloride into a mixture of benzonitrile and alcohol. The resulting hydrochloride was neutralized, and the IE liberated was extracted and finally distilled. MBI: Yield, 74.5%; bp 61.5—62.3°C/3 mmHg; d_4^{20} 1.0684; n_D^{20} 1.5442; content, 98.7% by gas-liquid phase chromatography (glc). Ethylbenziminoether: 77.0%; 96.2—97.8°C/10 mmHg; 1.0312; 1.5295; 95.7%. *n*-Propyl-: 74.8%; 92°C/4 mmHg; 1.0392; 1.5220; 96.9%. Isopropyl-: 32.6%; 73°C/4 mmHg; 1.0274; 1.5171; 95.0%. *n*-Butyl-: 63.9%; 102—104°C/4 mmHg; 1.0241; 1.5179; 99.6%. *sec*-Butyl-: 21.5%; 86.6°C/2 mmHg; 1.0159; 1.5132; 98.7%. The impurities in IE thus prepared were mainly benzonitrile and/or benzoates. The cyanopyridines were supplied by Koei Chem. Ind., and the melting points of α-, β-, and γ- were 28.3°C, 38.7°C, and 78.6°C respectively.

Reaction Apparatus and Procedure. Collapsible lead capsules with a volume of a few milliliters were filled with the starting materials and put into a Bridgeman-type pressure vessel, in which less than twelve capsules could be placed, and compressed just below the desired pressure by introducing compressed oil from the pressure generator. Then the vessel was quickly heated for 30—40 min until the temperature inside its wall reached just below the desired level; thereafter, the pressure and the temperature were maintained at the desired levels. The reaction pressure was determined by means of a manganin-cell-type assembly corrected by the phase transition pressure of mercury. When the desired reaction time had passed, the temperature of the vessel was reduced to 50°C or less within 30—50 min in order to stop the reaction by cooling the wall with water. Sometimes a glass syringe or a polytetrafluoroethylene capsule was employed; no substantial wall effect was found.

Analysis. For the determination of benzonitrile and IE, glc (Reoplex 400, 4 mm i.d. × 750 mm, 50—250°C, 4°C/min) was employed. The TPT was filtered from the reaction medium, washed in methanol, recrystallized from toluene, and weighed. Solubility correction was made for the calculation of the yield of TPT.

Identification. MBI: A mixture of benzonitrile and methanol (each 2.2 g) was treated at 120°C and at 7800 kg/cm² for 5 hr and then fractionated by glc. The IR spectrum and the retention time of the glc of the fraction (0.5 g) at 150—160°C agreed with those of the authentic sample mentioned above (Found: C, 70.64; H, 6.66; N, 10.86%). The other five preparations of IE were identified by the retention time of glc with the respective authentic samples. TPT: 4.2-g portions of benzonitrile and methanol were similarly treated at 7800 kg/cm² and at 145°C for 3 hr, the product was diluted with methanol and filtered. The TPT (mp 236.8°C; yield, 3.34 g and 79.1%) thus separated was recrystallized from toluene as fine needles (Found: N, 14.14%; mp 237.1°C; mol wt (mass spectroscopy (MS)) 309). The IR spectrum and melting point agreed with those of the authentic sample prepared by the trimerization of benzonitrile in the presence of chlorosulfonic acid.[11] Tris(2-pyridyl)-*s*-triazine: 8.73-g portions of 2-cyanopyridine and methanol were treated at 100°C and at 8000 kg/cm² for 24 hr. The triazine thus produced was completely precipitated by the addition of water (yield, 8.62 g (98.6%)) and was recrystallized from water (Found: C, 69.14; H, 3.92; N, 27.08%; mp 256°C). The melting point and IR spectrum agreed with those of an authentic sample (Tokyo Chem. Ind.; mp 255°C). Tris(3-pyridyl)-: 9.37-g portions of nicotinonitrile and methanol were treated at 100°C and at 8000 kg/cm² for 30 hr. The precipitate was filtered, washed in methanol, weighed 9.08 g (99.1%), and recrystallized from pyridine. Found: C, 68.94; H, 3.92; N, 27.04%; mp 311°C; mol wt (MS), 312; IR, 1580, 1520, 1360 cm⁻¹ for the triazine ring. Calcd for $C_{18}H_{12}N_6$: C, 69.22; H, 3.87; N, 26.91%; mol wt, 312. Tris(4-pyridyl)-: 8.92-g portions of isonicotinonitrile and methanol were treated similarly; the product was filtered and washed in methanol to yield 6.71 g (75.2%). The crude triazine was recrystallized from pyridine. Found: C, 69.29; H, 4.01; N, 26.81%; mp 374°C; mol wt (MS), 312; IR, 1570, 1515, 1370 cm⁻¹. Calcd for $C_{18}H_{12}N_6$: C, 69.22; H, 3.87; N, 26.91%; mol wt, 312. A conciderable amount of an oily matter containing the triazine was also separated.

Mr. Toshiro Minegishi of our Institute cooperated in designing the high-pressure apparatus employed in this study. The authors wish also to express their thanks to Dr. Masasuke Yamada of Koei Chem. Ind. for his gifts of the cyanopyridines used in the present investigation.

Conformations of the Esters. V.[1] The Conformations of Carbonates

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 13, 1971)

In alkyl or aryl carbonates, the presence of conformational isomers (*s-cis* and *s-trans*) has been confirmed by infrared and nuclear magnetic resonance spectroscopic techniques. The dipole-moment measurements also support the conclusions obtained from the spectroscopic data.

The conformation of the carbonate has been claimed by Kubo,[2] Thomson,[3] and Longster[4] to be *s-trans-s-trans* on the basis of the data on the dipole moments of dimethyl and diethyl carbonates. In the light of the fact that the *s-cis* conformer can exist together with the *s-trans* in some esters of formic acid which carry the bulky alkyl group,[5] and that carbamates have *s-cis* and *s-trans* conformers,[1] it seemed that it would be interesting to reinvestigate the conformation of carbonates, which are the analogs of esters.

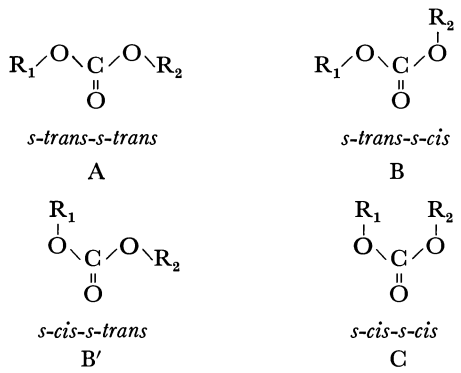

Fig. 1. Four conformational isomers of the carbonate.

In discussing the conformations of carbonates, the four conformers shown in Fig. 1 must be taken into account. C conformer (*s-cis-s-cis*) can be considered to be unimportant, for the repulsion between R_1 and R_2 groups is very large, even if both R_1 and R_2 groups are methyl groups. If the R_2 group is bulkier than the R_1 group ($R_2 > R_1$), the B conformer will be more stable than the B′ conformer, because the length of the C–O_{ether} bond (1.36 Å) is longer than that of C=O (1.20 Å); hence, the repulsion between O_{ether} and R_2 in the B conformer can be expected to be smaller than that between C=O and R_2 in the B′ conformer. As to the chief factors governing the preference of the conformations of the ester, three factors (dipole-dipole interaction, lone pair-lone pair interaction, and the steric repulsion between the carbonyl and the alkyl groups or between the two alkyl groups) were described in an earlier paper.[5] In the carbonates, two additional factors must be taken into account in discussing the conformations: the dipole-dipole interaction between C–O and O–R_2 and the lone pair-lone pair repulsion between two ether oxygens(the so-called "rabbit ear effect",[1,6] (Fig. 2)[7]). With regard to the first factor, the B conformer is favored over the A conformation, in the nonpolar media, while with regard to the second factor, the A conformer is destabilized by the larger repulsion between the two ether oxygens. Therefore, the possibility of the existence of the *s-cis* conformer is larger in the carbonate than in the ordinary ester. The purpose of this paper is to present various sepectroscopic and dipole-moment data to confirm the existence of the *s-trans-s-cis* conformer in some carbonates.

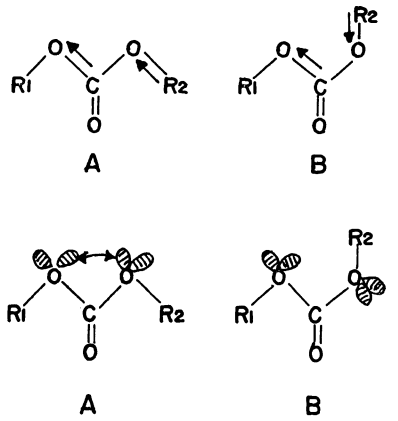

Fig. 2. Additional factors governing the conformations of the carbonate.

Experimental

The dimethyl and diethyl carbonates were of commercial origin and were purified by distillation before measurement. The ethyl methyl carbonate, *t*-butyl methyl carbonate, and 1,1-diethylporpyl methyl carbonate were prepared by pouring the corresponding sodium alkoxide into methyl chloroformate in dry ether with ice-cooling and then distilling under re-

The purities of the compounds used in this study were checked by studying their infrared spectra and NMR spectra, and by gas chromatography. The infrared spectra were measured on a Perkin Elmer single-beam grating spectrometer and a Hitachi EPI-G2 grating spectrophotometer. The NMR spectra were measured on JNM C-60, JNM-4H-100, and Hitachi R-20B Spectrometers. The dipole moment was measured by the heterodyne beat method, (the inaccuracy was about 0.05D at 1.0D). The calculation of the stability of dimethyl carbonate was carried out by the CNDO/2[8] method, using programs provided by the Computation Center of this University.

Results and Discussion

Nuclear Magnetic Resonance Spectra. In the expectation of obtaining some signs of the existence of A and B conformers, the NMR spectra of t-butyl methyl carbonate and 2,6-dimethylphenyl methyl carbonate were measured at room temperature. These two compounds were selected as the samples because they have a bulky alkyl or aryl group and because the repulsion between C=O and the R group is so large that the possibility of the existence of the *s-cis* conformer is also large. The results were, however, that both gave sharp singlets

for the methoxy groups and did not give any sign of the existence of the two isomers. These results could arise for two reasons: the existence of a single isomer, or rapid exchange between isomers. If the latter is the case, there is a possibility that the singals split at lower temperatures. Thus, the NMR spectra of these compounds were measured at low temperatures in a CS_2–CH_2Cl_2 solvent, with toluene as the internal standard.

The results are shown in Tables 1 and 2 and in Fig. 3. Neither the methoxy nor t-butyl methyl peak separated, even at low temperatures, but the peak of the t-butyl protons became very broad at −102°C. (The height of the t-butyl peak at −102°C is one third of that at 34°C, while the peak height of the methoxy at −102°C is 65% of that at 34°C.) These results can best be interpreted by assuming the presence of two or three conformers in this compound and by assuming that the exchange rate between these conformers is slow enough for the time scale of NMR at this low temperature. Judging from the fact that the broadest peak in t-butyl methyl carbonate at low temperatures is not the methoxy peak but the t-butyl, it may be postulated that the t-butyl group is more mobile, and that the A and B conformations are significant, but not the B′ conformation, because the influence of the anisotropy of the carbonyl must be large in determining the chemical shifts of these protons; the difference in the chemical shifts of the methyl groups in A and B′ conformers is expected to be at least as large as that of t-butyl protons. It may be argued that the difference in the chemical shifts of the methoxy protons in the A and B′ conformers is so small that the peak height decreases only slightly. However, this possibility is seen to be rather unlikely when the average anisotropy effects of the car-

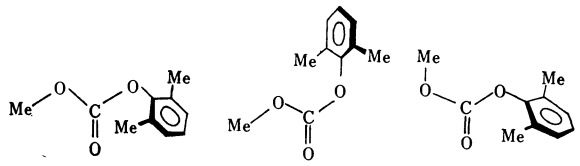
bonyl group to methoxy and *t*-butyl protons are considered. Thus, the contribution of the B′ conformer is small, at least; this consideration conforms with that deduced from the steric effect.

In the case of 2,6-dimethylphenyl methyl carbonate, the situation is somewhat different. The broadest peak at low temperatures is not that of the aromatic methyl but that of the methoxy. These results may again be interpreted by assuming that the anisotropy effect of the carbonyl group is larger for the methoxy methyl than for the aromatic methyl, although there is some difference from the situation of the *t*-butyl methyl carbonate. Therefore, it can be assumed that the main *s-cis* conformation of 2,6-dimethylphenyl methyl carbonate is not B but B′ (Fig. 4). The population of the B conformer is considered not to be significant.



A B B′

Fig. 4. Conformations of 2,6-dimethylphenyl methyl carbonate.

Infrared Spectra of Carbonyl Stretching Vibration Absorption. The infrared spectra of carbonates have been measured by several authors,[9] and it has been reported that carbonates have only one carbonyl absorption.

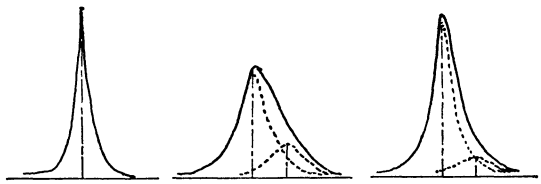


Fig. 5. ν_{CO} absorption of $MeOCO_2t$-Bu in three solvents.

No one has, however, reported about the shape of the carbonyl absorption. However, as has been described in previous papers,[1,5] some formates and carbamates have two carbonyl absorptions and can be assigned to two conformational isomers. From the NMR results on the carbonates, it is expected that a careful reinvestigation of the infrared spectra may produce further evidence for the conformational heterogeneity of the carbonates. Thus, the carbonyl stretching absorption was measured using an instrument with a high resolution. The results follow.

t-Butyl methyl carbonate was found to have an unsymmetrical carbonyl absorption in carbon tetrachloride and acetonitrile. This absorption was graphically separated into two absorptions using Lorenzian curves (Fig. 5). The infrared spectra of carbonyl absorptions of other carbonates were treated similiarly; the results are shown in Table 3.

Carbonates I, II, and III, whose two alkyl groups are relatively samll, all have one symmetrical carbonyl absorption in hexane, carbon tetrachloride, and ace-

tonitrile solvents. However, compounds IV—XII, which have relatively bulky alkyl or aryl groups, show two carbonyl bands in these solvents (compound XI has three absorptions). These results may be interpreted in the following way. In compounds I, II, and III, the steric repulsion between C=O and R_1 or R_2 is small. Thus, these compounds take the conformation, A, which is the most stable. On the other hand, in compounds IV, V, and VI, which have a large alkyl group, the steric repulsion described above becomes serious and the A conformer is so destabilized that the B conformer can exist to a significant extent. The coexistence of the A and B conformers explains the two carbonyl bands. In compound IV ($MeOCO_2t$-Bu), the intensity of the higher wave-number absorption is stronger than that of the lower one. The consideration of the directions of the bond dipoles of C=O and R_2–O[1,5] suggests that the *s-cis* conformer has a higher frequency band than the *s-trans*.[10] Therefore, in *t*-butyl methyl carbonate the B conformer (*s-trans-s-cis*) must be more stable than the A conformer (*s-trans-s-trans*). The solvent effect is found to be such that the intensity of the higher frequency band increases in polar solvents more than in nonpolar solvents. Since the calculated dipole moment of the B conformer (2.1D) is larger than that of the A conformer (0.1D), the results presented here necessarily mean that the B conformer is the one which is prefered in the polar solvents. The situation is somewhat different in compounds VII, VIII, IX, and X from that in compound IV. In these compounds, the intensity of the absorption of the lower wave number is stronger than that of the higher one. In assigning the two absorptions to two conformers in alkyl carbonates, the directions of the two bond dipoles can be considered to be the main factor, whereas in the aryl carbonates, the stability of the resonance canonical structures in addition to the directions of the bond dipoles must be taken into account. Although there are difficulties in assigning the absorptions because of the complexities arising from the steric and electronic effects, the authors would like to assign the tentatively as in the case of dialkyl carbonates. The band at the higher frequency is thus assigned to the *s-cis* conformer. Diphenyl carbonate has three absorptions in the region of carbonyl stretching. Three conformers may be considered: *s-cis-s-cis*, *s-cis-s-trans*, and *s-trans-s-trans*. The interaction between the two benzene rings in the *s-cis-s-cis* conformer will, however, be repulsive, and the repulsion is considered to be too large for the conformer to exist. Therefore, two conformations, *s-cis-s-trans* and *s-trans-s-trans*, will suffice in discussing the conformations of this compound. Thus, one of the bands in the carbonyl region must be attributed to the enhancement of an overtone or combination tone due to the Fermi resonance. Bis-(2,6-dimethylphenyl)carbonate shows two absorptions in which the higher band is stronger. If the analogy of dialkyl carbonate is still applicable, then it can be considered that the *s-cis-s-trans* conformer is to be favored over the *s-trans-s-trans*.

10) This was suggested to be true by the results of the calculation of the bond order of the carbonyl of dimethyl carbonate by the CNDO/2 method.

Surveying the stabilities of these conformers in dialkyl carbonates, alkyl aryl carbonates, and diaryl carbonates, we find that the *s-cis* conformer more stable in the first carbonates, and the *s-trans* conformer is favored in the second carbonates, while in the last the *s-cis* conformer is again more stable, if the above-mentioned assignments are accepted. The origin of these stabilities remains to be explored.

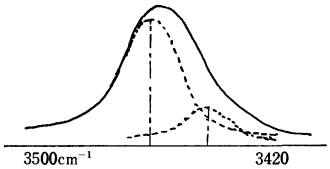

Fig. 6. Infrared spectra of carbonyl overtone of $MeOCO_2t$-Bu in CCl_4.

Infrared Spectra of Carbonyl Overtone. The infrared spectra in the carbonyl overtone region were measured in order to obtain further information about the conformations of the carbonates. The results are shown in Tabel 4 and Fig. 6. *t*-Butyl methyl carbonate (IV) has two absorptions of the carbonyl overtone, and the relative intensities of these two absorptions are almost the same as that of the carbonyl fundamental absorptions. These results suggest that the origin of the bifurcation of the carbonyl band is not the Fermi resonance but the heterogeneity of the conformations, thus supporting the assignment made earlier in this paper. The case of 2,6-dimethylphenyl methyl carbonate(VIII) is the same; the band at a lower frequency is stronger than that at a higher, as is observed in the carbonyl region. Dimethyl carobnate(I) and ethyl methyl carbonate(III), which show only one absorption in the carbonyl fundamental, give, astonishingly, two absorptions, and the intensity of the band at the higher wave number is stronger than that of the lower one, as in the case of *t*-butyl methyl carbonate. It is almost unbelievable that this bifurcation is due to Fermi resonance. Rather, this bifurcation may be explained by considering the existence of two conformers in these carbonates, although they are not detected by the C=O stretching absorption because of the small difference in frequencies. If this postulate is accepted, then in these carbonates with two small alkyl groups, the *s-cis* conformer can be considered from the relative intensity to be more stable than the *s-trans*.

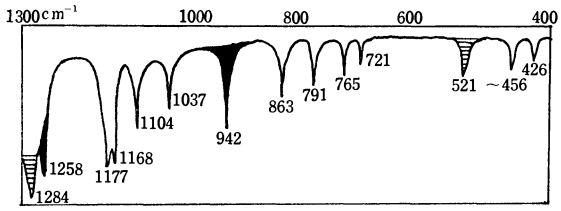

Fig. 7. Solvent effects on infrared spectra of $MeOCO_2t$-Bu in the region of 1300—400 cm^{-1}.
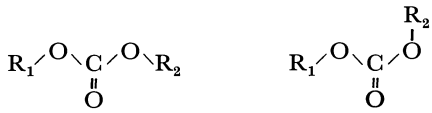
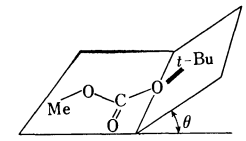
●: increasing band in polar solvent
⊜: decreasing band in polar solvent.

Solvent Effect on the Absorptions in the Region of 1300—400 *cm*$^{-1}$. The B conformer of the carbonate should be more polar than the A conformer, judging from the arrangement of the bond dipoles. This implies that the population of the B conformer will increase in a polar solvent relative to in a nonpolar solvent. Thus, the infrared spectra of *t*-butyl methyl carbonate were measured in various solvents, such as carbon disulfide(2.64),[11] acetone(20.7), chloroform(4.81), *N*,*N*-dimethylformamide(37.7), and dimethyl sulfoxide(48.9), in the region of 1300—400 cm^{-1}. (Fig. 7) The intensities of the absorptions at 942 and 1258 cm^{-1} apparently increase in polar solvents, whereas the intensities of the absorptions at 521 and 1284 cm^{-1} decrease. This apparent solvent effect can be interpreted as implying that *t*-butyl methyl carbonate exist as a conformational mixture, each conformer having a different polarity.



Dipole Moment. The calculated dipole moment values are 0.1D for the A conformer and 2.1D for the B conformer.[12] The dipole-moment values obtained by CNDO/2 calculation are 0.27D for the A conformer, and 2.04D for the B conformer, of dimethyl carbonate. The results obtained with a benzene solution are given in Table 5. *t*-Butyl methyl carbonate (IV) has a little larger dipole moment than the other carbonates at room temperature, and the value at 49°C is smaller than that at 28°C. This temperature dependence of the dipole moment of this compound means that the conformers exist and that the more polar conformer, B or B′, is more stable than the less polar conformer, A. This is in accord with the results obtained from the infrared spectral study. Although it was made clear that the B or B′ conformer is more stable than the A conformer, the observed dipole moment of this compound is in between the two calculated values for the *s-trans* and *s-cis* conformers. The reason for these results may be considered to be an inaccuracy in the calculation of the dipole moments from the bond dipoles, but the twisting of the *t*-butyl group from the plane of the other part of the molecule can be another reason; the latter possibility is supported by the molecular model and by the results obtained with other esters in this laboratory,



($\theta \neq 0°$). The dipole moment values of compounds I, II, and III are in the range of 0.7—0.9D at room temperature, in between the two calculated values of the A and B conformers.[13] Since these values are colse to that of compound IV, it may be concluded that dialkyl carbonates take two comformations in the liquid phase. This conclusion is supported by the results of an infrared spectroscopic study in the overtone region of the carbonyl stretching, although there remains some ambiguity in the relative populations.

Table 5. Dipole moments of carbonates in benzene

	Compound	μ (D)	T°C
I	$MeOCO_2Me$	0.94	16
		0.91	28

III	$MeOCO_2Et$	0.71	28
IV	$MeOCO_2t$-Bu	1.00	28
		0.89	41
		0.80	49

Conclusions

Nuclear magnetic resonance and infrared spectroscopies and dipole-moment techniques have revealed that *t*-butyl methyl carbonate has the A (*s-trans-s-trans*) and B (*s-trans-s-cis*) conformers, the latter being more stable than the former, although the possibility of the existence of the B′ conformer (*s-cis-s-trans*) cannot be ruled out. This is in interesting contrast with the case of *t*-butyl formate, in which the *s-trans* conformer is more stable than the *s-cis*.[5] The difference may be explained by considering the stabilization of the B conformer of the carbonate due to the dipole-dipole interaction between C–O and R–O bonds and the destabilization of the A conformer due to the "rabbit ear effect." Other carbonates also give signs of conformational heterogeneity.

The authors wish to express their hearty thanks to Professor T. Kunii and Mr. K. Morio for their technical assistance in the CNDO/2 calculations.

11) The numbers shown in parentheses are dielectric constants.
12) The calculation was made on the basis of a bond moment value of 0.4D for the C–H bond, a 2.4D value for the C=O bond, and a 0.9D value for the C–O bond.
13) The dipole moments of dimethyl and diethyl carbonates in the gaseous phase were reported by Kubo *et al.*[2] not to change seriously from 55°C to 206°C. The carbonates are, therefore, considered to exist in a *s*-trans conformation only by these authors.

Syntheses of Acylurea Derivatives as Model Compounds for a Highly Specific Organic Reaction

Tadashi ENDO, Shigeru NOGUCHI, and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

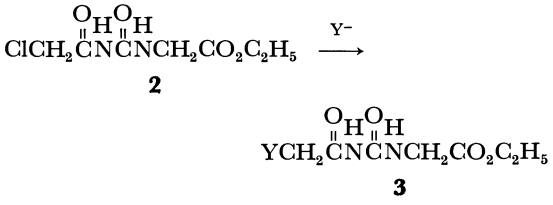
(Received May 14, 1971)

Some types of acylurea derivatives were prepared as model compounds for a highly specific organic reaction by molecular association. When ethyl chloroacetate was treated successively with *o*-aminobenzenethiol (**4**) and chloroacetyl isocyanate (**1**) under mild conditions, triacylurea derivative (**9**) was obtained in total 84% yield. It was found that the use of "amino acid amide and oxalyl chloride" method led to the formation of diacylurea derivative (**11**) in high yield.

Increasing attention has recently been drawn to "molecular interaction" between proteins themselves and between proteins and nucleic acids or lipids in the field of biochemistry. The purine and pyrimidine bases in coenzymes and nucleic acids may play an important role in the control of enzyme reactions by forming hydrogen bonding and charge-transfer complexes with each other or with other biochemical macromolecules in living cells. Acylurea derivatives are regarded as a sort of open chain analogue of the pyrimidine bases. The present paper deals with the fundametal studies on syntheses of acylurea derivatives as model compounds which lead to a specific organic reaction by an intermolecular association.

In preparing acylurea derivatives it was found that the use of acyl isocyanates as carbamoylating reagents is the most effective. The desired acylurea derivatives were obtained in high yields by treatment with amines under mild conditions. Chloroacetyl isocyanate (**1**)[1] readily reacted with ethyl glycinate at 0°C in ether to give 5-chloroacetylhydantoic acid ethyl ester (**2**) in 94% yield.

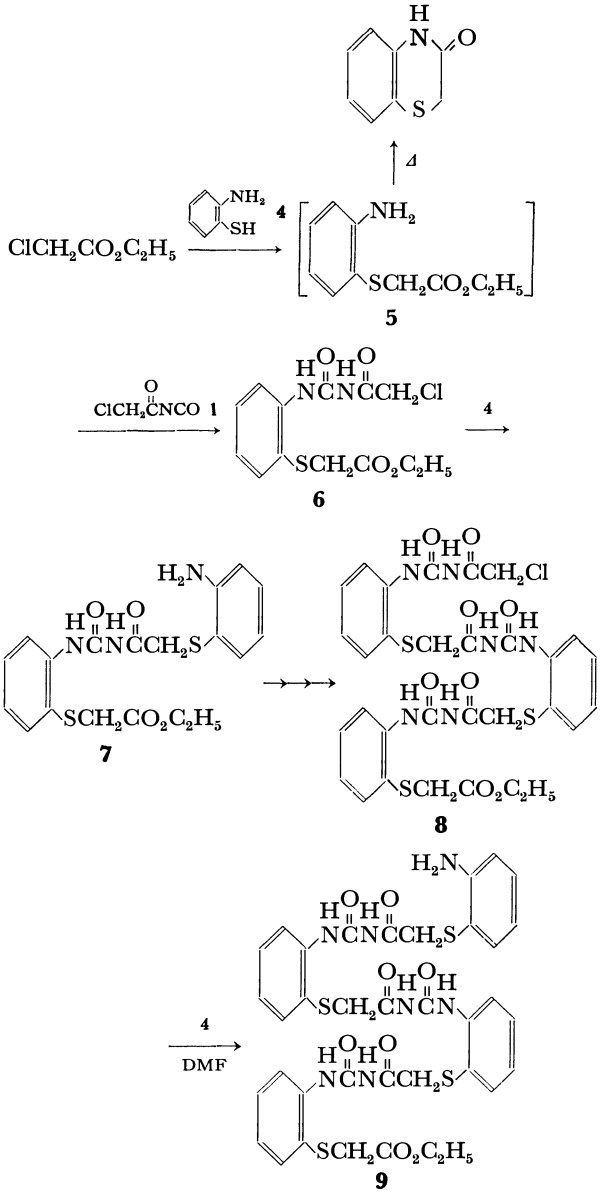
Nucleophilic substitution at the terminal carbon of **2** was investigated for an introduction of a functional group which can be utilized in the formation of the next acylurea linkage. The aminated product (Y= NH_2) (**3**) could not be isolated by the use of Gabriel



2 **3**

or Sommelet method or by treatment with ammonia[2] in methanol. However, it was found that **2** easily underwent nucleophilic substitution by thiols. Treatment of **2** with benzenethiol, *o*-aminobenzenethiol (**4**), 4-pyridinethiol, and thiobenzoic acid at room temperature in the presence of triethylamine gave the corresponding sulfides in 96, 96, 95, and 88% yields, respectively. Physical properties and analytical data of these sulfides are listed in Table 1. It is of special interest to note that the thiols did not attack the carbonyl carbon of the chloroacetyl group in **2**.

On this basis, it was expected that the successive use of thiols containing the N–H bonds and of **1** would lead to the formation of the desired *polyacylurea* derivatives. An oily product (**5**), easily obtained by the reaction of ethyl chloroacetate with **4** and triethylamine at room temperature, decomposed to give 2*H*-1,4-benzo-



5 **6** **7** **8** **9**

1) A. J. Speziale and L. R. Smith, *J. Org. Chem.*, **27**, 3742 (1962).

2) In this case, chloroacetamide and hydantoic acid ethyl ester were obtained. This may be explained as nucleophilic attack of ammonia on the carbonyl carbon of chloroacetyl group in **2**.

thiazin-3(4*H*)-one in 95% yield when distilled. Thus, compound **5** was converted into the acylurea derivative (**6**), without isolation, on rapid treatment with **1**. Similarly, compound **6** reacted with **4** to afford the amine (**7**). It was found that triacylurea derivative (**9**) was prepared by treatment of **7** successively with **1** and **4**. All processes proceeded almost quantitatively at room temperature. Compound **9** could be isolated in total 84% yield. It should be noted that in contrast to the chloroacetylurea derivatives such as **6** and **8**, **9** is very soluble in organic solvents, especially in dichloromethane, benzene, and acetone. The protons of the methylene groups attached to the sulfur in **7** resonated as two doublets at τ 6.50 and 6.58. However, those of **9** resonated as a singlet at 6.50. The infrared spectrum of **9** showed broader absorptions than that of **7** (Fig. 1).

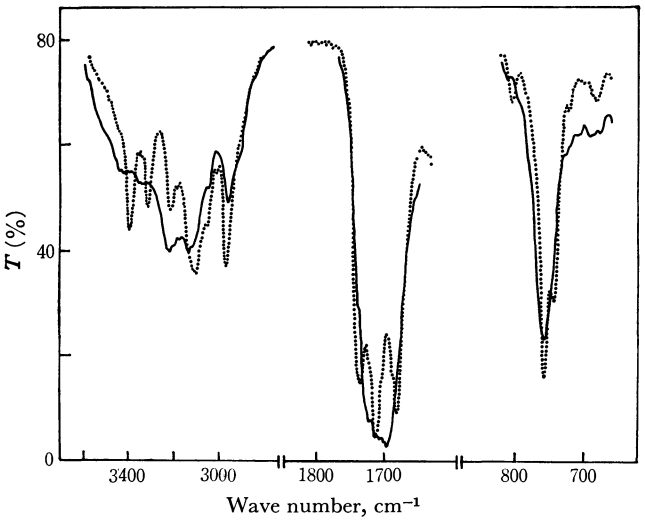

Fig. 1. Infrared spectra of **7** (·····) and **9** (——) in KBr disks.

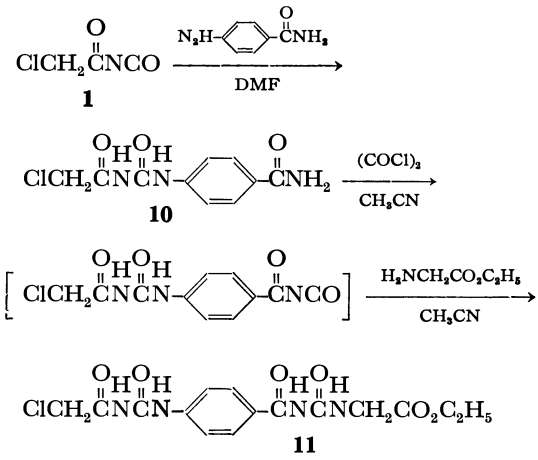
Preparation of another type of polyacylurea derivatives was studied by the use of amino acid amides on the assumption that amides are easily converted into the corresponding acyl isocyanates[1] when treated with oxalyl chloride. Compound **1** reacted with *p*-aminobenzamide in DMF to give the corresponding acylurea derivative (**10**) in 88% yield. The diacylurea derivative (**11**) was prepared in 70% yield by treatment of **10** first with oxalyl chloride in refluxing acetonitrile and then with ethyl glycinate at room temperature. Compound **11** showed remarkably high decomposition point (323—325°C) and could be recrystallized from DMF-ethanol to give colorless plates.



From these results, it seems reasonable to conclude that polyacylurea derivatives could be prepared by the use of either "N–H bond-containing thiol and haloacyl isocyanate" method or of "amino acid amide and oxalyl chloride" method.

Experimental[3]

Materials. Chloroacetyl isocyanate (**1**) was prepared according to the method of Speziale.[1] Benzenethiol, ethyl chloroacetate, *o*-aminobenzenethiol, and *p*-aminobenzamide were all commercial materials and purified by distillation or recrystallization before use. Thiobenzoic acid, 4-pyridinethiol, and ethyl glycinate were prepared in the usual manner.

Preparation of **2** *and* **10**. To a stirred solution of ethyl glycinate (2.10 g, 0.02 mol) in 30 m*l* of ether was added a solution of **1** (2.40 g, 0.02 mol) in 10 m*l* of ether under cooling at 0°C. After stirring had been continued for 1 hr at room temperature, the resulting precipitate of **2** (4.10 g, 94%) was collected by filtration and washed twice with a small amount of ether. Recrystallization from ether gave analytically pure colorless needles, mp 144—145°C (lit,[4] mp 145—146°C). (Found: C, 37.74; H, 4.70; N, 12.86%).

Similarly, **10** was obtained in 88% yield by the reaction of **1** with *p*-aminobenzamide in DMF. Recrystallization from DMF-water gave analytically pure colorless needles, mp 229—230°C (dec.) (lit,[5] mp 236—237°C (dec.)). (Found: C, 47.05; H, 3.84; N, 16.39%).

3) All melting points were uncorrected. The IR spectra were recorded with a Hitachi EPI-G3 Spectrophotometer. The NMR spectra were measured at 100 MHz with a Japan Electron Optics JNM-4H-100 Spectrometer. All the solvents used for reactions were purified by the usual methods.

4) A. H. Corwin and C. I. Damerel, *J. Amer. Chem. Soc.*, **65**, 1974 (1943).

5) W. A. Jacobs and M. Heidelberger, *ibid.*, **39**, 2438 (1917).

Reaction of **2** *with Benzenethiol.* To a solution of **2** (2.23 g, 0.01 mol) in 40 m*l* of acetone was added dropwise a solution of benzenethiol (1.10 g, 0.01 mol) and triethylamine (1.01 g, 0.01 mol) in 10 m*l* of acetone with stirring at room temperature. Stirring was continued for 1 hr at room temperature. After the reaction mixture had been concentrated *in vacuo* to dryness, the residual solid was treated with water for removal of triethylamine hydrochloride. The resulting cyrstals were collected by filtration, washed repeatedly with water and dried over phosphorus pentoxide *in vacuo* to give 2.85 g (96%) of **3** (Y=C_6H_5S). Recrystallization from ether gave white needles.

By a similar procedure the corresponding sulfides were obtained from other thiols. Physical properties and analytical data of these sulfides are listed in Table 1.

Preparation of 2H-1,4-Benzothiazin-(4H)-one. A solution of **4** (2.50 g, 0.02 mol) and triethylamine (2.02 g, 0.02 mol) in 20 m*l* of ether was added to a solution of ethyl chloroacetate (2.45 g, 0.02 mol) in 20 m*l* of ether with stirring at room temperature. A slightly exothermic reaction took place immediately and triethylamine hydrochloride precipitated. Stirring was continued for 1 hr at room temperature. After the reaction mixture had been filtered off, the filtrate was evaporated *in vacuo*. Residual oil (**5**) gave crystals of 2*H*-1,4-benzothiazin-3(4*H*)-one (3.14 g, 95%) with loss of ethanol when heated under reduced pressure. Recrystallization from acetone gave pure colorless needles, mp 175.0—175.5°C (lit,[6] mp 176°C). (Found: C, 58.85; H, 4.15; N, 8.44; S, 19.70%).

Similarly, the oil (**5**) gave 2*H*-1,4-benzothiazin-3(4*H*)-one in 40% yield when allowed to stand for 6 days at room temperature.

Preparation of **6**. To a stirred solution of ethyl chloroacetate (2.45 g, 0.02 mol) in 20 m*l* of ether was added a solution of **4** (2.50 g, 0.02 mol) and triethylamine (2.02 g, 0.02 mol) in 20 m*l* of ether at room temperature. Work-up of the reaction mixture as described above gave the oil (**5**). To a solution of this oil in 30 m*l* of dichloromethane was added a solution of **1** (2.40 g, 0.02 mol) in 20 m*l* of dichloromethane with stirring at room temperature. Stirring was continued for 30 min at room temperature. After removal of dichloromethane, the resulting solid was treated with ether. A white precipitate of **6** (6.30 g, 95%) was collected by filtration and recrystallized from ethanol to give white needles, mp 146.0—146.5°C.

Found: C, 47.43; H, 4.72; N, 8.73; S, 9.94%. Calcd for $C_{13}H_{15}ClN_2O_4S$: C, 47.21; H, 4.57; N, 8.47; S, 9.68%.

Preparation of **9** *and* **7**. A solution of **4** (0.63 g, 0.005 mol) and triethylamine (0.51 g, 0.005 mol) in 10 m*l* of DMF was added to a solution of **8** (3.74 g, 0.005 mol) in 30 m*l* of DMF with stirring at room temperature. Colorless crystals of triethylamine hydrochloride were soon formed. Stirring was continued for 1 hr at room temperature. After evaporation of DMF, the residue was treated with water. The resulting solid was collected by filtration, washed with water, and dried over phosphorus pentoxide *in vacuo* to afford **9** (4.10 g, 98%). Slow addition of ether in small portions to a solution of **9** in dichloromethane gave a white powder, mp 122.0—122.5°C. IR (KBr): 3220 (N–H), 3135 (N–H), 1738 (C=O), 1722 (C=O), 1715 (C=O), 1706 (C=O), 1700 (C=O), and 1696 (C=O) cm^{-1} (see Fig. 1). NMR ($CDCl_3$): τ 8.85 (t, 3H, J=7.0 Hz, CH_3), 6.50 (s, 8H, –S–CH_2–CO–), 5.93 (q, 2H, J=7.0 Hz, –O–**CH_2**–CH_3), and 2.42—3.40 (m, 16H, aromatic protons).

Found: C, 53.37; H, 4.68; N, 11.60; S, 15.18%. Calcd for $C_{37}H_{37}N_7O_8S_4$: C, 53.16; H, 4.46; N, 11.73; S, 15.31%.

Similarly, **7** was obtained in 97% yield by treatment of **6** with **4** and triethylamine in acetone at room temperature. Recrystallization from ethanol gave an analytically pure sample, mp 124.5—125.0°C. IR (KBr): 3405 (N–H), 3325 (N–H), 3225 (N–H), 3110 (N–H), 1736 (C=O), 1712 (C=O), and 1682 (C=O) cm^{-1} (see Fig. 1). NMR ($CDCl_3$): τ 8.87 (t, 3H, J=7.0 Hz, CH_3), 6.58 (d, 2H, J=9.0 Hz, –S–CH_2–CO–), 6.50 (d, 2H, J=10.0 Hz, –S–CH_2–CO), 5.97 (q, 2H, J=7.0 Hz, –O–**CH_2**–CH_3), and 2.42—3.40 (m, 8H, aromatic protons).

Found: C, 54.10; H, 4.94; N, 10.04; S, 15.12%. Cacld for $C_{19}H_{21}N_3O_4S_2$: C, 54.41; H, 5.05; N, 10.02; S, 15.26%.

Preparation of **11**. Oxalyl chloride (1.45 g, 0.012 mol) and **10** (2.56 g, 0.01 mol) were refluxed in 30 m*l* of acetonitrile for 1 hr. Vigorous evolution of hydrogen chloride and carbon monoxide was observed. After the reaction mixture had been concentrated *in vacuo* to dryness for complete removal of the excess of oxalyl chloride, the dark red residue was dissolved in 30 m*l* of acetonitrile. To this solution was added a solution of ethyl glycinate (1.03 g, 0.01 mol) in 10 m*l* of acetonitrile at room temperature with stirring. A slightly exothermic reaction soon took place. Stirring was continued for 30 min at room temperature. After evaporation of the solvent, the residue was treated with ether. The pale yellow crystals of **11** (2.65 g, 70%) were collected by filtration. Repeated recrystallization from DMF-ethanol gave analytically pure colorless plates, mp 323—325°C (dec.). IR (KBr): 3270 (N–H), 3125 (N–H), 1748 (C=O), 1724 (C=O), 1705 (C=O), 1692 (C=O), and 1675 (C=O) cm^{-1}.

Found: C, 47.35; H, 4.69; N. 14.70%. Calcd for $C_{15}H_{17}ClN_4O_6$: C, 46.78; H, 4.45; N, 14.56%.

Preparation of Carboxylic Esters and Phosphoric Esters by the Activation of Alcohols[1)]

Oyo MITSUNOBU and Masahiko EGUCHI

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

(Received May 29, 1971)

The reaction of dibenzyl hydrogen phosphate with alcohols in the presence of diethyl azodicarboxylate and triphenylphosphine, followed by catalytic hydrogenation, resulted in the formation of the corresponding alkyl dihydrogen phosphates. When *p*-tolyl dihydrogen phosphate and ethanol were allowed to react with diethyl azodicarboxylate and triphenylphosphine, ethyl *p*-tolyl hydrogen phosphate and diethyl *p*-tolyl phosphate were obtained. On the other hand, dipyridinium *p*-tolyl phosphate gave ethyl *p*-tolyl hydrogen phosphate and di-*p*-tolyl pyrophosphate. The reaction of alkyl *N,N'*-tetraethylphosphorodiamidites with carboxylic acids in the presence of diethyl azodicarboxylate resulted in the formation of corresponding carboxylic esters. When these reactions (benzoylation) were carried out with the use of optically active 2-octanol, 2-octyl benzoate was obtained with inverted configuration.

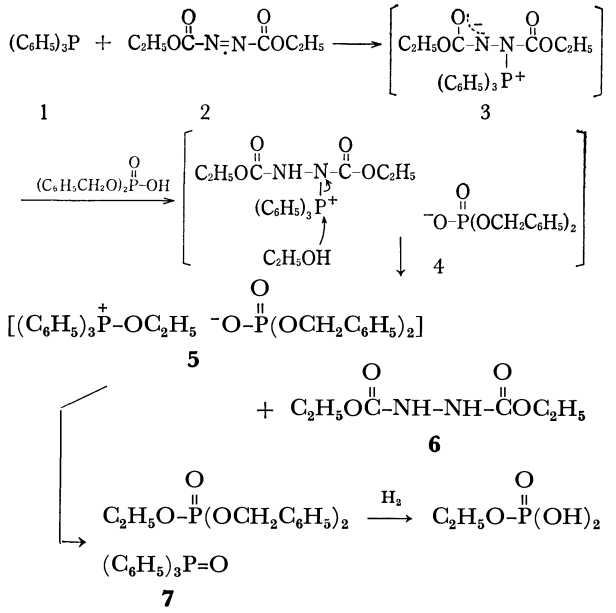
A number of phosphorylating systems have been devised with a view to preparing phosphate and pyrophosphate diesters by intermolecular dehydration between phosphate monoesters and either an alcohol or a phosphate monoester. In order to bring the phosphate into reaction with an alcohol, most systems employed initial activation of phosphate monoesters by organic dehydrating reagents such as dicyclohexylcarbodiimide,[2)] trichloroacetonitrile[3)] or ketene dimer.[4)] There are, however, few reports on phosphorylation of alcohols which involves initial activation of alcohols.[5-7)]

The present study was carried out with a view to producing esters of phosphoric acid and carboxylic acid *via* activation of alcohols.

Results and Discussion

Preparation of Esters of Phosphoric Acid. Recently, preparation of symmetrical pyrophosphate diesters by means of quinonedibenzimide and tri-*n*-butylphosphine has been reported.[8)] A successful method for the preparation of esters of carboxylic acid by means of triphenylphosphine (**1**) and diethyl azodicarboxylate (**2**) was reported.[9)] The reaction was applied to the phosphorylation of alcohols.

When dibenzyl hydrogen phosphate was treated with a small excess of ethanol in the presence of **1** and **2** at room temperature, followed by catalytic hydrogenation, ethyl dihydrogen phosphate was isolated as its anilinium salt in 92% yield. An exothermic reaction set in as soon as **1** was added to a solution of **2**, dibenzyl hydrogen phosphate and ethanol. It may be reasonable to assume that the reaction intermediate, a quaternary phosphonium salt (**3**),[10)] is protonated to give a second phosphonium salt (**4**). Since ethanol is a



more reactive nucleophile than phosphate anion, **4** primarily undergoes nucleophilic attack by the ethanol to give triphenyl ethoxy phosphonium salt (**5**) and diethyl hydrazodicarboxylate (**6**). The phosphonium salt decomposes into dibenzyl ethyl phosphate and triphenylphosphine oxide (**7**).

When *p*-tolyl dihydrogen phosphate was used in place of dibenzyl hydrogen phosphate in the above reaction, ethyl *p*-tolyl hydrogen phosphate was obtained in a 48% yield along with an undesirable side product, diethyl *p*-tolyl phosphate (23%). Twenty-four percent of *p*-tolyl dihydrogen phsophate was recovered unchanged. The results are summarized in Table 1.

The reaction of dipyridinium *p*-tolyl phsophate with ethanol in the presence of **1** and **2** resulted in the formation of ethyl *p*-tolyl hydrogen phosphate and di-*p*-

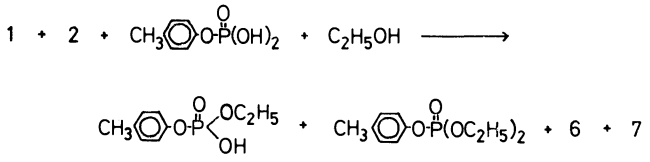
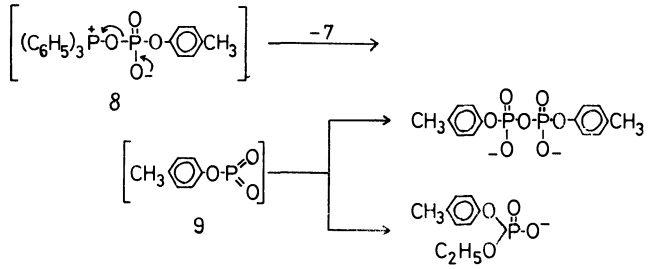
a) 23.1% of diethyl p-tolyl phosphate was isolated.



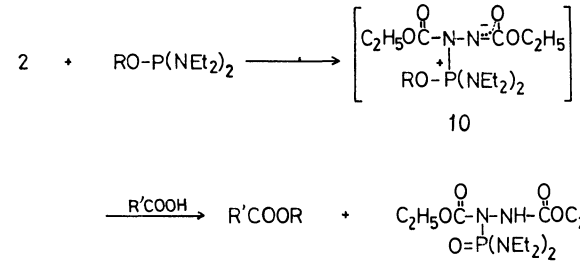
tolyl pyrophosphate as indicated by paper chromatography. Since metaphosphates are generally believed to be reactive intermediates for the phosphorylation of alcohols by means of phosphoric monoesters and dehydrating reagents,[11-14] the result might be explained as follows. The nucleophilic reactivity of the phosphate anion is enhanced by the presence of pyridine[4,15] and the formation of dipolar ion (**8**) takes place. The dipolar ion subsequently decomposed into metaphosphate (**9**) or the trimetaphosphate which gave the phosphate diester and the pyrophosphate diester.



Preparation of Esters of Carboxylic Acid. The above phosphorylation method could not be applied to the phosphorylation and acylation of 2′ and/or 3′-hydroxy groups of nucleosides.[16] Thus, alkyl N,N'-tetraethylphosphorodiamidites prepared from alcohols and N,N'-tetraethylphosphorodiamidous chloride were allowed to react with **2** and carboxylic acids.

When n-propyl N,N'-tetraethylphosphorodiamidite was treated with equimolar amounts of **2** and benzoic acid at room temperature for 3 hr, n-propyl benzoate and diethyl N-(bisdiethylaminophosphoryl) hydrazodicarboxylate were obtained in 78% and 62% yields, respectively. The fact that no rearranged product, isopropyl benzoate, could be detected by NMR spectra indicates the exclusion of a carbonium ion mechanism.

Similarly, various alkyl benzoate and alkyl caproate were obtained. The results are summarized in Table 2.



Steric Course of the Reactions. Dealkylation of alkoxyphosphonium salt is generally a simple bimolecular displacement at saturated carbon. Gerrard and Green[17] have shown that the phosphite derived from (+)-2-octanol reacts with ethyl iodide to give octyl iodide with inverted configuration.

In order to clarify the formation of alkoxyphosphonium salts (**5** and **10**) as intermediates in the present reactions, acylation of an optically active alcohol was attempted.

When S-(+)-2-octanol was allowed to react with **1**, **2**, and benzoic acid at room temperature, 2-octyl benzoate was obtained with a specific rotation of $[\alpha]_D$ −39.5°. The reaction of **2** and benzoic acid with R-(−)-2-octyl N,N'-tetraethylphosphorodiamidite derived from R-(−)-2-octanol resulted in the formation of 2-octyl benzoate with a specific rotation of $[\alpha]_D$+32.3°. As the 2-octyl benzoate prepared from S-(+)-2-octanol

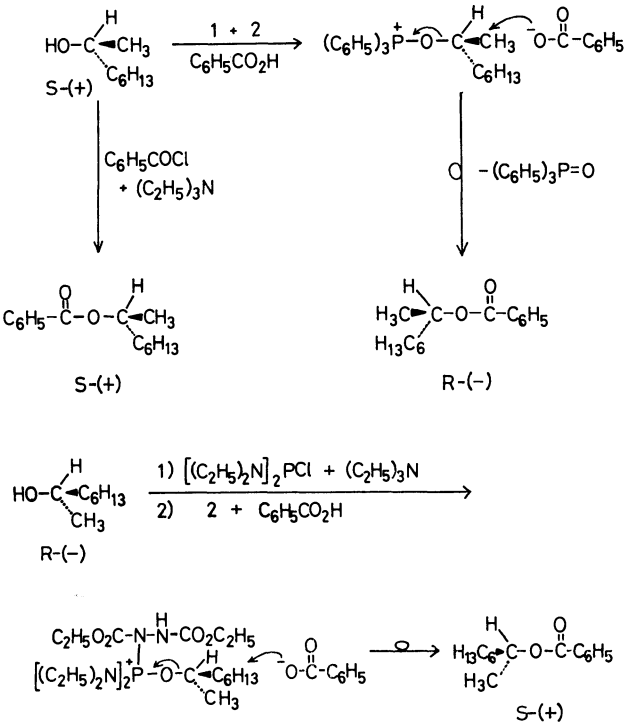
and benzoyl chloride showed a specific rotation of $[\alpha]_D$ +38.9°, the present reactions proceeded stereospecifically with inversion of configuration at the alkyl group.



The result can be best explained by assuming the formation of alkoxyphosphonium salts (**5** and **10**). Inversion of the cofiguration takes place on dealkylation. Thus it can be concluded that acylation of alcohols by the present methods involves initial acitvation of alcohols and not of carboxylic acids. Phosphorylation of alcohols may also proceed through an analogous activation process.

Experimental

The IR spectra were measured on a Nippon Bunko IR-G spectrophotometer. The NMR spectra were obtained on a Hitachi Perkin-Elmer R-20 high-resolution spectrometer at 60 MHz, using tetramethylsilane as an internal standard. Optical rotations were measured with JASCO ORD/UV-5.

Reagents. Diethyl azodicarboxylate,[18] dibenzyl hydrogen phosphate,[19] aryl dihydrogen phosphate,[4,20] and S-(+)- and R-(−)-2-octanols[21] were prepared by known procedures. Alkyl *N,N'*-tetraethylphosphorodiamidites were prepared from *N,N'*-tetraethylphosphorodiamidous chloride and alcohols. The alcohols, carboxylic acids, and solvents were purified by ordinary procedures.

Phosphorylation of Ethanol by Means of Dibenzyl Hydrogen Phosphate, Diethyl Azodicarboxylate and Triphenylphosphine. A solution of **1** (1.31 g; 0.005 mol) in 5 m*l* of tetrahydrofuran (THF) was added dropwise to a solution of **2** (0.87 g; 0.005 mol), dibenzyl hydrogen phosphate (1.39 g; 0.005 mol) and ethanol (0.5 m*l*) in 10 m*l* of THF at room temperature under stirring. After the solution was kept standing over night at room temperature, the solvent was removed under reduced pressure. Ethanol (5 m*l*) was added to the residue and undissolved precipitate (mp 128—134°C; 0.42 g) was removed by filtration. Ethanol-water (1: 1; 30 m*l*) was added to the filtrate and the solution was hydrogenated over Pd-C (500 mg) at room temperature and atmospheric pressure. After absorption of hydrogen ceased, the catalyst was filtered off and the solvent was removed under reduced pressure. Water (5 m*l*) and aniline (0.47 g) were added to the residue and undissolved white precipitate, a mixture of **6** and **7** (mp 125—149°C; 1.63 g), was removed by filtration and washed with water. The filtrate and washings were evaporated to dryness to give anilinium ethyl hydrogen phosphate (1.01 g; 91.7%; mp 130—156°C). An analytical sample was obtained by recrystallization from acetonitrile containing a few drops of water, mp 168—170°C. Found: C, 43.88; H, 6.58; N, 6.80. Calcd for $C_8H_{14}NO_4P$: C, 43.83; H, 6.45; N, 6.39.

Phosphorylation of Ethanol by Means of p-*Tolyl Dihydrogen Phosphate, Diethyl Azodicarboxylate, and Triphenylphosphine.* A solution of **1** (10.48 g; 0.04 mol) in 30 m*l* of THF was added dropwise to a solution of **2** (6.96 g; 0.04 mol), *p*-tolyl dihydrogen phosphate (7.52 g; 0.04 mol) and ethanol (5 m*l*) in 50 m*l* of THF at room temperature under stirring. After the solution was kept standing overnight at room temperature, aniline (3.72 g) was added. Paper chromatogram of the reaction mixture showed the existence of a trace of di-*p*-toly pyrophosphate which could not be isolated. Precipitated anilinium *p*-tolyl hydrogen phosphate (2.34 g; 20.8% recovered, mp 176—182°C) was filtered off and the solvent was removed under reduced pressure. Benzene (30 m*l*) was added to the residue and heated to dissolve it. After cooling the solution in a refrigerator, **6** (5.66 g, 80.4%; mp 134—137°C; a mixed melting point with an authentic sample was not depressed) was removed by filtration and the filtrate was concentrated under reduced pressure. The residue was taken up in 20 m*l* of ether and the undissolved precipitate was removed by filtration. The filtrate was washed with water (10 m*l*×5), dried (Na_2SO_4) and distilled to give diethyl *p*-tolyl phosphate (bp 97—100°C at 0.1—0.2 mmHg; 2.26 g; 23.1%; redistillation gave bp 92—95°C at 0.1 mmHg). The diethyl *p*-tolyl phosphate was shown to be identical with the authentic sample by comparison of the infrared spectra (IR (liquid) 1167 (P–OEt), 1280 cm^{-1} (P=O)). From the residue of the fractionation, **7** (mp 145—154°C, after recrystallization from CCl_4) was obtained. The white crystalline compound undissolved in the ether in the above procedure was washed with warm water (100 m*l*) giving **7** (mp 153—156°C; 9.78 g; 88.0%). The washings were evaporated to dryness to give anilinium ethyl *p*-tolyl phosphate (mp 95—120°C; 6.31 g), which was washed with ether and recrystallized from ethyl acetate, mp 103—105°C. A small amount of anilinium *p*-tolyl hydrogen phosphate (0.42 g; 3.7%, mp 175—182°C) was removed by this procedure because it was not soluble in hot ethyl acetate. The yield of the anilinium ethyl *p*-tolyl phosphate was 47.7%.

Found: C, 57.84; H, 6.52; N, 4.89. Calcd for $C_{15}H_{20}NO_4P$: C, 58.24; H, 6.53; N, 4.53.

Ethyl phenyl, phenyl *n*-propyl, and *p*-tolyl *n*-propyl hydrogen phosphates were prepared in an analogous way. They are summarized in Table 1. The corresponding dialkyl aryl phosphates were not isolated.

Reaction of ethyl N,N'-*tetraethylphosphorodiamidite with* n-*caproic acid and diethyl azodicarboxylate.* A solution of ethyl *N, N'*-tetraethylphosphorodiamidite (2.20 g, 0.01 mol) in 15 m*l* of THF was added dropwise to **2** (1.74 g, 0.01 mol) and *n*-

a) R-(−) b) S-(+)

caproic acid (1.16 g, 0.01 mol) in 30 m*l* of THF at room temperature. The solution was stirred for 3 hr and concentrated to a sirup. After the sirup was kept standing in a refrigerator overnight, diethyl *N*-(bisdiethylaminophosphoryl)-hydrazodicarboxylate was obtained by filtration: 1.86 g, 50.8%, mp 102—104°C. An analytical sample was obtained by recrystallization from petroleum ether, mp 112—114°C.

Found: C, 45.96; H, 8.39%. Calcd for $C_{14}H_{31}N_4O_5P$: C, 45.89; H, 8.53%. IR(KBr) cm^{-1}: 3170(N–H), 1760, 1730(C=O), 1240(P=O).

The filtrate was distilled to give ethyl caproate, 54.5%, bp 58—59°C/15 mmHg.

Reaction of Ethyl N,N'-*Tetraethylphosphorodiamidite with Benzoic Acid and Diethyl Azodicarboxylate.* A solution of ethyl *N,N'*-tetraethylphosphorodiamidite (2.20 g, 0.01 mol) in 10 m*l* of THF was added dropwise to **2** (1.74 g, 0.01 mol) and benzoic acid (1.22 g, 0.01 mol) in 20 m*l* of THF at room temperature and stirred for 3 hr followed by concentration. After the residue was kept standing overnight in a refrigerator, ethyl benzoate (1.36 g, 90.7%, bp 95—97°C/17 mmHg) and diethyl *N*-(bisdiethylaminophosphoryl)hydrazodicarboxylate (2.29 g, 62.6%, bp 140—142°C/0.25 mmHg) were obtained by distillation.

Similarly, various alkyl benzoates were prepared in good yields as summarized in Table 2. Satisfactory NMR and IR data were obtained for all these esters.

Preparation of R-(−)-2-Octyl N,N'-*Tetraethylphosphorodiamidite.* R-(−)-2-octanol (8.97 g, 0.069 mol) and triethylamine (6.97g, 0.069 mol) in 150 m*l* of benzene were added dropwise to an ice cooled solution of *N,N'*-tetraethylphosphorodiamidous chloride (14.53 g, 0.069 mol) in 150 m*l* of benzene and the mixture was stirred for additional 7 hr. After the mixture was kept standing 2 days, water was added and the benzene layer was separated. The aqueous phase was extracted with benzene. The organic layer was dried by sodium sulfate. The benzene was removed and the residue was distilled to give a 77.5% yield of R-(−)-2-octyl *N,N'*-tetraethylphosphorodiamidite (bp 112—133°C/2 mmHg) which upon redistillation had bp 125—132°C/2 mmHg, $[\alpha]_D-15.0°$ (60.6 mg/cc in ethanol).

Reaction of R-(−)-2-Octyl N,N'-*tetraethylphosphorodiamidite with Benzoic Acid and Diethyl Azodicarboxylate.* A solution of R-(−)-2-octyl *N,N'*-tetraethylphosphorodiamidite (3.05 g, 0.01 mol) in 15 m*l* of THF was added dropwise to a solution of benzoic acid (1.22 g, 0.01 mol) and **2** (1.74 g, 0.01 mol) in 30 m*l* of THF at room temperature. After stirring for 3 hr, the solvent was removed and the residue was kept standing overnight in a refrigerator. A white crystalline compound was collected by filtration and washed with petroleum ether giving diethyl *N*-(bisdiethylaminophosphoryl)hydrazodicarboxylate (2.16 g, 59.0%, mp 110—113°C). The filtrate was distilled to afford S-(+)-2-octyl benzoate (54.1%, bp 96—113°C/0.35 mmHg) which upon redistillation had bp 98—100°C/0.35 mmHg, $[\alpha]_D+33.4°$ (62.0 mg/cc in ethanol).

Reaction of S-(+)-2-Octanol with Benzoic Acid, Diethyl Azodicarboxylate, and Triphenylphosphine. Diethyl azodicarboxylate (0.871 g, 0.005 mol) in 5 m*l* of THF was added dropwise to a solution of **1** (1.31 g, 0.005 mol), S-(+)-2-octanol (0.652 g, 0.005 mol) and benzoic acid (0.611 g, 0.005 mol) in 5 m*l* of THF at room temperature. After the solution was kept standing overnight, the slovent was removed. Ether (5 m*l*) was added to the residue and undissolved white crystalline compound was filtered off. The filtrate was distilled to give a 20.2% yield of 2-octyl benzoate with $[\alpha]_D-39.5°$ (0.032 mol/*l* in THF); bp 114°C/1.5 mmHg.

Preparation of S-(+)-2-Octyl Benzoate. Benzoyl chloride (35.1 mg, 0.0025 mol) in benzene (2 m*l*) was added dropwise to a solution of S-(+)-2-octanol (32.5 mg, 0.0025 mol) and triethylamine (25.2 mg, 0.0025 mol) in benzene (2 m*l*) at room temperature. After removal of triethylammonium chloride by filtration, the residue was distilled to give S-(+)-2-octyl benzoate (380 mg, 65%, bp 97—100°C/0.4 mmHg). Redistillation gave a pure sample, bp 98°C/1 mmHg, $[\alpha]_D+38.9°$ (0.081 mol/*l* in THF).

The authors wish to express their appreciation to Professor Tatsuya Samejima and staff for performing the optical rotation measurements. They also thank Miss Naoko Ikeda for her assistance in a part of the experiments.

Synthesis and the Iodine-Catalyzed Rearrangement of Isohibaene

Masayuki KITADANI, Ken ITO, and Akira YOSHIKOSHI*

College of General Education, Kobe University, Nada-ku, Kobe

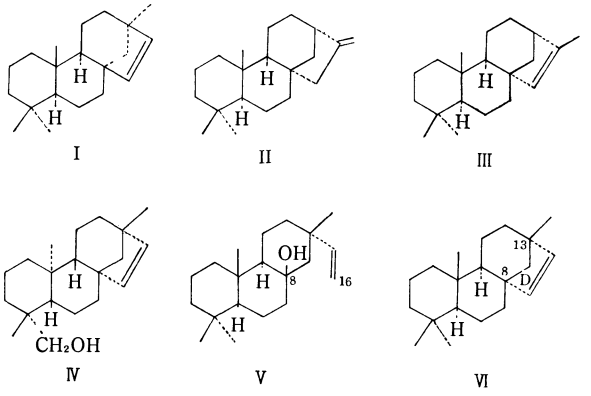
**Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai*

(Received June 3, 1971)

A partial synthesis of isohibaene (VI) starting with nezukol (V) has been accomplished. It involves, as the key step, the intramolecular insertion reaction of a ketocarbene generated by cuprous oxide-catalyzed decomposition of diazoketone (XI) under irradiation. It has been found that isohibaene undergoes rearrangement into a mixture of phyllocladene (XIV) and isophyllocladene (XV) by iodine catalytically.

In a previous paper[1] we (A. Y. and M. K.) reported on iodine-catalyzed skeletal rearrangement equilibrating among (−)-hibaene (I), (+)-kaurene (II), and (+)-isokaurene (III), in which we found hibaene as the most predominant component. The rearrangement was also utilized for the total synthesis of (±)-monogynol[2] (IV).

This paper deals with the transformation of nezukol[3] (V) into isohibaene[4] (VI) and the iodine-catalyzed rearrangement of the latter compound, which is a stereoisomer of hibaene concerning the C_8 and C_{13} positions.



Results and Discussion

A. Synthesis of Isohibaene (VI). For the construction of the five-membered ring (ring D) of isohibaene by forming a bond between C_8 and C_{16} of isopimarane framework (formula V), a copper-catalyzed intramolecular insertion toward a C–H bond[5] as depicted by the step XI→XIIa was seen as a promising process (Scheme 1).

Ozonization of V followed by the reduction of the resulting ozonide with sodium iodide produced hydroxyaldehyde VII along with hydroxy-acid VIII. The former was oxidized with potassium permanganate to obtain VIII. More conveniently, V could be directly oxidized to acid VIII by potassium permanganate in warm acetone. This process gave a better yield. Attempted dehydration of VIII to an unsaturated acid with various dehydrating agents (*e.g.*, thionyl chloride, phosphorus oxychloride, or iodine) resulted in the formation of a complex mixture of products. When VIII was heated in methanol containing a catalytic amount of mineral acid, the acid-catalyzed esterification caused simultaneous dehydration which produced a mixture of the unsaturated esters IXa, IXb, and IXc in the ratio 7 : 2 : 1 (determined by glc). These unsaturated esters were separated by recrystallization and preparative glc, and their structures were assigned as follows. The crystalline ester IXa, the major product, showed no olefinic proton signals in the NMR spectrum and no absorption due to C=C in the IR spectrum. Provided no skeletal rearrangement occurs during the reaction, the double bond of IXa might be located on $\Delta^{8(9)}$. The oily ester IXb, formed in a ratio of 20%, showed a broad olefinic one-proton singlet and absorptions due to a trisubstituted double bond in the NMR and IR spectra, respectively. Hence the structure IXb was

4) For an alternate synthesis of this compound, see E. Wenkert, P. W. Jeffs, and J. R. Mahajan, *J. Amer. Chem. Soc.*, **86**, 2218 (1964).

5) E. Wenkert, B. L. Mylari, and L. L. Davis, *ibid.*, **90**, 3870 (1968).

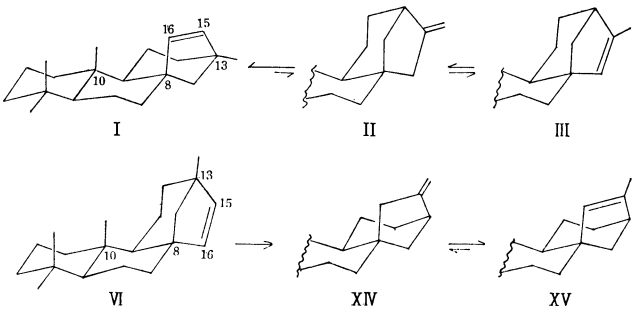
assignable as the ester. The NMR spectrum of the third ester exhibited a narrow olefinic one-proton singlet, and absorptions due to a trisubstituted double bond were shown in the IR spectrum. Thus, the structure IXc is likely to fit the last ester. The unsaturated ester IXa was hydrogenated in acetic acid over platinum under pressure, and the saturated ester Xa was obtained in 90% yield. Conclusive evidence was not available for the stereochemistry of the saturated ester at this stage. However, the fact that the final product of this synthesis was isohibaene (VI) indicated that the saturated ester had a *trans-anti-cis* stereochemistry. For the preparation of Xa, a mixture of the unsaturated esters IXa—c was similarly hydrogenated and gave a better yield of Xa.

The ester Xa, resistant to alkaline hydrolysis under standard conditions, was heated with potassium hydroxide in boiling ethylene glycol to obtain acid Xb. Treatment of Xb with thionyl chloride gave an acyl chloride, and the latter, without purification, was then converted into a diazoketone by the reaction with diazomethane. The IR spectrum of the product showed strong absorptions due to a diazoketo group at 2140 and 1620 cm^{-1}, and a sharp singlet due to the methine proton located between a carbonyl and a diazo group were observed at δ 5.5 in the NMR spectrum. These spectra supported the view that the product was the desired diazoketone XI.

The intramolecular ketocarbene insertion reaction was effected by addition of the diazoketone XI to boiling cyclohexane in which finely powdered cuprous oxide was suspended, while the reaction mixture was irradiated with a tungsten lamp. A ketone, whose carbonyl group showed absorption at 1740 cm^{-1} in IR was obtained almost quantitatively. In XI, two C–H bonds, *i.e.*, C_8–H and C_{11}–H (axial), toward which the generated ketocarbene may intramolecularly be inserted to form five-membered ketone, were available. Participation of the former bond should lead to the formation of the desired ketone XIIa. The ketone was submitted to the Wolff-Kishner reduction under forced conditions, and the spectra of the resulting hydrocarbon were compared with those of an authentic specimen of isohibane[6] (XIIb). The results including the identity of optical rotation confirmed the hydrocarbon as isohibane. The melting point remained undepressed on admixture with the authentic sample. This demonstrates that the intramolecular ketocarbene insertion toward the *tert.* C–H (C_8–H) bond predominated the attack toward the *sec.* C–H bond (C_{11}-axial H), as has been generally observed in insertion reactions with other carbenes.[7]

Tosylhydrazone XIIc of the ketone was treated with excess methyl lithium to obtain isohibaene (VI), which was identified by comparison of its IR and NMR spectra with those of an authentic specimen. On the other hand, sodium borohydride reduction of ketone XIIa gave alcohol XIIIa, whose hydroxyl group was tentatively assigned to *endo*. Tosylate XIIIb or mesylate XIIIc of the alcohol was heated in collidine affording a mixture of isohibaene (VI), phyllocladene (XIV), and isophyllocladene (XV). XIV and XV were identified by comparison with authentic specimens.

B. Iodine-catalyzed Rearrangement of Isohibaene (VI). Heating isohibaene (VI), phyllocladene (XIV), or isophyllocladene (XV) with a catalytic amount of iodine in boiling xylene caused isomerization of the olefin, and each olefin finally gave a mixture of XIV and XV. In contrast to the rapid isomerization between XIV and XV,[8] isohibaene (VI) rearranged slowly and was exhausted after *ca.* 24 hr. The results on the hibaene-kaurene-isokaurene system[1] and those just mentioned concerning the isohibaene-phyllocladene-isophyllocladene system indicate that the ring system in which the C_8–C_{16} bond is *cis* with regard to the C_{10}-methyl group is thermodynamically most favorable, *viz.*, in equilibrium, hibaene (I) and isophyllocladene (XV) are most stable in respective series (Scheme 2).



Scheme 2

Experimental

Melting points were uncorrected. IR and UV spectra were run on JASCO Model IR-E and Hitachi Model 124 spectrophotometers, respectively. NMR spectra with carbon tetrachloride as solvent (unless otherwise stated) and tetramethylsilane (δ=0 ppm) as internal standard were taken on a JEOL JNMC-60HL spectrometer, and coupling constants were given in Hz. Mass spectra were obtained by using a Hitachi RMU-6D spectrometer.

Ozonization of Nezukol (V). Excess ozonized air was passed through a solution of nezukol (8.5 g) in ethyl acetate (65 m*l*) at −75°C, and the ozonized solution was treated with sodium iodide (25.5 g) dissolved in acetic acid (85 m*l*). The mixture was allowed to stand overnight at room temperature. Liberated iodine was reduced by the addition of 3% aq. solution of sodium thiosulfate. The resulting solution was concentrated in a vacuum in a bath maintained below 50°C, and the residue was diluted with water. The product was extracted with ether, and the combined extracts were washed with aq. sodium carbonate solution, then with water, and dried over anhydrous magnesium sulfate. Evaporation of the ether left 5.6 g of a semisolid residue, which was recrystallized from ethanol - ether (5:1); 4.85 g (57%) of the hydroxy-aldehyde VII, mp 148—150°C, was obtained as colorless prisms. IR (KBr): 3550, 2725, 1725 cm^{-1}. NMR ($CDCl_3$): 7.33 (1H, s., CHO). M^+=292.

Found: C, 77.90; H, 10.71%. Calcd for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03%.

6) W. Herz, D. Melchior, R. N. Mirrington, and P. J. S. Pauwels, *J. Org. Chem.*, **30**, 1873 (1965).

7) W. Kirmse, "Carbene Chemistry," Academic Press, New York (1964).

8) The iodine-catalyzed isomerization of phyllocladene into isophyllocladene has been reported. L. H. Briggs, B. F. Cain, R. C. Cambie, and B. R. Davis, *J. Chem. Soc.*, **1962**, 1840.

The above sodium carbonate extracts were acidified with mineral acid, and liberated carboxylic acid was extracted with ether. From the extracts, 680 mg (7.6%) of the hydroxy-acid VIII, mp 187—189°C, was obtained as colorless leaflets. IR (KBr): 3560, ~2400, 1678 cm^{-1}.

Found: C, 73.98; H, 10.46%. Calcd for $C_{19}H_{32}O_3$: C, 74.02; H, 10.13%.

Permanganate Oxidation of the Hydroxy-aldehyde VII. To an acetone solution of the hydroxy-aldehyde VII (500 mg) was added potassium permanganate (250 mg) dissolved in water (5 m*l*) over a period of 30 min in an ice-bath. Stirring was continued for an additional 1 hr, and sulfur dioxide was passed through the solution to reduce precipitated manganese dioxide. The resulting solution was filtered and the filtrate was concentrated in a vacuum. The residue was diluted with water and extracted with ether. The extracts were combined, washed with water, and dried. Evaporation of the ether left crystals (500 mg), which were recrystallized from ether - *n*-hexane (1:5) giving hydroxy-acid VIII (498 mg; 94%) metling at 189—190°C.

Permanganate Oxidation of Nezukol (V). Powdered potassium permanganate (11 g) was added portionwise to a stirred solution of nezukol (5.0 g) in acetone (130 m*l*). The temperature of the solution rose gradually. Stirring was continued for an additional 13 hr while the temperature was maintained at 50°C. The reaction mixture was allowed to stand overnight at room temperature. Working up as described above for permanganate oxidation of hydroxy-aldehyde VII gave hydroxy-acid VIII (4.7 g; 90%) melting at 189—190°C.

Unsaturated Esters IXa—c. A suspension of hydroxy-acid VIII (1 g) in dry methanol (15 m*l*) containing concd. sulfuric acid (0.5 m*l*) was refluxed for 30 min. The reaction mixture was poured into water and extracted with ether. The combined extracts were washed with aq. sodium carbonate solution, then with water, and dried. Evaporation of the ether gave a semisolid residue (890 mg), whose glc (20% PEG-20M column) showed three peaks in the ratio of 7:1:2 in elution sequence. Most of the major product IXa, mp 90—91°C, was separated from the residue by recrystallization with methanol as colorless leaflets. IR (KBr): 1720, 1189 cm^{-1}. NMR ($CDCl_3$): 3.64 (3H, s.).

Found: C, 78.94; H, 10.74%. Calcd for $C_{20}H_{32}O_2$: C, 78.89; H, 10.57%.

From the filtrate of the recrystallization, two minor esters were separated by preparative glc (20% PEG-20M column; ϕ, 3 mm×2 m; column temperature, 225°C; hydrogen flow, 30 m*l*/min).

Ester IXb, an oil, corresponded to the last peak in glc. IR (liquid): 1663, 857, 835 cm^{-1}. NMR: 3.63 (3H, s.), 5.38 (1H, br. s., $W_{1/2}=10.5$).

Found: C, 78.65; H, 10.83%. Calcd for $C_{20}H_{32}O_2$: C, 78.89; H, 10.57%.

Another ester IXc was also oily. IR (liquid): 1730, 856, 836 cm^{-1}. NMR: 3.64 (3H, s.), 5.50 (1H, s., $W_{1/2}=4.5$).

Found: C, 78.46; H, 10.89%. Calcd for $C_{20}H_{32}O_2$: C, 78.89; H, 10.57%.

Hydrogenation of the Unsaturated Ester IXa. Freshly prepared Adams' catalyst (1.48 g) suspended in acetic acid (100 m*l*) was activated by treatment with hydrogen in an autoclave. A solution of ester IXa (1.5 g) in acetic acid (100 m*l*) was added to the above suspension, and the mixture was shaken with hydrogen under 50 atm at 30°C for 24 hr. After the catalyst was separated, the solution was concentrated in a vacuum. The residue was dissolved in ether. The solution was washed with aq. sodium carbonate solution and then with water. Evaporation of the organic layer gave a crystalline residue (1.45 g) melting at 85—88°C, whose glc showed two peaks in the ratio of 19:1. Recrystallization of the crude crystals from the methanol solution afforded 1.35 g (90%) of the saturated ester Xa, mp 94—96°C. IR (KBr): 1723 cm^{-1}. NMR: 3.62 (3H, s.).

Found: C, 78.36; H, 10.92%. Calcd for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18%.

A mixture of the unsaturated esters IXa—c provided the saturated ester Xa in 98% yield in a similar manner.

Hydrolysis of the Saturated Ester Xa. A solution of ester Xa (810 mg) and potassium hydroxide (6.4 g) in freshly distilled ethylene glycol (100 m*l*) was refluxed for 30 min. The solution was concentrated to a half volume by distillation, and then cooled down to room temperature. Water (50 m*l*) was added, and carboxylic acid Xb was extracted with chloroform. The crude carboxylic acid (770 mg) was recrystallized from ether - *n*-hexane (4:1) affording 750 mg (97.5%) of colorless prisms, mp 228—230°C. IR (KBr): ~2400, 1695 cm^{-1}.

Found: C, 78.10; H, 10.61%. Calcd for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03%.

Diazoketone XI. A solution of acid Xb (1.012 g), thionyl chloride (20 m*l*), and pyridine (5 drops) in dry ether (45 m*l*) was allowed to stand at room temperature for 24 hr. The solvent and the excess reagent were distilled off in a vacuum, and the residue was redissolved in dry ether (20 m*l*). Excess ethereal diazomethane was added into the above solution over a period of 40 min, and the solution was stirred for 2 hr. After standing overnight the solvent was eliminated. The residue was dissolved in a small volume of ether, and the solution was filtered to remove insoluble substances. The filtrate was allowed to stand at room temperature giving 650 mg of pale yellow crystals, mp 118—121°C. The crystals were collected by filtration, and the filtrate was chromatographed on a silica gel column. An additional amount of diazoketone (400 mg), mp 119—122°C, was obtained by eluting with ether - *n*-hexane (1:4). The combined crystals were recrystallized from petroleum ether to give diazoketone XI (980 mg; 90%) as glossy pale yellow leaflets, mp 122—123°C. UV (cyclohexane): 251 nm (log ε 3.75). IR (KBr): 3150, 2140, 1620 cm^{-1}. NMR ($CDCl_3$): 5.5 (1H, s., $COCHN_2$).

Found: C, 76.23; H, 10.14; N, 8.87%. Calcd for $C_{20}H_{32}ON_2$: C, 76.01; H, 10.21; N, 8.87%.

Ketone XIIa. To a stirred boiling suspension[9] of finely powdered cuprous oxide (5 g) in dry cyclohexane (150 m*l*) was added dropwise a hot solution of diazoketone (2.71 g) in dry cyclohexane (100 m*l*) over a period of 1.5 hr. Stirring was continued overnight at the same temperature. The catalyst was filtered off. Evaporation of cyclohexane left crystals (2.48 g). Recrystallization from *n*-hexane provided ketone XIIa (2.35 g; 95%), mp 145—146°C, as colorless long needles. IR (KBr): 1740 cm^{-1}.

Found: C, 83.65; H, 11.21%. Calcd for $C_{20}H_{32}O$: C, 83.40; H, 11.16%.

An experiment carried out without irradiation gave ketone in a lower yield.

Isohibane (XIIb). Sodium (60 mg) was dissolved in freshly distilled ethylene glycol (3 m*l*); ketone XIIa (280 mg) and anhydrous hydrazine (100 mg) were added to the above solution. The solution was refluxed for 2 days. Water was added, and the product was extracted with ether. The ether layer was washed with water and dried. Crystals (210 mg) obtained by evaporating the ether were chromatographed on an alumina column using petroleum ether - ether (9:1) as an eluting solvent giving isohibane (XIIb). Recrystallization

9) A 375 W tungsten lamp (National) was used for heating.

from *n*-hexane gave colorless needles melting at 76—77.5°C (lit,[6] 65—67°C). $[\alpha]_D$+63.4°C (*c* 0.83, methanol) (lit,[6] $[\alpha]_D$+56°).

Found: C, 87.38; H, 12.65%. Calcd for $C_{20}H_{34}$: C, 87.51; H, 12.49%.

The IR and NMR spectra of the hydrocarbon were identical with those of an authentic specimen.

Tosylhydrazone XIIc. A solution of ketone XIIa (72 mg) and *p*-tosylhydrazine (65 mg) in ethanol (3 m*l*) was refluxed for 1 hr. Water was added, and the product was extracted with ether and dried. A crystalline residue obtained by evaporation of the solvent was chromatographed on an alumina column, and tosylhydrazone (104 mg) was eluted with methanol - ether (1:20). Recrystallization from methanol - ether (5:1) gave crystals (100 mg; 90%) melting at 206—208°C. UV (methanol): 205 (log ε 3.99), 228 (log ε 3.93), 275 (sh.) nm. NMR ($CDCl_3$). 2.44 (3H, s.), 7.30, 7.88 (2H, d., J=8 each, an AB-type).

Isohibaene (VI). A large excess of methyllithium, prepared from methyl iodide and lithium in dry ether, was added to a suspension of tosylhydrazone XIIc (77.3 mg) in dry ether in an ice bath. The suspension changed into a clear solution after 30 min. Stirring was continued for an additional 2 hr at room temperature. The resulting solution was poured on crushed ice and extracted with ether. The ether extracts were dried over anhydrous magnesium sulfate. The semisolid residue obtained by evaporating the ether was recrystallized from methanol. 40 mg (87%) of isohibaene, mp 83—84°C (lit,[5] mp 73—75°C), was obtained. In spite of the fact that the specific rotation observed for our sample, $[\alpha]_D^{25}$+93° (*c* 0.375, methanol) differs from the value reported for isohibaene ($[\alpha]_D$+8°),[5] the IR and NMR spectra of our sample were identical with those of an authentic specimen. IR (KBr): 751, 740 cm^{-1}. NMR: 0.85, 0.88 (3H, s. each), 1.01 (6H, s.), 5.36, 5.51 (1H, d., J=6 each; an AB-type). M^+=272.

Found: C, 88.25; H, 12.10%. Calcd for $C_{20}H_{32}$: C, 88.16; H, 11.84%.

Alcohol XIIIa. Ketone XIIa (628 mg) was dissolved in a 1:1 mixture (20 m*l*) of dry methanol and dry ether, and sodium borohydride (110 mg) was added into the stirred solution in an ice bath. After stirring for 5 hr at the same temperature, the reaction mixture was poured into ice water and extracted with ether. The ether layer was washed with 1N hydrochloric acid, then with water and dried. Ether was evaporated to leave crystals (630 mg), which were recrystallized from methanol to give alcohol XIIIa (625 mg; 96%), mp 130—131°C. IR (KBr): 3490 cm^{-1}. NMR: 3.82 (1H, q., J=10.2 and 5).

Found: C, 82.58; H, 11.80%. Calcd for $C_{20}H_{34}O$: C, 82.69; H, 11.80%.

Tosylate XIIIb. A solution of alcohol XIIIa (1 g) and *p*-toluenesulfonyl chloride (2 g) in dry pyridine (20 m*l*) was allowed to stand for 3 days at room temperature. The reaction mixture was poured into ice-cooled 0.5N hydrochloric acid and extracted with ether. The organic layer was washed with saturated sodium bicarbonate solution, then with water and dried. Evaporation of the solvent left a crystalline residue (1.5 g), which was poured into an alumina column. Elution with ether-petroleum ether (1:5) gave tosylate XIIIb. A pure sample was obtained from petroleum ether by recrystallization as colorless plates (1.35 g; 88%), mp 134—135°C. UV (methanol): 226 (log ε 3.85), 262 (log ε 2.42), 273 (log ε 2.38)nm. IR (KBr): 1598, 1496, 1362, 1188, 1167 cm^{-1}. NMR ($CDCl_3$): 2.46 (3H, s.), 4.42 (1H, q., J=10 and 5), 7.4, 7.9 (2H, d., J=9 each, an AB-type).

Found: C, 73.23; H, 9.30%. Calcd for $C_{27}H_{40}O_3S$: C, 72.94; H, 9.07%.

Mesylate XIIIc. From alcohol XIIIa (450 mg) and mesyl chloride (460 mg), mesylate was obtained in 85% yield in the same manner as for tosylate. After recrystallization from chloroform - petroleum ether (1:5) a pure sample melted at 139—141°C. IR (KBr): 1355, 1180, 1170 cm^{-1}. NMR ($CDCl_3$): 3.0 (3H, s.), 4.61 (1H, q., J=10 and 4.8).

Found: C, 68.75; H, 9.85%. Calcd for $C_{21}H_{36}O_3S$: C, 68.44; H, 9.85%.

Solvolysis of Sulfonates XIIIb and XIIIc. A soultion of tosylate XIIIb (800 mg) and freshly distilled collidine (30 m*l*) was refluxed for 40 hr and then concentrated by distillation. The residue was poured into 1N hydrochloric acid and extracted with ether. The organic layer was washed with saturated sodium bicarbonate solution, then with water and dried. Evaporation of the solvent afforded an oily residue which crystallized on standing. Glc analysis (20% PEG-20M column; φ, 3 mm×2 m; column temperature, 200°C; hydrogen flow, 8.3 m*l*/min) showed three peaks (1.4: 1.2: 1.0 in ratio) at the retention times of 4.0, 4.3, and 5.2 min. The reaction mixture was chromatographed on a 10% silver nitrate-impregnated silica gel column to separate each product. Petroleum ether - ether (9:1) eluted isohibaene (VI), mp 82—83°C (153 mg; 40%), (+)-isophyllocladene (XV; 130 mg; 33%), mp 109—111.5°C, $[\alpha]_D^{25}$+25.6° (lit,[10] mp 111—112°C, $[\alpha]_D$+23°) and (+)-phyllocladene (XIV; 110 mg; 28%), mp 94—96°C, $[\alpha]_D^{25}$+19.3° (lit,[11] mp 98°C, $[\alpha]_D$+16°) in order. Under the same conditions as described above, the retention times of isohibaene, isophyllocladene, and phyllocladene in glc were 4.0, 4.3, and 5.2 min., respectively. Each olefin was identified by comparison of its IR and NMR spectra with those of an authentic specimen.

A result in line with ours was obtained for the solvolysis of mesylate XIIIc.

Iodine-catalyzed Isomerization of Isohibaene, Phyllocladene, and Isophyllocladene. Each olefin was dissolved in dry xylene, and a piece of iodine was added. The solution was refluxed in an oil bath, while monitoring the reaction by 10% silver nitrate-impregnated silica gel tlc using *n*-hexane - ether - benzene (20: 1: 1) as an eluting solvent. Equilibrium between phyllocladene and isophyllocladene was attained in the predominant formation of the latter after about 2 hr, while isohibaene slowly rearranged into a mixture of phyllocladene and isophyllocladene under the same conditions and was exhausted after about 24 hr.

The reaction mixture of each run was vigorously shaken with mercury and then passed through a short alumina column to removed colored materials. The eluate was rechromatographed on a 10% silver nitrate-impregnated silica gel column affording phyllocladene and isophyllocladene in an approximate ratio of 1:3. These isomerization products were identified by their spectra and melting points on admixture with authentic specimens.

The authors would like to thank Professors Ernest Wenkert and Werner Herz for the identification of isohibaene and isohibane, respectively.

Studies of Hydroxy Amino Acids. II.[1] The Separation of Diastereoisomers of Hydroxy Amino Acids

Yasuo ARIYOSHI and Naotake SATO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa

(Received June 9, 1971)

It has been found that *erythro*-β-hydroxy-DL-norvaline, *erythro*-β-hydroxy-DL-norleucine, and *threo*-β-hydroxy-DL-leucine form scarcely-soluble compounds in water with α-naphthylphosphoric acid, tetrachlorophthalic acid, and chlorendic acid, respectively. On the other hand, the compounds of their diastereoisomers with the reagents were soluble in water. On the basis of these facts, β-hydroxy-DL-norvaline, β-hydroxy-DL-norleucine, and β-hydroxy-DL-leucine were successfully separated into their diastereoisomers. The configurational assignment of α-amino-β-hydroxy acids without a branched side chain on the γ-carbon atom was established by means of NMR spectroscopy.

α-Amino-β-hydroxy acids are easily obtained by the condensation of copper glycinate with aldehydes or ketones, the method of which was originally proposed by Akabori *et al.*[2] and developed by Mix[3] and by Otani and Winitz.[4] However, this method usually gives a mixture of two diastereoisomeric racemates. Furthermore, the separation of the diastereoisomers is generally so difficult and complicated that only a few methods of doing so have been known. In these methods, β-hydroxy-DL-norvaline and β-hydroxy-DL-norleucine were changed to their copper chelates[3] and β-hydroxy-DL-leucine was converted to its sodium salt.[5]

In the previous paper, the present authors reported the separation of DL-threonine.[1] The separation and the configurational assignment of the diastereoisomers of β-hydroxy-DL-norvaline, β-hydroxy-DL-norleucine, and β-hydroxy-DL-leucine will be described in this paper. *erythro*-β-Hydroxy-DL-norvaline, *erythro*-β-hydroxy-DL-norleucine, and *threo*-β-hydroxy-DL-leucine formed scarcely-soluble compounds in water with α-naphthylphosphoric acid, tetrachlorophthalic acid, and chlorendic acid respectively. The elementary analyses showed that the compound consisted of the amino acid and the reagent in a 1:1 molar ratio, except for the compound with chlorendic acid, of which we failed to obtain an analytical sample. The IR spectra of all the compounds showed the absorption band in a region of 1715—1720 cm^{-1} due to the free carboxyl group as the salt of the amino acids with the strong acids. On the contrary, the compounds of their diastereoisomers with the reagents were soluble in water. These characteristics were successfully used in the separation of the two diastereoisomers of β-hydroxy-DL-norvaline, β-hydroxy-DL-norleucine, and β-hydroxy-DL-leucine.

The precipitates and the mother liquors were individually treated with hydrochloric acid. After removing the liberated reagents by filtration, the *erythro*- and *threo*-forms of the amino acids were recovered from the acidic solutions with an ion-exchange column. The results are summarized in Table 1. The *threo*-forms of β-hydroxy-DL-norvaline and β-hydroxy-DL-leucine also formed comparatively insoluble compounds in water with trimesic acid. These characteristics were also successfully used in the separation of the *threo*-forms of these amino acids, but the separation of the *erythro*-forms failed because of contamination with the *threo*-forms.

TABLE 1. SEPARATION OF THE DIASTEREOISOMERS

Amino acid	Ratio of diastereoisomers		Reagent	Recovery of pure isomers %	
	erythro	*threo*		*erythro*	*threo*
HyNva	53	47	NP	68	64
HyNle	44	56	TCP	71	66
HyLeu	25	75	CA	68	75

Abbreviations used are as follows:
HyNva, β-Hydroxy-DL-norvaline; HyNle, β-Hydroxy-DL-norleucine; HyLeu, β-Hydroxy-DL-leucine; NP, α-Naphthylphosphoric acid; TCP, Tetrachlorophthalic aicd; CA, Chlorendic acid.
To *erythro*-forms of HyNva and HyNle, and *threo*-form of HyLeu, 1.2 equimolar amount of the reagents was used.

α-Amino-β-hydroxy acids with long side chain are difficult to separate into their diastereoisomers by paper or thin-layer chromatography, and a convenient method of determining the configuration has not been found in the literature. The NMR spectra of the diastereoisomers of the amino acids obtained in the investigation were observed at 60 MHz in aqueous solutions, with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal reference.

In an alkaline solution, the chemical shifts of α-CH protons of the *erythro*- and *threo*-forms without a branched side chain on the γ-carbon atom were found in the region of δ 3.30—3.32 ppm and δ 3.13—3.16 ppm respectively (Table 2). However, no such regularity was observed in a neutral or an acidic solution for any of them (Table 2). From these results, it is possible to distinguish the diastereoisomers of α-amino-β-hydroxy acid without a branched side chain on the γ-carbon atom by means of NMR spectroscopy in an alkaline solution. Thus, the ratio of the *erythro*- and *threo*-forms of the synthetic DL-α-amino-β-hydroxy pelargonic acid could be determined to be 30:70 on the basis of the NMR spectrum, though the amino acid could not be clearly separated into its diastereoisomers by paper or thin-layer chromatography.

Table 2. Chemical shifts (δ ppm) of α-CH in aqueous solutions

Amino acid	Configuration	Solution		
		alkaline	neutral	acidic
DL-α-Amino-β-hydroxybutyric acid	*erythro*	3.30	3.83	3.92
	threo	3.16	3.58	3.72
β-Hydroxy-DL-norvaline	*erythro*	3.32	3.82	4.22
	threo	3.15	3.62	4–4.2
β-Hydroxy-DL-norleucine	*erythro*	3.32	3.82	3.95
	threo	3.13	3.62	3.85
β-Hydroxy-DL-leucine	*erythro*	3.33	3.90	4.33
	threo	3.32	3.82	4.08
DL-α-Amino-β-hydroxypelargonic acid[a)]	*erythro*	3.29	—	—
	threo	3.13	—	—

a) The compound is insoluble in a neutral or an acidic solution.

Experimental

The melting points are uncorrected. The NMR spectra were obtained with a Varian A-60 or T-60 spectrometer at 60 MHz in aqueous solutions, and chemical shifts are given from sodium 2,2-dimethyl-2-silapentane-5-sulfonate, used as the internal reference. Paper chromatography was carried out by the descending method on Toyo Roshi No. 51 paper with the solvent system of *n*-butanol - methyl ethyl ketone - 28% aqueous ammonia - water (5:3:1:1 v/v). The determination of the diastereoisomers was described in the previous paper.[1] The IR spectra were recorded in Nujol mull with a JASCO IR-S spectrometer.

Preparation of Starting Materials. β-Hydroxy-DL-norvaline, β-hydroxy-DL-norleucine, and DL-α-amino-β-hydroxypelargonic acid were synthesized by the method described by Mix.[3] β-Hydroxy-DL-leucine was obtained according to the method described by Ikutani *et al.*[5] DL-allothreonine and DL-threonine were on hand from the previous investigation.[1]

Salt of Erythro-*β-Hydroxy*-DL-*norvaline with α-Naphthylphosphoric Acid (I).* A solution of 1.3 g of *erythro*-β-hydroxy-DL-norvaline and 3.2 g of disodium α-naphthylphosphate in a mixture of 25 m*l* of water and 1 m*l* of concentrated hydrochloric acid was stored overnight in a refrigerator. The crystals thus formed were collected by filtration; yield, 1.2 g (32%). The compound was recrystallized from aqueous methanol to give **I** as fine crystals; mp 172.5—173.5°C (decomp.). IR: 3360, 3180, 1720, 1595, 1515 cm^{-1}. Found: C, 47.81; H, 6.03; N, 3.74; P, 8.20%. Calcd for $C_{15}H_{20}O_7NP \cdot H_2O$: C, 48.00; H, 5.91; N, 3.73; P, 8.25%.

Salt of Erythro-*β-Hydroxy*-DL-*norleucine with Tetrachlorophthalic Acid (II).* Into a solution of 1.47 g of *erythro*-β-hydroxy-DL-norleucine in 30 m*l* of water, 3.1 g of tetrachlorophthalic acid hemihydrate was dissolved with shaking at room temperature. The crystals precipitated immediately were dissolved by the addition of methanol. The resulting solution was stored overnight in a refrigerator to give **II** as needles; yield, 3.0 g (64%); mp 129.5—130°C (decomp.). IR: 3340, 3200, 1715, 1630, 1535 cm^{-1}. Found: C, 35.85; H, 3.74; N, 2.92; Cl, 30.03%. Calcd for $C_{14}H_{15}O_7NCl_4 \cdot H_2O$: C, 35.84; H, 3.65; N, 3.00; Cl, 30.23%. *threo*-β-Hydroxy-DL-leucine failed to give such a crystalline compound with chlorendic acid in an analytically pure state.

Separation of Diastereoisomers of β-Hydroxy-DL-*norvaline.* A solution of 6.4 g of disodium α-naphthylphosphate and 5.0 g of β-hydroxy-DL-norvaline (*erythro*: *threo*=53: 47) in 55 m*l* of water containing 4 m*l* of concentrated hydrochloric acid was stirred for 2 hr at room temperature, and then stored overnight in a refrigerator. The crystals thus formed were collected by filtration. The IR spectrum of the compound was identical with that of **I**. The crystals were dissolved in a mixture of 50 m*l* of water and 8 m*l* of concentrated hydrochloric acid by warming. The resulting solution was poured onto a column of Dowex 50 W×8 (in the H-form). After washing with water, the amino acid was eluted with 2N ammonium hydroxide (If α-naphthylphosphoric acid crystallized out from the acidic solution, it was filtered off and the filtrate was treated as above). The eluate was filled up to 500 m*l* with water, and 5 μl of it was subjected to quantitative analysis. The solution contained 2.4 g of the *erythro*-form and 0.3 g of the *threo*-form. It was concentrated *in vacuo* to dryness. The residue was crystallized from water - ethanol to give *erythro*-β-hydroxy-DL-norvaline as plates; yield, 1.8 g (68%); mp 247–248°C (decomp.). lit,[3] 245—246°C (decomp.). The compound was confirmed to be a pure *erythro*-form by paper chromatography. (Found: C, 45.38; H, 8.46; N, 10.46%).

The mother liquor excluding the *erythro*-form was poured onto a column of Dowex 50 W×8 (in the H-form) and treated as has been described above. The eluate contained 2.1 g of the *threo*-form and 0.2 g of the *erythro*-form. The eluate was concentrated *in vacuo* and crystallized from water. The *threo*-form was obtained as plates; yield, 1.5 g (64%); mp 218—219°C (decomp.). lit,[3] 217—218°C (decomp.). (Found: C, 45.15; H, 8.44; N, 10.33%). The crystals were confirmed to be pure *threo*-β-hydroxy-DL-norvaline by paper chromatography.

Separation of Diastereoisomers of β-Hydroxy-DL-*norleucine.* A solution of 18.5 g of β-hydroxy-DL-norleucine (*erythro*: *threo*= 44: 56) and 20.8 g of tetrachlorophthalic acid hemihydrate in 185 m*l* of water was stirred for 3 hr at room temperature and then stored overnight in a refrigerator. The crystals (26 g) thus formed were collected by filtration. The IR spectrum of the compound was identical with that of **II**. The crystals were suspended in a mixture of 130 m*l* of water with 10 m*l* of concentrated hydrochloric acid and then boiled under reflux for 30 min. The reaction mixture was stored overnight in a refrigerator. The tetrachlorophthalic acid (17.2 g) thus liberated was filtered off. The filtrate was poured onto a column of Dowex 50 W×8 (in the H-form) and treated in the manner used in the separation of β-hydroxy-DL-norvaline to give the *erythro*-form as plates. Yield, 5.8 g (71%); mp 253—254°C (decomp.). lit,[3] 248—250°C (decomp.). (Found: C, 49.19; H, 8.96; N, 9.54%).

The filtrate (pH 2.70) from the scarcely-soluble compound was acidified to pH 1.20 with concentrated hydrochloric acid and kept for 2 hr at room temperature. The tetrachlorophthalic acid (2.5 g) thus liberated was filtered off. The

filtrate was treated in the manner used in the separation of the *erythro*-form to give the *threo*-form as plates. Yield, 6.8 g (66%); mp 232—233°C (decomp.). lit,[3] 224—226°C (decomp.). (Found: C, 48.90; H, 8.89; N, 9.64%).

*Separation of Diastereoisomers of β-Hydroxy-*DL*-leucine.* A mixture of 10 g of β-hydroxy-DL-leucine (*erythro*: *threo*=25: 75) and 23.8 g of chlorendic acid in 100 m*l* of water was stirred for 2.5 hr at room temperature and then kept overnight in a refrigerator. The scarcely-soluble compound (30.9 g) thus formed was collected by filtration and dissolved in a mixture of 150 m*l* of water and 10 m*l* of concentrated hydrochloric acid by heating. The resulting suspension, containing an oily substance formed during the heating, was stirred at room temperature for 30 min. In the course of stirring, the oily substance turned to crystals, which were then filtered off. The crystals were identified as chlorendic acid by studying the IR spectrum. The filtrate was treated in the manner used in the separation of β-hydroxynorvaline to obtain the *threo*-form as plates. Yield, 5.6 g (75%), mp 232—233°C (decomp.). Recrystallization from water - ethanol raised the melting point to 239—240°C (decomp.). lit, 240—241°C (decomp.),[5] 239—240°C (decomp.).[6] The IR spectrum of the compound was identical with that of the *threo*-form.[7] (Found: C, 48.95; H, 8.96; N, 9.58%).

The filtrate (pH 3.20) from the addition compound was acidified to pH 1.20 with concentrated hydrochloric acid. After standing for 1 hr at room temperature, the chlorendic acid thus liberated was filtered off. The filtrate was treated in the manner used in the separation of the *threo*-form to afford the *erythro*-form as plates. Yield, 1.7 g (68%); mp 241—242°C (decomp.). Recrystallization from water raised the melting point to 249—250°C (decomp.). lit, 255—256°C (decomp.),[5] 253—255°C (decomp.).[6] The compound was obtained as hemihydrate. The IR spectrum of the compound was almost identical with that of the *erythro*-form except for the band due to the water of crystallization.[7] Found: C, 46.27; H, 9.13; N, 9.11%. Calcd for $C_6H_{13}O_3N \cdot 1/2H_2O$: C, 46.14; H, 9.04; N, 8.97%.

The authors are indebted to Miss Yohko Koguchi of our laboratory for the NMR measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3437—3440(1971)

The Synthesis and Photo Reaction of 7,11-Dimethyl-1,6,10-dodecatrien-3-one

Tadahiro KATO, Hideo MAEDA, Mitsuaki TSUNAKAWA, and Yoshio KITAHARA*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received June 15, 1971)

For the purpose of constructing a pinene skeleton (I), a promising intermediate for the synthesis of bergamotenes (III), the vinyl ketone (II), was synthesized from geranyl bromide (IV) by the application of Meyer's method, followed by a Grignard reaction with vinylmagnesium bromide and subsequent oxidation. The irradiation of II in absolute ether afforded an unexpected keto ether (X) in a low yield; it was characterized by means of a deuterium-exchange reaction and physical methods. No other product except X was isolated from the photoreaction mixture of II.

For the purpose of constructing a pinene skeleton (I) by the photocyclization[1] of olefinic ketone (II), we have synthesized (II) and examined its photoreaction. Compound (I) is a promising intermediate for the synthesis of bergamotenes (III), the structures of which were unequivocally confirmed by an elegant synthesis[2] from β-pinene.

Geranyl bromide (IV), easily obtainable from geraniol by treatment with phosphorous tribromide, was chosen as the starting material. The reaction of the bromide with lithium salt of 2,4,4,6-tetramethyl-5,6-dihydro-1,3-oxazine afforded the coupled product (V) in a 68% yield. The dihydrooxazine (V) was carefully reduced with sodium borohydride to give a fairly unstable tetrahydrooxazine derivative (VI), which, without purification, was hydrolyzed by oxalic acid to give two products, (VII) and (VIII), in 15 and 9% yields respectively.[3] The hydrolysis required the conditions of steam distillation, and the low yield of VII is due to its unstability toward acid at high temperatures. The acyclic aldehyde (VII) is fairly unstable even in a refrigerator under a nitrogen atmosphere.

The reaction of VII with vinylmagnesium bromide afforded the vinyl alcohol (IX) in a 78% yield, this substance was subsequently oxidized with active manganese dioxide to give vinyl ketone (II) in a 60% yield. Compounds (VII), (IX), and (II), especially VII and II, are fairly unstable and should be stored in a refrigerator under a nitrogen atmosphere.

The irradiation of II in absolute ether with a 100-W high-pressure mercury lamp under a nitrogen atmosphere resulted in the formation of several products, from which only a keto-ether (X) was isolated by re-

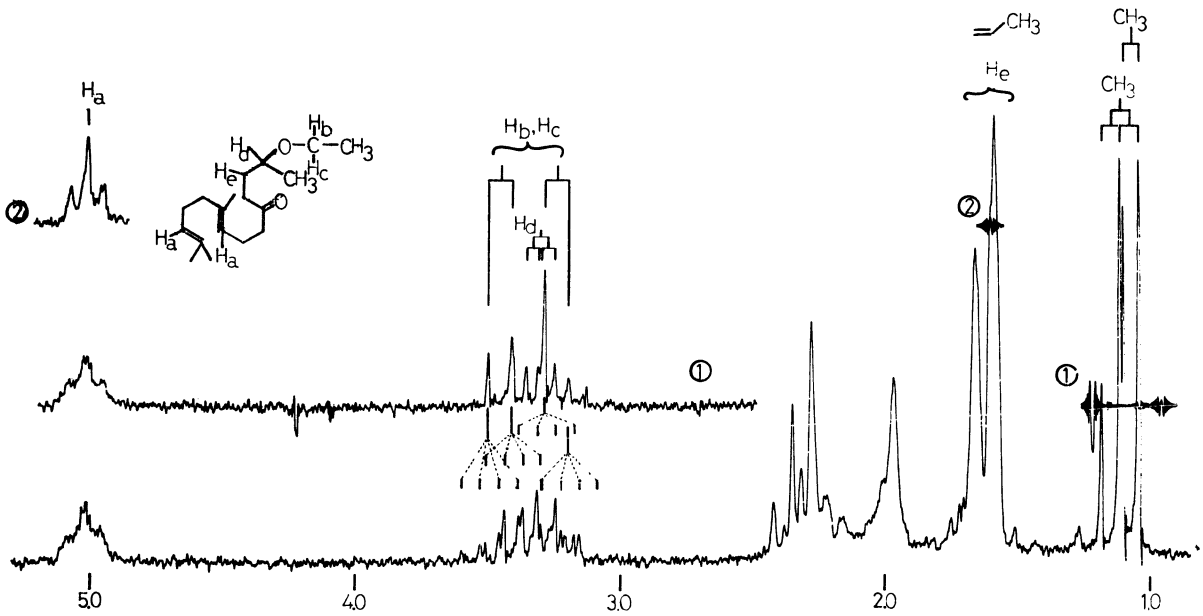

Fig. 1. 100 Mc NMR spectrum of keto ether (X) in CCl_4 plus 10% C_6D_6.

peated column chromatography in a 2% yield.

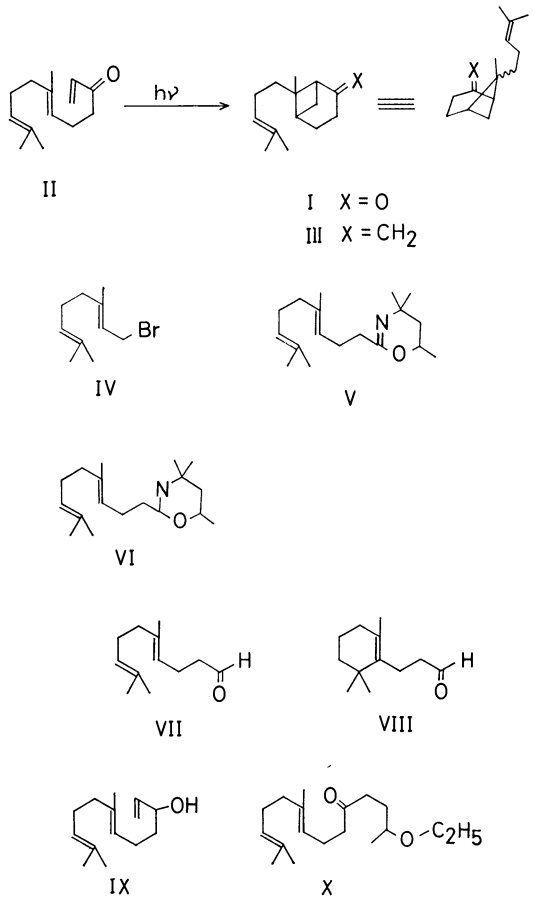
The gross structure of X was determined on the basis of the following evidence. The active hydrogens of X were replaced by deuterium under alkaline conditions[4] to give the deuterated keto ether. A comparison of the mass spectra of the original and the deuterated keto ether showed that X contained four replaceable hydrogens.

The 100-Mc NMR spectrum[5] of X in CCl_4 plus 10% C_6D_6 (Fig. 1) shows, in addition to two olefinic protons (Ha) at 5.01 and three olefinic methyl groups near 1.60 ppm, complex multiplets between 3.08 and 3.60 due to Hb, Hc, and Hd, a doublet and a triplet of the primary and secondary methyl groups respectively.

The irradiation of both the secondary and primary methyl groups (Fig. 1, ①) causes the multiplets between 3.20 and 3.50 ppm to appear as a pair of doublets centered at 3.45 and 3.24 ppm due to Hb and Hc, and a doublet of doublet at 3.31 (Hd). Simultaneous irradiation at 3.17 and 3.51 converts the triplet and doublet at 1.07 and 1.10 of the primary and secondary methyl groups to sharp singlets and at the same time affects the signals near 1.6 due to the He proton, which appears overlapping with three olefinic methyl groups. Irradiation at 1.60 ppm not only changes the broad multiplet at 5.01 due to olefinic protons (Ha) to a broad triplet (Fig. 1, ②), but also disturbs the multiplets near 3.2 ppm. These decoupling results are best explained in terms of a $-CH_2CH(CH_3)OCH_2CH_3$ grouping and an acyclic geranyl moiety which remains unchanged during the photoreaction.

Although a pinene skeleton could not be constructed by photocyclization, as has been expected at the outset of our study, it was found that the vinyl group of the vinyl ketone (II) is reactive toward ethyl ether under photoirradiation. This reaction may be general, as has been reported[6] recently in the case of conjugated cyclopentenones.

The chemical shifts and coupling modes of Hb, Hc,



4) B. Nolin and R. N. Jones, *Can. J. Chem.*, **30**, 727 (1952).

5) NMR spectra were measured with Varian T-60 and H-100 spectrometers in carbon tetrachloride if otherwise stated. The Chemical shifts were expressed with ppm from an internal standard of tetramethylsilane.

6) Z. Yoshida, M. Kimura, and I. Tabuse, Symposium of Photochemistry (Japan), symposium paper, p. 100 (1970).

and Hd in X are of interest since they indicate that Hb and Hc are magnetically non-equivalent and that the free rotation near the ether linkage of X is restricted. This may be due to a reason similar to that reported in the case of ethyl isobutyl ether,[7] where the methylene of the ethyl group appaers as an AB of the ABX_3 system.

Experimental

2-(4,8-Dimethyl-3,7-nonadienyl)-4,4,6-trimethyl-5,6-dihydro-1,3-oxazine (V). An ether solution of *n*-butyl lithium (120 m*l*) prepared from *n*-butyl bromide (34.4 g) and lithium (4.3 g) in absolute ether (150 m*l*), was dropped, at −60°C over a one-period into an absolute tetrahydrofuran solution of 2,4,4,6-tetramethyl-5,6-dihydro-1,3-oxazine (18.6 g, 0.13 mol) which had been cooled to −60°C before the addition. After 2 hr stirring at −60——70°C, geranyl bromide (31 g, 0.143 mol) in absolute tetrahydrofuran (40 m*l*) was dropped in over a 30 min period at that same temperature, after which the stirring was continued for a further 30 min. The cooling bath was removed to make the reaction mixture come to room temperature. All the above operations were carried out under a nitrogen atmosphere. The reaction mixture was then poured into ice water. The aqueous solution, after being acidified with 9N hydrochloric acid, was washed with *n*-hexane and then made alkaline by adding a 40% sodium hydroxide solution.

The alkaline solution was extracted with ether, and the ether solution was evaporated to give a residual oil. The residual oil was then purified by distillation to afford a dihydrooxazine derivative (V) (24.4 g, 68% yield); bp 95—97°C/1 mmHg. V: IR (film) 1670 cm^{-1} (*v* C=N–). NMR (*δ*), 1.10 (sharp s, C_4–Me×2), 1.23 (d, J=6.2, C_6–Me), 1.63 (olefinic methyls), 4.02 (m, C_6–H), and 5.13 (olefinic protons). Mass, M^+ 277, Mol Wt ($C_{18}H_{31}NO$) 277.44.

Found: C, 77.49; H, 11.56; N, 4.99%. Calcd for $C_{18}H_{31}NO$: C, 77.92; N, 11.26; N, 5.05%.

2-(4,8-Dimethyl-3,7-nonadienyl)-4,4,6-trimethyl-2,3,5,6-tetrahydro-1,3-oxazine (VI). The dihydrooxazine (V) (30 g, 0.11 mol) was dissolved in 230 m*l* of a mixed solvent of tetrahydrofuran and ethanol (1:1). The solution, after being cooled to −50°C, was carefully neutrallized with 9N hydrochloric acid to pH 7 and sodium borohydride in an aqueous solution [$NaBH_4$(4.25 g, 0.11 mol), H_2O(7 m*l*); 40% NaOH (one drop)] was gradually dropped in over a 30 min period, during which time the solution was kept neutral (pH 6—8) by the occasional addition of 9N hydrochloric acid. After the completion of the addition, the stirring was kept up for an additional hour.

The above operations were carried out at −40——50°C. The reaction mixture was made alkaline by adding a 40% sodium hydroxide solution, and this poured into water. After extraction with ether, the ether solution was washed with a saturated sodium chloride aqueous solution and then dried over anhydrous potassium carbonate. The evaporation of the ether afforded a crude oil (VI) (30.2 g), which, due to its unstability toward heat and silica gel, was used for the next step without purification. IR (film) 3300 cm^{-1}. NMR 1.06, 1.10, and 1.13 (C_4 and C_6-methyls), 1.60 and 1.67 (olefinic methyls), 3.65 (m, C_6-H), 4.13 (t, J=6, C_2–H), and 5.16 (olefinic protons).

5,9-Dimethyl-4,8-decadienal (VII). A mixture of the crude tetrahydrooxazine (VI) (3.05 g), water (30 m*l*), and anhydrous oxalic acid (1.33 g) was steam-distilled under a nitrogen atmosphere, and then the distillate was extracted with ether.

From the ether solution we obtained 1.30 g of oil after an usual work-up. The crude oil was chromatographed on silica gel (20 g) by elution with a mixed solvent of benzene - cyclohexane (1:1) to afford 544 mg of an aldehyde fraction. The aldehyde fraction was then further chromatographed on silica gel (5 g) impregnated with 5% silver nitrate. Successive elution afforded monocyclic aldehyde (VIII) (174 mg) from a benzene - cyclohexane (1:1) mixture and acyclic aldehyde (VII), (287 mg) from an ether eluent. Aldehyde (VII): IR (film) 2750, 1730, 830 cm^{-1}. NMR 1.60 and 1.63 (olefinic methyls), 5.10 (olefinic protons), and 9.80 ppm (bs, aldehyde proton). Mass M^+ 180, Mol wt ($C_{12}H_{20}O$) 180.28. Aldehyde (VIII): IR (film) 2750, 1730 cm^{-1}. NMR 1.00 (sharp s, Me×2), 1.60 (sharp s, olefinic methyl), and 9.83 (bs, aldehyde proton). Mass M^+ 180.

Found: C, 79.90; H, 11.25%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

Tosyl Hydrazone of VIII. A mixture of the aldehyde (VIII) (73 mg), *p*-tosylhydrazine (100 mg), and methanol (5 m*l*) was stirred overnight at room temperature. The subsequent recrystallization of the crude hydrazone with methanol afforded a pure specimen (85 mg); mp 117°C.

Found: C, 65.26; H, 8.11; N, 8.14%. Calcd for $C_{19}H_{27}N_2O_2S$: C, 65.67; H, 7.83; N, 8.06%.

7,11-Dimethyl-1,6,10-dodecatrien-3-ol (IX). To a tetrahydrofuran solution of vinyl magnesium bromide, prepared from magnesium (200 mg), vinyl bromide (980 mg), and anhydrous tetrahydrofuran (3 m*l*), we added the aldehyde (VII) (477 mg) in anhydrous tetrahydrofuran (6 m*l*) under a nitrogen atmosphere; the reaction mixture was then stirred overnight at room temperature.

The reaction mixture, after being poured into an aqueous ammonium chloride solution, was extracted with ether. From the ether solution we obtained, after an usual work-up, crude oil; this oil was chromatographed on silica gel (16 g) with benzene to give oily vinyl alcohol (IX) (447 mg, 78%). A pure specimen of IX was obtained by rechromatography on silica gel and subsequent distillation. IR (film) 3300, 1670, 1645, 920 cm^{-1}. NMR 1.60 and 1.67 (olefinic methyls), 4.05 (m, CHOH), 5.05—6.13 (five olefinic protons). Mass M^+ 208, Mol wt ($C_{14}H_{24}O$) 208.33.

Found: C, 80.34; H, 11.41%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

7,11-Dimethyl-1,6,10-dodecatrien-3-one (II). A mixture of the alcohol (IX) (200 mg), active manganese dioxide (2.2 g), and carbon tetrachloride (10 m*l*) was stirred at room temperature overnight. The subsequent removal of the solid and the evaporation of the combined solvents afforded a crude oil (170 mg) which was passed through silica gel (8 g) with a mixed solvent of benzene - cyclohexane (1:1) to give pure ketone (II) (113 mg, 60%). IR (film) 1700 (W), 1680, 1615 cm^{-1}. NMR 1.60 (olefinic methyls), 5.10(b, 2H), and 5.73—6.5(–CH=CH_2 group). Mass M^+ 206, Mol wt ($C_{14}H_{22}O$) 206.32. UV λ_{max}^{MeOH} 324 mμ (64).

Photoreaction of Vinyl Ketone (II). Vinyl ketone (II) (173 mg) in 100 m*l* of absolute ether was irradiated under a nitrogen atmosphere for 8 hr with a 100-W high-pressure mercury lamp. Similarly, 253-, 250-, and 250 mg portions of vinyl ketone were separately irradiated under the same conditions until the starting material disappeared on thin-layer chromatography.

The above reaction mixtures were then combined and passed through 70 g of silica gel by changing the solvents successively. From cyclohexane - benzene (1:1) and benzene -

7) E. Bullock, E. E. Burnell, and B. Gregory, *Chem. Commun.*, **1967**, 193.

isopropylether (4: 1) we obtained 30 mg of the recovered material and 373 mg of a crude oil respectively. The latter was further chromatographed on 5% silver nitrate - silica gel (170 g) with cyclohexane - isopropyl ether (10:1) to give 54 mg of oil, which was then rechromatographed on a short silica-gel column with benzene to afford the pure photoproduct (X) (23 mg). No other product was obtained in a pure form. IR (film) 1715 cm^{-1}. NMR (Fig. 1).

Deuterium Exchange of the Photoproduct (X). The photoproduct (X) and anhydrous sodium carbonate (5 mg) were dissolved in a mixture of CH_3OD (4 m*l*) and D_2O (0.5 m*l*). After the mixture has been refluxed for an hr under a nitrogen atmosphere, the solvents were removed *in vacuo*.

The residue was successively worked up by the addition of CH_3OD (4 m*l*) and D_2O (0.5 m*l*), refluxing, and the subsequent removal of the solvents. The residue was picked up in absolute ether to obtain the deuterated product. Major fragment ions of X and its deuterated product. X: 280(M^+), 234, 191, 165, 151, 136, 121, 111, 98. deuterated X: 284(M^+), 238, 195, 194, 169, 168, 155, 136, 121, 114, 102.

The authors wish to thank Dr. T. W. Gibson (Proctor and Gamble Co.) for his kind information on the cyclization of vinyl ketone (II). They also wish to thank Dr. A. I. Meyers for his sending of copies of the experimental details on the reactions of 5,6-dihydro-1,3-oxazine and its related compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3440—3443 (1971)

The Photochemistry of Large-ring Cycloalkanones[1)]

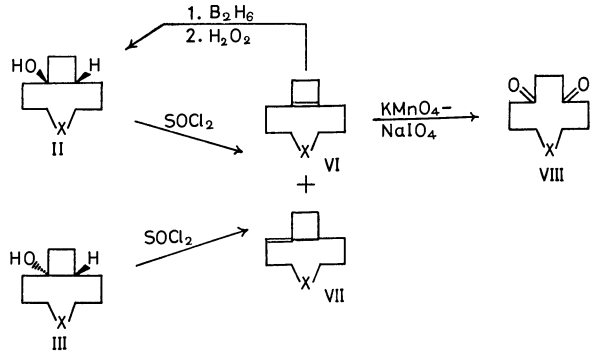
Kiyohide MATSUI, Takasi MORI, and Hitosi NOZAKI*
Department of Industrial Chemistry, Kyôto University, Kyôto

(Received June 29, 1971)

The photoreactions of 11-, 12-, and 13-membered cycloalkanones (Ia, Ib, and Ic) are described. The major products are *cis*, *trans* isomers of bicyclo[*n*.2.0]alkan-1-ol ($n=7$, 8, and 9; II, III). The stereochemistry and multiplicity of the reactive species have been discussed with emphasis on the effect of the ring size. The Ib cyclododecanone is most readily susceptible to the photochemical cyclization *via* its S_1 state, affording the *cis*-cyclobutanol IIb stereoselectively.

The interest in the effect of the ring size upon transannular reactivity as well as in the syntheses of 1,4-cycloalkanedione[2)] prompted the present authors to investigate the photoreactions of 11-, 12-, and 13-membered cycloalkanones; we have found a remarkable influence of the ring size upon the behavior of the reactive photoexcited species. As is known already, the irradiation of cyclodecanone gives 9-hydroxydecalin or bicyclo[4.4.0]decan-1-ol,[3)] whereas that of cyclododecanone affords bicyclo[8.2.0]dodecan-1-ol.[4)] We first wanted to learn further details on the photoreaction of cyclododecanone (Ib), including its stereochemistry,[5)] and then we proceeded to examine a borderline case, the reaction of cycloundecanone (Ia) and cyclotridecanone (Ic). We obtained the results summarized in Table 1.

The structures of the II and III cyclobutanols were determined to be as shown in Scheme 1. The dehydration of both II and III with thionyl chloride gave a mixture of olefins, VI and VII. The oxidative cleavage of VI with potassium permanganate-sodium metaperiodate led to the known 1,4-diketones, VIII.[2)] The *cis*-hydration of VI by means of hydroboration afforded II. The structure of Va (a *cis*, *trans* mixture) was tentatively assigned on the basis of IR, NMR (two olefin protons), and its catalytic hydrogenation into IVa.



Scheme 1

The cyclobutanol formation was commonly observed in the irradiation of three ketones, Ia, Ib, and Ic, and no other bicyclic product was isolated. However, the reactivity of each ketone was strongly controlled by the ring size, as may be summarized as follows: (1) In a qualitative sense, the reaction of Ib proceeded most rapidly. (2) This ketone, Ib, afforded the best yield of the cyclobutanol derivatives, IIb and IIIb. (3) The highest *cis*/*trans* ratio (II/III) was observed with Ib; the next, with cycloundecanone (Ia), and the lowest,

5) The stereochemical aspect of the photochemical cyclization of I_b was briefly descrived by Schulte-Elts (Ref. 3b) in a footnote, with no experimental details. No further report has yet appeared.

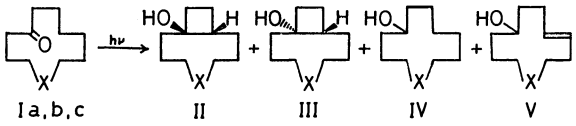

TABLE 1. THE PHOTOLYSIS OF CYCLOUNDECANONE (I_a), CYCLODODECANONE (I_b), AND CYCLOTRIDECANONE (I_c)

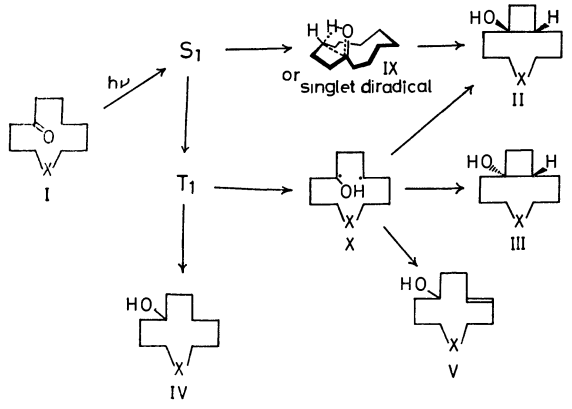
	Solvent	Irradiation time (hr)	Recovered I (%)	Product yields (%)				
				II	III	IV	V	unidentified
I_a	benzene	48	8	45	13	trace	8	4
	cyclohexane	48	5	34	9	7	5	3
	2-propanol	48	7	19	8	26	trace	3
	piperylene	144	69	0	0	0	0	trace
I_b	benzene	25	0	70	6	0	0	1
	cyclohexane	8	0	75	12	trace	0	1
	2-propanol	10	0	67	7	12	0	0
	piperylene	119	0	55	0	0	0	trace
I_c	benzene	48	8	36	19	trace[a]		3
	cyclohexane	48	8	37	20	trace[a]		3
	2-propanol	48	8	30	20	3[a]		2
	piperylene	130	21	38	0	0		trace

a) Identification could not be effected because of the small amounts obtained.

with cyclotridecanone (Ic). (4) Cycloundecanone (Ia) was most susceptible to photoreduction to IVa. (5) Only Ia gave unsaturated alcohol, Va.

The presence of piperylene as a triplet quencher drastically reduced the reaction rates. Remarkably, the single product from Ib was, stereoselectively, *cis*-cyclobutanol IIb when the starting material had completely disappeared. Under the same conditions, Ic gave IIc as a sole product; here the reaction proceeded rather sluggishly. In contrast, Ia afforded none of the products, IIa—Va, and decomposed slowly into a tarry product after prolonged irradiation in a piperylene solution.

The photochemical cyclization of open-chain ketones has been the subject of previous investigation,[6] and mechanisms have been discussed by Jeger,[7] Yang,[8] and their co-workers. Some possible explanations of the present case are shown in Scheme 2.



Scheme 2

The stereoselective formation of the *cis*-cyclobutanols, IIb and IIc, on the quenching of Ib (T_1) and Ic (T_1) might be explained by assuming the concerted cyclization of Ib (S_1) and Ic (S_1) through a transition state such as IX or, alternatively, through a singlet diradical intermediate of a similar geometry. The direct cyclization from Ia (S_1) must be conformationally much less favored, as is evident on an inspection of the model. In this case, therefore, Ia (T_1) is the sole active species undergoing transannular cyclization. The cyclotridecanone, Ic, appears to be least porne to cyclization, possibly for conformational reasons.

The selective formation of the IIc *cis*-cyclobutanol under the condition of triplet-quenching may be explained in terms much like those used to explain the IIb formation. The lowest ratio of IIc/IIIc in other solvents indicates that Ic (T_1) is the more important species of the photocyclization in such solvents.

We may conclude that the product distributions are strongly controlled by the transannular proximity of the excited carbonyl group and the reacting methylene proton, which depends on the conformation of the respective ring and, therefore, on the presence or absence of an additional methylene in the long undecamethylene group of Ib. The cyclization of Ib is characterized by the fact that the greatest contribution to the ring closure is made by the excited singlet (S_1). This is in sharp contrast with the open-chain case of ketones and also with 11- and 13-membered cycloalkanones (Ia, Ic).

Experimental

All the temperatures are uncorrected. The NMR spectra were obtained on a JOEL C-60-H spectrometer in CCl_4 solutions, with tetramethylsilane as the internal reference. Chemical shifts are given in ppm from this reference, with a multiplicity of signals in an abbreviated form. The glc

was performed on HVSG on Chromosorb W, with nitrogen as the carrier gas. The tlc was conducted on Silica-gel G, with *n*-hexane or benzene as the developing solvent. The product yields were calculated on the basis of the peak areas of glc.

Photoreaction of Cycloalkanones (Ia—c). General Procedure: A solution of I (1.00 mmol) in a purified and degassed solvent (20 m*l*) was placed in a Pyrex tube (25 mm in diameter) and covered with nitrogen. Irradiation was effected externally with a high-pressure mercury lamp (200 W). The solution was then evaporated, and the residual oil was distilled. The products were effectively separated from each other by preparative tlc, using benzene or a mixed solvent of *n*-hexane and ether (10: 1) as the eluant. *cis*-Cyclobutanols (II) were more polar than *trans*-isomers (III) on tlc. Monocyclic alcohols (IV, V) were more polar than II and III. Each product was purified by recrystallization or by distillation.

cis-*Bicyclo*[*7.2.0*]*undecan-1-ol (IIa)*. Separation and distillation gave IIa as a colorless solid; mp 42—43°C. IR (Nujol): 3350 cm^{-1} (OH). NMR δ: 1.05—2.60 (m, 19H), 2.75 (s, 1H). Found: C, 78.8; H, 11.8%. Calcd for $C_{11}H_{20}O$: C, 78.5; H, 12.0%.

trans-*Bicyclo*[*7.2.0*]*undecan-1-ol (IIIa)*. The IIIa *trans*-isomer formed a colorless oil. IR (neat): 3470 cm^{-1} (OH). NMR δ: 1.05—2.30 (m, 19H), 2.30—2.80 (m, 1H). Found: C, 78.8; H, 11.7%. Calcd for $C_{11}H_{20}O$: C, 78.5; H, 12.0%.

cis-*Bicyclo*[*8.2.0*]*dodecan-1-ol (IIb)*. A work-up gave IIb as a colorless solid; mp 47—49°C (lit,[4b] mp 48—49°C). IR (Nujol): 3380 cm^{-1} (OH). NMR δ: 1.05—1.70 (m, 16H), 1.70—2.10 (m, 4H), 2.10—2.70 (m, 1H), 2.27 (s, 1H, OH).

trans-*Bicyclo*[*8.2.0*]*dodecan-1-ol (IIIb)*. The IIIb *trans*-isomer was isolated as a colorless oil. IR (neat): 3470 cm^{-1} (OH). NMR δ: 1.05—1.70 (m, 16H), 1.69 (s, 1H, OH), 1.70—2.20 (m, 4H), 2.20—2.75 (m, 1H).

cis-*Bicyclo*[*9.2.0*]*tridecan-1-ol (IIc)*. The IIc *cis*-alcohol formed a colorless solid; mp 45—47°C. IR (Nujol): 3400 cm^{-1} (OH). NMR δ: 0.75—2.30 (m, 23H), 2.74 (s, 1H, OH). Found: C, 79.5; H, 12.5%. Calcd for $C_{13}H_{24}O$: C, 79.5; H, 12.3%.

trans-*Bicyclo*[*9.2.0*]*tridecan-1-ol (IIIc)*. The IIIc *trans*-alcohol was a colorless oil. IR (neat): 3460 cm^{-1} (OH). NMR δ: 1.05—2.15 (m, 23H), 2.10—2.65 (m, 1H). Found: C, 79.7; H, 12.3%. Calcd for $C_{13}H_{24}O$: C, 79.5; H, 12.3%.

Dehydration of II and III. General Procedure:[9] A solution of II or III (2.75 mmol) in dry ether (2.00 m*l*) was stirred, drop by drop, into a solution of thionyl chloride (0.40 m*l*) and pyridine (1.00 m*l*) in dry ether (2.00 m*l*) at 3—5°C. After the reaction had subsided (*ca.* 2 hr), the mixture was poured into ice water and extracted with *n*-hexane. The combined extracts were washed once with water, once with aqueous sodium bicarbonate, and twice more with water. Distillation afforded a mixture of *cis* and *trans* olefins, which were separated by preparative glc (HVSG 2 m, helium).

$\Delta^{1(9)}$-*Bicyclo*[*7.2.0*]*undecene (VIa)*. Separation and distillation gave VIa as a colorless oil in a 31% yield. IR (neat): 1450, 877 cm^{-1}. NMR δ: 0.65—2.65 (m, 14H), 2.68 (s, 4H). Found: C, 87.4; H, 12.2%. Calcd for $C_{11}H_{18}$: C, 87.9; H, 12.1%.

Bicyclo[*7.2.0*]*undec-1-ene (VIIa)*. A work-up gave VIIa as a colorless oil in a 25% yield. IR (neat): 1475, 1450, 869, 792 cm^{-1}. NMR δ: 0.70—2.95 (m, 17H), 4.80—6.15 (m, 1H). Found: C, 87.5; H, 12.2%. Calcd for $C_{11}H_{18}$: C, 87.9; H, 12.1%.

$\Delta^{1(10)}$-*Bicyclo*[*8.2.0*]*dodecene (VIb)*. The VIb olefin was a colorless oil (35% yield). IR (neat): 1465, 1442, 882 cm^{-1}. NMR δ: 1.25—1.85 (m, 12H), 1.95—2.20 (m, 4H), 2.26 (s, 4H). Found: C, 88.0; H, 11.8%. Calcd for $C_{12}H_{20}$,: C, 87.8; H, 12.2%.

Bicyclo[*8.2.0*]*dodec-1-ene (VIIb)*. The VIIb isomer was a colorless oil (28% yield). IR (neat): 1470, 1440, 887, 858, 750, 700 cm^{-1}. NMR δ: 1.15—2.70 (m, 18H), 3.10—3.45 (m, 1H), 4.75—5.15 (m, 1H). Found: C, 87.8; H, 11.9%. Calcd for $C_{12}H_{20}$: C, 87.8; H, 12.2%.

$\Delta^{1(11)}$-*Bicyclo*[*9.2.0*]*tridec-1-ene (VIc)*. This olefin, VIc, was a colorless oil (33% yiled). IR (neat): 1470, 1447, 890, 862, 810, 788 cm^{-1}. NMR δ: 1.15—1.90 (m, 14H), 1.90—2.50 (m, 4H), 2.46 (s, 4H). Found: C, 88.1; H, 12.8%. Calcd for $C_{13}H_{22}$: C, 87.6; H, 12.4%.

Bicyclo[*9.2.0*]*tridec-1-ene (VIIc)*. The VIIc isomer was a colorless oil (27% yield). IR (neat): 1462, 1448, 1010, 970, 887 cm^{-1}. NMR δ: 1.10—2.80 (m, 21H), 4.75—5.15 (m, 1H). Found: C, 88.1; H, 12.7%. Calcd for $C_{13}H_{22}$: C, 87.6; H, 12.4%.

Oxidative Ring Opening of Cyclobutene Derivatives (VIa—c). General Procedure:[10] To a solution of VI (1.00 mmol) in *tert*-butyl alcohol (70 m*l*) there was added a saturated aqueous solution of potassium carbonate (19 mg) and then a stock solution (40 m*l*) which had been freshly prepared from potassium permanganate (20 mg), sodium metaperiodate (1.04 g) and water (40 m*l*). The reaction mixture was stirred for 5 hr and extracted with *n*-hexane, and the extracts were evaporated *in vacuo*. The purification was effected by preparative tlc (Silica-gel G benzene) and distillation or by recrystallization. Each product was identified with an authentic sample.

Hydroboration of Cyclobutene Derivatives (VIa—c). To a solution of VIb (50 mg) in tetrahydrofuran (1.00 m*l*), a tetrahydrofuran solution of diborane (1M, 0.80 m*l*) was added drop by drop, after which the mixture was stirred for a half hour at 0—3°C. Water (1.00 m*l*) was then added carefully, and the mixture was treated with a 3N NaOH solution (1.00 m*l*). To this a 30% H_2O_2 solution was added, drop by drop, at room temperature, and then the whole was allowed to stand overnight. After the subsequent addition of an aqueous NaCl solution, the mixture was extracted with *n*-hexane and the combined extracts were evaporated *in vacuo*. Distillation afforded a colorless solid (43% yield), which was found to be identical with the IIb photoproduct (IR, glc, NMR, and mixed mp). Two other olefins VIa and VIc were treated similarly to afford IIa and IIc respectively.

Cycloundecenol (Va). A mixture containing IVa and Va was separated by preparative tlc (Silica-gel G, benzene). Perfect separation was effected by repeated preparative tlc. (The yield was calculated on the basis of the NMR peak areas of the olefinic protons. This product showed the following spectra in support of the assigned structure. IR (neat): 1645 cm^{-1} (C=C). NMR δ: 0.70—2.50 (m, 16H), 3.20—3.90 (m, 2H), 4.65—5.65 (m, 2H). Found: C, 78.3; H, 11.9%. Calcd for $C_{11}H_{20}O$: C, 78.5; H, 12.0%. The hydrogenation of Va on palladium charcoal afforded saturated monocyclic alcohol. The IR spectrum of its phenylurethane was superimposable on that of authentic cycloundecanol phenylurethane (mp 56—58°C) (literature[11] mp 58—59°C).

The IVa Photoreduction Product. This product was separated by preparative tlc (Silica-gel G, *n*-hexane: ether=

The Preparation of 9-Ethynylanthracene and 9-Ethynyltriptycene and Their Oxidative Coupling

Shuzo AKIYAMA, Fumio OGURA, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 1, 1971)

The formation of 9,10-dichloroanthracene by reaction of 9-acetylanthracene with phosphorus pentachloride is described. 9-Ethynylanthracene and 9-ethynyltriptycene have been prepared according to Köbrich's method. The resulting ethynyl compounds have been converted to the corresponding di-ynes using the Eglinton's oxidative coupling reaction.

The treatment of methyl ketone with phosphorus pentachloride followed by dehydrochlorination using a strong base such as sodium amide in liquid ammonia is a general method of preparation of ethynyl compound. However, evolution of acetyl chloride and chlorine was observed on treatment of 9-acetylanthracene with phosphorus pentachloride. A small amount of crystalline 9, 10-dichloroanthracene could be isolated from the viscous oily reaction product. The mechanism for formation of the dichloroanthracene is not yet clear, but considering a similar reaction of anthracene with phosphorus pentachloride to give 9,10-dichloroanthracene,[1] deacetylation and subsequent chlorination seem to be caused by the catalysis of phosphorus pentachloride. The viscous oily product separated from the dichloroanthracene was treated with sodium amide in liquid ammonia. Chromatographic purification of the reaction product yielded unstable yellow crystals contaminated with some chlorine compound. The IR spectrum of the yellow crystals indicates the presence of 9-ethynylanthracene; however, it was not feasible to remove impurity containing chlorine.

Because of these difficulties, the authors adopted the method of Köbrich[2] for the preparation of 9-ethynyl compounds. As indicated in the following scheme, the reaction of 9-anthracenecarboxaldehyde (I_a) in tetrahydrofuran with chloromethylenetriphenylphosphorane (II) yielded a viscous liquid which is presumably a mixture of *cis* and *trans* isomers of the chlorovinyl compound (III_a). The dehydrochlorination of III_a by means of sodium amide in liquid ammonia yielded 9-ethynylanthracene (IV_a) in a reasonable quantity. The rather rapid decomposition of IV_a even in solution contrasts fairly strongly with the stable nature of other arylacetylene. The oxidative coupling of IV_a according to Eglinton's method resulted in 9,9′-dianthryldiacetylene (V_a) which was shown to be identical with an authentic specimen.[3] Using an analogous procedure, 9-triptycenecarboxaldehyde (I_b)[4] was converted to 9-ethynyltriptycene (IV_b). The ethynyl compound (IV_b) was found to be highly stable compound. The oxidative coupling of IV_b gave 9,9′-ditriptycyldiacetylene (V_b) in a quantitative yield as colorless cubes. The recrystallization of V_b could not be performed because of the extremely poor solubility. The material (V_b) gave satisfactory elemental analysis after digestion with a diluted hydrochloric acid. The unusual thermal stability and the extremely poor solubility seem to be attributable to the rigid and bulky cage structure of the terminal triptycene groups.

TABLE 1. HYPOCHROMISM OF 9-SUBSTITUTED TRIPTYCENES
λ IN nm IN ETHANOL

Triptycene		9-Ethynyltriptycene (IV_b)		9-Formyltriptycene (I_b)

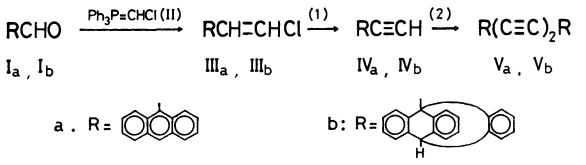
5) W. Theilacker, K. Albrecht, and H. Uffmann, *Chem. Ber.*, **98**, 428 (1965).

IV_b also show a similar hypochromism in the region of 270—280 nm. However, the strong absorption bands at shorter wavelength region (190—210 nm) exhibit no hypochromism.[6]



Scheme 1. (1) $NaNH_2$/liq. NH_3; (2) $Cu(OAc)_2$/pyridine-methanol. THF=tetrahydrofuran.

Experimental

All the melting points were uncorrected. The IR and nmr spectra were obtained on a Hitachi EPI-2 and a Varian A-60 spectrometers, respectively. A Hitachi EPS-3T spectrometer was used for the electronic spectroscopy except for short-wavelength region. The spectra below 210 nm were measured on a Zeiss PMQ II, M4Q III spectrometer.[6]

Reaction of 9-Acetylanthracene with Phosphorus Pentachloride. A mixture of 9-acetylanthracene, phosphorus pentachloride, and benzene or phosphoryl chloride was heated under reflux until the evolution of gas ceased (*ca.* 1 hr). The reaction mixture was worked up in the usual manner. The yellow fine needles deposited were filtered to remove the viscous oily material and recrystallized to give pure 9,10-dichloroanthracene. As summarized in Table 2, the increase in the ratio of phosphorus pentachloride to 9-acetylanthracene increases the yield of dichloroanthracene.

Table 2. The formation of 9,10-dichloroanthracene

Run	Acetylanthracene A (g)	PCl_5 B(g)	B/A (molar ratio)	Solvent[a] (ml)	Dichloroanthracene (g)	Yield based on A (%)
1	1.10	1.0	1	b5	0.07	6
2	1.10	2.1	2	b5	0.09	7
3	1.10	5.2	5	b5	0.17	14
4	1.10	1.0	1	p5	0.02	1
5	1.10	9.15	9	p5	0.23	19

a) b=benzene; p=phosphoryl chloride.

Attempted Synthesis of 9-Ethynylanthracene (IV_a). The viscous oily material mentioned earlier was mixed with a small amount of tetrahydrofuran and added to a suspension of sodium amide in liquid ammonia. After 3 hr, ammonium chloride was added to the reaction mixture, and the ammonia was allowed to evaporate. The residue was digested with petroleum ether and subjected to chromatography on alumina. The yellow crystals (mp 54—64°C), thus obtained, were found to be highly unstable and contaminated with chlorine compound.

9-Ethynylanthracene (IV_a). 9-(α-Chlorovinyl)anthracene (III_a): An ethereal solution of *n*-butyllithium (1.04N, 28.8 ml, 0.03 mol) was added to a suspension of chloromethyltriphenylphosphonium chloride[2] (10.70 g, 0.03 mol) over a period of 30 min at −70°C. After, 20 min, a solution of 9-formylanthracene (6.18 g, 0.03 mol) in tetrahydrofuran (100 ml) was added and the cooling bath was removed. The reaction mixture was stirred overnight at room temperature. The solvent was removed under reduced pressure and the viscous oily residue was dissolved in benzene (180 ml). The benzene solution was passed through a short column of alumina (40 g). The filtrate was concentrated and the oily residue was re-dissolved in benzene (40 ml). The benzene solution was percolated through a layer of alumina (20 g). The light yellow liquid obtained by the concentartion of the filtrate was subjected to the following reaction.

Dehydrochlorination of III_a. A solution of the crude III_a in tetrahydrofuran (25 ml) was added over a period of 30 min to a suspension of sodium amide (prepared from 5 g of sodium) in liquid ammonia (200 ml) maintained at −65°C. After the mixture had been stirred for 4 hr, the ammonia was allowed to evaporate. A saturated solution of ammonium chloride was added to the residue under cooling with ice-water. The organic solvent and some part of water were removed under reduced pressure, and extracted with ether (200 ml). Concentration of the extract gave an oily material, which was dissolved in benzene (50 ml) and passed through a short column of alumina (20 g). The oily residue obtained by the concentation of the filtrate was repeatedly digested with petroleum ether (bp 40—60°C, total 800 ml). After triphenylphosphine oxide, which deposited on standing the extract, had been removed by filtration, the filtrate was passed through a thin layer of alumina (10 g) and concentrated to yield yellow crystals (3.65 g, 59% based on I_a). The crystals were re-dissolved in petroleum ether, and the chromatographic purification was repeated 3 times. The final filtrate was chilled in an ice-bath to afford IV_a as light yellow needles, mp 76—76.5°C. IV_a gave orange cuprous and yellow silver acetylides.

Found: C, 94.96; H, 5.00%. Calcd for $C_{16}H_{10}$: C, 95.02; H, 4.98%. IR (KBr-disk): 3290 (−C≡CH) cm^{-1}. NMR (CCl_4): τ 6.16 (s, 1H) (C≡CH), 1.7—2.8 (m, 9H) (aromatic H). UV: $\lambda_{max}^{n\text{-hexane}}$ (log ε) 218 (4.06), 253 (4.96), 259.5 (5.24), 343 (3.54), 360 (3.90), 379 (4.13), 400 (4.31) nm.

9-Ethynyltriptycene (IV_b). 9-(α-Chlorovinyl)triptycene (III_b): The reaction of 9-formyltriptycene[4] (I_b, 5.64 g, 0.02 mol) with chloromethylenetriphenylphosphorane (II) according to the analogous procedure described earlier yielded III_b as a light yellow viscous liqued. Because crystallization was unsuccessful, the liquid was subjected to the subsequent reaction.

Dehydrochlorination of III_b. The dehydrochlorination was performed according to a procedure similar to that used for III_a. The reaction product was digested with benzene (100 ml), and the extract was passed through a short column of alumina (15 g). The light brown liquid obtained from the filtrate was re-digested with petroleum ether (bp 60—80°C, 200 ml). The extract was percolated through a thin layer of alumina (5 g). The colorless crystals (3.35 g, 60% based on Ib) obtained from the filtrate were dissolved in pertoleum ether (bp 40—60°C), and the solution was passed twice through a short column of alumina to yeild colorless cubes. The crystals were recrystallized from benzene-methanol to give pure IV_b as colorless cubes, mp 222.5—223.5°C.

Found: C, 94.73; H, 5.15%. Calcd for $C_{22}H_{14}$: C, 94.93; H, 5.07%. NMR (CCl_4): τ 6.77 (s, 1H) (C≡CH), 4.53 (s, 1H) (bridge head H), 1.83—2.93 (m, 12H) (aromatic H). IR (KBr-disk): 3300 (C≡CH) cm^{-1}.

9,9'-Dianthryldiacetylene (V_a). A mixture of IV_a (0.02 g, 1.1 mmol), cupric acetate monohydrate (5.0 g), pyridine (10 ml) and methanol (1 ml) was stirred for 3 hr at 50°C. The insoluble material was collected by filtration and washed with a small amount of methanol, water, and a small amount of ethanol, successively. The orange tiny cubes (0.20 g, 91%, mp 287—291°C), thus obtained, were dissolved in toluene,

6) The authors are indebted to Professor J. Tanaka of Nagoya University for the measurements of spectra at short wavelength.

and passed through a short column of alumina to give orange cubes, mp 290—292°C which were found to be identical with the authentic sample.[3]

9,9′-Ditriptycyldiacetylene (V_b). The Eglinton's oxidative coupling of analytically pure IV_b (0.60 g) according to a procedure used for V_a gave colorless fine needles in a quantitative yield. The crystals were thoroughly digested with dilute hydrochloric acid to remove inorganic material, and were washed with water, and dried.

Found: C, 95.02; H, 4.81%. Calcd for $C_{44}H_{26}$: C, 95.28; H, 4.72%.

Recrystallization of V_b was infeasible owing to its extremely poor solubility in various organic solvents.

Studies on Stable Free Radicals. VI.[1] Synthesis of Substituted 4-Imidazolidinone-1-oxyls

Toshimasa TODA, Syoji MORIMURA, Eiko MORI, Hideo HORIUCHI, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received July 15, 1971)

It was found that the reaction of α-amino nitriles with carbonyl compounds gave the substituted 4-oxoimidazolidines in the presence of basic catalyst. These imidazolidinones were oxidized by hydrogen peroxide: although the imidazolidinones containing an α-hydrogen at the 2- or 5-position gave no radical products, 2,2,5,5-tetrasubstituted imidazolidinones afforded new stable nitroxide radicals. By this method, stable biradicals were also prepared; but, no corresponding stable nitroxide radical was isolated by oxidation of substituted imidazolidine-4-thiones.

Since Rozantsev and Neiman[2] were successful in the preparing of very stable nitroxide radicals, such as 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl, interest seems to have increased in the studies of these stable free radicals.[3–6]

We also reported[7] a suitable method for preparing 2,2,6,6-tetramethyl-4-oxopiperidine which afforded a stable nitroxide radical by oxidation.

In present paper, we wish to report that the reaction of α-amino nitriles with aldehydes of ketones in the presence of basic catalyst gave substituted 4-oxoimidazolidines.

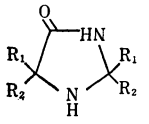
Subsequently, we obtained new, stable nitroxide radicals by oxidation of these imidazolidinones; but the imidazolidinones containing an α-hydrogen at 2- or 5-position gave no radical products.

Attempts to prepare corresponding stable nitroxide radicals from substituted imidazolidine-4-thiones failed.

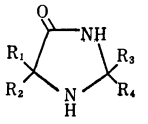
Results and Discussion

Cyclization reaction. Noland *et al.*[8] have reported that cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-1″-cyclohexane (IIa) is obtained by self-condensation of 1-amino-1-cyanocyclohexane (IV) catalyzed by sodium ethoxide in ethanol solution containing a small amount of water.

In this method, only two different substituents can be introduced in 2- and 5-positions of the 4-oxoimidazolidine ring (I). In this work, we established a general method for preparing imidazolinones (II) having four different substituents in the 2- and 5-positions.



(I)



(II)

A crystalline solid was obtained on the reaction of 1-amino-1-cyanocyclohexane (IV) with cyclohexanone in the presence of sodium ethoxide in ethanol solution. This product was identified as IIa by comparison of melting point, IR spectrum and elementary analysis with those of an authentic sample of IIa.[8]

Further, the yield of IIa in this reaction was over 100% based on 1-amino-1-cyanocyclohexane (IV). This result was considered to show that cyclohexanone reacted with the α-amino nitrile, IV to give IIa. The

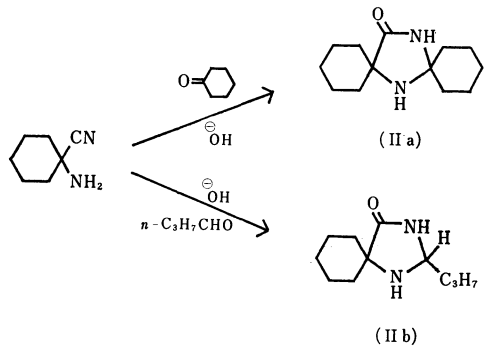
reaction of IV with *n*-butyraldehyde in the presence of a catalytic quantity of aqueous sodium hydroxide afforded similarly the 4-oxoimidazolidine, 1,3-diaza-2-*n*-propyl-4-oxo-spiro[4.5]decane (IIb), as proved by IR spectrum (the presence of carbonyl band at 1691 cm^{-1}) and elementary analysis.



Thus, we confirmed that α-amino nitriles condensed with carbonyl compounds in the presence of a basic catalyst to yield substituted imidazolidinones (II).

The products, IIa—w obtained in this method are listed in Table 1. The structures of these products were confirmed by IR spectra (the presence of carbonyl band at about 1690 cm^{-1}), elementary analysis and the stable nitroxide radicals afforded by oxidation as described in next section.

These imidazolidinones were useful as light stabilizers for synthetic polymers.[9]

Oxidation reaction. Oxidation of the imidazolidinones (II) provided new stable nitroxide radicals (III).

The oxidation[5] of the imidazolidinones were carried out with hydrogen peroxide in the presence of catalytic amount of sodium tungstate and ethylenediaminetetraacetic acid (EDTA) in acetic acid solution.

a): measured in 10^{-3} mol/l benzene solution at room temperature, are given in gauss and are accurate to within ±0.1G.

The structures of the products (IIIa—g) were assinged by ESR spectra (triplet lines), elementary analysis and IR spectra in which the carbonyl band of corresponding amines at about 1690 cm^{-1} shifted approximately 20 cm^{-1} toward higher frequency. The nitroxide radicals obtained by the oxidation are listed in Table 2.

These radicals are very stable and no change has occurred on standing at room temperature for several years.

The ESR spectra of these radicals exhibited only three lines, which arise through hyperfine interaction with a ^{14}N nucleus, in evacuated benzene solution. The values of the nitrogen hyperfine splitting are shown in Table 3.

Table 3 indicates that the magnitude of the nitrogen hyperfine splitting in the imidazolidinone-1-oxyl radicals, IIIa,c,e,f, and IIIw, are smaller than that of the derivatives of 2,2,6,6-tetramethylpiperidine-1-oxyl radicals, III,p,q,r, and IIt.

It has been reported[10] that the a_N values of the derivatives of 2,2,6,6-tetramethylpiperidine-1-oxyl, measured in the same solvent, decrease as the carbon atom at the 4-position in the piperidine ring becomes more electron deficient.

Therefore, the fact that the a_N values of the imidazolidinone-1-oxyls are smaller than those of the piperidine-1-oxyls could be considered to be due to the difference of dipolar field effect on the radical moiety between the amide group in imidazolidinone-1-oxyl and the substituents at 4-position in piperidine-1-oxyl.

Furthermore, we were interested in the ESR spectra of bi-nitroxide radicals, IIt, IIIl, and IIIp to determine any intramolecular interaction between the two radical part within a single molecule.

10) R. Briere, H. Lamaire, and A. Rassat, *Bull. Soc. Chim. Fr.*, **1966**, 3273.

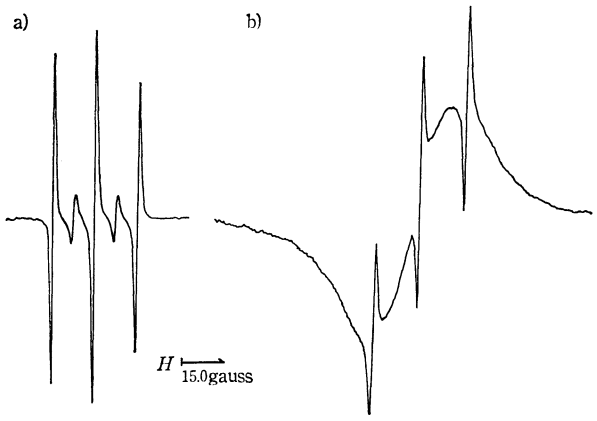

Fig. 1. The ESR spectra of bi-nitroxide radicals.[A)]
A): measured in 10^{-3}mol/*l* benzene solution at room temperature.
a): 2,2,6,6-tetramethylpiperidine-4-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (IIt).
b): cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine)-1′,1″-dioxyl (IIIp).
The ESR spectra of IIIl and IIIp are basically very similar.

As shown in Fig. 1a, IIt gave a quintet lines like the spectrum of the carbonate diester of 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl.[11] The spectra of IIIl and IIIp were more complicated than that of IIt (Fig. 1b).

This suggests that the intramolecular interaction between the two nitroxide radical groups was stronger than in IIt. The ESR studies of these bi-nitroxide radicals are currently under detailed investigation.

In the case of imidazolidinones containing an α-hydrogen adjacent to the secondary amino group, the oxidation products were non-radicals.

Treatment of 1,3-diaza-2-phenyl-4-oxo-spiro[4,5]decane (IIi) with hydrogen peroxide in the presence of sodium tungstate in methanol solution gave white crystals. This product was presumed to be 1,3-diaza-2-phenyl-4-oxo-spiro[4.5]-1-decene-1-oxide (V) from its spectral data (the presence of $\nu_{C=N\to O}$ band[12] at 1588 and 1564 cm^{-1} in IR spectrum and a *m/e* 244 molecular peak in mass spectrum), elementary analysis and the following reaction. The nitroxide, V was converted into 1,3-diaza-2-phenyl-4-oxo-spiro[4.5]decene-1 (VI) on treating with triphenylphosphine. The structure of VI was assigned by IR spectrum (the presence of $\nu_{C=N}$ at 1625 cm^{-1}, mass spectrum (at *m/e* 228 molecular peak) and elementary analysis.

Similarly, 1,4-diaza-2-phenyl-3-oxo-sprio[4.5]-1-decene-1-oxide (VII) and 1,3-diaza-2-*n*-propyl-4-oxo-spiro[4.5]-1-decene-1-oxide (VIII) were obtained by the oxidation of corresponding amines, IIu and IIb, respectively.

This reaction would proceed as shown in Chart 1.

It seems reasonable that the intermediate, nitroxide radical, IX disproportionates to V and X, since dimethylamino radicals disproportionate into dimethylamine and *N*-methylformaldimine.[13] The hydroxylamine, X would regenerate the nitroxide radical, IX by oxidation with hydrogen peroxide.

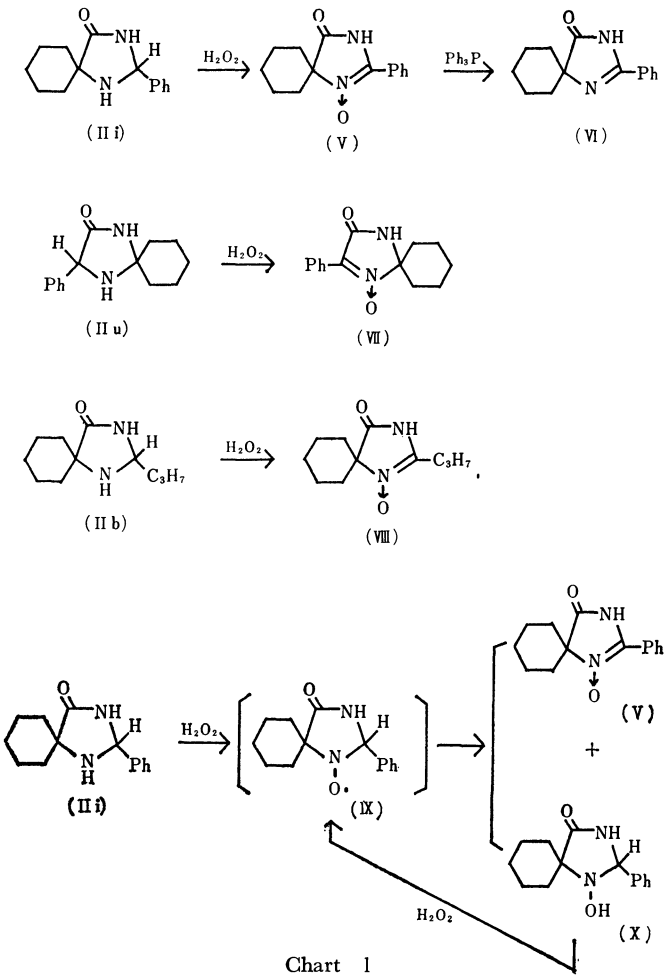

Chart 1

However, it has been reported[14] that norpseudopelletierine containing an α-hydrogen adjacent to a secondary amino group provides a corresponding stable nitroxide radical. In this case, the disproportionation reaction mentioned above, would be hindered by steric factors (Bredt rule).

Oxidation of substituted imidazolidine-4-thiones. We attempted to prepare another stable nitroxide radicals with imidazolidine-4-thione ring.

Rassat *et al.*[15] have suggested the formation of the free radicals of this type in their ESR studies, where they have observed a triplet spectrum on mixing 2,2,5,5-tetramethylimidazolidine-4-thione (XII)[16] and *p*-nitroperbenzoic acid in benzene, but they did not isolate this free radical.

However, we obtained no radical products from the oxidation of imidazolidine-4-thiones.

Treatment of cyclohexane-1-spiro-2′-(imidazolidine-

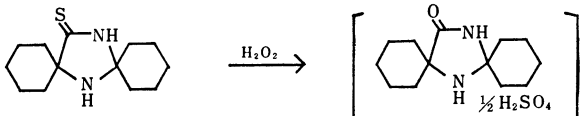
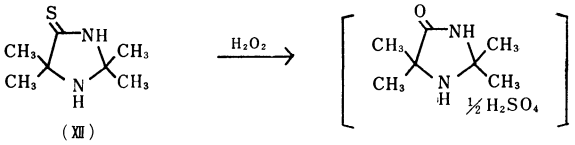
4'-thione)-5'-spiro-1''-cyclohexane (XI)[16] with hydrogen peroxide under similar conditions used in the oxidation of IIa gave white crystals. This product was identified as the sulfate of IIa by direct comparison of IR spectrum with that of an authentic sample prepared from IIa and sulfuric acid.

Treatment of XI with perbenzoic acid or excess hydrogen peroxide gave also the sulfate of IIa. Under similar reaction conditions, XII gave the sulfate of IIc.



(XI) (IIa)



(XII) (IIc)

This reaction would proceed analogously to that in which thiopyrin reacts with hydrogen peroxide in aqueous alkali to give antipyrin and sulfuric acid.[17]

Experimental

Melting points are uncorrected. The IR spectra were determined by means of Nujol mulls and liquid films. The NMR spectra were obtained using a Varian A-60 NMR spectrometer, using tetramethylsilane as the internal standard at 32°C. The mass spectra were obtained using a JEOL-JMS-OIS mass spectrometer. The ESR spectra were recorded on a Hitachi MES 4001 type X-band spectrometer employing 100 kc modulation and the splitting constants were measured relative to aqueous solution of Fremy's salt.

Synthesis of α-Amino Nitriles. α-amino nitriles were prepared from corresponding carbonyl compounds by the Strecker reaction.

4-Amino-4-cyano-2,2,6,6-tetramethylpiperidine. A solution of 2,2,6,6-tetramethyl-4-oxopiperidine[7] (31.0 g, 0.2 mol) in 50 m*l* of methanol saturated with ammonia were added slowly to stirred solution of potassium cyanide (26.0 g) and ammonium chloride (21.5 g) in 200 m*l* of aqueous ammonia (28%) and 60 m*l* of methanol saturated with ammonia at 0—5°C and the solution was stirred at room temperature for 9 hr. The resulting precipitates were removed by filtration and methanolic filtrate was evaporated under reduced pressure at room temperature. The organic layer was extracted with 200 m*l* of methyl ethyl ketone, dried over potassium carbonate and evaporated under reduced pressure to give crude 4-amino-4-cyanotetramethylpiperidine. Recrystallization from petroleum ether gave an analytical sample mp 75—76°C, yield 11.4 g (31.6%). Found: C, 66.45; H, 10.68; N, 23.33%. Calcd for $C_{10}H_{19}N_3$: C, 66.25; H, 10.57; N, 23.18%. IR (cm^{-1}): $\nu_{C\equiv N}$ 2240, ν_{NH} 3470, 3340, 3260, and 3170.

4-Amino-4-cyano-2,2,6,6-tetramethylpiperidine-1-oxyl. In the same manner described above, 34.6 g (0.2 mol) of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl[7] was reacted to give 4-amino-4-cyano-2,2,6,6-tetramethylpiperidine-1-oxyl as a red crystalline solid. Recrystallization from methanol gave an analytically pure sample: mp 129—130°C, yield 15.4 g (40.0%). Found: C, 60.99; H, 9.16; N, 21.42%. Calcd for $C_{10}H_{18}ON_3$: C, 61.19; H, 9.24; N, 21.42%. IR (cm^{-1}): $\nu_{C\equiv N}$ 2200, ν_{NH} 3360, and 3300. ESR (in benzene): a_N= 15.2 gauss.

Cyclization Reactions. In general, the products shown in Table 1 were prepared by the reaction of α-amino nitriles with carbonyl compounds in the presence of catalytic amount of aqueous sodium hydroxide (40%) in ethanol or methanol solution in the manner described below.

Cyclohexane-1-spiro-2'-(4'-oxoimidazolidine)-5'-spiro-1''-cyclohexane (IIa). To a stirred solution of 1-amino-1-cyclohexane (IV) (12.4 g, 0.1 mol) and cyclohexanone (9.8 g, 0.1 mol) in 50 m*l* of methanol was added 1 m*l* of aqueous sodium hydroxide (40%) and the solution was stirred at room temperature for 8 hr. The white product was sepapated (from solution) by filtration, washed with water and ethanol and dried under vacuum. The crude crystals, IIa were recrystallized from ethanol to give an analytically pure sample. IR (cm^{-1}): $\nu_{C=O}$ 1687, ν_{NH} 3300, 3220, and 3020.

Oxidation Reactions. The nitroxide radicals shown in Table II were prepared by oxidation of corresponding substituted imidazolidinones with hydrogen peroxide in a similar way as described previously.[5]

1,3-Diaza-2-phenyl-4-oxo-spiro[4.5]-1-decene-1-oxide (V). To a solution of 9.3 g (40 mmol) of IIi in 50 m*l* of methanol were added 75 mg of EDTA and 50 mg of sodium tungstate and then 20 m*l* of aqueous hydrogen peroxide (30%) with stirring at room temperature. Stirring was continued for 6 days at room temperature. The resulting precipitate was separated by filtration, washed with water and dried *in vacuo* to give 6.0 g (61.5%) of crude crystals, V. The crude crystals, V were recrystallized from methanol to give an analytically pure sample: mp 251—251.5°C. Found: C, 68.35; H, 6.66; N, 11.36%. Calcd for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%. IR (cm^{-1}): $\nu_{C=N\to O}$ 1588, 1564, and 1256, $\nu_{C=O}$ 1748. NMR (τ) (in DMF): 7.85—8.35 (10H, broad), 2.34—2.46 (3H, multiplet), 1.27—1.47 (2H, multiplet). Mass spectrum: M^+=244.

1,4-Diaza-2-phenyl-3-oxo-spiro[4.5]-1-decene-1-oxide (VII). From 21.5 g (95 mmol) of IIu, crude crystals, VII were obtained (15.0 g, 65.0%). Recrystallization from methanol gave an analytical sample: mp 259—261°C. Found: C, 68.60; H, 6.60; N, 11.24%. Calcd for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%. IR (cm^{-1}): $\nu_{C=N\to O}$ 1555, $\nu_{C=O}$ 1715. NMR (τ) (in DMF): 7.94—8.44 (10H, broad), 2.35—2.47 (3H, multiplet), 1.03—1.23 (2H, multiplet). Mass spectrum: M^+=244.

1,3-Diaza-2-n-propyl-4-oxo-spiro[4.5]-1-decene-1-oxide (VIII). In a similar manner as mentioned above, 6.3 g (32 mmol) of IIb gave 1.8 g (28.6%) of crude crystals, VIII. The crude crystals were recrystallized from cyclohexane to give pure sample: mp 182—183°C. Found: C, 62.99; H, 8.68; N, 13.38%. Calcd for $C_{11}H_{18}O_2N_2$: C, 62.83; H, 8.63; N, 13.32%. IR (cm^{-1}): $\nu_{C=N\to O}$ 1578 and 1242, $\nu_{C=O}$ 1705. Mass spectrum: M^+=210.

1,3-Diaza-2-phenyl-4-oxo-spiro[4.5]decene-1 (VI). A mixture of 3.4 g (14 mmol) of V and 3.7 g (14 mmol) of triphenylphosphine were heated at 270°C for 10 min. The reaction mixture was cooled, dissolved in minimum amount of benzene and chromatographed on a alumina column. Eluting with benzene afforded 2.7 g (87.0%) of VI: mp 178—181°C. Found: C, 74.05; H, 7.63; N, 11.70%. Calcd for $C_{14}H_{16}ON_2$: C, 73.63; H, 7.06; N, 12.27%. IR (cm^{-1}): $\nu_{C=N}$ 1625,

17) R. Kitamura, *Yakugaku Zasshi*, **58**, 676 (1938).

$\nu_{C=O}$ 1714. NMR (τ) (in DMF): 7.95—8.45 (10H, broad), 2.44—2.56 (3H, multiplet), 1.83—2.03 (2H, multiplet). mass spectrum: $M^+=228$. The methanol eluates yielded 1.5 g of triphenylphosphine oxide (mp 156°C) which was confirmed by comparison of IR spectrum with that of an authentic sample.

Sulfate of Cyclohexane-1-spiro-2'-(4'-oxoimidazolidine)-5'-spiro-1''-cyclohexane (IIa). To a solution of 2.4 g (10 mmol) of cyclohexane-1-spiro-2'-(imidazolidine-4'-thione)-5'-spiro-1''-cyclohexane (XI)[15] in 30 m*l* of acetic acid were added 11 mg of EDTA and 9 mg of sodium tungstate and then 30 m*l* of aqueous hydrogen peroxide (30%) at 0—5°C. The solution was stirred at room temperature for additional 1 hr. After the solvent had been evaporated under reduced pressure, a colorless crystalline mass remained. By the recrystallization from ethanol, the sulfate of IIa was obtained as an analytically pure sample: mp 230—231°C, yield 2.4 g (89.0%). Found: C, 57.32; H, 8.54; N, 10.33; S, 5.62%. Calcd for $C_{26}H_{46}O_6N_4S$: C, 57.54; H, 8.85; N, 10.05; S, 5.90%. IR (cm^{-1}): $\nu_{NH_2^+}$ 2000—2600, $\nu_{C=O}$ 1708.

Sulfate of 2,2,5,5-Tetramethyl-4-oxoimidazolidine (IIc). Similarly as described above, 3.2 g (20 mmol) of 2,2,5,5-tetramethylimidazolidine-4-thione (XII)[16] was converted into 2.3 g (60.2%) of sulfate of IIc: mp 236—237°C. IR (cm^{-1}): $\nu_{NH_2^+}$ 2100—2550, $\nu_{C=O}$ 1720.

The authors wish to thank professor Makoto Okawara of the Tokyo Institute of Technology for his valuable comments, Dr. G. Sunagawa, the director of these laboratories for his encouragement and Mr. Tomiji Tsuji for his technical assistance.

(Received July 19, 1971)

In order to examine the nature of charge and radical electron migration in mass spectral fragment ions, 5,5′-di-*n*-valeryl-2,2′-spirobiindan (**3**) was prepared and its mass spectrum was measured. The successive loss of two propylene molecules from the molecular ion to give peaks at *m/e* 346 (**b**) and 304 (**c**) was clearly indicated by observing appropriate metastable ion peaks. As the radical electron is one of the prerequisites for these fragmentations to occur, the results demonstrate that the charge and radical electron can migrate through sigma bonds in fragment ion **b**, since the two *n*-valerophenyl groups cannot be brought into close proximity even with C–C bond fission of the spiro ring. While the strongest peak at *m/e* 331 (**a**) is ascribable to the ordinary α-fission of the carbonyl group in **3**, a moderately intense peak at *m/e* 289 (**d**) can adequately be explicable by the similar α-fission of the carbonyl group in ion **b**, the process of which again involves radical electron migration prior to fragmentation.

Electron impact induced fragmentation patterns of organic compounds in a mass spectrometer have been widely rationalized with application of the concept of localized positive charge and localized unpaired electron in the molecular ion.[2] Wachs and McLafferty[3] presented a typical example using a series of substituted 1-(4-*n*-butyrophenyl)-2-phenylethanes (**1**). They suggested that the random removal of an electron from any part of a given molecule was followed by rapid localization of charge and unpaired electron at a particular site. The concept was shown by Howe and Williams[4] not to be inconsistent with the quasi-equilibrium theory of mass spectra.

In certain cases, however, a dynamic distribution of charge appears to operate in fragment ions. For instance, Mandelbaum and Biemann[5] examined mass spectra of 1,3-diphenylcyclopentane derivatives (**2**) of unknown stereochemistry, and concluded that charge would be free to migrate among distant functional groups, and the distribution of charge would be governed by the ionization potentials of the various sites. Kinstle and Oliver[6] also showed that charge would migrate in fragment ions in some instances, though it is difficult to predict the extent of charge mobility in a particular ion.

Although some proposals were made,[7] the precise

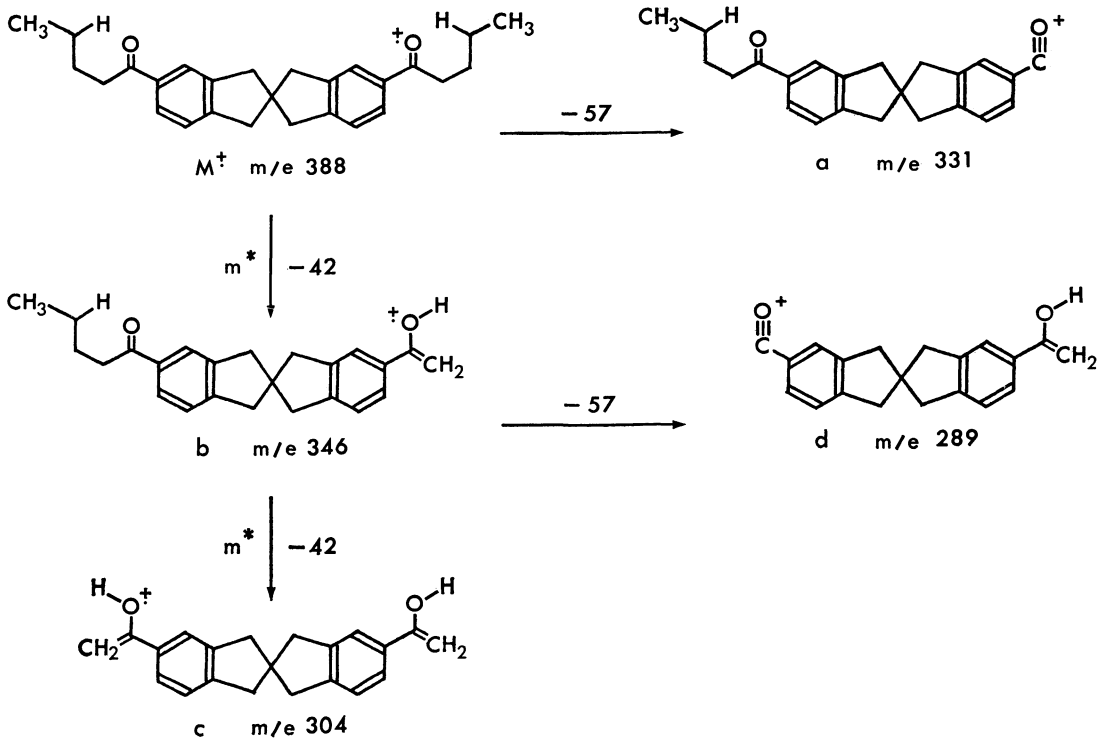
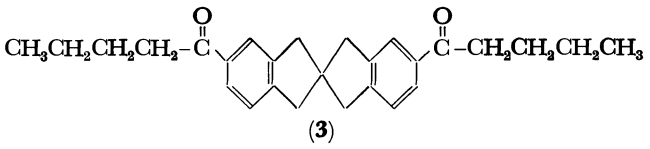


Scheme 1

mechanism of this charge and unpaired electron migration is still unknown. One obvious possibility is that the charge might transfer from one functional group to the other through the space, instead through the sigma bonds, if two groups approach closely enough to permit spatial overlap of their orbitals, as pointed out by Wagner.[8] In order to clarify this point, we have examined the mass spectrum of 5,5′-di-*n*-valeryl-2,2′-spirobiindan (**3**), which apparently cannot be in the conformation that the two phenyl groups approach each other.



(**3**)

Results and Discussion

5,5′-Di-*n*-valeryl-2,2′-spirobiindan (**3**) was prepared by Friedel-Crafts condensation of *n*-valeryl chloride with 2,2′-spirobiindan, which, in turn, was synthesized from diethyl dibenzylmalonate through 2,2′-spirobiindan-1,1′-dione according to the procedure of Leuchs *et al.*[9,10] The structure of the product was confirmed by IR, UV, and NMR spectral analyses (see, Experimental Section).

The mass spectrum of **3**, shown in Fig. 1, is fairly simple, and the fragmentation sequences are summarized in Scheme 1. As is seen, the molecular ion undergoes two competing fragmentations. An α-fission of the carbonyl group in one of the side chains with loss of a butyl radical produces a peak at *m/e* 331 (ion **a**), whereas the McLafferty cleavage gives a peak at *m/e* 346 (ion **b**). Although the peak at *m/e* 331 is the strongest in the spectrum taken at 70 eV, lowering of impact electron energies resulted the sharp decrease of its intensity relative to that of the ion **b**. This trend is in good agreement with the recent convincing argument[11] on the intensity ratio of peaks from simple cleavage and rearrangement reactions.

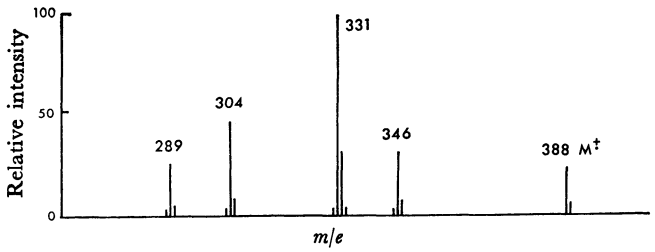


Fig. 1. The mass spectrum of 5,5′-di-*n*-valeryl-2,2′-spirobiindan (**3**).

The most pronounced feature of the spectrum is the appearance of a moderately intense peak at *m/e* 304. The well-defined metastable ion peaks were observed for the processes *m/e* 388 ($M^{+\cdot}$)→*m/e* 346 and *m/e* 346→*m/e* 304, indicating the successive elimination of two propylene molecules from the molecular ion. The exact mass measurement of the *m/e* 304 ion (**c**) (304.150) agreed with the calculated value of $C_{21}H_{20}O_2$ (304.146). With decreasing impact electron energies the intensity ratio of **c**/**b** markedly decreased, and this also suggests the step-wise fragmentation. These results clearly indi-

8) P. J. Wagner, *ibid.*, **3**, 1307 (1970).
9) H. Leuchs and D. Radulescu, *Ber.*, **45**, 189 (1912).
10) H. Leuchs and L. Lock, *Ber.*, **48**, 1432 (1915).
11) P. Brown, *Org. Mass Spectrom.*, **3**, 1175 (1970).

cate that the first McLafferty cleavage of one side chain in **3** was followed by the second McLafferty cleavage of the other side chain. Therefore, the transfer of the ion radical from one site to the other through several sigma bonds is required in the fragment ion **b**, as the radical electron is one of the prerequisites for mass spectral reactions to occur.

There would be three possible routes of formation of ion **d**, since ion **a**, **b**, or **c** could be a precursor ion. A route from ion **a** with elimination of propylene must involve a biradical ion intermediate generated by unpairing of the carbonyl π-electrons and may appear highly improbable.[12] This is also supported by the intensity ratio of **d**/**a** that was almost independent of impact electron energies. The alternative route from ion **c** with loss of a methyl radical may assume ketonization of ion **c** prior to fragmentation, and the process would not be important because enol-keto interconversion in a fragment ion was usually not observed.[13]

The most adequate explanation for the formation of ion **d** is, therefore, from ion **b** with loss of a butyl radical, as indicated in Scheme 1. Although the process is not confirmed by observing an appropriate metastable ion peak, this fragmentation reaction is mechanistically quite feasible, for it merely involves an α-fission of the carbonyl group. Thus, the fragmentation of **b** to **d** is, again, explicable only by assuming the radical electron migration in ion **b**.

Since in our compound **3** the two *n*-valerophenyl groups cannot be brought into close proximity even with C–C bond fission of the spiro ring, the above results clearly demonstrate that the charge and radical electron can migrate through sigma bonds. After completion of the present work, a paper by Lengyel, Uliss, and Mark on the same subject has appeared.[14] Their results are consistent with our. conclusions presented above. It is, however, still unknown whether or not any particular structural limitations and odd- or even-electronic nature of fragment ions can be correlated with the effective charge migration. Studies are in progress in our laboratory to attempt to provide further insight in such problems.

Experimental

All melting points were determined on a Kofler hot stage and are uncorrected. Infrared spectra (IR) were taken as potassium bromide disks using a Nihon Bunko IR-G instrument. Ultraviolet spectra (UV) were measured by a Hitachi EPS-3T spectrophotometer. Nuclear magnetic resonance spectra (NMR) were taken on a Varian A-60 spectrometer, and the peak positions are recorded in ppm from internal tetramethylsilane standard. Mass spectra were measured by a Hitachi RMU-7 mass spectrometer under the following conditions: ionizing voltage 70—14 eV, ion accelerating voltage 1800 V, total emission current 80 μA, ion source temperature 250°C.

5,5′-Di-n-*valeryl-2,2′-spirobiindan (3).* To a solution of 0.46 g of 2,2′-spirobiindan (mp 60—62°C)[9,10] in 10 m*l* of methylene dichloride, 0.55 g of *n*-valeryl chloride and 0.6 g of aluminum chloride were added and the mixture was allowed to stand for 26 hr at room temperature. After the addition of diluted hydrochloric acid under cooling, the mixture was extracted with chloroform. The extracts were combined and evaporated *in vacuo*. The residual brown oil was chromatographed on silica gel. The pure product of **3** was obtained by recrystallization from petroleum ether, mp 73°C, yield 0.56 g, IR (KBr) 1675 cm^{-1} (aromatic ketone); UV λ_{max}^{EtOH} 258 mμ (ε 30200); NMR (CCl_4) 0.94 (6H, deformed t, J=6 Hz), 1.1—2.0 (8H, broad m), 2.83 (4H, t, J=6 Hz), 2.93 (8H, s), 7.16 (2H, d, J=8 Hz), 7.67 (4H, m).

Found: C, 83.61, H, 8.03%. Calcd for $C_{27}H_{32}O_2$: C, 83.46; H, 8.30%.

Decomposition of Saturated Gaseous Hydrocarbons in Induction-Coupled Argon Plasma Jet

Yukio NISHIMURA, Arata SATOH, Kenjiro TAKESHITA, and Wataru SAKAI*

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

**Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka*

(Received August 31, 1970)

The decomposition of methane, ethane, and isobutane has been studied in an induction-coupled argon plasma jet at atmospheric pressure. Methane was decomposed to give mainly acetylene, soot, and hydrogen, and to give the traces of ethylene and ethane. From the dependence of both the conversion of methane and the product distribution on methane feed rate, the input and argon flow rate, it was concluded that methane was not completely mixed with the plasma jet but the decomposition of methane took place mainly in the outer flame of the plasma jet and its surroundings. In the decomposition of ethane, ethylene, and methane were formed in 20—27% and 3—5% selectivity based on carbon, respectively, in addition to acteylene, soot, and hydrogen. In the decomposition of isobutane, propylene was produced in 10—14% selectivity based on carbon, besides the above mentioned products. From these results together with those on propane and *n*-butane,it was suggested that radicals formed by a fission of C–H or C–C bond played the main role in the decomposition of saturated gaseous hydrocarbons in the induction-coupled argon plasma jet.

The thermodynamic calculation of the carbon-hydrogen system at pressures ranging from 0.1 to 10.0 atm suggests that among the products at equilibrium above 2500°K acetylene is the only gaseous hydrocarbon that is stable at room temperature.[1,2] It is also reported that in the reaction of graphite with hydrogen, the formation of acetylene is favored over that of methane and ethylene above 2500°K[3]. On the other hand, in the decomposition of propane[4] and *n*-butane[5] which are charged into the plasms jet countercurrently, methane and ethylene have been obtained in 5—8% and 16—20% selectivity based on carbon, respectively. Furthermore, we assumed in the previous paper[5] that the decomposition of *n*-butane occurred mainly in the outer flame of the plasma jet and its surroundings, and methane and ethylene were formed in the comparatively lower temperature region.

The present paper describes the decomposition of methane, ethane and isobutane, and discusses the region in which the decomposition of hydrocarbons occurs and the decomposition process of saturated gaseous hydrocarbons in the induction-coupled argon plasma jet.

Experimental

Material. Argon was supplied from Osaka Sanso Co. Methane, ethane, and isobutane were obtained from Seitetsu Kagaku Co. (above 99.0% purity) and were used without further purification.

Apparatus and Procedures. Details of the apparatus have been already given in the previous papers.[4,5] Hydrocarbons were countercurrently fed into the induction-coupled argon plasma jet through the spiral coil. The analysis of products was carried out by gas chromatography. Molecular sieve 13X column was used for the separation of hydrogen and methane, and 3% squalane supported on alumina column was used for the analysis of the other gaseous products. The conversion, the selectivity and the yield were calculated on carbon base. The selectivity and the yield of soot were estimated from the carbon balances.

Results and Discussion

Decomposition of Methane. The effect of operating conditions was discussed in terms of the conversion of methane and selectivities of carbon-containing products. Figure 1 shows the effect of methane feed rate on the conversion and the selectivities of carbon-containing products at 9.35±0.01 kW input and 1.56±0.02 *l*/min argon flow rate. Besides the products shown in Fig. 1,

a large amount of hydrogen and a trace of ethane were obtained. Acetylene and soot are formed in 56—65% and 34—42% selectivity, respectively, but the selectivity of ethylene reduced to less than 2%, in contrast to the case of the decomposition of *n*-butane in which ethylene was formed in 18—20% selectivity.[5] It is seen from Fig. 1 that the conversion decreases with increasing methane feed rate, while the product distribution reaches almost constant at higher feed rates of methane. A similar dependence of the conversion and the product distribution on hydrocarbon feed rate was also observed

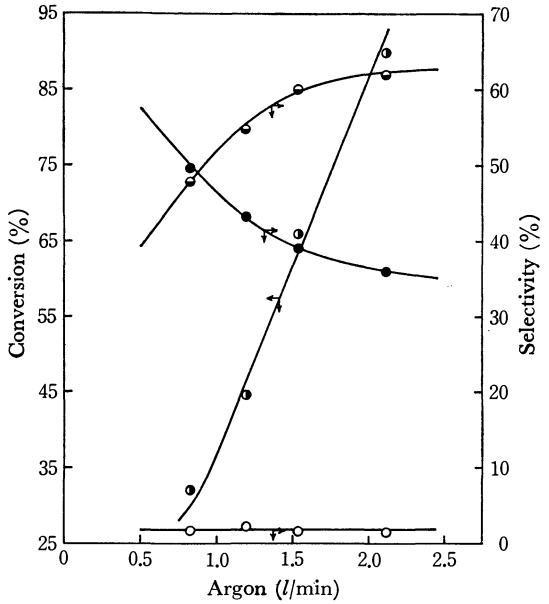

Fig. 3. Effect of argon flow rate on conversion of methane and selectivities of products.

for the decomposition of propane[4] and *n*-butane.[5] Figure 2 shows the effect of the input at 0.100±0.005 *l*/min methane feed rate and .1.56±0.02 *l*/min argon flow rate. The conversion of methane decreases almost linearly with the lowering of the input, but the product distribution is independent of the imput. On the other hand, it has been reported that in the decomposition of propane[4] and of *n*-butane,[5] the lowering of the input was inclined to decrease the selectivities of acetylene and soot, but to increase those of methane and ethylene. This reflects that more energies are required for the complete decomposition of propane and *n*-butane to atomic carbon and atomic hydrogen compared with that of methane to atomic carbon and atomic hydrogen.

Figure 3 shows the effect of argon flow rate at 0.100± 0.005 *l*/min methane feed rate and 9.35±0.01 kW input. As for *n*-butane,[5] the conversion decreases markedly with reducing argon flow rate. At the same time, the lowering of argon flow rate decreases the selectivity of acetylene and increases that of soot. At argon flow rate below 0.82 *l*/min, the formation of soot tends to be favored over that of acetylene, and from the thermodynamic consideration[1,2] it suggests that the decomposition temperature rises with reducing argon flow rate. On the other hand, as shown in Fig. 4, ArI line (4158

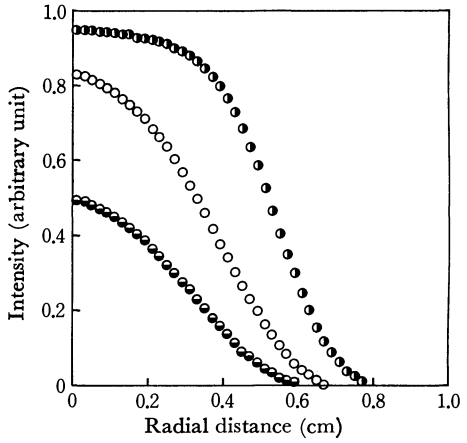

Fig. 4. Radial intensity profiles of ArI (4158 Å) at a distance of 1 cm from methane inlet at various argon flow rate.
-◒- 1.19 *l*/min, -○- 1.56 *l*/min, -◑- 2.12 *l*/min

Å) is observed at a distnace of 1 cm from the methane inlet and its intensity decreases with the lowering of argon flow rate. These results suggest that at the higher argon flow rate, the comparatively high temperature region extends over the neighborhood of the methane inlet and methane can be decomposed in this region. But the decomposition temperature is presumed to be lower in this region than in the upstream of the plasma jet since it has been reported that the temperature of the induction-coupled argon plasma jet dropped toward the downstream of the plasma jet.[6] Therefore, the decomposition at the lower argon flow rate occurs apparently at the higher temperature. These results further suggest that methane is not completely mixed with the plasma jet. That is, from the results stated above together with those on the decomposition of propane[4]

and of *n*-butane,[5] we may conclude that saturated gaseous hydrocarbons are not completely mixed with the plasma jet but the decomposition of these hydrocarbons takes place predominantly in the outer flame of the plasma jet and its surroundings under the condition that hydrocarbons are charged into the plasma jet countercurrently.

Decomposition of Ethane and Isobutane. As stated above, the decomposition of methane gave mainly acetylene, soot, and hydrogen with a small amount of ethylene. Consequently, we studied the decomposition of ethane and isobutane in order to know the effect of the structure of hydrocarbons on the conversion, the product distributions and formation processes of methane and ethylene in the decomposition of propane and

Table 1. Selectivities of carbon-containing products in isobutane decomposition

i-C_4H_{10} (*l*/min)	Selectivity of product (%)					
	CH_4	C_2H_6	C_2H_4	C_3H_6	C_2H_2	Soot
0.056	9.7	1.3	10.1	10.7	42.0	26.2
0.073	9.8	2.1	9.5	9.7	45.7	23.2
0.092	9.1	1.3	9.6	10.8	43.4	25.8
0.108	10.1	2.3	10.3	12.6	41.2	23.5
0.131	11.7	1.9	11.3	13.6	37.8	23.7
0.154	11.7	1.5	11.6	13.3	37.1	24.8
0.221	11.3	1.7	11.3	11.6	40.5	23.6

n-butane. Ethane and isobutane were decomposed under the same condition as methane were. Figure 5 shows the variation of conversion of ethane and isobutane with the feed rate of hydrocarbons. Conversions of methane, propane and *n*-butane are included in Fig. 5 for comparison. It is seen from Fig. 5 that the saturated gaseous hydrocarbons become difficult to be decomposed as carbon chains increase and both butane isomers are decomposed in the similar way.

Figure 6 and Table 1 show selectivities of products at various feed rates of ethane and isobutane, respectively. In ethane, appreciable amounts of methane and ethylene are obtained in addition to acetylene, soot, and hydrogen. Especially, ethylene is obtained in 20—27% selectivity. In isobutane, the selectivity of ethylene reduces to 10—12%, but propylene is obtained in 10—14% selectivity and methane is formed in higher selectivity than in the decomposition of ethane, propane,[4]

Table 2. Yields of decomposition products in various hydrocarbons
Hydrocarbon: 0.100±0.005 *l*/min, Ar: 1.56±0.02*l*/min, Input: 9.35±0.01kW

Hydrocarbon	Yield (%)						
	CH_4	C_2H_4	C_2H_6	C_3H_6	C_3H_8	C_2H_2	Soot
CH_4	—	1.0	trace	—	—	40.0	25.5

C_3H_8	3.1	8.3	trace	2.9	—	19.8	14.4
n-C_4H_{10}	2.6	8.5	trace	1.1	trace	17.6	10.5
i-C_4H_{10}	4.1	4.0	0.9	5.1	—	16.1	9.3

and *n*-butane.[5] Table 2 illustrates the products and their yields for the decompositions of methane, ethane, propane, *n*-butane, and isobutane at the hydrocarbon feed rate of 0.100±0.005 *l*/min. As is seen from Table 2, the decomposition products and their distributions closely relate with the structure of hydrocarbons. In the decomposition of methane, major products are acetylene, soot, and hydrogen. Acetylene and soot occupy above 98% of carbon-containing products. Thus, methane introduced into the decomposition region is decomposed almost to carbon and hydrogen, and then, acetylene, soot, and hydrogen are formed. That is, the decomposition of methane is assumed to proceed *via* following steps;

$$CH_4 \longrightarrow CH_3 \longrightarrow CH_2 \longrightarrow CH \longrightarrow C_1 \quad (1)$$

$$2C_1 \longrightarrow C_2 \quad (2)$$

$$C_1 + CH \longrightarrow C_2 + H \quad (3)^{7)}$$

$$C_2 + H \longrightarrow C_2H \xrightarrow{H} C_2H_2 \quad (4)$$

$$2CH \longrightarrow C_2H_2 \quad (5)$$

$$nC_1 \longrightarrow C_n \xrightarrow{H} C_nH \quad (6)$$

$$C_1, C_2, \cdots\cdots C_n \longrightarrow C_s \quad (7)$$

$$CH, CH_2, CH_3, C_2H, \cdots\cdots C_nH \longrightarrow C_s + H_2 \quad (8)$$

$$H + H \longrightarrow H_2 \quad (9)$$

where C_s: soot

It is difficult to explain the formation process of ethylene, but it may be concluded that ethylene is formed from carbon and hydrogen under the condition used in this experiment. Saturated hydrocarbons with two or more carbon atoms are decomposed to give appreciably byproducts such as methane, ethylene, or propylene, in addition to acetylene, soot, and hydrogen. If these hydrocarbons are decomposed mostly to carbon and hydrogen, and then, a large portion of methane, ethylene, or propylene is formed, a similar product distribution must be obtained in the decomposition of both *n*-butane and isobutane. The high selectivity of propylene in isobutane decomposition gives the strong support for the intervention of isopropyl radical in the decomposition step.[8] Therefore, it may be concluded that radicals formed by a fission of C–H or C–C bond intervene in the decomposition of saturated gaseous hydrocarbons in the induction-coupled argon plasma jet. That is, these radicals are decomposed to give appreciably methane, ethylene, or propylene, *etc.* at the comparatively lower temperature region in the reaction zone. At the higher temperature region in the reaction zone, these radicals are further decomposed to carbon and hydrogen, and then, acetylene, soot, and hydrogen are produced. For example,

$$C_2H_6 \longrightarrow 2CH_3 \quad (10)$$

$$C_2H_6 \longrightarrow C_2H_5 + H \quad (11)$$

$$C_2H_6 + H \longrightarrow C_2H_5 + H_2 \quad (12)$$

$$C_2H_6 + CH_3 \longrightarrow C_2H_5 + CH_4 \quad (13)$$

$$C_2H_5 \longrightarrow C_2H_4 + H \quad (14)$$

$$C_2H_5 + C_2H_5 \longrightarrow C_2H_4 + C_2H_6 \quad (15)$$

$$CH_3 + H \longrightarrow CH_4 \quad (16)$$

in the decomposition of ethane, methyl and ethyl radicals are formed by the reactions (10), (11), (12), and (13).[9–11] In the lower temperature region, methane and ethylene are formed from these radicals by the reactions (13), (14), (15), and (16). In the higher temperature region, methyl and ethyl radicals are further decomposed to carbon and hydrogen or partly to methyne and methylene radicals, and then, acetylene, soot, and hydrogen are formed through the same process as that for methane decomposition.

Anodic Oxidation of Anthracene in Acetonitrile at a Rotating Ring-disk Electrode

Tetsuaki KIHARA, Kazuo SASAKI,* and Haruo SHIBA
Department of Applied Chemistry, Hiroshima University, Sendamachi, Hiroshima
(Received October 30, 1970)

Although many works have been reported on anodic oxidation of anthracene, there still remains some uncertainty as to its detailed mechanism.

Bard and his coworkers,[1] who studied the reaction in methylene chloride with linear potential sweep technique, reported that the oxidation product undergoes a rapid follow-up chemical reaction. Oxidation in pyridine media[2] gives rise to the formation of 9,10-dihydroanthranyl dipyridinium perchlorate indicating the reaction intermediate to be anthracene dication. The product obtained by the controlled potential electrolysis in acetonitrile was bianthrone.[3]

Anodic oxidation of anthracene has also been studied in relation to electro-chemiluminescence.[4-9] Although many of these studies suggest that it proceeds through two successive one-electron transfer, no definite proof for the formation of one-electron intermediate, anthracene monocation, has been reported. As an only exception, Peover and White,[10] who studied the oxidation of several polycyclic hydrocarbons by means of cyclic voltammetry, stated that a poorly developed cathodic current due to the reduction of anthracene monocation was detectable at high scan-rates. Application of cyclic potential sweep technique is, however, limited by the rate of charge transfer step. If the rate is not rapid enough the current-potential curve observed at high scan-rates becomes deformed and allows no quantitative analysis.

A rotating ring-disk electrode is receiving growing attention[11-14] as a powerful tool for studies of labile intermediates of an electrode reaction. We have attempted to apply this new technique to the reaction concerned.

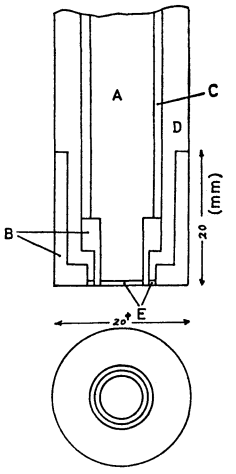

Fig. 1. Cross section of rotating ring-disk electrode. A, shaft (SS45C); B, teflon; C, bakelite; D, copper; E, platinum.

The shape and size to the ring-disk electrode used is schematically shown in Fig. 1. Platinum was used for both ring and disk electrodes. The maximum eccentricity of the electrode caused by rotation was found within 0.01 mm at a periphery of bottom surface. Potentials of both the ring and disk electrodes were independently controlled using a couple of electronic potentiostats. Currents flowing through the electrodes were respectively recorded by two X-Y recorders. The collection efficiency which is defined as the ratio of ring current to disk current was determined experimentally by measuring two representative redox reactions of $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ and Cu(I)/Cu(II) couples. The values determined from the two reactions were exactly in agreement with 0.36. These values can be compared to the theoretical one, 0.40, calculated according to the Albery-Bruckenstein's equation.[11] Acetonitrile was used as a solvent and was purified carefully according to the directions of O'Donnell *et al.*[15] 0.1M tetrabutylammonium perchlorate was used as a supporting electrolyte.

Prior to measuring anthracene, the reaction of 9,10-diphenylanthracene (DPA) known to give a stable monocation was studied. Curves A and B in Fig. 2 represent currents flowing through disk and ring elec-

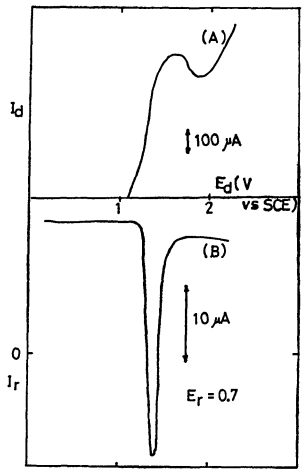

Fig. 3. I-E curves of anthracene.
(A) disk current, (B) ring current with ring potential set at 0.7 V. Solution, 10^{-3}M ANT in acetonitril. Supporting electrolytes, 0.1M tetrabutylammonium perchlorate. Rotation speed, 940 rpm. Sweep rate of disk potential, 40 sec/V.

trodes, respectively, as a function of linearly changing potential of the disk electrode. It should be noted that these curves were obtained by changing the disk potential linearly and fixing the ring potential constant at 0.8 V. Curve C is a background disk current observed in a solution containing no DPA.

The results with DPA can be summarized as follows.

1) DPA is anodically oxidized through two one-electron steps since curve A consists of two waves of approximately equal height.

2) Product at the first wave, DPA monocation, is quite stable and gives rise to a hump-like strong cathodic current at the ring electrode (curve B). The collection efficiency for this species was 0.36.

3) Product at the second anodic wave, DPA dication formed at the potential range of 1.7 to 2.4 V, is labile and undergoes rapid chemical reaction with surroundings. As a result, the ring current diminishes markedly at this potential range.

A small but definite deflection of the disk current appears before the final rise and a corresponding deflection appears also in the ring current. The species responsible for this is uncertain.

Similar curves for unsubstituted anthracene (ANT) are shown in Fig. 3. Disk current exhibits a single wave with the same height as that found in the second wave of DPA. This seems to indicate that the oxidation of ANT proceeds in one step with two electron transfer, $ANT \rightarrow ANT^{2+} + 2e$. However, a sharp rise of cathodic current appearing in the ring current suggests that the electroactive species for this ring current is the monocation of anthracene, ANT^+, rather than its dication. In the case of DPA, the two-electron product was inactive to the ring current. It was reported[16] that the cathodic counterpart of DPA^{2+} appears at a much more negative potential than that of DPA^+. This may be also the case in the oxidation of ANT. A close resemblance in the behavior of ring currents shown in Figs. 2 and 3 strongly suggests that ANT is also oxidized through a consecutive two one-electron steps.

The collection efficiency for the ring-active species, ANT^+, was as low as 0.052 indicating that the species is quite labile. If anthracene monocation undergoes a pseudo-first order reaction during the movement from disk to ring electrode, the fraction f which is collected by the ring electrode can be estimated by the equation

$$f = Ncal\, 2^{-\Delta t/\tau}$$

Transformation of this equation gives

$$\tau = -\Delta t \log 2 / \log (f/Ncal),$$

where $Ncal$ is the calculated collection efficiency, τ the half-life time of anthracene monocation and Δt the mean transit time from disk to ring. Under normal conditions, Δt was estimated to be 0.02—0.1 sec. Corresponding half-life time of ANT^+ is in the range 0.7—3.4×10^{-2} sec. This figure is in agreement with the value estimated roughly as "a few millisecond" by Peover.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3459—3460(1971)

An Investigation of the Stability Constant of the 2,3-Dihydroxybenzoic Acid Complex with Copper(II)

Hikaru HARADA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received December 4, 1970)

It has been shown that the stability constants of some metal complexes with tiron (disodium 1,2-dihydroxybenzene-3,5-disulfonate) are larger than those with catechol.[1] This is contrary to what is to be expected from their acid dissociation constants.[2,3]

As this peculiarity seemed to come from the fact that tiron has a negative sulfonic group in the vicinity of the OH group which coordinates to a metal ion, 2,3-dihydroxybenzoic acid (DBA) was used to see whether the COOH group gives any larger stability to the metal-DBA complex. Another problem, however, may rise about this ligand; as DBA is a derivative of salycilic acid with the OH group at the 3 position, there are two possible types of chelation in the complex, namely, the catechol-type and the salycilic acid-type chelate.

Experimental

All the measurenents were carried out by using the same apparatus as was reported previously:[2,4] the reaction vessel and the quartz cell for the measurement of the absorbancy were connected by a Teflon tube. All the reaction solutions were prepared and mixed in a purified nitrogen atmsphere; then the absorbancy and the pH were simultaneously measured. During the measurements, constant-temperature water of 25.0±0.1°C was circulated through the double walls of the reaction vessel. Sodium perchlorate was used to make ionic strength 0.1. The DBA was recrystallized twice from water just before the measurements.

TABLE 1. ACID DISSOCIATION CONSTANTS OF DBA AND RELATED CATECHOL DERIVATIVES

Ligand	pK_{HL}	pK_{H_2L}	pK_{H_3L}
DBA	11.68	9.84	3.10
3,4-Dihydroxybenzoic acid[a)]	11.65	8.89	4.61
Tiron[b)]	11.96	7.89	
Catechol[a)]	12.03	9.32

2) Y. Oka and H. Harada, *ibid.*, **88**, 441 (1967).
3) This problem has also been pointed out in the paper by R. F. Jameson (*J. Inorg. Nucl. Chem.*, **28**, 2667 (1966)), but no explanation is to be found there.
4) H. Harada, *Nippon Kagaku Zasshi*, **90**, 207 (1969).

Results and Discussion

The acid dissociation constants of DBA were obtained by the method previously used with catechol derivatives.[4] The results are shown in Table 1. The larger K_{H_3L} values and the smaller K_{H_2L} value of DBA than the respective values of 4-carboxy catechol may be due to the formation of a hydrogen bond between the OH and COOH groups of DBA through the H atom of the OH group.

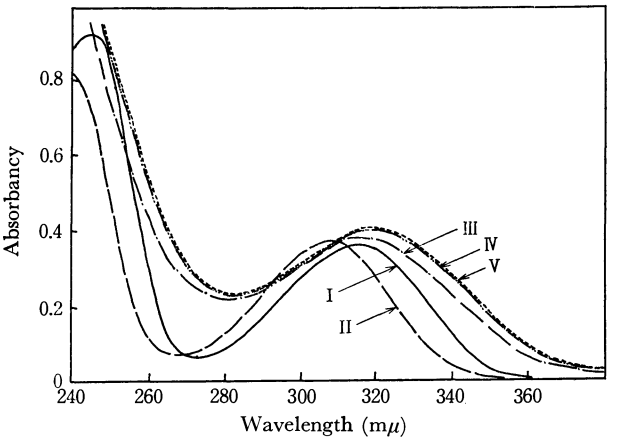

Fig. 1. pH dependence of absorption curve of Cu(II)-DBA system.
pH: I, 2.24 (——)
II, 4.14—4.80 (— —)
III, 5.95 (—·—)
IV, 7.20 (—··—)
V, 7.54 (---------)
concentration:
$Cu(ClO_4)_2$, 1.103×10^{-4} mol/*l*
DBA, 1.103×10^{-4} mol/*l*

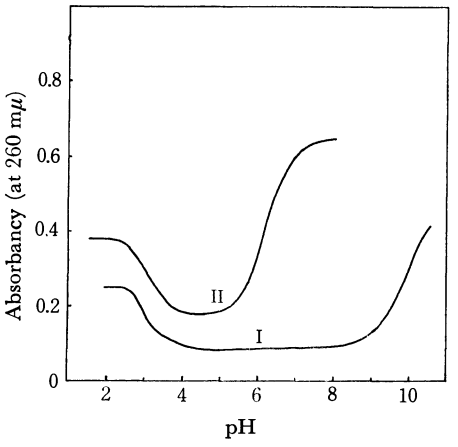

Fig. 2. pH dependence of absorbancy at 260 mμ.
Curve I: DBA
II: Cu(II)+DBA

The stability constant of the Cu-DBA (1: 1) chelate was obtained in a manner to be described below. The absorption spectra of the solution containing the Cu(II) ion and DBA are shown in Fig. 1. The pH-dependence of absorbancy change at 260 mμ is shown in Fig. 2, together with that of the ligand itself.

As is shown in Fig. 2, the decrease in absorbancy at about pH 3 can be ascribed to the dissociation of the carboxyl group of DBA, as was expected from its pK_{H_3L} value.

On increasing the pH, the absorbancy also increased in the pH range from 5.5 to 6.5; this increase was attributed to the formation of the complex.

Here, it is assumed that the Cu-DBA (1: 1) chelate is formed in the pH 5.5—6.5 range according to the following equation:

$$Cu + H_2L = CuL + 2H \quad (1)$$

The equilibrium constant of this reaction may be described as:

$$K_1 = \frac{[CuL][H]^2}{[Cu][H_2L]} \quad (2)$$

When the solution is prepared to make the concentrations of Cu and DBA equal (1.084×10^{-4} mol/l) and when its hydrogen ion concentration is varied, the following equation (reported previously[5]) is obtained:

$$A - a\varepsilon_{H_2L} = a(\varepsilon_{CuL} - \varepsilon_{H_2L}) - [H](A - a\varepsilon_{H_2L})^{1/2}\left(\frac{\varepsilon_{CuL} - \varepsilon_{H_2L}}{K_1}\right)^{1/2} \quad (3)$$

where A is the absorbancy, a is the concentration of the Cu ion and also that of DBA, and ε_{H_2L} and ε_{CuL} are the molar extinction coefficients of DBA and CuL respectively.

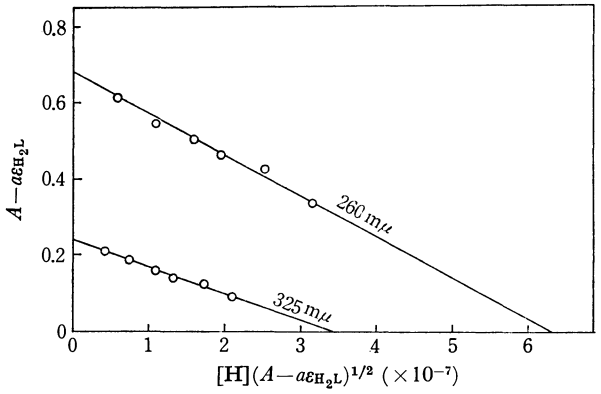

Fig. 3. Relation between $A-a\varepsilon_{H_2L}$ and $[H](A-a\varepsilon_{H_2L})^{1/2}$.
concentration: $Cu(ClO_4)_2$: 1.084×10^{-4} mol/l
DBA: 1.084×10^{-4} mol/l

5) H. Harada, *Nippon Kagaku Zasshi*, **91**, 1064 (1970).

If a plot of $[H](A-a\varepsilon_{H_2L})^{1/2}$ on the right-hand side against $A-a\varepsilon_{H_2L}$ on the left-hand side of Eq. (3) is linear, the variation in absorbancy over the pH 5.5—6.5 range can be considered to be due to the formation of the 1: 1 chelate by means of Eq. (1). Figure 3 indicates that the linear relation holds. The division of the intercept of the line by the square of the slop and again by the concentration of Cu(=DBA), a, gave K_1. The value of K_1, thus obtained was divided by the acid dissociation constant of DBA; then the stability constant of the 1: 1 chelate, k_1, was obtained.

Table 2. Stability constants of Cu(II)-complexes with DBA and related catechol derivatives

Ligand	log k_1
DBA	13.24
Salycilic acid[a)]	10.64
Catechol[b)]	13.50
3,4-dihydroxybenzoic acid[b)]	13.15
Tiron[c)]	14.43
3,5-Dinitrocatechol[d)]	10.45

a) from A. E. Martell and L. G. Sillén, "Stability Constants of Metal Ion Complexes. Section II, Organic Ligands," Chemical Society, London (1964).
b) H. Harada and Y. Oka, *Nippon Kagaku Zasshi*, **90**, 898 (1969).
c) Y. Oka, N. Nakazawa, and H. Harada, *ibid.*, **86**, 1158 (1965).
d) K. S. Math, K. A. Ven Katachalam, and M. B. Kabadi, *J. Indian Chem. Soc.*, **36**, 65 (1959).

As is shown in Table 2, the k_1 value of Cu-DBA is 13.24, which is much nearer to the k_1 value of Cu-catechol (13.50) than to the k_1 value of Cu-salycilic acid (10.64). It can, therefore, be concluded that the DBA in the Cu-complex has a catechol-type-chelation.

When the stability constant of Cu-tiron is compared with that of Cu-DBA, which has a 3-carboxyl group, it can be noticed that Cu-tiron has an appreciably higher value. It seems that the higher stability constant of tiron is not caused by the ordinary substitution effect of the 3-position substituent.

It is supposed that the sulfonic group is more strongly solvated by water than the carboxyl group; hence, the degree of desolvation may also be larger in the sulfonic group when the Cu-chelate is formed. It can perhaps be concluded that the entropy change for the complex formation contributes greatly to the higher stability constant of the Cu-tiron chelate.

Formation Constants of Several Copper(II) Alkylthioacetates in a Dioxane-Water Solvent

Akira OUCHI, Toshio TAKEUCHI, and Yayoi OHASHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received January 14, 1971)

Recently the present authors synthesized and studied the alkylthioacetates of several metals in the solid state.[1-3] Concerning the stability of alkylthioacetato complexes, Irving[4] and Sandell[5] have published the formation constants of some ethylthioacetates of some metals, and Yamasaki[6] has reported on the phenylthioacetates of some metals. Recently Pettit[7] has studied the silver complexes of a series of alkylthioacetic acids and found a linear relation between their stabilities and the Taft σ^* values of their alkyl groups. However, the relation has not yet been examined with regard to the complexes of other metals. Consequently, it seems interesting to furnish the formation-constant data of the copper(II) complexes of a series of alkylthioacetic acids.

Experimental

Materials. *Alkylthioacetic acids*: Methyl-, ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, isobutyl-, *s*-butyl-, and benzylthioacetic acids were synthesized by the method described in the papers of Larsson[8] and Pettit.[7] They were used after the redistillation under reduced pressure.

1,4-Dioxane: G. R.-grade reagent of the Wako Chemical Co., Ltd. was used after being purified according to the directions of Riddich and Toops.[9]

All other reagents were G. R. reagents of the Wako Chemical Co., Ltd., and were used without any further purification.

General Procedure. The techniques employed were those of Calvin.[10] A Toa Denpa Co. model HM-5A pH meter, a saturated calomel electrode, and a glass electrode were used. All the measurements were made at 30.0 ± 0.1°C. The pH meter was standardized against aqueous buffer solutions (6.86 and 4.00) of the Wako Chemical Co.

The Measurement of the Acid Dissociation Constants: 25 m*l* of dioxane, 5 mmol of potassium nitrate, and 1 mmol of alkylthioacetic acid were diluted to 50 m*l* with water. The sample was titrated with a 1.000N sodium hydroxide standard aqueous solution[11] to record the pH meter reading (B): the B value of the half-neutralization point on the titration curve was thus obtained. pK_D, where K_D is the acid dissociation constant, was obtained by $pK_D=B+(\log U_H^0+\log 1/\gamma)$ where U_H^0 is a conversion factor independent of the ionic concentration and where the γ is the activity coefficient of the strong electrolytes in the solution; they were conveniently obtained by means of the diagram of Uitert.[12]

The Determination of the Formation Constants of the Complexes. 25 m*l* of dioxane, 4 mmol of potassium nitrate, 1 mmol of nitric acid, 0.1 mmol of metal nitrate, and 1 mmol of the ligand were mixed and diluted to 50.00 m*l* with water. The sample was thermostatted more than 4 hr to attain the equilibrium. However, to avoid the effect of decomposition, the sample was titrated within 6 hr after the dissolution. Each run was repeated 4 times, and the average readings were adopted. No precipitation was found during the process ($\bar{n}<2$). The calculation of the formation constants, including the correction for the effect of the dioxane solution, was made as has been described by Calvin,[10] Uitert,[12-14] and Goldberg.[15]

Results and Discussion

A typical run of the data and the results of the calculations are shown in Table 1. The acid dissociation constants obtained, as well as the formation constants of copper(II) complexes of alkylthioacetates are shown in Table 2.

The dissociation constants of these acids are almost all the same. This fact suggests that the inductive effect of the alkyl group does not seriously affect the carboxyl group, as they are separated by a $-S-CH_2-$ group. On the other hand, the coordination ability of sulfur atom should be affected by the alkyl group.

10) M. Calvin and K. W. Wilson, *J. Amer. Chem. Soc.*, **67**, 2003 (1945).
11) As the sample was titrated with sodium hydroxide aqueous solution, the concentration of dioxane was not always 50% during the titration. Consequently, the conversion factors of each dioxane concentration were used for each of the calculations, assuming that the total volume was obtained by the addition of both volumes. In these regions the difference of $(U_H^0+\log 1/\gamma)$ per 1% difference of dioxane concentration is about 0.02. Therefore the above correction is enough to keep the calculation error below 0.01, and the difference of pK_D and $\log K$ values in this dioxane concentration region is expected to be below 0.02. In Table 2, the concentration of dioxane was shown as 50%. It is only the approximate concentration where the data were obtained, even though the error from the value at 50% is expected to be below 0.02.

(Ch$^-$): Mole concentration of the monovalent chelate anion Ch$^-$.
$\bar{n}$: The number of coordinated ligand molecules per one metal ion.

Table 2. The dissociation constants and the formation constants of copper(II) complexes of alkylthioacetic acids in 50% dioxane[11] at 30°C

Metal Ligands (R=)	H^+ log K_1	Cu^{2+} log K_1	Cu^{2+} log K_2
$C_6H_5\cdot CH_2-$	-5.7_3	3.0	2.4
CH_3-	-5.5_6	3.4	2.7
C_2H_5-	-5.6_6	3.5	2.7
C_3H_7-	-5.6_8	3.5	2.9
$(CH_3)_2CH\cdot CH_2-$	-5.5_5	3.5	2.8
C_4H_9-	-5.6_6	3.6	2.9
$(CH_3)_2CH-$	-5.5_9	3.6	2.8
$(CH_3)(C_2H_5)CH-$	-5.6_6	3.6	2.8

Ligands are $RSCH_2COOH$ where R s are shown in the column above.

The relationship between the formation constants (in log *K*) of the copper complexes and the Taft σ* functions[16] of the substituent, R, for the $R\cdot S\cdot CH_2CO_2H$ ligand is shown in Fig. 1. As is shown in the figure, there is almost a linear relationship between them. This fact also seems to prove the existence of the sulfur-metal bond in the copper complexes, even in the solution.

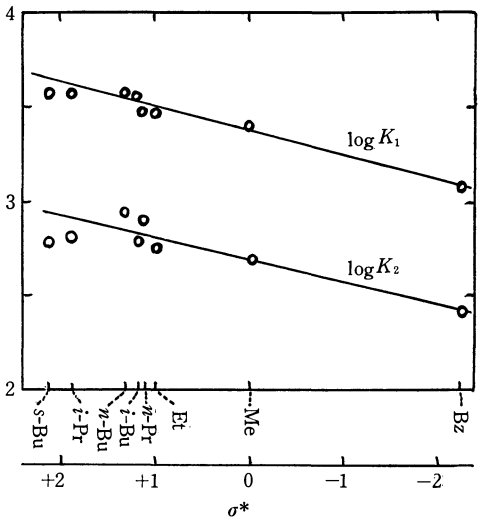

Fig. 1. The relationship between the formation constants of the copper(II) complex and the Taft σ* functions of the substituents R for the ligands $R\cdot S\cdot CH_2COOH$.
R of the ligansd are as follows: Bz : $C_6H_5CH_2$, Me : CH_3, Et : C_2H_5, *n*-Pr : C_3H_7, *i*-Pr : $(CH_3)_2CH$, *n*-Bu : C_4H_9, *i*-Bu : $(CH_3)_2CH\cdot CH_2$, *s*-Bu : $(C_2H_5)(CH_3)CH$

The points of isopropyl- and *s*-butyl-thioacetates, however, all a little lower than the line; this is probably due to the difficulty of the complex formation because of the steric effect of the ligand.

The authors wish to thank Professor Yukichi Yoshino and our colleagues of this laboratory for their helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3463—3464(1971)

The Reduction of Some Quinones and Enones by Ferrocene in the Presence of Aluminum Chloride

Yoshimori OMOTE, Ryuichiro KOBAYASHI, Choji KASHIMA, and Noboru SUGIYAMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received March 3, 1971)

Ferrocene is known to be easily oxidized in the presence of an acid to give ferricinium ion.[1-4] One of us reported that the reaction of ferrocene with fumaroyl chloride in the presence of aluminum chloride did not give 1,2-di(ferrocenylcarbonyl)ethylene, but afforded 1, 2-di(ferrocenylcarbonyl)ethane and β-(ferrocenylcarbonyl)propionic acid.[5] Schaaf and Lenk[6] reported the oxidation of ferrocene in the Friedel-Crafts reaction of ferrocene with some acyl or aroyl chlorides.

We now wish to report our finding that some quinones and enones are reduced by ferrocene in the presence of aluminum chloride to give phenols and saturated ketones respectively.[7] The limitation of the reaction is also examined.

Reduction of Quinones by Ferrocene. Coan *et al.*[8] found the formation of a charge-transfer complex of ferrocene with *p*-benzoquinone or chloranil, but they failed to isolate the complex. We examined the reaction of *p*-benzoquinone with ferrocene in dichloromethane in the presence of aluminum chloride and found that the products were hydroquinone and ferricinium chloride in the molar ratio 1: 1.8. Chloranil and ferrocene afforded tetrachlorohydroquinone and ferricinium chloride in a molar ratio 1: 1.7 under similar conditions.

Thus it might be concluded that two moles of ferrocene react with one mole of a quinone to give two moles of ferricinium ion and one mole of the corresponding hydroquinone.

Reduction of Enones by Ferrocene. The reduction of a variety of enone compounds and other olefinic compounds by ferrocene in the presence of aluminum chloride has been checked. The results are summarized in Table 1 from which it might be concluded that an enedione structure –COCH=CHCO– is essential for the reduction by ferrocene.

As regards stoichiometry of this reaction, the reduction of 1,2-dibenzoylethylene by ferrocene was examined in detail. When 1,2-dibenzoylethylene was brought into reaction with ferrocene in the presence of aluminum chloride in a molar ratio 1: 1: 2 (substrate: ferrocene: aluminum chloride), about half of the substrate was reduced to 1,2-dibenzoylethane, and ferrocene gave ferricinium ion in the molar ratio 1: 1.9 (product: ferricinium ion). This reveals that one mole of an enone whose structure contains –COCH=CHCO– is reduced by two moles of ferrocene.

Table 1. Reducibility of some enones compared with that of some olefinic compounds

RCH=CR′R″

R	R′	R″	Reducibility
C_6H_5CO–	C_6H_5CO–	H–	+
C_6H_5CO–	HOOC–	H–	+

C_6H_5–	C_6H_5–	H–	–
–$CH_2CH_2CH_2CH_2$–		H–	–
C_6H_5–	HOOC–	H–	–
CH_3–	HOOC–	H–	–
CH_3CO–	CH_3–	CH_3–	–
FcCO–	C_6H_5–	H–	–

Fc: Ferrocenyl

Experimental

Quinones, Enones and Related Compounds. The following compounds were prepared according to literature: bromosuccinic anhydride,[9] bp_{25} 148°C, β-benzoylacrylic acid,[10] mp 94—95.5°C, 1,2-diacetylethylene,[11] mp 76—79°C, *trans*-1, 2-dibenzoylethylene,[12] mp 108°C, *trans*-β-acetylacrylic acid,[13] mp 125—126°C. Other compounds used were commercial products.

Reduction of p-*Benzoquinone by Ferrocene.* Aluminum chloride (0.39 g, 2.94 mmol) and *p*-benzoquinone (0.11 g, 1.02 mmol) were added into 35 m*l* of dry dichlolomethane and stirred for 5 min. Ferrocene (0.186 g, 1.00 mmol) was then added. After stirring for 80 min at room temperature, the reaction mixture was poured into ice water and the dichloromethane layer was washed with water, dried and evaporated to dryness. The residue was purified by silica-gel chromatography with benzene-ethyl acetate (2: 1) to give hydroquinone (0.079 g, 0.72 mmol), which was identified by comparing with an authentic sample by UV and tlc technique. For comparison, *p*-benzoquinone (0.11 g) was treated in the same procedure as described above but without fer-

13) L. Wolff, *Ann.*, **246**, 246 (1891); H. Schinz, G. Gonbani, and V. Theus, *Helv. Chim. Acta*, **38**, 255 (1955).

rocene, and hydroquinone (0.039 g, 0.36 mmol) was obtained. The net amount of hydroquinone, obtained from the reduction of *p*-benzoquinone by ferrocene is 0.36 mmol.

The aqueous layer from the reaction in the presence of ferrocene was treated with tin(II) chloride acidified with hydrochloric acid to afford ferrocene (0.123 g, 0.66 mmol). The amount of ferrocene was assumed to be equal to that of ferricinium ion. The molar ratio of hydroquinone to ferricinium ion is calculated to be about 1: 1.8.

Reduction of Chloranil with Ferrocene. The same procedure as described above was applied to chloranil, which was found to be not reduced by aluminum chloride without ferrocene. The molar ratio of the obtained tetrachlorohydroquinone to ferricinium ion was about 1: 1.7.

Reduction of Enones and Related Compounds. Aluminum chloride (0.14 g, 1.08 mmol) and a substrate (0.54 mmol) were added into 30 m*l* of dry dichloromethane, and stirred for 5 min. Ferrocene (0.54 mmol) was then added. After stirring for 60 to 120 min, an aliquot was taken out from the reaction mixture, poured into ice water and the organic layer was checked for the reduction product by tlc, UV, or glpc (Table 1). In a control experiment, in which each substrate was treated by aluminum chloride without ferrocene under similar conditions, no reduction product was detected.

Stoichiometric Reduction of 1,2-Dibenzoylethylene by Ferrocene. Aluminum chloride (0.12 g), ferrocene (0.1 g), and 1,2-dibenzoylethylene (0.12 g) were added into 30 m*l* of dry dichloromethane and stirred for 90 min at room temperature. After the reaction mixture was poured into ice water, the dichloromethane layer was washed with water, dried and evaporated to dryness, and the residue was purified by silica-gel chromatography with benzene to afford 1,2-dibenzoylethane[14] (0.054 g). The aqueous layer gave ferrocene (0.078 g) when treated with tin(II) chloride.

Reaction of Ferrocene with Bromosuccinic Anhydride. Dabard[15] reported the preparation of β-ferrocenylcarbonylacrylic acid by the Friedel-Crafts reaction of ferrocene with bromosuccinic anhydride. We examined the same reaction in order to confirm the formation of the reduction product. Ferrocene (0.74 g, 4 mmol), bromosuccinic anhydride (0.72 g, 4 mmol), and aluminum chloride (1.16 g, 8.7 mmol) were added into 30 m*l* of dry dichloromethane, and stirred for 5 hr at room temperature. After methylation of the products with diazomethane and purification by silica-gel chromatography with benzene-ethyl acetate (6: 1), methyl β-ferrocenylcarbonylacrylate (84 mg) and methyl β-ferrocenylcarbonylpropionate (150 mg) were obtained. Boron trifluoride, iron(III) chloride, or titanium(IV) chloride instead of aluminum chloride were examined, but no reaction products were detected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 3464—3465(1971)

Studies on Rydberg Orbitals. III. Calculation of the 4*s*, 4*p*, and 4*d* Orbitals of Carbon Atom

Haruo Hosoya[1)]

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received March 26, 1971)

Many different approaches to the calculation of Rydberg orbitals of small[2)] atoms and molecules have been undertaken.[3-7)] Apart from its mathematical interest, the information from these studies is useful not only for interpreting the Rydberg spectra but also for estimating, by perturbation calculations, the contribution of Rydberg orbitals of states in several problems such as electronic spectra of charge-transfer complexes and reaction mechanisms.[8)]

The author calculated the 3*s*, 3*p*, and 3*d* orbital wavefunctions and energies of Li(I)-F(I) and their isoelectronic series in their unhybridized Rydberg valence states with the lowest energy,[3)] *e.g.*, for

$$\mathrm{C(I)}\ 1s^2 2s^2 2p 3l,\ V_2\ (l=s, p, d) \tag{1}$$

In this paper the least-STO-basis wavefunctions and orbital energies of carbon 4*s*, 4*p*, and 4*d* orbitals of the valence state

$$\mathrm{C(I)}\ 1s^2 2s^2 2p 4l,\ V_2\ (l=s, p, d) \tag{2}$$

will be reported.

Since the calculation is an extension of the 3 l orbitals, only a brief account is given. The radial part of the least-STO-basis wavefunction 4 l, R_{4l}, has $2(4-l)$ parameters to be optimized (four C_{nl}'s and four μ_{nl}'s).

$$R_{4l} = \sum_{n=l+1}^{4} C_{nl} S(n, \mu_{nl}) \tag{3}$$

where $S(n,\mu_{nl})$ is a normalized Slater type orbital

$$S(n, \mu_{nl}) = (2\mu_{nl})^{n+1/2}\{(2n)!\}^{-1/2} r^{n-1} \exp(-\mu_{nl} r).$$

The function R_{4l} should be orthogonal to all the inner orbitals $R_{nl}(n=l+1,\cdots,3;\ 3-l$ conditions). The orbital exponents of the inner loops μ_{nl}'s$(n=l+1,\cdots,3;\ 3-l$ constants) were fixed as in the $3\,l$ calculation. Then by using the normalization condition we are left a single parameter μ_{4l}, which can be determined by optimization process as adopted in the $3\,l$ calculation. The wavefunctions of the $1s$, $2s$, and $2p$ orbitals forming the fixed core potential were taken from the table by Clementi[9] for the ion

a) See Eq. (3). b) Ref. 3.

With these analytical expressions and potential the orbital energy of $4\,l$ electron in the valence state can be calculated for a given μ_{4l} value. Since in this case interaction between the Rydberg electron and core electrons is negligibly small compared to the orbital energy of the Rydberg electron, the orbital R_{4l} giving the lowest orbital energy is close enough to what would be obtained by the Hartree-Fock method. Table 1 gives the wavefunctions, orbital energies and quantum defects of the $4\,l$ orbitals obtained by this optimization procedure and also contains, for the sake of comparison, the least-STO-basis $3\,l$ orbitals.[3]

The observed energy values in Table 1 were obtained by taking the weighted means of all the term values in the Moore table.[10] Although the calculated energy of the $4s$ orbital surpasses the observed value due to several approximations taken, all the results are very close to the observed values. Accuracy of the calculation of Rydberg sates can be better checked with the quantum defects than with the absolute values of the orbital energies. Differences between the observed and calculated values for the $4\,l$ orbitals are as large as those for the $3\,l$ orbitals. As the quantum number of the Ryberg orbital increases, the error due to penetration into the core orbitals will decrease, although the consecutive orthogonalization procedure will pile up the error of the lower members to some extent. Thus this type of calculation of the Rydberg orbitals may be expected to be equally applied to the higher members and also to other systems.

All the calculations were performed in 1967 by using a Facom 202 computer at the Institute for Solid State Physics of the University of Tokyo. Thanks are due to Professor Saburo Nagakura for his interest and criticism.

Solvent Effect on the Photochemical Oxidation of Phenothiazine with Oxygen

Teiki IWAOKA, Hiroshi KOKUBUN, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai
(Received March 31, 1971)

The photochemical production of neutral radical in the aerated ethanol solution of phenothiazine (PTH) has been studied by means of steady light experiments, flash technique, and ESR measurements.[1] A reaction scheme proposed is 1) $PTH \xrightarrow{h\nu} PTH^*$, 2) $PTH^* \longrightarrow PTH^T$, 3) $PTH^T + O_2 \longrightarrow PTH\cdots O_2$, 4) $PTH\cdots O_2 \longrightarrow PT\cdot + HO_2\cdot$ in which $PTH\cdots O_2$ was presumed to be a certain type of C–T complex with a lifetime $\sim 6\times 10^{-3}$ sec.

Gilbert,[2] however, has pointed out that the spectrum of the ultimate product resembles that of phenothiazine-5-oxide (5-oxide) and that our transient intermediate might be a radical which gives rise to 5-oxide. In fact our ESR studies were made on 10^{-2}M solutions of PTH while the kinetic studies were chiefly for 10^{-4}M of PTH, so that it might be possible that under the former conditions the main product is radical and under the latter, 5-oxide.

In this note it is demonstrated that the same product, *i.e.* the neutral radical, is produced in the two cases. Further, the solvent effect of the overall reaction and also on the transient intermediate are investigated. The results also support our mechanism.

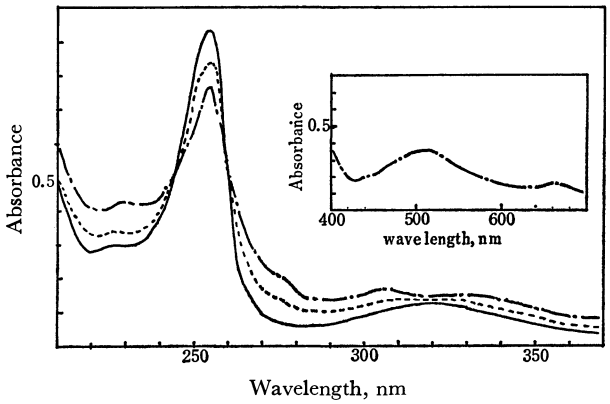

Fig. 1. Spectral change for the ethanol solution of phenothiazine in high concentration (2×10^{-2}M) upon UV illumination.
——; no irradiation ------; 2 hr irradiation
—·—; 12 hr irradiation

First it was reconfirmed that the irradiated solutions of PTH, 2×10^{-2}M in ethanol give an ESR spectrum characteristic of neutral radical which remains unaltered after being kept for more than two hours. When diluted 30 times, the irradiated solutions gave UV spectra as shown in Fig. 1. It is seen that the spectral change is similar to that for the dilute solution.[1] The spectrum in the visible region was taken without dilution.

Table 1. Quantum yields in various solvents

Solvent	DK	Φ
Acetonitrile	37.5	1.4×10^{-3}
Methanol	32.6	8.0×10^{-3}
Ethanol	24.3	6.0×10^{-3}
n-Butanol	17.8	8.0×10^{-3}
Ethyl ether	4.3	2.0×10^{-2}
Cyclohexane	2.0	2.4×10^{-2}

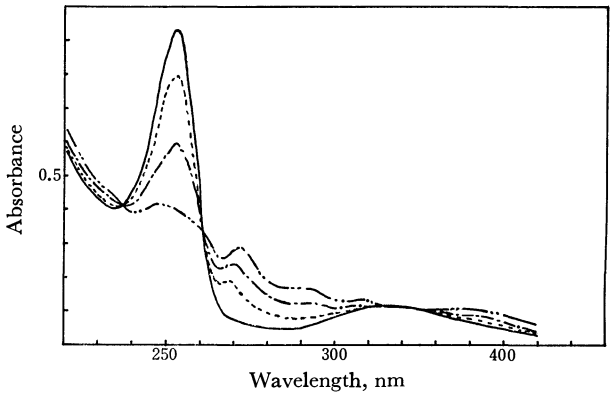

Fig. 2. Spectral change upon illumination (253.7 nm) of phenothiazine solution in the aerated cyclohexane; —— 0 sec, ---- 10 sec, —·— 35 sec, —··— 95 sec, [PTH] $=2.0\times 10^{-5}$M.

The existence of a peak at ~500 nm is consistent with the radical nature of the species.

Table 1 gives the quantum yields of the reaction in several solvents of different polarity. The spectral change is similar in all the solvents and there is no indication of a drastic change in the reaction scheme such as the formation of radical to that of 5-oxide. As an example, the spectral change in the cyclohexane solution is given in Fig. 2. Although ESR measurements were not made for all the cases, the ESR spectrum in the acetonitrile solution of 2×10^{-2}M PTH confirmed that the product is the neutral radical. From Table 1 it is evident that the values of Φ are one order larger in the weakly polar solvents (DK$<\sim$5) than in the polar solvents (DK$>$15); an approximate parallelism exists between Φ and DK.

This may be interpreted as follows. C–T complex is considered in general to be stabilized more or less by the interaction with the solvent molecules in the solvent sphere, and the more polar the solvent molecules, the greater the interaction is expected to be, resulting in a stronger solvation in more polar solvents. Thus the reorientation of molecules in the solvent sphere might be required for any reaction. In the present system it is likely that a more drastic reorientation is necessary for reaction $PTH\cdots O_2 \longrightarrow PT\cdot + HO_2$ than for the backward reaction $PTH\cdots O_2 \longrightarrow PTH + O_2$. It

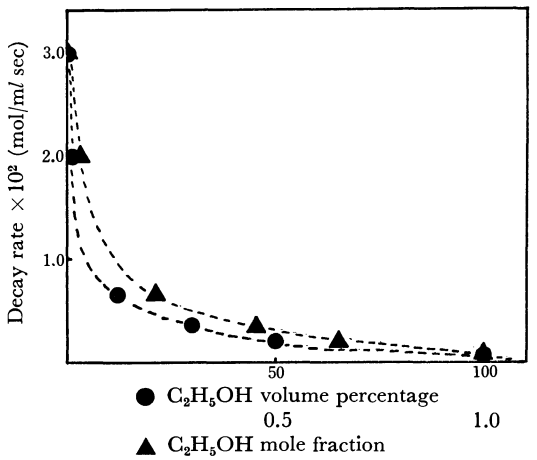

Fig. 3. The rate of disappearance of phenothiazine in the mixed solvent of cyclohexane and ethanol.
[PTH] $=2.0\times10^{-5}$M
light intensity, $I_0=8.7\times10^{-9}$M/sec.cm.

can be expected that the relative ease with which the former reaction occurs becomes smaller in the more polar solvent as was verified by experiment. The change of the decay constant and hence Φ in the mixed solvents of cyclohexane and ethanol given in Fig. 3 can be understood by the above reasoning. Thus a sharp drop in decay rate in the low concentration region of ethanol can be attributed to the selective solvation of the more polar ethanol molecules around PTH, which makes the formation of PT· more difficult.

Table 2 gives the peak positions of the transient spectrum which has been interpreted to be due to C–T complex[1] together with their decay constants. Although it is rather difficult to decide the peak positions accurately due to their low intensity and location at the foot of the original main absorption band, it can be said that in polar solvents (with DK larger than that of pyridine) the peaks are clearly observed around 385—395 nm, while in ethyl acetate, ethyl ether, and cyclohexane they are not observable. This might be due to the blue shift of the peak. The decay constants in these weakly polar solvents were determined from the rise of absorption at 290 nm. It was confirmed that in cases where ~390 nm peaks are observable, their decline and the rise at 290 nm agree well. The decay constants in nonpolar solvents are one order higher than those for polar solvents, indicating that the C–T complex is less stable in these solvents.

Table 2. Solvent effect on the nature of the PTH···O_2 complex

Solvent	DK	Absorption max (nm)	Decay const. (sec^{-1})
Acetonitrile	37.5	385	1.4×10^2
Methanol	32.6	375—385	
Ethanol	24.3	385	1.6×10^2
Acetone	20.7	385	1.5×10^2
n-Butanol	17.8	395	1.2×10^2
Pyridine	12.3	390	7.5×10
Ethyl acetate	6.1	<380	3.9×10^3
Ethyl ether	4.3	<380	$>10^3$
Cyclohexane	2.0	<380	$>10^3$

All the present results support the view that the intermediate is a C–T type complex which yields the neutral radical as a final product. Although simultaneous production of 5-oxide cannot be denied completely, its participation, if it does occur, can be said to be very small. If this were not the case, the spectral change having clear-cut isosbestic points in all the solvents could not be explained.

β-Substituted α-Cyanoglycidic Esters and Their Reactions

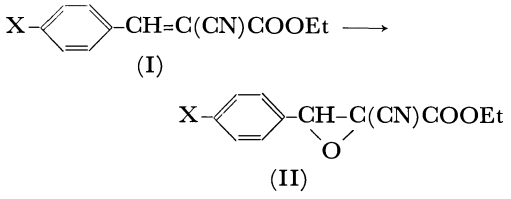
Minoru IGARASHI,*,** Mamoru TAMURA,* and Masae YANAGI*

*Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Ibaraki

**The Institute of Physical and Chemical Research, Wako, Saitama

(Received May 11, 1971)

The reaction of β-alkyl-α-cyanoacrylic esters with hydrogen peroxide was outlined previously as a useful method of synthesizing epoxy nitriles.[1] The applicability of the reaction has now been extended to give β-aryl-α-cyanoglycidic esters from α-cyanocinnamic esters.



(I) (II)

X: H, Cl, CN, NO_2

Ethyl α-cyanocinnamates (I) were prepared by using the conditions developed by Cope.[2] The epoxidation of these unsaturated esters with hydrogen peroxide proceeded smoothly at 80—85°C without a catalyst. In an ethanolic solution, ethyl α-cyanocinnamate (I, X=H) gave the corresponding epoxy ester (II, X=H) in a 30% yield after 15 hr. Under similar conditions, ethyl α-cyano-β-(*p*-nitrophenyl)acrylate (I, $X=NO_2$) reacted more rapidly with hydrogen peroxide; the epoxy ester (II, $X=NO_2$) was formed in a 96% yield, with the complete consumption of the olefin, after only 1 hr.

The results shown in Table 1 reveal that the electron-withdrawing *p*-substituents accelerate the epoxidation of I, whereas the electron-releasing groups have the reverse effect.

The epoxy compounds obtained above gave unknown products upon hydrolysis with acid or alkali. By the reaction with aqueous ammonia, β-phenyl, β-(*p*-nitrophenyl), and β-(*p*-chlorophenyl)-α-cyanoglycidic esters (II; X=H, NO_2, Cl) gave the corresponding diol amides, accompanied by the epoxy ring opening, and the β-(*p*-cyanophenyl)-α-cyanoglycidic ester (II, X=CN) gave β-(*p*-cyanophenyl)-α-cyanoglycidamide.

Ethyl α-cyano-β,β-dimethylglycidate (III) had previously been synthesized from ethyl α-cyano-β-methylcrotonate.[1] The conversion of III to α-cyano-β,β-dimethylglycidic acid (IV) was effected by alcoholic alkaline hydrolysis. When IV was kept at 140—150°C in an oil bath, decarboxylation took place and the product was the expected 3-methyl-2-oxobutyronitrile (V), which gave the anilide, VI, upon reaction with aniline. The epoxy ester, III, gave the epoxy amide, VII, on treatment with aqueous ammonia.[3] Under similar conditions, the epoxy acid, IV, gave amino-hydroxy acid, VIII.

Experimental

Ethyl α-Cyanocinnamates (I). The unsaturated esters (I, X=H, Cl, CN, NO_2, CH_3, CH_3O, OH) were prepared according to the method of Cope.[2]

Epoxidation of I. *A)* A mixture of I (0.1 mol), 30% hydrogen peroxide (0.2 mol), and ethanol (30 m*l*) was refluxed at 80—85°C on a water bath. To the mixture, water (100 m*l*) was then added, after which it was extracted with chloroform. After the removal of the solvent, the residual oil was distilled to give the epoxy ester (X=H).

B) The reaction was carried out as above. The solution was cooled, and the resulting precipitate was collected by filtration. Recrystallization from ethanol gave the epoxy ester (X=Cl, CN, NO_2).

α-Cyano-β,β-dimethylglycidic Acid (IV). To a solution of ethyl α-cyano-β,β-dimethylglycidata (III)[1] in ethanol, ethanolic potassium hydroxide was added at room temperature. A white precipitate formed during the addition. After the mixture had stood overnight, it was separated by filtration,

a) Reaction temp., 80—85°C

washed with ethanol, and dried. The potassium salt was dissolved in water and neutralized with hydrochloric acid at 0—5°C. After the mixture had stood overnight in an ice box, the resulting precipitate was collected by filtration. The yield was 80%. Recrystallization from benzene gave colorless needles of IV; mp 107°C (decomp) (lit,[3] mp 106—108°C (decomp). Found: C, 50.71; H, 4.84; N, 9.85%).

Reaction of IV with Ammonia. Epoxy acid, IV (1.4 g), was dissolved in concentrated aqueous ammonia (6 ml) and allowed to stand overnight at room temperature. The solution was then concentrated under a vacuum to dryness. Recrystallization from ethanol afforded colorless needles; mp 193°C (decomp). The yield was 1.4 g (89%). The product had an empirical formula in agreement with that of 3-amino-2-cyano-2-hydroxy-3-methylbutyric acid or its isomer, 2-amino-2-cyano-3-hydroxy-3-methylbutyric acid (VIII).

Found: C, 45.95; H, 6.36; N, 18.06%. Calcd for $C_6H_{10}O_3N_2$: C, 45.56; H, 6.37; N, 17.71%.

Decarboxylation of IV. The epoxy acid, IV, was placed with anhydrous sodium sulfate or liquid paraffin in a Claisen flask and heated in an oil bath at 140—150°C until the decarboxylation had ceased. The product was then distilled directly from the reaction flask. Redistillation gave 3-methyl-2-oxobutyronitrile (V); bp 115—120°C (lit,[4] bp 116—118°C) (yield, 45%).

The reaction of a sample of the keto nitrile, V, with aniline gave isobutyranilide (VI); mp 105°C (lit,[5] mp 106—107°C. Found: C, 73.70; H, 8.81; N, 7.74%).

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa for his kind advice and encouragement. Thanks are also due to Dr. Haruo Homma and his staff for the microanalyses.

Copolymerization of Styrene and Liquid Sulfur Dioxide in the Presence of α-Toluenethiol, 1-Butanethiol, or Bromotrichloromethane

Masashi Iino,* Tateo Iguchi, and Niichiro Tokura

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received May 12, 1971)

We have carried out copolymerization (telomerization) of styrene and liquid sulfur dioxide (liq. SO_2) in the presence of α-toluenethiol, 1-butanethiol, or bromotrichloromethane by using a radical initiator (AIBN) in order to study of the propagation mechanism in styrene polysulfone formation.

It is well known that aliphatic olefins, such as ethylene and propylene, always form alternate copolymers with SO_2 by a radical initiator. Kharasch and Friedlander obtained telomers (**1** and **2**), by copolymerizing octene-1 and SO_2 in the presence of bromotrichloromethane, but no telomer having $-SO_2Br$ group.[1] Styrene also copolymerizes with SO_2, but unlike aliphatic olefin forms copolymers having various compositions.[2]

$CCl_3CH_2CH(C_6H_{13})Br$

(**1**)

$CCl_3CH_2CH(C_6H_{13})S(O_2)CH_2CH(C_6H_{13})Br$

(**2**)

We have obtained the following telomers (**3**, **4**, and **5**) (the head to tail structure of the first styrene unit in product **5** could not be confirmed) in the case of α-toluenethiol.

$C_6H_5CH_2SCH_2CH_2(C_6H_5)$ (**3**)

$C_6H_5CH_2SStStH$ (**4**)

$C_6H_5CH_2SStS(O_2)StH$ (**5**)

(St=$-CH_2CH(C_6H_5)-$)

* Present address: Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai.

1) M. S. Kharasch and H. N. Friedlander, *J. Org. Chem.*, **13**, 882 (1948).

2) M. Matsuda and M. Iino, *Macromolecules*, **2**, 216 (1969).

The propagation steps in this chain reaction are considered to be as follows.

$$C_6H_5CH_2S\cdot + CH_2{=}CH(C_6H_5) \longrightarrow \underset{(A)}{C_6H_5CH_2SSt\cdot} \quad (a)$$

$$A + CH_2{=}CH(C_6H_5) \longrightarrow \underset{(B)}{C_6H_5CH_2SStSt\cdot} \quad (b)$$

$$A + SO_2 \longrightarrow \underset{(C)}{C_6H_5CH_2SStSO_2\cdot} \quad (c)$$

$$C + CH_2{=}CH(C_6H_5) \longrightarrow \underset{(D)}{C_6H_5CH_2SStS(O_2)St\cdot} \quad (d)$$

$$A, B, D + C_6H_5CH_2SH \longrightarrow \text{Product, } \mathbf{3}, \mathbf{4}, \mathbf{5} + C_6H_5CH_2S\cdot \quad (e)$$

As in the case of octene-1 – SO_2 system,[1] the telomer with $-SO_2H$ group expected to be formed by termination of (C) radical was not obtained. We carried out copolymerization in the presence of 1-butanethiol or bromotrichloromethane. In these cases also the telomer having $-SO_2H$ group or $-SO_2Br$ (in the case of bromotrichloromethane) group was not obtained. This is probably due to the fact that either the sulfonyl radical is inert to hydrogen abstraction reaction from thiol (and bromine abstraction reaction from bromotrichloromethane) or the life time of sulfonyl radical is very short compared to that of styryl radical at this temperature (60°C).

Structures of products **3**, **4**, and **5** suggest that styrene polysulfone has head to tail structure.

The photo-decomposition of α-toluenethiol or 1-butanethiol in liq.SO_2 was also carried out and only disulfide which was formed by coupling reaction of thiyl radicals was obtained. Sulfone expected to be formed from the reaction of thiyl radical with SO_2 was not obtained.

Experimental

Materials. Styrene, azobisisobutyronitrile (AIBN) and liq. SO_2 were purified by the method described previously.[3] α-Toluenethiol and 1-butanethiol were purified by distillation. Bromotrichloromethane was prepared[4] from bromine and chloroform and distilled just before use.

Telomerization with α-Toluenethiol. 9.0 g (0.09 mol) of styrene, 10.8 g (0.09 mol) of α-toluenethiol, 29.7 g (0.46 mol) of liq. SO_2 and 0.5 g (0.003 mol) of AIBN, were charged in a reaction vessel,[3] and reacted at 60°C for 8 hr. Unreacted liq. SO_2, styrene and α-toluenethiol were then distilled off and the residue was chlomatographed on an alumina column. The liquid obtained by elution with petroleum ether was distilled under a reduced pressure. The distillate (161—164°C/1.5 mmHg) gave 11.8 g (58% yield based on styrene) of **3**, $C_6H_5CH_2SStH$ (St=$-CH_2CH(C_6H_5)-$). Found: C, 79.30; H, 7.04; S, 13.96%. Calcd for $C_{15}H_{16}S$: C, 78.90; H, 7.06; S, 14.04%. NMR (CCl_4): τ, 2.9—3.1 (10H, phenyl), 6.5 (2H, $-CH_2S-$), 7.1—7.7 (4H, $-CH_2CH_2(C_6H_5)$). The residue of the distillation gave about 1 g (6%) of **4**, $C_6H_5CH_2SStStH$, identified as sulfoxide and sulfone by oxidation using $KMnO_4$ in $CHCl_3$. Sulfoxide ($C_6H_5CH_2S(O)$-StStH). Found: C, 78.55; H, 6.89; S, 9.51%. Calcd for $C_{23}H_{24}SO$: C, 79.27; H, 6.94; S, 9.20%. Mp 122—125°C (recrystallized from methanol), IR 1020 cm^{-1} (SO). Sulfone ($C_6H_5CH_2S(O_2)StStH$); mp 102—103°C (recrystallized from methanol), lit,[5] 98—99.5°C, IR 1300, 1120 cm^{-1} (SO_2). Elution with ether gave 0.8 g (4%) of (5), $C_6H_5CH_2SStS$-$(O_2)StH$. Found: C, 69.55; H, 6.03; S, 15.98%; mol wt (mass spectrum) 396. Calcd for $C_{23}H_{24}S_2O_2$: C, 69.66; H, 6.10; S, 16.17%; mol wt 396.6. mp 116.5—118°C, NMR ($CDCl_3$): τ, 2.4—3.1 (m, 15H, phenyl), 5.9—6.1 (quar, 1H, $-CH-$), 6.5 (s, 2H, $C_6H_5C\underline{H}_2-$), 6.4—7.0 (2H, $-S(O_2)CH_2-$), 7.0—7.3 (m, 4H, $-SCH_2-$, $-C\underline{H}_2(C_6H_5)$), showed no methyl group expected from head to head structure of terminal styrene unit.

Telomerization with 1-Butanethiol. 9.0 g (0.09 mol) of styrene 8.3 g (0.1 mol) of 1-butanethiol, 28.7 g (0.45 mol) of liq. SO_2 and 0.5 g (0.003 mol) of AIBN were reacted at 60°C for 30 hr. By the same procedure as in the case of α-toluenethiol, C_4H_9SStH, (7.8 g, 45%), $C_4H_9SStStH$ (about 0.5 g, 4%) and $C_4H_9SStS(O_2)StH$(0.3 g, 2%) were obtained. C_4-H_9SStH. Found: C, 74.41; H, 9.56%. Calcd for $C_{12}H_{18}S$: C, 74.19; H, 9.34%. Bp 88—89°C/<1 mmHg, lit,[6] 96—97°C/1 mmHg. $C_4H_9SStStH$. Speculated from its boiling point (>100°C/<1 mmHg, lit[6] 170°C/1 mmHg), IR spectrum (almost the same as that of C_4H_9SStH) and refractive index (n_D^{25}, 1.5524, lit,[6] 1.5539). $C_4H_9SStS(O_2)StH$. Found: C, 66.05; H, 7.24%. Calcd for $C_{20}H_{26}S_2O_2$: C, 66.26; H, 7.23%. IR 1310, 1130 cm^{-1} (SO_2).

In the reactions using 18 g (0.18 mol) and 36 g (0.36 mol) of styrene, we obtained 0.2 g and 2 g, respectively, of styrene polysulfone other than the products described above.

Telomerization with Bromotrichloromethane. 36.0 g (0.36 mol) of styrene, 40 g (0.2 mol) of CCl_3Br, 168 g (2.6 mol) of liq. SO_2 and 4 g (0.02 mol) of AIBN were reacted at 60°C for 42 hr. By the same procedure as described above, about 20 g (18%) of CCl_3StBr was obtained. We carried out the reaction with various feed compositions, but could not obtain the telomer having $-SO_2Br$ group. CCl_3StBr. Found: C, 35.94; H, 2.50%. Calcd for $C_9H_8BrCl_3$: C, 35.74; H, 2.67%. Mp 51.5°C, lit,[7] 54—55°C.

Photo-decomposition of α-Toluenethiol in Liq. SO_2. A mixture of 10.8 g (0.09 mol) of α-toluenethiol and 28.6 g (0.45 mol) of liq. SO_2, was charged in a quartz vessel, and irradiated with a 300 W mercury lamp (high-pressure) at room temperature for 24 hr. Unreacted SO_2 and α-toluenethiol were distilled off. The residue gave 4.5 g (41% yield based on α-toluenethiol) of $(C_6H_5CH_2S)_2$, identified from IR spectrum of an authentic sample. Only $(C_4H_9S)_2$ was obtained in the case of 1-butanethiol.

The Reaction of Iodine Azide with Diphenylfulvene

Tadashi SASAKI, Katsumaro MINAMOTO, and Ken USAMI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received May 28, 1971)

Fulvenes, structural isomers of benzenoids, have attracted the interest of organic chemists, especially because of the dual characters between conjugated olefins and aromatics. They give Diels-Alder Adducts in their 1,4-positions[1] as well as substitution products with bromine.[2] We were interested in the introduction of nitrogen atoms into the fulvene skeleton to examine possible modifications of the original chemical features.

Fulvenes might be converted into azides by Hassner's method using iodine azide.[3] Application of this method seems to be of interest since Hassner's documents are limited to mono-olefinic compounds except for 1,3-cyclooctadiene.[3] This paper deals with the elucidation of the structures of the reaction products from diphenylfulvene (**1**) and iodine azide.

The reaction of iodine azide with **1**[4] gave an oily mixture consisting of two diastereoisomeric diazido racemates, complete purification of which was unsuccessful. Treatment of the mixture with two equivalents of dimethyl acetylenedicarboxylate (DAC) gave two crystalline racemates (**3a—b**). The yields and physical constants of the racemates are summarized in Table 1, and their UV spectra given in Fig. 1. Their IR spectra are quite similar except slight differences in the finger print regions. Thus, the spectral similarities confirmed their skeletal and functional identity. Unequivocal assignments of the NMR signals in the region of τ 3.1—3.9 (2 olefinic protons and 2 protons on C_1 and C_2) were impossible due to their ambiguous resolutions.

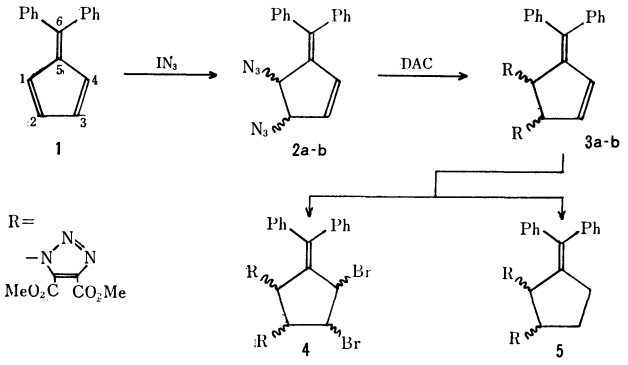
Thus, the initial products should be diazido compounds with the same skeleton and π-conjugation system.



Attempts were made to saturate a double bond in **3a—b** by hydrogenation and bromination for the exclusion of another possible 1,4-adduct (**2'**). Thus, the dibromo compound (**4**) and tetrahydrofulvene (**5**) were obtained from **3b**, whereas the corresponding reaction products from **3b** were intractable. The UV spectra

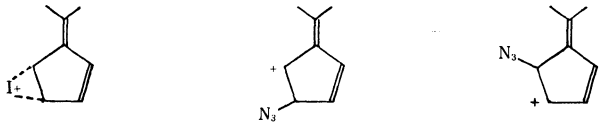
of **4** and **5** (Fig. 1.) show complete disappearance of the absorption at 288 nm of **3a**, leaving the overlap of absorptions due to the triazole rings and the diphenylethylene group as inflections. It is well-known that 1,1-diphenylethylene absorbs at 250 nm ($\log \varepsilon$ 4.0)[5] and that the extention of a π-conjugation system by a double bond usually causes a bathochromic shift of approximately 30 nm. The absorption at 288 nm coincides with the expected value 280 nm, even assuming some steric restrictions between the diphenylethylene group and one of the triazole rings in **3**. It is anticipated that the saturation of an isolated double bond as in **2** would cause no essential change of a UV spectrum related to a major chromophore as diphenylethylene in **2'**.

It is thus concluded that **3a**—**b** are *cis* and *trans* racemates of 1,2-bis[4,5-bis(methoxycarbonyl)-1*H*-1,2,3-triazolyl]-1,2-dihydro-6,6-diphenylfulvene and **2a**—**b** should be the corresponding steric isomers of the 1,2-diazido compounds. Configurational ascription for each compound is difficult at the present stage.



6 7a 7b

Addition of iodine azide to olefins generally results in *trans* addition through the cationic intermediate like **6**.[3] The fact that any addition product having both I and N_3 groups, could not be detected under the present reactions would be rationalized by the marked reaonance stabilization of the intermediate carbonium ion (**7a** or/and **7b**), formed by elimination of I^-, due to the extended conjugation which would involve the polar azide group itself. Thus, the attack of the nucleophilic azide ion on **7a** or/and **7b**, most probably in an S_N1 manner, would yield only one set of *cis* and *trans* isomes (**2a**—**b**) in roughly similar yields. This is in good accordance with our results. At present, it is difficult to say which of **7a** and **7b** was actual or major intermediate.

Experimental

All the melting points are uncorrected. The electronic spectra were measured on a JASCO Model ORD/UV-5 spectrophotometer and the infrared spectra on a JASCO Model IR-S spectrophotometer. The NMR spectra were recorded with a JNM C-60HL NMR spectrometer, TMS being used as an internal standard.

1,2-Diazido-1,2-dihydro-6,6-diphenylfulvene (2a—b). To a stirred suspension of sodium azide (3.0 g, 46 mmol) in dry acetonitrile (20 m*l*) in a methanol-ice bath was slowly added iodine monochloride (3.7 g, 23 mmol) for over 5 min. A solution of diphenylfulvene (**1**) (4.6 g, 20 mmol) in benzene (10 m*l*) was added. The mixture was allowed to attain room temperature and was stirred for additional 24 hr. The red-brown slurry was poured into water (50 m*l*) and the mixture was extracted with ether (3×50 m*l*). The combined ethereal solutions were washed with 5% sodium thiosulfate sloution. It turned out that the dark color of the ethereal layer could not be completely removed even by repeated washing. The ethereal layer was then washed with water, dried over magnesium sulfate and evaporated *in vacuo* to a dark-brown paste, which was chromatographed on a silica gel column (40×2 cm) using benzene as an eluant. A small amount of the starting material was recovered from the first few fractions. TLC with the use of silica gel and benzene showed one major spot with a couple of slower-moving traces. After removal of the benzene *in vacuo*, the residue gave monoclinic needles on standing at −30°C. The crude yield was 80%. IR(KBr): 2120 cm^{-1} (ν N_3). This product was used as such for the next synthesis to evade possible danger of explosion during the course of recrystallization.

1,2-Bis[4,5-bis(methoxycarbonyl)-1H-1,2,3-triazolyl]-1,2-dihydro-6,6-diphenylfulvene (3a—b). To a solution of the diazido mixture (**2a**—**b**) (1 g) in benzene (20 m*l*) was added DAC (1 g, 7 mmol), and the mixture was heated to reflux overnight. After the solvent was evaporated off, the residual paste was applied on a silica gel column (40×2 cm). Elution with benzene removed the excess DAC and unreacted starting material. The column was then eluted with 0.7% ethanol in benzene. The faster-moving fractions gave a pale yellow powder (**3a**) of mp 165—167°C from a mixture of chloroform and methanol. The slower-moving fractions also gave a pale yellow powder of mp 162—164°C from the same solvent.

Found for **3a**: C, 60.32; H, 4.53; N, 13.93%. Found for **3b**: C, 60.12; H, 4.63; N, 13.93%. Calcd for $C_{30}H_{26}N_6O_8$: C, 60.19; H, 4.38; N, 14.04%.

1,2-Bis[4,5-bis(methoxycarbonyl)-1H-1,2,3-triazolyl]-1,2-dihydro-3,4-dibromo-6,6-diphenylfulvene (4). To a stirred cold solution of **3a** (0.5 g, 0.84 mmol) in chloroform (8 m*l*) was added bromine (160 mg, 1 mmol) and the mixture was allowed to stand at room temperature for 2 hr. The dark-brown mixture was evaporated *in vacuo* to give **4** (0.44 g, 70%) as colorless powder, mp 205—207°C (from chloroform-acetone). Beilstein test: positive. IR(KBr): 1720 cm^{-1} (ν C=O). UV spectrum is given in Fig. 1. NMR($CDCl_3$) τ: 2.4—3.0 (m, 10H, 2Ph), 3.0—3.3 (m, 2H, 1- and 2-protons), 4.1—4.4 (m, 2H, 3- and 4-protons), 6.05 (s, 3H, Me), 6.1 (s, 3H, Me), 6.25 (s, 3H, Me), and 6.45 (s, 3H, Me).

Found: C, 47.30; H, 3.54; N, 11.11%. Calcd for $C_{30}H_{26}N_6O_8Br_2$: C, 47.51; H, 3.46; N, 11.08%.

1,2-Bis[4,5-bis(methoxycarbonyl)-1H-1,2,3-triazolyl]-1,2,3,4-tetrahydro-6,6-diphenylfulvene (5). **3a** (0.5 g, 0.84 mmol) was dissolved in acetone (10 m*l*) and hydrogenated in the presence of Pd–C at atmospheric pressure for 5 hr. After standing overnight in hydrogen, the mixture was separated from the catalyst and evaporated *in vacuo* to give **5** as colorless granules, mp 165—167°C (from methanol). Yield: 0.33 g (65%). IR(KBr): 1720 cm^{-1} (ν C=O). For the UV spectrum, see Fig. 1. NMR($CDCl_3$) τ: 2.7—3.2 (m, 10H, 2Ph), 4.0—4.5 (m, 2H, 1- and 2-protons), 6.0—6.2 (broad singlet, 6H, 2Me), 6.25—6.6 (m, 6H, 2Me), 7.2—7.7 (m, 2H), and 7.8—8.2 (m, 2H).

Found: C, 59.48; H, 4.74; N, 13.83%. Calcd for $C_{30}H_{28}N_6O_8$: C, 59.99; H, 4.70; N, 13.99%.

ESR Studies of the Sulfite Radical Anion

Toshihiko OZAWA, Morio SETAKA, and Takao KWAN
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo
(Received June 1, 1971)

Rapid-mixing flow techniques coupled with ESR measurements have so far enabled us to identify several unstable radicals formed during chemical reactions.[1-4]

Further work has now been carried out on the oxidation of bisulfite ions in connection with the biologically significant reaction involving sulfite - bisulfite ions.[5] As a result, we found that the sulfite radical anion, SO_3^-, is formed during the reaction of sodium bisulfite with Ce^{4+}. Since the ESR of the sulfite radical anion in aqueous solutions has not yet been reported, we wish briefly to communicate the ESR of the radical anion and its chemical characteristics.

Experimental

The ESR measurements were carried out on a JEOL-P-10 spectrometer (X-band) with 100 kHz field modulation, in conjunction with a JEOL mixer. This apparatus enabled us to detect radicals formed in the reaction time of the order of 5—100 msec. The spectra were recorded at room temperature. The *g*-values were determined relative to DPPH, for which $g=2.0036$. The concentrations of the spins were approximated to the peak-to-peak height of a given signal. Commercial samples of $Ce(NO_3)_4 \cdot 2\ NH_4NO_3$ and $NaHSO_3$ were used without further purification. Each aqueous solution was acidified by sulfuric acid at pH=1. The concentration was 0.01 M for the cerium salt and 0.1 M for the bisulfite in most experiments. Details of the experimental procedure were previously described.[2]

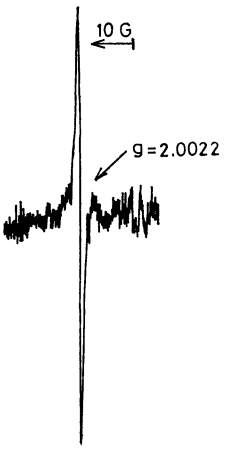

Fig. 1. ESR spectrum of the radical species (SO_3^-) formed during the reaction of Ce^{4+} with $NaHSO_3$ in aqueous solutions.

Results and Discussion

An ESR spectrum characterized by a single line with a nearly isotropic *g*-value was observed, as is shown in Fig. 1, when two solutions, containing Ce^{4+} and HSO_3^- respectively, were subjected to a rapid-mixing flow passing through the ESR cavity. The spectrum was well detectable for reaction times from several to about 100 msec without changing the *g* value (2.0022) and the linewidth of about 2.4 gauss. In view of the strong one-electron oxidizing capability of Ce^{4+}, the sulfite radical anion, SO_3^-, must be formed according to the reaction:

$$HSO_3^- + Ce^{4+} \longrightarrow SO_3^- + H^+ + Ce^{3+} \qquad (1)$$

While no ESR has been reported hitherto with respect to the SO_3^- ion in aqueous solutions, its formation has already been reported for γ-irradiated K_2SO_4 crystals,[6] where an axially symmetric resonance line at the *g*-value of 2.0023—2.0033 has been attributed to the SO_3^- radical anion. The irradiated K_2SO_4 sample gave rise to another spectrum charaterized by a highly anisotropic *g*-tensor (2.0486, 2.0082, 2.0037), which was attributed to the SO_4^- radical anion. The average *g*-value of the SO_4^- is calculated therefrom to be 2.0235, which is much greater than the value observed above. Thus, the spectrum of Fig. 1 can probably be assigned to SO_3^-. This supposition was confirmed by the following observation.

It is well known that pyrosulfite is hydrolyzed according to the reaction:

$$S_2O_5^{2-} + H_2O \longrightarrow 2HSO_3^- \qquad (2)$$

The mixture of Ce^{4+} and pyrosulfite may, then, be expected to produce the SO_3^- radical anion. Experiments have in fact shown that the same signal as that of Fig. 1 was obtained when pyrosulfate and Ce^{4+} were subjected to rapid-mixing flow reactions.

Apart from the ESR measurements, the sulfate radical anion, SO_4^-, is a well established intermediate in the thermal and photochemical decomposition of inorganic persulfates. The one-electron reduction of persulfate ions by Fe^{2+} or Ti^{3+} is known also to produce the radical anion according to:

$$S_2O_8^{2-} + Fe^{2+} \longrightarrow SO_4^{2-} + SO_4^- + Fe^{3+} \qquad (3)$$

Unfortunately, no ESR signal ascribable to the SO_4^- radical anion has been reported in aqueous solutions. However, in the presence of olefinic compounds, the rapid-mixing flow technique has provided ESR evidence for the formation of SO_4^- adducts,[7] suggesting that the

7) R. O. C. Norman, P. M. Storey, and P. R. West, *J. Chem. Soc., B*, **1970**, 1087.

SO_4^- radical anion was present, but was very short-lived.

The presence of the SO_2^- radical anion in aqueous solutions of sodium dithionite has also been reported;[8,9] the radical is formed by the monomerization of the dithionite ion:

$$S_2O_4^{2-} \longrightarrow 2SO_2^- \quad (4)$$

We have found an isotropic ESR line for the aqueous solution of sodium dithionite at the g-value of 2.0055; this is in accordance with a recent report.[10] A typical ESR spectrum of SO_2^- is shown in Fig. 2. The signal was fairly stable; it remained for reaction times exceeding one hour at room temperature.

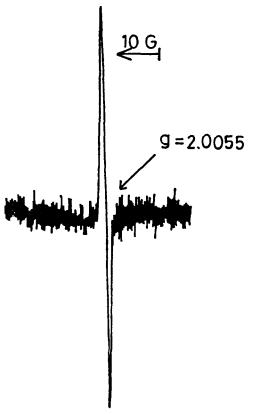

Fig. 2. ESR spectrum of the radical species (SO_2^-) formed in an aqueous solution containing $Na_2S_2O_4$.

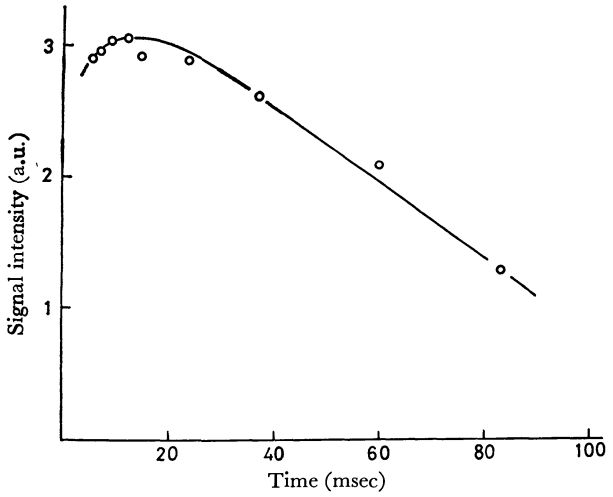

Fig. 3. The signal intensity of SO_3^- *vs.* reaction time relationship.

Figure 3 shows the spin concentrations of SO_3^- against the reaction times. As is shown in Fig. 3, the concentration of SO_3^- reached a maximum at about 10 msec after mixing and gradually decreased thereafter. It was detectable for 100 msec. The stability of the radical anion was, then, distinguishable from that of SO_2^- or SO_4^-. The difference in the thermal stability for SO_3^- and SO_4^- has been noted also in γ-irradiated K_2SO_4 crystals;[6] accordingly, the SO_4^- radical was much less stable than the SO_3^-, which is consistent with the present observation in aqueous solutions. Consequently, the possibility that the spectrum of Fig. 1 could be due to either SO_2^- or SO_4^- can be excluded on the basis of the argument of their stability.

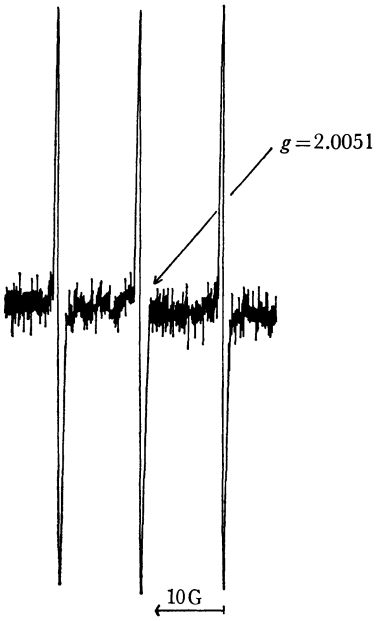

Fig. 4. ESR spectrum of the radical species ($ON(SO_3^-)_2$).

To compare the chemical reactivity of SO_3^- with that of SO_4^-,[7] we further investigated the reaction of SO_3^- with inorganic and organic additives by utilizing the rapid-mixing technique. Some results will be mentioned below. The SO_3^- signal appeared and was stable enough when an ethanol-containing bisulfite was mixed with the Ce^{4+} solution, while the signal was absent when allyl alcohol was substituted for ethanol. These results suggest that the SO_3^- reacts only with olefinic compounds, perhaps forming SO_3^- adducts.

A triplet signal was obtained (Fig. 4) when a $NaNO_2$-containing bisulfite was allowed to react with Ce^{4+}. The signal was exactly the same as that obtainable from potassium nitrosodisulfonate, the Fremy salt ($\cdot O\text{–}N(SO_3K)_2$). This radical may be formed by the one-electron oxidation of the hydroxylamine sulfonate ion, $HON(SO_3^-)_2$, by Ce^{4+} (6). The latter can be formed by the reaction of NO_2^- with HSO_3^- according to (5):[11]

$$NO_2^- + 2HSO_3^- \longrightarrow HON(SO_3^-)_2 + OH^- \quad (5)$$

$$HON(SO_3^-)_2 + Ce^{4+} \longrightarrow ON(SO_3^-)_2 + H^+ + Ce^{3+} \quad (6)$$

The above findings suggest that the SO_3^- radical anion is less reactive than the SO_4^-, the reactivity of which has already been worked out by Norman *et al.*[7] The problem of the relative reactivity of the SO_2^-, SO_3^-, and SO_4^- radical anions awaits further investigations.

Aroyl Arenesulfonyl Peroxides. II.[1] Phenylation with Phenyl Radical Generated from Benzoyl *p*-Toluenesulfonyl Peroxide

Ryuki HISADA, Nobumasa KAMIGATA, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received June 10, 1971)

We previously reported that spontaneous decomposition of benzoyl *p*-toluenesulfonyl peroxide (BPT) in benzene gave phenyl *p*-toluenesulfonyl carbonate (yield, 48 mol%), *p*-toluenesulfonic acid (33 mol%), benzoic acid (23 mol%), and biphenyl (1 mol%), and that in the presence of magnesium oxide 44 mol% of biphenyl and 22 mol% of phenyl *p*-toluenesulfonyl carbonate together with *p*-toluenesulfonic acid (57 mol%) and benzoic acid (10 mol%) were produced.[1] It was suggested that the biphenyl obtained was produced by the attack of phenyl radical on benzene. In order to ascertain whether or not the intermediate is phenyl radical, the orientation and the partial rate factors for phenylation with BTP in substituted benzenes were determined. The results will be described in this paper.

Experimental

Materials. Purification of benzene and substituted benzenes[2] and preparations of BTP[1] and the authentic samples of substituted biphenyls[2] have been described previously.

Magnesium oxide was used after heating in a crusible for 2 hr.

Decomposition of BTP. Into a mixture of 300 mmol each of a substituted benzene and benzene (or chlorobenzene), 5 mmol of BTP and 50 mmol of magnesium oxide were added at 10°C. After nitrogen gas was bubbled through the mixture for 20 min, the reaction flask was placed and stirred in a constant-temperature bath at 45.0°C. After 15 hr the reaction mixture was washed with a 5% sodium hydroxide solution to remove acidic products, washed with water, and dried over anhydrous magnesium sulfate. The amounts of the substituted biphenyl isomers were determined gas-chromatographically by the method described previously.[2]

Results and Discussion

The spontaneous decomposition of BTP in benzene was not a simple homolysis, and acid-catalyzed rearrangement to phenyl *p*-toluenesulfonyl carbonate always took place. A detailed study on the mechanism of this rearrangement is being carried out, and the results will be published soon.

When magnesium oxide was suspended in benzene for adsorption of *p*-toluenesulfonic acid produced, the rearrangement was suppressed considerably. In order to check the effect of magnesium oxide on yields of products, decomposition of benzoyl peroxide in benzene

Table 1. Orientations and partial rate factors for phenylation at 45.0°C

PhX	Orientation (%)			Partial rate factors			
	o-	*m*-	*p*-	k_o/k	k_m/k	k_p/k	k_x/k_H
PhOMe	62.3	26.7	11.0	4.75	2.03	1.65	2.53
PhEt	58.0	28.9	13.1	2.28	1.14	1.03	1.31

$PhNO_2$	64.6	9.5	25.9	10.8	1.58	8.66	5.58

a) These data are the average values of two experiments. Errors for orientations are usually 3% except that for *m*-methoxy (6%). Errors for partial rate factors are usually 2% except those for *m*-methoxy (7%) and *p*-methoxy (9%).

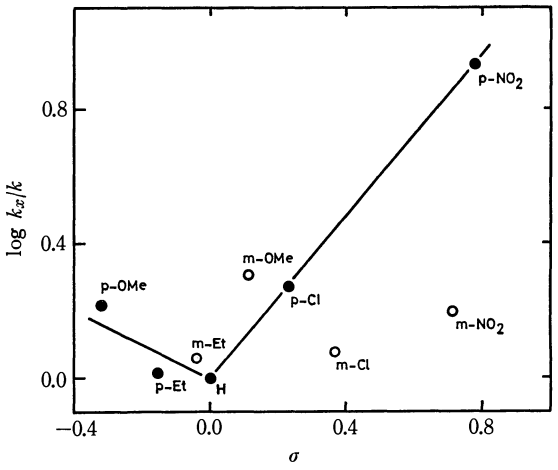

Fig. 1. Hammett's plots for the phenylation at 45.0°C. ●: log k_p/k, ○: log k_m/k $\rho_p = -0.78$ (left half) and $+1.20$ (right half).

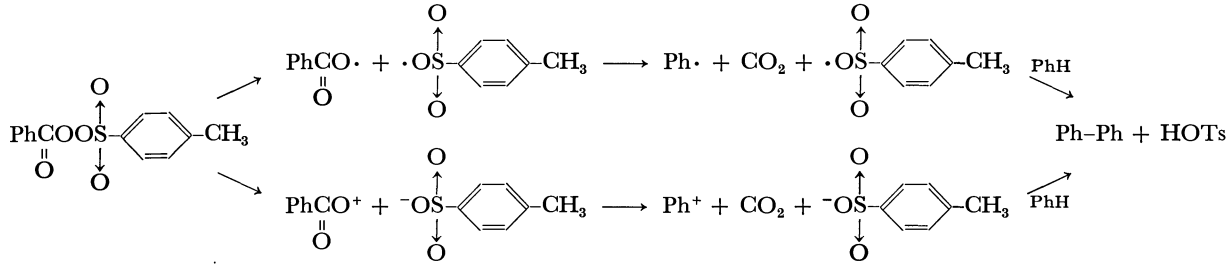

1) For the previous paper in this series, see R. Hisada, H. Minato, and M. Kobayashi, This Bulletin, **44**, 2541 (1971).

2) M. Kobayashi, H. Minato, E. Yamada, and N. Kobori, *ibid.*, **43**, 215 (1970).

in the presence and in the absence of magnesium oxide was studied. Yields of biphenyl, benzoic acid, and phenyl benzoate were the same within experimental error.

The main products of the decomposition of BTP in benzene in the presence of magnesium oxide were biphenyl and *p*-toluenesulfonic acid in addition to the rearranged product, phenyl *p*-toluenesulfonyl carbonate.[1] Biphenyl and *p*-toluenesulfonic acid could arise *via* either phenyl radical or phenyl cation according to the scheme shown above.

The orientations and the partial rate factors for phenylation of substituted benzenes are shown in Table 1. Figure 1 is the Hammett plots of the partial rate factors of *meta* and *para* positions. V-shaped straight lines could be drawn for *para* positions with $\rho=-0.78$ and $+1.20$. Similar results were obtained by the phenylation with phenyl radical produced from benzoyl peroxide ($\rho_p=-1.42$ and $+1.15$ at 80°C)[3] or *N*-nitrosoacetanilide ($\rho_p=-0.39$ and $+1.27$ at 20°C).[4] Both the orientations and the partial rate factors obtained with BTP were quite different from those for phenylation with phenyl cation.[2,5] These data prove that biphenyls are produced by the attack of phenyl radical.

The partial rate factors for *meta* phenylations are not too different from unity except that for the *m*-methoxy position. Experiments were repeated, but the abnormality was reproduced within experimental error. It is possible that nucleophilic anisole and electrophilic BTP have some kind of weak interaction.

The Determination of the Stability Constant of the Copper(II) Chelate of 2-(*o*-Acetylphenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic Acid

Shinichi NAGAMORI* and Haruo MIYATA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama-shi

(Received June 14, 1971)

We have synthesized the *o*-substituted phenylazochromotropic acids and investigated the effect of substituents on the metal-chelate stabilization. In a previous paper,[1] we reported that the acid dissociation constant of 2-(*o*-acetylphenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid (2-(*o*-acetylphenylazo)chromotropic acid) and the stability constant of its 1:1 chelate with alkaline earth metals could be determined by means of a pH titration method. In the present investigation, the stability constant of the copper(II) chelate was determined spectrophotometrically at 25°C and at an ionic strength of 0.1, with potassium nitrate as the supporting electrolyte. The procedures for the measurements were similar to those described in another previous paper.[2]

The absorption spectra of the reagent and its copper chelate were measured by means of a Hitachi Model EPS-3T recording spectrophotometer; they are shown in Fig. 1. Two sulfonic groups in the reagent are completely dissociated, and the dissociation constant for one of the naphthoic hydroxyl groups was calculated from the absorbance at 566 nm using a Hitachi Model 139 spectrophotometer. The pH measurements were made with a Hitachi-Horiba Model F-5 SS pH meter. The pK_a value is 9.66; Katayama *et al.*[1] have reported that the value is 9.65 by pH titration. The dissociation of another hydroxyl group is very weak because of the strong hydrogen bridge. The reagent thus behaves like a monobasic acid under these experimental conditions. Moreover, the effect of the acetyl group on the pK_a value is unusual, irrespective of its electron-attractive effect. That is, the value of pK_a is higher than 9.19 for the phenylazochromotropic acid.[1]

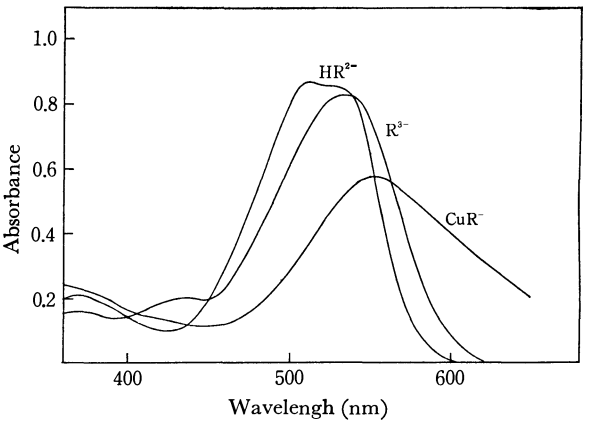

Fig. 1. Absorption spectra of the reagent and its copper chelate.
HR^{2-} at pH 1.0, R^{3-} at pH 12.6, and CuR^{-} at pH 5.57.
ligand concentration, 3.0×10^{-5}M.
copper concentration, 3.0×10^{-3}M.

The chelate formation of this reagent with the copper(II) ion become distinct at a pH of about 5, and the ratio of the reagent to the copper ion, as determined by the continuous-variation method, was 1:1. The stability constant of the copper chelate was calculated

by means of the following equations:

$$HR^{2-} \rightleftarrows H^+ + R^{3-} \quad (1)$$

$$K_a = \frac{[H^+][R^{3-}]}{[HR^{2-}]}$$

$$Cu^{2+} + HR^{2-} \rightleftarrows CuR^- + H^+ \quad (2)$$

$$K' = \frac{[CuR^-]}{[Cu^{2+}][HR^{2-}]} = \frac{[CuR^-]}{(C'_{Cu}-[CuR^-])(C_R-[CuR^-])}$$

$$Cu^{2+} + R^{3-} \rightleftarrows CuR^- \quad (3)$$

$$K = \frac{[CuR^-]}{[Cu^{2+}][R^{3-}]} = \frac{[CuR^-]}{(C'_{Cu}-[CuR^-])\{(K_a/[H^+](C_R-[CuR^-])\}}$$

where

K': the conditional stability constant of the copper chelate

K: the stability constant of the copper chelate

C_R: the total concentration of the reagent, $C_R = [HR^{2-}]+[CuR^-]$

C'_{Cu}[3]: the corrected concentration of copper, $C'_{Cu} = [Cu^{2+}]+[CuR^-]$

$[CuR^-]$: the concentration of the copper chelate.

The calculation procedure has been described in detail in a previous paper.[2] The values of the constants, $\log K'$ and $\log K$, of the copper chelate are listed in Table 1. The plots of the $\log K'$ *vs.* pH are shown in Fig. 2. The slope of this line is equal to 1, showing that the chelate is formed according to Eq. (2). In general, it is considered that the relation between the metal and the reagent is a Lewis-acid-and-base reaction. By comparing the $\log K$ value of the copper chelate with the value of 7.5 of the copper-phenylazochromotropic acid chelate, we can see that the stabilization of the copper chelate with this reagent is possibly due to the increase in the pK_a value of the reagent because of the effect of acetyl group existing in the *ortho* position.

The Use of Nickel Peroxide as Oxidizing Agent of Phenylhydrazine for the Generation of Phenyl Radicals

Hiroyuki OHTA and Katsumi TOKUMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 14, 1971)

It was reported that phenylhydrazine was oxidized with silver oxide,[1] mercuric oxide,[1] and lead tetraacetate[2] to give, probably *via* phenyldiimide, phenyl radicals, which can substitute on aromatic substrates to afford biaryls. These reactions as well as the decomposition of *N*-nitrosoacetanilide have often been employed to generate phenyl radicals at room temperature, though it is not convenient since silver oxide and *N*-nitrosoacetanilide have to be freshly prepared immediately before use and lead tetraacetate must be stored in acetic acid until use. With mercuric oxide, phenylhydrazine undergoes somewhat complicated reactions accompanied by the production of diphenylmercury.[1] In order to find a convenient procedure for the generation of phenyl radicals at room temperature, we investigated the treatment of phenylhydrazine with nickel peroxide, a new oxidizing agent of current interest,[3] on account of its ready availability and its stability during the course of storage. As a result, the reaction was found to be adequate for the present purpose.

Results and Discussion

Gradual addition of phenylhydrazine dissolved in a solvent to a suspension of excess nickel peroxide in the same solvent as above under stirring at room temperature under nitrogen atmosphere gave rise to a mild exothermic reaction with evolution of gas. The reaction carried out in cyclohexane gave benzene (68% yield based on the hydrazine used) together with a small amount of biphenyl (less than 1%). The reaction in carbon tetrachloride afforded chlorobenzene (53.5%), benzene (less than 2%), biphenyl (less than 2%), and hexachloroethane (10.1%). The reaction in benzene gave biphenyl (30%) along with very small amount of 1,4-dihydrobiphenyl (less than 0.2%) and phenol (trace). Treatment of *p*-nitrophenylhydrazine with nickel peroxide in benzene yielded *p*-nitrobiphenyl (34.8%) and nitrobenzene (5.6%).

These results indicate that phenylhydrazine, on treatment with nickel peroxide, gives phenyl radicals, which abstract hydrogen atoms from cyclohexane to afford benzene, or abstract chlorine atoms from carbon tetrachloride to give chlorobenzene[4] and trichloromethyl radicals followed by their dimerization to hexachloroethane.

Formation of biphenyl in benzene is mostly attributable to the substitution of phenyl radicals on benzene, although less than 2% of biphenyl might arise solely from phenylhydrazine moiety without participation of benzene in view of the formation of a small amount of biphenyl in cyclohexane or in carbon tetrachloride. Production of very low yield of 1,4-dihydrobiphenyl suggests that either dihydrobiphenyl does not result appreciably from the reaction or it is once formed but subsequently oxidized to biphenyl by nickel peroxide as demonstrated by a separate experiment. However, the absence of quaterphenyl in addition to the very low yield of dihydrobiphenyl among the products from benzene suggest that phenyl radicals add to benzene to give phenylcyclohexadienyl radicals, which may be oxidized with nickel peroxide to biphenyl rather than disproportionate or dimerize to give biphenyl and 1,4-

TABLE 1. DISTRIBUTION OF ISOMERIC BIARYLS RESULTING FROM THE PHENYLATION OF AROMATIC SUBSTRATES

Substrate	Reaction condition[a]	Biaryls: Total yield[b]	Biaryls: Isomer distribution (%) *o*	*m*	*p*
Toluene	PH–NiPO (1:1)	28	67	19	14
	PH–NiPO (1:3)	34	68	19	13
	NNA[8]		71	18	11
Chlorobenzene	PH–NiPO (1:1)	22	63	20	17

4) Formation of chlorobenzene by way of benzenediazonium chloride, though not detected in the present reaction, cannot be completely excluded in view of reports for the detection of benzenediazonium salt in the reaction of phenylhydrazine with lead tetraacetate in dichloromethane[2] and in the decomposition of *N*-nitrosoacetanilide in carbon tetrachloride (W. S. M. Grieve and D. H. Hey, *J. Chem. Soc.*, **1934**, 1797; C. Rüchardt, Chuan-Cheng Tan, and B. Freudenberg, *Tetrahedron Lett.*, **1968**, 4019.

dihydrobiphenyl or tetrahydroquaterphenyl.[5,6] Production of a trace of phenol shows that phenyl radicals are not readily oxidized with nickel peroxide to phenol, in contrast to triphenylmethyl radicals which were reported to suffer oxidation with nickel peroxide to afford triphenylmethanol.[3b]

Oxidation of phenylhydrazine with nickel peroxide in chlorobenzene, nitrobenzene, and toluene gave *o*-, *m*-, and *p*-chloro-, nitro-, or methyl-biphenyl, respectively, the total yields of the respective isomeric biaryls being 30—50%, together with a small amount of biphenyl. The isomer ratios of the biaryls are summarized in Table 1. The increase in the ratio of nickel peroxide to phenylhydrazine from 1 : 1 to 3 : 1 equivalents caused only 1.4 fold increase in the yield of the isomeric biaryls without affecting the distribution among the isomers. The observed ratios of the isomeric biaryls accord well with those obtained from the decomposition of benzoyl peroxide[7] or *N*-nitrosoacetanilide,[8] or the treatment of phenylhydrazine with silver oxide[1] or with lead tetraacetate[2] in aromatic substrates, showing the generation of phenyl radicals from the present reactions.

Experimental

Reagents. Nickel peroxide was determined by iodometric titration,[3a] to contain 0.00323 g-atom of active oxygen per 1 g. Phenylhydrazine was distilled through a spinning band distillation column under reduced pressure and stored in a desiccator under nitrogen.

Solvents. Cyclohexane, benzene, carbon tetrachloride, toluene, and chlorobenzene were purified by conventional methods, and finally distilled through a 1 m high Vigreux column. Nitrobenzene was purified by partial freezing, dried with phosphorus pentoxide and finally distilled.

Authentic Samples. Biphenyl derivatives were prepared and purified by the well-known methods.[9] 1,4-Dihydrobiphenyl was prepared according to the reported procedure.[10]

Reaction of Phenylhydrazine with Nickel Peroxide. In a 100 m*l* three necked round bottomed flask fitted with a nitrogen inlet tube and a reflux condenser was placed 3 g of nickel peroxide and 10 m*l* of a solvent, and the mixture was stirred with a magnetic stirrer in nitrogen stream. After 20 min, 3 mmol of phenylhydrazine dissolved in 10 m*l* of the same solvent as above was gradually added, stirring was continued further 1 hr. The reaction mixture was filtered through a quantitative filter paper on a funnel and the precipitate was successively washed and the combined filtrate and washings were concentrated. No tetrahydroquaterphenyl was precipitated or detected by spectroscopy. The concentrated solution was subsequently examined by gas chromatography.

Reaction of 1,4-Dihydrobiphenyl with Nickel Peroxide. A benzene solution of 1,4-dihydrobiphenyl, 0.315 g, was treated with nickel peroxide, 2.1306 g (6.78 mg atom of active oxygen), under nitrogen and kept to stand overnight and worked up as above. In a control run, the dihydrobiphenyl in benzene was kept to stand without nickel peroxide to confirm that the dihydrobiphenyl was not consumed.

Gas Chromatographic Analysis. A Hitachi K-52 TCD gas chromatograph was used with a 2 m column of 10% silicone grease on chromosorb H for the determination of chlorobenzene, nitrobenzene, and hexachloroethane, with a 2 m column of 10% diisodesyl phthalate on chromosorb P for benzene and a 6 m column of 10% silicone grease on chromosorb H for biaryls.

The authors are indebted to Prof. Osamu Simamura for his encouragement throughout this work and to Dr. Ryusei Konaka, Shionogi Research Laboratory, for the supply of nickel peroxide.

5) Decomposition of benzoyl peroxide in benzene at 80°C carried out in the presence of nickel peroxide was shown to give 1,4-dihydrobiphenyl in a negligible amount and biphenyl in moderately higher yield than without nickel peroxide (O. Simamura and Hiromichi Ohta, private communication).

5-Bromo-2,3-benzotropone and its Maleic Anhydride Adduct[1]

Seiji EBINE, Masamatsu HOSHINO, and Takahisa MACHIGUCHI

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama

(Received June 17, 1971)

5,7-Dibromo-2,3-benzotropone (I),[2,3] obtained by the dehydrobromination of a tetrabromo derivative of 2,3-benzocycloheptenone, was debrominated on heating with a mixture of acetic and hydrobromic acids at 160°C to give 5-bromo-2,3-benzotropone (II). The position of the bromo substituent in II was established by the following NMR data. The spectrum of II (Fig. 1) contains an AB-type pattern consisting of H-7 at 6.67 ppm (d, $J_{7,6}=12.8$ Hz) and H-6 at 7.19 ppm (dd, $J_{6,7}=12.8$ and $J_{6,4}=2.05$ Hz), with perturbation arising from H-4 at 7.72 ppm (d, $J_{4,6}=2.05$ Hz). 7-Bromo-2,3-benzotropone (III),[4] prepared from 7,7-dibromo-2,3-benzocycloheptenone on treatment with lithium chloride, showed an entirely different NMR spectrum.[5a]

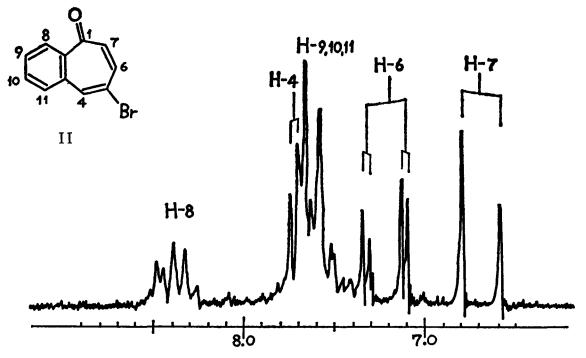

Fig. 1. NMR spectrum in deuteriochloroform at 60 MHz with TMS internal reference.

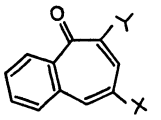
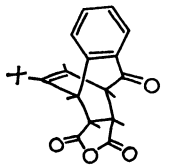
Chloro-2,3-benzotropone (IV), obtained by the reaction of 1-methoxynaphthalene with dichlorocarbene, has previously been assumed to be a 5- or 7-chloro compound.[6] The NMR spectrum of IV has an AB-type pattern consisting of H-7 at 6.88 ppm (d, $J_{7,6}=13.0$ Hz) and H-6 at 7.15 ppm (dd, $J_{6,7}=13.0$ and $J_{6,4}=1.9$ Hz) perturbed by H-4 at 7.81 ppm (d, $J_{4,6}=1.9$ Hz). The pattern is very similar to that of II, suggesting that IV is also 5-substituted. The dipole moment measurement of II and IV in a benzene solution has supported the above conclusion.[7] The X-ray crystal structure analysis of II and related compounds has also recently been undertaken.[5b]



I, X=Y=Br II, X=Br, Y=H
III, X=H, Y=Br IV, X=Cl, Y=H



V, X=Br VII, X=Cl

The Diels-Alder reaction of monocyclic troponoids has been studied,[8] and that of benzotroponoids has been briefly reported.[2,9] II underwent a Diels-Alder reaction with maleic anhydride on heating at 160—165°C to give an adduct (V). V was hydrolyzed, on standing in a dilute acetone solution at room temperature, to give the corresponding dicarboxylic acid (VI) which was, in turn, dehydrated with ease on refluxing in a benzene solution to give the original V, proving

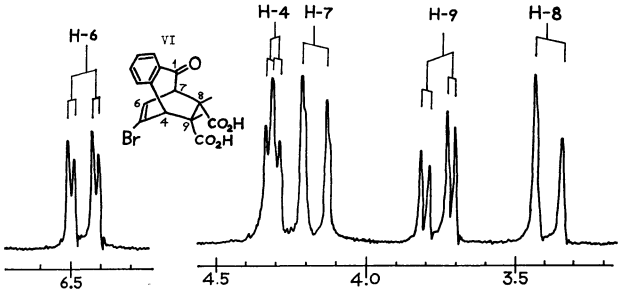


Fig. 2. NMR spectrum in acetone at 100 MHz with TMS internal reference.

that VI is a *cis*-dicarboxylic acid. The stereochemistry of VI has now been established on the basis of the following NMR spectral analysis (Fig. 2). An apparent triplet at 4.31 ppm and a doublet at 4.17 ppm collapse to simpler signals on irradiation at an olefinic proton, H-6 at 6.45 ppm, and, alternately, a double doublet ($J_{6,7}$=8.1 and $J_{6,4}$=1.9 Hz) of H-6 collapses to a doublet ($J_{6,7}$=8.1 Hz) on irradiation at 4.31 ppm and to a doublet ($J_{6,4}$=1.9 Hz) on irradiation at 4.17 ppm. The aforementioned triplet and doublet, therefore, are ascribable to H-4 and H-7 respectively. By the use of a similar double-resonance method, an AB-type pattern in the higher field can be assigned to H-8 at 3.40 ppm (d, $J_{8,9}$=9.0 Hz) and H-9 at 3.75 ppm (dd, $J_{9,8}$= 9.0 and $J_{9,4}$=2.6 Hz) perturbed by H-4 (d, $J_{4,9}$=2.6 Hz). It follows, therefore, that, in agreement with the above chemical evidence, VI should be a *cis*-dicarboxylic acid based upon a large value of $J_{8,9}$ and should have an *endo*-configuration based upon a small value of $J_{4,9}$. The *endo-cis*-configuration of VI is further supported by the Nuclear Overhauser Effect (10.4%) observed between H-8 and H-9, and by a small value of $J_{7,8}$ ($\leq$1) not obserbable even in the 100 MHz spectrum, but evidenced by the sharpening of the H-7-doublet on irradiation at H-8, and *vice-versa*. The stereochemistry of V could not be concluded from the NMR spectrum because V failed to give a satisfactory chart because of its difficut solubility, but a facile interconversion between V and VI suggests that V assumes the same *endo*-configuration as VI. V and VI, however, did not undergo Alder-Stein bromolactonization,[10] presumably because of the presence of the 5-bromo substituent. IV reacted with maleic anhydride to afford an adduct (VII), which again failed to give detailed NMR spectral data.

Experimental

5-Bromo-2,3-benzotropone (II). A solution of 200 mg of I[2] in 20 m*l* of 47% hydrobromic acid and 25 m*l* of acetic acid was heated in a sealed tube at 160—165°C for 5 hr. The solution gave a positive potassium iodide-starch test, indicating the presence of free bromine. The hydrobromic and acetic acids were removed by evaporation *in vacuo*, and the residue was recrystallized from methanol to yield 100 mg (76% yield) of II as pale yellow needles melting at 102—103.5°C.

Found: C, 55.99; H, 3.20%. Calcd for $C_{11}H_7OBr$: C, 56.20; H, 3.00%.

I remained unchanged on treatment with hydrochloric acid in the same manner as above.

A solution of 100 mg of II and 70 mg of bromine in 10 m*l* of acetic acid was refluxed for 40 min; the product was then recrystallized from methanol to give 90 mg (67% yield)of I.

Diels-Alder Reaction of 5-Halo-2,3-benzotropones with Maleic Anhydride. The Adducts (V and VII): A mixture of 440 mg of II and 220 mg of maleic anhydride was heated at 160—165°C for 30 min. The mixture was treated with anhydrous ether to remove the excess maleic anhydride, and the crude product (570 mg; 91% yield; mp 220°C dec.) was recrystallized from benzene to give colorless granular crystals of the 5-bromo-2,3-benzotropone-maleic anhydride adduct (V); mp 242°C (dec.).

Found: C, 54.32; H, 2.97%. Calcd for $C_{15}H_9O_4Br$: C, 54.08; H, 2.72%.

A similar treatment of 100 mg of IV[6] with 150 mg of maleic anhydride gave 130 mg (87% yield) of colorless granular crystals of the 5-chloro-2,3-benzotropone-maleic anhydride adduct (VII); mp 217.5—218.5°C.

Found: C, 62.62; H, 3.31%. Calcd for $C_{15}H_9O_4Cl$: C, 62.40; H, 3.14%.

Derivatives of V. a) Dicarboxylic Acid (VI): A solution of 340 mg of V in dilute acetone (35 m*l* of acetone and 20 m*l* of water) was allowed to stand at room temperature for 3 days. On the subsequent evaporation of the solvent below 30°C *in vacuo*, there remained 330 mg (91% yield) of colorless prisms of VI melting at 241—242°C (dec.). The hydrolysis of V with dilute alkali at room temperature gave the same result. VI gave the original V in 90% yield on refluxing in a benzene solution for 1.5 hr.

Found: C, 51.31; H, 3.19%. Calcd for $C_{15}H_{11}O_5Br$: C, 51.30; H, 3.16%.

b) Monomethyl Ester: A solution of 300 mg of V in 160 m*l* of methanol was allowed to stand at room temperature for a day. The subsequent evaporation of the solvent and recrystallization of the residue from dilute acetone (1:1) gave 290 mg (88% yield) of the monomethyl ester as colorless needles; double mp 112°C and 238°C.

Found: C, 50.15; H, 3.94%. Calcd for $C_{16}H_{13}O_5Br \cdot H_2O$: C, 50.15; H, 3.95%.

c) Dimethyl Ester: The methylation of 200 mg of VI with diazomethane in an ether solution afforded 120 mg (55% yield) of the dimethyl ester as colorless granular crystals; mp 113—113.5°C.

Found: C, 53.84; H, 4.07%. Calcd for $C_{17}H_{15}O_5Br$; C, 53.84; H, 3.99%.

Substituent Effects on the NH Proton Chemical Shifts of *p*-Substituted Phenylureas

Yoshihiro ASABE and Yojiro TSUZUKI*

Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigayafunagawara-machi, Shinjuku-ku, Tokyo

**Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo*

(Received June 18, 1971)

It has been recognized that the NH proton chemical shifts of substituted anilines[1,2] obey the Hammett's rule as do the side chain CH proton chemical shifts of substituted benzenes.[3] In this study the chemical shifts of the NH protons of *p*-substituted phenylureas were measured to study some correlations between the chemical shifts and vairous substituent constants, and discussions will be given about the substituent effect of *p*-substituent groups on the ureido(–NHCONH$_2$) group.

Dimethyl sulfoxide(DMSO) was chosen as solvent for the reason that DMSO dissolve the samples insoluble in most organic solvents, and also in order to eliminate complication due to the onset of proton exchange among the NH and NH$_2$ groups which provide an additional source of line broadening and coalescence. Under these conditions, the molecules of *p*-substituted phenylureas are isolated from each other and are hydrogen-bonded to the DMSO molecules with which they can not hydrogen exchange.[4–6]

The signals near 6.2 ppm and 3.6 ppm from the reference methyl signal of DMSO are assigned to the NH and NH$_2$ protons respectively and the signals near 4—5 ppm are assigned to the phenyl ring protons. In the phenylureas as well as in formamide, the ^{14}N–H spin-spin coupling is not observed because of the rapid relaxation of ^{14}N quadrupole due to the strong electric field gradients around the N nucleus caused by the CO group.[7] And the NH proton gives only a rather broadening signal due to this ^{14}N–H spin-spin interaction and the quadrupolar effect. For the NH$_2$ protons some difference in chemical shift would be expected between them due to the restricted rotation about the C–N bond, but only a very broadening signal is observed for the above mentioned reasons. It was observed that all the *p*-substituted phenylureas, except the NO$_2$ derivative, show a slight shift towards the higher field with dilution

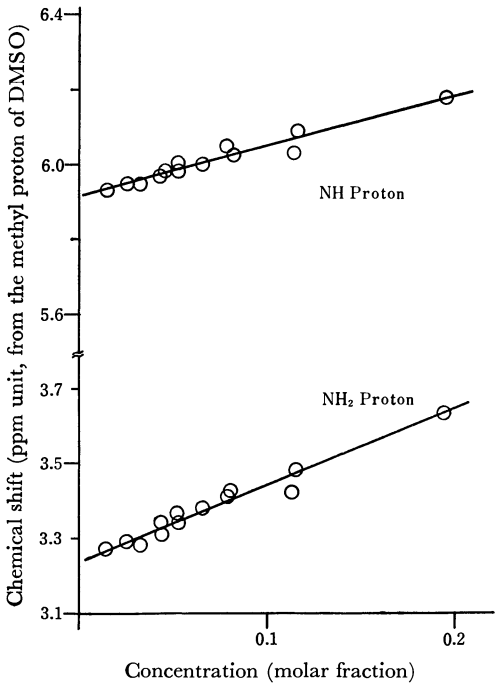

Fig. 1. Plottings of the NH and NH$_2$ proton chemical shift *vs.* concentration (molar fraction) of the phenylurea.

and the chemical shifts show a linear relationship with concentration (Fig. 1). The chemical shifts extrapolated to infinite dilution were obtained by the least square methods.

Now, the following factors may be considered, which affect on the chemical shifts of NH$_2$ and NH protons.

1) Hydrogen bonding and hydrogen exchange.
2) Magnetic anisotropy of the *p*-substituted phenyl group.
3) Variation of the electron density on each N atom.

As mentioned above, the phenylurea molecules in dilute solution exist in a solvated form with the DMSO molecules, and thus the intermolecular as well as intramolecular[8] hydrogen bondings could be ignored. Although detailed studies at various temperatures will be left in future, it is to be allowed from the example by Sunners *et al.*,[5] that the proton exchange is not very important at room temperature. Hence the hydrogen exchange between the NH and NH$_2$ groups may be assumed to be constant. As regards the factor (2), the anisotropic influence of the phenyl ring may predominantly exert

8) Intramolecular hydrogen bonding between the NH$_2$ protons and the phenyl ring can be considered.

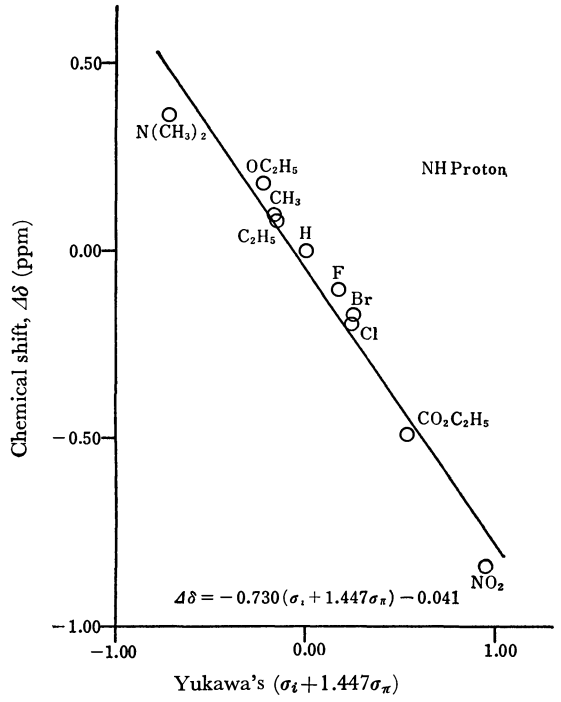

Fig. 2. Correlation of the NH proton chemical shifts and Yukawa's $(\sigma_i+\gamma\sigma_\pi)$ constant.

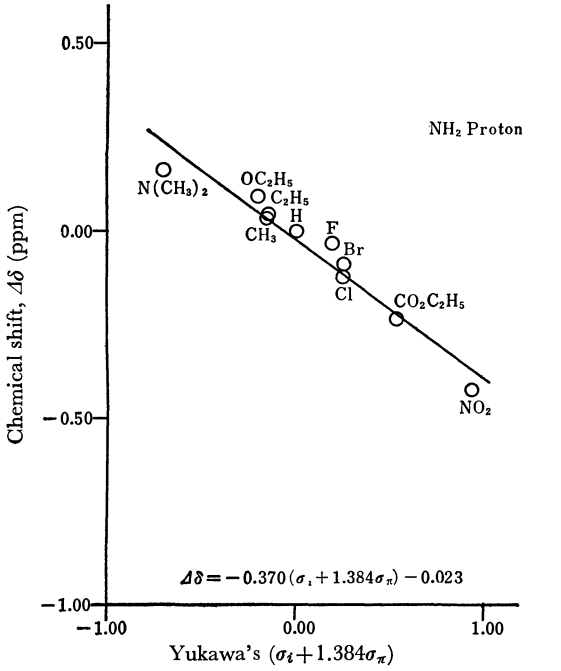

Fig. 3. Correlation of the NH_2 proton chemical shifts and Yukawa's $(\sigma_i+\gamma\sigma_\pi)$ constant.

on the chemical shifts, but the *p*-substituent may be almost ignored sterically and then the anisotropic effect may be considered to be constant. Consequently, only the factor (3), that is, the variation of shielding around the protons by the change of the electron densities on the N atoms is to be considered.

Then, studies were made as to the correlations between the difference of chemical shifts from the standard sample (phenylurea) and the various substituent constants. A fairly good linearity was obtained with Hammett's σ_p values[9] as well as with Taft's $(\sigma_I+2\sigma_R^0)$ values,[10] and the best result with Yukawa's $(\sigma_i+\gamma\sigma_\pi)$ values,[11] but not with other substituent constants. In Figs. 2 and 3 are shown the plottings against Yukawa's $(\sigma_i+\gamma\sigma_\pi)$ values except the I group since the substituent constant can not be estimated. Both the NH and NH_2 protons give a good linear relationship with Yukawa's values, namely, $\Delta\delta=-0.730(\sigma_i+1.447\sigma_\pi)-0.041$ for the NH proton and $\Delta\delta=-0.370(\sigma_i+1.384\sigma_\pi)-0.023$ for the NH_2 proton.

It is, therefore, concluded that the variation of the electron density on the N atom due to the electronic effect of *p*-substituent group determine the NH proton chemical shift. Furthermore, from the fact that the chemical shifts of the NH_2 protons as do the chemical shifts of the NH protons also in accordance with the Hammett's rule, it is confirmed that the N atom of NH_2 group is capable of conjugation with the phenyl ring system through the π-electrons of the CO group.

The ratio of the line slopes(ρ) of the NH proton to that of the NH_2 proton is about 2, that is, the NH proton shows twice as much σ-dependance as the NH_2 proton, and it appears that the H atom of the NH group directly bonded to the phenyl ring ought to be rather more sensitive to the *p*-substituent effect than do the NH_2 protons.

Experimental

Preparation of Samples. The *p*-substituted phenylureas (R-C$_6$H$_4$-NHCONH$_2$) were prepared by the reaction of sodium cyanate with the corresponding anilines in aqueous acetic acid solutions[12] and were purified by recrystallization. The identity and purity was confirmed by the mp determination and also by the IR spectra in a KBr disk.

Measurements. The PMR spectra were measured with a Varian A-60 Spectrometer at 30°C. The spectra were referred to the methyl signal of DMSO, and the chemical shifts were taken in ppm units lower field side from the reference. They were checked and corrected with the water signal of the external standard (in capillary) as a secondary reference. The position of each signal was measured using it's signal peak. A commercial guaranteed reagent was used as solvent (DMSO) and was treated with a molecular sieve before use in order to remove the contaminating water.

Dimerization of Malononitrile by Palladium and Platinum Complex Catalysts

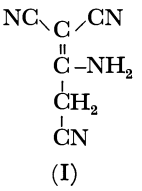
Kuniyuki TAKAHASHI, Akihisa MIYAKE, and Go HATA

Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura, Kanagawa

(Received July 20, 1971)

Previously we reported the palladium catalyzed reactions of 1,3-dienes with active methylene compounds.[1] In the course of the studies a novel catalytic dimerization of malononitrile has been found.

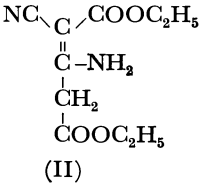
As described in the previous report,[1] malononitrile reacts with butadiene in the presence of a palladium catalyst to give 2,7-octadienyl and bis(2,7-octadienyl)-malononitrile in high yields. However, in the presence of a platinum catalyst, *e.g.*, tetrakis(triphenylphosphine)-platinum(0), the reaction gave only a small amount of the 2,7-octadienyl derivatives, with a large amount of a yellow solid product. The yellow product was insoluble in benzene. The elemental analysis and molecular weight measurement indicated that the product (mp 168—169°C) was a dimer of malononitrile. The dimer exhibited IR absorptions at 3350 and 3230 cm^{-1} (νN–H), 2180 cm^{-1}(νC≡N) and the NMR signals at τ 6.24 (s, 2H), 1.19 and 1.08 (broad, 2H). Its UV spectrum showed the maximum absorption at 274 mμ (ε 14000 in ethanol) due to conjugated double bonds. These spectral characteristics suggest the following structure (I).



(I)

Carboni[2] prepared the malononitrile dimer (I) for the first time using bases and acids. The IR and NMR spectra of the present product were identical with those of the dimer prepared by the Carboni's method.

Ethyl cyanoacetate also dimerized by the platinum catalyst to give 1-cyano-1,3-diethoxycarbonyl-2-amino-1-propene (II). Ethyl cyanoacetate was not so reactive as malononitrile. The dimer (II) showed IR absorptions at 3420, 3300, and 3230 cm^{-1}(νN–H), 2200 cm^{-1}(νC≡N), and 1740 cm^{-1}(νC=O, ester). The NMR spectrum of II in CCl_4 exhibited signals at τ 8.69 (t, 6H, J=7.0 Hz, –O–C–CH_3), 6.43 (s, 2H, =C–CH_2–CO), 5.80 and 5.77 (two quartet, J=7.0 Hz, –CO–O–CH_2–), 2.55 and 0.68 (broad, 2H, N–H, equal intensities). The maximum absorption of UV spectrum was at 277 mμ (ε 17600 in ethanol).



(II)

Tetrakis(triphenylphosphine)platinum is most efficient for the dimerization of malononitrile, but inefficient for the reaction of malononitrile with 1,3-butadiene.[1] A combination of dichloro bis(triphenylphosphine) platinum (II) and sodium phenoxide also showed the catalytic activity. The palladium catalysts, which are quite effective for the reaction of malononitrile with butadiene, was found to be effective for the dimerization reaction of malononitrile, as shown in Table 1, but their activities were low as compared with those of the platinum ones.

It was confirmed that triphenylphosphine or sodium phenoxide alone had no catalytic activity under the present reaction conditions. From the fact that the zerovalent platinum and palladium complexes are effective catalysts, the zerovalent metal atoms appear to play an important role in the catalytic dimerization reactions of malononitrile and ethyl cyanoacetate.

TABLE 1. DIMERIZATION OF MALONONITRILE BY PLATINUM AND PALLADIUM COMPLEXES

Catalyst mmole	Reaction time hr	Dimer yield %
$Pt(Ph_3P)_4$ 0.25	1	82.1
$PtCl_2(Ph_3P)_2$–C_6H_5ONa 0.25	20	80.3
$Pd(Ph_3P)_4$ 0.25	4	39.5
$Pd(Ph_3P)_2$  0.25	20	13.6
$PdCl_2(Ph_3P)_2$–C_6H_5ONa 0.25 2.5	20	33.4

malononitrile 0.1 mol, benzene 20 m*l*, 80°C

Experimental

Catalysts. $Pd(Ph_3P)_4$,[3] $Pd(Ph_3P)_2$  ,[4] $PdCl_2(Ph_3P)_2$,[3] $Pt(Ph_3P)_4$,[5] and $PtCl_2(Ph_3P)_2$[5] were prepared by the methods described in the literatures. Sodium phenoxide was prepared by the usual method from sodium metal and phenol.

Dimerization of malononitrile by $Pt(Ph_3P)_4$. In a two-necked 50 m*l* round-bottomed flask were placed 6.6 g (0.1 mol) of malononitrile, 0.31 g (0.00025 mol) of tetrakis(triphenylphosphine)platinum(0) and 20 m*l* of benzene. The mixture was stirred at 80°C for 1 hr under an argon atmosphere. The precipitated yellow solid was separated by filtration, washed several times with hot benzene and dried to give 5.4 g (82.1% yield) of 1,1,3-tricyano-2-amino-1-propene (I); mp 168—169°C (lit,[2] mp 172—173°C); IR(KBr): 3350, 3230, 2180, 1655, 1555, 1387, 1309, and 906 cm^{-1}; NMR (in hexadeuterodimethyl sulfoxide): 6.24 (s, 2H), 1.19 (broad, 1H), and 1.08 (broad, 1H); UV (in ethanol): λ_{max} 274 mμ (ε 14000). Found: C, 54.42; H, 3.17; N, 42.44%; mol wt, 135.7. Calcd for $C_6H_4N_4$: C, 54.54; H, 3.05; N, 42.41; mol wt, 132.1.

Dimerization of Ethyl Cyanoacetate. The mixture of 11.4 g (0.1 mol) of ethyl cyanoacetate, 0.62 g (0.0005 mol) of tetrakis(triphenylphosphine)platinum(0) and 20 m*l* of benzene was stirred at 80°C for 20 hr. The reaction mixture was fractionally distilled to give 1.8 g (15.8% yield) of 1-cyano-1, 3-diethoxycarbonyl-2-amino-1-propene (II); bp 153—155°C/0.02 mmHg, mp 54—55°C; IR(KBr): 3420, 3300, 3230, 2990, 2200, 1740, 1680, 1630, 1528, 1270, 1185, 1095, 1020, and 785 cm^{-1}; NMR (in carbon tetrachloride): τ 8.69 (t, 6H, J= 7.0 Hz), 6.43 (s, 2H), 5.80 and 5.77 (two quartet, J=7.0 Hz), 2.55 (broad, 1H), and 0.68 (broad, 1H); UV (in ethanol): λ_{max} 277 mμ (ε 17600). Found: C, 53.01; H, 6.22; N, 12.37%; mol wt, 227.3. Calcd for $C_{10}H_{14}N_2O_4$: C, 53.09; H, 6.24; N, 12.37; mol wt, 226.2.

SHORT COMMUNICATIONS

Stereochemical Study of *N,N'*-Dimethylethylenediamine Cobalt(III) Complex *trans*-Dinitrobis(*N,N'*-dimethylethylenediamine)cobalt(III) Ion

Shigenobu YANO, Masahiko SABURI,* and Sadao YOSHIKAWA*

(Received May 29, 1971)

Recently Buckingham *et al.*[1] prepared *trans,trans*-$[CoX_2(N\text{-Meen})_2]^+$ ($X=Cl^-$, NO_2^-; *N*-Meen=*N*-methylethylenediamine) ion whose *N*-methyl groups are *trans* to each other. They obtained three isomers of the meso (R,S) and the optically active (R,R and S,S) forms, where R and S refer to the chirality of the coordinated nitrogen centers. In these complexes, the nonbonding interactions between the N–CH_3 groups and the N–H groups do not seem to be so large as to exclude their sterically crowded meso isomer. However, in the case of *trans*-$[CoX_2(N,N'\text{-}Me_2en)_2]^+$, where *N,N'*-$Me_2$en denotes *N,N'*-dimethylethylenediamine, strong nonbonding interactions can be expected to be present between the N–CH_3 groups on neighboring ligand molecules. On the other hand, seven isomers are theoretically possible for *trans*-$[CoX_2(N,N'\text{-}Me_2en)_2]^+$ complex owing to the asymmetry of coordinated nitrogen centers, three meso {(RR,SS), (RS,RS), and (RS,SR)} and four optically active {(RR,SR) and (SS,SR), and (RR,RR) and (SS,SS)} forms. Of these, the last two forms in which all four *N*-methyl groups have an equatorial arrangement are likely to be the most favorable sterically.

In order to see the presence of isomerism in the complexes of such type, we investigated *trans*-$[Co(NO_2)_2(N,N'\text{-}Me_2en)_2]I$ as follows.

$Na_3[Co(NO_2)_6]$ (22 g) was allowed to react with a refluxing solution of *N,N'*-Me_2en (10 g) and water for 2 hr. Addition of sodium iodide, then, gave brown crystals of the pure compound. Found: C, 21.06; H, 5.14; N, 18.58%. Calcd for $C_8H_{24}N_6O_4CoI$: C, 21.16; H, 5.33; N, 18.51%. The PMR spectrum of the product in D_2O showed one *N*-methyl singlet (2.2 ppm) and a methylene multiplet (2.4—3.2 ppm) which was regarded to be of AA'BB' pattern by means of iterative analysis.[2] It was shown by PMR study[2] that in aqueous solution *N,N'*-Me_2en chelate rings have a similar *gauche* conformation (Fig. 1). The fact that only one PMR signal of the *N*-methyl group is observed suggests that this complex is assigned to *trans*-$[Co(NO_2)_2(N,N'\text{-}Me_2en)_2]^+$ composed of the most preferred isomers in optically active form. To examine whether it was the unique product under the given conditions, the reaction product of $Na_3[Co(NO_2)_6]$ and *N,N'*-Me_2en was evaporated to dryness and its PMR spectrum was measured in D_2O. An *N*-methyl singlet (2.2 ppm) and a methylene multiplet (2.4—3.2 ppm) were observed. The iodide was successfuly resolved into its optical forms with silver α-bromo-π-camphorsulfonate. It is very likely that all four asymmetric nitrogen atoms in $(-)_{589}$-*trans*-$[Co(NO_2)_2(N,N'\text{-}Me_2\text{-}en)_2]^+$ are of *S*-configuration in view of their CD spectrum as compared with those of some *trans*-dinitrobis(*N*-methylated diamine)cobalt(III) ions which have asymmetric nitrogen atoms with a known configuration.[3]

The Oxidation of Chroman-4-ols with Chromic Acid

Shozo YAMAGUCHI, Kuninobu KABUTO, Yoriko KIKUCHI, and Naoto INOUE
College of General Education, Tohoku University, Kawauchi, Sendai

(Received August 2, 1971)

With regard to the oxidation rates with chromic acid of epimeric cyclohexanols(CYHs), it is well known[1] that the axial alcohols are oxidized faster than the equatorial ones and that the bulky substituent adjacent to the hydroxyl group accelerates the reaction. Although isolated studies of the oxidation rates of allyl alcohols are on record,[2] no systematic investigation has yet been reported. We wish to report the oxidation of chroman-4-ols; the results are summarized in the table. Only the most interesting results different from those in the saturated series can be discussed here.

TABLE 1. OXIDATION RATES OF SUBSTITUTED CHROMAN-4-OLS

a) l/mol sec$\times 10^2$ in 85.5% (by volume) HOAc, 25°C. Rates followed spectrophotometrically at 380 mμ. $[CrO_3]3.00\times10^{-4}$M; $[ROH]2.25\times10^{-4}$M. All data average of 2—4 runs.
b) The conformation of these compounds were determined by NMR.
c) CR: Chroman-4-ol

In this series of compounds, the rates of *cis*-2-substituted chroman-4-ols (2-CRs) are markedly larger, and in *cis*-2- and *trans*-2-CRs the rates are little affected with an increase in the size of the respective substituent. Both *cis*-2- and *cis*-3-CRs react more rapidly than the corresponding *trans* isomers. In all the 2-CRs except 2-Ph-CRs, the ratios of the rates of *cis*/*trans* (9—12) are larger than those of 3-CRs and CYHs. Since the 2-CRs are almost conformationally homogeneous, as is indicated in the table, the above results can be explained to some extent by the fact that the acceleration by the strain relief in the *cis*-2-CRs ($A^{(1,3)}$ strain, *ca.* 1.0 kcal/mol)[3] is greater than that of *trans* ones (*ca.* 0.35 kcal/mol).[4] However, the rate ratio of *cis*/*trans* (*ca.* 3.8), as calculated[4] from the free energy difference (*ca.* 0.65 kcal/mol) between the two isomers, is not so large as the observed value (9—12); consequently, the observed ratio should be attributed to both the stereoelectronic effect[5] and the strain relief.

It is a striking fact that *cis*- and *trans*-3-*t*-Bu-CRs (XIV, XV) show the smallest rates of all the 3-isomers. In the 2-substituted CYHs, the rate ratios of *t*-Bu/Me are 9.3(*trans*)—11(*cis*)[1] due to the presence of a bulky adjacent group. Although similar effects can be expected for the 3-CRs, the ratios are markedly reversed. Since XV exists mostly in the diaxial conformation, it is considered that the *t*-Bu group has little effect on the steric compression of the hydroxyl group, and the ground state can be assumed to be similar to that of *trans*-3-Me-CR(XI). In the transition state, however, the repulsion[4] between the developing carbonyl group and the *t*-Bu group is much larger than that of XI; consequently, XV has the larger activation free energy. This assumption is also supported by the fact that the rates decrease with an increse in the size of the substituent in *trans*-3-CRs.

Contrary to the reactivity anticipated from its preferred conformation, the rate of XIV is quite small compared to that of *cis*-3-Me-CR(X) and *cis*-2-*t*-Bu-CYH ($k=79.7\times10^{-2}$). In the case of strongly hindered alcohols, it has been reported[6] that the formation of the ester is concerned in the rate-controlling step and the rate decreases. In the initial stage of the reaction of XIV, an induction period characteristic of a successive reaction and a smaller isotope effect is observed. These results suggest that the esterification step is connected to some extent with the rate-determining step because of its sterically-crowded situation, in which the hydroxyl group is surrounded by the *t*-Bu group and the hydrogen in a peri-position.

A Novel Synthesis of Ethyl β-Diethoxyphosphinyl-α,β-unsaturated-carboxylates

Chung-gi SHIN, Yasuchika YONEZAWA, and Juji YOSHIMURA*

Laboratory of Organic Chemistry, Kanagawa University, Kanagawa-ku, Yokohama

**Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo*

(Received August 28, 1971)

Although there have been numerous reports on the reaction of aromatic nitro and nitroso compounds with tervalent organophosphorus reagents,[1-5] little attention has been paid to that of aliphatic nitro compound.

In the course of studies on the reaction of ethyl α,β-unsaturated α-nitrocarboxylates (I),[6] we have found that the reaction of I with triethyl phosphite gave ethyl β-diethoxyphosphinyl-α,β-unsaturated-carboxylates (II) in good yield, accompanied by liberation of ethyl nitrite. Only two kinds of vinylphosphonates (IIa and IIb) have recently been prepared by nucleophilic substitution of the corresponding activated vinyl halides with triethyl phosphite as useful synthetic intermediates (Arbusov reaction).[7,8]

When a solution of I (0.1 mol) and triethyl phosphite (0.1 mol) in dry benzene (30 ml) was refluxed for about 3 hr, evolution of gaseous substance took place. Fractional distillation of the reaction mixture gave colorless oil (Table 1). The gaseous substance trapped was identified to be ethyl nitrite by gas chromatography.

The stereochemical assignments of II were made on the basis of independent preparation from vinyl halides and phosphite, and spectroscopic analysis. The vinyl hydrogen signal with J_{P-H}=23.5—28.4 Hz appearing in a lower magnetic field, and that with J_{P-H}=43.5—46.3 Hz in a higher field were assinged to *cis* and *trans*, respectively[9] (Table 2). Consequently, the composition of *cis* and *trans* isomers in II was evaluated from the intensity of the vinyl protons.

From the results it is postulated that the triethyl phosphite reacted nucleophilically to β-position of the nitrocarboxylic esters (aci-form; Ib) and cyclized to afford five membered intermediates (III), and the subsequent concerted reaction in III occurred to give II and ethyl nitrite (Scheme 1). In fact, in the case of isopropyl derivative, an unstable intermediate (bp 95—105°C/0.001 mmHg. Found: N, 4.14%. Calcd for $C_{14}H_{28}NO_7P$: N, 3.97%) was obtained under mild conditions and was decomposed to IIe and ethyl nitrite during the course of redistillation.

Some Short-lived Isotopes of Lanthanum

Akira OHYOSHI,* Emiko OHYOSHI,** Tadaharu TAMAI,*** and Mutsuaki SHINAGAWA****

*Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto-shi, Kumamoto

**Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto-shi, Kumamoto

***Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka

****Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received August 30, 1971)

Because of the difficulty of the rapid isolation of lanthanum from fission product of ^{235}U, the nuclear data on short-lived isotopes of lanthanum, the existence of which has been confirmed, have not yet been reported in detail. In a previous paper,[1] it has been shown that the isolation of lanthanum, cerium, and praseodymium was carried out within 4 min by electromigration at a selected concentration of nitrilotriacetate ions. The time taken for the isolation on lanthanum alone must be much shorter since there is a greater difference in the stabilities of the NTA complexes of lanthanum and cerium as compared with those of other adjacent lanthanide pairs. This method was applied to the rapid isolation of lanthanum isotopes, and some nuclear properties were measured.

A small amount (0.1 m*l*) of 10^{-2}M uranyl nitrate, irradiated for 1 min in KUR at the temperature of dry ice, was diluted by the carrier solution (3×10^{-4}M, 0.4 m*l*) in order to detect the migrating zone of lanthanum by studying color reaction with Arsenazo(III). Using NTA (3.7×10^{-4}M, pH=2.0), the separation was carried out by applying a potential gradient of 80 V/cm for 90 sec. Although this concentration of the ligand ion is lower than the optimum one for the separation of the La-Ce pair,[2] a high mobility is more feasible for separation from other fission products. After detection by color reaction, the γ-ray spectrum of the separated zone was measured with a CAMBERA Ge(Li) detector (30 cc). Starting 4.5 min after the end of irradiation, 20-sec countings were made at 30 sec intervals and each spectrum was recorded on a magnetic tape.

The first and third γ-ray spectra are reproduced in Fig. 1, in which two prominent photopeaks, at 0.395 and 0.541 MeV, may be found to have appreciably short lives. The decay plots of these peak areas are shown in Fig. 2. The half-lives obtained from three runs are given as 40 ± 2 sec for the peak at 0.395 MeV and as 43 ± 3 sec for that at 0.541 MeV. The two other photopeaks, at 0.619 and 0.644 MeV, observed in Fig. 1 were ascribed to the 14 min ^{143}La and the 92 min ^{142}La from their decay rates. No photopeak which should be assigned to particular nuclides of any element other than lanthanum one was found in this experiment.

For short-lived isotopes of lanthanum formed by

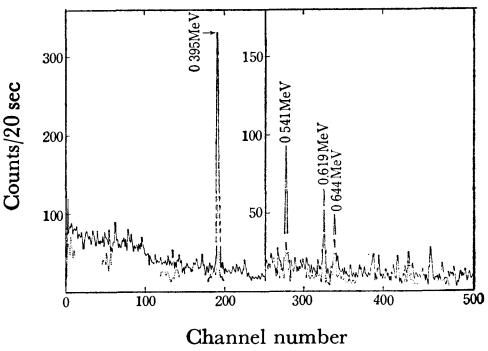

Fig. 1. γ-Ray spectra of La nuclides

fission, values of 92 min ^{142}La,[3] 14.0 min ^{143}La,[3] and 41 sec ^{144}La[4] are listed in the literature. For ^{142}La and ^{143}La, both the γ-ray energies and their abundances have been reported, but there have been no data for ^{144}La. As has been described above, a half-life of about 40 sec is given for both photopeaks at 0.395 and 0.541 MeV; therefore, we presumed that these two photopeaks could be attributed to the ^{144}La.

The Oxidative Coupling of Butyrophenone by Ferric Chloride

Hiroo INOUE, Mitsuya SAKATA, and Eiji IMOTO
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received September 4, 1971)

We wish to report a novel oxidative coupling of enolizable ketone, butyrophenone (I), which takes place thermochemically and photochemically in the presence of ferric chloride, leading to the formation of the γ-diketone, 3,4-benzoylhexane (II), accompanied by chlorination in the α-position of the carbonyl group to give α-chlorobutyrophenone (III).

A solution of 0.22 g (1.34 mmol) of anhydrous ferric chloride in 5 m*l* of I was heated at 70—80°C for 48 hr. During the course of the reaction, ferric chloride was reduced to ferrous chloride in a 67% yield. The two products of II and III were isolated by gas chromatography after work-up; II (yield, 49%) exhibited NMR (CCl_4) signals at 0.7—1.3 (*m*, 6H, CH_3), 1.6—2.1 (*m*, 4H, CH_2), 4.05 and 5.55 (*q* and *t*, 2H, CH), and 6.9—8.0 (*m*, 10H, aromatic protons), and an IR (liquid film) peak at 1680 cm^{-1} (CO). Mass *m/e*; 294 (parent peak).

Found: C, 81.56; H, 7.55%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%.

III[1] (yield, 31%) exhibited NMR (CCl_4) signals at 1.05 (*t*, 3H, CH_3), 1.7—2.3 (*m*, 2H, CH_2), 4.75 (*t*, 1H, CH), and 7.2—7.9 (*m*, 5H, aromatic protons), and an IR (liquid film) peak at 1693 cm^{-1} (CO).

The yields of II and III, which were calculated by 200×(the number of moles of the product / that of ferric chloride), increased as the reaction time proceeded and then became constant after 3 hr. Over 3 hr, III was not converted to II. When a mixture of 0.11 g (0.58 mmol) of III and 0.063 g (0.48 mmol) of ferrous chloride in 5 m*l* of I was heated at 70°C, II was not obtained, but III was recovered unchanged. These facts indicate that the coupling reaction does not proceed *via* the process involving the reduction of III by ferrous chloride. The yield of II increased with an increase in the concentration of ferric chloride up to the saturation of ferric chloride. Furthermore, the addition of pyridine to the ferric chloride - I system resulted in a decrease in the yield of II. With the molar ratio of pyridine to ferric chloride of 1: 1, III was obtained selectively in a 64% yield.

On the other hand, a solution of 0.21 g (1.27 mmol) of ferric chloride in 5 m*l* of I, which had been placed in a quartz tube, was irradiated with a 100-W high-pressure mercury lamp at a distance of 4 cm under an atmosphere of air at room temperature for 24 hr. During the course of this reaction, white crystals of ferrous chloride precipitated (yield, 83%). The reaction products were II, III, β-chlorobutyrophenone (IV), and acetophenone, which were obtained in 26, 26, 14, and 31% yields respectively. The formation of ethylene was also confirmed by converting the ethylene to 1,2-dibromoethane. Acetophenone and ethylene were produced after the complete conversion of ferric chloride to ferrous chloride. When pyridine was added to the reaction system, with the molar ratio of pyridine to ferric chloride of 1: 1, III, IV, and crotophenone were obtained in 48, 14, and 6% yields respectively after irradiation for 24 hr.

The formation of II and III indicates that the initial step involves the oxidation of the ketone by ferric chloride, thus leading to the α-keto radical. Such a process has been found in the oxidation of ketones by either manganic or ceric ions.[2-4] The α-keto radicals couple with each other to form II or are oxidized by the ferric chloride to give α-chloroketone (III).[5] Further work is in progress and will be reported in the future.

The Crystal Structure of $(-)_{589}$-Dinitrobis(ethylenediamine)cobalt(III) $(+)_{589}$-Bis(malonato)ethylenediaminecobaltate(III)

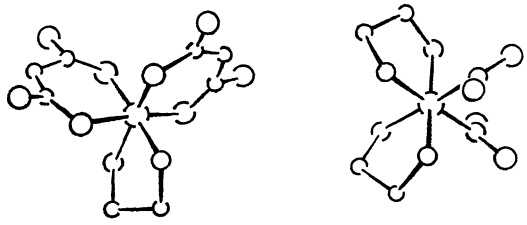
Keiji MATSUMOTO and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 10, 1971)

The CD and ORD spectra of $(+)_{589}$-[Co mal_2en]$^-$ (mal=malonate ion) were studied by Douglas and his co-workers.[1] They identified the lowest-frequency CD peak with a negative sign as the *A* component and gave it the *Δ* configuration by making use of Mason's empirical rule.[2] Recently, Judkins and Royer[3] confirmed experimentally Piper's prediction[4] that the sign of the Cotton effect is reversed as the coordination angle(θ) in the chelate ring goes from less than to greater than 90°. This was, however, not taken into account by Douglas *et al.* in applying Mason's rule to $(+)_{589}$-[Co mal_2en]$^-$. In order to reexamine directly the absolute configuration of the complex anion, we have carried out a crystal-structure analysis of $(-)_{589}$-[Co$(NO_2)_2en_2$] $(+)_{589}$-[Co mal_2en].[5,6]

The crystal structure has been determined from the three-dimensional photographic data. The structure was refined by a least-squares method to an *R* factor of 0.101 for 1442 reflections. The absolute configurations of the complex anion as well as of the cation were determined by means of the anomalous dispersion effect of the cobalt atoms for Cu$K\alpha$ radiation. Crystal data: triclinic, space group $P\bar{1}$; $a=10.58(2)$, $b=7.98(1)$, $c=7.99(1)$ Å, $\alpha=122.8(2)$, $\beta=105.3(2)$, $\gamma=74.6(2)°$; $Z=1$ ($D_m=1.81$, $D_c=1.82$ g·cm^{-3}); $\mu=35.9$ cm^{-1} for Ni$K\alpha$.



$(+)_{589}$-[Co mal_2en]$^-$ $(-)_{589}$-[Co$(NO_2)_2en_2$]$^+$

Fig. 1. The absolute configurations of the complex ions

The perspective drawings of $(-)_{589}$-[Co$(NO_2)_2en_2$]$^+$ and $(+)_{589}$-[Co mal_2en]$^-$ are presented in Fig. 1. Each of the complex ions has an approximate two-fold axis. The ethylenediamine ligands in both complexes are of the *ob*-conformation. The two six-membered malonate chelate rings are nearly planar, the O–Co–O angle being 96° and greater than the N–Co–N angle in the cobalt(III)-trimethylenediamine chelate ring.[7]

The absolute configuration of $(-)_{589}$-[Co$(NO_2)_2en_2$]$^+$ can be denoted as *Δ* in accordance with the assignment made by those investigating ORD[8] and CD.[2,9,10] It is notable that an empirical rule connecting the absolute configuration of a metal complex and the sign of the Cotton effect of the $^1A_1 \rightarrow A$ electronic transition holds for this complex.

The absolute configuration of $(+)_{589}$-[Co mal_2en]$^-$ has been determined as of *Δ* and is in agreement with the assignment made by Douglas *et al.* Their assignment of the *A* component seems to be correct. However, if Piper's prediction still holds in the case of the trismalonatocobalt(III) complex, the E_a component of $\Delta(+)_{589}$-[Co ox_3]$^{3+}$($\theta<90°$) and that of *Δ* trismalonatocobalt(III) ($\theta>90°$, possibly) will be opposite in sign. The *A* component of the bismalonatocobalt(III) complex derives mainly from the E_a component of the trismalonatocobalt(III) complex.[2] Consequently, the sign of the *A* component of $\Delta(+)_{589}$-[Co mal_2en]$^-$ should be the reverse of that of the E_a component of $\Delta(+)_{589}$-[Co ox_3]$^{3-}$, though these two complexes have the same configuration. Therefore, the assignment of the *A* component by Douglas *et al.* is not entirely satisfactory.

Note on the Formation Constant of the Mono(ethylenediamine)-chromium(III) Complex

Jannik BJERRUM and Ole MØNSTED

Chemistry Department I, Inorganic Chemistry, H. C. Ørsted Institute, University of Copenhagen, Copenhagen, Denmark

(Received September 6, 1971)

In a paper in this journal, Tsuchiya and his co-workers[1] have given values for the 1st formation constant in the chromium(III)-ethylenediamine system. Their procedure was as follows: Aqueous solutions of tris(ethylenediamine)chromium(III) perchlorate to which an excess amount of perchloric acid had been added, were maintained at 25°C for one or two months. On the assumption that equilibrium was established, the solutions containing mono(ethylenediamine) and hexa-aqua ions were then analyzed spectrophotometrically. In this way values of the 1st formation constant were found to be about $10^{16.5}$. As this value in our opinion is much too high, we suspected that the solutions examined by Tsuchiya and his co-workers had not been in equilibrium, and we have, therefore, made similar measurements but at a higher temperature in order to reach equilibrium more rapidly. A solution with the following total concentrations of $[Co\ en_3](ClO_4)_3$ 0.0085M and $HClO_4$ 0.072M was placed in a thermostat at 50°C, and the advancing hydrolysis was followed spectrophotometrically. In our experiment the spectrum changed relatively little over a long period of time in the "equilibrium" range of Tsuchiya and his co-workers, but after the lapse of about three months the spectrum was indistinguishable from that of a solution of the hexa-aquachromium(III) ion. The same was the case with a 0.0096M solution of $Cr(H_2O)_6(ClO_4)_3$, 0.032M in $enH_2(ClO_4)_2$ and 0.022M in $HClO_4$. These results are also consistent with a kinetic study by Garner and his co-workers[2] which implies that the systems studied by Ohta, Matsukawa, and Tsuchiya were not at equilibrium, and that their "equilibrium constants" are not accurate. According to our findings the amount of mono(ethylenediamine) complex not hydrolyzed must be less than one percent of the total chromium. The hydrogen ion concentration in the aquated solution is 0.020M, that of enH_2^+ 0.026M, and by introducing the acid dissociation constants of the last-mentioned ion at 50°C $K_{A,1} \times K_{A,2} = 10^{16.06}$ [3] a simple calculation shows that the 1st formation constant in the chromium(III) ethylenediamine system must be smaller than $\sim 10^{12}$. This value is more than 10^4 times smaller than the value $\sim 10^{16.5}$ given by Ohta, Matsukawa, and Tsuchiya.[1] Tsuchiya and his co-workers[4] have published formation constants for many other chromium(III) complexes but have not made sure that equilibrium is reached by approaching it from both sides. A critical revision of their data therefore seems necessary.

Hydrogen-Deuterium Exchange in the Methyl Group of Four Bisdimethylglyoximatocobalt(III) Complexes

Hayami YONEDA,* Ichiro TAKAGI,* and Yukiyoshi MORIMOTO**

*Department of Chemistry, Wakayama University, Masagocho, Wakayama

**Research Laboratories, Fujisawa Pharmaceutical Company, Kashimacho, Higashiyodogawa-ku, Osaka

(Received September 11, 1971)

Organic ligands in chelate compounds are under the influence of the electron-withdrawing effect of a central metal ion, and as a result, proton dissociation from the ligands is more or less facilitated. Thus, hydrogen-deuterium exchange is to be observed in some complexes, when they are dissolved in deuterium oxide. We noticed this kind of exchange from the fact that the intensity of the PMR signal of methylene in malonato chelates dissolved in deuterium oxide decreased with time.[1] Thus, the NMR technique proved to be useful for the study of proton exchange reactions. Several other examples have been found, *i.e.* in the methylene of the glycinatocobalt(III) complex,[2] in the methylene of the palladium Schiff base complex of glycine and pyruvic acid,[3] in the methyl of the acetylacetoneethylenediiminecobalt(III) complex[4] and in the ethylene of the EDTA-cobalt(III) complex.[5]

We would like to report a similar hydrogen-deuterium exchange in the methyl group of a series of bisdimethylglyoximatocobalt(III) complexes of the formula $[CoX_2(dgH)_2]^{+or-}$ in which X is CN^-, NO_2^-, NH_3, or CH_3NH_2. It should be noticed that the exchange rate is dependent on the kind of the axial ligand X.

Figure 1 shows the time change of the PMR spectrum of $[Co(CH_3NH_2)_2(dgH)_2]Cl$ in 2% NaOD deuterium oxide solution at 20°C. The methyl signal of the dimethylglyoximato ligand lies in the middle of the spectrum and shows the intensity decrease and line-broadening with time (Fig. 1, (1), (2), and (3)). This is clearly due to the hydrogen-deuterium exchange

$$-CH_3 \longrightarrow -CH_2D \longrightarrow -CHD_2 \longrightarrow -CD_3$$

The line-broadening is due to the spin-spin coupling between H and D in the intermediates CH_2D and CHD_2.

Thus, the exchange reaction can be followed as the intensity decrease of the methyl signal of the coordinated ligand. The result obtained for the four complexes is shown in Fig. 2. We see that the exchange rate for the free ligand is negligibly small, compared with that of any one of the four complexes tested, and we can conclude that the activation of ligand protons is induced by chelation. It should be pointed out that the exchange in the cyano complex goes very slowly while the exchange in the methylamine complex proceeds fairly fast. Thus, the exchange rate is in the order $CH_3NH_2 > NH_3 > NO_2^- > CN^-$. The half-value periods for these complexes are 7.5 hr for the methylamine, 11 hr for the ammonia, 200 hr for the cyano complexes and more than 1000 hr for the free ligand. The half-value period for the nitro complex lies between those of the ammonia and cyano complexes, but decomposition of the complex prevented determination of the exact value. This exchange rate order is just the reverse of the order of positions of these ligand X in the spectrochemical series. This trend can be interpreted in the following way. Since the activation of ligand protons is induced by the electron-withdrawing effect of a central metal ion, the less positive the effective charge of the metal ion, the smaller the exchange rate of the ligand protons. The smallest exchange rate for the cyano complex is the reflection of the almost complete neutralization of the positive charge of the central metal ion which is caused by the strong coordination of the cyano groups.

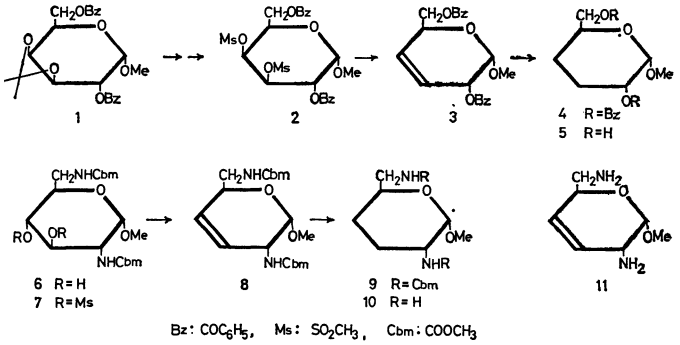
Syntheses of 3,4-Dideoxy-3-enosides and the Corresponding 3,4-Dideoxy Sugars

Sumio UMEZAWA, Tsutomu TSUCHIYA, and Yasushi OKAZAKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received September 16, 1971)

From a biological point of view studies on unsaturated sugars have been drawing attention in recent years, but the introduction of 3,4-unsaturated linkages into sugars is rarely reported. Recently, we described the synthesis of 3′,4′-dideoxykanamycin B,[1] which is active against drug-resistant bacteria, by utilizing a 3,4-unsaturated intermediate. The present work was undertaken to see if a practical method could be worked out for converting aminoglycosidic antibiotics into their unsaturated and dehydroxylated derivatives.



Here we described the syntheses of methyl 3,4-dideoxy-α-D-*erythro*-hexopyranoside (**5**) and methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranoside (**10**). The syntheses were achieved by way of the corresponding 3,4-unsaturated intermediates. Methyl 3,4-*O*-isopropylidene-α-D-galactopyranoside prepared from methyl α-D-galactopyranoside was benzoylated to give **1**. Removal of the isopropylidene group followed by mesylation gave the corresponding di-*O*-mesyl derivative (**2**). When **2** was treated with sodium iodide and zinc dust in DMF at 130°C for 1.5 hr according to the procedure of Tipson and Cohen[2] and Horton *et al.*,[3] a 3,4-unsaturated derivative, namely, methyl 2,6-di-*O*-benzoyl-3,4-dideoxy-α-D-*erythro*-hex-3-enopyranoside (**3**) was obtained in a yield of 93%, syrup, $[\alpha]_D^{22}$ −17.3° (*c* 1, $CHCl_3$); NMR (in $CDCl_3$): τ 4.05 (2-proton slightly broadened singlet, H-3,4), $J_{1,2}$ 4 Hz, $J_{2,(3,4)} = J_{(3,4),5}$ ~0 Hz. Catalytic hydrogenation of **3** gave methyl 2,6-di-*O*-benzoyl-3,4-dideoxy-α-D-*erythro*-hexopyranoside (**4**), mp 70—71°C, $[\alpha]_D^{22}$ +56.7° (*c* 1, $CHCl_3$). Removal of the protecting groups of **4** gave methyl 3,4-dideoxy-α-D-*erythro*-hexopyranoside (**5**), syrup, $[\alpha]_D^{22}$ +126° (*c* 1.1, water); NMR (in D_2O): τ 5.28 (1-proton doublet, $J_{1,2}$ 3.5 Hz, H-1), τ 7.9—8.6 (4-proton multiplet, H-3,3,4,4).

Methyl 2,6-dideoxy-2,6-dimethoxycarbonylamido-α-D-glucopyranoside (**6**), mp 175—177°C, $[\alpha]_D^{21}$ +108° (*c* 0.7, water) prepared from neamine was mesylated to give the corresponding di-*O*-mesyl derivative (**7**), mp 193—195°C, $[\alpha]_D^{23}$ +94° (*c* 1.5, $CHCl_3$); NMR (in $CDCl_3$): τ 6.77 and 6.90 (each 3-proton singlet, SO_2CH_3). 3,4-Unsaturation was performed likewise in a yield of 90% to give a 3-eno derivative (**8**), mp 157—158°C, $[\alpha]_D^{20}$ −35° (*c* 0.7, methanol); NMR (in $CDCl_3$): τ 4.29 (2-proton slightly broadened singlet, H-3,4), $J_{1,2}$ 4.2 Hz, $J_{2,(3,4)} = J_{(3,4),5}$ ~0 Hz, $J_{2,5}$ ~4 Hz. Catalytic hydrogenation of **8** gave the corresponding tetradeoxy derivative (**9**), syrup, $[\alpha]_D^{19}$ +126° (*c* 0.7, methanol). Removal of the protecting groups of **9** gave methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hexopyranoside (**10**) as needles of monosulfate, mp>180°C, $[\alpha]_D^{22}$ +128° (*c* 1, water). Removal of the protecting groups of **8** gave methyl 2,6-diamino-2,3,4,6-tetradeoxy-α-D-*erythro*-hex-3-enopyranoside (**11**) as needles of monosulfate hemihydrate, mp>180°C, $[\alpha]_D^{22}$ +26° (*c* 1, water); NMR (in D_2O): τ 3.95 (2-proton slightly broadened singlet, H-3,4).

The Photoreduction of Polyacenes by Tri-*n*-Butyl Stannane

Itsuo FUJIHARA, Masao OKUSHIMA, Satoshi HIRAYAMA, Shigeru KUSUHARA, and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received September 23, 1971)

There have been previous reports on the photoreduction of anthracene derivatives[1] and some polyacenes[2,3] by tri-*n*-butyl stannane. This reaction gives one of the few examples of hydrogen-atom abstraction in a pure π-π^* excited state. Preliminary experiments have shown that the lowest triplet state is susceptible to photoreduction. It is interesting to investigate the mechanism of this reaction and the reactivity of polyacene. Fortunately, the flash-photolysis method gives direct information on the reactivity of the lowest triplet state toward photoreduction. In this communication, we wish to report that some polyacenes were photoreduced in the presence of stannane and that the rate constants of hydrogen abstraction reactions *via* the lowest triplet state were determined by this method.

Prior to kinetical experiments, we investigated the photochemical behavior of deaerated *n*-hexane solutions of polyacenes in the presence of stannane. The samples degassed by repeating a freeze-pump-thaw cycle six times in the dark were irradiated for a series of known time intervals, and the spectral changes were recorded with a Shimadzu SV-50A spectrophotometer for each interval. The results will now be presented. Phenanthrene, naphthacene, 1,2-benzanthracene and chrysene containing stannane were found to lose their characteristic absorption bands in the ultraviolet and the visible regions. For phenanthrene and naphthacene, new bands, which seemed to be assignable to 9,10-dihydrophenanthrene and 5,12-dihydronaphthacene respectively, appeared in the ultraviolet region. However, we haven't yet identified the photochemical products of 1,2-benzanthracene and chrysene. Under the same conditions, though, Brimage and Davidson[3] have recently reported that phenanthrene and 1,2-benzanthracene gave 9,10-dihydrophenanthrene and 7,12-dihydro-1,2-benzanthracene respectively; therefore, we consider that chrysene will be similarly photoreduced to the corresponding dihydro-product.

The flash photolytic experiments were done in deoxygenated benzene solutions of polyacenes containing various concentrations of stannane at room temperature. The decay curves of the lowest triplets after the flash were obtained by observing the transmittance changes at the triplet-triplet-absorption maximum wave lengths: 481 mμ (phenanthrene), 460 mμ (naphthacene), 492 mμ (1,2-benzanthracene), and 570 mμ (chrysene).[4] The apparent rate constants, k, calculated from these curves disregarding the triplet-triplet annihilation, may be related to the photoreduction rate constants, k_r, as follows:

$$k = k_d + k_r[Q]$$

where k_d is the decay constant in the absence of stannane and where $[Q]$ is the concentration of stannane. By plotting k *versus* $[Q]$, the relationship between k and $[Q]$ was found to be almost linear, and from the slopes, we obtained the photoreduction rate constants, $k_r = 1.8\times10^5\,\mathrm{M^{-1}sec^{-1}}$ for phenanthrene (10^{-3}M), $k_r \leqq 10^4\,\mathrm{M^{-1}.sec^{-1}}$ for naphthacene (4×10^{-5}M), $k_r = 1.5\times10^4\,\mathrm{M^{-1}sec^{-1}}$ for 1,2-benzanthracene (10^{-4}M), and $k_r = 1.5\times10^5\,\mathrm{M^{-1}.sec^{-1}}$ for chrysene (10^{-4}M).

On the other hand, Brimage and Davidson[3] obtained $k_r = 4.7\times10^5\,\mathrm{M^{-1}sec^{-1}}$ for phenanthrene and $k_r = 1.8\times10^5\,\mathrm{M^{-1}sec^{-1}}$ for 1,2-benzanthracene using steady illumination; we also got $k_r = 7.1\times10^4\,\mathrm{M^{-1}sec^{-1}}$ for naphthacene and $k_r = 9.4\times10^4\,\mathrm{M^{-1}sec^{-1}}$ for 1,2-benzanthracene by their method.

In comparison with these results, the values obtained by the flash-photolysis method were smaller than those obtained by the steady-state method in any compound. The reason for this is not obvious, but this is a very interesting fact. Particularly, there is a noticeable discrepancy between the values obtained by the two methods for naphthacene. This may suggest that there exists another excited state (or states) which is more reactive than the lowest triplet state. More investigations of the other compounds will offer clear information on the reactive excited states of cata-condensed aromatic hydrocarbons.

Effects of Fluoroborates on the Visible Absorption Spectra of Lanthanum(III)-Alizarin Complexon Chelate[1]

Yoshiki Moriguchi, Tsuneko Kuwabara, and Iwao Hosokawa
Department of Chemistry, Fukuoka University of Education, Munakata-machi, Munakata-gun, Fukuoka
(Received September 27, 1971)

Recently, lanthanum(III) and cerium(III) chelates of alizarin complexon (ALC, 1,2-dihydroxyanthraquinone-3-yl-methylamine-*N*,*N*'-diacetic acid) have been widely utilized as a colorimetric reagent in trace analysis of fluorine since reported by Belcher *et al.*[2] The effectiveness and interesting behavior of the chelates have been described.[3] However, it has been reported that some anions and cations interfere with the determination of fluorine in the ALC method.[4]

We wish to report that, in the presence of potassium tetrafluoroborate (KBF_4) and one of its hydrolysis products, potassium monohydroxytrifluoroborate (KBF_3OH), the visible absorption spectrum of ALC-La chelate changes to that of ALC and this effect is especially remarkable in the presence of KBF_3OH.

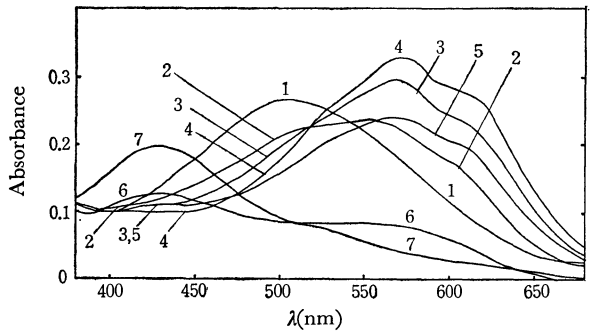

Fig. 1. Effect of KBF_4 on spectrum of ALC-La(III) chelate in acetic acid-sodium acetate buffer (pH 4.65) at 25°C.
1: 5×10^{-5}M ALC-La(allowed to stand for 90 min after adding ALC to $La(NO_3)_3$), 7: 5×10^{-5}M ALC. After adding 5×10^{-3}M KBF_4 to 1, 2: 1 min, 3: 5 min, 4: 11 hr, 5: 5 days, 6: 10 days.

As is shown in Fig. 1, in the presence of 100: 1 molar ratio of KBF_4 to ALC-La chelate, a peak of ALC-La chelate at 505 nm shifts to 572 nm and its spectrum nearly fits that of ALC-La-F ternary complex after 5 min. The spectrum gradually changes and a new peak corresponding to that of ALC appears at 428 nm after 10 days. The changes are accelerated with the rise of reaction temperature and KBF_4 concentration. Thus it is assumed that the effective species on these spectrum changes is not BF_4^- but one or more species of its hydrolysis products as described by the following equations.

$$BF_4^- + OH^- \rightleftharpoons BF_3OH^- + F^- \quad (1)$$

$$BF_3OH^- + OH^- \rightleftharpoons BF_2(OH)_2^- + F^- \quad (2)$$

$$BF_2(OH)_2^- + OH^- \rightleftharpoons BF(OH)_3^- + F^- \quad (3)$$

$$BF(OH)_3^- \rightleftharpoons B(OH)_3 + F^- \quad (4)$$

This is also supported by the results in Fig. 2. KBF_3OH is clearly more effective than KBF_4, that is, its spectrum quickly changes to that of ALC-La-F ternary complex at 20: 1 molar ratio of KBF_3OH to ALC-La chelate, and almost becomes that of ALC after 18.5 hr. The effect of KBF_3OH is also remarkable at 10: 1 molar ratio. It occurs in 40% acetone-water mixed solvent as well as aqueous solution.

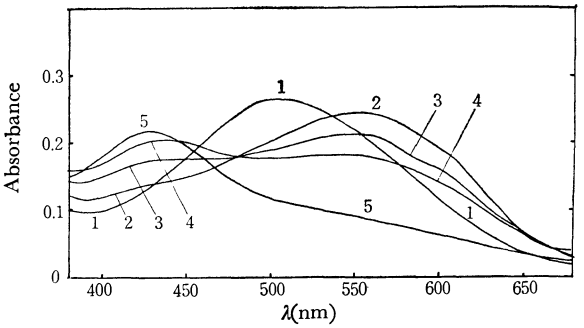

Fig. 2. Effect of KBF_3OH on spectrum of ALC-La(III) chelate in acetic acid-sodium acetate buffer (pH 4.65) at 25°C.
1: 5×10^{-5}M ALC-La(allowed to stand for 90 min after adding ALC to $La(NO_3)_3$). After adding 1.0×10^{-3}M KBF_3OH to 1, 2: 2 min, 3: 6 min, 4: 30 min, 5: 18.5 hr.

Thus we presume that the coexistence of boron has a considerable influence on the ALC method, and dissolved species of fluorine in the presence of boron and its behavior to ALC-La chelate become very important. In a previous paper,[5] we reported that the dissolved state of fluorine in sodium fluoride-boric acid-water system depended on the pH of the solution. The colorimetric determination of fluorine in the ALC method is usually carried out in the pH region 4.5—5. A considerable extent of fluorine in the sample solution is assumed to exist in fluoroborate forms in this region as described in Eqs. (1)—(3), unless boron is previously removed from the sample solution. Thus it seems that fluoroborates interfere with the formation of ALC-La-F ternary complex and are the cause of error in the determination of fluorine.
