The surface and bulk properties of silica-titania systems, prepared by the co-hydrolysis of silicon ethoxide and titanium tetrabutoxide, were investigated by measuring the heat of immersion, the adsorption of nitrogen, water, and ammonia, the X-ray diffraction, the DTA, and the TGA. It was found that the addition of silica to titania has a large suppressive effect on the crystal growth of anatase and on the transformation of anatase to rutile. The heat of immersion, the surface hydrophilicity (the surface area by water adsorption/the surface area by nitrogen adsorption) and the amount of ammonia adsorbed gave inverted sigmoid curves when the titania content was varied. Especially, the shape of the curve of the change in the heat of immersion coincides approximately with that of the surface hydrophilicity.

Recently, the methods of the preparation of metal oxides by the hydrolysis of metal alkoxides have often been reported. Such oxides synthesized by an ion-free process are suitable for the study of the surface properties of metal oxides. Meguro *et al.*[1,2] studied the surface properties of alumina-titania and silica-alumina systems prepared by the co-hydrolysis of metal alkoxides.

In this experiment, we have investigated the surface properties of the silica-titania system obtained by the co-hydrolysis of silicon ethoxide and titanium tetrabutoxide.

2) H. Murayama and K. Meguro, This Bulletin, **43**, 2386 (1970).

Experimental

Materials. Several samples of the silica-titania system were obtained by the co-hydrolysis of silicon ethoxide and titanium tetrabutoxide mixtures with different molar ratios. The purities of the alkoxides were checked by infrared analysis. The hydrolysis reaction was carried out by dropping a water-methanol mixture (water : methanol= 4:1 in weight) into a butanol solution of alkoxide (butanol : alkoxide= 1:1 in weight), keeping the total molar ratio of the water to alkoxide at 20:1. The water used was deionized and was then distilled. The alcohols used were of a reagent grade. After the liquid had been stirred for 10 hr at the boiling point, the precipitate was separated, washed with deionized water and then methanol, and dried at 100°C *in vacuo*. The dried samples were calcined for 2 hr in an electric furnace at temperatures from 500 to 1000°C. The samples calcined at 500°C were used for the study of the surface properties. The composition of the samples, as determined by X-ray fluorescence analysis were 21, 55, and 83 in the weight-percentage ratio: (titania)/(silica+titania); they will be designated as 4ST (silica : titania≒4:1 in weight), ST, and S4T respectively.

Apparatus and Procedure. The thermogravimetric and differential thermal analyses of the samples have been made by means of an automatic recording instrument of the Shimadzu Seisakusho Co.; the rate of heating was 10°C per minute. The X-ray diffraction patterns were recorded with a Geigerflex X-ray diffractometer of the Rigaku Denki Co., using Ni-filtered Cu radiation.

The heat of immersion was measured with a semimicro-calorimeter which had been devised in our laboratory.[3,4] A thermistor was used for measuring small temperature changes. A wide-mouthed, silvered Dewar flask with a 400 m*l* capacity served as the calorimeter vessel. It was attached to a Bakelite flange with stainless steel rings equipped with a Neoprene gasket. The calorimeter assembly included a small, 10 ohm heating manganin wire for calibration, a stirrer, a sample holder, and a thermistor. The whole assembly was immersed in a constant-temperature bath at 25°C. The heat evolved at immersion was calculated by means of galvanometer readings. The adsorption isotherms of nitrogen at −195°C, of water at 25°C, and of ammonia at 260°C were determined by means of a conventional, volumetric, gas-adsorption apparatus. For the water adsorption, the apparatus was maintained at 25°±0.5°C in an air thermostat. Each sample for water adsorption was outgassed at 100°C for 1 hr at 10^{-5} Torr and then cooled to 25°C prior to the adsorption studies. The nitrogen and water-surface areas of the samples were calculated by the BET formula, using 16.2 and 10.8 Å^2 for the cross-sectional areas of the nitrogen and water molecules respectively.

The compositions of all the samples were measured with a Rigaku Denki X-ray vacuum spectrograph by means of X-ray fluorometry.[5] The analyser crystal was ethylenediamine ditartrate. The chromium target was adjusted at 45KV, 12 mA (for Si) and 30KV, 6mA (for Ti). The X-radiation was detected by a proportional counter (90% Ar+10% CH_4) and discriminated as follows: for Si: base line, 70/1000, and channel width, 100/100, and for Ti: base line, 80/1000, and channel width, 100/100.

Results and Discussion

(*i*) *Differential Thermal Analysis, Thermogravimetric Analysis, and X-Ray Investigation.* Typical results of the differential thermal analysis (DTA) and the thermogravimetric analysis (TGA) are shown in Fig. 1. The DTA of the samples are given in Fig. 1; they are characterized with an endothermic peak at 150°C and a small broad exothermic peak at 250—400°C. The endothermic peak is supposed to be due to the loss of adsorbed water, while the exothermic peak is supposed to be caused by the oxidation of a chemically-adsorbed solvent, which seems to be identified by the weight loss shown in the TGA curves at the same temperature. Therefore, in order to avoid the effect of the adsorbed solvent on the surface property, the chosen temperature of calcination was 500°C.

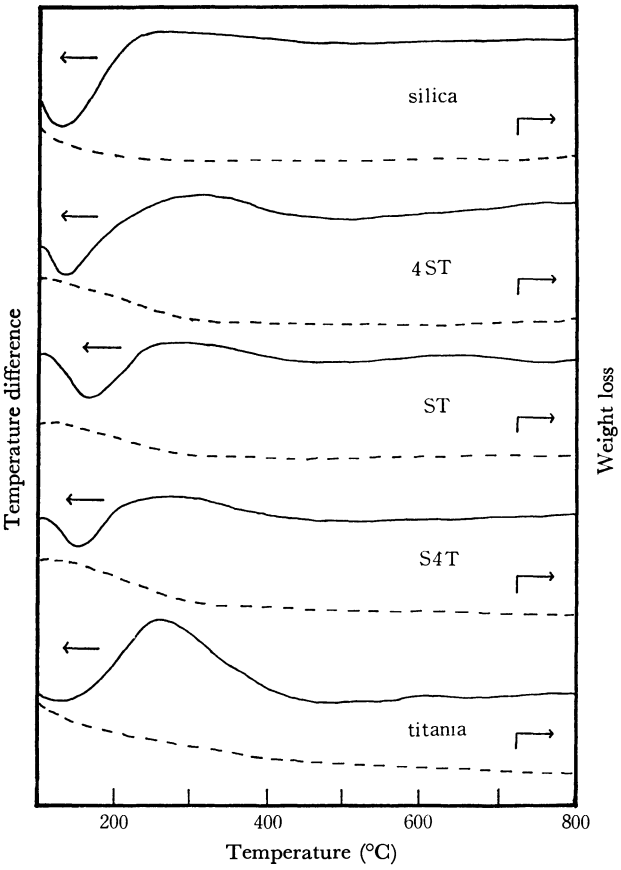

Fig. 1. DTA (solid lines) and TGA (dotted lines) curves of the silica-titania systems.

Typical X-ray diffraction patterns of the samples are shown in Fig. 2. The patterns of the silica calcined at 100—1000°C showed an almost amorphous structure. Broad lines characteristic of anatase are seen in the patterns of the titania heated at 100°C. These broad lines became sharper with a rise in the temperature of calcination. Moreover, the lines of rutile begin to appear in the patterns of the product calcined at 600—700°C. The silica-titania systems have different X-ray patterns from the parent oxides, but they show no lines which are not found in the patterns of the parent oxides. The X-ray-diffraction study showed that the addition of silica to titania has a large suppressive effect on the

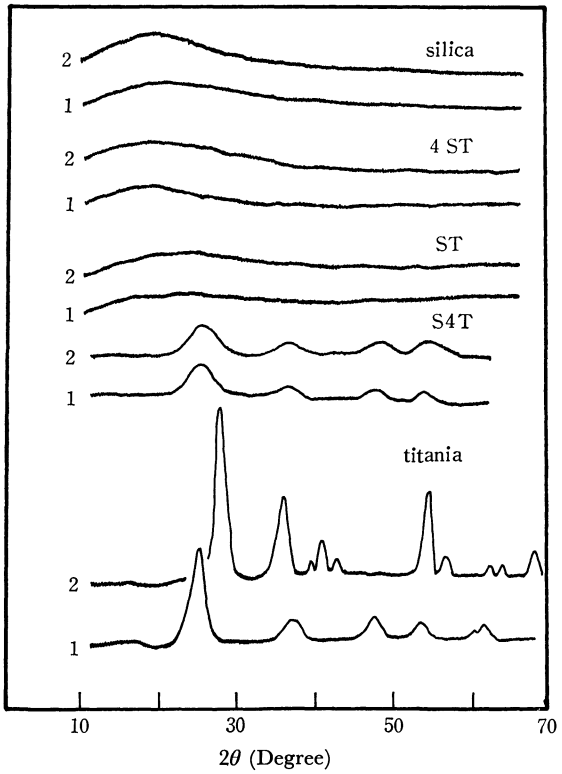

Fig. 2. X-Ray diffraction patterns at different temperatures (1:500°C 2:800°C) of the silica-titania systems.

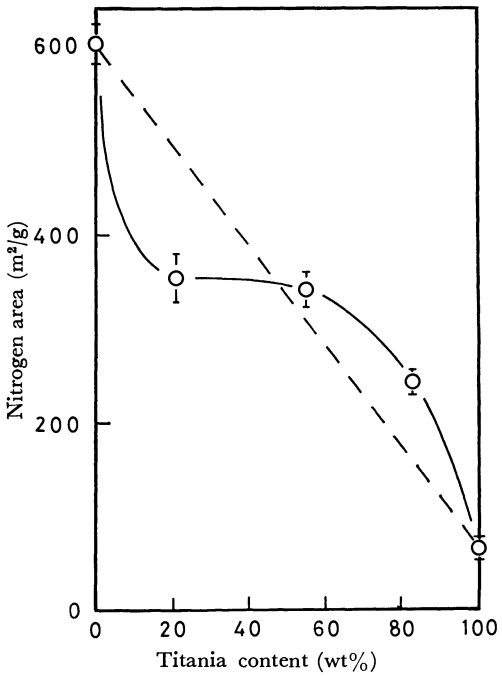

Fig. 3. The change of the nitrogen surface area of the silica-titania systems calcined at 500°C with composition. Dotted line, the dry-mixed oxides.

crystal growth of anatase and on the transformation of anatase to rutile. This effect was evidenced by the fact that the samples of 4ST and ST remained amorphous even when the calcining temperature was raised to 800°C. In the case of S4T, which has a higher titania content, only broad lines of anatase was observed in the calcination at 500°C; this anatase pattern remained the same up to 800°C. This suppressive effect increases as the silica content increases. Typical patterns are shown in Fig. 2. It is well known that the rate of the anatase-rutile transformation is affected by the presence of foreign ions, entering either substitutionally or interstitially.[6] From the suppressive effects on the crystal growth and the transformation, it may be supposed that the silica-titania systems prepared by the co-hydrolysis are different in structure from simple mechanical mixtures of dry silica and titania.

(*ii*) *Specific Surface Area.* The specific surface areas of the samples obtained by nitrogen adsorption change with the titania content, giving a sigmoid curve, as is shown in Fig. 3, in which the surface area is plotted as a function of the weight percentage of titania. This is compared with the straight dotted line in Fig. 3, which shows the theoretical surface area as calculated as the mechanical mixtures. In practice, however, the specific surface areas of the samples do not change proportionally with the composition, but give a sigmoid curve. The surface area decreases steeply between silica (600m²/g) and S4T (348m²/g), gradually decreases between 4ST and S4T (239m²/g), and then decreases steeply again between S4T and titania (63.9m²/g).

(*iii*) *Water Adsorption and Heat of Immersion.* Figure 4 represents the specific surface area derived from the water adsorption versus the composition of the silica–titania systems. The curve of the surface area versus the composition in Fig. 4 is not a straight line, as might be expected in the case of a simple mixture of dry silica and titania.

Healey and his co-workers[7] have shown that the ratio of the apparent surface area, as determined by the water adsorption, to the total area, as determined by the nitrogen adsorption, is a direct measure of the fraction of the hydrophilic surface present in a finely-

Table 1. Surface properties of the silica-titania system calcined at 500°C for2 hr

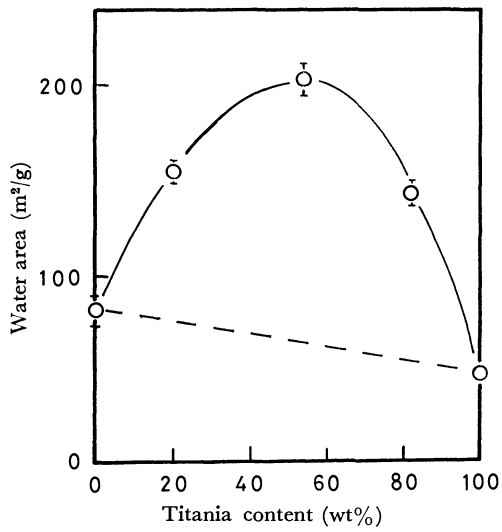

Fig. 4. The change of the water surface area of the silica-titania systems with composition. Dotted line, the dry-mixed oxides.

divided solid. The ratio may also be considered to be a measure of the hydrophobicity; the smaller the ratio the more hydrophobic the surface. Therefore, the surface hydrophilicity in percentage may be expressed as: (the surface area by water adsorption/the surface area by nitrogen adsorption) × 100. The change in the surface hydrophilicity of the samples is illustrated in Fig. 5 as a function of the titania content. The straight dotted line in Fig. 5 shows the theoretical surface hydrophilicity calculated as were the mechanical mixtures. It is noticeable that the experimental hydrophilicity deviates from the straight line. The hydrophilicity of the samples rises steeply between silica (14%) and 4ST (44%), rises gradually between 4ST (60%), and then again rises steeply beween S4T and titania (86%).

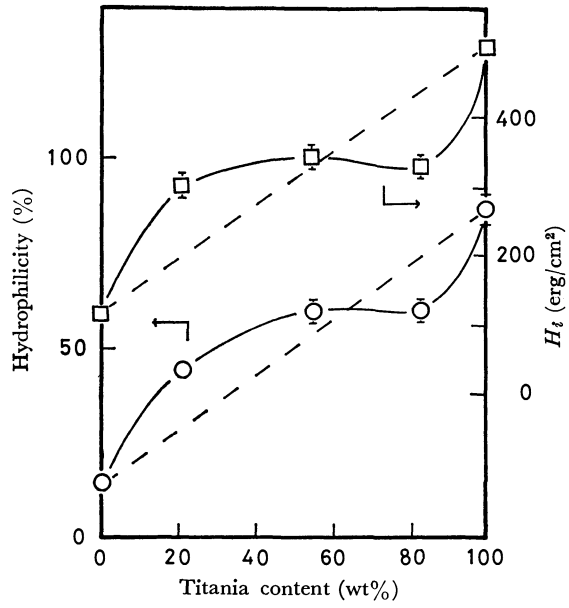

Fig. 5. The change of the heat of immersion and the surface hydrophilicity of the silica-titania systems with composition. □-Heat of immersion. ○-Surface hydrophilicity. Dotted lines, the dry-mixed oxides.

The change in the heat of immersion with the composition of the samples is represented in Fig. 5, in which the heat of immersion is plotted as a function of the titania content. The straight dotted line in Fig. 5 shows the theoretical heat of immersion calculated as were the mechanical mixtures. The heat of immersion increases steeply between silica (119erg/cm²) and 4ST (303erg/cm²), changes gradually between 4ST and S4T (332erg/cm²), and then increases greatly between S4T and titania (506erg/cm²). The crystal structures of silica, 4ST, and ST are almost amorphous, while those of S4T and titania are anatase. From these results, it may be concluded that the heat of immersion of the samples is not affected by the change in the crystal structure. The change in the surface hydrophilicity with the composition approximately coincides with that of the heat of immersion, as is shown in Fig. 5. The same results have been reported on alumina-titania[1] and silica-alumina[2] systems. The coincidence of the changes in the surface hydrophilicity of these samples with the composition and those of the heat of immersion of these samples with the composition can be explained as resulting from the fact that alumina, silica and titania surfaces are usually covered with hydroxyl groups, which act as primary adsorption sites for polar molecules. Since the surface hydrophilicity has an intimate relation with surface hydroxyl groups, the coincidence of this curve with that of the heat of immersion is reasonable.

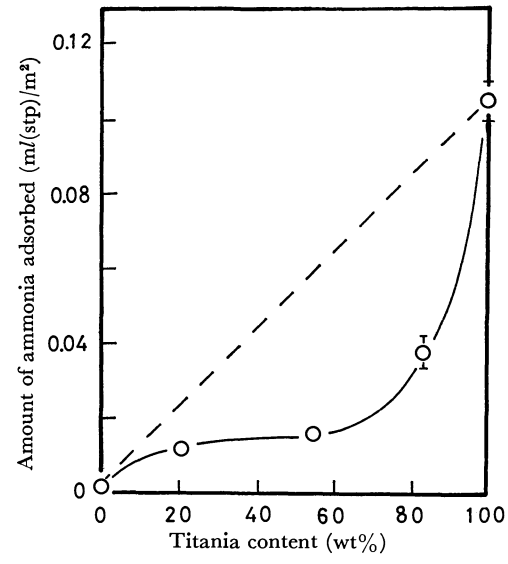

Fig. 6. The change of the amount of ammonia adsorbed on the silica-titania systems with composititon. Dotted line, the dry-mixed oxides.

(iv) Surface Acidity. Another important character of the surface of the silica-titania system is the surface acidity. The ammonia adsorption isotherm at 260°C, where the highest equilibrium pressure was about 10Torr, was determined.[8,9] The surface acidity of the samples was determined by the adsorption of ammonia at 260°C. The shape of the adsorption

isotherms of the samples is that of the Langmuir type. The saturated amount of the adsorption of ammonia can be calculated from the Langmuir equation; the calculated values of the saturated adsorption are listed in Table 1. Figure 6 shows the relation between the amount of ammonia and the titania content in the silica-titania system. In this case, the amount of ammonia adsorbed on the samples does not change proportionally with the titania content. The straight dotted line in Fig. 6 shows the theoretical value of ammonia adsorption, calculated as were the mechanical mixtures. The change in the surface acidity with the titania content shows an inverted sigmoid curve like those of the heat of immersion and of the hydrophilicity. This suggests that there is a relationship between the sites responsible for the ammonia adsorption and the surface hydroxyl groups. This suggestion agrees with the results of Stöber.[10]

It should be noted that the observed values of the silica-titania system, such as those of the nitrogen area, the water area, the surface hydrophilicty, the heat of immersion, and the surface acidity, are very different from those obtained on the assumption that this system is composed of a simple mechanical mixture of the two components. These deviations may originate in the method of the preparation of the systems; they suggest that the surface structures of the systems prepared by the co-hydrolysis of these metal alkoxides are different from those of simple mechanical mixture of dry silica and titania.

Photochemical Reaction of 9-Cl-Acridine in Aerated and Deaerated Ethanol. I

Katsumi NAKAMARU, Shigeya NIIZUMA, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received October 22, 1970)

It was established that upon irradiation, the degassed ethanol solution of 9-chloroacridine is quickly converted into 9,9′-biacridyl by the reaction $2(\text{9-Cl-acridine}) \xrightarrow[(h\nu)]{+2H} \text{9,9′-biacridyl} + 2HCl$ and that 9,9′-biacridyl produced is then reduced photochemically to 9,9′-biacriden as the main product. The reaction scheme completely denies the scheme previously proposed (V. Zanker and W. Flügel, *Z. Naturforsch.*, **19(b)**, 376 (1964)) in which the primary photoproduct is a charge transfer complex between 9-Cl-acridine and its reduced form. 9,9′-biacridyl is photoreduced to an acridan-like compound even in the aerated solution perhaps *via* molecular mechanism in contrast to 9-Cl-acridine which yields acridone under similar conditions. ESR spectrum with hfs was detected in the acidic solution (degassed) containing 9,9′-biacriden produced photochemically. The mechanism of its production was discussed. Similar reactions using various solvents (aerated and deaerated) were examined and the general feature of the primary processes was described.

Photoreduction of acridine in various H-containing solvents has been studied extensively by the authors[1-3] and others.[4-7] Reactive sites on the acridine molecule are always 9C– and 10N– positions, the latter usually being hydrogenated preferentially in the primary act; the final products are acridans or biacridan according to experimental conditions.

Concerning the effect of substitution at 9-position, Zanker and Flügel studied the photoreaction of 9-halogen-acridine under various conditions[8] and reported that 9-Cl-acridine (9-Cl-A) in the aerated ethanol yields acridone while in the atmosphere of nitrogen, a photoproduct of quite a different type having an absorption peak at 430 nm (for the sake of convenience will refer to it as X-species) is produced which by prolonged irradiation is gradually transformed into another different species (Y-species) with a peak at 530 nm. Although they gave no suggestions as to the structure of Y-species, they proposed that X-species may be a charge transfer type molecular complex between the starting substance and the phtoproduct, perhaps 9-Cl-acridan. No work has been reported on these interesting reactions since then.

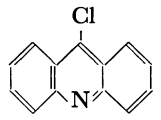
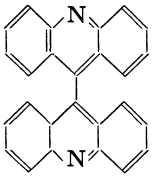
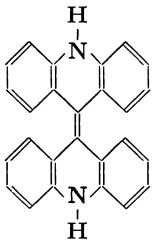
We found a CT type complex somewhat analogous to that stated by Zanker and Flügel in a solution containing acridine and acridan or phenazine and dihydrophenazine.[9] The latter system has also been investigated by Bailey *et al.*[10] It was also found that these systems give ESR signals under suitable conditions. We were interested in the complex formation between oxidized and reduced forms and investigated the reaction of 9-Cl-A (I), studying in particular the reaction scheme up to the formation of X-species in detail. Careful reinvestigation of the overall reaction has revealed, however, that the fomation of X-species is preceded by another quite rapid process which yields 9,9′-biacridyl (II), and that X-species is 9,9′-biacriden (III) instead of a C-T complex.



(I)



(II)



(III)

Another interesting finding is that the photoproduct at the stage of X-species fomation, gives an ESR spectrum in acidic medium. Zanker and Flügel's observation of acridone formation in the aerated solution has been reconfirmed but we strongly suggest quite a different mechanism. Solvent effect on the reactions both in aerated and deaerated solutions has been examined.

Experimental

Materials. 9-Cl-acridine was prepared and purified according to the method of Albert and Ritchie (*Organic Synthesis*, **22**, 5 (1942)). Since 9-Cl-acridine in ethanol easily undergoes thermal transformation into acridone, the solution was always prepared immediately before the experiment. The concentration was 1×10^{-4}M unless otherwise stated. Ethanol was dried according to the method of Lund and Bjerrum.[11] Methyltetrahydrofuran was dehydrated with Na-K alloy in vacuo repeating freeze-pump-thaw 7—8 times.

Apparatus and Procedures. The apparatus for reaction was a similar one to that employed in our laboratory. The light source is a 100 W high pressure mercury lamp. 365 nm monochromatic light was taken out through a filter system consisting of a glass plate and U-2 filter. Fluorescence spectrum was measured with a Hitachi MPF-2 spectrofluorometer, and ESR spectrum with a JEOL P-10 type ESR spectrometer.

Results and Discussion

Reaction in the Deaerated Ethanol Solution. Figure 1 shows the change in the absorption spectrum caused by irradiation.

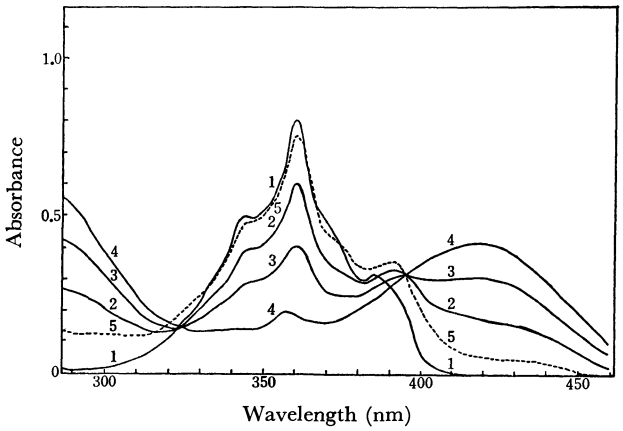


Fig. 1. Change of absorption spectra when the degassed ethanol solution of 9-Cl-A was irradiated by 365 nm (25°C).
1) 9-Cl-A
2) 1 min and 10 sec irradiation
3) 3 min and 20 sec irradiation
4) 7 min irradiation
5) air is introduced to 4),
for about 40 sec irradiation of 9-Cl-A, essentially the same spectrum as 5).

About 40 seconds after starting irradiation, the main peak shifted slightly to the shorter wavelength accompanied with a complicated change in the 385 nm region. This stage was then followed by a second extensive change *i.e.* a large decline of the main peak and a rise of a new broad maximum around 420 nm (X-species). Prolonged irradiation caused a gradual replacement of this band with a new band near 530 nm (Y-species). The two last changes are in complete agreement with Zanker and Flügel's observation but the first one escaped their notice. In Fig. 2, curve a) is the plot of $\ln(e^{acd}-1)$ (α, absorption coefficient at 365 nm; c, concentration of 9-Cl-A) against time for the reaction of 9-Cl-A. It is evident that a certain type of induction period exists corresponding to the spectral change in the earliest stage.

10) D. N. Bailey, D. K. Roe, and D. M. Hercules, *J. Amer. Chem. Soc.*, **90**, 6291 (1968).
11) H. Lund and J. Bjerrum, *Ber.*, **64**, 210 (1931).

Concerning the behavior of X-species, Zanker and Flügel only mentioned that it is gradually reconverted into the initial substance in the dark. We have found in addition to this recovery of absorption spectrum (but not of the initial substance), that the introduction of air quickly converts X-species into a compound with a spectrum resembling that of 9-Cl-A, as shown in Fig. 1. We concluded, however, by close examination that the spectrum agrees almost completely with that of the species produced during the first 40 second irradiation. This solution when irradiated again after having been degassed, turned into X-species. We found no induction period in this case, and the spectrum changed with a clear isosbestic point at 393 nm from the beginning. Quantum yield for X formation was almost the same as the value for 9-Cl-A obtained from the run after the induction period. The chemical behavior of this compound was found to be quite different from that of 9-Cl-A. Thus the latter is transformed into acridone when the aerated ethanol solution is irradiated as observed by Zanker and Flügel and as confirmed by us, whereas the former gives acridan-like product instead of acridone. This is shown in Fig. 3.

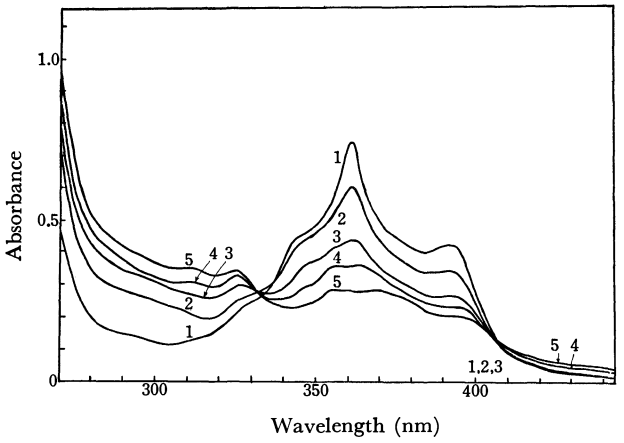

Fig. 3. Spectral change of Z-species in the aerated ethanol solution upon irradiation at 365 nm (25°C). Time of irradiation,
1) 0
2) 2 min and 30 sec
3) 9 min and 30 sec
4) 22 min
5) 127 min

These findings strongly suggest that 9-Cl-A is quickly transformed photochemically into a different substance which we denote tentatively by Z-species. The Z-species (oxidized form) is reduced to X which is reoxidized by oxygen to Z. It was confirmed that the reactions

$$Z \xrightarrow[h\nu]{\text{in ethanol}} X \qquad X \xrightarrow{O_2} Z \qquad (1)$$

can be repeated as shown by curves b) and c) in Fig. 2. Thus the identification of Z-species prior to that of X-species is required.

Identification of Z-species. It is well known that 9-Cl-A is susceptible to dechlorination and dimerization and yields 9,9′-biacridyl under reductive conditions such as with Raney nickel in methanol, with hydrogen and palladium on barium sulphate and with zinc dust in hydrochloric acid.[12] This leads to the expectation that Z-species in the present system is 9,9′-biacridyl. If a chlorine atom remains in the molecule, the molecular weight is ~214, while the molecular weight of 9,9′-biacridyl is 356. Hence a mass spectrometric determination of molecular weight was undertaken. To do this, preparation of Z-species was carried out on a large scale using a Riko-Kagaku K.K.'s irradiation apparatus. 1—1.5 *l* of the ethanol solution of 9-Cl-A $1—2 \times 10^{-4}$M, was irradiated by 365 nm in the atomsphere of argon. It was confirmed that the product gives the same spectrum as that for Z-species obtained by small-scale reaction. The crystal obtained by distilling off the solvent was subjected to thin layer chromatography and Z-species was separated by using the mixture of benzene (10) and ethylacetate (1) as a developer. It was established that the material thus separated undergoes essentially the same reactions as those for Z-species.

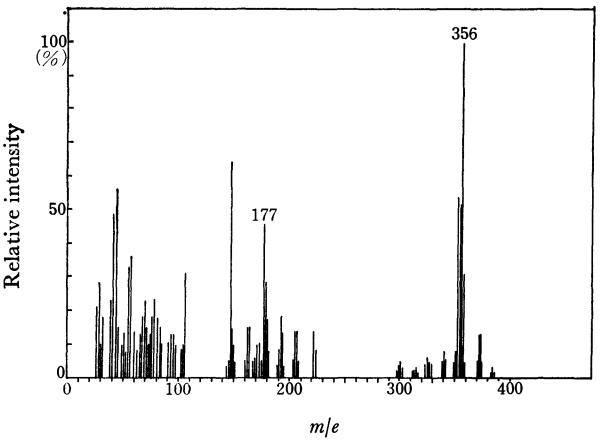

Fig. 4. Mass spectrum of Z-species prepared on a large scale and purified by thin layer chromatography. Relative intensity in reference to that for m/e=356 (100%). Temperature measured, 160°C.

Results of mass spectrometry are shown in Fig. 4. It is seen that a principal peak lies at 356 and there is no peak near 214. All the physical properties observed support the view that Z-species is 9,9′-biacridyl. Thus we have the results:

1) melting point, 379°C (literature value, 382°C[13])
2) Scarecely soluble in nearly all the solvents
3) The absorption spectrum agrees with that reported by Levshin.[14]
4) pH dependence of the absorption indicates the presence of two nitrogen atoms in a molecule as shown in Fig. 5.

It was confirmed that the solution, after 9-Cl-A has been converted into X-species, contains chlorine anion and is acidic and that the spectrum of Z-species in the solution (aerated) agrees very well with that for 10^{-4}M HCl given in Fig. 5.

2) 1×10^{-4}M
3) 5×10^{-4}M
4) 5×10^{-3}M
5) 0.1M

We can now conclude that Z-species is 9,9′-biacridyl which is produced by reaction

$$2(9\text{-Cl-A}) \xrightarrow[(h\nu)]{2H} \text{biacridyl} + 2HCl \qquad (2)$$

X-Species and ESR Spectrum of the Photoproduct. Now that Z-species, a precursor of X-species, has been identified to be 9,9′-biacridyl, it is highly probable that X-species is a compound obtained by the photochemical reduction of 9,9′-biacridyl. 9,9′-biacriden is considered most likely to be such a compound. This compound was prepared by Decker and Petsch for the first time. According to their results, *N,N′*-dimethyl derivative is stable in the air, but not *N*-monomethyl derivative. These compounds emit green fluorescence as X-species does. Figure 6 shows the fluorescence spectrum of X-species together with those of 9-Cl-A and of Y. The absorption and fluorescence spectra of *N,N′*-dimethyl derivative reported recently by Legg and Hercules[15] essentially agree with those of X-species. Thus we can conclude that X-species is biacriden.

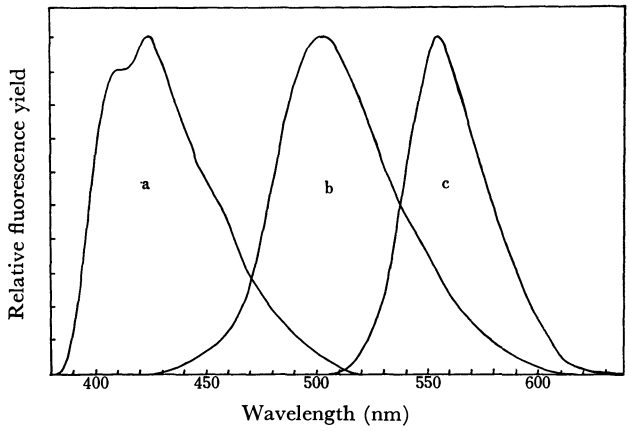

Fig. 6. Fluorescence spectra of 9-Cl-A, X, and Y in ethanol.
a : 9-Cl-A
b : X (obtained by 10 minutes irradiation of the degassed solution of 9-Cl-A)
c : Y (obtained by 33 hours irradiation of the degassed solution of 9-Cl-A)

The photoproduct involving X-species has been found to give ESR spectrum with well separated hfs, the analysis of which has not yet been completed. At present it is interesting to note that the general feature of the spectrum strongly suggests the existence of the two equivalent NH groups which supports the view that the radical is originated from biacriden. Another important fact is that the ethanol solution of 9,9′-biacridyl separated by thin layer chromatography exhibits no ESR spectrum upon irradiation, although on the basis of quite a similar spectral change the photochemical reaction is thought to proceed essentially in the same way, as shown in Fig. 7. In view of scheme (2) for the photochemical formation of biacriden from

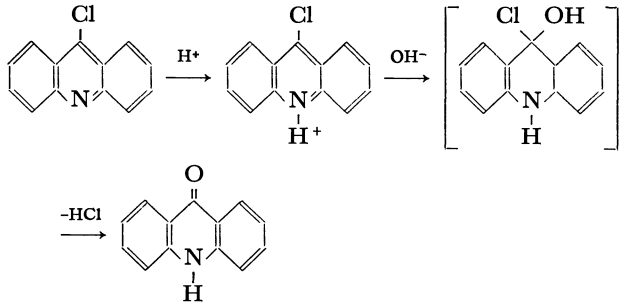
9-Cl-A, it was suspected that the acidic medium is necessary for the appearance of ESR. In fact we could confirm that the irradiated solution of the separated 9,9′-biacridyl in ethanol gives a similar ESR spectrum when a small quantity of HCl was added to the solution in a degassed condition. It should be added that 9,9′-biacridyl dissolved in acetic acid does not undergo photoreduction. This may be due to the non-reactivity of the double protonated species.

Reaction in the Aerated Ethanol Solution. Zanker and Flügel's observation that acridone is the main photoproduct in the aerated ethanol solution was reconfirmed. The solvent they used was 96% aqueous ethanol. They proposed the following mechanism for the photochemical reactions as well as for the thermal reaction.

About 100 times increase of the rate in the photochemical reaction as compared with that in the thermal one was attributed to the increased basicity of the

15) K. D. Legg and M. Hercules, *J. Amer. Chem. Soc.*, **91**, 1902 (1969).



excited state.

Our results on the effect of oxygen concentration and of the addition of water are shown in Figs. 8 and 9. It is evident from Fig. 8 that the existence of oxygen above 5×10^{-4}M is necessary for the occurrence of photochemical formation of acridone. Figure 9 shows that the addition of a large quantity of water does not induce the formation of acridone in the absence of oxygen. The results indicate that oxygen instead of water plays a dominant role in the reaction. In order to confirm definitely the none-participation of water in the reaction we carried out an experiment using a carefully dehydrated ethanol (aerated). It was found that the formation of acridone proceeds at essentially the same rate. A similar experiment was repeated using carefully dehydrated methyltetrahydrofuran. Formation of acridone was confirmed, though acridan-type compound was produced at the same time. Thus,

a) acridan-type compound may be produced simultaneously.
b) agrees with Zanker's result.
c) Quantum yields are the preliminary values obtained simply from the decrease of the optical density.

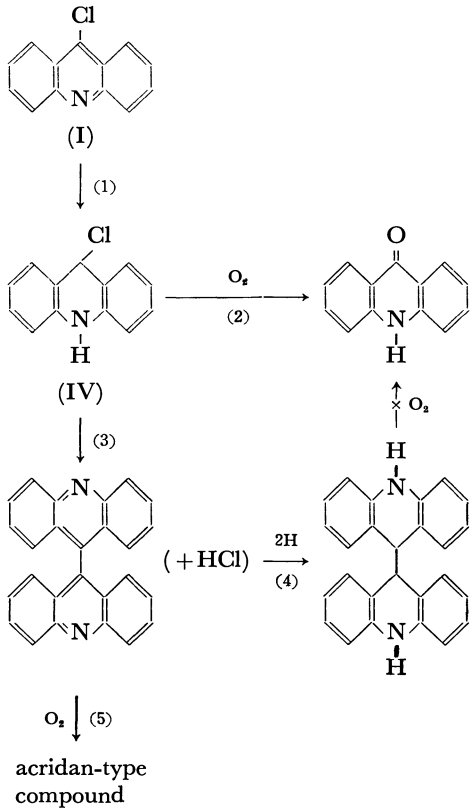
there is no room to doubt that the formation of acridone proceeds in a different mechanism from Zanker and Flügel's, in which oxygen instead of water plays an essential role.

Investigations on the Solvent Effect on the Reactions in Aerated and Deaerated Conditions. Table 1 gives preliminary results on the type of reaction and their quantum yields for various solvents aerated and deaerated.

A survey of the results leads us to the following conclusion. In an aerated condition, formation of acridone proceeds in all the solvents except for benzene and carbon tetrachloride which have no easily detachable hydrogen atoms. This suggests that the primary process for the production of acridone is the formation of semiquinone of 9-Cl-acridine with H-atom attached on N-atom, (C-radical). A larger quantum yield of acridone formation in ethanol than in methanol is also in line with this view. The effect of the addition of water to the aerated ethanol on the acridone formation quantum yield, also supports this view (Table 2).

Table 2. Quantum yield (Φ) of acridone formation in the aerated ethanol-water mixture

$EtOH:H_2O$ (in vol%)	100:0	95:5	90:10	75:25	50:50	33.3:66.7
Φ	0.033	0.027	0.020	0.016	0.009_3	0.005_1



Oxygen may perhaps oxidize the semiquinone and the resulting HO_2 or H_2O_2 may lead to acridone formation. A slight increase of the rate of acridone formation by the addition of H_2O_2 seems to support this mechanism. There is scarcely any sign of the formation of acridan-type compound in the solvents of A group. In the deaerated solution, two types of reaction occur, the formation of acridan-type compound and the formation of biacriden. However, it is not known whether the formation of acridan-type compound occurs *via* biacridine or directly from 9-Cl-acridine in the solvents of B group. Whether biacridan- or 9-(9-acridanyl)-acridine-type compound is produced in the former case is also unknown. One exception is cyclohexanol in which acridone is formed even in the absence of oxygen. Benzyl alcohol is of particular interest for its high reactivity and for the result that biacriden is likely to be produced even in the presence of oxygen.

Conclusion

A general feature of the photochemical reaction of 9-Cl-acridine may be summarized as follows.

Process (1) may occur both in the presence and in the absence of oxygen. One conceivable scheme for Process (2) is the formation of HO_2 and H_2O_2 and their attack on (IV). Process (3) is suppressed when the oxygen concentration is larger than $\sim 10^{-4}$M. It is not known whether the detachment of HCl preceeds or succeeds the dimerization. It is most likely that molecular mechanism does not occur at all or is negligible for 9-Cl-acridine in alcohols. Process (5) occurs most likely *via* molecular mechanism; primary product may perhaps be 9-(9-acridanyl)-acridine compound. In the deaerated alcohols, the reaction yielding biacriden is predominant, but formation of acridan-type compound can also occur *via* molecular mechanism. The relative magnitudes of the two type reactions depend on the nature of the solvent.

The formation of radical species (most likely radical ion) might be due to some kind of reaction between two substances, for instance, electron transfer between biacriden and 9,9′-biacridyl or between biacriden and 9-(9-acridanyl)-acridine. This is likely because the concentration of radical species is very small compared with that of biacriden. That the acidic medium is necessary for the appearance of ESR[16] suggests an analogous mechanism to that for the system of phenazine (ϕ) and dihydrophenazine (ϕH_2), in which radical cation is produced by the interaction of ϕ and ϕH_2 in a strong acidic medium[10] or by acidifying the ethanol solution containing an associated complex between ϕ and ϕH_2.

16) According to Maeda and Hayashi, lucigenine (10,10′-dimethyl 9,9′-biacridinium dinitrate) exhibits ESR in the solid state while 10,10′-dimethylbiacriden does not. These observations might have some relation with the present result. K. Maeda and T. Hayashi, This Bulletin, **40**, 169 (1967).

The Crystal and Molecular Structure of 2,5-Distyrylpyrazine

Yoshio SASADA, Hirotaka SHIMANOUCHI, Hachiro NAKANISHI,* and Masaki HASEGAWA*

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Meguro-ku, Tokyo

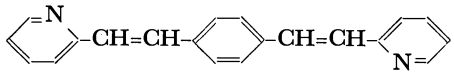
(Received October 27, 1970)

2,5-Distyrylpyrazine($C_{20}H_{16}N_2$), which has photo-polymerizability in the crystalline state, crystallizes in the orthorhombic system with cell dimensions of $a=20.638$, $b=9.599$, and $c=7.655$ Å, including four molecules in the unit cell. The space group is *Pbca*. The structure has been determined by the direct method and refined by the block-diagonal-matrix least-squares method using three-dimensional data. The molecules is not planar; the average plane of the pyrazine ring makes a dihedral angle of 12.09° with that of the benzene ring. The molecules are spaced by the *c*-translation forming an almost parallel plane-to-plane stack. In this stack, the ethylenic double bonds approach each other at the shortest intermolecular distances of 3.939 Å, since the long axis of the molecule makes an angle of about 30° with the *c*-axis. Therefore, the polymerization may occur between these double bonds to form a cyclobutane ring.

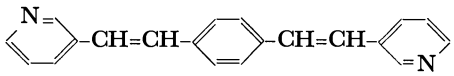
Recently, Hasegawa and his collaborators have reported that 2,5-distyrylpyrazine (DSP) (I) is polymerized by photo-irradiation in the crystalline state to result in a linear polymer (II) containing a cyclobutane ring in the main chain.[1,2]

In the course of exploring the photo-polymerizability of various related diolefinic compounds, it has been found that 1,4-bis[β-pyridyl-(2)-vinyl]benzene (P2VB) (III) gives a polymer just like DSP.[2] Under a polarizing microscope, both polymers look like aggregates of bar-like crystals which are elongated in the direction of the *c*-axis of the monomer crystal.[3] The crystallinity of these polymers corresponds to the highest among known polymers.

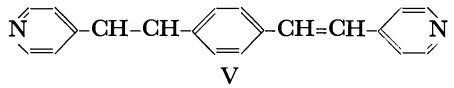
In order to investigate the mechanism of polymerization, X-ray powder photographs have been taken for these two monomers and the related diolefinic compounds.[4] The powder diagrams of DSP and P2VB are nearly identical with each other.



III



VI



V

On the other hand, 1,4-bis[β-pyridyl-(3)-vinyl]benzene (P3VB) (IV) and 1,4-bis[β-pyridyl-(4)-vinyl]benzene (P4VB) (V), which have nearly the same molecular dimensions as P2VB, give X-ray patterns different from those of I and III, and do not polymerize under the same conditions. These observations suggest that the molecules of DSP and P2VB are favourably arranged for polymerization in the crystal, while P3VB and P4VB are not.

Moreover, the results of the analysis of kinetic behavior indicate that the polymerization of DSP is controlled by the molecular arrangement in the monomer crystal.[3]

The present paper will deal with the crystal structure of DSP as one of a series of studies aiming to clarify the relationship between the polymerization mechanism and the molecular arrangement in the crystal.

Experimental

DSP was prepared by the dehydration of 1 mol of 2,5-dimethylpyrazine and 2 mol of benzaldehyde in the presence of benzoic anhydride. By the slow evaporation of a saturated THF solution at room temperature, crystals suitable for the X-ray work were obtained. They were yellowish-green hexagonal plates with a thickness of about 1 mm.

The unit cell dimensions were determined by the least-squares treatment of the spacing of high-angle *hk*0 and *h*0*l* reflections, which were measured on Weissenberg photographs and calibrated with the powder lines of Al-wire. The density calculated by assuming 4 molecules in a unit cell, is 1.244 $g \cdot cm^{-3}$, while the density measured by floatation is 1.257

$g \cdot cm^{-3}$. From the systematic absences of reflections, the space group is determined to be *Pbca*; the absent reflections are $0kl$ when k is odd, $h0l$ when l is odd, and $hk0$ when h is odd. Since the general positions are eight-fold in this space group, the number of the molecules in the unit cell indicates that the molecule must have a centre of symmetry. The crystal data of DSP are given in Table 1.

Table 1. Crystallographic and physical data

Formula	$C_{20}H_{16}N_2$
MW	284
Mp	230°C
Crystal system	Orthorhombic
Space group	*Pbca*
a	20.638 Å
b	9.599 Å
c	7.655 Å
Z	4
Vol.	1517 Å^3
D_{calcd}	1.244 g·cm^{-3}
D_{obsd}	1.257 g·cm^{-3}
μ	6.83 cm^{-1}
$F(000)$	600

The intensity data were collected from equi-inclination multiple-film Weissenberg photographs. The layers from 0 to 5 along the c-axis and from 0 to 7 along the b-axis were recorded using Cu-Kα radiation. The crystals used had cross sections, perpendicular to the rotation axis, of 0.10×0.05 cm and of 0.05×0.05 cm for the c- and b-axis rotations respectively. The intensities were measured visually by comparison with a calibrated scale prepared with the same crystal. Of these 1246 reflections, 297 were measured as having zero intensity, while the others range from 1 to 19837 in their relative intensities. Corrections were made for the Lorentz and polarization factors and for spot size, but not for absorption. The data were put onto an absolute scale by means of Wilson's plot. The structure factors, $|F_h|$, and the normalized structure factors, $|E_h|$, were computed together.

Structure Determination

The symbolic addition procedure was applied for sign determination. As a starting set, the signs of five strong reflections were chosen; three of them specified the origin, and the other two were symbols, as is shown in Table 2. After six cycles of the phase-determining process using the Σ_2 relationship, the signs of 103 reflections out of 180 with $|E_h|>1.5$ were determined in terms of the a and b with a probability greater than 0.97. Further, by investigating the list of the Σ_2 relations, it seemed most probable that $a=+$ and $b=-$.

An E-map was computed using these 103 reflections with $a=+$ and $b=-$. All eleven non-hydrogen

Table 2. Assignment of signs of five strong reflections

3	7	6	3.95	+
4	1	1	3.24	+
12	4	4	5.04	a
3	7	2	3.12	b

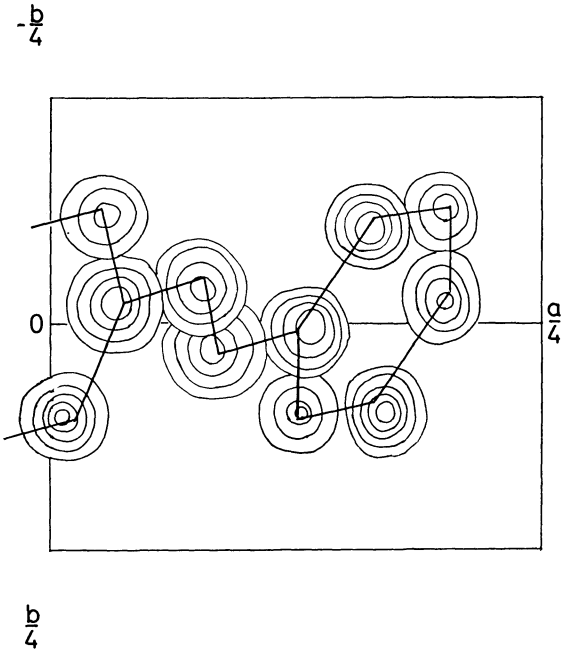

Fig. 1. Composite E-map. Contours are at equal intervals on an arbitrary scale. The final molecular shape is indicated with solid line.

atoms in the asymmetric unit were well resolved in the resulting E-map, as is shown in Fig. 1. Two additional appreciable peaks appeared, one of which is at the centre of the pyrazine ring, and the other, at the centre of the benzene ring; they were easily excluded as being insignificant. The only ambiguity was in the choice of the position of the N atom from between the alternative assignments.

Refinement

The coordinates of the eleven atoms as read on the E-map were subjected to Fourier refinement. On the first electron-density distribution map, the N atom was assigned easily from the peak height. The discrepancy factor, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, was 0.284 for the observed reflections. The parameters were refined by the block-diagonal-matrix least-squares method using isotropic temperature factors for all the atoms. After four cycles, the R value was reduced to 0.150. Further refinement was performed by introducing anisotropic temperature factors of the $exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$ form. After four cycles, the R value became 0.132. A difference Fourier synthesis at this stage revealed all the hydrogen atoms. The absence of a residual peak outside the N atom proved that the assignment of nitrogen based on the peak height was correct. The subsequent refinement was, however, initiated by using the positions of hydrogens computed by assuming suitable geometries of the C–H bond (C–H=1.08 Å), and the parameters of all the atoms including isotropic hydrogens were refined. After four cycles, the R value was 0.098. In the final cycles of refinement, the strongest reflection, 020, was excluded because it seemed to suffer from extinction. After four cycles, the R value reached 0.086.

The final atomic coordinates and the temperature

factors are given in Table 3, and their standard deviations, in Table 4. The observed and calculated structure factors are listed in Table 5. The final three-dimensional electron density distribution is shown in Fig. 2.

The atomic scattering factors used in the calculation were taken from the International Tables for X-ray Crystallography (1962). The computations were done on CDC 3600 and HITAC 5020E computers with the programs written by T. Ashida.

Results and Discussion

Molecular Structure. The bond lengths and angles are listed in Table 6, along with their standard deviations; they are also shown in Fig. 3.

The mean value of the C–C bond lengths in the benzene ring is 1.397 Å, very close to that given by Sutton.[5] The C(6)–C(5)–C(7) angle, 117.7°, is somewhat smaller than the others. A decrease in the corresponding angle is observed in the benzene ring with the –CH=CHR substituent: 118.2 and 117.5° in 1,1-di-*p*-toluylethylene,[6]

TABLE 3. FINAL ATOMIC COORDINATES AND TEMPERATURE FACTORS

The anisotropic temperature factors are expressed in the form of $exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$

C(9)–C(10)–H(10)	120.5	3.1

118.2° in diethylstilbestrol,[7] 118.2° in 1.8-diphenyl-1,3,5,7-octatetraene,[8] 118.2° in chalcone,[9] 117° in *p*-methoxychalcone[10] and 118.4° in *p*-coumaric acid.[11] Such a decrease may be interpreted as being due to interatomic repulsion induced by the substituent.

In the pyrazine ring there are two kinds of C–N bonds. The C–N bond adjacent to the substituent (C(2)–N(1)=1.346 Å) is longer than the other (C(1)'–N(1)=1.328 Å). Similar differences are observed in the substituted pyridine ring: 1.37 and 1.35 Å for 2,2-bipyridine,[12] and 1.362 and 1.337 Å for 2-(2-pyridylmethyldithio)benzoic acid.[13] The C–C bond length of the pyrazine ring, 1.395 Å, is compared to that of the benzene ring. These bond lengths are different

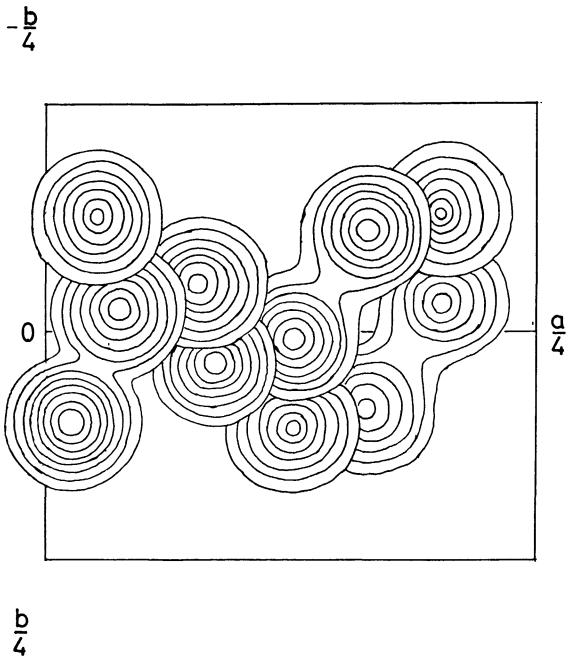

Fig. 2. Composite electron density diagram of sections parallel to (001). Contours are at intervals of 1.0 e.Å^{-3}, starting at 1.0 e.Å^{-3}.

from those of pyrazine itself;[14] C–N and C–C are 1.334 and 1.378 Å respectively. The C–N–C bond angle, 115.8°, is similar to that of pyrazine, 115.7°, and somewhat smaller than that in substituted pyridine: 116.7° in 1-phenyl-2-(2-pyridyl)ethanedione-1,2,[15] 118.5° in 2-(2-pyridylmethyldithio)benzoic acid,[13] and 120.6° in *cis*-β-bromo-β-(2-pyridyl)styrene.[16]

The bond lengths of C(2)–C(3) (1.463 Å), C(4)–C(5) (1.469 Å), and C(3)–C(4) (1.330 Å) are reasonable as those in a conjugated system; for example, in 1,8-diphenyl-1,3,5,7-octatetraene[8] the single bond length is 1.468 Å and the double bond length is 1.350 Å. The C(2)–C(3)–C(4) angle (126.0°) and the C(3)–C(4)–C(5) angle (127.0°) are considerably greater than 120°. Similar results have been reported for di-substituted ethylene: 128° for stilbene,[17] 126.8° for 1,8-diphenyl-1,3,5,7-octatetraene,[8] 127.6° for chalcone,[9] 127.2° for *p*-methoxychalcone,[10] 125.8° for *p*-coumaric acid,[11] 122.2° for diethylstilbestrol,[7] and 122.7° for 1,2-di-2-pyridylethenediol-1,2.[18]

It is noteworthy that the bond angles of nearly planar styryl groups (in the above-mentioned substances as well as the present compound) show very common features. The angles of C(3)–C(4)–C(5), C(4)–C(5)–C(7), and C(6)–C(5)–C(7) are 127°, 123°, and 118° respectively within a range of about one degree.

The equations of the average planes were evaluated by the method of least-squares. None of the hydrogen atoms were include because of the large standard deviations in their atomic coordinates. The equations are:

$$0.78278x + 0.41637y + 0.46215z - 3.53357 = 0 \quad (1)$$

for the plane of all eleven atoms;

$$0.75315x + 0.48099y + 0.44879z - 3.39271 = 0 \quad (2)$$

for the plane of the benzene ring;

$$0.81100x + 0.28777y + 0.50939z - 3.89936 = 0 \quad (3)$$

for the plane of the pyrazine ring, and

$$0.77506x + 0.43947y + 0.45404z - 3.46952 = 0 \quad (4)$$

Table 7. Displacements (Å) from the average planes

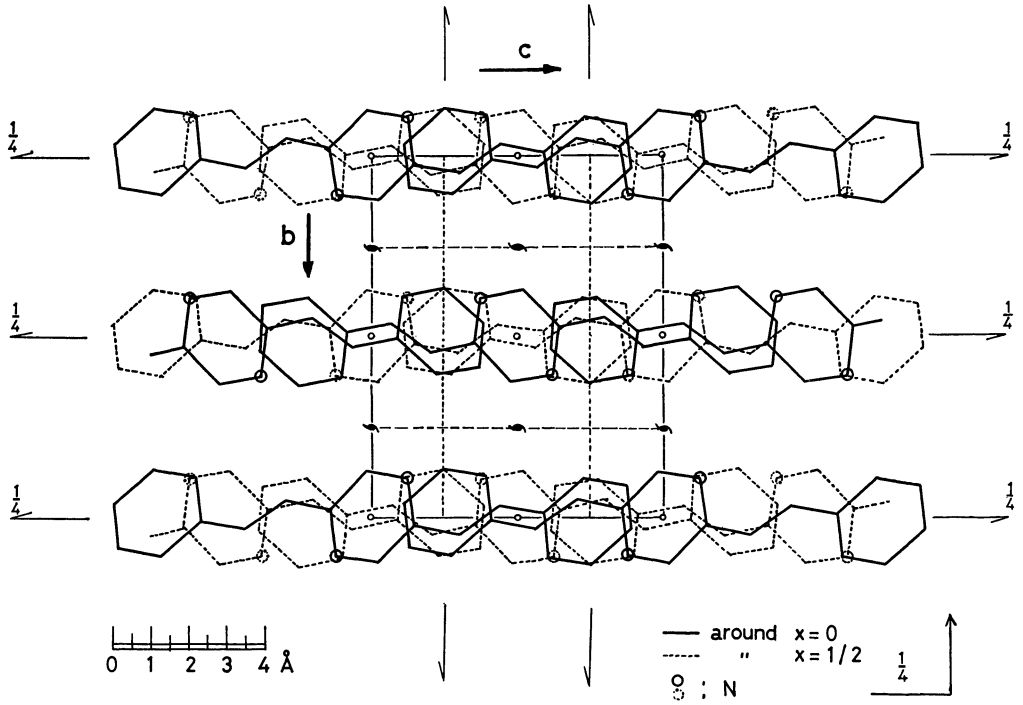

Fig. 6. The crystal structure viewed along the *a*-axis.

for the plane through the atoms C(2), C(3), C(4), and C(5), where x, y, and z are in Å.

The displacement of the atoms from each plane are shown in Table 7. The maximum deviations are 0.008 Å for the plane (2), 0.006 Å for the plane (3), and 0.001 Å for the plane (4). Therefore, these three groups of the atoms are planar.

However, the molecule as a whole is not planar, as may be seen from Table 7. The benzene ring rotates by 2.61° about the bond C(4)–C(5), and the pyrazine ring rotates by 9.42° about C(2)–C(3) in the opposite direction. Therefore, the dihedral angle between the planes (2) and (3) is 12.09°. The rotation about C(4)–C(5) may be due to a repulsion between the

Table 8. Intermolecular distances less than 4.0 Å

a) Listed for investigating the distances between double bonds.

Molecule	General coordinate
1	x, y, z
2	$x, y, -1.0+z$
3	$0.5-x, -y, 0.5+z$
4	$x, -0.5-y, -0.5+z$
5	$x, 0.5-y, -0.5+z$

hydrogen atoms attached to C(3) and C(7). The interatomic distance between these hydrogen atoms is 2.04 Å (e.s.d.=0.08 Å). Although, for the rotation about C(2)–C(3), no such repulsion is operative because of the absence of any hydrogen attached to the N atom, the rotation about C(2)–C(3) is larger than that about C(4)–C(5). This may be interpreted in terms of some intermolecular interactions.

Crystal Structure. The arrangements of molecules in the crystal viewed along the *c*-, *b*-, and *a*-axes are shown in Fig. 4, 5, and 6 respectively. Intermolecular distances less than 4.0 Å are listed in Table 8. No unusual short approaches are observed.

The molecules are oriented in such a way that their long axes are nearly perpendicular to the *b*-axis, as may be seen in Figs. 4 and 6. This arrangement can well explain the UV dichroism; the absorption parallel to the *c*-axis is ten times as strong as that parallel to the *b*-axis when measured on (100).[19]

The molecules spaced by the *c*-translation are also related by the centre of symmetry, the corresponding planar parts in these molecules being parallel to each other. As the long axis of the molecules makes an angle of about 30° to the *c*-axis, the molecules are piled up infinitely plane-to-plane, sliding in the direction of the long axis by half a molecule, as may be seen in Fig. 7.

The ethylenic double bonds, which are antiparallel to each other, approach to a distance of 3.939 Å from each other. This intermolecular distance between ethylenic double bonds is the shortest, while the second shortest contact of the same kind is 5.417 Å found between the molecules which are related by the *b*-glide plane. It is most probable that the double bonds related by the centre of symmetry react to form a a cyclobutane ring by photo-irradiation,[20] resulting in a linear ploymer. Thus, polymer chains should grow in the direction of the *c*-axis. This is confirmed by X-ray-crystallographic[21] and electron-microscopic[22] studies of the polymer thus obtained.

In order to investigate the intermolecular contacts involving the double bonds, the molecule 2 is projected on the best plane of the moecule 1 in Fig. 7. The

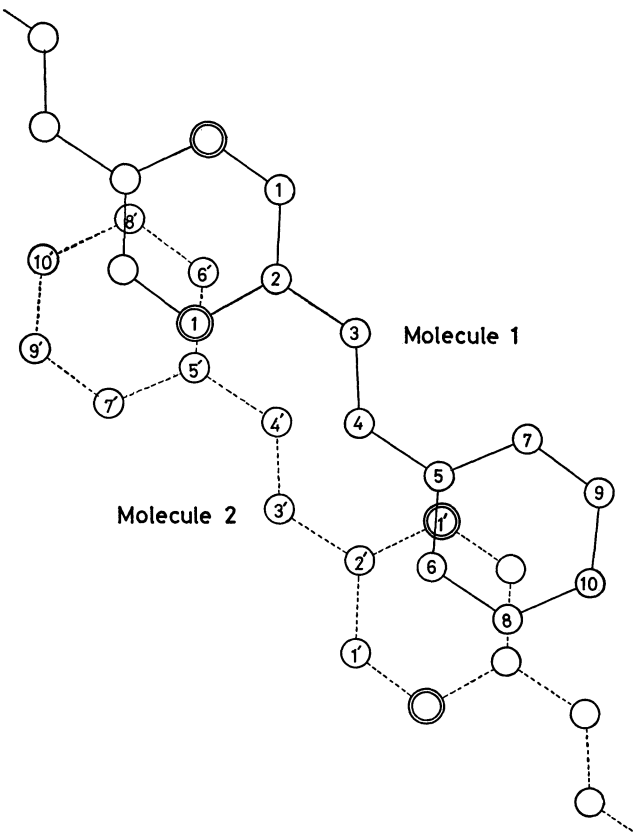

Fig. 7. The overlapping of the molecules viewed along the normal of the average plane of the reference molecule.

benzene ring in one molecule overlaps with the pyrazine ring in the other molecule. This type of parallel stacking of the aromatic rings has been observed in several other compounds. In the crystals of 1-phenyl-(2-pyridyl)ethanedione-1,2[15] and 2,2-pyridyl,[23] there are parallel pairs between the same aromatic rings and the perpendicular distances range from 3.49 to 3.80 Å. In the present crystal there are close contacts between unlike rings, with a plane-to-plane distance of 3.52 Å. Similar contacts are found in 2-(2-pyridylmethyl-dithio)benzoic acid. The UV spectrum of DSP in the crystalline state is different from that in solution, the former having a shoulder on the side of the longer wavelength[19]. The fact indicates that there is some kind of intermolecular interaction. As the short contacts are observed only between the parallel rings, it may be that the interaction of the overlapping part in Fig. 7, mainly determines the packing of the molecules in the crystal.

Some Information Derived from the Infrared Spectra of Ion-radical Molecules. The Spin-density Distribution for the *p*-Chloranil Anion Radical[1]

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 30, 1970)

The spin-density distribution in the *p*-chloranil anion radical was determined by means of the difference in the bond orders of the conjugated systems between *p*-chloranil and its anion radical, which was estimated on the basis of the stretching force constants. It was found that the spin-density distribution calculated by this method was in good agreement with that estimated by means of the molecular orbital calculations or by means of the hyperfine splitting constants in the ESR absorption. In view of these results, it was suggested that the present method might become a new tool for investigating the unpaired electron distributions of ion-radical molecules in general.

The infrared spectrum of an ion radical is known to be appreciably different from that of its neutral molecule.[2,3] In a previous paper,[3] we examined the infrared spectra(650—4000cm^{-1}) of *p*-chloranil and its anion radical.[4] In order to explain the appreciable frequency differences between their corresponding bands, the fundamental frequencies were assigned, and the simple Urey-Bradley force fields were determined for both the neutral and anion radical molecules. Their stretching-force constants for the bonds in the π conjugated systems were related to the bond orders by the use of the formula of Coulson and Longuet-Higgins.[5] The values of the bond orders thus obtained for *p*-chloranil ant its anion radical were in good agreement with those evaluated by the molecular orbital calculation, except for the C=O bond in the anion radical. These results are presented in Table 1. In view of these results, it seems that the difference in the infrared spectra between these two molecules is almost entirely attributable to the difference in their electronic structures caused by an extra electron on the *p*-chloranil anion radical.[3]

TABLE 1. THE VALUES OF THE BOND ORDERS OF THE C–C, C=C, AND C=O BONDS FOR *p*-CHLORANIL AND ITS ANION RADICAL

Bond	*p*-Chloranil		Its anion radical	
	IR[a]	MO[b]	IR[a]	MO[b]
C–C	0.27	0.30	0.37	0.41
C=C	0.87	0.91	0.79	0.81
C=O	0.82	0.85	0.40	0.70

a) The values obtained from the stretching force constants, which were evaluated from the fundamental frequencies observed in the infrared spectra.

b) The values calculated from the molecular orbitals for *p*-benzoquinone. See T. L. Kunii and H. Kuroda; Rep. Compt. Centre, Univ. Tokyo, **1**, 119 (1968).

The purpose of the present paper is to indicate that the difference in the bond orders between *p*-chloranil and its anion radical, which was obtained from their infrared spectra, leads to the spin-density distribution for the *p*-chloranil anion radical. In this respect, it is interesting to compare the results of our calculations with the spin-density distribution derived from the molecular orbital calculations and with that derived from the hyperfine splitting constants in the ESR absorption.

Calculations

It was assumed, to a first approximation, that the coefficients of the atomic orbitals for the molecular orbitals of the *p*-chloranil anion radical were not so different from the respective ones of *p*-chloranil, when an extra electron enters into the lowest vacant orbital of *p*-chloranil.[6] In this case, the difference in the bond orders between *p*-chloranil and its anion radical seems to be caused solely by the extra electron in the half-occupied molecular orbital of the *p*-chloranil anion radical. The effect of chlorine can be taken into account either by treating chlorine as a heteroatom or by treating the carbon atom bonded to chlorine as a heteroatom.[7] As will be explained below, it was

7) M. Broze, Z. Luz, and B. L. Silver, *J. Chem. Phys.*, **46**, 4891 (1967).

found that the result of our calculations can be well understood by the latter approach. Therefore, let c_i (i=1—8) be the coefficient of the i th atomic orbital in the half-occupied molecular orbital for the p-chloranil anion radical, the structural formula and the numbering of atoms of which are illustrated in Fig. 1. Since, as has already been remarked in a previous paper,[3] the value of the C=O bond order obtained for the anion radical involves some contribution of the self-polarizability, this value must be excluded in our treatment. We use only the values of the bond orders for the homopolar C=C and C–C bonds. Then, from Table 1, as for the C=C bond:

$$c_2c_3 = -0.08 \pm 0.005. \quad (1)$$

The point group for the p-chloranil anion radical belongs to the D_{2h} symmetry. From the symmetry properties, the absolute value of c_2 is equal to that of c_3. If we take c_2 as positive, these relations lead to:

$$c_2 = -c_3 = 0.283 \pm 0.009. \quad (2)$$

As for the C–C bond:

$$c_1c_2 = 0.10 \pm 0.005. \quad (3)$$

Putting the c_2 value into Eq. (3), we obtain:

$$c_1 = 0.354 \pm 0.029. \quad (4)$$

Similarly, since $c_1c_6=c_3c_4=c_1c_2$, and $c_5c_6=c_2c_3$:

$$c_6 = -c_5 = c_2, \quad (5)$$

$$c_4 = -c_1. \quad (6)$$

Although, as has been mentioned above, the values of c_7 and c_8 cannot be obtained directly from Table 1, the following normalization condition allows us to compute these values as:

$$|c_7|^2 = |c_8|^2 = \frac{1}{2}(1.00 - 2|c_1|^2 - 4|c_2|^2)$$

$$= 0.213 \pm 0.010. \quad (7)$$

As we can see from Table 1, the C=O bond order is obviously decreased in the anion radical: $c_1c_7=c_4c_8<0$. Therefore,

$$c_7 = -c_8 = -0.462 \pm 0.010.^{8)} \quad (8)$$

Judging from the signs of the coefficients of the atomic orbitals, the symmetry of the half-occupied molecular orbital for the p-chloranil anion radical proves to belong to the b_{3g} irreducible representation; this is in good accordance with that predicted by the electronic-spectrum measurements or the molecular-orbital calculations.[9-11]

The spin density, ρ_i(IR), at the ith atom can, then, be calculated by:[12]

$$\rho_i(\mathrm{IR}) = |c_i|^2. \quad (9)$$

The values of ρ_i(IR) thus obtained for i=1, 2, and 7 are collected in Table 2.

Table 2. The spin density distribution in p-chloranil anion radical

Position, i[a]	ρ_i(IR)[b]	ρ_i(MO)[c]
1	0.127±0.020	0.0918

c) The values estimated from the molecular orbital calculation by Broze, Luz, and Silver. See Ref. 7.

Discussion

Comparison with the Results of the Molecular-orbital Calculations. In order to account for the ^{17}O hyperfine splitting constant in the ESR absorption, Broze *et al.* have calculated the Hückel molecular orbitals for the p-chloranil anion radical.[7] They assumed the carbon atom bonded to chlorine to be a heteroatom, X, and determined the best-fit value for the ^{17}O hyperfine splitting constant. The optimum parameters for the heteroatom, X, are:

$$\alpha_X = \alpha - 0.012\beta, \quad (10)$$

$$\beta_{CX} = 0.962\beta. \quad (11)$$

As for the oxygen atom:

$$\alpha_O = \alpha + 1.17\beta, \quad (12)$$

$$\beta_{CO} = 1.46\beta. \quad (13)$$

They calculated the spin density, ρ_i(MO), for the p-chloranil anion radical by means of McLachlan's approximation. The values of ρ_i(MO) for i=1,2, and 7 are also collected in Table 2.[7]

As is shown in Table 2, although ρ_1(IR) $-\rho_1$(MO) $\approx$ 0.035, ρ_2(IR) $-\rho_2$(MO) ≈ -0.023, and ρ_7(IR) $-\rho_7$(MO) $\approx$0.010, the agreement between ρ_i(IR) and ρ_i(MO), where i=1, 2, and 7, is fairly good.

Since the α_X and β_{CX} values in Eqs. (10) and (11) are close to those of the corresponding carbon atoms in the p-benzoquinone anion radical, the unpaired-electron distribution in the conjugated system for the p-chloranil anion radical appears to be similar to that for the p-benzoquinone anion radical.

Comparison with the Results on the ESR Hyperfine Splitting Constants. As the p-chloranil anion radical does not include any hydrogen atom, no experimental

8) By the use of the c_1c_7 value and the C=O bond order for p-chloranil, the C=O bond order for the anion radical is corrected to 0.66±0.02. According to the formula of Coulson and Longuet-Higgins,[5] a C=O stretching force constant, K(C=O), in the infrared spectrum is represented by:

$$K(\mathrm{C{=}O}) = \{(1-p(\mathrm{C{=}O}))K_s + p(\mathrm{C{=}O})K_d\} + \left[\left\{\frac{K_sK_d(s-d)}{K_s(1-p(\mathrm{C{=}O}))+K_dp(\mathrm{C{=}O})}\right\}^2 \frac{\pi(\mathrm{COCO})}{2}\right].$$

The notation of this equation and the values of K_s=5.0 md/Å and K_s=10.7 md/Å have already been described in a previous paper.[3] If this equation is applicable to the p-chloranil anion radical, the first term is found to be equal to 8.8 md/Å by the use of p(C=O)=0.66. In this case, since the observed K(C=O) value for the anion radical is 7.3 md/Å, the numerical difference, −1.5 md/Å, may be attributable to the second term involving the self-polarizability. See Ref. 3.

12) The notation, ρ_i(IR), was used for distinguishing it from the ρ_i(MO) or ρ_i(ESR) to be described in the next section.

result is available for the hyperfine splitting constants except for that due to the ^{17}O of the carbonyl group. Broze *et al.* examined the ESR spectra of the ^{17}O-labeled *p*-chloranil anion radical in various solvents.[7] For example, the ^{17}O hyperfine splitting constant was found to be $a_7^O(\text{obs}) = -8.89 \pm 0.02$ G in a dimethylformamide solution. On the other hand, the theoretical oxygen hyperfine splitting constant, $a_7^O(\text{calc})$, in a carbonyl group can be evaluated by the following equation:[7,13,14]

$$a_7^O(\text{calc}) = Q_{OC}^O \rho_O + Q_{CO}^O \rho_O, \qquad (14)$$

where the values of $Q_{OC}^O = -40.7 \pm 5.2$ G and $Q_{CO}^O = -9.5 \pm 6.1$ G were proposed by Broze *et al.*;[7] ρ_O and ρ_C are the spin densities in the $p\pi$ orbitals of the oxygen and the neighbouring carbon atoms respectively. If the values of $\rho_1(\text{IR})$ and $\rho_7(\text{IR})$ are put into Eq. (14), $a_7^O(\text{calc})$ is evaluated to be -10.05 ± 2.48 G; this value is in good agreement with the foregoing experimental value of -8.89 ± 0.02 G.

At present, there appear no experimental data for use in comparing the spin densities on the carbon atoms in the *p*-chloranil anion radical. However, since the unpaired-electron distribution in the conjugated system for the *p*-chloranil anion radical seems to be similar to that for the *p*-benzoquinone anion radical, the values of $\rho_i(\text{IR})$ were compared with the spin densities of the *p*-benzoquinone anion radical as determined from the hyperfine splitting constants.

Das and Fraenkel measured the proton and ^{13}C hyperfine splittings in the ESR spectrum of the *p*-benzoquinone anion radical; they found $a_2^H = -2.395 \pm 0.002$ G and $a_1^C = -2.21 \pm 0.02$ G in the dimethoxyethane solution, while the values were $a_2^H = -2.368 \pm 0.001$ G and $a_1^C = -0.40 \pm 0.04$ G in the C_2H_5OH-H_2O solution.[13] When $i=1$, 2, and 7, the spin densities, $\rho_i(\text{ESR})$, derived from these experimental results were 0.1487, 0.0896, and 0.1721 in the dimethoxyethane solution, while they were 0.1796, 0.0877, and 0.1450 in the C_2H_5OH-H_2O solution respectively.[13] Although there are appreciable differences in the spin densities for the two solvents at the carbonyl carbon and oxygen atoms, we can see that the set of $\rho_i(\text{IR})$, where $i=1$, 2, and 7, is well fitted to that of $\rho_i(\text{ESR})$ in the dimethoxyethane solution. In the case of the C_2H_5OH-H_2O solution, the agreement between $\rho_i(\text{IR})$ and $\rho_i(\text{ESR})$ is not satisfactory, except for that between $\rho_2(\text{IR})$ and $\rho_2(\text{ESR})$.

Concluding Remarks

It has been well established that hyperfine splitting constants in the ESR spectra provide one of the most important means for determining the spin-density distribution of radical molecules.[14] However, this technique involves the following difficulties:

(1) If a radical molecule does not include atoms with a nuclear magnetic moment, no experimental data are available for the hyperfine splitting constants. In practice, when the H, ^{13}C, ^{14}N, or ^{17}O atom is not contained in a radical molecule, the information is, accordingly, quite limited.

(2) If radical molecules exist in an aggregate state, such as in the solid state or in a highly concentrated solution, the hyperfine splittings should be narrowed by intermolecular spin-exchange interaction, which gives only a single exchange-narrowed line.[15] Therefore, the hyperfine splitting constants cannot be obtained in such a situation.

Instead of the use of the hyperfine splitting constants, the spin-density distribution of a radical molecule can be evaluated, in some cases, on the basis of an accurate determination of the *g*-values in the ESR absorption or from the chemical shifts in the NMR spectrum.[14] However, besides these techniques, the present use of the infrared spectra of a neutral molecule and its ion radical constitutes a new approach to this problem. In contrast to the use of hyperfine splitting constants, our method has the following advantages:

(1) A radical molecule need not necessarily include atoms with a nuclear magnetic moment, because the spin densities are derived from the differences in the bond orders.

(2) One can estimate the spin-density distribution for a radical molecule not only in an isolated state, but also in an aggregate state. The latter information seems to be valuable for investigating the intermoleculer interaction of radical molecules. In fact, the values of $\rho_i(\text{IR})$, where $i=1$, 2, and 7, of the *p*-chloranil anion radical are those in the solid state,[3] in which the charge-transfer interaction between *p*-chloranil anion radical molecules has been known to take place by means of the solid-state spectrum.[11] In this respect, one reason for the previously-mentioned small deviation of the $\rho_i(\text{IR})$ values from the $\rho_i(\text{MO})$ or $\rho_i(\text{ESR})$ values, where $i=1$, 2, and 7, may be the difference in the spin-density distributions between the solid state and the isolated state. However, we should keep in mind that, in our treatment, the $\rho_i(\text{IR})$ values include some uncertainties in the course of the derivation of the bond orders from the stretching force constants. This means that more reliable values for the spin densities will be obtained if a more precise estimation of the bond orders and the self-polarizabilities can be made from the stretching force constants.

The Crystal and Molecular Structure of Pyromellitic Acid Dihydrate (Benzene-1,2,4,5-tetracarboxylic Acid Dihydrate)[1]

Fusao TAKUSAGAWA, Ken HIROTSU, and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received November 4, 1970)

The crystal structure of pyromellitic acid dihydrate has been determined by the method of X-ray diffraction. The crystal is triclinic in the $P\bar{1}$ space group, with $Z=1$ and cell dimensions of $a=10.05$, $b=6.45$, $c=5.45$ Å, $\alpha=74.5°$, $\beta=112.2°$, and $\gamma=77.3°$. The structure was derived from the three-dimensional Patterson function and was later refined by the least-squares method, using the anisotropic thermal parameters, to give a final R index of 7.4%. All the hydrogen atoms were located on the difference-synthesis map. The average C(ring)–C(ring) distance is 1.386 Å, while the average C(ring)–C(carboxyl) distance is 1.496 Å. One carboxyl group is twisted by 17.9°, and the other is twisted by 74.5°, out of the plane of the benzene ring. The C–O(H) and C=O distances differ significantly from each other, the average values being 1.302 and 1.211 Å respectively. Four types of hydrogen bonds, with an average O–H···O distance of 2.732 Å, form a three-dimensional network. Thus, each molecule is joined, through hydrogen bonds around the center of symmetry, to two other molecules, forming an endless chain in the [1 $\bar{1}$ 1] direction. Water molecules are arranged on the plane parallel to (1 1 0) so as to hold the chains together by hydrogen bonds.

The pyromellitic acid dihydrate, $C_6H_2(COOH)_4\cdot 2H_2O$, with two pairs of vicinal carboxyl groups, is one of 12 benzene carboxylic acids. The crystal structures of several of these acids have already been studied by means of X-ray work to give valuable information in the field of crystal chemistry: benzoic acid;[2] phthalic acid;[3,4] terephthalic acid;[5] trimesic acid[6] and mellitic acid.[7] However, no X-ray investigation has been reported on hydrates of these benzene carboxylic acids. In view of this situation, it seemed that it would be of interest to examine the crystal and molecular structure of this compound in detail, so as to elucidate the steric hindrance of adjacent carboxyl groups and the way of hydrogen bonding in this crystal. It will also be of significance to compare the results of this study with the results of studies of other carboxylic acids, such as the oxalic acid,[8–17] thoroughly investigated, with special reference to the hydrogen-bond formation in the crystal.

Experimental

The crystals were obtained in the form of colorless plates by recrystallization from an aqueous solution. The cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines. They are given with other crystal data in Table 1. By the assumption of one chemical unit in a unit cell, the density is calculated to be 1.64 g/cm³, this value is in good agreement with the observed value (1.63 g/cm³) determined by the floatation method.

Table 1. Crystal data

Pyromellitic acid dihydrate,	$C_6H_2(COOH)_4\cdot 2H_2O$
Formula weight, 290.20	
Crystal system, Triclinic	Space group, $P\bar{1}$
Cell dimension	
$a=10.05(1)$Å	$\alpha=74.5(3)°$
$b=6.45(2)$	$\beta=112.2(1)$
$c=5.45(1)$	$\gamma=77.3(1)$
$D_m=1.63$ g/cm³	
$D_c=1.64$ g/cm³ (Z=1)	
$\mu_r=15.223$ cm^{-1} (CuK_α)	

The crystals were ground to cylinders with average diameters of 0.26 mm for the b-axis and 0.33 mm for the c-axis specimens. They had lengths of 0.83 and 0.74 mm along the b and c axes respectively. The intensity data were collected for the 0-3 layers around the b and c axes by the use of the multiple-film equi-inclination Weissenberg technique, using Cu$K\alpha$ radiation. The intensities of the diffraction spots were estimated visually by comparison with a calibrated intensity standard. Of the possible 1370 reflections within the Cu$K\alpha$ sphere, 1100 independent reflections were measured; 148 were too weak to be measured. The data were corrected for spot-shape, absorption, and Lorentz and polarization factors. They are then correlated and reduced to the structure factors by the procedure presented by Hamilton, Rollet and Sparks.[18] Finally, the structure factors were placed approximately on an absolute scale by the method of Wilson.[19]

There were no reflections systematically absent. Of the two possible space groups, $P\bar{1}$ and $P1$, the former was assigned by testing the intensity distributions.

Structure Determination

Since the crystal belongs to the $P\bar{1}$ space group with only one molecule in the unit cell, the center of a benzene ring of pyromellitic acid must lie on a center of symmetry. This is of considerable aid in structure analysis. At first, two three-dimensional unsharpened and sharpened Patterson maps were calculated to derive a rough idea of the orientation of the benzene ring. Although these two maps differed from each other in several features, they gave trial coordinates of the three carbon atoms forming the benzene ring with the knowledge of the aromatic carbon-carbon distance.

With this orientation of the benzene ring, three arrangements of the two carboxyl groups are possible. Hence, attempts were made, using conventional bond distances and angles, to fit the interatomic vectors among the carboxyl groups to the observed peaks in the Patterson maps. However, this method could not give a fruitful clue, so three sets of structure factors and three-dimensional Fourier syntheses were calculated in order to rule out the wrong arrangements. The R indices for the three sets were found to be almost the same, but one of the three electron-density maps indicated the peaks of five oxygen atoms of the two carboxyl groups and one water molecule, as well as those of two carbon atoms of the carboxyl groups.

The refinement of the positional parameters, thermal parameters, and the scale factor was carried out by means of the block-diagonal least-squares method, using a modified version of the HBLS program written by Okaya and Ashida.[20] The initial calculations were based on about 600 reflections with $\sin\theta/\lambda \leq 0.5$ and the weighting scheme of $w=1.0$ to accelerate the convergence. Five cycles of refinement with isotropic themal parameters lowered the R index to 18.0%. At this stage, anisotropic thermal parameters were introduced for all the atoms except the hydrogen atoms; four subsequent cycles of refinement dropped the R index to 10.0%. However, several reflections showed rather large $|Fo-Fc|$ discrepancies; this disagreement in structure factors seemed to be caused by the neglect of the hydrogen atoms.

Therefore, we have prepared a three-dimensional difference map, using $(Fo-Fc')$ as the coefficients; here Fc' stands for the calculated structure factor with all the atoms except the hydrogen atoms. This map showed the peaks for hydrogen atoms near the positions expected, although there remained a few spurious peaks comparable in height to those of the hydrogen atoms. Several cycles of least-squares refinement were attempted with the hope of improving the parameters belonging to the atoms beside the hydrogen atoms. In this case, we did not try to refine the parameters of the hydrogen atoms. During these cycles, the residual did not reduce significantly; the weighting scheme was altered to $w=A/Fo$ for $Fo \geq A$, $w=1.0$ for $1.5 \leq Fo \leq A$ and $w=0.5$ for $Fo \leq 1.5$ in later refinements. The A parameter was re-evaluated several times during the refinement so as to give approximately a constant average of $w(Fo-Fc)^2$ in groups of increasing $\sin\theta/\lambda$—0.000—0.291, 0.291—0.411, 0.411—0.503, 0.503—0.650; the final value was 5.0. After several least-squares cycles, the difference map was again calculated without hydrogen atoms. This new map indicated the peaks of five hydrogen atoms with several ghost peaks. With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R index was 7.4%, excluding unobserved reflections. The observed and calculated structure factors are listed in Table 2.[21]

Table 3. The final parameters and their standard deviations (in parentheses)

The coordinates of the heavy atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic temperature parameters of the heavy atoms are of the form $\exp[-(b_{11}h^2+b_{22}k^2+b_{33}l^2+2b_{12}hk+2b_{13}hl+2b_{23}kl)]$, and have been multiplied by 10^5. For the hydrogen atoms the values listed are isotropic temperature parameters B.

Discussion of the Structure

The final positional and thermal parameters are listed, along with their standard deviations, in Table 3. Figure 1 shows the electron-density and difference maps along the *c* axis calculated at the end of the refinement.

The right-hand side is a composite of a number of electron-density sections. The left-hand side is composite of difference sections calculated with the structure factors excluding the hydrogen atoms. The bond distances and angles are listed, along with their estimated standard deviations, in Table 4 and are also given in Fig. 2, which shows the projection of a molecule onto the plane of the benzene ring. In Table 5, the molecular dimensions obtained in the present crystal are compared with those of related benzene carboxylic acids.

There are three structurally distinct ring C–C distances. The average value is 1.386 Å; this does not differ significantly from the accepted value. Similarly, the bond angles in the benzene ring require no special comment. The least-squares plane was calculated through the six ring atoms. The benzene ring is essentially planar. The equation of the plane is given in Table 6, together with the out-of-plane distances of various atoms in a molecule. The dimensions of the two carboxyl groups are very similar to each other, but the two C–O distances in each group are distinctly different. The bonds between the carbon and carbonyl oxygen atoms, C(4)–O(2) and C(5)–O(4), are shorter than those between the carbon and hydroxyl oxygen atoms, C(4)–O(1) and C(5)–O(3), by an average value of 0.091 Å. The hydrogen atoms of pyromellitic acid are definitely associated with the hydroxyl oxygen atoms, as no evidence was found for any disordering of the hydrogen position or the presence of the H_3O^+ ion. In both carboxyl groups, the C–C–O angles associated with the short C–O bonds are smaller than those associated with the longer C–O bonds by an average value of 9.7°; the O–C–O angles are also found to be clearly larger than 120°, as is usually observed in carboxylic acids.

One carboxyl group is twisted by 17.9° out of the plane of the benzene ring, while the other is twisted by 74.4°. Furthermore, C(4) and C(5) deviate from the least-squares plane by 0.12 and −0.08 Å respectively. These twists and deviations might be due to the repulsion of the oxygen atoms of the adjacent carboxyl groups, and also to the formation of the hydrogen-bond network, as will be discussed later. The C(1)–C(2)–C(5) angle is 122.4°, which is significantly larger than 120°; this might also be caused by the interaction of the vicinal carboxyl groups, although the corresponding angle related to another carboxyl group does not differ significantly from 120°. In general, the distances of the C–C bond external to the central ring fall in the

range of 1.48 and 1.54 Å, such as found in the benzoic acid[2] and the acetic acid,[22] which vary according to the differences in the contribution of the π-bond character. In the present structure, the two C(ring)-C(carboxyl) distances are 1.486 and 1.506 Å respectively. The difference between these two distances may be inside the limits of experimental error. However, it is likely that the changing of these bond lengths can be explained by the difference in the contribution of the π-bond character resulting from the twisting angles of related carboxyl groups.

The most interesting features of the structure are the intricate arrangement of hydrogen bonds and the resulting three-dimensional network. Four types of hydrogen bonds, with O-H···O distances of 2.549, 2.687, 2.807, and 2.876 Å, form a three-dimensional net work, as is shown in Figs. 3 and 4. Each molecule is joined, through a hydrogen bond around the center of symmetry, to two other molecules, forming an endless chain in the [1 $\bar{1}$ 1] direction. Water molecules are arranged on the plane parallel to (1 1 0) so as to hold the chains together by hydrogen bonds. The distance between the oxygen atoms of the carboxyl groups related by a center of symmetry is 2.687 Å; this is normal for this type of hydrogen bond. The three hydrogen bonds through the medium of a water molecule differ significantly in length and strength, the distances being 2.549 Å for the H_2O···HO bond and 2.807 and 2.876 Å for the two O···H_2O bonds. The O(1‴)–H(2‴)··· O(5″) angle of 166° indicates that the hydrogen atom lies more closely to the line joining O(1‴) and O(5″) (2.549 Å) than in the case of the weaker O(5″)–H(4″)··· O(4″) (2.876 Å) and O(5″)–H(5″)···O(4⁗) (2.807 Å) hydrogen bonds, in which the corresponding angles are 152° and 165° respectively.

In connection with the mode of hydrogen bonding in this crystal mentioned above, it is interesting to compare it with that found in the oxalic acid, which

O(5)-O(4″)-O(5″)	93.7(2)	97.9

has been studied in detail. The oxalic acid is well known to have polymorphs, occurring in two anhydrous forms[8,9] and also in two dihydrate forms,[10-17] one of which is found in the deutrated dihydrate. While there is only one independent carboxyl group in an oxalic acid molecule, there are two independent carboxyl groups in a pyromellitic acid. It will be seen that one kind of hydrogen bond is used to form the endless chain, as in the β-form of the anhydrous oxalic acid. Except for this hydrogen bond, there still remain six hydrogen atoms to be hydrogen bonded in a pyromellitic acid dihydrate as in an oxalic acid dihydrate. The hydrogen bonds formed by those remaining hydrogen atoms seem to resemble those found in the α-form of oxalic acid dihydrate. The hydrogen-bonding distances and angles are compared in Table 7. Moreover, the direction of the line joining the water oxygen atom and carboxyl hydrogen atom O(5″)···H(2‴) makes an angle of 47° with the plane of the water molecule in the present crystal. The corresponding angle in the oxalic acid dihydrate is 51°; this is one of the main features of hydrogen bonds in the α-oxalic acid dihydrate.[14,17]

Photochemical Reactions of Uranyl Ions with Organic Compounds III. The Correlation between the Reaction Mode and the Pre-Equilibrium in the Photolysis of the Uranyl-lactate System

Shukichi SAKURABA and Ryoka MATSUSHIMA
Faculty of Engineering, Shizuoka University, Hamamatsu

(Received November 28, 1970)

On the basis of the assumed mechanism for the photolysis of the uranyl-lactate system, the equilibrium constant for the complex formation, K, was evaluated from the photo-kinetic data by using a monochromatic 4047 Å light; it was then compared with those obtained from the usual spectrophotomeric measurements. A comparison of the K values obtained by means of the photo-kinetic data ($1.0-1.1\times10^{-1}$) and by means of the analytical data ($1.1-1.2\times10^{-1}$) gave an excellent agreement; there was also a good agreement between the slope of the plot of the photo-kinetic data and that predicted from the assumed mechanism. The results supported the crude mechanism assumed earlier.

In a previous paper[1] it was reported that the photo-oxidation of lactic acid by uranyl ions gave acetaldehyde (with an evolution of carbon dioxide) and pyruvic acid as the oxidation products besides, the equimolar uranium-(IV) species as the reduction product. The dependence of the relative ratio of the organic products upon the various experimental conditions was attributed to the difference in the initial species of the system to be photolized; the formation of acetaldehyde involves an intra-molecular decomposition of the uranyl-lactate complex initially formed, while the formation of pyruvic acid involves encounter collisions between lactic acid and the excited uranyl ions (initially uncomplexed):

$$U + HL \rightleftharpoons UL + H^+$$

$$U + h\nu \longrightarrow U^*$$

$$UL + h\nu \longrightarrow UL^*$$

$$U^* \xrightarrow{k_1} U + h\nu' \text{ or heat}$$

$$UL^* \xrightarrow{k_2} UL + h\nu'' \text{ or heat}$$

$$U^* + HL \xrightarrow{k_3} U(V) + HL^+$$

$$UL^* \xrightarrow{k_4} UL' + CO_2$$

$$HL^+ + U \xrightarrow{\text{fast}} \text{pyruvic acid} + U(V) + 2H^+$$

$$2U(V) \xrightarrow[H^+]{\text{fast}} U(IV) + U$$

$$UL' \xrightarrow{\text{fast}} \text{acetaldehyde} + U(IV) + H^+$$

where U: uranyl ion; HL: lactic acid; HL^+: intermediate radical cation $CH_3C^+H(OH)CO_2H$, and UL′: intermediate species, such as $CH_3C^+H\!\!<\!\!\begin{matrix}O\\H\end{matrix}\!\!>UO^+_2$ (the last

1) S. Sakuraba and R. Matsushima, This Bulletin, **43**, 1950 (1970).

two intermediates would lose protons to form radicals, but the true intermediate species are still uncertain).

The present investigation was undertaken to see whether or not the equilibrium constant (for the uranyl lactate complex) which can be evaluated from the kinetic data by using the assumed equations is consistent with that determined by means of the usual analytical method.

Experimental

De-oxygenated solutions containing 0.2M lactic acid and 0.02M uranyl nitrate, of the pH-range of 0.1—2.5 and the ionic strength of 0.3—0.5, were irradiated with the light of the 4047—4078 Å region at 20°C by means of an interference filter and a 500-W high-pressure mercury arc. The concentrations of the acetaldehyde (A) and pyruvic acid (P) formed were determined spectrophotometrically as their 2,4-dinitrophenylhydrazones. The separation of the hydrazone derivative from each other was carried out with ethyl acetate[2] and an aqueous Na_2CO_3 (0.5N) solution.[1]

The quantum yield of the formation of pyruvic acid, ϕ_P, and that of acetaldehyde, ϕ_A, under various pH's were obtained from the molar ratios [A]/[P] by using a calibrated graph of the total quantum yield[3] as a function of the pH preliminarily measured repeatedly with a much more stable Hg-lamp source(100W). This method seems to make possible simplified procedures and a much higher accuracy than the direct measurements of the quantum yields, since the [A]/[P] ratio is independent of the total number of the light quanta absorbed by the system.[1] The adjustments of the pH(or [H]) of the solutions, both that to be photolyzed and that for analytical use (for the measurement of the k value), were carried out with solutions of perchloric acid and sodium hydroxide, using a pH-meter (Toa Denpa Co., Ltd.).

Results and Discussion

The Photo-Kinetic Results. For simplification, the experimental conditions were so chosen that only the 1:1 complex of the uranyl-lactate was formed;

$$U + HL \overset{K}{\rightleftarrows} UL + H^+$$

It is evident both from Fig. 1 and from the linearity of the plots in Figs. 5 and 6 that only the 1:1 complex[4] is formed when the initial concentrations, at pH≤3, of the uranyl ions and lactic acid are 0.02M and 0.2M respectively. The hydrolysis and polymerizations of uranyl ions are negligible at pH values below 2.5.[5]

The formation quantum yields, ϕ_P and ϕ_A, for the photolysis of the uranyl-lactate system in which initial formation of the 1:1 complex is involved will be given by the following equations, (1) and (2) respectively,

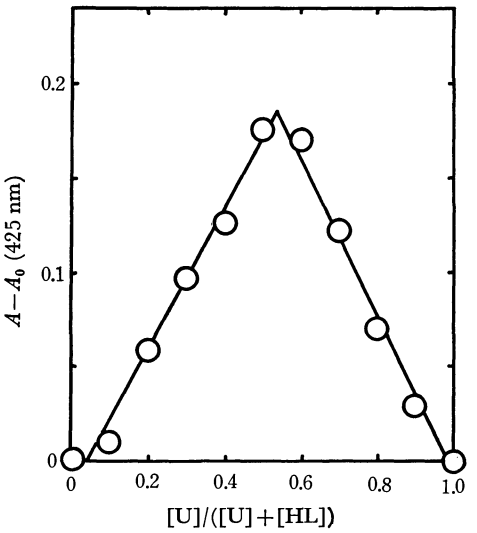

Fig. 1. Application of the continuous variation method to the uranyl-lactate system, as measured at 425 nm peak. [U]+[HL]= 0.04M, pH=3.0.

which are based on the assumed mecahnism.

$$\phi_P = \frac{k_3[HL]}{k_1 + k_3[HL]} \cdot \frac{\varepsilon_1[U]}{\varepsilon_1[U] + \varepsilon_2[UL]} \quad (1)$$

$$\phi_A = \frac{k_4}{k_2 + k_4} \cdot \frac{\varepsilon_2[UL]}{\varepsilon_1[U] + \varepsilon_2[UL]} \quad (2)$$

Equations (1) and (2) can be rewritten as Eqs. (1′) and (2′):

$$\log\left(\frac{\phi_P^0}{\phi_P} - 1\right) = \log C + \mathrm{pH} \quad (1')$$

$$\log\left(\frac{\phi_A^0}{\phi_A} - 1\right) = -\log C - \mathrm{pH} \quad (2')$$

where:

$$\phi_P^0 = k_3[HL]/(k_1 + k_3[HL]) \quad (3)$$

$$\phi_A^0 = k_4/(k_2 + k_4) \quad (4)$$

$$C = \varepsilon_2 K[HL]/\varepsilon_1 \quad (5)$$

$$K = [UL][H]/[U][HL] \quad (6)$$

ε_2 and ε_1 are the absorption coefficients of the complex and the uncomplexed uranyl ions respectively at the

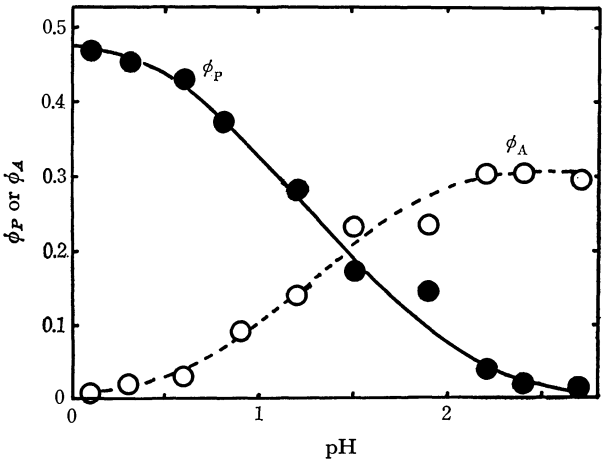

Fig. 2. Plots of the quantum yields *vs.* pH, showing $\phi_P^0 = \phi_P(\text{at } \phi_A \to 0) = 0.48$, $\phi_A^0 = \phi_A(\text{at } \phi_P \to 0) = 0.32$.
ϕ_A: The quantum yield of acetaldehyde formation.
ϕ_P: The quantum yield of pyruvic acid formation.

2) The extraction by ethyl acetate was superior to the extraction by chloroform or carbon tetrachloride because of its higher solubility and more complete separation.

3) The total quantum yield was equal to the quantum yield of the U(IV) formation.[1]

4) See also I. Feldman and J. R. Harvill, *J. Amer. Chem. Soc.*, **76**, 2114, 4726 (1954).

5) E. Rabinowitch and R. L. Belford, "Spectroscopy and Photochemistry of Uranyl Compounds," Pergamon Press, London (1964) pp. 91—110.

irradiated wavelength (4047 Å). ϕ_P^0 can be regarded as a limited value of ϕ_P when ϕ_A reaches zero (Eqs. (1) and (3)), and ϕ_A^0 as a limited value of ϕ_A when ϕ_P reaches zero (Eqs. (2) and (4))(*cf.* Fig. 2). When the initial concentration of lactic acid is much higher than that of the uranyl ion, the change in the lactic acid concentration due to the complex formation may be neglected: $[HL]_i \gg [U]$, $[HL]_i \gg [UL]$. Thus, Eqs. (5) and (6) may be rewritten as Eqs. (5′) and (6′):

$$C = \varepsilon_2 K[HL]_i/\varepsilon_1 \ (=\text{constant}) \qquad (5')$$

$$K = [UL][H]/[U][HL]_i \qquad (6')$$

Then, if the quantum yields, ϕ_P and ϕ_A, are measured under various pH's, with the initial concentration of lactic acid kept constant and much higher than that of the uranyl ion, the plot of log $(\phi_P^0/\phi_P - 1)$ *vs.* pH and log $(\phi_A^0/\phi_A - 1)$ *vs.* pH should be straight lines with slopes of 1 and −1 respectively. A good agreement with these predictions is shown in Fig. 3, though the A plot is somewhat scattered. Either from the intercept of the P plot or from that of the A plot, the equilibrium constant, K, can be evaluated by using Eq. (5′) if ε_1 and ε_2 are determined by an appropriate method. The absorption coefficient of the uranyl ions, ε_1, at 4047 Å was 7.0 and was constant over the pH range from 0.1 to 2.4 (Fig. 4). The absorption coefficient of the complex, ε_2, at 4047 Å can be obtained from the intercept of the corresponding plot in Figs. 5 or 6 by using Eq. (7). The 3 plot in Fig. 5 gives $\varepsilon_2 - \varepsilon_1$ (at 405 nm) = 7.0, and the 1 plot in Fig. 6 gives $\varepsilon_2 - \varepsilon_1$(at 405 nm) = 7.1. When $[HL] = 0.20$ M, $\varepsilon_1 = 7.0$, $\varepsilon_2 = 14.0$, and log $C = -1.35$ (the intercept of plot P in Fig. 3), are substituted in Eq. (5′), K becomes 1.1×10^{-1}; while the substitution of $-\log C = 1.4$ (the intercept of plot A) gives $K = 1.0 \times 10^{-1}$.

Determination of the Equilibrium Constant by the Spectrophotometric Method[6,7] In order to compare the K-value evaluated on the basis of the photo-kinetic data with those evaluated by means of the usual analytical

method, spectrophotometric measurements were made for the uranyl-lactate system prior to photolysis under the conditions mentioned above. The absorption spectra of the uranyl-lactate complex and the uncomplexed uranyl ions are shown in Fig. 4. The equilibrium constant, K, can be obtained from the plot of $[U]_t/(A-A_0)$ either as a function of [H] by keeping $[HL]_t$ constant, or as a function of $[HL]_t^{-1}$ by keeping [H] constant, using Eq. (7):

$$\frac{[U]_t}{A-A_0} = \frac{1}{\varepsilon_2-\varepsilon_1} + \frac{[H]}{(\varepsilon_2-\varepsilon_1)K[HL]_t} \qquad (7)$$

Here, A is the total absorption of the system at a wavelength in the visible region (where absorption by lactic acid is zero), A_0 is equal to $\varepsilon_1[U]_t$ at the same wavelength, and $[U]_t$ is kept constant (0.02M). The results,

Wavelength (nm)	$K^{a)} \times 10$	$K^{b)} \times 10$
363	1.19	
397	1.27	
405	1.20	1.13
408	1.20	
432	1.03	1.00
458	1.20	

a) Obtained from the plot of $[U]_t/(A-A_0)$ *vs.* [H]
b) Obtained from the plot of $[U]_t/(A-A_0)$ *vs.* $[HL]_t^{-1}$

measured at several wavelengths, are shown in Figs. 5 and 6, while the K values are listed in Table 1. A comparison of these values with those evaluated from the photo-kinetic data ($1.0—1.1\times10^{-1}$) gave excellent agreement.

The close relationship indicates that the variation in the reaction mode (or in the molar ratio of the products) is merely a direct reflection of the initial equilibria of the solutions to be photolyzed. Thus, the assumptions that the formation of acetaldehyde involves an intramolecular decomposition of the uranyl-lactate complex initially formed, and that the formation of pyruvic acid involves collisions between the excited uranyl ions initially uncomplexed, are supported. The results also suggest that the formation of an intermediate donor-acceptor complex during the lifetime of the excited state is not likely to be an important factor in governing the variations in the reaction mode in the photolysis of the uranyl-lactate system, though such an intermediate complex (exciplex) seems to play an important role in the transfer mechanisms of many other systems.[8,9] Of course, our results give no information on the redox-intermediate species (radical or radical ions), on which further clarification is needed.

The Adsorption of Water on SiO_2, Al_2O_3, and $SiO_2 \cdot Al_2O_3$. The Relation between the Amounts of Physisorbed and Chemisorbed Water

Tetsuo Morimoto, Mahiko Nagao, and Junichiro Imai

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received December 14, 1970)

The specific surface area, the water content, and the water adsorption isotherm have been measured in order to investigate the interaction between the surfaces of SiO_2, Al_2O_3, and $SiO_2 \cdot Al_2O_3$ and water molecules. Al_2O_3 gives II-type adsorption isotherms and the amount of adsorbed water on it increases with a rise in the temperature of pretreatment, whereas SiO_2 gives isotherms approximate to the III-type and the amount of adsorbed water is larger when treated at lower temperatures. With $SiO_2 \cdot Al_2O_3$, it was found that the type of isotherms and the effect of the pretreatment temperature are similar to those of Al_2O_3, and that the amount of adsorption increases with an increase in the Al_2O_3 content. By analysing the adsorption data, the ratio of the amount of physisorbed water in the first layer to the amount of the underlying chemisorbed water was calculated. As a result, it was found that the H_2O:OH ratio is 1:2 on the surface of Al_2O_3, whereas it is 1:1 on the surface of SiO_2. The analysis of the isotherms on $SiO_2 \cdot Al_2O_3$ showed that the adsorption property of water on them is not additive: *e.g.*, the amount of adsorbed water on $SiO_2 \cdot Al_2O_3$ is larger than the sum of the water adsorbed on each component. Thus, it has been concluded that, on the surface of SiO_2 in contact with Al_2O_3, the surface hydroxylation proceeds more rapidly than on the surface of pure SiO_2.

Silica-alumina ($SiO_2 \cdot Al_2O_3$) is a catalyst widely used for such reactions as cracking and isomerization, and its surface properties have been studied extensively. Among these, the relation between the surface acidity and the catalytic activity[1-4] has been the most important property; it has been studied by using such basic substances as ammonia,[5-7] amine,[8] and pyridine[9,10] as adsorbates. Recently, it has become clear that the surface hydroxyl groups are present on the surfaces of most metal oxides placed in the usual atmosphere, that they affect their surface properties, and that they also play important roles in catalytic actions.[11,12] Finch and Clark[12] have reported that more than 0.45% water is necessary for the isomerization reaction of 1-butene by using $SiO_2 \cdot Al_2O_3$ as a catalyst; in this case, water acts cooperatively with a complex for polymerization.

In the preceding papers the ratio of the number of physisorbed water molecules to the amount of the underlying chemisorbed water (surface hydroxyl groups) has been investigated; it was found to be 1:2 (H_2O:OH) for TiO_2 (rutile) and α-Fe_2O_3[13] and 1:1 for ZnO[14] in the monolayer coverage of physisorbed water. On the surface of the $SiO_2 \cdot Al_2O_3$ catalyst there should be two kinds of surface hydroxyl groups, silanol and aluminol, differing in properties. It has been reported that the remaining surface hydroxyl groups of $SiO_2 \cdot Al_2O_3$ after the treatment at higher temperatures were those on SiO_2.[15] There have been many discussions of the nature of acidic sites on $SiO_2 \cdot Al_2O_3$,[16] but the water adsorption property, which should affect the surface acidity, has not yet been investigated in detail. The purpose of this work is to investigate the water adsorption property on SiO_2, Al_2O_3, and three kinds of $SiO_2 \cdot Al_2O_3$, all differing in composition in order to ascertain the relation between the amounts of physisorbed and chemisorbed water on them, and to clarify the details of the interaction between oxide surfaces and water molecules.

Experimental

Materials. Pure SiO_2 gel (S) was produced by the hydrolysis of ethyl-silicate with water at 100°C, the latter being purified by double distillation from a commercial, guaranteed reagent. Al_2O_3 gel (A) was prepared by the following process. Metallic aluminum was treated with a 5% NaOH solution to remove the surface impurity, and then washed with water, absolute ethanol, and ether. The 25 g of metallic aluminum thus treated were permitted to react with 300 m*l* of pure isopropanol in a reflux flask, in the presence of 1 g of mercuric chloride as a catalyst. The aluminum isopropoxide thus formed[17] was distilled under a reduced pressure of 2.5 Torr (108—108.5°C). An Al_2O_3 gel sample was obtained by the hydrolysis of this aluminum isopropoxide in a mixed solution of isopropanol and water (3:1). Three kinds of $SiO_2 \cdot Al_2O_3$ were obtained by mixing SiO_2 (S) and Al_2O_3 (A) samples of different compositions. SA-25, SA-50, and SA-75 contain Al_2O_3 gel of 25, 50, and 75wt.% respec-

tively. The mixing of SiO_2 and Al_2O_3 gels was carried out in an agate-ball mill. Finally, the pure and mixed gels thus obtained were washed sufficiently with distilled water, dried at 100°C, and calcined at 500°C for 10 hr in air.

Specific Surface Area. The specific surface area of the samples pretreated at 600°C for 4 hr under the reduced pressure of 10^{-5} Torr was measured by applying the BET theory[18] to the nitrogen adsorption data at −196°C. The conditions of the pretreatment were the same as those for the water adsorption measurement. The molecular area of nitrogen was assumed to be 16.2 Å^2. The values obtained on the S, A, SA-25, SA-50, and SA-75 samples were 640, 189, 423, 427, and 317 m^2/g respectively.

Water Content. The water content of the samples was measured by the successive-ignition-loss method.[19] The samples were treated in the same apparatus as was used for the adsorption measurement for 4 hr at various temperatures, from room temperature to 1100°C; the vapor evolved was determined volumetrically at each step. From these data, the water content remaining on the surface could be obtained as a function of the pretreatment temperature. In this calculation the water content at 1100°C was assumed to be zero, as the amount of water vapor expelled at 1100°C was negligibly small.

Water-adsorption Isotherm. The sample was at first treated at 600°C for 4 hr under the reduced pressure of 10^{-5} Torr. The measurement of the water adsorption isotherm was carried out volumetrically at 20°C, by using an oil manometer to read the equilibrium pressure. After the first adsorption isotherm had been determined, the sample was again treated at 30°C for 4 hr at 10^{-5} Torr, and then the second adsorption isotherm was measured at the same temperature as before. The same adsorption measurements were repeated subsequently for one sampling after the sample had been treated at various temperatures, from 100 to 500°C.

Results

The water content of the samples is shown in Fig. 1 as a function of the pretreatment temperature. It indicates the amount of water bonded to the surface treated at the given temperatures, expressed in the number of hydroxyl groups per 100 Å^2. At lower temperatures there is a large possibility that it includes the amount of physisorbed water. It can be seen from Fig. 1 that the water content of pure Al_2O_3 is the most, and that the value of SiO_2 is the least. With $SiO_2 \cdot Al_2O_3$, the greater the portion of Al_2O_3, the more the water content. Furthermore, the water-content curve of pure SiO_2 is characteristic in that it decreases almost linearly with the rise in the temperature.

The water-adsorption isotherms of five samples are given in Figs. 2—4. In the case of Al_2O_3, the adsorption isotherms belong to the II-type of Brunauer's classification;[20] the amount of adsorbed water is the largest in the measurement after 600°C treatment, and the smallest in the measurement after 30°C treatment. When the pretreatment temperature rises from 30

to 500°C, the amount of adsorbed water increases and approaches the value of the 600°-treated sample. Moreover, Fig. 2 shows that the sample of Al_2O_3 chemisorbs water considerably. The same situation appears in the case of $SiO_2 \cdot Al_2O_3$ (Fig. 3), and the amount of adsorbed water increases with an increase in the content of Al_2O_3.

The water-adsorption isotherms on pure SiO_2 are given in Fig. 4; they are quite different from those on pure Al_2O_3 and $SiO_2 \cdot Al_2O_3$. First, the results generally show that the higher the pretreatment temperature, the less the amount of adsorbed water. Second, the shape of the isotherms on the sample pretreated at lower temperatures is of the II-type, whereas it seems to approach the III-type when the pretreatment temperature rises. Young[21] has reported that, on a flame silica, the water-adsorption isotherms were of the III-type and that the amount of adsorbed water decreased with the rise in the pretreatment temperature to 450°C. Most metal oxides chemisorb water molecules, even at the lowest equilibrium pressure, to form surface hydroxyl groups, and further physisorb water molecules on them through hydrogen bonding, resulting in II-type isotherms, as is shown in Figs. 2 and 3. On the contrary, the surface of pure SiO_2 adsorbs more water when the pretreatment temperature is lower and, accordingly, when the remaining surface hydroxyl groups are larger in number, as may be seen from Figs. 1 and 4. Moreover, the amount of adsorbed water on the 600°C-treated sample is quite small at lower pressures, but it increases more sharply at higher pressures compared to the cases of the other samples, as is shown in Fig. 4. These results suggest that the rate of the surface hydroxylation of SiO_2 is slower than in the cases of Al_2O_3 and other metal oxides and that, therefore, the physisorption only occurs during the water-adsorption measurement. Our experience has shown that, in the first adsorption-isotherm measurement on SiO_2 (after 600°C treatment), the time required for the attainment of the equilibrium pressure was within 20 min in the low-pressure range, but was prolonged in the higher-pressure range,

21) G. J. Young, *J. Colloid Sci.*, **13**, 67 (1958).

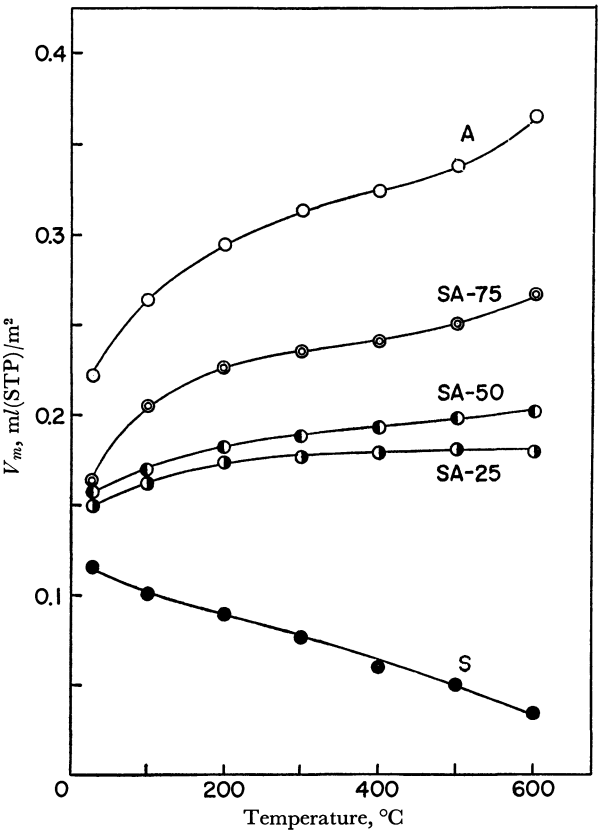

Fig. 5. Dependence of V_m value on pretreatment temperature.

taking more than a few hours. In the second adsorption measurement, however, the equilibrium was attained within 30 min over the whole range of pressure. The results of Hockey and Pethica[22] and those of Egorova *et al.*[23] agree with the present findings, supporting of the idea that, on the surface of SiO_2, the rate of surface hydroxylation is so slow that the surface can only be hydroxylated at higher relative pressures.

By applying the BET method[18] to the adsorption isotherms, the monolayer capacity, V_m, of water was calculated and plotted against the pretreatment temperature (Fig. 5). The V_m value on Al_2O_3 increases with a rise in the temperature of pretreatment. In a previous paper, the same plot was taken on ZnO, TiO_2, and α-Fe_2O_3.[24] In the cases of ZnO and TiO_2, the temperature at which the steep increase in V_m starts was distinct; this was explained in terms of the commencement of the removal of chemisorbed water by the pretreatment and the reversible rehydroxylation on exposing the surface to water vapor. Also, in the present case additional chemisorption on Al_2O_3 is considered to occur, though the temperature showing the commencement of the steep increase in V_m is not clear similarly to the case of α-Fe_2O_3. The removal of chemisorbed water may occur at least at 150°C, as is to be expected from Fig. 1. On the other hand, the V_m value of SiO_2 decreases almost linearly with the rise in the pretreatment temperature; this is parallel to the decrease in water content shown in Fig. 1. This suggests that, on the surface of SiO_2, the physisorption of water only occurs on the surface hydroxyl groups during the adsorption measurement. With $SiO_2 \cdot Al_2O_3$, the V_m value increases similarly to that of pure Al_2O_3, but the increase in V_m becomes slower when the content of SiO_2 is greater, as is shown in Fig. 5.

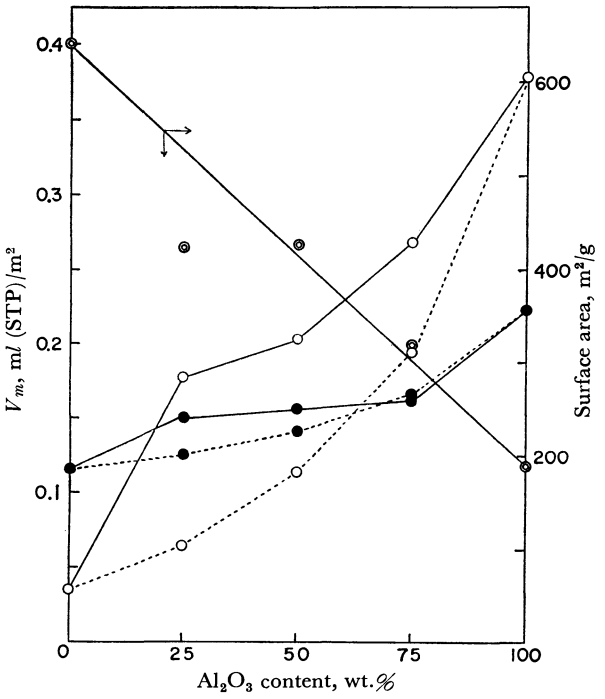

Fig. 6. Dependence of V_m value and specific surface area on Al_2O_3 content: pretreated at 600°C, ○; 30°C, ●.

In order to ascertain the dependence of V_m on the composition, V_m is replotted against the Al_2O_3 content in Fig. 6. This plot can be taken for each pretreatment temperature, but in Fig. 6 only two limiting cases are represented (600° and 30°C treatments). The other plots at the intermediate temperatures can be inserted in a regular order between them. The specific surface area of the sample is also plotted in Fig. 6. As may be seen from Fig. 6, the surface areas of $SiO_2 \cdot Al_2O_3$ are almost all on the straight line connecting the values of SiO_2 (640 m²/g) and Al_2O_3 (189 m²/g); the one exception is the SA-25 sample, which gives a fairly smaller value than would be expected from the composition. If the surface area of $SiO_2 \cdot Al_2O_3$ is composed of the sum of each component, the portion of the surface of Al_2O_3 in $SiO_2 \cdot Al_2O_3$, $S_{(A)}/S_{(SA)}$, is about 9, 23, and 47% for SA-25, SA-50, and SA-75 respectively. Furthermore, if the water adsorption occurs additively on the surfaces of $SiO_2 \cdot Al_2O_3$, the V_m value will change as shown by the dotted curves. The experimental results on $SiO_2 \cdot Al_2O_3$, especially on SA-25, deviate greatly from these synthetic curves, indicating that the water adsorption does not occur additively on the surface of $SiO_2 \cdot Al_2O_3$. It has been established that $SiO_2 \cdot Al_2O_3$ of a composition of 13—25 wt.% Al_2O_3

has a large catalytic activity.[6,25] The present results seem to show a characteristic activity of SA-25 in the adsorption of water.

Discussion

On the basis of these experimental results, the relation between the amounts of physisorbed and chemisorbed water on pure SiO_2 and Al_2O_3 was first obtained as is shown in Table 1. V_m is the monolayer capacity obtained from the water-adsorption isotherm. This may be considered to include only physisorbed water in the case of SiO_2, as has been discussed above. V_p is the amount of physisorbed water, expressed in the number of water molecules per 100 Å². For the same reason, the amount of chemisorbed water, V_c, on SiO_2 is zero in the initial stage of the adsorption process. V_h is the water content; it indicates the amount of water chemisorbed before the adsorption measurement, expressed in the number of hydroxyl groups per 100 Å². Thus, the value of V_h is equal to the total amount of chemisorbed water in the case of SiO_2. It may be seen from Table 1 that the ratio of V_p to V_h is approximate to 1 on every surface of SiO_2 treated at different temperatures. This finding indicates that the initial physisorption of water occurs only on silanol groups in the ratio of 1:1. The surface density of silanol groups is 2.78 OH groups/100 Å² at most; this is reasonable compared with the maximum value calculated by Schneider[26] on the surface of amorphous SiO_2 (5.0 OH groups/100 Å²), although it is considerably smaller than the number of surface hydroxyl groups on Al_2O_3 and the other metal oxides.[13] Several authors have also found that the number of the surface hydroxyl groups on SiO_2 is small.[21,22,27] These silanol groups are, therefore, believed to be scattered and isolated on the surface of SiO_2, on which each water molecule is bonded through hydrogen bonding in the ratio of 1:1. On the surface of ZnO a similar ratio has also been found,[14] but there the mechanism of water adsorption seems to be different from the present case.

The V_m value on Al_2O_3 treated at various temperatures is composed of both physisorbed and chemisorbed water, as has been described above, but the second adsorption isotherm obtained after the treatment at 30°C contains only physisorbed water, for the reason discussed in previous papers.[13,24] Therefore, in the case of Al_2O_3, the V_m value obtained from the second adsorption isotherm (after the 30°C treatment) was taken as the amount of physisorbed water, V_p, and the difference between V_m and V_p, as the amount of the chemisorbed water, V_c.[28] The sum of V_c and V_h is, accordingly, the total amount of the chemisorbed water after the adsorption measurement. Thus, in the case of Al_2O_3, the $V_p:(V_c+V_h)$ ratio should be the true ratio of the amounts of physisorbed and chemisorbed water in the first layer of physisorption; it is found to be approximately 1 : 2, as is shown in Table 1. This suggests that, on the surface of Al_2O_3, one water molecule is physisorbed onto two surface hydroxyl groups, as in the cases of TiO_2 (rutile) and α-Fe_2O_3.[13] In addition, when the pretreatment temperature of Al_2O_3 rises over 200°C, V_h decreases, V_c

increases, and the sum of V_h and V_c is almost constant; this suggests that the rehydroxylation of the dehydroxylated sites occurs reversibly on the surface of Al_2O_3 upon exposure to water vapor.

In the case of $SiO_2 \cdot Al_2O_3$, the meaning of the H_2O: OH ratio is fairly obscure, since water molecules can be adsorbed differently on the two kinds of surfaces. The SA-50 data listed in Table 1 are temporarily-calculated values, the mean value of the values on the two kinds of surfaces, which are obtained by the same method as was used in the case of pure Al_2O_3. In this calculation it is assumed that the physisorption only occurs on the 30°-treated surface of SA-50, and that V_p is constant on every surface treated at different temperatures. The H_2O:OH ratio of SA-50 thus calculated increases remarkably with the rise in the pretreatment temperature, though the values of pure SiO_2 and Al_2O_3 are almost invariable. This tendency becomes smaller in the order: SA-25 (0.72—1.53), SA-50 (0.61—1.16), SA-75 (0.36—0.63); the larger the portion of SiO_2, the greater the effect. Certainly, this effect results from the fact that, when the surface treated at higher temperatures is exposed to water vapor, the rehydroxylation occurs reversibly and rapidly on the dehydroxylated sites of both SiO_2 and Al_2O_3 in $SiO_2 \cdot Al_2O_3$, as in the case of pure Al_2O_3, in spite of the fact that the rehydroxylation is difficult on SiO_2. Since the physisorption of water initially occurs on the surface hydroxyl groups, the amount of physisorbed water on $SiO_2 \cdot Al_2O_3$ is also expected to decrease, as in the case of pure SiO_2, when the pretreatment temperature rises. Thus, in calculation of SA-50 shown in Table 1, V_p was overestimated and, accordingly, V_c+V_h was underestimated, resulting in the increase in the H_2O:OH ratio at higher pretreatment temperatures.

Another calculation was made on the SA-50 sample as an example (Table 2), assuming that the surface of SiO_2 in $SiO_2 \cdot Al_2O_3$ only physisorbs only water molecules. On this sample, the portion of the surfaces occupied by Al_2O_3 is 23%. By subtracting the amount of physisorbed water on 77 Å² of pure SiO_2 from the V_m value of SA-50, we can obtain the sum of the amounts of physisorbed and chemisorbed water, $V_{m(A)}$, on 23 Å² of Al_2O_3. By means of the same method as was used in the case of Al_2O_3, $V_{m(A)}$ can be separated into the amounts of chemisorbed ($V_{c(A)}$) and physisorbed water ($V_{p(A)}$); assuming that the $V_{m(A)}$ value obtained after the 30°C treatment is composed of only the amount of physisorbed water, as in the case of pure Al_2O_3, the $V_{p(A)}$ value of 1.83 water molecules per 23 Å² for SA-50 is obtained. On the measurements after the pretreatment at higher temperatures, the chemisorption of water also occurs; its amount can be determined by subtracting $V_{p(A)}$ from $V_{m(A)}$. On the other hand, the water content of SA-50 illustrated in Fig. 1 should be composed of those on SiO_2 and Al_2O_3. On the basis of the above assumption that the surface of SiO_2 does not chemisorb water molecules, the water content of Al_2O_3, $V_{h(A)}$, can be calculated. Thus, the ratio of the amount of physisorbed water ($V_{p(A)}$) to the total amount of chemisorbed water ($V_{c(A)}+V_{h(A)}$) can be given as 0.30—0.36 for every measurement, whatever the treatment temperature may be, as is shown in Table 2. Similar results were obtained on the SA-25 (0.21—0.31) and SA-75 (0.24—0.34) samples; they are all considerably smaller than that on pure Al_2O_3 (0.5).

Such small values seem to be quite difficult to accept if we take into account the surface hydrophilicity of pure Al_2O_3. These unlikely small values probably arise from the assumptions that the water chemisorption does not occur on the surface of SiO_2 and that, consequently, all the chemisorption of water on $SiO_2 \cdot Al_2O_3$ in the adsorption process is to be attributed to the surface of Al_2O_3 in $SiO_2 \cdot Al_2O_3$. Rather, it may be reasonable

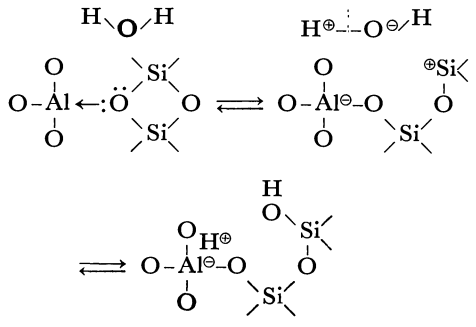
to suppose that water molecules can be chemisorbed also on the surface of SiO_2 in $SiO_2 \cdot Al_2O_3$. In the calculation in Table 2, the number of the silanol groups thus probably formed is included in $V_{c(A)}$; this results in the overestimation of $V_{c(A)}$ and, accordingly, the underestimation of $V_{p(A)}$: $(V_{c(A)} + V_{h(A)})$. The overestimation of $V_{c(A)}$ can be understood more clearly by recalculating the data per 100 Å^2 from those per 23 Å^2, as in Table 3. The number of surface aluminum atoms of α-Al_2O_3 is estimated crystallographically to be 10.20 aluminum atoms per 100 Å^2 on the (0001) plane of α-Al_2O_3. Peri and Hannan[29] assumed the value of 12.5 OH groups/100 Å^2 as the surface density of hydroxyl groups on the fully hydroxylated surface of γ-Al_2O_3. The surface density of aluminum atoms and, accordingly, the maximum number of surface aluminol groups on the $SiO_2 \cdot Al_2O_3$ samples tested here can be expected to be almost the same as has been cited above. The V_c values on pure Al_2O_3 in Table 1 are, therefore, reasonable, but the $V_{c(A)}$ values are extraordinarily large, as is shown in Table 3; this proves that $V_{c(A)}$ has been overestimated.

Next, let us estimate the amount of chemisorbed water on SiO_2 in $SiO_2 \cdot Al_2O_3$, as has just been suggested. On the basis of the value of $V_{c(A)}$ in Table 3 and that of V_c of pure Al_2O_3 in Table 1, the excess amount of chemisorbed water per 23 Å^2 can be calculated; this water is transferred to the surface of 77 Å^2 of SiO_2. Here, the amount of water chemisorbed on Al_2O_3 in $SiO_2 \cdot Al_2O_3$ is assumed to be the same as that chemisorbed on pure Al_2O_3. The $V_{m(S)}$ value thus obtained is given in Table 3, expressed in the number of hydroxyl groups per 100 Å^2. When the chemisorption of water occurs on SiO_2 to form the silanol groups, additional physisorption will also occur on them. Accordingly, assuming that the physisorption on SiO_2 in $SiO_2 \cdot Al_2O_3$ would occur in the ratio of 1:1 (H_2O:OH), as in the case of pure SiO_2, one third of the $V_{m(S)}$ value is the amount of chemisorbed water. The $V_{c(S)}$ value thus obtained is 2.61 OH groups/100 Å^2 at most, as is shown in Table 3; this is comparable with the V_h value on SiO_2 and indicates the number of silanol groups retained before the water-adsorption measurement. $V_{c(S)}$ is the mean value on the unit surface area of SiO_2 in $SiO_2 \cdot Al_2O_3$, but the silanol groups newly formed during the adsorption process are probably concentrated in the contacting surface region of SiO_2 and Al_2O_3.

Finally, assuming that the V_h value of each oxide in $SiO_2 \cdot Al_2O_3$ is the same as that of single oxide, and taking into account the surface areas occupied by the two components, we can calculate the V_h values of $SiO_2 \cdot Al_2O_3$ and compare them with the experimental data read from Fig. 1 (Table 4). It may be seen from Table 4 that the experimental V_h value is always larger than the calculated one, but that the former approaches the latter as the sample is pretreated at higher temperatures. In other words, the water content is not additive and the partial chemisorption of water occurs on $SiO_2 \cdot Al_2O_3$ before the adsorption measurement.

From the above results and considerations, we may conclude, with a large degree of probability, that the formation of silanol groups or new kinds of hydrated sites is fairly easy on SiO_2 in $SiO_2 \cdot Al_2O_3$, but is difficult on pure SiO_2. The mechanism of this reaction can be considered to be as follows: each aluminum atom on the surface of Al_2O_3 will attract lone-pair electrons from the surface oxygen atom of SiO_2 when they come in contact with each other. Such an excited site formed on the contacting surface region of the two oxides will react easily with a water molecule according to the formula:



In this process, the water molecule can be adsorbed *via* dissociation; on the surface of SiO_2 a silanol group is formed, and on the surface of Al_2O_3, H^+ is adsorbed on the negative site of the aluminum atom.

Stability Constants of Cu(II) Chelates with *o*-Phenylenediamine Derivatives

Kenyu KINA and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received May 11, 1970)

The stability constants of copper(II) chelates with *o*-phenylenediamine derivatives have been determined by the pH titration method. The measurements have been carried out at 25.0±0.1°C and μ=0.10(by KNO_3). *o*-Phenylenediamine derivatives, which have a substituent group (CH_3, CH_3O, COOH, or Cl, *etc.*) at the 4 positions, were used as ligands. The overall stability constants of the copper chelates are of the order: CH_3, CH_3O, H, COO^-, Cl, COOH; their values were 8.50, 8.42, 7.72, 7.06, 5.76, and 5.35 respectively. The effects of substituent groups on the stability constants have been studied. The plot of the overall stability constants against the sum of Hammett σ_m and σ_p values was found to be linear. The chelate stability and acid dissociation constants of the acido complexes of 3,4-diaminobenzoic acid were determined by the use of an augmented matrix.

Chelate-compound formation between transition metal ions and aliphatic diamines such as ethylenediamine has been extensively studied.[1] However, an aromatic diamine has not yet been widely studied. The present investigation was undertaken in order to determine the stability constants of copper(II) chelates of aromatic diamines, that is, *o*-phenylenediamine and its derivatives. The stability constants were calculated by the method of the least squares. If the acido complexes are present, the calculation will become enormously troublesome. According to Schwarzenbach, some kinds of ionic species can be neglected in a solution with a certain ratio of the ligand to the metal ion. From this point of view, the problem can be simplified; the acid dissociation and stability constants of acido complex were thus determined.

Experimental

Reagents. *m*-Phenylenediamine, *p*-phenylenediamine, 4-methyl-*o*-phenylenediamine (Wako Pure Chemical Co.), *o*-phenylenediamine (Daiichi Pure Chemical Co.), 4-chloro-*o*-phenylenediamine, 1,2,4-triaminobenzene dihydrochloride (Tokyo Chemical Industry Co.), and 3,4-diaminobenzoic acid (Aldrich Chemical Co.) were treated with active carbon and were recrystallized from conc. HCl before use.[2] 4-Methoxy-*o*-phenylenediamine was systhesized by the reduction of 2-nitro-4-methoxyaniline.[3] The dihydrochlorides of *o*-phenylenediamine derivatives, and 1,2,4-triaminobenzene trihydrochloride were obtained as white crystals. The hydrochlorides were used for the titration. A carbonate-free potassium hydroxide solution was prepared by the method of ion exchange and was standardized with potassium hydrogen phthalate titrimetrically.

Reagent Solutions. The stock solution of copper(II) ($Cu(NO_3)_2 \cdot 3H_2O$) was standarized by the usual procedures of chelatometric titration.[4] Solutions of all the ligands were made up with redistilled water just before the titration.

pH Titration Method. The hydrogen-ion concentration was measured by using an HRL-Model P pH meter (made by the Horiba Instruments Inc., Kyoto), with glass and calomel electrodes. Before and after each titration, the pH meter was calibrated with an acetate buffer.[5] The titration was carried out in a jacketed titration cell the volume of which was 100m*l*. For the determination of the dissociation constants of the protonated ligands, 2.5×10^{-3}M solutions of ligand in 0.10M potassium nitrate were used. On the other hand, solutions containing 1:1, 2:1, 3:1, 4:1, 5:1, 6:1, or 10:1 molar ratios of the ligand to the metal ion were used for the determination of the stability constants, while the ionic strength was maintained at approximately 0.10M with potassium nitrate. By circulating water from a constant-temperature bath through the water jacket, the temperature of the solution to be measured was kept at 25.0±0.1°C, and the room temperature, at 25±1°C. A carbon dioxide-free nitrogen atmosphere was maintained above the solution.

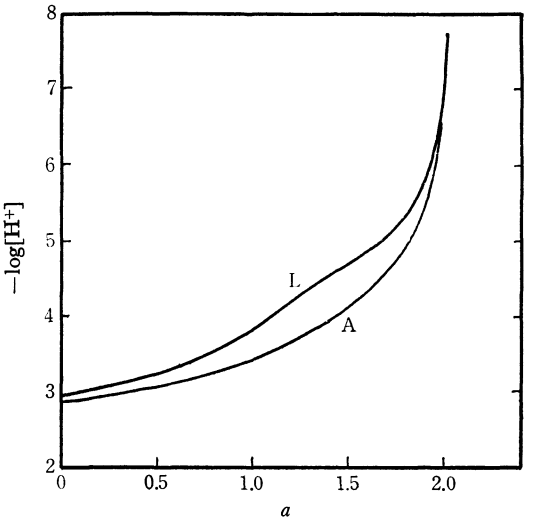

Fig. 1. Titration of *o*-phenylenediamine dihydrochloride, and 2:1 metal chelate, at 25°C, μ=0.10, L, ligand only; A, Cu(II) and ligand mixture [Ligand]=2[Metal ion]=1.052×10^{-3}M, [KOH]=1.072×10^{-3}M, *a*=moles of base added per mol of ligand.

Mathematical Treatment

a) Acid-dissociation Constants. The acid-dissociation constants of the protonated ligands were calculated

1) L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," Special Publication No. 17, The Chemical Society, Burlington House, London (1964), P. 390.

2) K. Tôei and K. Ito, *Talanta*, **12**, 773 (1965).

3) F. Wrede and E. Strack, *Ber.*, **62**, 2050 (1920).

4) K. Ueno, "Chelatemetric Titration" (in Japanese), Nankodo, Ltd., Tokyo (1967), P. 250.

5) S. Nakashima, H. Miyata, and K. Tôei, This Bulletin, **40**, 870 (1967).

by a method analogous to that of Murakami *et al.*[6] The equilibria and the dissociation constants involved are:

$$H_2L^{2+} \rightleftarrows H^+ + HL^+, \quad K_{a1} = [H^+][HL^+]/[H_2L^{2+}],$$
$$HL^+ \rightleftarrows H^+ + L, \quad K_{a2} = [H^+][L]/[HL^+],$$
$$1/K_{a1} = AK_{a2} + B \qquad (1)$$

where:

$$A = (2T_L - T_{OH} - [H^+] + [OH^-])/[H^+]^2(T_{OH} + [H^+] - [OH^-])$$
$$B = (T_L - T_{OH} - [H^+] + [OH^-])/[H^+](T_{OH} + [H^+] - [OH^-]),$$

and where L represents the *o*-phenylenediamine or its derivatives. T_L and T_{OH} are the total ligand concentration, and the concentration of the base added to the system, respectively. In all the calculations, the concentrations were corrected for the change in volume produced by the addition of the KOH. The acid-dissociation constants for protonated ligands were calculated by solving simultaneous equations from two points on the titration curve in the range of the buffer region. The pK_{a2} can be determined accurately by solving the simultaneous equations, because it has an order of magnitude of 3—5. If the pK_{a1} is below 2.0, an accurate value can not be obtained by this method. On the basis of Eq. (1) we assume that pK_{a1} is known and that pK_{a2} is the unknown. Then, pK_{a1} is obtained by the application of iterative approximation, by using an electronic computer (NEAC-2203: Nippon Electric Co., Ltd.).

b) Stability Constants. The ligands, 4-chloro, 4-methyl, or 4-methoxy-*o*-phenylenediamine and *o*-phenylenediamine, can have only one proton in the pH 2.8—4.5 region. Such ligands are treated as monoprotic acid in such a region. The equilibria and the stability constants are as follows:

$$M^{2+} + L \rightleftarrows ML^{2+}, \quad K_1 = [ML^{2+}]/[M^{2+}][L],$$
$$ML^{2+} + L \rightleftarrows ML_2^{2+}, \quad K_2 = [ML_2^{2+}]/[ML^{2+}][L].$$

The stability constants, K_1 and K_2, were calculated by fitting the data to the Irving and Rossotti equation:[7]

$$\bar{n}/(\bar{n}-1)[L] = [(2-\bar{n})[L]/(\bar{n}-1)]K_1K_2 - K_1, \qquad (2)$$

which is a linear form.

Here

$$\bar{n} = (T_L - [L] - [HL^+])/T_M,$$
$$[L] = K_{a2}(2T_L - T_{OH} - [H^+] + [OH^-])/[H^+],$$
$$[HL^+] = (2T_L - T_{OH} - [H^+] + [OH^-]),$$

and T_M is the total metal-ion concentration. The stability constants, K_1 and K_2, are best evaluated by the method of "least squares." The reliability of the constants was verified the theoretical formation curve with the experimental one. Eq. (2) can be rewritten as follows:

$$[L] = [(1-\bar{n}) - \{(\bar{n}-1)^2K_1^2 - 4\bar{n}(\bar{n}-2)K_1K_2\}^{1/2}/K_1]2(\bar{n}-2)K_2. \qquad (3)$$

The theoretical formation curves can be generated by the stability constants reported in Table 3 and by Eq. (3).

When the acido complex are present, the acid dissociation and chelate stability constants are obtained by a treatment based on that described by Nagano *et al.*[8] The following equation and equilibria were considered in the 3,4-diamino-benzoic acid system:

$$M^{2+} \overset{9)}{\rightleftarrows} M(OH)^+ \overset{10)}{\rightleftarrows} M(OH)_2$$
$$K_{M1} \updownarrow$$
$$MHL^{2+} \overset{k_1}{\rightleftarrows} ML^+$$
$$K_{M2} \updownarrow$$
$$M(HL)_2^{2+} \overset{k_2}{\rightleftarrows} ML(HL)^+ \overset{k_2'}{\rightleftarrows} ML_2.$$

The equilibrium constants are defined as follows:

$$K_{M1} = [MHL^{2+}]/[M^{2+}][HL],$$
$$K_{M2} = [M(HL)_2^{2+}]/[MHL^{2+}][HL],$$
$$k_1 = [H^+][ML^+]/[MHL^{2+}],$$
$$k_2 = [H^+][ML(HL)^+]/[M(HL)_2^{2+}],$$
$$k_2' = [H^+][ML_2]/[ML(HL)^+],$$
$$K_{a1} = [H^+][H_2L^+]/[H_3L^{2+}],$$
$$K_{a2} = [H^+][HL]/[H_2L^+],$$
$$K_{a3} = [H^+][L^-]/[HL].$$

The first step of the acid dissociation of protonated ligands is thus complete. As for the total ligand concentration, T_L, the total proton concentration, T_H and the total metal-ion concentration, T_M, the following relations hold:

$$T_L = \sum_{j=0}^{2}[H_jL] + [MHL^{2+}] + [ML^+] + 2[M(HL)_2^{2+}] + 2[ML(HL)^+] + 2[ML_2] \qquad (4)$$

$$T_H - [H^+] + [OH^-] = T_L \cdot g = \sum_{j=0}^{2} j[H_jL] + [MHL^{2+}] + 2[M(HL)_2^{2+}] + [ML(HL)^+] \qquad (5)$$

$$T_M = [M^{2+}] + [MHL^{2+}] + [ML^+] + [M(HL)_2^{2+}] + [ML(HL)^+] + [ML_2] \qquad (6)$$

The average number of hydrogen ions bound per total of the ligands, g, is given by the expressions:

$$g = \sum_{j=1}^{3} j[H_jL]/T_L, \quad g = 3 - a + ([OH^-] - [H^+])/T_L,$$

a=moles of base added per mole of ligand.

Here a group of brief symbols will be introduced:

$$A = T_L, \quad B = T_L \cdot g, \quad C = T_M, \quad D_1 = K_{M1}, \quad D_2 = K_{M1}k_1,$$
$$D_3 = K_{M1}K_{M2}, \quad D_4 = K_{M1}K_{M2}k_2, \quad D_5 = K_{M1}K_{M2}k_2k_2',$$
$$m = [M^{2+}], \quad h = [HL], \quad a_0 = (K_{a3}/[H^+] + 1 + [H^+]/K_{a2}),$$
$$b_0 = (1 + 2[H^+]/K_{a2}).$$

Equations (5), (6), and (7) may be rewritten as follows:

$$A = h\{a_0 + (D_1 + D_2/[H^+])m + (2D_3 + 2D_4/[H^+] + 2D_5/[H^+]^2)mh\} \qquad (7)$$

$$B = h\{b_0 + D_1m + (2D_3 + D_4/[H^+])mh\} \qquad (8)$$

9), 10) The hydroxo complexes were not taken into consideration, because the equilibria were investigated between pH 2.5 and 5.0.

$$C = m\{1 + (D_1+D_2/[H^+])h + (D_3+D_4/[H^+] + D_5/[H^+]^2)h^2\}. \quad (9)$$

The elemination of h and m from three independent equations, (7), (8), and (9) will lead to one equation, into which the observed values of five points on the titration curves may be substituted; if the simultaneous equations are solved, all constants can, in principle, be obtained. However, their solution is, in practice, enormously troublesome. This difficulty was overcome by selecting suitable experimental conditions and by iterative approximation using the electronic computer.

1) *Metal-ion-excess Solution.* In this case, the concentration of the free neutral ligand, h, is very small, and only 1:1 species can be present. Equations. (7), (8), and (9) then become:

$$A = h\{a_0 + (D_1+D_2/[H^+])m\} \quad (10)$$

$$B = h(b_0+D_1m) \quad (11)$$

$$C = m\{1 + (D_1+D_2/[H^+])h\}. \quad (12)$$

The elimination of the h from (10) and (11) will lead to Eq. (13), $D_1=\{(b_0-ga_0)/m(g-1)\}-\{gD_2/[H^+](g-1)\}$. Assuming that m is approximately equal to the total metal concentration, and solving simultaneous equations from two points on the titration curve, a first approximation of D_1 and D_2 can be obtained; their temporary constants and m are then substituted into Eq. (10), from which a reasonable value of h is obtained. By the use of these h, D_1, and D_2 values, a more reasonable value of m can be calculated by Eq. (12). This value of m is substituted into Eq. (13), and more reasonable values of D_1 and D_2 are obtained by solving simultaneous equations from two points on the titration curve. This procedure is repeated until the values of these constants converge.

2) *Ligand-excess Solution.* Here, D_1 and D_2 have already been determined from the above solution. In this condition, three chelates, $M(HL)_2^{2+}$, $ML(HL)^+$, and ML_2, are present. The elimination of the m from Eqs. (7), (8), and (9) will lead to Eq. (14):

$$l_3D_3 + l_4D_4 + l_5D_5 = L \quad (14)$$

where;

$$l_3 = (Cf_3-Fh)h,$$
$$l_4 = (Cf_4-F[H^+]^{-1}h)h,$$
$$l_5 = (Cf_5-F[H^+]^{-2}h)h,$$
$$L = F\{1 + (D_1+D_2/[H^+])h\} - C(f_1D_1-f_2D_2),$$

$f_1 = (g-1)$, $f_2 = g[H^+]^{-1}$, $f_3 = 2f_1$, $f_4 = (2g-1)[H^+]^{-1}$, $f_5 = 2g[H^+]^{-2}$, $b_0 - ga_0 = F$.

As l_3, l_4, l_5, and L are entirely of known or measurable quantities, D_3, D_4, and D_5 can be obtained by solving simultaneous equations. For the treatment of Eq. (14), a matrix representation is extremely useful. The augmented matrix is:

$$\begin{bmatrix} l_{31} & l_{41} & l_{51} & L_1 \\ l_{32} & l_{42} & l_{52} & L_2 \\ l_{33} & l_{43} & l_{53} & L_3 \end{bmatrix} \quad (15)$$

which is solved by the method of Gauss-Jordan.

Results and Discussion

Acid-dissociation Constants. The acid-dissociation constants of protonated *o*-phenylenediamine derivative were calculated from the titration curve; they are summarized in Table 1. An example of the titration curve is given in Fig. 1. The first step of the acid dissociation of protonated *o*-phenylenediamine derivatives is very

strong. This may be attributed to the steric hindrance. When the substituent group is a chloride or amino group, the pK_{a1} values of these derivatives can be calculated by the iterative approximation method; the pK_{a1} values are (0.6) and (1.2) respectively. The introduction of a chlorine atom to *o*-phenylenediamine decreases the value of pK_{a2}; the same effect is observed in carboxyl and amino groups. The relation between the pK_{a2} and the σ_p values shows a good linearity, but the σ_m values do not show such a good linearity. It is implied that the para-position effect, that is, the mesomeric effect, is the main factor rather than the inductive effect (the meta-position effect). The second dissociation of 3,4-diaminobenzoic acid is due to one of the diammonium protons, while the third dissociation is due to the carboxyl proton, because the pK_a (4.75) is comparable with those of 3-aminobenzoic acid (4.79) and 4-aminobenzoic acid (4.92). Table 2 shows the pK_a values for amino-substituted benzoic acids.

Table 2. Value of pK_a for amino-substituted benzoic acids in water[12]

X	*ortho*	*meta*	*para*
(H)	(4.20)	(4.20)	(4.20)
NH_2	4.98	4.79	4.92
NHMe	5.33	5.10	5.04
NMe_2	8.42	5.10	5.03
NH_3^+	2.04	—	—

The pK_a values of *o*-phenylenediamine derivatives with CH_3, H, Cl, or CH_3O as a substituent group at the 4 position, are 4—5. The second dissociation of 1,2,4-triaminobenzene trihydrochloride is depressed to an order of magnitude of 3 by the electron-withdrawing effect of the NH_3^+ group.

Stability Constants. The formation curve was obtained by titration. The values of $\bar{n}$ near the center of the formation curve ($0.9<\bar{n}<1.1$) are omitted, because they are very sensitive to slight experimental errors. Selected values of $\bar{n}$ and [L] were used to calculate the overall chelate stability constants, β_1 and β_2, by the use of the method of least squares on a linear form of the Irving and Rossotti equation. The theoretical formation curve is generated by the stability constants reported in Table 3. As can be seen from Fig. 2, the theoretical formation curve was in good agreement with the experimental one.

When 3,4-diaminobenzoic acid system is treated, the relationship between the equilibrium constants and $\log D_i$ ($i=1,2,\cdots,5$) is as follows:

$$\log K_{M1} = \log D_1,\ pk_1 = \log D_1 - \log D_2,\ \log K_{ML} = pK_{a3} + \log D_2,\ pk_2 = \log D_3 - \log D_4,\ \log K_{M2} = \log D_3 - \log D_1,$$
$$pk_2' = \log D_4 - \log D_5,\ \log K_{ML_2} = 2pK_{a3} + \log D_5.$$

The pK_{a3} value of the 3,4-diaminobenzoic acid was 4.75; however, the acid-dissociation constant (pK_{a1}) of the Cu(II) chelate was 3.84. The depression of the pK_a value is 0.91 (=4.75−3.84). The pK_a values of benzoic acid and *p*-nitro-benzoic acid are 4.18 and 3.43 respectively.[11] Therefore, the *p*-nitro group has

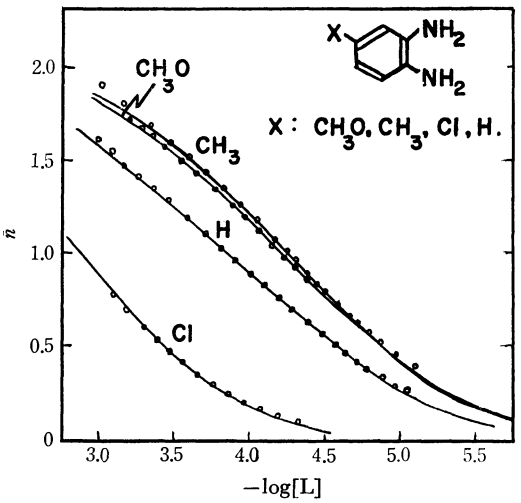

Fig. 2. Experimental and theoretical formation curve, at 25°C and $\mu=0.10$.
—, Theoretical; ○, Experimental

Table 3. Stability constants of Cu (II) complexes with *o*-phenylenediamine derivatives

Ligand	$\log K_1$	$\log K_2$	$\log K_1K_2$
	4.78	3.64	8.42
	4.74	3.76	8.50
	4.55	3.17	7.72
	3.32	2.44	5.76

an electron-withdrawing effect of 0.75 pK_a units. The Cu(II) ion has a stronger electron-withdrawing effect than does the *p*-nitro group. The introduction of substituent groups in the 4 position of *o*-phenylenediamine leads to marked changes in the log β_2 value, changes which clearly reveal two effects (inductive and meso-

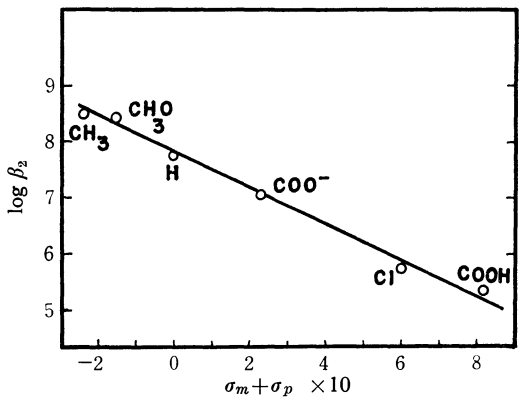

Fig. 3. Relationship between log β_2 and the sum of Hammett's sigma values.

11) A. Albert and E. P. Serjeant, "Ionization Constants of Acids and Bases," Methuen, London (Japanese Edition, Maruzen) (1962), P. 121.

12) S. Patai, "The Chemistry of the Amino Group," John Wiley and Sons, London (1968), p. 224.

meric). The plot of log β_2 against the sum of σ_m and σ_p was found to be linear. As can be seen from Fig. 3, the sums of the Hammett's σ_m and σ_p values of the COOH group and the COO^- group are 0.82 and 0.23 respectively. The difference in value between the COOH and COO^- groups is 0.59; that is, the electron-withdrawing effect is decreased after the dissociation, and as a result log β_2 is increased 0.71 units. When the ligand is 1,2,4-triaminobenzene, some converged values were obtained from the metal-ion-excess condition, but different behavior was observed in the ligand-excess condition; therefore, calculation became very difficult. In the reaction between *o*-phenylenediamine and other divalent ions (Mn, Co, Ni, Zn, *etc.*), the pH effect was very small; therefore, their stability constants may be lower.

The authers are grateful to Dr. G. Nakayama (Tokyo Chemical Industry Co.) for a gift of 1,2,4-triamino-benzene dihydrochloride.

(Received May 27, 1970)

The kinetics of Fe^{2+} reductions of *cis*-α-Co(trien)Cl_2^+, *cis*-α-Co(trien)OH_2Cl^{2+} and *cis*-β_1-Co(trien)OH_2Cl^{2+} (trien=triethylenetetramine) have been studied at 25°C, $[H^+]=0.10$ M and $\sum[ClO_4^-]=1.0$ M. The second-order rate constants obtained are 4.0×10^{-4} M^{-1} sec^{-1}, 1.6×10^{-4} $M^{-1}sec^{-1}$, and 9.8×10^{-5} M^{-1} sec^{-1} for *cis*-α-Co(trien)Cl^{+2}, *cis*-α-Co(trien)OH_2Cl^{2+}, and *cis*-β_1-Co(trien)OH_2Cl^{2+} respectively. It is demonstrated, by comparing with other rate data for the Fe^{2+} reductions of *cis*-CoN_4XCl^{n+} (N=NH_3, 0.5 en and 0.25 trien, and X=H_2O and Cl^-) that the rate decreases with an increase in the number of chelate rings in the Co(III) complexes. The chelate effect of the nonbridging ligand on the electron-transfer reactions of Co(III) complexes is discussed on the basis of a model which involves the ligand-field strength of the *trans*-ligand to the bridging one, the energy needed for stretching the *trans*-group away from the Co(III) center, and the effect of the solvation.

The iron(II) reductions of $Co(en)_2XY^{n+}$ [1,2] and $Co(NH_3)_4XCl^{n+}$ [3] and electron-transfer reactions between aquochromium(II) ion and chromium(III) complexes[4-10] have been studied in order to investigate the effect of the nonbridging ligand on the rate of electron-transfer reactions. The effect of the nonbridging ligand on the electron-transfer reactions of $Co(en)_2XY^{n+}$ can be classified in the following three categories[2]: i) the effect of the geometry, ii) the effect of changing the nature of one nonbridging ligand, and iii) the effect of chelation. The investigation was also carried out on the effect of chelation by nonbridging ligands on the reductions of aquo-, sulfato- and chlorocobalt(III) complexes by chromium(II) and vanadium(II).[11,12] Fraser[12] introduced the solvation theory to explain the results obtained by these reactions. However, it has since been suggested that the results for the reactions of *cis*- and *trans*-$Co(en)_2XCl^{n+}$ complexes with iron(II) did not conform to this solvation treatment of the chelation effect.[2]

The present authors wish now to report the effects encountered in the reductions of some Co(trien)XCl^{n+} complexes by iron(II).

Experimental

Preparation of Complexes. The *trans*-[Co(trien)Cl_2]Cl, *cis*-α-[Co(trien)Cl_2]Cl, and *cis*-β-[Co(trien)Cl_2]Cl were prepared in a manner previously described.[13] The identity and purity of the complexes were confirmed analytically and spectrophotometrically.

Materials. A solution of iron(II) perchlorate was prepared by dissolving analytical-grade iron wire in an excess of perchloric acid. The concentration of the iron(II) was determined by titration with a standared potassium permanganate solution. The iron(III) concentration was calculated

from the difference in the amonts of the total iron and that of the iron(II) found. In all cases, the amounts of iron(III) were less than 5% of the total iron. The perchlorate concentration was analyzed by the titration of the hydrogen-ion concentration when an aliquot of the iron(II) solution was passed through a column of cation-exchange resin in the hydrogen form. The hydrogen-ion concentration of the iron(II) solution was calculated from the concentrations of perchlorate, ion(II), and iron(III). In most cases, the hydrogen-ion and perchlorate concentrations of the iron(II) solution were adjusted to 0.20 M and 2.0 M respectively by the addition of perchloric acid and sodium perchlorate solutions. All the other chemicals were of a reagent grade.

Kinetic Measurements. Erlenmeyer flasks containing the iron(II) solution, redistilled water, and weighed amounts of the solid complex respectively were kept in a thermostat. A 5-m*l* portions of the water was pipeted into the flask, and, after the complete dissolution of the complex had been achieved, 5-m*l* of the iron(II) solution were added by means of an injection syringe. Then, this solution was rapidly transferred into a spectrophotometer cell of a Hitachi Model 125 spectrophotometer. The reaction rate was measured at a sufficiently high concentration of iron(II) in order to minimize the complications arising from aquation.

Reductions of cis-α-*Co(trien)*Cl_2^+ *and* cis-α-*Co(trien)* OH_2Cl^{2+}. The aquation processes and the rate constants for the aquation reactions of the Co(III) complexes under investigation have been given by Sergeson and Searle.[14,15] The rate constant for the aquation of the first chloride ion in *cis*-α-RCl_2^+, where R represents $Co(trien)^{3+}$, is 9.4×10^{-3} min^{-1} at 25°C. Since *cis*-α-ROH_2Cl^{2+} is formed in a 100% retention by aquation of the *cis*-α-RCl_2^+ and since the rate of aquation of the second chloride ion in the *cis*-α-ROH_2Cl^{2+} is very slow,[2] a kinetic scheme for the iron(II) reductions of *cis*-α-RCl_2^+ and *cis*-α-ROH_2Cl^{2+} is given by:

$$\begin{array}{ccc} cis\text{-}\alpha\text{-}RCl_2^+ & \xrightarrow{k_{a_1}} & cis\text{-}\alpha\text{-}ROH_2Cl^{2+} \\ k_1 \downarrow \ Fe^{2+} & & k_2 \downarrow \ Fe^{2+} \\ Co(II) + Fe(III) & & Co(II) + Fe(III) \end{array}$$

The rate constant of k_{a1} is known, and the two rate constants to be determined are k_1 and k_2. Since the rate of the aquation of *cis*-α-RCl_2^+ is relatively large as compared with the reduction rates of *cis*-α-RCl_2^+ and *cis*-α-ROH_2Cl^{2+} even at high iron(II) concentrations, k_1 and k_2 were determined in a manner similar to that used by Benson and Haim.[2] The absorbance of the reaction mixture was measured at 525 nm, which is the isosbestic point for *cis*-α-RCl_2^+ and *cis*-α-ROH_2Cl^{2+}, as a function of the time. Then, values of $\log(A_t-A_\infty)$, where A_t is the absorbance at time t, and A_∞, the absorbance after all the Co(III) complex has been reduced to Co(II), were plotted as a function of the time. One of the plots is illustrated in Fig. 1. After a certain period of time, the plots conformed to linearity; the slope of the linear portion gives a measure of the pseudo-fist-order rate constant for the disappearance of *cis*-α-ROH_2Cl^{2+}. The linear behavior begins when the *cis*-α-RCl_2^+ has been exhausted and the only Co(III) species present in an appreciable concentration is *cis*-α-ROH_2Cl^{2+}. The linear portion of the $\log(A_t-A_\infty)$ *vs.* t plot gives a slope which is equal to $-k_2[Fe^{2+}]/2.303$. When A_c is defined as the value of A_t obtained by extrapolating the linear portion of the $\log(A_t-A_\infty)$ *vs.* t plot to zero time, the plot of $\log(A_t-A_c)$ *vs.* t gives a slope which is equal to $-\{k_{a1}+k_1[Fe^{2+}]\}/2.303$.

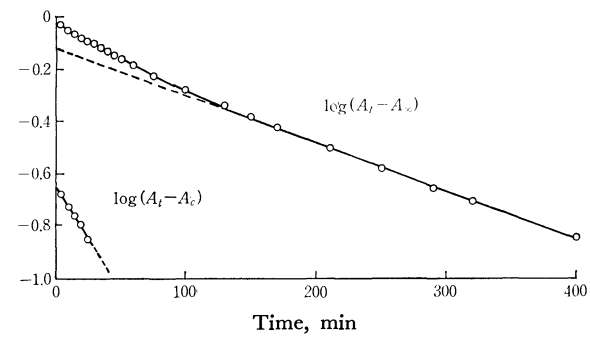

Fig. 1. Plots of log (A_t-A_∞) *vs.* time and log (A_t-A_c) *vs.* time for iron(II) reduction of *cis*-α-$Co(trien)Cl_2^+$.
8.28×10^{-3} M *cis*-α-$[Co(trien)Cl_2]Cl$, 0.415 M Fe^{2+}, $[H^+]=0.10$ M, $\sum(ClO_4^-)=1.0$ M, 525 nm, 25°C.

The values of k_1 and k_2 were calculated from the known values of k_{a1}, $[Fe^{2+}]$, and the slope.

Reduction of cis-β_1-*Co(trien)*OH_2Cl^{2+}. Our attempt to determine the rate constant for the ion(II) reduction of *cis*-β-RCl_2^+ by this method failed because of the fast aquation ($k=8.7\times10^{-2}$ min^{-1} at 25°C)[14] of this complex. Since the aquation of the *cis*-β-RCl_2^+ gives two different species of the mono-aquo complexes (94% of *cis*-β_1-ROH_2Cl^{2+} and 4% of *cis*-β_2-ROH_2Cl^{2+}),[14] the rate constants for the iron(II) reductions of these complexes could not be determined separately either by the method in which *cis*-β-RCl_2^+ was used as a starting material. A rapid first aquation of *trans*-RCl_2^+ ($k=21.1\times10^{-2}$ min^{-1} at 25°C)[14] gives only *cis*-β_1-ROH_2Cl^{2+}, and the rate of aquaion of the latter species is relatively slow ($k=1.40\times10^{-3}$ min^{-1} at 25°C).[14] The *trans*-species is almost completely converted into the *cis*-β_1-species about 30 min after the dissolution of the *trans*-species at 25°C, and the min after the dissolution of the *trans*-species at 25°C, and the aquation of the second chloride ion of the *cis*-β_1-species produced in the aquation reaction can be neglected within this period. Therefore, the determination of the rate constant for *cis*-β_1-ROH_2Cl^{2+} could be achieved by adding the iron(II) solution to that of *cis*-β_1-ROH_2Cl^{2+} which had been prepared by keeping the pure *trans*-RCl_2^+ solution in a thermostat for 30 min at 25°C. The kinetic scheme for the iron(II) reduction of *cis*-β_1-ROH_2Cl^{2+} is given as follows:

$$\begin{array}{ccccc} trans\text{-}RCl_2^+ & \xrightarrow{25°C,\ 30\ min} & cis\text{-}\beta_1\text{-}ROH_2Cl^{2+} & \xrightarrow{k_{a_2}} & cis\text{-}\beta\text{-}R(OH_2)_2^{3+} \\ & & k_3 \downarrow \ Fe^{2+} & & \\ & & Co(II) + Fe(III) & & \end{array}$$

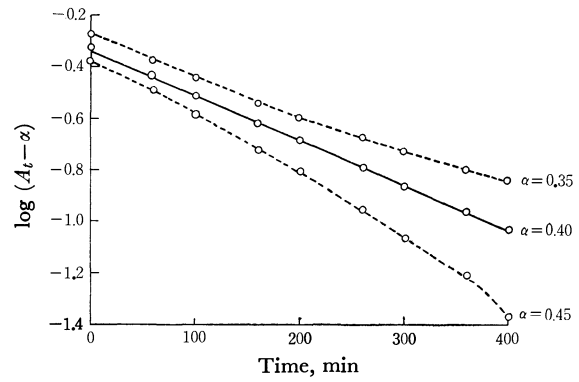

Fig. 2. Plots of log $(A_t-\alpha)$ *vs.* time for iron(II) reduction of *cis*-β_1-$Co(trien)OH_2Cl^{2+}$.
9.1×10^{-3}M *cis*-β_1-$[Co(trien)OH_2Cl]Cl_2$, 0.448M Fe^{2+}, $[H^+]=0.10$M, $\sum(ClO_4^-)=1.0$M, 488 nm, 25°C.

14) A. M. Sargeson and G. H. Searle, *Nature*, **200**, 356 (1963).
15) A. M. Sargeson and G. H. Searle, *Inorg. Chem.*, **6**, 2172 (1967).

As will be shown in the Appendix, the following equation can be derived when the width of the cell used is 1-cm:

$$A_t - \alpha = (E'_t - E')\{[ROH_2Cl]_0 - A\}e^{-Bt}$$

In this equation, the A_t is the absorbance of the reaction mixture at the isosbestic point (488 nm) for the ROH_2Cl^{2+} and $R(OH_2)_2^{3+}$, and E_t' and E' are the molar extinction coefficients of these species, and that of aquo-cobalt(II) ion at this wavelength, respectively. The A, B, and α are obtained by means of the equations shown in the Appendix. Since the value of α was unknown, the value of k_3 was determined as follows: as may be seen in Fig. 2, a straight line is obtained by adjusting the α value so that a plot of the $\log(A_t - A_\infty)$ *vs.* t becomes linear. Since the linear plot gives a slope which is equal to $-(ka_2 + k_3[Fe^{2+}])/2.303$, k_3 can be obtained from the known values of k_{a_2} and $[Fe^{2+}]$.

Results and Discussion

Since $CoCl^{2+}$ [16] and, probably, $Co(en)_2XCl^{n+}$ (X= H_2O and Cl^-)[2] react with Fe^{2+} *via* the chloride-bridged activated complex, it is reasonable to assume a similar mechanism for our reactions.

Table 1. Rate constants[a] for reductions of $RXCl^{n+}$ by Fe(II) (R=Co (trien), X=H_2O and Cl^-)

Complex	Rate constant ($M^{-1}sec^{-1}$)
cis-α-RCl_2^+	4.0×10^{-4}
cis-α-ROH_2Cl^{2+}	1.6×10^{-4}
cis-β_1-ROH_2Cl^{2+} [b]	9.8×10^{-5}

a) At 25° C, $\sum(ClO_4^-)=1.0$ M, $[H^+]=0.10$ M
b) Starting material is *trans*-RCl_2^+.

The values of the measured second-order rate constants and the specific rates of *cis*-CoN_4XCl^{n+} with Fe^{2+} are represented in Tables 1 and 2 respectively. The relatively low reduction rate of the $CoN_4OH_2Cl^{2+}$ as compared with that of the corresponding $CoN_4Cl_2^+$ may be mainly due to its dipositive charge.

In the *cis*-$CoN_4Cl_2^+$ system, the order of effectiveness is $Co(en)_2Cl_2^+ > Co(trien)Cl_2^+$, while in the *cis*-$CoN_4OH_2Cl^{2+}$ system it is $Co(NH_3)_4OH_2Cl^{2+} > Co(en)_2OH_2Cl^{2+} > \alpha$-$Co(trien)OH_2Cl^{2+} > \beta_1$-$Co(trien)OH_2Cl^{2+}$. The configurations of the *cis*-α- and *cis*-β_1-ROH_2Cl^{2+} have been determined by Sergeson *et al.*[13,14] As the rate constants for the *cis*-α- and *cis*-β_1-ROH_2Cl^{2+} are in the same order, the rate seems not to be strinkingly affected by their configurations with respect to the ligand of trien.

Table 2. Rate constants for Fe^{2+} reductions of *cis*-$CoN_4Cl_2^+$ and *cis*-$CoN_4OH_2Cl^{2+}$ (N=NH_3, 0.5 en and 0.25 trien)

Complex	Rate constant[a]	R_{NH3}[b]	R_{en}[c]
$Co(en)_2Cl_2^+$	16[e]		1
$Co(trien)Cl_2^+$	4.0		0.25
$Co(NH_3)_4OH_2Cl^{2+}$	353[d]	1	
$Co(en)_2OH_2Cl^{2+}$	4.5[e]	0.013	
α-$Co(trien)OH_2Cl^{2+}$	1.6	0.0045

a) At 25° C, $\sum(ClO_4^-)=1.0$ M, $[H^+]=0.10$ M, units are 10^{-4} M^{-1} sec^{-1}.
b) Ratio of rate constant to the rate constant for $Co(NH_3)_4OH_2Cl^{2+}$.
c) Ratio of rate constant to the rate constant for $Co(en)_2Cl_2^+$.
d) From Ref. 3.
e) From Ref. 2.

The results indicate that the relative effectiveness is decreased with an increase in the number of the chelate ring, so the trend in the rate can be ascribed to the chelate effect of the nonbridging ligand on the electron-transfer reactions. Orgel[17] and Taube[18] suggested that electron-transfer to the unoccupied d_{z^2} orbital on the Co(III) will take place more rapidly the lower the energy of the d_{z^2} orbital. The orbital energy would be lower by: (i) a *trans*-ligand to the bridgnig one with a weak ligand field,[2,17,18] and (ii) the removal of the *trans*-ligand in the z direction away from the Co(III) center.[2]

The rate of the Cr^{2+} reductions of $CoN_5SO_4^+$ (N_5= $(NH_3)_5$, $(en)_2NH_3$, and tetren[19]) is rather decreased with an increase in the number of the chelate ring in the Co(III) complexes, whereas the rate is hardly affected by an increase in the number of the chelate ring in the Cr^{2+} reductions of CoN_5OAc^{2+} and perhaps CoN_5Cl^{2+}.[12] Fraser explained these results on the basis of solvation. Such a solvation effect is now represented by the effect (c).

The effects of the ligand-field strength of the *trans*-ligand (represented by the effect (a)) and the energy for the bond stretching in the Co–N bond in the z direction (represented by the effect (b)) appear to be of little importance in such reaction as the Cr^{2+} reductions of *cis*- and *trans*-$Co(en)_2NH_3Z^{2+}$ (Z=Cl^- and OH^-),[19] nor as has been described above, in the Cr^{2+} reductions of CoN_5Cl^{2+}, CoN_5OAc^{2+}, and, possibly, $CoN_5SO_4^+$.[12] This may be ascribed to the fact that the relative bond-stretching energies in the Co-N bonds in such reactions as CoN_5Cl^{2+}, CoN_5OAc^{2+}, and $CoN_5SO_4^+$ with Cr^{2+}

Table 3. Analysis of chelate effect in electron-transfer reactions

Type of reaction	Example	$\Delta F_s/\Delta F^{\neq}$	Effects[c,d] a	b	c	Effects of chelation[b]
A	$Cr^{2+}-CoN_5Cl^{2+}$ [a]	small	−	−	−	−
	$Cr^{2+}-CoN_5OAc^{2+}$ [a]		−	−	−	−
	$Cr^{2+}-CoN_5SO_4^+$ [a]		−	−	+	+
B	$Fe^{2+}-CoN_4Cl_2^+$ [b]	large	+	+	+	+
	$Fe^{2+}-CoN_4OH_2Cl^{2+}$ [b]		+	+	−	+

a) $N_5=(NH_3)_5$, $(en)_2$ NH_3, and tetren.
b) N=NH_3, 0.5 en and 0.25 trien.
c) + indicates that effect is relatively large, −, effect is negligible small.
d) a, b, and c indicate that the effect of ligand field strength of the *trans*-ligand, effect of removal of the *trans*-ligand away from the Co(III) center and effect of solvation, respectively.

19) tetren=tetraethylenepentamine.

(type-A reactions) would be small compared with those in such reactions as the Fe^{2+} reductions of *cis*-CoN_4XCl^{n+} (type-B reactions). In fact, it was demonstrated by Green *et al.*[20] that there is little stretching of the Co-N bonds in the reactions of *cis*- and *trans*-$Co(en)_2NH_3Z^{2+}$ complexes with Cr^{2+}. The relative bond-stretching energy mentioned above is defined as: $\Delta F_s/\Delta F^*$ where ΔF_s is a free-energy change to stretch the Co-N bond in the z direction away from the Co(III) center prior to the transfer of an electron.

An analysis of the chelate effect on the electron-transfer reactions of the CoN_5X^{n+} and CoN_4XCl^{n+} complexes is shown in Table 3. In the Fe^{2+} reductions of *cis*-$CoN_4OH_2Cl^{2+}$, where the relative bond-stretching energy would be important and where the effect of solvation energy may be less important since the resulting cobalt(II) and iron(III) in the reactions have over-all charges of +2, there should be no change in the ΔF^* as the chelation is increased;[12] the results obtained can be explained mainly by the (a) and (b) effects. Since the order of the increasing ligand-field strength may be: $NH_3 <$ en $<$ trien and that of the increasing energy for the removal of the *trans*-ligand seems to be: $NH_3 <$en $<$ trien, it is expected that the relative rate will decrease with an increase in the number of the chelate ring in the Fe^{2+} reductions of CoN_4XCl^{n+}. It is considered that the energy required to stretch the metal-ligand bond along the z axis in the *cis*-CoN_4XCl^{n+} is increased as the stability of the complex increases, though the approximation is poor because of the lack of information about the force constants for the Co-N bonds discussed.

Appendix

The kinetic scheme for the Fe^{2+} reductions of *cis*-β_1-ROH_2Cl^{2+} is:[21]

$$ROH_2Cl + Fe^{2+} \xrightarrow{k_3} Co(II) + Fe(III) \quad (1)$$

$$ROH_2Cl + H_2O \xrightarrow{k_{a_1}} R(OH_2)_2 + Cl^- \quad (2)$$

The integrated rate equations for reactions (1) and 2) are:

$$[ROH_2Cl]_t = [ROH_2Cl]_0 e^{-Bt} \quad (3)$$

$$[R(OH_2)_2] = A - Ae^{-Bt} \quad (4)$$

where:

$$A = \frac{k_{a_1}[ROH_2Cl]_0}{k_{a_1} + k_3[Fe^{2+}]}$$

$$B = k_{a_1} + k_3[Fe^{2+}]$$

By stoichiometric considerations, the absorbance at the isosbestic point of ROH_2Cl and $R(OH_2)_2$ at time t is found to be:

$$A_t = E_t'[ROH_2Cl]_t + E_t'[R(OH_2)_2]_t + E'[Co(II)]_t$$

where E_t' is the molar extinction coefficient for ROH_2Cl and $R(OH_2)_2$ at the isosbestic point and where E' is the molar extinction coefficient for the Co(II) ion.

Since

$$[Co(II)]_t = [ROH_2Cl]_0 - [ROH_2Cl]_t - [R(OH_2)_2]_t$$

$$A_t = E'[ROH_2Cl]_0 + (E_t' - E')\{[ROH_2Cl]_t + [R(OH_2)_2]_t\} \quad (5)$$

from Eqs. (3), (4), and (5), we obtain:

$$A_t - \alpha = (E_t' - E')\{[ROH_2Cl]_0 - A\}e^{-Bt}$$

where:

$$\alpha = E'[ROH_2Cl]_0 + (E_t' - E')A$$

A part of this research was carried out with a Scientific Research Grant from the Ministry of Education, to which the authors thanks are due.

The Thermodynamic Properties of the Nonstoichiometric Ceric Oxide at Temperatures from 900 to 1300°C

Bunji IWASAKI* and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 8 ,1970)

Oxygen partial pressure in equilibrium with nonstoichiometric ceric oxide of a definite composition were determined by equilibration with pure oxygen, air, CO_2, and CO_2-H_2 mixtures at 900, 1000, 1100, 1227, and 1300°C, using a thermobalance. The values for the activities and the relative partial enthalpies and entropies of both Ce_2O_3 and CeO_2 were calculated on the basis of the relation between the P_{O_2} and its composition.

During the last 10 years, studies of nonstoichiometric ceric oxide have been made by many investigators, especially from a view to clarifying the behavior of the solid solution in the Ce_2O_3-CeO_2 system at high temperatures. Brauer *et al.*,[1] for example, determined oxygen-dissociation pressures in the Ce_2O_3-CeO_2 system at temperatures from 600 to 1050°C by a thermogravimetric technique and calculated the enthalpy of oxidation of Ce_2O_3 to CeO_2. Furthermore, Brauer and Gingerich[2] determined the phase relations in the same system at temperatures from 20 to 1000°C using a high-temperature X-ray diffractometer and constructed a phase diagram. Kuznetsov *et al.*[3] reported on oxygen-dissociation pressures in the same system at temperatures from 694 to 1010°C; their results were based on emf measurements. Bevan and Kordis[4] reported their results on the same system at temperatures from 636 to 1169°C; these results were based on thermogravimetry.

These investigations have indeed revealed the presence of an extensive solid solution with a definite structure of CeO_2, but it is still desirable to study in more detail the relationship between the composition and the oxygen partial pressure at which the composition is equilibrated, especially at temperatures above 1100°C, in order to determine the precise thermodynamic properties. It is also necessary to measure directly the actual oxygen partial pressure in the furnace instead of using the calculated oxygen partial pressure based on the thermochemical data.

The objectives of the present study are, therefore, to determined the oxygen partial pressure in equilibrium with the ceric oxide of a definite composition by means of a solid electrolyte cell and thermogravimetry at temperatures from 900 to 1300°C, and to present some thermodynamic properties of the present solid solution.

Experimental

The ceric oxide obtained from the Nichisan Rare Element Co., was 99.9% pure. The oxide sample was heated at 1200°C in the air for 2 hr to make a suitable pellet.

The details of the procedure have been described by Katsura and Muan,[5] Katsura and Kimura,[6] and Katsura and Hasegawa.[7] A brief description will suffice for the general procedure.

A thermobalance was used to measure the isothermal weight change of a pellet as a function of the oxygen partial pressure. A quenching method was also used to check the thermogravimetric result.

As a results of the preliminary work, it was found that the weight of a pellet remained constant over a range of oxygen partial pressures from 0.2 to 1 atm at all the temperatures used. In addition, the chemical analysis of the quenched samples obtained from this range of oxygen partial pressures always had the stoichiometric composition of $CeO_{2.00}$, as may be seen in Table 1. On the basis of these facts, we chose the $CeO_{2.000}$ prepared under an oxygen partial pressure of 0.2 or 1 atm as the reference-weight standard.

The desired partial pressures of oxygen were obtained by using pure oxygen, air, carbon dioxide, and CO_2-H_2 mixtures. The actual oxygen partial pressures in the CO_2 and CO_2-H_2 mixtures at 900 to 1227°C were measured by an improved solid electrolyte cell composed of $(ZrO_2)_{0.85}(CaO)_{0.15}$.[7] It had been found previously[7,8] that the actual oxygen partial pressures produced by the CO_2-H_2 mixtures at 1300°C agreed well with the values calculated on the basis of the thermochemical data within the limits of experimental error. Thus, the oxygen partial pressures in the mixtures at 1300°C were calculated from the data summarized by Elliott and Gleiser[9] and by Coughlin.[10]

The O/Ce ratio in the weight-standard material, $CeO_{2.000}$ was determined volumetrically by using the persulfate method.[11] The O/Ce ratios in samples quenched in various atmospheres were determined thermogravimetrically by a weight-gain method as follows: the samples of the inner parts obtained by being taking the outer parts out of the the quenched samples were heated at 1000°C for 2 hr in the air until complete oxidation to $CeO_{2.000}$ had been achieved. The weight-gain corresponds to the increase in oxygen content in the quenched samples.

The phase present in the inner parts of the quenched samples were identified by an X-ray diffraction method using CuKα.

The rate of approach to the equilibrium state was studied thermogravimetrically. To ensure the equilibrium, the

b) Obtained by volumetric analysis.

equilibrium composition was established from two courses, *i.e.*, the course from a reduced state to an oxidized, and the reverse course. It was found that, in general, the equlibrium was approached quickly, even in the slowest case, in which the time of equilibration was approximately 2 hr.

The weight-loss due to the vaporization of the nonstoichiometric ceric oxide could not be observed even in the case of the lowest oxygen partial pressure at 1300°C.

Results

Table 1 compares the O/Ce ratios determined by various methods and the phases present in the quenched samples, together with the maximum uncertainties in the measurements. As is shown in Table 1, the O/Ce ratios obtained by a weight-gain method are slightly larger than the thermogravimetric results. As an O/Ce ratio is found to become slightly larger with a falling temperature at a given ratio of CO_2 to H_2 in the atmosphere, and as the reaction rate is rapid, as has been described previously, these results obtained by a weight-gain method are considered to be due to oxidation during quenching. As may be seen in Table 1, the cubic form of the sample at 900°C could not be quenched to ice temperature without an exsolution of the pseudo-cubic form. Judging from the shape of the curve of the oxygen partial pressure against CeO_{2-x} at 900°C in Fig. 1, as will be seen later, and the phase diagram obtained by a high-temperature X-ray-diffraction method,[2)] the phase assemblages of the CeO_{2-x} obtained in the present study at all the temperatures used are considered to be a single solid solution.

Table 2 shows the experimental results obtained thermogravimetrically at various temperatures.

Discussion

Variation in the Composition of CeO^{2-x} with the Oxygen Partial Pressure. Figure 1 shows the variation in the composition of the nonstoichiometric ceric oxide with the oxygen partial pressures at various temperatures, together with the results of Bevan and Kordis.[4] These curves above 1100°C nearly agree with those of Bevan and Kordis[4] in shape, but the curves below 1000°C are inconsistent with each other, especially from 0.1 to about 0.2 of x. This might be largely the result of the oxygen partial pressure calculated in the study of Bevan and Kordis,[4] because, in the case of such a low temperature, the establishment of the equlibrium within the gas phase may be suspicious, even at a usual flow-rate of gases of, say, about 1 cm/sec. Therefore, the P_{O_2} must be actually measured by the solid electrolyte cell used in the present study. We will use the present results in respect to composition and P_{O_2} as the most reliable relation to calculate the thermodynamic properties of the Ce_2O_3-CeO_2 system, as will be seen later.

Activities of Ce_2O_3 and CeO_2 in Nonstoichiometric Ceric Oxide. To begin with, we assume that the nonstoichiometric ceric oxide is a mixture of two components, CeO_2 and O_2. The real composition of the CeO_2 phase is, however, CeO_{2-x}, and the reaction between these components may be written as follows;

$$CeO_2 = CeO_{2-x} + x/2O_2 \qquad (1)$$

Thus, from the Gibbs-Duhem Equation, the activity of CeO_2 in the solution may be related as follows;

$$\log a_{CeO_2} = \int_2^x (2-x)\mathrm{d}\log P_{O_2}^{1/2} \qquad (2)$$

where x is related to Eq. (1). The activity of CeO_2 is planimetrically measured by the integration of Eq. (2) from the stoichiometric composition to that under consideration.

Next, we may take the present solid solution as a homogeneous mixture of two components, CeO_2 and Ce_2O_3. Since the activity of CeO_2 has already been determined as a function of P_{O_2}, the activity of the other component, Ce_2O_3, may be determined directly. However, the α-function method[12] is more reliable

for graphic integration, and here we may adopt the equation proposed by Wagner,[13] which may, in order to calculate the activity of Ce_2O_3, be written as follows;

$$\log a_{Ce_2O_3} = \int_0^Y \frac{\log a_{CeO_2}}{(1-Y)^2} dY - \frac{Y}{1-Y} \log a_{CeO_2} \qquad (3)$$

where Y is the mol fraction of CeO_2 in the binary system.

The first term on the right side of Eq. (3) is obtained by integration from the stoichiometric composition of Ce_2O_3 to that under consideration. The value of $(\log a_{CeO_2})/(1-Y)^2$ at the stoichiometric composition of Ce_2O_3

is an extrapolated value.

The activity relations thus obtained at various temperatures are illustrated in Figs. 2—6, together with the lines giving the behavior of an ideal solution. It is clear from these figures that the activity of CeO_2 obeys Raoult's law up to a 0.2 mol fraction of Ce_2O_3 at temperatures above 1200°C, but at 1000 and 900°C the activity of CeO_2 changes in a singular manner and

—— Relative partial molal entropy of a regular solution

obeys Raoult's law only in a narrowly limited range of mol fractions of Ce_2O_3. The a_{CeO_2}-$X_{Ce_2O_3}$ relation at 1100°C seems to be intermediate between those obtained at higher and lower temperatures. Thus, the Ce_2O_3-CeO_2 solid solution will continuously change in its thermodynamic properties with a decrease in the temperature. However, the change in the same relation is very rapid at temperatures between 1000 and 1100°C compared with that at other intervals of temperature.

The activity of Ce_2O_3 reflects the behavior of the activity of CeO_2 at each temperature; it seems to obey Henry's law up to a 0.2 mol fraction of Ce_2O_3 above 1100°C.

Variation in the Free Energy of Mixing with the Temperature. In order to avoid a direct temperature effect, $\Delta G^m/\boldsymbol{R}T$ was selected instead of the total free energy of mixing ΔG^m, where $\boldsymbol{R}$ is gas constant and T is the absolute temperature. Figure 7 shows the variation in $\Delta G^m/\boldsymbol{R}T$ with the mol fraction of Ce_2O_3 at various temperatures, together with the curve showing the $\Delta G^m/\boldsymbol{R}T$ of an ideal solution. The widths of the lines in Fig. 7 show the experimental errors.

As is shown in Fig. 7, these curves move upward with a fall in the temperature. Considered this fact and the activity relations shown in Figs. 2—6, this tendency seems to show a tendency toward the immiscibility of the solid solution. This inference is consistent with the fact that a miscibility-gap appears about 685°C at a composition of $CeO_{1.92}$.[2)]

As is shown in Fig. 7, these curves above 1100°C deviate negatively from the curve giving the ideal behavior. According to a quasi-chemical approach,[14)] this indicates an attractive interaction of the same atom. Thus, this may be assumed to be due to a tendency toward ordering or clustering in which cerium ions in normal sites enter interstitial sites.

Relative Partial Enthalpy and Entropy of Mixing. The relative partial enthalpies and entropies of the mixing of CeO_2 and Ce_2O_3 obtained by means of the mean least-squares method from the activity relations are shown in Figs. 8 and 9 respectively. The widths of the lines how the experimental errors. Curves showing the relative partial entropy of a regular solution are also included in Fig. 9.

As is shown in Fig. 9, these observed curves are similar in shape to those of a regular solution, but deviate too much from those of a regular solution.

The minimum of the curves of CeO_2 in Figs. 8 and 9 may be assumed to be due to a tendency toward compound formation.

Dr. Iwaji Iwasaki, Professor of chemistry, Toho University, encouraged us throughout the present study.

The pH Dependence of Anion Exchange Chromatographic Separation of Tri- and Tetraphosphate Anions

Terumasa NAKAMURA, Mitsuyasu KIMURA,* Hirohiko WAKI, and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received October 9, 1970)

The anion-exchange distribution ratios of tri-, tetra-, and pentaphosphate were determined in a Dowex 1-X4-potassium chloride system at different pH by the batch method. The difference between the mean charges of the phosphates in resin phase and solution was explained in terms of a higher pH of resin phase than that of the solution. pH dependence of the separation factors for tri- and tetraphosphate and for tetra- and pentaphosphate was estimated from the batch equilibrium data, and the relative elution positions of these phosphates were confirmed by the practical chromatographic runs.

We employed gradient-elution chromatography with anion-exchange resins for the separation of a series of linear oligophosphates.[1,2] In the course of the experiments[1,2] we found that when ammonium acetate solutions with pH 7 or potassium chloride solutions with pH 8 are used as an eluent, a mixture of linear oligophosphates can be almost completely separated from one another, but the difference between the elution positions of tri- and tetraphosphate is remarkably smaller than that between the elution positions of other adjacent pairs. However, when the mixture is eluted with potassium chloride solutions with pH 9.3, separation of tri- and tetraphosphate does not occur. The same pH dependence of the elution positions of these two phosphates can be seen in the elution diagrams for a series of linear oligophosphates by Matsuhashi.[3]

The present investigation was undertaken to clarify the pH dependence of the anion-exchange chromatographic separation of tri- and tetraphosphate. The mean charges of these phosphates in a resin phase and in a solution at equilibrium are discussed.

Experimental

Batch Experiment. Resin: The anion-exchange resin Dowex 1-X4 (100—200 mesh) was conditioned to chloride form and dried at 60°C in a vacuum desiccator for 5 hr.

Preparation of Sample Solutions: Commercial pentasodium triphosphate hexahydrate was purified by recrystallization with ethyl alcohol, and dissolved in potassium chloride solutions of various concentrations and pH values. Chloride concentrations; 0.150, 0.200, 0.250, 0.300, and 0.350 M. pH 5.2; 0.001 M potassium hydrogen phthalate-dilute sodium hydroxide buffer. pH 7.1; 0.003 M sodium maleate-dilute acetic acid buffer. pH 9.5; 0.010 M ammonium chloride-dilute aqueous ammonia buffer. Solutions of tetra- and pentaphosphate were prepared from glassy sodium polyphosphate with an average degree of polymerization of 4.5 by means of the gradient-elution chromatographic method. Fractions of the effluent-containing tetra- or pentaphosphate were collected, and after addition of 1 g of dry Dowex 1-X4 the volume of this mixture was increased by a factor of more than 100 times with water so that the greater part of the phosphate anions was adsorbed in the resin phase. The resin was then separated from the solution and immersed in a concentrated potassium chloride solution for 1 hr. The phosphate anions adsorbed in the resin phase were thus recovered into the solution. From this solution, tetra- or pentaphosphate solutions of the different chloride concentrations and pH values were prepared.

Determination of Distribution Ratios: A weighed amount of dry Dowex 1-X4 (about 0.5 g) was put into a stoppered Erlenmeyer flask which contains 10 m*l* of a potassium chloride solution with a definite chloride concentration and pH. This was kept standing overnight, and after 5 m*l* of a linear oligophosphate solution of the corresponding chloride concentration and pH value was added, the mixture was shaken for 2 hr at 20°C.

The phosphorus content in the solution was determined colorimetrically with the molybdenum(V)-molybdenum(VI) reagent.[4] The distribution ratio D is defined by the equation

$$D = \frac{\text{millimoles of phosphorus per m}l\text{ resin bed}}{\text{millimoles of phosphorus per m}l\text{ solution}} \quad (1)$$

Gradient-Elution Chromatography. Glassy Sodium Polyphosphate: Glassy sodium polyphosphate with an average degree of polymerization of 4.5 was prepared by quenching the melt of a mixture of sodium dihydrogen orthophosphate dihydrate and disodium hydrogen orthophosphate dodecahydrate with a molar ratio of 5 to 4 after complete dehydration and condensation.

Chromatographic Run: An aliquot of a solution containing 1 mg of sodium dihydrogen orthophosphate dihydrate and 50 mg of the glassy sodium polyphosphate was loaded on a column of Dowex 1-X4 (100—200 mesh, ϕ 1.24×66.5 cm) and eluted with potassium chloride solution by means of gradient-elution technique. The initial chloride concentration of the eluent in a mixing bottle and the chloride concentration of the eluent in a reservoir were 0.209 and 0.468 M, respectively. The pH of the eluents was adjusted to 4.5 with 0.001 M potassium hydrogen phthalate and dilute sodium hydroxide solution or to 3.0 with 0.001 M potassium hydrogen phthalate and dilute hydrochloric acid. The volume of the eluent in the mixing bottle was kept to 1000 m*l*. Chromatographic runs were carried out with the flow rate of 36—45 m*l*/hr at 20°C. Effluents were collected into 9 m*l* fractions with an automatic fraction collector.

Determination of Phosphorus and Chloride Concentrations: Molybdenum(V)-molybdenum(VI) reagent was used for the determination of phosphorus contents. Determination of chloride

concentrations was carried out by Mohr's method for the fractions containing no phosphate anions.

Results and Discussion

Koguchi *et al.*[5] reported that the mean charge of the phosphate species in a resin phase $\bar{i}_R$ is given by the following equation for the system of an anion-exchange resin and an ammonium acetate solution.

$$\partial \log D/\partial \log(AcO^-) = \bar{i}_R \quad (2)$$

This treatment is applicable to the system where potassium chloride is used in place of ammonium acetate as follows. The linear phosphate anion with a degree of polymerization of n, $H_{n+2-j}P_nO_{3n+1}^{j-}$, is abbreviated to $H_{a-j}P^{j-}$ or P^{j-}. The distribution ratio D and the dissociation constants in a resin phase and in a solution $\bar{K}_j$ and K_j are defined by the following equations for a given linear phosphate.

$$D = \sum[P^{j-}]/\sum(P^{j-}) = \{[P^0]+[P^-]+\cdots+[P^{j-}]+\cdots+[P^{a-}]\}/\{(P^0)+(P^-)+\cdots+(P^{j-})+\cdots+(P^{a-})\} \quad (3)$$

$$\bar{K}_j = [H^+]^j[P^{j-}]/[H_aP] \quad (4)$$

$$K_j = (H^+)^j(P^{j-})/(H_aP) \quad (5)$$

where the concentrations of ions in the resin phase and in the solution are distinguished by [ ] and ( ), respectively. Donnan's equilibrium gives the following equation for the pair of hydrogen and chloride ions.

$$[H^+]\cdot[Cl^-] = (H^+)\cdot(Cl^-)\cdot\gamma_{(H^+)}\cdot\gamma_{(Cl^-)}/\gamma_{[H^+]}\cdot\gamma_{[Cl^-]}$$

where γ's represent activity coefficients. The distribution coefficient of a non-ionized phosphate species between the resin phase and the solution are considered to be constant,

$$[P^0]/(P^0) = \gamma_{(P^0)}/\gamma_{[P^0]} = \text{constant} \quad (7)$$

From Eqs. (3), (4), and (5), we get

$$D = \{[P^0]/(P^0)\}\cdot\{1+\cdots+K_j/[H^+]^j+\cdots+K_a/[H^+]^a\}/\{1+\cdots+K_j/(H^+)^j+\cdots+K_a(H^+)^a\} \quad (8)$$

If a pH of the solution is kept constant,

$$\{[P^0]/(P^0)\}/\{1+\cdots+K_j/(H^+)^j+\cdots+K_a/(H^+)^a\} = K(\text{const.}) \quad (9)$$

From Eqs. (8) and (9), we get

$$\log D = \log K + \log(1+\cdots+\bar{K}_j/[H^+]^j+\cdots+\bar{K}_a/[H^+]^a) \quad (10)$$

In order to differentiate Eq. (8) with respect to $\log(Cl^-)$, the following relation is used.

$$\{\partial \log D/\partial \log(Cl^-)\}_{(H^+)=\text{const.}} = \left\{\frac{\partial \log D}{\partial[H^+]}\cdot\frac{\partial[H^+]}{\partial(Cl^-)}\cdot\frac{\partial(Cl^-)}{\partial \log(Cl^-)}\right\}_{(H^+)=\text{const.}} \quad (11)$$

The components of the right-hand side of Eq. (11) are expressed as follows.

$$\partial[H^+]/\partial(Cl^-) = \{(H^+)/[Cl^-]\}\cdot\gamma_{(H^+)}\gamma_{(Cl^-)}/\gamma_{[H^+]}\gamma_{[Cl^-]} \quad (12)$$

$$\partial \log D/\partial[H^+] = \{-\bar{K}_1/[H^+]^2-\cdots-j\bar{K}_j/[H^+]^{j+1}-\cdots-a\bar{K}_a/[H^+]^{a+1}\}/\{1+\bar{K}_1/[H^+]+\cdots+\bar{K}_j/[H^+]^j+\cdots+\bar{K}_a/[H^+]^a\} \quad (13)$$

$$\partial(Cl^-)/\partial \log(Cl^-) = (Cl^-) \quad (14)$$

Thus, Eq. (11) can be written as

$$\{\partial \log D/\partial \log(Cl^-)\}_{(H^+)=\text{const.}} = \{[P^-]+\cdots+j[P^{j-}]+\cdots+a[P^{a-}]\}/\{[P^0]+[P^-]+\cdots+[P^{j-}]+\cdots+[P^{a-}]\} = \sum j[P^{j-}]/\sum[P^{j-}] = \bar{i}_R \quad (15)$$

The distribution coefficient of a particular ionic species P^{j-}, f_j, is derived from Donnan's equilibrium for the pair of this ionic species and chloride ion:

$$f_j = [P^{j-}]/(P^{j-}) = \{[Cl^-]/(Cl^-)\}^j\cdot\gamma_{(P^{j-})}\gamma^j_{[Cl^-]}/\gamma_{[P^{j-}]}\gamma^j_{(Cl^-)} \quad (16)$$

Eq. (15) can then be transformed into the following equation.

$$\bar{i}_R = \{f_1(P^-)+\cdots+jf_j(P^{j-})+\cdots+af_a(P^{a-})\}/\{f_0(P^0)+f_1(P^-)+\cdots+f_j(P^{j-})+\cdots+f_a(P^{a-})\} = \sum jf_j(P^{j-})/\sum f_j(P^{j-}) \quad (17)$$

On the other hand, the mean charge of the phosphate species in the solution, $\bar{i}$, is given by

$$\bar{i} = \sum j(P^{j-})/\sum(P^{j-}) \quad (18)$$

The concentration of chloride ion in the resin phase is usually much greater than that in the solution, thus Eq. (16) gives

$$f_j \gg 1 \quad (19)$$

From Eqs. (17), (18), and (19), the following relation can be obtained.

$$\bar{i}_R \geqq \bar{i} \quad (20)$$

This relation can be understood from the fact that a weak acid such as phosphoric acids is much dissociated at a higher pH and that the hydrogen ion concentration in an anion-exchange resin phase is in general higher than that in a solution.

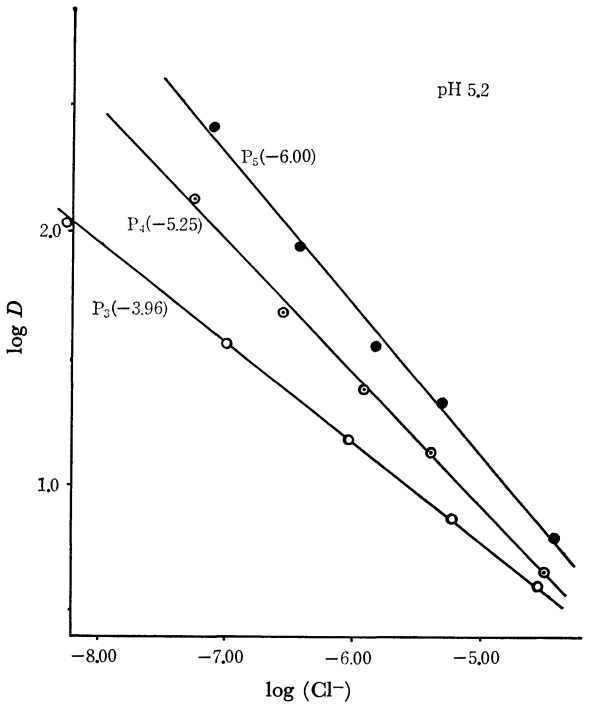

Fig. 1. $\log D$ *vs.* $\log(Cl^-)$ for tri-(P_3), tetra-(P_4) and penta-(P_5) phosphate at pH 5.2. The slope for each straight line is given in parentheses.

5) K. Koguchi, H. Waki, and S. Ohashi, *J. Chromatogr.*, **25**, 398 (1966).

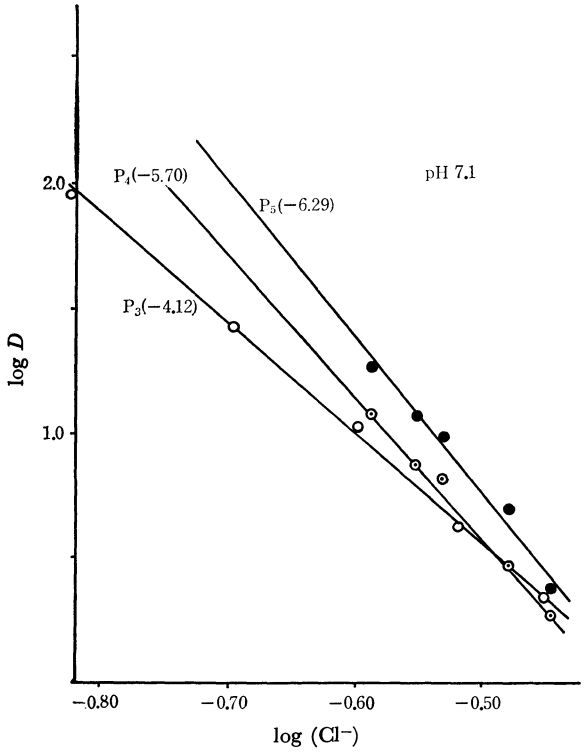

Fig. 2. log D *vs.* log(Cl⁻) for tri-, tetra-, and pentaphosphate at pH 7.1.

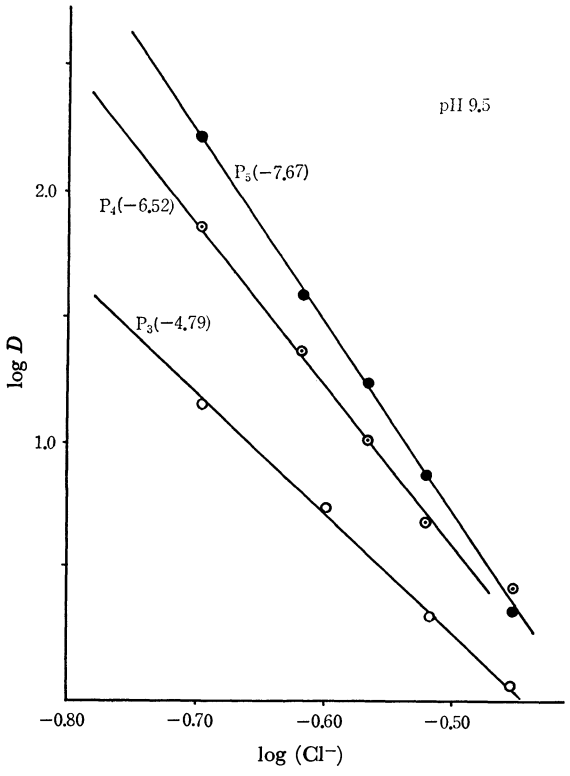

Fig. 3. log D *vs.* log (Cl⁻) for tri-, tetra-, and pentaphosphate at pH 9.5.

The relationship between the distribution ratio and the chloride ion concentration in the solution is given in Figs. 1, 2, and 3. From Eq. (15), the slope of each straight line gives the mean charge of each phosphate

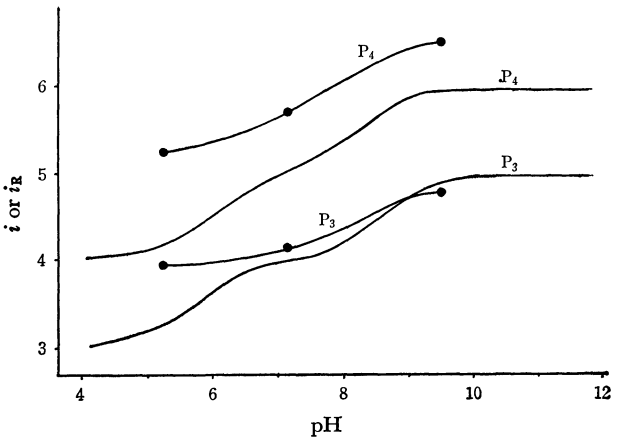

Fig. 4. Relationship between $\bar{i}$ or $\bar{i}_R$ and the pH values in solution.
——: calculated $\bar{i}$ values, ●—●: observed $\bar{i}_R$ values.

species in the resin phase at a given pH of the solution. In Fig. 4, the resulting mean charges are compared with the calculated mean charges in the solution for tri- and tetraphosphate. For these calculations the dissociation constants obtained by Irani and Callis[6] were employed. The relationship of Eq. (20) is confirmed by Fig. 4. Since in the higher pH region the fully dissociated phosphate species predominate in both phases, the decrease of the difference between $\bar{i}_R$ and $\bar{i}$ is expected from Eqs. (17) and (18). The difference still remaining will be attributed to the change of the activity coefficients.

The chromatographic separation of linear oligophosphates will be discussed in terms of a separation factor α_a^b which is defined by

$$\alpha_a^b = D_b/D_a \qquad (21)$$

where D_a and D_b represent the distribution ratios of phosphate species a and b, respectively. From the definition, α_3^4 and α_4^5 were calculated from the batch distribution ratios for the pairs of tri- and tetraphosphate

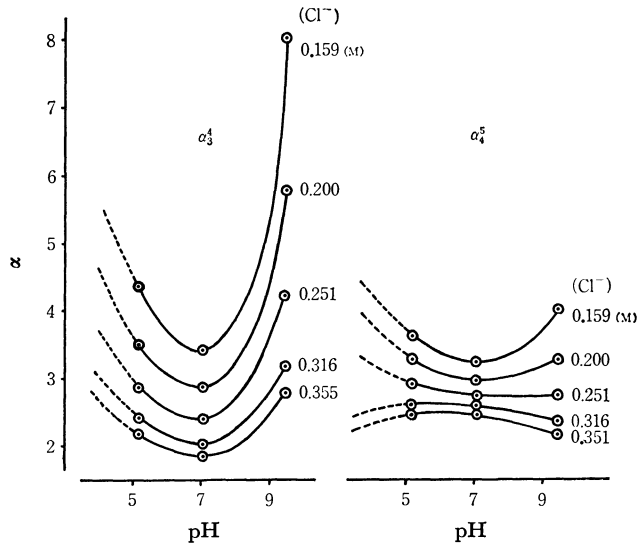

Fig. 5. The pH dependence of α_3^4 and α_4^5 at various chloride concentrations.

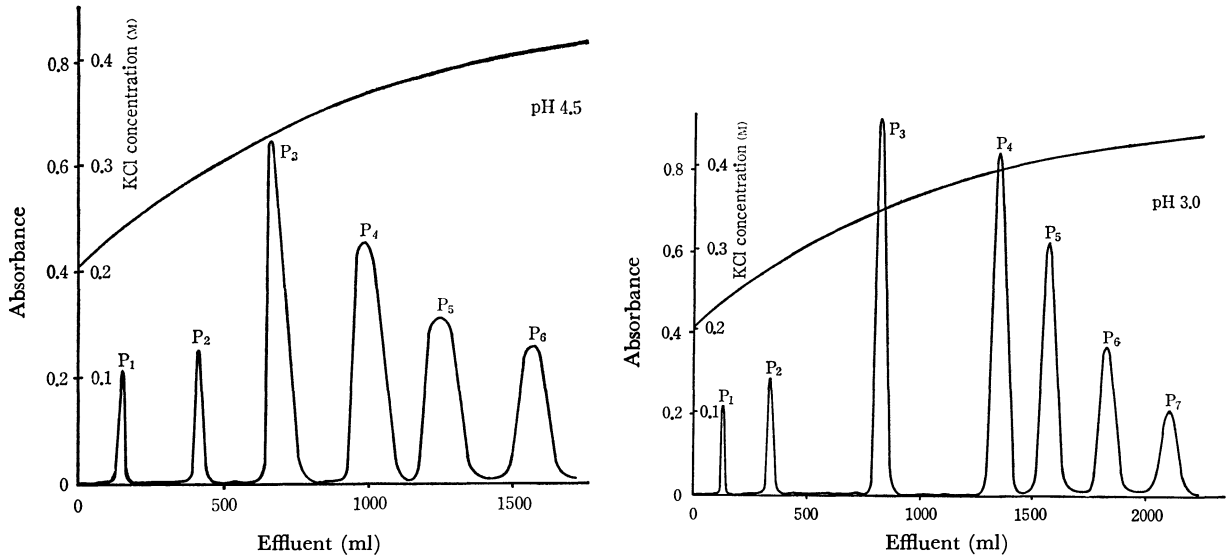

Fig. 6. Elution curves of linear oligophosphates at pH 4.5 and 3.0.

and of tetra- and pentaphosphate. The pH dependence of these separation factors is shown in Fig. 5. All the curves for α_3^4 give the minium values near pH 7 for all chloride concentrations. On the other hand, the curves for α_4^5 exhibit a tendency similar to those for α_3^4 at low chloride concentrations, but those at the high chloride concentrations seem to have maximum values. This suggests that the separation of tri- and tetraphosphate will be improved if the pH of eluent is kept apart from pH 7, but the separation of tetra- and pentaphosphate will not appreciably improved by changing the pH of eluent in the high chloride concentration region where these two phosphates are practically eluted out. This was confirmed by the chromatographic runs at different pH values of 4.5 and 3.0, which are shown in Fig. 6. The two elution diagrams indicate that the separability of tri- and tetraphosphate is improved by decreasing a pH, but not of tetra- and pentaphosphate.

The Chemistry of Protactinium. IX. A Study of the Solvent Extraction of Protactinium(V) from a Perchloric Acid Solution Using Di(2-ethylhexyl)phosphoric Acid as the Extractant

Toshiaki MITSUGASHIRA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira, Sendai

(Received November 5, 1970)

Studies of the chemical behavior of protactinium(V) in a perchloric acid solution were carried out by the HDEHP-benzene extraction method. When the protactinium concentration was lower than 10^{-7} M, the extraction reaction was considered to proceed as:

$$PaO(OH)^{2+}_{aq.} + 3(HA)_{2\ org.} = PaO_p(OH)_qA_{5-2p-q}(HA)_{2p+q+1\ org.} + 2H^+_{aq.} + (2-p-q)H_2O_{aq.}$$

where $p=1$, $q=0$ or 1, and $p=2$, $q=0$

and

$$Pa(OH)_3{}^{2+}_{aq.} + 3(HA)_{2\ org.} = PaO_p(OH)_qA_{5-2p-q}(HA)_{2p+q+1\ org.} + 2H^+_{aq.} + (3-p-q)H_2O_{aq.}$$

where $p=0$, q=0, 1, 2, or 3; p=1, $q=0$ or 1 and $p=2$, $q=0$.

It has been said that the aqueous solution of protactinium(V) is unstable because of its strong tendency to hydrolyze and to precipitate, even in a relatively strong acid solution. This tendency is especially noticeable in a perchloric acid solution, which is considered to be the most fundamental of the aqueous systems. Although many investigations have been carried out into the chemistry of protactinium(V) in a perchloric acid solution, the species present in this medium are far from having been established.

Suzuki and Inoue[1] reported that protactinium(V) in a perchloric acid solution existed in the forms of PaO-

1) S. Suzuki and Y. Inoue, This Bulletin, **39**, 1705 (1966).

$(OH)^{2+}$ or $Pa(OH)_3^{2+}$ and PaO^+_2, $PaO(OH)_2^+$ or $Pa(OH)_4^+$ when the concentration of protactinium(V) was lower than 10^{-6}M and the acidity was 0.3—2.0 M; they reached these conclutions by means of an investigation by the TTA-benzene extraction method, by the ion-exchange adsorption method, and by a filtration method using several kinds of filter paper and of membrane filter. They also observed that the distribution ratio (D) of protactinium (V) in the TTA-benzene extraction varied with the method of the preparation of the perchloric acid solution of protactinium, and pointed out that this fact was one of the reasons for the disagreement among the results obtained by various authers. This implies the necessity for a suitable choice of the experimental conditions if the thermodynamic treatment is to be made possible. Even when precautions were taken, the experimental error was too high for quantitative knowledge to be obtained.

Recently, solvent extraction studies using acidic organophosphoric esters have been successful. Among these esters di(2-ethylhexyl)phosphoric acid(HDEHP) is known to be effective for the separation of the lanthanides and of the actinides, particularly of the transplutonium elements, by means of extraction chromatography.[2-6] The acidic organophosphoric esters have greater acid dissociation constants than TTA.[7,8] HDEHP is considered to extract cations by a cation-exchange mechanism and thus is expected to have a selectivity in the solvent extraction according to the charge of the cation. Therefore, for a complete understanding of the chemical behavior of protactinium in the perchloric acid solution, it is worthwile to make a solvent-extraction study by using HDEHP as an extractant, for it has different characteristics than TTA.

Akatsu[9] pointed out, in her paper on the chemistry of neptunium, that protactinium(V) had a greater distribution ratio than neptunium(V) in a HDEHP-perchloric acid extraction system. She also emphasized the difference in the acid dependency of the distribution ratio between protactinium(V) and neptunium(V); *i.e.*, protactinium(V) showed an inversely second-power dependency, while neptunium(V) showed an inversely proportional dependency. However she did not say anything about the extraction mechanism of protactinium(V) nor the abnormal behavior of protactinium(V) in the perchloric acid solution pointed out by Suzuki and Inoue in their TTA-extraction studies. If her results indicate a special stability of the Pa(V)-HDEHP extraction system, we can except that remarkable progress in Pa(V)-solution chemistry can be attained by HDEHP-extraction study.

In this investigation, the author studied the HDEHP-extraction in order to clarify the chemical species of protactinium(V) in a perchloric acid solution.

Experimental

Reagents and Apparatus. *^{231}Pa and ^{233}Pa*: ^{231}Pa which had been obtained from The Radio-chemical Centre (Amersham, England) was purified by a method reported previously.[10] The radiochemical purity was certified by α-ray and γ-ray spectroscopy. The concentration of protactinium in the ^{231}Pa solution was determined by absolute α-ray counting and by gravimetry, using protactinium pentoxide as the weighing form. These two results agreed well within the limits of experimental error, so we can say that there was no contamination by non-radioactive impurities.

^{233}Pa was prepared by the method of Suzuki and Inoue.[10]

HDEHP and Other Reagents: Commercially-available HDEHP was purified by the method reported by Peppard *et al.*[11] In order to determine the purity of HDEHP, about a 0.1 N HDEHP-10% alcohol-benzene solution was titrated by a 0.1 N NaOH standard solution. The purity was at least 99.8%. Benzene was used as a diluent of HDEHP, which is dimeric in this solvent.[11] The benzene was purified by extracting thiophene by concentrated sulfuric acid, followed by distillation. The other reagents used in this experiment were of the highest purity.

Glass Apparatus: All of the glass apparatus, including pipettes, beakers, separatory funnels and flask, used in this experiment was preliminarily saturated with protactinium by being brought in contact with the perchloric acid solution of protactinium for a time sufficient for the saturation of the adsorption to be reached. The material balance held well under this treatment, except otherwise noted.

Procedures. *The Preparation of the Pa-perchloric Acid Solutions*: Appropriate amounts of the ^{231}Pa-stock solution and the ^{233} Pa-stock solution were placed in a platinum dish and evaporated to dryness. The residue was dissolved in concentrated perchloric acid. The solution was then diluted to 10^{-7}M with respect to protactinium with perchloric acid of a suitable concentration. In order to regulate the ionic strength (μ) of the solution, the lithium perchlorate solution, which has the same acidity as the Pa-perchloric acid solution under investigation, was added.

The Determination of the Distribution Ratio: Ten milliliters of a Pa-perchloric acid solution and 10 ml of a HDEHP-benzene solution were mixed in a separatory funnel for 15 min. After the two phases had completely separated, an aliquot of each phase was taken into a polyethylene test tube and the γ-radioactivity of ^{233}Pa was counted by means of a $1^1/_2''$ welltype NaI(Tl) scintillation counter. The distribution ratio was calculated by means of the usual relationship:

$$D = \frac{\gamma\text{-radioactivity per ml of the organic phase}}{\gamma\text{-radioactivity per ml of the aqueous phase}}$$

As a result of the preliminary experiment, it was established that the distribution ratio did not change even when the Pa-perchloric acid solution was left to stand for 1—7 days after its preparation. Thereafter, the distribution ratio gradually varied with time. This change reflects the change in the composition of the Pa-species in the perchloric acid solution. In this experiment, the solutions which were allowed to stand

for 1—4 days were used, unless otherwise noted. Thus, the error in the distribution ratio was minimized to about 10% when the distribution ratio was nearly 1.0.

It was found that a 10 min shaking was sufficient to get a constant distribution ratio. The equilibrium in the aqueous phase which is established in a 10 min shaking, is called "rapid equilibrium" in the rest of this report.

The distribution ratio obtained from the backward extraction varied markedly with respect to the standing time of the Pa-HDEHP-benzene solution and did not show a constant value in any interval of the standing time. The distribution ratio obtained from the backward extraction was generally higher than that obtained from the forward extraction.

Thus, in this investigation one can not, contrary to expectations, make a quantitative discussion of the thermodynamic equilibrium of the protactinium in a perchloric acid solution but can merely get the extraction behavior of Pa-species which are in rapid equilibrium with the extractable species.

Results

The Relation between the Distribution Ratio and the Acidity. The influence of the acidity on the distribution ratio was investigated by means of the constant ionic strength of the aqueous phase, as is shown in Fig. 1.

One of the important results concerns the different acid dependency between the solutions with the inonic strengths of 2.5 and 1.5. In the former case, the log-log plot of D and the acidity shows a linear relation, with a slope of -2, if the acidity is higher than 0.7 M. In the latter case, however, the slope is about -1.2. When the acidity of the aqueous phase was very low, the material balance did not hold well because protactinium was adsorbed on the wall of the glass separatory funnel in every experiment, even though the vessels had first been saturated with protactinium from a perchloric acid solution of moderate acidity. This tendency was prominent at acidities lower than 0.5 M when the ionic strength was 2.5. When the ionic strength was 1.5, this tendency was even more pronounced, and, in addition, inextractable species were found. The percentage fraction of the total protactinium contributed by the inextractable species was greater than 30% when the acidity was between 0.15 M and 0.3 M. Therefore, Fomin's method was applied in order to obtain the true distribution ratio (D_t) of the extractable species.[12] The results are shown in Fig. 2. The maximum standard deviation of D_t amounted to about 50%. This large error seems to be caused by two independent factors: one is the scattering of data caused by the adsorption of protactinium on the wall of separatory funnel, and the other is the limitation in the application of the Fomin method. In spite of this difficulty, one can read from Fig. 2 that the log-log plot of D_t and the acidity shows a linear relation, with a slope of -2, similar to the case of the inoic strength of 2.5.

The Relation between the Distribution Ratio and the HDEHP Concentration. The relation between the distribution ratio and the HDEHP concentration was

also investigated; the results are shown in Figs. 3 and 4. Figure 3 was obtained from the solution without lithium perchlorate, and Fig. 4 was obtained from the solution of a constant acidity, but at various ionic strengths. The dotted line indicates the slope of +3. It is clear from these figures that the log-log plot of D and the concentration of the dimeric HDEHP shows a linear relation, with a slope of about 3.

○ org. phase, 5×10^{-3}M $(HA)_2$
□ org. phase, 7.5×10^{-3}M $(HA)_2$

The Relation between the Distribution Ratio and the Ionic Strength. The relation between the distribution ratio and the ionic strength is shown in Fig. 5. In this experiment the acidity was kept constant (1.3 M). When the ionic strength is not higher than 2.5, the distribution ratio does not vary when the ionic strength does. On the other hand, when the ionic strength is higher than 2.5, the distribution ratio increases with an increase in the ionic strength. This observation is consistent with the results shown in Fig. 4, where the values of the distribution ratio and its dependency on the HDEHP concentration are shown to be the same in the solutions having ionic strengths of both 1.5 and 2.5, but in the case of an ionic strength of 4.8 the values of the distribution ratio become larger and the linearity between the logarithm of the distribution ratio and the logarithm of the HDEHP concentration becomes poor.

Discussion

It is obvious from Figs. 1 through 4 that the distribution ratio is proportional to the cube of the HDEHP concentration and inversely proportional to the square of the acidity. If the species extractable into the organic phase are considered to have no charge, the general equation for the HDEHP extraction reaction can be written as:

$$PaO_m(OH)^{5-2m-n}_{n\,aq.} + k(HA)_{2\,org.} = PaO_p(OH)_qA_{5-2p-q}(HA)_{2k+2p+q-5\,org.} + (5-2m-n)H^+_{aq.} + (m+n-p-q)H_2O_{aq.} \quad (1)$$

where HA, $(HA)_2$, and A^- represent the HDEHP molecule, the dimeric HDEHP, and the dissociated HDEHP anion respectively. The distribution ratio is defined by the following relation (if one omits the designation of the phase for the sake of simplicity):

$$D = \frac{\sum_{p,q,k}[PaO_p(OH)_qA_{5-2p-q}(HA)_{2k+2p+q-5}]}{\sum_{m,n}[PaO_m(OH)_n{}^{5-2m-n}]} \quad (2)$$

where brackets show the activity of the enclosed species. The equilibrium constant is defined by the following relation:

$$K_{m,n,p,q,k} = \frac{[PaO_p(OH)_qA_{5-2p-q}(HA)_{2k+2p+q-5}][H^+]^{5-2m-n}[H_2O]^{m+n-p-q}}{[PaO_m(OH)_n{}^{5-2m-n}][(HA)_2]^k} \quad (3)$$

By taking the partial derivative of the logarithm of the distribution ratio with respect to the logarithm of $[(HA)_2]$ and of $[H^+]$, we obtain:

$$\frac{\partial \ln D}{\partial \ln [(HA)_2]} = \sum_{p,q,k} k f_{p,q,k} \quad (4)$$

and

$$\frac{\partial \ln D}{\partial \ln [H^+]} = -5 + \sum_{m,n} (2m+n) f_{m,n} \quad (5)$$

where $f_{p,q,k}$ is the fraction of the total activity of protactinium in the organic phase contributed by the $PaO_p(OH)_qA_{5-2p-q}(HA)_{2k+2p+q-5}$ species and where $f_{m,n}$ is that of the aquous phase contributed by the $PaO_m(OH)_n$ species.

If the activity coefficients of any species are assumed to be constant over the entire range of the conditions in a series of experiments, Eqs. (4) and (5) are valid when the activities are replaced by the concentrations. The conditions applied in this experiment can be considered to satisfy this assumption. Thus, according to the results of this experiment, $\partial \ln D/\partial \ln [(HA_2)]$ should be 3 and $\partial \ln D/\partial \ln [H^+]$, -2. Thus we obtain:

$$\sum_{p,q,k} k f_{p,q,k} = 3 \quad (6)$$

and

$$\sum_{m,n} (2m+n) f_{m,n} = 3 \quad (7)$$

If one excludes the fortuitous agreement between the slope obtained empirically and the values calculated from the left-hand sides of Eqs. (6) and (7) by considering the complex combination of many species, Eqs. (8) and (9) are obtained from Eqs. (6) and (7):

$$k = 3 \quad (8)$$

$$2m + n = 3 \quad (9)$$

Therefore, the species of protactinium in the perchloric acid solution are considered to be $PaO(OH)^{2+}$ or $Pa(OH)_3{}^{2+}$. The existence of such species as $Pa(OH)_4{}^+$, $PaO(OH)_2{}^+$ or $PaO_2{}^+$, which were observed by the TTA-extraction, is negligible.

We can make some assumptions which seem reasonable considering the nature of the strong Pa-O bond and the large acid-dissociation constant of HDEHP. The former tells us that p is equal to or larger than m, while the latter tells us that q is queal to or less than n, as long as the molecular form of HDEHP is present in the extracted species. Furthermore, the degree of hydrolysis can not proceed by the complex formation, *i.e.*, $p+q \leq m+n$.

From the above consideration, one can represent the reaction mechanism as:

$$PaO(OH)^{2+}{}_{aq.} + 3(HA)_{2\,org.} = PaO_p(OH)_qA_{5-2p-q}(HA)_{2p+q+1\,org.} + 2H^+{}_{aq.} + (2-p-q)H_2O_{aq.} \quad (10)$$

where $p=1$, $q=0$ or 1 and $p=2$, $q=0$,
and:

$$Pa(OH)_3{}^{2+}{}_{aq.} + 3(HA)_{2\,org.} = PaO_p(OH)_qA_{5-2p-q}(HA)_{2p+q+1\,org.} + 2H^+{}_{aq.} + (3-p-q)H_2O_{aq.} \quad (11)$$

where $p=0$, $q=0$, 1, 2, or 3; $p=1$, $q=0$ or 1, and $p=2$, $q=0$.

In Fig. 1, the absolute value of the slope of log-log plot of D and the acidity is lower than 2 and the presence of the charge of $+1$ and $+2$ was expected when the ionic strength was 1.5. However, this is the effect of the existence of the inextractable species, as is quite clear from the results shown in Fig. 2. This conclusion seems at first sight to be contradictory to the results reported by Suzuki and Inoue,[1] but it can at least qualitatively be explained by the following consideration. In the TTA-benzene extraction, the inextractable species were not observed [1,13] but unadsorbable species were observed in the cation exchange study.[1] Essentially, the reaction of the HDEHP-extraction reaction is considered to be a cation-exchange reaction; therefore, the existence of the inextractable species is not so surprising. Figure 2 shows the results obtained by the Fomin method, in which the contribution from the inextractable species can be omitted. This shows the prominent species, which is in rapid equilibrium with the extraction, to have a charge of $+2$. Thus, no contributions from such species as $PaO(OH_2)^+$, $Pa(OH)^+_4$, and $PaO_2{}^+$ were observed, though the existence of these species had been concluded in the TTA-extraction. Therefore, the inextractable species may be $PaO(OH)^+_2$, $Pa(OH)^+_4$, or PaO^+_2 if we do not take the presence of the polymer into account.

Thus far we have considered the monomeric species only, but it is natural also to consider the inextractable species to be some polymeric species whose charge per atom of Pa is lower than 1. Further study is necessary to make a correct choice out of two possibilities mentioned above. At any rate, the presence of the TTA anion will play an important role in the establishment of the equilibrium between the extractable and the inextractable species.

Another interesting fact is shown in Fig. 1. Although the extraction conditions of the curves 1 and 2 were identical except for the standing time, the values of the distribution ratio were not the same. This difference can be explained by the difference in the standing time; *i.e.*, the equilibrium in the aqueous phase has not yet been established in the curve 1 while it has nearly been

13) R. T. Kolarich, V. A. Ryan, and R. P. Schuman, *J. Inorg, Nucl. Chem.*, **29**, 783 (1967).

established in the curve 2. On the other hand, when the ionic strength is 1.5, the difference in the distribution ratio is not observed between the curves 4 and 5, which were obtained under identical extaction conditions except for the standing time. These observations are consistent with the results of the preliminary experiment and show that the choice of the length of the standing time; *i.e.*, 1—4 days, is proper. However, their distribution ratios in the low acidity range are not identical with the extrapolated values of the curve 1 nor of the curve 2, although the HDEHP concentration is identical; *i.e.*, 5×10^{-3} M. Then the correction by the Fomin method was made, as is shown in Fig. 2, and the corrected distribution ratio was compared with the curves 1 and 2. Even by this procedure, the difference was still pronounced. In order to investigate this difference in more detail, the dependency of the distribution ratio on the perchloric acid concentration was examined by using a 5×10^{-3} M HDEHP-benzene solution. The results were compared with the results obtained by the use of the Fomin method (Fig. 2) and with the curve 2 in Fig. 1 (*cf.* Fig. 6).

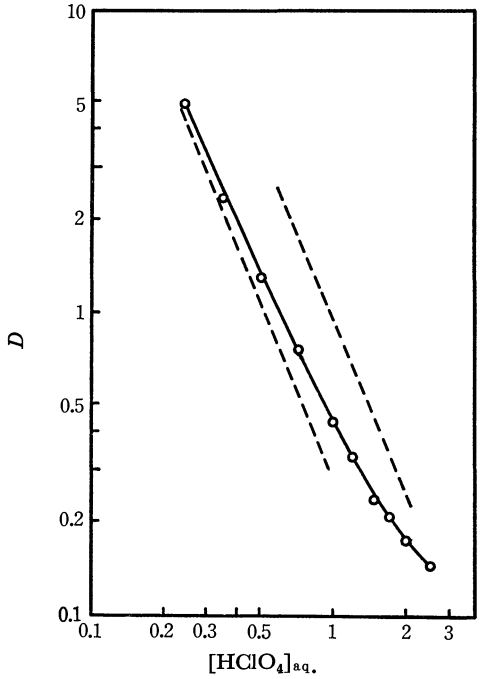

Fig. 6. The relation between the distribution ratio and the perchloric acid concentration. The upper dotted line indicates the curve 2 in Fig. 1 and the lower one, curve in Fig. 2.

In this figure the upper dotted line corresponds to the curve 2 of Fig. 1 and the lower one, to the curve shown in Fig. 2. The values of the distribution ratio obtained by extraction from the pure perchloric acid solution are distributed between the two dotted lines. The slope of the curve obtained by plotting the logarithm of the distribution ratio *vs.* the logarithm of the perchloric acid concentration asymptotically approaches −2 with a decrease in the acid concentration. This tendency is not so unusual in the adsorption on the cation-exchange resin. The most significant difference in the physical properties of the solution is the activity of water; in this case, the activity is higher when the ionic strength is 1.5. The transformation to the inextractable species and the adsorption on the glass vessel seem to occur upon the addition of lithium perchlorate to the perchloric acid solution of protactinium. However, as has been outlined above, their contribution to the distribution ratio is negligible when the acidity is 1.3 M or higher.

Therefore, the gradual approach of the slope to −2 seems to be explainable by the gradual increase in the activity of water. If there exists this equilibrium;

$$PaO(OH)^{2+} + H_2O = Pa(OH)_3^{2+} \qquad (12)$$

between the extractable species, the $Pa(OH)_3^{2+}$ must be more stable than $PaO(OH)^{2+}$ at lower acid concentrations or in media of lower ionic strengths, where the activity of water is lower. Thus, the dependency of the distribution ratio on the inoic strength can be explained by the change in $f_{1,1}$ and $f_{0,1}$ in Eq. (7). In order to confirm this assumption, it is necessary to investigate directly the dependency of the distribution ratio on the activity of water.

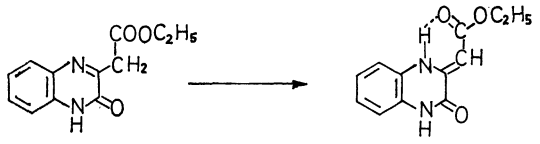
The author wishes to thank professor Shin Suzuki and Dr. Yasushi Inoue for their valuable advice throughout this study.

The Reaction of Acetylenecarboxylic Acid with Amines. XV.[1] Reaffirmation of the Enamine Structure Facilitated by Intramolecular Hydrogen Bonding Common to the Reaction Products

Yasuo IWANAMI
Sasaki Institute, Kanda-Surugadai, Tokyo
(Received March 3, 1970)

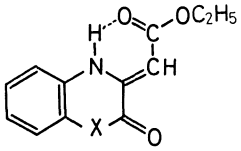
The reactions of dimethyl acetylenedicarboxylate (V) with *p*-chloroaniline, ethanolamine, ethylenediamine, *o*-aminophenol, and *o*-phenylenediamine gave dimethyl *N*-(*p*-chlorophenyl)aminofumarate(VI), 3-methoxycarbonylmethylene-3,4,5,6,-tetrahydro-2*H*-1,4-oxazin-2-one (VII), 3-methoxycarbonylmethylenepiperazin-2-one (VIII), 3-methoxycarbonylmethylene-3,4,-dihydro-2*H*-1,4-benzoxazine-2-one(IX), and 3-methoxycarbonylmethylene-3,4-dihydro-2(1*H*)-quinoxalinone(X), respectively. It has been shown that methoxycarbonylmethylene is a common structural element in all products, where the carbonyl is hydrogen-bonded with an amino group to form an enamine form. The spectra measured for crystals (IR) and for solutions in inert solvents (NMR) exhibited the fixation of the enamine form preferentially to the imine form, while NMR spectra for trifluoroacetic acid solutions indicated both forms in equilibrium. Tautomerization occurring in the acid is discussed.

In a preceding paper of this series,[2] we reported that the substance customarily called ethyl 2(1*H*)-quinoxalinone-3-acetate (I) should be named 3-ethoxycarbonylmethylene-2-oxo-1,2,3,4-tetrahydroquinoxaline (II) in consideration of IR spectral data, *viz.*, this compound exists in the enamine form as expressed by II which is facilitated by an intramolecular hydrogen bonding.

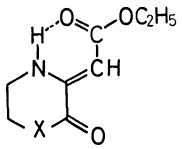


I II

The preceding report was the first to present evidence for the structural predomination common to a series of pyrazinone-type compounds (III and IV) having a *β*-carbonyl group in their side chain.[3,4] It was also reported that such a carbonylmethylene structure, facilitated by hydrogen bonding, predominates not only in these heterocycles but also commonly in *β*-iminopropionyl derivatives.[5]



X=NH, O and S
(II: *X*=NH)
III



X=NH and O
IV

Chapman[6] described the same enamine structure of I (*i.e.*,II) five years after. There is a contradiction[7] between his and our results, and our reports are inadequately cited in his paper. Some other workers also described simliar enamine forms[8–10] of heterocycles closely related to I or II, and they refer the enamine structure to imine-enamine tautomerism. In our papers, however, we refrained from explaining the enamine form by tautomerism, since we could not obtain any evidence for the presence of the corresponding imine form in our experiments carried out under ordinary conditions.

This paper deals with a reconfirmation of the enamine structure of several types of compounds with emphasis on the point that the imine form can not be detected in chloroform and methanol solutions.

Results

We synthesized methyl ester homologues of the compounds,[2–5] in order to extend our study on their enamine structures by means of IR and NMR spectroscopy. The syntheses were carried out by the reactions of dimethyl acetylenedicarboxylate (V) with *p*-chloroaniline, ethanolamine, ethylenediamine, *o*-aminophenol and *o*-phenylenediamine, as follows:

X=O and NH V IX: X=O X: X=NH

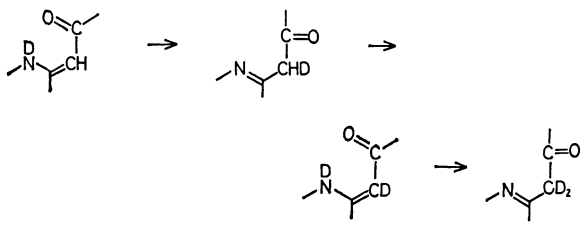
The IR spectra of these reaction products (VI—X) were measured for potassium bromide disks. All ester carbonyl bands exhibit marked lower frequency shifts compared to those of normal esters. Since absorption bands of the carbon-carbon double bond are observed in all cases, a double bond adjacent to the carbonyl (α, β-unsaturated) probably contributes to the shifts. Every carbonyl band, however, is not in the expected range[11] of 1730—1717 cm^{-1} for an α, β-unsaturated ester carbonyl, but in a less wave number region of 1696—1659 cm^{-1}. This can be explained by the intramolecular hydrogen bonding of the carbonyl with the amino group displacing its band toward much lower frequency side.[11] These results show that all the products are in enamine structure but not in imine form.

The products are thus to be named dimethyl *N*-(*p*-chlorophenyl)aminofumarate (VI), 3-methoxycarbonylmethylene-3,4,5,6-tetrahydro-2*H*-1,4-oxazin-2-one (VII), 3-methoxycarbonylmethylenepiperazin-2-one (VIII), 3-methoxycarbonylmethylene-3,4-dihydro-2*H*-1,4-benzoxazin-2-one (IX), 3-methoxycarbonylmethylene-3,4-dihydro-2(1*H*)-quinoxalinone (X).

The NMR spectra of VI, VII, VIII, and IX in deuteriochloroform commonly show singlets due to an olefinic (methine) proton instead of expected methylene if they exist in imine forms. Moreover, each spectrum shows at least one amino proton signal, the integration of which represents a single proton on nitrogen (two signals appear in the case of VIII). Its position in a lower field suggests hydrogen bonding involving the amino proton.

Main IR absorption bands and NMR signals of these compounds are shown in Fig. 1, together with the structural formulas which illustrate the actual forms of enamine type (the ring amide structures of VIII and X are also supported by both spectral data). Since IR spectra were measured for potassium bromide disks and NMR spectra for solutions, all these compounds can be satisfactorily expressed by the formulas shown in Fig. 1 both in solution and crystalline states.

If interconversion of imine and enamine (tautomerism) takes place, the hydrogen of side chain methine or methylene should be exchangeable with deuterium in the presence of deuterium oxide. One of the possible exchange mechanisms would be as follows:



When the NMR spectra of these compounds were measured in deuteriomethanol (CD_3OD), exchange with deuterium oxide removed the amino proton signal(s) (Table 1). Nevertheless, the signal of the methine proton did not disappear. Its relative intensity remained unchanged to afford 1:3 ratio to the integration of methyl singlet in every case. Hence it appears that tautomerism never occurs in deuteriomethanol and probably in deuteriochloroform.

On the other hand, some different results were

IX	3.49	—	6.92	3.52	3.52	5.62

The values are in ppm (δ) relative to internal tetramethylsilane. The mark—: no indication of the signal (side chain) at all. Compound was sparingly soluble in CD_3OD. The signals of X in CF_3COOH were already reported.[8]

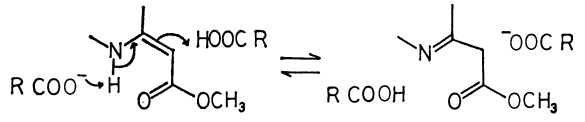
obtained from the measurement using trifluoroacetic acid. Both methine and methylene proton signals are exhibited in this acid as listed in Table 1. Methylene proton signals can be interpreted as due to the side chain methylene of each compound existing in the imine form. The enamine and imine forms are, therefore, equilibrated in the acid.

A variety of the existing ratios of enamine to imine in the acid are shown by calculation based upon the relative intensities of methine singlets, as follows: approximately 1:2, 1:0.5, 1:8, and 1:>10 for VI, VII, VIII, and IX, respectively.

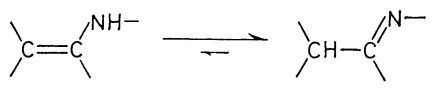
In deuteriotrifluoroacetic acid, either methine or methylene proton signal disappears by replacement with deuterium. It can therefore be said that tautomerization becomes possible under certain conditions caused by trifluoroacetic acid.

Discussion

The phenomenon observed on the compounds in trifluoroacetic acid is noteworthy. However, there is an essential difference between the compounds and β-diketones such as acetylacetone or ethyl acetoacetate, which ordinarily exist as an equilibrium mixture of keto and enol tautomers, while all the compounds in the present study shut themselves much more firmly in the enamine form in crystals and chloroform or methanol solution (at least the imine form is extremely minimized). The imine formation and tautomerization therewith in trifluoroacetic acid may be caused by a concerted reaction[12] which proceeds by simultaneous attack of the acid and the base as illustrated below.



Generally, imine form is predominant[13,14] in imine-enamine tautomerism:



Enamines are stable only when there is no hydrogen on the nitrogen (—C=C–NRR′).[13,14] It is interesting that all our products possess a hydrogen on the nitrogen atom but the enamine forms remain stable.

This series represents a special case of proton-shift isomerization or tautemerization. However, we recently encountered a perfectly converse predominance of the imine form observed on the same side-chain derivative of a more complicated heterocycle, which will be reported in the following paper.

Experimental

IR spectra were measured for KBr disks with a Nippon Bunko DS-301 spectrophotometer, and NMR spectra were determined on a Hitachi H-60 model.

The synthetic procedures of the all compounds were essentially the same as the corresponding ethyl derivatives[2-5] except that diethyl acetylenedicarboxylate was replaced by dimethyl acetylenedicarboxylate (V) and methanol was used as the solvent instead of ethanol. Only their melting points (uncorr.), yields in percent, and data of elementary analyses are described.

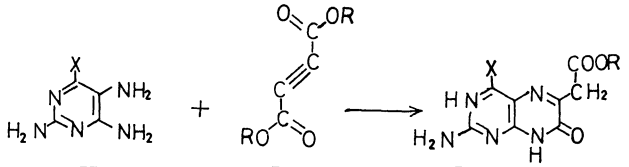
The Reaction of Acetylenecarboxylic Acid with Amines. XVI.[1] Formation of Alkyl Isoxanthopterinacetates Possessing Imine Structure[2]

Yasuo IWANAMI
Sasaki Institute, Kanda-Surugadai, Tokyo
(Received March 3, 1970)

Methyl and ethyl isoxanthopterin-6-acetates and their 4-amino analogues have been prepared *via* a new route from acetylenedicarboxylate and 2,5,6-triamino-4-hydroxypyrimidine or 2,4,5,6-tetraaminopyrimidine. These compounds uniquely exist in the imine form as evidenced by NMR and IR spectral data. This is the only exceptional case so far examined, since a number of related compounds exist in enamine form. When dissolved in sulfuric acid, however, tautomerization of imine to enamine is observed. It was demonstrated by NMR inspection that the methylene hydrogen on the side chain is exchangeable with deuterium. The tautomerism in sulfuric acid is discussed.

The reactions of ethyl and methyl acetylenedicarboxylates (Ia and Ib) with 2,5,6-triamino-4-hydroxypyrimidine (IIa) or 2,4,5,6-tetraaminopyrimidine (IIb) gave the corresponding alkyl isoxanthopterin-6-acetates (IIIa and IIIb) or their 4-amino analogues (IIIc and IIId). Although the preparation of the ethyl ester (IIIa and IIIc) by a different route is known,[3] this procedure provides another route.

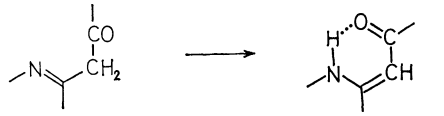


II
a : X=OH
b : X=NH_2

I
a : R=Et
b : R=Me

III
a : X=OH; R=Et
b : X=OH; R=Me
c : X=NH_2; R=Et
d : X=NH_2; R=Me

In a previous paper[4] we reported that the compound customarily called ethyl 2(1*H*)-quinoxalinone-3-acetate exists in the enamine form, *i.e.* in a structure to be named 3-ethoxycarbonylmethylene-3,4-dihydro-2(1*H*)-quinoxalinone. The enamine form is facilitated by an intramolecular hydrogen bonding. The preceding report was the first to present evidence for such a chelate structure. Since then, many examples of similar enamines possessing intramolecular hydrogen bonding have been reported from our laboratory in condensed[1,4-6] and noncondensed[1,4,6] nitrogen-containing heterocycles of five-,[5] six-,[1,4-6] and seven-membered[5] rings or even in simpler alkyl β-aminoacrylates.[1,5,7]



imine form enamine form

Because of their structural resemblance to the heterocycles,[1-4] compounds IIIa—d were expected to exist in the enamine form. Nevertheless, IR and NMR spectroscopic data have disclosed the predominancy of the imine form both in their solution and crystalline states.

The IR spectra of III exhibited ester carbonyl bands in the range 1747—1716 cm^{-1}, but not 1698—1644 cm^{-1}, which was expected for an intramolecularly hydrogen-bonded α,β-unsaturated ester carbonyl common to all the related compounds reported in the preceding papers. This suggests that the side chain of III exists in an alkyl acetate form rather than in chelated alkoxycarbonylmethylene form.

In order to obtain further evidences the NMR spectra of III were examined. Although solubility of III in the usual solvents was not high enough for the spectroscopy, we found that sulfuric acid was good solvent in which III was stable at ordinary temperature.

The NMR spectra of IIIa in sulfuric acid are shown in Fig. 1. A triplet at 1.78 ppm and a quartet at 4.75 ppm are observed besides two broad signals due to NH protons at 5.24 and *ca.* 8.00 ppm. The profile of the quartet appears deformed. The relative intensity of the quartet represents 4: 3 to the triplet due to methyl protons of the ethoxyl group. This can be explained by the overlapping of a quartet due to methylene protons of the ethoxyl group with a singlet due to the other methylene protons adjacent to the pteridine ring. In deuteriosulfuric acid, the coinciding singlet has disappeared together with amino proton signals, and the intensity of the remaining quartet diminishes to two-thirds that of the triplet. Namely, the triplet and quartet turn out typical bands of an ethoxyl group.

The spectrum of IIIa in deuteriodimethyl sulfoxide is essentially the same as that in sulfuric acid. Similar phenomena have been observed in the spectra of IIIb—d.

From these results except those in deuteriosulfuric acid, it is evident that this compound exists as ethyl isoxanthopterin-6-acetate (IIIa) but not as 6-ethoxy-

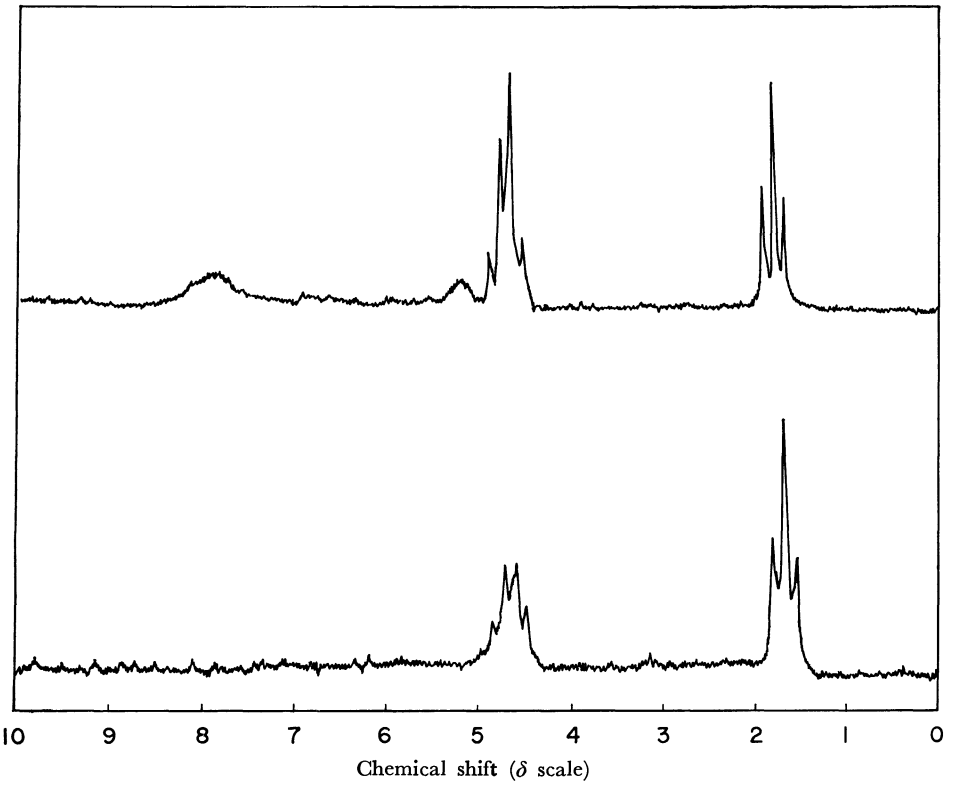

Fig. 1. NMR spectra (60 MHz) of ethyl isoxanthopterin-6-acetate (IIIa) in sulfuric acid (above) and deuteriosulfuric acid (below).

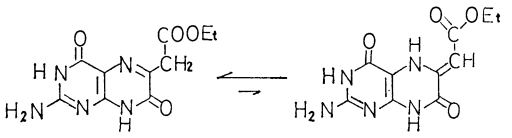
carbonylmethylene-5,6-dihydroisoxanthopterin (IVa).

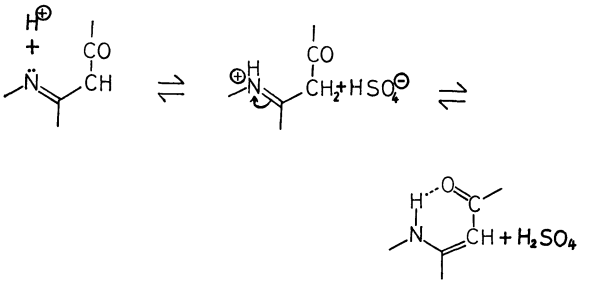


IIIa IVa

However, tautomerization between IIIa and IVa is not excluded as shown by the fact that the methylene protons adjacent to the ring are exchangeable with deuterium of the solvent. This exchange is fully explained by tautomerization which causes direct and repeated additions of deuterium to the carbon bearing an olefinic proton in another tautomeric (enamine) form or replacements occuring stepwise to exchange an amino proton with deuterium and then to transfer it onto olefinic carbon, in deuteriosulfuric acid.

Thus, the structure of III in solution and crystalline state has been estableished by NMR and IR spectra, respectively.

Indication of imine-enamine tautomerism is given only when the spectrum in sulfuric acid is compared with that in deuteriosulfuric acid. This was the only successful experiment to detect tautomerism. Unfortunately, we could not see whether or not the interconversion of imine to enamine occurs in inert solvents, because of low solubility. On the basis of our previous observation,[1] however, we deduce that III would exclusively exist in the imine form under ordinary circumstances (for example, in crystalline state or in an inert solvent). When III is dissolved in sulfuric acid or other protic solvents, protonation by the acids would cause the interconversion of imine to enamine as follows:



This mechanism is well explained by the above deuterium exchange. Probably, concerted reaction[1] of the solvent cation and anion equilibrate both tautomeric forms.

It is of interest that an isomer of IIIa, ethyl xanthopterin-7-acetate,[8] exists in the enamine form[9] in deuteriodimethyl sulfoxide, in contrast to III, while the compound exists as a 1 : 1 mixture of imine and enamine forms in trifluoroacetic acid. The tautomerism occurring in trifluoroacetic acid can also be accounted for the above hypothetical mechanism.

8) L. Merlini, W. von Philipsborn, and M. Viscontini, *Helv. Chim. Acta*, **46**, 2592 (1963).

9) Recently, we have examined the structures of 6-phenacylisoxanthopterines and 7-phenacylxanthopterins, which possess β-carbonyl groups in their side chains as do III and above mentioned ethyl xanthopterin-7-acetate.[8] It was found that both phenacylpterins exist in the enamine form, and the interconversion of enamine to imine is evidenced by NMR spectra in deuteriosulfuric acid. The results will be reported elsewhere.

Experimental

IR spectra were measured for potassium bromide disks on a Nippon Bunko DS-301 spectrophotometer. NMR spectra were determined with a Hitachi H-60 spectrometer and recorded in δ values with tetramethylsilane as external standard.

Ethyl Isoxanthopterin-6-acetate (IIIa). Into a suspension of IIa sulfate (0.4 g) in an aqueous solution (10 m*l*) of sodium acetate (0.8 g), a solution of Ia (0.35 g) in ethanol (10 m*l*) was added dropwise with stirring at room temperature. After the mixture was stirred for further 3 hr, it was allowed to stand overnight. The precipitated crystals (0.5 g) were collected by filtration and recrystallized repeatedly from dimethyl sulfoxide. The crystals were washed well with water and ethanol successively on a glass filter and kept *in vacuo* over phosphorus pentoxide at an elevated temperature (100°C) for a few hours in order to eliminate completely the solvent to give IIIa as dark yellow powders; mp>300°C.

Found: C, 41.08; H, 4.55; N, 23.45%. Calcd for $C_{10}H_{11}O_4N_5 \cdot 3/2H_2O$: C, 41.12; H, 4.79; N, 23.94%.

Methyl Isoxanthopterin-6-acetate (IIIb). In a similar manner to IIIa, the crude product of IIIb (0.15 g) from IIa sulfate (0.2 g) and Ib (0.15 g) was recrystallized from dimethyl sulfoxide to afford IIIb; mp>300°C.

Found: C, 39.10; H, 4.10; N, 25.22%. Calcd for $C_9H_9O_4N_5 \cdot 3/2H_2O$: C, 38.87; H, 4.32; N, 25.10%.

Ethyl 2,4-Diamino-7(8H)-pteridinone-6-acetate (IIIc). Similarly, the crude product of IIIc (0.56 g) from IIb sulfate (1.2 g) and Ia (0.85 g) was recrystallized from dimethyl sulfoxide. The crystals collected on a glass filter were washed with a 1:1 mixture of dimethyl sulfoxide and 50% sulfuric acid, water, and ethanol, successively, and then kept *in vacuo* to give IIIc; mp>300°C.

Found: C, 40.97; H, 4.46; N, 28.71%. Calcd for $C_{10}H_{12}O_3N_6 \cdot 1/4H_2SO_4 \cdot 1/4H_2O$: C, 40.95; H, 4.47; N, 28.66%.

Methyl 2,4-Diamino-7(8H)-pteridinone-6-acetate (IIId). The crude product of IIId (0.73 g) from IIb sulfate (1.20 g) and Ib (1.14 g) was recrystallized from dimethyl sulfoxide; mp>300°C.

Found: C, 41.98; H, 4.47; N, 32.59%. Calcd for $C_9H_{10}O_3N_6 \cdot 1/2H_2O$: C, 41.70; H, 4.28; N, 32.42%..

Heterocycles Structurally Influenced by a Side Chain. I. 3-Phenacyl-2(1*H*)-quinoxalinones and 3-Phenacyl-2*H*-1,4-benzoxazin-2-ones[1)]

Yasuo IWANAMI and Taketsugu SEKI*
Sasaki Institute, Kanda-Surugadai, Chiyoda-ku, Tokyo
Takeshi INAGAKI
Central Research Laboratories, Nitto Chemical Industry Co., Ltd., Daikoku-cho, Tsurumi-ku, Yokohama

(Received March 17, 1970)

Seven phenacyl derivatives of 2(1*H*)-quinoxalinone and 2*H*-1,4-benzoxazin-2-one (IV and V) have been synthesized to introduce a common structural element $-CH_2-CO-$ into their 3-positions. Their structures are compared with those of the related compounds described previously. The main purpose of the present study was to see whether or not their ring double bonds (–N=C–) have ever been displaced onto the side chains, constituting an enamine so as to form =CH–CO–, the carbonyl of which is hydrogen bonded with the secondary amino group of the rings thereby formed. Consequently, existence as the enamine form, facilitated by an intramolecular hydrogen bonding, has been evidenced by IR and NMR spectral data. It is, therefore, fitting to call them by the more practical expression "3-phenacylidene-3,4-dihydro-2(1*H*)-quinoxalinone" (IVa), and so on. Hydrolysis of IV gave the corresponding 3-methyl-2-(1*H*)-quinoxalinones (VI) and benzoic acid (VII), while that of V afforded the starting substances, *o*-aminophenols (III) and benzoylpyruvic acid (VIII) which had been partially decomposed into pyruvic acid (IX) and VII.

One of the authors reported[2–7)] in and after the year of 1961 that many nitrogen-containing heterocycles having a β-carbonyl on their side chains introduced onto the carbon adjacent to the nitrogen atom tend to isomerize so that the carbon-nitrogen double bond is displaced onto the side chain to form an α,β-unsaturated carbonyl group. Isomerization is facilitated by the resulting intramolecular hydrogen bonding[3)] between the carbonyl and the secondary amino group thus newly formed.

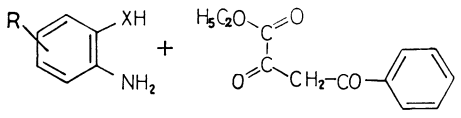
imine enamine

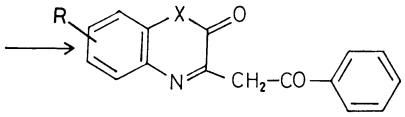
However, we recently encountered[8] an exceptional case of alkyl isoxanthopterin-6-acetates, which exist in the imine form indicating a converse predominance.

We have, therefore, extended our study to 3-phenacyl-2(1*H*)-quinoxalinones (IV) and 3-phenacyl-2*H*-1,4-benzoxazin-2-ones (V).

Condensation of ethyl benzoylpyruvates (I) with *o*-phenylenediamine (IIa), *o*-aminophenol (IIIa) and some of their derivatives (IIb, c, and IIIb—d) gave the corresponding 3-phenacyl-2(1*H*)-quinoxalinones (IVa—c) and 3-phenacyl-2*H*-1,4-benzoxazin-2-ones (Va—d). Five of the products except IVa and Va are new compounds.



IIa: R=H, X=NH
IIb: R=4-Cl, X=NH
IIc: R=Benzo[*d*], X=NH
IIIa: R=H, X=O
IIIb: R=4-CH_3, X=O
IIIc: R=4-Cl, X=O
IIId: R=Benzo[*c*], X=O



IVa: R=H, X=NH
IVb: R=7-Cl, X=NH
IVc: R=Benzo[*g*], X=NH
Va: R=H, X=O
Vb: R=6-CH_3, X=O
Vc: R=6-Cl, X=O
Vd: R=Benzo[*f*], X=O

IR spectra of these compounds were measured for KBr disks. The absorption bands of carbonyls and carbon-carbon double bonds (both in the side chains) are shown in all cases (Table 1). The results suggest that a nitrogen-carbon double bond in the ring is just visionary and the double bond has ever been displaced onto the side chain. Moreover, the carbonyl bands are not in the region 1670—1663 cm^{-1} expected[9] for an α,β-α',β'-unsaturated ketone, but in a lesser wavenumber region 1623—1620 cm^{-1}. This lower frequency shift is probably accounted for an intramolecular hydrogen bonding of the carbonyl with the amino group of the ring. The secondary amino group can not occur unless the imaginary nitrogen-carbon double bond has been displaced onto the side chain. Thus, these compounds exist in the enamine form, which is

Table 1. IR absorption bands of the products (cm^{-1})

Compound	$\nu_{C=O}$			$\nu_{C=C}$
	Lactone	Lactam	Ketone	
IVa		1689	1622	1613
IVb		1690	1622	1613
IVc		1693	1620	1610
Va	1755		1620	1611
Vb	1755		1621	1613
Vc	1757		1623	1612
Vd	1750		1620	1613

All spectra were measured for KBr disks.

attributable to the internal hydrogen bond by the analogy of a number of their related compounds.[2-7]

The enamine structure is further evidenced by NMR spectra determined for dimethyl sulfoxide-d_6 solutions (the solubilities of these compounds in the usual solvents are not high enough for spectroscopy). The NMR spectra of IVa and Vb are shown in Fig. 1. In the spectrum of IVa (above), no signals appear in the region between 6.91 and 0 ppm, except for those due to protons of the solvent, but a singlet appears at 6.91 ppm (δ scale). Therefore, we can conclude that IVa does not involve methylene but a methine group in its structure. Bands at lower fields are due to aromatic protons, and the carbonyl adjacent to the phenyl ring would displace the signals due to the *ortho* protons down-field giving the band at *ca.* 8.07. Consequently, the carbonyl group does not exist as an enol in IVa. The two broad signals at 12.09 and 13.88 ppm are due to amino protons. Existence of amino protons is also proper only to the enamine form. Hydrogen bonding between the carbonyl and amino groups is suggested by the lowest-field position of the amino proton signal. The structure consistent with these chemical shifts is designated as "3-phenacylidene-3,4-dihydro-2(1*H*)-quinoxalinone."

This is not exceptional to the existing forms of many other related compounds.[2-7]

Similarly, Vb showed a methine, an amino, and aromatic *ortho* (to a carbonyl) proton signal (Fig. 1, below). In this case, Vb possesses a methyl group attached to the benzoxazine ring, and the corresponding signal appears at 2.32 ppm. The relative intensity of the methine singlet represents exactly one proton when compared to three protons of another singlet due to the ring methyl group. Presence of the methine group in Vb is thus satisfactory from this quantitative point of view. The customary name of V, 3-phenacyl-2*H*-1,4-benzoxazin-2-one, is not fitting, and the most practical designation would be "3-phenacylidene-3,4-dihydro-2*H*-1,4-benzoxazin-2-one."

The NMR spectra of the other products (IVb and Va,c,d), except for that of IVc sparingly soluble in dimethyl sulfoxide-d_6, are essentially the same as those of IVa and Vb described above. The broad amino proton signals of Vc and Vd are indistinctly observed because of their insufficient solubility. The δ values of the methine, amino benzoyl *ortho* protons are listed in Table 2. The IR spectra were measured for potas-

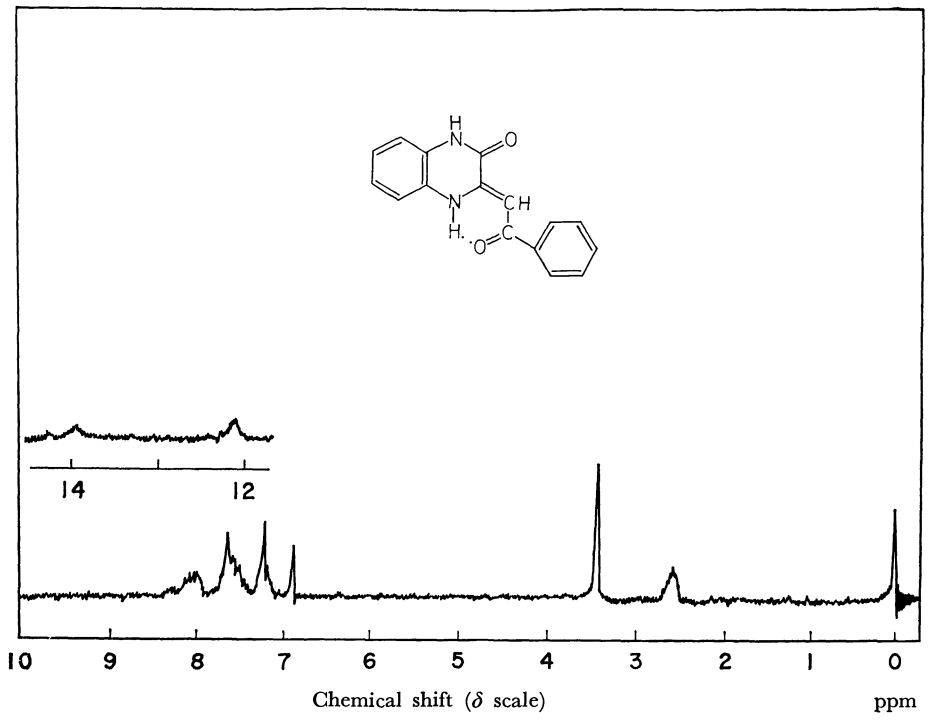

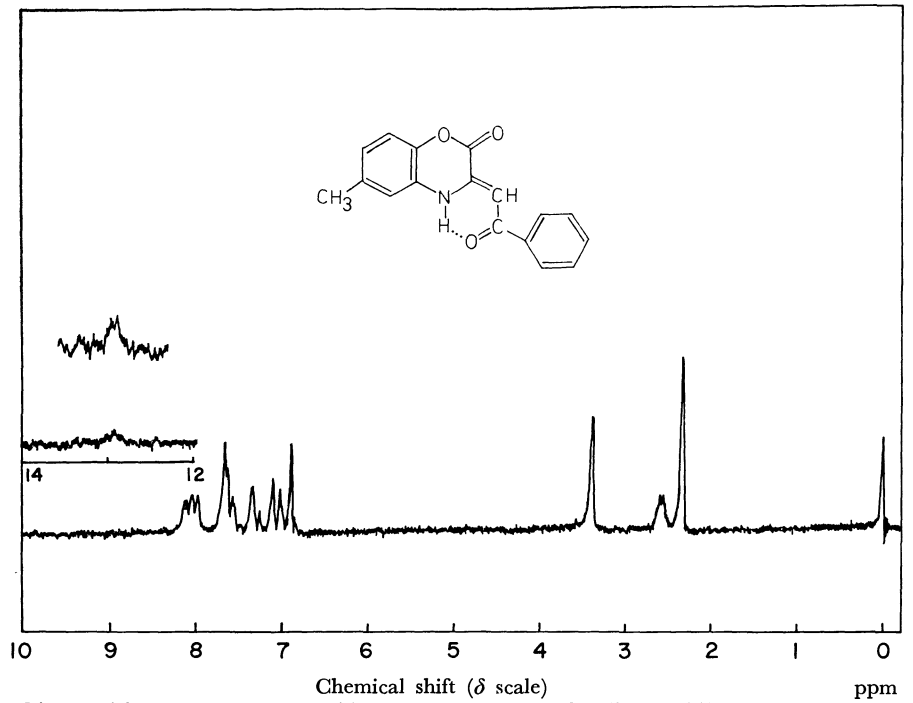

Fig. 1. NMR spectra (60 MHz) of 3-phenacylidene-3,4-dihydro-2(1*H*)-quinoxalinone (IVa) (above), and 6-methyl-3-phenacylidene-3,4-hydro-2*H*-1,4-benzoxazin-2-one (Vb) (below) in DMSO-d_6 (internal TMS).

sium bromide disks (Table 1) and the NMR spectra for dimethyl sulfoxide-d_6 solutions (Table 2). Structure in solution or crystalline state has, therefore, been confirmed to be the same (the enamine form) by both spectroscopies.

Profiles of the NMR spectra, measured for trifluoroacetic acid solutions, were greatly different. Three or four singlets appeared in the region 6.98—4.39 ppm (Table 2). This probably accounted for the tautomerism as follows:

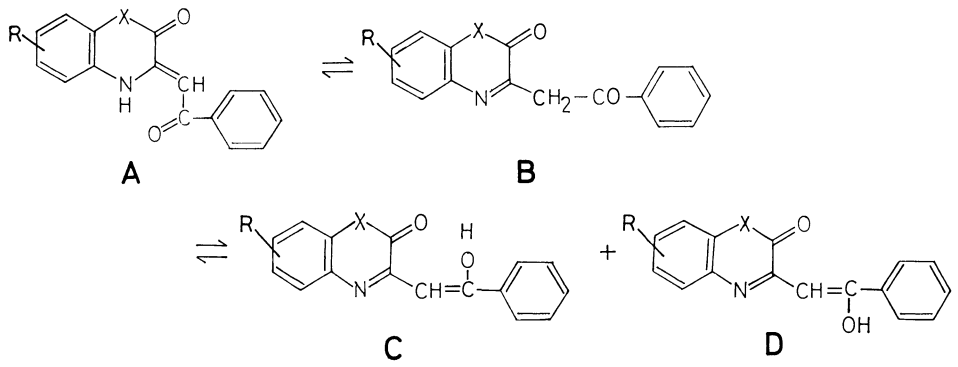

Table 2. Chemical shifts of the products

Compound	DMSO-d_6			CF_3COOH	
	=CH	Benzoyl(*ortho*)	NH	=CH	CH_2
IVa	6.91	*ca.* 8.07	13.88 12.09	6.59 5.70	4.79
IVb	6.92	*ca.* 8.10	13.68 12.12	6.78 6.43 5.54	4.39
IVc	—	—	—	6.98 6.55 5.69	4.79
Va	6.98	*ca.* 8.13	12.97	6.26 5.35	4.53
Vb	6.89	*ca.* 8.05	12.92	6.65 6.45 5.55	4.65
Vc	7.07	*ca.* 8.19	(12.02)	6.44 5.56	4.65
Vd	7.11	*ca.* 8.13	(12.18)	6.97 6.43 5.56	4.69

Values are on δ scale, unmeasurable: —, and indistinct: ( ).

In crystalline state or in dimethyl sulfoxide, these compounds exist as A, as already mentioned. In a strongly ionizing solvent like trifluoroacetic acid, however, the solvent forces them to tautomerize between A and B, B and C (or D), and possibly A and C (or D). This effect of the ionizing solvent would be due to solvation with proton and the anion. The mechanism can be explained by a simultaneous attack (concerted reaction) of an anion and a proton,[10] analogous to similar phenomena observed[7,8] on the related compounds in trifluoroacetic acid or sulfuric acid.

The interconversions are supported by the following interpretations and experiments. In trifluoroacetic acid, a methylene ($-CH_2-$) proton signal (Table 2) is shown in every case. This is satisfactory for B. Although no direct evidences are given to the presence of both tautomers C (*cis*) and D (*trans*), occurrence of three methine (=CH–) ptoron signals (Table 2) can be interpreted as that one methine belongs to A and the two others to C and D. Since intramolecular hydrogen bonding possibly occurs as well in C as in A, a couple of the signals both fallen in a range 6.98—6.43 ppm would be attributable to the methines of A and C. Thus, the remaining signal in the higher field 5.70—5.35 ppm is likely to be that of D (when only two methine signals appear, one form may be minimized or two of the three signals overlapped). Moreover, the typical benzoyl (*ortho*) proton signals observed in dimethyl sulfoxide-d_6 are weakened in trifluoroacetic acid. Enolized forms C and D explain this felicitously.

On the other hand, the spectra determined in trifluoroacetic acid-*d* exhibit no methylene nor methine proton signals, *i.e.* all hydrogens on the aliphatic carbon have been replaced with deuterium. As an example, two of the possible exchange mechanisms would be as

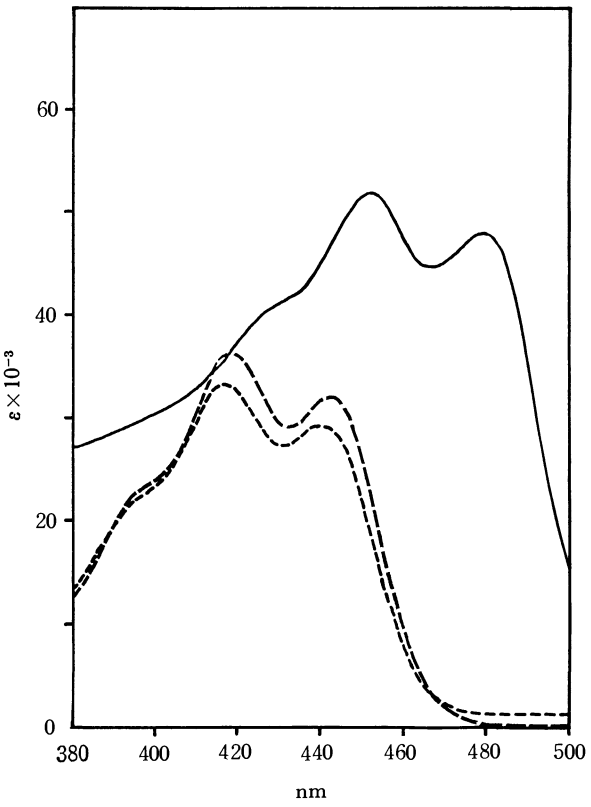

Fig. 2. Electronic absorption spectra of 3-phenacylidene-3,4-dihydro-2(1*H*)-quinoxalinone (IVa); in EtOH: ------, in DMSO: ——, and in CF_3COOH: ——.

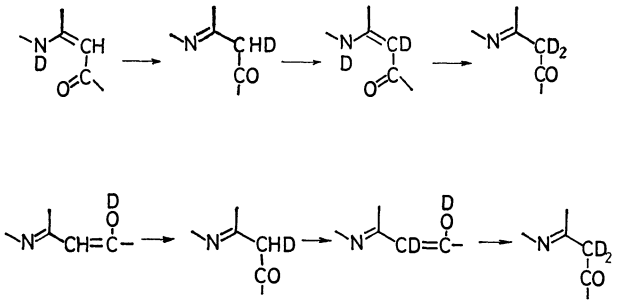
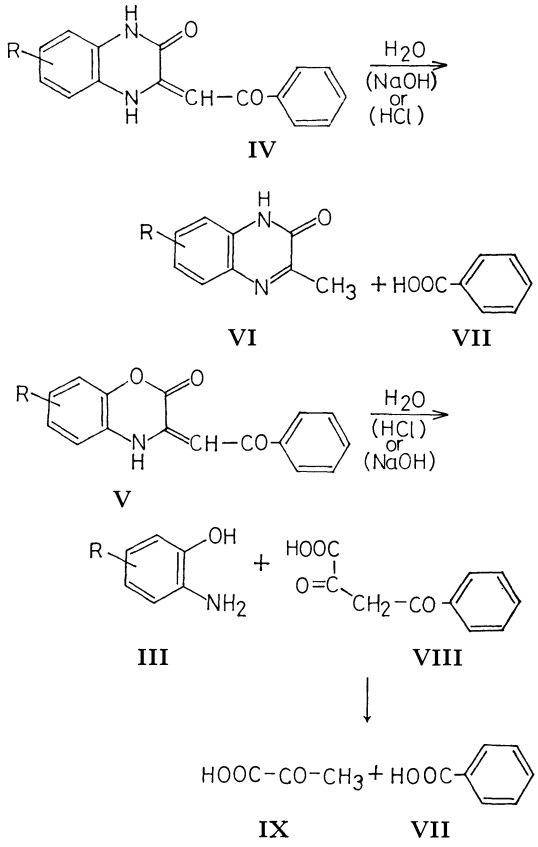
10) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Henry Holt and Co., Inc., London (1960), p. 385.

follows:



Besides the interconversion between A and B[7] (above), the keto-enol tautomerism involving B, C, and D (below) probably contributes to the deuterium exchange. At least, disappearance of the signals is consistent with the above tautomerisms forced by the acid.

In addition to these supports,[11] another evidence for C and D is obtained from electronic absorption. The spectra of IVa are shown in Fig. 2. The absorptions in ethanol and in dimethyl sulfoxide are almost the same, whereas that in trifluoroacetic acid shows a bathochromic shift. This is consistent with the enol forms C and D, since the enol double bond connects two aromatic rings so as to intensify the resonance through this new conjugated double bond.



Hydrolysis of IV gave the corresponding 3-methyl-2(1*H*)-quinoxalinones (VI) and benzoic acid (VII), while that of V afforded the starting substances, *o*-aminophenols (III) and benzoylpyruvic acid (VIII) which had been partially decomposed into pyruvic acid (IX) and VII.

The reasons why V gave starting materials whereas IV preserved its quinoxaline ring would be exactly the same as those given for their analogues.[5]

Experimental

IR spectra were measured for KBr disks with a Nippon Bunko DS-301 spectrophotometer, NMR spectra were determined on a Hitachi H-60 spectrometer, and electronic absorption spectra were taken on a Hitachi 124 spectrophotometer.

The starting material, ethyl benzoylpyruvate (I), was prepared according to the method of Beyer and Claisen.[12] All melting points are uncorrected.

3-Phenacylidene-3,4-dihydro-2(1H)-quinoxalinone (*IVa*). Preparation was essentially the same as that reported.[13] Yield 95%. Recrystallization from acetone gave IVa as yellow needles; mp 268—269°C (lit.[13,14] mp 267—268°C). Found: C, 72.84; H, 4.64; N, 10.38%.

7-Chloro-3-phenacylidene-3,4-dihydro-2(1H)-quinoxalinone (*IVb*). Into a solution of IIb (0.7 g) in ethanol (20 m*l*), a solution of sodium salt of I (1.4 g) 50% acetic acid (25 m*l*) was dropped with stirring. After the mixture had been stirred for further 2 hr, it was allowed to stand overnight. The precipitated crystals (84% yield) were recrystallized from hot dimethyl sulfoxide to give IVb as yllow prisms; mp 323°C.

Found: C, 64.58; H, 3.88; N, 9.37%. Calcd for $C_{16}H_{11}O_2N_2Cl$: C, 64.34; H, 3.68; N, 9.38%.

The other compounds were synthesized in a similar manner.

3-Phenacylidene-3,4-dihydro-2(1H)-benzo[g]quinoxalinone (*IVc*). Yield 61%. Orange-yellow needles from dimethyl sulfoxide; mp 343°C.

Found: C, 76.62; H, 4.59; N, 9.27%. Calcd for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%.

3-Phenacylidene-3,4-dihydro-2H-1,4-benzoxazin-2-one (*Va*). Yield 72%. Orange-yellow prisms from acetone; mp 200—201°C (lit.[15,16] mp 201°C). Found: C, 72.65; H, 4.20; N, 5.60%.

6-Methyl-3-phenacylidene-3,4-dihydro-2H-1,4-benzoxazin-2-one (*Vb*). Yield 86%. Yellow prisms from acetone; mp 174.5—175°C.

Found: C, 73.40; H, 4.81; N, 5.31%. Calcd for $C_{17}H_{13}O_3N$: C, 73.11; H, 4.69; N, 5.02%.

6-Chloro-3-phenacylidene-3,4-dihydro-2H-1,4-benzoxazin-2-one (*Vc*). Yield 74%. Yellow prisms from acetone; mp 212—213°C.

Found: C, 64.25; H, 3.42; N, 4.80%. Calcd for $C_{16}H_{10}O_3NCl$: C, 64.12; H, 3.36; N, 4.67%.

3-Phenacylidene-3,4-dihydro-2H-naphtho[2,1-b]-1,4-oxazin-2-one (*Vd*). Yield 89%. Orange fibers from acetone; mp 200—200.5°C.

Found: C, 75.90; H, 4.15; N, 4.72%. Calcd for $C_{20}H_{13}O_3N$: C, 76.18; H, 4.16; N, 4.44%.

11) IR spectral data also support a lactam structure of IV, as shown in the structurel formulae, but not lactim. This partial structure is the same in dimethyl sulfoxide-d_6, as proved by NMR spectroscopy. In spite of a reasonable interpretation of the NMR spectra in trifluoroacetic acid, the possibility of decomposition in the acid may not be ruled out because of the variety of signals.

12) C. Beyer and L. Claisen, *Ber.*, **20**, 2181 (1887).

13) S. Fatutta and A. Stener, *Gazz. Chim. Ital.*, **88**, 89 (1958).

14) Reported as 3-phenacyl-2(1*H*)-quinoxalinone.

15) E. Biekert, D. Hoffmann, and F. J. Meyer, *Chem. Ber.*, **94**, 1664 (1961).

16) Reported as 3-phenacyl-2*H*-1,4-benzoxazin-2-one.

Hydrolysis of IVa. A suspension of IVa (0.75 g) in 2 N sodium hydroxide (25 m*l*) was refluxed for 1 hr. The reaction mixture soon turned into a solution upon heating. Into the solution, after cooling, 6 N hydrochloric acid was dropped with stirring until it remained slightly alkaline. The hydrolysate was repeatedly extracted with chloroform. From the combined extracts, the solvent was removed *in vacuo*, and the residue was recrystallized from ethanol to give 3-methyl-3, 4-dihydro-2(1*H*)-quinoxalinone (VIa) (0.28 g) as colorless needles; mp 243—244°C, undepressed on admixture with a sample which had been prepared.[2] Found: N, 17.57%.

The aqueous layer was acidified with 6 N hydrochloric acid, and extracted with ether repeatedly. Ether was removed from the combined extracts, and the residue was recrystallized from ethanol to afford benzoic acid (VII) (0.29 g) as colorless plates; mp 122—122.5°C, undepressed on admixture with a commercial sample. The product VII was UV-spectroscopically identical with the sample.

Hydrolysis of Va. A solution of Va (1.20 g) in a mixture of acetic acid (40 m*l*) and 6 N hydrochloric acid (20 m*l*) was refluxed for 2 hr. After it had been cooled, the hydrolysate was extracted with benzene three times. The combined extracts were dried over anhydrous sodium sulfate, and the solvent was removed. The residue (0.61 g) was recrystallized from ether to give benzoylpyruvic acid (VIII) as yellowish prisms; mp 155—156°C. (lit.[11] mp 155—156°C), undepressed on admixture with a sample prepared according to literature. Its identity was also proved by UV spectroscopy. The acidity of the aqueous layer was reduced to pH 5 by adding sodium hydrogencarbonate powder, and the aqueous solution was extracted with ether three times. The combined extracts were dried over anhydrous sodium sulfate, and ether was removed. The residue was recrystallized from ethanol to afford *o*-aminophenol (IIIa) (0.48 g); mp 172—174°C, undepressed on admixture with a commercial sample used for the synthesis of Va. UV spectra proved its identity.

From the mother liquors, small amounts of VII and pyruvic acid (IX) were isolated (IX was precipitated as its 2,4-dinitrophenylhydrazone). They were identified by mixed melting points and UV spectroscopy. When Va was refluxed with 6 N hydrochloric acid for 3 hr, the yields of VII and IX which were probably derived from the partial hydrolysis of VIII, increased.

Hydrolyses of the Other Compounds. The hydrolyses of IVb, c and Vb–d were performed in a similar manner to that described above. The corresponding 3-methyl-2(1*H*)-quinoxalinones (VIb,c) were obtained from IVb,c in similar yields and were identical with the respective samples prepared[3] by the mixed melting points and by comparison of their UV spectra. From Vb–d, the corresponding *o*-aminophenols (IIIb–d) and VIII were formed, and their identity with those used for the syntheses of Vb–d was similarly checked by means of melting points and UV spectra.

Similar results were obtained from the hydrolyses of IVa–c with hydrochloric acid and those of Va–d with sodium hydroxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1321—1327(1971)

The Oligomerization of Butadiene with Nickel Complexes Produced by Means of the Electrolysis of Nickel(II) Chloride

Takayuki OHTA, Keisuke EBINA, and Noboru YAMAZAKI
Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 23, 1970)

The oligomerization of butadiene has been found during the electrolysis of solutions containing nickel(II) chloride and electron donors. The oligomerization was affected by the nature of the electron donors used. When the ethanolic solutions of tetrakis(pyridine)nickel(II) chloride or nickel(II) chloride and pyridine with tetra-*n*-butyl ammonium perchlorate or methanolic solutions without the perchlorate were electrolyzed in the presence of butadiene, a number of linear and dihydrogenated oligomers, with small amounts of branched oligomers, were obtained. The main oligomers were identified as *n*-octadiene, *n*-dodecatriene, and *n*-hexadecatetraene. By adding triphenylphosphine to the reaction system in place of pyridine, *n*-octatriene and alkoxyoctadiene were catalytically produced instead of hydrooligomers, accompanied by tetrakis(triphenylphosphine)nickel(0). A mechanism involving π-allyl intermediates was proposed for the oligomerization.

It has been known that butadiene is oligomerized selectively to cyclic dimers and trimers with various catalyst systems containing lower-valency transition-metal compounds. Recently, several reports on the linear dimerization of butadiene by cobalt,[1] iron,[2] rhodium,[3] palladium,[4] and nickel[5] catalysts have been

presented.

In a previous paper,[6] we reported that dihydrogenated linear dimers, trimers, and tetramers of butadiene were obtained with catalysts composed of nickel (II) chloride, electron donors, and lithium aluminum hydride or sodium borohydride. In the course of our studies of the synthesis of oligoolefin-metal complexes by means of the electrolytic reduction of metal salts, a novel tetramer of butadiene has been found.[7] We have also studied the oligomerization of butadiene in detail. This paper will deal with the results of butadiene oligomerizations by means of the electrolysis of alcoholic solutions containing nickel(II) chloride and electron donors, and with the identification of the oligomers obtained.

Experimental

Materials. Methyl and ethyl alcohols were purified and dried with the corresponding magnesium alkoxides according to the method by Lund and Bjerrum.[8] Ethyl ether was dried over Na and then with $LiAlH_4$, and distilled under a nitrogen stream. Butadiene was dried with $LiAlH_4$ and freshly distilled before use. Triphenylphosphine was recrystallized from ethyl alcohol. Pyridine, piperidine, and triethylamine were distilled over sodium hydroxide under nitrogen. Nickel(II) chloride, tetrakis(pyridine)nickel(II) chloride, and tetra-*n*-butylammonium perchlorate were prepared according to the known procedures and were purified by the usual methods.[9]

A, ammeter; V, voltameter; 1, electrode; 2, sintered glass disk; 3, magnetic stirring bar

Electrolyses. The electrolyses were carried out in the modified H-type glass cell shown in Fig. 1. In a typical experiment, a cell equipped with a stopcock and containing 25 mmol of tetrakis(pyridine)nickel(II) chloride and magnetic stirring bars was dried under a vacuum. The atmospheric pressure was then restored using purified nitrogen. Under a blanket of nitrogen, 180 m*l* of methyl alcohol was transferred to the cell, which was then cooled in a dry ice-methyl alcohol bath and degassed on a vacuum system. Under a vacuum, butadiene was introduced *via* the trap-to-trap method. The stopcock connecting the cell to the vacuum line was then closed, and the electrolyte was warmed to the room temperature. The electrolysis was performed at ambient temperature, with the terminal voltage maintained at about 50 V for 20—40 hr; during this time, an amount of electricity of 2 Faradays per mol of nickel(II) chloride, as calculated from the current and time, was passed through the solution. The current was almost constant throughout the electrolysis, being 30 mA in ethyl alcohol and about 70 mA in methyl alcohol.

After electrolysis, the catholyte was treated with dilute hydrochloric acid in order to destroy the produced nickel complexes, which consisted of an oligoolefin, pyridine, and nickel. A mixture of the butadiene oligomers formed was extracted with diethyl ether, followed by washing with water and drying over anhydrous sodium sulfate, and concentrated under reduced pressure. Then the oligomers were fractionated by distillation.

Analyses. The amounts of all the oligomers obtained herein were calculated from the calibration curve for cyclododeca-1,5,9-triene, assuming that the molar responses of the dimers, trimers, and tetramers of butadiene to cyclododeca-1,5,9-triene are 1.25, 1, and 0.8 respectively, (It has been observed that the molar responses of 1-octene and hexadeca-1,6,10,14-tetraene to cyclododeca-1,5,9-triene are 1.25 and 0.8 respectively). The yields of the oligomers were based on the amounts of butadiene introduced. Each oligomer was isolated by fractional distillation and or by preparative gas chromatography, and their structures were verified by IR, NMR, and mass spectrometries and by elemental analyses.

A gas chromatograph (Shimadzu Seisakusho Ltd., GC-4APT) fitted with a copper tube (3 mm × 3 m) packed with Apiezon grease-L on Diasolid was employed to detect and determine dimeric, trimeric, and tetrameric isomers. The gas chromatograph was operated under the following conditions: for the analyses of the dimers of butadiene, the temperatures of the column and the injection part were 120 and 200°C respectively, and the hydrogen flow rate was 60 m*l*/min. For trimers and tetramers, the temperatures of the column and the injection part were 180 and 200°C respectively, and the hydrogen flow rate was 120 m*l*/min. In order to isolate the respective oligomers, a gas chromatograph (Ohkura-Rikagaku) fitted with a copper tube (4 mm × 2 m) packed with Apiezon grease-L or polydiethylene glycol succinate on Diasolid was used under the same conditions as those presented above.

The infrared spectra were recorded on a Jasco IR spectrophotometer, Model IR-G, as a liquid film, the UV and visible spectra, on a Shimadzu Model SV-50A spectrophotometer, the NMR spectra, at 60 MHz on a JEOL Model C-60 in a carbon tetrachloride solution, with tetramethylsilane as the internal standard, and the mass spectra, on a Hitachi Model RMU-5B.

Identification of Oligomers. The results of the IR and NMR spectra, the elemental analyses, and the molecular-weight measurements of each oligomer of butadiene are shown in Table 1. On the basis of these results, the four oligomer fractions, 3-MOD, 1-MOD, 3-EOD, and 1-EOD, were confirmed to be 3-methoxyocta-1,7-diene, 1-methoxyocta-2,7-diene, 3-ethoxyocta-1,7-diene, and 1-ethoxyocta-2,7-diene respectively. On the contrary, to the other oligomer fractions, P-6, P-7, P-9, P-10, and P-11, many isomeric structures

which give essentially identical IR and NMR spectra can be derived from the results of their spectrometric analyses. However, in view of the formation mechanism of the oligomers described in a following section, the structures of P-6, P-7, P-9, P-10, and P-11 of the oligomer fractions may be assumed to be 5-vinyldeca-2,8-diene, 3-methylundeca-1,5,10-triene, 1-methoxydodeca-2,6,11-triene, 5-vinyltetradeca-1,8,13-triene, and *n*-hexadeca-1,6,10,15-tetraene respectively (Table 2).

The other oligomers, *n*-octa-1,6- and -1,7-diene, *n*-octa-1,3,7-triene, and *n*-dodeca-1,6,10-triene, were identified by vpc. The identification by vpc was conducted by comparing the retention times with those of authentic samples, which were prepared by the previously-described reactions.[6]

Results and Discussion

On the electrolysis of the alcoholic solutions containing nickel(II) chloride and electron donors in the presence of butadiene, the initial blue or yellow color of nickel(II) ion in the solution changed to a dark brown-red, which color disappeared in air. Using pyridine as an electron donor, a number of linear and dihydrogenated oligomers were obtained, plus small amounts of branched oligomers. By adding triphenylphosphine to the reaction system in place of pyridine, *n*-octatriene and alkoxyoctadiene were catalytically produced instead of hydrooligomers, accompanied by tetrakis(triphenylphosphine)nickel(0). In neither case were cyclic oligomers produced. The yields and selectivities of the oligomers were affected by the nature of the electron donors and solvents used (Tables 3 and 4). The current efficiency of the nickel(0) complex was about 75%, based on the 2e process.

Effects of Electron Donors on the Oligomerization of Butadiene. (I) Effects of Pyridine: When pyridine was used as the electron donor, an air-sensitive and dark brown-red solution containing oligoolefin-nickel (0) complexes was produced. The properties and structures of the complexes will be reported in a following paper. Most of the oligomers obtained by decomposing the complexes with dilute hydrochloric acid were found to be linear and dihydrogenated dimers, trimers, and tetramers. No oligomers higher than tetramers could be detected by gas chromatography or gel-permeation chromatography. A programmed-temperature gas chromatogram of a mixture of the oligomers is indicated in Fig. 2. Oligomers at the peak numbers of 6, 7, 8, 9, 10, and 11 were isolated by means of preparative gas chromatography with Apiezon grease-L and polydiethyleneglycol succinate; they were spectrometrically analyzed (Table 1). Their structures may be characterized as in Table 2. Although dimeric butadiene isomers at the peak numbers of 2 and 3 could not be separated with any of the columns employed (Apiezon grease-L, polydiethyleneglycol succinate, dioctylsebacate, and squalene), they were identified as octa-1,6- and -1,7-diene respectively by comparing the retention times with those of authentic samples. In the same way, oligomers corresponding to the peak numbers of 4 and 5 have also been found to be 3-methoxyocta-1, 7-diene and 1-methoxyocta-2,7-diene respectively.

A gas chromatogram of a mixture of those oligomers

was very close to that of the oligomers obtained by reducing tetrakis(pyridine)nickel(II) chloride with lithium aluminum hydride or sodium borohydride in the presence of butadiene.[6] This finding might suggest a similarity in mechanisms for the oligomerization in these reaction systems. For the oligomerization by the catalysts participated with the chemical reducing agents, we previously proposed a mechanism involving bis-π-allylic $C_8H_{12}Ni$ and $C_{12}H_{18}Ni$ complexes as intermediates.[6]

The yields of the oligomers were affected by the molar ratios of pyridine to nickel(II) chloride, but not by the amounts of the electric current when it was passed over two Faradays to mol of nickel(II) chloride. The maximum yield was obtained at the molar ratio two of pyridine to nickel(II) chloride.[10]

(II) Effects of triphenylphosphine: On the electrolyses of ethanolic solutions containing nickel(II) chloride, a four-fold excess of triphenylphosphine in place of pyridine, and the supporting electrolyte, the initial yellow color of the catholyte changed to a dark brown-red, and at the end of the electrolysis a brown solid precipitated. The dark brown-red color of the cathodic solution faded when it was exposed to the air.

From the cathodic solution, octa-1,3,7-triene was obtained catalytically, plus small amounts of 3-ethoxyocta-1,7-diene and 1-ethoxyocta-2,7-diene. From the anolyte were obtained small amounts of the oligomers. Probably, the oligomers formed in the catholyte were transferred through the glass filter of the cell to the anodic compartment. When methyl alcohol containing a small amount of benzene to dissolve triphenylphosphine was substituted for ethyl alcohol as a reaction medium, approximately equimolar amounts of octa-1, 3,7-triene, 3-methoxyocta-1,7-diene, and 1-methoxyocta-2,7-diene were obtained (Table 4).

The brown precipitate described above was filtered, washed with ethyl alcohol, and dried under a vacuum

a) Dimerization of butadiene was carried out in a 100-ml glass tube at 20—30°C for 48 hr
b) Based on the mole of butadiene introduced.
c) Octa-1,3,7-triene.

at room temperature. The compound was assumed to be a tetrakis(triphenylphosphine)nickel(0) complex from elemental analysis (Calcd for $C_{72}H_{60}P_4Ni$: C, 78.06; H, 5.45; Ni, 5.30. Found: C, 76.35; H, 5.05; Ni, 5.25); the yield was 87% based on nickel(II) chloride. When this complex was used separately as a catalyst for the dimerization of butadiene in ethyl or methyl alcohol containing benzene, octa-1,3,7-triene 3-alkoxyocta-1,7-diene, and 1-alkoxyocta-2,7-diene were formed; their proportions were similar to those of the oligomers produced by electrolysis in each case (Table 5). These results led us to assume that nickel (II) chloride, in the presence of triphenylphosphine, was electrochemically reduced to the tetrakis(triphenylphosphine)nickel(0), and that the resulting complex in alcohol reacted with butadiene to give, catalytically, octa-1,3,7-triene and alkoxyoctadiene. It is noteworthy that tetrakis(triphenylphosphine)nickel(0) was prepared by means of the electrolytic reduction of nickel(II) chloride in the presence of triphenylphosphine in ethyl alcohol.

Octa-1,3,7-triene and alkoxyoctadienes have also been obtained with palladium-complex catalysts or other metal complexes of the VIII group (*e.g.*, Ru and Pt).[4b)] These oligomers may be produced through a π-allyl intermediate analogous to that proposed by Wilke.[11)]

(III) Effects of Other Electron Donors: Differently from the cases of pyridine and triphenylphosphine, the addition of acetonitrile, piperidine, or triethylamine to the electrolysis system resulted in a change in the color of neither the catholyte nor oligomers, but a large amount of metallic nickel was deposited on the cathodic electrode, as in the absence of electron donors. The absence of a color change in the catholyte on electrolysis indicates that no nickel complexes were produced. The use of hexamethylphosphoramide as an electron donor gave a small amount of the oligomers, composed predominantly of the dimers.

Pyridine and triphenylphosphine have both σ-donor and π-acceptor properties and can stabilize lower-valency transition-metal complexes by a combination of the two properties. On the other hand, acetonitrile, piperidine, and triethylamine, which lack suitable low-lying empty orbitals, act only as donors and formed less robust metal complexes than pyridine and triphenylphosphine. The above facts suggest that nickel(II) chloride, in the presence of pyridine and triphenylphosphine, is electrochemically reduced to yield lower-valency nickel-electron donor complexes and that the butadiene oligomers are produced on the complexes.

Electrochemical Reduction Process of Nickel(II) Chloride In the present electrolysis systems, three components, Ni^{2+} salt, the electron donor, and butadiene, can be reduced, and three probable modes of reduction can be visualized: (1) a direct electron transfer from the cathode to the nickel ion; (2) the reduction of the nickel(II) ion with the anion radicals (or dianions) formed by the reduction of the electron donors,[12,13)] and (3) the reaction of the nickel(II) ion with the anionic species produced by direct-electron transfer from the cathode to butadiene.

It was previously reported that the electron was preferably transferred from the cathode to butadiene, followed by the initiation of anionic polymerization in the *n*-Bu_4NClO_4-dimethoxyethane system.[14)] However, in protic solvents, neither polymers nor oligomers could be obtained. The addition of nickel(II) chloride and electron donors to the electrolysis system gave a variety of linear oligomers of butadiene. Probably, the anionic species produced by path (3) would react with the solvent prior to reacting with nickel(II) chloride.[15)] These results may exclude path (3). In the absence of electron donors, small amounts of oligomers were obtained, plus a large amount of metallic nickel. This indicates that nickel(II) chloride was electrochemically reduced through path (1). A half-wave potential of $Ni(pyridine)_4^{2+}$, -0.78 V *vs.* SCE (1 M KCl, 0.5 M pyridine)[16)] is less negative than those of butadiene ($E_{1/2}=-3.27$ V *vs.* SCE in dimethoxyethane).[14)] pyridine ($E_{1/2}=-2.48$ V or less in pyridine),[12)] and triphenylphosphine ($E_{1/2}=-2.70$ V in dimethylformamide);[13)] this finding also supports path (1).

On the basis of these results, we assume that path (1) is predominant for the primary electrode process, although path (2) cannot be ruled out.

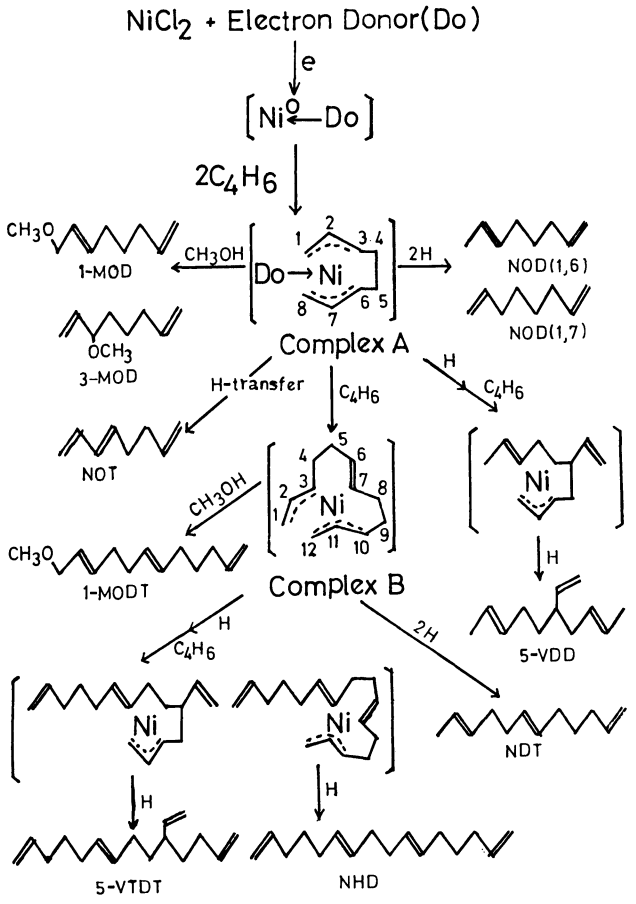

Fig. 3. A scheme for the oligomerization.

Mechanism of Oligomerization. The dark brown-red solution produced on the electrolysis of tetrakis(pyridine)nickel(II) chloride in the presence of butadiene was concentrated by evaporating methyl alcohol, unreacted butadiene, and free pyridine. The resulting dark brown-red compound was soluble in benzene and methyl alcohol to give brown-red solutions which were air-sensitive and which gradually decomposed to nickel metal and the corresponding oligomers at room temperature. The UV and visible spectra of the compound in *n*-hexane showed the maximum absorptions at 290—295 mμ ($\varepsilon \sim 3.2 \times 10^3$) and 422 m$\mu$ ($\varepsilon \sim 5.9 \times 10^2$); these absorptions disappeared in air. In its infrared spectrum, absorptions at 1000, 910, and 965 cm^{-1} due to terminal and trans-internal double bonds were observed. A far-infrared spectrum of the compound gave two air-sensitive absorptions at 530 and 305 cm^{-1} and showed two air-sensitive absorptions at 630 and 430 cm^{-1} due to pyridine coordinated to nickel. These results led us to assume that nickel complexes bonded with π-allylic structure of oligoolefins, such as octa-2,6-diene-1,8-diyl(pyridine)nickel(0), complex A, and dodeca-2,6,10-triene-1,12-diylnickel(0), complex B, shown in Fig. 3, were produced in the catholyte. When triphenylphosphine was used instead of pyridine, the resulting complex, tetrakis(triphenylphosphine)nickel (0), has been found to catalyze the dimerization of butadiene to *n*-octatriene and alkoxyoctadiene (Table 4).

On the basis of these findings, a mechanism for the oligomerization of butadiene by means of the electrolysis of alcoholic solutions containing nickel(II) chloride, electron donors, and butadiene may be proposed to be as follows. Nickel(II) chloride is electrochemically reduced to give electron donor-nickel(0) complexes, and butadiene is reacted with the complexes to yield complexes A and B (Fig. 3); then the 1,6- or 3,6-carbon of C_8H_{12} in complex A and the 1,10-carbon of $C_{12}H_{18}$ in complex B are hydrogenated or alkoxylated to octa-1,6- and -1,7-diene, and dodeca-1,6,10-triene or 1-alkoxyocta-2,7-diene, 3-alkoxyocta-1,7-diene, and 1-alkoxydodeca-2,6,11-diene respectively. In the formation of a linear tetramer and a branched trimer and tetramer, one hydrogen atom attacks the 1-carbon of a π-allylic group of complex A and the 3-carbon of a π-allylic group of complex B to destroy a rare gas structure of nickel atom and activate the other π-allylic groups of complexes A and B. Then one molecule of butadiene is inserted in the bond between the nickel atom and the 6-carbon of complex A or the 10- or 12-carbon of complex B, and the $C_{12}H_{19}$ or $C_{16}H_{25}$ produced on the nickel atom is hydrogenated to 5-vinyldeca-2,8-diene, and 5-vinyltetradeca-1,8,13-triene or hexadeca-1,6,10,15-tetraene.

It has been reported that cyclic dimers were formed *via* $C_8H_{12}NiPR_3$, similar to complex A in the reaction of butadiene with $Ni(CO)_2(PR_3)_2$ in benzene,[11] whereas octa-1,3,7-triene, accompanied by small amounts of octa-2,6-diene and acetone, were formed in isopropyl alcohol and monodeutrated octa-1,3,7-triene in C_6H_5OD.[17] In the IR spectra of a mixture of dimers obtained by means of electrolysis, an absorption at 1740 cm^{-1} due to the aldehyde group was observed. These facts suggest that the octa-1,3,7-triene obtained herein may be produced by the hydrogen transfer of C_8H_{12} in a complex with alcohol, and that hydrogen required for the hydrooligomerizations may originate from the alcohol used as a solvent.

The Zinc Bromide-catalyzed Rearrangement of Pulegone Oxide and Piperitone Oxide

Hajime WATANABE, Jun KATSUHARA, and Noriyuki YAMAMOTO
Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka
(Received July 29, 1970)

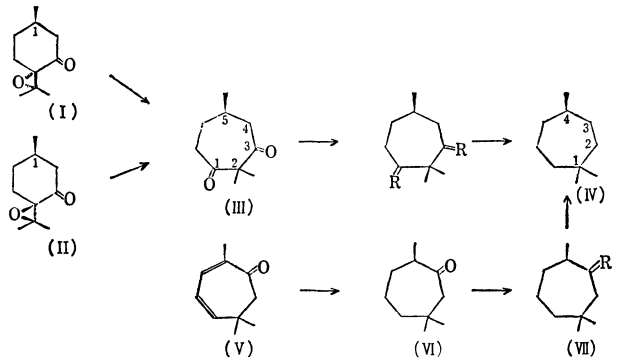
The rearrangement of (+)-*cis*- (I) and (−)-*trans*-pulegone oxide (II) was effected by the catalysis of zinc bromide in boiling benzene to give the same (−)-2,2,5-trimethylcyclohepta-1,3-dione (III), with a retention of the optical activity. The structure of (−)-III with the expanded 7-membered ring was confirmed by the chemical transformation into 1,1,4-trimethyl-cycloheptane(IV), which was identical with that derived from eucarvone(V). Piperitone oxide(VIII) was also converted into diosphenol(X) in the same manner as in pulegone oxides.

Reusch[1] has recently reported that both (+)-*cis*- (I) and (−)-*trans*-pulegone oxide (II), upon gas-phase pyrolysis at 200°C, yielded the same crystalline solid melting at 50—51°C; its structure was suggested to be 2,2,5-trimethylcycloheptane-1,3-dione on the basis of the IR and NMR spectra alone.

We also have obtained a colorless crystal (III), mp 55—56°C, by treating I or II with zinc bromide in boiling benzene according to the Settine procedure.[2] A comparison of the elemental analysis and the NMR, IR, and mass spectra of III with those of the Reusch compound described in the literature[1] has shown the identity of these two compounds, although there is a slight difference in their melting points. No description has been reported for the optical activity of the Reusch compound; however, levo-rotation is found for III in the present work.

We now wish to describe the confirmation of the structure proposed by Reusch and the stereochemistry of this compound, as determined by means of unambiguous chemical transformation.

Eucarvone (V) (semicarbazone, mp 184°C) was hydrogenated over palladium charcoal to give the corresponding tetrahydro-compound (VI), which was converted into the tosylhydrazone (VII) and then reduced with lithium aluminum hydride to yield 1,1,4-trimethylcycloheptane (IV).



Scheme 1

On the other hand, (−)-III was converted, *via* its ditosylhydrazone, into IV. The identity of these two oily products (IV), obtained by different transformations, was shown by a comparison of their physical properties and IR and NMR spectra. This conversion provides further convincing evidence for the 2,2,5-trimethylcycloheptane-1,3-dione structure of the Reusch dione as well as for that of the (−)-III obtained by the present authors. Since the configuration at C-5 of the rearrangement product, (−)-III, must be the same as that (R-) at the C-1 of the parent compounds, (+)-*cis*-I and (−)-*trans*-II, the R-configuration can safely be assigned to the C-5 of (−)-III.

Piperitone oxide (VIII), upon treatment with zinc bromide in boiling benzene, gave diosphenol (X).

The zinc bromide-catalyzed rearrangements of I, II, and VIII in the present work seem to proceed *via* ionic intermediates; this is contrast to the thermal and photochemical rearrangements,[1,3-5] which have been looked upon as proceeding through radical pathways and which may be reasonably interpreted in terms of anionotropy.[6]

By Lewis-acid catalysis, the oxirane ring of piperitone oxide (VIII) undergoes heterolytic fission so as to form the most stable inoic intermediate (IX), in which the positive charge resides on the tertiary carbon, 1; there follows the 1,2-hydride shift (anionotropy), which fulfils the electron deficiency of the carbonium center, as is shown in Scheme 2. The same mechanism can be given for the formation of III (Scheme 3).

Under the same circumstances, the epimeric pule-

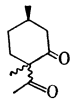
gone oxides, (+)-I and (−)-II, are converted into the transient polar-state intermediate (XI in Scheme 3), which then spontaneously rearranges with the anionoid migration of the carbonyl group (C-3) bearing the more negative charge. This mode of rearrangement can reasonably be preferred to that involving the migration of the C-5 methylene residue with the less negative charge. The intermediate (XI) should also be preferred, on the same basis, to an alternative which would lead to XII, the product obtained by the photo-induced rearrangement.[3-5]



(XII)

It should be noted that the ground-state reaction under the acid catalysis of both epimeric epoxides (I) and (II) produced exclusively (−)-III, with an expanded carbocycle resulting from the anionotropy of the carbonyl group, while the photo-induced rearrangement (excited-state reaction) afforded the isomeric diketone (XII),[3-5] which resulted from the rather unusual methyl migration, and the pyrolysis gave a mixture of the two.[1]

Experimental

Zinc Bromide-catalyzed Rearrangement of Pulegone Oxide. (+)-*cis*-Pulegone oxide (mp 59°C, $[\alpha]_D^{20}$ +46.6° (*c* 0.3, methanol), 6.4 g: 0.038 mol) was boiled with zinc bromide (3.2 g: 0.014 mol) in dry benzene (200 m*l*) for 6 hr. After this period, water was added to the reaction mixture and it was extracted with ether. The combined extract was dried and the solvent was removed to give a crude crystalline product, III-a, (5.8 g, 90%), which melted at 55—56°C after several recrystallizations from petroleum ether.

Found: C, 71.23; H, 9.61%. Calcd for $C_{10}H_{16}O_2$: C, 71.37; H, 9.59%. $[\alpha]_D^{25}$ −81.6° (*c* 1.15, ethanol). IR spectrum: 1690 (cm^{-1}), 1730, 1370, 1355. NMR spectrum: τ 8.99 doublet 3H (-CH_3). τ 8.79 singlet 6H (-C(CH_3)$_2$). CD: mμ ([θ] in methanol) 342(0), 313.5(−8170), 240(0), 212 (+11100); mμ ([θ] in isooctane) 345(0), 325(−7830), 321(−7030), 315(−9790), 307(−7680), 304(−4900), 240—225(0), 210(+15500).

(−)-*trans*-Pulegone oxide (II: mp 54—55°C; $[\alpha]_D^{20}$ −18.8° (*c* 2.4, ethanol); 0.4 g; 0.0024 mol) was treated with zinc bromide (0.2 g, 0.0089 mol) in benzene (25 m*l*) in exactly the same manner as has been described above and then worked up to give III-b (mp 55—56°C 0.32 g, 80%). The melting point of this crop was not depressed by the admixture of III-a. The IR- and NMR spectroscopical comparisons, as well as the polarimetrical comparisons, corroborated the identity of these two crops, III-a and III-b, from different sources.

Reduction of 2,2,5-Trimethylcycloheptane-1,3-dione (III). According to the usual procedure in the literature,[7] (−)-III was converted into ditosylhydrazone (mp 262°C); a 2-g portion was then reduced with lithium aluminum hydride (1.2 g) to yield an oily product (IV) after purification by means of preparative vpc; yield, 0.1 g (14%). The optical activity of this compound was substantially null at the wavelength of sodium D-line, but it seemed to possess a feeble dextrorotation in the shorter-wavelength region.

Reduction of Eucarvone (V). Eucarvone (V; its semicarbazone, mp 184°C) was hydrogenated over palladium charcoal (150 mg) to yield tetrahydroeucarvone (VI; its semicarbazone, mp 190°C; yield, 1.8 g (90%). The tosylhydrazone of VI (mp 262°C; 0.3 g, 0.0009 mol) was reduced with lithium alminium hydride (0.46 g) and then worked up as usual[7] to yield a liquid, 1,1,4-trimethylcycloheptane (0.11 g, 84%). The IR and NMR spectra of this compound were identical in every respect with those of IV.

Zinc Bromide-catalyzed Rearrangement of Piperitone Oxide. In the same manner as with pulegone oxides (*vide supra*), (−)-piperitone oxide (3 g, 0.0178 mol) was treated with zinc bromide (1 g) in benzene (200 m*l*) and then worked up to give crude diosphenol (1.8 g, 60%), which, after washing with a 3% sodium bicarbonate solution and recrystallizations, melted at 82—83°C. The melting point was not depressed at all by the admixture of the authentic specimen prepared from menthone.

The authors wish to thank Professor Yuzo Inouye of Kyoto University, and Dr. Hitoshi Minato and Dr. Kaoru Kuriyama of the Shionogi Research Laboratory for many helpful discussions during the course of this work. Thanks are also due to Dr. Shigeru Muraki of the Takasago Perfumery Co. for his measurements of the NMR and mass spectra.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XVIII

Yoshiharu IZUMI and Kazuo OHKUBO

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received September 7, 1970)

The asymmetric activities of the catalysts modified with L-α-amino and L-α-hydroxy acids, which have two asymmetric centers on α, β and α, γ-carbons were studied, and the participation of the β- and γ-configurations to the asymmmetric activity of the catalyst was made clear. It was found that the S:β-configuration and the S:γ-configuration increase the asymmetric activity of the + and − directions respectively.

The asymmetric hydrogenation with a modified Raney nickel catalyst has been widely studied by our research group on the basis of the relationship between the stereochemical structures of the modifying reagents and the asymmetric activities of the modified catalyst.[1] The studies have mainly been done using α-amino or α-hydroxy acids which have one α-asymmetric carbon; it was found that the catalysts modified with L-α-amino and L-α-hydroxy acids predominantly give (−) and (+)-3-hydroxybutyrate respectively in the asymmetric hydrogenation of methyl acetoacetate.[2,3]

In order to elucidate the participation of the β- or the γ-asymmetric center of the modifying reagents to the asymmetric activities of the catalysts and to make clear the relationship between the diastereoisomeric structures of the modifying reagents and the asymmetric activities of the catalysts, the asymmetric activities of the catalysts modified with α-amino or α-hydroxy acids, which have two asymmetric centers, have been studied in the present investigation.

Moreover, the effect of the configuration of the β-methoxyl group was also investigated using the diastereomers of *O*-methylthreonine and compared with that of the β-ethyl group of the diastereoisomers of isoleucine.

Experimental

Materials. Modifying Reagents: The optical rotations of the modifying reagents used in this study are listed in Table 1.

Preparation, Modification and Measurement of the Asymmetric Activities of the Catalysts. The preparation of the R-Ni catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activities of the catalysts were carried out by the procedures described in the previous paper.

The catalysts were modified with 1% aqueous solutions of modifying reagents at isoelectric points for the amino acids, and at pH 2.9 for the hydroxy acids, by the procedure described in the previous paper.

Results and Discussion

Asymmetric Activity of the Catalyst Modified with Diasymmetric Amino and Hydroxy Acid. The asymmetric activities of the catalysts modified with diastereomers of L-isoleucine, L-β-methylnorleucine and L-β-methylleucine are listed and compared with that of the one modified with valine in Table 2.

As can be seen in Table 2, the asymmetric activities

of the catalysts modified with these amino acids at 100°C are higher than those of the catalysts modified at 0°C, and the catalysts modified with threo-isomers have higher asymmetric activities than with corresponding erythro-isomers, whether the modifying temperature is 0°C or 100°C.

Furthermore, the asymmetric activity of the catalyst modified with valine was slightly lower than those of the catalysts modified with erythro-isomers, which are less active than the threo-isomers.

In the cases of modifications with diasymmetric L-2-hydroxy-3-methylvaleric acid, L-2-hydroxy-3-methylcaproic acid, and L-2-hydroxy-3-methylisocaproic acid, scarcely no simple correlation was observed between the asymmetric activities of the catalysts and the diastereomeric configurations of the modifying reagents, and, in some cases, the asymmetric direction of the catalysts was inverted, as is shown in Table 3.

As has been mentioned above, a considerably strong effect of the β-configuration of the modifying reagent on the asymmetric activity of the catalyst is observed in the cases of modifications with both amino and hydroxy acids, and the effect of the β-configuration of hydroxy acid often overcomes that of the α-configuration. The mode of the contribution of the β-configuration of the modifying reagent to the asymmetric activity of the catalyst can ben concluded from the results shown in Tables 2 and 3; the S:β-configuration brings the asymmetric activity of the + direction[4] to the catalyst, and the R:β-configuration brings the asymmetric activity of the − direction, without regard to the kind of modifying reagent, whether amino or hydroxy acid.

The effect of the γ-asymmetric center of the modifying reagent on the asymmetric activity of the catalyst was

4) Asymmetric direction of the catalyst. The asymmetric activity consists of two factors; one is presented as the value of the optical purity of the product of the asymmetric hydrogenation, and the other is presented by the sign + or − and correlates with the absolute configuration of the product. In usual discussions, the asymmetric activity of the catalyst is discussed only in connection with the former factor. However, in a special case, the second factor has to be discussed as the problem of the "asymmetric direction of the catalyst."

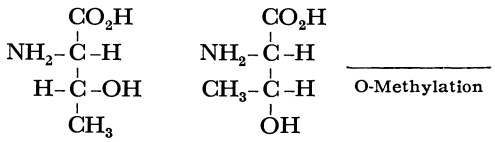
investigated using L-(2S:4S)-γ-methylnorleucine, L-(2S:4R)-γ-methylnorleucine, L-(2S:4S)-2-hydroxy-4-methylcaproic acid, and L-(2S:4R)-2-hydroxy-4-methylcaproic acid as the modifying reagents, while the asymmetric activities of the catalysts modified with these α,γ-diasymmetric amino acids or hydroxy acids were compared with those with norvaline, leucine and norleucine.

The difference between the asymmetric activities of the catalysts modified with L-(2S:4S)-γ-methylnorleucine and those modified with L-norvaline, L-leucine and L-norvaline can be hardly observed in Table 4. However, when the asymmetric activities of the catalysts modified with two diastereoisomers of γ-methylnorleucine were compared, the effect of the γ-asymmetric center was observed; the catalyst modified with L-(2S:4S)-diastereoisomer has a higher asymmetric activity than the one with L-(2S:4R)-diastereoisomer.

From those results, it seems that the S:γ-methyl group of the amino acid used as a modifying reagent does not increase the asymmetric activity of the catalyst. On the other hand, the R:γ-methyl group of the modifying reagent considerably decreases the asymmetric activity of the catalyst; that is, the R-configuration of γ-carbon brings the asymmetric activity of the + direction and has an effect on the asymmetric activity of the catalyst opposite to that of the R:β-configuration.

On the other hand, in the cases of the modifications of the diastereoisomer of the hydroxy acids, the asymmetric activities of the catalysts modified with these hydroxy acids were too low for us to discuss the exact role of the γ-asymmetric center in the asymmetric activities of the catalysts.

As is shown in Table 5, *threo-O*-methylthreonine has less ability as a modifying reagent than does *erythro-O*-



L-Threonine

methylthreonine, contrary to the results obtained in the cases of the modifications with α,β-diasymmetric amino acids. Furthermore, the asymmetric activities of the catalysts modified with the two diastereoisomers of *O*-methylthreonine are both considerably lower than those of catalysts modified with isoleucine isomers:

These results can be understood as follows. If the CH_3-C-C-COOH structure is replaced by CH_3-O-C-C-COOH as the main chain in *O*-methylthreonine, as is shown by the Fischer diagram in Fig. 1, because the methoxyl group is bulkier than the methyl group, the L-threo-isomer corresponds with L-isoleucine and the L-erythro-isomer corresponds with L-alloisoleucine. Accordingly, the relationship between the asymmetric activities of the catalyst and the configurations of the α,β-diasymmetric amino acid used as the modifying reagent is also established in the case of *O*-methylthreonine.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XX. The Effect of Additives on the Asymmetric Activity

Fukuji HIGASHI,* Toshio NINOMIYA, and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received October 24, 1970)

The effects of various additives in methyl acetoacetate were tested in the asymmetric hydrogenation reaction. Among them, water has a particular effect on the asymmetric activities of the catalysts; in the presence of a certain amount of water, the catalysts modified with L-Glu, L-Val, and L-Ala hydrogenated methyl acetoacetate to methyl $L_S(+)$3-hydroxybutyrate, while, without the addition of water, the catalysts promoted the hydrogenation to yield methyl $D_S(-)$3-hydroxybutyrate. The catalyst modified with L-Ala at pH 6.0 and the catalyst modified with L-Glu at pH 5.0 and 100°C were especially sensitive to water, and both catalysts showed (+) asymmetric activity when a trace of water was also present. Even in the hydrogenation without the addition of water, the recovered catalysts modified with L-Glu, L-Val, and L-Ala from the hydrogenation in the presence of water gave results similar to those in the hydrogenation in the presence of water. The effect of water as an additive was discussed, and it was concluded that the water affects the asymmetric site of the catalyst rather than the keto-enol equilibrium of the substrate.

In the previous reports of this series on asymmetric hydrogenation with a Raney nickel catalyst modified with optically active amino acid or hydroxy acid, the asymmetric activity of the catalyst has been demonstrated to be affected by the structure of the modifying reagent, and by the pH and temperature in the modifying procedures.[1)]

The present paper will report on the effects of various additives in the hydrogenation system on the asymmetric activity of the catalyst modified with L-amino acid. As modifying reagents, L-glutamic acid (L-Glu), L-valine (L-Val), and L-alanine (L-Ala) were used because the effect of the modifying temperature on the asymmetric activity of the catalyst is quite different in each case, as was shown in a previous paper.[2)]

The present paper will also discuss the particular effect of water on the asymmetric activity of the catalyst modified with L-amino acid and will refer to the irregular asymmetric activity of the catalyst modified with L-Ala at pH 6.0 and 0°C reported in the previous paper.[2)]

Experimental

The preparation and modification of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were carried out in the manner described in a previous paper.[3)]

The Addition of the Additives. The additive was introduced into the autoclave with methyl acetoacetate and the catalyst at the same time.

Recovery of the Catalyst and the Recovered Catalyst. After the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, the hydrogenation product was removed by decantation; then the catalyst was washed three times with a small amount of methanol. The catalyst thus obtained, served as the recovered catalyst in the hydrogenation of methyl acetoacetate.

Results and Discussion

Table 1 shows the asymmetric activity of the catalyst modified with L-Glu in the hydrogenation of methyl acetoacetate (MAA) in the presence of various additives. As Table 1 shows, water caused a (+) asymmetric activity of the catalyst, while other additives caused a (−) asymmetric activity of the catalyst. A similar tendency

was also observed with the catalysts modified with L-Val and L-Ala (Tables 2 and 3).

It is well known that the acetoacetic ester exists in the keto-enol mixture and that the proportion of the keto form of ethyl acetoacetate increases in the following order of the solvents: *n*-hexane (enol form 46.4%) < diethyl ether (27.1%) < ethanol (12%) < ethyl acetoacetate (7.7%) < methanol (6.9%) < acetic acid (5.7%) < water (0.4%).[4]

Therefore, in the case of MAA (94% keto form in the pure state), the proportion of the keto form of MAA in the above solvents can be considered to increase in the same order.

However, the asymmetric activity of each catalyst does not change regularly with the increase in the proportion of the keto form of the substrate, as is shown in Tables 1,2, and 3. Thus the change in the asymmetric activity of the catalyst in the presence of additives can not be explained only by the shift of the keto-enol equilibrium of MAA from the one side to the other.

On the basis of the above discussion, water seems to have a specific effect on the catalyst. Hence, the effect of water was examined in detail. The effect of water on the asymmetric activities of the catalysts modified with L-Glu, L-Val, and L-Ala at 0°C and 100°C was studied; the results are summarized in Figs. 1 and 2.

The increase in the amount of water added brought about a depression not only in the (−) asymmetric activity, but also in the (+) asymmetric activity relative to the catalysts modified with the above three amino acids, and the amount of water which caused the inversion of the asymmetric direction[5] of the catalyst from (−) to (+) was different in each catalyst.

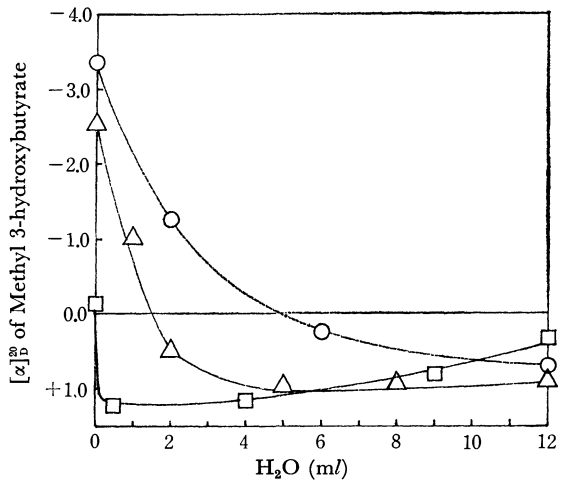

Fig. 1. Effect of water on the asymmetric activities of the catalysts modified at 0°C.
○ L-Glu (at pH 5.0)
△ L-Val (at pH 6.0)
□ L-Ala (at pH 6.0)

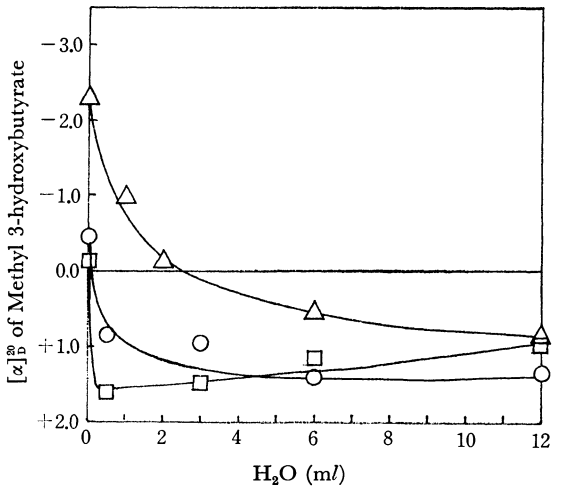

Fig. 2. Effect of water on the asymmetric activities of the catalysts modified at 100°C.
○ L-Glu (at pH 5.0)
△ L-Val (at pH 6.0)
□ L-Ala (at pH 6.0)

These facts indicate that the degree of the influence of water on the catalyst is characteristic of the modifying reagent. It may be concluded that water affects the asymmetric site of the catalyst, while it does not affect the keto-enol equilibrium of MAA; if the water affected the equilibrium, the degree of the influence of water on each catalyst would be similar.

Figures 3, 4, and 5 show the symmetric activities of the catalysts modified with L-Glu, L-Val, and L-Ala at 0°C in the hydrogenation with the addition of

▲ Asymmetric activity of the recovered catalyst under the standard hydrogenation conditions.

water and those of the recovered catalyst in the hydrogenation under the standard conditions.[6]

The catalysts recovered from the hydrogenation of MAA containing water show considerably lower (−) asymmetric activities in the standard hydrogenation of methyl acetoacetate than do the catalysts modified with L-GIu, L-Val, and L-Ala in the hydrogenation under the standard conditions. On the other hand, it has been established that both catalysts modified with these amino acids at 0°C and the recovered catalysts

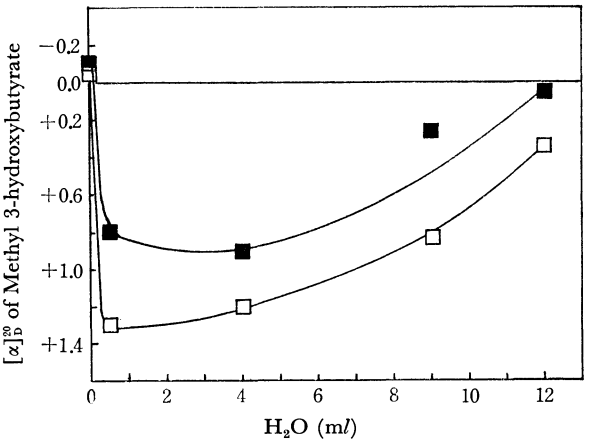

Fig. 5. Asymmetric activityes of the catalyst modified with L-Ala at 0°C and of its recovered catalyst.
□ Asymmetric activity of the catalyst in the hydrogenation with addition of water.
■ Asymmetric activity of the recovered catalyst under the standard hydrogenation conditions.

show the same asymmetric activities in the hydrogenation of MAA alone. These facts suggest that the asymmetric site of each catalyst is greatly affected by water and that water affects the recovered catalyst. If the water had no effect on the symmetric site of the catalyst, the recovered catalyst would show the same asymmetric activity as the catalyst used first under the standard conditions.

The Catalyst Modified with L-*Glu.* As has been described previously, the catalyst modified with L-Glu at 0°C shows (−) asymmetric activity, while on the other hand, the one modified at 100°C shows(+) asymmetric activity The catalyst modified with L-Glu at 100°C was studied with the expectation that the (+)asymmetric activity of the catalyst would be produced by the water absorbed during the modification.

In Fig. 6, the asymmetric activities of the catalyst modified at 100°C and those of the recovered catalyst are plotted against the number of repeated recoveries under the standard conditions.

The asymmetric activities of the recovered catalyst

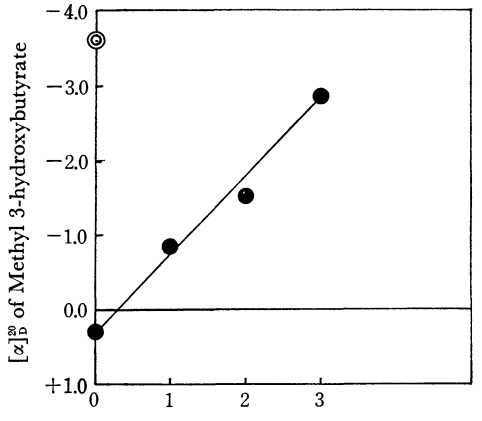

Fig. 6. Asymmetric activity of the catalyst modified with L-Glu at 100°C.
vs. Number of repeating of recovery procedure.

6) The standard hydrogenation conditions are the conditions of the hydrogenation of methyl acetoacetate alone, without any additives.

modified at 100°C gradually approaches that of the catalyst modified at 0°C. This finding suggests that the asymmetric site of the catalyst modified at 100°C is unstable and that it gradually becomes similar to the state of that modified at 0°C through the recovery procedure.

The Catalyst Modified with L-*Val.* It has been reported in a previous paper[1] that (−) asymmetric activity of the catalyst modified with L-Val does not change with the modifying temperature. However, the addition of water causes the (+) asymmetric activity in the catalyst as is shown in Figs. 1 and 2. These facts indicate that the catalyst modified with L-Val, which seems to show only (−) asymmetric activities, also include a factor inducing (+) asymmetric activity.

The Catalyst Modified with L-*Ala.* The catalyst modified with L-Ala is the most sensitive to water among the catalysts modified with the amino acids investigated, as is shown in Fig. 1. From the above fact it can be supposed that the considerably high (+) asymmetric activity of the catalyst modified with L-AIa reported in the previous paper[2] is due to the effect of the contaminant water on the catalyst surface.

As it seemed to be difficult to prevent perfectly the inclusion of water in the hydrogenation system in the ordinary modification procedure described above, it seems that the constant values of the asymmetric activities can be obtained only with difficulty with the catalysts modified with L-Ala at 0°C and 100°C, and with L-Glu at 100°C, by the standard method.

Intramolecular Interaction between Hydroxyl Group and π-Electrons. XXIV.[1] The Interaction Involving the Cyano Group

Michinori Ōki and Takashi Yoshida

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 14, 1970)

The infrared O–H stretching spectra of various 1- and 2-cyano alcohols have been measured, and the presence of intramolecular O–H···π interaction has been detected. Some discussion of the confirmation of such alcohols is given.

Various olefins and aromatics are known to behave as proton acceptors to establish interaction between the hydroxyl group and π-electrons. Since we have reported in a previous paper[1] that the π-electrons of the carbonyl group, which involves the hetero atom, can act as proton acceptors, we have now naturally extended the work to the π-electrons of the carbon-nitrogen system. Although the intramolecular interaction between the hydroxyl group and π-electrons of the cyano group was briefly treated by Allerhand and Schleyer,[2] and although the possibility of such an interaction was implied by Casadevall *et al.*,[3] more precise work has been clearly needed. The purpose of this paper is to present the results of our investigation.

Experimental

Materials. All the cyano alcohols used in this study were known compounds and were prepared according to the published methods. The purity of the sample was checked prior to use.

Infrared Spectra. The spectra were recorded on a Perkin Elmer 112 G grating spectrophotometer. The samples were dissolved in carbon tetrachloride to make up a 3—6 mmol/*l* concentration. The absorption bands due to the hydroxyl group of the 1-cyano alcohols were either completely symmetric or slightly unsymmetric. Thus, no effort was made to divide these bands into their components. On the other hand, 2-cyano alcohols showed two-peaked bands which were divided into symmetric curves, as has been described previously.[4]

Results and Discussion

1-Cyano Alcohols. The O–H stretching (ν_{O-H}) absorptions of 1-cyanocyclohexanol are given in Fig. 1.

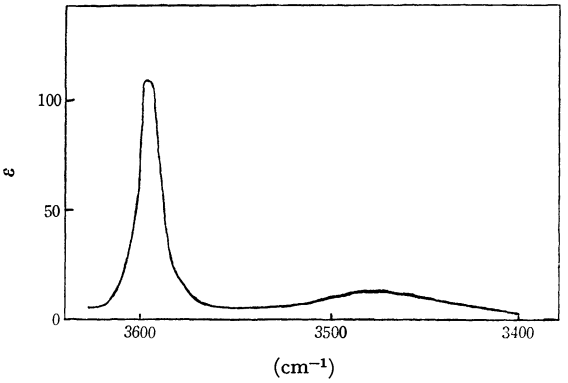

Fig. 1. The ν_{O-H} absorption of 1-cyanocyclohexanol.

1) M. Ōki, H. Iwamura, J. Aihara, and H. Iida, This Bulletin, **41**, 176 (1968).

2) A. Allerhand and P. von R. Schleyer, *J. Amer. Chem. Soc.*, **85**, 866 (1963).

3) E. Casadevall, M. Lasperas, and L. Mion, *Tetrahedron Lett.*, **1970**, 1525.

4) M. Ōki, H. Iwamura, T. Murayama, and I. Oka, This Bulletin, **42**, 1986 (1969).

It will be seen that 1-cyanocyclohexanol shows a broad and weak absorption at *ca.* 3480 cm^{-1} and a sharp and strong absorption at *ca.* 3600 cm^{-1}. This feature is generally observed with 1-cyano alcohols. Since the intramolecular O–H···N distance is too far to form a hydrogen bond, the absorption at the lower frequency may be attributed to the presence of the intermolecular hydrogen bond. Indeed, when the concentration of 1-cyano alcohol is increased, the absorption at the lower wave number increases in its intensity. The presence of the intermolecular hydrogen bond at the concentration where other ordinary alcohols exist solely as monomers may be attributed to the larger proton-donating ability of the hydroxyl group as a result of the electronic effect of the cyano group. In the following discussion, it is assumed that the effect of the absorption band resulting from the intermolecular hydrogen bond on the monomeric absorption is negligible, and so only the data on the monomeric band are given.

Table 1. The ν_{O-H} data of 1-cyano alcohols derived from ketones [RR'C(OH)CN]

R	R'	ν_{OH} (cm^{-1})
CH_3	CH_3	3601
CH_3	C_2H_5	3602
CH_3	$CH_3(CH_2)_2$	3602
CH_3	$(CH_3)_2CH$	3605
$(CH_2)_5$		3594

The data concerning the ν_{O-H} absorption of 1-cyano alcohols derived from ketones are given in Table 1. It will be seen that 1-cyano alcohols prepared from ketones show only one symmetric absorption, the location of which is fairly low when compared with the cases of normal tertiary alcohols (*ca.* 3616 cm^{-1}). The results can be interpreted in either of the following two ways: 1) All the hydroxyl groups are free; in other words, the hydroxyl group does not interact with the cyano group. The shift of the band to the lower frequency is caused by the high electronegativity of the cyano group.[5] 2) All the hydroxyl group interacts with the cyano groups, and the lower shift of the ν_{O-H} is to be ascribed to the interaction.

A comparison of the data with those of the corresponding ethynyl compounds may throw light on this problem.

Since propargyl alcohol is known from microwave spectroscopy[6] to exist solely as a conformation in which the hydroxyl group is close to the π-electrons, it is natural to assume that propargyl alcohol takes a similar conformation in solution with a nonpolar solvent. Indeed, propargyl alcohol has been reported to show only one ν_{O-H} band, at 3620 cm^{-1}, in a carbon tetrachloride solution[7]; its conformation has been suggested to be as such that the hydroxyl group and π-electrons interact because of the lower location of the band.

1-Ethynylcyclohexanol shows only one symmetric ν_{O-H} band, at 3607 cm^{-1}. Although this location could be ascribed to the ordinary tertiary alcohol, because 1-adamantanol and 1-hydroxybicyclo [2.2.2]-octane are known to give bands at 3605 and 3608 cm^{-1} respectively,[8] it is also known that other non-rigid tertiary alcohols never give the ν_{O-H} band below 3610 cm^{-1}.[9] Therefore we choose to attribute the lower location of the ν_{O-H} band of 1-ethynylcyclohexanol to the presence of the O-H···π interaction. Then, the rather large shift of the ν_{O-H} absorption of 1-cyanocyclohexanol to 3594 cm^{-1} is in the direction to be expected from the electronegativity.

Table 2. The ν_{O-H} data of 1-cyano alcohols derived from aldehydes [RCH(OH)CN]

R	ν_{OH}(cm^{-1})	β/α
CH_3	3607	1.0
C_2H_5	3611	1.44
$CH_3(CH_2)_2$	3609	1.87
$(CH_3)_2CH$	3614	1.48
$(CH_3)_3C$	3612	2.0

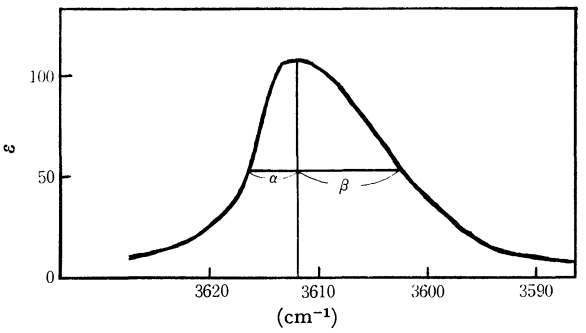

Fig. 2. The ν_{O-H} absorption of α-cyanoneopentyl alcohol, showing the notation of α and β.

Considering these factors, it is most probable to assume that the 1-cyano alcohols shown in Table 1 give only one ν_{O-H} absorption because of the sole presence of a conformer in which the hydroxyl group and π-electrons of the cyano group interact with each other.

On the other hand, 1-cyano alcohols derived from aldehydes show unsymmetric ν_{O-H} bands, as is shown in Table 2. The α and β in Table 2 are the values proposed by Rader and Aaron[10], as is shown in Fig. 2. That is, the line corresponding to the half-band-width is cross-cut by a straight line corresponding to the maximum absorption. The α value is, then, the section of the higher-frequency side, and β, that of the lower-frequency side. If the β/α value is larger than unity, it can be interpreted as that there is a small peak on the lower-frequency side. As may be seen in Table

5) In phenol derivatives, if a compound carries an electron-withdrawing substituent at the *m*- or *p*-position, the ν_{O-H} band appears at the lower frequency. See, for example, P. J. Stone and H. W. Thompson, *Spectrochim. Acta*, **10**, 16 (1957).

6) E. Hirota, *J. Mol. Sepctry.*, **26**, 335 (1968); K. Bolton, N. L. Owen, and J. Sheridan, *Nature*, **217**, 164 (1968).

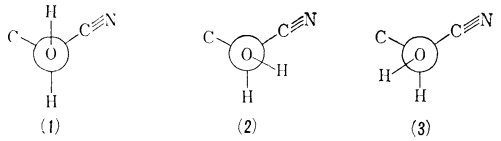
10) H. S. Aaron and C. P. Rader, *J. Amer. Chem. Soc.*, **85**, 3046 (1963); H. S. Aaron, C. P. Ferguson, and C. P. Rader, *ibid.*, **89**, 1431 (1967).

2, all the cyano alcohols derived from aldehydes except acetaldehyde give ν_{O-H} absorptions which possess β/α values larger than 1.

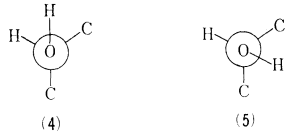
These results can also be interpreted in two ways. The two bands could arise from the free and the interacting forms of the cyano alcohols, or, the reason could be the presence of the two interacting conformations. Either way is possible, but the present authors wish tentatively to ascribe the phenomena to the second reason in consideration of the results with ketone-cyanohydrin and propargyl alcohol.



(1) (2) (3)

Three conformations, **1**, **2**, and **3**, are possible for the aldehyde-cyanohydrins concerning the rotation about the C–O axes. Since it has been assumed that all the molecules are intramolecularly O–H···π interacting species, the conformation **3** may be neglected in the following discussion. The hydroxyl proton and the cyano group are too far separated to interact with each other, and the geometry is not favorable for the interaction. There are, then, clearly two conformations in which O–H and π-systems can interact, and these conformations may be reflected in the ν_{O-H} absorptions.

Next, the question may be raised as to which conformation corresponds to the absorption at a higher frequency. There is no definite answer to this question. However, from the analogous consideration in secondary alcohols[9], the O–H absorption at the higher frequency may be assigned to the conformation **2**, since the conformation **4** of secondary alcohols is known to give rise to absorptions at higher freqencies than does the conformation **5**.



(4) (5)

To a question why aldehyde-cyanohydrins having the bulkier alkyl group give large β/α values, we wish to attribute this tentatively to the shift to the lower freqencies of absorption corresponding to the conformation **1** because of the stronger interaction caused by the proximity of the two groups due to the buttressing effect of the alkyl group. A similar effect was also observed with cyano alcohols derived from alkyl methyl ketones, where alkyl is a bulky group.

Table 3. The data of 2-cyano alcohols $RR'C(OH)CH_2CN$

R	R′	ν_h[a]	ν_l[a]	intensity ratio[b]
H	H	3634	3615	0.99
H	CH_3	3625	3607	1.83
CH_3	CH_3	3611	3593	0.69

a) The suffixes *h* and *l* refer to absorptions at higher and lower frequencies, respectively.
b) The intensity ratios were obtained by taking the ratio of the products of molecular extinction coefficients and the half-band widths after graphical separation, corresponding to the A_l/A_h value.

That is, a slightly unsymmetrical ν_{O-H} band is observed for those compounds, although it is hard to estimate the difference from unity in the β/α value because of the low degree of unsymmetrv.

2-Cyano Alcohols. The ν_{O-H} data of several 2-cyano alcohols are given in Table 3. Apparently these alcohols give two ν_{O-H} absorptions, the two maxima being separated by *ca.* 18 cm^{-1}. Although the shifts are observed with the bands at higher frequencies, they are located at the ordinary positions for the free hydroxyls when the class of the alcohols is considered. Therefore, those at the higher wave numbers are assigned to the free hydroxyl group.

The separation of the two bands at the higher and the lower frequencies, namely, *ca.* 18 cm^{-1}, is a little too large to attribute its origin to the presence of the second conformer of the alcohol. The intensity ratios are also too small to attribute to the conformational heterogeneity of the alcohols.[8,9,11] These facts together with a consideration of the molecular models, which reveals that the hydroxyl group can come close to the π-electron system, lead to the conclusion that the band at the lower wave number should be assigned to the O–H···π interacting species, although it could include absorption due to the free hydroxyl group of the second conformer in the cases of primary and secondary alcohols.

The higher intensity ratios for propylene cyanohydrin may be attributed to the steric effect between the cyano and the methyl groups, through which the conformation with the hydroxyl group and the cyano group in the gauche relation is relatively favored. However, no explanation of the results with isobutylene cyanohydrin is possible using this idea. Clearly, further study is needed to understand these numerical values.

11) The separation of the two peaks and the intensity ratio (A_l/A_h) due to the conformational heterogeneity of secondary alcohols are usually 10—14 cm^{-1} and 3—5 respectively.[8,9]

The Polymerizations of 2-Vinyl-4-acryloxy-1,3-dioxolane and 2-Vinyl-4-methacryloxy-1,3-dioxolane

Tatsuro OUCHI, Kaneyuki YOKOI, Kenzi YOSHIMURA, and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received September 16, 1970)

The polymerizations of 2-vinyl-4-acryloxy-1,3-dioxolane(VADO) and 2-vinyl-4-methacryloxy-1,3-dioxolane (VMDO), and the copolymerizations of those divinyl cyclic acetals with styrene (St) and acrylonitrile(AN), have been carried out at 60°C, using 2,2′-azobisisobutyronitrile as the initiator. They were discussed kinetically. The following results were obtained: 1) The polymerizations of the above cyclic acetals containing allylidene and vinyl groups proceeded primarily on the acryl or methacryl group, and the allylidene group was extinguished a little by means of cyclization; the ratios of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation reaction of the uncyclized radical were 0.065 mol/*l* (VADO) and 0.114 mol/*l*(VMDO). 2) The following monomer reactivity ratios were obtained at 60°C: VADO(M_1)-St(M_2) $r_1=0.22$, $r_2=0.81$; VADO(M_1)-AN(M_2) $r_1=0.89$, $r_2=0.95$; VMDO(M_1)-St(M_2) $r_1=0.51$, $r_2=0.49$. The Q and e values of the two monomers were calculated from these values: VADO, $Q=0.41$, and $e=0.65$; VMDO, $Q=0.81$ and $e=0.38$.

In previous papers, the polymerizations of cyclic acetal compounds containing two equivalent functional groups were kinetically investigated, but the difference in reactivity between allylidene and vinyl groups has not been discussed in detail.[1-4]

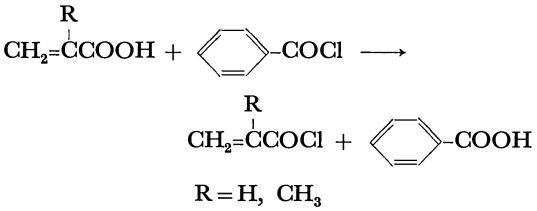
In the present experiment, the polymerization of 2-vinyl-4-acryloxy-1,3-dioxolane (VADO) was carried out; by employing the kinetic equation derived in a previous paper,[2] we will kinetically discuss our results in view of the difference in reactivity between the allylidene and acryl groups.

The polymerization of 2-vinyl-4-methacryloxy-1,3-dioxolane (VMDO) was further carried out; we will investigate the influence of the α-methyl group on the vinyl group.

The copolymerizations of the above divinyl cyclic acetals with styrene (St) or acrylonitrile (AN) were also carried out, and the reactivity ratios were estimated.

Experimental

Materials. The oxochlorides were prepared by the reactions of acrylic and methacrylic acids with benzoyl chloride in the presence of anthraquinone, according to the procedure of Stempel *et al*:[5]

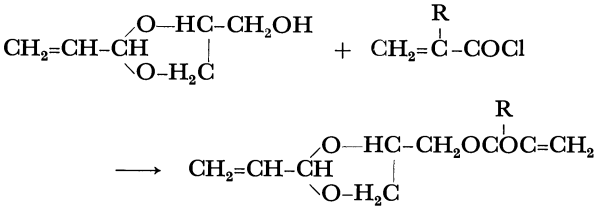


R = H, CH_3

The oxochlorides (1 mol) were slowly dropped into a mixture of 1 mol of 2-vinyl-4-hydroxymethyl-1,3-dioxolane (VHDOL), 1 mol of trimethylamine as a catalyst, 0.1 wt% anthraquinone as an inhibitor, and benzene (1500 m*l*) as a solvent at 0—3°C over a 5-hr period; the mixtures were then washed with water to remove any unreacted VHDOL, oxochlorides, and the ($(C_2H_5)_3N\cdot HCl$) salt.

The products remaining in the benzene layer were separated, dried over calcium carbonate, and then distilled *in vacuo*; VADO bp 87—89°C/2mmHg, VMDO bp 95—98°C/3mmHg. The yields were 20—25%.

The final products were confirmed to be the new monomers of VADO and VMDO by a determination of the infrared spectrum, the molecular weight (MW), the saponification value (SV), and the bromine value (BV).



R = H, CH_3

VADO Found: C, 57.89; H, 6.31%; MW, 184.6; BV, 172.2; SV, 302.5. Calcd for $C_9H_{12}O_4$: C, 58.69; H, 6.57%; MW, 184.2; BV, 173.5; SV, 304.6.

VMDO Found: C, 60.67; H, 7.21%; MW, 200.1; BV, 159.8; SV, 281.8. Calcd for $C_{10}H_{14}O_4$: C, 60.60; H, 7.12%; MW, 198.2; BV, 161.2; SV, 283.1.

The St, AN, 2,2′-azobisisobutyronitrile (AIBN), benzene, and dimethylformamide (DMF) used as the solvents were purified by conventional methods.

Polymerization Procedure. A glass ampoule was charged with the prescribed amount of each monomer, a solvent, and AIBN; it was then degassed, sealed off under a vacuum, and set in a thermostatted water bath at 60±0.1°C. The reaction solution was poured into a large amount of methanol, and the polymer thus separated was filtered and then dried *in vacuo* until it reached a constant weight. The conversion was less than 10%. The homopolymers of these divinyl acetals were purified from benzene-methanol.

The copolymers obtained on VADO or VMDO-St and VADO-AN systems were also reprecipitated from benzene-methanol and DMF-methanol respectively.

Analyses of the Polymer and Copolymer. The overall residual double bonds of the polymer and the copolymer

(allylidene+acryl) were calculated by means of the bromine values measured by the method of Siggia (BV_{a+v});[6] the residual allylidenic double bonds were then calculated by means of those determined according to the usual bromite-bromate method (BV_a).[7]

The composition of the copolymer was determined by C, H, and N elementary analyses.

The infrared spectra were measured on a Shimadzu infrared spectrophotomerte, Model IR-27.

The infrared spectra of the resulting monomer and polymer are shown in Fig. 1. The absorption peaks at 1598, 1740, and 1200—1040 cm^{-1} may be assigned to C=C, >C=O, and cyclic acetal respectively.

Results and Discussion

Homopolymerization. The VADO and VMDO polymerizations were carried out under different initiator and monomer concentrations at 60°C. The results are given in Tables 1 and 2, in which the values of BV_{a+v} and BV_a are estimated by extrapolating to zero at yield.

As can be seen from Tables 1 and 2, the residual unsaturation of the polymer, $2R_{us}$, is not equal to 1.00, and it does not depend on the initiator concentration, but decreases with a decrease in the monomer concentration. Accordingly, the polymerizations of these monomers may proceed by a mechanism of cyclopolymerization such as that of DβMPP.[2] Since the value of BV_a is nearly equal to that of BV_{a+v}, it may be considered that the pendant double bonds in the polymer almost corresponded to the allylidene groups; since the reactivity of acryl is larger than that of allylidene, it can be pointed out that the usual propagation is assumed to be related to the acryl and that the cyclization is related to the acryl and the allylidene.

Table 1. Polymerization of VADO at 60°C

(I) ($\times 10^{-3}$ mol/l)	(M) (mol/l)	R_p ($\times 10^{-4}$ mol/l·sec)	$BV^{a)}_{a+v}$	$BV^{a)}_a$	$2R^{b)}_{us}$

2.44	2.01	3.92	76.45	76.41	0.947
3.66	2.01	4.81	76.43	76.42	0.947
4.88	2.01	5.55	76.48	76.41	0.948
1.83	1.15	1.87	73.36	73.35	0.909
1.83	1.34	2.21	74.57	74.55	0.924
1.83	1.61	2.68	75.45	75.43	0.935
1.83	2.68	4.65	77.39	77.33	0.959

a) The values were obtained by extrapolating to zero for the conversion.
b) $2R_{us}=BV_{a+v}/BV_{fd}$.

The results of these homopolymerizations were then analyzed by the kinetic equations according to the following reaction scheme:

		Rate const.
Decomposition of initiator	$I \rightarrow 2R\cdot$	k_d
Initiation	$R\cdot + M \rightarrow M\cdot$	k_i
Cyclization	$M\cdot \rightarrow M_c\cdot$	k_c
Propagation	$M\cdot + M \rightarrow M\cdot$	k_p
	$M_c\cdot + M \rightarrow M\cdot$	k_{cp}
Termination	$M_c\cdot + M_c\cdot \rightarrow P_c$	$\alpha^2 k_t$
	$M_c\cdot + M\cdot \rightarrow P_c'$	$\alpha\beta k_t$
	$M\cdot + M\cdot \rightarrow P$	$\beta^2 k_t$

(1)

If a steady-state condition is assumed, Eqs. (2)—(6) can be obtained.

When the monomer concentration is kept constant, the relation of the rate of polymerization, R_p, to the initiator concentration, (I), can be written by Eq. (2):

$$R_p/(I)^{1/2} = A(I)^{1/2} + B \tag{2}$$

where:

$$\left.\begin{aligned} A &= (k_{cp}/k_c)(2fk_d)(k_p/k_{cp}-\beta/\alpha)(M) = \text{const.} \\ B &= (k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(M)\{(k_p/k_{cp}-\beta/\alpha) \\ &\quad \times (k_{cp}/k_c)(M)+1\} = \text{const.} \end{aligned}\right\} \tag{3}$$

Similarly, when the initiator concentration is kept constant, the relation between R_p and the monomer concentration, (M), can be written by Eq. (4):

$$R_p/(M) = C(M) + D \tag{4}$$

where:

6) S. Siggia, "Quantitative Organic Analysis *via* Functional Groups," 3rd ed., J. Wiley & Sons, New York and London (1963), p. 301.

7) I. P. Losev and O. Y. Fedotoba, "Praktikum po Khimii Vysokopolimernykh Soedinenii," Gosudarstvennoe Nauchno-Tekhnicheskoe Izdatelstvo Khimicheskoi Literatury, Moskova.

$$\left.\begin{aligned} C &= (k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(k_p/k_{cp}-\beta/\alpha) \\ &\quad \times (k_{cp}/k_c)(\mathrm{I})^{1/2} = \text{const.} \\ D &= (k_{cp}/k_c)(2fk_d)(k_p/k_{cp}-\beta/\alpha)(\mathrm{I}) \\ &\quad + (k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(\mathrm{I})^{1/2} = \text{const.} \end{aligned}\right\} \quad (5)$$

On the other hand, the residual unsaturation of the polymer, $2R_{us}$, is given by:

$$(1-2R_{us})^{-1} - (1+E(\mathrm{I})^{1/2}/(\mathrm{M}))^{-1} = \frac{k_p}{k_c}(\mathrm{M}) \quad (6)$$

where:

$$E = \alpha(2fk_dk_t)^{1/2}/k_{cp}$$

Influence of the Initiator and Monomer Concentrations on the Rate of Polymerization. When the monomer concentration is varied, it may be kinetically expected from Eq. (2) that the plots of $R_p/(\mathrm{I})^{1/2}$ *vs.* $(\mathrm{I})^{1/2}$ will have straight lines. Similarly, if the initiator concentration is kept constant and the monomer concentration is varied, a linear relationship between $R_p/(\mathrm{M})$ and (M) may be expected on the basis of Eq. (4). The results are plotted in Fig. 2, in which the fit of the experimental data to the linear relationship is fairly good. From the slopes and intercepts of the straight lines shown in Fig. 2, the *A*, *B*, *C*, and *D* of VADO

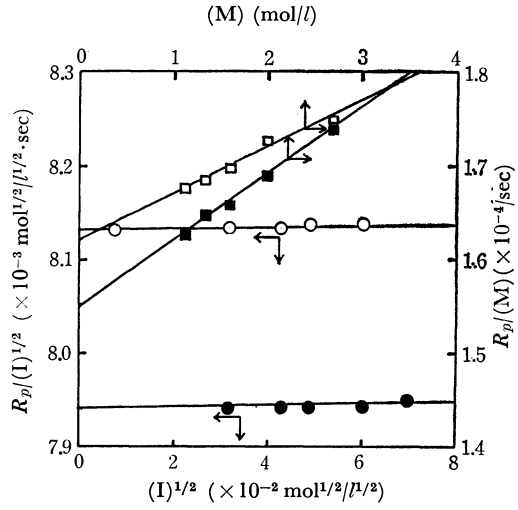

Fig. 2. Plots of $R_p/(\mathrm{I})^{1/2}$ *vs.* $(\mathrm{I})^{1/2}$ and R_p (M) *vs.* (M).
○, □: VADO; ●, ■, VMDO

were estimated to be 5.97×10^{-6}, 8.13×10^{-3}, 4.90×10^{-6}, and 1.62×10^{-4} respectively; the corresponding values of VMDO were found to be 3.05×10^{-6}, 7.94×10^{-3}, 6.94×10^{-6}, and 1.55×10^{-4} respectively. Accordingly, the ratios of the rate constant, as calculated from the above values, are shown in Table 3.

Table 3. The parameters of polymerization

Monomer	$2fk_d$ ($\times10^{-5}$ sec^{-1})	$k_{cp}/k_t^{1/2}$ ($\times10^{-1}$ mol$^{1/2}$/$l^{1/2}$·sec$^{1/2}$)	$(k_p/k_{cp}-\beta/\alpha)(k_{cp}/k_c)$ ($\times10^{-2}l$/mol)	E ($\times10^{-2}l^{1/2}$/mol$^{1/2}$)
VADO	9.34	3.92	3.18	2.47
VMDO	3.39	6.22	4.48	9.36×10^{-1}
DβMPP	6.95	0.57×10^{-1}	2.26	1.46×10^{2}

Here, the $2fk_d$ value of the order of 10^{-5} seems to be pertinent when AIBN is used as an initiator.

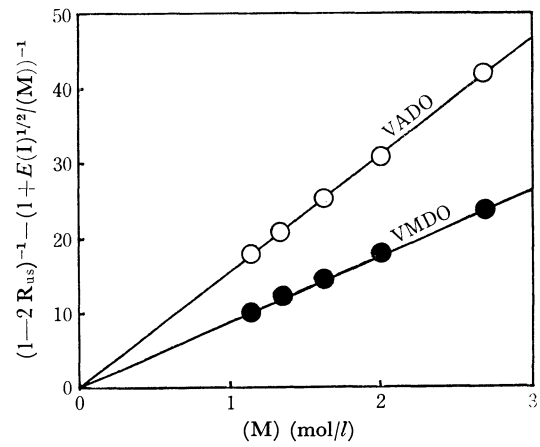

Fig. 3. Plots of $\{(1-2R_{us})^{-1}-(1+E(\mathrm{I})^{1/2}/(\mathrm{M}))^{-1}\}$ *vs.* (M).

On the other hand, the $k_{cp}/\alpha k_t^{1/2}$ values of VADO and VMDO were larger than that of DβMPP; the termination between the two $M_c\cdot$ values in the polymerizations of VADO and VMDO might be slower than that of the DβMPP polymerization.

The Residual Unsaturation. The plots of $\{(1-2R_{us})^{-1}-(1+E(\mathrm{I})^{1/2}/(\mathrm{M}))^{-1}\}$ *vs.* (M) are shown in Fig. 3; there is a good linear relationship, as was predicted by Eq. (6). The ratios of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation of the uncyclized radical, k_c/k_p, were estimated to be 0.065 mol/*l*(VADO), and 0.114 mol/*l*(VMDO) from the slopes of the straight lines. The results show that the pendant double bonds in polymers are almost not cyclized at all because the acryl double bond is more active than the allylidene double bond. The difference between VADO and VMDO could not be seen in these polymerizations; the influence of methyl groups could not be observed, either.

Therefore, although VADO and VMDO both undergo cyclopolymerization, they act as monofunctional monomers rather than as bifunctional monomers.

Copolymerization. The composition and the unsaturation of polymer as functions of the monomer

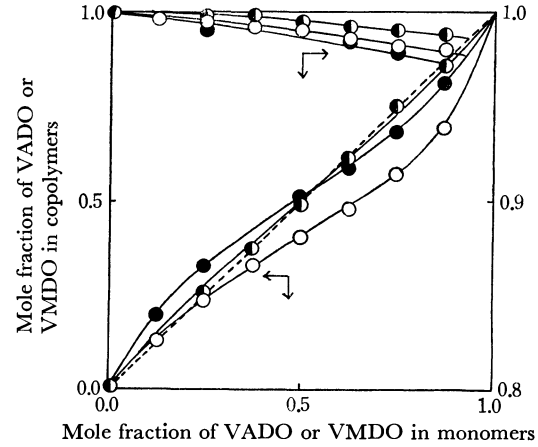

Fig. 4. Relation of the copolymer composition and the residual unsaturation to the monomer composition.
○: [VADO+St] = 3.49 mol/*l*, ◑: [VADO+AN] = 6.10 mol/*l*, ●: [VMDO+St] = 3.49 mol/*l*, —: calculated curve

composition are shown in Fig. 4. It may be seen in the figure that the residual unsaturations of the copolymer thus obtained decreased slightly with an increase in the comonomer composition until they became nearly constant at 1.0. Accordingly, the cyclization may be approximately negligible, the ratio being obtainable by the well-known Fineman-Ross method; the results are summarized in Table 4.

Table 4. Reactivity ratios for VADO or VMDO (M_1)-monovinyl compounds(M_2) systems

M_1	M_2	r_1	r_2	Q_1[10]	e_1[10]	Q_2	e_2
VADO	St	0.22	0.81	1.00	−0.80	0.43	0.51
VADO	AN	0.89	0.95	0.60	1.20	0.39	0.79
VMDO	St	0.51	0.49	1.00	−0.80	0.80	0.30

In Fig. 4 the theoretical solid curves as calculated from the resulting reactivity ratios agreed well with the results of the experimental measurements.

The average values of Q and e for VADO, VMDO were estimated as follows: VADO, $Q=0.41$, and $e=0.65$; $Q=0.80$, and $e=0.30$.

These values are not equal to Q, e values of diallylidene cyclic acetals[8-9] but those of DβMPP,[2] methyl acrylate[10] and methyl methacrylate.[10] Consequently, VADO and VMDO may be suggested to be polymerized as same as monoacryl and methacryl esters.

The Q value for VMDO was larger than that for VADO; it might be influenced by the hyperconjugation of methyl group.

On the other hand, the e value of VMDO was more negative than that of VADO; it might be contributed to the methyl group which was a proton donor.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1342—1345(1971)

The Reaction of Ethyl Alkylchloropyruvate with Sodiomalonate and Sodioacetoacetate[1)]

Akira TAKEDA, Satosi WADA, Masatosi FUJII, Isao NAKASIMA, and Shoiti HIRATA
Department of Synthetics Chemistry, School of Engineering, Okayama University, Tusima, Okayama

(Received October 1, 1970)

The reaction of alkylchloropyruvate (**1**) with sodiomalonate gave γ-alkyl-α,β-dialkoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolide (**2**), which led to γ-ketocarboxylic acid (**3**). The reaction of **1** with sodioacetoacetate gave 2-alkyl-5-methylfuran-3,4-dicarboxylate (**6**) *via* the intermediate 2-alkyl-3-hydroxy-5-methyl-2,3-dihydrofuran-3,4-dicarboxylate (**5**). It has been shown unambiguously that the carbanions of both sodiomalonate and sodioacetoacetate attack the carbonyl carbon of **1** predominantly.

Reichstein *et al.* disclosed in 1933 that bromopyruvic ester reacted with sodiooxaloacetate to yield 2,3,4-furantricarboxylic ester.[2)] Dunlop and Hurd[3)] assumed that the cyclization process involved the formation of 3-hydroxy-2,3-dihydrofurantricaboxylate as the intermediate. Cantlon *et. al.* later discussed and confirmed its structure by means of NMR data.[4)] We reported that the reaction of ethyl chlorophenylpyruvate with diethyl sodiomalonate gave γ-phenyl-α,β-diethoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolide, which on hydrolysis and subsequent decarboxylation afforded γ-benzoylpropionic acid.[5)]

Since the mode of reactions of carbanions such as sodiomalonate and sodioacetoacetate with alkylhalopyruvate has not been investigated, it appears to us worthwhile to elucidate the structures of intermediates as well as products in reactions, which lead to 2,5-dialkyl-3,4-dialkoxycarbonylfurans, or to γ-alkyl-α,β-dialkoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolides. The facility of

obtaining alkylchloropyruvic esters (**1**)[6] also prompted us to study these reactions in order to find new synthetic routes to 2,5-dialkylfurans and γ-oxoalkanecarboxylic acids.

This paper deals with the preparation of four γ-alkyl-α,β-diethoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolides (**2a—d**), which were readily converted to γ-ketocarboxylic acids (**3a—d**), together with the preparation of three 2-alkyl-5-methylfuran-3,4-dicarboxylates (**6b—d**), which were converted to 2-alkyl-5-methylfurans (**8b—d**). These furans were finally transformed to the corresponding 1,4-diketones (**9b—d**). The intermediate 2-alkyl-3-hydroxy-5-methyl-2,3-dihydrofuran-3,4-dicarboxylates (**5b—d**) also were isolated and characterized.

The reaction of **1** with sodiomalonate gave the product (**2**) in a 40—50% yield, which was separated as a colorless oil and purified by vacuum distillation. The structure of **2** was confirmed by elemental analyses and IR spectra (lactone C=O 1835, 1820 cm^{-1}; ester C=O 1750, and conjugated ester C=O 1725 cm^{-1}; C=C 1665 cm^{-1}). Further evidence to support the $\Delta^{\beta,\gamma}$-butenolide structure of **2** was provided by the fact that the treatment of **2b** with p-chloroaniline gave N-(p-chlorophenyl)-2,3-diethoxycarbonyl-4-oxocapramide (**4**) in 95% yield. The acid hydrolysis of **2** and the subsequent decarboxylation yielded γ-ketocarboxylic acids (**3a—d**) in good yield (Scheme 1). IR spectra of **3** exhibited a characteristic band at 1695 cm^{-1} due to C=O and were identical with those of the authentic sample.[7] A series of γ-alkyl-α,β-diethoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolides (**2a—d**) and γ-keto acids (**3a—d**) derived in this way are listed in Tables 1 and 2, respectively.

Table 2. Preparation of γ-keto acids (**3**) from $\Delta^{\beta,\gamma}$-butenolides (**2**)

Compound	R	Yield, %	Mp, °C

7) A. Takeda, K. Takahasi, S. Torii, and T. Moriwake, *J. Org. Chem.*, **31**, 616 (1966).

The reaction of **1** with ethyl sodioacetoacetate was carried out in dry ethanol. Ethyl 3-chloro-2-oxononanoate (**1b**) gave ethyl 2-n-hexyl-3-hydroxy-5-methyl-2,3-dihydrofuran-3,4-dicarboxylate (**5b**) as the condensation product in 73% yield. Treatment of **5b** with sulfuric acid effected the dehydration to afford ethyl 2-n-hexyl-5-methylfuran-3,4-dicarboxylate (**6b**) in quantitative yield. The structural assignment of **5b** was based on IR spectra (OH 3490 cm^{-1}; ester C=O 1735, 1706 cm^{-1}; C=C 1640 cm^{-1}) and NMR spectra ($CDCl_3$) (τ 7.74, s, 3H, $-\overset{}{\underset{}{C}}(=O)-CH_3$; τ 7.58, s, 1H, OH). When treated with alcoholic potassium hydroxide solution, **5b** underwent both dehydration and hydrolysis to give 2-n-hexyl-5-methylfuran-3,4-dicarboxylic acid (**7b**) in good yield. **7b** was transformed into dimethyl ester (**11**) with diazomethane and identified. While **1b** (R=n-C_6H_{13}) gave only **5b** as the major product, **1c**(R=n-C_7H_{15}) and **1d** (R=n-C_8H_{17}) afforded

a) Measured at 27°C. b) Obtained as a mixture. Separation into the components was by tlc (Experimental). c) Temperature range at which the mixture distilled. d) Yield from **6b**. e) The mixture of **5** and **6** was used as the starting material (Experimental). f) Bp 102—105°C/30 mmHg.[8] g) Bp 107—110°C/16 mmHg.[8] h) Bp 95—97°C/11 mmHg.[8] i) Mp 33°C.[9] j) Mp 40.5°C.[9]

the mixtures of the corresponding intermediate (**5c, 5d**) and the dehydrated product (**6c, 6d**). These mixtures were used without fractionation for the preparation of **7c** as well as **7d** by means of alkaline hydrolysis. Decarboxylation of acids **7b—d** carried out in quinoline by heating with copper powder, afforded 2-alkyl-5-methylfurans (**8b—d**). IR spectra and the boiling point of the furans (**8b—d**) were identical with those of the authentic samples, which were obtained in the alternative way.[8] The ring-opening of **8b—d** to give the 1,4-diketones (**9b—d**) was effected by heating with aqueous acetic acid containing a small amount of sulfuric acid. The sequence of these reactions is shown in Scheme 2. Table 3 shows the yields, physical properties, and analytical data of three 1,4-diketones obtained in this experiment and their intermediates. Diketone **9b** was converted to 2-n-pentyl-3-methyl-2-cyclopenten-1-one (**10**) by the usual method.

Since substrate (**1**) has two reactive positions, α and β, in the molecule, there are possibilities of forming two kinds of ring skeleton for both reactions described in Schemes 1 and 2. The formation of **3** from **2** and that of **8** from **5** unambiguously indicate that the carbanions of sodiomalonate and sodioacetoacetate have attacked the carbonyl carbon of **1** predominantly.

Experimental[10]

All boiling points and melting points are uncorrected. Thin layer chromatography was carried out on silica gel G (E. Merck AG, Darmstadt), where the spots of materials were detected by spraying with sulfuric acid solution of potassium permanganate (7: 3 in wt.). Infrared spectra were determined on a Hitachi IR EPI-S2 spectrophotometer.

Ethyl alkylchloropyruvates (**1**) other than **1a** used in this experiment were prepared by the Darzens type condensation of the appropriate aldehydes and ethyl dichloroacetate.[6] Ethyl 3-chloro-2-oxohexanoate (**1a**) was obtained as a pure product by direct chlorination of ethyl 2-oxohexanoate[11] with sulfuryl chloride.

The followings are typical of the experiments to derive **2, 3, 5, 6, 7, 8,** and **9**.

*Ethyl 3-Chloro-2-oxohexanoate (**1a**).* To a stirred solution of ethyl 2-oxohexanoate (7.9 g, 0.05 mol) was added dropwise 7.0 g (0.052 mol) of sulfuryl chloride at 25—30°C. The reaction mixture was stirred at room temperature for additional 60 hr. Distillation of the crude product gave 7.3 g (76%) of **1a**: bp 98—100°C/16 mmHg; n_D^{25} 1.4387; IR (cm^{-1}, liquid) 1755 (ketone C=O) and 1735 (ester C=O).

Found: C, 50.18; H, 6.83%. Calcd for $C_8H_{13}ClO_3$: C, 49.88; H, 6.80%.

*γ-n-Hexyl-α,β-diethoxycarbonyl-$\Delta^{\beta,\gamma}$-butenolide (**2b**).* Diethyl malonate (20.0 g, 0.125 mol) and ethyl 3-chloro-2-oxononanoate (**1b**)[6] (11.7 g, 0.05 mol) were added to 60 m*l* of anhydrous ethanol in which 2.3 g (0.1 g-atom) of sodium was dissolved. The mixture was heated for 7 hr at 65—70°C with stirring and allowed to stand overnight. The reaction mixture was acidified with 10% aqueous sulfuric acid and taken up in ether. The ethereal extract was washed with aqueous sodium bicarbonate and then with water, dried over anhydrous magnesium sulfate, and concentrated. Distillation of the residual oil afforded 7.2 g (46%) of **2b**; bp 155—157°C/3 mmHg; IR (cm^{-1}, liquid) 1835, 1820 (lactone C=O), 1750 (ester C=O), 1725 (conjugated ester C=O), and 1665 (C=C).

*4-Oxodecanoic Acid (**3b**).* A mixture of 3.0 g (0.01 mol) of **2b**, 60 m*l* of sulfuric acid, and 90 m*l* of water was stirred for 10 hr at 170°C in an oil bath. The reaction mixture was cooled, extracted with ether. The ethereal layer was shaken with 5% aqueous sodium hydroxide. The aqueous layer was acidified and then taken up in ether. The extract was

10) Elementary analyses were carried out by Mr. Eiichiro Amano of our laboratory. We are indebted to Dr. Akira Suzuki and Mr. Sigezo Simokawa, both of Hokkaido University, Sapporo, for NMR measurements.

11) M. Igarasi and H. Midorikawa, *J. Org. Chem.*, **29**, 2082 (1964).

dried over anhydrous magnesium sulfate and the solvent was removed. The residual solid was recrystallized from *n*-hexane to give 1.1 g (59%) of **3b**: mp 66—67°C.

N-(p-*Chlorophenyl*)-*2,3-diethoxycarbonyl-4-oxodecanamide (4)*. A mixed solution of **2b** (0.6 g, 0.002 mol) and *p*-chloroaniline (0.25 g, 0.002 mol) in 2 m*l* of chloroform was stirred at room temperature for 1 hr. After evaporation of the solvent 0.6 g (95%) of **4** was obtained: mp 80—81°C; IR (cm^{-1}, Nujol) 3300 (amide NH), 1730 (ester C=O), 1715 (ketone C=O), and 1665 (amide C=O).

Found: C, 59.94; H, 7.11; N, 3.33%. Calcd for $C_{22}H_{30}ClNO_6$: C, 60.06; H, 6.87; N, 3.18%.

Ethyl 2-n-Hexyl-3-hydroxy-5-methyl-2,3-dihydrofuran-3,4-dicarboxylate (5b). To a solution of ethyl sodioacetoacetate, prepared from sodium (2.3 g, 0.1 g-atom), anhydrous ethanol (100 m*l*), and ethyl acetoacetate (26.0 g, 0.2 mol), was added 23.5 g (0.1 mol) of **1b**. The mixture was heated at 60—65°C with stirring for 7 hr. After being kept standing overnight at room temperature, the reaction mixture was acidified with 20% aqueous sulfuric acid and taken up in ether. The ethereal extract was washed with water, dried over anhydrous sodium sulfate, and concentrated. Distillation of the residue yielded 24.4 g (73%) of **5b**: bp 158—161°C/3 mmHg; R_f 0.54.[12]

Ethyl 2-n-Hexyl-2-methylfuran-3,4-dicarboxylate (6b). Sulfuric acid (50 m*l*) was added dropwise to 10.0 g (0.03 mol) of **5b** in an ice bath. After being heated for 5 min at 50°C, the reaction mixture was poured into 50 m*l* of ice water and extracted with ether. The ethereal layer was washed with water and subsequently with 10% sodium carbonate solution. After being dried over anhydrous sodium sulfate, the solvent was removed. Distillation of the residue under diminished pressure gave 9.1 g (99%) of **6b**: bp 150—152°C/2 mmHg; R_f 0.73;[12] IR (cm^{-1}, liquid) 1720 (ester C=O) and 1590 (C=C).

2-n-Hexyl-5-methylfuran-3,4-dicarboxylic Acid (7b).

(a) From 6b: To a solution of potassium hydroxide (1.0 g, 0.018 mol) in 10 m*l* of 50% aqueous ethanol, 1.0 g (0.003 mol) of **6b** was added. The reaction mixture, after being refluxed for 6 hr, was acidified with 10% aqueous sulfuric acid, and extracted with ether. The ethereal extract, which was treated in the usual manner, gave 0.75 g (99%) of acidic material. The crude product was recrystallized from *n*-hexane - benzene to yield pure sample of **7b**: mp 120—121°C; IR (cm^{-1}, Nujol) 1685, 1630, and 1570.

(b) From 5b: A mixture of **5b** (1.4 g, 0.005 mol) and the solution of potassium hydroxide (5.0 g, 0.09 mol) in 10 m*l* of aqueous 50% ethanol was refluxed for 6 hr. The crude product of **7b** was isolated in the same manner as described in the foregoing experiment. Recrystallization from *n*-hexane - benzene gave 0.8 g (63%) of the prdouct: mp 120—121°C; IR (cm^{-1}, Nujol) 1685, 1630, and 1570.

Reaction of Ethyl 3-Chloro-2-oxodecanoate (1c) with Ethyl Acetoacetate. Ethyl 3-chloro-2-oxodecanoate[6] (37.0 g, 0.15 mol) was added to a solution of ethyl sodioacetoacetate, prepared from 3.4 g (0.15 g-atom) of sodium, 38.7 g (0.3 mol) of ethyl acetoacetate, and 100 m*l* of anhydrous ethanol. The stirred mixture was heated at 60—65°C for 7 hr and allowed to stand overnight at room temperature. After being acidified with 20% aqueous sulfuric acid, the reaction mixture was extracted with ether. The extract was washed with water, dried over anhydrous sodium sulfate, and concentrated. Distillation of the resudie yielded 27.3 g of the liquid, which was collected at 183—185°C/6 mmHg. For analysis and spectral determination, the liquid was fractionated to **5c** and **6c** by means of preparative thin layer chromatography. R_f values[13] were 0.30 for **5c** and 0.56 for **6c**. From 0.4 g of the mixture 0.3 g of **5c** and 0.1 g of **6c** were obtained. IR spectra (cm^{-1}, liquid): **5c**, 3490 (OH), 1735(ester C=O), 1705(conjugated ester C=O), and 1640 (C=C); **6c**, 1720 (ester C=O), and 1590 (C=C).

2-n-Heptyl-5-methylfuran-3,4-dicarboxylic Acid (7c). The liquid mixture (25.0 g) obtained in the foregoing experiment was refluxed with much excess of potassium hydroxide dissolved in 50% aqueous ethanol for 6 hr. It gave 11.0 g of the crude product (**7c**): mp 105°C (from *n*-hexane - benzene); IR (cm^{-1}, Nujol) 1685, 1630, and 1570.

Reaction of Ethyl 3-Chloro-2-oxoundecanoate (1d) with Ethyl Acetoacetate. Condensation was carried out in the same manner as that of **1c**. The following reactants were used: 23.5 g (0.09 mol) of **1d**; 23.4 g (0.18 mol) of ethyl acetoacetate; 2.1 g (0.09 g-atom) of sodium which was dissolved in 100 m*l* of anhydrous ethanol before use. Distillation afforded 30.5 g of the liquid which was collected at 180—182°C/2.5 mmHg. The liquid was fractionated to **5d** and **6d** by preparative tlc. R_f values[13] were 0.22 for **5d** and 0.43 for **6d**. IR spectra (cm^{-1}, liquid): **5d**, 3490 (OH), 1735 (ester C=O), 1705 (conjugated ester C=O), and 1640 (C=C); **6d**, 1720 (ester C=O) and 1590 (C=C).

2-n-Octyl-5-methylfuran-3,4-dicarboxylic Acid (7d). The liquid mixture (17.8 g) obtained in the above experiment, gave 8.4 g of the crude product (**7d**) on the alkaline hydrolysis: mp 112.5°C (from benzene); IR (cm^{-1}, Nujol) 1685, 1630, and 1570.

2-n-Hexyl-5-methylfuran (8b). A mixture of **7b** (10.0 g, 0.039 mol) and quinoline (25 m*l*) was refluxed for 5 hr in the presence of copper powder (5.0 g). After filtration, the mixture was extracted with ether. The extract, washed with water, diluted hydrochloric acid, then with water, was dried over anhydrous sodium sulfate. The fraction distilling at 101—103°C/29 mmHg was collected: yield 5.0 g (77%), IR (cm^{-1}, liquid) 1570.

2,5-Undecanedione (9b). A mixture of **8b** (3.0 g, 0.018 mol), glacial acetic acid (7 m*l*), water (2.5 m*l*), and a few drops of sulfuric acid was refluxed for 2 hr. The mixture was poured into 10 m*l* of water and taken up in ether. The ethereal layer was separated, washed with saturated sodium bicarbonate and water, and dried over anhydrous sodium sulfate. Removal of the solvent yielded crystals. Recrystallization of the crude product from methanol gave 2.6 g (79%) of **9b**: mp 34°C; IR (cm^{-1}, Nujol) 1715 (ketone C=O).

2-n-Pentyl-3-methyl-2-cyclopentene-1-one (10). Dione **9b** (0.7 g, 0.04 mol) was heated with 3% aqueous sodium hydroxide (7 m*l*) at reflux temperature for 7 hr with vigorous stirring. The mixture was taken up in ether, washed with water and dried over anhydrous sodium sulfate. Removal of the solvent gave 0.4 g (61%) of **10**. The 2,4-dinitrophenylhydrazone of **10**, mp 119—120°C, was identical with the authentic sample.[14]

Metyl 2-n-Hexyl-5-methylfuran-3,4-dicarboxylate (11). When treated with diazomethane, **7b** was transformed into its methyl ester **11**: bp 145—148°C (bath)/3 mmHg;[15] n_D^{25} 1.4755; IR (cm^{-1}, liquid) 1720 (ester C=O) and 1590 (C=C); NMR (τ, $CDCl_3$) 7.56 (s, 3H, CH_3), and 6.18 (s, 6H, $2CH_3$-OCO).

Found: C, 64.15; H, 7.59%. Calcd for $C_{15}H_{22}O_5$: C, 63.81, H, 7.85%.

(Received October 2, 1970)

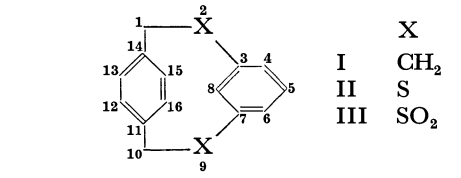
Sulfur analogs of [2.2]metaparacyclophane, II, III, and IV were prepared and their NMR spectra were examined. Of the three possible inversion mechanism, the one which involves the inversion of the *m*-phenylene unit is proposed.

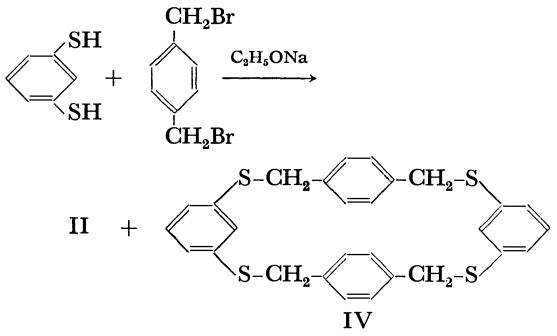
The unique features of [2.2]metaparacyclophane (I) system[1-5] resulting from the crowding of two aromatic rings give rise to interesting physical and chemical properties. They include anomalies in the ultraviolet[4] and nuclear magnetic resonance spectrum.[3,5]

In a paper[2] dealing with the NMR spectra of I, it was shown that inversion of the 11-membered ring occurred at temperatures higher than 187°C. In order to study the inversion mechanism further, 2,9-dithia[2.2]metaparacyclophane (II) and its derivative III were prepared and their NMR spectra were examined.

Compound II was prepared according to the procedure of Vögtle[3] by the reaction of *m*-benzenedithiol with 1,4-bis(bromomethyl)benzene under high dilution conditions. A colorless amorphous compound, mp 99—100°C was obtained. A 22-membered tetrathia compound IV[6] was isolated in 3.4% yield by the condensation between two moles each of the halide and the dithiol. When the reaction was carried out in THF only IV was formed even under high-dilution conditions.

The NMR spectrum[7] of II in CCl_4-CS_2 (1:1) at room temperature shows absorptions at δ 5.73 and 7.39 (broad signal, A_2B_2 pattern, $C_{12,13}$ and $C_{15,16}$ aryl protons), δ 6.90—7.40 (AB_2 pattern, $C_{4,5,6}$ aryl protons), δ 6.22 (triplet, C_8 aryl proton) and at δ 3.87 and 3.90 (broad absorption, AB pattern, methylene protons). The spectrum was essentially similar to that of Vögtle.[3] The C_8 and half-side of *p*-phenylene aryl protons exhibited unusual high field shifts due to the ring current effects of the opposite benzene ring. No such upfield shift was observed with the larger ring compound IV, which in DMSO-d_6 showed absorptions at δ 4.06 (singlet, methylene protons), δ 7.00 (singlet, *p*-phenylene unit aryl protons), δ 7.10 and 7.20 (AB_2 pattern, outer *m*-phenylene protons) and at δ 7.39 (inner *m*-phenylene protons). The peak for methylene protons of compound IV was a sharp singlet, which suggests that the comformation of cyclic compound is flexible, with no fixation.





Oxidation of II with 30% hydrogen peroxide in acetic acid gave III as colorless high-melting needles.

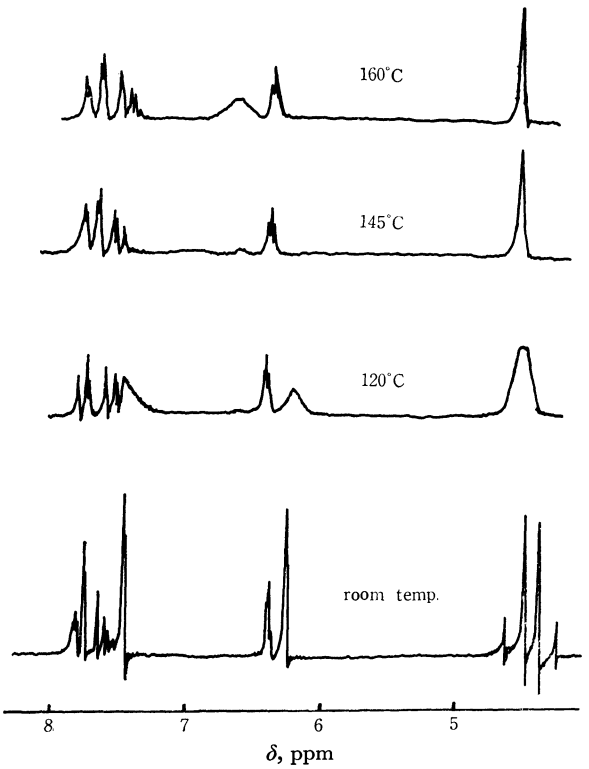


Fig. 1. NMR spectra of III in DMSO-d_6 (100 MHz).

6) Parent peak, *m/e* 488. The spectrum was recorded on a Hitachi RMU-6 spectrometer.
7) The spectra were recorded on a JNM-4H-100 spectrometer TMS as a reference.
8) H. S. Gutowsky and C. H. Holm, *J. Chem. Phys.*, **25**, 1228 (1956).

The structure was supported by elemental analysis and spectral data. As shown in Fig. 1, the NMR spectrum of III in DMSO-d_6 shows absorptions at δ 7.50 and 7.82 (AB_2 pattern, $C_{4,5,6}$ aryl protons), δ 6.28 and 7.48 (A_2B_2 pattern, $C_{12,13,15,16}$ aryl protons), δ 6.40 (triplet, C_8 aryl proton) and at δ 4.34 and 4.54 (AB pattern, J=13 Hz, methylene protons). Downfield shift (0.18 ppm) of C_8 aryl proton of III compared with that of II could be attributed mainly to the anisotropy effects of two sulfone groups. With the rise of temperature of the solution individual signals of A_2B_2 pattern collapse to a broad signal at about 145°C as shown in Fig. 1.

Temperature dependence of the A_2B_2 pattern is in line with the exchange between $C_{12,13}$ and $C_{15,16}$ proton environments resulting from the ring inversion among conformers A and B. Based on the chemical shift at 23°C ($\Delta\nu$=120 Hz) and temperature of coalescence (T_c=145°C), the energy barrier to interconversion is calculated to be $\Delta G_c^{\ddagger}$=20.0±0.3 kcal/mol.[8,9] Inversion energy was calculated to be $\Delta G_c^{\ddagger}$=20.1±0.4 kcal/mol from methylene proton signals (T_c=118°C, $\Delta\nu$=20 Hz). The energy barrier for II,[10] however, was found to be as low as $\Delta G_c^{\ddagger}$=14.8±0.4 kcal/mol (calculated from methylene protons, $\Delta\nu$=20 Hz, T_c= 23.0°C).[10] The difference is attributable mainly to the bulkiness and rigidness of sulfone groups as compared with bivalent sulfur groups.

There are three types of possible inversion mechanisms, (a), (b), and (c). In (a), inversion of the *m*-phenylene ring occurs through the rotation of C_1–C_2 and C_9–C_{10} bonds. In (b), rotation of *p*-phenylene unit occurs similarly about C_1–C_{14} and C_{10}–C_{11} bonds. In (c), rotation of the meta-ring occurs in a concerted fashion. Examination of molecular model[11] of I indicates that the para-ring is more strained that the meta-ring and inversion of the latter occurs more easily. By similar consideration (c) can be ruled out by steric hindrance of internal aryl protons. If the inversion was due to (b), one might not expect the coalescence of methylene protons of II and III at higher temperatures. At higher temperatures, however, II and III showed a sharp singlet due to methylene protons and a downfield shift of C_8 aryl protons. This suggests that the inversion may occur by (a).

9) S. Glasstone, K. J. Laidler, and H. Eyring, "The Theory of Rate Processes," McGraw-Hill, Inc., London, 1941, Chapt. 1.

10) In Ref. 3, a value of $\Delta G_c^{\ddagger}$ was calculated as 14.7 kcal/mol based on the aryl protons of A_2B_2 pattern and as 14.9 kcal/mol based on the methylene signals of AB pattern.

Experimental

2,9-Dithia[2.2]metaparacyclophane (II). 1, 4-Bis(bromomethyl)benzene in 250 m*l* of dried tetrahydrofuran and solution of 7.1 g (0.05 mol) of *m*-benzenedithiol in 250 m*l* of 75% ethanol containing 5 g of sodium hydroxide were added separately drop by drop through a modified Hershberg dropping funnel to 1.5 *l* refluxing ethanol during the course of 48 hr. Stirring was carried out throughly during the addition. When it was complete, the resulting mixture was filtered for removal of sodium bromide. The filtrate was dissolved in benzene, washed with water. The benzene solution was then dried, concentrated and subjected to column chromatography on alumina using benzene as an eluent. From the first elute a colorless solid was isolated. By recrystallization from chloroform-benzene II was obtained in a 6.9% yield, mp 99—100°C, lit,[3] 99—100°C.

Found: C, 68.50; H, 4.64; S, 26.45%. Calcd for $C_{14}H_{12}S_2$: C, 68.85; H, 4.83; S, 26.27%.

From the second elute IV was isolated. It was recrystallized from chloroform to give 0.25 g (3.4% yield) of colorless solid, mp 218—220°C.

Found: C, 68.32; H, 4.88; S, 26.50%. Calcd for $C_{28}H_{24}S_4$: C, 68.85; H, 4.83; S, 26.27%.

When a solution of 10 g (0.07 mol) of *m*-benzenedithiol in 320 m*l* absolute ethanol containing 5 g of sodium hydroxide and a solution of 18.5 g (0.07 mol) of 1,4-bis(bromomethyl)-benzene in 320 m*l* of dried tetrahydrofuran were added to 200 m*l* of tetrahydrofuran in the course of 98 hr at room temperature. A 5.7% yield of IV, mp 218—220°C, was obtained.

2,9-Dithia[2.2]metaparacyclophane-2,2,9,9-tetroxide(III). A mixture of 2.25 g of II dissolved in 30 m*l* glacial acetic acid containing 30% hydrogen peroxide was put to stand at room temperature overnight. It was concentrated *in vacuo* to give white crystals, which were dissolved in chloroform and subjected to silica gel column chromatography using chloroform as an eluent. Compound III was obtained as colorless needles, recrystallized from chloroform, mp >300°C, in an 8% yield, ν_{max} 1310 and 1150 cm^{-1}.

Found: C, 54.67; H, 3.76%. Calcd for $C_{14}H_{12}S_2O_4$: C, 54.55; H, 3.92%.

Kinetics of Liquid-phase Hydrogenation of Aliphatic α,β-Unsaturated Aldehyde over Raney Cobalt Catalyst

Kazuhiko HOTTA and Teruo KUBOMATSU

The Osaka Municipal Technical Research Institute, Kita-ku, Osaka

(Received October 6, 1970)

Kinetic studies on the hydrogenation of 2-methyl-2-pentenal (UD) over the Raney cobalt catalyst were performed at temperatures ranging from 10 to 40°C in *n*-hexane. The products were found to be 2-methylpentan-1-ol (SA), 2-methyl-2-penten-1-ol (UA) and 2-methylpentanal (SD). The initial rates of the formation of SA(r_{SA}), SD(r_{SD}), and UA(r_{UA}) were determined in the concentrations of UD(C_{UD}), 0.026—0.263 mol/*l*. It was found by kinetic analysis that ($r_{SA}+r_{SD}$) was represented by a Langmuir-type rate equation and r_{UA} by another one. The rate equations which fitted the rate data are as follows.

$$r_{SA}+r_{SD}=\frac{1.1\times10^{10}e^{-15200/RT}C_{UD}}{(1+4.4\times10^{5}e^{-7500/RT}C_{UD})^2}$$

$$r_{UA}=\frac{1.2\times10^{8}e^{-13500/RT}C_{UD}}{(1+9.3\times10^{3}e^{-5600/RT}C_{UD})^2}$$

A mechanism in which the formation of SA and SD and that of UA proceed through different types of adsorbed UD was proposed. The adsorbed species in enol form and that in keto form were considered with respect to the formation of SA and SD. Activation energies for the formation of SA plus SD and of UA were determined to be 7.7 and 7.9 kcal/mol, respectively. The selectivity defined as the ratio of r_{SA} to ($r_{SA}+r_{SD}$) was found to increase with the increase of the surface coverage of hydrogen.

The vapor phase hydrogenation of 2-ethyl-2-hexenal over the supported copper catalyst was studied by Tanaka and Yada.[1] It was found that each reaction order with respect to the carbon-carbon double bond and the aldehyde group was unity. The hydrogenation of crotonaldehyde over the Raney copper-cadmium catalyst has also been kinetically studied in the vapor phase by Yada and Kudo.[2] In order to determine the rate constant, they assumed that the reaction order with respect to the reactant was unity, and neglected to consider the adsorption factor.

We have studied the liquid phase hydrogenation of α,β-unsaturated aldehydes over the Raney nickel catalyst with or without modifiers and have found that the products were saturated aldehydes and alcohols and that unsaturated alcohol was not produced.[3] Over the Raney cobalt catalyst, on the other hand, unsaturated alcohol was found to be formed with saturated aldehyde and alcohol. There have been only few kinetic studies on such a complicated reaction system in the liquid phase, consisting of both parallel and successive reactions.

It is the purpose of this paper to elucidate the kinetic behavior of the hydrogenation of 2-methyl-2-pentenal over the Raney cobalt catalyst in *n*-hexane. The kinetics was found to be best fitted to the rate equation based on the Langmuir-Hinshelwood mechanism. A detailed discussion is also made on the mechanism of the reactions.

Experimental

Catalyst. A commercial Raney cobalt-aluminum alloy (Co:50 wt%) was developed with a 15% sodium hydroxide solution at 50°C for 1 hr. The sample was washed with minimum volume of distilled water until the washings became neutral, then 5 times with 2-propanol, and 10 times with *n*-hexane in a hydrogen atomsphere. *n*-Hexane was then evaporated with hydrogen stream. The resulting catalyst, 540 mg (Co: *ca.* 500 mg), in dry form was weighed and stored in *n*-hexane under a hydrogen atmosphere. Decrease in the activity of the catalyst could be ignored within 4 weeks after the preparation.

Apparatus and Procedure. The catalyst, 540 mg, and *n*-hexane were put into a glass reaction vessel with a rubber-stoppered branch tube, and then the reaction vessel was equipped with a metal flange with three needle valves and with a mechanically sealed stirrer. After replacing air with hydrogen by making use of valve(1), the reactor was immersed in a constant temperature water bath controlled to ±0.05°C. Hydrogen was bubbled into the catalyst-solvent system through valve (2). In order to carry out the reaction under normal pressure, hydrogen was exhausted through valve (3) to atmosphere through a bubble counter. The catalyst-solvent system was stirred with 500 rpm in the hydrogen flow to saturate the catalyst with hydrogen. The reactant to be hydrogenated was then injected to this system. The total volume of the reactant and the solvent was kept to 50 m*l*. When the reactant was injected to the catalyst-solvent-hydrogen system, rapid absorption of hydrogen took place. The rate dropped to almost constant after 30 sec. Thus, the reaction was considered to reach the steady state within 30 sec after the injection of the reactant.

The total rate of the formation of the products was found to increase and become saturated with increased stirring. Hydrogenation was carried out under the conditions where the rate is independent of stirring. The maximum of the apparent activation energy observed in this study is 10 kcal/mol, indicating that diffusional process plays no important role under the conditions adopted.

The reaction mixture was sampled from the branch tube through a rubber stopper and the composition of the liquid phase was determined by glc employing a column packed with 20% PEG 6000/C-22.

Materials. *n*-Hexane was purified by hydrogenating reducible impurities. Cylinder hydrogen and 2-propanol were used without further purification. 2-Methyl-2-pentenal, pre-

pared from propionaldehyde and stored in portions of (0.2—1.8) m*l*, in sealed glass ampoules under a nitrogen atmosphere at −15°C, was 99% up pure.

Results

Determination of the Initial Rate. A representative of the change in product pattern as a function of reaction time of the hydrogenation of 2-methyl-2-pantenal (UD) over the Raney cobalt catalyst is shown in Fig. 1. The plots shown by the symbol ♁ are from a catalyst prepared in one batch and those by the symbol ♀ from a catalyst in another batch. Reproducibility in the rate measurement is satisfactory.

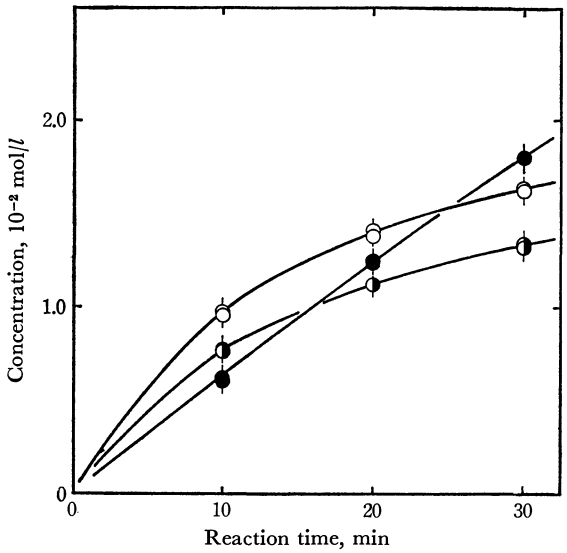

Fig. 1. Product concentration-time curves at 40°C, C_{UD}, 0.105 mol/*l*; SD, ○; SA, ●; UA, ◑

The rate of formation of the saturated aldehyde, 2-methylpentanal (SD), and that of the unsaturated alcohol, 2-methyl-2-penten-1-ol (UA), decrease gradually with reaction time. The rate of formation of the saturated alcohol, 2-methylpentan-1-ol (SA), is practically constant. It was also observed that the rate of formation of SA, however, showed a negative order dependence at higher concentration of UD and at lower reaction temperature. This indicates that (i) the hydrogenation of UD consists of a consecutive reaction which proceeds *via* SD or/and UA, and (ii) SA is the terminal product.

Isomerization from UA to SD and the dehydrogenation of SA and UA were not observed.

It was found that each product concentration-time curve could be represented by the third order equation as shown by the solid line in Fig. 1:

$$C = Xt^3 + Yt^2 + Zt \qquad (1)$$

where C denotes the concentration of a product at the reaction time t, and X, Y, Z are constants. The rate at t is given by differentiating Eq. (1) with respect to t, *viz.*,

$$\frac{dC}{dt} = 3Xt^2 + 2Yt + Z \qquad (2)$$

Thus the initial rate is given by

$$\left(\frac{dC}{dt}\right)_{t=0} = Z$$

Therefore the initial rate is the rate at the reaction time $t=0$, obtained by extrapolation from the rate of formation-time curve experimentally determined in the period in which the reaction proceeds in steady state. The kinetic analysis is made with the assumption that the reaction proceeds in steady state even at the reaction time $t=0$.

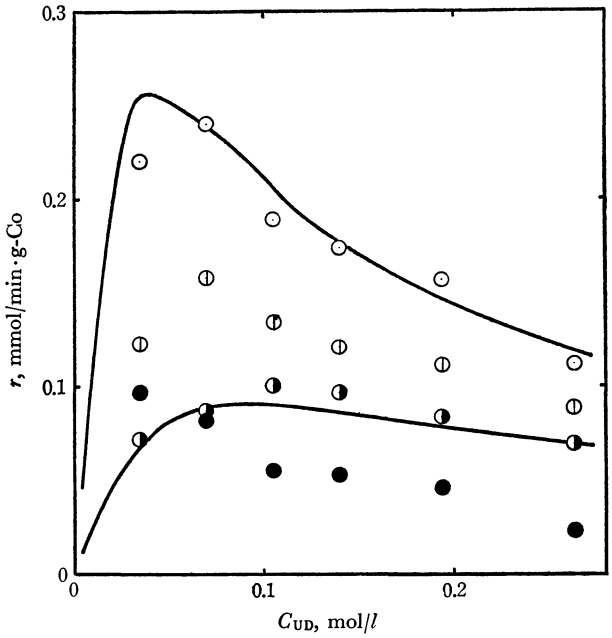

Fig. 2. Concentration dependence of the initial rate of the formation of, SD, ⦶; SA, ●; SA+SD, ○; UA, ◑, at 40°C.

Concentration Dependence of the Initial Rate: The initial rate of formation of SA, SD, and UA were plotted against the concentration of UD in Fig. 2. The curves for SD and UA have maxima, while the one for SA showed a progressive decrease with increasing the concentration of UD. This suggests that the reaction proceeds by the Langmuir-Hinshelwood mechanism, in which hydrogen and UD are adsorbed competitively. The rate equation corresponding to the mechanism is

$$r = k\theta_H\theta_{UD} \qquad (3)$$

where k denotes the rate constant of the surface reaction, θ_H, the surface coverage of hydrogen, and θ_{UD}, that of UD. The following equation can be derived from Eq. (3) as has been reported by Kishida and Teranishi[4]

$$r = \frac{kbC_{UD}}{(1+bC_{UD})^2} \qquad (4)$$

where C_{UD} denotes the concentration of UD, and b the ratio of the adsorption equilibrium constant of UD to that of hydrogen, divided by the liquid phase concentration of hydrogen, *i.e.* $b=K_{UD}/K_H\cdot C_H$, and called adsorption coefficient. When the rate measurement is carried out under a constant pressure of hydrogen, and the solubility of hydrogen is considered to be independent of the composition of reaction mixture

4) S. Kishida and S. Teranishi, *J. Catal.*, **12**, 90 (1968).

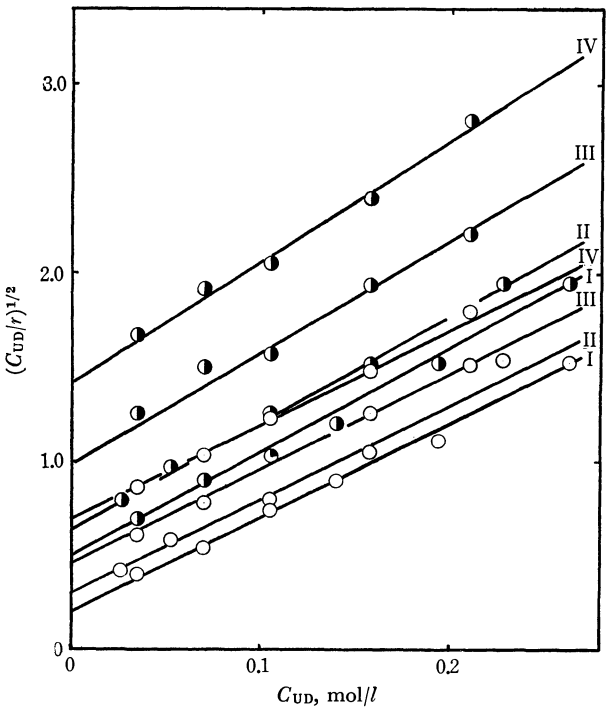

Fig. 3. $(C_{UD}/r)^{1/2}$ *vs.* C_{UD} plots for, $r_{SA}+r_{SD}$, ○; r_{UA}, ◑ at 40°C, I; 30°C, II; 20°C, III; 10°C, IV.

the adsorption coefficient b has a constant value at a given temperature. The adsorption of *n*-hexane as a solvent is neglected. The re-adsorption of products can be neglected in the initial rate treatment performed in this study.

Rearranging Eq. (4), we obtain

$$\left(\frac{C_{UD}}{r}\right)^{1/2} = \frac{1}{(kb)^{1/2}} + \left(\frac{b}{k}\right)^{1/2} \cdot C_{UD} \qquad (5)$$

This gives a linear relation between $(C_{UD}/r)^{1/2}$ and C_{UD}. In Fig. 3, plots of $(C_{UD}/r_{UA})^{1/2}$, and $(C_{UD}/(r_{SA}+r_{SD}))^{1/2}$ *vs.* C_{UD} are shown, where r_{UA}, r_{SA}, and r_{SD} denote the initial rates of formation of UA, SA, and SD, respectively. These plots obvioulsy give straight lines. We see that the plot of $(C_{UD}/r_{SA})^{1/2}$ *vs.* C_{UD} deviates from a straight line. This trend of plots can be interpreted as indicating that SA and SD were formed through the same adsorbed species. The kinetic parameters k and b were determined from the plots in Fig. 3, and are given in Table 1. The behavior of the concentration dependence of the initial rate of formation of SA plus SD and that of UA, employing such values of k and b, reveal satisfactory agreement between the experimental data and the calculated values, as shown by solid lines in Fig. 2.

Table 1. Kinetic parameters

Temperature (°C)	With respect to the formation of SA+SD: k (mmol/min·g-Co)	b (l/mol)	UA: k	b
40	1.0	25	0.38	11
30	0.68	17	0.28	9.0
20	0.44	11	0.17	6.1
10	0.29	7.1	0.11	4.5
Temperature coefficient (kcal/mol)	7.7	7.5	7.9	5.6
Frequency factor (mmol/min·g-Co)	2.5×10^4	—	1.3×10^4	—
Pre-exponential factor (l/mol)	—	4.4×10^5	—	9.3×10^3

The activation energies for the formation of SA plus SD and of UA were 7.7 and 7.9 kcal/mol, respectively. The values are considered to the reasonable compared with those reported by other workers.[5,6] The temperature coefficients of b were also determined to be 7.5 and 5.6 kcal/mol, for SA plus SD and for UA,

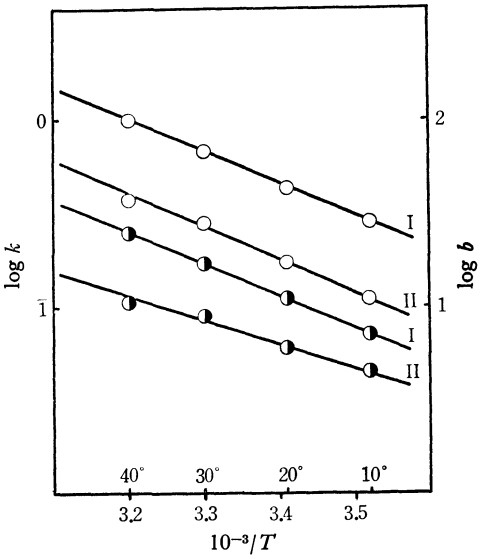

Fig. 4. Arrhenius plots, ○, for the formation of SA+SD, I; UA, II, and log b *vs.* $(1/T)$ plots, ◑, for the formation of SA+SD, I; UA, II.

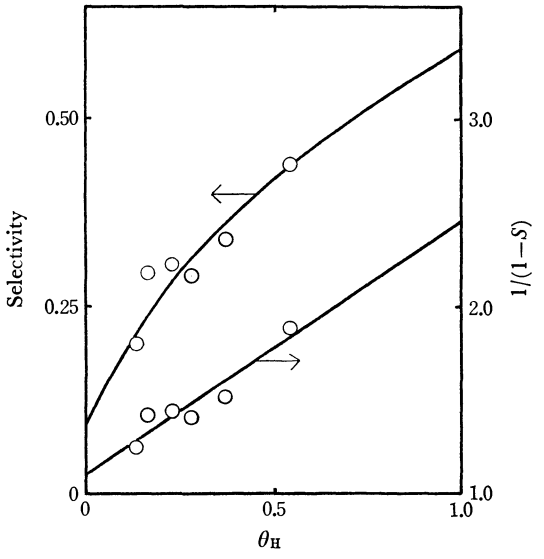

Fig. 5. Relations between the selectivity (S), $1/(1-S)$, and the surface coverage of hydrogen at 40°C.

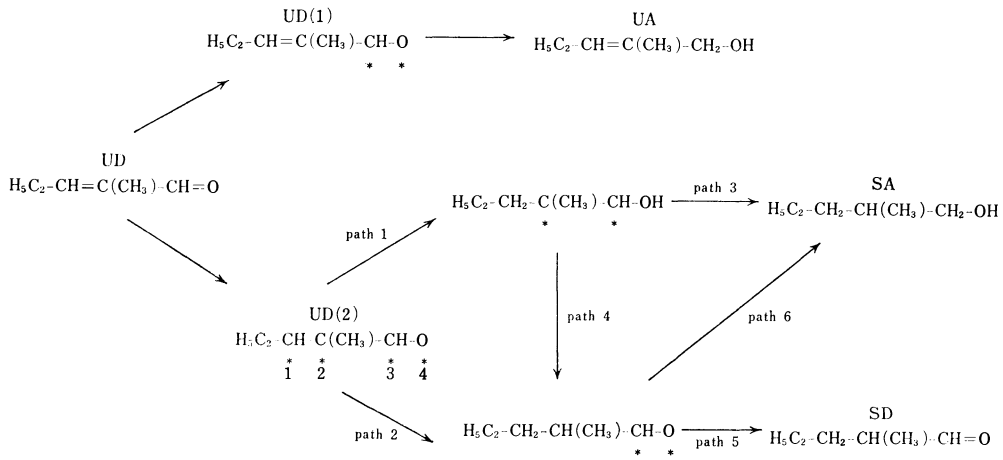

Fig. 6. Scheme of the hydrogenation mechanism.

respectively. This indicates that hydrogen is adsorbed more strongly than UD. The frequency factors of the rate constants for SA plus SD and for UA were determined to be 2.5×10^4 and 1.3×10^4 mmol/min·g-Co, respectively. The pre-exponential factors of the adsorption coefficients for SA plus SD and for UA were also determined to be 4.4×10^5 and 9.3×10^3 l/mol, respectively. Plots of the logarithm of k and b *vs.* the reciprocal of absolute temperature are shown in Fig. 4.

The relation between selectivity and surface coverage of hydrogen can be calculated employing the kinetic parameters obtained above. Selectivity S is defined as the ratio of r_{SA} to $(r_{SA}+r_{SD})$ and the surface coverage of hydrogen is calculated by the equation $\theta_H = 1/(1+bC_{UD})$. The result at 40°C is shown in Fig. 5. It is found that selectivity increases with the increase of hydrogen coverage.

Discussion

The hydrogenation mechanism which is considered to be consistent with the experimental results above mentioned is shown in Fig. 6. Two different types of adsorbed UD are considered in the mechanism. Formation of UA proceeds through UD (1), and that of SA and SD occurs through UD (2). The adsorbed species UD (2) is hydrogenated by 1,2 addition (path 2) to form the adsorbed species in keto form and by 1,4 addition (path 1) to form that in enol form. The reaction mechanism which involves both 1,2 and 1,4 additions of hydrogen has been proposed by McQuillin *et al.*[7] The adsorbed enol species is hydrogenated to SA or isomerized to the adsorbed keto species, while the isomerization from the latter to the former does not occur as reported by Badin and Pacsu.[8]

If UD is adsorbed competitively as UD (1) and UD(2) on the same catalyst site and reacts with adsorbed hydrogen, the rate equations for the formation of UA and of SA plus SD can be derived as follows.

$$r_{UA} = \frac{k_{UD(1)}b_{UD(1)}C_{UD}}{\{1+(b_{UD(1)}+b_{UD(2)})C_{UD}\}^2} \quad (6)$$

$$r_{SA}+r_{SD} = \frac{k_{UD(2)}b_{UD(2)}C_{UD}}{\{1+(b_{UD(1)}+b_{UD(2)})C_{UD}\}^2} \quad (7)$$

where $k_{UD}(1)$ denotes the rate constant for the formation of UA, $k_{UD}(2)$ that of SA plus SD, $b_{UD}(1)$ the adsorption coefficient of UD(1), and $b_{UD}(2)$ that of UD(2). Rearranging these equations, we have

$$\left(\frac{C_{UD}}{r_{UA}}\right)^{1/2} = \frac{1}{(k_{UD(1)}b_{UD(1)})^{1/2}} + \frac{b_{UD(1)}+b_{UD(2)}}{(k_{UD(1)}b_{UD(1)})^{1/2}}\cdot C_{UD} \quad (8)$$

$$\left(\frac{C_{UD}}{r_{SA}+r_{SD}}\right)^{1/2} = \frac{1}{(k_{UD(2)}b_{UD(2)})^{1/2}} + \frac{b_{UD(1)}+b_{UD(2)}}{(k_{UD(2)}b_{UD(2)})^{1/2}}\cdot C_{UD} \quad (9)$$

which give linear relations between $(C_{UD}/r_{UA})^{1/2}$, $(C_{UD}/(r_{SA}+r_{SD}))^{1/2}$ and C_{UD}. Then relations between the slopes and the intercepts of the plots of Eqs. (8) and (9) are obtained as follows.

$$x_1/y_1 = b_{UD(1)} + b_{UD(2)}$$

$$x_2/y_2 = b_{UD(1)} + b_{UD(2)}$$

where x_1 denotes the slope of the plot for r_{UA}, y_1 the intercept of that for r_{UA}, x_2 the slope of the plot for $(r_{SA}+r_{SD})$, and y_2 the intercept of that for $(r_{SA}+r_{SD})$. This indicates that the ratio of the slope and the intercept of the Langmuir-plots for r_{UA} and for $(r_{SA}+r_{SD})$ have the same value. It was found, however, from the plots in Fig. 3 that the values of the term, x/y, were not identical for both lines. This suggests that the part of the catalyst surface on which UD(1) is hydrogenated differs from that on which UD(2) is hydrogenated, and the formation of UA and that of SA plus SD can be treated seperately.

Following discussion is made to analyze semi-quantitatively the result shown in Fig. 5 on the basis of the mechanism assumed. According to the mechanism, the rate of the formation of SA and SD can be written as

$$r_{SA} = k_6\theta_H\theta_{keto} + k_3\theta_H\theta_{enol} \quad (10)$$

$$r_{SD} = k_5\theta_{keto} \quad (11)$$

where k_i denotes the rate constant whose subscript i represents each reaction path shown in Fig. 6, and θ the surface coverage. Equating the rates of the formation and the removal of the adsorbed enol species and those of the adsorbed keto species, we get

7) F. J. McQuillin, W. O. Ord, and P. L. Simpson, *J. Chem. Soc.*, **1963**, 5996.

8) E. J. Badin and E. Pacsu, *J. Amer. Chem. Soc.*, **66**, 1963 (1944).

$$k_1\theta_H\theta_{UD(2)} = k_3\theta_H\theta_{enol} + k_4\theta_{enol}$$
$$k_2\theta_H\theta_{UD(2)} + k_4\theta_{enol} = k_6\theta_H\theta_{keto} + k_5\theta_{keto}$$

where the re-adsorption of products were neglected in the "initial rate" treatment, and the fraction of the surface coverage of the adsorbed enol species and that of the adsorbed keto species are obtained:

$$\theta_{enol} = \frac{k_1\theta_H\theta_{UD(2)}}{k_3\theta_H+k_4} \quad (12)$$

$$\theta_{keto} = \frac{k_2(k_3\theta_H+k_4)+k_1k_4}{(k_6\theta_H+k_5)(k_3\theta_H+k_4)}\cdot\theta_H\theta_{UD(2)} \quad (13)$$

Substituting Eqs. (12) and (13) into Eq. (10), the rate of formation of SA is obtained as

$$r_{SA} = \left[\frac{k_1k_3\theta_H}{k_3\theta_H+k_4} + \frac{k_2k_6\theta_H(k_3\theta_H+k_4)+k_1k_4k_6\theta_H}{(k_3\theta_H+k_4)(k_6\theta_H+k_5)}\right] \times \theta_H\theta_{UD(2)} \quad (14)$$

The rate of formation of SA is divided into three terms. The first term represents it through the reaction path 1—3 *via* the adsorbed species in enol form, the second term through the path 2—6, and the third term through the path 1—4—6. Equation (14) is then rewritten as

$$r_{SA} = (r_{SA})_{1-3} + (r_{SA})_{2-6} + (r_{SA})_{1-4-6} \quad (15)$$

Addition of Eqs. (10) and (11) leads to

$$r_{SA} + r_{SD} = (k_6\theta_H+k_5)\cdot\theta_{keto} + k_3\theta_H\theta_{enol} \quad (16)$$

Insertion of Eqs. (12) and (13) into Eq. (16) gives, after rearrangement.

$$r_{SA} + r_{SD} = (k_1+k_2)\cdot\theta_H\theta_{UD(2)} \quad (17)$$

Selectivity S is also derived as follows.

$$S = \frac{r_{SA}}{r_{SA}+r_{SD}} = \frac{k_1k_3\theta_H(k_6\theta_H+k_5)+k_1k_4k_6\theta_H+k_2k_6\theta_H(k_3\theta_H+k_4)}{(k_3\theta_H+k_4)(k_6\theta_H+k_5)(k_1+k_2)} \quad (18)$$

Equation (18) can be rearranged as

$$S = 1 - \frac{\left(\frac{k_2\theta_H}{k_1+k_2}+\frac{k_4}{k_3}\right)\cdot\frac{k_5}{k_6}}{\left(\theta_H+\frac{k_5}{k_6}\right)\left(\theta_H+\frac{k_4}{k_3}\right)} \quad (19)$$

After rearrangement, Eq. (19) can be reduced as follows. (i) If $k_4/k_3=0$, then

$$\frac{1}{1-S} = \frac{k_6}{k_5}\cdot\frac{k_1+k_2}{k_2}\cdot\theta_H + \frac{k_1+k_2}{k_2} \quad (20)$$

and (ii) if $k_2/(k_1+k_2)=1$, then

$$\frac{1}{1-S} = \frac{k_6}{k_5}\cdot\theta_H + 1 \quad (21)$$

A linear relation between $1/(1-S)$ and θ_H was experimentally found as shown in Fig. 5. The values of the slope and the intercept determined by the least square method were 1.36 and 1.10, respectively. Thus we have from Eq. (20) $k_2/(k_1+k_2)=1/1.10$, $k_5/k_6=1.10/1.36$. Hence $k_1=0.1k_2$.

As the rate constant of 1,2 addition (k_2) is much larger than that of 1,4 addition (k_1), and the rate constant of reaction path 4 is negligibly small compared with that of reaction path 3, SD is considered to be formed through the adsorbed keto species *via* path 2—5.

Employing the values of the rate constants, the three terms in Eq. (15) can be calculated referring to Eq. (14). The first and second term are reduced as

$$(r_{SA})_{1-3} = 0.1k_2\cdot\theta_H\theta_{UD(2)}$$
$$(r_{SA})_{2-6} = k_2\theta^2_H\theta_{UD(2)}/(\theta_H+0.81)$$

The third term is negligibly small since k_4 is zero. Thus a fraction of $(r_{SA})_{2-6}$ over r_{SA} is

$$(r_{SA})_{2-6}/r_{SA} = 0.91\theta_H/(\theta_H+0.073) \quad (22)$$

It is found from Eq. (22) that the contribution of paths 2—6 to the formation of SA increases with the increase of hydrogen coverage. It can therefore be said that the formation of SA occurs dominantly through the adsorbed enol species *via* paths 1—3 at lower hydrogen coverage and through the adsorbed keto species *via* paths 2—6 at higher hydrogen coverage.

The fact that the selectivity, $r_{SA}/(r_{SA}+r_{SA})$, increases with the increase of hydrogen coverage as shown in Fig. 5 can be interpreted as due to the increase of the fraction of adsorbed keto species consumed for the formation of SA.

Reactions of Allenes. IV.[1] New Palladium Complexes Having a Bridged Allene Trimer Ligand

Tadashi OKAMOTO

Institute for Chemical Research, Kyoto University, Gokasho, Uji

(Received October 6, 1970)

Di-μ-acetato-[2,2′-(1-methyleneethylene)bis-π-allyl]dipalladium (I) was obtained (18%) by the reaction of allene and palladium acetate. Its structure was estimated from the data of elemental analysis, molecular weight, hydrogenolysis reaction, IR, and NMR. Complex I was synthesized otherwise by the reaction of allene with di-μ-acetato-2,2′-bi-π-allyldipalladium. The insertion mechanism for the latter reaction was confirmed by the product of the reaction using allene-d_4, $Pd_2(C_9H_8D_4)(CH_3COO)_2$. It was found that this insertion reaction was by far faster than analogous reactions with bis(acetylacetonato)-2,2′-bi-π-allyldipalladium or di-μ-acetato-bis-(π-allyl palladium). The observed acceleration was assumed to be due to strain in the substrate. From NMR data of I and other π-allylpalladium complexes already published, it was shown that the difference in chemical shifts between *syn* and *anti* protons of π-allyl complexes is dependent on the substituents on the central carbon; the non-conjugated substituents give smaller values (0,9—1.01 ppm for μ-chloro complexes), and α,β-unsaturated substituents give larger values (1.27 − 1.28 ppm for μ-chloro complexes). Chloro and acetylacetonato derivatives of I, and the activation energy for spin exchange of saturated methylene protons in I are also described.

It is well known that an allenic compound produces various stable σ-, π-, and π-allyl complexes by the reaction with transition metal compounds.[2] This suggests that some organometallics affording information on catalytic reactions might be obtained, by the reaction of allene with transition metal compounds which are useful as catalysts in organic syntheses.

On this assumption, the author examined the reaction of allene with palladium acetate, and obtained some new π-allyl complexes.[3,4] This paper deals with a full description of the formation and the structure of the palladium complexes having a new bridging ligand of allene trimer, 2,2′-(1-methyleneethylene)bis-π-allyl. Results are given also on the NMR of the μ-acetato complex with variation of temperature and the fast insertion of allene into a strained π-allyl complex.[4]

Results and Discussion

Isolation and the Structure of Di-μ-acetato-[2,2′-(1-methyleneethylene)bis-π-allyl]dipalladium. Palladium acetate and allene were stirred in benzene overnight. Subsequent separation of the resulting solution with a silica-gel column gave a yellow crystal, di-μ-acetato-[2,2′-(1-methyleneethylene)bis-π-allyl]dipalladium (I). Analytical data and the molecular weight determination showed that the complex had a molecular formula $Pd_2C_{13}H_{18}O_4$. Presence of acetate ligands was estimated by the carboxylate stretching absorptions of its IR spectrum (1570 and 1410 cm^{-1}) and the absorption of acetyl protons (2.0 ppm) on the NMR spectrum. The IR spectrum further showed absence of an ester carbonyl group. This was confirmed by the NMR spectrum of chloro complex VI. Hydrogenolysis of I made it clear that five moles of hydrogen were necessary for complete hydrogenation, and the organic ligand had the carbon framework of 2,3,5-trimethylhexane. At this stage, I was formulated as $Pd_2(C_9H_{12})(CH_3COO)_2$. Further studies of the structure were carried out with the aid of NMR spectra. The spectra are shown in Fig. I. The broad absorptions observed at ambient temperature became sharp at elevated temperatures and the relative intensities of the absorptions became clear; corresponding to the absorptions in the order of decreasing δ value, relative intensities are 1H, 1H, 2H, 2H, 2H, 2H, 2H, and 6H. The spectra are interpreted as consisting of the absorptions by one vinylidene, two π-allyls, and one saturated methylene group from their chemical shifts.[2i,2j,5]

Formula. Structure and NMR Assignment of I (δ value in CD_3COOD at 40°C).

They were supported also by the spectra of the deuterated complex. The structure elucidated from the NMR spectra and their assignments are shown in Formula. The assignments of four absorptions of two π-allyl groups are of interest. An interpretation that the deshielding effect caused by a neighboring unsaturated bond gives higher δ values for the π-allyl group adjacent to a carbon-carbon double bond is not correct. For complex I, the absorptions by the isolated π-allyl appear inside the two absorptions by the π-allyl adjacent to an unsaturated bond. In other words, the difference in chemical shifts between the absorptions by *syn* and *anti* protons of a π-allyl group,

$$\Delta\delta = \delta_{syn} - \delta_{anti}$$

is larger for the π-allyl group adjacent to an unsaturated bond than for the isolated π-allyl. This seem to be the general rule at least for palladium complexes. For di-μ-chloro dipalladium complexes, an isolated π-allyl gives the $\Delta\delta$ value from 0.90 to 1.01 ppm for 5 examples in $CDCl_3$, and a conjugated π-allyl gives the value of 1.28 or 1.27 in three cases (Table 1). Di-μ-acetato complexes also follow this rule. The results are interpreted as follows. The electronic effect of a substituent on the central carbon of a π-allyl group delivered through the carbon-carbon bond is nearly equal for *syn* and *anti* protons of a π-allyl group, and is cancelled in the remainder of the subtraction of their chemical shifts. The $\Delta\delta$ value is, therefore, nearly constant for isolated π-allylic palladium complexes having the same anion ligands. For π-allyls adjacent to unsaturated bonds, however, magnetic anisotropy of the unsaturated carbons influences *syn* and *anti* protons unequally, and gives different $\Delta\delta$ values from those of isolated π-allyl groups. The spectra of I, in which ring formation hinders the rotation of bonds, show that the *syn* proton of a π-allyl suffers a deshielding effect by an adjacent unsaturated carbon and the *anti* proton suffers more shielding.

Synthesis of Complex I from Di-μ-acetato-2,2'-bi-π-allyldipalladium and Allene. Complex I was also synthesized in a high yield by bubbling allene into a dichloromethane solution of di-μ-acetato-2,2'-bi-π-allyldipalladium (II).

$$Pd_2(C_3H_4)_2(CH_3COO)_2 + C_3H_4 \longrightarrow Pd_2(C_3H_4)_3(CH_3COO)_2$$
(II) (I)

The reaction proceeded almost quantitatively. when allene-d_4 was used for this reaction, $Pd_2(C_9H_8D_4)(CH_3COO)_2$ (III) was obtained. NMR spectra of III are shown in Fig. 2. The spectra show that two absorptions at δ 3.65 and 2.78 ppm in the corresponding complex I have disappeared. The structure of tetradeutero complex III clearly indicates that this complex is formed *via* insertion of allene between the bridged bi-π-allyl and palladium. The coupling of newly coordinated allenes with replacement of π-allyl ligands,

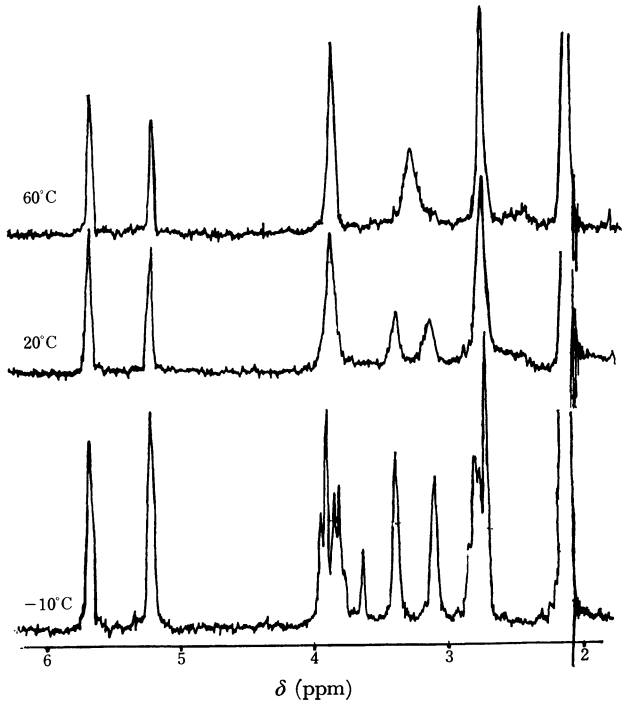

Fig. 2. Temperature-dependent NMR spectra of III (in $CDCl_3$).

observed by the reaction of allene with acetylacetonato-π-allylpalladium,[2k] did not take place in this case.

Such a bridge elongation by insertion has not yet been reported and suggests that there is some allowance in length of the ligand bridging two palladium metals combined with μ-acetato ligands. The result is interesting from the fact that palladium acetate acts as a catalyst for dimerization[7,8] or co-dimerization[9] of ethylenic compounds and arenes.

Concerning insertion, the reaction was found to be an assisted one. Experimental results are listed in Table 2. Under the same conditions as in the reaction of allene and II, di-μ-acetato-bis(π-allylpalladium) (IV) and bis(acetylacetonato)-2,2'-bi-π-allyldipalladium (V) did not insert allene, and the substrates were recovered almost quantitatively. Thus, it is clear that the acceleration observed for II is not simply due to the presence of μ-acetato ligands or a bi-π-allyl ligand. Hughes and Powell reported that there is some strain in complex II on the basis of its NMR spectra of a lower symmetry than C_{2v} and that rigid μ-acetato bridges impart the strain.[2k] Temperature-independent spectra from −100°C to 60°C suggest that no exchange of the μ-acetato ligand occurs in this complex at least faster than NMR time scale. Temperature-dependent NMR spectra of I and simple inspection of a scaled model suggest there is less strain in this complex.

The insertion of allene might be explained to occur easily by the relief of the strain in the substrate complex. This is a new factor besides steric repulsion and electronic factors[10] controlling the insertion into a π-allyl-metal bond.

Derivatives of I. When I was treated with an aqueous sodium chloride solution, it exchanged all acetate ligands for chloride ions, and a yellowish gray complex, dichloro-[2,2'-(1-methyleneethylene) bis-π-allyl]dipalladium (VI), was precipitated. Complex I was regenerated from VI by treatment with silver acetate in acetone. An acetylacetonato complex, bis-(acetylacetonato)-[2,2'-(1-methyleneethylene) bis-π-allyl]dipalladium (VII), was obtained from VI as usual with thallium acetylacetonate.[2j] The NMR spectrum of VII was similar to the spectra of I at high temperatures.

Temperature-dependent NMR Spectra of I and III. I shows temperature-dependent NMR spectra and the spectra at low temperatures are very complicated due to the overlap of absorptions. In the case of tetradeutero complex III, however, interpretation of the spectra became simple. At −10°C, two saturated methylene protons of complex III exhibited AB type couplings with a coupling constant of 15.5 Hz. This value is reasonable for the coupling constant of geminal methylene protons on a sufficiently large ring. It shows that the ring is fixed at the temperature. With the rise of temperature, the AB quartet changed into a broad doublet at room temperature, and finally coalesced

into a singlet at 46°C (Fig. 3). As the origin of the dynamic nuclear magnetic resonance observed, two factors might be considered, the molecular fluctuation of the complex, and the dissociation of the μ-acetato bridge followed by the rotation of the organic ligand. A rough estimate of the activation energy from the coalescence temperature[11] with the assumption that the frequency factor is 10^{12},[12] gave 14.5 kcal/mol, which might be too large for the energy of the former mechanism.

For π-allyl parts, the spectra of I and III are also dependent on temperature (Figs. 1 and 2). At −10°C *syn* and *anti* protons of III were each separated into two doublets with coupling constants 1.0 and 1.5 Hz, respectively. The separation between the doublets was greater for *syn* protons, as can be seen from inspection of a scaled model. Coalecsence of both doublets starts almost at the same temperature as that for saturated methylene protons, suggesting that these processes occur by the same mechanism. Contrary to what has been reported for IV,[13] the magnetic unequality in I and III would arise from the difference in a stereochmical situation against the bridging 1-methyleneethylene group.

The exchange of *syn* and *anti* protons was not detected at least until 100°C in acetic acid-d_4, indicating that no terminal CH_2 rotation is present in these complexes.

Experimental

All reagents were obtained commercially and used without further purification unless otherwise stated. Melting points were determined with a Yanagimoto melting point apparatus. IR spectra were measured as KBr pellets using a Perkin-Elmer 521 spectrometer; NMR spectra, on a Varian A-60 spectrometer for dilute solutions in the specified solvents. The chemical shifts were expressed in δ value (ppm) relative to TMS used as the internal standard. The temperature of measurement was 40°C unless otherwise specified. Mass spectra were obtained with a JMS-01SG spectrometer; the molecular weight was determined with a vapor pressure osmometer of Mechrolab-301. A gas chromatograph of Yanagimoto GCG 220 type was used for both analytical and preparative purposes.

Formation of Complex I from Allene and Palladium Acetate. Into a solution of palladium acetate[14] (5.0 g) in benzene (250 m*l*) was introduced allene gas (6.7 *l*); stirring was continued overnight at ambient temperature. After addition of hexane (250 m*l*), the resulting solution was chromatographed on silica-gel (Wako-gel C200). Stepwise elution with diethyl ether and ethyl acetate afforded complex I as an ethyl acetate solution. After evaporating the solvent, recrystallization of the residue from dichloromethane-hexane gave a pure product as a yellow crystal (0.92 g, 18.3%), mp 148—150°C (dec).

Found: C, 34.63; H, 4.10%; mol wt (benzene, 37°C), 466. Calcd for $Pd_2(C_9H_{12})(CH_3COO)_2$: C, 34.58; H, 4.11%; mol wt, 451. IR: 1620(C=C), 1570(COO^-), 1468, 1410(COO^-), 1340, 1042, 1020, 945, 932, and 760 cm^{-1}. NMR(in $CDCl_3$): 5.63 (1H, $=CH_2$), 5.17 (1H, $=CH_2$), 3.82 (2H, π-allyl), 3.65 (2H, π-allyl), 3.32 and 3.09 (2H, $-CH_2-$), 2.78 (2H, π-allyl), 2.68 (2H, π-allyl), and 2.02 ppm (6H, CH_3CO).

Hydrogenolysis of I. Complex I (0.78 mmol) was dissolved in chloroform and hydrogen was fed from a gas buret after evacuation with dry-ice cooling. A rapid gas absorption ceased in 65 min with consumption of 3.55 mmol of hydrogen.[15] The products were palladium metal, acetic acid, and hydrocarbons. The hydrocarbons were found to be a mixture of three compounds by gas chromatography (VPC, PEG 6000) with a relative ratio[16] of 37:14:50 in the order of retention time. Absence of C_3 hydrocarbons was confirmed by VPC (β,β'-oxydipropionitrile, 25°C). The three hydrocarbons were separated by gas chromatography using the same column (PEG 6000). The first effluent was identified as 2,3,5-trimethylhexane by peak to peak correspondence with the standard NMR chart (API 214). The other two products were identified as 2,3,5-trimethyl-2-hexene and 2,4,5-trimethyl-2-hexene by their NMR spectra, and mass spectra of the brominated products.

2,3,5-trimethyl-2-hexene; NMR(in CCl_4): 0.85 (d, 6H), 1.60 (s, 9H), and 1.88 ppm (s, 2H). The mass spectrum for the brominated product; m/e^+ 285 $(M-1)^+$.

2,4,5-trimethyl-2-hexene; NMR(in CCl_4): 0.7—0.9 (m, 9H), 1.4—1.6 (m, 1H), 1.57 (d, 3H), 1.67 (d, 3H), 2.03 (m, 1H), and 4.92 ppm (d, 1H), The mass spectrum for the brominated product; m/e^+ 285 $(M-1)^+$.

Calculation of the theoretical amount of hydrogen based on the molecular formula and the ratio of the three hydrocarbons above gave 3.62 mmol, which is in good accordance with the experimental value.

Synthesis of I from Di-μ-acetato-2,2'-bi-π-allyl-dipalladium. Allene gas (100 m*l*) was introduced into the dichloromethane solution (20 m*l*) of complex II[2k] (0.222 mmol), and the mixture was stirred at ambient temperature overnight. When the solvent was distilled off, a yellow crystal was obtained. Recrystallization from dichloromethane-hexane afforded I (0.207 mmol, 93.5%). Under the same conditions, tetradeutero complex III was obtained using allene-d_4,[18] mp 150—152°C (dec).

Found: C, 34.57; H, 5.06%. Calcd for $Pd_2(C_9H_8D)_4(CH_3COO)_2$: C, 34.31; H, 4.87%. IR: 1570, 1410, 1340, 1040, 1020, 940, 930, and 672 cm^{-1}. NMR(in $CDCl_3$): 5.63 (s, 1H), 5.17 (s, 1H), 3.80 (s, 2H), 3.30 and 3.08 (each broad s, sum 2H), 2.68 (s, 2H), and 2.02 ppm (s, 6H); (in $CDCl_3$, −10°C): 5.60 (s), 5.15 (s), 3.85 (d, J=1.5 Hz), 3.77 (d, J=1.0 Hz), 3.43 and 2.93 (AB, J=15.5 Hz), 2.72 (d, J=1.0 Hz), 2.65 (d, J=1.5 Hz), and 2.05 ppm (s).

Comparison of Various Complexes for Insertion of Allene. Di-μ-acetato-bis(π-allylpalladium) (IV) was prepared by the method of Robinson and Shaw.[6]

Bis(acetylacetonato)-2,2'-bi-π-allyldipalladium (V) was prepared by the method of Hughes and Powell[1c] as a white crystal, mp 187—190°C (dec).

11) G. Binsch, in "Topics in Stereochemistry," Vol. 3, ed. by E. L. Eliel and N. L. Allinger, Interscience Publishers, New York, N. Y. (1968), p.97.

12) Selection of this value is arbitrary. However, from the fact that the value is in the same order as that of the interconversion of cyclohexane and the valence isomerization of bullvalene,[11] this would be a reasonable selection.

13) J. Powell, *J. Amer. Chem. Soc.*, **91**, 4311 (1969).

14) T. A. Stephenson, S. M. Morehouse, A. R. Powell, J. P. Heffer, and G. Wilkinson, *J. Chem. Soc.*, **1965**, 3632.

15) To avoid the error caused by the adsorption of hydrogen by palladium, hydrogen feeding was stopped when the rapid absorption of gas was over.

16) It was assumed that the relative response per gram of these hydrocarbons was equal. Values in literature[17] suggest that the error caused by this assumption is within 5%.

The author is grateful to Professor Sango Kunichika and Dr. Yasumasa Sakakibara for their helpful discussions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1357—1361 (1971)

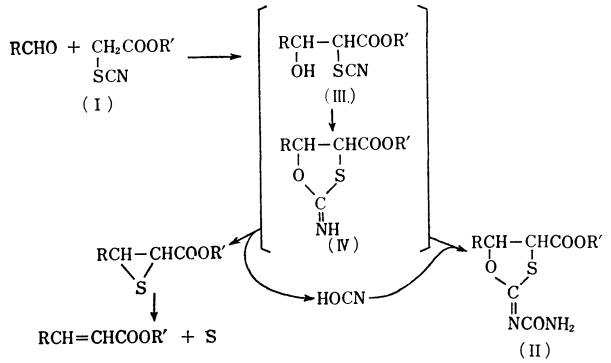
Thiocyanoacetate. I. Reactions of Thiocyanoacetic Esters with Aldehydes[1)]

Satoshi KAMBE,
Toshio HAYASHI,* Heinosuke YASUDA,*[2)] and Hiroshi MIDORIKAWA*
Oyama Technical College, Oyama, Tochigi
**The Institute of Physical and Chemical Research, Wako-shi, Saitama*

(Received October 8, 1970)

Thiocyanoacetic esters (I) and aldehydes reacted in the presence of potassium fluoride or carbonate to give α,β-unsaturated ester as a major product and an unexpected solid product (II) as a minor one, which was determined to be *N*-carbamoyl-2-imino-5-substituted 1,3-oxathiolane-4-carboxylic esters.

The thiocyanato group which is often referred to as "pseudohalogen," is strongly electron-attractive. The thiocyanoacetic esters (I) would thus be expected to have an active methylene group.[3)] I is structurally similar to chloroacetic and cyanoacetic esters, which easily react with carbonyl compounds. However, little is known so far about the reactions of **I** with carbonyl compounds. This might be ascribed to the fact that the thiocyanato group is extremely sensitive to the bases usually used as a catalyst, giving cyclization compounds[4)] or resinous matters. However, if a suitable catalyst is found, I is expected to react with carbonyl compounds. The purpose of this investigation is to find the possibility of I as an active methylene compound.



Scheme 1

Results and Discussion

Equimolecular reactions of thiocyanoacetic ester (I) with an aldehyde in the presence of potassium fluoride or carbonate were carried out in moist ether at low temperatures. The reaction consistently gave liquid products as major ones, and an unexpected, solid product (II) as a minor one and elemental sulfur. Glpc analysis and NMR spectra showed that the liquid products contain a stereoisomeric mixture of *cis*- and *trans*- α,β-unsaturated esters and two other components which could not be identified. In the case of the

f) Methoxyl protons.
g) Methyl group.
h) Methylene group.
i) Methine group.
j) Methyl *N*-carbamoyl-2-imino-1,3-oxathiolane-5-ethyl-4-carboxylate.
l) Measured in a $CDCl_3$ solution.

reaction between ethyl thiocyanoacetate and benzaldehyde, the liquid products were found to be only a mixture of *cis*- and *trans*-cinnamic esters (*cis*:*trans*= 25:75).

The structural elucidation of the solid product (II) is based on elemental analysis, spectral studies, and chemical reactivity. Product (IIa), for example, was white needles having a structural formula $C_{13}H_{14}N_2O_4S$, *m/e* 294, and mp 190—191°C. All the solid product (II) obtained have the general formula $RC_4H_5N_2O_2COOR'$ which corresponds formally to an addition compound between β-substituted β-hydroxy

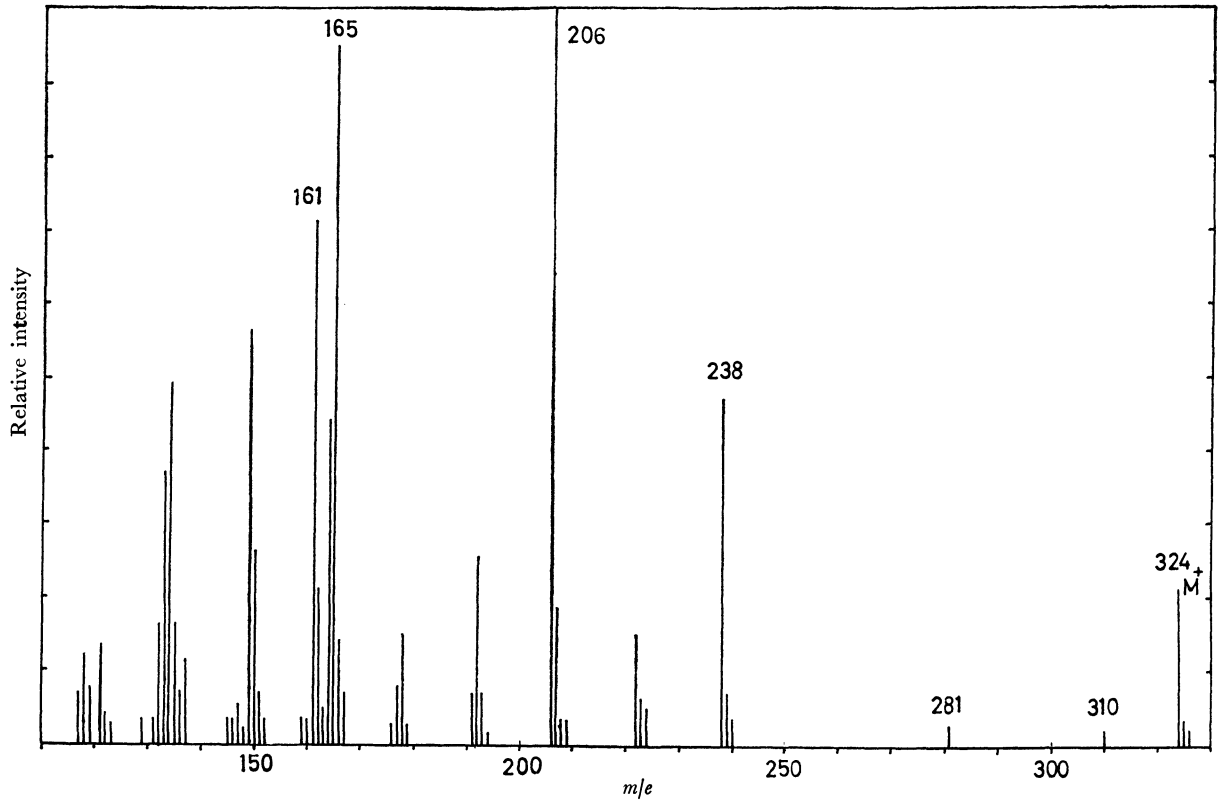

Fig. 5. Mass spectrum of IIc.

α-thiocyano-propionic ester (III) and cyanic acid. II, when treated with ethanol solution of sodium hyroxide, gives rise to α,β-unsaturated ester. We see from Table 2 that the IR spectra of II (KBr pellet) exhibit broad stretching bands in the range 3450—3180 cm^{-1}, the ester C=O band near 1740 cm^{-1}, and the C=N and carbamoyl C=O bands in the range 1688—1615 cm^{-1}. As shown in Figs. 1 and 2, the spectra in the region between 1700 and 1550 cm^{-1} are very similar in position and shape to those of *N*-carbamoyl-2-imino-1,3-oxathiolane. The NMR spectra of II (DMSO-d_6) also revealed that the signals of the NH_2 protons in II are similar in position and shape to those of the carbamoyl NH_2 protons in *N*-carbamoyl-2-imino-1,3-oxathiolane (Figs. 3 and 4). The doublet of the NH_2 protons near 7.00 ppm in a DMSO-d_6 solution coalesces into one broad signal near 5.75 ppm in a $CDCl_3$ solution (Table 3). However, the reason why the NH_2 signal splits into doublet in a DMSO-d_6 solution, could not be elucidated. The mass spectra of II also suggested the presence of *N*-carbamoyl-2-imino-1,3-oxathiolane system (Figs. 5

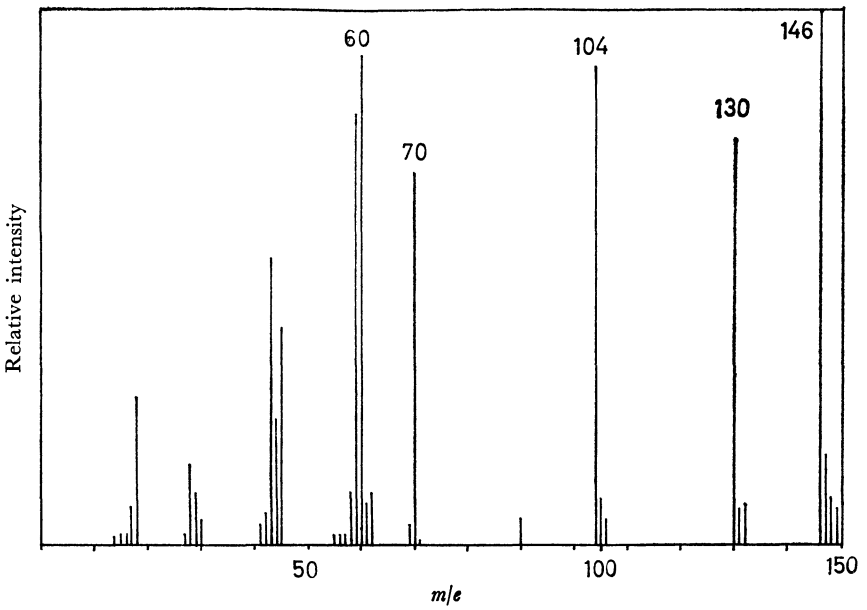

Fig. 6. Mass spectrum of *N*-carbamoyl-2-imino-1,3-oxathiolane.

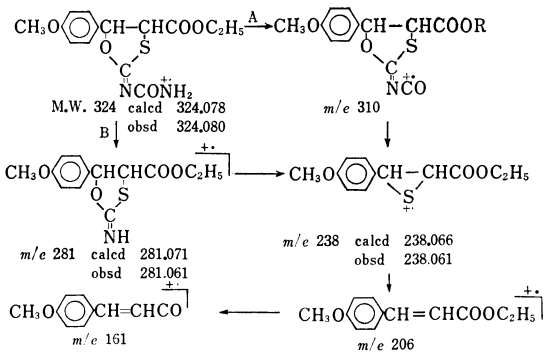
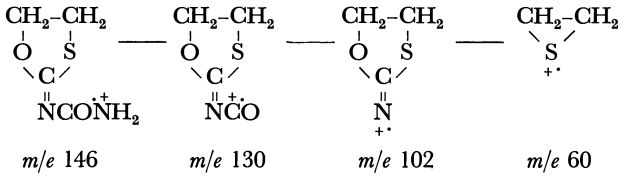


Scheme 2



Scheme 3

and 6, and Scheme 2). Although the fragmentation of II proceeds in two ways A and B as shown in Scheme 3, route A is similar to the fragmentation of the oxathiolane. We have determined the structure of II to be *N*-carbamoyl-2-imino-5-substituted 1,3-oxathiolane-4-carboxylic ester.

A plausible reaction pathway is postulated in Scheme 1. Wagner-Jauregg *et al.*[5] and Price and Kirk[6] found that 2-thio-cyanoethanols are slowly converted into thiirane and *N*-carbamoyl-2-imino-1,3-oxathiolane at room temperature. Intermediate III which is produced initially from I and aldehyde, would be converted into II and thioglycidic ester by the same mechanism. Owen *et al.*[7] reported that the thioglycidic esters are unstable and lose sulfur, forming unsaturated esters. The reason why II is obtained as a minor product might be ascribed to slowness of reaction by which liberated cyanic acid is added to III, because II once formed is stable against potassium carbonate in ether.

NMR spectra suggest that II obtained in the present work is all in the same configuration. However, without isolation of any isomeric form, the configuration cannot be determined by means of NMR technique.

Experimental

NMR spectra were obtained on a JNM-C-60 high-resolution NMR spectrometer at temperatures 19—20°C. Tetramethylsilane was used as an internal reference standard. IR spectra were determined in the KBr pellet using a Perkin-Elmer 521 spectrophotometer. Mass spectra were measured with a JMS-01S instrument operating at 75 eV.

Reaction of Thiocyanoacetic Ester (I) with Aldehyde. General Procedure. Thiocyanoacetic ester (0.05 mol) was added dropwise below 10°C to a mechanically stirred solution of potassium carbonate or fluoride (0.05 mol) and aldehyde (0.05 mol) in 20 m*l* of moist ether. Stirring was continued for 10 hr, and the solution was allowed to stand overnight. The catalyst was removed by filtration, and the precipitated solid product was collected on a filter, washed with a small amount of water and then dried. Repeated recrystallization yielded pure *N*-carbamoyl-2-imino-5-substituted 1,3-oxathiolane-4-carboxylic ester (II). The filtrate was subjected to Glpc analysis.

Conversion of IIa into Ethyl Cinnamate. A solution which contained 1.0 g of IIa and 1.0 g of sodium hydroxide in 15 m*l* of ethanol was refluxed for an hour. After ethanol was removed with a vacuum evaporator, the remaining liquid was subjected to glpc and NMR analysis.

Formation of Ketenimines by the Reaction of Thioamides with Diethyl Azodicarboxylate and Triphenylphosphine

Oyo MITSUNOBU, Koki KATO, and Makoto WADA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

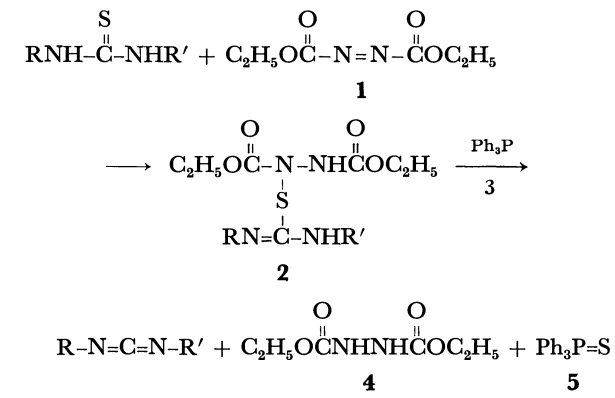
(Received October 14, 1970)

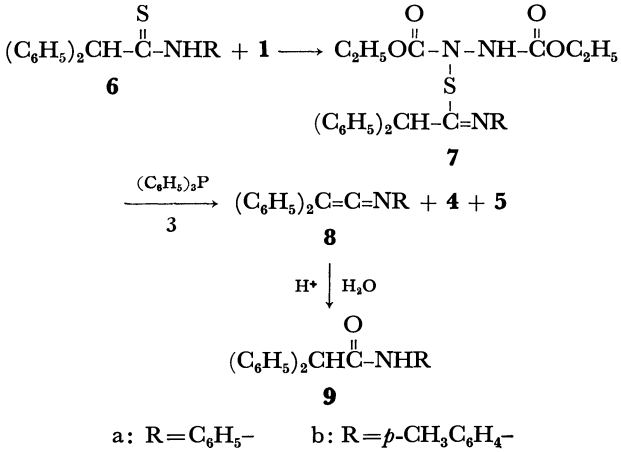
The reaction of diphenylacetothioanilide with diethyl azodicarboxylate and triphenylphosphine gave rise to the formation of diphenylketene(*N*-phenyl)imine. Similarly, the reaction of *N*-(*p*-tolyl)diphenylacetothioamide gave diphenylketene(*N*-*p*-tolyl)imine. On treatment with diethyl azodicarboxylate in the presence of sodium ethoxide, diphenylacetothioanilide afforded bis(*N*-phenylbenzalimidoyl) disulfide in a good yield. The intermediate of the formation of the ketenimines is also discussed.

Ketenimines have attracted considerable attention because of their importance as versatile reagent. Their use as condensing agents in the preparation of peptides[1] and nucleotides[2] has been examined. The preparation of ketenimines has been accomplished in various ways, 1) the interaction of phosphinimine and ketene,[3] 2) the reaction of diazomethane with nitriles,[4] 3) dehydrochlorination or dechlorination of imino chlorides,[5] 4) dehydration of amides,[6] 5) the Beckmann rearrangement,[7] 6) the reaction of α-haloxime with triphenylphosphine,[8] 7) photolysis of diphenyldiazomethane in the presence of isonitrile,[9] and 8) ring opening of isoxazolium salts.[10]

A new approach to the synthesis of disubstituted carbodiimides from *N,N'*-disubstituted thioureas using diethyl azodicarboxylate (**1**) and triphenylphosphine (**3**) was described in the preceding paper.[11] The reaction proceeds through the initial formation of an 1:1 adduct (**2**) of the thiourea and **1**. Formation of the carbodiimide couples to a redox system.

Since thioamides (**6**) are similar in structure to thioureas, **6** would be expected to react with **1** giving an 1:1 adduct (**7**). In view of the reactivity of **2**, we might expect that the **7** is desulfurized by **3** to give the corresponding ketenimine (**8**), diethyl hydrazodicarboxylate (**4**) and triphenylphosphine sulfide (**5**).





a: R=C_6H_5– b: R=*p*-$CH_3C_6H_4$–

Equimolar amounts of **1** and diphenylacetothioanilide (**6a**) in tetrahydrofuran (THF) were allowed to react for 4 hr, and then an equimolar amount of **3** was added. After the solution was kept standing for 7 days, the solvent was removed to give a yellow syrup. The infrared spectrum of the syrup shows a strong absorption at 2000 cm^{-1} which is attributed to N=C=C of the ketenimine. From the syrup, however, diphenylketen(*N*-phenyl)imine (**8a**) could not be isolated in pure state. In a repetition of the above experiment, the resulting yellow syrup was therefore treated with 2N hydrochloric acid to convert the **8a** into diphenylacetanilide (**9a**). The mixture was separated by column chromatography on silica gel to give **9a**, **4**, **5**, and triphenylphosphine oxide (**12**) in 35.5%, 98.0%, 36.1%, and 60.0% yields, respectively, and 63.0%

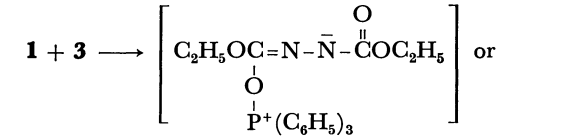
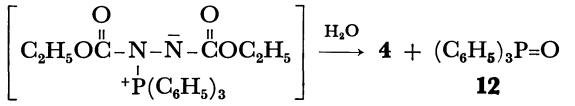
of **6a** was recovered. This indicates that up to 35.5% of **8a** was formed by the present procedure. Similarly, diphenylketene(*N*-*p*-tolyl)imine was formed in a 42.5% yield. The formation of **12** can be explained as follows. The addition reaction of **6a** to **1** is a time consuming step and on treatment the reaction mixture with **3**, unreacted **1** forms a quaternary phosphonium salt (**11**)[12] which is hydrolyzed to **4** and **12**. In fact, thin layer chromatography (tlc) of the solution resulting from the reaction of **1** and **6a** showed that the starting materials survived even after 7 days.



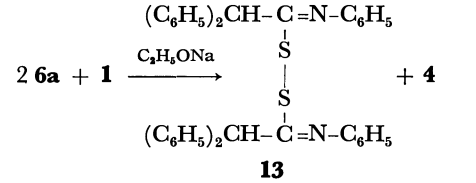
11a



11b

It was therefore considered desirable to accelerate the reaction of **1** with **6** for preparation of **8**. Thus, ethanol was used as solvent in place of THF. As expected, the reaction of **1** with **6a** in ethanol was shown to proceed more faster than in THF, namely, **1** and **6a** were consumed within 1 day as indicated by tlc. After treatment with **3**, followed by treatment with 2N hydrochloric acid, the products were separated by column chromatography. The yield of **8a** increased to a 61.2% and **5** was isolated in a 91.2% yield, although a small amount of **12** was still isolated.

Other attempts to promote the reaction met with no success. For example, when *p*-toluensulfonic acid or benzoyl peroxide was used as a catalyst, the starting materials remained in considerable extent after one day as indicated by tlc. On the other hand, when sodium ethoxide was used as a catalyst, the reaction proceeded in an unexpected direction. When one half of **1** was added to **6a** in THF in the presence of sodium ethoxide, the color of the solution immediately faded. However, when the remaining half was added, disappearance of the orange red of **1** was no longer observed. Thus, **1** was allowed to react with 2 mol of **6a** at room temperature and bis(*N*-phenylbenzalimidoyl) disulfide (**13**) was obtained in a 97% yield. The structure of **13** was confirmed by elementary analysis and infrared spectrum.



13

Concerning the intermediate of the present reaction, two possibilities could be considered, the initial formation of **7** and the formation of bis(*N*-arylbenzalimidoyl) disulfide (**13**).[13] In order to confirm the reaction path, the reaction of **1** with an equimolar amount of **6a** in THF was followed by infrared absorption spectrum. The spectrum indicated that the intensity of the C=O absorption of **1** gradually decreased and new absorptions appeared at 1740 cm^{-1} (C=O) and 1645 cm^{-1} (C=N) with the progress of reaction. The tlc of the solution revealed a new spot[15] which disappeared, on treatment of the solution with **3**, and the spot of the ketenimine was observed. That the disulfide is not an intermediate was further proved by a separate experiment in which **13** was treated with an equimolar amount of **3**. No **8a** was formed as indicated by tlc.

An attempt was made to isolate the proposed intermediate, **7**. However, from the reaction solution of **1** and **6a**, only a yellow oily substance was obtained which could not be purified.

The present procedure is unique since the reaction is coupled to a redox system, namely, triphenylphosphine is oxidized to triphenylphosphine sulfide and diethyl azodicarboxylate is reduced to diethyl hydrazodicarboxylate.

Experimental

Solvents were purified and dried in the usaual way. Tri phenylphosphine was of commercial grade and was used after recrystallization from ethanol. Diphenylacetic acid[16] and diethyl azodicarboxylate[17] were prepared according to published procedures. IR spectra were recorded on a Nippon Bunko IR-G spectrometer and measured as KBr disk. IR spectra of the reaction solution were measured in a 0.05 cm matched cell (NaCl). Tlc were carried on silica gel (Wako Gel B-O) plates with benzene as the solvent and spots were developed with iodine vapor.

Diphenylacethyl Chloride. A modification of the procedure used for the preparation of glutarimide-*β*-acetyl chloride[18] was used. A mixture of diphenylacetic acid (30 g) and thionyl chloride (26 g) was heated at 100°C for 15 min. On being cooled to room temperature, 3 drops of dimethylformamide were added to the solution and refluxed for 15 min during which time vigorous evolution of HCl and SO_2 took place. Diphenylacethyl chloride was isolated by distillation; 26 g, 80%, bp 121—122°C/3mmHg.

Diphenylacetothioanilide and N-*(p-Tolyl)diphenylacetothioamide.* A modification of the procedure in literature[19] was used.

Twenty grams of diphenylacetanilide and 35 g of phosphorus pentasulfide were suspended in 150 m*l* of dioxane and stirred for 30 min at 80°C. The material was then extracted with dioxane and the combined extract was evaporated to dryness *in vacuo*. The residue was crystallized from xylene and diphenylacetothioanilide amounted to 17 g (78%), mp 187—188°C. In a similar way, *N*-(*p*-tolyl)diphenylacetothioamide was obtained in an 80% yield, mp 190—191°C.

*Preparation of Bis(*N*-phenylbenzalimidoyl) Disulfide (**13**).* To a solution of 0.303 g (0.001 mol) of diphenylacetothioanilide and a catalytic amount (one heaping of spatula) of sodium ethoxide in 14 m*l* of tetrahydrofuran (THF) was added dropwise to 0.087 g (0.0005 mol) of diethyl azodicarboxylate in 6 m*l* of THF. The color of the reaction mixture immediately faded. The solution was then evaporated under reduced pressure and the residue was chromatographed on silica gel (2.3 cm × 15 cm) to separate the products. Elution with benzene gave bis(*N*-phenylbenzalimidoyl) disulfide (0.29 g, 97%) which was dissolved in THF and precipitated with petroleum ether to give a pure sample, mp 169—170°C.

Found: N,4.39%. Calcd for $C_{40}H_{32}N_2S_2$:N,4.63%. IR(KBr) 1625 cm^{-1}(C=N) ; no N–H absorption.

Elution next with methanol gave diethyl hydrazodicarboxylate(0.087 g, 98%, mp 130—131°C).

Reaction of N-*(*p*-Tolyl)diphenylacetothioamide with Diethyl Azodicarboxylate and Triphenylphosphine.* To a stirred solution of 0.317 g (0.001 mol) of *N*-(*p*-tolyl)diphenylacetothioamide and 0.262 g (0.001 mol) of triphenylphosphine in 18 m*l* of THF was added 0.174 g (0.001 mol) of diethyl azodicarboxylate in an atmosphere of nitrogen at room temperature. After the solution was kept standing for 7 days at room temperature, it was evaporated *in vacuo*. The residue was dissolved in 10 m*l* of acetone and 4 m*l* of 2N hydrochloric acid and allowed to stand overnight to convert the diphenylketene-*N*-(*p*-tolyl)imine to *N*-(*p*-tolyl)diphenylacetamide. On being concentrated to dryness, the products were chromatographed on silica gel (2.3 cm × 50 cm). Elution with benzene gave two unknown substances (0.007 g and 0.002 g), recovered *N*-(*p*-tolyl)diphenylacetothioamide (0.148 g, 46.7%), triphenylphosphine sulfide (0.157 g, 53.4%), *N*-(*p*-tolyl)diphenylacetamide (0.128 g, 40.4%), diethyl hydrazodicarboxylate (quantitative) and triphenylphosphine oxide (0.135 g, 46.0%).

Reaction of Diphenylacetothioanilide with Diethyl Azodicarboxylate and Triphenylphosphine. *a) THF as Solvent.* To a solution of diphenylacetothioanilide (0.303 g, 0.001 mol) and triphenylphosphine (0.262 g, 0.001 mol) in THF (14 m*l*) was added dropwise diethyl azodicarboxylate (0.174 g, 0.001 mol) in THF (6 m*l*). After the solution had been kept standing for 7 days and subjected to the same work-up, diphenylacetanilide, diethyl hydrazodicarboxylate, triphenylphosphine sulfide, and triphenylphosphine oxide were obtained in 35.5%, 98.0%, 36.1%, and 60.0% yields, respectively, along with a small amount of an unknown product. Sixty three percent of diphenylacetothioanilide was recovered unchanged.

A change in the order of the addition does not affect the yield of the amide. The reaction also proceeds at 0°C. Triphenylphosphine in THF was added to diphenylacetothioanilide and diethyl azodicarboxylate in THF at 0°C. After the solution was allowed to stand in a refrigerator for 7 days and subjected to the same work-up, diphenylacetanilide was obtained in a 40.8% yield.

b) Ethanol as Solvent. To a stirred solution of 0.303 g (0.001 mol) of diphenylacetothioanilide in 5 m*l* of ethanol was added dropwise 0.174 g (0.001 mol) of diethyl azodicarboxylate in 6 m*l* of ethanol at 40°C. After 1 day at 40°C, diphenylacetothioanilide and diethyl azodicarboxylate were consumed as indicated by tlc and then the reaction mixture was evaporated *in vacuo* to give a yellow oily substance. Triphenylphosphine (0.262 g, 0.001 mol) was added and it was then dissolved in 6 m*l* of THF and kept standing for 7 days at room temperature. On being evaporated and treated with dilute hydrochloric acid in a similar manner as described above, the products were separated by columm chromatography (eluate: benzene) on silica gel to give an unknown compound (0.016 g), bis(*N*-phenylbenzalimidoyl) disulfide (0.011 g), triphenylphosphine sulfide (0.268 g, 91.2%), diphenylactanilide (0.176 g, 61.2%), diethyl hydrazodicarboxylate (0.166 g, 94.3%) and triphenylphosphine oxide (0.022 g, 8%).

The Reactions of Aroyl Peroxides with Grignard Reagents. III. On the Structure and the Reaction of the Complex Containing Benzoyl Peroxide[1]

Masao Ōkubo, Kazuhiro Maruyama,* and Jirō Ōsugi*
Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya
**Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto*
(Received October 17, 1970)

The orange-colored complex which is formed in the reaction of benzoyl peroxide with Grignard reagent was studied by infrared spectra, and the reaction of the complex with Grignard reagent was also examined. In this complex, the structure of BPO was still maintained by coordinating with magnesium atom through the peroxidic as well as the carbonyl oxygen atoms. Reaction products of this complex with phenylmagnesium bromide were benzoic acid(as Mg-salts), phenyl benzoate, benzophenone, triphenylcarbionol, and bromobenzene. The heterolytic mechanism on the formation of bromobenzene was proposed. The molar ratio of products depended seriously upon the mode of addition of Grignard reagents. The exclusive formation of bromobenzene and Mg-salts of benzoic acid without phenyl benzoate under an experimental condition was explained by assuming the electron-transfer process through the coordinating bond in the complex.

The two complexes were isolated in the reaction of benzoyl peroxide (BPO) with Grignard reagents, and analytical data of their components were reported previously.[2] The mechanism of the first stage of this reaction has been proposed on the basis of the relative reactivities of several peroxides.[3] In this paper, the detailed studies on the second stage of the reaction, which was found to proceed more slowly than the first stage,[3] will be reported.

Results and Discussion

Structure of the Complex II. The white complex, which has been named as the Complex I, is produced when the molar ratio [PhMgBr]:[BPO] is 1.33: 1.0, and this was found to be the same structure with the carbonated PhMgBr. Another orange-colored complex, which is named as the Complex II, is obtained when the molar ratio is 0.66:1.0,[3] and this is obtained also by mixing 2 mol of the Complex I with 1 mol of BPO.[2] In order to confirm the previous and tentatively proposed formulae for these complexes, they were submitted to infrared spectroscopy. The tetrahydrofuran (THF) solutions of the Complex I and II have very similar absorption bands with one another as shown in Figs. 1 and 2. The solution of BPO shows a quite different spectrum, which has three intense absorption bands at 1792, 1770, and 1214 cm^{-1} (Fig. 3). If these data were solely taken into consideration, one may arrive at an erroneous conclusion that the peroxide linkage, which had been proposed to be maintained in the Complex II, has already been broken. However, the Complex II produces phenyl benzoate if it is allowed to react with PhMgBr. Considering that phenyl benzoate is the primary product of the reaction of BPO with PhMgBr and that PhCOOMgBr reacting with PhMgBr does produce benzophenone, benzoyl peroxide is concluded to be alive in the Complex II.

The IR spectra of the Complex I and II have two main absorption bands at 1640 and 1415 cm^{-1}, both of which are poorly resolved triplets. The Complex I, reacts with PhMgBr to produce benzophenone and triphenylcarbinol in the similar manner to phenyl benzoate, though the reaction is remarkably slow. This fact means that the grouping –CO–O–MgBr in the Complex I has substantially an ester character. Thus, the absorption band at 1640 cm^{-1} can be assigned mainly to the C=O stretching vibration, which

3) M. Ōkubo, K. Marayama, and J. Ōsugi, *ibid.*, in press.

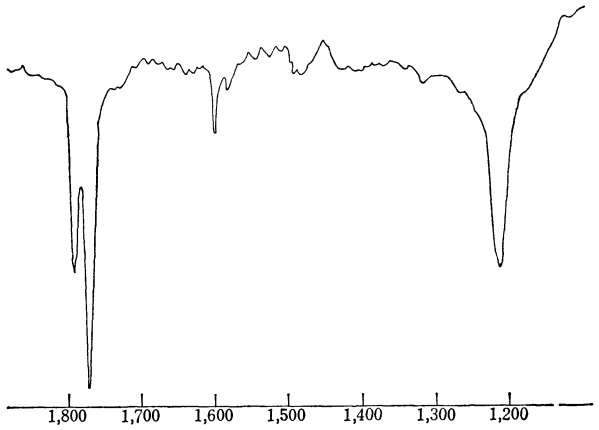

Fig. 3. IR spectrum of BPO in THF. (cm^{-1})

appears at 1770 and 1792 cm^{-1} in the case of free BPO(the difference is about -140 cm^{-1}). The other band at 1415 cm^{-1} can be assigned mainly to the C–O stretching vibration, which appears at 1214 cm^{-1} in the case of free BPO(the difference is about $+200$ cm^{-1}). These shifts(-140 and $+200$ cm^{-1}) are considered to correspond to reasonable changes of bonding energies which are about -0.4 and $+0.6$ kcal/mol. Taking account of analytical data of the Complex I[1] and of the fact that the coordination number of magnesium can be varied between four and six, the Complex I would exist as dimeric state which is depicted in Fig. 4.

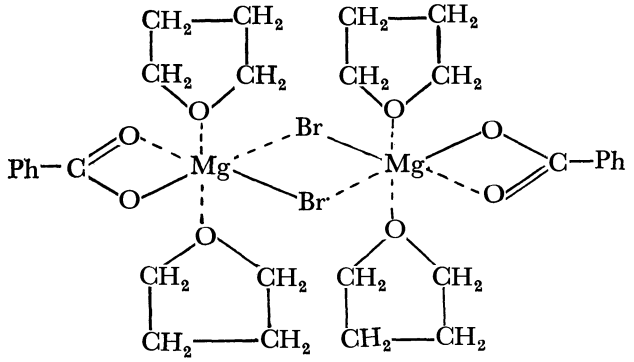

Fig. 4. Structure of the complex I.

Benzoyl peroxide in the Complex II, which shows the quite similar IR spectrum to that of the Complex I, must have almost the same structure as the PhCOO-grouping in the Complex I. Taking account of analytical data of the Complex II[2] and of the coordination number of magnesium, the structure of the Complex II may be depicted as Fig. 5.

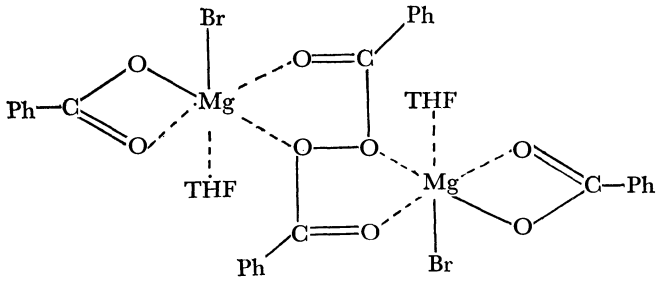

Fig. 5. Structure of the complex II.

Molar ratio [PhMgBr]:[BPO]=1:1
Numbers in the Fig. : Molar concn. $\times 10^3$ mol/*l*

The visible absorption spectra of Complex II in THF was found to be dependent on the concentration as shown in Fig. 6. As the concentration is higher, the absorption maximum is shifted to longer wavelengths. This fact may be explained by considering the change of the degree of aggregation of this complex with the change of concentration. This suggestion is borne out by the examination of the effect of the concentration on the rate of the decomposition of BPO with PhMgBr when the molar ratio is 1:1 (Fig. 7). The second stage of the reaction is remarkably slow,[3] and the main reaction of this stage is apparently concerned with the reaction of the Complex II with remaining PhMgBr. It is noted that the curve for the second stage in Fig. 7 becomes steeper as the concentration of the initial reactants is lower though the crease of the curve falls down as the concentration is higher. This fact may be the result that the lower aggregates which might exist in diluted solutions react faster with the remaining Grignard reagent. Thus, the Complex II is considered to exist as aggregated state in the more concentrated solution.

Reaction of the Complex II For the purpose of clarification of the second stage of the reaction, the reaction of the Complex II with PhMgBr must be

Table 1. Reactions of the complex II with PhMgBr

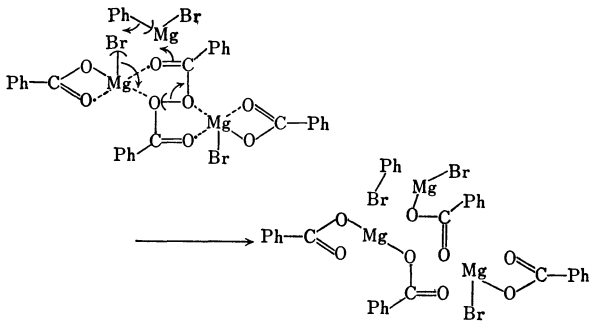
d) The yield is calculated bassd on PhMgBr used ([PhMgBr]/[Complex II]=1.5).

examined.[4] If the twice moles of Grignard reagent were added at once to the THF solution of the Complex II at 0°C, the orange color of the solution disappeared immediately and the peroxide was found to be consumed almost completely. Bromobenzene (26.6%), phenyl benzoate (36.0%), benzophenone (17.8%), and triphenylcarbinol (10.3%) were obtained from the neutral part. The latter three products obviously come from the reaction of PhMgBr with BPO in the Complex II. The formation of the appreciable amount of bromobenzene must be the result of the attack on the Mg-Br linkage in the Complex II by the phenyl group of the Grignard reagent. The question, whether the Mg–Br bond in the complex is broken heterolytitcally or homolytically, is then to be solved.

The molar ratio of the products was found to be affected remarkably by the mode of addition of PhMgBr solution. The results were summarized in Table 1. In the experiment No. 1, two molar equivalents of PhMgBr were added at once to BPO solution. In No. 2, a first equivalent of PhMgBr is added to BPO solution at once and the second equivalent was also added at once after 2 hr. In No. 3, two molar equivalents were added dropwise as slow as the orange color of the solution did not fade during the addition, using an ordinary dropping funnel. In No. 4 and No. 5, 2 and 1.5 equivalents were added in very small drops by using a burette, respectively, and slowly in the similar manner to No. 3. It is to be noted that the amounts of bromobenzene and benzoic acid gradually increased and those of phenyl benzoate, benzophenone and triphenylcarbinol decreased remarkably as the rate of addition is slowed down and as the size of a drop of PhMgBr solution becomes small. This result can be interpreted by the following discussion. The localized high PhMgBr concentration which may appear in the reaction systems of No. 1 and No. 2, will cause a number of Grignard molecules to make attack on the several sites of the Complex II. Thus, bromobenzene is formed if the Mg–Br bond is attacked, and phenyl benzoate is formed if BPO is attacked when it is dissociated as the Complex II is decomposed. On the other hand, if PhMgBr is added slowly and in very small drops, the Mg–Br bond is attacked exclusively



as the result of the electron-transfer process which leads to the selective formation of bromobenzene and magnesium salts of benzoic acid probably according to the following mechanism: This electron–transfer process must be fairly slow though the most reactive site of the Complex II is the one of the Mg–Br bonds, since the exclusive formation of bromobenzene and benzoic acid salts is effected only if the Grignard reagent is added very slowly. It is shown in Table 1 that the slow addition causes the yield of benzoic acid to approach 200%, and this fact is also explained by the above mechanism.

The recovery of the phenyl group of PhMgBr is about 100% in the experiments No. 1 and No.2(50% based on PhMgBr), and as low as about 30—39% in the experiments No. 3, No. 4, and No. 5. As benzene was detected in No. 4 and No. 5, the Complex I which is reproduced in the reaction may coordinate to the unreacted PhMgBr and may stabilize this.[5] However, the important fact is that the yield of bromobenzene increases as the rate of addition is slowed down but does not exceed 50% based on the Complex II.[6] This

4) The solution of the Complex II was prepared by adding a half equivalent of BPO to a completely carbonated PhMgBr solution.[2] See experimental section.

5) The coordination of PhMgBr to PhCOOMgBr is reasonable, since the Complex I can react with PhMgBr at higher temperatures to produce benzophenone and finally triphenylcarbinol. But this reaction is very slow at 0°C as stated in the preceding section.

6) In No. 4, the orange color of the reaction mixture disappeared before the total volume of the PhMgBr solution was added. In No. 5, the orange color of the Complex II was just found to disappear when 1.5 molar equivalents of PhMgBr solution were added. On this base, the yield of bromobenzene is 49%. Since two molar equivalents of the Complex I are reproduced from one molar equivalent of the Complex II according to the above-proposed mechanism, one molar equivalent of PhMgBr is consumed to produce bromobenzene, and the remaining molar equivalent may be coordinated by the reproduced Complex I at 0°C.

may be illustrated by considering that only one bromine atom in the Complex II reacts as bromonium cation to afford bromobenzene from PhMgBr.

Different behaviors of the Complex II in the three solvents, namely tetrahydrofuran, ethyl ether, and water, would provide a key to solve this problem. The Complex II is remarkably soluble in THF without any decomposition, but it does not dissolve in ethyl ether.[2] In water, this complex decomposes with release of molecular bromine.[2] The similar complex containing peroxide is not obtained from the reaction in ethyl ether. Since ethyl ether is more weakly basic than THF,[7] the complex containing BPO, if it is formed in ethyl ether, may have a lower electron density around the Mg–atom than in the case of the Complex II itself and may thus make easier the Br–atom to be detached as cationic bromonium ion. The stability of the Complex II itself may thus be ascribed to the strong coordination of THF to Mg–atoms. Another fact that a heavy precipitate appears easily when the ethyl ether solution of PhMgBr is carbonated, can also be ascribed to the easier disproportionation of PhCOOMgBr into $(PhCOO)_2Mg$ and $MgBr_2$ because of the lower coordinating ability of ethyl ether. Thus the complex similar to the Complex II is hard to exist in such a system. The easy releasing of molecular bromine upon treatment of the Complex II with water may be the result that the water molecule replaces the THF molecules and makes stronger the polarity of the Mg–Br bond and finally expels the bromine as bromonium ion. Thus, the different behaviors of the Complex II in the three solvents can be illustrated if the Mg–Br bond in the Complex II is considered to be broken heterolytically to produce bromonium ion.

Another observation which supports the consideration clearly is the fact that reaction of the Complex II with cyclohexene produces 1,2-dibromocyclohexane in the yield as high as more than 85%. Thus, the olefine may be attacked by the bromonium ion, which is produced through the slow electron-transfer process, to give 2-bromocyclohexyl carbonium ion, and this carbonium ion attacks another Mg–Br bond to afford 1,2-dibromide. Therefore, the formation of bromobenzene may be the result of the nucleophilic attack of phenyl anion on the Mg–Br bond. The oxidation of one of the two Mg–Br linkages through the slow electron-transfer process may thus be the characteristic mechanism of the Complex II.

Experimental

Reagents. All the reagents were prepared and/or obtained in the same manner with those used in the preceding paper.[3]

Measurements of Spectra. IR spectra were measured as Nujol-mulls and as THF solutions with Nihon Bunko IR-S-type and DS-401-type spectrometers. Visible absorption spectra were measured with Perkin–Elmer 202-type spectrometer.

Preparation of the Solution of the Complex II. Ten mililiters of stocked solution of PhMgBr in THF (0.57 M) was pipetted into the N_2-purged flask and 20 m*l* of THF was added. The three-way glass-cock was turned and dried CO_2 was introduced with vigorous stirring. The stirring was continued for 30 min after the absorption of CO_2 was completed. The flask was then warmed up to about 50°C for 30 min to expel the excess CO_2 completely with slow nitrogen stream. After the solution was cooled to 0°C, 0.690 g of BPO (0.00285 mol) and 20 m*l* of THF were added successively with gentle stirring. The mixture was stirred at 0°C for 30 min and at room temperature for 90 min. The orange–colored solution of 0.00285 mol of the Complex II in THF (50 m*l*) was thus prepared and was used for the next reaction.

Reaction of the Complex II with PhMgBr. Ten mililiters of PhMgBr solution (0.57 M) was diluted to 30 m*l* and added to the solution of the Complex II prepared above. In the experiments No. 1 and No. 2, the mixing apparatus described in the preceding paper[3] was used. In No. 3, a pressure-equalized dropping funnel was used. In No. 4 and No. 5, a burette equipped with a pressure-equalizing tube was used. All the experiments were conducted under nitrogen stream.

Product Analysis. The reaction mixtures were concentrated to a small volume under reduced pressure, treated with aqueous ammonium chloride, extracted with ethyl ether and washed with aqueous sodium hydrogencarbonate. The ether extracts were dried over anhydrous magnesium sulfate and concentrated for vpc analysis. The ether solution of neutral products was analyzed with Yanagimoto GCG-55A-type and GCG-2-type vapor fractometers. The water extracts were acidified, and the precipitated benzoic acid was extracted with ether, evaporated to dryness and weighed.

Reaction of the Complex II with Cyclohexene. To a 90 m*l* of the orange-colored solution of the Complex II (0.00546 mol), the same moles of cyclohexene in 10 m*l* of THF was added at once at room temperature. One mililiter portions of the reaction mixture were pipetted out at definite time intervals, and titrated with thiosulfate solution according to Wibaut.[8] After about 4 hr, the thiosulfate euqivalent comes down to a value to about 10% of used peroxide, and the color of the reaction mixture faded almost completely. The solution was evaporated to a small volume under reduced pressure, ethyl ether was added, and the pale-yellow crystals were removed by filtration. The filtrate was treated as usual manner, and the neutral part was analyzed again by vpc technique using hexachloroethane as the inner reference. Any product other than 1,2–dibromocyclohexane was not detected.

The Elimination Orientation in the Fluoride-promoted Olefin Formation. A Comparison with the Alkoxide-promoted Eliminations[1]

Noboru Ono

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received October 20, 1970)

When the 2-butyl and 2-pentyl derivatives were treated with tetraethylammonium fluoride in acetonitrile, an olefin-forming elimination took place and an overwhelming Saytzeff orientation was observed. The relative yield of 1-olefin was little affected by changes in the leaving group and β-alkyl group. These results were compared with the results of the eliminations with the conventional base-solvent systems (EtO^- in EtOH, t-BuO^- in t-BuOH, and t-BuO^- in DMSO).

Directive effects in elimination reactions have been well documented.[2] Recently, the transition state of the E2 reaction has attracted the interest of many workers. Brown[3] has shown that the Hoffmann-rule product increases with an increase in the steric requirements of the attacking base, of the alkyl group in the incipient double bond, or of the leaving group. Some results contradicting Brown's explanation have also been presented.[4-8] Bunnett[4-6] has explained the orientation rule by the variable-transition-state theory. According to this theory, a positional orientation correlates with the relative degree of the breaking of the C_β-H and C_α-X bonds in the transition state.

Nearly all of the results cited above have been obtained in studies where alkoxides were used as the base. A thorough investigation of other base-solvent effects is worthwhile in order to elucidate the fine aspects of the mechanism of the olefin-forming elimination reaction.

In previous papers,[9-12] it has been reported that tetraethylammonium fluoride behaves as a strong base in dipolar aprotic solvents, and that styrene and substituted styrenes were produced in high yields in the E2 reaction of 2-arylethyl halides. The fluoride-induced eliminations were considered to proceed through a very tight transition state where the β-proton is less than half transferred to the base.[11] This fact indicates that the fluoride ion plays an interesting role in the β-eliminations from 2-alkyl derivatives. In the present paper, the orientation of the fluoride-induced eliminations from 2-alkyl derivatives will be determined, and the results will be compared with those of alkoxide-induced reactions.

Results and Discussion

The reactions were carried out at 50°C with a base that has a molar ratio to the substrate of two to one. To prevent the isomerization of the olefinic products during the eliminations, a constant stream of dry nitrogen was bubbled through the reaction mixture and the products were collected at −76°C in a cold trap containing a few milliliters of dimethylformamide. Using gas-liquid partition chromatography (glpc), the relative proportions of the isomeric olefins obtained in the eliminations from 2-alkyl derivatives (Eq. (1)) have been determined.

$$RCH_2\underset{\displaystyle X}{\underset{|}{C}}HCH_3 \longrightarrow RCH_2CH{=}CH_2 + \underset{H}{\overset{R}{\diagdown}}C{=}C\underset{CH_3}{\overset{H}{\diagup}} + \underset{H}{\overset{R}{\diagdown}}C{=}C\underset{H}{\overset{CH_3}{\diagup}} \qquad (1)$$

R = Me, Et X = Cl, Br, I, OTs

The results, together with the results for the reactions with ethoxide in ethanol, t-butoxide in t-butanol, and t-butoxide in dimethylsulfoxide (DMSO), are summarized in Table 1. Most of the data with alkoxide ions are taken from earlier papers. For convenience in comparing these results, these data are presented graphically in Figs. 1—4. The changes in the 1-olefin/2-olefin ratio in the eliminations from 2-butyl and 2-pentyl derivatives are plotted *versus* the change in the leaving group (X) in Figs. 1 and 2. Similar plots for 2-alkyl bromides and tosylates *versus* the change in the alkyl group (R) attached to the β-position to the leaving group are shown in Figs. 3 and 4. The scales of the abscissae are arbitrary, but are chosen so that the straight line is obtained for the reaction with ethoxide in ethanol.

A previous report[11] from this laboratory showed that the 2-arylethyl derivatives underwent fluoride-induced E2 reaction in the acetonitrile solvent. For example, the reaction of 2-arylethyl chloride followed second-order kinetics, first-order in tetraethylammonium fluoride and first-order in the substrate. The Hammett $\sigma\rho$ relation was established with ρ equal to 2.033, k_0

being 3.89×10^{-3} *l*/mol sec at 25°C. The kinetic isotope effect was also determined, k_H/k_D being 3.99. In the present instances, no butene was obtained in the reaction of 2-butyl iodide in the acetonitrile solvent, even in the presence of tetraethylammonium perchlorate. There is little possibility that the El mechanism is operative in the present instances of the olefin-forming eliminations.

The outstanding features of the fluoride-induced elimination reaction are clearly shown in Figs. 1—4. The changes in the leaving groups and alkyl groups had essentially no effect upon the orientation of elimination from 2-alkyl derivatives. These is a definite predominance of the Saytzeff orientation, the ratio of the 1-olefin to 2-olefin ranging from 0.10 to 0.16. Bartsch[16] has reported the orientation in the elimination from 2-alkyl halides induced with halide ions in demethylformamide and DMSO. He has reported the Saytzeff orientation in the reaction of 2-butyl halides with fluoride, but his fluoride is not free of water, and, therefore, there may be trouble in discussing the nature of the base-solvent system. As has been reported earlier,[9,12] the presence of two molar equivalents of water in the fluoride-acetonitrile system reduced the reactivity drastically.

The explanations that have been postulated for the base-solvent effect upon the orientation of the elimination reaction fall into two categories. One is that the size of the attacking bases affects the orientation of

the elimination, and the other is that the base strength affects the orientation of the elimination. Brown[3] has proposed that, in the absence of significant steric interaction, the reaction proceeds to form the more stable of the two possible olefins; however, an increase in the steric requirement of the attacking base and the environment should tend to shift the course of the reaction from the Saytzeff toward the Hoffmann elimination. On the other hand, Bunnett[5] and also, Froemsdorf[7,8] have proposed that an increase in the Hoffmann elimination is attributable to the carbanion character in the transition state induced by an increase in the base strength, the "poorer" leaving group also assisting the carbanion character.

The explanation based on the base strength is not adequate to explain the present results in the light of the following facts. First, the variations in the olefin proportion in each of the figures (Figs. 1—4) are smallest for the elimination with the fluoride ion in acetonitrile and are intermediate for the reactions with ethoxide in ethanol, and with t-butoxide in DMSO, and are largest for the reaction with t-butoxide in t-butanol. These orders scarcely correlate at all with the reactivity of the base.[17] Second, in the eliminations from 2-alkyl derivatives with t-butoxide in t-butanol, more 1-olefin is produced than in the same reactions with the stronger base, t-butoxide in DMSO. Third, as Saunders[19] has pointed out, in a reaction of 2-arylethyl-ammonium bromides, the kinetic isotope effect and the substituent effect indicate a distinctly less carbanion character for the reaction with t-butoxide in t-butanol than for that with ethoxide in ethanol, although the relative yield of 1-olefin increases on the change from ethoxide in ethanol to t-butoxide in t-butanol for the reactions of 2-alkyl derivatives. It may be concluded, therefore, that the change in the apparent base strength does not play any major role in altering the olefin proportion in the present reactions.

In explaining the present results, the role of the steric requirements of the entities attacking the substrate should be taken into account. As Brown[3] has pointed out, solvation, both of the attacking base and of the leaving group, must be considered in estimating their steric requirements and their influence on the direction of elimination. Considering the anion solvation, it is quite plausible that the fluoride ion in acetonitrile has the smallest steric requirement, and that the t-butoxide ion in t-butanol has the largest steric requirement, among the four base-solvent systems.[20] The largest change in the 1-olefin/2-olefin ratio is observed in the reactions induced by t-butoxide in t-butanol, because this base-solvent system has the largest steric requirement. When the steric requirements of the attacking entities become smaller, the attacking entities should become less sensitive to smaller changes in the steric requirements of the environment (the leaving group the alkyl group, and solvation), and *vice versa*. As a result of this steric interrelation, the more stable Saytzeff-type product definitely predominates and the changes

17) The relative reactivity of the base increases from the alkoxide ion in alcohol to the fluoride ion in acetonitrile to the alkoxide ion in DMSO. Tetraethylammonium fluoride in acetonitrile is about 800 times as effective as sodium ethoxide in ethanol in promoting the E2 reaction from 2-phenylethyl chloride at 25°C,[10,11] and t-butoxide in DMSO is several times stronger than fluoride in acetonitrile.[18]

18) A. F. Cockerill, S. Rottschaefer, and W. H. Saunders, Jr., *J. Amer. Chem. Soc.*, **89**, 901 (1967).

19) W. H. Saunders, Jr., D. G. Bushman, and A. F. Cockerill, *ibid.*, **90**, 1775 (1968).

20) It is uncertain which has the larger steric requirement, the ethoxide ion in ethanol or the t-butoxide ion in DMSO; however, the results in Figs. 1—4 are suggestive and can be correlated with steric requirements better than with the reactivities of the attacking entities.

in the leaving groups and alkyl groups have little effect on the orientation in the fluoride-induced eliminations.

The data in Table 1 also reveal interesting changes in the *trans*-2-olefin/*cis*-2-olefin ratios with the solvents. High *trans*/*cis* ratios of about 4—5 are observed in dipolar aprotic solvents; on the contrary, smaller *trans*/*cis* ratios of about 1—2 are observed in *t*-butanol. Bartsch and Bunnett have reported similar results.[6] A high *trans*/*cis* ratio of about 5 was observed in the reaction of 2-hexyl halides with *t*-butoxide in DMSO, and a *syn*-elimination stereochemistry was postulated. However, the possibility of the intervention of *syn*-elimination has been ruled out recently by an experiment with erythro-3-deutero-2-bromobutane.[21] The *trans*/*cis* ratios have been interpreted as indicating the extent of the double-bond character in the transition states.[5,6]. However, at present no direct relationship between the 1-olefin/2-olefin ratio and the *tran*/*cis* ratio has been found for the reactions discussed above.[6,22] The reason for the high *trans*/*cis* ratio in dipolar aprotic solvents is hard to find and needs to be studied further.

Experimental

Materials. *2-Alkyl Halides*: The 2-butyl halides were either commercial samples or were prepared from alcohols by the usual method. 2-Pentyl iodide was prepared analogously to the procedure used for Coe[23]: 2-pentanol (25 g) was added, drop by drop, to triphenylphosphite diiodide (from 76 g of iodine and 100 g of triphenyl phosphite); the mixture was then kept at room temperature for 30 min. Two distillations gave 2-pentyl iodide (11 g, 20%); bp 55°C/50mmHg (lit,[24] 139—142°C). 2-Pentyl bromide was prepared by a procedure similar to that used for 2-pentyl iodide except that bromine was used instead of iodine. 2-Pentyl chloride was prepared by the method of Whitmore and Karnatz[25] from 2-pentanol, pyridine, and thionyl chloride. Two distillations gave a material with a bp of 94—96°C (lit,[14] 96°C). These 2-pentyl halides were shown to be free of isomers by glpc.

2-Alkyl Tosylates: The tosylates were prepared in the usual fashion[26] by treating the alcohols with freshly-recrystallized *p*-tolueneuslfonyl chloride in dry pyridine. After having been stored in a refrigerator for one day, the mixture was poured onto ice and dilute sulfuric acid, and extracted with methylene chloride. After washing and drying, the solvent was replaced by hexane and the solution was treated with charcoal. The hexane was then removed at reduced pressure, leaving a pale yellow liquid.

Base and Solvent. The solvents were purified by the usual method. The tetraethylammonium fluoride was prepared by a method reported previously.[12]

Elimination Products from Reactions of 2-Alkyl Derivatives. The reactions of 2-alkyl derivatives with Et_4NF in acetonitrile were performed as follows. In a typical case, 2-butyl iodide (1.8 g, 0.01 mol) was treated with 3 g (0.02 mol) of Et_4NF in 30 ml of acetonitrile at 50.0°C. Volatile products were bubbled out of the reaction vessel with a slow nitrogen stream in order to minimize the isomerization of the olefins. The products were then collected at −76°C in a cold trap containing a few milliliters of dimethylformamide and were then analyzed by glpc. Gas-liquid partition chromatographic analyses were performed with a Yanagimoto GCG-5DH instrument. Activated alumina was used as the solid support; the three isomers of butene or pentene were thus successfully separated at an ambient temperature on a 6 m×3 mm dimethylformamide column (40%).

The author is indebted to Professor Aritsune Kaji for helpful discussions. Special thanks are due to Dr. Jun-ichi Hayami who has always encouraged the author and also has given him invaluable suggestions and advices to this work.

Peptide Synthesis by Oxidation-Reduction Condensation. II.[1] The Use of Disulfide as an Oxidant

Rei MATSUEDA, Hiroshi MARUYAMA, Masaaki UEKI, and Teruaki MUKAIYAMA
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received October 23, 1970)

A peptide synthesis starting from free *N*-protected amino acid and free amino acid ester by the use of triphenylphosphine, an oxygen acceptor, and disulfide, a hydrogen acceptor, was studied. The oxidation-reduction condensation reaction affords peptides with high optical purity in excellent yields by simple procedure.

In the preceding report,[2] it was shown that *N*-*o*-nitrophenylsulfenyl(NPS)-amino acid, in which NPS group is generally known as a protecting group of amino component in peptide synthesis, affords a new peptide linkage by one step procedure when it was treated with triphenylphosphine and carboxyl component. During this peptide forming reaction, phosphine is used as an oxygen acceptor and sulfenyl group of the amide is reduced to accept a hydrogen.

In the present experiment, a direct peptide synthesis by the oxidation-reduction condensation starting from free *N*-protected amino acid and free amino acid ester was tried by the use of disulfide as an oxidant.

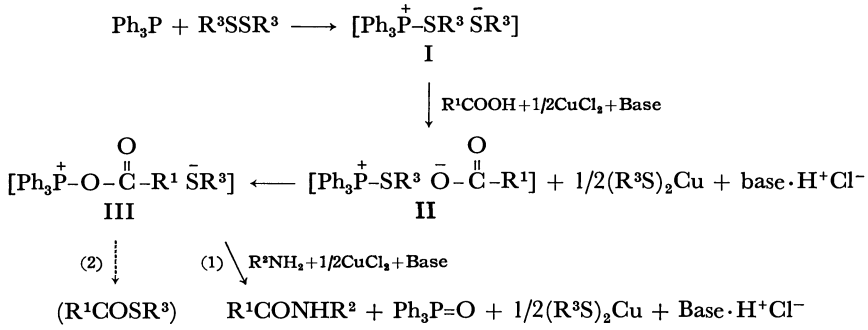
In the model reaction of carboxamide formation, *N*-*n*-butylhexanamide was obtained in 62% yield from hexanoic acid and *n*-butylamine by the use of *p*,*p*′-dichlorodiphenyl disulfide as an oxidant and cupric chloride as a mercaptan scavenger according to the following equation.

$$n\text{-}C_5H_{11}COOH + n\text{-}C_4H_9NH_2 + Ph_3P + (p\text{-}ClC_6H_4S)_2 + CuCl_2 + 2Et_3N \xrightarrow[\text{in } CH_2Cl_2]{\text{room temp., 3hr}} n\text{-}C_5H_{11}CONH(n\text{-}C_4H_9) + Ph_3P{=}O + (p\text{-}ClC_6H_4S)_2Cu + 2Et_3NH^+Cl^-$$

In this reaction, a small amount (2% yield) of thiohexanoic acid *S*-*p*-chlorophenyl ester was isolated along with *N*-*n*-butylhexanamide. The thiolester did not react with *n*-butylamine in methylene chloride when they were allowed to stand for 3 hr, indicating that the thiolester is not an intermediate of this reaction. The result shows that the reaction may proceed through an initial formation of phosphonium salt I, which in turn reacts with carboxylic acid to form the salt II; this subsequently, is transfomed into III, conceivably by way of an internal nucleophilic displacement. The active intermediate of acyloxyphosphonium mercaptide III has two possible pathways of decomposition: namely, (1) the formation of amide by nucleophilic attack of amine on carboxyl carbon and (2) the formation of thiolester by an intramolecular nucleophilic attack of mercapto anion on carboxyl carbon as shown in Scheme 1.

In order to minimize the undesirable formation of thiolester in the above experiment, the effects of various kinds of metal compounds were examined with the assumption that pathway (2) would be skipped when soft metallic compounds are used as mercaptan scavengers. The mercapto anion (soft base) in the intermediate of acyloxyphosphonium salt is expected to react readily with soft metallic cation (soft acid) as predicted by Pearson's principle.[3] Expectedly, the results showed a good agreement with the Pearson's principle and thiolester formation was completely prevented when mercuric chloride and silver chloride were used (see Table 1).

Then, the reaction was applied to peptide synthesis by using mercuric chloride as a metal component. First, the synthesis of benzyloxycarbonyl (Z)-L-phenylalanylglycine ethyl ester which has an optical active amino acid as a carboxyl component was tried and the dipeptide was obtained in 89% yield without racemization.



Scheme 1. Reaction pathway for the formation of amide from acid, amine, phosphine, and disulfide in the presence of $CuCl_2$ and base.

TABLE 1. EFFECTS OF METAL COMPONENTS ON THE PREVENTION OF THIOLESTER FORMATION

Metal compound	n-$C_5H_{11}CONH$-(n-C_4H_9) Yield, %	n-$C_5H_{11}COS$-C_6H_4Cl-p Yield, %
AgCl	72	0
$HgCl_2$	66	0
HgCl	62	0
CdI_2	57	0
$HgSO_4$	47	0
$CuCl_2$	62	2
$PdCl_2$	60	3
$PbCl_2$	54	2
$NiCl_2$	42	9
CuCl	43	8
$ZnCl_2$	38	6
$CoCl_2$	23	8

Z-L-Phe-OH + H-Gly-OEt + Ph_3P + (o-$NO_2C_6H_4S)_2$ + $HgCl_2$ + $2Et_3N$ ⟶ Z-L-Phe-Gly-OEt + Ph_3P=O (89% yield) + (o-$NO_2C_6H_4S)_2Hg$ + $2Et_3NH^+Cl^-$

Next, the synthesis of Z-Gly-L-Phe-OEt which has an optical active amino acid as an amino component was tried and the dipeptide was obtained in 91% yield as an oil by column chromatography on silica gel. This oily substance was identified to be an optical pure dipeptide by the subsequent saponification to Z-Gly-L-Phe-OH.

The results show that the peptide forming reaction is applicable for a stepwise elongation of peptide chain.

Next, the racemization was further studied in order to know the applicability of this reaction to the fragment condensation which is very sensitive to racemization.

In the synthesis of peptides, the complete retention of optical activity is an important though rarely achieved goal. Recent work[4] has established that oxazolone is an essential intermediate for the racemization of most of the activated species in the peptide synthesis. In order to check the racemization in the fragment condensation, the above mentioned new reaction was further examined by the Young test[5] (benzoyl(Bz)-L-leucylglycine ethyl ester synthesis) which is known to be the most sensitive racemization test. The authentic samples of the L and DL peptides were synthesized according to Young's report[5] and it was found that the infrared spectra of the two peptides were different to each other as shown in Table 2.

TABLE 2. INFRARED SPECTRA OF L AND DL Bz-Leu-Gly-OEt (KBr pellets)

	L Peptide (cm^{-1})	DL Peptide (cm^{-1})
NH stretching absorption	3300 (singlet)	3275, 3330 (doublet)
	1024 (singlet)	1039, 1024 (doublet)

Since the L peptide was observed to be more soluble in solvent than the DL peptide, the procedure of Young test in this reaction was determined to measure a specific rotation of an unrecrystallized crude product which is isolated by dry column chromatography[6] or a preparative layer chromatography on silica gel. By this procedure, azide method gave the value of $[\alpha]_D^{20}$ −32.6° (c 3.1 EtOH), L-isomer 96%.[5] While the oxidation-reduction condensation reaction carried out in methylene chloride at room temperature gave a poor result as shown in the following equation.

Bz-L-Leu-OH + 3H-Gly-OEt + Ph_3P + (o-$NO_2C_6H_4S)_2$ + $HgCl_2$ ⟶ Bz-Leu-Gly-OEt + Ph_3P=O (76% yield) $[\alpha]_D^{20}$ −7.6° (c 3.1, EtOH), L isomer 22%[6] + (o-$NO_2C_6H_4S)_2Hg$ + $2Cl^-H^+$·H-Gly-OEt

As to the Young test, the racemization intermediate is known to be 4-isobutyl-2-phenyloxazolone whose formation is catalyzed by bases.[7] A base-catalyzed enolization mechanism which involves two proton abstraction steps from the amide hydrogen and from the oxazolone hydrogen was also reported by Kemp and his associates.[8]

In the above reaction, hydrochloric acid is produced along with the peptide by the reaction of the supposed key intermediate of acyloxyphosphonium salt, ($Ph_3\overset{+}{P}$-O-COR^1) $\bar{S}$R^2, ethyl glycinate and mercuric chloride. Therefore, tertiary amine must be used in order to scavenge hydrochloric acid produced at the same time.

In order to eliminate the basic substances as tertiary amine from the reaction system, the reactions were tried by using various kinds of organo-mercuric compounds. These mercuric compounds were classified into two groups through the mercuric mercaptide formation reaction: class a) mercuric salts of urea, succinimide, p-nitrophenol, *etc.* which yield mercuric mercaptide by the reference anion exchange of the phosphonium mercaptide, ($Ph_3\overset{+}{P}$-SR) $\bar{S}$R, with mercuric compounds; class b) di-p-methoxyphenylmercury and p-methoxyphenylmercuric bromide which yield mercuric mercaptide through the protonation of mercaptan to mercuric compounds, but not by the reference anion exchange. The results of the Young test by employing class a) compounds are shown in Table 3.

In these cases, the acyloxyphosphonium mercaptide readily reacts with the metal compounds (MX) to produce metal mercaptides and the second acyloxy phosphonium salts, ($Ph_3\overset{+}{P}$-O-COR^1)X$^-$, by the reference anion exchange. The X$^-$ anion involved in the salt would be expected to have a significant effect on racemization and in accordance with this expectation, the optical purity increased as the X$^-$ anion stability

	13.8	Pivalic acid (pKa 5.0)	(p-$ClC_6H_4S)_2$	76	60
	13.8	(pKa 9.4)	(p-$ClC_6H_4S)_2$	89	92

Table 4. The young test by the use of class b) compounds

Metal compounds MX_2	$(RS)_2$	Reaction Period, day	Crude Bz-Leu-Gly-OEt		
			Yield, %	$[\alpha]_D^{20}$ (c 3.1 EtOH)	L isomer, %
	(p-$ClC_6H_4S)_2$	3	88	−30.5°	90
	(o-$O_2NC_6H_4S)_2$	2	92	−32.4°	95
	(o-$O_2NC_6H_4S)_2$	2	92	−32.0°	94

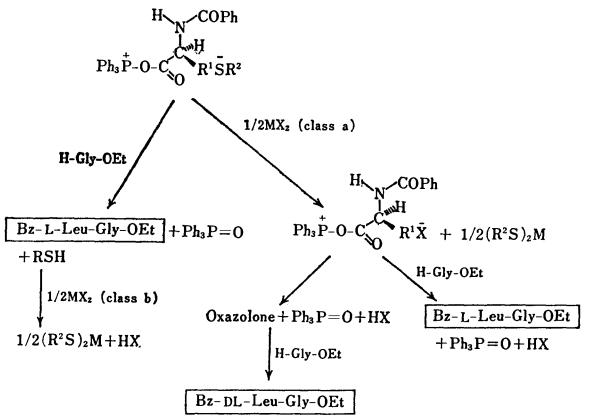
increased except in the case of *N*-hydroxysuccinimide. To investigate the characteristic effect of *N*-hydroxysuccinimide which is well known to give a favorable result in the dicyclohexylcarbodiimide method,[9] the reactions using mercuric salt of urea in the presence of acidic substances were studies. *N*-hydroxysuccinimide gave a better result than pivalic acid which has a smaller pK_a value. On the other hand, the more favorable results were obtained s shown in Table 4 when class b) compounds were used.

In these cases, the intermediate, acyloxyphosphonium salt, is attacked only by ethyl glycinate to produce the peptide and mercaptan. The mercaptan is in turn scavenged by the reaction with bis(p-methoxyphenyl)-mercury to yield mercuric mercaptide and anisole as shown in the following Scheme 2.

Since anisole is produced directly through the protonation of mercaptan to the mercuric compound, p-methoxyphenyl anion would not be produced during this mercaptide formation reaction and oxazolone formation can be prevented. The reaction by using bis(p-methoxyphenyl)mercury was further studied in various kinds of solvents and the results are shown in Table 5.

The reaction was found to proceed in all the solvents examined, but a partial racemization was observed in polar solvents as acetonitrile and *N*,*N*-dimethylformamide; while addition of *N*-hydroxysuccinimide also gave an improved result. As described above, peptides with high optical purity are produced in excellent

9) J. E. Zimmerman and G. W. Anderson, *J. Amer. Chem. Soc.*, **89**, 7151 (1967). Special character of preventing racemization of *N*-hydroxysuccinimide is also reported by H. Goodman, *Chem. Eng. News*, **1968**, 40.



Scheme 2. Reaction pathways for the formation of L-and DL-Bz-Leu-Gly-OEt from Bz-L-Leu-OH, H-Gly-OEt, Ph_3P, and $(o\text{-}NO_2C_6H_4S)_2$ in the presence of either class a) or class b) metallic compound.

TABLE 5. EFFECTS OF SOLVENTS ON RACEMIZATION BY THE YOUNG TEST

Solvent	Dielectric constant	Crude Bz-Leu-Gly-OEt Yield %	L isomer %

DMF[2]	37.0	86	37
CH_3CN	37.5	88	66
CH_3CN + HO-N(succinimide)	37.5	87	86

1) THF: tetrahydrofuran
2) DMF: *N,N*-dimethylformamide

yields in solution by stepwise synthesis but also by the model reaction of fragment condensation (Young test) when mercuric compounds, mercaptan scavenger, are used in this oxidation-reduction condensation.

In recent years, the potential utility of the solid phase method in peptide synthesis has been extended. With respect to this problem, insoluble metal mercaptides, produced at the same time in the above mentioned reaction, seem to be troublesome problem when it is applied to the solid phase method. Then, various kinds of non-metallic mercaptan scavengers were investigated in an attempt to purge the insoluble mercaptide from the reaction system.

First, the reaction was tried by the use of olefins as mercaptan scavengers since some olefins such as 2,3-dihydropyran is known to react readily with cysteine in the presence of Lewis acid,[10] and good results were obtained. When the Young test was carried out in methylene chloride by using 2,3-dihydropyran and zinc chloride as catalyst, Bz-L-Leu-Gly-OEt was obtained in 92% yield, $[\alpha]_D^{20}$ −32.9° (*c* 3.1 EtOH), L-isomer 97%. Good result was also obtained in the case when *n*-butyl vinyl ether is employed (90% yield, L-isomer 95%).

Next, the reaction was further examined by the Young test with sulfenate esters which can behave as both oxidant and mercaptan scavenger (see Table 6).

Bz-L-Leu-OH + H-Gly-OEt + Ph_3P + $2R^1S\text{-}OR^2$
⟶ Bz-L-Leu-Gly-OEt + Ph_3P=O + $(R^1S)_2$ + $2R^2OH$

TABLE 6. THE YOUNG TEST BY THE USE OF SULFENATE ESTERS AS BOTH OXIDANT AND MERCAPTAN SCAVENGER

Sulfenate ester	Crude Bz-Leu-Gly-OEt Yield %	L isomer %
$o\text{-}O_2NC_6H_4SOCH_3$	84	55
$2,4\text{-}(O_2N)_2C_6H_3SO^tBu$	85	78
$2,4\text{-}(O_2N)_2C_6H_3SO^tBu$ + HO-N(succinimide)	84	95

Partial racemization observed in these reactions may be due to the basic character of alkoxy anion of the intermediate phosphonium salt which is produced by the reaction of triphenylphosphine and sulfenate ester, but a favorable result was also obtained in the presence of 1 equivalent of *N*-hydroxysuccinimide.

It is known that some of thiols such as mercaptopyridine, mercaptopurine, *etc.*, which bear a mercapto group α or γ with respect to a ring nitrogen exist in solution predominantly in the thione form.[11] This fact indicates that by employing 2,2′-dipyridyl disulfide as a disulfide component, the peptide forming reaction can be carried out in the absence of a mercaptan scavenger with the consideration that 2-mercaptopyridine produced along with peptide would isomerize to the stable thione form. The reaction by the Young test in methylene chloride was completed within 30 min at room temperature and the peptide was obtained in 91% yield, $[\alpha]_D^{20}$ −32.6° (*c* 3.1 EtOH), L-isomer 96%, according to the following equation.

Bz-L-Leu-OH + H-Gly-OEt + Ph_3P + $\left(\text{N}\!\!\diagup\!\!\diagdown\text{S-}\right)_2$
⟶ Bz-L-Leu-Gly-OEt + Ph_3P=O + 2 N,S-heterocycle (H)

In conclusion, it is noted that peptide with high optical purity is produced in excellent yield from free *N*-protected amino acid, free amino acid ester, phosphine (an oxygen acceptor), and disulfide (a hydrogen acceptor) during oxidation-reduction process.

Experimental

All melting points are uncorrected. Infrared spectra were determined on a Hitachi Model EPI-G2 Spectrophotometer

11) R. A. Jones and A. R. Katritzky, *J. Chem. Soc.*, **1958**, 3610.

and optical rotation was determined on a Perkin-Elmer Model 141 Polarimeter.

Reagents. Mercuric salts of urea,[12] succinimide and phthalimide, *p*-methoxyphenylmercuric bromide[13] and bis(*p*-methoxyphenyl)mercury[14] were prepared by the literature procedures. Mercuric salt of *N*-hydroxysuccinimide was prepared by the following procedure: A solution of 9.45 g(30 mmol) of mercuric acetate in ethanol (100 m*l*) was added with vigorous stirring to a solution of 6.09 g (60 mmol) of *N*-hydroxysuccinimide in ethanol. The white precipitate was collected by filtration, washed with ethanol and dried, 11.59 g (90%), mp 194—195°C (dec).

Found: C, 22.26; H, 2.18; N, 6.69%. Calcd for $C_8H_8N_2O_6Hg$: C, 22.41; H, 1.88; N, 6.69%. Mercuric salts of *p*-nitrophenol and 2,4-dinitrophenol were prepared by the same procedure in aqueous solution.

Methyl *o*-nitrobenzenesulfenate[15] and *t*-butyl 2,4-dinitrobenzenesulfenate[16] were prepared by the method described in the literature. 2-Mercaptopyridine was prepared by the method in the literature[11] with some modification: A solution of 2-chloropyridine 45.2 g (0.4 mol), thiourea 30.4 g (0.4 mol), and iodine 0.3 g in ethanol (120 m*l*) was refluxed for 6 hr. After cooling, 60 m*l* of concentrated aqueous ammonia (*d* 0.88) was added and the solution was kept standing for 5 days at room temperature. After evaporation of ethanol, the aqueous solution was acidified by acetic acid to pH 3 and extracted with chloroform. The chloroform layer was dried over sodium sulfate and evaporated to dryness. Crude material was recrystallized from benzene to give pure 2-mercaptopyridine, 27.7 g (62%), mp 124—126°C. 2,2′-Dipyridyl disulfide was obtained quantitatively by potassium ferricyanide oxidation of the 2-mercaptopyridine.[17]

Reaction of Hexanoic Acid, n-Butylamine, Triphenylphosphine (IV), and p,p′-Dichlorodiphenyl Disulfide in the Presence of Cupric Chloride and Triethylamine (TEA). To a mixture of hexanoic acid 1.16 g (10 mmol), cupric chloride 1.34 g (10 mmol), and *p,p′*-dichlorodiphenyl disulfide 2.87 g (10 mmol) in methylene chloride (20 m*l*) were added with ice cooling TEA 2.02 g (20 mmol), IV 2.62 g (10 mmol), and *n*-butylamine 0.73 g (10 mmol) in methylene chloride (10 m*l* each) in this order. The resultant solution was stirred for 4 hr at room temperature. After filtration off of the precipitated copper mercaptide, the solution was washed with water, N HCl, water, 5% $NaHCO_3$ solution and water and dried. The solvent was evaporated off and from the residue *N-n*-butylhexanamide was obtained by chromatography on silica gel, 1.06 g (62%), bp 115—118°C (2 mmHg).

Found: C, 69.94; H, 12.25; N, 8.08%. Calcd for $C_{10}H_{21}NO$: C, 70.12; H, 12.36; N, 8.18%. In addition, a small amount of thiohexanoic acid *S-p*-chlorophenyl ester was isolated, 0.05 g (2%), bp 138—140°C (2 mmHg).

Found: C, 59.67; H, 6.18; Cl, 14.52; S, 13.27%. Calcd for $C_{12}H_{15}ClOS$: C, 59.38; H, 6.19; Cl, 14.64; S, 13.20%.

The yields of amide obtained when various kinds of metallic compounds were used in place of cupric chloride in the above reaction are shown in Table 1.

Reaction of Z-L-Phe-OH, H-Gly-OEt, IV, and o,o′-Dinitrodiphenyl Disulfide(V) in the Presence of Mercuric Chloride and TEA. To a stirred mixture of Z-L-Phe-OH 2.99 g (10 mmol), mercuric chloride 2.71 g (10 mmol), and V 3.08 g (10 mmol) in methylene chloride (20 m*l*) was added successively with ice cooling TEA 2.02 g (20 mmol), IV 2.62 g (10 mmol), and H-Gly-OEt 1.03 g (10 mmol) in 10 m*l* each of the same solvent. The resultant mixture was stirred for 3 hr at room temperature and the precipitated mercury mercaptide was filtered off. The filtrate was washed with water, N HCl, water, 5% $NaHCO_3$ solution, water and dried over sodium sulfate. The solvent was evaporated *in vacuo* and from the residue Z-L-Phe-Gly-OEt was obtained by dry column chromatography[6] on silica gel using methylene chloride as solvent, 3.43 g (89%), mp 110—110.5°C, $[\alpha]_D^{20}$ −17.1° (*c* 2 EtOH). [lit,[18] mp 110—113°C, $[\alpha]_D^{25}$ −16.6° (*c* 2 EtOH)].

Found: C, 65.83; H, 6.53; N, 7.42%. Calcd for $C_{21}H_{24}N_2O_5$: C, 65.61; H, 6.29; N, 7.29%.

Reaction of Z-Gly-OH, H-L-Phe-OEt, IV, and V in the Presence of Mercuric Chloride and TEA. Substitution of Z-L-Phe-OH for Z-Gly-OH and H-Gly-OEt for H-L-Phe-OEt in the above reaction gave Z-Gly-L-Phe-OEt in 91% yield as an oil [lit.[19] oil]. This oily material (0.97 g) was saponified by N NaOH in aqueous dioxane by the literature procedure[19] to yield Z-Gly-L-Phe-OH, 0.74 g (83%), mp 125—126°C, $[\alpha]_D^{25}$ 36.2° (*c* 2 acetone). [lit,[18] mp 125—126°C, $[\alpha]_D^{25}$ 37° (*c* 2 acetone)].

Found: C, 64.04; H, 5.64; N, 7.66%. Calcd for $C_{19}H_{20}N_2O_5$: C, 64.03; H, 5.66; N, 7.86%.

The Test for the Racemization in This Type of Reactions by Young's Method.[5] Authentic samples of L- and DL-Bz-Leu-Gly-OEt were prepared by the azide method in the Young's report. Since the solubilities of L and DL peptides were observed to be different to each other, general isolation procedure was determined to be made by dry column chromatography or preparative layer chromatography on silica gel and $[\alpha]_D$ values of crude peptides were determined without recrystallization. By this procedure, Bz-L-Leu-Gly-OEt was obtained in 68% yield, $[\alpha]_D^{20}$ −32.6° (*c* 3.1 EtOH), L-isomer 96%,[5] according to the azide method carried out in ether.

Reaction of Bz-L-Leu-OH, H-Gly-OEt, IV, and V in the Presence of Mercuric Chloride and TEA. To an ice cooled mixture of Bz-L-Leu-OH 2.35 g (10 mmol), V 3.08 g (10 mmol), and mercuric chloride 2.71 g (10 mmol) in methylene chloride (30 m*l*) was added with strirring a solution of IV 2.62 g (10 mmol) and H-Gly-OEt 3.03 g (30 mmol) in 20 m*l* of the same solvent. Stirring was continued for 4 hr at room temperature and the precipitated mercury mercaptide was filtered off. The filtrate was washed with water, N HCl, water, 5% $NaHCO_3$ solution and water, dried and evaporated *in vacuo*. The residue was separated by preparative layer chromatography on silica gel by developing with ethyl ether. Zone corresponding to the peptide was scraped and eluted by methylene chloride and methanol (10:1). The eluate was evaporated to dryness and the residue was dissolved in methylene chloride, washed with water, and dried over sodium sulfate. After evaporation of the solvent, Bz-L-Leu-Gly-OEt was washed with petroleum ether (30—50°C) and collected by filtration, 2.58 g (81%), mp 144—147°C, $[\alpha]_D^{20}$ −7.9° (*c* 3.1 EtOH), L-isomer 23%.

Found: C, 63.99; H, 7.38; N, 8.98%. Calcd for $C_{17}H_{24}N_2O_4$: C, 63.73; H, 7.55; N, 8.74%.

Reactions of Bz-L-Leu-OH, H-Gly-OEt, IV, and V in the Presence of Organomercuric Compounds. (General Procedure) Each 10 mmol of H-Gly-OEt and IV in methylene chloride

(20 ml) was added at room temperature to vigorously stirred mixture of equimolar amounts of Bz-L-Leu-OH, V, and organomercuric compound in the same solvent (30 ml). The reaction mixture was stirred for a few hours in the case of class a) compounds, and for a few days in the case of class b) compounds. The peptide was isolated by dry column chromatography or preparative layer chromatography as described above. Results is are shown in Tables 3 and 4.

Reactions of Bz-L-Leu-OH, H-Gly-OEt, IV, and V in the Presence of Olefins. To a mixture of Bz-L-Leu-OH 1.17 g (5 mmol), V 1.54 g (5 mmol), 2,3-dihydropyran 1.68 g (20 mmol), and zinc chloride 0.68 g (5 mmol) in methylene chloride (30 ml) was added with ice cooling a solution of IV 1.31 g (5 mmol) and H-Gly-OEt 0.52 g (5 mmol) in the same solvent. The resultant mixture was stirred for 6 hr at room temperature, washed with 5% $NaHCO_3$ solution and water and dried. After evaporation of the solvent, the residue was chromatographed on silica gel. A fraction eluted by benzene gave *o*-nitrophenyl 2-tetrahydropyranyl sulfide, 2.04 g (85%), mp 60—61°C.

Found: C, 55.50; H, 5.49; N, 5.97; S, 13.58%. Calcd for $C_{11}H_{13}NO_3S$: C, 55.21; H, 5.47; N, 5.86; S, 13.40%. Bz-L-Leu-Gly-OEt was obtained by elution with ether, 1.47 g (92%), $[\alpha]_D^{20}$ −32.9° (*c* 3.1 EtOH), L-isomer 97%.

Substitution of 2,3-dihydropyran for *n*-butyl vinyl ether gave the peptide in 90% yield with 95% L-isomer content.

Reactions of Bz-L-Leu-OH, H-Gly-OEt, IV, and Sulfenate Esters. A solution of H-Gly-OEt (5 mmol) and IV (5 mmol) in methylene chloride was added to a solution of Bz-L-Leu-OH (5 mmol) and sulfenate ester (10 mmol) and the mixture was stirred for a few hours. Work up was done as above and the results are shown in Table 6.

Reaction of Bz-L-Leu-OH, H-Gly-OEt, IV, and 2,2′-Dipyridyl Disulfide. A solution of IV 1.31 g (5 mmol) and H-Gly-OEt 0.52 g (5 mmol) in methylene chloride (20 ml) was added drop by drop at room temperature to a stirred solution of Bz-L-Leu-OH 1.17 g (5 mmol) and 2,2′-dipyridyl disulfide 1.10 g (5 mmol) in the same solvent (30 ml). Stirring was continued for 30 min and the solution was washed with N HCl, water, 5% $NaHCO_3$ solution and water, and dried over sodium sulfate. Work up as mentioned above gave Bz-L-Leu-Gly-OEt, 1.46 g (91%), mp 148—152°C, $[\alpha]_D^{20}$ −32.6° (*c* 3.1 EtOH), L-isomer 96%.

Liquid Phase Chlorination of Olefins with Cupric Chloride. III. Effect of Additives and Kinetics

Takashi KOYANO and Osamu WATANABE

Central Research Laboratory, Toa Nenryo Kogyo Co., Oi-machi, Iruma-gun, Saitama

(Received October 23, 1970)

Chlorination of 1-octene with cupric chloride has been investigated in methanol at 110—130°C. The yield of 1,2-dichlorooctane (I) increased by addition of lithium chloride in the reaction mixture, while that of 1-chloro-2-methoxyoctane (II) decreased. Addition of water and cuprous chloride markedly retarded the reaction. The initial rates of formation of I and II could be expressed as $v=k[\text{octene}]_0\,[CuCl_2]_0^{1.6}$ and $v=k[\text{octene}]_0\,[CuCl_2]_0$, respectively. These results can be explained as an initial formation of a complex between olefin and cupric chloride molecule, followed by competitive attack on the complex by chloride ion and methanol. In the less polar reaction media containing more octene, the ratio of I/II increased. This may be ascribed to the steric effect of cupric chloride in the intermediate.

In our previous investigations on the mechanism of chlorination of olefins with cupric chloride in liquid phase, the initial formation of an open-type cationic intermediate by electrophilic addition of cupric chloride to the olefin and the succeeding competitive attacks on the intermediate by the second chlorinating species and the solvent have been suggested.[1,2] However, the nature of this second chlorinating agent has not been clarified and we have continued the study in order to understand the reaction thoroughly. This paper reports the effect of additives on product composition and the kinetic results for the reaction of octene in methanol.

Results

All reactions were carried out by a sealed tube technique. Octene was selected as the olefin because of its relatively low vapor pressure at the reaction condition and convenience in analysis of the products by gas chromatography. The products consised of 1,2-dichlorooctane (I) and 1-chloro-2-methoxyoctane (II). Effects of reaction medium and added lithium chloride on the product composition are shown in Table 1.

The product composition is subject to the influence of cupric chloride concentration and the products ratio I/II decreases as the reaction progresses.[1] This can be predicted from the different rate orders in cupric chloride for the formations of I and II. Therefore, the data should be compared at the same conversion of cupric chloride, when the effects of environment on the products ratio are discussed. The rate of methanolysis of I or II is sufficiently small even in the presence of cupric chloride under the reaction conditions and can be ignored.

$CuCl_2$ 0.20 mol/l, 125°C
a) ratio of dichloride/ethoxychloride

Increase of octene content in the reaction solution increased the portion of I in the products. However, the conversion was not increased linearly in proportion to the octene content, probably due to marked retardation effect of cuprous chloride formed as well as to instability of the intermediate cationic complex in less polar media. Partial replacement of octene by heptane reduces the rate but the ratio I/II is the same as that in the case of octene without heptane. Thus, the effect of octene except for the action as a reactant resembles that of heptane, which means that it seems to be related to polarity of the solution.

Addition of water retarded the reaction. In discussing the product composition of this case, a possibility of nucleophilic attack of water may also have to be taken into account, although no apparent peaks of hydroxylic compounds were observed in the gas chromatogram and no hydroxylic products have been reported in the reactions with styrene in the presence of hydrated or added water.[3-5]

A comparatively large I/II ratio in ethanol solvent reaction can be attributed to its low polarity, although steric disadvantage of ethanol as an attacking agent at the reaction center should also be duly considered. It should be noted that steric inhibition is not important in the chlorination of ethylene.[6]

When lithium chloride was added in the reaction system, both the conversion of cupric chloride and the ratio I/II increased considerably with the amount of the salt. It is noteworthy that, in contrast to the striking increase in yield of I, that of II decreased; *i.e.*, on additions of lithium chloride in 0, 0.1, 0.2, 0.4, and 0.6 mol/l, the yields of II were 9.3, 8.3, 3.7, 1.5, and 1.0% on the basis of cupric chloride.

The reaction was followed by titrating cuprous chloride formed. Since the reaction was inhibited significantly by the presence of cuprous chloride, the rates were expressed by initial rates in order to avoid complication as made by Walling[7] and Uemura *et al.*[5] The results are given in Table 2.

Table 2. Rate of reaction

v_1: initial rate of formation of I (mol/l sec)
v_2: initial rate of formation of II (mol/l sec)

In changing octene concentration, a suitable amount of n-octane was added to compensate the change of solvent polarity. The rate of formation of I was approximately 0.9 th order and that of II was 1st order in octene. Hence the initial rates may be expressed by the following equations, where v_1 and v_2 are the initial rates for I and II, respectively, and k_1 and k_2 are the corresponding rate constants.

$$v_1 = k_1[\text{octene}]_0[CuCl_2]_0^m \quad (1)$$

$$v_2 = k_2[\text{octene}]_0[CuCl_2]_0^n \quad (2)$$

Terms concerned with cuprous chloride, water and other additives can be excluded from these equations when these materials are not present in the initial step of reaction. Plots of log v_1 and log v_2 *vs.* log $[CuCl_2]_0$ show straight lines at each temperature. From the slopes of the lines m and n were calculated and the results are summarized in Table 3 together with the corresponding k_1, k_2, and entropies of activation. Energies of activation were calculated to be 29.9 kcal/mol for I and 29.0 kcal/mol for II.

ΔS_2: entropy of activation for formation of II

Discussion

The decrease in absolute yield of II which took place when lithium chloride was added strongly suggests that the amount of certain active species responsible for formation of II decreased in the reaction mixture. Since the concentration of methanol did not change practically in these instances, another factor, *viz.*, the concentration of cupric chloride molecule integrated over the reaction time, must have decreased. Nevertheless, the yield of I increased. Thus, it should be assumed that the second chlorinating species for I differs from cupric chloride molecule and increases on addition of lithium chloride. Chloride ion might be such a reactive species. If this is true, the reactions are represented by the following rate equations.

$$v_1 = k_1[\text{octene}][CuCl_2][Cl^-] \quad (3)$$

$$v_2 = k_2[\text{octene}][CuCl_2][MeOH] \quad (4)$$

Cupric chloride molecule exists probably as a distorted octahedral complex in methanol solution, and replacement of the coordinating methanol with the olefin is indispensable for initiation of the reaction. However, addition of water decreases the concentration of cupric chloride molecule by substituting chlorine in the complex as a result of its high coordinating power.[8] Water can also substitute the coordinating methanol. Since water is not so readily replaced by an olefin, a much weaker ligand, initial formation of the reaction intermediate complex should be seriously hindered.

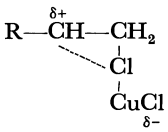
$$CuCl_2(MeOH)_4 \overset{\text{olefin}}{\rightleftharpoons} [CuCl_2\cdot\text{olefin}](MeOH)_3 \longrightarrow \text{reaction}$$

$$\uparrow \downarrow H_2O$$

$$[CuCl(H_2O)(MeOH)_4]^+Cl^- \text{ (inactive)}$$

$$CuCl_2(H_2O)(MeOH)_3 \text{ (less active)}$$

When the solution becomes less polar by increasing addition of octene, dissociation of cupric chloride should become less favorable and the concentration of chloride ion smaller. However, experimental results were contrary to those predicted from the chloride ion concentration. Therefore, in these cases, the ratio of k_1 to k_2 must have changed and overshadowed the change of chloride ion concentration.[11] A possible interpretation is that the charge separation between Cl–CuCl is disadvantageous in less polar solvents and Cl–CuCl bond becomes tighter, that is, more bulky around the cationic center in the intermediate complex.



This assumption is in line with the explanation for stereochemical behavior in the chlorination of inner olefins by cupric chloride.[2] Then, the attack of methanol is more restricted than that of chloride ion. The smaller entropy of activation, although the difference was not remarkable, favors the view that the activation complex for the formation of II is more crowded than the one for the formation of I and the attack of methanol is more sensitive to steric factors.

The formation of I was 1.6th order in cupric chloride added while that of II followed 1st order kinetics. The lower rate order for II indicates that major part of II was not formed by methanolysis of I, but directly through a different route. This kinetic observation is another evidence for the competitive reactions.

It is interesting that Uemura *et al.* reported the rate order in chlorination of styrene was 1.8th order in cupric chloride in 1-propanol solution.[5] If the chlorination takes place by the action of one mole of cupric chloride molecule and one mole of chloride ion, the reaction order must be much smaller than 2 in cupric chloride added, $[CuCl_2]_0$. On the other hand, the rate would be approximately proportional to $[CuCl_2]_0^2$, if two moles of cupric chloride molecules participate in the reaction. This may be evident when the concentrations of cupric chloride molecule and chloride ion are expressed in terms of $[CuCl_2]_0$, and Eqs. (3) and (5), are rewritten:[12]

8) According to the spectrochemical series,[9] ligand field splitting increases in the following order. In fact, the order of ligand field strength toward Cu^{2+} has been shown to be EtOH $<$ H_2O[10]

$$Cl^- < ROH < H_2O$$

9) L. E. Orgel, "An Introduction to Transition Metal Chemistry (Ligand Field Theory)," Methuen Co., London (1960), p. 96.

10) N. J. Friedman and R. A. Plane, *Inorg. Chem.*, **2**, 11 (1963).

11) If the formation of I is explained by the attack of 2 moles of cupric chloride molecules, the tendency can be understood by considering the change in concentration of cupric chloride molecule. However, this possibility can be denied for several reasons given in this paper.

12) For the sake of simplification, assume that the dissociation of $CuCl_2$ in methanol is only of the type

$$CuCl_2 \rightleftharpoons CuCl^+ + Cl^-$$

$$K = \frac{[CuCl_2]}{[CuCl^+][Cl^-]}$$

Concentrations of $[Cl^-]$ and $[CuCl_2]$ are calculated to be

$$[Cl^-] = \frac{1}{2K}(\sqrt{4KC_0+1}-1)$$

$$[CuCl_2] = \frac{1}{4K}(\sqrt{4KC_0+1}-1)^2$$

where C_0 is the formal concentration of $CuCl_2$.
Then,

$$v_1' = k'[CuCl_2][Cl^-] = \frac{k'}{8K^2}(\sqrt{4KC_0+1}-1)^3$$

$$v_1'' = k''[CuCl_2]^2 = \frac{k''}{16K^2}(\sqrt{4KC_0+1}-1)^4$$

From the fact that the formation of II is lst order in $[CuCl_2]_0$, $(\sqrt{4KC_0+1}-1)$ could be simplified as $\sqrt{4KC_0}$. Then, we have as first approximation

$$v_1' \propto C_0^{3/2}, \qquad v_1'' \propto C_0^2$$

$$v_1 = k_1'[\text{octene}][CuCl_2]^2 \quad (5)$$

Our results seem to fit the former case. Thus, we presume that the chlorination occurs mostly by attack of chloride ion[13] on the intermediate complex formed between cupric chloride molecule and olefin. Possibility of participation of other anionic species such as $CuCl_3^-$ and $CuCl_4^{2-}$ can not strictly be ruled out. However, such species are supposed to be less nucleophilic because of their anionic charge dispersion over large molecules and also sterically less advantageous as compared to chloride ion. Then, the overall reaction sequence is represented by the following scheme, the second steps being rate-determining.

$$R\text{-}CH{=}CH_2 + CuCl_2 \longrightarrow [\overset{\delta+}{R}CHCH_2Cl \cdots \overset{\delta-}{Cu}Cl]$$

$$\xrightarrow{Cl^-} RCHClCH_2Cl$$

$$\xrightarrow[MeOH]{} RCH(OMe)CH_2Cl$$

Addition of cuprous chloride suppressed the reactions significantly. If all the added cuprous chloride form one to one complexes with cupric chloride[14] and the complexes are inert or at least far less reactive than cupric chloride itself,[7] active cupric chloride concentration would be 0.262 mol l in our experiment. Therefore, v_1 should be larger than that in the case of cupric chloride concentration at 0.256 mol/l. However, v_1 was five times smaller while v_2 was slightly larger than those expected. These results indicate that the main reason for the decrease of v_1 is other than the decrease of cupric chloride molecule. A plausible explanation is that chloride ion plays an important role in the formation of I and the concentration of chloride ion decreased by complex formation with cuprous chloride. Although the complex Cu_2Cl_3 may actually exist in the reaction solution, the predominant cuprous chloride complexes would still be $CuCl_2^-$ and $CuCl_3^{2-}$.[14]

The fact that existence of oxygen is disadvantageous for the formation of dichloride has been interpreted by the same sort of consideration, *i.e.*, the decrease of chloride ion.[6]

Addition of lithium chloride together with cuprous chloride did not compensate the retardation completely. A fairly large portion of lithium chloride seems to exist undissociated in the reaction solution.

Experimental

Materials. 1-Octene (Schuchardt, München) was dried over Na_2SO_4 and distilled under N_2 before use, which was gas-chromatographically pure. Methanol (GR, Koso Chemical Co.) was distilled from $Mg(OMe)_2$ under N_2. Anhydrous cupric chloride and lithium chloride were of GR grade (Koso). Cuprous chloride was prepared by the reduction of cupric chloride with sodium sulfite under N_2[15]. 1,2-Dichlorooctane was prepared by the chlorination of 1-octene with sulfuryl chloride in the presence of benzoyl peroxide[16] (bp 67—68°C/4 mmHg). 1-Chloro-2-methoxyoctane was synthesized by the action of *t*-butyl hypochlorite on 1-octene in methanol.[17]

Analytical Methods. Cupric chloride was determined by iodometry.[1] Cuprous chloride was titrated with 0.1 N ceric ammonium sulfate solution using ferroin as an indicator.[18,19] The reaction products were analyzed by gas chromatography. Conditions (apparatus, column, temperature and carrier gas): (A). Shimadzu GC-4APT, Apiezon L on Chromosorb W, 150°, He; (B). Shimadzu GC-5F, Silicone DC-200 on Diasolid L, 160°, N_2.

Procedure. In each 15 ml sealed tube was placed 10 ml of the prescribed reaction mixture under N_2. After an appropriate period of heating in a constant temperature bath ($\pm$0.05°C) the sealed tube was taken out and cooled in ice-water. The reaction solution was subjected to gas chromatography. All the solution was then poured into 10 ml of 0.1 M ferric ammonium sulfate solution (in 3 M H_2SO_4) and the cuprous ion was titrated with a standard ceric solution. Since the products practically consisted of only I and II, the amount of consumed cupric chloride was divided between I and II in the proportion of the analytical result by gas chromatography, and the amounts of formation were calculated.[20] The rate of reaction was very sensitive to retardation caused by the products. Therefore, the initial rate of formation was conveniently calculated by reading the reaction time at 2% conversion from the time-conversion plot.

Methanolysis of I. A 10 ml solution of I (0.114 mol/l) with $CuCl_2$ (1.0 mol/l) in MeOH was heated at 120°C in a 15 ml glass sealed tube. After 13 hr a trace of II was detected in the solution, and after 19.5 hr 1.6% of I was converted to II.

The authors wish to thank Professor Naoki Inamoto, Dr. Keinosuke Suzuki and Dr. Ken'ichi Takeuchi for valuable discussions and suggestions.

Studies on Reactions of Isoprenoids. XIV.[1] Facile Lactone Formations from 2-*endo*-Cyano-, 2-*endo*-Cyanomethyl-, and 2-*endo*-Carboxymethyl-5-norbornenes

Tadashi SASAKI, Shoji EGUCHI, and Michio SUGIMOTO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received October 29, 1970)

Treatment of 2-*endo*-cyano-5-norbornene (I) with polyphospholic acid (PPA) at 60°C afforded 6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (V) in 40—46% yields, while 2-*endo*-cyanomethyl-5-norbornene (IV) prepared from 2-*endo*-methoxycarbonyl-5-norbornene (II) *via* the corresponding alcohol (III) gave 3-*exo*-hydroxybicyclo[2.2.1]heptane-2-*exo*-acetic acid lactone (VIII) in 25% yield by a similar treatment with PPA. With sulfuric acid, IV gave only intractable polymeric materials. However, under milder conditions using a sulfuric acid-acetic acid mixture, IV afforded 2-*exo*-cyanomethyl- (VI) and 2-*exo*-carbamoylmethyl-6-*exo*-acetoxynorbornane (VII) in 69 and 2% yields, respectively. On the other hand, iodolactonization of the carboxylic acid (IX) derived from IV afforded 5-*exo*-iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-acetic acid lactone (X) in 68% yield. The formation of VIII from IV was explained by the successive Wagner-Meerwein rearrangement, 3,2- and 6,2-hydride shifts, followed by cyclization.

Although a number of cyclizations in the 2-*endo*-substituted 5-norbornene (*i.e.*, bicyclo[2.2.1]hept-5-ene) system have been extensively studied recently,[2] no reports seem to have been given on the cyclization reactions under the Ritter reaction conditions. Only a limited number of intramolecular Ritter reactions of acyclic-, monocyclic-, and bicyclic unsaturated nitriles[3] have been reported in contrast to numerous examples of intermolecular reactions.[4] From an interest in the synthesis of cage compounds like adamantane,[5] we investigated the chemical behaviors of 2-*endo*-cyano-5-norbornene (I) and 2-*endo*-cyanomethyl-5-norbornene (IV) under several Ritter reaction conditions,[6] and the iodolactonization of bicyclo[2.2.1]hept-5-enyl-2-*endo*-acetic acid (IX).

Preparation of Starting Materials

Starting nitriles, I and IV, and carboxylic acid IX were prepared by a sequence of reactions summarized in Scheme 1. The Dieles-Alder reaction of acrylonitrile with cyclopentadiene at 160°C produced only a 1:1 mixture of 2-*exo*- and -*endo*-cyano-5-norbornene. The reaction was carried out by mixing acrylonitrile cooled to 0°C with freshly prepared cyclopentadiene trapped at −73°C. The 1:1 adduct thus obtained was confirmed to be the desired 2-*endo*-cyano-5-norbornene (I) on the basis of IR and NMR spectral data, though vpc analysis revealed some (*ca.* 10%) contamination with *exo*-isomer.

The Diels-Alder reaction of methyl acrylate with cyclopentadiene proceeded more stereospecifically under similar conditions and afforded 2-*endo*-methoxycarbonyl-5-norbornene (II) in 79% yield, the vpc analysis of which showed *ca.* 3% contamination of the *exo*-isomer. II could be converted to the corresponding alcohol III by means of lithium aluminum hydride reduction. The tosylate of III was treated with sodium cyanide in dimethyl sulfoxide at 90—95°C to afford 2-*endo*-cyanomethyl-5-norbornene (IV) in 33% overall yield from II. The structure of IV was confirmed by analytical and spectral data. Vpc analysis showed only one peak.

Alkaline hydrolysis of IV afforded the corresponding carboxylic acid IX in 86% yield, and the structure was confirmed by analytical and spectral data.

Results and Discussion

Treatment of I with concd. sulfuric acid (98%, sp. gr., 1.84) under common Ritter reaction conditions[3,6] produced a solid material which was purified by sublimation to give colorless crystals (V), mp 155—157°C, in 41% yield. The IR spectrum (KBr) exhibited a strong absorption band at 1770 cm^{-1} (γ-lactone) but no amide bands. The NMR spectrum ($CDCl_3$) gave signals at τ 5.32 (1H, d, d, J=6.0 and 4.5 Hz, C_{6x}–H),[7] 6.85 (1H, broad t, J=*ca.* 5 Hz, C_{2x}-H), 7.30—7.70 (2H, broad s, C_1–H and C_4–H), 7.90—8.50 (6 H, m, other ring protons), suggesting

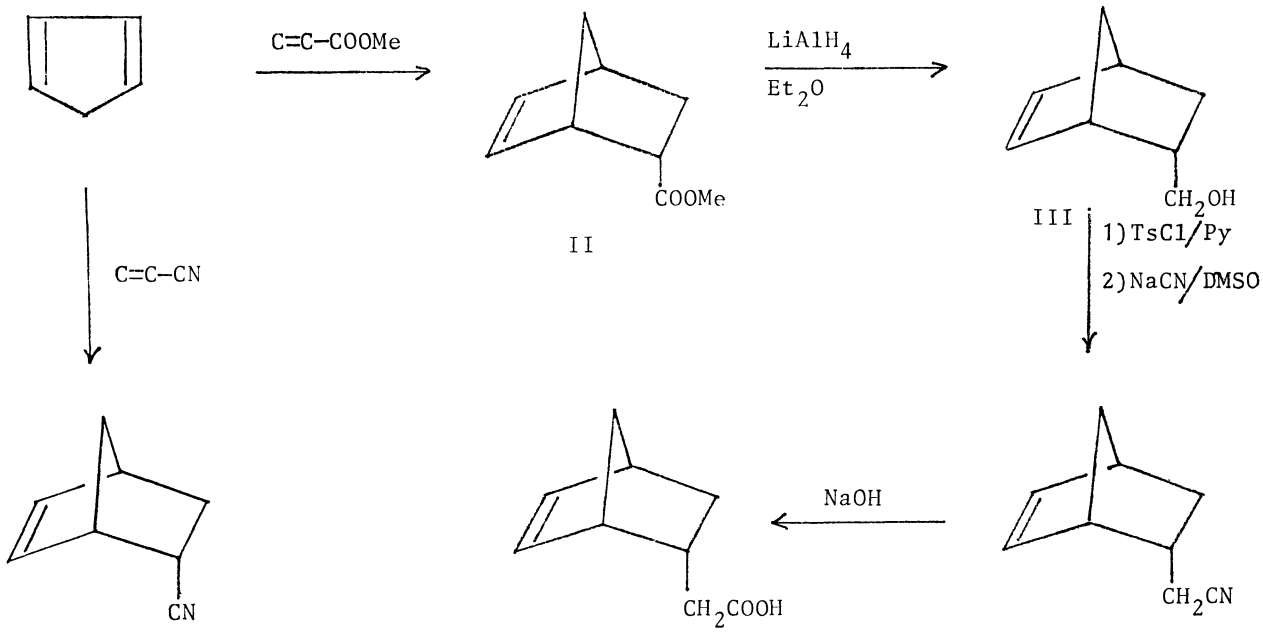
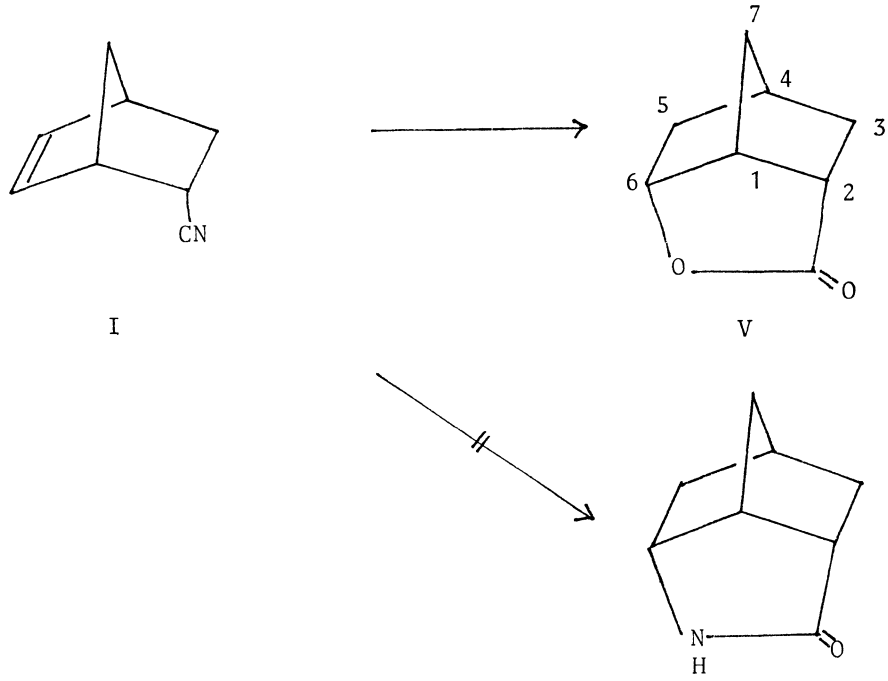


Scheme 1

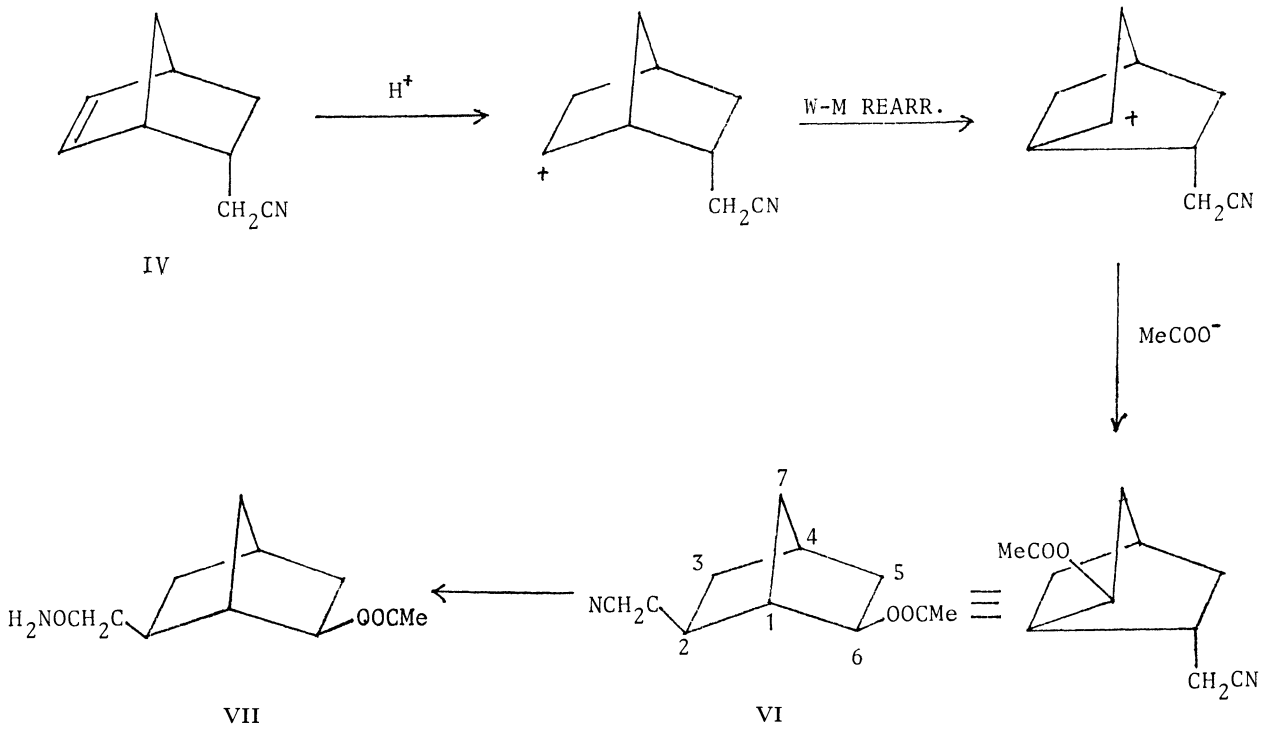
V to be 6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone. The assignment was confirmed by means of mixed melting point determination and complete superimposable IR spectrum with an authentic sample.[8]

Since no intramolecular Ritter reaction products were obtained under the above conditions, PPA was used instead of sulfuric acid. When I was stirred into about 5 times excess PPA (*ca.* 85%), an exothermic reaction took place and the mixture raised the temperature up to *ca.* 60°C, at which temperature the stirring was continued for a day. The product was taken up in chloroform after dilution with water. Chromatography on a silica gel column afforded a semisolid which was purified by sublimation to give the γ-lactone V in 46% yield, together with oily products in *ca.* 10% yield which was still a mixture of at least two compounds as confirmed by tlc and IR (neat) spectrum (γ_{max} 1730 and 1705 cm^{-1}). Further purification of the oily products was unsuccessful.

The results indicate that the normal intramolecular Ritter reaction of I is not favored and cyclization to C_6-position is preceded by the solvolytic reactions of nitrile. This might be ascribed to the steric remoteness



8) S. Beckmann and H. Geiger, *Chem. Ber.*, **94**, 48 (1961).



Scheme 2

of the nitrogen atom from C_6-position.

Treatment of 2-*endo*-cyanomethyl-5-norbornene (IV) with concd. sulfuric acid afforded very insoluble polymeric materials, but treatment of IV with a sulfuric acid-acetic acid mixture (1:10 vol/vol) at room temperature gave an oily acetate VI in 69% yield together with a crystalline acetate VII, mp 122—125°C in 2% yield after chromatography on a silica gel column. In the same reaction at 55—60°C, VI and VII were obtained in 13.8 and 44.2% yields, respectively. However, their structures turned out to be 2-*exo*-cyanomethyl- and 2-*exo*-carbamoylmethyl-6-*exo*-acetoxybicyclo[2.2.1]heptane, respectively, on the basis of analytical and spectral data and mechanistic considerations:[9] VI exhibited IR absorption bands (neat) at 2260 ($\nu_{C\equiv N}$), 1720 ($\nu_{C=O}$), 1245, and 1025 (ν_{C-O}) cm^{-1}, and NMR signals ($CDCl_3$) at τ 5.45 (1H, d, d, d, J=6.7, 3.0, and 2.3 Hz, C_{6n}–H), 7.48—7.90 (4H, m, CH_2CN and C_1–H and C_4–H), 8.00 (3 H, s, $OCOCH_3$), and 8.10—9.60 (7 H, m, other ring protons). VII had IR absorption bands (KBr) at 3320, 3180 (ν_{NH}), 1720 ($\nu_{C=O}$), 1245 and 1020 (ν_{C-O}) cm^{-1}, and NMR signals ($CDCl_3$) at τ 3.50—4.35 (2 H, s, disappeared on deuteration, NH_2), 5.20—5.50 (1 H, m, C_{6n}–H), 7.20—8.12 (7 H, m, other ring protons). Although the stereochemistry of both VI and VII was not conclusive from NMR data, we were led to assign their structures as given in Scheme 2 from the well-established Wagner-Meerwein rearrangement proclivity of the system under the employed conditions[9] and from the fact that no lactone or lactam was produced in the above reaction.

When IV was stirred into PPA in about 5 times excess amount, exothermic reaction (temperature rise to *ca.* 60°C) took place. After being kept at 60°C for a day, the mixture was worked up as above to give an oily product which was purified by chromatography. The major product VIII was obtained as an oil in *ca.* 25% yield. VIII exhibited a strong IR absorption band (neat) at 1770 (δ-lactone) cm^{-1}, indicating that VIII is a γ-lactone derivative but not amide or lactam. Microanalysis indicated a molecular formula of $C_9H_{12}O_2$ and the NMR spectrum ($CDCl_3$) gave signals at τ 5.50 (1 H, d, d, d, J=5.5, 2.0 and 1.0 Hz, C_{3n}–H), 6.80—8.06 (5 H, m, other ring protons); appearance of a signal at τ 5.50 excluded the possibility of 1-hydroxybicyclo[2.2.1]heptane-2-*exo*- or -*endo*-acetic acid lactone for VIII. Finally VIII was confirmed to be 3-*exo*-hydroxybicyclo[2.2.1]heptane-2-*exo*-acetic acid lactone. Possibility of the existence of its *endo*-isomer was excluded since the observed coupling constant 5.5 Hz for the signal due to C_3–H was in the range of the generally accepted value[10] for $J_{3n,2n}$ but not for $J_{3x,2x}$ (9—10 Hz) as shown in Fig. 1. The observed signal pattern was also compatible with the expected one from the dihedral angles.

Several other minor products were also produced in the reaction of IV with PPA. However, their purification by chromatography on a silica gel column was unsuccessful.

9) T. G. Traylor, *Accounts Chem. Res.*, **2**, 152 (1969).

10) However, the value should be considered as a guide, since it varies according to substituents as well as to the presence of another ring. For example, V exhibited 6 Hz as $J_{6X,5X}$ which is apparently affected by γ-lactone, *cf.* L. M. Jackman and S. Sternhell, "Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," 2nd Ed., in "International Series of Monographs in Organic Chemistry," ed. by D. H. R. Barton and W. Doering, Pergamon Press, New York, N. Y. (1969), p. 289, and references cited therein.

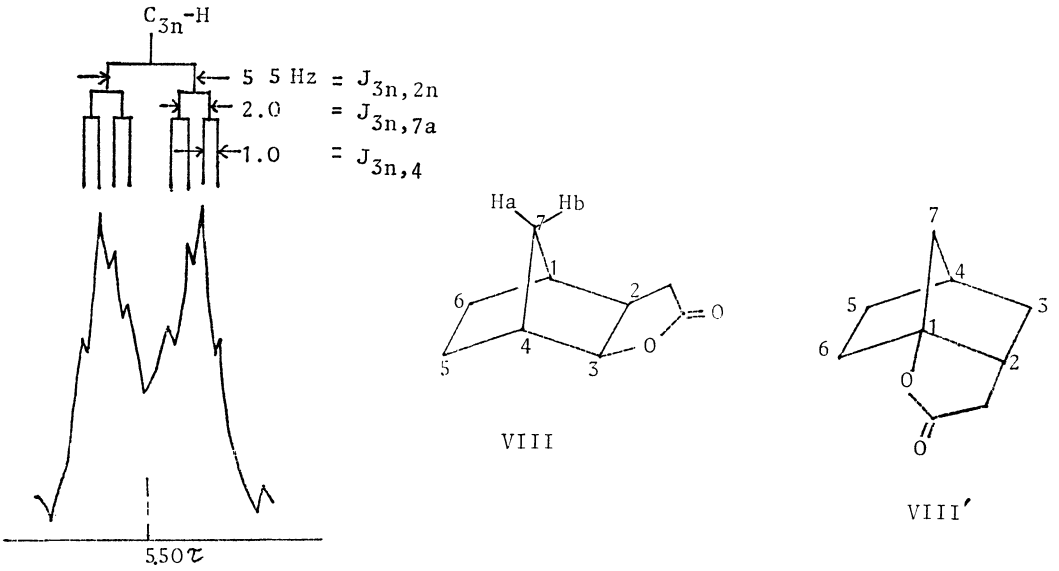


Fig. 1

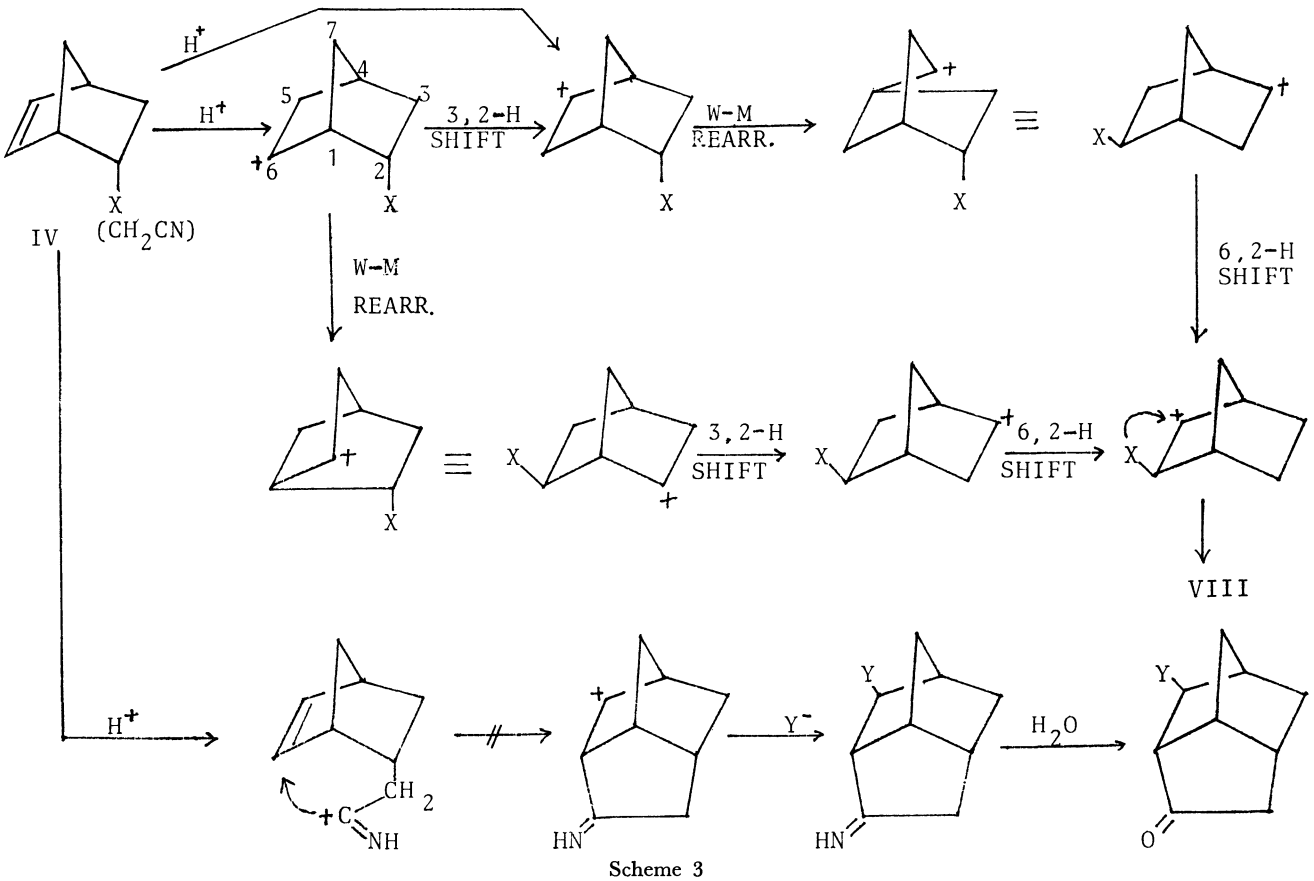
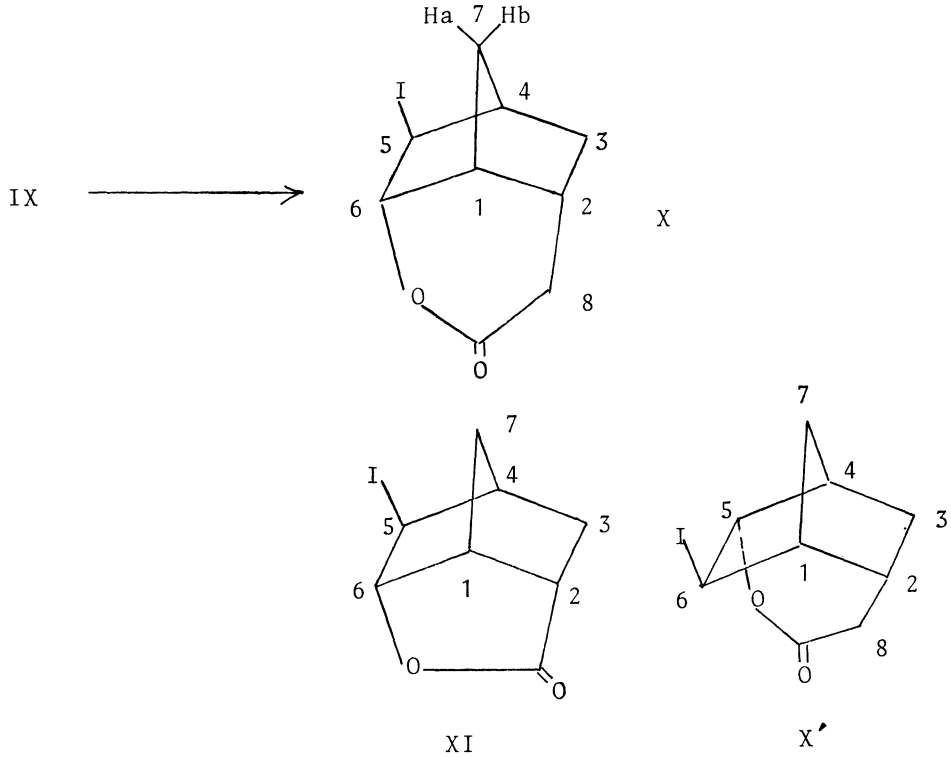


Scheme 3

Formation of VIII from IV could be explained by assuming the reaction paths involving a protonation at C_6 followed by the Wagner-Meerwein rearrangement and a 6,2-H shift, and/or a protonation at C_5 followed by a 3,2-H shift, the Wagner-Meerwein rearrangement and a 6,2-H shift, and/or followed by the Wagner-Meerwein rearrangement, a 3,2-H shift and a 6,2-H shift as explained in Scheme 3. The rearrangement might provide another example of the 6,2-H shift and also the 3,2-H shift in the norbornene ring system in addition to recently reported data.[11]

Iodolactonization of bicyclo[2.2.1]hept-5-ene-2-*endo*-acetic acid (IX), a derived carboxylic acid from IV,

11) *Cf.* C. C. Lee, B-S. Hahn, and L. K. M. Lam, *Tetrahedron Lett.*, **1969**, 3049 and references cited therein, and R. D. Hughes and J. K. Stille, Abst. Paper, The 159th Amer. Chem. Soc. National Meeting (Houston, Texas, Feb., 1970), ORGN 125.



was examined since IV did not produce the corresponding δ-lactone cyclized at C_6-position but afforded a novel γ-lactone (VIII) on treatment with PPA, while I gave a γ-lactone (V) under the same conditions. IX gave crystalline iodolactone X, mp 93—95°C in 68% yield by the standard iodolactonization procedure.[2a] X gave a strong IR absorption band (KBr) at 1737 (δ-lactone) cm^{-1} and NMR signals ($CDCl_3$) at τ 4.75 (1 H, d, m, J=4.5 and *ca.* 1 Hz, C_{6x}–H), 6.22 (1 H, d, d, J=3.0 and 1.5 Hz, C_{5n}–H), 7.20—7.93 (7 H, m, other protons), 8.23 (1 H, d, d, J=10.5 and 3.0 Hz, each peak was further split into m with J=*ca.* 1 Hz, C_{7b}–H), and 8.85 (1 H, d, d, J=11.5 and 2.3 Hz each peak was further split with J=*ca.* 1 Hz, C_{3n}–H). On irradiation of the signal at τ 8.23, the signal at τ 6.22 changed into a doublet with J=1.5 Hz, while the signal at τ 4.75 remained unchanged. Irradiation of the signal at τ 4.75 caused a simplification of the signal at τ 6.22 to a doublet with J=3.0 Hz. From the above spectral data and the analogy of the iodolactonization of bicyclo[2.2.1]hept-5-ene-2-*endo*-carboxylic acid,[2a] the structure of X was assigned to 5-*exo*-iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-acetic acid lactone.[12] The chemical shifts and the coupling were very similar to those reported for 5-*exo*-iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (XI). Only a slight difference is observed between X and XI; X had a larger $J_{5n,6x}$ (1.5 Hz) than XI ($J_{5n,6x}$=*ca.* 0.3 Hz) as was demonstrated by the double resonance experiments.

It should be mentioned that the formation of VIII from IV is the result of the extensive Wagner-Meerwein rearrangement and hydride shifts. No trace of 5-membered ketonic product expected from the Houben-Hoesch type cyclization[4] was found in the reaction of IV (Scheme 3). This also indicates the preference of the above rearrangement and the hydride shifts in this system.

Experimental[13]

2-endo-*Cyano-5-norbornene (I).* Freshly prepared cyclopentadiene collected at *ca.* −73°C was added to an equimolar amount of cooled acrylonitrile (*ca.* 0°C) with stirring. Stirring was continued for one day, keeping the temperature below 0°C for the first several hours, and then at an ambident temperature. The product was distilled under reduced pressure to give I as a colorless oil in 73.6% yield: bp 98—101°C/37 mmHg; n_D^{20} 1.4910 (lit,[14] bp 84—89°C/13 mmHg; n_D^{25} 1.4934); IR (neat) 2260 ($\nu_{C\equiv N}$) cm^{-1}; NMR ($CDCl_3$) τ 3.63 (1, H, d, d, J=6.5 and 3.0 Hz, C_5-H), 3.85 (1 H, d, d, J=6.5 and 3.0 Hz, C_6–H), 6.72 and 6.91 (each 1 H, broad s, C_1–H and C_4–H), 7.15 (1 H, d, d, J=9.0 and 3.0 Hz, each signal was further split with J=*ca.* 0.5 Hz, C_{2x}–H), 7.55—8.20 (2 H, m, C_3-protons), and 8.24—8.82 (2 H, m, C_7-protons).

Found: C, 80.69; H, 7.62; N, 11.69%. Calcd for C_8H_9N: C, 80.63; H, 7.61; N, 11.76%.

Vpc revealed two peaks in *ca.* 9:1 ratio.

2-endo-*Cyanomethyl-5-norbornene (IV).* The Diels-Alder reaction of cyclopentadiene with methyl acrylate under similar

12) Further chemical studies would be necessary for the absolute exclusion of an alternative structure X', though there seem to be no reasons for IX producing the electronically and sterically unfavored product (X') preferentially.

13) All melting points were determined on a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses were carried out on a Perkin-Elmer 240 Elemental Analyzer. Infrared spectra were recorded on a JASCO Model IR-S infrared spectrometer and NMR spectra were obtained with a JEOL Model JMN-C-60HL NMR spectrometer using TMS as an internal standard. Vpc analyses were performed on a K-23 Hitachi gas chromatograph.

14) K. Alder, H. Krieger, and H. Weiss, *Ber.*, **88**, 144 (1955).

conditions afforded *ca.* 97% pure 2-*endo*-methoxycarbonyl-5-norbornene (II) in 79% yield as a colorless oil: bp 96—99°C/36 mmHg; n_D^{19} 1.4750 (lit,[14] bp 63.5°C/5.2 mmHg; n_D^{25} 1.4718); the structure was confirmed by IR and NMR data.

Lithium aluminum hydride reduction of II afforded 2-*endo*-hydroxymethyl-5-norbornene (III) in 74.5% yield as an oil: n_D^{19} 1.4988 (lit,[16] n_D^{20} 1.5028).

III was treated with a small excess amount of *p*-toluenesulfonyl chloride in pyridine at room temperature for 1 day. Work-up in the usual way afforded the corresponding tosylate as an oil, n_D^{19} 1.5340, which was treated with an equimolar amount of sodium cyanide in dry dimethyl sulfoxide at 90—95°C for 2 hr. The product was taken in benzene after dilution with water. Removal of the solvent and distillation afforded 2-*endo*-cyanomethyl-5-norbornene (IV) in 33% overall yield from II as a colorless oil: bp 80—82°C/12 mmHg; n_D^{19} 1.4868; IR (neat) 2240 ($\nu_{C\equiv N}$) cm^{-1}; NMR ($CDCl_3$) τ 3.70—4.18 (2 H, complex m, C_5–H and C_6–H), 7.12 (2 H, broad and unsymmetrical s, C_1–H and C_4–H), 7.40—8.85 (6 H, m, other protons), and 9.40 (1 H, d split to m, $J=13.5$ Hz, C_{3n}–H).

Found: C, 81.55; H, 8.24; N, 10.20%. Calcd for $C_9H_{11}N$: C, 81.16; H, 8.33; N, 10.52%.

Vpc showed a single peak.

Treatment of I with Sulfuric Acid. To ice-cooled concd. sulfuric acid (40 m*l*) was added slowly I (14.0 g) with stirring which was continued for 1 day at room temperature. The mixture was poured onto ice-water (*ca.* 400 m*l*) and then extracted with chloroform after neutralization with 10% aq. sodium hydroxide. The combined chloroform extracts were dried (Na_2SO_4) and the solvent was removed to give a yellowish residue which on sublimation at 60—80°C/30 mmHg afforded a colorless solid (6.63 g, 40.7%) of 6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-carboxylic acid lactone (V), mp 150—153°C. Recrystallization from aq. ethanol raised mp to 155—157°C (lit,[7] 157—158°C).

Treatment of I with PPA. To PPA (*ca.* 25 g) was added I (4.8 g) with stirring. Stirring was continued for several minutes to produce a homogeneous viscous solution (temperature rise to *ca.* 60°C due to heat generation), which was kept at the same temperature for 1 day with occasional stirring. The product was taken in chloroform by extraction after dilution with water and the crude product was purified on a silica gel column eluting with dichloromethane-methanol system. The major product was γ-lactone V (45.8%) and the minor product was a mixture of unidentified amides (*ca.* 10%)

Treatment of IV with Acetic Acid-Sulfuric Acid Mixture. To an ice-cooled mixture of concd. sulfuric acid (0.5 m*l*) and glacial acetic acid (5 m*l*) was added slowly IV (0.5 g) with stirring which was continued for 12 hr at room temperature. The product was taken in chloroform by extraction after dilution of the mixture with water and neutralization with 10% aq. sodium hydroxide. The combined chloroform extracts were dried (Na_2SO_4) and the solvent was removed to give an oily residue (0.76 g) which was chromatographed on a silica gel column eluting with dichloromethane-methanol system. The first fraction afforded 0.51 g (68.9%) of 6-*exo*-acetoxy-2-*exo*-cyanomethylbicyclo[2.2.1]heptane (VI) as an oil, n_D^{17} 1.4816.

Found: C, 68.76; H, 7.81; N, 7.18%. Calcd for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.87; N, 7.25%.

The second fraction gave 0.15 g (2.0%) of 6-*exo*-acetoxy-2-*exo*-carbamoylmethylbicyclo[2.2.1]heptane (VII) as colorless crystals, mp 122—125°C.

Found: C, 62.76; H, 8.13; N, 6.39%. Calcd for $C_{11}H_{17}O_3N$: C, 62.54; H, 8.11; 6.63%.

A similar treatment of IV at 55—60°C for 12 hr and work-up as above gave VI and VII in 13.1 and 44.2% yield, respectively.

Treatment of IV with PPA. A mixture of PPA (*ca.* 7 g) and IV (1.4 g) was stirred manually to give a homogeneous viscous solution (temperature rise to *ca.* 60°C) which was kept at 60°C for 1 day with occasional stirring. The product was taken up in chloroform by extraction after dilution with water. The chloroform extract was dried and evaporated to give an oily residue (1.1 g) which was chromatographed on a silica gel column eluting with dichloromethane-methanol system. The first fraction afforded 0.35 g (25%) of 3-*exo*-hydroxybicyclo[2.2.1]heptane-2-*exo*-acetic acid lactone (VIII) as an oil, n_D^{17} 1.5032.

Found: C, 71.24; H, 7.90%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

The second fraction was an oil (*ca.* 0.3 g) which was still a mixture of several unidentified products.

Bicyclo[2.2.1]hept-5-ene-2-endo-*acetic Acid (IX).* A mixture of IV (1.5 g) and 20% aq. sodium hydroxide was stirred at room temperature for 1 day to afford a clear solution. The solution was washed once with benzene and neutralized with 10% sulfuric acid, and extracted with benzene (20 m*l*×5). The combined extracts were dried (Na_2SO_4) and evaporated to dryness affording a colorless oil (1.47 g, 85.7%) of IX: n_D^{21} 1.4958; IR (neat) 3000—2500 (ν_{OH}), 1710 ($\nu_{C=O}$), and 1410 (ν_{C-O}, δ_{OH}) cm^{-1}.

Found: C, 71.31; H, 7.86%. Calcd for $C_9H_{12}O_2$: C, 71.62; H, 7.95%.

Iodolactonization of IX. To a solution of IX (0.5 g, 3.3 mmol) in aq. sodium carbonate (*ca.* 3%, 100 m*l*) was added slowly a mixture of iodine (1.3 g, 4.9 mmol) and potassium iodide (1.2 g, 6.9 mmol) in water (50 m*l*) with stirring. After stirring was continued for 5 hr, sodium hydrogen sulfite was added until the decolorization was complete. The mixture was then extracted with chloroform (20 m*l*×5). The combined extracts were washed with 3% aq. sodium bicarbonate and dried (Na_2SO_4). Removal of the solvent and work-up with *n*-hexane gave colorless crystals (0.6 g, 68%) of 5-*exo*-iodo-6-*endo*-hydroxybicyclo[2.2.1]heptane-2-*endo*-acetic acid lactone (X), mp 93—95°C.

Found: C, 38.93; H, 3.93%. Calcd for $C_9H_{11}O_2I$: C, 38.87; H, 3.99%.

The Beilstein test was positive.

The authors wish to thank Miss T. Ikushima for NMR measurements and Mr. M. Okada for elemental analyses.

(Received November 6, 1970)

Allyl iodide has been pyrolyzed in a flow system over a wide range of conditions (temperature, 800—1100°C; contact time, $1.44\times10^{-4}-14.0\times10^{-4}$ sec; concentration, 1.8—6.5 mol%; pressure, atmospheric pressure) in order to find suitable conditions for producing methylacetylene and allene and in order to elucidate the reactions of the allyl radical with iodine or the iodine atom at high temperatures. In addition, a study of the mechanism of the pyrolysis of allyl iodide at high temperatures (800—1100°C) has been made. A total yield of allene and methylacetylene of 10 mol per 100 mol of allyl iodide pyrolyzed was obtained under suitable conditions. In the pyrolysis, little cleavage of the C–C bonds of allyl iodide occurred, and propylene, allene, methylacetylene,diallyl, benzene, and an unidentified product were found to be the main products. By means of the zero-conversion method, diallyl alone has been found to be the major product in the early stage of the pyrolysis, while propylene, allene, methylacetylene, and benzene have been found to be the chief products at higher conversions. On the basis of the observed results, a free-radical mechanism has been proposed for the main reactions. It has further been concluded that the pyrolysis is a radical decomposition initiated by the $C_3H_5I \rightarrow C_3H_5\cdot+I$ reaction and that the overall mechanism in the early stage of the pyrolysis may be represented essentially by the $2C_3H_5I \rightarrow C_6H_{10}+I_2$ reaction.

In previous papers, the present authors reported the synthesis of methylacetylene by the pyrolysis of propylene[1] and allyl halides.[2] Since the C–I bond dissociation energy of allyl iodide[3] (43.5 kcal/mol) is considerably lower than that of the α(C–H) of propylene[3] (87.5 kcal/mol), the pyrolysis of allyl iodide may be expected to bring about better results under moderate conditions and to give information about the reactions of the allyl radical with iodine and the iodine atom at high temperatures. It was further found, by the pyrolysis of allyl halides,[2b] that iodine or the iodine atom has a catalytic effect in converting the allyl radical into allene. Therefore, the pyrolysis of allyl iodide was investigated with the aim of producing methylacetylene and allene and elucidating the catalytic action of iodine on the allyl radical.

Although several papers[2b,4-7] have been published on the pyrolysis of allyl iodide, the investigations have been generally concerned with the strength of the C–I bond and have been carried out at low temperatures, except for our own study[2b] and that of Lossing, Ingold, and Henderson.[6] With the exception of our study,[2b] product analyses have been limited and little is known about the decomposition products. Diallyl alone was positively identified in the pyrolysis products; there was no data for the identification of other pyrolysis products. Of course, methylacetylene and allene were not found in the products. The reaction products reported by previous investigators are summarized in Table 1.

TABLE 1. SUMMARY OF PREVIOUS INVESTIGATIONS

	Reference	Temperature range (°C)	Product
4)	Szwarc	a)	diallyl
6)	Lossing, Ingold and Henderson,	750 to 915	diallyl
7)	Benson	a)	C_6H_{10} [b]
2b)	Kunichika, Sakakibara and Taniuchi	800 to 1100	propylene, allene, methylacetylene, diallyl, and benzene

a) No accurate information was obtained about the temperature range of the pyrolysis.

b) Benson says that the C_6H_{10} is undoubtedly cyclohexene or methylcyclopentene.[7]

Butler and Polanyi[5] first studied the pyrolysis of allyl iodide kinetically. From the kinetics of the pyrolysis, Szwarc[4] and Benson[7] proposed a simple radical mechanism involving an initial dissociation of allyl iodide into the iodine atom and the allyl radical. Lossing *et al.*[6] found that the production of the allyl radical appeared to be almost quantitative in the high-temperature pyrolysis of allyl iodide, the only hydrocarbon product of any importance being the dimerization product, diallyl.

The purpose of the present investigation is to determine suitable conditions for the production of methylacetylene and allene by the pyrolysis of allyl iodide, and to obtain data on the distribution of the pyrolysis products. On the basis of the observed experimental results, an effort will be made to clarify the reaction mechanism for the pyrolysis at high temperatures (800—1100°C) and the reactions of the allyl radical with iodine and the iodine atom.

Experimental

Materials. The allyl iodide was prepared from allyl chloride.[8] Bp 101—102°C; n_D^{22}1.5540. Cylinder nitrogen of a 99.9 mol% purity was used as diluent and carrier gas.

Apparatus and Procedure. The apparatus and the technique were essentially the same as had been used previously for the pyrolytical study of allyl chloride,[2a] except for the use of toluene as an absorbent. In order to prevent the reactions of unsaturated hydrocarbon products (especially, allene and methylacetylene) with hydrogen iodide or residual iodine after emergence from the reaction tube, the gaseous effluent, after passage through a water trap, was bubbled through a 200-m*l* portion of an aq. 2 N NaOH solution which had been put in two washing bottles. The alkaline solution was extracted twice with 50-m*l* portions of toluene, and then a portion of the toluene extract was taken up as has been described previously.[2a]

Analysis. The analytical method for the pyrolysis products was essentially the same as that described previously.[2a]

Results

Some of the experimental results are shown in Tables 2 and 3. In the pyrolysis, little cleavage of the C–C bonds of allyl iodide occurred. Consequently, all the decomposition products possessed C_3 and C_6 skeletons derived from the allyl and iodoallyl radicals; the C_1, C_2, and C_4 hydrocarbons were detected in only small amounts. Propylene, allene (A-C_3H_4), methylacetylene (M-C_3H_4), diallyl, benzene, and an unidentified product were found to be the main products. Except for the products mentioned above, no other products, not even hydrogen, were detected in any considerable amount. The kinds of the decomposition products were appreciably fewer than those in the pyrolyses of allyl chloride and bromide.[2b] In addition, larger amounts of propylene and diallyl were obtained, but smaller amounts of benzene were found.

The Effect of the Temperature on the Product Yields. The results obtained in the conversion range from 13 to 16% are shown in Table 2 and Fig. 1. As the temperature was increased, the yield of allene gradually increased to reach 6 mol at 1000°C, and that of propylene increased from 15 mol at 800°C to 27 mol at 1000°C. The yield of diallyl decreased from 39 mol to 28 mol, while that of benzene increased slowly from 3 mol to 6 mol. At a higher conversion range from 27 to 34%, the yield of allene increased from 5 mol at 800°C to 10 mol at 1100°C, while that of propylene decreased from 41 mol to 38 mol. The yield of diallyl

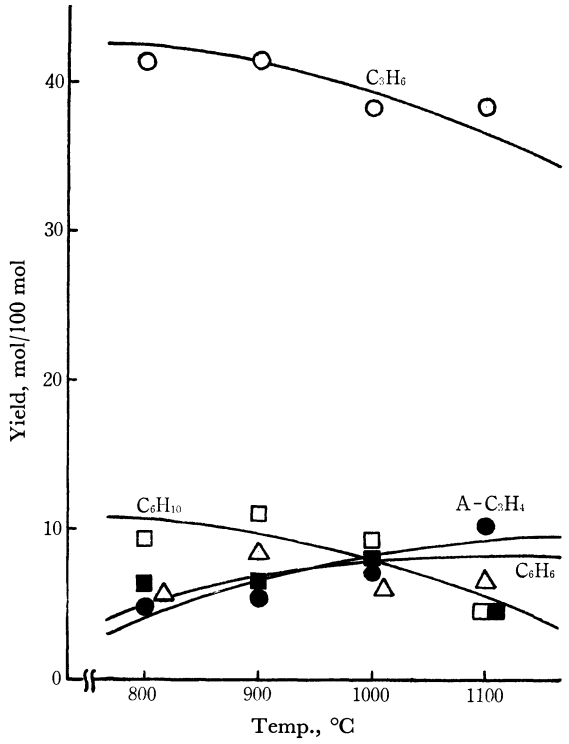

Fig. 2. Effect of temperature on product yields.
conversion, 27—34%
■: unidentified product

decreased from 10 mol to 5 mol. On the contrary, the yield of benzene was almost constant at 7 mol (Fig. 2).

The yield of methylacetylene was very small over the conversion range studied, and so the effect of temperature on its yield could not be examined. The carbon and hydrogen balance became remarkably worse at higher temperatures as a result of the increase in tarry and carbonaceous products (Table 2).

The Relation between the Conversion and the Yields. The results of the pyrolysis at 1000°C are shown in Table 3 and Fig. 3. The total yields of methylacetylene and allene increased with an increase in the conversion, ranging from 4 mol at 10% conversion to 10 mol at 70% conversion. As the conversion was increased, the yield of allene increased from 4 mol at 10% conversion to 7 mol at 70% conversion, while that of methylacetylene increased slowly in the 50—70% conversion range, reaching 2 mol at 70% conversion. The yield of propylene increased from 22 mol

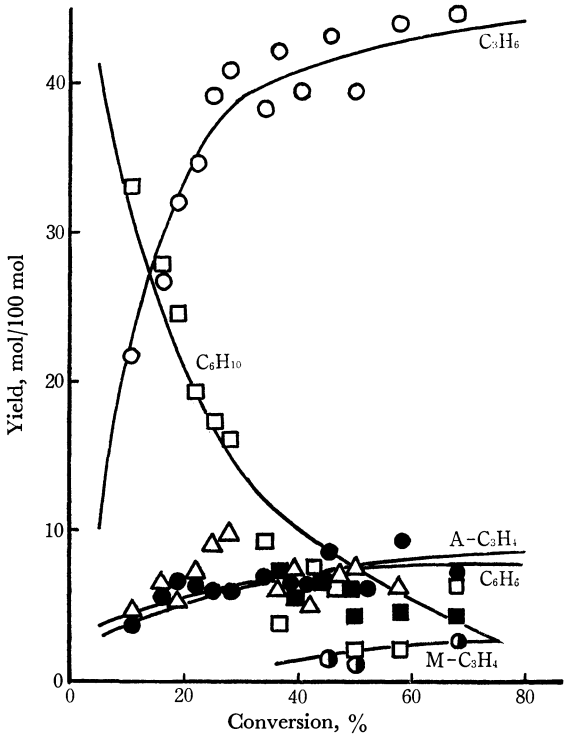

Fig. 3. Relation between conversion and product yields.
temp., 1000°C
■: unidentified product

at 10% conversion to 44 mol at 70% conversion. Although its yield increased rapidly at lower conversions, the increase was much slower at higher conversions (ranging from 30% conversion to 70% conversion). The yield of diallyl, on the other hand, decreased from 33 mol at 10% conversion to 6 mol at 70% conversion. Though its yield decreased quickly at lower conversions, the decrease was much slower at higher conversions. Thus, the tendency of change in diallyl was found to be nearly the reverse of that in propylene. The yield of benzene increased from 4 mol at 10% conversion to 7 mol at 70% conversion. The yield of an unidentified product increased in the 30—70% conversion range, reaching 5 mol at 70% conversion. The amount of tarry and carbonaceous products increased with the increasing conversion to make the material balance remarkably worse, as is described in Table 3. Moreover, it was determined by the zero-conversion method that the major product in the early stage of the pyrolysis was diallyl, as is shown in Fig. 3.

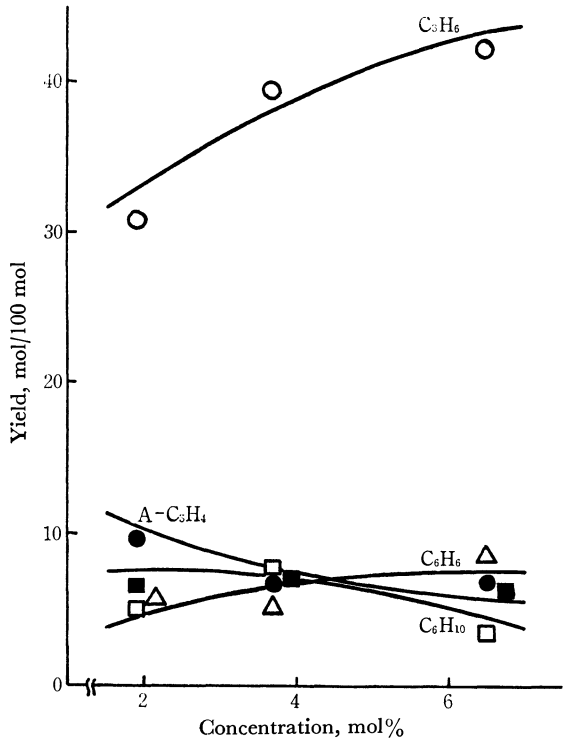

Fig. 4. Effect of concentration on product yields. conversion, *ca.* 40%
■: unidentified product

The Effect of the Concentration on the Yields. The yields of products obtained in a concentration range from 2 to 7 mol% at 1000°C are shown in Fig. 4 (also in Table 3). As the concentration was increased, the yield of propylene gradually increased from 31 mol to 42 mol, while that of allene slowly decreased from 10 mol to 7 mol. The yield of benzene increased from 6 mol to 8 mol, and that of diallyl decreased from 6 mol to 4 mol. The yield of an unidentified product was almost constant at about 6 mol over the concentration range studied.

In closing, it is worthy of special mention that all the decomposition products possess C_3 and C_6 skeletons derived from the allyl and iodoally radicals. It was further found that the amount of propylene was approximately equal to the sum of the amounts of allene, methylacetylene, and four times the amounts of benzene (Fig. 3 and Table 3).

Discussion

Mechanism. On the basis of the experimental results, a mechanism for the pyrolysis of allyl iodide may be proposed. The heats of reaction for the reactions mentioned below are also given when available. The values of the heats of formation of the various materials used in their computation are shown in Table. 4.

Table 4. Heats of formation of gases at 298°K and 1 atm(kcal/mol)

C_3H_5I[9a]	21.5	I_2[9b]	14.9
C_3H_6[9b]	4.9	HI[9c]	6.2
A-C_3H_4[9b]	45.9	I[9b]	25.5
M-C_3H_4[9c]	44.3	C_3H_5·[9b]	40.6
C_6H_{10}[9d]	17.8	H[9b]	52.1

A possible explanation may be offered for the formation of allene and methylacetylene in the pyrolysis of allyl iodide.

$$C_3H_5I \longrightarrow C_3H_5\cdot + I \qquad \Delta H = 44.6 \qquad (1)$$

$$I + C_3H_5I \longrightarrow C_3H_5\cdot + I_2 \qquad \Delta H = 8.5 \qquad (2)$$

$$I + C_3H_5I \longrightarrow HI + \cdot C_3H_4I \qquad (3)$$

$$C_3H_5\cdot + C_3H_5I \rightleftharpoons C_6H_{10} + I \qquad \Delta H = -18.8 \qquad (4)$$

$$C_3H_5\cdot + C_3H_5I \longrightarrow C_3H_6 + \cdot C_3H_4I \qquad (5)$$

$$C_3H_5\cdot + HI \longrightarrow C_3H_6 + I \qquad \Delta H = -16.4 \qquad (6)$$

$$C_3H_5\cdot + I \longrightarrow C_3H_4 + HI \qquad \Delta H = -14.0 \qquad (7)$$

$$C_3H_5\cdot + I_2 \longrightarrow C_3H_4 + HI + I \qquad \Delta H = 22.1 \qquad (8)$$

$$2C_3H_5\cdot \longrightarrow C_6H_{10} \qquad \Delta H = -63.4 \qquad (9)$$

$$2\dot{C}_3H_4I \longrightarrow C_6H_6 + 2HI \qquad (10)$$

$$A\text{-}C_3H_4 + I \longrightarrow M\text{-}C_3H_4 + I \qquad \Delta H = -1.6 \qquad (11)$$

$$2I + M \longrightarrow I_2 + M \qquad \Delta H = -36.1 \qquad (12)$$

Reactions (1) to (12) are the main reactions in the pyrolysis. Reaction (1) is the initiation step, which features the dissociation of allyl iodide into the allyl radical and the iodine atom. All the main products—propylene, allene, diallyl, benzene, and methylacetylene— except for an unidentified product, are formed largely by subsequent reactions— (5) and (6), (7) and (8), (4), and (9), (10), and (11) respectively. As the formation step of allene, the unimolecular decomposition of the allyl radical[1,10] is also considered, but the

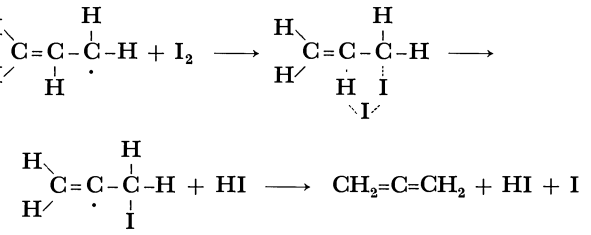
activation energy of Reaction (13) (*ca.* 62 kcal/mol)[2a]

$$C_3H_5\cdot \longrightarrow C_3H_4 + H \qquad (13)$$

is fairly high compared to that of Reaction (1). Therefore, Reaction (13) may be discounted energetically. Thus, two possible alternatives, Reactions (7) and (8), may be considered as the formation reactions of allene. The ΔH value of the overall process for Reaction (8) is *ca.* 22 kcal/mol. Although Reaction (7) should have a high specific rate in view of its exothermicity (*ca.* 14 kcal/mol), Reaction (8) may also be considered in view of the high ratio of molecular iodine to atomic iodine.[11] The pathway of Reaction (8) can probably be written as follows:[12]



The values of the activation energy for hydrogen abstraction from propane by the allyl radical and the iodine atom have been reported to be *ca.* 25 kcal/mol in both cases.[13] It may, therefore, be presumed that the allyl radical and the iodine atom show almost the same reactivity for hydrogen abstraction. In addition, the corresponding value for an allylic hydrogen in propylene by the iodine atom has been estimated to be 18 kcal/mol.[14] Consequently, assuming that the α (C–H) bond energies of propylene and allyl iodide are essentially the same, it may be considered that an allylic hydrogen in allyl iodide would be abstracted easily by the allyl radical (Reaction (5)) and the iodine atom (Reaction (3)) under the present conditions. Reactions (2) and (3) of the iodine atom with allyl iodide are in competition with each other since, although Reaction (2) is better than Reaction (3) from an energetic point of view, the latter reaction may also play an important role at higher temperatures. Reactions (4) and (5) of the allyl radical with allyl iodide will proceed competitively. In addition, Reactions (4) and (9) involving the allyl radical, leading to diallyl, will be competitive reactions under our reaction conditions.[7] In Reaction (10), benzene would arise *via* the combination and cyclization of two iodoallyl radicals, formed by the α-hydrogen (allylic hydrogen) abstraction of allyl iodide, as in the cases of the other allyl halides.[2,15] The isomerization of allene to methylacetylene (Reaction (11)) would proceed through the same mechanism as the iodine-catalyzed, positional isomerization of butene.[16]

Figure 3 shows that the only major product in the early stage of the pyrolysis is diallyl. Hence, the stoichiometry of the reaction in the early stage is very well represented by the $2C_3H_5I \rightarrow C_6H_{10} + I_2$ reaction. This is fitted to the mechanism proposed by Szwarc[4] and Benson[7] in the pyrolysis of allyl iodide. It can, therefore, be presumed that Reactions (2) and (4) may play an important role in the early stage of the pyrolysis.[4,7] From the relationship between the yield and the conversion (Fig. 3), diallyl in the pyrolyzed gas appears to reach an equilibrium state in the early stage of the pyrolysis and to exist thereafter in an equilibrium concentration. Thus, Reaction (4) is presumed to be an equilibrium.

As the temperature increases (Fig. 1), the yields of propylene and allene increase, while that of diallyl decreases. This may be explained by the following two reasons. First is temperature effect on the reaction rates; generally, subtituent reactions prevail over addition reactions at higher temperatures.[17] Therefore, Reaction (5) would be relatively favored over Reaction (4) with an increase in the temperature. Thus, the yield of propylene increases, while that of diallyl decreases. Second is the temperature effect on the equilibrium constant of Reaction (4); the heat of formation of the forward reaction of Reaction (4) is negative. Consequently, the equilibrium constant of Reaction (4) decreases with an increase in the temperature. This leads to a decrease in the formation of diallyl, while an increase in the formation of propylene and allene results from Reactions (5) and (6), and (7) and (8), respectively, these being reactions consuming allyl radical. In the higher conversion range, from 27 to 34% (Fig. 2), more amounts of iodine and the iodine atom are considered to exist at an equilibrium concentration in the pyrolysis system than is the case with a lower conversion. Thus, the allyl radical formed is apt to be converted into allene through Reactions (7) and (8) in the higher conversion range with an increase in the temperature. Thus, the yield of propylene seemingly decreases, but the total yield of propylene and allene increases with an increase in the temperature.

As the conversion proceeds (Fig. 3), the yields of propylene and allene increase, while that of diallyl decreases. This may be explained by considering Reaction (4) to be a rapid equilibrium reaction; because its equilibrium constant is invariable with respect to the conversion, diallyl becomes the major product in the early stage of the pyrolysis. Thus, after the equilibrium was attained in the early stage of the pyrolysis, the yields of propylene and allene are increased by Reactions (5) and (6), and by Reactions (7) and (8), but that of diallyl decreases.

Besides, the amount of propylene is approximately equal to the sum of the amounts of allene, methylacetylene, and four times the amount of benzene, and the amount of hydrogen is very small. These experimental results may be well explained by the mechanism mentioned above.

Assuming that almost all the hydrogen iodide is consumed by Reaction (6), we obtain the following stoichiometric relations:

From Reactions (5), (10) and (6):

$$4C_3H_5\cdot + 2C_3H_5I \longrightarrow 4C_3H_6 + C_6H_6 + 2I$$

Similarly, from Reactions (3), (10), and (6):

$$4C_3H_5\cdot + 2C_3H_5I \longrightarrow 4C_3H_6 + C_6H_6 + 2I$$

From Reactions (7) and (6):

$$2C_3H_5\cdot \longrightarrow C_3H_6 + C_3H_4$$

From Reactions (8) and (6):

$$2C_3H_5\cdot + I_2 \longrightarrow C_3H_6 + C_3H_4 + 2I$$

Therefore, when 1 mol of benzene is formed, 4 mol of propylene is formed. In addition, when 1 mol of allene (methylacetylene) is formed, 1 mol of propylene is formed. The experimental data seem to confirm this (Fig. 3 and Table 3). Thus, it can be concluded that propylene is formed nearly exclusively by Reactions (5) and (6), and that the rate of Reaction (6) is very rapid, since the amount of hydrogen is very small.

As the conversion increases (Fig. 3), the yield of benzene increases, while that of diallyl decreases. As a result, it may be presumed also that benzene will be formed to some extent through diallyl.[7,18] With the increasing conversion, the pyrolysis reaction would become more complex, since the participation of hydrogen abstraction by the allyl radical or the iodine atom in secondary reactions increases remarkably. Consequently, it is difficult to account for the experimental results at higher conversions.

(Received November 17, 1970)

The thermal rearrangement of aryl thionocarboxylates was kinetically investigated in diphenyl ether. The rate constants of the rearrangement of aryl *N,N*-dimethylthionocarbamates were well correlated with the σ^- values, but the plots of the electron-releasing *para*-substituents deviated slightly on the lower side of the *meta* correlation line. A good linear free-energy relationship existed between the rearrangement of aryl *N,N*-dimethylthionocarbamates and the bimolecular nucleophilic reaction of 4- or 5-substituted 1-chloro-2-nitrobenzenes with piperidine. By the use of the substituent constants obtained from the latter reaction for the electron-releasing *para*-substituent constants, a fairly good ρ-σ^- relationship was obtained. Linear free-energy relationships also existed between the rearrangements of aryl *N,N*-dimethylthionocarbamates and aryl thionobenzoates, and between the rearrangements of aryl *N,N*-dimethylthionocarbamates and *O*-aryl *S*-phenyl dithiocarbonates. The order of the reaction constants was in accord with that of the inductive effects of the α-substituents of the thiocarbonyl group, so the electron-releasing conjugative effects of the α-substituents of the thiocarbonyl group did not play important roles in the rate-determining step. The present results indicate that the thermal rearrangement of aryl thionocarboxylates is an intramolecular S_N–Ar which involves a four-membered cyclic transition state formed by a nucleophilic attack of the lone-pair electrons of the thiocarbonyl sulfur atom on the migrating aromatic ring.

Since Schönberg and his co-workers reported the thermal rearrangement of diaryl thionocarbonates (I) to diaryl thiolcarbonates (II)[2,3)] (the so-called Schönberg rearrangement), a number of thermal rearrangements have been reported regarding the intramolecular 1,3 aryl migration from oxygen to sulfur. Tarbell and his co-workers reported that the Schönberg rearrangement proceeds by a nucleophilic attack of the thiocarbonyl sulfur atom on the aromatic ring, with a four-membered cyclic transition state.[4,5)]

Recently we reported the rearrangement of *O,S*-diaryl dithiocarbonates (III) to *S,S*-diaryl dithiocarbonates (IV)[6)] and the rearrangement of aryl thionobenzoates (V) to aryl thiolbenzoates (VI).[7)] These rearrange-

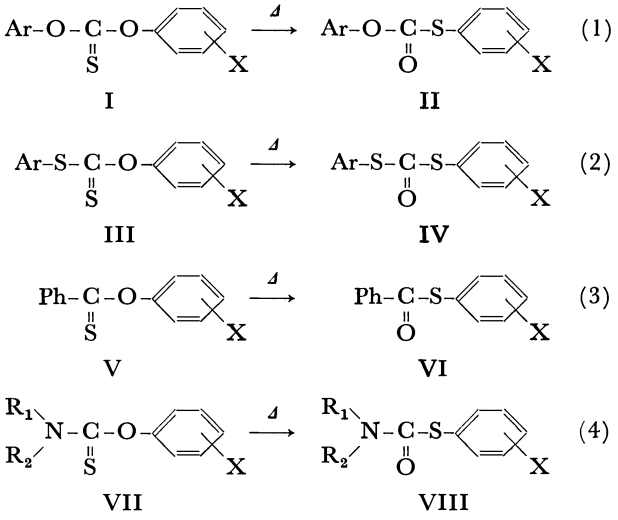
ments are facilitated by an electron-withdrawing group on the migrating aromatic ring and proceed *via* a four-membered cyclic transition state through the intramolecular nucleophilic attack of the thiocarbonyl sulfur atom on the migrating aromatic ring. Since a good linear free-energy relationship exists between these rearrangements, the existence of hetero-atoms directly bound to the thiocarbonyl group is not essential for the rearrangements with intramolecular 1,3 aryl migration from oxygen to sulfur.



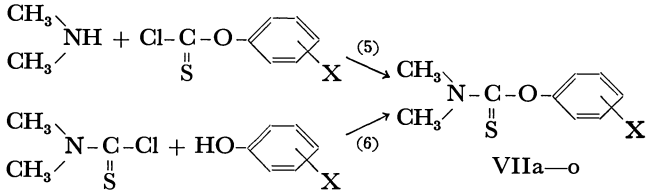
Aryl *N,N*-disubstituted thionocarbamates (VII) were also found to rearrange to aryl *N,N*-disubstituted thiolcarbamates (VIII).[8] A kinetical investigation in the absence of any solvent showed that this rearrangement proceeds by the intramolecular mechanims just as in the above rearrangements. It was also reported that ordinary Hammett plots of log k against σ^- do not give a satisfactory linear relationship (the correlation coefficient is 0.982), and that, by assuming that $r=1.60$ in the Yukawa-Tsuno equation,[9] the plots between log k and $\sigma^0+r\Delta\sigma_R$ give a better straight line (the correlation coefficient is 0.987). It is noteworthy that this value of r is extraordinary large. On the other hand, Relles and Pizzolato, in their study of the substituent effect of the same rearrangement in dipheny ether, reported that, when the log k values are plotted against Hammett σ values, the correlation coefficient is only 0.839, but when the log k values are plotted against the σ^- values, the correlation coefficient is 0.954,[10] which is inferior to the correlation coefficient reported by Miyazaki. However, they did not report the effects of the *meta*-substituents and of the strongly electron-withdrawing *para*-substituents.

It is obvious that all of the Schönberg-type rearrangements proceed *via* a four-membered cyclic transition state through an intramolecular nucleophilic attack of the thiocarbonyl sulfur atom on the migrating aromatic ring. However, as for the substituent effects, many obscure points remain. Therefore, we studied kinetically the thermal rearrangements of the various *meta*- or *para*-substituted aryl *N,N*-dimethylthionocarbamates and diaryl thionocarbonates in diphenyl ether and compared them with other Schönberg-type rearrangements.

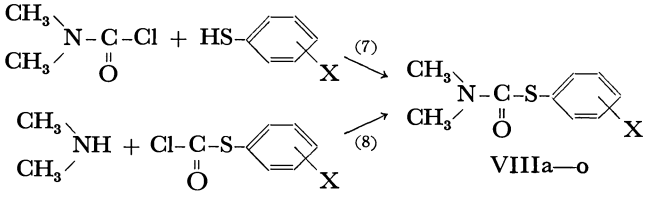
This paper will discuss a detailed mechanism of the Schönberg-type rearrangements.

Results and Discussion

The various aryl *N,N*-dimethylthionocarbamates (VIIa—o) were synthesized by the reaction of dimethylamine with an aryl chlorothionoformate (Eq. (5)) and/or by the reaction of *N,N*-dimethylthiocarbamoyl chloride with an appropriate phenol (Eq. (6)).



The various aryl *N,N*-dimethylthiolcarbamates (VIIIa—o) were obtained by heating the corresponding compounds VII. The compounds VIII were identified by a mixed-melting-point test and by a comparison of the infrared spectra with those of the corresponding authentic samples, which were prepared by the reaction of *N,N*-dimethylcarbamoyl chloride with an appropriate thiophenol (Eq. (7)) and/or by the reaction of dimethylamine with an aryl chlorothiolformate (Eq. (8)).



In order to clarify the substituent effects, the kinetics of the thermal rearrangement of aryl *N,N*-dimethylthionocarbamates were investigated at 200.5±0.1°C in diphenyl ether. The reactions were followed by the ampoule techniques, and the rates were determined by ultraviolet spectrophotometric measurements. As has been noted previously,[8,10] this rearrangement obeyed fairly good first-order kinetics. The first-order rate constants were derived from the slopes of the straight lines obtained by plotting ln[VII]/([VII]+[VIII]) against the time; the results are summarized in Table 1. The rates of the rearrangement are much faster for the electron-withdrawing substituents than for the electron-releasing substituents.

The logarithms of the rate constants can be plotted against the σ^- values[11] to give a straight line (Fig. 1). By means of the method of least-squares, the ρ value was calculated to be 1.97 (the correlation coefficient is

0.993). These results establish that this rearrangement is an intramolecular nucleophilic aromatic substitution reaction and that the additional delocalization by the resonance of the negative charge produced at the reaction site occurs in the transition state in diphenyl ether. The good correlation coefficient shows that it is sufficient if the *r* value in the Yukawa-Tsuno equation is 1.00 for this rearrangement in diphenyl ether. On the other hand, the *r* value of 1.60 has been obtained in the absence of any solvent.[8] It is clear that the solvent affects the rates of this rearrangement. In the absence of any solvent, the substrates themselves behave as solvents; these solvent effects, "self-solvent effects," presumably vary in parallel with the variation in the substituents on the materials, so that *r* in Yukawa-Tsuno equation may become as large as 1.60.

The Hammett plots of the electron-releasing *para*-substituents deviate slightly on the lower side of the *meta* correlation line (Fig. 1). The electron-releasing *para*-substituents may be expected to cause an additional resonance between the substituent and the reaction center in a manner similar to that of the electron-withdrawing *para*-substituents. However, such a resonance is ordinarily found to be very minor and negligible. Consequently, with regard to the electron-releasing *para*-substituents, the Hammett σ values are usually used instead of σ^- values in such nucleophilic reactions. However, the electron-releasing *para*-substituents of aryl *N,N*-dimethylthionocarbamates obviously exert a higher retardation of the rearrangement than would be anticipated from the ρ—σ^- relationship. It is necessary to give suitable σ^- values for the electron-releasing *para*-substituents instead of the Hammett σ values in this case. With respect to the σ^- value of the *para*-methoxy group, values of −0.11 for the reactions of phenols and −0.25 for the reactions of anilines have been provided,[12] but these values are very unsatisfactory for correcting the above Hammett plots.

The bimolecular nucleophilic aromatic substitution reactions[13] are reactions very similar to the Schönberg-type rearrangements. These nucleophilic aromatic substitution reactions do not correlate with the Hammett σ values, σ^n values[14] and σ^0 values,[15] but correlate well with the σ^- values.

Brieux and his co-workers, in their study of the substituent effects on the nucleophilic aromatic substitution reactions, calculated the *para*-substituent constants by using ρ values obtained from the *meta*-substituent series.[16,17] These *para*-substituent constants are very similar to the σ^- values. Two series are available. They are the $\sigma_{C_6H_5S}^-$ values obtained from the reactions of 4- or 5-substituted 1-chloro-2-nitrobenzenes with sodium thiophenoxide, and the $\sigma_{C_5H_{10}NH}$ values obtained from the reactions of the same compounds with piperidine. When the logarithms of the rate constants in Table 1 were plotted against $\sigma_{C_6H_5S}^-$ instead of the σ^- values, a rather unsatisfactory correlation was obtained (the correlation coefficient was 0.980) (Fig. 2). However, a very good linear relationship was observed against $\sigma_{C_5H_{10}NH}$ instead of the σ^- values (the correlation coefficient was here 0.994)

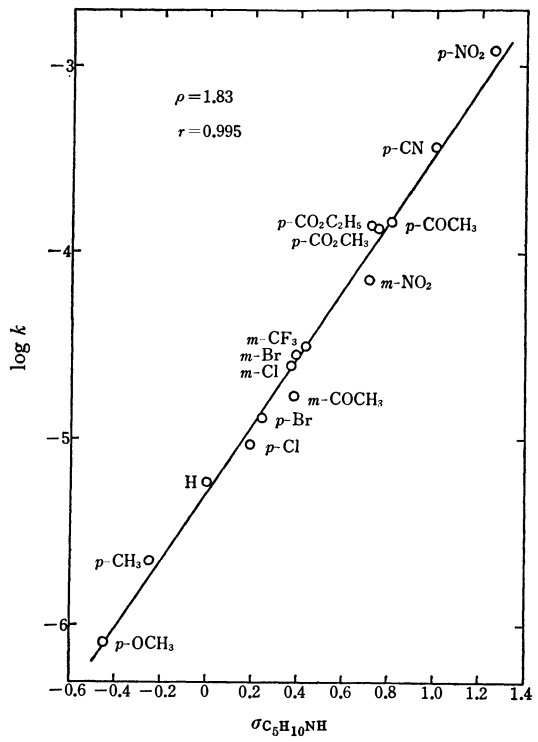

Fig. 3. Plot of the rates of the thermal rearrangement of aryl *N,N*-dimethylthionocarbamates (VII) in diphenyl ether at 200.5±0.1°C against $\sigma_{C_5H_{10}NH}$.

(Fig. 3).

Then, by the use of $\sigma_{O_5H_{10}NH}$ for the electron-releasing *para*-substituent constants, a linear free-energy correlation between log k from Table 1 and the σ^- values was established. This was the best correlation (Fig. 4). The ρ value calculated using the method of least squares is 1.83, and the correlation coefficient is 0.995.

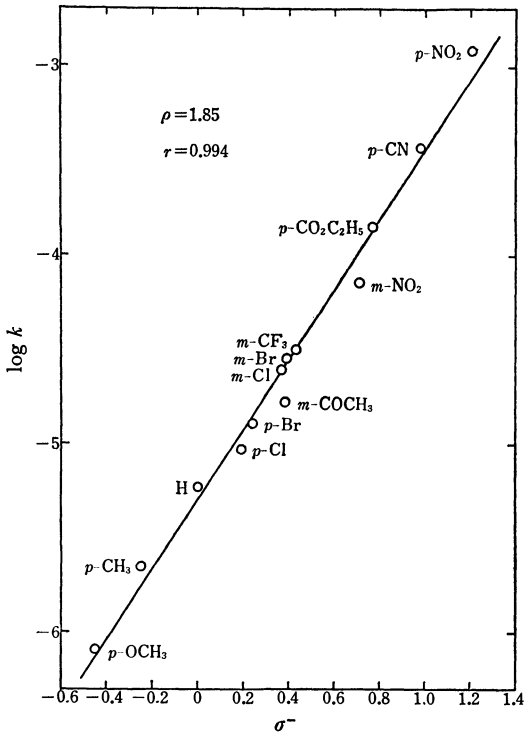

Fig. 4. Plot of the rates of the thermal rearrangement of aryl *N,N*-dimethylthionocarbamates (VII) in diphenyl ether at 200.5±0.1°C against σ^-, using $\sigma_{C_5H_{10}NH}$ for the electron-releasing *para*-substituent constants.

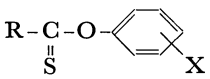
A very good linear free-energy relationship was observed in diphenyl ether between the rearrangements of aryl *N,N*-dimethylthionocarbamates and aryl thionobenzoates and also between the rearrangements of aryl *N,N*-dimethylthionocarbamates and *O*-aryl *S*-phenyl dithiocarbonates (the correlation coefficients were 0.999).

These results and the previously-reported results show that all of the Schönberg-type rearrangements probably proceed by the same mechanism in diphenyl ether. Therefore, on the rearrangements of aryl thionobenzoates[7] and *O*-aryl *S*-phenyl dithiocarbonates,[6] linear free-energy correlations between log k and the σ^- values were examined, using $\sigma_{C_5H_{10}NH}$ as the electron-releasing *para*-substituent constants. The ρ values calculated using the method of least squares and the correlation coefficients, r, are listed in Table 2.

TABLE 2. REACTION CONSTANTS AND CORRELATION COEFFICIENTS OF THE THERMAL REARRANGEMENT OF



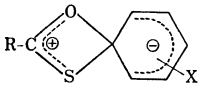
IN DIPHENYL ETHER AT 200.5±0.1°C

R	ρ	r
$(CH_3)_2N$	1.83	0.995
C_6H_5	1.33	0.997
C_6H_5S	1.19	0.995
C_6H_5O	1.06	—

From the foregoing discussion, it is evident that all of the Schönberg-type rearrangements are intramolecular nucleophilic aromatic substitution reactions. Therefore, it is very plausible that the Schönberg-type rearrangements proceed by an addition-elimination mechanism, in analogy with the intermolecular nucleophilic aromatic substitution reactions.

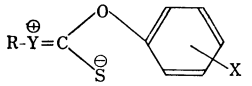
The rates of the thermal rearrangements of diphenyl thionocarbonate and *p*-nitrophenyl phenyl thionocarbonate[18] at 200.5±0.1°C in diphenyl ether were determined by the same method as was used for that of aryl *N,N*-dimethylthionocarbamates. Their first-order rate constants are 1.04×10^{-6} sec^{-1} (the half-value of the observed rate constant) and 2.34×10^{-5} sec^{-1} respectively. From these data, the ρ value was calculated (Table 2).

As is shown in Table 2, the order of the ρ values of the Schönberg-type rearrangements is as follows: aryl *N,N*-dimethylthionocarbamates>aryl thionobenzoates>*O*-aryl *S*-phenyl dithiocarbonates>aryl phenyl thionocarbonates. This order is in accord with that of the inductive effects of the α-substituents of the thiocarbonyl group.[19] This indicates that the proportions of the negative charge on aromatic rings in the transition state are governed by the inductive effects of the α-substituents of the thiocarbonyl group. According to Hammond's postulate,[20] it may be expected that, in endothermic steps, the transition states will resemble the products. Since the activation energies of the Schönberg-type rearrangements are highly positive values,[5-7,10] it may be expected that the transition state of the Schönberg-type rearrangements will closely resemble the intermediate. Therefore, the Schönberg-type rearrangements may proceed *via* an intermediate, as is shown in Scheme 1.



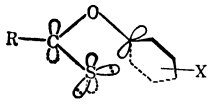
Scheme 1

Moreover, the rate constants of *p*-nitrophenyl *N,N*-dimethylthionocarbamate, *p*-nitrophenyl thionobenzoate,[7] *O*-*p*-nitrophenyl *S*-phenyl dithiocarbonate,[6] and *p*-nitrophenyl phenyl thionocarbonate in diphenyl ether at 200.5±0.1°C are 1.21×10^{-3} sec^{-1}, 1.18×10^{-4} sec^{-1}, 1.06×10^{-4} sec^{-1}, and 2.34×10^{-5} sec^{-1}, respectively. Since the Schönberg-type rearrangements may be governed by the enthalpy of activation at temperatures near 200°C[7], this order will not change under any possible conditions. It is suprising that this order is not in accord with that of the electron-releasing conjugative effects, but is in accord with that of the inductive effects of the α-substituents of the thiocarbonyl group. If the electron-releasing conjugative effects of the α-substituents of the thiocarbonyl group play important roles in the rate-determining step, as Newman and Karnes suggested with regard to the rearrangement of aryl *N,N*-disubstituted thionocarbamates[21] (Scheme 2), the rate constants should decrease in the order of: *p*-nitrophenyl *N,N*-dimethylthionocarbamate>*p*-nitrophenyl phenyl thionocarbonate>*p*-nitrophenyl thionobenzoate>*O*-*p*-nitrophenyl *S*-phenyl dithiocarbonate.[22]



Scheme 2

From these results and the fact that the Schönberg-type rearrangements unsatisfactorily correlate the reactions of 4- or 5-substituted 1-chloro-2-nitrobenzenes with sodium thiophenoxide, but well correlate the reactions of the same compounds with piperidine, it is plausible that the Schönberg-type rearrangements are intramolecular S_N–Ar which involve a four-membered cyclic transition state formed by the nucleophilic attack of the lone-pair electrons of the thiocarbonyl sulfur atom on the migrating aromatic ring, as is shown in Scheme 3:



Scheme 3

If the π electron of the thiocarbonyl sulfur atom attacks the migrating aromatic ring, there will necessarily be considerable extra strain because of the necessity of the rotation of the thiocarbonyl sulfur atom to permit the overlap between a *p* orbital initially perpendicular to the plane of the four-membered ring and a *p* orbital of the migrating aromatic ring initially on the plane of the four-membered ring.

Experimental[23]

Materials. The *N,N*-dimethylcarbamoyl chloride was prepared according to the method reported by Sugasawa and Deguchi.[24] The *N,N*-dimethylthiocarbamoyl chloride was prepared by the procedure recorded for the synthesis of the diethyl-analogue;[25] mp 40—41°C (lit,[26] mp 41°C). The aryl chlorothionoformates were prepared by a known method:[27] *m*-acetylphenyl-, light yellow oil, bp 148—149°C/8.5 mmHg (Found: C, 50.28; H, 3.10; Cl, 16.41%. Calcd for $C_9H_7ClO_2S$: C, 50.35; H, 3.27; Cl, 16.55%). *p*-Cyanophenyl-, colorless needles (from ligroin), mp 65—67°C

18) This compound certainly rearranges only to *O*-phenyl *S*-*p*-nitrophenyl thiolcarbonate, but it is very probable that any other unsymmetrical thionocarbonate can rearrange to two products.

19) The Hammett σ_m values of $(CH_3)_2N$, C_6H_5, C_6H_5S, and C_6H_5O are −0.21, 0.06, 0.18, and 0.25 respectively.

20) G. S. Hammond, *J. Amer. Chem. Soc.*, **77**, 334 (1955).

21) M. S. Newman and H. A. Karnes, *J. Org. Chem.*, **31**, 3980 (1966).

22) The $(\sigma_p^+-\sigma_m^+)$ values of $(CH_3)_2N$, C_6H_5O, C_6H_5, and C_6H_5S are −1.49, −0.75, −0.29, and 0.11, respectively. The σ_m^+ values of $(CH_3)_2N$ and C_6H_5O are not available; accordingly, σ_m values were used in place of σ_m^+ values. The σ^+ values of C_6H_5S are not available, either; therefore, the $(\sigma_p-\sigma_m)$ value was used in place of the $(\sigma_p^+-\sigma_m^+)$ value.

23) All the boiling and melting points are uncorrected.

Method A (Eq. (5)): To a solution of 15 g (0.10 mol) of 30%-dimethylamine in 50 m*l* of acetone was added, drop by drop, 0.05 mol of aryl chlorothionoformate under agitation at 5—10°C over a period of 10 min. After the addition had been completed, the mixture was warmed to 40—50°C for 5 min. It was then cooled to room temperature and poured into *ca.* 150 m*l* of cold water; the desired product was thereby obtained as a pale yellow oil and crystallized spontaneously on standing. Recrystallization from a suitable solvent gave pure crystals. The data are shown in Table 3.

Method B (Eq. (6)): To a solution containing 0.05 mol of an appropriate phenol and 2 g (0.05 mol) of sodium hydroxide in 50 m*l* of aqueous acetone (90%) was added, all at once, 6.2 g (0.05 mol) of *N,N*-dimethylthiocarbamoyl chloride. The mixture was heated under reflux for 30 min and then cooled to room temperature. Thereafter, the reaction mixture was worked up in the same manner as has been described in Method A. The date are also shown in

Table 3. The compounds VIIf, VIIg, VIIh, VIIl, and VIIn are new compounds. VIIf, Found: C, 59.05, H, 5.35; N, 6.02%. Calcd for $C_{11}H_{13}NO_2S$: C, 59.20; H, 5.44; N, 5.86%. VIIg, Found: C, 49.87; H, 4.40; N, 6.33%. Calcd for $C_9H_{10}ClNOS$: C, 50.15; H, 4.64; N, 6.50%. VIIh, Found: C, 41.70; H, 3.67; N, 5.18%. Calcd for $C_9H_{10}BrNOS$: C, 41.55; H, 3.85; N, 5.38%. VIIl, Found: C, 56.70; H, 6.06; N, 5.76%. Calcd for $C_{12}H_{15}NO_3S$: C, 56.95; H, 5.93; N, 5.53%. VIIn, Found: C, 58.30; H, 4.91; N, 13.52%. Calcd for $C_{10}H_{10}N_2OS$: C, 58.30; H, 4.86; N, 13.60%.

Aryl N,N-*Dimethylthiolcarbamates (VIIIa—o).* The following general methods were employed for the preparation of the compounds VIII.

Thermal Rearrangement of VII, Method C (Eq. (4)): The apparutus used for this method consisted of a 5 m*l*, round-bottomed flask. About 500 mg of VII was placed in the flask and kept at 205—210°C in an oil bath for the desired period, nitrogen being passed into the flask at a slow rate throughout the heating. The flask was then cooled to room temperature, and the contents were scratched in an ice bath to induce crystallization. The product thus obtained was recrystallized from a suitable solvent. The results are summarized in Table 4.

Method D (Eq. (7)): The reaction conditions of *N,N*-dimethylcarbamoyl chloride with an appropriate thiophenol to give VIII correspond to those of the Method B used in the preparation of VII. The data are shown in Table 4.

Method E (Eq. (8)): The reaction conditions of dimethylamine with the aryl chlorothiolformate to give VIII are nearly identical with those described for the Method A used in the preparation of VII. The results are listed in Table 4. The compounds VIIIc, VIIId, VIIIf, VIIIg, VIIIh, VIIIl, and VIIIn are new compounds. VIIIc, Found: C, 59.33; H, 5.84; N, 7.70%. Calcd for $C_9H_{11}NOS$: C, 59.64; H, 6.12; N, 7.73%. VIIId, Found: C, 50.19; H, 4.29; N, 6.61%. Calcd for $C_9H_{10}ClNOS$: C, 50.12; H, 4.67; N, 6.49%. VIIIf, Found: C, 59.25; H, 5.87; N, 6.26%. Calcd for $C_{11}H_{13}NO_2S$: C, 59.20; H, 5.44; N, 5.86%. VIIIg, Found: C, 50.35; H, 4.37; N, 6.66%. Calcd for $C_9H_{10}ClNOS$: C, 50.15; H, 4.64; N, 6.50%. VIIIh, Found: C, 41.45; H, 3.96; N, 5.60%. Calcd for $C_9H_{10}BrNOS$: C, 41.55; H, 3.85; N, 5.38%. VIIIl, Found: C, 56.80; H, 5.81; N, 5.49%. Calcd for $C_{12}H_{15}NO_3S$: C, 56.95; H, 5.93; N, 5.53%. VIIIn, Found: C, 57.90; H, 5.05; N, 13.38%. Calcd for $C_{10}H_{10}N_2OS$: C, 58.30; H, 4.86; N, 13.60%.

Aryl Phenyl Thionocarbonates (I). The method of preparing diphenyl thionocarbonate was previously reported.[6] *p*-Nitrophenyl phenyl thionocarbonate was prepared by the reaction of phenol and *p*-nitrophenyl chlorothionoformate[6] with triethylamine in a manner similar to that described in an earlier paper.[6] Colorless plates (from acetone-ethanol), mp 184—185°C (lit,[4] 181—182°C).

O-*Phenyl* S-*Aryl Thiolcarbonates (II).* These compounds were prepared by the reactions of phenol and aryl chlorothiolformate with triethylamine in a manner similar to that described in an earlier paper.[6] Phenyl-: colorelss needles (from *n*-hexane), mp 53.5—54°C (lit,[2] 57°C). *p*-Nitrophenyl-: colorless needles (from *n*-hexane), mp 76.5—77.5°C (lit,[4] mp 65—67°C).

Kinetic Measurements. The rates were followed by the ampoule technique and were determined by ultraviolet spectrophotometric measurements in a manner similar to that described in an earlier paper.[6]

The authors wish to express their sincere thanks to Dr. Jun-ichi Hayami for his invaluable discussions.

The Synthesis of the Polymer Containing the Si-O-phenylene Bond, using Transition Metal Salts as Catalysts[1]

Yoshio IWAKURA, Keikichi UNO, Fujio TODA, Kenjiro HATTORI, and Minoru ABE*

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received November 20, 1970)

Various transition metals were found to be effective as catalysts in the dehydrocondensation of phenols and silanes.

$$R_3SiH + PhOH \xrightarrow{\text{metal salt}} R_3SiOPh + H_2$$

The effective species were $PdCl_2$, $H_2PtCl_6 \cdot 6H_2O$, $PtCl_2$, $RhCl_3$, $NiCl_2$, silane-treated $NiCl_2$, PtI_2, PtS, Raney Ni, Pd-black, Pt-black, Au-black, $FeCl_3$, $ZnCl_2$, $CuSO_4$, CuCl, Cu–Cr, $Cu(CH_3CO_2) \cdot CuO$, the methyl ethyl ketoxime complex of Pd, $Pt(OX)_3$, and $Pd(OX)_2$. The ineffective species were metal mirrors of Pd, Au, Ag, Pt, and Cu, and the acetylacetonato complex of Ni, Co(II), Co(III), and Cu. The reaction was then extended to the preparation of polymers containing a Si–O–phenylene linkage in the main chain. Dihydricphenols, *e.g.*, bisphenol A, hydroquinone, 4,4′-dihydroxydiphenyl gave high-molecular-weight polymers with an equimolar amount of a dihydrosilane, *e.g.*, diphenylsilane, *p*-toluylmethylsilane and *p*-bisdimethylsilylphenylene, in bulk or in a solvent at temperatures above 150°C. The polymer obtained began to flow above 100°C.

It has been known that Group VIII metals and metal halides catalyze the reaction of an organosilane with compounds containing a hydroxy group:[2-7]

$$R_3SiH + ZOH \xrightarrow{\text{cat.}} R_3SiOZ + H_2$$

Z = H, alkyl, aryl, acyl, *etc.*

Dolgov *et al.*[7] reported that the dehydrocondensation of trialkylsilanes with alcohols and mono- or polyhydric phenols proceeded smoothly at the temperature of 100°C and that gave alkoxy- and phenoxysilanes in almost quantitative yields in the presence of a catalytic amount of colloidal nickel prepared from $NiCl_2$.

We now wish to report in the catalytic activity of various transition metals, especially the salts of Ni, Pd, and Pt, in the reactions of organosilanes and phenols. Among these catalysts, several metal salts, such as $PdCl_2$ and the Pd complex of methyl ethyl ketoxime, initiated the reaction, even at room temperature. Such a reation was used in the preparation of polymers containing siloxane linkage in the main chain from difunctional phenols and difunctional silanes.

Polyaryloxysilanes have been reported to be obtained from difunctional phenols and dianilino- or diphenoxysilanes through a melt-polycondensation reaction procedure at temperatures above 200°C and under reduced pressure.[8,9] Here, a similar polymer was prepared under much milder conditions.

Experimental

Materials. 4,4′-Dihydroxydiphenyl was prepared by the hydrolysis of a diazonium compound derived from commercial 4,4′-benzidine according to the usual method. Recrystallization from dioxane gave pure 4,4′-dihydroxydiphenyl; mp 277—278°C. All the other phenols were commercially available, and they were recrystallized before use. The phenyldimethylsilane, *p*-toluylmethylsilane,[10] diphenylsilane,[11] and *p*-bis(dimethylsilyl)-benzene[12] were prepared by methods previously reported. The purity of the silanes was ascertained by gas chromatography, using dioctyl phthalate (D.O.P.) or thermol-3 as the liquid phase.

The Reaction of Silane with Phenol. To a mixture of 3.0 g of phenyldimethylsilane and 2.35 g of phenol, were added 0.02 g of metal salt. In the case of a very active catalyst, $PdCl_2$, for example, a vigorous exothermic reaction occurred, hydrogen gas evolved immediately after the addition of the catalyst at room temperature, and the solution turned dark. In the case of a catalyst with a mild activity, such as $NiCl_2$, an exothermic reaction occurred when the bath temperature was 110°C. After the reaction, the catalyst was removed by filtration and the product was distilled under reduced pressure to give phenoxysilane. The identity of the product was confirmed by infrared spectroscopy and gas chromatographs. The evolved gas was analysed by gas chromatography using a Molecular Sieve 13X column.

Polycondensation. The polymerization was carried out by heating a mixture of 5.00 g of bisphenol A and 4.03 g of diphenylsilane with 0.02 g of $PdCl_2$ at 150—160°C for 10 hr. The resulting polymer was purified by reprecipitation from THF-*n*-hexane and dried. The powdery polymer thus obtained was submitted to elemental analysis and other analyses. The other polymers were prepared by a similar method. The viscosity was determined by the use of an Ubellohde viscosimeter at 30°C in a tetrahydrofuran solution and in a concentration of 0.5 g/d*l*.

Results and Discussion

Activity of Catalyst in the Reaction of Silane and Phenol.

The reaction of phenyldimethylsilane with phenol and bisphenol-A was carried out in the presence of a metal salt as a catalyst. The reaction products were confirmed to be siloxanes by elemental analysis, as is shown in Table 1.

Table 1. Reaction between silane and phenol with $PdCl_2$ as catalyst

Product	Bp °C/mmHg	Yield %	Elemental analysis Found (Calcd) C%	H%	Si%
$PhMe_2SiOPh$	94—95/0.3	93	74.19 (74.68)	7.26 (7.02)	12.9 (12.3)
O-$SiMe_2$Ph / CMe_2 / O-$SiMe_2$Ph	220—223/0.2	92	74.63 (74.95)	7.32 (7.30)	11.1 (11.3)

Table 1. The yield of the products was almost quantitative, and the gas evolved was found to be composed of hydrogen and a trace of methane. From these results, therefore, the reaction was considered to proceed as is shown in Eqs. (1) and (2):

$$PhMe_2SiH + PhOH \xrightarrow{cat.} PhMe_2SiOPh + H_2 \quad (1)$$

$$PhMe_2SiH + HO\text{-}C_6H_4\text{-}CMe_2\text{-}C_6H_4\text{-}OH \xrightarrow{cat.}$$

$$PhMe_2SiO\text{-}C_6H_4\text{-}CMe_2\text{-}C_6H_4\text{-}OSiMe_2Ph + 2H_2 \quad (2)$$

The infrared spectra of phenyldimethylphenoxysilane, phenyldimethylsilane, and phenol are summarized in Fig. 1. In this figure, the absorptions around 3300, 2100, 920, and 880 cm^{-1} were identified as the absorptions of OH(3300), SiH(2100, 880), and Si-O-  (920) respectively. When the reaction proceeded, the absorptions of OH and SiH diminished and the appearance of a new absorption of Si-O-  was observed. The rates of the reactions using various kinds of metal derivatives as catalysis were estimated by the volumetry of the hydrogen gas evolved and by infrared spectroscopy. The order of the rates thus obtained may be attributed to the order of the activity of the catalysis used, because all the reactions were carried out under the same conditions. The orders of the activity of catalysts used were as follows:

1) For metal halide:

$$PdCl_2 > H_2PtCl_6 \cdot 6H_2O > PtCl_2 > RhCl_3 > NiCl_2$$

2) For metal black:

Pd-black > Pt-black ≈ Raney Ni (W_2) > Au-black

3) For other metal salts:

PtI_2, PtS, $Pt(OX)_3$,[13] $Pd(OX)_2$, methyl ethyl ketoxime of Pd, $CuSO_4$, CuCl, Cu–Cr, $Cu(CH_3CO_2)CuO$, $FeCl_3$, $ZnCl_2$

The metal mirrors of Pd, Au, Ag, Pt, and Cu showed little activity. We tried to use acetylacetonato complexes of Ni, Cu, Co(II), and Co(III) as homogeneous catalysts, but they provoked no reaction. As is shown in Table 2, all the metals which are active as catalysts in the reactions of phenols and silanes were found to be transition metals.

In these reactions, the reaction mixtures turned dark when heated, and the formation of colloidal metal was observed in the reactions, using almost all of the metal salts. The metal salts seemed to be reduced by silane; the colloidal metal black thus formed had a high catalytic activity in the reaction of silane and phenol. The results will be presented in detail in the following paper.

Polycondensation. The polycondensation reactions of various phenols and dihydrosilanes were carried out in bulk (or in solution); the results are shown in Table 3. These polymers tend to flow above 100°C as a consequence of the chain mobility of the silicon-oxygen bond.

The authors are grateful to the Shinetsu Chem. Ind. Co. for the supply of the chlorosilanes used in this experiment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1402—1407 (1971)

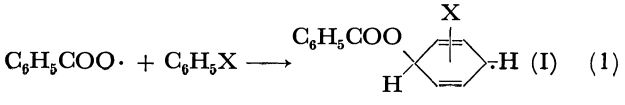
Radikalische aromatische *m*-Nitrierung bei Umsetzung von Benzoylperoxyd mit Stickstoffdioxyd und bei Umsetzung von *p*-Chlorperoxybenzoesäure mit Stickstoffoxyd in Toluol

Tadashi SUEHIRO, Mikio HIRAI, und Takehira KANEKO
Chemisches Institut der Gakushuin Universität, Mejiro, Tokio

(Eingegangen am 7. Dezember, 1970)

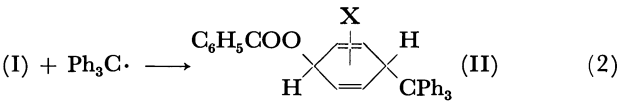
Die radikalische Nitrierung des Toluols findet bei der Umsetzung von Benzoylperoxyd mit Stickstoffdioxyd bei 60—100°C in 4—15% Ausbeute und bei der Umsetzung von *p*-Chlorperoxybenzoesäure mit Stickstoffoxyd bei 20—80°C in 30—50% Ausbeute statt. In beiden Umsetzungen waren die Isomeren-Verhältnisse der gebildeten Nitrotoluole *o*/*m*/*p*=6—25/75—91/0—3. Daß diese *m*-orientierende Nitrierung über das Zwischenprodukt, Aroyloxycyclohexadienyl-Radikal, abläuft, wurde sichergestellt aufgrund der Isomeren-Verhältnisse der Nitrotoluole im Vergleich zu denen der Benzoesäureester von Kresolen aus der konkurrierenden Benzoyloxylierung (*o*/*m*/*p*=40—54/13—16/33—45) und aufgrund der relativen Reaktivität des Toluols (2—4) gegenüber Benzol bei der Nitrierung und der Benzoyloxylierung.

In den früheren Mitteilungen[1-3] haben wir den Mechanismus der homolytischen Tritylierung bei der Umesetzung von Trityl-Radikal mit Benzoylperoxyden in Aromaten klar gemacht. Die Reaktion läuft über das Zwischenprodukt, Benzoyloxycyclohexadienyl Radikal (I), ab, dann folgen die Additions- und Spaltungsreaktionen, (2) und (3), in die substituierten Tetraphenylmethane.



$$C_6H_5COO\cdot + C_6H_5X \longrightarrow C_6H_5COO(X)H \text{ (I)} \quad (1)$$

1) T. Suehiro, A. Kanoya, T. Yamauchi, T. Komori, und S. Igeta, *Tetrahedron*, **24**, 1551 (1968).
2) T. Suehiro, S. Igeta, O. Kuwabara, und M. Hirai, ebenda, **26**, 963 (1970).
3) T. Suehiro, S. Igeta, O. Kuwabara, M. Hirai, M. Ishida, und J. Yamazaki, Dieses Bulletin, **43**, 3303 (1970).



$$(II) \longrightarrow XC_6H_4CPh_3 + C_6H_5COOH \quad (3)$$

Diese Reaktionen lassen darauf schließen, daß Trityl-Radikal, wenn es auch außerordentlich stabil ist, doch noch in die Reaktion eingehen kann, wenn I als Zwischenprodukt auftritt, und dessen Addukt II in die stabilen Produkte zerfällt. Dies weist auf eine neue Möglichkeit der aromatischen Substitution mittels stabilen Radikals in Gegenwart des bestimmten Radikal-Startmittels hin.

Der Mechanismus der Tritylierung ist eigenartig: Im Gegensatz zu der üblichen radikalischen aromatischen Substitution von *o*- und *p*-Orientierung[4] fällt die Tritylierung als *m*-Orientierung auf. Wenn also eine Nitrierung des Toluols durch Stickstoffdioxyd oder durch Stickstoffoxyd in Gegenwart von Benzoyloxy-Radikal stattfindet, kann *m*-Nitrotoluol als Hauptprodukt gebildet werden. Dies wurde in der Tat verwirklicht und darüber wollen wir hier berichten.

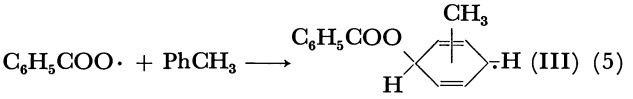
System Benzoylperoxyd - Stickstoffdioxyd

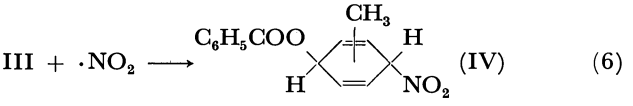
Es ist bekannt, daß Stickstoffdioxyd und Stickstoffoxyd oft als Radikal-Abfänger verwendet werden können.[5] Gill und Williams[6] nahmen Interesse an der Reaktion von Benzoylperoxyd in Gegenwart von Stickstoffdioxyd und untersuchten die Produkte des Zerfalls vom Peroxyd in Tetrachlorkohlenstoff und in Benzol in der Stickstoffdioxyd-Atmosphäre, wobei sie Nitrobenzol in mäßiger Ausbeute isolierten. Weil Nitrobenzol durch die Kombination von Phenyl-Radikal aus dem Peroxyd mit Stickstoffdioxyd gebildet wird, und weil die Autoren nur in begrenzten Sorten von Lösungsmitteln die Umsetzung durchführten, konnten sie die Rolle des Benzoyloxycyclohexadienyl-Radikals nicht ausfindig machen.

Wir haben die Umsetzung in der Absicht durchgeführt, das Auftreten des Benzoyloxycyclohexadienyl-Radikals zu untersuchen. Wir wählten infolgedessen Toluol oder dessen Mischung als Lösungsmittel und ermittelten die Isomeren-Verhältnisse der Nitrierungs- und Benzoyloxylierungsprodukte. Die Umsetzung von Benzoylperoxyd in Toluol in Gegenwart von Stickstoffdioxyd ist sehr kompliziert: Die Oxydation des Toluols durch Stickstoffdioxyd unter Bildung von ω-Nitrotoluol, Benzylnitrit, Benzaldehyd und Salpetrigesäure, der thermische Zerfall vom Peroxyd und dessen Folgereaktionen in Gegenwart von Stickstoffdioxyd und die radikalische und auch vielleicht die heterolytische Zersetzung vom Peroxyd durch Salpetrigesäure usw. laufen nebeneinander. Obwohl der richtige Reaktionsmechanismus unter diesen Umständen der Umsetzung sehr schwer herauszufinden ist, nahmen wir unter den Produkten Rücksicht besonders auf Nitroaromate und Benzoesäureester von Phenolen und bestimmten die rationalen Verhältnisse.

Wenn das Zwischenprodukt III mit Stickstoffdioxyd kombiniert und das Addukt IV zerfällt, müssen Nitroaromaten und Benzoesäure einerseits (Reaktion (7)) und Benzoesäureester von Phenolen und Salpetrigesäure andererseits (Reaktion (8)) entstehen.

$$(C_6H_5COO)_2 \longrightarrow 2\ C_6H_5COO\cdot \quad (4)$$





$$IV \longrightarrow CH_3C_6H_4NO_2 + C_6H_5COOH \quad (7)$$

$$IV \longrightarrow C_6H_5COOC_6H_4CH_3 + HNO_2 \quad (8)$$

Es kann bei der Reaktion (6) auch Alkylnitrit entstehen. Dies, zusammen mit ω-Nitrotoluol und Benzylnitrit aus Toluol und Stickstoffdioxyd, kann man durch Waschen mit Alkali oder durch Hydrolyse beseitigen. Die Isomeren-Verhältnisse gemäß der Reaktion (5)—(8) müssen bei Nitrotoluol *m*-orientierend sein und bei Benzoesäureestern von Kresolen *o*- und *p*-orientierend. Das Verhältnis $(m)/(o+p)$ in Nitrotoluol muß mit

a) Die Konzentration des Stickstoffdioxyds war 0.33 mMol/6 m*l* Lösung.

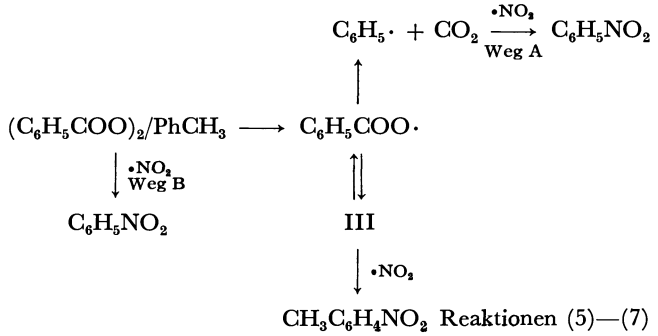
b) Ohne Korrektur mit dem Benzoesäurephenylester, der aus Benzoyloxyd allein in 2.0—2.4% Ausbeute gebildet wird.

dem $(o+p)/(m)$ von Benzoesäureestern übereinstimmen und die relative Reaktivität des Toluols zu Benzol in beiden Substitutionen dieselbe sein.

Die Umsetzungen wurden im Einschlußrohr im Vakuum oder in Stickstoff-Atmosphäre durchgeführt, und die Ergebnisse sind in den Tabellen 1—4 wiedergegeben. In Gas-Chromatogramm findet man die Produkte in der Reihenfolge: Lösungsmittel, Benzaldehyd, Benzylalkohol, Nitrobenzol, eine unbekannte Verbindung, *o*-, *m*-, und *p*-Nitrotoluole, Biphenyl und Methylbiphenyle, und Benzoesäureester von Phenol und Kresolen. Wie aus der Tabelle 1 ersichtlich ist, wird Nitrobenzol auch bei Abwesenheit von Benzol gebildet. Phenyl-Radikal aus dem Peroxyd kann durch Kombination mit Stickstoffdioxyd Nitrobenzol geben. Durch dieses Nitrobenzol muß die Ausbeute bei der Umsetzung in der Benzol-Toluol-Mischung korrigiert werden.

Bei der Konzentration vom Stickstoffdioxyd 0.01—0.1 m*l*/6 m*l* Lösung nimmt die Ausbeute an Nitrobenzol und auch an Nitrotoluolen mit der Konzentration des Stickstoffdioxyds zu, d.h. die Reaktion (6) bestimmt die Geschwindigkeit der Bildung der Nitrotoluole. Stickstoffdioxyd ist unter diesen Bedingungen wahrscheinlich nicht wirksam genug als Radikal-Abfänger. Die Isomeren-Verhältnisse müssen infolgedessen von dem Standpunkt aus verwertet werden, daß die Reaktion (5) eine rapide umkehrbare Reaktion ist. Das gilt auch bei der Verwertung der relativen Reaktivität des Toluols. Bei der Konzentration des Stickstoffdioxyds höher als 0.1 m*l*/6 m*l* Lösung wurde die Ermittlung von Nitroaromaten durch Nebenprodukte, Benzaldehyd und Benzylalkohol, erschwert und wir mußten darauf verzichten, unter den Bedingungen die Umsetzung durchzuführen, in denen die Hinreaktion (5) die Geschwindigkeit bestimmt.

In der Tabelle sieht man weiter einen deutlichen Unterschied zwischen den Zunahmen der Ausbeute an Nitrobenzol und an Nitrotoluolen: Nitrobenzol nimmt *ca.* 10 mal so viel zu mit der Zunahme des Stickstoffdioxyds, während Nitrotoluole *ca.* 2 mal so viel zunehmen. Wenn Nitrobenzol durch die Kombination von Stickstoffdioxyd und Phenyl-Radikal gebildet wird (Weg A), muß die Zunahme der Ausbeute an Nitrobenzol genau so groß oder kleiner sein wie die von Nitrotoluolen je nachdem, ob die Reaktion (5) geschwindigkeits-bestimmend ist oder ob es eine umkehrbare Reaktion ist. Die Ergebnisse sind diesen Vorstellungen entgegen, das hat zur Folge, daß Nitrobenzol auch auf einem anderen Weg B gebildet wird. Es



scheint doch sehr gut möglich, daß der Weg B über Phenyl-Kation läuft.

Beim Umsetzen des Toluols allein mit Stickstoffdioxyd von der Konzentration 0.01 m*l*/6 m*l* Lösung werden Nitrotoluole in einer Ausbeute von 0.4% gebildet, deren Isomeren-Verhältnisse bei 80°C *o*/*m*/*p*=4/53/43 sind. Wenn aber Benzoylperoxyd zugesetzt wird, steigt die Ausbeute 10 mal so hoch und die Isomeren-Verhältnisse wechseln in die *m*-Orientierung (*o*/*m*/*p*=13/85/2). In der Berechnung haben wir den Effekt von Nitrotoluolen, die bei Abwesenheit vom Peroxyd gebildet werden, vernachlässigt. Die Isomeren-Verhältnisse liegen sehr nahe denen der Tritylierung (*o*/*m*/*p*=10/81/9).[2] Die Ausbeute der Nitroaromate waren aber wesentlich kleiner (6—14%).

Die Benzoyloxylierung des Toluols bei 80°C (*o*/*m*/*p*=50/16/34) verläuft wie bei der Umsetzung vom Benzoylperoxyd in Gegenwart von Kupfer(II)chlorid[7] (*o*/*m*/*p*=56/18/26) bzw. in Gegenwart von Jod[8] (*o*/*m*/*p*=53/16/31).

Die relative Reaktivität des Toluols bei der Nitrierung, 2.0—2.7, kann mit der bei der Benzoyloxylierung, 3.0—4.1, mit der bei der Benzoyloxylierung im System Benzoylperoxyd-Kupfer(II)chlorid,[7] 2.51, bzw. im System Peroxyd-Jod,[8] 2.85, und mit der bei Tritylierung,[2] 2.82, verglichen werden. Diese Ergebnisse können am besten mit dem Schema der Reaktionen (4)—(8) erklärt werden.

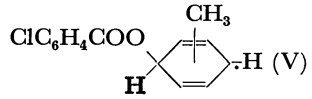
Die Ausbeute an Nitroaromaten relativ zu Benzoesäureester 6/19 bei 80°C zeichnet sich als die relative Geschwindigkeit der Reaktion (7) zu (8) aus. Die Reaktion im System Benzoylperoxyd-Stickstoffdioxyd ist in dem Sinne von Bedeutung, daß sie die Nitrierung und die Benzoyloxylierung über ein gemeisames Zwischenproduct III veranlaßt.

System *p*-Chlorperoxybenzoesäure-Stickstoffoxyd

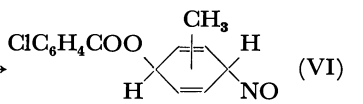
Die radikalische *m*-Nitrierung in besserer Ausbeute findet man im System Peroxybenzoesäure-Stickstoffoxyd. Hydroperoxyde wie *t*-Butylhydroperoxyd und Peroxybenzoesäure können durch Stickstoffoxyd zertzt werden.[9] Wenn *p*-Chlorperoxybenzoesäure durch Stickstoffoxyd zersetzt wird, wird *p*-Chlorbenzoyloxy-Radikal frei gesetzt (Reaktion(9)), das sich dann an den aromatischen Doppelbindungen anlagert. In Gegenwart von Stickstoffoxyd-Überschuß wird das Aroyloxycyclohexadienyl-Radikal von Stickstoffoxyd abgefangen. Das Nitroso-Addukt VI kann auf zwei Wege zerfallen: Es entstehen Nitrosoaromate und Chlorbenzoesäure einerseits (Reaktion (12)) und Chlorbenzoesäureester und HNO (falls vorhanden) andererseits (Reaktion (13)). Obwohl die Nitroso-Verbindung an sich ein Radikal-Abfänger ist, wird sie leicht durch Peroxycarbonsäure in die Nitro-Verbindung übergeführt.

$$ClC_6H_4COOOH + NO\cdot \longrightarrow ClC_6H_4COO\cdot + HONO \quad (9)$$

$$ClC_6H_4COO\cdot + PhCH_3 \longrightarrow$$



(V) (10)



(VI) (11)

$$VI \longrightarrow CH_3C_6H_4NO + ClC_6H_4COOH \quad (12)$$

$$VI \longrightarrow ClC_6H_4COOC_6H_4CH_3 + HNO \quad (13)$$

$$HNO + ClC_6H_4COOOH \longrightarrow HONO + ClC_6H_4COOH \quad (14)$$

$$HONO + ClC_6H_4COOOH \longrightarrow HONO_2 + ClC_6H_4COOH \quad (15)$$

$$CH_3C_6H_4NO + ClC_6H_4COOOH \longrightarrow CH_3C_6H_4NO_2 + ClC_6H_4COOH \quad (16)$$

Die Oxydation des Nitrosobenzols zum Nitrobenzol durch Peroxycarbonsäure ist gut untersucht worden.[10] Bei höheren Temperaturen wie z.B. 50°C läuft die Oxydation zum Nitrobenzol quantitativ. Auf diese Weise oxydiert *p*-Chlorperoxybenzoesäure Nitrosobenzol bei 50°C sehr schnell ($\tau_{1/2}$ 30 Min.). Bei niedrigen Temperaturen wird aber *p*-Nitrosodiphenylhydroxylamin erzeugt.[10] Die Oxydationsgeschwindigkeiten der isomeren Nitrosoaromaten zu Nitroaromaten sind verschieden voreinander, und dieser Unterschied kann einen Fehler in der Ermittelung der Isomeren-Verhältnisse und auch in der relativen Reaktivität herbeiführen. Um diesen Fehler möglichst zu unterdrücken, ließen wir die Reaktionsmischung nach dem Einleiten des Stickstoffoxyds eine halbe Stunde bei 50°C oder höheren Temperaturen stehen, damit die Oxydation der Nitroso-Verbindung verfertigen wird.

Die Umsetzung wurde auf folgender Weise durchgeführt: Man leitet in die Lösung von *p*-Chlorperoxybenzoesäure in Toluol oder dessen Mischung in Stickstoff-Atmosphäre in 15 Minuten einen Überschuß Stickstoffoxyd bei 20—80°C. Man hält die Mischung eine weitere halbe Stunde unter Stickstoff-Leitung bei 50°C oder höheren Temperaturen. Die Produkte wurden nach der Gas-Chromatographie ermittelt. Die Ergebnisse sind in den Tabellen 5 und 6 aufgestellt.

Man findet im Chromatogramm außer Nitrobenzol und Nitrotoluole nur wenig Benzaldehyd (~4%), keinen Benzylalkohol, Spuren von *p*-Nitrochlorbenzol und Biphenylen, und keine *p*-Chlorbenzoesäureester von Phenolen: Die Umsetzung von Peroxybenzoesäure mit Stickstoffoxyd verläuft viel einfacher als die vom Benzoylperoxyd mit Stickstoffdioxyd. *p*-Chlorbenzoyloxy-Radikal lagert sich an die aromatische Doppelbindung genau so an wie das nicht substituierte Benzoyloxy-Radikal, wenn man die Reaktivität des

c) Nach dem Einleiten von Stickstoffoxyd hält man die Mischung eine halbe Stunde bei 50°C.
d) Nach dem Einleiten von Stickstoffoxyd hält man die Mischung eine halbe Stunde bei der Reaktionstemperatur.

TABELLE 6. ISOMEREN-VERHÄLTNISSE DER NITROTOLUOLE UND RELATIVE REAKTIVITÄT DES TOLUOLS BEI DER NITRIERUNG IM SYSTEM *p*-CHLORPEROXYBENZOESÄURE-STICKSTOFFOXYD

Reakt. Nr.	Isomeren-Verhältnisse, %			k_{PhCH_3}/k_{PhH}
	o-	*m*-	*p*-	
1	6.0	94.0	0	3.19
2	10.6	89.4	0	3.05
3	15.9	84.1	0	2.89
4	12.8	87.2	0	2.90
5	23.4	76.6	0	1.78
6	28.0	72.0	0	2.09

Radikals aus der Orientierung bei Tritylierung entnimmt.[2)] Die Nitrierung im System Peroxybenzoesäure-Stickstoffoxyd läuft *m*-orientierend. Wenn man die Möglichkeit in Betracht zieht, daß zwei bis drei Mole Peroxycarbonsäure je nach dem Ablauf der Reaktion (15) verbraucht werden, dürfte die oberflächliche Ausbeute von 30—50% bei 20—50°C befriedigend hoch sein. Auf Grund der Produkten-Analyse scheint die Reaktion (13) nicht merklich abzulaufen. Das kommt wahrscheinlich aus der unbeständigen Natur von HNO her: die Stabilität des Endproduktes aus dem Addukt VI übt eine entscheidende Wirkung auf den Verlauf der Reaktion aus.

Die Isomeren-Verhältnisse von Nitrotoluolen (*o*/*m*/*p*=15/85/0) bei 50°C stimmen mit denen bei der Nitrierung im System Benzoylperoxyd-Stickstoffdioxyd (*o*/*m*/*p*=13/85/2) überein. So ist auch das Verhältnis mit der relativen Reaktivität des Toluols, 2.90, zu der bei der Benzoyloxylierung im System Benzoylperoxyd-Kupfer(II)chlorid,[7)] 2.51, und zu der bei der Tritylierung,[2)] 2.82. Daß die Isomeren-Verhältnisse und die relative Reaktivität des Toluols mit der Temperatur-Erhöhung ausgeglichen zu werden scheinen, ist sehr auffallend. Weil es noch nicht bestimmt wurde, daß die Reaktion (10) die Geschwindigkeit bestimmende Stufe der Nitrierung ist, kann man darüber noch nicht diskutieren.

Die aromatische *m*-Substitution nach dem Mechanismus wie die Reaktionen (1) bis (3) ist sehr selten berichtet worden, außer der Tritylierung[1,2)] und der radikalischen *m*-Nitrierung in dieser Arbeit. Ein Beispiel in der elektrophilen Substitution haben Kovacic und andere[11)] bei der *m*-Aminierung mitgeteilt. Ein anderes Beispiel einer vielleicht radikalischen Reaktion wurde von Heslop und Robinson[12)] gezeigt, wo Anisol durch eine saure Mischung von Wasserstoffperoxyd-Salpetrigesäure in 2-Nitro-4-methoxy-phenol übergeführt wird und Toluol in Nitrotoluol verwandelt wird, die Struktur des letzteren allerdings nicht geklärt wurde.

Beschreibung der Versuche

a) Nitrierung und Benzoyloxylierung im System Benzoylperoxyd-Stickstoffdioxyd. Die Reaktion wurde im Einschlußrohr im Vakuum oder in Stickstoff-Atmosphäre durchgeführt. Man stellt Stickstoffdioxyd durch Erhitzen von Bleinitrat im Stickstoff-Strom dar und sammelt es als Abfall bei der Temperatur vom festen Kohlenstoffdioxyd-Methanol. Man ermittelt die Menge an Stickstoffdioxyd aus dessen Volumen im flüssigen Zustand bei −9°C und destilliert das Oxyd in die Lösung vom Benzoylperoxyd in Toluol oder dessen Mischung im Vakuum ein und schließt die Mischung im Vakuum oder in Stickstoff-Atmosphäre ein.

Die Bestimmung von Nitrobenzol, *o*-, *m*-, und *p*-Nitrotoluolen erfolgte mit der Gas-Chromatographie an Kolonne Apiezon L 25% auf Shimalite, 3 m, bei 155°C mit Helium 15 m*l*/15 Sek oder an Kolonne UCON-Öl LB550-X auf C-22 (mit Salzsäure gewaschen und erhitzt), 3 m, bei 185°C mit Helium 15 m*l*/8 Sek. Der innere Standard war *p*-Nitrochlorbenzol.

Die Ermittlung von Benzoesäureestern von Phenolen wurde auch gas-chromatographisch an Kolonne Apiezon L auf Shimalite bei 215°C durchgeführt.

Die Reaktionsmischung wäscht man zunächst mit Alkali so lange, bis die wäßrige Lösung sich nicht mehr orange färbt, und dann mit Wasser, und man bringt die neutrale Lösung zur Bestimmung von Benzoesäureestern. Für die Analyse der Nitro-Verbindungen destilliert man die neutrale Lösung mit Wasserdampf ab und nimnt das Destillat in Methylenchlorid auf.

b) Nitrierung im System p-*Chlorperoxybenzoesäure-Stickstoffoxyd.*

11) P. Kovacic, C. T. Goralski, J. J. Hiller, Jr., J. A. Levsky, und R. M. Lange, *J. Amer. Chem. Soc.*, **87**, 1261 (1965); P. Kovacic und J. A. Levsky, ebenda, **88**, 1000 (1966); P. Kovacic und A. K. Harrison, ebenda, **89**, 32 (1967).
12) R. B. Heslop und P. L. Robinson, *J. Chem. Soc.*, **1954**, 1271.

Man stellt Stickstoffoxyd aus Kaliumjodid und Salpetrigesäure in 50%iger Schwefelsäure her und wäscht mit konz. Schwefelsäure und dann mit Alkali und trocknet bei der Temperatur vom festen Kohlenstoffdioxyd-Methanol. Zu einer Mischung aus 15 m*l* Benzol und 15 m*l* Toluol gibt man 3 mMol durch Sublimation gereinigte *p*-Chlorperoxybenzoesäure, Schmp. 123°C (Zers.) im Einschlußrohr, und leitet in die Lösung in Stickstoff-Atmosphäre einen Überschuß Stickstoffoxyd, 30 mMol, in einer Geschwindigkeit von 2 mMol/Minute ein. Nach dem Einleiten des Stickstoffoxyds spült man die Mischung durch Durchleiten von Stickstoff und hält die Mischung eine halbe Stunde bei 50°C oder bei der Reaktionstemperatur. Dann bestimmt man titrimetrisch den Überschuß von Peroxycarbonsäure, wäscht die Mischung mit Alkali und destilliert mit Wasserdampf ab, um die Nitro-Verbindungen zu reinigen.

Die Ermittelung der Nitro-Verbindungen erfolgte gaschromatographisch wie oben beschrieben. Der innere Standard war *o*-Dichlorbenzol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1407—1410(1971)

The Synthetic Intermediate of Pyridoxine. II.[1] The Thermal Cyclization of Ethyl α-Isocyanopropionate to 5-Ethoxy-4-methyloxazole[2]

Itsutoshi MAEDA, Kazushi TOGO, and Ryonosuke YOSHIDA
Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received December 9, 1970)

The thermal cyclization of ethyl α-isocyanopropionate (I) was performed to 5-ethoxy-4-methyloxazole (II) as an intermediate for the synthesis of pyridoxine. The similar reaction of several new alkyl esters of α-isocyanocarboxylic acid to the corresponding 5-alkoxy-4-substituted oxazole was also carried out. The reaction products of the thermal cyclization of I were investigated. When the cyclization was carried out at 180°C for 5 hr, the maximum yield of the main product, II, was 20%; unreacted I (30%), ethyl α-cyanopropionate (20%), and dimer of I (5%) were also obtained. The α-hydrogen of ethyl α-isocyanosuccinate (X) can be more easily removed than that of I, so X may be expected to be more readily converted to 5-ethoxy-4-ethoxycarbonylmethyloxazole (XI), which is also an intermediate of pyridoxine. The yield of XI from X did not exceed 30% because of the side reaction.

By Firestone *et al*,[3] 5-ethoxy-4-methyloxazole, an important intermediate for the synthesis of pyridoxine by the Diels-Alder reaction with dienophiles, has been prepared from ethyl *N*-formylalaninate and phosphorus pentoxide. Recently, as a modification[4] of this procedure, it has been reported that ethyl *N*-formylalaninate was converted to its boron trifluoride complex, after which the complex was treated with phosphorus pentoxide to prepare 5-ethoxy-4-methyloxazole. However these methods have the defect that the reaction mixture forms a hard or powderlike mass which is difficult to remove from the vessel.

The present investigation was undertaken in an attempt to prepare this oxazole without the use of phosphorus pentoxide. This paper will present our findings on the thermal cyclization of ethyl α-isocyanopropionate to produce 5-ethoxy-4-methyloxazole.

Results and Discussion

Ethyl *N*-formylalaninate was converted to ethyl α-isocyanopropionate (I) following the methods of Ugi *et al.* for the synthesis of the derivatives of isonitrile.[5] Several new alkyl esters of α-isocyanocarboxylic acid were synthesized from the alkyl esters of *N*-formylamino acid. The results are listed in Table 1. In order to examine the possibility of the thermal cyclization of I, the solution of I was kept at 170°C. Upon being heated, the solution gradually turned brown-red. In order to analyze the reaction products, the resulting solution was submitted to gas chromatography. Various kinds of 5-alkoxy-4-substituted oxazoles were obtained through the cyclization of the alkyl esters of α-isocyanocarboxylic acid by external heating. The yield of 5-alkoxy-4-substituted oxazoles was calculated on the basis of the area of each peak in a gas chromatograph after a usual calibration using authentic samples; the results are listed in Table 2.

The thermal cyclization from ethyl α-isocyanopropionate (I) to 5-ethoxy-4-methyloxazole (II) was carried out at various temperatures in order to determine the temperature at which the maximum conversion can be obtained. The set of curves in Fig. 1 is presented to show; (A) the conversion of I to II; (B) the decrease in I, and (C) the residue of II at various temperatures. The maximum conversion of I to II, obtained by

Reaction time; ○—○ 1 hr, △—△ 3 hr, ●—● 5 hr

keeping the compound I for 5 hr at 180°C was 21.4%. The results suggest that the compound II first formed from compound I is decomposed by further subsequent reactions and that the thermal conversion of I to II is accompanied by a side reaction. In order to investigate the side-reaction products compound I (30 g) was heated at 180°C for 5 hr and then distilled. The results are shown Table 3. The products of each fraction were identified by gas chromatography, NMR, and IR-spectra analyses. The gas chromatograms of fraction 2 (low-boiling materials) and fraction 5 (high-boiling materials) are shown in Fig. 2. Compounds I and II were identified as ethyl α-isocyanopropionate and 5-ethoxy-4-methyloxazole respectively by comparing their retention times with those of authentic samples. Compound I and III were observed in fraction 3 by gas chromatography. The IR spectrum of fraction 3 showed bands at 2270 cm^{-1} ($\nu_{C\equiv N}$), 2180 cm^{-1} ($\nu_{N\equiv C}$) and 1750 cm^{-1} ($\nu_{C=O}$), while the NMR spectrum exhibited peaks at 8.70τ (triplet 6H, $CH_2\underline{CH_3}$), 8.48τ (doublet 3H, $C\underline{H_3}CH$), 8.38τ (doublet 3H, $C\underline{H_3}CH$), 6.36τ (quartet, 1H, $CH_3C\underline{H}$) 5.88τ (quartet, 4H, $CH_3C\underline{H_2}$), and 5.62τ (quartet, 1H, $CH_3C\underline{H}$). These facts show that the fraction 3 was a mixture of I and ethyl α-cyanopropionate (III). The compound V in fractions 4 and 5 was identified as ethyl *N*-formylalaninate by a comparison of its retention time with that of an authentic sample. For the identification of the unknown product, compound VI, each of the components of fractions 4 and 5 was collected by preparative

gas chromatography. The mass spectrum of compound VI showed a molecular ion peak at *m/e* 254, supporting the molecular formula of $C_{12}H_{18}N_2O_4$ (mol wt 254.28) obtained by elementary analysis. The IR spectrum of compound VI showed bands at 2270 cm^{-1} ($\nu_{C\equiv N}$), 1740 cm^{-1} ($\nu_{C=O}$), 1670 cm^{-1} ($\nu_{C=O}$), and 1600 cm^{-1} ($\nu_{C=C}$, $\nu_{C=O}$). The NMR spectrum showed peaks at 8.70τ (double triplet, 6H, $CH_2C\underline{H}_3$), 8.50τ (doublet, 3H, $CHC\underline{H}_3$), 8.00τ (singlet, 3H, $C\underline{H}_3C=$), 5.80τ (double quartet, 4H, $C\underline{H}_2CH_3$), 5.75τ (quartet, 1H, $C\underline{H}CH_3$), and 1.73τ (broad doublet, 1H, NH). The UV spectrum indicated a maximum absorption at 316 mμ. Futhermore, compound VI was hydrolyzed by heating it at 180°C for 30 min with an aqueous solution of sodium hydroxide. The resulting compound was identified as alanine by paper chromatography. On the basis of these data, compound VI was identified as ethyl *N*-(3-cyano-2-ethoxy-2-butenoyl)-alaninate. The amount of each product was determined by the usual gas-chromatography method using authentic samples. The results are shown in Table 4 and Scheme 1.

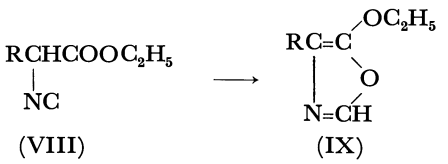
The oxazole derivative (IX) seems to be formed by α-hydrogen abstraction from isocyano derivatives (VIII).



The facility of the cleavage of the α-carbon–hydrogen linkage depends on the electron density around the α-carbon. An electrophilic effect of R, such as $CH_2COOC_2H_5$, can reduce the electron density around the α-carbon. Therefore, diethyl α-isocyanosuccinate ($R=CH_2COOC_2H_5$) may be expected to be more readily converted to an oxazole derivative than ethyl α-isocyanopropionate ($R=CH_3$). At various temperatures diethyl α-isocyanosuccinate (X) was converted to 5-ethoxy-4-ethoxycarbonylmethyloxazole (XI), which is an intermediate for the synthesis of pyridoxine. The results are shown in Fig. 3. The rate of decrease in the starting material, X, was larger than that of I, though the rate of decrease in the residue of XI was similar to that of II. This indicates that the side reaction of X to XI occurs much more than that of I to II. Therefore, the maximum conversion of X to XI did not exceed 30% in spite of the facility of the cleavage of the αC–H linkage.

Experimental[6]

Ethyl α-Isocyanopropionate (I). Ethyl *N*-formylalaninate (43.5 g, 0.3 mol) and 100 m*l* of triethylamine were dissolved in 50 m*l* of chloroform. To the solution, 238 g of a chloroform solution containing phosgene (30 g, 0.3 mol) was added, drop by drop under ice-cooling at 25°C over a 1 hr period. The reaction mixture was stirred a further 30 min at room temperature and then washed with 160 m*l* of water to remove triethylamine hydrochloride. The chloroform layer was dried over anhydrous magnesium sulfate, and the solvent was evaporated *in vacuo*. The residue was distilled to give ethyl α-isocyanopropionate (bp 85—86°C/20 mmHg; yield; 26.8 g, 70.4%). Similarly, alkyl esters of α-isocyanocarboxylic acids were synthesized from alkyl esters of *N*-formyl amino acids, as is shown in Table 1.

The Thermal Cyclization of Alkyl Esters of α-Isocyanocarboxylic Acids to 5-Alkoxy-4-substituted Oxazoles. The alkyl ester of α-isocyanocarboxylic acid (2 g) was poured into a 10-m*l* ampoule. The ampoule was then sealed and placed in an oil bath equipped with a thermometer. The temperature was maintained as is shown in Table 2. The resulting liquid

6) All the boiling points are uncorrected.

a) 5% Dinonyl phthalate on Chromosorb T b) 1C (2mmϕ) 2B (4mmϕ)

was analyzed by gas chromatography. Gas chromatography was carried out on a model GC-2B and 1C compact chromatographic analysis unit of Shimadzuseisakujo, Ltd. The operation conditions are shown in Table 5. The authentic samples were prepared, using the technique for 5-ethoxy-4-methyloxazole from ethyl *N*-formylalaninate, using phosphorus pentoxide.[3] All of the above authentic samples were confirmed by gas-chromatographic analysis to have no impurity affecting the results.

5-Ethoxy-4-methyloxazole from Ethyl α-Isocyanopropionate. Ethyl α-isocyanopropionate (1 g) was added to an ampoule. The ampoule was then sealed and placed in an oil bath. The reaction was carried out at 140—190°C at intervals of 10°C for 1, 3, and 5 hr. After the reaction, the contents of the ampoule were diluted with benzene to 50 m*l*; then, the 5-ethoxy-4-methyloxazole and the unreacted ethyl α-isocyanopropionate were analyzed by gas chromatography, using a stainless-steel column packed with 5% dinonyl phthalate on Chromosorb T (2 mmϕ×3.75 m; column temperature: 85°C; flow rate of He: 20 m*l*/min; internal standard: isoamyl acetate). The curves (A) and (B) in Fig. 1 were thus drawn. Similarly, 5-ethoxy-4-methyloxazole (1 g) was heated under the above reaction conditions and analyzed; the curve (C) in Fig. 1 was thus drawn.

The Products of the Thermal Cyclization of Ethyl α-Isocyanopropionate. Ethyl α-isocyanopropionate (30 g) was put into a dried autoclave with a 100 m*l* capacity by means of a magnetic stirrer. The autoclave was kept at 180°C by electrical heating for 5 hr and then it was chilled. The reaction mixture was distilled under reduced pressure. The fractions of the distillate shown in Table 3 were thus obtained. Each fraction of the distillate was analyzed by gas chromatography; the compounds shown in Table 4 were identified by comparing their retention times with those of authentic samples. The yields of the compounds I, II, V, and VI were calculated from the total weight of the mixture on the basis of the calibration curves of the gas chromatography for an authentic sample. The authentic samples were prepared as follows: 5-ethoxy-4-methyloxazole (II) was prepared from ethyl *N*-formylalaninate with phosphorus pentoxide. Ethyl *N*-formylalaninate (V) was prepared from ethyl alaninate hydrochloride and formic acid. Compound VI was separated from the fractions 4 and 5 by preparative gas chromatography (10% Carbowax 20 M on Diasolid L; 8 mmϕ×3 m; column temperature, 190°C; flow rate of He, 75 m*l*/min); it was shown to be $C_{12}H_{18}N_2O_4$ by elementary analysis.

Found: C, 56.77; H, 7.35; N, 10.76%. Calcd: C, 56.68; H, 7.14; N, 11.02%.

The yield of ethyl α-cyanopropionate (III) was calculated from the calibration curves of compound I.

5-Ethoxy-4-ethoxycarbonylmethyloxazole from Diethyl α-Isocyanosuccinate. The reaction and analysis of 5-ethoxy-4-methyloxazole from ethyl α-isocyanopropionate were similar to those described above except that gas chromatography was carried out with 3% Silicone XE-60 on Chromosorb T (4 mmϕ× 1.875 m glass column; column temperature, 140°C; flow rate of He, 70 m*l*/min; internal standard, dibenzyl ether).

The authors wish to thank Professor Dr. M. Matsui of Tokyo University and Professor Dr. Y. Nakatani of Ochanomizu University for their many helpful discussions and suggestions.

Studies on Aminosugars. XXVI. A New Method for the Simultaneous Protection of Amino and Hydroxyl Groups in Aminosugars and Aminocyclitols[1]

Sumio UMEZAWA, Yasushi TAKAGI, and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received December 11, 1970)

2-Deoxystreptamine-1,6:3,4-dicarbamate (II), methyl 2-amino-2-deoxy-α-D-glucopyranoside-2,3-carbamate (VIII) and methyl 6-amino-6-deoxy-α-D-glucopyranoside-4,6-carbamate (X) were prepared by utilizing *p*-nitrophenoxycarbonyl chloride or phenoxycarbonyl chloride.

The simultaneous protection of amino and hydroxyl groups is useful in synthetic chemistry, and this has been performed in case of *cis* amino and hydroxyl groups in cyclic compounds as well as in adjacent amino and hydroxyl groups in open-chain compounds by protection in the form of oxazolidine,[2] 2-oxazoline,[3] and 2-oxazolidone.[4] However, since natural aminosugars and aminocyclitols often have *trans*-equatorial substituents, the simultaneous protection of *trans*-diequatorial amino and hydroxyl groups or *trans*-diequatorial aminomethyl (or hydroxymethyl) and hydroxyl (or amino) groups are often desired.

Recently, Miyai and Gross[5] prepared the 2,3-carbamate derivative of benzyl 2-amino-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside by use of *N,N'*-carbonyl-diimidazole in absolute tetrahydrofuran. In the course of our investigation[6] of synthesis of aminoglycosides we have found a successful protection of the above-described couples of amino and hydroxyl groups by utilizing *p*-nitrophenoxycarbonyl chloride (NPCC) or phenoxycarbonyl chloride (PCC). Brief report of some of our findings has been published earlier.[1] The characteristic features of our method lie in that 1) the protection is performed in one-step procedure in good yields, 2) in a medium containing water which is a requisite condition in dealing with aminosugars or aminocyclitols, and 3) couples of amino and hydroxyl groups are selectively protected in the presence of other hydroxyl groups.

As typical examples, we here described the preparation of 2-deoxystreptamine-1,6:3,4-dicarbamate (II), methyl 2-amino-2-deoxyl-α-D-glucopyranoside-2,3-carbamate (VIII), and methyl 6-amino-6-deoxy-α-D-glucopyranoside-4,6-carbamate (X) from 2-deoxystreptamine (I), methyl 2-amino-2-deoxy-α-D-glucopyranoside, and methyl 6-amino-6-deoxy-α-D-glucopyranoside, respectively.

An aqueous solution of deoxystreptamine (I) was treated with a cold solution of NPCC in acetone in the presence of appropriate amount of anion exchange resin (OH form) and subsequent solvent extraction followed by column chromatography gave a cyclic dicarbamate derivative (II) in a yield of 73%. Structural proof of II was performed on the basis of its elemental analysis, IR (Chart I) and NMR spectra. The absence of the absorption peak at ~1550 cm^{-1} (amide II) indicated the cyclic amide structure and the chair conformation as shown in Chart 2 was confirmed by the splitting pattern of H-2,2' signals in its NMR spectrum. Further confirmation was obtained from its mono-*O*-acetyl derivative (III), which gave *m/e* 256 (molecular ion) by mass spectroscopy and, in the NMR spectrum, large coupling constants (J=9.4—11.2 Hz) between H_1–H_{2a}(H_3–H_{2a}), H_3–H_4(H_1–H_6), and H_4–H_5(H_5–H_6)

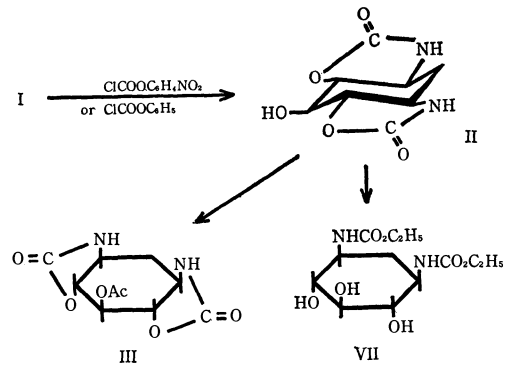

Chart 2

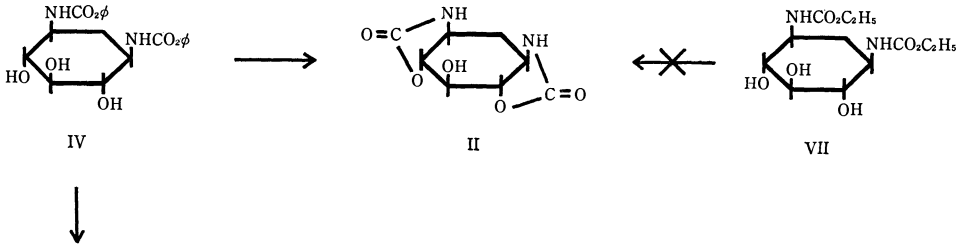
indicated the presence of all *trans*-axial protons. Compound II could also be prepared from I and PCC in the presence of anion-exchange resin or sodium carbonate, but the reaction required a longer period than that by NPCC.

When, however, I and PCC were brought into reaction in the presence of sodium hydrogen carbonate for a short period, *N,N'*-diphenoxycarbonyl-2-deoxystreptamine (IV) was formed. The spectroscopic data of its tri-*O*-acetyl derivative (V) and 4,5,6-tri-*O*-acetyl-*N,N'*-diacetyldeoxystreptamine (VI) support the structure for IV. When the solution of the compound IV in aqueous acetone was treated with a small amount of anion-exchange resin, IV was converted to a cyclic dicarbamate (II) in one hour in a yield of 81%. This result indicates that the reaction intermediate to II is IV, not an *O*-phenoxycarbonyl derivative.[7] Since *N*-ethoxycarbonyl derivative[6] (VII) of I could not be cyclized under the similar conditions, electron-withdrawing properties of phenyl and nitrophenyl groups may facilitate the cyclization.

We have found the properties of the cyclic carbamate group useful for synthetic purposes. When II was treated with barium hydroxide at 100°C, the carbamate groups were broken to give I; whereas, when II was refluxed in ethanol with a catalytic amount of sodium it was converted to VII in a yield of 77% (Chart 2). Thus, the protected hydroxyl group in a cyclic carbamate group could be made free leaving the amino group still protected.

By the similar treatment of methyl 2-amino-2-deoxy-α-D-glucopyranoside[8] with NPCC, a cyclic carbamate (VIII) was obtained in a yield of 78%. The structure was proved from its elemental analysis and spectroscopic data, and also from those of its di-*O*-acetyl derivative (IX) (Chart 3): The absence of any absorption peak near 1550 cm^{-1} in VIII and IX and the large coupling constants ($J_{2,3}$, $J_{3,4}$, and $J_{4,5}$=9—12Hz) of these compounds showed that both are cyclic carbamates of CI conformation, and these results exclude the pos-



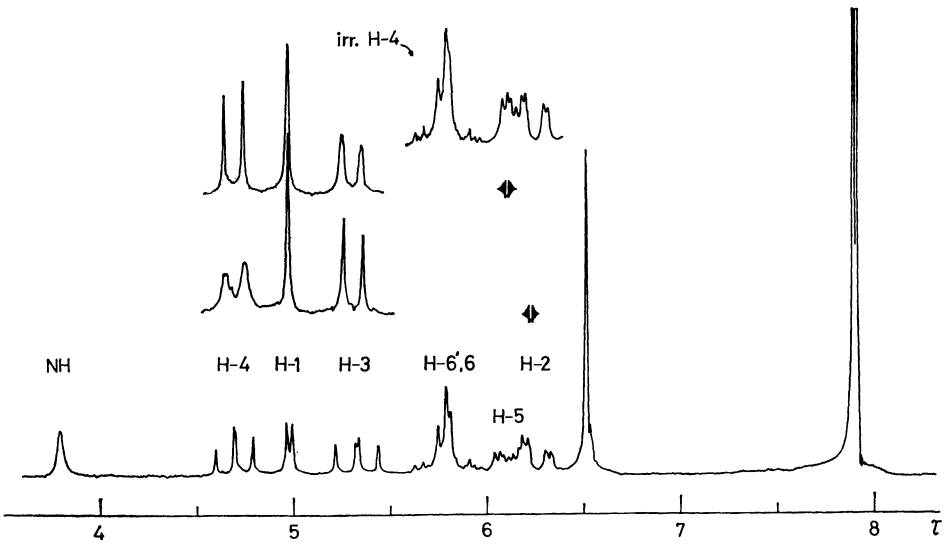


Chart 3. NMR spectrum of methyl 4,6-di-*O*-acetyl-2-amino-2-dexoy-α-D-glucopyranoside-2,3-carbamate (IX) in $CDCl_3$ at 100 MHz.

Ⅺ R=Ac

sibility of a 2,4-cyclic carbamate structure for the carbamate.

When similarly treated with NPCC, methyl α-D-glucopyranoside gave no reaction indicating that NPCC does not come into reaction with any hydroxyl group under a similar condition. This result also precludes the possibility of formation of an *O*-phenoxycarbonyl intermediate.

Methyl 6-amino-6-deoxy-α-D-glucopyranoside[9] was converted to 4,6-cyclic carbamate (X) in a yield of 78%. The structure was proved by its elemental analysis and spectroscopic data, and also from those of its di-*O*-acetyl derivative (XI), the CI conformation of these compounds being confirmed. These results exclude the possibility of 3,6-cyclic carbamate for the carbamate.

In glucopyranosides, the 2-*O*-, 3-*O*-, and 2,3-di-*O*-substituted derivatives was readily prepared *via* corresponding 4,6-*O*-benzylideneglucopyranosides, but the protecting method was not applicable in such case as 6-amino-6-deoxy-glucopyranosides. The above described cyclic carbamate method gives a solution for this problem.

Experimental

Thin-layer chromatography (tlc) was performed by the use of silica gel and the chromatograms were visualized by spraying with sulfuric acid. The NMR spectra were recorded with Varian A-60D and HA-100D spectrometers. Tetramethylsilane (τ 10.00; for the solutions other than deuterium oxide) and sodium 4,4′-diemthyl-4-silapentane-1-sulfonate (τ 10.00; for the solutions of deuterium oxide) were used as the internal standards.

2-Deoxystreptamine-1,6 : 3,4-dicarbamate (II). a) From 2-Deoxystreptamine (I) and p-Nitrophenoxycarbonyl Chloride (NPCC) in the Presence of Dowex Resin: To an ice-cold mixture of an aqueous solution (1 m*l*) of I (104 mg, 0.64 mmol) and wet Dowex 1×2 resin (OH form, 3.5 m*l*), a cold solution of NPCC (340 mg, 1.7 mmol) in acetone (3.4 m*l*) was added under stirring within several minutes and the mixture was stirred at that temperature for 1 hr. A weakly acidic yellow slurry resulted. Another Dowex resin (3.5 m*l*) and NPCC (340 mg) in acetone (3.4 m*l*) was added and stirring was continued for 1 hr in the cold. On tlc with acetone-ethyl acetate (2:1), three spots (R_f 0.95, 0.5, and 0) appeared; the first is a mixture of NPCC, *p*-nitrophenol, and some derivatives originated from NPCC, and the last a by-product, which gave R_f 0.35 on tlc with DMF. The mixture was extracted with ether to remove the first mixture (R_f 0.95) and the residual mixture was filtered off, washed with hot aqueous acetone (1:2). The combined filtrate and the washings were then evaporated to give a yellow solid (109 mg). The solid was chromatographed on a column of silica gel (1.4×18 cm) with DMF and the fraction containing II (R_f 0.5 with acetone-ethyl acetate 2:1) was evaporated to give a colorless solid (100 mg, 73%), which was recrystallized from aqueous methanol (1:1); mp >285°C.

Found: C, 41.14; H, 5.30; N, 12.35%. Calcd for $C_8H_{10}O_5N_2 \cdot H_2O$: C, 41.38; H, 5.21; N, 12.07%.

IR spectrum: 3410 (s), 3300, 2920 (w), 1760 (s), 1735 (s), 1470 (w), 1435, 1390, 1315, 1230, 1210, 1175, 1130 (w), 1095, 1085, 960 (s), 935, 905 (w), 885 (w), 775, 740 cm^{-1}. NMR spectrum (in DMSO-d_6 at 60 MHz): τ : 2.3 (2H s., disappeared on deuteration, NHCO), 4.0 (1H short-range multiplet, disappeared on deuteration, OH), 5.6—6.7 (5H m., H-1,3,4,5,6), 7.80 (1H double triplets H-2_e), 8.40 (1H q., H-2_a); $J_{1,2a}=J_{3,2a}=J_{2a,2e}=11$ Hz, $J_{1,2e}=J_{3,2e}=3$ Hz.

b) From I and Phenoxycarbonyl Chloride (PCC) in the Presence of Dowex Resin: To an ice-cold mixture of an aqueous solution (2 m*l*) of I (108 mg, 0.67 mmol) and wet Dowex 1×2 resin (OH form, 4.1 m*l*), a cold solution of PCC (470 mg, 3.0 mmol) in acetone (4.2 m*l*) was added under stirring within several minutes, whereupon the resultant mixture became weakly acidic (pH 6) and gave a precipitate, which was proved to include compound II. After continuation of stirring at room temperature overnight followed by ice-cooling, Dowex resin (2.2 m*l*) and a cold solution of PCC (227 mg) in acetone (2 m*l*) were added successively, and the mixture (pH 5) was stirred at room temperature overnight. The resultant mixture (pH 6.5) gave almost no precipitation. On tlc with ethyl acetate-methanol (10:1), a spot (R_f 0.34, major) was accompanied with weak spots at R_f 0.56 and 0; the latter was ninhydrin-positive and the former faded as the reaction proceeded. Incidentally, compound II and the *N*, *N*′-diphenoxycarbonyl derivative (IV) of I gave almost identical R_f value with several developing solvent mixtures, and this made the determination of the reaction period by monitoring the tlc patterns difficult. The mixture was filtered and the resin was washed with hot aqueous acetone (1:2). On combining the filtrate and the washings, some solid precipitated. After filtration, the solution was treated with ether until the ethereal solution became negative for DQC reagent.[10] The aqueous suspension was concentrated to give a solid which was filtered off, washed with water until the washing became negative for ninhydrin reagent. Colorless solid (86 mg, 60%) was obtained and was identical with II obtained by method a) in its IR and NMR spectra.

c) From I and PCC in the Presence of Sodium Carbonate: To an ice-cold solution (5 m*l*) of I (200 mg 1.23 mmol) and sodium carbonate (160 mg), a cold solution of PCC (427 mg, 2.73 mmol) in acetone (8 m*l*) was added under stirring and the resultant suspension (pH ~8) was stirred at room temperature overnight, whereupon a clear solution (pH ~7.5) resulted. On tlc with ethyl acetate-methanol (10:1), a spot (R_f 0.34, major) appeared accompanied with minor spots of R_f 0.56 and 0. Sodium hydrogencarbonate (30 mg) was added and the mixture was again stirred overnight. The reaction mixture was treated with ether until the ethereal solution became negative for DQC reagent; the aqueous solution gave a precipitate. Filtration and washings with water gave II (193 mg, 73%).

d) From N,N′-Diphenoxycarbonyl-2-deoxystreptamine (IV) in the Presence of Dowex Resin: To a solution of IV (102 mg) in aqueous acetone (1:3, 10 m*l*), Dowex 1×2 resin (OH form, 0.1 m*l*) was added and the mixture was stirred at room tem-

10) This reagent was used for the detection of phenol liberated. A tlc plate spotted with a solution containing phenol is sprayed with 0.2% solution of 2,6-dichloroquinone chlorimide (DQC) in ethanol and the plate is exposed to the vapour of ammonia. Blue color appears.

perature for 1 hr. After neutralization with hydrochloric acid, the mixture was heated to 45°C to dissolve the precipitate, filtered, and the filtrate was evaporated to give a residue which was washed with ether and then with water to give a colorless solid (II) 43.5 mg (81%).

N N'-*Diphenoxycarbonyl-2-deoxystreptamine (IV).* To an ice-cold solution of I (508 mg, 3.13 mmol) and sodium hydrogencarbonate (658 mg, 7.82 mmol) in water (11 m*l*), a solution of PCC (1.22 g, 7.80 mmol) in acetone (18 m*l*) was dropped under stirring in 10 min and the mixture was stirred for more 30 min. After neutralization with hydrochloric acid the precipitate was filtered off, washed thoroughly with ether and with water to give a solid (IV), 716 mg (57%); mp > 295°C, R_f 0.33 (tlc with ethyl acetate - methanol 10:1).

Found: C, 59.57; H, 5.68; N, 6.83%. Calcd for $C_{20}H_{22}O_7N_2$: C, 59.69; H, 5.51; N, 6.96%.

IR spectrum: 3400, 3330, 3050 (w), 2930 (w), 2870 (w), 1710 (s, NH*C*O*O*), 1595 (w, phenyl), 1540 (s, amide II), 1495 (phenyl), 1340 (w), 1305, 1285, 1215 (s), 1150, 1115, 1075, 1030, 985, 960, 910, 855, 840, 790, 765, 715, 690 cm^{-1}. NMR spectrum (in DMSO-d_6 at 60 MHz): τ : 2.1—3.0 (12 H m., phenyl and N*H*CO).

This compound was unstable and attempted recrystallization from aqueous methanol caused partial convertion to II.

Preparation of N,N'-*Bis(ethoxycarbonyl)-2-deoxystreptamine (VII) from II.* To a suspension of II (78.4 mg) in dry ethanol (1.6 m*l*), 0.01 N sodium ethoxide in ethanol (1 m*l*) was added and the mixture was refluxed for 1.5 hr. On tlc with ethyl acetate - methanol (10:1), starting material (R_f 0.34) had disappeared and VII (R_f 0.23) and a product (R_f 0) appeared. When the solution was then allowed to stand at room temperature overnight, the product of R_f 0 almost disappeared and crude VII precipitated. The product was collected by centrifuge, washed with cold ethanol and then dissolved in water (0.7 m*l*) Additon of acetone (14 m*l*) gave some precipitates, which were removed by centrifuge, and the solution was evaporated to give a solid (VII), 86 mg (77%). The IR and NMR spectra of the product were superimposable with those of the authentic sample.[6] The product did not depress the melting point (218°C) when mixed with the authentic sample.

5-O-*Acetyl-2-deoxystreptamine-1,6:3,4-dicarbamate (III).* To a suspension of II (158 mg) in pyridine (3 m*l*) acetic anhydride (0.15 m*l*) was added and the mixture was stirred at room temperature for 3 hr. After addition of a drop of methanol, the clear solution was evaporated to give a residue, which was washed with cold water to give a chromatographically homogeneous solid, 143 mg (76%), R_f 0.57 (tlc with acetone - ethyl acetate 2:1). Recrystallized from aqueous acetone (1:2); mp 276°C (decomp.); molecular weight 256 (M^+, by mass spectrum).

Found: C, 47.03; H, 5.07; N, 10.46%. Calcd for $C_{10}H_{12}O_6N_2$: C, 46.88; H, 4.72; N, 10.93%.

IR spectrum: 3300 (νNH), 2930 (w), 1770 (s), 1735, 1475 (w), 1415, 1395, 1380, 1340, 1295, 1245 (acetyl ester), 1225, 1105, 1070, 1040, 980, 955, 925, 895, 870, 800, 775, 745 cm^{-1}. NMR spectrum (in DMSO-d_6 at 60 MHz): τ : 2.2 (2H s., N*H*CO), 4.45 (1H t., H-5), 5.91 (2H q., H-4,6), 6.30 (2H double triplets, H-1,3), 7.85 (1H double triplets, H-2$_e$), 7.90 (3H s., OAc), 8.40 (1H q., H-2$_a$); $J_{1,2a}=J_{3,2a}=J_{2a,2e}=11$ Hz, $J_{1,2e}=J_{3,2e}=3.2$ Hz, $J_{3,4}=J_{1,6}=11$ Hz, $J_{4,5}=J_{5,6}=9.4$ Hz. Irradiation at τ 5.91 caused the signals at τ 4.45 (H-5) to collapse to a singlet.

4,5,6-*Tri*-O-*acetyl*-N,N'-*diphenoxycarbonyl-2-deoxystreptamine (V).* To a solution of IV (74.3 mg) in pyridine (1.5 m*l*), acetic anhydride (0.21 m*l*) was added and the solution was allowed to stand overnight. After a slight precipitate was removed by filtration, the solution was coevaporated with toluene to give a solid, which was washed thoroughly with water to give a chromatographically homogeneous solid, 81.1 mg (83%), mp 192.5—194.5°C, R_f 0.52 (tlc with ether).

Found: C, 59.07; H, 5.31; N, 5.40%. Calcd for $C_{26}H_{28}O_{10}N_2$: C, 59.08; H, 5.34; N, 5.30%.

IR spectrum: 3420, 3350, 3080 (w), 2960 (w), 1760 (s), 1730, 1600 (w, phenyl), 1545 (sh, amide II), 1525 (amide II), 1500 (phenyl), 1385, 1365, 1310, 1260, 1235, 1205 (s), 1170 (w), 1065, 1030, 980, 920 (w), 895 (w), 845 (w), 790, 765, 720, 695 cm^{-1}. NMR spectrum (in DMSO-d_6 at 60 MHz): τ: 1.9—3.0 (12 H m., phenyl and NHCO), 7.99 (6H s., O(4,6)Ac), 8.03 (3H s., O(5)Ac).

4,5,6-*Tri*-O-*acetyl*-N,N'-*diacetyl-2-deoxystreptamine (VI).* This substance was prepared by the usual way from acetic anhydride and pyridine, mp >300°C (lit,[11] 340—350°C)

Found: C, 51.96; H, 6.80; N, 7.53%. Calcd for $C_{16}H_{24}O_8N_2$: C, 51.60; H, 6.50; N, 7.52%.

IR spectrum: 1750 (s); 1655 (s, sh), 1640 (s)(amide I); 1555 cm^{-1} (amide II). NMR spectrum[11,12] (in methanol-d_4 - D_2O at 60 MHz): τ: 8.02 (9H s., OAc), 8.13 (6H s., NAc).

*Methyl 2-Amino-2-deoxy-α-*D*-glucopyranoside-2,3-carbamate (VIII).* To a solution of methyl 2-amino 2-deoxy-α-D-glucopyranoside (base, 616 mg, 3.19 mmol) in water (8 m*l*), wet Dowex 1×2 resin[13] (OH form, 100—200 mesh, 15.5 m*l*) was added and the mixture was ice-cooled. A cold solution of NPCC (1.63 g, 8.07 mmol) in acetone (16 m*l*) was added under vigorous stirring for 10 min, when the mixture became a viscous yellow slurry. After gentle stirring for 1 hr at room temperature, the slurry (pH ~7) was washed with ether and the resultant aqueous suspension was filtered and the residual mass was washed with hot water. The filtrate and the washings were combined and made acidic (pH ~3) by the addition of hydrochloric acid. The solution was extracted with ether to remove *p*-nitrophenol accompanied until the ethereal solution gave no yellow color when sodium hydroxide solution was added. The aqueous solution was then neutralized with Dowex 1×2 resin (OH form), filtered, and evaporated to give a solid (~650 mg). Since the solid still contained an impurity (tlc, R_f 0 with ethyl acetate - methanol 5:1), chromatography on a small column of silica gel (16 g) with ethyl acetate - methanol (5:1) was carried out and the fraction containing the carbamate (VIII, R_f 0.54) was evaporated and the residue was dried by coevaporation with ethanol and benzene. Hygroscopic solid was obtained; 542 mg (78%); $[\alpha]_D^{21}+110°$ (*c* 0.5, water).

Found: C, 43.76; H, 5.70; N, 6.61%. Calcd for $C_8H_{13}O_6N$: C, 43.83; H, 5.98; N, 6.39%.

IR spectrum: 3350 (s, broad), 2940, 1760 (s, broad), 1455, 1400 (broad), 1335, 1290, 1205, 1185, 1140, 1105, 1065, 1040, 1005, 945, 915, 785 cm^{-1}. NMR spectrum (in D_2O at 60 MHz): τ: 4.86 (1H d., H-1), 5.40 (1H q., H-3), 5.93 (1H t., H-4), 6.22 (1H q., H-2), 6.5 (3H s., OCH_3); $J_{1,2}=3$ Hz, $J_{2,3}=12$ Hz, $J_{3,4}=9.3$ Hz, $J_{4,5}=\sim 9$ Hz. Irradiation at τ 4.86 (H-1) caused the quartet at τ 6.22 (H-2) to collapse to a doublet ($J=\sim 12$ Hz).

*Methyl 4,6-Di-O-acetyl-2-amino-2-deoxy-α-*D*-glucopyranoside-2,3-carbamate (IX).* To a solution of VIII (202 mg) in

13) The aqueous suspension of the resin in a cylinder was set aside for a while and the volume of the resin was measured under pressing with a glass rod with a flat top having the same diameter with that of the cylinder.

pyridine (4 ml), acetic anhydride (0.3 ml) was added and the mixture was allowed to stand at room temperature overnight. On tlc, a single spot (R_f 0.67, with ethyl acetate) appeared. After a drop of water was added, the solution was evaporated and the residue was dissolved in chloroform. The solution was washed successively with potassium hydrogensulfate solution, water, sodium hydrogencarbonate solution and water, dried over sodium sulfate and coevaporated with benzene to give a hygroscopic solid, 219 mg (78%); $[\alpha]_D^{21}$ +94° (*c* 0.5, chloroform).

Found: C, 47.34; H, 5.77; N, 4.32%. Calcd for $C_{12}H_{17}O_8N$: C, 47.52; H, 5.65; N, 4.62%.

IR spectrum: 3400 (νNH), 2960, 1780 (s), 1750 (s), 1455, 1375, 1245 (s, ester), 1185, 1140, 1110, 1045 (s), 1005 (s), 940, 785, 755 cm^{-1}. NMR spectrum (in $CDCl_3$ at 100 MHz): τ: 3.8 (1H s., NHCO), 4.70 (1H q., H-4), 4.98 (1H d., H-1), 5.33 (1H q., H-3); 5.76 (H-6′) and 5.81 (H-6) (each 1H quartet forming in total the AB part of an ABX system); 6.10 (1H m., H-5), 6.25 (1H q., H-2), 6.52 (3H s., OCH_3), 7.90 and 7.92 (each 3H s., OAc); $J_{1,2}$=3 Hz, $J_{2,3}$=11.8 Hz, $J_{3,4}$=10 Hz, $J_{4,5}$=9.2 Hz, $J_{5,6}$=~3 Hz, $J_{5,6'}$=~4.5 Hz, $J_{6,6'}$=12.4 Hz. Irradiation at τ 5.33 (H-3) caused the quartet of H-2 to collapse to a doublet (J=~3 Hz) and the quartet of H-4 to a doublet (J=~9 Hz). Irradiation at τ 6.25 (H-2) caused the quartet of H-3 to collapse to a doublet (J=10 Hz), the doublet of H-1 to a singlet and the quartet of H-4 to an incomplete doublet. Irradiation at τ 6.10 (H-5) caused the quartet of H-4 to collapse to a doublet (J=10 Hz). Irradiation at τ 4.70 (H-4) caused the multiplet of H-5 to collapse to a quartet (J=~3 and ~4.5 Hz).

Methyl 6-Amino-6-deoxy-α-D-glucopyranoside-4,6-carbamate (X). To a solution of methyl 6-amino-6-deoxyl-α-D-glucopyranoside hydrochloride (715 mg, 3.11 mmol) in water (7 ml), wet Dowex 1×2 resin (OH form, 100—200 mesh, 18 ml, the volume was measured under pressing) was added and the mixture was ice-cooled. A cold solution of NPCC (1.63 g, 8.07 mmol) in acetone (16 ml) was added to the mixture under vigorous stirring for 40 min, when a viscous yellow slurry (pH~6) resulted. On tlc, a spot (R_f 0.85 with acetone-methanol 3:1) appeared. The slurry was made acidic (pH ~3) with hydrochloric acid and extracted with ether several times. The aqueous suspension was filtered, and the residual mass was washed with hot water. The combined filtrate and washings were neutralized with Dowex 1×2 resin (OH form), filtered, and evaporated to give a solid (~690 mg). This was dissolved in water (1.4 ml), filtered and concentrated almost to dryness. Addition of acetone gave colorless cystals, 529 mg (78%), mp 233—236°C, $[\alpha]_D^{25}$ +38.1° (*c* 0.7, water).

Found: C, 44.14; H, 6.01; N, 6.36%. Calcd for $C_8H_{13}O_6N$: C, 43.83; H, 5.98; N, 6.39%.

IR spectrum: 3430 (s), 3300, 2950 (w), 2900 (w), 1725 (s), 1660, 1495, 1460, 1405, 1385, 1370, 1320, 1280 (s), 1210, 1135, 1110, 1090, 1065, 1050, 1015, 995 (s), 945, 895, 855, 765 (s), 745, 710, 660 cm^{-1}. NMR spectrum (in D_2O at 60 MHz): τ: 5.09 (1H d., H-1), 6.54 (3H s., OCH_3); $J_{1,2}$= 3.2 Hz.

Methyl 2,3-Di-O-acetyl-6-amino-6-deoxy-α-D-glucopyranoside-4,6-carbamate (XI). To a solution of X (224 mg) in pyridine (5 ml), acetic anhydride (0.5 ml) was added and the mixture was allowed to stand at room temperature overnight. On tlc, a single spot (R_f 0.42 with ethyl acetate) appeared. Hereafter the solution was treated likewise as in the preparation of IX and a colorless solid (300 mg, 97%) was obtained. Recrystallization from chloroform-petroleum ether or from ethanol; mp 207—209°C, $[\alpha]_D^{21}$ +61.4° (*c* 0.8, chloroform).

Found: C, 47.80; H, 5.73; N, 4.68%. Calcd for $C_{12}H_{17}O_8N$: C, 47.52; H, 5.65; N, 4.62%.

IR spectrum: 3430 (w, NH), 2950 (w), 1760 (s), 1740 (s), 1715 (s), 1490, 1460, 1400, 1375 (s), 1270, 1240 (s, ester), 1220 (s, ester), 1195, 1180, 1160, 1145, 1095, 1075, 1055, 1000, 945, 920, 885, 850, 765, 755, 735, 680 cm^{-1}. NMR spectrum (in $CDCl_3$ at 100 MHz): τ: 3.2 (1H broad doublet in appearance, J=~3.5 Hz, NHCO), 4.42 (1H t., H-3), 5.03 (1H d., the signal in the higher field being strong, H-1), 5.13 (1H q., at τ 5.07, 5.11, 5.17, and 5.21, the signals at 5.07 and 5.17 being strong, H-2), 5.8—6.05 (2H m., H-4 and H-5 ?), 6.35—6.85 (2H m., H-6,6′ ?), 6.55 (3H s., OCH_3), 7.91 (6H s., OAc); $J_{1,2}$=3.5 Hz, $J_{2,3}$=9.7 Hz, $J_{3,4}$=~9.5 Hz. Irradiation at τ 3.2 caused the signals at τ 6.35—6.5 to change. Irradiation at τ 4.42 (H-3) caused the signals at τ 5.13 (H-2) to collapse to a doublet (J=~3.5 Hz) and the multiplet at τ 5.8—6.05 (which contained H-4) to change. Irradiation at τ 5.07 (H-1 and 2) or at τ 5.92 caused the signals at τ 4.42 (H-3) to collapse to a doublet (J=~9 Hz), respectively.

We are grateful to Dr. Hiroshi Naganawa of Institute of Microbial Chemistry for the measurements of NMR spectra at 100 MHz and to Mr. Saburo Nakada of our Laboratory for the elemental analysis.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel Catalyst. XVI

Yoshiharu IZUMI, Shinichi YAJIMA,* Kazuo OKUBO, and Kirill K. BABIEVSKY**
Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka
(Received June 8, 1970)

In the course of the investigation of the asymmetrically modified R-Ni catalyst, it was found that catalysts modified with α-amino or α-hydroxy dicarboxylic acids have higher asymmetric hydrogenation activities than do those modified with α-amino or α-hydroxy monocarboxylic acids. That is, the asymmetric activity of the catalyst modified with aspartic acid, glutamic acid, or malic acid is higher than that of the catalyst modified with alanine, butyrine, norvaline, or lactic acid.[1-6]

The expectation that the excellent property of α-amino or α-hydroxy dicarboxylic acid as a modifying reagent will greatly depend on the ω-carboxyl group is also supported by the fact that the optimum asymmetric activity of the catalyst modified with α-amino or α-hydroxy dicarboxylic acid is produced by the modification at pH 5, which is the point where the ω-carboxyl group is neutralized. The contribution of the ω-carboxyl group to the increase in the asymmetric activity of the catalyst may be ascribable to its ionic and steric effects and to its electronegativity. Therefore, it can be expected that more acidic, more electronegative, and bulkier substituents than the carboxyl group, such as the sulfonyl group, will increase the asymmetric activity of the catalyst.

In the present work, the abilities of L-α-hydroxy-β-sulfopropionic acid, L-homocysteic acid, and L-cysteic acid as modifying reagents were tested at various modifying pH values in order to test the expectation mentioned above. The results are shown in Figs. 1 and 2, where they are compared with those obtained with aspartic acid and malic acid.

As may be seen in Figs. 1 and 2, unexpected results were obtained. The asymmetric activities of the catalyst modified with the sulfonic acids were considerably lower than those of the catalysts modified with

the α-amino or α-hydroxy dicarboxylic acids. Scarcely no effect of the modifying pH is found in the case of modifications with cysteic acid and α-hydroxy-β-sulfopropionic acid, although a slight effect was found in the case of modification with homocysteic acid.

The asymmetric directions of the catalysts modified with L-homocysteic acid and L-α-hydroxy-β-sulfopropionic acid come under the general rule of the relation between the absolute configuration of the modifying reagent and the asymmetric direction of the catalyst —the catalysts modified with L-α-amino acids or D-α-hydroxy acids at 0°C produce predominantly methyl D-3-hydroxybutyrate in the hydrogenation of methyl acetoacetate. However, cysteic acid gives a catalyst which has an asymmetric direction, contrary to the general rule, as was also found in the case of the catalyst modified with serine, cysteine, and threonine.[7]

From the results described above, the regular correlations between the asymmetric activities of the catalysts modified with sulfonic acids and the ones modified with amino dicarboxylic acids were difficult to be found, from the simple view point of ionic effect, electronegativity or steric hindrance of the β- or γ-substituent.

As it was reported in the previous paper that the modifying reagent might be adsorbed on the catalyst surface with the chelate formation,[8] the contribution of the sulfonyl group to the chelate formation must be discussed. In connection with the sulfonyl group, however, it is generally known that, as the dissociation constant of the sulfonic acid is much larger than that of the carboxylic acid, the ability of the chelate formation with the metal ion is considerably weaker than that of the carboxyl group.

Accordingly, it is hard to accept the idea that the unexpected results obtained with the catalysts modified with the β- or γ-sulfonyl substituted amino and hydroxy acids are brought about by the different types of adsorption of the modifying reagent.

Therefore, it can be expected that the amino acids or hydroxy acids which have a sulfonyl group on the β- or γ-carbon are adsorbed by amino and carboxyl groups or by hydroxy and carboxyl groups.

As a conclusion of the present work, it was made clear that the electronegativity and bulkiness of the sulfonyl group on the β- or γ-carbon of the amino or hydroxy acid did not simply affect the asymmetric activity of the catalyst, and that the other new effect of the sulfonyl group overcame the effects of the electronegativity and bulkiness of the sulfonyl group.

The new effect of the substituent will be discussed in detail in This Bulletin in the near future.

The L-α-hydroxy-β-sulfopropionic acid was prepared from L-cysteic acid and was successively purified as benzidine and dicyclohexylamine salts.

Experimental

The asymmetric activity of the catalyst was measured by a method reported in a previous paper.[6]

Preparation of the Dicyclohexylamine Salt of L-α-Hydroxy-β-sulfopropionic Acid. In 150 m*l* of 10% hydrochloric acid, 18.7 g of L-cysteinic acid monohydrate was dissolved. Into this solution, 50 m*l* of isoamyl nitrite was vigorously stirred, drop by drop, at room temperature, and then the reaction mixture was stirred continuously overnight. The isoamyl alcohol thus separated was removed, and the aqueous layer was washed thoroughly with ether. The aqueous solution was evaporated to a syrup, and the resulting syrup was taken up in a small amount of water and again evaporated. This syrup gave, quantitatively, benzidine salt in an alcohol solution; mp 260°C.

Found: C, 50.54; H, 4.71; N, 7.88%. Calcd for $C_{15}H_{18}O_6N_2S$: C, 50.85; H, 5.12; N, 7.91%.

To 17 g of syrup dissolved in 100 m*l* of acetone, was added 35 g of dicyclohexylamine, drop by drop, with ice cooling. The dicyclohexylamine salt thus precipitated was collected and washed with acetone. Two recrystallizations from ethanol-ether (1:5) gave 29.5 g (53.6%); mp 260°C.

Found: C, 58.83; H, 9.59; N, 5.22%. Calcd for $C_{27}H_{54}O_7N_2S[HSO_3CH_2CH(OH)\cdot CO_2H\cdot 2$  $\cdot H_2O]$: C, 59.00; H, 9.82; N, 5.09%. $[\alpha]_D$ −8.57 (*c* 2.3 EtOH).

Preparation of a Modifying Solution of L-α-Hydroxy-β-sulfopropionic Acid. In 30 m*l* of water, 5.36 g of the dicyclohexylamine salt was dissolved. The dicyclohexylamine was removed using a column of Amberite IR 120(400—600 mesh, 1×18 cm), and with water. The total volume of the eluted solution was adjusted to 100 m*l*. The specific rotation $[\alpha]_D$ −13.3 (*c* 1.65, H_2O) for L-α-hydroxy-β-sulfopropionic acid was calculated from the α_D of the solution obtained. An attempt to isolate the free acid failed.

The authors wish to express their thanks to Professor Shōichirō Yamada and Professor Yōichi Shimura, Osaka University, for their helpful discussions, and to the Ajinomoto Co., Ltd., Tokyo, for the gift of L-homocysteic acid.

6) Y. Izumi, S. Tatsumi, and M. Imaida, *ibid.*, **42**, 2373 (1969).

7) Proline, hydroxyproline, and alanine all produced catalysts which have an asymmetric direction, thus contradicting the general rule. However, proline and hydroxyproline are special amino acids which have a pyrrole ring, and the modification with alanine is very sensitive to the modifying condition, so such results are reasonable even according to the general rule. The details of the asymmetric activity of the catalyst modified with alanine will be discussed in This Bulletin in the near future.

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received June 8, 1970)

In the course of our studies of the asymmetric hydrogenation catalyst, it was found that the Raney nickel catalysts modified with various optically-active compounds catalyze asymmetrically the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate; the relationship between the structure of the modifying reagent and the asymmetric activity of the catalyst has been studied in detail.[1] From the facts that *N*-substituted amino acids, *N*-cyanoethyl, *N*-benzoyl, and *N,N*-dimethyl derivatives of L-glutamic acid and L-aspartic acid, produce catalysts with much lower asymmetric activities than the original amino acids, it was concluded that a primary amino residue of amino acid is necessary for an effective modifying reagent.[2]

However, the role of the α-carboxyl group of the amino acid or hydroxy acid used as a modifying reagent for the asymmetric activity of the catalyst has not yet been made clear.

In the present paper, the asymmetric activities of the catalysts modified with optically-active 2-amino alcohols, R-C*H(NH_2)CH_2OH, are examined in order to investigate the role of the α-carboxyl group.

The activities of the catalysts modified with amino alcohols are shown in Table 1, where they are compared with those of the catalysts modified with the corresponding amino acids. Also, the results of the adsorption-stability test of the modifying reagent on the catalyst are shown in Table 2.

Table 1. Asymmetric activities of the catalysts modified with optically active 2-amino alcohols, and 2-amino acids

Modifying reagent	Modifying conditions		$[\alpha]_D$ of methyl 3-hydroxybutyrate
	pH	Temp. °C	
L-Alaninol	11.6	0	−0.04
L-Leucinol	11.4	0	−0.25
L-Valinol	11.4	0	−0.15
L-Alanine	6.1	0	+0.45
L-Leucine	6.0	0	−1.65
L-Valine	5.9	0	−2.64

Table 2. The asymmetric activities of the catalysts after the contact with the substrate before use

Modifying reagent	Modifying temp., °C	$[\alpha]_D$ of methyl 3-hydroxybutyrate
L-Leucine	0	−1.40
L-Leucinol	0	−0.08

As is shown in Table 1, the catalyst modified with 2-amino alcohol has a lower asymmetric activity than that modified with the corresponding amino acid, and so it is evident that it is desirable for the modifying reagent to have an α-carboxyl group.

Moreover, the Raney nickel catalysts modified with L-leucine and L-leucinol were employed in the hydrogenation of methyl acetoacetate after contact with the substrate before use in order to study the adsorption stabilities of the modifying reagents on the catalysts in the presence of the substrate. As may be found in Table 2, the process of the contact with the substrate reduced the asymmetric activity of the catalyst modified with L-leucinol to about 30%, while the process did not result in any remarkable change in that of the catalyst modified with L-leucine. These facts show that the displacement of a carboxyl group by a hydroxymethyl group results in a considerable decrease in the adsorption stability on the catalyst, and that this poor adsorption stability of the amino alcohol in the presence of methyl acetoacetate causes the considerably lower asymmetric activity of the catalyst.

Materials

2-Amino Alcohols. These compounds were synthesized from the corresponding optically-active 2-amino acid ethyl esters by the method of Karrer and Naik.[3]

Experimental

Preparation of the Modified Raney Nickel Catalyst. Into a solution of 4.5 g of sodium hydroxide in 20 m*l* of deionised water, 1.5 g of Raney nickel alloy (Ni:Al=4:6) was added, in small portions, and then the solution was allowed to stand for 1 hr at 100°C. Then, the catalyst was washed with water until the pH of the washing was about neutral. The catalyst so obtained was added a 1—2% aqueous solution of the modifying reagent, and the mixture was allowed to stand at the specified temperature, with occasional shaking, for 1.5 hr. After the subsequent removal of the modifying solution by decantation, the catalyst was washed once with water and three times with methanol.

Hydrogenation. Methyl acetoacetate (17.5 m*l*, The Nippon Syntehtic Chemical Industry Co., Ltd.) was hydrogenated with a modified Raney nickel catalyst prepared from 1.5 g of the alloy under an initial hydrogen pressure of about 90 kg/cm² at 60°C in a shaking autoclave.

Adsorption-stability Test. The catalysts modified with L-leucine and L-leucinol, prepared by the procedure described above, were placed in contact with 20 m*l* of methyl aceto-

acetate at room temperature for 30 min, and then washed three times with methanol. The resulting catalyst was used for the hydrogenation of methyl acetoacetate.

Measurement of the Asymmetric Activity of the Catalyst. After the removal of the catalyst by filtration, the hydrogenation products were distilled under reduced pressure (bp 61—62°C/12 mmHg). The optical rotatory power of the distilled product was measured by a conventional polarimeter in a 1 dm tube without dilution. The optical rotatory power of methyl D-3-hydroxybutyrate, prepared by esterification with diazomethane of D-3-hydroxybutyric acid ($[\alpha]_D^{20} = -25.1$, *c* 10, H_2O), is $[\alpha]_D^{16}$ −22.05; literature value,[4] $[\alpha]_D^{20}$ −20.9.

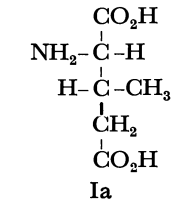
Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel.[1] XIX

Tadao HARADA, Masami IMAIDA,* and Yoshiharu IZUMI

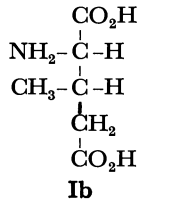
Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received October 20, 1970)

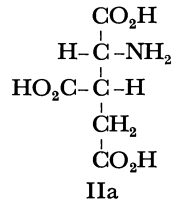
In the previous papers of this series,[2] it has been reported that, in the presence of the Raney nickel catalyst modified with optically-active α-amino or α-hydroxy acid, methyl acetoacetate is asymmetrically hydrogenated to methyl 3-hydroxybutyrate. Thereafter, the correlation of the asymmetric activity of the catalyst and the chemical and steric structures of the modifying reagent was studied.



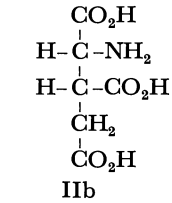
Ia



Ib



IIa



IIb

In the present paper, the asymmetric activities of catalysts modified with optically-active 3-methylglutamic acid[3] (Ia, Ib) and 2-aminotricarballylic acid[4] (IIa, IIb) are described, and the effect of the β-substituent of the modifying reagent on the asymmetric activity of the catalyst and the relationship between the asymmetric activities of the catalysts modified with the *thero* and the *erythro* isomers are discussed.

TABLE 1. OPTICAL ROTATIONS OF MODIFYING REAGENTS

Modifying reagent		Optical rotation, $[\alpha]_D$
3-Methylglutamic acid	Ia (2S, 3R)	+22 (*c* 2.2, 4N HCl)
	Ib (2S, 3S)	+42 (*c* 3, 4N HCl)
2-Aminotricarballylic acid	IIa (2R, 3S)	−49 (*c* 1, 5N HCl)
	IIb (2R, 3R)	−36 (*c* 1, 5N HCl)

Experimental

The preparation of the modified Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were done as described in a previous paper.[5]

Results and Discussion

Measurements were made of the asymmetric activities of the catalysts modified with aqueous solutions of L-*threo*-3-methylglutamic acid (Ia), L-*erythro*-3-methylglutamic acid (Ib), D-2-aminotricarballylic acid ((2R, 3S), IIa), and D-2-aminotricarballylic acid ((2R, 3R), IIb), the pH of which had been adjusted to specified values with a sodium hydroxide solution; the results are shown in Figs. 1 and 2.

Correlation of the Asymmetric Activity of the Catalyst and the β-Configuration of the Modifying Reagent. As has been reported in the previous papers of this series, the direction of the optical rotation of the hydrogenation product, methyl 3-hydroxybutyrate, is decided by the α-configuration of the modifying reagent (for example, in the hydrogenation with the catalysts modified with D-glutamic acid and L-glutamic acid, the directions of

○ L-*erythro*-3-methylgutamic acid
● L-*threo*-3-methylglutamic acid

the optical rotations of the hydrogenation product were (+) and (−) respectively), and the β-configuration of the α,β-diasymmetric amino or hydroxy acid used as a modifying reagent greatly affects the asymmetric activity of the catalyst (for example, the asymmetric activity of the catalyst modified with the *threo* isomer of α,β-diasymmetric amino acid (2R, 3S) or (2S, 3R)) is higher than that of the catalyst modified with the corresponding *erythro* isomer ((2R, 3R) or (2S, 3S))). These differences in the asymmetric activities of the catalysts modified with the *erythro* and the *threo* isomers are ascribable to the disagreement of the β-configuration, which is distinguished mainly in terms of the bulkiness of the two β-alkyl substituents. As can be seen in Figs. 1 and 2, the catalyst modified with the *threo* isomer (1a or IIa) had a higher asymmetric activity than the one modified with the corresponding *erythro* isomer (Ib or IIb). Accordingly, the similarlity between α,β-diasymmetric monoamino monocarboxylic acids and these β-substituted glutamic acids, in the correlation of the β-configuration of the modifying reagent and the asymmetric activity of the catalyst, suggests that the effect of the β-configuration of 3-methylglutamic acid and 2-aminotricarballylic acid is also due to the differences in bulkiness between a β-carboxymethyl group and either a methyl or a carboxyl group.

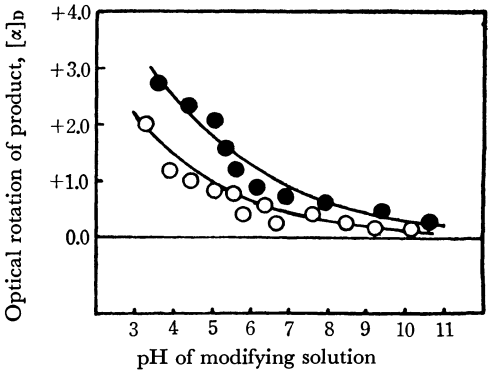

Fig. 2. Asymmetric activities of the catalysts modified with isomeric 2-aminotricarballylic acids.
● D-2-aminotricarballylic acid (2R, 3S)
○ D-2-aminotricarballylic acid (2R, 3R)

Correlation of the Asymmetric Activity of the Catalyst and the β-Substituent of the Modifying Reagent. As is shown in Figs. 1 and 2, the catalysts modified with Ia (*threo*) and Ib (*erythro*) had higher asymmetric activities than those modified with IIa (*threo*) and IIb (*erythro*) respectively.

As has been reported in a previous paper,[6] the asymmetric activity of the catalyst modified with monoasymmetric amino acid increases with an increase in the bulk of the α-alkyl substituent (R–CH–COOH), while that of the catalyst modified with monoasymmetric hydroxy acid decreases with an increase in the bulk of the α-alkyl substituent. From the facts that both *threo*- and *erythro*-3-methylglutamic acids are more effective asymmetric modifying reagents than the corresponding 2-aminotricarballylic acids, although a carboxyl group is bulkier than a methyl group, it seems that the asymmetric activity of the catalyst depends not only on the bulk of the β-substituent of the modifying reagent, but also on the electronic factor of the β-substituent. Similar effects of the β-substituents on the asymmetric activities of the catalysts can be found in the asymmetric activities of the catalysts modified with serine and threonine.[7]

Retention Index in Programmed Temperature Gas Chromatography

Isao TAKEMURA

Quality Control Laboratory, Max Factor Co., Ltd., Nishi-Gotanda, Shinagawa-ku, Tokyo

(Received July 23, 1970)

Linear programmed temperature gas chromatography (PTGC) can be applied to simultaneous analysis of mixtures consisting of many ingredients with a wide range of boiling points. However, fundamental data of ingredients under the same conditions, such as retention temperature and relative retention values, should be collected prior to qualitative or quantitative analysis of unknown samples. Recently the data on ingredients of many stationary liquids in isothermal gas chromatography (IGC) have been summarized systematically by many workers. If the data in IGC could be applied to PTGC, the complexity in PTGC would be reduced considerable.

For a linear PTGC with constant flow rate, the author has presented the following linear relationship between logarithmic relative retention value (α^{IT}) of IGC and relative retention value (α^{PT}) of PTGC.[1]

$$\log \alpha^{IT} = m(\alpha^{PT} - 1) \tag{1}$$

where m is a constant dependent upon the column temperature in IGC, the evaporation potential of internal standard material, the program rate, the flow rate of carrier gas, the initial temperature and the column length in PTGC.[2] If the operating conditions do not change, Eq. (1) holds in different homologous series on both polar and nonpolar columns.[3]

The Kovats index system[4] is widely accepted in IGC. In this system, the relative retention is referred to the series of normal paraffin hydrocarbons as standard substances. Retention indices I_{IT} are calculated by means of the relation

$$I_{IT} = 100\frac{\log \alpha_{X,N}}{\log \alpha_{N+1,N}} + 100N \tag{2}$$

where $\alpha_{X,N}$ is the relative retention value of unknown compound X compared to the n-paraffin with N carbon atoms, and $\alpha_{N+1,N}$ the relative retention value of the two n-paraffins with $N+1$ and N carbon atoms. Van den Dool and Kratz[5] and also Kaiser[6] have shown that for PTGC the retention indices can be calculated by means of the following relation and that the values are equal to those calculated by Eq. (2) for IGC provided that the indices measured are independent of temperature.

$$I_{PT} = 100\frac{T_r(X) - T_r(N)}{T_r(N+1) - T_r(N)} + 100N \tag{3}$$

where $T_r(X)$, $T_r(N)$, $T_r(N+1)$ are retention temperatures of unknown compound and n-paraffins of carbon number N and $N+1$, and $T_r(N) \leq T_r(X) \leq T_r(N+1)$. Guiochon[7] realized that, when the column temperature in IGC was 0.92 times the retention temperature of unknown compound X in PTGC, the retention index for IGC was approximately the same as that for PTGC.

In this paper, it is shown that Eq. (3) can be obtained from Eqs. (1) and (2).

The retention index for IGC gives the relative retention values for PTGC obtained from Eqs. (1) and (2):

$$I_{IT} = 100\frac{\alpha^{PT}_{X,N} - 1}{\alpha^{PT}_{N+1,N} - 1} + 100N \tag{4}$$

The relative retention value of n-paraffin of carbon number $N+1$ in PTGC is given by

$$\alpha^{PT}_{N+1,N} = \frac{\{T_r(N+1) - T_0\}/r - t_0}{\{T_r(N) - T_0\}/r - t_0} \tag{5}$$

It follows that

$$\alpha^{PT}_{N+1,N} - 1 = \frac{T_r(N+1) - T_r(N)}{T_r(N) - (T_0 + rt_0)} \tag{6}$$

where T_0 is the initial temperature, r is the program rate and t_0 is the time of air peak from the starting point. Similarly, for unknown compound X, we get

$$\alpha^{PT}_{X,N} - 1 = \frac{T_r(X) - T_r(N)}{T_r(N) - (T_0 + rt_0)} \tag{7}$$

Substituting Eqs. (6) and (7) into Eq. (4), the same equation as Eq. (3) is obtained:

$$I_{IT} = 100\frac{T_r(X) - T_r(N)}{T_r(N+1) - T_r(N)} + 100N \tag{8}$$

This is the equation of retention index for IGC related with retention temperature in PTGC. It may indicate that retention index for PTGC is the same as that for IGC.

The Coupling Reaction of Phenylmagnesium Bromide with Mn(III) or Co(III) Tris(acetylacetonate)

Tadao NAKAYA, Hideo ARABORI, and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received September 14, 1970)

It is well known that aryl Grignard reagents give the corresponding diaryls with suitable metallic halides, such as $CoCl_2$, $CuCl_2$, $NiBr_2$, and AgBr.[1,2] However, no report has appeared concerning the coupling reaction of aryl Grignard reagents by means of the salts of Mn(III) or Co(III).

This note will deal with the coupling reaction of phenylmagenesium bromide with Mn(III) or Co(III) tris(acetylacetonate).

Results and Discussion

Into an ethereal solution of phenylmagnesium bromide under nitrogen we stirred, drop by drop, on cooling a dry benzene solution of a 0.8 molar equivalent of Mn(III) tris(acetylacetonate) to give mainly biphenyl, together with a small amount of acetophenone. The reaction conditions and yields are indicated in Table 1. During the course of the reaction, a precipitate was formed which had Mn(II) bis(acetylacetonate) as its main ingredient[3]; acetylacetone was never detected. When the mole ratio of Mn(III) tris (acetylacetonate) to phenylmagnesium bromide was decreased to 1:3, the relative yield of biphenyl was reduced, whereas that of acetophenone was considerably increased. The increasing yields of acetophenone were probably due to the reaction[4-6] of the excess of phenylmagnesium bromide with the acetylacetonate ion[5,7] liberated from Mn(III) tris(acetylacetonate) in the reaction mixture, though the exact reaction route remains obscure. When Mn(II) bis(acetylacetonate) was used as a coupling agent, only biphenyl was obtained in a low yield. A similar reaction using manganous chloride afforded a relatively high yield of biphenyl.[8]

TABLE 1. REACTIONS OF PHENYLMAGNESIUM BROMIDE WITH VARIOUS METAL SALTS IN THE PRESENCE AND ABSENCE OF α-METHYLSTYRENE

PhMgBr mol	Metal salt	mol	α-Methylstyrene mol	Time min	Products: Biphenyl mmol (Yield, %)[a]	Products: Acetophenone mmol
0.025	$Mn(Acac)_3$	0.02	—	60	12.0 (98)	0.4
0.03	$Mn(Acac)_3$	0.01	—	60	7.0 (47)	6.9
0.03	$Mn(Acac)_3$	0.01	0.015	60	6.7 (45)	6.5

0.03	$MnCl_2$	0.01	—	60	4.1 (27)	0
0.06	$Co(Acac)_3$	0.01	—	60	15.5 (52)	0
0.04	$Co(Acac)_2$	0.01	—	60	5.0 (25)	0

a) Based on reacted PhMgBr.

In order to obtain information concerning the nature of the coupling reaction by Mn(III) tris(acetylacetonate), the reaction was carried out in the presence of α-methylstyrene, which would be expected to be a radical acceptor.[9] As can be seen in Table 1, the presence of the radical acceptor does not affect the yields of the products. Accordingly, it may be said that the reaction does not involve free radical steps. The finding that Mn(II) bis(acetylacetonate) is relatively unreactive toward phenylmagnesium bromide may be ascribed to the fact that it is a stable metal complex.[3,10]

On the other hand, the slow addition of a suspension of Co(III) tris(acetylacetonate) in benzene to a ethereal solution of phenylmagnesium bromide gave the relatively good yield of biphenyl. No other products were detected. Thus, the result suggests a useful method for the coupling of aryl Grignard reagents. Co(II) bis(acetylacetonate) was similarly, but much less effective than Co(III) tris(actylacetonate).

Experimental

Reagent. The bromobenzene and α-methylstyrene were purified by distillation. The Co(II) bis(acetylacetonate), Co(III) tris(acetylacetonate), Mn(II) bis(acetylacetonate), and manganous chloride were of all of a special reagent grade and were used without further purification. The Mn-(III) tris(acetylacetonate) was prepared by the method of Charles.[11] The phenylmagnesium bromide solution was prepared according to the procedure of Kharasch and Fields.[12]

Small portions of the Grignard solution were taken out with a pipet, hydrolyzed by cold 1 N hydrochloric acid, and

analysed with a Yanagimoto Model GCG-550-EP-type gas chromatograph, with columns packed with Silicone SE 30, in order to determine the quantity of biphenyl present in the Grignard solution.

General Procedure for the Reaction of Phenylmagnesium Bromide with Metal Salts. An outline of one reaction follows, while the general results are presented in Table 1. Into an anhydrous ethereal solution of 0.03 mol of phenylmagesium bromide, we stirred, drop by drop, and on cooling, 0.01 mol of Mn(III) tris(acetylacetonate) in a dry benzene solution, keeping the temperature at 10°C for 30 min. The reaction mixture was stirred at room temperature for another 30 min. The mixture was quickly filtered through a glass filter, and the precipitate was washed with benzene. The filtrate was hydrolysed by cold 1 N hydrochloric acid, and the hydrochloric acid layer was extracted with benzene. After separation, the combined organic layers were dried over sodium sulfate, and the solvent was removed under reduced pressure. The residue was submitted to gas-liquid partition chromatography (glpc). The yield data were obtained by glpc, with *n*-dodecane used as the internal standard. The products were identified by a comparison of their gas chromatograms and IR spectra with those of authentic samples obtained commercially.

The yields of biphenyl listed in Table 1 are freed from t hose formed in the preparation of the Grignard reagents.

ESR Studies of the $(RO)_2PSS$ Radicals in UV-Irradiated *O,O'*-Dialkyl Dithiophosphate Glasses

Mitsuo SATO, Michiyasu YANAGITA, Yuzaburo FUJITA, and Takao KWAN
Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received October 22, 1970)

ESR studies have been reported on γ-irradiated phosphate crystals such as KH_2PO_4, where the formation of the phosphate radical, PO_4^{2-}, was observed, and its electronic nature has been discussed.[1-3] For example, according to Subramanian *et al.*,[3] the phosphate radical showd an isotropic ^{31}P ($I=1/2$) hyperfine splitting in the range of 20—40 gauss, leading one to suggest that 0.6—1.1% spins are localized on the phosphorus 3*s* orbital.

We have investigated the UV-irradiation of *O,O'*-dialkyl dithiophosphate glasses and found that dithiophosphate radical species are formed. The radical showed electronic characteristics quite similar to those of the phosphate radicals, the results will be reported in this note.

Experimental

Four kinds of *O,O'*-dialkyl dithiophosphate $(RO)_2PSSH$, where R is CH_3, C_2H_5, *n*-C_3H_7, or *n*-C_4H_9 were synthesized by the reaction of phosphorus pentasulfide with the corresponding alkyl alcohols; they were purified by subsequent distillation under reduced pressure.

Each sample was placed in a quartz tube, 4 mm id, carefully degassed, and then immersed in a quartz Dewar vessel filled with liquid nitrogen. The sample was then irradiated at the temperature of liquid nitrogen with the light of a low-pressure mercury lamp (Ushio Electric Co. UL-200W). After the irradiation, the sample was transferred, without warming, to a Dewar vessel kept inside the microwave cavity; electron-spin resonance measurements were then made with an X-band spectrometer (JES P-10) operated at 100 kHz field modulation.

Results and Discussion

Upon the UV irradiation of *O,O'*-dialkyl dithiophosphates, the ESR signals of the radical species shown in Fig. 1 were observed, along with that of

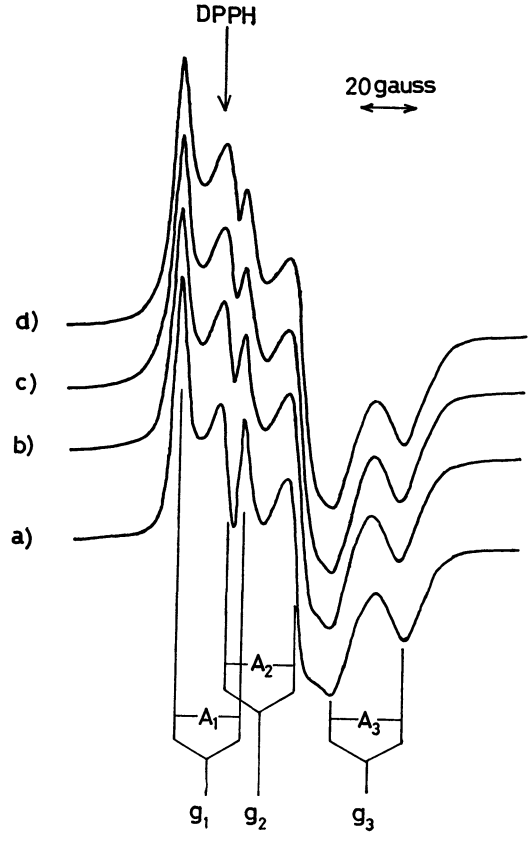

Fig. 1. ESR spectra of dialkyl dithiophosphate radicals. (a) $(CH_3O)_2PSS$, (b) $(C_2H_5O)_2PSS$, (c) $(n\text{-}C_3H_7O)_2$-PSS, (d) $(n\text{-}C_4H_9O)_2$ PSS

hydrogen atoms. The spectra were almost identical for all the compounds employed, and the signal intensities increased with the time during 20 minutes' irradiation with little variation in the line shape. Thus, it can be considered that a very similar sort of radical was produced by the liberation of hydrogen atoms. No other photolytic reactions were detectable at least under our experimental conditions.

In the light of the ESR informations on sulfur radicals[4-7] and on phosphate radicals,[1-3] each spectrum in Fig. 1 can be readily interpreted as due to the $(RO)_2$-PSS radical: a triplet due to the anisotropy in the g factor splits to doublets as a result of the action of three canonical components of a hf tensor. The observed g-values and hf coupling constants are listed in Table 1.

It is shown in Table 1 that the g-values are almost identical for all the compounds within the limits of experimental error, and that the g-value shifts (Δg) from that of a free spin (2.0023) are $\Delta g_1=0.000$, $\Delta g_2=0.013$, and $\Delta g_3=0.038$ for g_1, g_2, and g_3 respectively. Generally speaking, this kind of g-value shift depends upon the magnitude of the spin-orbit coupling of an atom with an unpaired electron and increases rapidly with the atomic number. Also, it depends upon the energy separations between the ground state and excited states of the radical. For example, in carbon radicals, including alkyl and aromatic radicals, the g-value shift is relatively small and usually lies within 0.002. On the contrary, much larger shifts have been observed for sulfur radicals[4-7] ($\Delta g_1=0.001$, $\Delta g_2=0.020$—0.030, $\Delta g_3=0.040$—0.60), and for phosphate radicals,[3] most of which exhibit anisotropy with an axial symmetry ($\Delta g_1=\Delta g_2=0.002$—$0.005$, $\Delta g_3=0.010$—0.050).

The unpaired electron of the dithiophosphate radical may not be involved in the alkyl group, because the observed spectra did not show any hf structure due to protons in the alkyl groups (R), irrespective of the variation in R from the methyl to the n-butyl group. Instead, the hf splitting shown in the spectra may be interpreted most reasonably as that of $^{31}P(I=1/2)$, which is common to all the compounds investigated. The hf coupling constant is almost isotropic, in contrast to the g-factor, and its isotropic component of 25.5 gauss is too small for an unpaired electron to be localized on the phosphorus atom, as will be discussed below.

If the unpaired electron is localized on the oxygen atom, one may expect hf splitting or unresolved hf-line broadening due to the protons in the adjacent alkyl group, as in the case of alkoxy radicals.[8] Since the observed spectra do not show any appreciable change with R, it seems very likely that the unpaired electron is localized mainly on the sulfur atom.

It is assumed that the radical is formed by the scission of the S–H bond and that unpaired electrons are confined mainly on the sulfur atom. The structure of the radical is, then, one with C_{2v} symmetry where two P–S bonds are equivalent, and the orbital for the unpaired electron is a non-bonding $3p(\pi)$-orbital of the sulfur atom with a_2 symmetry.[9]

Although the a_2 orbital of the sulfur atom occupied by the unpaired electron does not give the spin density on the phosphorus atom in the first approximation, it is well known that some spin density arises in the $3s$ orbital of the phosphorus atom *via* the mechanism of spin-polarization[10] or that of configurational interaction of P–S σ-electrons.

The isotropic ^{31}P hf coupling constant (A_p) of 25.5 gauss (72.1 MHz) corresponds to the following spin density (f_{3s}) in the $3s$ orbital of the phosphorus atom:

$$f_{3s}=\frac{A_P}{A_P^\circ}=\frac{72.1\ (\mathrm{MHz})}{10178\ (\mathrm{MHz})}\simeq 0.7\%$$

where A_P° (10178 MHz) is the calculated hf coupling constant for an electron in the phosphorus $3s$ orbital.[11] As is shown above, the calculated spin density, f_{3s}, for the dithiophosphate radical nearly coincides with those for phosphate radicals (0.6—1.1%[3,12]).

The value of f_{3s} may reflect the extent of the spin polarization and the $3s$ character of phosphorus in the P–S σ-orbital.[10] Thus, it may be suggested that the extent of spin-polarization and the $3s$ character of phosphorus are nearly the same in both dithiophosphate and phosphate radicals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1425—1427(1971)

Notiz zur charakteristischen Färbung der mit farblosen Anionen, OH^-, J^- und S^{2-}, beladenen, starkbasischen Anionenaustauscherharze schwacher Eigenfarbe durch Messungen der diffusen Reflexionsspektren[1]

Masatoshi FUJIMOTO und Tadayoshi SUGA*

II. Chemisches Institut der Naturwissenschaftlichen Fakultät der Universität Hokkaido, Sapporo

(Eingegangen am 22. Oktober 1970)

Im Anschluß an die Harztüpfelmethode[2] beobachteten wir häufig charakteristische Färbung, die die starkbasischen Anionenaustauscherharze schwacher Eigenfarbe auch beim Beladen der farblosen anorganischen Anionen wie Hydroxid-, Jodid- oder Sulfidionen annehmen. Die sind nämlich schmutziger Ocker bzw. Hellbraun an der Hydroxidform, Zitronengelb bzw. Hellgelb an der Jodidform und Grünlichhellgelb bzw. Hellgrün mit Stich ins Dunkelblau an der Sulfidform.[3] Aus dem Interesse für äußerliche Ähnlichkeit zwischen den Farbtonen betreffender Harzphase und denjenigen schwerlöslicher Salze entsprechender Anionen mit den sog. weichen Säuren wie Silber(I), Quecksilber(II) sowie Blei(II) usw. vermuteten wir zuerst unbekannte besondere Wechselwirkungen zwischen hydrophoben Haftgruppen und stark polarisierbaren Gegenanionen in der äußerst hochkonzentrierten Ionenatmosphäre an gequollener Polyelektrolytphase. Diese Vermutung wurden doch durch Messungen der diffusen Reflexionsspektren der Harzphase fast ausgeschlossen, und dadurch kommt eine andere unerwartete und wichtige Tatsache in Rede, die beim dauernden Anwenden der Anionenaustauscherharze auf die Harztüpfelmethode immer in Betracht zu ziehen ist, worauf wir unten zurückkommen.

Experimentelles

Es wurden die folgenden handelsüblichen kugelförmigen Anionenaustauscherharze auf Styrolbasis geprüft: Dowex 1 (X1～X16), Dowex 2 (X1～X8), Diaion SA ♯100 (analytischer Grad, mittelmäßig vernetzt), Diaion PA (304～320 sowie 404～420). Dielet zten zwei sind sog. Popcorn-Harze[4] verschiedener Vernetzungsgrade aber fast unverändert weitmaschiger schwammartiger Struktur und besonders weiß an Untergrundfarbe (vgl. dazu Abb. 1). Die Harze wurden vor Gebrauch zweimal mit 0.5 M Salzsäure, 2 M Natronlauge und daran anschließend mit 2 M und 0.5 M Salzsäure[5] nacheinander umbeladen bis zur Abwesenheit der Spuren Eisen(III)-ionen im Ablauf, mit entionisiertem Wasser völlig ausgewaschen und luftgetrocknet. Die so behandelten Harze wurden beim Versuch erneut über Hydroxid- oder Chloridform in die genannte Form umbeladen (s.u.). In Tabelle 1 steht der Aschengehalt an einigen der angewendeten Harzproben in der Chloridform, zusammen mit dem der nicht raffinierten käuflichen Harzproben.

TABELLE 1. ASCHENGEHALT AN EINIGEN DER BENUTZTEN ANIONENAUSTAUSCHERHARZE (mg Asche als Oxide, bezogen auf 1 g lufttrockenes Harz in der Cl-Form)

Harz	nicht raffinierte käufliche Probe	völlig raffinierte Harzprobe
Dowex 1-X10	— (—)	0.2_7 (bräunlich)
Diaion PA-310	0.3_0 (dunkelgrün)	0.0_0 (bräunlich?)
Diaion PA-410	0.6_0 (bräunlich)	0.0_4 (braunlich)

Zur Herstellung der Meßproben des Harzes wurde immer die frisch hergestellte wäßrige Lösung des p.a.-Reagens benutzt, damit unerwünschte Verunreinigung streng auszuschalten ist. Der Schwefelwasserstoff wurde aus Eisensulfid und dest. Salzsäure hergestellt. Das entwickelte Gas wurde zur Entfernung eventuell spurenweise vorhandenen Staubs durch zwei Waschflasche mit entionisiertem Wasser nacheinander geleitet, und dann ins entionisierte Wasser geleitet. Die so frisch hergestellte Lösung des Schwefelwasserstoffs wurde sogleich zur Umbeladung des Harzes verwendet. Das handelsübliche Natriumsulfid, in dem sich beim Aufbewahren etwas intensiv gelbe Polysulfide bildeten, wurde angewendet entweder ohne weitere Reinigung oder nach dem Durchlaufen der wäßrigen Lösung durch Anionenaustauschersäule bis zur Entfärbung; die gelben Polysulfidionen wurden am oberen Teile der Säule sicher und leicht beseitigt.

Zur Messung der Reflexionsspektren wurde das Hitachi-Registrierende Spektralphotometer EPS-3T mit Quarzoptik und Remissionsansatz R-10 benutzt. Zur Vorbereitung der Meßproben wurde etwa 1 g frisch umbeladener Anionenaustauscher durch ein quantitatives Filterscheibchen abfiltriert, dreimal mit je 1 m*l* entionisiertem Wasser gewaschen und im Dunkeln stehengelassen. Die fast getrockneten Proben wurden in den etwa 3 mm tiefen und mit Quarzscheibe versehenen Probenteller eingefüllt und glatt gewalzt und gegen das gleich behandelte Harz in der Chloridform gemessen, um eventuelle reguläre Reflexionsanteil auszuschalten.[6] Bei der Sulfidform wurde die frisch hergestellte Meßprobe gleich nach kurzem Absaugen in den Meßteller fest einge-

spektren der genannten Harze in der Sulfid-, Jodid- und Hydroxidform wiedergegeben. Dabei zur Deutung der Meßdaten ist der Einfluß der unterschiedlichen Quellung an den völlig umbeladenen Harzproben auf den Streukoeffizienten der Kügelchen nicht gefährlich, obwohl er nicht so vollständig auszuschalten ist, daß man die typische Farbkurve einwandfrei zeichnen könnte. In Abb. 3 stehen die zum Vergleich gemessenen typischen Farbkurven der zermahlten Kriställchen der schwerlöslichen Jodide besonders charakteristischer Farbe, die jedoch ganz anders sind als diejenigen der Harzproben in der Jodidform.

Die bei der Jodidform sogar mit reinstem Kaliumjodid immer deutlich hervorgerufenen gelblichen Farben an Harzphase sind aber durch Zusatz von Natriumsulfit langsam verschwunden. Überdies deutet die bedeutende Ähnlichkeit der betreffenden Farbkurve mit der Absorptionskurve der wäßrigen Trijodidionen wie in Abb. 2C ursprüngliche Anwesenheit der Spuren etwaiger Oxidationsmittel in der völlig raffinierten Harzphase an. Weitere Beweise dafür werden dadurch geführt, daß die aus dem Schwefelwasserstoff und ROH[7] sowie aus der durch Harzsäule farblos gereinigten Natriumsulfidlösung und RCl[7] sorgfältig hergestellten Harzproben auch, sehr langsam aber nach lang dauerndem Durchlauf der Lösung immer mehr oder weniger dunkelgrünliche Farbe annehmend, mindestens ein deutliches Maximum bei etwa 630 nm und manchmal zusätzliche Maxima bzw. Schulter bei 530 und etwa 440 nm zeigen. Diese drei Maxima bei 630, 530 und 440 nm entsprechen also genau den Absorptionsmaxima der grünen alkalischen Lösung aus Eisen(II)- bzw. Eisen(III)-ionen und überschüssigen Sulfidionen wie in Abb. 4.[8] Aus der bei den Harztüpfelnachweisen berichteten Erfassungsgrenze für Eisen(III)[9,10] schätzen wir den Höchstgehalt an Eisen in ein paar Körnchen des starkbasischen Anionenaustauschers wie Dowex 1 auf wesentlich weniger als 1 ng ab.[11] Daß das genannte Absorptionsmaximum bei etwa 630 nm auch bei sorgfältig raffinierten Harzproben so deutlich wie in

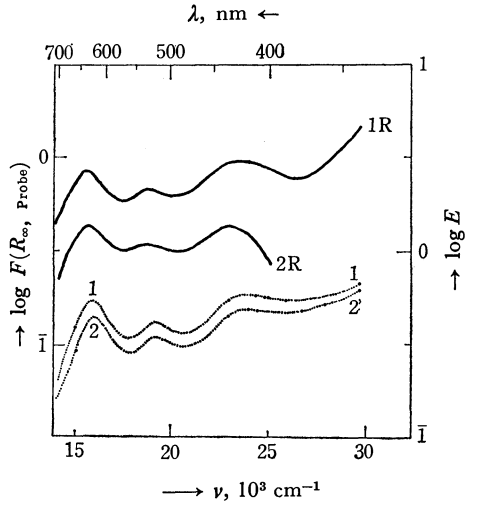

Abb. 4. Typische Farbkurven der an Anionenaustauscher angereicherten grünen Komplexe aus Eisensalzen und Natriumsulfide, gegenübergestellt mit Durchsichtspektren. Kurve 1: Durchsichtspektrum der dunkelgrünen Lsg. aus Mohrschem Salze, und Na_2S (pH=11.60) und Kurve 2: dasjenige aus Ammoniumeisenalaun und Na_2S (pH=11.72) [Beide Lsgg. enthalten $[Fe]_{total}=1.5\times10^{-4}$ M und $[S]_{total}=4\times10^{-3}$ M]. Die Kurven 1R und 2R: typische Farbkurven der an Dowex 1-X10 angereicherten grünen Komplexe 1 und 2 [1.00 g RCl+5 m*l* Lsg.-1 od. 2].

der Kurve 2a der Abb. 2B erkennbar ist, weist uns ursprüngliche Anwesenheit der Spuren des dreiwertigen Eisens selbst in den völlig gereinigten Harzproben.

Die dauerhaft grünen Komplexe, die sich aus Überschuß von Sulfidionen und Eisen(II) oder Eisen(III) in der alkalischen wäßrigen Lösung bilden, lassen sich an Anionenaustauscherharze in der Chloridform schnell anreichern und färben die Harzphase gleichmäßig schwach smaragdgrün bzw. grünlichocker (vgl. Abb. 4). Die werden an Kationenaustauscher in der Natriumform gar nicht angereichert. Die grünliche Farbe an Anionenaustauscher ist aber bei niedrigerer Konzentration an Sulfidionen luftempfindlich. Die klingt beim Trocknen an der Luft ziemlich schnell ab.

Wir haben aus den Messungen der diffusen Reflexionsspektren der Harzproben festgestellt die ursprüngliche Anwesenheit der Spuren Eisens und zwar des Eisens-(III) selbst in sehr sorgfältig raffinierten Anionenaustauschern. Diese Tatsache muß man daher beim Anwenden genannter Anionenaustauscher zu genauen Messungen oder auf die Harztüpfelanalyse besonders bei allzu langem Aufbewahren der Harzkügelchen in der Versuchslösung wie 24 Std immer sehr vorsichtig in Betracht ziehen.

7) RX bedeutet den Anionenaustauscher in der X-Form.

8) Unabhängig davon wurde eine Anwendung der genannten Absorption auf die Bestimmung geringer Menge des Eisens berichtet; vgl. dazu T. Fukazawa, M. Iwatsuki and H. Asakawa, Vortrag Nr. 20442 der 23. Hauptversammlung der Japanischen Chemischen Gesellschaft in Tokio, 4. April 1970.

11) Der so hoch abgeschätzte höchste Eisengehalt wie 1 ng in 10 Kügelchen der 200 mesh (etwa 70 μm Durchmesser) gequollenen Harze entspricht etwa 0.5 mg Eisen pro Gramm Harz.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1428—1429(1971)

The NMR Spectra of Several *N*-(2-Biphenylyl)carboxamides

Mamoru Ohashi, Kazuo Tsujimoto, Akira Yoshino, and Teijiro Yonezawa
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto
(Received October 24, 1970)

During the course of an investigation of the structures of the photochemical decomposition products of several 1-acylbenzotriazoles,[1] it was discovered that the NMR spectrum of *N*-(2-biphenylyl)-pivalamide exhibited two signals farther downfield than usual aromatic protons. In connection with this finding, we examined the NMR spectra of several *N*-(2-biphenylyl) carboxamides and found that the two peaks were observed for all the spectra so far studied.

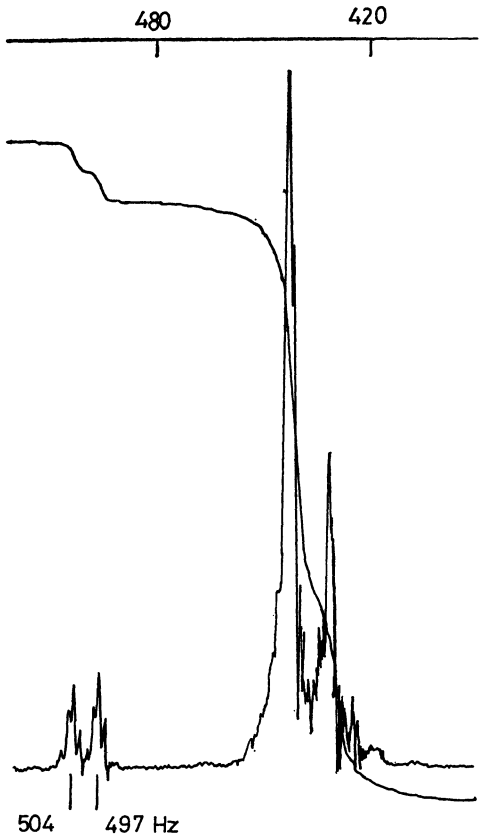

Fig. 1. The partial 60 MHz NMR spectrum of *N*-(2-biphenylyl)-pivalamide ($CDCl_3$) at room temperature.

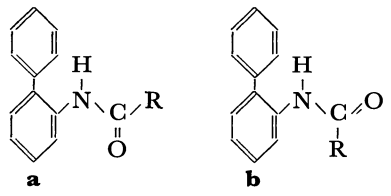
Figure 1 shows the lower region of the spectrum of *N*-(2-biphenylyl)pivalamide. The two signals at 497 and 504 Hz from TMS at 60 MHz seemed assignable to the protons on the nitrogen atom of two geometrical isomers, **Ia** and **Ib**; this is in accord with the well-documented hindered rotation of amides.[2] Similar signals were also observed in the spectra of *N*-(2-biphenylyl) benzamide (II, 508 and 515 Hz) and *N*-(2-biphenylyl) acetamide (III, 490 and 497 Hz).



I R=C(CH$_3$)
II R=ph
III R=CH$_3$

Two conformations, **a** and **b**, were conceivable for the amide[2] from the viewpoint of steric factors, and the relative intensity of the two signals might reflect the relative abundance of the isomers (1:1). When the spectrum of I was measured in dimethyl sulfoxide-d_6, the two signals collapsed to a broad singlet which appeared at 519 Hz. This seemed to indicate that, in dimethyl sulfoxide, one of the two conformers became predominant and a strong hydrogen bonding between N–H and the solvent made the N–H signals deshielded.

On the other hand, no temperature dependence was observed for the spectrum of I in carbon tetrachloride in the range from room temperature to 150°C. Furthermore, the 220 MHz NMR spectrum of I (Fig. 2) exhibited the same intervals between the two signals as in the case of 60 MHz, suggesting that the two signals are caused by coupling. These phenomena were, however, inconsistent with the aforementioned assumption. Therefore, we carried out a decoupling experiment in order to clarify the cause of the two signals. When the aromatic protons at 435 Hz were irradiated, the two signals collapsed to singlet peak. Similarly, the shape of signals of aromatic protons markedly changed on irradiation at the center of the signals. These facts clearly demonstrated that the lowfield proton couples with the aromatic protons, the coupling constant being 7.2 Hz. Although a great number of works on long-range coupling, including a favourable coupling path in a planar zig-zag arrangement,[3] have been reported, only a few reports have been concerned with couplings between the proton on the nitrogen atom and the other protons across more than four bonds.[3-5] However, such a large coupling constant as 7.2 Hz has never been reported.

The presence of a five-bond coupling to the N–H proton seemed so unlikely that we looked for other explanations. One possibility was that the signals at

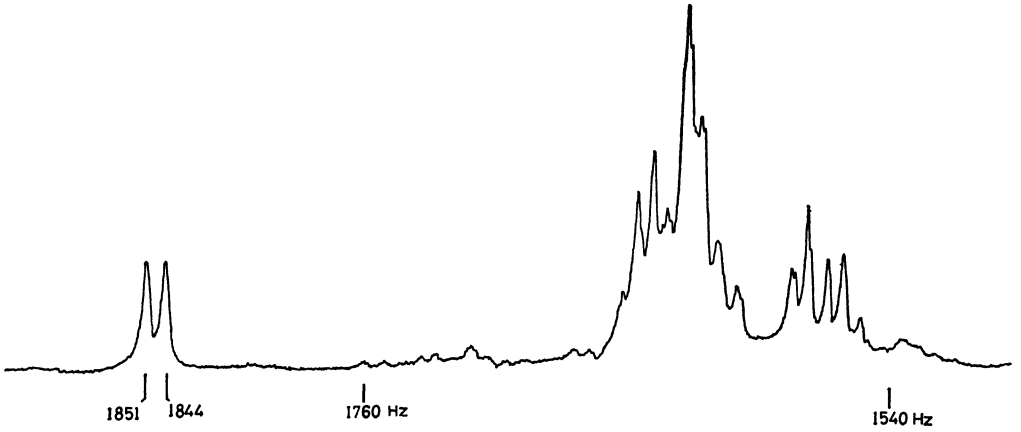

Fig. 2. The partial 220 MHz NMR spectrum of *N*-(2-biphenylyl)-pivalamide ($CDCl_3$) at room temperature.

497 and 504 Hz were due to one of the aromatic protons. In order to clarify this point, deuterium exchange was carried out. The sample recrystallized from methanol-d_4 - deuterium oxide showed a strong N–D absorption at 2400cm^{-1} in its IR spectrum; its NMR spectrum exhibited the two unchanged signals at the same positions, but the shapes of the signals of the usual aromatic protons changed markedly. This result indicated that the N–H proton which was obscured by the intense signals of the aromatic protons and that the two distinct signals at the downfield is probably due to an aromatic proton.

Since neither *N*-phenylbenzamide nor *N*-(4-biphenylyl)-carboxamides shows such spectral features, steric factors in *N*-(2-biphenylyl) carboxamides must be responsible for this remarkable deshielding effect.

On the basis of the aforementioned facts, it was deduced that the pivaloylamino group must lay on the same plane as that of the phenyl ring and that the anisotropy of the carbonyl group[6] might cause such a big deshielding effect on the proton at the ortho position to the amino group.[7] Steric effects and intramolecular π-NH hydrogen bonding were conceivable as factors fixing the conformation of the amino group as **a** in the scheme.

The spectrum of II was measured in a $CDCl_3$ solution to which a few drops of dimethyl sulfoxide has been added. The spectrum's two signals and the N–H signal moved up- and down-field respectively. Finally, the spectrum measured in dimethyl sulfoxide did not exhibit the two signals, but showed a broad singlet at 595 Hz which disappeared on deuterium exchange. These phenomena can be explained on the basis of the aforementioned conclusion; that is, the strong hydrogen bonding between the solvent and N–H proton would destroy the coplanarity of the carbonyl group, and hence the negative anisotropy effect on the ortho-proton would disappear to give the signals in the usual aromatic region.

Experimental

All the melting points are uncorrected. The NMR spectra were measured on JEOL JNM-3H60 or Varian HR 220-MHz spectromerters in a ca. 20% solution in either chloroform-*d* ($CDCl_3$) or dimethyl sulfoxide-d_6, with TMS as the internal standard.

N-(2-Biphenylyl)pivalamide (I). A solution of pivaloyl chloride (3.0 g) in methylene chloride (30 m*l*) was stirred, drop by drop, into a solution of *o*-biphenylamine (4.2 g) in methylene chloride (20 m*l*) and cooling with ice-water. To the reaction mixture we then added a solution of triethylamine (3.0 m*l*) in methylene chloride, after which the mixture was stirred for half an hour at room temperature. The mixture containing precipitates was washed with water (100 m*l*) three times and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent gave *N*-(2-biphenylyl) pivalamide (3 g). After recrystalization from ethanol, it had a mp of 69.7—70.1°C.

Found: C, 80.45; H, 7.44; N, 5.61%. Calcd for $C_{17}H_{19}ON$: C, 80.57; H, 7.56; N, 5.53%.

IR(KBr) 3260(NH), 1640(C=O), 770, 740, 700 cm^{-1} (benzene ring)

N-(2-Biphenylyl)benzamide(II) and N-(2-Biphenylyl)acetamide(III). The same experimental technique was used as that reported for *N*-(2-biphenylyl)pivalamide. The identification was made by a comparison of IR spectra of these products with the standard IRDC cards.[10]

N-(2-biphenylyl)benzamide mp 86.7—87.0°C (lit, 85—86°C).[8]

N-(2-biphenylyl)acetamide mp 116°C (lit, 117°C.)[9]

The authors wish to express their hearty thank to Dr. Isao Morishima for his helpful discussions and encouragement.

Electron-accepting Properties of 2,3-Dicyano-1,4-benzoquinone and 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received November 11, 1970)

Various methods are available for determining the electron affinities of electron-acceptor molecules.[1] The 7,7,8,8-tetracyanoquinodimethane (TCNQ), 2,3-dicyano-1,4-benzoquinone (p-H_2QCy_2), and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (p-Cl_2QCy_2) molecules are known to be strong electron acceptors and to form stable anion radical salts with some diamagnetic counter cations.

Several years ago, we reported on the preferred electron transfer reaction between anion radicals in solution.[2] When p-X_2QCy_2, (X=H or Cl), was added to an acetonitrile solution of the sodium salt of the TCNQ anion radical, the oxidation-reduction reaction was found to take place simply through a one-electron transfer from the TCNQ anion radical to p-X_2QCy_2. This reaction was expressed by the following oxidation-reduction equilibrium:

$$Na^+TCNQ^- + p\text{-}X_2QCy_2 \rightleftharpoons TCNQ + Na^+p\text{-}X_2QCy_2^-, \quad (1)$$

where X=H or Cl. The equilibrium constant in acetonitrile at 20±1°C was determined spectroscopically as $K=30$ for the case of X=H, while it was $K \geq 2\times10^3$ for the case of X=Cl. As for this oxidation-reduction equilibrium, the observed equilibrium constant at temperature, T, is expressed as:

$$-RT\ln K = E(TCNQ) - E(p\text{-}X_2QCy_2) + \Delta\Delta G^0_{solv}(TCNQ, TCNQ^-) - \Delta\Delta G^0_{solv}(p\text{-}X_2QCy_2, p\text{-}X_2QCy_2^-), \quad (2)$$

where E(A) is the electron affinity of the neutral A molecule and $\Delta\Delta G^0_{solv}$(A,A$^-$), the difference in the free energy of solvation between the molecule and its anion radical. Therefore, if one assumes $\Delta\Delta G^0_{solv}$(TCNQ, TCNQ$^-$)$\approx\Delta\Delta G^0_{solv}$($p$-$X_2QCy_2$, p-$X_2QCy_2^-$), one can obtain:

$$-RT\ln K = E(TCNQ) - E(p\text{-}X_2QCy_2). \quad (3)$$

From the observed values of K, the difference in the electron affinities between TCNQ and p-H_2QCy_2 was estimated to be $E(p\text{-}H_2QCy_2)-E(TCNQ)=0.09$ eV, while that between TCNQ and p-Cl_2QCy_2 was $E(p\text{-}Cl_2QCy_2)-E(TCNQ)\geq0.19$ eV.

On the other hand, TCNQ, p-H_2QCy_2, and p-Cl_2QCy_2 form charge-transfer complexes with many electron donor molecules in solution. It has been known, in general, that the energy of the charge-transfer band of a molecular complex, $h\nu_{CT}$ (D,A), can be described as:

$$h\nu_{CT}(D, A) = I(D) - E(A) - C + P, \quad (4)$$

where I(D) is the ionization potential of the donor, D, and E(A), the electron affinity of the acceptor, A; C is the coulombic energy of the dative-bond structure, and P is the difference between all the other energy quantities in the dative-bond and no-bond structures with both partners at their equilibrium internuclear separation in the complex.[3] This relation has often been used for the estimation of the electron affinity.[1] In the present paper, the difference in the electron affinities, $E(p\text{-}X_2QCy_2)-E$(TCNQ), where X=H or Cl, was estimated from the difference in the charge-transfer energies between $h\nu_{CT}$ (D, p-X_2QCy_2) and $h\nu_{CT}$ (D, TCNQ). We shall examine how these values of $E(p\text{-}X_2QCy_2)-E$(TCNQ) correspond to those evaluated previously from the oxidation-reduction equilibria.

The charge-transfer complexes of TCNQ, p-H_2QCy_2, and p-Cl_2QCy_2 were examined in an ethylene dichloride solution. Various aromatic hydrocarbons were employed as the electron donors. The charge-transfer spectra were measured by means of a Beckman DK-2A spectrophotometer. Table 1 shows the observed maximum positions of the charge-transfer absorptions under investigation.[4]

As for the complexes containing TCNQ, p-H_2QCy_2, or p-Cl_2QCy_2 as an acceptor, the I(D) value is constant for a common donor. In these cases, the great variation will occur in E(A). It is assumed that the other quantities are more or less constant, since the molecular sizes and the shapes of the acceptors are all similar. In this case, the energy difference of the charge-transfer bands, $h\nu_{CT}$ (D, TCNQ)–$h\nu_{CT}$ (D, p-X_2QCy_2), where X=H or Cl, can be approximately written as:

$$h\nu_{CT}(D, TCNQ) - h\nu_{CT}(D, p\text{-}X_2QCy_2) = E(p\text{-}X_2QCy_2) - E(TCNQ). \quad (5)$$

2) Y. Iida and H. Akamatu, This Bulletin, **40**, 231 (1967).

3) S. P. McGlynn, *Chem. Rev.*, **58**, 1113 (1958); G. Briegleb, "Elektronen-Donator-Acceptor Komplexe," Springer-Verlag, Berlin-Göttingen-Heidelberg (1961).

4) Two charge-transfer bands were observed for the complex containing naphthalene, 2,3-dimethylnaphthalene, acenaphthene or pyrene as a donor, and p-H_2QCy_2 or p-Cl_2QCy_2 as an acceptor. We can see that the energy difference of the complex between the first and the second charge-transfer bands remains nearly constant for a given donor; the value of this energy difference was found to be $(5.05\pm0.15)\times10^3$ cm^{-1} for the naphthalene complexes, $(3.95\pm0.05)\times10^3$ cm^{-1} for the 2,3-dimethylnaphthalene complexes, $(7.45\pm0.05)\times10^3$ cm^{-1} for the acenaphthene complexes, and $(6.75\pm0.15)\times10^3$ cm^{-1} for the pyrene complexes. This means that these two charge-transfer bands can be attributed to the transitions from the highest and the next occupied orbitals of the donor to the lowest vacant orbital of the acceptor. The energy difference between the highest and the next occupied orbitals of the donor is approximated by that between the first and the second charge-transfer bands. See, for example, H. Kuroda, T. Kunii, S. Hiroma, and H. Akamatu, *J. Mol. Spectrosc.*, **22**, 60 (1967).

Table 1. The data on the maximum positions of the charge-transfer bands (in unit of 10^3 cm^{-1})[a)]

Donor	Acceptor		
	TCNQ	p-H_2QCy_2	p-Cl_2QCy_2
Benzene	—	25.9	24.2
Toluene	—	24.1	22.5
p-Xylene	—	21.1	19.4
Naphthalene	18.6	17.9	15.9
		22.8	21.1
2,3-Dimethylnaphthalene	17.0	16.8	14.7
		20.7	18.7
Acenaphthene	15.4	14.9	13.2
		22.4	20.6
Phenanthrene	19.5	19.0	17.1
Pyrene	13.7	13.7	11.8
		20.6	18.4

a) They were measured in ethylene dichloride solution at room temperature, although benzene, toluene, or p-xylene was used as a solvent as well as a donor.

When the complexes showed two charge-transfer absorptions, the maximum positions of the first charge-transfer bands were employed for $h\nu_{CT}$(D, A). Unfortunately, the maximum positions for the complexes of TCNQ with benzene, toluene, and p-xylene were not determined, because the absorption due to TCNQ hindered the observation of their charge-transfer bands. Therefore, the data on the charge-transfer bands for the complexes of p-H_2QCy_2 or p-Cl_2QCy_2 with the same donor molecules were not available for comparison. We used, then, the values of $h\nu_{CT}$(D, A), where D is naphthalene, 2,3-dimethylnaphthalene, acenaphthene, phenanthrene, or pyrene, and where A is TCNQ, p-H_2QCy_2, or p-Cl_2QCy_2. These values were taken from Table 1. By the use of Eq. (5), $E(p\text{-}X_2QCy_2)-E$(TCNQ), where X=H or Cl, was evaluated for each common donor. For the above five donors, the average value of $E(p\text{-}H_2QCy_2)-E$(TCNQ) was estimated to be $(0.4\pm0.4)\times10^3$ cm^{-1} (*i.e.*, 0.05 ± 0.05eV), while that of $E(p\text{-}Cl_2QCy_2)-E$(TCNQ) was estimated to be $(2.3\pm0.4)\times10^3$ cm^{-1} (*i.e.*, 0.29 ± 0.05 eV). If the standard value is once given to the electron affinity for TCNQ, $E(p\text{-}H_2QCy_2)$ and $E(p\text{-}Cl_2QCy_2)$ will be determined from these relations. When E(TCNQ) $=1.7$ eV is taken as a reference,[5)] $E(p\text{-}H_2QCy_2)$ and $E(p\text{-}Cl_2QCy_2)$ are estimated to be 1.75 ± 0.05 eV and 1.99 ± 0.05 eV respectively. These values are found to be in good accordance with $E(p\text{-}H_2QCy_2)=1.79$ eV and $E(p\text{-}lC_2QCy_2)\geq1.89$ eV respectively; these latter values were determined from the method of the oxidation-reduction equilibrium between the anion radicals by using the same standard value of E(TCNQ)$=1.7$ eV.[2)] It is interesting to note that the introduction of the chlorine substituents into p-H_2QCy_2 increases the value of the electron affinity by at least 0.1—0.2 eV.

Judging from these results, the previous estimation of the $E(p\text{-}H_2QCy_2)$ and $E(p\text{-}Cl_2QCy_2)$ values from the method of oxidation-reduction equilibrium is strongly supported by the present method of the charge-transfer spectra. Therefore, it may be concluded that the application of the oxidation-reduction equilibrium between anion radicals in solution is a new method for determining the electron affinities of acceptor molecules generally. However, we should keep in mind that, in this method, the E(A) values include some uncertainties, since the $\Delta\Delta G^0_{solv}$(A, A^-) value does not remain constant for each of the acceptor molecules.

5) Although Briegleb reported E(TCNQ)$=1.7$ eV,[1)] no definite value has yet been determined for E(TCNQ).

The Novel Synthesis of Halodeoxy Sugars

Saburo INOKAWA, Kuniaki SEO,* Hiroshi YOSHIDA, and Tsuyoshi OGATA

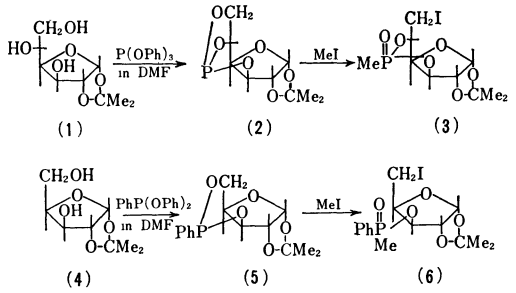
Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

**Department of Applied Chemistry, College of Technology, Ooka, Numazu*

(Received December 3, 1970)

The halodeoxy sugars are important synthetic intermediates,[1] but their preparation is often an involved process. This paper will describe a facile method for the formation of halodeoxy sugars by the reaction of cyclic phosphite or phosphonite derivatives of sugars with methyl iodide. The usefulness of this reaction is demonstrated by the conversion of 1,2-*O*-isopropylidene-α-D-glucofuranose (**1**) into 6-deoxy-6-iodo-1,2-*O*-isopropylidene-3,5-*O*-(methylphosphonate)-α-D-glucofuranose (**3**) *via* the intermediate 1,2-*O*-isopropylidene-3,5,6-*O*-(phosphite)-α-D-glucofuranose (**2**). No evidence for the presence of another iodo isomer was obtained. To explore the scope of this facile reaction, 5-deoxy-5-iodo-3-*O*-(methylphenylphosphinate)-α-D-xylofuranose (**6**) was prepared *via* the 1,2-*O*-isopropylidene-3,5-(phenylphosphonite)-α-D-xylofuranose (**5**) from 1,2-*O*-isopropylidene-α-D-xylofuranose (**4**). The structures of the products were determined by studying the NMR spectra and by elementary analyses.

1) For reviews of halodeoxy sugars see: a) S. Hanessian, *Advan. Carbohyd. Chem.*, **21**, 142 (1966); b) J.E.G. Barnett, *ibid.*, **22**, 177 (1967).



Experimental

The nuclear magnetic resonance spectra were taken at 60 MHz on a Hitachi-Perkin-Elmer R-20 spectrometer, using tetramethylsilane as the internal reference. The thin-layer chromatograms were run on a silica-layer G;[2] phosphorus compounds were detected by spraying the plates with a cobalt chloride solution[3] and by then heating them. Periodic sampling and examination by thin-layer chromatography (tlc) permitted the determination of the most suitable reaction conditions for the preparation runs.

Materials. The 1,2-*O*-isopropylidene-α-D-glucofuranose (**1**)[4] and 1,2-*O*-isopropylidene-α-D-xylofuranose (**4**)[5] were prepared in the usual way. The triphenyl phosphite was used after the vacuum distillation of a commercial substance. The diphenyl phenylphosphonite[6] (bp 174—176°C/2 mmHg) was prepared by the reaction of an excess of phenol and phenylphosphonous dichloride.[7]

1,2-O-Isopropylidene-3,5,6-O-(phosphite)-α-D-glucofuranose (2). A solution of 5.0 g of **1** and 8.0 g of triphenyl phosphite in 30 m*l* of dimethylformamide (DMF) with 0.1 g of sodium ethoxide was allowed to stand at room temperature for 15 hr. The solution was then concentrated *in vacuo*; the residue was sublimated twice *in vacuo* at 120°C/2 mmHg to give, in an 80% yield (4.5 g), colorless needles; mp 155°C; $[\alpha]_D^{25}$ −24.3° (*c* 10, DMF); tlc upper (petroleum ether - ethyl acetate 4:1).

Found: C, 43.2; H, 5.25%. Calcd for $C_9H_{13}O_6P$: C, 43.6; H, 5.28%.

The PMR data (chloroform-*d*) were as follows: τ 3.88 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.47 (one-proton doublet, $J_{2,3}\fallingdotseq 0$ Hz, H_2), 5.6—6.2 (four-proton multiplets, $H_{3,4,5,6}$), and 8.54, 8.71 [six-proton singlets, $C(CH_3)_2$].

6-Deoxy-6-iodo-1,2-O-isopropylidene-3,5-O-(methylphosphonate) α-D-glucofuranose (3). A solution of 2 g of **2** in 15 m*l* of methyl iodide, with a small amount of copper powder, was heated at 100°C for 20 hr in a sealed tube. The solution was then filtered and concentrated *in vacuo*; the residue was dissolved in chloroform, washed with a sodium carbonate aqueous solution and water, dried over sodium sulfate, and concentrated *in vacuo* to give, in an 80% yield (2.5 g), colorless needles; mp 176—177°C (from methanol); $[\alpha]_D^{25}$ +15.2° (*c* 10, chloroform); tlc medium (petroleum ether - ethyl acetate, 4:1).

Found: C, 30.8: H, 4.17%. Calcd for $C_{10}H_{16}O_6PI$: C, 30.8; H, 4.13%.

The PMR data (chloroform-*d*) were as follows: τ 4.00 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.09 (one-proton multiplet, H_3), 5.33 (one-proton doublet, $J_{2,3}\fallingdotseq 0$ Hz, H_2), 5.5—5.9 (two-proton multiplets, $H_{4,5}$), 6.45 (two-proton doublet, $J_{5,6}$=7.0 Hz, H_6), 8.40 (three-proton doublet, $J_{P,CH}$=18.0 Hz, P-CH_3), and 8.49, 8.66 [six-proton singlets, $C(CH_3)_2$].

5-Deoxy-5-iodo-3-O-(methylphenylphosphinate)-α-D-xylofuranose (6). A solution of 7 g of **4** and 12 g of diphenyl phenylphosphonite in 40 m*l* of DMF with 0.1 g of sodium ethoxide was allowed to stand at room temperature for 20 hr. The solution was then concentrated *in vacuo*, and the resulting oil was fractionally distilled *in vacuo* to give 4.0 g of crude **5** contaminated with small amounts of phenol and diphenyl phenylphosphonite at 160—162°C/2mmHg; tlc medium (petroleum ether-ethyl acetate, 9:1). The crude **5** obtained above, without further purification, was dissolved in 15 m*l* of methyl iodide; then solution was heated with a small amount of copper powder at 100°C for 4 hr in a sealed tube. The solution was then filtered and concentrated *in vacuo*. Fractional high-vacuum distillation gave, in a 20% yield (3.1 g) based on **4**, a thick colorless sirup at 120°C/10^{-2}—10^{-3} mmHg; $[\alpha]_D^{20}$=−23° (*c* 3.04, carbon tetrachloride); tlc upper (petroleum ether - ethyl acetate, 1:4).

Found: C, 41.3; H, 4.65%. Calcd for $C_{15}H_{20}O_5PI$: C, 41.1; H, 4.60%.

The PMR data (carbon tetrachloride) were as follows: τ 2.0—2.8 (five-proton multiplets, C_6H_5), 4.25 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.20 (one-proton d. doublet, $J_{2,3}\fallingdotseq$O Hz, $J_{3,4}$=2.0 Hz. $J_{P,CH}$=9.0 Hz, H_3), 5.42 (one-proton doublet, H_2), 5.65 (one-proton broad doublet, H_4), 6.81 (two-proton doublet, $J_{4,5}$=7.0 Hz, H_5), 8.26 (three-proton doublet, $J_{P,CH}$=14.5 Hz, P-CH_3), and 8.60, 8.83 [six-proton singlets, $C(CH_3)_2$].

Results and Discussion

When a solution of **1** and triphenyl phosphite (1:1.2 molar ratio) in DMF was allowed to stand in the presence of sodium ethoxide at room temperature, **1** was transformed almost quantitatively into the product, **2**, as the tlc showed one major spot. When the solution was evaporated *in vacuo*, the sublimation of the resulting residue gave colorless needles in an 80% yield. The structure of **2** was established by elementary analysis and by studying the NMR spectrum.

The treatment of **2** with methyl iodide in a sealed tube at 100°C afforded **3** as colorless needles (from methanol) in an 80% yield. The structure of **3** was established by elementary analysis and by a study of the NMR spectrum. The appearance of the two-proton doublet at τ 6.45, shifted from 5.6—6.2 in the NMR spectrum of **1**, shows that **3** is a 6-deoxy-6-iodo compound, while the appearance of the three-proton doublet with a large coupling constant (J=18.0 Hz) at τ 8.40 shows that a CH_3 group is bonded to the phosphorus atom.

Similarly, the compound **6** was prepared by the reaction of **4** and diphenyl phenylphosphonite, followed by treatment with methyl iodide, in a poor yield (20%). Although the tlc showed that the reaction was rather clear, the poor yield seems to be due to difficulty in separation by fractional distillation.

This reaction may be effected to provide convenient and widely-usable route to halodeoxy sugars.

The X-Ray Powder Diffraction Pattern of Tetrasulfur Tetranitride

Shuichi HAMADA, Akira TAKANASHI, and Toshiaki SHIRAI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received December 11, 1970)

Tetrasulfur tetranitride, S_4N_4, is an eight-membered ring molecule, one which involves four coplanar nitrogen atoms. The molecular symmetry and the crystal system of tetrasulfur tetranitride have been reported to be $\bar{4}2\,m(D_{2d})$[1] and monoclinic[2-4] respectively. On the basis of an X-ray analysis on the single crystal, Clark[5] verified the unit cell dimensions and the space group reported by Buerger[4] to be as follows: $a_0=8.75$, $b_0=7.16$, $c_0=8.65$ Å, $\beta=92.5°$, and space group, $P2_1/n(C_{2h}^5)$. However, studies of X-ray powder diffractometry on tetrasulfur tetranitride have been reported only by Garcia-Fernandez,[6,7] and the Miller indices were not assigned in his reports.

In this work, a reexamination and an assignment of the Miller indices on the X-ray powder diffraction peaks will be attempted.

Experimental

Materials. The tetrasulfur tetranitride was prepared by the method reported by Villena-Blanco and Jolly.[8] A crude product was extracted with dry dioxane. When the dioxane solution was cooled to room temperature, tetrasulfur tetranitride crystallized out as orange-yellow crystals. These crystals were filtered off and dried in a paper-box contained silica-gel, and so a sample for tetrasulfur tetranitride was obtained without further purification.

Procedure. An infrared spectrophotometer, Model DS-403G, from the Japan Spectroscopic Company was used to obtain the infrared spectra of a carbon disulfide solution of the sample at wave numbers ranging from 2400 to 3600 cm^{-1}, and from 600 to 1000 cm^{-1}.

An Olympus reflecting microscope, Model STS, was used to determine the melting point of the sample in a heating block at the heating rate of 0.5°C/min. The temperatures of the heating block were calibrated by using materials with known melting points.

The thermal gravimetric analysis and the differential thermal analysis of the sample were carried out at a heating rate of 5°C/min in a nitrogen atmosphere using a Thermoflex, Model 8002, from the Rigaku Denki Company.

An X-ray diffractometer, Model JDX-5P, from the Japan Electron Optics Laboratory was used to obtain X-ray powder diffraction intensity diagrams; a goniometer and Cu$K\alpha$ radiation were also used. The diffraction angles were calibrated by using silicon.

Results and Discussion

The IR Spectra of the Sample. Only the characteristic absorption bands[9,10] of tetrasulfur tetranitride at 938 and 700 cm^{-1} were observed in the spectra of the carbon disulfide solution of the sample.

The Melting Point of the Sample. The melting point of the sample was estimated to be 182.0°C. The melting points for tetrasulfur tetranitride have been reported to range from 176°C to 187.5°C.[11-19] The value of the melting point for tetrasulfur tetranitride, which was prepared by the Jolly method,[8] was found to be 178—179°C.[20] However, by repeated recrystallization from benzene, or by purification on an alumina chromatographic column, tetrasulfur tetranitride with a melting point as high as 187—187.5°C has been obtained.[19] Therefore, the sample obtained in this work was considered to be pure enough for us to obtain a good diffraction pattern for tetrasulfur tetranitride from the results of the IR spectra and the melting point of the sample.

However, there is some doubt whether or not the observed melting point shows the proper melting point of tetrasulfur tetranitride. Figure 1 shows the results of the thermal gravimetric analysis and the differential thermal analysis of the sample. An abrupt weight loss near the melting point was found to be due to exothermic change in the sample. Moreover, an explosive decomposition occurred just after the measurements stopped. Judging from the standard heat of formation, ΔH^0, of tetrasulfur tetranitride (110±2 kcal/mol),[21] the thermal decomposition was considered to dominate the sublimation near the melting point. Therefore, the fusion of tetrasulfur tetranitride must accompany the thermal decomposition. Goehring and Voigt[22] have reported that tetrasulfur tetranitride decomposed into its elements at approximately 130°C.

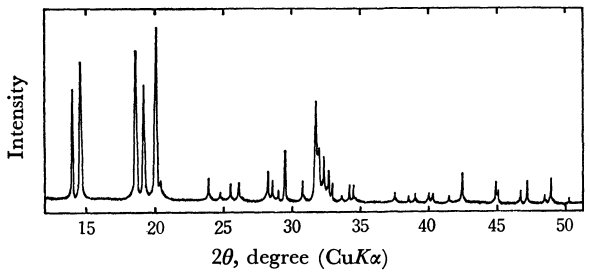

Fig. 2. X-Ray powder diffraction pattern of tetrasulfur tetranitride.

The X-Ray Powder Diffraction Pattern of Tetrasulfur Tetranitride. The X-ray powder diffraction pattern was obtained over the 2θ range from 13° to 50°, as is shown in Fig. 2. The observations in the 2θ range over 50° were omitted. The diffraction peak, d=5.06 Å, reported by Garcia-Fernandez was not observed in the sample, but this peak was observed in a residue of the dioxane solution. Therefore, the peak was considered to be due to a by-product, although the by-product was not identified.

The Miller indices were assigned to the corresponding observed d values as is shown in Table 1, since the observed d values agreed well with those calculated from the lattice constants reported by Clark.[5]

The observed relative intensities of diffraction peaks did not agree with the intensities which were calculated by using the structure factors reported by Sharma and Donohue.[23] The relative intensities were apt to change with the conditions of the sample in spite of a good agreement in the d values. The crystallization rate from the dioxane solution affected the relative intensities; decreases in the intensities of the ($\bar{1}11$), (111), and (200) peaks, and increases in the intensities of the (101) and (202) peaks were observed at a rapid crystallization, for example, while the pulverizing condition scarcely affected the intensities of the same sample at all.

Table 1. The d values and the relative intensities of tetrasulfur tetranitride

$h\,k\,l$	Calcd		This work		Garcia-Fernandez	
	d, Å	I/I_0	d, Å	I/I_0	d, Å	I/I_0
$\bar{1}\,0\,1$	6.29	40.4	6.28	64	6.32	33—80

The Thermochromism of Molybdenum(V) in Hydrochloric Acid Solutions

Yukichi Yoshino, Iwao Taminaga, and Shin Uchida

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received December 14, 1970)

During a systematic study of the autoxidation of molybdenum(V) in aqueous solutions,[1] it was found that the color of the hydrochloric acid solutions of molybdenum(V) changes remarkably with a rise in temperature. It was established that the change is prominent in the concentration range of 4—6 molar HCl, and is reversible between room temperature and 100°C. These observations have been explained on the basis of temperature dependence of the monomer-dimer equilibrium[2]

$$(MoOCl_4)_2O^{4-} + 2HCl \rightleftarrows 2MoOCl_5^{2-} + H_2O$$

Experimental

Molybdenum(V) solutions were prepared by dissolution of $(NH_4)_2MoOCl_5$[3] in an appropriate concentration of hydrochloric acid. Thrice distilled water was used throughout the experiment. The absorbance measurements were carried out by an Ito model QU-3 spectrophotometer using 1-cm stoppered quartz cells. The temperatures were controlled by circulating ethylene glycol from a Haake thermostat.

Results and Discussion

Figure 1 shows the effect of temperature on the visible spectra at 5 molar HCl. The molybdenum(V) solution has two absorption maxima at 450 mμ (I) and at 720 mμ (II), both of which are assigned to *d–d* transition in $4d^1$ electronic configuration.[4] It will be seen that the absorbance at 450 mμ decreases strikingly with a rise in temperature, while at 720 mμ absorbance remains almost unchanged. The net result is that the solution is yellow at room temperature but turns to light green at higher temperatures.

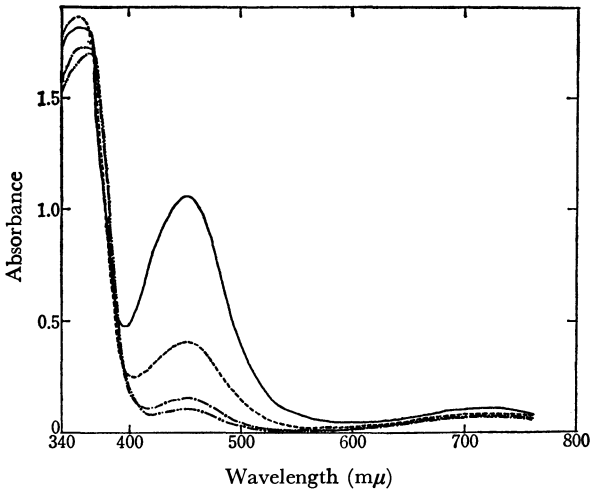

Fig. 1. The spectrum of 5×10^{-3} M $(NH_4)_2MoOCl_5$ in 5M HCl at various temperatures.
a) —— 33.5°C, b) —— 57.5°C, c) ----- 78.6°C, d) -·-·-· 94.0°C

It was established that, when the hot solution is allowed to cool to room temperature, the original pattern of spectra is recovered with slight decrease of absorbance. It was noted that the patterns of spectra at lower and higher temperatures are quite similar to those observed at lower and higher concentration ranges of hydrochloric acid.[2]

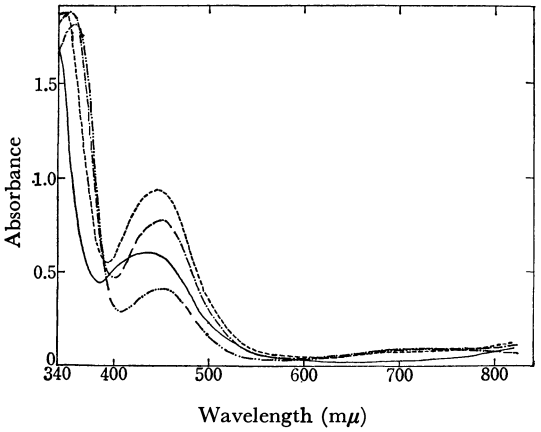

Fig. 2. The spectrum of 5×10^{-3} M $(NH_4)_2MoOCl_5$ in 4 M HCl at various temperatures.
a) —— 25.7°C, b) —— 58.6°C, c) ----- 78.2°C, d) -·-·-· 93.2°C

In a 6 molar HCl solution, the color of the solution is light green at room temperature, but with a temperature rise a slight decrease in absorbance is still observable at 450 mμ.

As shown in Fig. 2, when the concentraton of HCl is kept at 4 molar, the absorption maximum (I) decreases and shifts to shorter wave length at room temperature. When the temperature is raised, the absorption maximum (I) at first shifts to 450 mμ and increases in intensity, and then begins to decrease. By comparing such a change to that in a 5 molar HCl solution, it is suggested that another form of polymeric species (D_2) exists in the 4 molar HCl solution at room temperature, and that with a rise in temperature this species at first changes into yellow dimer (D_1), and then to green species (M). Moreover, it was confirmed that the spectral change is reversible with respect

to temperature.

To summarize the above observations, it may be concluded that the thermochromism of molybdenum(V) in approximately 5 molar HCl solution is due to the shift of equilibria between monomeric and dimeric species of molybdenum(V), and is the same sort of change observed in varying concentrations of hydrochloric acid. On this basis, the apparent equilibrium constants, K of the monomer (M)-dimer (D_1) equilibria,

$$D_1 \rightleftarrows 2M$$

were calculated according to Haight's approach.[2] The results are summarized in Table 1.

Table 1. Apparent equilibrium constants for dimer-monomer equilibria at various temperatures

6M HCl		5M HCl		4M HCl	
t°C	$K\times10^3$, M	t°C	$K\times10^3$, M	t°C	$K\times10^3$, M
23.8	3.18	33.5	0.368	25.7	(0.853)
56.3	14.9	57.5	1.37	58.6	(0.442)
75.5	30.0	78.6	5.78	78.2	5.79
92.5	54.2	94.0	12.1	93.2	1.37

Total concentration of molybdenum(V): 5×10^{-3}M.

Using these values, $-\log K$ was plotted against the reciprocal absolute temperature; the plots are shown in Fig. 3.

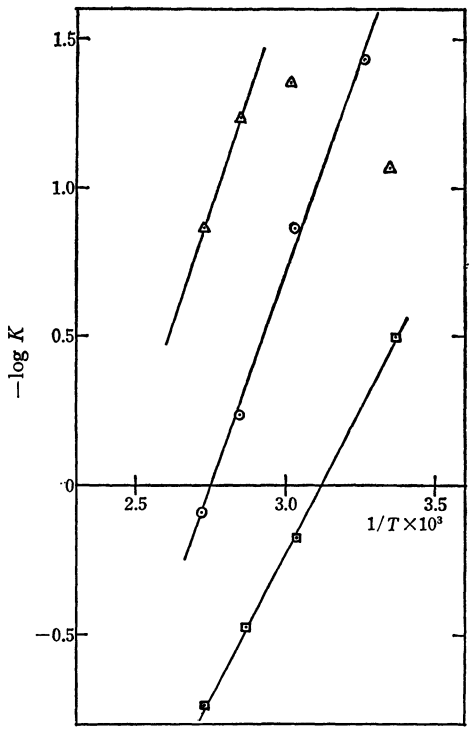

Fig. 3. The plots of $-\log K$ against $1/T$.
5×10^{-3} M Mo(V) in 4 M (△), 5 M (⊙), 6 M HCl (⊡)

Linear relations were found to hold in the cases of 6 and 5 molar HCl solutions over the temperature range studied, and this confirms the existence of monomer-dimer equilibria in these solutions. In the case of 4 molar HCl solution, however, the linear relation no longer holds in the lower temperature range as would be expected from the above-mentioned experiments.

From the slopes of the straight lines, the values of enthalpy change, ΔH, were evaluated as 8.9, 13.3, and 14.3 kcal/mol for 6, 5 and 4 molar HCl solutions respectively. These values are somewhate larger than Haight's, $\Delta H=6.0\pm0.2$ kcal/mol in 5 molar HCl solutions. The variation of the enthalpy values seems understandable in light of the possible overlapping of further hydrolytic equilibria in a relatively low concentration range of acid such as 4 to 6 molar HCl.

The Charge-transfer Complexes of Metal Chelates of 8-Hydroxyquinoline with 2,5-Diazido-3,6-dichloro-1,4-benzoquinone and 2,5-Diazido-3,6-dibromo-1,4-benzoquinone

Shigeo KOIZUMI and Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 14, 1970)

Charge-transfer complexes made from electron donors and acceptors have been studied extensively.[1] However, there are few donor molecules that are known to be composed of organic metal chelates. In 1965 Bailey *et al.* prepared the charge-transfer complexes of 8-hydroxyquinoline and its copper, palladium, and nickel chelates with various electron acceptors.[2] Bis(8-hydroxyquinolinato)palladium(II) ($Pd(Ox)_2$) and bis(8-hydroxyquinolinato)copper(II) ($Cu(Ox)_2$) are known to form stable crystalline (1:1) complexes with *p*-chloranil and *p*-bromanil.

On the other hand, the electron-accepting properties of 2,5-diazido-3,6-dichloro-1,4-benzoquinone (*p*-$Q(N_3)_2Cl_2$), one of the derivatives from *p*-chloranil, have been recently reported by Koizumi and Matsunaga.[3] In the present experiment, we found that $Pd(Ox)_2$ and Cu-

$Cu(Ox)_2$	p-$Q(N_3)_2Br_2$	41.12	2.04	15.29	41.19	1.73	16.01

a) The value calculated for the (1:1) complex.

$(Ox)_2$ can also form stable crystalline (1:1) charge-transfer complexes with p-$Q(N_3)_2Cl_2$ and p-$Q(N_3)_2Br_2$.[4] We shall examine the solid-state spectra of these complexes in order to study the charge-transfer interaction between $M(Ox)_2$ and p-$Q(N_3)_2X_2$, where M=Pd or Cu and where X=Cl or Br. The charge-transfer spectra of these complexes are interesting in comparison with those of the complexes of the same metal chelates with p-chloranil or p-bromanil.

Experimental

Four crystalline complexes were prepared according to a method similar to that described by Bailey *et al.*.[2]; $Pd(Ox)_2$-p-$Q(N_3)_2Cl_2$, $Cu(Ox)_2$-p-$Q(N_3)_2Cl_2$, $Pd(Ox)_2$-p-$Q(N_3)_2Br_2$, and $Cu(Ox)_2$-p-$Q(N_3)_2Br_2$. For each of these compounds, the mole ratio of the donor to the acceptor was determined to be (1:1) on the basis of the elementary analysis; the results of this analysis are given in Table 1.

The complexes were pulverized and diluted with sodium chloride. The diffuse reflection spectra of these complexes were recorded as the difference in reflectance between the mixture and pure sodium chloride by means of a Beckman DK-2A spectroreflectometer. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance.

Results

The p-$Q(N_3)_2Cl_2$ *Complexes.* The solid-state spectrum of the $Pd(Ox)_2$-p-$Q(N_3)_2Cl_2$ complex (Fig. 1, Curve a) shows band peaks at 29.0 kK, 22.6 kK, and 14.7 kK. The high-energy bands at 29.0 kK and 22.6 kK arise mostly from the absorptions due to the component molecules, while the band at 14.7 kK appears in the low-energy region where neither of the component molecules absorbs. The value for this low-energy band was found almost to coincide with that for the band at 14.8 kK of the $Pd(Ox)_2$-p-Chloranil complex, which Bailey *et al.* assigned to the charge-transfer transition from $Pd(Ox)_2$ to p-chloranil.[2] Therefore, the band at 14.7 kK for the $Pd(Ox)_2$-p-$Q(N_3)_2Cl_2$ complex is attributable to the charge-transfer transition from $Pd(Ox)_2$ to p-$Q(N_3)_2Cl_2$. Judging from these results, the electron affinity for p-$Q(N_3)_2Cl_2$ seems to be essentially the same as that for p-chloranil. Since the molecular sizes and the shapes of these acceptors are almost alike, the crystal structure of the $Pd(Ox)_2$-p-$Q(N_3)_2Cl_2$ complex may be similar to that of the Pd-

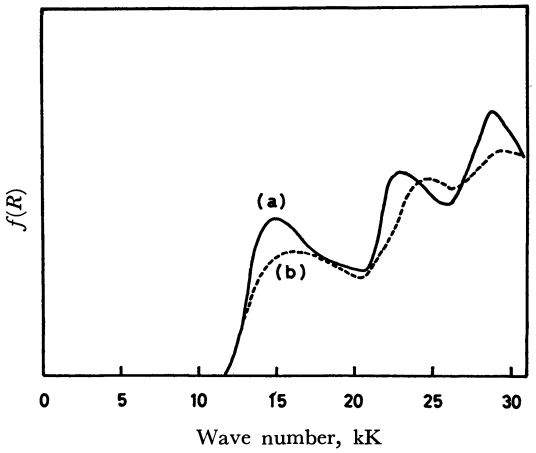

Fig. 1. The solid-state spectra of (a) $Pd(Ox)_2$-p-$Q(N_3)_2Cl_2$ and (b) $Cu(Ox)_2$-p-$Q(N_3)_2Cl_2$.

$(Ox)_2$-p-Chloranil complex as determined by Kamenar *et al.*[5]

On the other hand, the solid-state spectrum of the $Cu(Ox)_2$-p-$Q(N_3)_2Cl_2$ complex (Fig. 1, Curve b) shows band peaks at 29.3 kK, 24.6 kK, and 16.0 kK. The low-energy band at 16.0 kK can also be assigned to the charge-transfer transition from $Cu(Ox)_2$ to p-$Q(N_3)_2Cl_2$; this energy value was found to be close to the 15.9 kK value for the $Cu(Ox)_2$-p-Chloranil complex.[2] It is

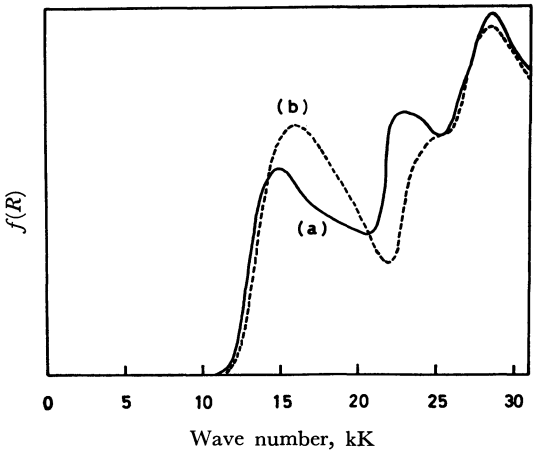

Fig. 2. The solid-state spectra of (a) $Pd(Ox)_2$-p-$Q(N_3)_2Br_2$ and (b) $Cu(Ox)_2$-p-$Q(N_3)_2Br_2$.

4) The acceptor of 2,5-diazido-3,6-dibromo-1,4-benzoquinone is abbreviated as p-$Q(N_3)_2Br_2$.

5) According to an X-ray diffraction study by Kamenar *et al.*, the crystal structure of the $Pd(Ox)_2$-p-Chloranil complex has the triclinic symmetry. The planar $Pd(Ox)_2$ and p-chloranil molecules, which are alternately stacked, are arranged in planes approximately parallel to the crystallographic (111) plane. See B. Kamenar, C. K. Prout, and J. D. Wright, *J. Chem. Soc.*, 4851 (1965).

important to note that the charge-transfer energy for the $Cu(Ox)_2$-*p*-$Q(N_3)_2Cl_2$ complex is larger than that for the $Pd(Ox)_2$-*p*-$Q(N_3)_2Cl_2$ complex by 1.3 kK. For a common acceptor, the great variation in the charge-transfer energy will arise from a difference in the ionization potentials of the donors. Therefore, the ionization potential of $Cu(Ox)_2$ seems to be higher than that of $Pd(Ox)_2$ by about 1.3 kK.

The p-$Q(N_3)_2Br_2$ *Complexes.* The solid-state spectrum of the $Pd(Ox)_2$-*p*-$Q(N_3)_2Br_2$ complex (Fig. 2, Curve a) shows high-energy bands at 28.6 kK and 22.9 kK, and a low-energy charge-transfer band at 14.8 kK. It is interesting to see that the charge-transfer energy for this complex coincides with that of 14.8 kK for the $Pd(Ox)_2$-*p*-Bromanil complex.[6] This leads to a value of the electron affinity for *p*-$Q(N_3)_2Br_2$ close to that for *p*-bromanil.

The $Cu(Ox)_2$-*p*-$Q(N_3)_2Br_2$ complex gives a solid-state spectrum (Fig. 2, Curve b) composed of a high-energy band at 28.3 kK, a shoulder at 25.0 kK, and a low-energy charge-transfer band at 15.9 kK. The energy difference in the charge-transfer transitions between the $Cu(Ox)_2$-*p*-$Q(N_3)_2Br_2$ and $Pd(Ox)_2$-*p*-$Q(N_3)_2Br_2$ complexes was found to be 1.1 kK, which is in good accordance with the 1.3 kK value for the energy difference in the charge-transfer transitions between the $Cu(Ox)_2$-*p*-$Q(N_3)_2Cl_2$ and $Pd(Ox)_2$-*p*-$Q(N_3)_2Cl_2$ complexes.

Discussion

The above-mentioned results on the solid-state spectra clearly indicate that the electron affinities of *p*-$Q(N_3)_2Cl_2$ and *p*-$Q(N_3)_2Br_2$ are essentially the same as those of *p*-chloranil and *p*-bromanil respectively. The azido group thus appears to be as effective as the chlorine or bromine substituent in improving the acceptor strength of *p*-benzoquinone. This conclusion is in good agreement with that given previously by Koizumi and Matsunaga.[3]

On the other hand, the ionization potential of a metal chelate of 8-hydroxyquinoline is very much affected by the species of the central metal ion. This was shown as an appreciable difference in the ionization potentials of $Cu(Ox)_2$ and $Pd(Ox)_2$. Moreover, we examined what kind of metal chelates of 8-hydroxyquinoline can form charge-transfer complexes with *p*-$Q(N_3)_2X_2$, where X=Cl or Br. The preparation of the charge-transfer complexes of $Cd(Ox)_2$, $Hg(Ox)_2$, $Mn(Ox)_2$, and $Ni(Ox)_2$ with *p*-$Q(N_3)_2X_2$ in various solvents was attempted for this purpose. However, no such crystalline compounds could be obtained from these metal chelates.[7] In view of these results, we can see that, for the metal chelates of 8-hydroxyquinoline, not only the magnitude of the ionization potential but also the ability of the formation of the charge-transfer complexes is strongly dependent on the species of the central metal ions.

6) Y. Iida, unpublished work.

7) Although a slight complex formation was detected with $Ni(Ox)_2$, the pure solid charge-transfer complex was not isolated, presumably because of the very poor solubility of $Ni(Ox)_2$ in the suitable solvents.

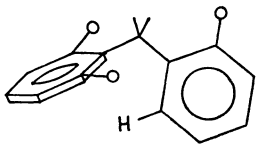
BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1439 (1971)

Conformational Factors Affecting the NMR Chemical Shifts of Nuclear Protons in Some Diarylmethanes

G. MONTAUDO, S. CACCAMESE, P. FINOCCHIARO, and F. BOTTINO
Institutes of Industrial and Organic Chemistry of the University, v.le A.Doria, Catania, Italy

(Received October 12, 1970)

We have been interested in the study of conformational properties of diphenylmethanes (DPM) and have proposed[1] that a number of tri-*ortho*-substituted DPM exist predominantly in a conformation (I) where the *ortho* aromatic hydrogen lies below the adjacent ring.



(I)

NMR data provide useful information on the conformation. In fact the shielding on the *ortho* positions, due to the ring current[2] of the adjacent nucleus, is a function of molecular conformation.[1] Some NMR data on variously substituted DPM, which appeared recently in this Journal,[3] can be interpreted as a further support of our previous results.

In Table 1 are collected the NMR chemical shifts of *ortho* aromatic protons for a number of tri-*ortho*-substituted DPM derivatives taken from Suzuki's work[3] together with our data. In tri-*ortho*-substituted DPM the *ortho* nuclear proton appears sensibly shielded with respect to the mono-substituted derivatives (Table 1, compounds 1 and 2). This can be accounted for by assuming that the tri-*ortho*-substituted compounds exist predominantly in form I where the *ortho* aromatic hydrogen lies below the adjacent ring. Other conformations become disfavored in this case because of the repulsive interaction between the *ortho* substituents and the π-electron cloud of phenyl ring.

The magnitude of the shielding effect observed for tri-*ortho*-substituted compounds (0.5—0.8 ppm) compares fairly well with the theoretical shielding value calculated for conformer I through the Johnson and Bovey tables.[2] Considerably lower shielding values are calculated for other (skew) conformations. The shielding effect could be calculated as the difference between the chemical shift values of *ortho* and *para* nuclear protons since the latter are unperturbed from the adjacent ring diamagnetic current. However, this is not always possible for the compounds in Table 1 and the shielding has been computed taking the pentamethylbenzene nuclear proton as reference. The new data[3] seem to be in substantial agreement with ours and appear to support our interpretation.

TABLE 1. CHEMICAL SHIFTS OF *ortho* AND *para* NUCLEAR PROTONS IN DPM DERIVATIVES

SHORT COMMUNICATIONS

Hydration of 2-Cyanopyridine with Metal Chelates

Sigeo KOMIYA, Shinnichiro SUZUKI, and Ken-ichi WATANABE

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received January 9, 1971)

It has been reported[1,2] that 2-cyanopyridine is hydrated with nickel(II) chloride or copper(II) chloride to afford the metal chelates of 2-pyridinecarboxamide. On the other hand, 2-cyanopyridine is hydrated into 2-pyridinecarboxamide by the catalytic action of metal chelates, *viz.* nickel(II) or copper(II) chealtes of picolinic acid and its amide.[1]

In this paper, we report that some other ordinary metal chelates are also effective for the hydration of 2-cyanopyridine to give only 2-pyridinecarboxamide. The metal chelates used as catalysts were $[Ni(en)_3]Cl_2 \cdot 2H_2O$, $[Cu(en)_2]Cl_2 \cdot 2H_2O$, $[Co(en)_3]Cl_2$, $Ni(piaH)_2Cl_2 \cdot 2H_2O$, and $Co(piaH)_2Cl_2 \cdot 2H_2O$ (en: ethylenediamine, piaH: 2-pyridinecarboxamide).

As a preliminary test, the hydration of 2-cyanopyridine was carried out without catalysts (60°C, 5 hr). It was found that no hydration took place in the pH range 5.5—8.5. Thus, the aqueous solution of 2-cyanopyridine (0.0471 M) containing each metal chelate (0.0058 M) was kept at 60°C in the pH range 5.5—8.5, and then a definite quantity of the reaction mixture was sampled every hour. The samples were charged into ion exchange column (Dowex 50 H-Type×2) and developed with water. Thus, 2-cyanopyridine unreacted was separated completely from the reaction mixture. Then the decrease in amount of the starting material was followed spectrophotometrically at 272 mμ, and the yield of reaction product, 2-pyridnecarboxamide, was calculated.

It was confirmed that the reaction product was only the 2-pyridinecarboxamide and the chelates used for the reaction were recovered without any change. The results are given in Fig. 1. The chelates of copper(II), nickel(II), and cobalt(II) have a catalytic activity, but not cobalt(III) chelate.

2-Pyridinecarboxamide (%)=
100−2-Cyanopyridine (%) (unreacted)

It is known that the former are labile complexes and the latter is an inert complex. Such characters of chelates were in accord with catalytic activity of the hydration. It is assumed that the hydration proceeds through the combination of the ligand exchange and the reaction of coordinated ligands.

The Reaction of Bis(2-cyanopyridine)copper(II) Chloride with Amines in Methanol

Shinnichiro SUZUKI, Masayoshi NAKAHARA,* and Ken-ichi WATANABE

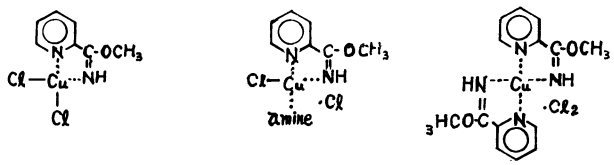
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

**Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo*

(Received January 9, 1971)

It has been reported [1] that 2-cyanopyridine is alcoholized with transition metal ions (*e.g.* Cu(II), Ni(II) and Co(II)) in alcohols to afford complexes of *O*-alkyl pyridine-2-carboximidate, Type I. It is assumed that the nitrile group of 2-cyanopyridine is activated by chelation with the metal ion and therefore the attack of the nucleophiles (*e.g.* OR^- or OH^- [2]) on it is promoted. To develop this idea, a test of amination to the nitrile group in chelates was made with various amines. We obtained not the expected complexes but new ones (Types II and III).

When ammonia, methylamine, dimethylamine, ethylamine, or benzylamine was used for the reaction, the chelates of Type II were obtained. On the other hand, when trimethylamine, diethylamine, or triethylamine was used, only the chelate of Type III was obtained. The methanol solution of bis(2-cyanopyridine)copper(II) chloride[1] and that of amines (1—2 mol to the complex) were mixed at 0°C and the reaction mixture was stirred for 45—60 min. The precipitate of the complex was then obtained by addition of ether, and was recrystallized from methanol-ether mixture at room temperature.



(MeOpy)$CuCl_2$ (I)[1] (MeOpy)(amine)$CuCl_2$ (II) (MeOpy)$_2CuCl_2$ (III)

The results of elementary analysis and spectroscopic measurements of the chelates are given in Tables 1 and 2. In Table 1, the chelates of Type II are 1)—5). The chelate of Type III is 6). The ultraviolet and the visible spectra of 6) differ from those of the chelates of Type II, which suggests the structural difference between the chelates of these two types. The formation of the chelate of Type III seems to be due to the steric hindrance of bulky alkyl groups in the amines.

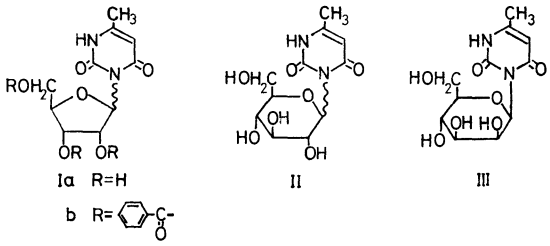
The Anomeric Configuration of 6-Methyl-3-D-glycosyluracil

Naotaka YAMAOKA, Hiroshi SUGIYAMA,* and Katsura TUZIMURA

*Faculty of Agriculture and *Chemical Research Institute of Non-Aqueous Solution, Tohoku Univerisity, Sendai*

(Received January 21, 1971)

Recent papers[1,2] in which Lemieux's PMR method was applied to determine the anomeric configuration of pyrimidine nucleosides prompt us to suggest the limitations of the method. The use of a seeming coupling constant in high-resolution PMR might be a mistake for the assignment of the anomeric proton of acylated ribofuranosyl nucleosides without consideration of the half-height width of the absorption peak,[3] since two heavily overlapped broad peaks seem to be one broad peak. We wish now to report the anomeric proton assignment of 6-methyl-3-D-glycosyluracils (Ia, b, and II) synthesized by the condensation of 6-methyluracil with acylglycosyl halide in nitromethane containing a hydrogen halide acceptor.[4]



6-Methyl-3-D-ribofuranosyluracil (Ia) [$[\alpha]_D^{22} = -18°$ (c 0.083, H_2O), $\lambda_{max}^{H_2O}$=266, $\lambda_{min}^{H_2O}$=234 mμ (Found: C, 46.56: H, 5.59; N, 11.08; Calcd for $C_{10}H_{14}N_2O_6$: C, 46.51; H, 5.47; N, 10.85; mol wt, 258.23): NMR data (DMSO-d_6) δ 6.10 (d, $J_{1',2'}$=3.7 Hz, H-1')] and 6-methyl-3-(tri-*O*-benzoyl-D-ribofuranosyl)uracil (Ib) [NMR data (DMSO-d_6) δ 6.55 (s, half-height width 3 Hz, H-1')] seemed to be pure β anomer judging from the NMR data.[1,2] 6-Methyl-3-D-glucopyranosyluracil [II, mp 196—200°C, $[\alpha]_D^{22}$=0° (c 0.091, H_2O), $[M]_{350}^{22}$ =0° (c 0.0032 M, H_2O), $\lambda_{max}^{H_2O}$=266 (ε 9370), $\lambda_{min}^{H_2O}$= 234 mμ (ε 2036): (Found: C, 45.48; H, 5.64; N, 9.52; Calcd for $C_{11}H_{16}N_2O_7$: C, 45.83; H, 5.59; N, 9.72; mol wt 288.25): NMR data (D_2O) δ 5.65 (d, $J_{1',2'}$=9.67 Hz, H-1'), 5.76 (d, $J_{1',2'}$=9.33 Hz, H-1'), 5.62 (q, $J_{5,6}$=0.7 Hz, H-5)] was an anomeric mixture. In order to prepare the pure anomer to give clear data, II was converted into 6-methyl-3-β-D-mannopyranosyluracil (III) [mp 237—238°C, $[\alpha]_D^{22}$ =−32.8° (c 0.091, H_2O), $\lambda_{max}^{H_2O}$=267, $\lambda_{min}^{H_2O}$=235 mμ: (Found: C, 45.83; H, 5.59; N, 9.79; Calcd for $C_{11}H_{16}N_2O_7$: C, 45.83; H, 5.60; N, 9.72; mol wt 288.25): NMR data (D_2O) δ 6.08 (d, $J_{1',2'}$=0.6 Hz, H-1')] in several steps.

The optical rotatory dispersion of the dialdehydes formed from a 0.01 mol solution of the free nucleosides (Ia, II, and III) containing excess sodium metaperiodate[5] gave the following data:

Ia, $[M]_{589}^{22} = -80°$, $[M]_{350}^{22} = -410°$
II, $[M]_{589}^{22} = -85°$, $[M]_{350}^{22} = -400°$
III, $[M]_{589}^{22} = -25°$, $[M]_{350}^{22} = -230°$

The anomeric configuration of furanosyl nucleoside could not be assigned only from the seeming PMR coupling constant of less than 1 Hz without a consideration of the broad half-height width of the absorption peak of the anomeric proton.

Polarographic Investigation of Copper(II)-Poly(α, L-Glutamic Acid) Complex in the Helix-Coil Transition Region

Senkichi INOUE, Kiwamu YAMAOKA,* and Masaji MIURA*

*Department of Chemistry, Faculty of General Education, and *Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima*

(Received January 25, 1971)

We wish to report results of a polarographic study of the aqueous solution of cupric chloride in the presence of poly (α,L-glutamic acid) in the pH range 3.0—6.0 where the polymer alone is known to undergo conformational transitions. The purpose of this investigation is to obtain electrochemical data for a better understanding of the mechanism of the pH induced helix-coil transition of synthetic polyamino acids with ionizable side chains. This can be achieved by adding, as a structural probe, a small amount of any polarographically reducible metallic ion which can form a stable complex with polymer but does not perturb polymer conformation.

The cupric ion, which is known to bind to poly (α, L-glutamic acid),[1] could be reduced at the dropping mercury electrode either in the presence or absence of the polymer in the pH range examined. The variation of the limiting current of Cu(II) in the Cu(II)-polymer solution with pH (i_l-pH curve) was affected most by the nature of supporting electrolyte. The paralellism between the i_l-pH curve and helix-coil transition curves obtained with other methods such as viscosity[2] and optical rotation[2] became apparent only when the concentration of the supporting electrolyte so decreased that it was comparable with the concentration of the polymer. The polarographic limiting currents were determined in two extreme sets of supporting electrolytes. The concentration of cupric ions was 1×10^{-4} M and the mean residue weight concentration of the polymer was 1.6×10^{-3} M, the ratio of the monomer unit of the polymer to cupric ion being 16 in the Cu(II)-polymer solution. The limiting current of Cu(II) could be attributed to the diffusion-controlled current (i_d)[3] both in the presence and absence of the polymer in the solution containing either of the two supporting electrolytes, since a strict linear relationship, which could be extrapolated to intercept the origin, was obtained between the observed current and the product of $m^{2/3}\cdot t^{1/6}$, where m is the flow rate of mercury and t the drop time. This relation also held for the Cu(II)-polymer solution at pH 3.5 or 6.5, where the complex is in helical or random-coil conformation, thus ruling out the contribution of migration current to i_l.

Without the polymer, Cu(II) was reduced at a half-wave potential $E_{1/2}=0.05$ V *vs.* SCE in the entire pH region and the diffusion current did not significantly decrease at pH 3.0—6.0 in either of the two supporting electrolytes. In the presence of the polymer, however, Cu(II) was reduced at $E_{1/2}=0.00$ V *vs.* SCE, while the diffusion current sharply decreased with increase in pH between 4 and 5. In Fig. 1 the data are expressed in terms of the ratio of diffusion current of Cu(II) with the polymer to that without it, $(i_d)_p/(i_d)_o$, in each supporting electrolyte system. Based on the fact that the electrode mechanism of the reduction of Cu(II) is invariant, the ratio of the two diffusion constant (D_p/D_o) was also calculated with the aid of Ilkovic's equation and is plotted in Fig. 1. On the assumption that two electrons are transferred from each Cu(II), the diffusion constants at pH 3.8 and 5.0 were calculated to be 6.3×10^{-6} and 0.97×10^{-6} (cm²/sec), respectively, for the Cu(II)-polymer solution in 1.5×10^{-3} M NaCl at 25°C.

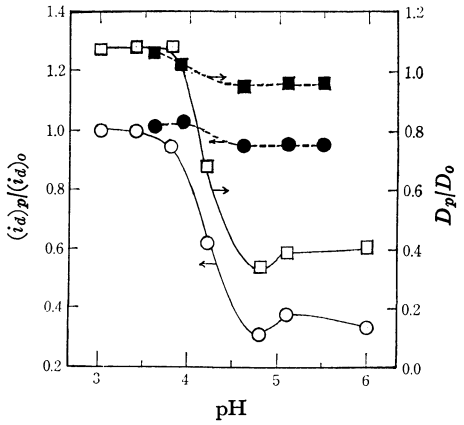

Fig. 1. The pH dependence of polarographic diffusion currents and diffusion constants of the Cu(II)-poly(α,L-glutamic acid). ●,■:$(i_d)_p/(i_d)_o$ and D_p/D_o in 0.2M acetic acid-sodium acetate buffer, ○,□: $(i_d)_p/(i_d)_o$ and D_p/D_o in 1.5×10^{-3}M sodium chloride. Polarographic currents were memeasured manually on a Yanagimoto Model P-8 polarograph.

The curves in acetate buffer indicate that cupric ions interact with acetate ions more strongly than with ionized polymer molecules, or that the electrode process is independent of the conformation of Cu(II)-polymer complex. On the other hand, the interaction between Cu(II) and polymer primarily controls the electrode reduction process in low sodium chloride concentration. The decrease in $(i_d)_p/(i_d)_o$ values at higher pH may be assumed to result from the formation of both electrostatic ion-pairs and inter- and/or intramolecular chelate complexes with the amide and carboxyl groups of the polymer. In conclusion, polarographic methods can be utilized in elucidating the mechanism of the helix-coil transition of ionizable polyamino acids.

Satellite X-Ray Scattering by TCNQ-Phenothiazine Complex and Diffuse Scattering by TCNQ-*N*-Methylphenothiazine Complex

Hayao KOBAYASHI and Yoshihiko SAITO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 15, 1971)

1:1 complexes formed between 7,7,8,8-tetracyanoquinodimethane (TCNQ) and two electron donors, phenothiazine (PHT) and *N*-methylphenothiazine (*N*-MePHT were investigated by X-ray diffraction method. The black PHT-TCNQ complex crystallizes in the form of needles elongated along the *a* axis It is monoclinic with space group $C2/c$ or Cc and has a super lattice structure with transverse phase modulation. The cell constants of fundamental lattice are: $a=7.04$, $b=25.38$, $c=10.51$ Å and $\beta=92.1°$. Crystals of *N*-MePHT-TCNQ are monoclinic with space group $C2/m$ and $a=10.90$, $b=13.32$, $c=7.09$ Å, $\beta=91.9°$, $Z=2$. General features of intensity distributions of both complexes indicate that the two structures are similar in a broad sense.

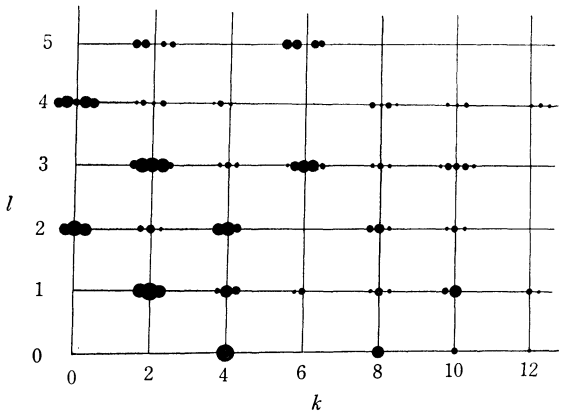

Fig. 1. Distribution of satellite scatterings around $(0,k,l)$ Bragg reflections from PHT-TCNQ. Magnitude of a circle is drawn in proportion to the intensity of X-ray reflection.

In the case of PHT-TCNQ complex, satellite reflections appear in reciprocal space at $(h, k\pm m\delta, l)$, where h, k, and l are Miller indices, $m=1, 2, 3$, and 4 and $\delta=0.232\pm0.015$ at room temperature. Distribution of satellites around $(0,k,l)$ reflections is schematically shown in Fig. 1. The general features of the satellite reflections are similar to those observed in the crystals of ferroelectric thiourea.[1] The observed diffraction patterns can be explained on the basis of the lattice with transverse phase modulation. That is, the lattice points are sinusoidally distorted. The position of the nth lattice point is approximately given by

$$\boldsymbol{r} = n_1\boldsymbol{a} + n_2\boldsymbol{b} + n_3\boldsymbol{c} + (p\boldsymbol{a}/a + q\boldsymbol{c}/c)\sin(2\pi n_2\delta),$$

where $(n_1\boldsymbol{a}, n_2\boldsymbol{b}, n_3\boldsymbol{c})$ is the position of the nth lattice point, p and q are 0.85 Å and 0.75 Å, respectively, and $1/\delta$ is the period of modulation and is equal to 4.3. The donor and acceptor molecules seem to be stacked alternately forming columns parallel to the *a* axis. The origin of this sinusoidal structure seems to be particularly interesting, because such a modulation may arise owing to the delicate balance of various interactions in the crystal, such as charge-transfer interaction, repulsion between non-bonding atoms, hydrogen-bonding, dipole-dipole interaction, *etc.* Detailed analysis is now under way.

The structure of *N*-MePHT-TCNQ complex was deduced from packing consideration and refined to an *R*-value of 0.096. The donor and acceptor molecules are alternately stacked face to face forming columns parallel to the *c* axis. Unlike PHT complex, diffuse scattering associated with strong Bragg reflections is observed. In fact, the orientation of *N*-MePHT molecule is disordered and the apparent molecular asymmetry is D_{2h}. The intermolecular spacing between *N*-MePHT and TCNQ is 3.43 Å. The molecular dimension of TCNQ is intermediate between those of $TCNQ^0$ [2] and $TCNQ^{-1/2}$ [3,4] where $TCNQ^0$ and $TCNQ^{-1/2}$ represent the neutral TCNQ molecule and TCNQ with formal charge of $-1/2$, respectively.

Studies of the Coordination Bonding and Stability of the Mixed-ligand Complexes of Copper(II)

Hiroshi Yokoi, Masaki Otagiri, and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received February 27, 1971)

In recent years, many studies of the stability of mixed-ligand complexes have been carried out; the importance of the chemical behavior of the complexes have received increasing attention from the viewpoint of its relationship to fundamental concepts in inorganic and biological chemistry.[1-3] More quantitative studies, however, seem to be necessary for determining definitely the factors governing the mixed-ligand complex formation.[3] We wish to report here on our new results concerning the coordination bonding and stability for the mixed-ligand complex written in the following equilibrium (the results were obtained by the use of ESR and optical absorption techniques):

$$CuA_2 + CuB_2 \rightleftharpoons 2\,CuAB \qquad (1)$$

$$K = \frac{[CuAB]^2}{[CuA_2]\,[CuB_2]} \qquad (2)$$

Here, two different bidentate ligands of ethylenediamine, its alkyl derivatives, trimethylenediamine, and various amino acids are represented as A and B, and an equivolume mixture of water and methanol was used as the solvent.

The observed ESR line shapes showed that the symmetry of the ligand field of all the mixed-ligand complexes employed is as axial as that of the parent complexes. It was found that the $g_{//}$ and $g_{\perp}$ values of almost all the mixed-ligand complexes are intermediate between those of the corresponding two parent complexes, as is shown in Fig. 1, for example, with regard to the $g_{//}$ value; furthermore, the wavelengths and intensities of the visible absorption maximum of the mixed-ligand complexes are intermediate. It may be concluded from these experimental facts that the mixed-ligand complexes are intermediate in the degree of covalency of the coordinate bond between the corresponding two parent complexes.[4]

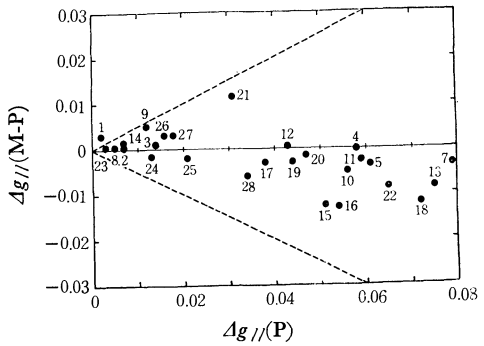

Fig. 1. A plot of $\Delta g_{//}$(M-P) against $\Delta g_{//}$(P) for 28 mixed ligand complexes.
$\Delta g_{//}(\text{M-P}) = g_{//}^{M} - (1/2)(g_{//}^{P_1} + g_{//}^{P_2})$
$\Delta g_{//}(\text{P}) = |g_{//}^{P_1} - g_{//}^{P_2}|$
where $g_{//}^{M}$, $g_{//}^{P_1}$, and $g_{//}^{P_2}$ are the $g_{//}$ values of a mixed ligand complex and its two parent complexes, P_1 and P_2, respectively.

Table 1. The value of log K[a]

Temperature	System[b]		
(°C)	I	II	III
50	1.38±0.02	0.80±0.03	0.15±0.03
20	1.44±0.02	0.78±0.04	0.14±0.03
ca. −100[c]		0.79±0.10	−0.45±0.15

a) The K values at 20 and 50°C were determined spectrophotometrically according to the Kida's method,[2] and the K values at *ca.* −100°C were determined from the X-band ESR spectra measured at 77°K by resolving the absorption lines into three components.
b) I: A=en, B=L-Ala, II: A=en, B=β-Ala, III: A=en, B=dmg (dmg: *N,N*-dimethylglycine anion, other abbreviations are the ones ordinarily used).
c) the assumed freezing point.

Table 2. Thermodynamic constants

	System		
	I	II	III
ΔG^0_{293}(kcal/mol)	−1.93±0.03	−1.05±0.06	−0.19±0.04
ΔH (kcal/mol)	−0.86±0.58	0.01±0.20	1.02±0.31
ΔS (e.u.)	3.65±0.21	3.62±0.09	4.12±1.20

The K values and the thermodynamic constants were determined for several equilibrium systems (A: ethylenediamine, B; amino acid) in order to estimate the factors governing the equilibrium; the data are listed in Tables 1 and 2. These results indicate that the entropy term plays a main role in determining the equilibrium, but that the differences in the K values are due to small differences in the enthalpy change. The fact that the enthalpy changes are small seems to be in agreement with the average of the Cu-A and Cu-B bond strengths in the mixed-ligand complexes, as has been mentioned above.

The details will soon be published elsewhere.

Triplet Dimers Observed for Several β-Diketone Chelate Complexes of Copper(II) in Toluene

Hiroshi Yokoi and Taro Isobe
Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai
(Received March 9, 1971)

We wish to report here on the new experimental fact that triplet dimers are formed at very high concentrations in the toluene solutions of several 1:2 β-diketone chelate complexes of copper(II). In this study, the following representative β-diketone chelate complexes were employed: $Cu(Etacest)_2$, $Cu(Meacest)_2$, $Cu(acac)_2$, and $Cu(bzac)_2$, where Etacest, Meacest, acac, and bzac are the anions of ethyl acetoacetate, methyl acetoacetate acetylacetone, and benzoylacetone respectively. The X-band ESR spectrum of $Cu(Etacest)_2$ in toluene as measured at 77°K is shown as an example in Fig. 1.

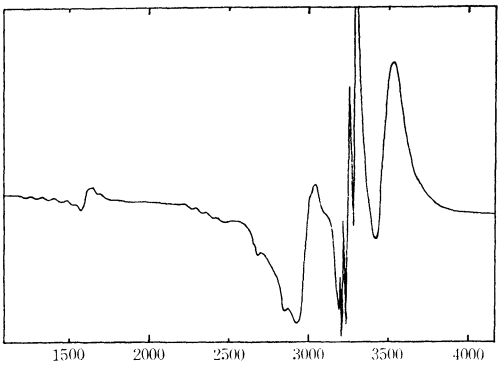

Fig. 1. The X-band ESR Spectrum of $Cu(Etacest)_2$ in toluene (c^0: 5×10^{-3} mol/l, measured at 77°K).

This spectrum clearly consists of two kinds of spectra superposed upon each other; one of them is due to monomer species (M), and the other, to triplet dimer species (D). The line shape of the latter spectrum is a typical one for magnetically-coupled Cu(II)–Cu(II) systems in the triplet state.[1-4]

It seemed that it would be very interesting to see whether or not the following type of equilibrium is established in the solution:

$$2\,M \rightleftharpoons D, \quad K=\frac{[D]}{[M]^2} \qquad (1)$$

When the observed intensity ratio between a particular ESR absorption line due to D and a particular line due to M is expressed as R, the following equation can be derived:

$$2R^2 + rR = Krc^0 \qquad (2)$$

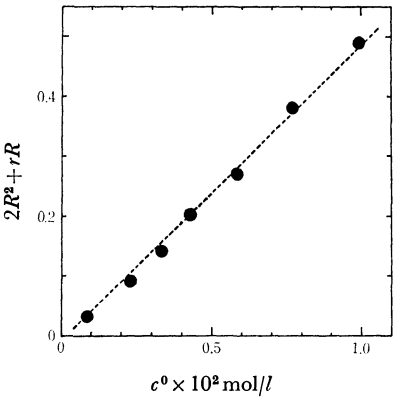

Fig. 2. A plot of $(2R^2+rR)$ against c^0 for $Cu(Etacest)_2$ in toluene

where c^0 is the initial concentration of a complex and r, the proportionality constant between R and the actual concentration ratio of D to M. The values of $(2R^2+rR)$ were plotted against c^0 for $Cu(Etacest)_2$ in toluene by putting $r=0.072$, which was the approximate value evaluated graphically from one of its ESR spectra, assuming that the actual ratio of [D] to [M] is proportional to the totally-integrated intensity ratio of the ESR absorptions of D to M. The existence of a linear relationship between them, as is shown in Fig.2, clearly indicates that the above-described equilibrium is held in the solution; accordingly, the K value could be calculated from its slope to be $(1.0\pm0.2)\times10^4$. Similarly, the K values of $Cu(Meacest)_2$, $Cu(acac)_2$, and $Cu(bzac)_2$ in toluene could be estimated to be $(6.0\pm2.0)\times10^3$, $(9.0\pm2.0)\times10^3$, and $(1.1\pm0.2)\times10^3$ respectively. The magnetic parameters determined for these systems (assuming the axial field) are listed in Table 1. The details will soon be published elsewhere, together with a discussion of these magnetic data in connection with the structures of the dimers.

Table 1. Magnetic parameters[a]

Copper(II) complex	Monomer $g_{//}$	Monomer $g_\perp$	Monomer $A_{//}\times10^3$ cm^{-1}	Monomer $A_\perp\times10^3$ cm^{-1}	Dimer $g_{//}$	Dimer $g_\perp$	Dimer D cm^{-1}
$Cu(Etacest)_2$	2.29	2.05	18	2.5	2.31	2.07	0.043 ±0.004
$Cu(Meacest)_2$	2.28	2.04	18	2.5	2.30	2.07	0.040 ±0.005
$Cu(acac)_2$	2.26	2.05	19	2.5	2.29	2.06	0.018 ±0.005

a) The data of $Cu(bzac)_2$ were omitted here because of some difficulty in determining the accurate ones of its dimer species from its ESR spectra.

On the Planar Structure of the Bis(dimethylglyoximato)cobalt(I) Complex

Nobufumi MAKI

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received March 16, 1971)

The bis(dimethylglyoximato)cobalt(III) complexes with a trans-configuration cited below have all been found to be reduced to the cobalt(I) state in non-aqueous solvents such as a DMSO (dimethyl sulfoxide); no further reduction to the metal takes place over the potential range between 0 and −2.70 V (*vs.* SCE): $H[CoCl_2(dgH)_2]$,[1] $Na[Co(NO_2)_2(dgH)_2]\cdot H_2O$, $H[Co(NCS)_2(dgH)_2]$, $H[Co(CN)(dgH)_2Cl]\cdot 4H_2O$, $(NH_4)_2[Co(CN)(dgH)_2(SO_3)]\cdot 4H_2O$, $[Co(CN)(dgH)_2(OH_2)]\cdot 3H_2O$,[2] $[Co(CN)(dgH)_2(NH_3)]\cdot \frac{1}{2}H_2O$, $[Co(dgH)_2(NH_3)_2]ClO_4$, $[Co(dgH)_2(py)(NH_3)]$,[1] $[Co(dgH)_2(OH_2)_2]ClO_4$,[2] $[Co(dgH)_2(OH_2)(NH_3)]OCOCH_3$, $[CoX(dgH)_2(NH_3)]$ (X=I, Br, Cl, F[2]), $Na[Co(CN)_2(dgH)_2]\cdot 2H_2O$.

The most striking feature of this result is that the liberation of the fifth and the sixth ligand occurs at the cobalt(I) state during the reduction, except for the case of cyanide ligands. The anodic wave of free ligand ions released from the complex was detected to exist by using a Kalousek commutator. Therefore, it seems likely that the contribution of the two ligands located above and below the $[Co(dgH)_2]$structure need not be accounted for in determining whether or not the cobalt(I) state can exist during the reduction. That is, the resulting cobalt(I) complex would take a planar structure of the $[Co^I(dgH)_2]$ type with a pair of hydrogen bonds, as is indicated in the following;

$$trans\text{-}[Co^{III}X_2(dgH)_2]^{n-} \xrightarrow{2e} [Co^I(dgH)_2]^- + 2X^{m-}.$$

In contrast to this behavior with a trans-configuration, the tris(dimethylglyoximato)cobalt(III) complex[3] was found to be reduced to the metal *via* the cobalt(II) complex in the DMSO containing 0.1 M $[(C_2H_5)_4N]ClO_4$ at the dropping mercury electrode:

$$[Co^{III}(dgH)_3] \xrightarrow{e} [Co^{II}(dgH)_3]^- \xrightarrow{2e} Co(metal).$$

No cobalt(I) state was found upon the reduction. This is consistent with the prediction that the $[Co^I(dgH)_2]^-$ anion with a planar structure could not be formed from the reduction of the cobalt(III) complexes with a *cis*-configuration, since it is not likely that the rearrangement of ligands, *viz.*, the isomerization, takes place in DMSO. Inversely, this result can be invoked to emphasize the importance of the planarity of the bis(dimethylglyoximato)cobalt(I) complex from the standpoint of the electronic structure.

Figure 1 illustrates the current-potential curves for the *trans*-$[Co^{III}F(dgH)_2(NH_3)]$ and $[Co(dgH)_3]\cdot 2.5H_2O$ complexes measured under the same experimental conditions. In the figure, the wave-height is approximately proportional to the number of electrons participating in the electrode processes, since the limiting current of both the waves is diffusion-controlled.

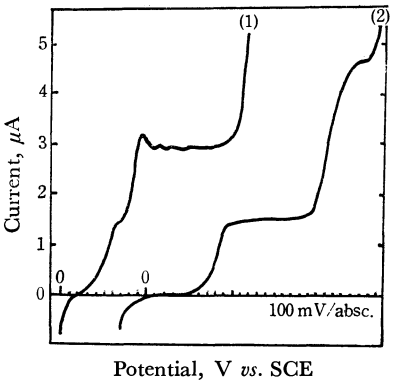

Fig. 1. Typical current-potential curves obtained at the concentration of 10^{-3}M under the same conditions (25°C): (1) *trans*-$[CoF(dgH)_2(NH_3)]$; (2) $[Co(dgH)_3]\cdot 5/2\ H_2O$ in the DMSO containing 0.1M$[(C_2H_5)_4N]ClO_4$.

TABLE 1. HALF-WAVE POTENTIALS OF *trans*- AND *cis*-BIS(DIMETHYLGLYOXIMATO)COBALT(III) COMPLEXES IN DMSO CONTAINING 0.1M$[(C_2H_5)_4N]ClO_4$(25°C)

Compound	lst Wave	2nd Wave

$[Co(dgH)_3]\cdot 5/2H_2O$	−0.81 ($Co^{III}\rightarrow Co^{II}$)	−2.11 ($Co^{II}\rightarrow Co^{0}$)
cis-$[Co(dgH)_2en]ClO_4\cdot 1/3H_2O$	−0.87 ($Co^{III}\rightarrow Co^{II}$)	−2.29 ($Co^{II}\rightarrow Co^{0}$)
cis-$[Co(dgH)_2(NH_3)_2]ClO_4\cdot 7H_2O$	−0.82 ($Co^{III}\rightarrow Co^{II}$)	−2.04 ($Co^{II}\rightarrow Co^{0}$)

a) The 1st wave lies at positive region of potential. V *vs.* SCE

Table 1 presents some examples of the electrode processes and their half-wave potentials. Thus, the cis- *vs.* trans-distinction has been clearly demonstrated polarographically with regard to the stability of the cobalt(I) complex in DMSO; a similar differentiation was shown to be possible for the *cis*- and *trans*- tetracyano cobalt(III) complexes in aqueous solutions.[4] This method of distinguishing steric isomers is more promising than that based on the spectra,[5] because the latter is more complicated; its interpretation and assignment is based on the infrared spectra.

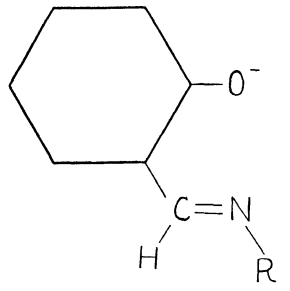
The Synthesis of Lanthanide(III) Complexes with Schiff Bases Obtained from Salicylaldehyde

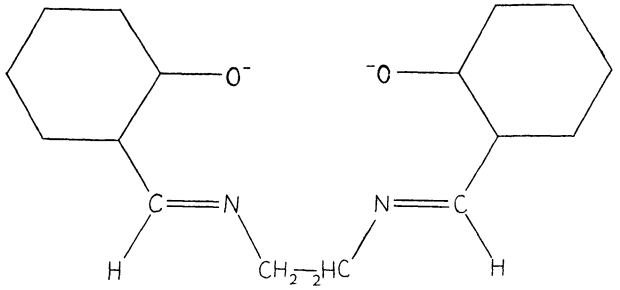
Shoichiro YAMADA, KUNIKO YAMANOUCHI, and Hiro KUMA
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka
(Received March 22, 1971)

There have been only a few papers available on lanthanide(III) complexes with Schiff bases as ligands.[1-3] Complexes with *N*-*n*-alkylsalicylideneiminates (I,



I

abbreviated as SAL·R) have not been reported in literature. With *N*,*N*′-ethylenebis(salicylideneiminate) (II, abbreviated as SALen), complexes of types $Ln_2(SALen)_3$ and $Ln_2(SALen)_3 \cdot nL$ were previously reported, L being H_2O and C_2H_5OH, and Ln a lanthanide(III)



II

ion. However, some properties, such as colour, solubility and melting point, widely differ from those of the complexes of a similar composition obtained in the present work. The method of preparation employed in the previous work differs from the present one, and recrystallization was not possible in the previous work, whereas the complexes were purified by recrystallization from organic solvents in our case. The present communication deals with tris(*N*-methylsalicylideneiminato)- and *N*,*N*′-ethylenebis(salicylideneiminato)-lanthanide(III) complexes.

Complexes of the type $Ln(SAL \cdot CH_3)_3 \cdot nH_2O$ were synthesized in the following way. To preformed *N*-methylsalicylideneimine (0.033 mol) was added lanthanide(III) chloride hydrate (0.01 mol), and the mixture was ground for about 1 hr, until it nearly solidified. No solvent was used in this process. The powder obtained was recrystallized from methanol or ethanol. They are soluble in methanol and ethanol, and slightly soluble in acetone and chloroform. The cerium(III) and neodymium(III) complexes are brownish orange and yellowish orange, respectively.

TABLE 1. ANALYTICAL DATA OF THE COMPLEXES OF THE TYPES $Ln(SAL \cdot CH_3)_3 \cdot nH_2O$ (COMPLEX I) AND $Ln_2(SALen)_3 \cdot nH_2O$ (COMPLEX II)

Ln	*n*	mp °C	Found, %			Calcd, %		
			C	H	N	C	H	N
Complex I								
Ce	4	159—161	46.40	5.05	6.55	46.90	5.25	6.84
Nd	3	259—261	48.21	4.94	6.90	47.98	5.03	6.99
Complex II								
Nd	4	227—229	46.61	4.54	6.44	46.81	4.75	6.83
Sm	4	275—277	45.56	4.53	7.14	46.35	4.70	6.76
Eu	4	164—166	45.98	4.50	6.22	46.23	4.69	6.74
Tb	3	167—169	47.37	4.33	6.71	47.07	4.44	6.86
Er	3	178—180	45.88	4.32	7.10	46.40	4.38	6.76

The complexes of the type $Ln_2(SALen)_3 \cdot nH_2O$ were prepared as follows. To a solution of *N*,*N*′-ethylenebis(salicylideneimine) (0.005 mol) in ethanol (10 ml) was added lanthanide(III) chloride hydrate (0.015 mol), and the resulting solution was stirred for 1 hr at about 40°C. The precipitate was filtered off and purified by recrystallization from methanol or ethanol. The complexes are soluble in methanol and ethanol, but slightly soluble in chloroform and acetone. They are yellow and show melting points as given in Table 1. The complexes reported previously melted with decomposition above 300°C, and were not soluble in common organic solvents.

Analytical data of the complexes are shown in Table 1.

The Photo-erasable Memory Effect Associated with a "Conductive Path" Formed in Ag-doped Chalcogenide Glasses

Hiraku SAKUMA, Isamu SHIMIZU, Hiroshi KOKADO, and Eiichi INOUE
Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received April 2, 1971)

We previously reported the rapid metal diffusion into chalcogenide glasses induced by light irradiation,[1] and also the remarkable increase in electrical conductivity in the metal-doped areas.[2] The conductivity of the metal-doped areas was about 10^6 times higher than that of the undoped areas. It has been pointed out that the differences in the chemical and electrical properties between the metal-doped and the undoped areas can be used for a new type of photo-imaging materials.

During the investigation of the electrical properties, a photo-erasable memory effect was found in the silver-doped chalcogenide glasses. The sample was prepared as follows. About a 1000 Å-thick layer of silver was doped with light[1] into the evaporated film of $As_{24}S_{70}$-Te_6 (atomic %). The surface-type cell shown in Fig. 1 (a) was made by the vacuum deposition of gold electrodes on the sample surface. The spacing between the electrodes was 1 mm. The cell showed two stable states in electrical conductivity—the low conductive state (1) and the high conductive state (2), as indicated in Fig. 1 (b). The cell changed from the (1) state to the (2) state at an applied voltage of over 20 V in this experiment. This high-conductive state easily changed back to the (1) state within half a minute upon light irradiation from a 250 W Hg high-pressure lamp. The ratio of the electrical conductivities of the (1) state to the (2) state was over the order of magnitude of 10^3.

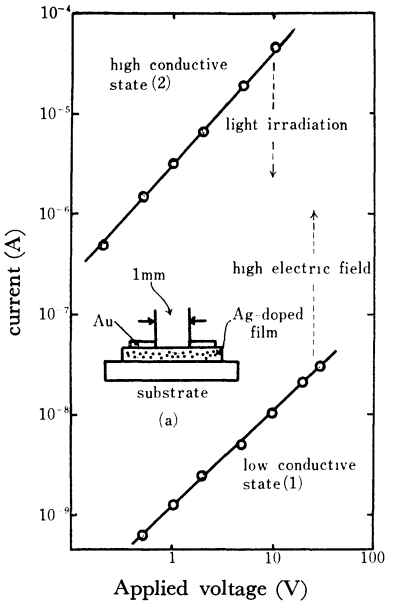

Fig. 1. (a) The structure of the surface type cell
(b) I-V characteristics of the Ag doped chalcogenide film

From observation with a microscope, the high-conductive state was found to be attained by the formation of a "conductive path" between the electrodes. When a high voltage was applied to the cell in the (1) state, the boundary of the negative electrode and the glass film began to darken, and then "branchlike" paths began to grow from the electrode. A microscopic photograph of the path is shown in Fig. 2. These paths stretched

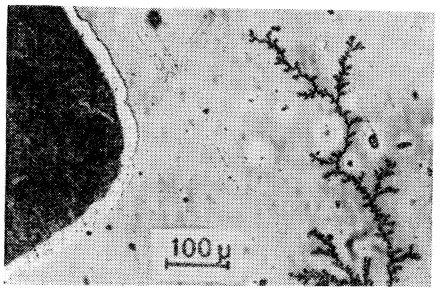

Fig. 2. The microphotograrh of condutive path formed in the surface of the Ag-doped chalcogenide glassfilm (black region on the left-hand is the positive electrode)

toward the positive electrode; high-conductive state (2) was attained when one of the paths reached the positive electrode. Upon the light irradiation, the path faded away and, at the same time, the electrical conductivity returned to the lower state (1). These results indicate that the formation and the disappearance of the "conductive path" caused the memory effect.

This photo-erasable memory effect is similar to the memory effects in chalcogenide glasses reported in other papers recently,[3-5] but the doped Ag is thought to play an important role in this case. At the present stage, the mechanism of the formation of conductive path is not clear in detail, but ionic process (such as the reduction of Ag^+, which is supposed to exsist in the chalcogenide glass) is suggested by the fact that the conductive path always grows from the negative electrode. The path is expected to have an Ag or Ag-rich composition. Its disappearance upon light irradiation can be considered to be connected with the optical diffusion of Ag into chalcogenide glasses.

Electrochemiluminescence of 9,10-Dichloroanthracene and 9,10-Dibromoanthracene

Tamotsu MATSUMOTO, Masanori SATO, Satoshi HIRAYAMA, and Shigeru UEMURA
Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto
(Received February 17, 1971)

Recent investigations on the electrochemiluminescence (ECL) of organic compounds have revealed that in most cases the emission spectra coincide with the fluorescence spectra of the corresponding compounds. However, in some compounds such as anthracene, the ECL spectra have components which cannot be assigned to fluorescence,[1] and their assignments are still in question. We recently found from an investigation of the ECL of 9,10-dichloroanthracene (9,10-di-Cl-A) and 9,10-dibromoanthracene (9,10-di-Br-A) that the ECL of the former was composed of two main components which were clearly distinguishable, while the ECL of the latter had only one component. In this communication we wish to elucidate the difference in ECL of these compounds.

Synthesized 9,10-di-Cl-A and 9,10-di-Br-A were purified by sublimation. In a *N,N*-dimethylformamide (DMF) solution containing potassium perchlorate as a supporting electrolyte, the ECL of both compounds was examined at a platinum wire electrode of 0.05 cm in diameter and 3 cm in length. A 40-Hz square-wave potential (less than 6V) was applied to the working electrode with a function generator. Dried nitrogen gas was passed through the solution during the measurements.

The results[2] obtained at room temperature are shown

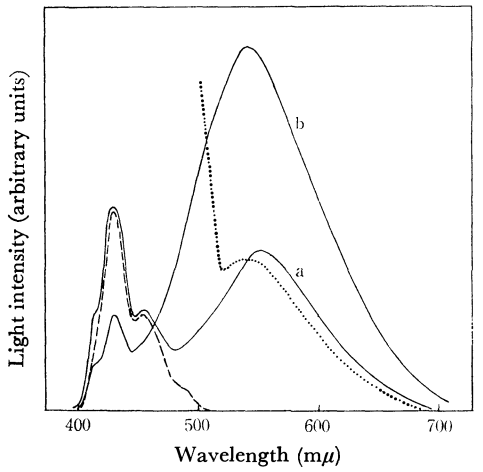

Fig. 1. Emission spectra of 9,10-di-Cl-A.
Solid line a: ECL (7×10^{-4} M)
b: ECL of 9,10-di-Cl-A (7×10^{-4} M) containing anthracene (10^{-3} M)
Broken line: Fluorescence (7×10^{-4} M)
Dotted line: Emission observed on the saturated DMF solution of 9,10-di-Cl-A (Irradiation at 366 mμ)

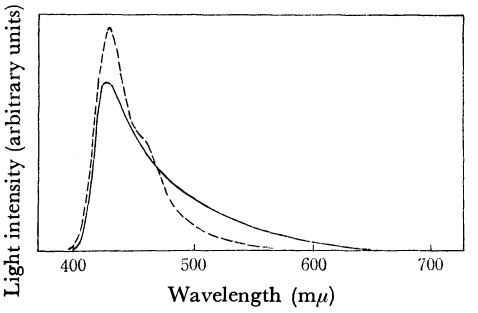

Fig. 2. Emission spectra of 9,10-di-Br-A.
Solid line: ECL (5×10^{-4} M)
Broken line: Fluorescence (5×10^{-4} M)

in Figs. 1 and 2 for 9,10-di-Cl-A (7×10^{-4}M) and 9,10-di-Br-A (5×10^{-4}M), respectively. Fluorescence spectra measured under the same conditions as those of ECL measurements are also given. Ordinate scales are arbitrary for ECL and fluorescence, hence their intensities cannot be compared with each other.

The ECL of 9,10-di-Br-A agrees with its fluorescence. However, the ECL of 9,10-di-Cl-A has a second component in the longer wavelength region, differing from its fluorescence component. The same ECL spectrum is also observed in methylene chloride instead of DMF. The long-wavelength component agrees with the excimer emission observed with a saturated DMF solution of 9,10-di-Cl-A (dotted line in Fig. 1).[3] When a small amount of anthracene (*ca.* 10^{-3}M) was added to the solution of 9,10-di-Cl-A, the long-wavelength ECL component was strongly enhanced as shown by curve b in Fig. 1. The observed spectral change was not due to the ECL of anthracene, because it had a maximum near 405 mμ.[1] Similar phenomena were also observed on addition of 9,10-dimethyl-A. However, the addition of 9,10-di-Br-A and 9,10-diphenyl-A, known to form an excimer or an exciplex with difficulty, caused no change in the ECL spectrum of 9,10-di-Cl-A.

On the other hand, the ECL spectrum of 9,10-di-Br-A did not change with the addition of anthracence and the observed emission was merely a superposition of each ECL spectrum.

To understand these behaviors the report by Chandross and Ferguson[3] that an excimer emission was observed on 9,10-di-Cl-A but no measurable one on 9,10-di-Br-A should be noted. They also found an exciplex emission of 9,10-di-Cl-A and anthracene.

Thus, the present results indicate conclusively that the long-wavelength component in 9,10-di-Cl-A ECL can be attributed to an excimer emission.

The Solvent Effect on the Catalytic Activity of Benzonitrile-Alkali Ion Salt Solutions for the Hydrogen Exchange Reactions

Masaru ICHIKAWA and Kenzi TAMARU

Sagami Chemical Research Center, Onuma, Sagamihara, Kanagawa

The Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 25, 1971)

Recently it has been reported that the activation of hydrogen takes place by means of some electron donor-acceptor (EDA) complexes of aromatic compounds with alkali metals in their solutions as well as in the solid state.[1] It was previously shown that the hydrogen absorption and the hydrogen exchange reaction proceeded homogeneously at room temperature in the anthracene dianion complex solutions,[2] much as on their films.[3] We would like to report here a marked solvent effect on the catalytic activity by the benzonitrile-alkali ion radical salt solutions for the hydrogen exchange reactions, especially, there is a strong inhibition of alkali cations by chelating solvents.

Benzonitrile-alkali ion radical salts were prepared in solution by a reaction between benzonitrile (10^{-4}—10^{-2} mol) and each of the alkali metals in *ca.* 80 cc of dry THF (tetrahydrofuran), MDE (monoethylene glycol dimethyl ether), DED (diethylene glycol dimethyl ether), TED (triethylene glycol dimethyl ether) and benzonitrile, much as has been described previously.[4] The composition of the complexes was confirmed by a study of their electronic spectra. Each of the complex solutions was introduced into a reaction vessel (*ca.* 270 cc) through a glass filter in order to remove an excess of the unreacted metal. When D_2 (10—45 cm Hg) was introduced to the complex solution, which was strongly stirred, the gaseous deuterium was reversibly exchanged with the hydrogen of the complex molecule in the temperature range from −20 and 50°C; a small amount of hydrogen was absorbed[5] at the same time in the benzonitrile-sodium or -lithium solution. The initial rates (in the first-order kinetics) or HD formation in the D_2–HZ (HZ=PhCN$^-$M$^+$; M=Li, Na, K, and Rb) exchange reaction are given in Table 1. It was demonstrated by the NMR spectrometry[6] that the PhCN$^-$K$^+$ complex was deutrated at the *p*-position of benzonitrile. The kinetics of the D_2–HZ exchange reaction was also investigated by changing the D_2 pressure and the concentration of the PhCN$^-$K$^+$ in THF (1.2×10^{-2}—2.8×10^{-3} mol):

TABLE. 1

Complex(HZ) (1.2×10^{-3} mol)	Solvent (80 cc)	D_2–HZ exchange reaction K_{HD}(cc/hr)	E(kcal/mol)
PhCN$^-$Li$^+$	THF	0.1	16
PhCN$^-$Na$^+$	THF	4.8	10
PhCN$^-$K$^+$	THF	10.0[a]	6
PhCN$^-$Rb$^+$	THF	0.3	—
PhCN$^-$K$^+$	MED	2.0	—
PhCN$^-$K$^+$	DED	0.58	—
PhCN$^-$K$^+$	TED	0.32	—
PhCN$^-$K$^+$	PhCN	>0.001	—
PhCN$^-$K$^+$	THF (9×10^{-3} mol; PhCN)	>0.2	—

a) The HD formation in the D_2–HZ exchange reaction took place homogeneously to reach nearly a monodeuteration of PhCN$^-$K$^+$ complex:

$$\frac{N_{exch.}}{(PhCN^-K^+)} = 0.87\ (25°C)$$

Where $N_{exch.}$ denotes the total number of the hydrogen exchanged with deuterium gas.

$$V_{HD} = kP_{D_2}(PhCN^-K^+)^2$$

It was interesting to note in Table 1 that the activity of the PhCN$^-$M$^+$ solution decreased strikingly when strong chelating solvents were used with alkali cations, such as DED, TED, or benzonitrile. When a small amount of benzonitrile (0.9×10^{-2} mol) was added to the THF solution of the benzonitrile – K stoichiometric complex, the exchange rates decreased; they were retarded completely by the addition of an excess.

The D_2–HZ and H_2–D_2 exchange reactions exhibited wide varieties of activities in solution; this was in contrast to the reactions over their complex films under similar reaction conditions.[7] The characteristic behaviour of such chelating solvents might be attributed to the solvation to alkali cations, which brings about a wide separation between anion and cation centers[8] in the complex molecule, thus preventing the development of favorable circumstances for the hydrogen activation.

A similar behavior of the different solvents was observed for the hydrogen exchange reaction and hydrogen absorption in their complex solutions, such as anthracene dianion, naphthalene monoanion and cyanonaphthalene dianion with alkali cations.

4) M. Ichikawa, S. Tanaka, S. Naito, M. Soma, T. Onishi, and K. Tamaru, *Trans. Faraday Soc.*, **66**, 981 (1970).

5) It was shown by the NMR and UV spectrometry that the PhCN$^-$Na$^+$ and PhCN$^-$Li$^+$ were decomposed very slowly at room temperature in the presence of hydrogen gas to produce benzonitrile and metal hydride (NaH and LiH).

6) After deuteration and the removal of the solvent, the PhCN$^-$K$^+$ complex was oxidized to neutral PhCN by dry oxygen gas at 25°C as measured by mass and NMR spectrometry.

New Finding of Glassy Liquid Crystal – a Non-equilibrium State of Cholesteryl Hydrogen Phthalate

Kazuhiro Tsuji, Michio Sorai, and Syûzô Seki
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received March 25, 1971)

The ordinary glassy state is realized for many liquids when they are supercooled below their glass transition points without crystallization. This type of glassy state, however, can be established by other procedures, *e.g.* condensation of vapor,[1] precipitation process,[2] or thermal decomposition.[3] Recently we reported also the possible existence of glassy state of crystalline materials as a non-equilibrium state of many plastic crystals.[4] In this communication, we should like to report the new finding of the glassy state for liquid crystal of cholesteryl hydrogen phthalate (abbrebiated as CHP).

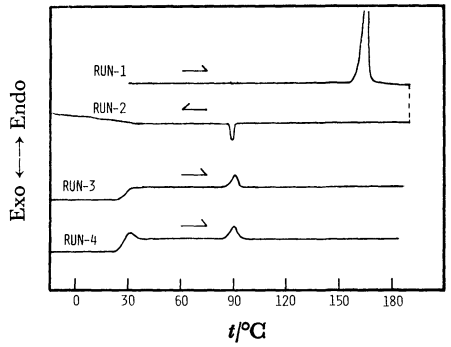

Fig. 1. DSC curves of cholesteryl hydrogen phthalate.

CHP obtained from Tokyo Kasei Kogyo Co., was recrystallized twice from ethanol. Thermal analysis was carried out for this specimen with a differential scanning calorimeter (Perkin-Elmer DSC-1B) as shown in Fig. 1. Run-1 shows a heating curve of crystalline CHP from room temperature to 190°C with the heating rate of 5°C/min. The crystalline CHP melted directly into an isotropic liquid at 160°C. Run-2 shows a cooling curve of the isotropic liquid with cooling rate of −5°C/min. The isotropic liquid was transformed into a liquid crystalline state at 90°C and no other thermal anomaly was observed between 90 and −100°C except for a slight baseline shift around 27°C. This implies that there exists only one liquid crystalline phase for CHP in contrast to the results by Barrall II *et al.*,[5] who reported two liquid crystalline states obtainable through monotropic transitions on cooling the isotropic liquid. Observation under polarizing microscope revealed a focal-conic texture for the present liquid crystal, but identification of its type has not been made. Run-3 shows a heating curve of the supercooled liquid crystal thus obtained. The DSC curve showed two thermal anomalies; a conspicuous stepwise anomaly at *ca.* 27°C which bears close resemblance to usual glass transition, and a phase transition at 90°C from liquid crystal to isotropic liquid.

Run-4 shows a heating curve of the supercooled liquid crystal annealed for 2 hr at 23°C just below the apparent glass transition point and then cooled down to −20°C before heating. It gave a stepwise curve with a small peak which corresponds to the enthalpy relaxation usually observed in an ordinary glass transition phenomenon. These facts confirm the view that the thermal anomaly at about 27°C might be considered to be a glass transition of the liquid crystalline state in CHP.

In order to examine more precisely the nature of this glass transition, activation enthalpy was determined according to McMillan's method.[6] Figure 2 shows the activation plot, from which the activation enthalpy was found to be 76.6 ± 3 K J mol^{-1}.

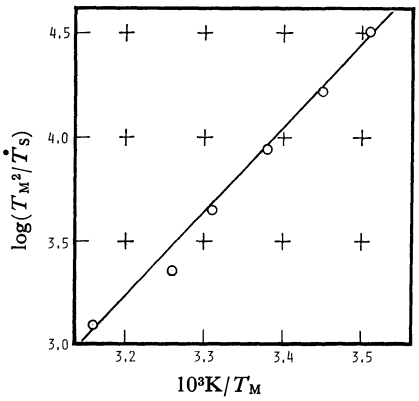

Fig. 2. Activation plot for glass transition of cholesteryl hydrogen phthalate (T_M, Inflection point; $\dot{T}_S$, Heating rate).

The glass transition temperature (T_g) was determined to be 22°C from the heat capacity measurements by use of an adiabatic calorimeter and the characteristic heat capacity jump at T_g, ΔC_p, was found to be 180 J K^{-1} mol^{-1}. The details of the present results of the heat capacity measurements will be given in due course.

From these results it can be concluded that the glassy state of liquid crystal has been established for the first time in the present study and we propose to designate this state as "**glassy liquid crystal**".

Infrared Longitudinal Bands in Crystalline Carbon Dioxide

Haruka YAMADA, Arata KIMOTO, and Kazuo SANNABE
Department of Chemistry, Kwansei Gakuin University, Nishinomiya

(Received March 31, 1971)

Recently two absorption peaks at 678.3 cm^{-1} and 2383.0 cm^{-1} were reported for the cubic crystal of carbon dioxide. They appeared at non-normal incidence and disappeared at normal incidence.[1] An attempt[1,2] has been made to interpret them as the longitudinal modes of ν_2 and ν_3 vibrations by means of the Haas-Hornig equation.[3] Assignment of these bands, however, still seems uncertain, because of the uncertainty of the value $d\mu/dQ$ used in the Haas-Hornig equation.

We have remeasured the absorption spectra of polycrystalline CO_2 films deposited fairly rapidly (60~90 sec) at liquid nitrogen temperature, the thickness being 1.8—2.8 μ. Spectra of each film were run at normal incidence, 0°, and at angles up to 30° from normal. The results are completely in agreement with those reported by Parker and Eggers.[1] The peaks at 678.0 cm^{-1} and 2379 cm^{-1} are angle-dependent, but the others do not shift or change significantly with the angle of incidence. We have further tried to confirm the longitudinal modes by a direct polarization measurement at non-normal incidence. As shown in Figs. 1 and 2, the peak at 678.0 cm^{-1} in the ν_2 region observed at non-normal incidence appears strongly in the *p*-polarized component of the radiation, where the electric vector is parallel to the incident plane, disappearing in the *s*-polarized radiation where the electric vector is perpendicular to the incident plane. The absorption curve observed at normal incidence shows no difference in *p*- and *s*- polarizations. The same holds for the peak at 2379 cm^{-1} in the ν_3 region.

Since the peaks occur only in the *p*-polarization, this strongly supports their assignment to the longitudinal optical modes.

Spatial Distribution of Potassium Atoms Scattered from the (001) Surfaces of Lithium Fluoride

Shinji TOMODA, Isao KUSUNOKI, and Kumasaburo KODERA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto
(Received March 19, 1971)

Investigation of gas-solid interactions by means of molecular beams has recently attracted a great deal of attention.[1] The object of the study is to make clear the gas-surface interaction from the scattering of rare gases or hydrogen from clean surfaces of metals.[2] On the scattering of metal atoms from alkali halide crystals, however, few papers have been published during the past thirty years.

In earlier studies on the scattering of metal atoms from alkali halide surfaces, three types of patterns were reported; one which corresponds to specular reflection,[3] a second which obeys the cosine law,[4] and the third which is called "quasi-specular" or broad lobular pattern.[5] The results reported by different authors do not seem to be consistent with each other. Thus, more complete information on the phenomena is desiable. Concerning the technique of thin film growth on solid surfaces, work in this field might be important for clarifying the initial process of sticking of metal atoms on the surfaces.

In the present work, scattering patterns of the potassium beam from the surface of lithium fluoride were measured at several angles of incidence between 55° and 70° (measured from the surface normal). To determine the angular distribution of the flux of scattered atoms, a surface ionization detector was rotated around the target crystal. The thermal beam of potassium (cross section: 0.46 mm × 11.7 mm) was produced by effusion from an oven. Background pressure with the beam on was 2×10^{-7} Torr. Targets with lithium fluoride (001) surface prepared in different ways were used, one with a surface made by cleaving a crystal in air and the other was made optically flat by polishing with corundum powder suspended in water. The crystal was heated in a vacuum at about 470°K before it was exposed to the beam. The measurements were carried out at several temperatures from 170°K to 470°K.

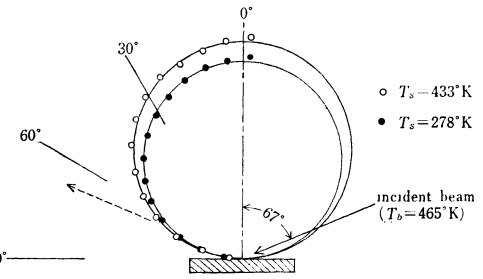

Fig. 1. Angular distribution of potassium atoms scattered from the cleavage surface of lithium fluoride (001). The solid curve indicates the cosine law. The broken line represents the specular direction. T_s and T_b are the surface temperature and the beam temperature, respectively.

Two different scattering patterns were obtained corresponding to the preparation of the surface. As is shown in Fig. 1, the spatial distribution from the cleavage surface closely follows the cosine law. This pattern indicates diffuse scattering and agrees with the results of Taylor.[4] Figure 2 shows the patterns from the polished surface. The peaks correspond approximately to the specular positions. The results give no definite conclusion but suggest that the molecules of water on the polished surface have some effect on the scattering pattern.

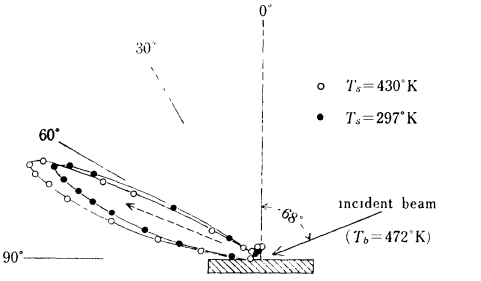

Fig. 2. Angular distribution of potassium atoms scattered from the polished surface of lithium fluoride (001). The broken line represents the specular direction. T_s and T_b are the surface temperature and the beam temperature, respectively.

Above room temperature, the scattering patterns and the scattered fluxes did not change significantly with the target temperature, while at temperatures below 250°K, the scattered fluxes decreased markedly and the patterns showed different directional features compared with those at high temperatures. The scattered flux attenuated rapidly with the time of exposure to the beam. This indicates the condensation of potassium atoms on the surface and the increase of the sticking probability. It is still difficult to explain the behavior of the two different surfaces.

A Chlorine NQR Study of Trichlorides of Group V Elements

Masao HASHIMOTO, Toshiaki MORIE, and Yoshifumi KATO

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

(Received June 19, 1970)

The NQR frequency of ^{35}Cl has been observed in polycrystalline PCl_3, $POCl_3$, $AsCl_3$, and $SbCl_3$ at 77°K and above. In all cases, the resonance frequency decreases at higher temperatures. The temperature coefficient of the resonance frequency is analyzed according to a modified Bayer-type treatment. A qualitative examination of the experimental results, including Robinson's results for $BiCl_3$ at 83 and 299°K, reveals that the strength of the intermolecular interactions in the solids of these trichlorides decreases in this order: $BiCl_3 > SbCl_3 > AsCl_3 > PCl_3$. The resonance was found to "fade-out" at temperatures below the melting point for the solids of PCl_3 and $POCl_3$, while the resonance was observed up to the melting point for the other compounds. The origin of this phenomenon is discussed.

As to the nuclear quadrupole resonance (NQR) of chlorine in trichlorides of the Group V elements, there have already been a number of investigations by several workers.[1-7] In the earlier studies, however, the measurements were made at only a few temperatures. Recently, though, Chihara *et al.*[8] measured almost continuously the NQR frequencies of chlorine and antimony in solid antimony trichloride in the range from 20°K to about 150°K.

The first theoretical elucidation of the temperature variation of resonance frequencies was given by Bayer,[9] who attributed the phenomenon to the influence of lattice vibration on the electric-field gradient tensor under a simple model with a one-dimensional torsional mode. This theory was later extended generally by Kushida[10] and Wang[4] separately. According to these treatments, the NQR frequencies are connected to the mean square amplitude of each normal vibration through both the electric-field gradient tensor and the asymmetry parameter. On the assumption that the mean energy of a normal mode is equal to that of the corresponding Planck oscillator, the resonance frequency may be said to be related explicitly to the temperature and the moment of inertia for the vibration concerned. Kushida *et al.*,[11] furthermore, discussed the dependence of the NQR frequency on the pressure as well as on the temperature.

In this investigation, the measurements of the NQR frequencies of ^{35}Cl in phosphorous, phosphoryl, arsenic, and antimony trichloride were carried out at 77°K and above at intervals of a few degrees. No reference to the temperature dependence of the NQR frequency of ^{35}Cl in phosphorous and phosphoryl trichloride has been found in previous works.

In all the compounds studied in this paper, the principal axes of the electric-field gradient tensor at a chlorine nucleus do not coincide with those of the moment of inertia of the molecule concerned. A treatment generalized for such a case is applied to the analysis of the temperature dependence of the NQR frequencies of ^{35}Cl in phosphorous trichloride. Some discussions of the torsional motions and the intermolecular interactions in the solid are given on the basis of the experimental results.

Experimental

The NQR frequencies of ^{35}Cl were measured with a super-regenerative spectrometer which was externally quenched and frequency-modulated.[12] For the frequency modulation, a 80 Hz sine wave was used. The quenching frequency was varied from 35 KHz to 70 KHz. The resonance frequencies were measured visually; that is, an NQR signal was compared directly on an oscilloscope screen with that from a standard frequency generator (National VP-828A), which was itself calibrated by means of a digital frequency counter (National VP-415 M). The accuracy of the frequency measurements is considered to be ±2 KHz.[13] Although the super-regenerative spectrometer used was not well suited for observing linewidths, the linewidths were estimated by recording the signals through a lock-in amplifier.

The resonance frequencies were measured at 77°K and above in liquid nitrogen and in various liquid baths. The temperature was determined by using two copper-constantan thermocouples, each in contact with the upper or the lower side of the sample tube. The accuracy of the temperature measurements may be considered to be better than ±1°K.[14]

Commercial compounds (Wako Pure Chemical Industries, Ltd.) were used without further purification. They were packed in glass tubes with an outside diameter of 18 mm.

13) By comparing our measurements with those already reported, we estimated the accuracy of our frequency measurements.

14) In Ref. 8, Chihara *et al.* tabulated the resonance frequencies of ^{35}Cl in antimony trichloride in the low-temperature region (from 21.5°K to 178°K). By comparing our data with theirs, we deduced the accuracy of our temperature measurements.

(designated as ν_1 and ν_2) were measured at temperatures above 77°K. The signals could be observed up to about 165°K. Above this temperature, the resonance was found to fade out, while this compound melts at 179°K. The temperature dependences of ν_1 and ν_2 are shown in Fig. 1. The line-width of ν_2 was almost constant between 77°K and about 150°K. Above this temperature, though, the width increased rapidly.

Phosphoryl Trichloride. Although the compound melts at 272°K, two NQR signals (designated as ν_1 and ν_2) were found to fade out at temperatures above about 200°K. By immersing the sample in chlorobenzene bath (228°K), the NQR signals were searched for over the frequency region of 20 MHz to 33.5 MHz. No signals was found under these conditions. As is shown in Fig. 2, ν_1 and ν_2 decrease parallel with an increase in the temperature. The linewidth of the ν_2 was found to increase gradually as the temperature increased. The width at 187°K was about three times as large as that at 77°K.

Arsenic Trichloride. Three resonance frequencies of ^{35}Cl (designated as ν_α, ν_β, and ν_γ) could be measured at temperatures between 77°K and the melting point of the compound (257°K). Their temperature dependences are shown in Fig. 3.

Antimony Trichloride. The resonance frequencies of ^{35}Cl due to two nonequivalent chlorine sites (designated as ν_1 and ν_2) could be measured up to the melting point of the compound (346°K). Our data were in good agreement with those of Chihara *et al.*[8] The linewidths of the ν_1 and ν_2 at 77°K were found to be almost equal to the corresponding values at room temperature.

Bismuth Trichloride. We could not observe the NQR signals of ^{35}Cl in this compound. The reason for our failure might perhaps be traced to the purity of the sample.

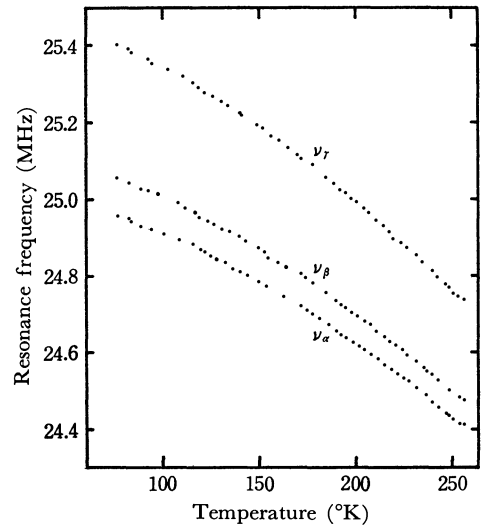

Fig. 3. Temperature dependence of ν_α, ν_β, and ν_γ in $AsCl_3$.

Theoretical

When the principal axes of the field gradient (x, y, and z) coincide with the inertial axes (X, Y, and Z) around which the torsional motions may take place, the z component of the field gradient seen at a nucleus in the vibrating molecule (q) can be related to that in the static molecule (q_0) by Wang's expression;[15]

$$q = q_0\{1 - \tfrac{3}{2}(\langle\theta_X^2\rangle + \langle\theta_Y^2\rangle) + \tfrac{1}{2}\eta(\langle\theta_Y^2\rangle - \langle\theta_X^2\rangle)\}, \quad (1)^{16}$$

where $\langle\theta_i^2\rangle$ is the average square torsional displace-

15) T. C. Wang, *Phys. Rev.*, **99**, 566 (1955).

16) As has already been pointed out by Chihara *et al.* (Ref. 8), a slight correction must be made in the right-hand side of Wang's original expression.

Table 1. The frequency (ω_i) and the mean square amplitude ($\langle\theta_i^2\rangle$) of the torsional motion in phosphorous trichloride

T (°K)	ω_1	ω_2 (cm^{-1})	ω_3	$\langle\theta_1^2\rangle$	$\langle\theta_2^2\rangle$ (10^{-3} rad^2)	$\langle\theta_3^2\rangle$
93	57±7	29±1	39±5	3.8±1.9	13.6±1.0	4.5±1.0
143	50±6	27±1	35±5	7.5±1.7	24·5±1.0	8.4±2.3

ment about an axis, i, and η, the asymmetry parameter. This expression can not be applied immediately to the analysis of the field gradient at the chlorine nucleus in an MCl_3 molecule in the absence of the coincidence between the principal axes of the field gradient and inertial axes. Therefore, one must modify Eq. (1) to obtain an expression valid for such a situation.[17]

Now, let q' represent the field gradient at the chlorine nucleus along an M–Cl bond direction (designated as the z axis of the field-gradient tensor) in an MCl_3 molecule. For the sake of simplisity, the field gradient is assumed to be axially symmetric (*i.e.*, $\eta=0$) and the symmetry of the MCl_3 molecule is assumed to be C_{3v}. As the principal axes of the moment of inertia, we take the system of axes (X_1, X_2, and X_3) shown in Fig. 4, in which the X_3 axis is chosen perpendicular to the plane of three chlorine atoms, and the X_2 axis, parallel with the Cl(2)–Cl(2) direction.

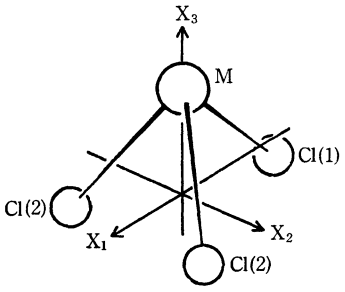

Fig. 4. The orientation of the coordinate system in the MCl_3 molecule.

A torsional motion around an X_i axis makes the z axis fluctuate by an angle of $c_i\theta_i$, where θ_i is a torsional displacement around the X_i axis, and c_i, a constant specified by the molecular geometry. As a first-order approximation, the total effect of the torsional motions around three inertial axes (X_i) on the field gradient at a chlorine nucleus may be written as follows:

$$q' = q_0'\{1 - 3/2 \sum_i \sin^2 \alpha_i \langle\theta_i^2\rangle\}, \quad (2)$$

where α_i is the angle between X_i and the z axis. Hence, the temperature-dependent frequency (ν') is related to the frequency of the stationary molecule (ν_0') by:

$$\nu' = \nu_0'\{1 - 3/2 \sum_i \sin^2 \alpha_i \langle\theta_i^2\rangle\}. \quad (3)$$

If the torsional motion is approximated by a quantum mechanical harmonic oscillator, the mean square displacement ($<\theta_i^2>$) is;

$$\langle\theta_i^2\rangle = \hbar/A_i\omega_i[1/2 + 1/\{\exp(\hbar\omega_i/kT) - 1\}], \quad (4)$$

where ω_i is the torsional frequency, and A_i, the moment of inertia associated with the torsional motion about the X_i axis.

The asymmetry parameter of the field gradient at a chlorine nucleus in $SbCl_3$ was found to be large,[18] and that in $BiCl_3$ seems likely to be large because of a strong intermolecular bond formation to be discussed later. In $AsCl_3$ there are three kinds of resonance frequencies; this make it difficult to regard the symmetry of the molecule as trigonal. Therefore, the assumptions included in the derivation of Eq. (2) or (3) are not valid for the cases of $SbCl_3$, $BiCl_3$, and $AsCl_3$ because of the large asymmetry parameter or the destruction of the trigonal symmetry. Since, however, as will be discussed later, the inter-molecular interactions in the solid of PCl_3 seem to be quite weak, the assumptions mentioned above may be valid for the case of this molecule.

The results of the analysis of the temperature dependence of ν_1 and ν_2 in PCl_3 according to Eqs. (3) and (4) are shown in Table 1. Unfortunately, we could not determine all the parameters definitely, although their values are considered to be reasonable.

Discussion

Although the crystal structure of the compounds studied in this work are, for the most part, unknown, here, we shall attempt a qualitative discussion of the intermolecular interactions in their crystals.

Two or three resonance frequencies are observed in each compound studied. The separation ($\Delta\nu$) between the multiple lines in each compound is shown in Table 2. According to Robinson's results,[5] the separation ($\Delta\nu$)

Table 2. The frequency separation ($\Delta\nu$) between non-equivalent sites in MCl_3 molecules at 77°K

Compound	$\Delta\nu$ (MHz)
$POCl_3$	0.05
PCl_3	0.10
$AsCl_3$	0.40[a]
$SbCl_3$	1.61
$BiCl_3$	3.68[b]

a) A separation between the highest resonance frequency and the mean of the lower two.
b) See Ref. 5.

17) I. Tatsuzaki and Y. Yokozawa, *J. Phys. Soc. Jap.*, **12**, 802 (1957).

18) T. Okuda, A. Nakao, M. Shiroyama, and H. Negita, This Bulletin, **41**, 61 (1968).

found for $BiCl_3$ is about 3.68 MHz at 83°K. A less drastic splitting occurs in $SbCl_3$. The separation ($\Delta\nu$) found for this compound is about 1.61 MHz at 77°K. Allen[19] pointed out that splittings greater than 0.5 MHz must be attributed to a different type of chemical bonding to the chlorine atoms. In fact, Peterson,[7] in his X-ray study of $SbCl_3$, found that one of the Sb–Cl bond lengths within a molecule is 2.30 Å, and the other two, 2.325 Å. Futhermore, the two nearest intermolecular Sb–Cl distances are 3.41 Å, which is smaller than the van der Waals distance (4 Å). Chihara *et al.* reasonably explained both the large separation ($\Delta\nu$) and the difference in the temperature dependence of the two lines of $SbCl_3$ in terms of this intermolecular-bond formation. That is, the intermolecular-bond formation mentioned above diminishes the electron density of the p_x or p_y orbitals of chlorine atoms participating in the bond formation and, therefore, their resonance frequencies. The decreases in this electron density and the resonance frequency due to the intermolecular-bond formation are proportional to the degree of the intermolecular overlap, which should tend to decrease as the molecular librations increase in amplitude at higher temperatures. The direct temperature effect, which tends to decrease the resonance frequency at higher temperatures, counteracts the above effect; their compromise determines the actual temperature coefficient of the resonance frequency.

If the formation of intermolecular covalent bonds similar to that found in $SbCl_3$ is possible in the crystal of $BiCl_3$, it accounts for the large separation ($\Delta\nu$) and the positive temperature coefficient found for $BiCl_3$. Both the fact that the separation ($\Delta\nu$) of $BiCl_3$ is considerably larger than that of $SbCl_3$ and the fact that one of the two lines in $BiCl_3$ exhibits a positive temperature coefficient suggest that the strength of the intermolecular covalent bonds in $BiCl_3$ is stronger than that in $SbCl_3$.

Because of the intermolecular interactions, the quadrupole coupling constant (eQq) of the solid determined from the pure quadrupole spectra may differ as much as 10% from that of gas determined from the hyperfine structure of the rotational spectra in the microwave region. Comparisons between the eQq values of PCl_3 and $POCl_3$ in the gaseous and solid states are given in Table 3, together with the values of some other molecules.

TABLE 3. COMPARISON OF eQq IN GAS AND SOLID

Compound	eQq gas (MHz)	eQq solid (MHz)	r(gas/solid)	Ref.
PCl_3	53.3	52.40	1.017	20
$POCl_3$	55.4	57.97	0.955	20
CH_3Cl	75.13	68.40	1.098	19
CH_2Cl_2	78.3	72.42	1.081	19
CF_3Cl	78.05	77.58	1.006	19

19) H. C. Allen Jr., *J. Phys. Chem.*, **57**, 501 (1953).
20) C. R. Nave, T. L. Weatherly, and Q. Williams, *J. Chem. Phys.*, **49**, 1413 (1968).

Since the difference in the eQq values in Table 3 and the $\Delta\nu$ values in Table 2 are rather small for PCl_3 and $POCl_3$, the intermolecular interactions in their solid states are considered to be weak.

The three M-Cl bonds within an MCl_3 molecule may be equivalent in its gaseous state, while in its solid state the intermolecular interactions destroy the equivalence. Therefore, the separation ($\Delta\nu$) between multiple lines may be a measure of the intermolecular interactions. In general, the melting point of a crystal reflects the degree of the intermolecular interactions. The relation between the melting point and the $\Delta\nu$ among these trichlorides is shown in Fig. 5. An expected correlation between them is found;

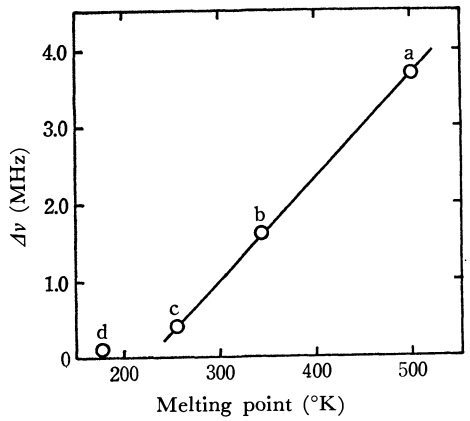

Fig. 5. Melting point versus $\Delta\nu$ plots: (a), $BiCl_3$; (b), $SbCl_3$; (c), $AsCl_3$; (d), PCl_3.

this indicates that the strength of the intermolecular interactions decreases in this order: $BiCl_3 > SbCl_3 > AsCl_3 > PCl_3$.

As the strength of the intermolecular interactions becomes weaker, the magnitude of the mean-square amplitudes ($<\theta_i^2>$) increases; consequently, the absolute values of their temperature coefficients ($|d<\theta_i^2>/dT|$) may be expected to increase. Furthermore, it may

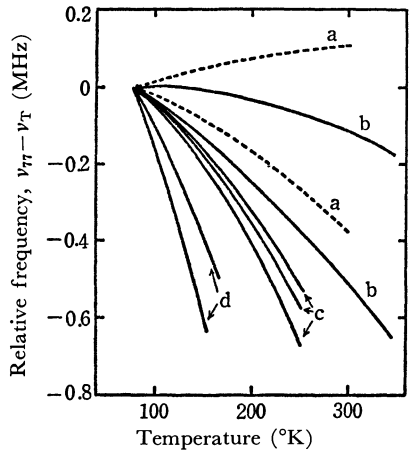

Fig. 6. Relative frequency (difference between the resonance frequency at 77°K (ν_{77}) and that at higher temperature (ν_T)) of ^{35}Cl in MCl_3 molecule as a function of temperature: (a), $BiCl_3$ (Estimated from the data at 83° and 299°K reported by Robinson.); (b), $SbCl_3$; (c), $AsCl_3$; (d), PCl_3.

be seen from Eqs. (1) and (2) that the absolute value of the temperature coefficient of the resonance frequency ($|d\nu/dT|$) is proportional to that of the mean-square amplitudes ($|d<\theta_t^2>/dT|$). Therefore, if the strengths of intermolecular interactions are assumed to become weaker from material to material in this order: $BiCl_3>SbCl_3>AsCl_3>PCl_3$, it seems reasonable that the absolute values of the mean temperature coefficient of the resonance frequency of chlorine in the MCl_3 molecule increase in this order: $PCl_3>AsCl_3>SbCl_3>BiCl_3$, as may be seen from Fig. 6.

A fade-out phenomenon analogous to that found for PCl_3 and $POCl_3$ has been observed for some other solids[21-23] which had phase transitions associated with internal or molecular reorientations in the solids. From the fact that the fade-out apparently occurred only in a solid where internal or molecular rotation was either definitely known to occur or was very likely, it had been considered that such motions were responsible for the fade-out.[22] Although no reference to such motions in the solids of PCl_3 and $POCl_3$ has been found in previous works, the fade-out found for them may be due to molecular rotation, which is expected to occur as a result of the weak intermolecular interactions. One of the mean-square amplitues of torsional motions found for the solid PCl_3 is about 13.6×10^{-3} rad^2 at 93°K. According to Chihara *et al.*,[8] that of the solid $SbCl_3$ is about 10×10^{-3} rad^2 at the same temperature. This indicates a rather high degree of torsional motion in solid PCl_3 at lower temperatures.

Structual information on the solid triiodides of the Group V elements is available.[24] From a structural point of view, it is impossible to regard the solid of the triiodide of arsenic, antimony, or bismuth as a molecular crystal; this is because of a layer-structure formed by the sharing of the edges of the MI_6 octahedra. On the other hand, in the solid of PI_3 the existence of the intermolecular bonds is not expected from its crystal structure. It is not unreasonable to consider that this trend in the triiodide series occurs also in the trichloride series. This confirms the above conclusion that, in the solid of PCl_3, the strength of the intermolecular forces is quite weak, whereas Lucken[25] estimated that the phosphorous trichloride was isomorphous with the antimony trichloride, in which the strong intermolecular forces exist. If $BiCl_3$ crystalizes with the BiI_3 structure, it is difficult to explain the large separation ($\Delta\nu$) found for $BiCl_3$, because in the BiI_3 structure all the metal-halogen bonds are expected to be equivalent. Therefore, it is tempting to conclude from the similarity of the resonance spectra and their temperature dependence that $BiCl_3$ and $SbCl_3$ are isostructural with each other.

The authors wish to express their thanks to Professor Mikio Takeyama and Dr. Yoshio Kamishina for their valuable discussions and suggestions on the fabrication of the equipment. One of the authors (M.H.) also wishes to Professor Ryôiti Kiriyama for his continual encouragement and interest.

The Catalytic Oxidation of Carbon Monoxide on Titanium Dioxide; Anatase and Rutile

Yoshito Onishi

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received July 18, 1970)

For the purpose of examining the surface state of titanium dioxide during the catalytic oxidation of carbon monoxide, the electric conductivities of anatase and rutile at 350—800°C, the amount of active oxygen on the catalyst surface at 400—600°C, and oxygen deficiency during the reaction were measured. The temperature-dependence of electric conductivities are represented by the formula $\sigma = A \cdot e^{-E/RT}$ in narrow temperature ranges. The amounts of active oxygen per unit surface area of rutile were 3—5 times as much as those of anatase at same temperatures, and 1—3% of them desorbed during the reaction. When the coverage fraction of active oxygen on the catalyst, θ, is assumed to be equal to 1 in oxygen, the following equation can express the relation between the rate constant of the reduction of titanium dioxide by carbon monoxide, k_{CO}, and that of the oxidation of reduced titanium dioxide by oxygen k_{O_2}, during the oxidation of carbon monoxide:

$$k_{CO} \cdot P_{CO} \cdot \theta = 2k_{O_2} \cdot P_{O_2} \cdot (1-\theta)^2 .$$

In the preceding paper,[1] the following results have been reported: the rate constant of oxidation of carbon monoxide on titanium dioxide is proportional to P_{CO} and it does not depend upon P_{O_2} nor P_{CO_2}, the rate-determining step is the reaction between the surface oxygen on the catalyst and carbon monoxide, and the difference between activation energies of the uptake of surface oxygen atoms by carbon monoxide from anatase and rutile is about 10 kcal/mol. Several papers[2-5] have discussed an amount of surface oxygen, oxygen defect, and active sites on the catalyst in the oxidation of carbon monoxide on metallic oxide catalysts. For the titanium dioxide, the oxygen defect is formed on its surface during the reaction, and there are surface oxygen which react easily with carbon monoxide, *i.e.*, active oxygen.[1]

In this paper, the amount of active oxygen and its deficient amount during the oxidation of carbon monoxide on the surface of two crystal forms will be determined. The relation between the amount of active oxygen and the rate constants of the reduction of titanium dioxide by carbon monoxide and the oxidation of the reduced titanium dioxide by oxygen will be studied.

Experimental

The samples used were anatase (A) and rutile (R). The latter was obtained by heating A at 1150°C for 3 hr.[1] The apparatus and the preparation of the reactant gas were described in the preceding paper.[1] The sample was evacuated and treated with a circulating oxygen at 600°C for 3 hr in the reaction system before the measurements.

The electric conductivity of the sample was calculated from the observed current under a constant D.C. voltage applied to a pair of gold electrodes which were pressed to the sample with a definite weight.

Results and Discussion

Dependence of Electric Conductivity of the Catalyst upon Temperature. The electric conductivity of the catalyst pretreated in oxygen at 600°C for 3 hr was determined in oxygen under pressure of 70 mmHg or in circulating mixed gas with a composition of $CO/O_2 = 2/1$ under pressure of 70 mmHg[6] at a constant temperature. The temperature-dependence of electric conductivities for anatase and rutile determined at 350—800°C are shown in Figs. 1 and 2. The measured points at 600°C and lower are almost linear for two samples and the conductivity σ can be represented

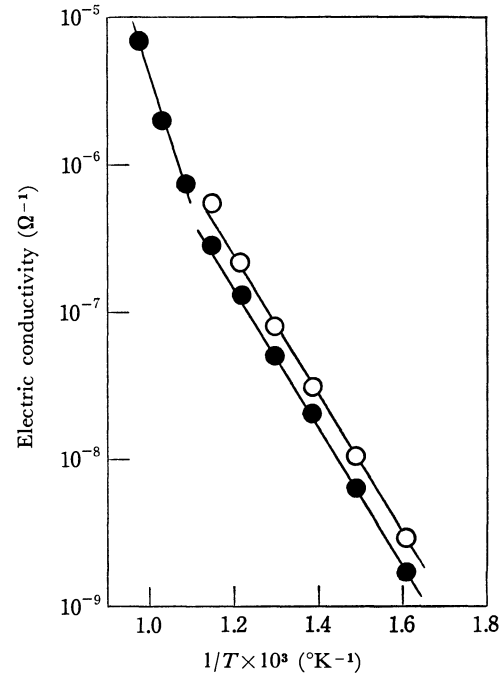

Fig. 1. Effect of temperature on electric conductivity of anatase.

6) In this case, carbon dioxide formed was condensed in the liquid nitrogen trap and the total pressure gradually decreased, but the electric conductivity did not change.

●: in O_2 ○: in $CO/O_2=2/1$

by the following equation:

$$\sigma = A\cdot e^{-E/RT} \quad (1)$$

where A is a constant, and E an activation energy, respectively. The plots at higher temperatures than 600°C gradually deviate upward from linear lines, but in narrow temperature ranges, Eq. (1) may be applied. The obtained values of E are listed in Table 1.

Table 1. Activation energies for electric conductivities of catalysts

Temp. (°C)	350—600 $CO/O_2=2/1$	350—600 O_2	600—800 O_2
Anatase (kcal/mol)	21.3	21.3	38.5
Rutile (kcal/mol)	25.7	29.5	46.9

The value of rutile determined under temperatures lower than 600°C in oxygen almost agrees with that of Gorelik,[7] and the value above 600°C, with those of Earle,[8] Cronemeyer,[9] and Hauffe.[10] The conductivity in the mixed gas is larger than that in oxygen for both anatase and rutile because of the reduction with carbon monoxide, and this fact shows that titanium dioxide is an n-type oxide semi-conductor.

Amount of Active Oxygen of the Catalyst. When the catalyst pretreated in oxygen at 600°C for 3 hr was cooled, their conductivities were function of the temperature, and these values almost unchanged upon the evacuation. Therefore, it is considered that the catalyst surface is clean and stable by this treatment, and the catalyst thus treated will be called its starting state hereafter.

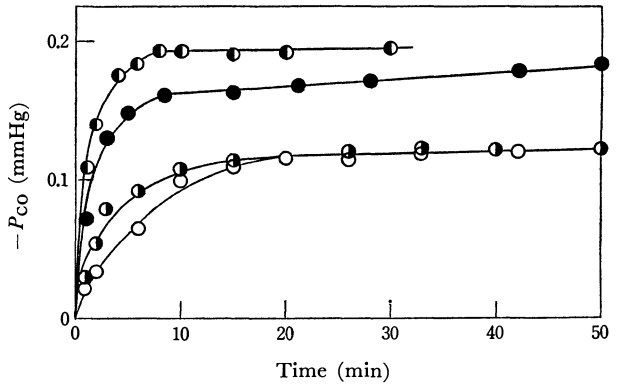

Fig. 3. Amounts of carbon monoxide reacted *vs.* time curves on anatase.

◐: $P_{CO}=149$ mmHg at 550°C
◑: $P_{CO}=75$ mmHg at 500°C
●: $P_{CO}=16$ mmHg at 550°C
○: $P_{CO}=14$ mmHg at 500°C

When titanium dioxide of the starting state was exposed to carbon monoxide under pressures of 10—150 mmHg at 400—600°C, carbon dioxide formed was condensed in the liquid nitrogen trap, and the CO pressure decreased, but the rate of decrease fell down with the time as is shown in Fig. 3. The total amount of carbon dioxide condensed was almost equal under the different initial pressure of carbon monoxide at the same temperatures. If a limited amount of the surface oxygen of the catalyst (it may be the oxygen of both crystal-lattice point and adsorbed one) is assumed to react easily with carbon monoxide (these oxygen will be called active oxygen hereafter), the amount of the active oxygen can be estimated from the amount of carbon dioxide condensed. The number of the active oxygen atoms per unit surface area, and its percentage to the surface lattice oxygen assuming that the surface is (011) for anatase and (110) for rutile,[11] are listed in Table 2.

Table 2. Numbers of active oxygen atoms and their percentages to surface lattice oxygen on anatase and rutile

under a pressure of about 10^{-2} mmHg at a definite temperature, it is reduced by carbon monoxide and its conductivity increases with the time. Therefore, the amount of the reduction product CO_2 formed until the conductivity becomes the same value in the mixed gas shows the deficient amount of the active oxygen during the reaction. The number of the deficient active oxygen sites and its ratio to total active oxygen atoms, $(1-\theta)$, are listed in Table 3; θ represents the coverage fraction of active oxygen on the catalyst and θ is equal to 1 at the starting state.

Table 3. Deficiencies of active oxygen atoms during the oxidation of carbon monoxide on anatase and rutile

	Temp. (°C)	600	550	500	450
A	Deficiency $\times 10^{-15}$ (atoms/m^2)	8.61	5.93	3.98	2.47
	$(1-\theta)\times 10^2$	1.68	1.82	1.92	1.98
R	Deficiency $\times 10^{-16}$ (atoms/m^2)	2.09	1.98	1.89	1.78
	$(1-\theta)\times 10^2$	1.29	1.75	2.26	3.14

Relation between Reduction Rate and Oxidation Rate of Titanium Dioxide. If the reduction starts from its starting state ($\theta=1$) in the above case, the value of θ at any point can be calculated by measuring the amount of carbon monoxide consumed. Therefore, the rate of decrease of carbon monoxide at any θ value can be estimated by measuring the CO pressure as a function of time. Similarly, when oxygen is introduced over the reduced titanium dioxide, it is oxidized by oxygen (some of the oxygen may be adsorbed on it), and the O_2 pressure decreases. Therefore, the oxidation rate of titanium dioxide of any θ value can be estimated by measuring the O_2 pressure. From these measurements, the following equations are obtained:

$$-\mathrm{d(CO)}/\mathrm{d}t = k_{CO}\cdot P_{CO}\cdot\theta \quad (2)$$

$$-\mathrm{d(O_2)}/\mathrm{d}t = k_{O_2}\cdot P_{O_2}\cdot(1-\theta)^2 \quad (3)$$

where k_{CO} and k_{O_2} are the rate constants of reduction and oxidation of titanium dioxide, respectively. The values of k_{CO} and k_{O_2} are listed in Table 4; k_{CO} are the same values shown in Fig. 3 of the preceding paper[1] in which they have been shown as k'. The oxidation rate of titanium dioxide by oxygen (the adsorption rate of oxygen) is far faster than the reduction rate by carbon monoxide.

Table 4. Estimated values of k_{CO} and k_{O_2}

Temp. (°C)	600	550	500	450
$k_{CO}\times 10^5$ (CO_2 mmol/min·cmHg·m^2)				
Anatase	7.50	3.96	1.76	0.896
Rutile	30.1	22.4	18.3	13.6
$k_{O_2}\times 10$ ($-O_2$ mmol/min·cmHg·m^2)				
Anatase	2.35	1.20	0.55	0.25
Rutile	18.0	7.50	3.40	1.33

The values of $k_{CO}\cdot\theta$ and $k_{O_2}\cdot(1-\theta)^2$ calculated from Eqs. (2) and (3) using the values in Tables 3 and 4 are listed in Table 5. The following relation is obtained at 450—600°C for both anatase and rutile during the catalytic oxidation of carbon monoxide using the mixed gas with the composition of $CO/O_2=2/1$:

Table 5. Calculated values of $k_{CO}\cdot\theta$ and $k_{O_2}\cdot(1-\theta)^2$

Temp. (°C)	600	550	500	450
$k_{CO}\cdot\theta\times 10^5$ (CO_2 mmol/min·cmHg·m^2)				
Anatase	7.38	3.90	1.73	0.87
Rutile	29.7	22.0	17.8	13.1
$k_{O_2}\cdot(1-\theta)^2\times 10^5$ ($-O_2$ mmol/min·cmHg·m^2)				
Anatase	6.70	4.00	2.03	0.98
Rutile	29.8	23.0	17.4	13.1

$$k_{CO}\cdot P_{CO}\cdot\theta = 2k_{O_2}\cdot P_{O_2}\cdot(1-\theta)^2 . \quad (4)$$

Above equation shows that the present reaction consists of both the reduction and the oxidation processes of the catalyst by carbon monoxide and oxygen.

The author wishes to express his deep thanks to Professor Takuya Hamamura of Kyoto Technical University and Professor Kumasaburo Kodera of Kyoto University for their kind advices and discussions.

An Adiabatic Calorimeter for Heat Capacity Measurements in the Temperature Range from 80 to 550 K. Heat Capacities of α-Alumina (Sapphire) and Anhydrous Magnesium Acetate

Natsuo Onodera,* Arata Kimoto,** Minoru Sakiyama, and Syûzô Seki
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received September 12, 1970)

An adiabatic calorimeter for the measurements of heat capacities of solid and liquid in the temperature range 80—550 K and the automatic temperature control system are described. The working platinum resistance thermometer is calibrated against a standard thermometer. The measurements of heat capacity of α-Al_2O_3 prove the precision to be $\pm 0.3\%$ and give an accuracy of $\pm 0.6\%$. By means of this calorimeter, heat capacities of anhydrous magnesium acetate have been measured for its glassy and crystalline states around the glass transition point.

Adiabatic calorimetry of the intermittent-heating type[1] determines most accurately heat capacities of solid and liquid below room temperature. If this method is carried out ideally, the adiabatic shield is always maintained at the same temperature as that of the sample container it surrounds so that there is no heat exchange between them. Hence the heat capacity of sample (including the container) is calculated from the electrical energy supplied to the sample and the consequent temperature rise. At elevated temperatures, however, heat transfer due to radiation becomes more significant with temperature rise and this makes it difficult to maintain adiabatic conditions during the measurement. Mainly for this reason, isothermal calorimetry (drop method) has been employed above room temperature. In this method, enthalpies at various temperatures relative to a reference temperature, $H(T)-H(T_0)$, are measured in high precision and heat capacity is calculated by differentiating the enthalpy function. Nevertheless, high temperature adiabatic calorimetry is more suitable for investigations of the anomalous thermal effects taking place in a narrow temperature range such as phase transitions or for the studies on non-equilibrium states, annealing effect, *etc.*

As already mentioned, the problem of heat exchange must be considered for adiabatic calorimetry at high temperatures.[2] Limitation in the choice of construction materials also offers a serious problem. For these reasons, an adiabatic calorimeter has not been used frequently in a high temperature region for heat capacity measurements of substances with poor thermal conductivities, as compared with one used in a low temperature region. However, in recent years, several calorimeters with high accuracy up to 500 K or 1000 K have been reported by West and Ginnings,[3] Trowbridge and Westrum,[4] Karasz and O'Reilly,[5] Grønvold,[6] and Leadbetter,[7] in which great attention was paid to the establishment of adiabaticity and the selection of construction materials. In our laboratory, two kinds of adiabatic calorimeters for low temperatures, from 1 to 20 K and 11 to 300 K, have been constructed[8,9] and studies carried out with them on various solid and liquid samples have been reported. We intended to extend our studies to the more elevated temperature region, since there are many substances indicating interesting thermal behavior above room temperature in view of the changes in state of aggregation or of chemical thermodynamics.

This paper describes an adiabatic calorimeter with an automatic control system which has been used for heat capacity measurements of solids and liquids in the temperature range 80—550 K. Although there was no essential alteration in the structure of this calorimeter in comparison with that[8] for low temperatures, some considerations for high temperature operation were made in the choice of construction materials. Heat capacity measurements of α-Al_2O_3 showed that the precision was within $\pm 0.3\%$ and the accuracy within $\pm 0.6\%$, which were sufficient for our purpose. The apparatus is employed mainly to study phase transitions in polyatomic ionic, ferroelectric, or liquid crystals and thermal behaviors in polymers, amorphous solids, or glasses and also to provide useful chemical thermodynamical data when combined with the measurements with low temperature calorimeters. Heat capacities of anhydrous magnesium acetate have been measured at 300—500 K for the glassy and crystalline states. The glass transition (T_g) of this substance[10] was also studied in detail.

Construction of the Calorimeter

The cross sectional view of the calorimeter is shown in Fig. 1. The main body of the calorimeter consists of a sample container A, an adiabatic jacket C which is separated into three parts C_a (side), C_b (top), and C_c (bottom), an upper block D, an outer jacket E, and a vacuum vessel H. The sample container A is suspended by three thin constantan wires from the top portion of the adiabatic jacket. The adiabatic jacket is in turn suspended from the copper upper block D, which serves together with the copper outer jacket E for attenuating the thermal effects from their surroundings and for making favorable adiabatic conditions in the inner system by controlling each heater current.

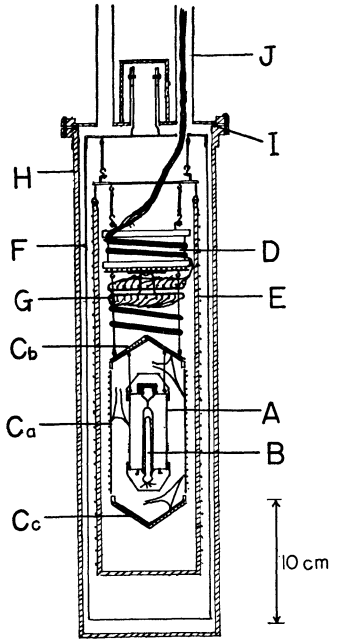

Fig. 1. Cross sectional view of the calorimeter.
A: Sample container B: Thermometer C_a, C_b, and C_c: Adiabatic jackets D: Upper block E: Outer jacket F: Radiation shield G: Terminals H: Vacuum vessel I: Gasket J: Stainless steel pipe

The sample container, whose schematic drawing is shown in Fig. 2, is made of copper, 0.3 mm thick and chromium-plated, with a central reentrant well for setting a combined thermometer-heater. Eight radial fins N silver-soldered to the well and to the inside wall of the container provide good thermal contact of the sample with the container assembly. The size of the main body of the container is 3 cm in diameter and 6 cm long. The total weight of the container is about 70 g and its effective capacity is *ca.* 35 cm^3. A sample entrance at the center of the top of the container is 8 mm in inner diameter. It is crucial to select a suitable seal in order to keep the container gas-tight at all temperatures. A silicone rubber disc-shaped gasket L cut from a sheet 1 mm thick was eventually found to be useful at least up to 550 K. A copper lid is screwed down tightly to the entrance by hand.

The container is equipped with a Leeds & Northrup

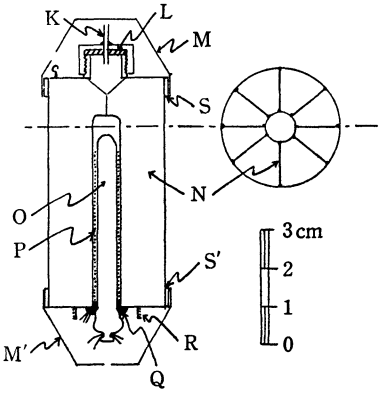

Fig. 2. Cross sectional view of the sample container.
K: Cu tubing L: Gasket M, M': Caps N: Radial fins O: Platinum resistance thermometer P: Heater Q: Beryllia cement R: Spool S, S': Cu bands

capsule type (type 8164) platinum resistance thermometer O, for the temperature measurement of the sample. Around the thermometer, approximately 70 ohms of doubly glass-wound B. & S. #36 constantan wire (Driver-Harris Co.) P is wound non-inductively and as closely as possible, which serves as the calorimeter heater for supplying energy to the sample container. Although the well is machined so as to be well fitted with the combined thermometer-heater, it was necessary to fill the gap with a beryllia cement Q at the entrance portion of the well in order to reduce the temperature gradient in the container assembly. It was confirmed that this device suppressed the temperature distribution to within 0.2 K in the container assembly even in the heating process at 550 K. All the lead wires from the combined thermometer-heater are wound several times around a spool R at the bottom of the container.

Since the outlines of the surface of the top and the bottom of the container are not completely uniform, it is very likely that a significant temperature distribution will arise in these parts particularly during the course of heating. To reduce this, two copper caps M and M' (0.5 mm thick and chromium plated) are closely fitted mechanically to copper bands S and S' soldered to the top and the bottom of the container.

The adiabatic jacket is also of chromium-plated copper and is made as thin as possible (0.5 mm) in order to get quick thermal response. Each part of the jacket, C_a, C_b, and C_c, is equipped with a separate heater: a glass-insulated B. & S. #36 constantan wire wound non-inductively. Adiabatic condition is maintained by adjusting the current in each heater independently. Around C_a are also wound the lead wires from the sample container and those of the thermocouples which detect the temperature differences between A and C_a, C_a and C_b, and C_a and C_c. All the wires are fixed and insulated with silicone varnish or Teflon tapes, aluminum foils being wrapped over them.

Temperature difference between the outer surface of the container and the inner surface of C_a is detected by a six junction (in series) copper-constantan thermocouple. Temperatures of C_b and C_c are also detected differentially against that of C_a by a similar method. The junctions of these thermocouples are insulated with

small, thin pieces of mica, protected with aluminum foils, and inserted tightly into stainless steel bands and pockets set on the sample container and the jacket, respectively. These thermocouples provide an error voltage of about 240 μV per degree of differential at 300 K.

Temperatures of D and E are controlled to an appropriate level lower than that of the adiabatic jacket depending on the operating temperature so that adiabaticity of the interior system may be best maintained.

For measurements in an elevated temperature region (higher than 100°C), another radiation shield F of nickel-plated brass is installed, which remarkably decreases the heat loss due to radiation toward the outside.

All the lead wires employed are Polyflon-coated B. & S. #38 copper wires prepared by immersing the cotton-wound copper wires in Daikin Polyflon dispersion D-1, and then decomposing cotton and sintering the adhered Polyflon at 380°C in a vacuum.[11] All the lead wires are brought to a copper terminal G, wound around the upper block, and then taken out of the calorimeter assembly through one of three stainless pipes J which suspend the assembly, and through a Picein seal. The lead wires are soldered to G by a Kyowa Shôji NEIS 105 silver solder which is composed of silver-cadmium alloy and has a relatively low melting point (*ca.* 380°C).

The interior of the brass vacuum vessel H, which is immersed in a liquid nitrogen or ice temperature Dewar vessel, is kept in high vacuum of 10^{-5} to 10^{-6} Torr by a seal fitted in a rectangular groove (3 mm in width and 1 mm in depth). For the seal a rectangular cross-sectional lead gasket or a neoprene rubber *O*-ring I is found to be suitable in liquid-nitrogen or ice temperatures respectively. It is difficult to attain a vacuum higher than 5×10^{-4} Torr at temperatures higher than 500 K, probably due to some decomposition of silicone varnish used as an insulating adhesive.

Temperature Measurements and Calibration of the Thermometer

Resistance of the platinum resistance thermometer is measured by a Leeds & Northrup type G-2 Mueller Bridge, a Riken high sensitivity galvanometer, and a telescope-scale system in which the distance between the galvanometer and the scale is *ca.* 5 m. This arrangement enables us to measure the temperature to 2×10^{-4} deg in the range 80—550 K.

The working thermometer was calibrated in the conventional manner against a standard thermometer of a similar type calibrated at the National Bureau of Standards (NBS), U.S.A., based on the International Temperature Scale of 1948. The relation between the difference in the resistances of the working and standard thermometers ΔR and the resistance of the standard thermometer R_s can be expressed as follows:

$$\left.\begin{aligned} \Delta R \times 10^5 &= 84.857R_s - 112.5, \\ &\text{for } 4.8 < R_s \leqq 24 \text{ (80—260 K)}, \\ \Delta R \times 10^5 &= 84.857R_s - 112.5 - 0.244(R_s - 24)^2, \\ &\text{for } 24 \leqq R_s < 53 \text{ (260—550 K)}, \end{aligned}\right\} \quad (1)$$

where both R_s and ΔR are in ohm. The accuracy of temperature measurements is estimated to be within ±0.01 deg in absolute value and within ±0.0001 deg in relative value.

Energy Measurements

The circuit for supplying and measuring the electrical energy to the calorimeter heater is nearly the same as the one reported.[8] The calorimeter heater is powered by three 6 V storage batteries in series and the current is adjusted with a six-dial decade resistor (0 to 111, 111.1 ohm). The current and the potential drop across the calorimeter heater are measured in the conventional way with an Otto-Wolff type KDE-3 five-dial potentiometer in conjunction with a Shimadzu galvanometer (type R, class C). Correction is made for the current passing through the by-pass resistors (1 and 100 kΩ) in computing the net current flowing through the calorimeter heater.

To avoid a correction for the small amount of heat generated in the current lead between the sample container and the adiabatic jacket, one of the potential leads terminates just near the container and another just near the jacket, as suggested by Ginnings and West.[12]

The energy input is started and stopped automatically with an electronic timer synchronized with a transistor clock and the heating interval is measured and presented on a digital counter with an accuracy of 0.05% or better.[8]

Adiabatic Control System

Detection of temperature differences for the maintenance of adiabaticity are carried out by use of thermocouples between C_a and A (temperature difference ΔT_1), between C_a and C_b (ΔT_2), between C_a and C_c (ΔT_3), between C_a and D (ΔT_4), and also between C_a and E (ΔT_5). The error signal given as thermal electromotive force of the thermocouples is fed into each servo-circuit, which controls the heater current of each portion of the jacket by on-off control mode.

The error voltage corresponding to ΔT_1 is amplified with an Ohkura AM-1001 microvoltmeter ($\pm10\,\mu$V in full scale) by a factor of 2000 and the output voltage is recorded on an Ohkura electronic recorder, while a cum connected with the pen-drive-motor shaft actuates two micro-switch relays and controls the heater current of C_a. The half-span of the recorder is 1 mV, which corresponds to 2×10^{-3} deg at 300 K. The error voltage due to ΔT_2 is amplified with a Tôa type AD-4 DC amplifier and then with a DC difference amplifier which uses a 12AX7. The output voltage is fed into a grid of 6AQ5. which actuates a microswitch for the control of the heater current for C_b. The error signals due to ΔT_3 and ΔT_5 are transformed into deflection of the mirrors of Shimadzu galvano-

11) Polyflon coated wires were inevitably used, as more favorable glass-wound thin copper wires could not be obtained at the time of construction.

12) D. C. Ginnings and E. D. West, *Rev. Sci. Instr.*, **35**, 965 (1964).

meters (type R, class C). Light beams which have passed through optical choppers are reflected by the mirrors and detected with the photoelectric tubes of electronic photo-relays, which actuate microswitches for the control of heater current. The temperature difference ΔT_4 is detected by an Ohkura type AM-101 microvoltmeter ($\pm 25\ \mu V$ in full scale) and is controlled manually, since the temperature of the upper block little influences the inner system.

Measurements of Heat Capacity

After the specimen was packed into the sample container, a small amount of helium gas, which facilitates attainment to thermal equilibrium in the container, is introduced through a narrow copper tube K. The tube is then pinched off to keep it gas-tight.

The temperature of the sample is measured at approximately one minute intervals for about ten minutes after adiabaticity and internal equilibrium are nearly established. Temperature drift was found to be within 3×10^{-4} deg·min^{-1} below room temperature, but gradually increases with temperature rise ultimately to 3×10^{-3} deg·min^{-1} at 550 K.

The electric power produced in the calorimeter heater is obtained by measuring the heater current at 0.21 τ and 0.79 τ and the voltage at 0.50 τ according to the Giauque method,[13] where τ is the heating interval (usually 1000 sec in our experiments). The energy supply is adjusted so that the temperature elevation in this heating period can be 4—6 deg in the empty case and 2.5—4 deg in the loaded one. For these heating rates, internal equilibrium in the sample container is attained within 5 min after heating was stopped.

When the automatic adiabatic control works normally, the temperature difference ΔT_1 is kept, in the equilibration period within $\pm7\times10^{-4}$ deg below room temperature and within $\pm3\times10^{-3}$ deg at 550 K, and in the heating period within $\pm4\times10^{-3}$ deg and within $\pm1\times10^{-2}$ deg, respectively. The ΔT_2 and ΔT_3 are controlled at least within 0.15 deg even in the heating period at 550 K.

Calibration of the Calorimeter

The reliability of the present calorimeter was examined by the measurements of heat capacity of the Calorimetry Conference standard sample of α-Al_2O_3 (synthetic sapphire).[14] Approximately 70 g of this sample was used for calibration. The heat capacity of the sample corresponds to about 70% of the total heat capacity above room temperature (including the container), while only about 30% at the lowest temperature employed.

The heat capacity of the sample was given by subtracting the smoothed heat capacity data of the empty cell (r.m.s.: 0.21%) from the total heat capacity. In Table 1 are tabulated the observed and smoothed molar heat capacities of α-Al_2O_3. As shown in Fig. 3 most of the observed points fall within $\pm0.3\%$ in relative deviation from the smoothed curve. The r.m.s. deviation is 0.25%. The difference of our smoothed values from those of Furukawa *et al.*[15] falls almost within $\pm0.6\%$ from 80 to 550 K. This agreement is sufficient for our present purpose.

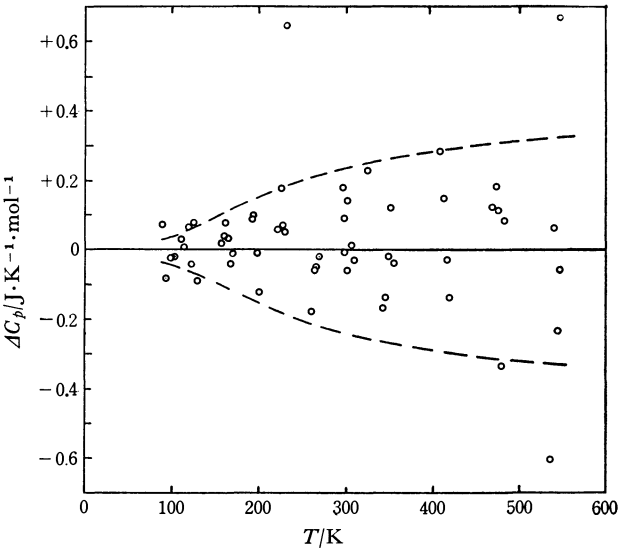

Fig. 3. Deviations of experimental heat capacities ΔC_p of α-Al_2O_3 from a smooth curve. Dashed curves show $\pm0.3\%$ of C_p.

Analysis of Errors

In order to account for the scattering of the experimental points as well as the possible occurrence of some systematic errors, the order of magnitude of errors due to the following instrumental and operational sources was estimated.

(1) Temperature Measurements. Errors in reading the resistance values do not exceed 0.5×10^{-3} deg in terms of temperature even at elevated temperatures where increase in the resistance with temperature reduces the sensitivity of the galvanometer. Therefore, this error source is not of primary importance. However, arbitrariness in drawing the drift straight line to the midpoint of the heating period, on a resistance *vs.* time curve, permits $\pm0.15\%$ error at the highest temperature.

(2) Energy Measurements. Total contribution to the error from instruments such as the potentiometer, the timer, and the standard resistances is estimated to be within $\pm0.05\%$.

(3) Heat Transfer due to Non-adiabaticity. Erroneous heat transfer may arise from or to the sample container owing to the transient non-adiabaticity which reveals itself as the error voltage of the thermocouples. This is significant just after the beginning and the end of the heat supply. This error can be estimated by evaluating various heat transfer coefficients between the container and the adiabatic jacket, which are subdivided as follows.

a) Heat Transfer by Lead-Wire Conduction: This includes the conduction through the lead wires of the combined thermometer-heater, the thermocouples brought to the container, and the constantan wires suspending the container. These are found to contribute below 2×10^{-3} W·deg^{-1} to heat transfer coefficient.

b) Heat Transfer by Gas Conduction: Thermal conductivity of gas is independent of the pressure if the mean free path of the gas λ is much smaller than the size of space in consideration L, and is proportional to the pressure if $\lambda \gg L$, where L is $\sim$1 cm in the present case. Below 500 K, the latter condition holds so sufficiently that heat transfer coefficient is easily evaluated to give approximately 1×10^{-5} W·deg^{-1}. Above 500 K, however, estimation becomes very difficult because λ gets nearer to L owing to the deterioration of vacuum. However, this value probably does not exceed 5×10^{-3} W·deg^{-1}.

c) Heat Transfer by Radiation: This effect becomes rapidly important with increase in temperature. Although the geometrical shape in the present apparatus is rather complicated, the standard equation for the radiative heat transfer[2] is sufficient for rough calculation. If we assume 0.1 both for the emissivities of two parallel planes with small temperature difference (the value is overestimated for polished metal surfaces), heat transfer coefficient by radiation amounts to 3×10^{-3} W·deg^{-1} at 300 K and 15×10^{-3} at 500 K.

Thus, the summation of all these effects give 5×10^{-3} W·deg^{-1} at 300 K and 2×10^{-2} W·deg^{-1} at 500 K. These values explain that under ordinary experimental conditions errors in measured heat capacity caused by transient non-adiabaticity may become $\pm 0.05\%$ at 300 K and $\pm 0.25\%$ at 500 K in maximum estimate. At higher temperatures, therefore, considerable part of the actual errors can be attributed to this source. In practice, fluctuation in the observed heat capacity is not so strongly dependent on temperature as expected from the preceding estimate (see Fig. 3). This may be due to the overestimate of the values for emmissivity.

(4) Heat Transfer due to Thermal Inhomogeneities. Important systematic errors arise frequently from the thermal inhomogeneities on the outer surface of the container or the inner surface of the adiabatic jacket. In the most probable case, heat exchange is caused by generation of temperature distribution on the surface of the container during the heating period. The greater part of this error is compensated if the temperature gradients in the empty and the loaded measurements are alike. Generally, however, the dif-

ference in thermal conductivity, heat capacity, and density in the container between the two cases prevents this situation.[2)]

This error is so difficult to estimate that great care must be taken about the design of the container to avoid the generation of the surface temperature gradient. We confirmed experimentally that the beryllia cement as a thermal conducting adhesive between the body of the container and the combined thermometer-heater as well as the two caps on the top and the bottom parts of the container served this purpose. Indeed, an agreement of our data with those of Furukawa *et al.*[15)] and also with those of other workers[3-7)] is regarded as an evidence showing that the sources of systematic error are sufficiently eliminated in the construction of the present apparatus.

Heat Capacities of Anhydrous Magnesium Acetate

Anhydrous magnesium acetate was prepared by dehydration of magnesium acetate tetrahydrate in a vacuum (10^{-3} Torr) at *ca.* 50°C for 7 days. Further dehydration was carried out in the sample container in a high vacuum (10^{-5} Torr) at 310 K for 20 hr. The dehydrated salt has been found to be in the glassy state.[10)] Heat capacities of the glassy sample are given in Table 2 and Fig. 4. The glass transition temperature is found to be located at *ca.* 470 K. The glassy sample crystallizes abruptly when it is heated above 475 K. The heat capacities of the crystalline sample thus formed are also given in Table 2 and Fig. 4. From the temperature drift curves during the measurements and the temperature elevation due to crystallization, the heat of crystallization was estimated to be *ca.* 11.4 kJ mol.$^{-1}$

Summary

An adiabatic calorimeter for the heat capacity measurements of solid or liquid sample in the temperature range 80—550 K was constructed with the main purpose of investigating various interesting thermal behaviors of substances demonstrated above room temperature. Most of the temperature control systems to keep an adiabatic condition are semi-automatic and thus need only one operator. The working platinum resistance thermometer was calibrated against a standard one calibrated by the NBS. The reliability of this apparatus was demonstrated through the measurements of heat capacity of the Calorimetry Conference sample of α-Al_2O_3. The results show that the relative errors in heat capacity values are almost within ±0.3% and the smoothed curve values agree with those of Furukawa *et al.* almost within ±0.6% over the whole temperature range available. The non-systematic errors are to some extent explainable in terms of the order of magnitude estimation based on the experiments. Heat capacities of amorphous and crystalline magnesium acetate were measured at 300—500 K. Glass transition phenomenon was observed at *ca.* 470 K. Heat of crystallization was also estimated to be 11.4 kJ·mol^{-1}.

The Dichroic Spectra of Hydroxy Derivatives of Naphthalene, Anthracene, and Phenanthrene in Polyvinylalcohol Sheets[1]

Hiroyasu INOUE, Takio NAKAMURA,* and Tetsutaro IGARASHI

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama

(Received October 1, 1970)

The dichroic spectra of 1,4-dihydroxynaphthalene, 9-hydroxyanthracene, sodium 9,10-dihydroxyanthracene-2-sulfonate, and 9,10-dihydroxyphenanthrene, which were usually unstable in a liquid solution, were measured in stretched polyvinylalcohol sheets. From a comparison of the results of the dichroic spectra with those of the MO calculations, the polarizations of the electronic bands were determined, and the bands were assigned in terms of the relevant bands of the corresponding unsubstituted aromatic compounds.

The electronic spectra of some hydroxy derivatives of naphthalene and of anthracene have been investigated theoretically and experimentally.[2-4] There have, however, been few reports on the electronic spectra of 1,4-dihydroxynaphthalene, 9-hydroxyanthracene, and 9,10-dihydroxyanthracene. This is also the case for 9,10-dihydroxyphenanthrene. The reason for such a situation is probably that these compounds are very unstable in a liquid solution and it is difficult to determine their absorption spectra by the usual procedure.

It has been well known that these unstable hydroxy aromatic compounds are temporarily formed when 1,4-naphthoquinone, anthrone, anthraquinone, and 9,10-phenanthrenequinone are irradiated by ultraviolet light in solutions. In these cases, the products are very sensitive to oxidation by dissolved oxygen in solution and, hence, change immediately to the original compounds. We have found, however, that the above-mentioned hydroxy aromatic compounds are fairly stable in polyvinylalcohol (PVA) sheets when they are produced in the sheets by photochemical reactions.[5]

Accordingly, in the present paper, the electronic spectra of these compounds will be presented and the assignment of the near-ultraviolet absorption bands will be confirmed by analyses of the dichroic spectra and by theoretical calculations.

Experimental

Materials. All the materials used here were obtained commercially. 1,4-Naphthoquinone and 9,10-phenanthrenequinone were purified by repeated recrystallizations from ethanol. Sodium anthraquinone-2-sulfonate was used in place of anthraquinone, because the latter has poor permeability into PVA sheets. Sodium anthraquinone-2-sulfonate was purified by repeated recrystallizations from an aqueous solution. Anthrone was purified by zone melting using a Shimadzu Zone Refiner CZ-1. The PVA powder used for the preparation of the sheets was used without further purification, and its mean degree of polymerization was 1500.

Preparation of Sample Sheets. To obtain the sample sheets, dried PVA sheets (0.2 mm thick) containing quinones or anthrone in a concentration of 10^{-2}—10^{-3} M were irradiated using a low-pressure mercury lamp as a light source. The quinones and anthrone were completely converted to hydroxy aromatic compounds after a few minutes' photoirradiation. For the measurement of the dichroic spectra, the PVA sheets were stretched prior to the photoirradiation.

Dichroic Spectra. The measurement and analysis of the dichroic spectra were carried out following the method developed by Tanizaki.[6] The spectra were measured with a Shimadzu Spectrophotometer QV-50 equipped with a Glan-Thomson-type calcite polarizer. The notations used in the figures of the dichroic spectra were as follows[4]:

$D_{\parallel}$ and $D_{\perp}$: Absorbances measured for incident light polarized, respectively, parallel and perpendicular to the stretched direction of a PVA sheet.

R_d: Ratio between $D_{\parallel}$ and $D_{\perp}$, $D_{\parallel}/D_{\perp}$.

R_s: Degree of stretching of a sheet.

θ: Orientation angle for the moment of the absorption band. From this, the angle between the transition moments of different bands can be obtained.

MO Calculations

We have used the semi-empirical ASMO SCF CI method, including a variable β approximation.[7] One-center repulsion integrals were evaluated by the Pariser-Parr approximation,[8] in which the ionization potentials and the electron affinities were taken as 11.42 and 0.58 eV respectively for the carbon atom, and as 33.00 and 11.47 eV for the oxygen atom. The two-center repulsion integrals were evaluated by means of the Mataga-Nishimoto equation.[9] All singly-excited configurations associated with the transitions between each of the five highest occupied levels and each of the five lowest vacant levels were included in the CI calculation.

Results and Discussion

1,4-Dihydroxynaphthalene. 1,4-Dihydroxynaphthalene was obtained from 1,4-naphthoquinone by

photoirradiation in a PVA sheet. The dichroic spectra are shown in Fig. 1. The features of the absorption curve were similar to that measured previously by Spruit.[10]

The intense band at 246 mμ has the highest R_d value; hence, the transition moment of this band is considered to be inclined to the stretched direction of the sheet (hereafter, such a band will be denoted as "a ∥ band", and the band whose transition moment is perpendicular to the ∥ band will be denoted as "a ⊥ band"). The R_d values in the region of 280—360 mμ were relatively small and varied to some extent, having a maximum and a minimum. From this behavior of the R_d curve, it may be deduced that there are two bands closely overlapping in this wavelength region. The tendency of the R_d value to increase with an increase in the wavelength indicates that the longer-wavelength one of the overlapped bands is a ∥ band, while the shorter-wavelength one is a ⊥ band.

According to the consideration of the symmetry of this molecule, an isolated band should be polarized along the *X*- or *Y*-axis of the molecule, so the sum of the orientation angles of two differently polarized bands can be expected to give a right angle if the bands are not overlapped with other bands. However, the observed orientation angles of the ∥ band at 246 mμ and of the ⊥ band at around 300 mμ were 47.5° and 52.0° respectively, and their sum (99.5°) was too large for the orthogonality of the direction of polarizations. This non-orthogonality is attributable to the large value of the apparent orientation angle of the 246 mμ band. A weak ⊥ band can, therefore, be predicted to be hidden under the 246 mμ band. However, the presence of this ⊥ band is not detected from the absorption curve.

Next, let us compare the experimental results described above with the calculated electronic transitions. The results of the calculations are presented in Table 1. The observed 246 mμ (∥) band can be

IV	5.04 (246)	Y	0.1324
V	5.44 (228)	Y	0.0148
VI	5.49 (226)	X	0.8593

a) Only the transitions appeared above 220 mμ were listed.
b) The molecular axes were shown in Fig. 1.

safely said to correspond to the III transition (X-polarized). Hence, the ∥ and ⊥ band in the dichroic spectra can be said to be polarized along the *X*- and *Y*-axes of the molecule respectively. Therefore, the ∥ and the ⊥ bands observed in the long wavelength region are due to the I (X) and II (Y) transitions respectively. The ⊥ band hidden under the 246mμ band may correspond to the IV transition (Y).

By the use of Platt's notation, we can assign the observed bands as follows. The 246 mμ band is the ^1B_b band, and the ∥ band and the ⊥ band appearing in the region of 280—360 mμ are the ^1L_b and the ^1L_a bands respectively. Consequently, the order of the positions of the bands for 1,4-dihydroxynaphthalene (the ^1B_b, ^1L_a, and ^1L_b bands as the wavelengths increase) is same as those for the other hydroxynaphthalenes studied by Tanizaki and Kubodera.[4] However, the ^1B_b and the ^1L_a bands of 1,4-dihydroxynaphthalene appeared at longer wavelengths than the corresponding bands of the other α-hydroxynaphthalenes (1-, 1,5-1,8-derivatives),[4] and it was remarkable that the fine structure disappeared in the ^1L_a and the ^1L_b bands of 1,4-dihydroxynaphthalene.

9-Hydroxyanthracene. 9-Hydroxyanthracene was obtained from anthrone by photoinduced tautomeriza-

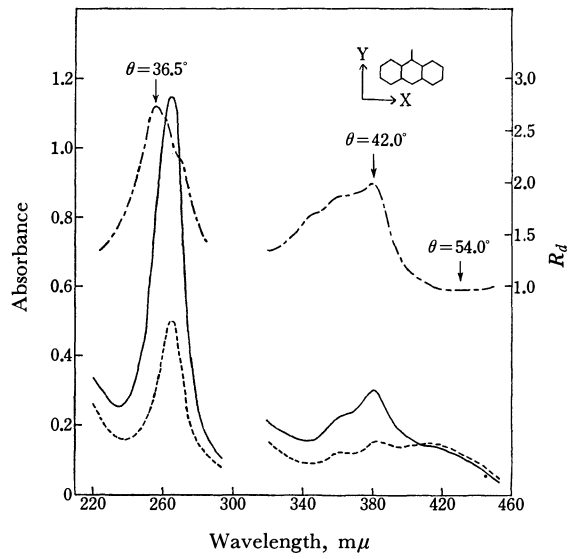

Fig. 2. Dichroic spectra of 9-hydroxyanthracene. R_s=9.8, ——: $D_{\parallel}$, ----: $D_{\perp}$, ——·——: $R_d(=D_{\parallel}/D_{\perp})$

tion.[11] Its absorption spectrum in a PVA sheet closely resembles that measured by Baba and Takemura[12] with a rapid-scan spectrophotometer in the region above 320 mμ. The dichroic spectra of 9-hydroxyanthracene are shown in Fig. 2. It may be seen in the figure that the intense 266 mμ band has a large R_d value, so it is a ∥ band. On the other hand, the relatively weak bands with three peaks appearing in the region of 340—460 mμ have medium and small R_d values, so it is clear that there are two bands in this region; the longer-wavelength one is a ⊥ band, and the shorter-wavelength one is a ∥ band. Since the sum of the orientation angles of this ⊥ band at 420 mμ and the ∥ band at 266 mμ is 90.5°, the orthogonality of the transition moments between these bands is almost satisfied. Thus, the absorption band in the region above 410 mμ consists of the pure ⊥ band. On the other hand, the band in the region of 340—410 mμ consists of this ⊥ band and a ∥ band, because the R_d values in this wavelength region are too small in comparison with that of the 266 mμ band to be that of a pure ∥ band.

Consequently, it was found that 9-hydroxyanthracene showed three absorption bands above 220 mμ; these bands may be interpreted as those of anthracene shifted to red by hydroxy groups. Concerning the electronic transitions of anthracene, the polarizations of the bands have already been investigated by Zimmermann and Joop,[13] and Craig and Hobbins.[14] According to their results, the intense 250 mμ band is polarized to the long axis of the molecule (X-axis) and assigned to the ^1B_b band, while the relatively weak band at longer wavelength is polarized to the short axis (Y-axis) and assigned to the ^1L_a band. The ^1L_b band of anthracene was not appreciably observed, but this band is considered to be hidden under the ^1L_a band. The absorption bands of 9-hydroxyanthracene can easily be interpreted on the basis of this assignment. At first, the 266 mμ band (∥) can be said to correspond to the ^1B_b band of anthracene (X-axis); consequently, the polarization of a ∥ band is determined to be along the long axis of the molecule (X-axis). Therefore, the ⊥ band in the region of 340—460 mμ is polarized to the short axis of the molecule (Y-axis); hence, this band can be said to correspond to the ^1L_a band of anthracene. Furthermore. it is apparent that the X-polarized ^1L_b band is present in the region of 340—410 mμ.

These experimental results are compared with the results of the MO calculations in Table 2. The V transition (265 mμ) can be said to correspond unequivocally to the observed 266 mμ band. There are four transitions (I—IV) in the longer wavelength region of the V transition; however, two of them correspond to the observed ^1L_a and ^1L_b bands. From a consideration of the position, the polarization, and the oscillator strength, the I and II transitions may be said to correspond to the ^1L_a and the ^1L_b bands respectively.

Table 2. The result of the MO calculation on the electronic transition of 9-hydroxyanthracene

	Transition energy, eV (mμ)[a]	Polarization[b]	Oscillator strength
I	3.22 (385)	Y	0.2900
II	3.38 (367)	X	0.0520
III	4.08 (304)	X	0.0221
IV	4.65 (267)	Y	0.0002
V	4.67 (265)	X	2.0347
VI	4.75 (261)	X	0.2683
VII	5.05 (246)	Y	0.0106
VIII	5.32 (233)	Y	0.0045

a) Only the transitions appeared above 220 mμ were listed.
b) The molecular axes were shown in Fig. 2.

Sodium 9,10-Dihydroxyanthracene-2-sulfonate. This was obtained from sodium anthraquinone-2-sulfonate by a photochemical reduction.[15,16] Since a sodium sulfonate group has only a slight influence on the electronic spectrum of an aromatic compound, the observed dichroic spectra shown in Fig. 3 may be regarded as those of 9,10-dihydroxyanthracene. The patterns of the absorption curve and of the R_d curve were very similar to those of 9-hydroxyanthracene; hence, each band can be assigned like that of 9-hydroxyanthracene. That is, the intense band at 272 mμ is the ^1B_b band and is polarized along the X-axis, and the longer- and the shorter-wavelength parts of the relatively weak band in the region of 340—460 mμ are determined to be the ^1L_a and the ^1L_b bands respectively.

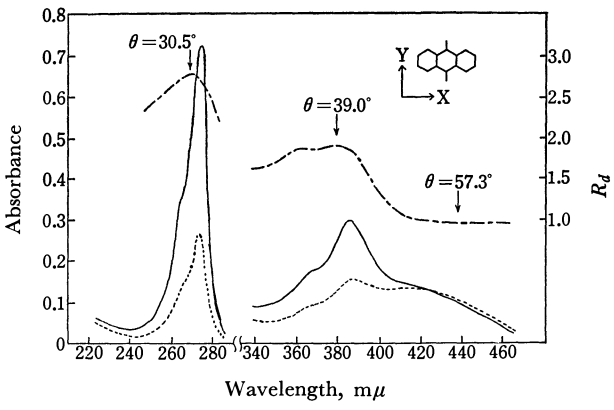

Fig. 3. Dichroic spectra of sodium 9,10-dihydroxyanthracene-2-sulfonate.
R_s=4.5, ——: $D_{\parallel}$, ----: $D_{\perp}$, —·—: $R_d(=D_{\parallel}/D_{\perp})$

The results of the MO calculations for 9,10-dihydroxyanthracene are shown in Table 3. The observed ^1L_a, ^1L_b, and ^1B_b bands can be said to correspond to the I, II, and V transitions respectively.

9,10-Dihydroxyphenanthrene. This was obtained from 9,10-phenanthrenequinone by photochemical

X	5.63 (220)	X	0.3625

a) Only the transitions appeared above 220 mμ were listed.
b) The molecular axes were shown in Fig. 3.

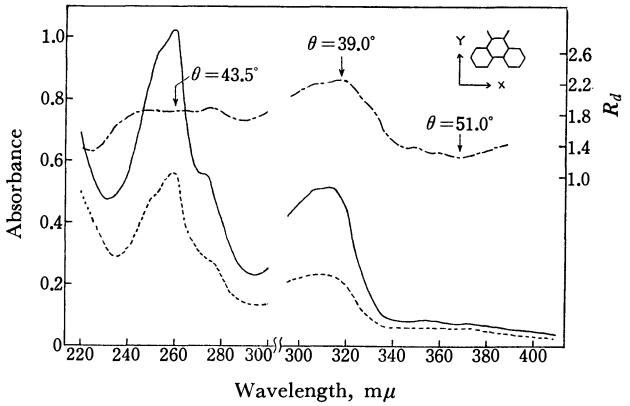

Fig. 4. Dichroic spectra of 9,10-dihydroxyphenanthrene. R_s=9.0, ——: $D_{\parallel}$, ----: $D_{\perp}$, —·—: $R_d(=D_{\parallel}/D_{\perp})$

reduction.[17] The dichroic spectra are shown in Fig. 4. From the behavior of the R_d curve, it can be deduced that the bands at 260 mμ and at 314 mμ are polarized in the same direction (∥ bands). However, the R_d values of the 260 mμ band are somewhat smaller than those of the 314 mμ band. This suggests the presence of a ⊥ band near the 260 mμ band.

A very weak band appears above 340 mμ. The polarization of this band is perpendicular to the transition moment of the 314 mμ band, because the sum of the orientation angles of these band makes a right angle; that is, this weak band is a ⊥ band.

These experimental results are compared with the theoretical results in Table 4. The most intense ∥ band, at 260 mμ, undoubtedly corresponds to the calculated transition VI, which is polarized along the X-axis of the molecule and which has the largest oscillator strength in the region above 220 mμ. Therefore, the ∥ bands may be considered to be polarized to the X-axis. Although there is no transition around

Table 4. The result of the MO calculation on the electronic transition of 9,10-dihydroxyphenanthrene

	Transition energy, eV (mμ)[a]	Polarization[b]	Oscillator strength
I	3.32 (374)	Y	0.0459
II	3.58 (346)	X	0.4001
III	4.35 (285)	Y	0.0676
IV	4.44 (280)	X	0.0160
V	4.64 (267)	Y	0.4000
VI	4.78 (259)	X	1.1400
VII	5.11 (243)	X	0.0452
VIII	5.42 (229)	Y	0.0823
IX	5.59 (222)	X	0.4076

a) Only the transitions appeared above 220 mμ were listed.
b) The molecular axes were shown in Fig. 4.

314 mμ in the present calculation, the II transition presumably corresponds to the observed 314 mμ band, judging from the direction of the polarization and the oscillator strength. Between the II and VI transition, there are two Y-polarized transitions, III (f= 0.0676) and V (f=0.400), at 285 mμ and 267 mμ. The lower R_d values of the 260 mμ band as compared with those of the 314 mμ band are ascribable to the presence of the Y-polarized bands corresponding to the III and V transitions. However, it can not be decided in the present study whether the shoulder at about 275 mμ corresponds to the V transition or whether it is the vibrational structure of the 260 mμ band. The ⊥ band appearing above 340 mμ may be considered to be due to the I transition, judging from its position, its intensity, and its polarization.

The results obtained above were compared with those on the absorption bands of phenanthrene. The electronic spectrum of phenanthrene has been studied in detail.[18–20] The two bands at 258 mμ and at 300 mμ have been found to be polarized along the X-axis and have been assigned to the ^1B_b and the ^1L_a bands respectively. Thus, the 260 mμ and the 314 mμ bands of 9,10-dihydroxyphenanthrene may be considered to be the ^1B_b and the ^1L_a bands respectively. The very weak band of phenanthrene around 330 mμ ($\log \varepsilon$= 2.2) may be interpreted as being due to the symmetry-forbidden ^1L_b transition. In the case of 9,10-dihydroxyphenanthrene, the ⊥ band appearing above 340 mμ (the I transition) may correspond to the ^1L_b band of phenanthrene. In contrast to the case of phenanthrene, the I transition of 9,10-dihydroxyphenanthrene is symmetry-allowed, f=0.0459.

The authors wish to thank Dr. T. Hoshi of Aoyama Gakuin University for his help in the MO calculations.

Studies on Intermolecular Complex Formation. I. Between Nucleotide Bases and Organic Compounds

Chihiro TAMURA, Noriko SAKURAI, and Sadao SATO

The Central Research Laboratories of Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received October 30, 1970)

The present investigation was focussed on a survey of the chemical compounds which are capable of binding with nucleotide bases. X-Ray powder patterns show that adenine and cytosine have a strong tendency to interact with many organic compounds having a carboxyl group and cyclic alternant CONH groups. A few compounds bind with thymine and uracil.

In view of the structure and function of DNA, many single crystal analyses of the complexes between the nucleotide bases have been analyzed.[1-7] Several types of base-pairing were found, and in these complexes the principal binding force is due to complementary hydrogen bonds. We had expected that complexes exist not only between the nucleotide bases themselves but also between nucleotide bases and other organic compounds having some characteristic structure. By infrared spectrum, Kyogoku *et al.* studied some biologically active compounds which interact with nucleotide bases in solution.[8]

The X-ray powder method was applied in surveying these compounds with respect to their ability to form complexes with nucleotide bases. A large number of combinations was found to give rise to a change in diffraction patterns which might indicate the formation of complex. Some of them were obtained in the form of single crystal and we succeeded in determining their crystal structures.[9,10] New types of intermolecular hydrogen bonding were found, the details of which will be published elsewhere. In the present paper we will describe the results of the survey and discuss the structural characteristics of the molecules which can form the complexes.

Experimental

The experimental procedure was as follows: equivalent moles (*ca.* 100 mg) of organic substance and the base were added to 70% aqueous ethanol (*ca.* 15 cc). The mixture was warmed on a water-bath until dissolution was complete and then allowed to stand for several days in a refrigerator. A glass holder with a depth of 0.2 mm was filled with crystalline material thus obtained, and X-ray diffractions were recorded up to $2\sin\theta=50°$ with a Rigakudenki model D6C diffractometer. Spacings of diffraction peaks are listed in Table 4, the height of the maximum peaks being normalized to one hundred.

The formation of new crystalline species was verified by comparing their diffraction patterns with those of components. An example of such comparison is shown in Fig. 1. All component samples were recrystallized by use of the same solvent in order to avoid an erroneous conclusion due to polymorphism of the components. The mass and infrared spectra of such crystals were sometimes useful in confirming the formation of new complexes. The stability of each crystal was examined by taking diffraction patterns of the same sample at intervals of several hours. Any changes in these patterns indicate that the substance is unstable at room temperature and humidity. Subsequently such samples were kept during measurements at a low temperature and at the same humidity as that in the refrigerator.

Some of the complexes showed only a small number of new peak superimposed over those of the diffraction patterns of the components. In such cases, the diffraction patterns were recorded repeatedly more than three times to confirm their reproducibility.

Results and Discussion

The results of the experiments, in part, are shown in Tables 1 and 2. A + sign denotes the formation of a new crystalline species and a 0 designates that no change for a pair was observed under these conditions. The sign ± indicates that only a few new diffraction peaks were observed in addition to the original peaks. Some of the new crystalline species were established as being due to complex formation by means of single crystal analysis, and some were suggested to be complexes by infrared spectra or mass spectra. Therefore, it

seems most probable to assume that the new crystalline-species correspond to those of the complexes, but not another modification of the components. Table 3 shows the number of substances forming complexes and the total number examined; they can be classified into six categories. It has been observed that adenine and cytosine form complexes with many organic compounds, while thymine and uracil form hardly any such complexes with those examined. Guanine was not included because of its poor solubility. The spacings listed in Table 4 are for the complexes and their components.

Table 3. Complex-formation ability of organic compounds with adenine and cytosine

number of substances forming complexes / total number of substances examined

	Category	For adenine		For cytosine	
1	Containing -COOH	33/36	91.8%	28/36	77.8%
2	Containing -CH(NH$_3^{\oplus}$)-COO$^{\ominus}$	0/18	0.0	0/18	0.0
3	Containing -CONH$_2$	1/17	5.9	0/17	0.0
4	Linear molecules containing CO & NH	0/10	0.0	0/10	0.0
5	Cyclic molecules containing CO & NH	6/39	15.4	5/39	12.8
6	Cyclic molecules containing -CONHCONH-	11/12	91.6	5/12	41.6

Carboxylic Acids. Table 3 shows that 92% of the carboxylic acids examined can bind with adenine and 78% with cytosine. Even long chain fatty acids, which are structurally different from the planar molecule of adenine, form the complexes as shown in Table 1. The structure of single crystal analysis,[9] in which the combination of the acid and base is of the type (acid$_4$-base$_2$) through the NH–O and OH–N hydrogen bonds is shown in Fig. 2. It seems that most of the other acid-adenine complex crystals are of a similar type.

It should be noted that many *p*-substituted benzoic acid derivatives do not form the complexes.

Aminoacids. In biological processes some interactions are expected to exist between nucleic acids

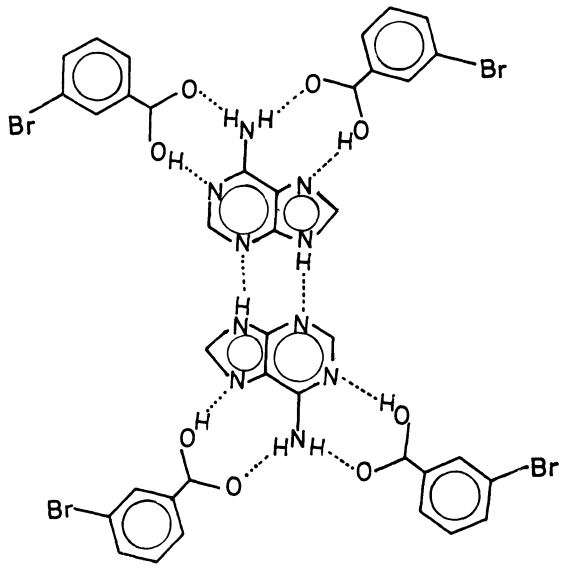

Fig. 2. The hydrogen bonding system of the complex crystal between *m*-bromobenzoic acid and adenine.

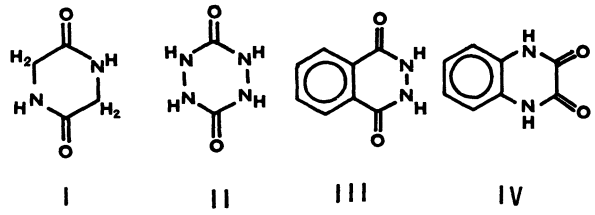
and amino acids. However, no amino acids were found to interact with these bases under the present conditions. The zwitter-ion form of amino acid might be related to this inertness. The substances tested in the present study were glycine, α-alanine, β-alanine, L-serine, L-threonine, L-valine, L-leucine, L-isoleucine, L-asparatic acid, L-histidine, L-proline, arginine, tryptophan, phenylalanine, methionine, cystein, creatine, and aminocapronic acid.

Acid Amides and Lactams. In view of complex-forming ability, acid amides and lactams could be classified into four categories (3 to 6) as shown in Table 3. Acid amides are inert; compounds tested are benzamide, *o*-, *m*-, and *p*-toluamide, *o*-, *m*-, and *p*-hydroxy benzamide, *o*-, *m*-, and *p*-chlorobenzamide, picolinamide, nicotinamide, and isonicotinamide. The only exception in amide group is pyrazinamide which can bind with adenine. Lactam group are inactive; the compounds tested are butyrolactam, valerolactam, ε-caprolactam, 2-azacyclononanone, tetrahydro-2-pyrimidone, succinamide, maleimide, phthalimide, glycinanhydride, 1,3-dimethylurea, acetylurea, 1-acetyl-3-methylurea, 1-phenyl-3-acetylurea. 1,3-diphenylurea, phenylurea, benzylurea, benzoylurea, and acetanilide.

Although the linear molecules containing CO and NH groups (category 4) do not interact with the bases, the corresponding atomic arrangement in cyclic molecules bind with adenine and/or cytosine; examples are benzoylurea/benzoyleneurea, and acetylurea/hydantoin. However even in cyclic molecules containing CO and NH groups, *e.g.*, anhydroglycine I, 3,6-dioxohydro-1,2,4,5-tetrazine II, 2,3-dihydroxyquinoxaline III and phthalazine-2,4-dione IV, binding



I II III IV

was not observed with these bases. This indicates that the atomic arrangement required for binding with adenine and cytosine would be cyclic alternant –CONH– groups. It should be noted that uracil[11] and thymine are regarded as typical members of category 5. In such a system, the proton donor and acceptor groups will be in the proper orientation with those in the bases to reinforce individual hydrogen bonds. In fact, the hydrogen bond system in the adenine-phenobarbital complex solved by Kim and Rich[13] is just the case as shown in Fig. 3.

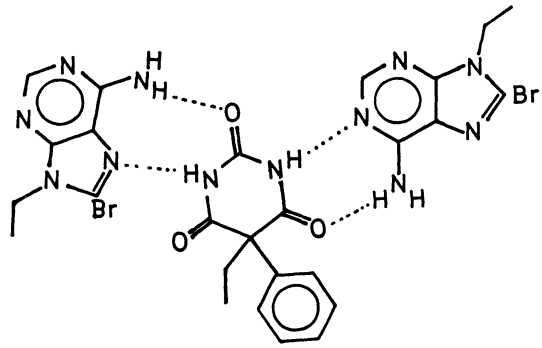


Fig. 3. The hydrogen bonding system of the complex crystal between phenobarbital and 8-bromo-9-ethyladenine, by Kim and Rich.

There are some other compounds which also bind with adenine and cytosine: 1-(2*H*)-phthalazinone, cycloserine, and 4,6-dihydroxy-1-mercaptopyrimidine. However, it is difficult to recognize any common features among them.

Amino and Nitrogen Heterocycles: A few compounds were found to bind with uracil and/or thymine; these are 1,3,5-triamino-2,4,6-triazine, azaadenine, and bromouracil. But many other related compounds, such as 2-methyl-4-amino-5-carbinopyrimidine, 2-aminopyridine, 2-aminopyrimidine, and 3-amino-1,2,4-triazole, do not form complexes.

We thank Professor Yoshio Sasada of Tokyo Institute of Technology for his valuable discussions and suggestions.

11) The complex of cytosine-uracil was found in this survey and its structure was determined by means of single crystal analysis.[10] The non-Watson-Crick pairing of uracil-cytosine found is almost the same as that of 5-fluorouracil-cytosine complex reported by Voet and Rich.[12]

Studies of the Alkaline Earth Complexes in Various Solutions. VI. The Extraction and Complex Formation of Beryllium(II) in Sodium Perchlorate Media Containing Some Univalent Inorganic Anions

Tatsuya SEKINE, Yū KOMATSU, and Mitsuo SAKAIRI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 2, 1970)

The distribution of beryllium(II) between methylisobutylketone containing TTA (thenoyltrifluoroacetone) and aqueous 4.0 M sodium perchlorate constant ionic media has been measured by using a carrier-free beryllium-7 tracer. The distribution behavior, determined as a function of the TTA and the hydrogen ion concentration, was explained in terms of the extraction of the $Be(TTA)_2$, the $Be(ClO_4)_2$ and the mixed species $Be(TTA)(ClO_4)$, and their extraction constants were determined. Then, the stability constants for the chloride, bromide, and nitrate complexes were determined from the decrease in the TTA extraction when some of the perchlorate ions in the aqueous phase were replaced by the ligand anions. Those of the thiocyanate complexes, on the other hand, were determined from the extraction of $Be(SCN)_2$ species with TBP (tributylphosphate) in hexane. It was concluded that the stabilities of these complexes are very low; the values β_1 and β_2 range between 1 and 0.1, but still these complexes should be taken into account in any discussion of the chemical behavior under some experimental conditions.

Although much has been reported on the complex formation of beryllium(II) with the fluoride ion in aqueous solutions, few seem to have studied those with other halide anions.[1]

In the present investigation, the authors have determined the distribution of beryllium(II) between aqueous sodium perchlorate media containing chloride, bromide, iodide, nitrate or thiocyanate ions and methylisobutylketone (MIBK) containing thenoyltrifluoroacetone (TTA) or hexane containing tributylphosphate (TBP). The distribution data were explained in terms of the complex formation, and the stability constants were determined by a graphic method. It was also found that the extraction of beryllium(II) mixed complexes with perchlorate and TTA anion or the beryllium(II) perchlorate should be taken into account in order to explain the distribution behavior of this metal ion under some experimental conditions.

Experimental

Tracer and Reagents. All of the reagents were of a reagent grade. Carrier-free beryllium-7 was used as the tracer. Sodium perchlorate was prepared from sodium carbonate and perchloric acid, and was recrystallized three times from water. MIBK and TBP were washed with 0.1 M perchloric acid, water, and 0.1 M sodium hydroxide, and then several times with water. The other reagents were used without further purification. The concentration of the stock perchlorate or nitrate solution was determined by weighing the residues after a certain amount of the solution had been dried in an air-bath at 120°C. The concentration of the chloride, bromide, iodide or thiocyanate stock solution was determined by titration with standard solutions of silver nitrate.

Procedures. Most of the procedures carried out were similar to those described in the previous paper.[2] MIBK containing TTA or hexane containing TBP was used as the organic phase. The aqueous phase was kept at 4.0 M (ClO_4) throughout the experiments, and when it was necessary, an acetate buffer (0.01 M initially) was added to the solution. The procedures were always carried out in a thermostatted room at 25°C. The hydrogen ion concentration in the aqueous phase was measured potentiometrically by using a standard solution containing 0.0100 M perchloric acid and 3.99 M sodium perchlorate as the standard of $-\log[H^+]=2.000$ in the 4.0 M ionic media.

Statistical Treatment

In the present work, the net distribution ratio, D, was defined and measured as follows:

$$D = [\mathrm{Be(II)}]_{org.total}/[\mathrm{Be(II)}]_{total}$$

In this paper, the chemical species in the organic phase are denoted by the subscript "org", while those in the aqueous phase have no subscript.

$$D = \frac{\gamma\text{-count-rate per ml of the org. phase}}{\gamma\text{-count-rate per ml of the aq. phase}} \quad (1)$$

1. Extraction of Be(II) in Perchlorate Solutions into MIBK Containing TTA. The equilibria for the extraction of beryllium(II) in a perchlorate medium with an acidic HA are generally described as follows:

$$Be^{2+} + 2HA(org) \rightleftarrows BeA_2(org) + 2H^+ \quad (2)$$

$$Be^{2+} + HA(org) + ClO_4^- \rightleftarrows BeAClO_4(org) + H^+ \quad (3)$$

$$Be^{2+} + 2ClO_4^- \rightleftarrows Be(ClO_4)_2(org) \quad (4)$$

When the perchlorate concentration in the aqueous phase is kept constant, the equilibrium constants can be described as:

$$K_{ex_0} = [BeA_2]_{org}[H^+]^2/[Be^{2+}][HA]^2_{org} \quad (5)$$

$$K_{ex_1} = [BeAClO_4]_{org}[H^+]/[Be^{2+}][HA]_{org} \quad (6)$$

$$K_{ex_2} = [Be(ClO_4)_2]_{org}/[Be^{2+}] \quad (7)$$

When we assume that only the Be^{2+} species is present in the aqueous perchlorate media, whereas the BeA_2, $BeAClO_4$ and $Be(ClO_4)_2$ species are all present in the organic phase, the net distribution ratio may be described as:

$$D = \frac{[BeA_2]_{org} + [BeAClO_4]_{org} + [Be(ClO_4)_2]_{org}}{[Be^{2+}]} \quad (8)$$

1) L. G. Sillén and A. E. Martell, "Stability Constants," the Chemical Society, spec, pub. **17** (1964).

2) T. Sekine and M. Sakairi, This Bulletin, **40**, 261 (1967).

Equation (8) can be also written from Eqs. (5), (6), and (7) as:

$$D = K_{ex_0}([HA]_{org}/[H^+])^2 + K_{ex_1}([HA]_{org}/[H^+]) + K_{ex_2} \quad (9)$$

or

$$D([H^+]/[HA]_{org})^2 = K_{ex_0} + K_{ex_1}([H^+]/[HA]_{org}) + K_{ex_2}([H^+]/[HA]_{org})^2 \quad (10)$$

Equation (9) shows that the value K_{ex_2} can be determined from the distribution ratio when the organic phase contains no HA, and Eq. (10) shows that the value $D([H^+]/[HA]_{org})^2$ should be constant at any $[H^+]/[HA]_{org}$ when the organic phase contains, practically, only the BeA_2 species, while it will increase with the increase in $[H^+]/[HA]_{org}$ when an extraction of metal species containing perchlorate ions into the organic phase occurs.

The above statistical treatments were made on the assumption that the ion-pairs, $Be(ClO_4)_2$ and $BeA\text{-}ClO_4$, undergo no dissociation in the organic phase. However, when there is a dissociation of perchlorate ions in the solvating polar solvent, MIBK, the organic concentration of beryllium(II) should be described as:

$$[Be(II)]_{org.\ total} = [BeA_2]_{org} + [BeAClO_4]_{org} + [BeA^+]_{org} + [Be(ClO_4)_2]_{org} + [BeClO_4^+]_{org} + [Be^{2+}]_{org} \quad (11)$$

and the following dissociation constants for the organic species should also be determined:

$$K_{diss.1(org)} = \frac{[BeA^+]_{org}[ClO_4^-]_{org}}{[BeAClO_4]_{org}} \quad (12)$$

$$K_{diss.2,1(org)} = \frac{[BeClO_4^+]_{org}[ClO_4^-]_{org}}{[Be(ClO_4)_2]_{org}} \quad (13)$$

$$K_{diss.2,2(org)} = \frac{[Be^{2+}]_{org}[ClO_4^-]_{org}}{[BeClO_4^+]_{org}} \quad (14)$$

The following equation are then obtained:

$$[BeAClO_4]_{org} + [BeA^+]_{org} = [BeA(ClO_4)]_{org}(1 + K_{diss.1(org)}/[ClO_4^-]_{org}) \quad (15)$$

$$[Be(ClO_4)_2]_{org} + [BeClO_4^+] + [Be^{2+}]_{org} = [Be(ClO_4)_2]_{org}(1 + K_{diss.2,1(org)}/[ClO_4^-]_{org} + K_{diss.2,1(org)} \times K_{diss.2,2(org)}/[ClO_4^-]^2_{org}) \quad (16)$$

The organic perchlorate ion concentration can be described as follows (disregarding the A^- ion and hydroxide ion):

$$[ClO_4^-]_{org} = [Na^+]_{org} + [H^+]_{org} + [BeA^+]_{org} + [BeClO_4^+]_{org} + 2[Be^{2+}]_{org} \quad (17)$$

Equation (17) shows that the perchlorate ion concentration in the organic phase is dependent not only on the sodium and hydrogen ion concentrations, but also on the concentrations of the cationic beryllium species in the organic phase. Consequently, if the total beryllium concentration is changed, or when the hydrogen ion or the extractant concentration is changed, the total organic perchlorate ion concentration in Eq. (17) which will be introduced into Eqs. (15) and (16) should be changed.

Fortunately such a consideration seems to be unnecessary. According to the results previously obtained by our laboratory,[3] the distribution ratio of sodium perchlorate between MIBK and an aqueous solution is 1.4×10^{-2}, thus, an MIBK phase in an equilibrium with 4.0 M sodium perchlorate should contain about 5×10^{-2} M sodium perchlorate. Furthermore, the extraction of perchloric acid from the aqueous phase will not be very large[4] and the perchlorate ion concentration in the organic phase should not be considerably changed even when the hydrogen ion concentration in the aqueous phase is changed within the range studied in this paper. For these reasons, even when the dissociation of the ion-pair species in the organic phase occurs, the expressions in Eqs. (6) to (10) can be used to describe the distribution behavior in the present system. However, when the aqueous sodium perchlorate concentration is much lower and/or the beryllium concentration is much higher, the possibility of the effect of the dissociation in the organic phase should be considered.

2. TTA Extraction and Complex Formation of Be(II). Under conditions where only the extraction of BeA_2 species is assumed, the following equation can be used instead of Eq. (10):

$$K_{ex_0} = D_0[H^+]^2[HA]^{-2}_{org} \quad (18)$$

where D_0 denotes the distribution ratio when the aqueous phase contains no complex forming ligands, that is, $D_0=[BeA_2]_{org}/[Be^{2+}]$.

When the Be^{2+} species associates with a uninegative ligand, L^-, the over-all stability constants for the n-th complex is defined as:

$$\beta_n = [BeL_n^{2-n}]/[Be^{2+}][L^-]^n \quad (19)$$

and the total aqueous concentration of beryllium(II) can be described as:

$$[Be(II)]_{total} = [Be^{2+}](1 + \sum \beta_n[L^-]^n) \quad (20)$$

The distribution ratio can then be described as:

$$D = [BeA_2]_{org}/[Be^{2+}](1 + \sum\beta_n[L^-]^n) \quad (21)$$

From Eqs. (18) and (21), the following equation is obtained:

$$D[H^+]^2[HA]^{-2}_{org}Ke\times0^{-1} = (1 + \sum\beta_n[L^-]^n)^{-1} \quad (22)$$

3. TBP Extraction of Neutral Complexes. When the neutral complex of beryllium(II) with L^- is extracted with e molecules of an organophilic adduct-forming extractant, E, the extraction can be described as:

$$BeL_2 + eE(org) \rightleftarrows BeL_2E_e(org) \quad (23)$$

$$K'_{DM} = [BeL_2E_e]_{org}/[BeL_2][E]^e_{org} \quad (24)$$

When the concentration of the extractant, E, is kept at a constant value, c_1, the following constant can be employed instead of that in Eq. (24):

$$K_{DM} = [BeL_2]_{org}/[BeL_2] \quad (\text{at } [E]_{org} = C\text{M}) \quad (25)$$

The net distribution ratio of beryllium(II) can then be described as:

$$D = \frac{[BeL_2]_{org}}{[Be^{2+}] + [BeL^+] + [BeL_2] + \cdots} \quad (26)$$

3) Y. Hasegawa, T. Ishii, and T. Sekine, This Bulletin, **44**, 275 (1971).

4) T. Sekine, T. Fukushima, and Y. Hasegawa, *ibid.*, **43**, 2638 (1970).

or

$$D[L^-]^{-2} = K_D\beta_2/(1 + \sum \beta_n[L^-]^n) \quad (27)$$

4. Graphic Determination of the Stability Constants. The equilibrium constants in these equations can be determined graphically from the experimental results as follows. When the D in Eq. (9) is denoted by $-y$, and the $[HA]_{org}/[H^+]$, by v, or when the $D[H^+]^2 \cdot [HA]_{org}^{-2}K_{ex_0}^{-1}$ or $D[L^-]^{-2}$ term in Eq. (22) or Eq. (27) is denoted by y, and the $[L^-]$ in these equations, by v, the equations can generally be described as:

$$\log y = \log c - \log(a_0 + a_1v + a_2v^2 + \cdots) \quad (28)$$

By plotting $\log y$ *vs.* $\log v$, the constants, a_0, a_1, a_2, $\cdots$, are determined by the "curve-fitting" method presented in previous papers.[5,6]

Results

Figure 1 shows the extraction of beryllium(II) in sodium perchlorate solutions at $-\log[H^+]$ 2.00 into MIBK. As no anionic species other than perchlorate ions is present in the aqueous phase, the extracted species should be the ion-pair $Be^{2+}(ClO_4^-)_2$ and the extraction can be given by Eq. (4). Although no control of the activity was made in these experiments, the slope of the plot is +2 between 1 M to 3 M sodium perchlorate, as can be expected from Eq. (4). The deviation of the data at the higher salt concentrations may be due to the change in the activities.

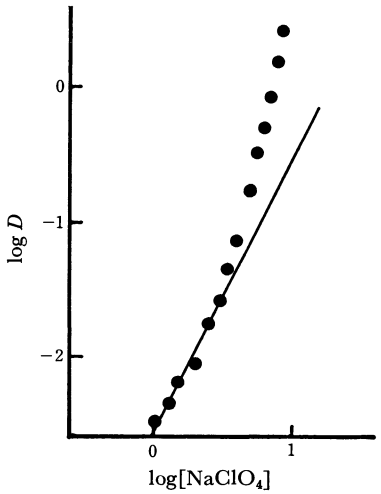

Fig. 1. Distribution of beryllium(II) between MIBK and aqueous sodium perchlorate at $[H^+]=10^{-2}$ M. The straight line shows the slope +2.

Figure 2 gives the $\log D$ *vs.* $\log[HA]_{org}/[H^+]$ plot for the distribution of beryllium(II) between MIBK containing TTA at various concentrations and 4 M sodium perchlorate solutions at various hydrogen ion concentrations. The distribution ratio of beryllium(II) in 4 M perchlorate media at $-\log[H^+]$ 2.00 into MIBK containing no TTA was found to be 6.9×10^{-2}, as may be seen from Fig. 1. This value gives the K_{ex_2} in Eq. (9). The distribution ratio increases with the increase in $[HA]_{org}/[H^+]$, and the slope of

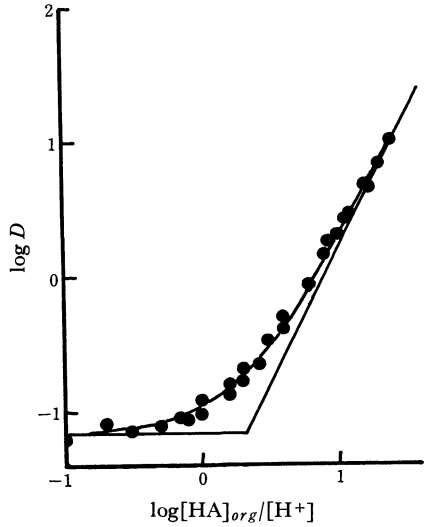

Fig. 2. Distribution ratio of beryllium(II) between MIBK containing TTA and 4 M (H, Na)ClO_4 as a function of $[HA]_{org}/[H^+]$. The two straight lines are $Y=-1.16$ and $Y=2X-1.80$. The solid curve gives $Y=\log(1.6\times10^{-2}X^2+2.3\times10^{-2}X+6.9\times10^{-2})$. Here $Y=\log D$ and $X=\log[HA]_{org}/[H^+]$.

the plot increases from zero to two. This can be explained as follows. In the lowest $[HA]_{org}/[H^+]$ region, where the slope is zero, beryllium(II) is extracted as the $Be(ClO_4)_2$ species, and in the highest region, where the slope is two, it is extracted as the BeA_2 species, while in the region where the slope is between zero to two, extracted beryllium species in the organic phase should be mixtures of $Be(ClO_4)_2$, $BeAClO_4$, and BeA_2. The plot in Fig. 2 was analyzed by the curve-fitting method; the equilibrium constants thus obtained are given in Table 1. The solid curve in Fig. 1 is the extraction curve calculated from these constants.

Figure 3 gives the $\log D[H^+]^2[HA]_{org}^{-2}K_{ex_0}^{-1}$ *vs.*

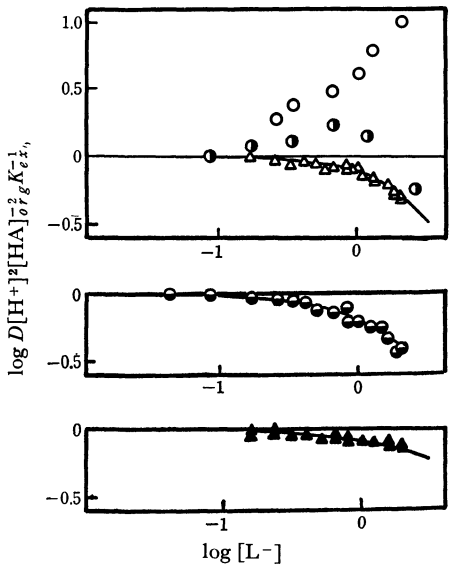

Fig. 3. Change in the extraction of beryllium(II) in 4 M Na(L, ClO_4) as a function of the ligand concentration. In the figure, L^- is Cl^-(◒), Br^-(△), I^-(◑), NO_3^-(▲), or SCN^-(○). The organic phase was MIBK containing 0.01 M TTA for the thiocyanate system and 0.2 M TTA for the others. The hydrogen ion concentration in the aqueous phase is $10^{-3.2}$ M for the thiocyanate system and $10^{-2.0}$ M for the others. The solid curves are $Y=-\log(1+a[L^-]+b[L^-]^2)$ where $a=0.44$ and $b=0.19$ for Cl^-, $a=0.13$ and $b=0.18$ for Br^- and $a=0.22$ and $b=0$ for NO_3^-. The constants for the iodide and thiocyanate systems were not determined by the reasons given in the text.

log [L^-] plot when the ligand anion in 4.0 M Na(ClO_4) was chloride, bromide, or nitrate ions. In these experiments, the TTA concentration in MIBK was 0.2 M, and the $-\log[H^+]$ in the aqueous phase was 2.00 or 2.53.

As may be seen from Fig. 2, the slope of the plot is practically +2 when $\log[HA]_{org}/[H^+]$ is 1.3 or 1.8. It has been observed that the extraction was practically proportional to $([HA]_{org}/[H^+])^2$ even when the concentration of chloride, bromide, or nitrate ions in the aqueous phase was 2.0 M. Thus, it may be concluded that the extraction of metal species containing the ligand, MAL or ML_2, is negligible and that only the BeA_2 species is extracted into the organic phase when the ligand concentration is less than 2.0 M. From these facts, we may see that Eq. (22) is valid for the calculation of the stability constants from these data. The constants thus determined are given in Table 2. The solid curves in Fig. 3 are the extraction curves calculated from the stability constants in Table 1 and the value $K_{ex_2}=10.^{-1.80}$

Table 2. Stability constants of beryllium(II) complexes in 4 M Na(ClO_4) at 25°C

$\beta_n = [BeL_n^{2-n}]/[Be^{2+}][L^-]^n$

ligand	$\log\beta_1$	$\log\beta_2$
Cl^-	−0.85	−0.70
Br^-	−0.70	−0.80
NO_3^-	−0.63	—
SCN^-	−0.16	−0.60

Beryllium(II) in 4.0 M perchlorate media containing iodide or thiocyanate ions was also extracted with TTA in MIBK. However, the results were complicated, as can also be seen in Fig. 3; the addition of the ligand even increases the extraction in some ligand concentration regions. This was assumed to be due to the extraction of the complex formed, BeL_2, or of the mixed complexes with TTA, BeAL, into MIBK. Thus, it was not possible to obtain the stability constants of the beryllium(II) iodide or thiocyanate complexes by the TTA-extraction method.

Beryllium(II) in 4.0 M sodium perchlorate containing one of these five ligands was also extracted into hexane containing TBP. It was observed that the distribution ratio is always very low (about 10^{-2} or less) when the aqueous phase contains chloride, bromide, iodide, or nitrate ions at various concentrations and when the organic phase contained 0.2 M TBP in hexane. However, when the aqueous phase contained thiocyanate ions, a remarkable extraction of beryllium(II) was observed.

Figure 4 gives the log D *vs.* log[SCN^-] plot when the organic phase is hexane containing 0.2 M TBP and when the aqueous phase is 4.0 M Na(SCN, ClO_4) at $-\log[H^+]$ values between 3.5 and 4.0. It may be seen from Fig. 4 that the distribution increases with the increase in the thiocyanate concentration and that the slope $d\log D/d\log[SCN^-]$ decreases from 2 to about 1 or less. Assuming that only the $Be(SCN)_2$ species is extracted with TBP, the results were analyzed using Eq. (27). Figure 5 gives the $\log D/[SCN^-]^2$ *vs.* log [SCN^-] plot. The constants were determined from Fig. 5 by the curve-fitting method; they are given in Tables 1 and 2. The solid curve in Fig. 5 is the curve calculated from these constants. When the thiocyanate concentration is lower than 0.1 M, the data deviate from the statistically expected curve based on Eq. (27).

In order to see the effect of the hydrogen ion concentration on the TBP extraction of beryllium thio-

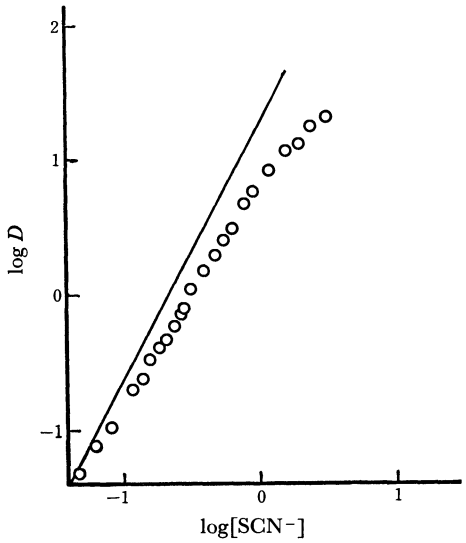

Fig. 4. Extraction of beryllium(II) from 4 M Na(SCN, ClO_4) at $[H^+]=10^{-4}$ M into hexane containing 0.2 M TBP as a function of the thiocyanate concentration. The straight line shows the slope of +2.

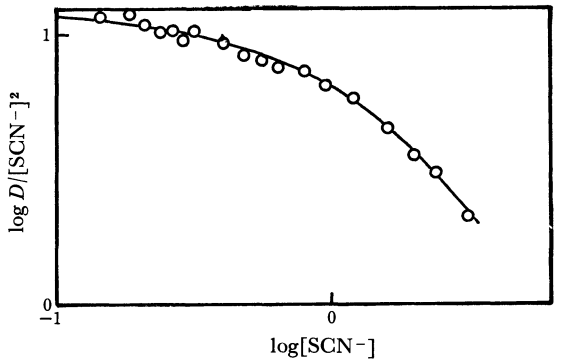

Fig. 5. Determination of the stability constants of the thiocyanate complexes by the curve fitting. The data in Fig. 4 were plotted as $\log D[SCN^-]^2$ *vs.* $\log[SCN^-]$ and were fitted with the curve $Y=\log c-\log(1+a[SCN^-]+b[SCN^-]^2)$ were a is $\beta_1(=0.69)$, b is $\beta_2(=0.25)$ and c is $K_D\beta_2(=12.6)$.

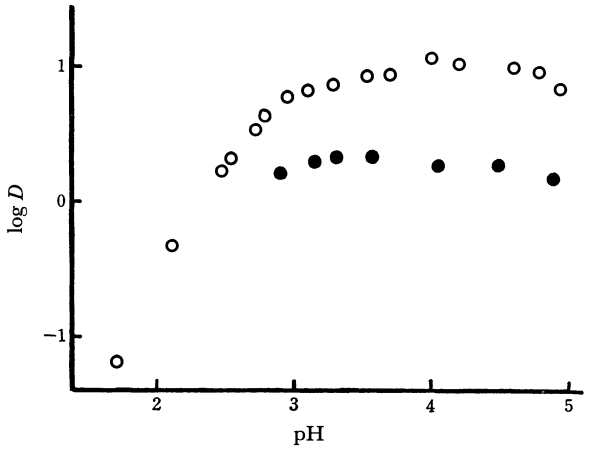

Fig. 6. Hydrogen ion concentration dependence of the extraction of beryllium thiocyanate complex.
Organic phase: Hexane containing 0.2 M TBP.
Aqueous phase: 2 M NaSCN+2 M $NaClO_4$ (open circles), 0.4 M NaSCN+3.6 M NaClO (closed circles).

cyanate, the distribution ratio was determined as a function of $-\log[H^+]$ when the TBP concentration was 0.2 M and when the thiocyanate concentration was 2.0 M or 0.4 M. The results are given in Fig. 6. As may be seen from Fig. 6, the distribution ratio is practically independent of the hydrogen ion concentration when it is between $10^{-3.5}$ and $10^{-4.5}$.

Figure 7 shows the distribution of beryllium(II) in the aqueous phase containing 3.0 M sodium perchlorate and 1.0 M sodium thiocyanate at a $-\log[H^+]$ value of about 4.0 into hexane as a function of the organic TBP concentrations. In Fig. 7, it may be seen that the slope of the plot is +3; thus, the extraction equilibrium can be described by the following equation:

$$Be(SCN)_2 + 3TBP(org) \rightleftarrows Be(SCN)_2(TBP)_3(org)$$

As has been described, two different solvent extraction methods were used for the determination of the beryllium complexes in the present study. The metal TTA chelate extraction method is applicable only to the chloride, bromide, and nitrate complexes, whereas the TBP adduct neutral complex extraction method

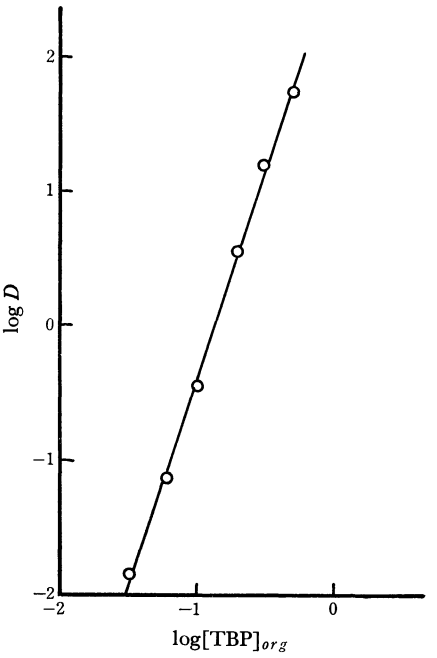

Fig. 7. TBP dependence of the beryllium thiocyanate extraction. Organic phase: hexane containing TBP. Aqueous phase: 3 M $NaClO_4$+1 M NaSCN and $[H^+]$ is about 10^{-4} M.

was applicable to the thiocyanate complexes. Neither of them was suitable for the iodide complexes.

Discussion

In a previous paper,[2] a deviation of the log D of beryllium(II) *vs.* $-\log[H^+]$ plot from the slope +2 was observed when the organic phase was MIBK containing 0.03 M TTA and when the aqueous phase was 1.0 M sodium perchlorate (Fig. 1 in Ref. 2). In that study, however, the deviation was too small to allow a reasonable analysis of the coextraction of the perchlorate or mixed TTA-perchlorate complex into MIBK (it may be seen from Fig. 1 in the present paper that the K_{ex_2} from 1.0 M perchlorate media is 3×10^{-3}). As may also be seen from Fig. 1, the beryllium perchlorate extraction increases with an increase in the aqueous sodium perchlorate concentration and in the extraction of beryllium(II) in 4.0 M sodium perchlorate into MIBK in Fig. 2, even in the absence of TTA; this can be explained in terms of the beryllium perchlorate extraction. The change in the slope of the extraction curve, log D *vs.* $\log[HA]_{org}/[H^+]$, can also be understood in terms of perchlorate extraction, as can be seen from the calculated curve in Fig. 2 based on the constants already given.

As has been pointed out,[7] the extraction constant of the mixed complex can be calculated from the extraction constants of the two other species:

$$K_{ex_1}(stat.) = 2(K_{ex_2} \times K_{ex_0})^{1/2} = 10^{-1.18}$$

This statistical value is about three times the experimentally observed value ($10^{-1.64}$); thus, the mixed complex is somewhat less stable than the statistical

7) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 2013 (1964).

value. The slope of the extraction curve is almost +2 when $\log[HA]_{org}/[H^+]$ is kept above 1.1; that is, the distribution ratio generally given by Eq. (8) in that range can be described as $D_0=[BeA_2]_{org}/[Be^{2+}]$. As all the determination of the stability constants by the TTA extraction is carried out in this $[HA]_{org}/[H^+]$ range, the analysis of the data based on Eq. (22) should be reasonable.

The use of Eq. (22) for the analysis of the data in Fig. 3 seems also to be reasonable because it was observed that the distribution ratio is proportional to the square of $[HA]_{org}/[H^+]$, even in the systems where some of the perchlorate ions were replaced by chloride, bromide, or nitrate ions.

As may be seen from Fig. 5, the experimental data well fit the solid line calculated from the constants based on Eq. (27). This seems to show that the distribution behavior of beryllium is represented by Eq. (27). It is remarkable that the stability of the extractable complex, $Be(SCN)_2$, is relatively low, but its extraction is high in the higher ligand concentration region. For example, when the thiocyanate concentration is 1.0 M, 13 percent of the aqueous beryllium(II) is in the form of $Be(SCN)_2$, but still about 86 percent of the initial aqueous beryllium is extracted into the organic phase. This is due to the high distribution constant of this complex. The extraction should be much higher at the higher TBP concentration.

Although the stabilities of the beryllium complexes given in Table 2 are not large, these very weak complexes are still important in order to understand the chemical behavior of this metal ion under certain experimental conditions, as we have seen in the TBP extraction of its thiocyanate.

The stability constants of beryllium(II) chloride and nitrate complexes were determined in 0.5 M perchlorate media at 18°C by Kolosova and Belyavskaya[8]; they were reported to be $\log\beta_1=1.11$, $\log\beta_2=0.30$, and $\log\beta_3=1.40$ for chloride complexes, and $\log\beta_1=-0.60$ and $\log\beta_2=1.62$ for nitrate complexes. These previous stability constants are much higher than the present data shown in Table 2, even if the lower ionic concentration is taken into account. No report seems to have been published on the stability constants for the beryllium(II) complexes with bromide or thiocyanate ions. Biermann and McCorkell[9] have studied the extraction of beryllium thiocyanate into MIBK, 1-hexanol, 2-octanol, and isoamylacetate when the initial aqueous beryllium concentration is rather high (above 0.1 M in the initial aqueous phase). They reported a remarkable pH dependence of the extraction; the percent extraction increases from pH 0.5 to 2.0, it is almost constant between pH 2.0 and 3.0, and then it decreases above pH 3.0. They explained it in terms that an increase of pH in the lower pH region causes the back extraction of the undissociated thiocyanic acid into the aqueous phase and increases the thiocyanate ion concentration. At the same time, the decrease in the thiocyanic acid in the organic phase increases the activity of the solvent. They also explained the decrease in the extraction in the higher pH region in terms of the hydrolysis of beryllium, which forms $BeOH^+$. They also assumed that the only beryllium species in the aqueous phase besides the above $BeOH^+$ is the Be^{2+} (no complex formation in the aqueous phase) and concluded that the extraction is given by the equation $D_{Be}=0.3[SCN^-]^2$ where $D_{Be}=[Be(SCN)_2]_{org}/[Be^{2+}]$.

As can be seen from Fig. 6, in the present study we have not observed such a drastic decrease in D above pH 4.0 as they reported. Thus, from the results in Fig. 6 and from the hydrolysis constants in the literature,[1] we have concluded that the hydrolysis around pH 4.0 is very small. Moreover, we can not accept the assumptions that the formation of the thiocyanate complex in the aqueous phase is negligible and that the slope of the $\log D$ *vs.* $\log[SCN^-]$ plot is two, as can be seen from the results in Fig. 4. The complex formation of alkaline earth metal ions with these ligand anions has not been studied very much because of the instability of the complexes, but, as is seen in this study, beryllium(II) shows some tendency to form complexes; this is probably due to the small ionic size of the Be^{2+}.

A part of this work has been carried out in the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of the Laboratory. They are also grateful to Mr. Akira Kaneko for his experimental aid.

Measurement of Negative Ions Formed by Electron Impact. VIII. Ionization Efficiency Curves of Negative Ions from Methyl and Ethyl Cyanides

Satoru TSUDA, Akira YOKOHATA, and Toshikatsu UMABA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received November 9, 1970)

The ionization efficiency (I.E) curves of *m/e* 26(CN^-), 27(HCN^-), 38(C_2N^-) and 39($CHCN^-$) ions from methyl and ethyl cyanides, besides 40(CH_2CN^-) ions from methyl cyanide, and 50(C_3N^-) ions from ethyl cyanide were measured to the extent of about 25 eV electron energies under the pressure of $\sim 10^{-6}$ mmHg by a Hitachi RMU-6D mass spectrometer. Schemes of plausible reactions expected to appear at each onset value observed in the respective IE curves were sought thermochemically by using ΔH_f values of the reactants and products. The estimation method of unknown ΔH_f values is described also. It should be noted that for CN^- ions one process (probably, $R+CN^-$) was observed in lower energies than 2 eV; C_2N^- ions are expected to be formed with excess energy; also, for CN^- and HCN^- ions rather strange phenomena of the decrement of their signal intensities with increasing electron energies were observed in the range of higher energies. Moreover, the IE curves of C_3N^- ions in the higher energy region were well interpreted in terms of the overlapping phenomena of dissociative capture process with ion pair formation process. It was found from this work that EA(HCN) $\gtrsim$1 eV, $\Delta H_f(CHCN^-) \sim 3.2$ eV, EA(CHCN) $\gtrsim$1.1 eV and EA(CH_2CN) $\gtrsim$1.6 eV. For the electron affinity of C_2N a value $\gtrsim$2.3 eV is tentatively introduced on the basis of EA(C_3N)=2.4 eV, EA(C_5N)=2.3 eV, and EA(CN)=3.4 eV.

Recently, several studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1-6] However, they were restricted to a limited number of compounds. Data on the ionization efficiency (IE) curves of negative ions are limited[7-12] and hardly any detailed discussions are given.

The authors reported the measurement results of the IE curves of NO_2^-, O^-, $CH_2NO_2^-$, CN^-, and CNO^- ions from nitroalkanes,[13] of O^- and OH^- ions from *n*-propyl and isopropyl alcohols,[14] O^-, C_2H^-, and C_2HO^- ions from tetrahydrofuran,[15] and Cl^- ions from alkyl chlorides,[16] and discussed plausible reaction schemes expected to appear at respective onset values from a thermochemical viewpoint. The work was extended to methyl and ethyl cyanides.[17] Emphasis was placed on the measurements of the IE curves of CN^-, HCN^-, C_2N^-, and $CHCN^-$ ions from both compounds, and CH_2CN^- ions from methyl cyanide and C_3N^- ions from ethyl cyanide.

Experimental

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with the T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier and a Faraday collector. All measurements were made with a total emission current of 20 μA, an accelerating voltage of 3.6 kV and an electron multiplier voltage of 2.8 kV, under a pressure of $\sim 10^{-6}$ mmHg in the source. The ionizing current then varied from 10.5 μA at above 10 eV to 6.4 μA at $\sim$3 eV.[16] The energy scale was calibrated in every measurement by the vanishing current method as compared with the appearance potential of *m/e* 16(O^-) ions from carbon monoxide, carbon dioxide and oxygen, as described previously.[16] The repeller voltage was adjusted to the best condition for collecting the ions. The chemicals used were of research grade.

Results and Discussion

IE curves. *CN^- Ions*: Figure 1 shows the IE curves of *m/e* 26 (CN^-) ions[18] obtained from methyl and ethyl cyanides. It can be seen that in every case at least two processes contribute to their formation. The first process appears at the energies lower than 2 eV and the second processes[19] do at $\sim$5.3 eV and

17) A report was recently made on the measurement of methyl cyanide in which the isotope effect and mechanism of formation of CH_3CN^- ions were mainly discussed. Hardly any detailed discussions were given on fragment negative ions. (T. Sugiura and K. Arakawa. The 22nd Annual Meeting of Chemical Society of Japan, Tokyo (1969)).
18) The possibility of $C_2H_2^-$ for *m/e* 26 ions can be excluded because of few signals of $C_2H_2^-$ ions from hydrocarbons.[1]
19) Since the tailing from the 1st process may overlap with the appearance of the 2nd process, it is generally difficult to determine exactly the appearance potential of the latter. In this case, however, it was not so difficult.

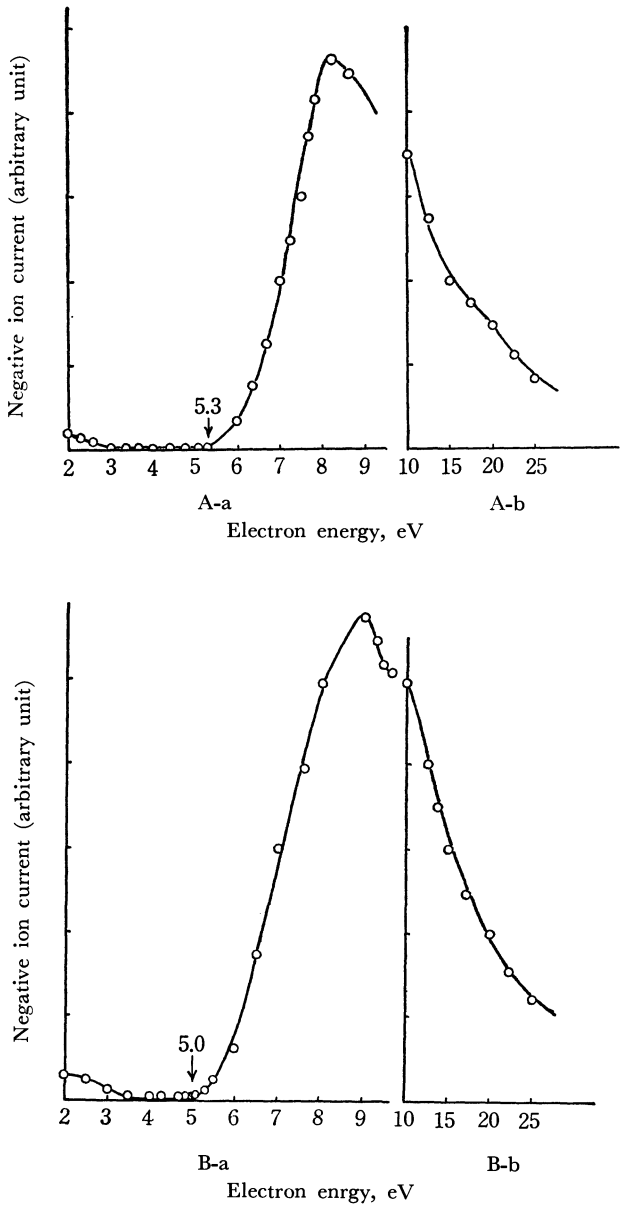

Fig. 1. Ionization efficiency curves of *m/e* 26(CN^-) ions from CH_3CN and C_2H_5CN.
A: CH_3CN B: C_2H_5CN

~5.0 eV, respectively, being of almost the same shape as the IE curves. They suggest dissociative electron capture processes except for the part in a higher energy region in which there is the possibility of an ion pair formation process.

The appearance potential (AP) of reaction (1) can be expressed by Eq. (2), if the kinetic energies of fragments are ignored and the ions formed are in ground state.

$$XYZ + e^- \rightarrow X^- + YZ \quad (1)$$

$$AP_{calc} = \Delta H = \Delta H_f(X^-) + \Delta H_f(YZ) - \Delta H_f(XYZ) \quad (2)$$ [20]

In the case of ion pair formation ($YZ \rightarrow YZ^+$), the following equation holds.

$$AP_{calc} = \Delta H = \Delta H_f(X^-) + \Delta H_f(YZ^+) - \Delta H_f(XYZ) \quad (3)$$

The schemes of plausible reactions expected to appear at each onset value (AP_{obs}) observed in the IE curves were sought thermochemically from Eqs. (2) and (3). For the first process, the following reactions might be assigned.

$$CH_3CN + e^- \rightarrow CN^- + CH_3 \quad (AP_{calc} = 1.08\ eV) \quad (4)$$

$$C_2H_5CN + e^- \rightarrow CN^- + C_2H_5 \quad (AP_{calc} = 1.08\ eV) \quad (5)$$

In the estimation of AP_{calc}, the values of $\Delta H_f(CH_3\text{-}CN) = 0.78$ eV,[21] $\Delta H_f(C_2H_5CN) = 0.49$ eV, $\Delta H_f(CH_3) = 1.39$ eV, $\Delta H_f(C_2H_5) = 1.10$ eV and $\Delta H_f(CN^-) = 0.47$ eV[22] were used.

The correspondence of AP_{calc} values to AP_{obs} values (below 2 eV) suggests the possibility of reactions (4) and (5). However, the cross section of these reactions seems to be very small. McDowell and Warren[23] failed to detect CN^- signals in this region, but this would probably be due to the fact that their detection method was not so improved as in the present time.

For the second process, although complicated, the following reactions might be considered.

$$CH_3CN + e^- \rightarrow CN^- + CH_2 + H \quad (AP_{calc} \simeq 4.45\ eV) \quad (6)$$

$$CH_3CN + e^- \rightarrow CN^- + CH + H_2 \quad (AP_{calc} \simeq 5.85\ eV) \quad (7)$$

$$C_2H_5CN + e^- \rightarrow CN^- + C_2H_3 + H_2 \quad (AP_{calc} \simeq 2.6\ eV) \quad (8)$$

$$C_2H_5CN + e^- \rightarrow CN^- + C_2H_4 + H \quad (AP_{calc} \simeq 2.78\ eV) \quad (9)$$

$$C_2H_5CN + e^- \rightarrow CN^- + C_2H_2 + H + H_2 \quad (AP_{calc} \simeq 4.59\ eV) \quad (10)$$

Estimation of each AP_{calc} value was made by use of values of $\Delta H_f(CH_2) = 2.5$ eV, $\Delta H_f(H) = 2.26$ eV, $\Delta H_f(CH) = 6.16$ eV, $\Delta H_f(C_2H_3) = 2.83$ eV, $\Delta H_f(C_2H_4) = 0.54$ eV and $\Delta H_f(C_2H_2) = 2.35$ eV.[24] Although the consistency of AP_{calc} values with AP_{obs} values is not so good, reactions (6) and (10) would probably correspond to each onset value. In these cases, the difference of 0.8—0.4 eV between AP_{calc}

20) $\Delta H_f(X)$: heat of formation of X.

21) By combining $D(CH_3\text{-}CN) = 4.48$ eV with $\Delta H_f(CH_3) = 1.39$ eV and $\Delta H_f(CN) = 3.87$ eV, a value of 0.78 eV for $\Delta H_f(CH_3\text{-}CN)$ can be estimated. Also, by assuming $D(CH_3\text{-}CN) = D(C_2H_5\text{-}CN)$, and using $\Delta H_f(C_2H_5) = 1.10$ eV, a value of $\Delta H_f(C_2H_5CN) = 0.49$ eV is obtained. (T. L. Cottrell, "The Strengths of Chemical Bonds," London, Butterworths (1958), p. 197. R. R. Bernecker and F. A. Long, *J. Phys. Chem.*, **65**, 1565 (1961). C. A. McDowell and J. W. Warren, *Trans. Faraday Soc.*, **48**, 1084 (1952).

22) To be estimated from $EA(CN) = 3.4$ eV and $\Delta H_f(CN) = 3.87$ eV (refer to (13)). EA(CN): electron affinity of CN.

23) C. A. McDowell and J. W. Warren, *Trans. Faraday Soc.*, **48**, 1084 (1952).

24) refer to Bernecker's paper in Ref. 21. The use of another value (4.23 eV) of $\Delta H_f(CH)$, as described in Ref. 25, gives $AP_{calc} = 3.92$ eV for the occurrence of reaction (7). However, the possibility of reaction (7) accompanied with the formation of H_2 due to the rearrangement would be probably smaller than that of reaction (6).

values (4.45 eV and 4.59 eV) and AP_{obs} values (5.3 eV and ~5.0 eV) might be assessed to the excess kinetic energy of fragments. Although McDowell and Warren[23] reported the value of ~5.6 eV for the appearance of CN^- ions from methyl cyanide, it might be interpreted to correspond to the second process in this work. However, they failed to detect the CN^- signals in the range below ~5.6 eV and no discussions were made in detail for CN^- ions from methyl cyanide. If a value of ~5.6 eV corresponds to the reaction of (CH_3+ CN^-), the excess kinetic energy of fragments seems to be too high. It would be reasonable to expect the occurrence of reaction (6). It is possible at least energetically.

Reasons for the existence of a long tail extending to the range from ~10 eV to the higher energies are not well known. Even if the overlapping of ion pair formation (reaction (11) or (12)) with reactions (6) or (10) is taken into consideration, the decrement of signal intensity with an increasing electron energy is a little strange. The possibility of the ion pair formation could be excluded.

$$CH_3CN + e^- \rightarrow CN^- + CH_3^+ + e^- \quad (AP_{calc} = 10.92\ eV) \quad (11)$$

$$C_2H_5CN + e^- \rightarrow CN^- + C_2H_5^+ + e^- \quad (AP_{calc} = 9.78\ eV) \quad (12)$$

HCN^- Ions: Figure 2 shows the IE curves of *m/e* 27 ions from methyl and ethyl cyanides. The possibility of $C_2H_3^-$ ions might be excluded from the fact that there is no occurrence of $C_2H_3^-$ ions from ethyl alcohol, propyl alcohol,[1] and tetrahydrofuran.[15] The two cyanides gave curves similar to each other. We see that the first process appears at ~2 eV for methyl cyanide and below 2 eV for ethyl cyanide, and the second process at ~6.0 eV and ~5.0 eV, respectively.

The appearance potential of reactions (13) and (14) can be estimated to be AP_{calc}=3.02 eV and AP_{calc}= 1.45 eV by using $\Delta H_f(HCN)$=1.30 eV[23]

$$CH_3CN \rightarrow HCN + CH_2 \quad (AP_{calc} = \Delta H_{calc} = 3.02\ eV) \quad (13)$$

$$C_2H_5CN \rightarrow HCN + C_2H_4 \quad (AP_{calc} = \Delta H_{calc} = 1.45\ eV) \quad (14)$$

Combining of AP_{calc}=3.02 eV with AP_{obs} ≃2 eV leads to EA(HCN) ≃1 eV.[25] Then, the appearance potential of the reaction containing HCN^- ion in (14) can be estimated to be ≲0.45 eV.

For the second process, reactions (15) and (16) might be expected, where a value of ΔH(CH)=4.23 eV[26] and a value of $\Delta H_f(HCN^-)$=0.3 eV are used.

$$CH_3CN + e^- \rightarrow HCN^- + CH + H \quad (AP_{calc} \simeq 6.01\ eV) \quad (15)$$

$$C_2H_5CN + e^- \rightarrow HCN^- + C_2H_3 + H \quad (AP_{calc} \simeq 4.90\ eV) \quad (16)$$

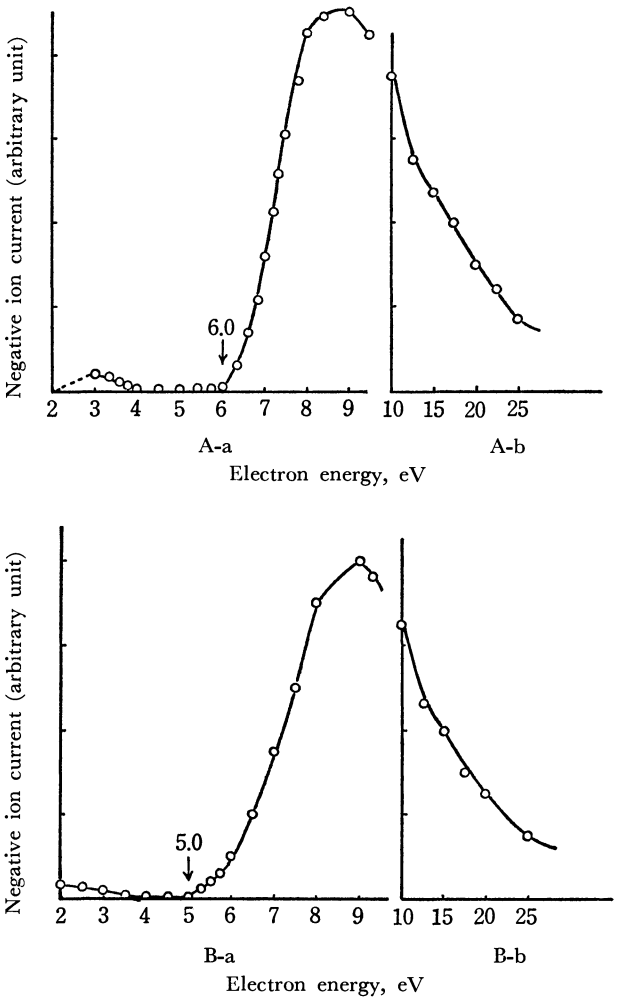

Fig. 2. Ionization efficiency curves of *m/e* 27(HCN^-) ions from CH_3CN and C_2H_5CN.
A: CH_3CN B: C_2H_5CN

The AP_{calc} values are in good agreement with the AP_{obs} values (~6.0 eV and ~5.0 eV).

Let us discuss the possibility of $C_2H_3^-$ ions. On the basis of ΔH_f(N)=4.9 eV,[27] the AP_{calc} value of reaction (17) can be estimated as follows.

$$CH_3CN \rightarrow C_2H_3 + N \quad (AP_{calc} = \Delta H_{calc} = 6.95\ eV) \quad (17)$$

Thus, if an electron affinity of C_2H_3 is assumed to be ~0.95 eV, the value of AP_{obs} ≃6.0 eV can be reasonably interpreted. If so, AP_{calc} of reaction (18) is given as ~5.2 eV which is almost consistent with AP_{obs} ≃5.0 eV.

$$C_2H_5CN + e^- \rightarrow C_2H_3^- + H_2 + CN \quad (AP_{calc} \simeq 5.2\ eV) \quad (18)$$

However, no formation of $C_2H_3^-$ ions from ethyl alcohol, propyl alcohol, and tetrahydrofuran would exclude the possibility of this ion. Moreover, the difficulty of interpretation of the first process by $C_2H_3^-$ ions affords additional evidence for their exclusion.

C_2N^- Ions: Figure 3 shows that we have

25) Since the ions might be formed with an excess kinetic energy, this shows the lowest value.

26) To be estimated from D(CH–H)=3.99 eV, ΔH_f(H)=2.26 eV and $\Delta H_f(CH_2)$=2.5 eV (refer to Cottrell's article Ref. 21, p. 174).

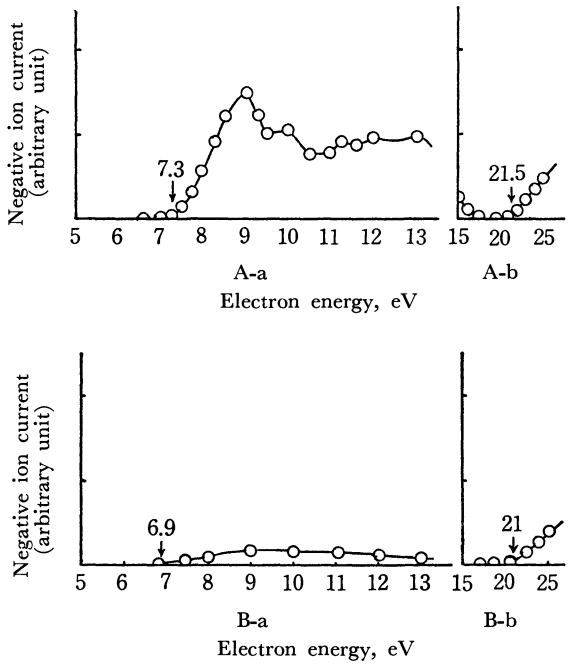

Fig. 3. Ionization efficiency curves of m/e 38(C_2N^-) ions from CH_3CN and C_2H_5CN.
A: CH_3CN B: C_2H_5CN

$AP_{obs} \simeq 7.3$ eV for the first process and $AP_{obs} \simeq 21.5$ eV for the second process in methyl cyanide, and $AP_{obs} \simeq 6.9$ eV and $AP_{obs} \simeq 21$ eV for the respective processes in ethyl cyanide. The IE curves from methyl cyanide show a relatively complicated shape for the first process, and a simple shape for that in ethyl cyanide. For the first process, we have

$$CH_3CN + e^- \rightarrow C_2N^- + H_2 + H \quad (AP_{calc} \leq 4.48\ eV) \quad (19)$$

$$CH_3CN + e^- \rightarrow C_2N^- + 3H \quad (AP_{calc} \leq 9.00\ eV) \quad (20)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + CH_3 + H_2 \quad (AP_{calc} \leq 3.90\ eV) \quad (21)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + CH_4 + H \quad (AP_{calc} \leq 3.99\ eV) \quad (22)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + CH_2 + H_2 + H \quad (AP_{calc} \leq 7.25\ eV) \quad (23)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + CH_3 + 2H \quad (AP_{calc} \leq 8.42\ eV) \quad (24)$$

In the estimation of AP_{calc}, a value of $\Delta H_f(C_2N^-) \leq 3$ eV was used which can be computed from $\Delta H_f(C_2N) = 5.3$ eV[28] and $EA(C_2N) \geq 2.3$ eV assumed tentatively. Evidently, we have no value of EA(C_2N) while EA(C_3N) and EA(C_5N) are known to be 2.4 eV and 2.3 eV,[28] being EA(CN) = 3.4 eV. Here, a value of ≥ 2.3 eV was assigned tentatively for EA(C_2N).

If reaction (19) is assumed to correspond to the first process, the difference (≥ 2.8 eV) between AP_{obs} ($\simeq 7.3$ eV) and AP_{calc} ≤ 4.48 eV might be ascribed to the excess kinetic energy of fragments. In the same way, the assignment of reaction (21) or (22) for the first process in ethyl cyanide may give a value ≥ 3 eV as the excess kinetic energy of fragments. In the present stage, however, this is still open to question.

For the second process, we have

$$CH_3CN + e^- \rightarrow C_2N^- + H^+ + H_2 + e^- \quad (AP_{calc} \leq 18.08\ eV) \quad (25)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + CH_3^+ + H_2 + e^- \quad (AP_{calc} \leq 13.70\ eV) \quad (26)$$

$$C_2H_5CN + e^- \rightarrow C_2N^- + H^+ + CH_4 + e^- \quad (AP_{calc} \leq 17.59\ eV) \quad (27)$$

The assignment of reactions (25) and (27) seems also to require a kinetic energy ≥ 3.5 eV for the fragments.

$CHCN^-$ Ions: The IE curves (Fig. 4) show that three processes in methyl cyanide and two processes in ethyl cyanide contribute to the formation of m/e 39 ($CHCN^-$) ions, where in the former the first process appears at $\sim$2.3 eV, the second process at $\sim$7.0 eV and the third process at $\sim$20 eV; in the latter the respective processes appear at $\sim$6.5 eV and $\sim$16.5 eV.

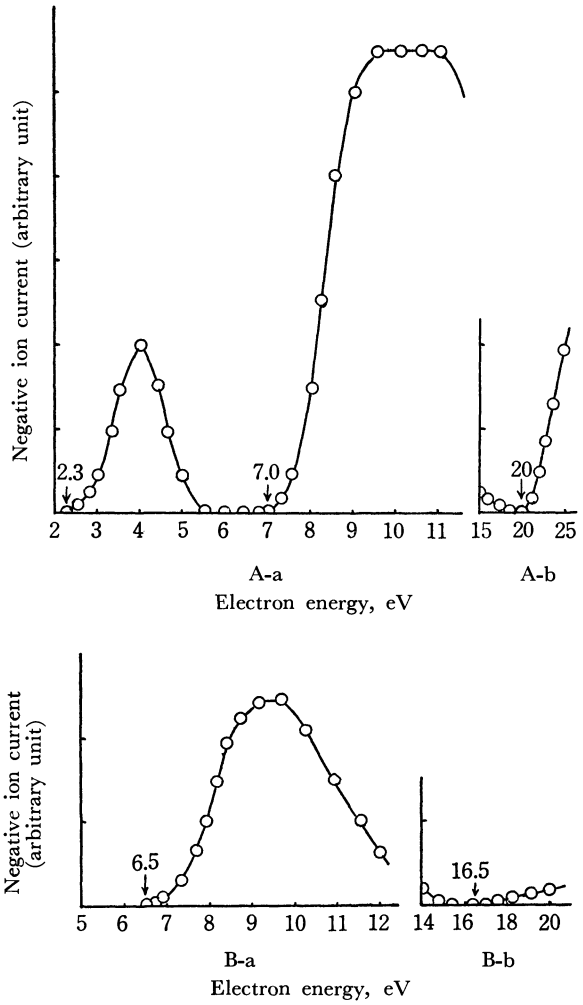

Fig. 4. Ionization efficiency curves of m/e 39 ($CHCN^-$) ions from CH_3CN and C_2H_5CN.

28) V. H. Dibeler, R. M. Reese, and J. L. Franklin, *J. Amer. Chem. Soc.*, **83**, 1813 (1961).

Since the ΔH_f(CHCN) and EA(CHCN) values are not known, it is impossible to estimate AP_{calc} values of the reactions assigned for each process. By setting $\Delta H_f(CHCN^-) = \Delta H_f(CHCN) - EA(CHCN) = X$ (eV), let us estimate the AP_{calc} values of the reactions to be assigned for each onset value in the IE curves.

For the first process in methyl cyanide,

$$CH_3CN + e^- \rightarrow CHCN^- + H_2$$
$$(AP_{calc} = X - 0.78 \text{ (eV)}) \quad (28)$$

For the second process in methyl cyanide and the first process in ethyl cyanide,

$$CH_3CN + e^- \rightarrow CHCN^- + 2H$$
$$(AP_{calc} = X + 3.74 \text{ (eV)}) \quad (29)$$
$$C_2H_5CN + e^- \rightarrow CHCN^- + CH_3 + H$$
$$(AP_{calc} = X + 3.16 \text{ (eV)}) \quad (30)$$

Combining these values with AP_{obs} values (2.3 eV, 7.0 eV, and 6.5 eV) we obtain the results 3.08 eV, 3.26 eV, and 3.34 eV for X; $\bar{X}$=3.23 eV. Then the AP_{calc} values of reactions expected for the last process can be estimated as follows.

For the third process in methyl cyanide and the second process in ethyl cyanide.

$$CH_3CN + e^- \rightarrow CHCN^- + H^+ + e^-$$
$$(AP_{calc} = 20.56 \text{ eV}) \quad (31)$$
$$C_2H_5CN + e^- \rightarrow CHCN^- + CH_3^+ + H + e^-$$
$$(AP_{calc} = 16.23 \text{ eV}) \quad (32)$$

The consistency of the AP_{calc} values with the AP_{obs} values ($\sim$20 eV and $\sim$16.5 eV) is relatively good. In other words, the assignment of each reaction and a value of $\Delta H_f(CHCN^-) \simeq 3.2$ eV might be reasonable.

Next, let us estimate a value of ΔH_f(CHCN). The appearance potential of reaction (33) gives the value of $\Delta H_f(CHCN^+) \simeq 15.9$ eV.[29] An estimation of ΔH_f(CHCN) is needed for the value of IP(CHCN)[30] but it is not known.

$$CH_3CN \rightarrow CHCN^+ + H_2 + e^- \quad (AP = 15.1 \text{ eV}) \quad (33)$$

According to Mulliken's assignment, the values of $IP(C_2H_6)$ (=11.65 eV[31]) and the onset ($\sim$11.7 eV)[32] in the IE curves of $C_2H_5OH^+$ ions from ethyl alcohol are considered to correspond to the removal of an electron from the C–C orbital. On the other hand, the removal of an electron from the C–H π orbital requires a value of about 13 eV.[33] Thus, let us assign tentatively IP(CHCN)$\simeq$11.7 eV, the energy required for the removal of an electron from the C–C orbital. We can then get a value of 4.2 eV for ΔH_f(CHCN). If so, a value of $\Delta H_f(CH_2CN) = 1.96$ eV[34] would lead to D(H–CHCN)$\simeq$4.5 eV. Judging from the usual C–H bond energy, this value seems to be reasonable.

Thus, EA(CHCN) could be estimated by combining the values of ΔH_f(CHCN) and $\Delta H_f(CHCN^-)$. Since the fragment ions may be formed with an excess kinetic energy, the following procedure is preferable. Let us assume EA(CHCN)=Y (eV) and excess kinetic energy=Z (eV). Then, the AP_{calc} of reaction (34) is estimated as follows.

$$CH_3CN + e^- \rightarrow CHCN^- + H_2$$
$$(AP_{calc} = 3.4 - Y + Z) \quad (34)$$

By combining this value with $AP_{obs} \simeq 2.3$ eV, we can get a value of EA(CHCN)$\gtrsim$1.1 eV.

CH_2CN^- Ions: The IE curves (Fig. 5) represent the typical dissociative electron capture process. We have $AP_{obs} \simeq 1.8$ eV.

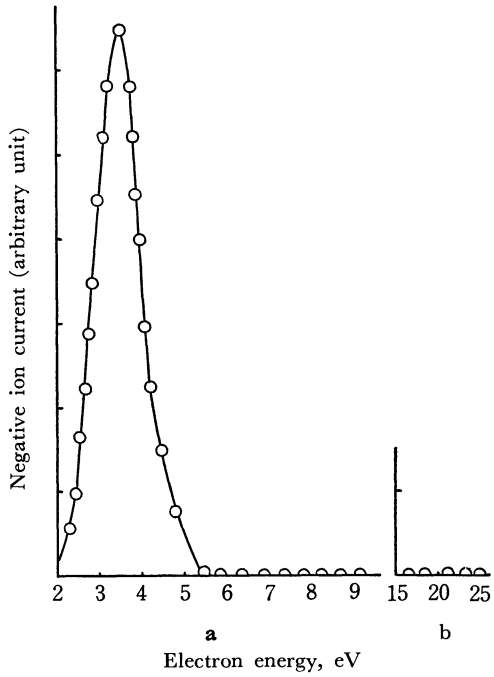

Fig. 5. Ionization efficiency curves of *m/e* 40 $(CH_2CN)^-$ ion from CH_3CN.

The appearance potential of reaction (35)[34] has been reported to be 3.44 eV which gives a value of $\Delta H_f(CH_2CN) = 1.96$ eV.

$$CH_3CN \rightarrow CH_2CN + H$$
$$(AP_{calc} = \Delta H_{calc} = 3.44 \text{ eV}) \quad (35)$$

The value EA(CH_2CN)$\geq$1.64 eV is obtained by combining AP_{calc} (=3.44 eV) with AP_{obs} (1.8 eV).

For the ion pair formation the following reaction is expected.

$$CH_3CN + e^- \rightarrow CH_2CN^- + H^+ + e^-$$
$$(AP_{calc} = 15.4 \text{ eV}) \quad (36)$$

However, few signals in the range of energies from $\sim$5.4 eV to 25 eV appear to exclude the possibility of ion pair formation.

C_3N^- Ions: Figure 6 shows that the first process appears at $\sim$9.4 eV and the second process at $\sim$13.9 eV, although their cross sections are small.

On the basis of $\Delta H_f(C_3N) = 131$ kcal/mol[28] and EA(C_3N)=55 kcal/mol,[28] the AP_{calc} values of reac-

34) R. F. Pottie and F. P. Lossing, *J. Amer. Chem. Soc.*, **83**, 4737 (1961).

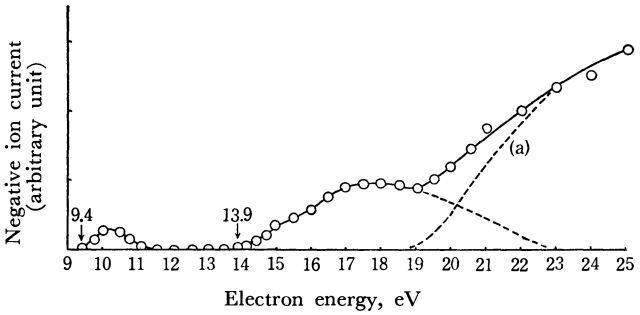

Fig. 6. Ionization efficiency curves of m/e 50(C_3N^-) ions from C_2H_5CN.

tions (37), (38), (39), and (40) can be estimated as follows:

$$C_2H_5CN + e^- \rightarrow C_3N^- + 2H_2 + H \quad (AP_{calc} = 5.09\,eV) \quad (37)$$

$$C_2H_5CN + e^- \rightarrow C_3N^- + H_2 + 3H \quad (AP_{calc} = 9.59\,eV) \quad (38)$$

$$C_2H_5CN + e^- \rightarrow C_3N^- + 5H \quad (AP_{calc} = 14.09\,eV) \quad (39)$$

$$C_2H_5CN + e^- \rightarrow C_3N^- + 2H_2 + H^+ + e^- \quad (AP_{calc} = 18.69\,eV) \quad (40)$$

Relatively good consistencies of AP_{calc} values (9.59 and 14.09 eV) with AP_{obs} values ($\sim$9.4 and $\sim$13.9 eV) suggest the possibility of reactions (38) and (39). Reaction (37) could be excluded.

The shape of the IE curve in the energy region higher than $\sim$18.7 eV can be well interpreted in terms of the overlapping due to the ion pair formation (reaction (40)) appearing at 18.69 eV. The IE curves expected from the ion pair formation process are expressed by a dotted curve, (a) in Fig. 6, which is consistent with the usual picture presumed for the ion pair formation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1491—1496 (1971)

The Hybridization Effect on the Equilibrium Distance. III[1]

Tomoo MIYAZAKI, Tsunehisa SHIGETANI, and Hiroyuki SHINODA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo

(Received November 30, 1970)

In order to re-examine the unexpected conclusion previously reported that the hybridization effect is unimportant in determining the C–C single bond length, a more reliable calculation involving the configuration interaction treatment and more elabolate calculations by the NDDO and unrestricted INDO methods have been performed. The results of the INDO-CI and unrestricted INDO calculations were in good agreement with those which were obtained by the previous calculations. According to the NDDO calculations, however, the equilibrium distances of different kinds of C–C single bonds were found to increase with the decreased *s* character in hybrids, although this effect was not very significant. The effect of interaction between non-adjacent atomic orbitals in determining the bond length has been discussed in full detail.

The object of the present paper is to explore the relative importance of the pi electron resonance and hybridization in the shortening of the single-bond length of conjugated hydrocarbons. During the past several years, many discussions have been presented concerning this problem.[4–6] Mulliken commented on this situation that it was rather necessary, and proper, to place considerable reliance on a theory, provided it was a reliable theory, since it was difficult to decide experimentally between hybridization and electron delocalization as causes of bond shortening.[7] In those days, however, there was no appropriate and direct method for calculating the equilibrium distance. At the present time, though, the interatomic distance can be calculated by such semi-empirical, self-consistent molecular orbital methods as the CNDO/2,[8–10] INDO,[11] NDDO[8] and MINDO[12] methods, in all of which all the valence electrons are taken into account. They have been developed mainly with the object of calculating the ground-state properties of molecules.

In a previous paper,[2] the CNDO/2 method was used to calculate the C–C and C–H equilibrium distances of the saturated and unsaturated simple hydrocarbons and those molecules which have broken pi bonds. The equilibrium distances of different types of C–C single and double bonds which are usually considered tri-tri, di-di single and di-di double bonds

were not much different from the te-te single and tri-tri double bond distances respectively. Moreover, it was found that the equilibrium distances are dependent upon the interaction between non-adjacent atomic orbitals.

In a previous communication,[3] the INDO method was used to determine the effect of the introduction of the one-center exchange integrals into the calculation of the C–C equilibrium distance. Both the INDO and CNDO/2 methods seemed to indicate that the hybridization effect is unimportant in the shortening of the C–C single bond length.

In view of the above results, a more reliable calculation involving configuration interaction (CI) treatment and more elabolate calculations by the NDDO and unrestricted INDO methods will be used in this paper to determine the normal and hypothetical C–C equilibrium distances. The effect of interaction between non-adjacent atomic orbitals in determining the bond length has been discussed in full detail. This is because these electronic interactions are appreciably effective in determining the C–C equilibrium distance.

Methods of Calculation

Calculation of the sp^2–sp^2 Single Bond Length. The calculation is illustrated schematically in the energy curve of Fig. 1. The equilibrium distance of the sp^2–sp^2 C–C single bond was estimated by minimizing an energy (E^+) with respect to the interatomic distance

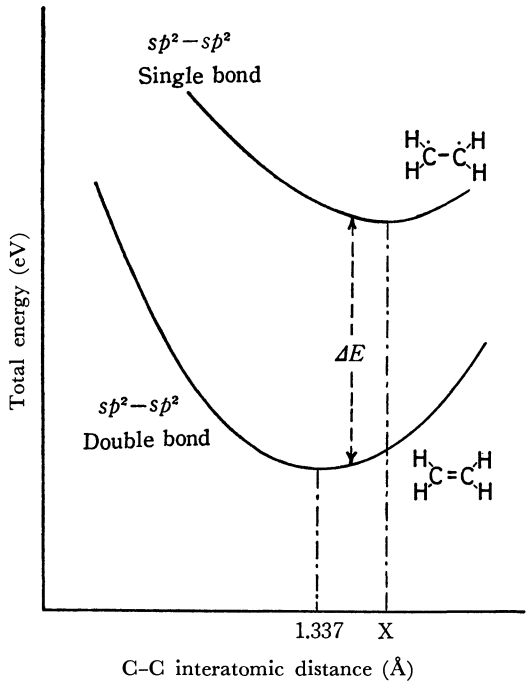

Fig. 1. Total energy as a function of C–C bond length. X is the equilibrium distance of sp^2–sp^2 single bond.

considered. The energy (E^+) was defined by the following equation:

$$E^+ = E_{\text{total}} - \Delta E \tag{1}$$

$$E_{\text{total}} = E_{\text{elec}} + E_{\text{repul}} \tag{2}$$

$$\Delta E = \frac{1}{4}\sum_{\mu}^{\pi}(P^{\pi}{}_{\mu\mu})^2\gamma_{\mu\mu} + \frac{1}{2}\sum_{\substack{\mu,\nu \\ (\mu\neq\nu)}} {}^{\pi}P^{\pi}{}_{\mu\nu}(H_{\mu\nu}{}^{\pi}+F^{\pi}{}_{\mu\nu})$$

$$= \frac{1}{4}\sum_{\mu}^{\pi}(P^{\pi}{}_{\mu\mu})^2\gamma_{\mu\mu} + 2P^{\pi}{}_{\mu\nu}\beta^{\pi}{}_{\mu\nu} - \frac{1}{2}(P^{\pi}{}_{\mu\nu})^2\gamma_{\mu\nu} \tag{3}$$

where E_{elec} is the total electronic energy of ethylene as determined by the molecular orbital calculation, where E_{repul} is the sum of the repulsion energy between cores, which is approximated by a point charge model, where $\sum^{\pi}$ describes the summation over the pi system, where $P^{\pi}{}_{\mu\mu}$ is the pi orbital charge density, where $P^{\pi}{}_{\mu\nu}$ is the pi bond order, where $\gamma_{\mu\mu}$ and $\gamma_{\mu\nu}$ are one-center and two-center electron-electron repulsion integrals respectively, and where $\beta_{\mu\nu}$ is the resonance integral between the atomic orbitals, χ_{μ} and χ_{ν}. The equilibrium distance was calculated by the variation of the interatomic distance, while the other bonds in the molecule were held fixed at their observed equilibrium distances.

The equilibrium distances of the *sp*–*sp* single and double bonds can be estimated in the same manner as has been described above.

The INDO and Other Methods. The intermediate neglect of the differential overlap (INDO) method employed in the present calculation is based upon an SCF treatment of all the valence electrons and is regarded as an improvement over the CNDO/2 method used to determine the equilibrium distance of the C–C bond in the previous investigation. In the INDO method, all two-electron integrals involving differential overlap are neglected except for one-center integrals of $(\mu\nu|\mu\nu)$ type; the other one-center integrals involving orbital overlap vanish through symmetry. The one-center repulsion integrals are written in terms of the Slater-Condon parameters, which are known from analyses of the multiplet energy splitting for the free atoms. The values of these terms used in the INDO method has been listed by Pople *et al.*[11] The monatomic core integrals differ somewhat from those of the CNDO/2 method because of the introduction of these parameters.

The molecular orbitals and their energies can be obtained by solving the set of secular equations and the corresponding secular matrix consisting of the Fock elements. The expressions for the Fock matrix elements and the details of the method can be found in Pople's original paper.[8–11]

The NDDO method disregards differential overlap only for atomic orbitals on different atoms. At this level of approximation, $(\mu_A\nu_A|\lambda_B\sigma_B)$ type integrals are taken into account. All the electronic repulsions are theoretically evaluated according to the formulas listed by Roothaan,[13] and the approximation where all the electron repulsion integrals are calculated as Coulomb integrals involving a valence *s* function is avoided.

A more reliable method of calculation for determining the equilibrium distance uses a configuration interaction (CI) treatment. The hypothetical bond length of a molecule, including the broken pi bonds,

13) C. C. J. Roothaan, *J. Chem. Phys.*, **19**, 1445 (1951).

can be calculated by the corrected total energy considering the interaction of the ground state with doubly-excited configurations (^1A_g) for the sigma system. All the doubly-excited configurations were taken into account for ethylene and acetylene, but the CI calculation was restricted to the 30 doubly-excited states for ethane.

The configurations of the molecules including the broken pi bonds are all open-shell. In applying the unrestricted INDO method to the calculation of these molecules, calculations for different types of spin multiplicity are possible. However, the spin multiplicity of the hypothetical molecule discussed in this work may be considered to be a singlet state.

In order to investigate the effect of electronic interaction between non-adjacent atomic orbitals in determining the bond length, the equilibrium distance has been determined from the total energy, neglecting some interactions between atomic orbitals. The invariance property of the INDO method under a simple transformation, such as the replacement of the s and p orbitals by hybrids, is effective for this investigation.

Through the similarity transformation by some appropriate matrix, the energy ($H'_{\mu\nu}$ and $F'_{\mu\nu}$) and population ($P'_{\mu\nu}$) matrices, with reference to the carbon hybrids, can be obtained from the results of the INDO calculation. The interactions (E^*) between non-adjacent hybrids are given by:

$$E^*_{\mu\nu} = P'_{\mu\nu}(H'_{\mu\nu}+F'_{\mu\nu}) . \quad (4)$$

Results and Discussion

The C–H equilibrium distances of ethane, ethylene, and acetylene calculated by both the CNDO/2 and INDO methods are shown in Table 1. In Table 2, the C–C equilibrium distances of C_2-hydrocarbons calculated by a variety of methods are collected. The distances obtained by the INDO-CI treatment of the present work are in complete agreement with those obtained by the CNDO/2 and INDO methods of the previous paper. Generally, the equilibrium distances calculated by the INDO and INDO-CI methods are slightly longer than those obtained by the CNDO/2 calculation. The C–C equilibrium distances calculated by the NDDO method were shorter than those obtained by the INDO and CNDO/2 calculations. The calculated interatomic distances of the tri-tri, di-di single, and di-di double bonds by the INDO-CI treatment are substantially in agreement with the results of the CNDO/2 calculation, the simplest form of calculation. The results of the unrestricted INDO calculations for the equilibrium distances in different types of spin states are listed in Table 3. They did not differ from one another in the calculated equilibrium distance.

However, a tendency for the bond length to decrease with an increased s character of the hybrid was found in the results of the NDDO calculations for the hypothetical tri-tri and di-di single and di-di double bond lengths. This is a noteworthy fact, but the difference between the te-te and tri-tri single bonds is negligible. The result obtained by the NDDO method must be due to the fact that all the electronic repulsions are theoretically calculated; that is, the usual approximation, in which they are assumed to depend only on the atoms and not on the actual type of orbital, is unnecessary in this calculation.

From the results of the NDDO calculation, it follows that the C–C single bond length is certainly affected by the types of the hybridization of the carbon atom, but this hybridization effect is not so large as has previously been believed.

The problem in this paper should be re-examined by the modified CNDO/2[14] and MINDO[15] methods, in which the off-diagonal bonding parameters are given by the different types of approximation. This is true because the off-diagonal bonding parameter

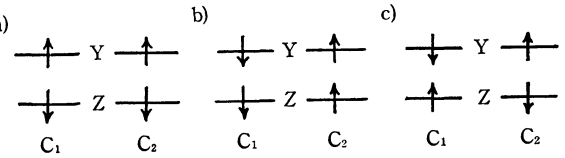
di-di single	1.479[a]		1.483
di-di single	1.485[b]		
di-di single	1.482[c]		

Electron spins are assigned as illustrated below.



(β_A^0) is given the same value for resonance integrals between sigma orbitals and those between pi orbitals in the CNDO/2 and INDO methods. In the modified CNDO/2 method proposed by Bene and Jaffé, the $\beta_{\mu\nu}^{\sigma}$, where μ and ν are sigma orbitals, is distinguished from the $\beta_{\mu\nu}^{\pi}$, where μ and ν are pi orbitals, by introducing a empirical parameter, k, as follows:

$$\beta_{\mu\nu}^{\sigma} = \frac{1}{2} S_{\mu\nu}(\beta_A^0 + \beta_B^0) \tag{5}$$

$$\beta_{\mu\nu}^{\pi} = \frac{1}{2} k S_{\mu\nu}(\beta_A^0 + \beta_B^0) \tag{6}$$

Also, in the MINDO method proposed by Dewar *et al.*, the resonance integrals are approximated by the following equation:

$$\beta_{\mu\nu} = \frac{1}{2} k' S_{\mu\nu}(I_\mu + I_\nu) \tag{7}$$

where k' is a constant and where I_μ and I_ν are valence-state ionization potentials for the atomic orbitals, χ_μ and χ_ν respectively. However, the energies and orbitals obtained using the approximation (Eq. (7)) will not be invariant to hybridization of the atomic-orbital basis set.

The results of the NDDO calculation indicate the hybridization effect on the equilibrium distance should be discussed by the use of the calculations presented above.

The effect of the interaction between non-adjacent atomic orbitals for determining the interatomic distance can be made clear by the use of Tables 4—6. The magnitude of the absolute value of Δr in Tables 4—6 proves the extent of the effect of non-adjacent atomic orbital interaction (E^*) in determining the equilibrium distance. It should be emphasized that the most effective factor in determining the interatomic distance is the gradient of the variation of the interaction energy (E^*) with the change in the interatomic distance rather than the magnitude of its absolute value.

Conclusion

The unexpected conclusion reported previously that the C–C bond length is little affected by the types of the hybridization of the carbon atom has been re-examined by the INDO-CI, NDDO and unrestricted INDO methods.

The conclusion from the INDO-CI and unrestricted INDO calculations has agreed with that obtained previously by the CNDO/2 calculation. However, a tendency for the bond length to decrease with an increase in the *s* character in hybrids was found in the results of the NDDO calculations for the hypothetical tri-tri and di-di single, and the di-di double bond

lengths. The tendency was, however, very small in comparison with those generally found.

It has been noted that the equilibrium distances are largely dependent on some electronic interactions between non-adjacent atomic orbitals.

A more extensive study of this problem by methods using different types of approximation for estimating the resonance integral will be the subject of a subsequent paper.

Our thanks are offered to Professor K. Higasi for his continuous interest and encouragement. The calculations were carried out on the IBM-7040 computer at the Computation Center of Waseda University. We would like to thank I.B.M. Japan, Ltd., for lending this computer to the university.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1496—1503 (1971)

The Protonation of Aromatic Hydrocarbon Radical Anions. I. A Comparison of Methods and a Study of the Mechanism[1)]

Shigeo HAYANO and Masamichi FUJIHIRA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 30, 1970)

The protonation mechanism of the aromatic hydrocarbon radical anions, such as biphenyl, naphthalene, phenanthrene, anthracene, 1,2-benzanthracene, and pyrene, in dimethylformamide (DMF) and water mixtures was studied. Three methods of measuring the concentration of the radical anions, *i.e.* polarography and ESR and UV absorption spectroscopy, were compared with each other by making simultaneous measurements of the same anthraquinone radical anion solution. A good linear relation of the polarographic anodic diffusion current to the UV absorbance was found, while the ESR signal intensity had linear relations with neither of the others in the system which contained an excessive number of parent molecules, 2×10^{-3} M. The change in the visible absorption spectra of the aromatic hydrocarbon radical anions as a function of the time suggested that all the aromatic hydrocarbon radical anions decay by a first-order reaction. As a result, the radical anions were considered to decay through the following sequence:

$$R^{\cdot-} + H_2O \xrightarrow{k} RH\cdot + OH^-,\ RH\cdot + R^{\cdot-} \rightleftarrows RH^- + R,\ \text{and}\ RH^- + H_2O \xrightarrow{k'} RH_2 + OH^-.$$

The electrochemical reduction of aromatic hydrocarbons in aprotic solvents has been the subject of a number of studies.[2,3)] These investigations have elucidated the mechanism of the reduction and the correlation between the polarographic half-wave potentials with electron affinities, ultraviolet absorption frequencies, or parameters of Hückel molecular orbital (HMO) calculations.[2-6)] In such aprotic media, aromatic hydrocarbons[7,8)] undergo reversible one-electron transfers at cathodes, yielding radical anions. Most radical anions undergo further reduction, at potentials half a volt more negative, to dianions, which are then usually rapidly protonated to carbanions, which themselves may then be protonated to the dihydro compounds. That is, the aromatic hydrocarbons usually give two one-electron waves in their polarograms. It was found, however, that on the addition of proton donors such as water,[7)] hydrogen iodide,[7)] and phenol,[8)] the first wave increased in height at the expense of the second wave. Hoijtink[7)] was the first to show that this phenomenon could be explained by means of the HMO theory; that is, for alternant aromatic hydrocarbons the radical, RH·, formed by the protonation of the radical anion, $R^{\cdot-}$, has a higher electron affinity than the parent molecule. The RH· radical can, therefore, be reduced without the necessity of further change in the electrode potential. Although the mechanisms have been studied extensively by polarography, very few investigations[9,10)] have made direct measurements of the mechanism and kinetics of protonations of radical anions.

The aims of this investigation were to examine the methods of measuring the radical anion concentrations and then to study the mechanism of the protonation of aromatic hydrocarbon radical anions in dimethylformamide (DMF) and water mixtures where radical anions were electrochemically generated by controlled potential electrolysis.

Experimental

Materials. All the organic reagents were obtained commercially. E.P.-grade anthraquinone, phenanthrene,

and naphthalene were purified by recrystallization from ethanol, ethanol, and methanol respectively. E.P.-grade anthracene was purified by sublimation. G.R.-grade pyrene and 1,2-benzanthracene were used without further purification. E.P.-grade biphenyl was also used without further purification.

Tetraethylammonium iodide (TEAI) and tetraethylammonium perchlorate (TEAP) were prepared according to the methods of Given *et al.*[11] and Fujinaga[12] *et al.*; these reagents showed no polarographic wave in a DMF solution in their accessible potential ranges of −0.6 V to −2.8 V and +0.4 V to −2.8 V, respectively, *vs.* SCE. Commercially-available G.R.-grade tetraethylammonium bromide (TEAB) was wet because of its deliquescent property and was consequently purified by recrystallization[13] from ethanol; then it was dried at 100°C for 12 hr in a vacuum and stored in a desiccator over silica gel. The TEAB also showed no polarographic wave in DMF in its accessible potential range, −0.5 V to −2.8 V *vs.* SCE.

The solvents used were purified in the usual manner,[12] the commercial, G.R. grade dimethylformamide (DMF) was dried over anhydrous K_2CO_3 for a few days with occasional shaking and then vacuum-distilled twice under nitrogen gas, and the water content of the DMF was determined to be 0.02% by Karl Fischer titration.

Polarography. An aqueous saturated calomel electrode was connected to the cell by a 1 N KNO_3-agar bridge[14] or a 1 N TEAB-agar bridge, the outlet of which was positioned just above the dropping mercury electrode. The 1 N KNO_3-agar bridge is adapted for measurements of the potential range of +0.4 V to −2.0 V *vs.* SCE, as in the case of anthraquinone, while the 1 N TEAB-agar bridge is adapted for measurements of the potential range of −0.5 V to −2.8 V *vs.* SCE, which was used for aromatic hydrocarbons; the bridges prevent the contamination of bromide or potassium ions from the TEAB- and KNO_3-bridges respectively. In order to lower the contamination of water from the bridge, one end of the bridge was aged in an aliquot of the supporting electrolyte solution for at least a day. The solution which contained a small amount of a depolarizer and 0.1 N of a supporting electrolyte was deaerated by bubbling pure nitrogen gas[15] for 15—20 min. No correction for the liquid-junction potential was taken into account. All the measurements were carried out at 25°C. The polarograph used was a Yokogawa Denki model POL-11.

The Simultaneous Measurements of Polarograms and UV and ESR Spectra of Anthraquinone Radical Anions. A solution containing 2×10^{-3} M of anthraquinone and 0.1 N of TEAP as the supporting electrolyte was placed in the electrolysis cell, as is shown in Fig. 1, and was deaerated for 20—30 min by bubbling pure nitrogen gas, which came through a flow-type 10-mm quartz cell for the absorption spectra and which came through a glass capillary for the ESR measurements. Then the bubbling was stopped and the nitrogen gas overflowed the catholyte by means of the cock, C_1, in Fig. 1; the DC polarogram of the base solution was recorded against the SCE (RE), which was also used in the controlled potential electrolysis as the reference electrode. Again, nitrogen bubbling was started and the solution was electrolyzed at the constant potential on the first plateau of the polarogram. The concentration of the radical anion could be controlled roughly by the length of the electrolysis time. After the electrolysis, the nitrogen gas again overflowed the catholyte, the solution in the center and in the anodic chamber was removed to prevent backflow, and then a DC polarogram was recorded. After that, the solution was introduced into the 10-mm quartz cell used for the UV spectrometry and the glass capillary used for the ESR spectrometry.

All the measurements were carried out at 20°C. A Japan Electron Optics Laboratory ESR spectrometer model JES-ME-3X, a Shimadzu recording spectrophotometer model MPS-50L, a Shimadzu polarograph model RP-50, and a Hokuto Denko potentiostat model PS-500B, were used.

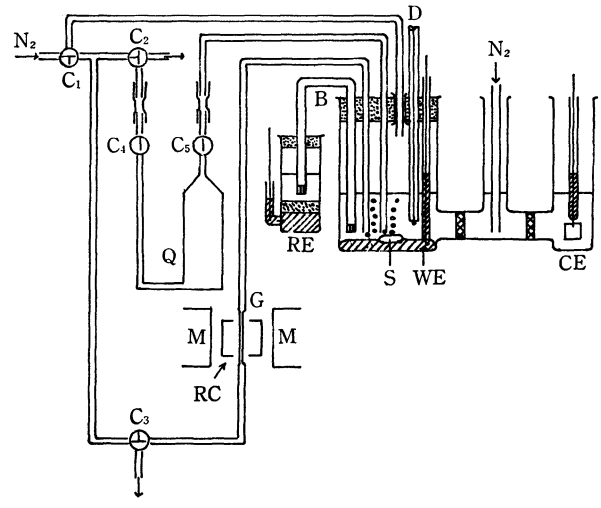

Fig. 1. Apparatus for simultaneous measurements of radical anions. N_2, pure nitrogen; C, cock; Q, UV quartz cell; M, magnet; G, glass capillary for ESR measurements; RC, resonant cavity; B, agar bridge; S, magnetic stirrer; RE, reference electrode (SCE); WE, mercury pool cathode; CE, Pt anode; D, d. m. e.

Visible Absorption Spectroscopy of Aromatic Hydrocarbon Radical Anions. The apparatus was almost identical with that used for the simultaneous measurements described above (Fig. 1). The following improvements were made, however: the 10-mm quartz cell and the electrolysis cell were kept at a constant temperature by means of a thermostat in order to make it possible to change the temperature. One more electrolysis cell, in which a DMF solution containing 5×10^{-3} M of the same aromatic hydrocarbon as was measured and 0.1 N of TEAB was placed, was connected to the line before the cock, C_1, in Fig. 1. After pure nitrogen had been bubbled in for 10—15 min, the solution in this cell was electrolyzed at the potential on the first diffusion plateau and the electrolysis was continued throughout each experiment. By this procedure, pure nitrogen gas was purified much more; the reduction potentials of the aromatic hydrocarbons are so negative that the oxygen is practically completely absorbed by the reaction with the radical anion.[16-18]

The main electrolysis was started after the nitrogen bubbling had continued for 45 min, and it was continued for 10 min. When the water content was small, the decay was slow enough to record the change in the spectra, but in the case of fast decay by the addition of considerable water, the absorbance against time must be recorded at the absorption maximum of the radical anions.

Results and Discussion

Controlled-Potential Electrolysis of Anthraquinone and Polarography of the Radical Anion of Anthraquinone. The polarographic reduction of anthraquinone (AQ) in DMF showed two well-defined waves with half-wave potentials of −0.90 V and −1.54 V *vs.* SCE (Fig. 2); these waves correspond to the formation of radical anions and dianions respectively:

$$AQ + e \rightleftharpoons AQ^{\cdot-} \qquad \text{1st wave} \qquad (1)$$

$$AQ^{\cdot-} + e \rightleftharpoons AQ^{2-} \qquad \text{2nd wave} \qquad (2)$$

However, the controlled potential electrolysis of anthraquinone at the potential (B), which was a little more negative than that of the second wave, gave radical anions as in the electrolysis at the potential (A) on the diffusion plateau of the first wave, but the rate of formation of the radical anions was double that of the latter. This is because a dianion, AQ^{2-}, reacts with a neutral AQ in solution to give two radical anions, as is shown below:

$$AQ^{2-} + AQ \rightleftharpoons 2AQ^{\cdot-} \qquad (3)$$

The equilibrium constant of this reaction:

$$K = \frac{[AQ^{\cdot-}]^2}{[AQ^{2-}][AQ]} \qquad (4)$$

is obtained[19] from Eq. (5):

$$E_{1/2}(1st) - E_{1/2}(2nd) = \frac{RT}{F} \ln K \qquad (5)$$

where $E_{1/2}(1st)$ and $E_{1/2}(2nd)$ are the half-wave potentials of the first and second waves respectively, where R is the gas constant, where T is the absolute temperature, and where F is the Faraday constant. The value of K is calculated to be 10^{11}; therefore, the equilibrium of Reaction (3) lies almost completely to the right. Thus, we can obtain the various concentrations of the radical anions of anthraquinone by changing the length of the electrolysis time of the controlled potential electrolysis at the potential on the first palteau (A), and when we want to generate the radical anions rapidly and in large quantities, electrolysis at the potential on the second plateau (B) is useful.

The polarogram (Fig. 2) for the solution containing $AQ^{\cdot-}$ which was prepared by the controlled potential electrolysis at either the potential on the first (A) or the second plateau (B) described above, shows an anodic wave with a large maximum (C) which suddenly drops at −0.4 V *vs.* SCE and which has a diffusion plateau at more positive potential (D). The shape of this anodic wave is very similar to that found by Santhanam and Bard[17] for the anodic oxidation of

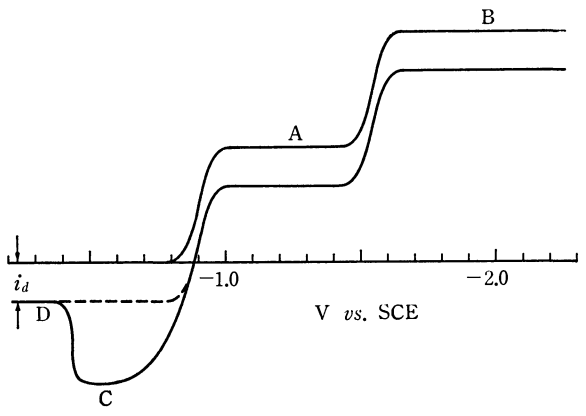

Fig. 2. DC polarograms of anthraquinone.

9,10-diphenylanthracene radical anions, and it probably can be explained by a similar mechanism. The base currents before electrolysis and anodic currents after electrolysis were measured with the various heads of the dropping mercury electrode (d.m.e.). From these data, we obtained the anodic currents, i_d, of $AQ^{\cdot-}$ in the anodic plateau (D) with the various heads of the d.m.e.; we found that this anodic current, i_d, varied as the square-root of the head of the d.m.e. (Fig. 3). Therefore, this anodic current may be diffusion-controlled and may be proportional to the concentration of $AQ^{\cdot-}$. Furthermore, this anodic diffusion current showed no change with time; *i.e.*, the radical anion $AQ^{\cdot-}$ was found to be stable[9,10,20] in DMF.

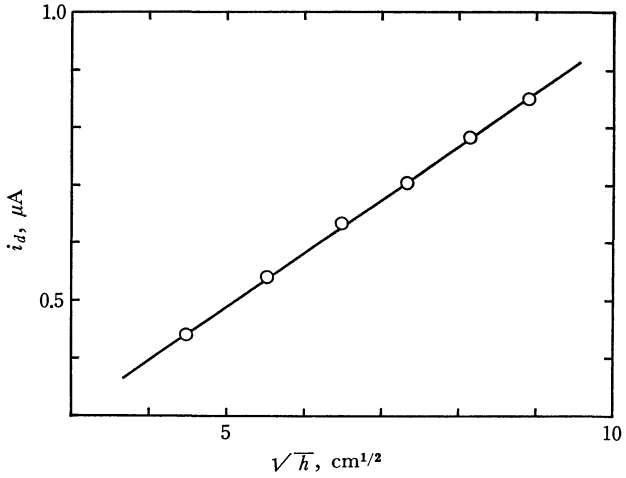

Fig. 3. Dependence of anodic current i_d on the square-root of the mercury head.

UV Absorption Spectra. The UV absorption spectra of radical anions and dianions of anthraquinone will be reported in detail in this Bulletin. The parent molecule, AQ, has an absorption band at the λ_{max} of 325 mμ in DMF, which itself has strong absorptions at wavelengths shorter than 270 mμ. The catholyte by controlled potential electrolysis had absorption bands at the λ_{max} of 390, 410, and 553 mμ in the visible region; these results are consistent with the absorption spectra of the anthraquinone radical anion reported

20) W. Sakai, I. Matsuo, K. Miyata, and F. Hori, *Denki Kagaku*, **37**, 618 (1969).

by other authors.[10,21,22] The intensity of the maxima showed no change with time. As a result of this observations, the AQ^- radical anion was found to be not only stable in DMF, but also completely free from oxygen in the UV cell.

ESR Spectra. The ESR spectra of anthraquinone radical anions in DMF solutions containing 1×10^{-4} M, 2×10^{-3} M, and 5×10^{-3} M of anthraquinone before controlled potential electrolysis, which were carried out at -1.20 V *vs.* SCE for 15 min, 45 sec, and 30 sec respectively, are given in Fig. 4. The hyperfine coupling constants obtained from the ESR spectrum of the solution containing 1×10^{-4} M of anthraquinone before electrolysis are $a_{H_1}=0.3$ gauss and $a_{H_2}=1.0$ gauss; these values almost agree with those in the literature.[9,21,23] As is shown in Fig. 4, the more parent molecules were present, the broader were the spectra obtained. This behavior can be explained as a result of rapid intermolecular electron-exchange[24] between the parent anthraquinone molecules and the radical anions:

$$AQ^- + AQ \rightleftharpoons AQ + AQ^- \qquad (6)$$

It can be said also that the radical anions were free from the oxygen throughout the measurements, for the ESR spectra showed no change with time.

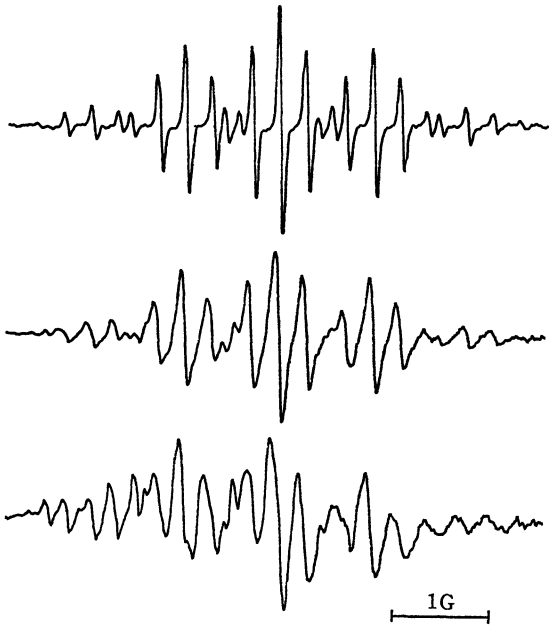

Fig. 4. ESR spectra of anthraquinone radical anions in DMF: above, 1×10^{-4}M; center, 2×10^{-3}M; below, 5×10^{-3}M of anthraquinone contained before partial reduction.

Comparison of Methods. It has been shown above from the measurements of polarograms and the UV and ESR spectra, that anthraquinone radical anions are stable in DMF and are free from oxygen. Therefore, the anthraquinone radical anions are suitable for the simultaneous measurements of the same solution by the three different methods; this can make clear the correlation of the measured quantities. The correlation between the anodic diffusion current, i_d, the absorbance, A, and the ESR signal intensity, I, of the derivative absorption curve are shown in Fig. 5. There exist a good linear relation between the diffusion currents and the absorbance, while the ESR signal intensity has no linear relation either with the diffusion currents or the absorbance. As the diffusion currents and the absorbance are usually proportional to the concentration, the above result leads to the conclusion that the ESR signal intensity of anthraquinone radical anions has no linear dependence on the concentration.

As the diffusion coefficients of the radical anion and the parent molecule are assumed to be approximately equal, the concentration of radical anions in Fig. 5 could be estimated from the i_d values to vary over the range of 2×10^{-5}—2×10^{-4} M; therefore, the molar extinction coefficient (at 553 mμ) of anthraquinone radical anions may be 1.2×10^4 M^{-1} cm^{-1}.

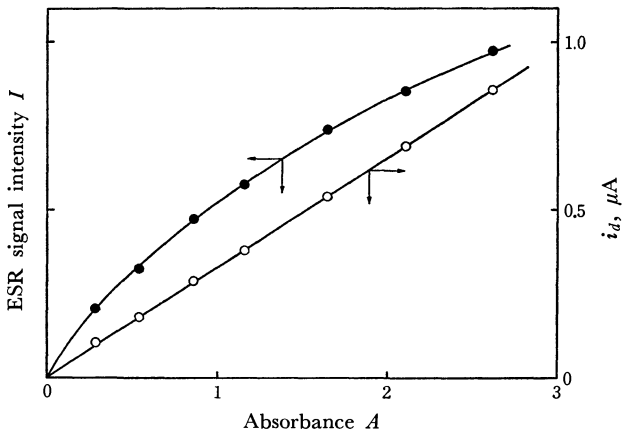

Fig. 5. Correlation between anodic diffusion current i_d, absorbance A and ESR signal intensity of the derivative absorption spectra I.

In the present system, it can be assumed, according to Weissman,[24] that the lines of ESR are close to Lorentzian and that the contributions to the line width from individual broadening mechanisms are additive. Then the line width of a line can be written as follows:

$$\Delta H_{p-p} = \Delta H_0 + \Delta H_e + \Delta H_s$$
$$= \Delta H_0 + h_e[R] + h_s[R^-] \qquad (7)$$

where ΔH_{p-p} is the line width as measured between points of extreme slope, *i.e.*, from peak to peak of the derivative spectrum, where ΔH_e is the contribution to the width from the electron-exchange reaction with the parent molecule, where ΔH_s is the contribution to the width from the intermolecular spin exchange reaction, and where ΔH_0 is the width in the absence of these two contributions, or when there is little such contributions. As is written in Eq. (7), these two contributions are known[24,25] to be proportional to the concentration of the parent molecule and the radical

anions respectively. Furthermore, the rate constants of these reactions are related to the line brodening by $k_e = 1.52 \times 10^7 h_e$ M^{-1} sec^{-1} or $k_s = 1.52 \times 10^7 h_s$ M^{-1} sec^{-1}. The sum of the concentrations of the parent molecules and the radical anions were kept constant, 2×10^{-3} M, in the above experiment. Hence:

$$\Delta H_{p-p} = (h_s - h_e)[\mathrm{AQ}^-] + \text{const.}$$

The plot of ΔH_{p-p} against $[\mathrm{AQ}^-]$ gave a straight line (Fig. 6). The direct measurements of ΔH_{p-p} from the ESR spectra are not so accurate. Therefore, ΔH_{p-p} was determined from $\sqrt{[\mathrm{AQ}^-]/I}$, since $I \times (\Delta H_{p-p})^2$ is proportional to the concentration of the radical anions.[26] The value of $(h_s - h_e)$ was determined from the slope of the straight line and was 140± 10 gauss M^{-1}. Similarly, the value of h_e could be determined from experiments where the concentrations of the radical anions were kept constant and where only the concentrations of parent molecules were varied; it was 10±5 gauss M^{-1} and the rate constants, k_e and k_s, were $(1.5 \pm 0.8) \times 10^8$ M^{-1} sec^{-1} and $(2.3 \pm 0.2) \times 10^9$ M^{-1} sec^{-1} respectively. These values are comparable to those of others.[25]

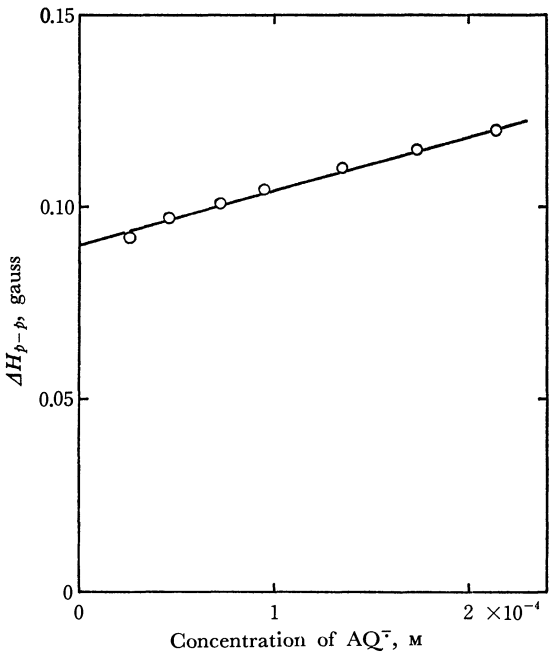

Fig. 6. Dependence of ΔH_{p-p} on $[\mathrm{AQ}^-]$ where the sum of the concentrations of parent molecules and radical anions were kept constant, 2×10^{-3} M.

As has been described above, the nonlinear dependence of the ESR signal intensity on the concentration of the radical anions was found to be due to the broadening caused by the rapid intermolecular spin exchange, even if the concentration of the parent molecule is constant. However, the ESR measurement is very useful for studying the mechanism of the protonation of radical anions, because it can detect only radicals. As the quantitative method, UV absorption spectroscopy is more appropriate than polarography because of its accuracy and simplicity, unless the absorption maxima of the radical anions overlap those of the parent molecule and other compounds produced during the reaction.

The Decay of Aromatic Hydrocarbon Radical Anions in DMF-Water Mixtures. The radical anions of aromatic hydrocarbons in a DMF solution which contains small amounts of water are considered to decay by this protonation mechanism:

$$\mathrm{R}^- + \mathrm{H_2O} \xrightarrow{k} \mathrm{RH}\cdot + \mathrm{OH}^- \quad (8)$$

$$\mathrm{RH}\cdot + \mathrm{R}^- \underset{}{\overset{k_{12}}{\rightleftharpoons}} \mathrm{RH}^- + \mathrm{R} \quad (9)$$

$$\mathrm{RH}^- + \mathrm{H_2O} \xrightarrow{k'} \mathrm{RH_2} + \mathrm{OH}^- \quad (10)$$

If the radical anions decay only through the sequence described above, the changes of the concentration of the radical anions with time are as given by Umemoto[9]:

$$\frac{\mathrm{d}[\mathrm{R}^-]}{\mathrm{d}t} = -2k[\mathrm{H_2O}][\mathrm{R}^-] \quad (11)$$

Equation(11) can be deduced from the facts that the reaction of Eq. (8) is slow, but the electron transfer reaction of Eq. (9) is very fast, and that, furthermore, the equilibrium of Eq. (9) lies completely to the right.[27]

26) However, the proportional constant must be determined from at least one direct measurement.

27) These facts are confirmed as follows. The equilibrium constant of Eq. (9) can be estimated by Eq. (14) if the half-wave potentials of Eq. (12) and Eq. (13) are known:

$$\mathrm{R} + \mathrm{e} \rightleftharpoons \mathrm{R}^- \quad (12)$$

$$\mathrm{RH}\cdot + \mathrm{e} \rightleftharpoons \mathrm{RH}^- \quad (13)$$

$$E_{1/2}(\mathrm{RH}\cdot \rightarrow \mathrm{RH}^-) - E_{1/2}(\mathrm{R} \rightarrow \mathrm{R}^-) = \frac{RT}{F} \ln K \quad (14)$$

The Hückel theory predicts that the protonated radicals, RH·, derived from alternant hydrocarbons should have the same half-wave potentials, about −1.1 V *vs.* SCE, since the highest occupied orbital into which a further electron is uptaken is the non-bonding molecular orbital. This fact was ascertained experimentally by Dietz and Peover[28] using rapid sweep cyclic voltammetry at a platinum electrode. Among the aromatic hydrocarbons used in the present work, anthracene shows the lowest half-wave potential; its value is −1.95 V *vs.* SCE. Therefore, the equilibrium constant of Eq. (9) is greater than 10^{14} in the present study.

The rate constants of such a rapid intermolecular electron exchange of aromatic hydrocarbon radical anions as Eq. (15) have been determined by studying the line broadening of the ESR spectra[29,30]:

$$\mathrm{R}^- + \mathrm{R} \underset{}{\overset{k_{11}}{\rightleftharpoons}} \mathrm{R} + \mathrm{R}^- \quad (15)$$

they are about 10^8 M^{-1} sec^{-1} in DMF and 10^7 M^{-1} sec^{-1} in DMF containing 10% of water.[29] The rate constants of Eq. (16) may also be the same order as Reactions (6) and (15):

$$\mathrm{RH}^- + \mathrm{RH}\cdot \underset{}{\overset{k_{22}}{\rightleftharpoons}} \mathrm{RH}\cdot + \mathrm{RH}^- \quad (16)$$

According to Marcus,[31] the rate constant of the forward reaction of Eq. (9) can be estimated as follows:

$$k_{12} \simeq (k_{11}k_{22}Kf)^{1/2} \quad (17)$$

where:

$$\ln f = (\ln K)^2/4 \ln (k_{11}k_{22}/Z^2) \quad (18)$$

In the present system, k_{12} is calculated to be $10^{10.94}$ M^{-1} sec^{-1} when k_{11} and k_{22} are 10^7 M^{-1}sec^{-1}, Z is 10^{11} M^{-1} sec^{-1} and K is 10^{14}. Thus, the k_{12} is nearly equal to the collision frequency of the hypothetical uncharged species in solution, Z.

a) Our results. b) See Ref. 32. c) See Ref. 33. d) See Ref. 34.
** The parent molecules have absorption bands in the same region.

Equation (11) suggests that the radical anions will decay by a first-order reaction when the concentration of water is much greater than that of the radical anions. These predictions can be confirmed by a study of the change in the absorbance of the radical anions with time. The positions of the electronic absorption bands of the aromatic hydrocarbon radical anions obtained are given in Table 1, where the spectra of other authors[32-34] are compared with our results. These results show a fairly good agreement, though the measurements were carried out with different solvents.

The parent molecules, R, used, except for anthracene and 1,2-benzanthracene and their dihydroderivatives, RH_2, have no strong absorption bands in the range of 350—750 mμ, but the carbanions, RH^-, formed by Eq. (9) or by the monoprotonation of the dianions Eq. (20) have absorption maxima in a visible region.[35,36] Furthermore, the spectra of the RH^- carbanion were found to be similar to that of the carbonium ion, RH^+.[37]

However, the spectra corresponding to the RH^- carbanion were not found during the decay of the radical anions. These results mean that the rate constant of the protonation of RH^- in Eq. (10) is much greater than that of $R^{\cdot-}$ in Eq. (8). The absorbances of all the radical anions in the present study decayed exponentially with time; that is, the $\log A$ against time plots gave straight lines, which means a first-order decay of the radical anions as expected from Eq. (11).

Now that the radical anions of the aromatic hydrocarbons investigated in this study have been shown to decay through the Eq. (8)—Eq. (10) sequence, let us consider the reason why the aromatic hydrocarbon radical anions do not decay through this sequence:

$$2R^{\cdot-} \rightleftharpoons R^{2-} + R \tag{19}$$

$$R^{2-} + H_2O \xrightarrow{k''} RH^- + OH^- \tag{20}$$

$$RH^- + H_2O \xrightarrow{k'} RH_2 + OH^- \tag{10}$$

First, let us consider the case in which the disproportionation reaction Eq. (19) is the rate-determining step. The rate constants are assumed to be given approximately by the theory of Marcus[38] even in a system where the standard free energy of the reaction, ΔG°, is very large, as follows:

$$k = Z \exp(-\Delta G^*/RT) \tag{21}$$

where Z is the collision number in the solution and where ΔG^* is as given by Eqs. (22)—(24):

$$\Delta G^* = e_1^* e_2^*/D_s r + m^2\lambda \tag{22}$$

where:

$$2m + 1 = -[\Delta G^\circ + (e_1 e_2 - e_1^* e_2^*)/D_s r]/\lambda \tag{23}$$

and:

$$\lambda = \left(\frac{1}{2a_1} + \frac{1}{2a_2} - \frac{1}{r}\right)\left(\frac{1}{D_{op}} - \frac{1}{D_s}\right)(\Delta e)^2 \tag{24}$$

In these equations, the notations are the same as those of Marcus.[38] In a disproportionation reaction such as Eq. (19), the work of bringing reactants tagether, $e_1^* e_2^*/D_s r$, is not neglected, but the work for the products, $e_1 e_2/D_s r$, is neglected, since one product is uncharged. The solvent reorganization parameter, λ, is assumed to be almost the same as that of the reaction of Eq. (15), and λ=13.1 kcal/mol, obtained from

a) See Ref. 9.

Eq. (24) by taking $a_1=a_2=6$Å, was used for the calculation of k_d.

The standard free energy of the disproportionation reaction, ΔG°, is also determined from the experimental results, the half-wave potentials of the first and second waves of aromatic hydrocarbons, by the following equation:

$$E_{1/2}(R^- \rightarrow R^{2-}) - E_{1/2}(R \rightarrow R^-) = \frac{RT}{F} \ln K \qquad (25)$$

which is an inverse of Eq. (5). The difference in the half-wave potentials, $\Delta E_{1/2}$, the standard free energy, ΔG°, and the calculated values of the rate constants, k_d, of the disproportionation reaction are given in Table 2. The differences in the half-wave potentials of biphenyl, naphthalene, and phenanthrene can not be obtained, since these compounds do not give the second wave in the accessible potential region. These differences, however, may not be smaller than those of the others obtained, because the electrostatic repulsion of the pair of electrons in the antibonding orbital, ϕ_{n+1}:

$$E_{rep} = \iint \phi_{n+1}(1)\phi_{n+1}(2)\frac{e^2}{r}\phi_{n+1}(1)\phi_{n+1}(2)d\tau_1 d\tau_2$$

is larger in the case of smaller molecules, such as biphenyl, naphthalene and phenanthrene[39]; furthermore, the values of $\Delta E_{1/2}$ were found[40] to have a linear dependence on E_{rep}.

Hence, if the forward reaction of Eq. (19) is rate-determining, the decay of the radical anion by the sequence of Eqs. (19), (20), and (10) is given by:

$$\frac{d[R^-]}{dt} = -k_d[R^-]^2$$

As the concentrations of the radical anions are of the order of 10^{-4} M in the initial period, the products, $k_d[R^-]$, are $10^{-1}-10^{-2}\,sec^{-1}$ and are comparable to the apparent first-order rate constants, $2k[H_2O]$, in Eq. (11), the values of which are $10^{-1}-10^{-3}\,sec^{-1}$ in the present system.

As the present work has shown that the radical anion obeys the first-order decay, the rate-determining reaction may be the protonation reaction of dianions, Eq. (20), if the calculated order for k_d is correct.

At present, however, k_d is not obtained experimentally; furthermore, attempts to test the theory of Marcus for the dependence of ΔG^* on ΔG° have beem made[41,42] for the system, where ΔG° is not so large, 2—3 kcal/mol, but have never been made for the system where ΔG° is as large as 10 kcal/mol in the aromatic hydrocarbon radical anion disproportionation reaction. The values of ΔG° calculated from $\Delta E_{1/2}$ as Table 2 shows, are, however, possibly smaller than the true values, because $E_{1/2}$ (2nd) may be shifted to a positive potential by the rapid protonation of dianions, as is ascertained from the fact that AC polarography almost did not give the second wave. For the calculation of k_d, $10^{11}\,M^{-1}\,sec^{-1}$ was used as the value of Z, but 10^9—$10^{10}\,M^{-1}\,sec^{-1}$ may be more appropriate as the collision number between radical anions in solution, because the rate constants of spin exchange described before are considered[25] to be diffusion-controlled. Considering these factors, the disproportionation reaction itself is possibly slower than the protonation reaction of radical anions, Eq. (8), in the present system.

It is very interesting that the decay of benzophenone radical anions is known[9] to consist of the contributions of a first- and second-order reaction for radical anion concentrations. This is explained by the smaller ΔG° of benzophenone (in Table 2), as has been discussed by Fujinaga *et al.*[9,10]

The protonation reactions through either the Eqs. (8), (9), and (10) sequence or the Eqs. (19), (20), and (10) sequence lead to an increase in the first wave height at the expense of the second wave, because the reducible substance, *i.e.*, RH or R, is regenerated at the potential of the first plateau by these sequences, which are examples of ECE mechanisms. However, the radical anion and dianion of anthraquinone are not protonated in the DMF-alkaline water system.[43] Therefore, by the addition of water, no increase in the first wave height is found, although the second wave shifts to the positive potential and the two waves approach each other. This is because the strong solvation of the dianion by hydrogen bonding with water lowers the standard free energy of disproportionation

reaction, $\Delta G°$. As a result, R is reproduced to some extent and may be reduced at the potential of the first plateau, but at the same time R^{2-} is generated equally. The latter may be oxidized and may compensate for the reduction of neutral species.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1503—1506 (1971)

The Solubilization of Orange OT in Anionic Surfactant Solutions: A Polarographic Study

Shigeo HAYANO and Noriko SHINOZUKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 1, 1970)

Orange OT (1-*o*-tolyl-azo-β-naphthol) solubilized in sodium dodecyl sulfate (SDS) and sodium dodecylbenzene sulfonate (SDBS) solutions showed a well-defined irreversible polarographic wave. The proportionality of the limiting current to the square root of the mercury height and to the dye concentration indicates the wave to be diffusion-controlled. It is noted that the anionic surfactants showed the waves due to the adsorption-desorption and reorientation of the surfactant molecules on the electrode. The apparent diffusion coefficients of the solubilized dye calculated from the polarographic data were in good agreement with those of the anionic surfactant micelle with electrolyte. We may conclude that the polarographic diffusion coefficient of the solubilized dye is equal to that of the micelle of the solubilizer surfactant. The marked surfactant concentration dependence of the diffusion coefficient was observed with both surfactants and was attributed to the interaction of the micelles. The transfer coefficient of the electrode reaction of Orange OT increased with an increase in the concentration of the surfactant. This tendency is different from the effect of the surface-active agents on the transfer coefficient in the reduction of inorganic ions. From the experimental observations, it seems that the electrode reaction of the solubilized dye is little effected by the charged micelles.

The preceding papers[1,2] described the polarographic behavior of the solubilized dye in nonionic surfactant solutions. The solubilized neutral dyes (anthraquinone derivatives) showed well-defined, diffusion-controlled polarographic waves, and the diffusion constants calculated from the polarographic data were in good accordance with those for the micelles of the nonionic surfactants. This means that the solubilized dye diffused from the bulk solution to the electrode with micelles of the surfactant and that the dye was reduced polarographically where the surfactant micelles seemed to have little effect on the reduction process of the dye.

In this paper, we shall report the polarographic results of the solubilized dye (Orange OT), which showed a well-defined, irreversible, diffusion-controlled wave in anionic surfactant solutions and shall conclude that the diffusion coefficient of the dye is equal to that of the micelle of the surfactant.

Experimental

Materials. Orange OT (1-*o*-tolyl-azo-β-naphthol) was recrystallized twice from ethanol. Sodium dodecylbenzene sulfonate (SDBS) was obtained through the courtesy of the Lion Oil and Fats Co. and was recrystallized from petroleum ether. Sodium dodecyl sulfate (SDS) made by the Kao-Atlas Co., Ltd., was extracted from ether and was recrystallized from ethanol.

Procedure. Orange OT was solubilized in an anionic surfactant solution containing a 0.1 M sodium acetate-acetic acid buffer solution (pH=4.62) as a supporting electrolyte. The solution was stored for a week at 25°C. The excess dye was removed by filtration through a G4 glass filter. The concentration of the filtrates were rechecked by their solid contents on the filter, which had been determined by the measurement of the spectroscopic absorbancy.

The polarographic measurements were carried out at 25°C with Yokogawa POL-11 and POL-21 polarographs. The DME had the following characteristics: $m=2.075$ mg/sec (in pure water without applied potential) and $t=3.58$ sec (in a 10^{-2} M SDBS buffer solution at -0.5 V *vs.* SCE). The height of the mercury head was 75.5 cm.

Results

Orange OT in the Ethanol-water Solution. The polarogram of Orange OT in an 40% ethanolic solution showed pH-dependent waves. In an alkaline solution a maximum of the first kind was observed, while in an acidic solution the wave was well-defined and the current was proportional to the square root of the mercury-column height. (Fig. 1) From the log-plots of the waves, a value of $n\alpha=1.22$ (α being the transfer coefficient) was obtained in a solution of pH=4.6. Supposing that the reduction of Orange OT proceeds with a two-electron transfer,[3] the diffusion coefficient of the dye in an ethanolic solution at pH=4.6 was calculated to be 3.8×10^{-6} cm²/sec.

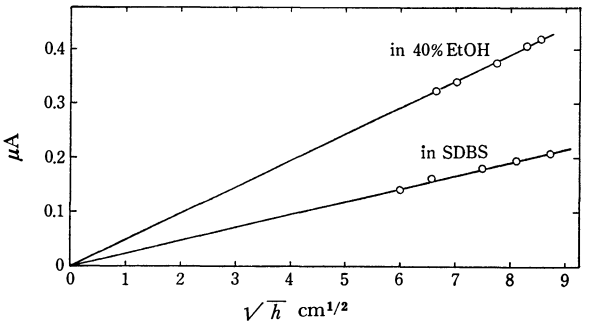

Fig. 1. Dependence of current of Orange OT on mercury height.

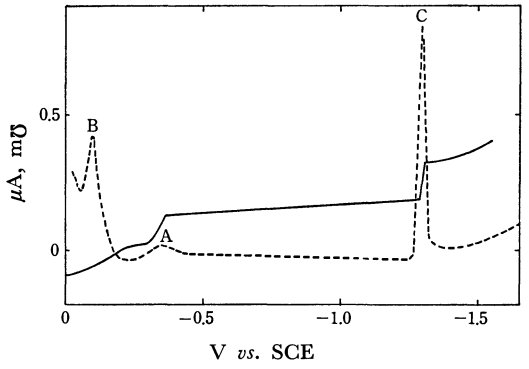

Fig. 2. DC and AC polarograms of the solubilized Orange OT in SDBS solution.

Orange OT Solubilized in SDBS Solution. Orange OT solubilized in a SDBS solution showed a well-defined, irreversible wave in DC polarograms; the AC polarographic peak was very small and round (Fig. 2). In the polarograms of the solubilized dye in anionic surfactant solutions, there appear waves due to the adsorption-desorption of the surfactant molecules on the electrode. In Fig. 2, the A wave is attributed to the reduction of Orange OT, while the B and C waves are adsorption and desorption waves respectively of SDBS molecules. These waves were of course observed with the base solution containing no Orange OT.

The relation of the limiting current to the mercury height shown in Fig. 1 indicates the diffusion-controlled character of the current. A linear line between the current and the dye concentration was also obtained. From these experimental results, the limiting current of Orange OT may be thought to be diffusion-controlled.

TABLE 1. DEPENDENCE OF POLAROGRAPHIC PARAMETERS ON SDBS CONCENTRATION

SDBS concn. (M)	$-E_{1/2}$ (V)	i_d (μA)	D ($\times 10^{-6}$ cm²/sec)	$n\alpha$
10^{-2}	0.380	0.182	1.77	0.72
3×10^{-2}	0.375	0.166	1.35	0.71
5×10^{-2}	0.392	0.152	1.14	—
8×10^{-2}	0.410	0.120	0.71	0.80
10^{-1}	0.400	0.104	0.53	0.81

Dye concn. 5.78×10^{-5} M

Table 1 summarizes the effects of the SDBS concentration on $E_{1/2}$, i_d, D, and $n\alpha$ of the dye.

The half-wave potential of the dye reduction became more negative with the increase in the SDBS concentration, but the change in $E_{1/2}$ was small compared with the potential shift when the complex formation occurred. The 3rd column of Table 1 shows a marked effect of the concentration of SDBS upon the current; this indicates that the diffusion coefficient of the dye decreased with the increase in the SDBS concentration.

The change in $n\alpha$ values with the surfactant concentration is shown in the 5th column of Table 1. It is evident that the $n\alpha$ value increased with the SDBS concentration.

The effects of the solubilized dye concentration upon $E_{1/2}$, D, and $n\alpha$ were also investigated, but the changes in these factors were very small.

Orange OT Solubilized in the SDS Solution. The polarogram of Orange OT solubilized in a SDS solution is shown in Fig. 3, where the A wave is the diffusion current of Orange OT. The B, C, D, and E waves were observed without Orange OT and were due to the adsorption phenomena of SDS molecules on the electrode. The change in the peak potentials of these waves with the SDS concentration is shown in Fig. 4. The behavior of the C and D waves, which were attributed to the reorientation of the surfactant

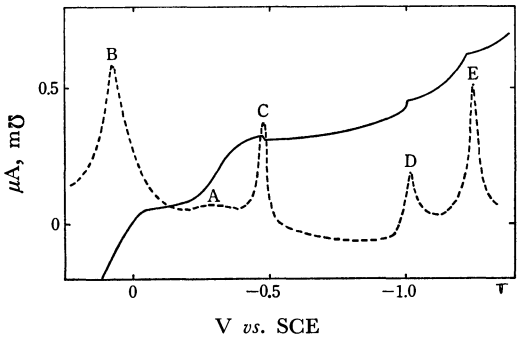

Fig. 3. DC and AC polarograms of the solubilized Orange OT in SDS solution.

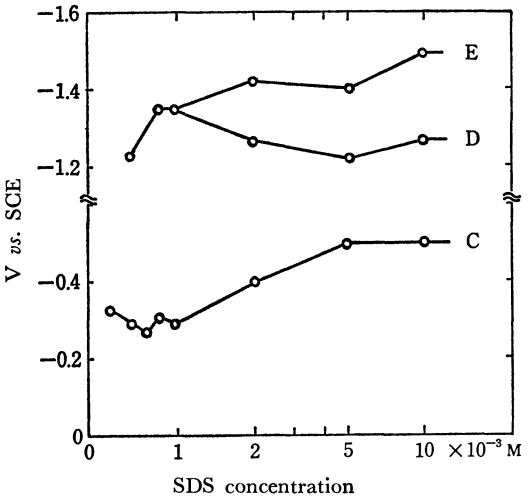

Fig. 4. Changes of peak potential of C, D, and E waves with SDS concentration.

molecules by Eda,[4] was carefully observed in order to evaluate the limiting current of Orange OT; the overlap of these waves with the limiting current of Orange OT may cause considerable error. The B and E waves may be adsorption and desorption waves respectively. The details of these nonfaradaic currents will be published elsewhere.

The effects of the SDS concentration on $E_{1/2}$, i_d, D, and $n\alpha$ are given in Table 2. $E_{1/2}$ was almost constant throughout the SDS concentrations used in this study, and in this case the complex formation was also negligible. The apparent diffusion coefficient of the dye was markedly decreased with the increase in the SDS concentration in a way similar to that in SDBS solutions. The value of $n\alpha$, which was larger than that for SDBS solutions, increased with the SDS concentration.

Discussion

Diffusion Coefficient of the Solubilized Dye. The apparent diffusion coefficients of the solubilized dye, as calculated from the polarographic data, were in good agreement with those of the anionic surfactant micelle with the electrolyte reported in the literature. Mankowich[5] calculated the molecular weight to be about 20,000 for a SDBS micelle in a 1% SDBS solution with 0.1 N Na_2SO_4. This molecular weight corresponds to a D value of about 8.7×10^{-7} cm^2/sec. Mysels' values[6] of the self-diffusion coefficient for 1.7—10.1×10^{-2} M SDS with 0.1 N NaCl were between 0.92 and 0.82×10^{-6} cm^2/sec. Although our results are somewhat larger than the above values, on the whole, there seems to be no great discrepancy. This fact indicates the diffusing particle to be the micelle solubilizing the dye in it.

The marked surfactant concentration dependence of D could be due to a large growth of the micelle, to the interaction with other micelles, or to the diffusion of the dye not solubilized in the micelle at the lower surfactant concentrations. Schott[7] has reported, that in SDS solutions, only one dye molecule was solubilized per micelle above the critical micelle concentration and that the aggregation number of SDS in the presence of 0.1 M NaCl was 131. With the present dye/surfactant ratio (below 1/170), all the dye molecules were solubilized in micelles. As to the size of the micelle reported in the literature[8], no drastic change appears throughout the experimental range; SDS concentration was 10^{-2}—10^{-1} M, and the dye concentration, 10^{-5}—1.5×10^{-4} M, in the presence of the 0.1 M acetate buffer. Therefore, it is the interaction with other micelles that must be responsible for the concentration dependence of D.

The empirical plots of $1/D$ *vs.* the square roots of the surfactant concentration suggested by Stigter *et al.*[6] are shown for SDBS in Fig. 5. The extrapolated value to the cmc (approximately 10^{-3} M) is 2.8×10^{-6} cm^2/sec, which is rather large compared with that in the literature.[5] The bending point of the line may be attributed to the change in the interaction of the micelles, but it cannot be interpreted in detail.

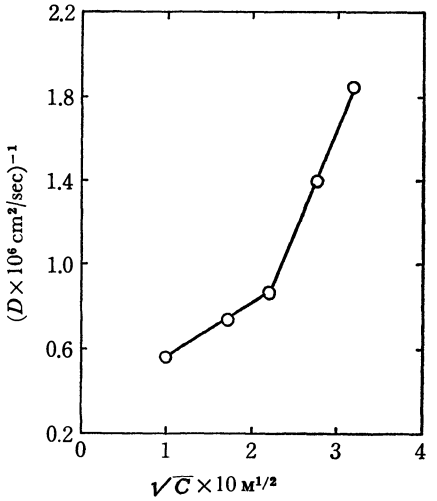

Fig. 5. Relation of the reciprocal of D to the square root of the SDBS concentration.

The value of D for SDS at 7×10^{-2} M, 0.935×10^{-6} cm^2/sec, is somewhat different from the value of Stigter *et al.*[6] at 7×10^{-2} M SDS, 0.858×10^{-6} cm^2/sec (with 0.1 M NaCl), but these values may be thought to be equal considering the difference in methods.

The Change in the Transfer Coefficient. The change in $n\alpha$ values with the surfactant concentration indicates the effect of the surfactant molecules on the electrode process. Kuta and Smoler[9] have been studied the transfer coefficient of TiO_2^+ and the vanadyl ion with surface-active substances such as polyvinyl alcohol and tribenzyl amine; they concluded that the α on the covered surface is usually less than that on the free surface. In this study, the transfer coefficient increases with an increase in the concentration of the surfactant, and the value for SDS is greater than that for SDBS. The latter fact can be interpreted by the fact that SDS is adsorbed in the micelle-like form at the potential of Orange OT reduction.[4] In 5×10^{-2} M SDS, $n\alpha$ is 1.23; this is comparable with the value of $n\alpha=1.22$ in 40% ethanolic solution. The change in the transfer coefficient with the surfactant and its

concentration is now under investigation in our laboratory.

The Effect of the Surfactant Adsorption on the Reduction of the Solubilized Dye. The adsorption-desorption waves of the SDBS and SDS molecules show that, at the potential of Orange OT reduction, the anionic surfactant molecules are adsorbed on the electrode. Therefore, an effect from the anionic-charged particles may be expected. The dye is reduced at the potential of the positively-charged DME range; however, the dye gives a diffusion-controlled wave and remains unaffected by the anionic surfactant. These results, and the large α value obtained with a large surfactant concentration, suggest that the electrode reaction proceeds as if there were no effect of charged micelles near the electrode.

Proton Spin-Lattice Relaxation Studies of Intermolecular Interactions in the Mixtures of Chloroform and Proton-Acceptor Solvents

Kazuo SATO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 11, 1970)

Proton spin-lattice relaxation measurements were carried out on chloroform in carbon tetrachloride, benzene, pyridine, acetone, and dimethylsulfoxide (DMSO) in order to investigate the effect of the intermolecular interaction on the spin-lattice relaxation time, T_1, of chloroform. It was found that the order of the effects of solvents on T_1 is as follows: DMSO>acetone, pyridine>benzene, carbon tetrachloride; this order corresponds to that of the association constant of chloroform with these solvents. The T_1 values of benzene and acetone were also determined on chloroform-benzene and chloroform-acetone mixtures. On the basis of the results obtained on these solutions together with the results on the T_1 of chloroform in various solvents, we estimated the lifetimes of the chloroform-benzene complex and of the chloroform-acetone hydrogen-bonding complex. We tried to keep the proton-density constant throughout the solutions, in order to avoid an ambiguity arising from its change, by adopting the corresponding deuterated compounds.

Proton magnetic resonance (PMR) relaxation studies are an important and useful tool for the study of the microdynamic behavior of liquids.[1,2] Giulotto, Lanzi, and Tosca[3] studied the hydrogen-bonded molecular clusters of phenol in carbon tetrachloride, and showed that the proton spin-lattice relaxation is sensitive to the molecular clustering. Recently Anderson and Fryer[4] and Anderson[5,6] examined both theoretically and experimentally the effect of molecular association on the rotatory motions of molecules in the liquid state; they concluded that the molecular association moved as a unit whose lifetime is longer than the molecular rotational correlation time, τ_c, (for most molecular liquids, τ_c is of the order of 10^{-11}—10^{-12} sec) should affect the spin-lattice relaxation considerably.

Huntress[7,8] studied the quadrupolar relaxation experiments on chloroform and chloroform-*d* and on equimolar mixtures of chloroform-*d*—benzene and chloroform—benzene-d_6, and calculated the rotational diffusion constants from the relaxation times obtained. Huntress interpreted the change in the reorientation of chloroform molecules between neat and benzene solutions in terms of the formation of a complex between chloroform and benzene. However, Anderson showed that the proton spin-lattice relaxation time, T_1, of benzene in chloroform-*d* is equal to those in benzene-d_6 and in carbon tetrachloride. He concluded that the complex between chloroform and benzene is a weak one and does not move as a unit.

In this paper, we will present the experimental results of our proton spin-lattice relaxation studies of mixtures of chloroform and various proton-acceptor solvents (basic solvents), including a chloroform-benzene mixture, and will discuss the intermolecular association and microdynamic behavior of molecules.

It has been well established that the chloroform proton is active and possesses the ability of forming hydrogen bonding, and various chloroform solutions have been studied extensively by means of various experimental techniques.[9-12] So far, PMR chemical shift measurements[11-17] have often been made on mix-

tures of chloroform and several basic solvents, such as dimethyl sulfoxide (DMSO), acetone, triethylamine, pyridine, acetonitrile, some ethers and ketones, and aromatic solvents. The results have been interpreted in terms of hydrogen-bonding formation or in terms of the formation of a complex between chloroform and solvents, and the association constant has been estimated by means of various procedures.

The greatest advantage of the PMR relaxation study may be its sensitivity to the molecular microdynamic motions and the change in molecular motions due to intra- or intermolecular interactions. We consider that information obtained through T_1 measurements, together with the results of the chemical shift and infrared absorption measurements, should lead us to understand in detail the nature of intermolecular interaction.

We therefore carried out PMR relaxation measurements on the following chloroform solutions: chloroform — chloroform-*d* — carbon tetrachloride, chloroform — chloroform-*d* — benzene-d_6, benzene — benzene-d_6 — chloroform-*d*, chloroform — chloroform-*d* — acetone-d_6, acetone — acetone-d_6 — chloroform-*d*, chloroform — chloroform-*d* — pyridine-d_5, and chloroform — chloroform-*d* — DMSO-d_6. In order to avoid the ambiguity arising from the variation in the proton density, we tried to keep the proton density of the solutions constant by adopting a deuterated analogue.

Experimental

Materials The chloroform and benzene were reagent-grade samples purchased from the Tokyo Kasei Co., Ltd., and were distilled by the usual procedures before use. The acetone and carbon tetrachloride were spectroscopic-grade samples from the Tokyo Kasei Co., Ltd., and were used without further purification. The chloroform-*d*, benzene-d_6, acetone-d_6, DMSO-d_6, and pyridine-d_5 were provided by E, Merck AG, Darmstadt, and were also used without further purification.

The atmospheric oxygen dissolved in the sample was carefully removed by several freeze-pump-thaw cycles in a NMR tube, then, under a vacuum, the sample tube was sealed. After sealing, the sample was used for the experiment immediately.

NMR measurements. The NMR spectrometer used in this study was JNM-C-60H spectrometer of Japan Electron Optics. Lab. operated at 60 MHz. The T_1 measurements were made at 25±1°C by the adiabatic rapid-passage and saturation-recovery methods with sampling. The experimental errors were within ±3%. The chemical shifts were measured by the usual side-band technique, with cyclohexane as the internal standard. The solution viscosities were measured at 25±0.1°C with a Cannon-Ubbelohde viscometer.

In the viscosity measurements, however, deuterated analogues were not used because the isotopic effects of deuterium on the viscosity are considered to be small.

Results and Discussion

The results of the chemical-shift and T_1 measurements of five chloroform solutions are shown in Figs. 1 and 2 respectively.

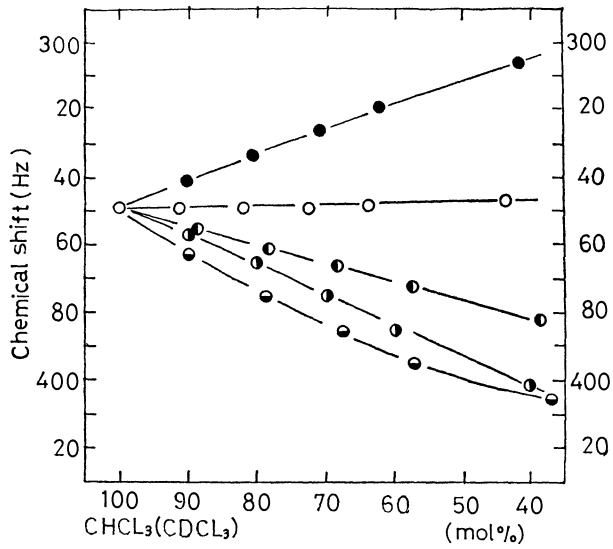

Fig. 1. Plots of chemical shifts of chloroform proton in various solvents *vs.* apparent mole fraction of chloroform.
solvent; benzene-d_6 (●), carbontetrachloride (○), acetone-d_6 (◐), pyridine-d_5 (◑), DMSO-d_6 (◒).
The number of chloroform proton per unit volume is constant; $N=29.8\times10^{20}$.
Apparent mole fraction of chloroform was varied by addition of chloroform-*d*.

solvent; benzene-d_6 (●), carbontetrachloride (○), acetone-d_6 (◐), pyridine-d_5 (◑), DMSO-d_6 (◒).
The number density of chloroform proton is constant; $N=29.8\times10^{20}$.
Apparent mole fraction of chloroform was varied by addition of chloroform-*d*.

Before proceeding to a discussion of each solution, we should like to make several remarks. Strictly speaking, the solutions studied are systems of three components which contain two deuterated analogues. We examined the PMR chemical shift of the chloroform of all solutions in order to test whether or not isotopic effects on the intermolecular interaction between chloroform and basic solvents are negligible.

It is clear from Fig. 1 that the concentration dependence of the chemical shift is almost identical with the literature data.[11-17] Therefore, it may be considered that the isotopic effects on the intermolecular interaction are negligible.

Secondly, we must consider the proton relaxation mechanism of chloroform. Winter[1,18] proposed that, in addition to the dipolar relaxation, the scalar coupling between a proton and chlorine nuclei modulated by the rapid quadrupolar relaxation of the latter may become another relaxation mechanism. On the other hand, Pritchard and Richards[19] proposed that the spin-rotation interaction is another important relaxation mechanism and that the scalar coupling may be unimportant.

In any case, it may be reasonable to assume that the dipolar relaxation mechanism is predominant for the chloroform proton; this assumption is supported by the experimental fact that the T_1 value of the chloroform proton changes from 80 sec for neat chloroform[20] to 120 sec for 40% chloroform in chloroform-*d*. Because the scalar coupling and the spin-rotation mechanisms should not be unchanged by deuterated dilution, this change in T_1 value may be due to the predominant intermolecular dipole-dipole interaction. Moreover, because of the small gyromagnetic ratio, deuteron and chlorine are considered to contribute negligibly to the relaxation of chloroform in this study.

Thirdly, let us consider the effect of the self-association of chloroform.[7,8,21,22] Jumper, Emerson, and Howard,[21] from the PMR chemical shift, estimated the self-association constant of chloroform to be $K=0.16\pm 0.006$ $(\mathrm{m\cdot f})^{-1}$. This value of K is roughly of an order of magnitude smaller than the association constant found for the association of chloroform to basic solvents studied in this paper. Jumper *et al.* found also that, in carbon tetrachloride, the fraction of chloroform participating in the self-association decreases. The T_1 values measured in carbon tetrachloride do not change over the experimental concentration range of chloroform, so we may conclude that the self-association of chloroform is not so strong as to affect the proton spin-lattice relaxation of chloroform in solution. Therefore, the change in T_1 accompanied by dilution with basic solvents may really be due to the effect of intermolecular chloroform-solvent interaction.

Finally, the effect of the macroscopic solution viscosity on T_1 must be considered. According to the Debye-B.P.P. theory,[1,23] the spin-lattice relaxation rate, $1/T_1$, is proportional to the solution viscosity, η. However, it has been well recognized that the B.P.P. theory gives τ_c values of an order of magnitude larger than those estimated from the experiment.[24,25] The proportionality between $1/T_1$ and η is considered to be doubtful. Bull and Jonas[26] studied the pressure dependence of T_1 on benzene and acetone, and showed that the proportionality between $1/T_1$ and η does not hold.

In this study, for example, the η of a carbon tetrachloride solution of chloroform (the mole fraction of chloroform is 40%) is about 1.3 times that of neat chloroform. Nevertheless, T_1 does not change entirely. Therefore, we did not carry out the corrections of the solution viscosity on T_1 in this study.

Now, we should like to turn our attention to the results obtained. It is clear from Fig. 2 that we can classify the solutions studied into three groups. The first group, in which the T_1 values of chloroform are not affected by the presence of solvents, includes chloroform-carbon tetrachloride and chloroform-benzene solutions. Especially, it is interesting that the π-complex between chloroform and benzene does not affect the spin-lattice relaxation of chloroform greatly. Several interpretations of the molecular microdynamics of the π-complex will be shown in the successive discussion in connection with the results of Huntress and Anderson.

The second group, in which T_1 values of chloroform are affected to some extent through the intermolecular interaction with basic solvents, includes chloroform-acetone and chloroform-pyridine solutions. In these solutions, the intermolecular interactions are due to the hydrogen bonds, which is considered to be stronger than the π-complex. Indeed, Abraham[27] pointed out that the complex between chloroform and benzene is essentially similar to other hydrogen bonds; that is, it is essentially electrostatic in character, but because of the weak ionic character of the C–H bond, it is considerably less stable than the more common hydrogen bonds.

The chloroform-DMSO solution is classified in the third group, in which T_1 values of chloroform are affected considerably by the strong intermolecular interaction. In this solution, the spin-lattice relaxation rate of chloroform increases by a factor of about 4 as a result of the presence of a small amount of DMSO. Anderson has also shown that the T_1 value of DMSO protons is affected by the presence of chloroform. Therefore, it may be concluded that the intermolecular interaction between chloroform and DMSO is the strongest, and that the associated species should move as a unit with a lifetime longer than the rotational or translational correlation times of DMSO and chloroform.

The order of the affinity of solvents in associating with chloroform is found to be as follows: DMSO> acetone, pyridine>benzene, carbon tetrachloride. This order corresponds well to that of the association constants between chloroform and solvents described above, obtained through the chemical shift measure-

ment.[11-17] Thus, in addition to the information about the microdynamic molecular motion, the strength of the association can be estimated through PMR relaxation measurements. Moreover, if the rotational or translational correlation times of each component molecule are known, the order of the lifetimes of the association can also be presumed.

Hubbard[28] has derived an equation for the intermolecular relaxation time which takes account of both the rotational and translational molecular motions:

$$(1/T_1)\text{inter} = (\pi\hbar^2\gamma^4 N/10r^3)\tau_t[1 + 0.233\ (b/r)^2 + 0.15(b/r)^4 + \cdots] \quad (1)$$

where N is the number of spins per unit of volume, r is the molecular radius, b is the distance of the nucleus from the center of the molecule, and τ_t is the translational correlation time, and where all other notations represent their ordinary meanings. We assume, as has been described above, that for the chloroform proton the intermolecular dipole-dipole relaxation is predominant over the other relaxation mechanisms within the experimental conditions in this study. Therefore, Eq. (1) is applicable in calculating τ_t of chloroform in solutions. The following values of r and b were used in the calculation: r=2.81 Å, b=1.10 Å. The radius was obtained by assuming hexagonal closed packing, and b was taken to be equal to the C–H bond length.[29]

In Figs. 3 and 4 respectively, the T_1 values of benzene — benzene-d_6 — chloroform-d, and acetone — acetone-d_6 — chloroform-d solutions are shown. The result of T_1 measured in carbon tetrachloride is also shown in Fig. 3. The T_1 values of both benzene and acetone are affected by the presence of chloroform, but not the T_1 of benzene in carbon tetrachloride. These results imply that the molecular motions of

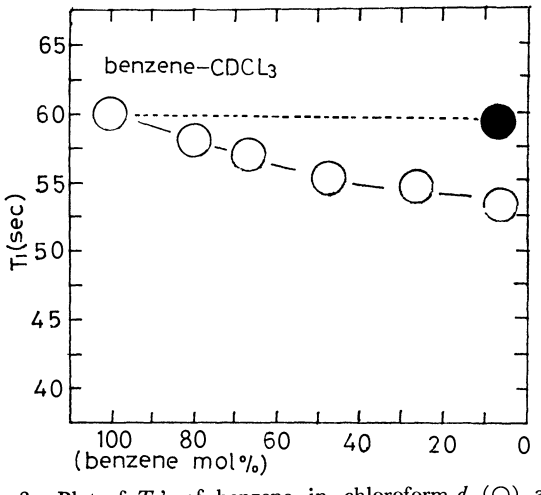

Fig. 3. Plot of T_1's of benzene in chloroform-d (○) and carbontetrachloride (●) *vs.* apparent mole fraction of benzene.
The number density of benzene proton is constant; N= 40.5×10^{20}.
Apparent mole fraction of benzene was varied by addition of benzene-d_6.

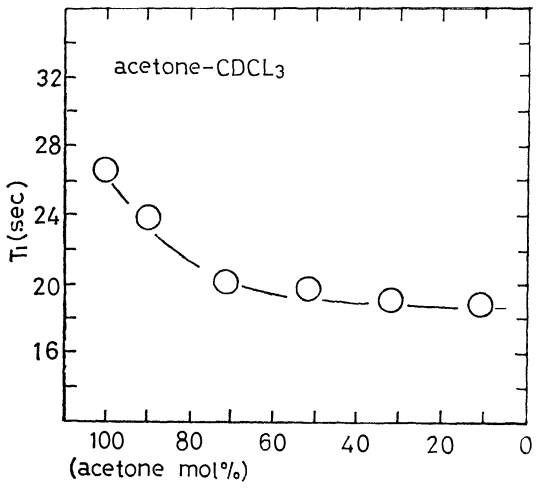

Fig. 4. Plot of T_1's of acetone in chloroform-d *vs.* apparent mole fraction of acetone.

benzene and acetone are influenced to some extent by the intermolecular interaction with chloroform, the former due to the π-complex, and the latter, to the hydrogen bond. These results do not, however, coincide with the those of Anderson. We speculate that this discrepancy may arise from the difference in the experimental temperature (Anderson made his experiment at 35°C).

It is reasonable to assume that the intramolecular dipole-dipole relaxation is predominant for both benzene and acetone protons because of their small fractions in the present study. As will be shown later, this assumption is supported by the fact that the τ_c values of benzene and acetone calculated by this assumption correspond to those of Bonera and Rigamonti.[30,2] We calculate τ_c using the following expression:[1,23]

$$(1/T_1)\text{intra} = 3/2\hbar^2\gamma^4 \sum \langle r_{ij}^{-6}\rangle \cdot \tau_c \quad (2)$$

where r_{ij} is the hydrogen-hydrogen interatomic distance. For benzene and acetone, the values of r_{ij} were taken from Zeidler's work.[31]

Chloroform-Benzene Solution. In Table 1, the (T_1) inter, τ_t of chloroform and the (T_1)intra, τ_c of benzene are shown at various solution compositions. The order of the magnitude of τ_t roughly agrees with Hertz's result[2]: 1.1×10^{-10} sec. The values of (T_1) intra and τ_c in neat benzene also agree with those of Bonera and Rigamonti. It may easily be seen that the translational motion of chloroform is not influenced by the π-complex with benzene, but that the rotational motion of benzene is influenced slightly. On the basis of this experimental fact, we conclude that the π-complex does move as a unit, but that its lifetime is short, probably of the order of 10^{-12} sec. According to the theory of Anderson, it is reasonable to consider

Table 1. The values of (T_1)inter, τ_t (chloroform) and (T_1)intra, τ_c (benzene) of chloroform-benzene solution

Chloroform -benzene mole ratio	Chloroform		Benzene	
	(T_1)inter (sec)	$\tau_t \times 10^{10}$ (sec)	(T_1)intra (sec)	$\tau_c \times 10^{12}$ (sec)
100 : 0	120	2.9		
90 : 10	120	2.9	54	2.1_8
50 : 50	120	2.9	56	2.1_0
0 : 100			60	1.9_6

τ_t and τ_c were calculated by using Eqs. (1) and (2), respectively.

that the association whose lifetime is of the order of 10^{-12} sec does not modulate the molecular motion, the correlation time of which is about 10^{-10} sec. The slight influence on the rotational motion of benzene may be due to the fact that the C_6 rotation (the C_6 axis of benzene coincides with the C_3 axis of chloroform) in the π-complex is almost free. Indeed, Andrew and Eades[32] have found that benzene molecules reorient quite freely about the C_6 axis even in a solid.

The conclusion we proposed above does not conflict with that of Huntress that the tumbling motion of of chloroform is slowed by a factor of 4 by complexing with benzene. That is, the correlation time of the tumbling motion of chloroform is of the order of 10^{-12} sec, sufficiently short to be affected by π-complexing. Anderson has shown experimentally that the intramolecular spin-lattice relaxation of benzene is not affectedgreatly through π-complexing with chloroform at 35°C, and he has suggested that the molecular rotation of benzene about the C_2 axis takes place by large-angle jumps rather than by small diffusive steps. However, in the present study, no such insensibility of the spin-lattice relaxation of benzene to π-complexing was found. It seems necessary to reexamine this problem over a wide range of experimental conditions.

Chloroform-Acetone Solution. In Table 2, the (T_1)inter, τ_t and (T_1)intra, τ_c of chloroform and acetone respectively are shown. The values of (T_1)-intra and τ_c of acetone in neat acetone agree with those of Bonera and Rigamonti. It is clear from the table that both the translational motion of chloroform and the rotational motion of acetone in solution are affected to a certain degree by the intermolecular hydrogen-bonding interaction. Therefore, we may conclude that the hydrogen bond is moderately strong, and that its lifetime is of the order of 10^{-11} sec. One may consider that the association whose lifetime is of the order of 10^{-11} sec should reduce the molecular motion of acetone to a greater extent. According to Debye-B.P.P., τ_c is proportional to the third power of the radius of the molecule. Thus, if the association between chloroform and acetone is rigid and if its lifetime is much longer than the correlation time, the τ_c of acetone in the associated complex may be several times larger than that of acetone in the neat liquid. However, the chloroform-acetone association seems not so rigid as in a single molecule, and the C_3 rotation of the methyl group of acetone in the association is considered to be relatively free. From their line-width measurements Gutowsky and Pake[33] have found that the methyl groups rotate even in solid acetone. Because of these two situations, the τ_c of acetone might not become so large as expected.

Table 2. The values of (T_1)inter, τ_t (chloroform) and (T_1)intra, τ_c (acetone) of chloroform-acetone solutions

Chloroform -acetone mole ratio	Chloroform		acetone	
	(T_1)inter (sec)	$\tau_t \times 10^{10}$ (sec)	(T_1)intra (sec)	$\tau_c \times 10^{12}$ (sec)
100 : 0	120	2.9		
90 : 10	105	3.5	$18._7$	0.9_3
50 : 50	85	4.4	$19._6$	0.9_1
0 : 100			$26._5$	0.6_7

τ_t and τ_c were calculated by using Eqs. (1) and (2), respectively.

We expect that the lifetime of the chloroform-pyridine complex may be of the same order as that of the chloroform-acetone complex, and that the chloroform-DMSO complex may have the longest lifetime of all the solutions studied in this paper. A more detailed consideration of these solutions is possible, the spin-lattice relaxation measurements being made of pyridine and DMSO protons.

The Liquid-phase γ-Radiolysis of Benzene-Nitrous Oxide Mixtures

Shun-ichi HIROKAMI, Seishi SHISHIDO, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama Meguro-ku, Tokyo

(Received December 12, 1970)

The γ-radiolysis of the benzene-nitrous oxide liquid mixtures has been studied at room temperature and at 0°C, the mixing ratios covering almost all the range from pure benzene to pure nitrous oxide. Phenol was found to be one of the main products; its G-value is about a half of that of nitrogen at the lower concentration of nitrous oxide. Kinetic analysis shows that the G-values of electrons from benzene are 3.2 ± 0.2. An empirical equation for expressing the G-value of nitrogen from the benzene solution of nitrous oxide proposed by Hentz and Sherman (*J. Phys. Chem.*, **73**, 2676 (1969).) was examined. The agreement was very poor at higher concentrations of nitrous oxide. Possible reasons were discussed.

In recent years there has been much interest in the formulation of quantitative descriptions of the non-homogeneous kinetics of charge scavenging in the liquid-phase radiolysis.[1-4] Warman, Asmus, and Schuler proposed an empirical equation for the charge scavenging and adduced much experimental evidence for the validity of this equation, especially in connection with the radiolysis of cyclohexane:[5]

$$G_s = G_{fi} + G_{gi}\frac{\sqrt{\alpha S}}{1+\sqrt{\alpha S}} \qquad \text{(I)}$$

Here, G_s is the 100 eV yield of electrons or cations scavenged by an additive, the molarity of which is denoted by S. G_{fi} is the yield of free ion pairs; *i.e.*, these pairs escape from their mutual Coulombic field. G_{gi} is the yield of geminate-ion pairs, which are restrained in their mutual Coulombic field. The α parameter can be considered to be proportional to the specific rate of the charge-scavenging reaction. When nitrous oxide is used as an electron scavenger and when the G-value of nitrogen from the solution is used as a measure of the electron scavenging, Eq. (I) has to be modified, because the production of nitrogen from a hydrocarbon solution is believed to consist of two steps.[6] Hentz and Sherman discussed four possible mechanisms for the formation of nitrogen in a benzene solution.[7] The mechanism they preferred was the following:

$$e^- + N_2O \rightarrow N_2O^- \qquad (1)$$

$$N_2O^- + C_6H_6 \rightarrow N_2 + C_6H_6O^- \qquad (2)$$

$$C_6H_6O^- + N_2O \rightarrow N_2 + \text{residue} \qquad (3)$$

In any mechanism, however, the formation of nitrogen has two origins, such as the reactions (2) and (3), both of which complete with neutralization. Therefore, if we use Eq. (I) as an analogy, the empirical equation for $G(N_2)$ should have the following form:

$$G(N_2) = 2G_{fi} + G_{gi}\frac{\sqrt{\alpha S}}{1+\sqrt{\alpha S}}\left(1+\frac{\sqrt{\beta S}}{1+\sqrt{\beta S}}\right) \qquad \text{(II)}$$

Here, G_{fi}, G_{gi}, and S have the same meanings as in Eq. (I). The β parameter is for the reaction (3), the analog of α in the reaction (1). Hentz and Sherman used this equation to analyze their experimental results on the radiolysis of the benzene solution of nitrous oxide and thus estimated the values of G_{gi}, α, and β.

When comparing the radiolyses of cyclohexane and benzene solutions of nitrous oxide, the most remarkable difference observed is in the G-value of nitrogen; the $G(N_2)$ from the cyclohexane solution is more than twice that from the benzene solution at the same concentrations of nitrous oxide up to 0.5 mol/l.[8] A possible explanation of this is that the G-value of the electrons from benzene might be much smaller than that of those from cyclohexane. However, this is not likely because the W-values of these two compounds in the gas phase are believed to be not very different. Another explanation is that the ratio between the rate of the recombination reaction of geminate-ion pairs and the rate of the electron-scavenging reaction of nitrous oxide is much larger in benzene than in cyclohexane. If this is the case, the $G(N_2)$ from the benzene solution should approach the value obtained from the cyclohexane solution with an increase in the concentration of nitrous oxide to more than 0.5 mol/l.

Experimental

Tokyo Pure Chemical Co. benzene (spectro grade) was used as supplied. Since the G-values of the hydrogen (0.04) and biphenyl (0.08) were in good agreement with the reported values, further purification was not made. Nitrous oxide (Matheson Co. pure grade) was distilled bulb-to-bulb, and the head and tail fractions were rejected.

All the mixtures were sealed into small sampling glass tubes (about 3 ml) with a breakable seal attached. The amount of benzene was measured by a small pippet or a micro syringe, and that of nitrous oxide, volumetrically. The nitrous oxide concentrations at room temperature were calculated by using the Ostwald solubility coefficient of 3.8. At this temperature, more than 4 mol/l could not be attained because of the fragility of the breakable seal. At 0°C, however, almost all the mixing ratios could be obtained. At concentrations lower than 0.2 mol/l, the solution was crystallized. Several runs were made at the temperature of a dry

ice-methanol mixture. In this case, solid benzene floated in the liquid nitrous oxide.

Samples were irradiated at their respective temperatures by ^{60}Co γ rays with a dose rate of 0.88×10^6 R/hr, usually for 4 hr. To analyze the gases noncondensable at the liquid-nitrogen temperature, the irradiated sample tubes were used to a conventional vacuum line, and after had been broken the seal, the gas in the two liquid nitrogen traps was collected by a Toepler pump and placed in a gas buret connected to a cuprous oxide furnace in order to combust the trace of hydrogen produced. In order to analyze the products in the solution, the seal was broken in the atmosphere, and a micro syringe was used to inject a small amount of the solution into the gas chromatographs (a 1-m dioctyl-phthalate column at 130°C and a 0.5-m alkyl-benzene-sulfonic-acid-sodium-salt column at 125°C). The quantitative estimation was made by comparing the peak areas with those of the prepared solutions. To ascertain the formation of phenol, a Millon reagent was also used. The yield calculated from the absorbance at 400 nm was in fair agreement with that estimated by gas chromatography.

Results

Tables 1 and 2 summarize the results obtained at room temperature. The G-value of nitrogen increased with the increase in the concentration of nitrous oxide, reached 6.74 at the highest concentration examined, and still showed a tendency to increase. The yields of phenol and biphenyl also increased with the increase in the nitrous-oxide concentration, but the yield of an unspecified product (probably hydrogenated biphenyl) stayed constant.

The results obtained at 0°C are summarized in Tables 3 and 4. In these cases, the concentration was expressed by the mole fraction, because the liquid volume was substantially affected by the amount of nitrous oxide.

Table 1. G-Value of nitrogen from the γ-radiolysis of benzene solution of nitrous oxide at room temperature[a)]

N_2O mol/l	$G(N_2)$	N_2O mol/l	$G(N_2)$
0.118	1.37	1.30	4.30
0.119	1.26	1.37	4.41
0.203	1.87	1.54	4.82
0.313	2.16	1.70	4.95
0.615	3.16	1.81	5.01
0.965	3.70	2.01	5.00
1.01	3.92	3.04	6.06
1.27	4.28	4.64	6.74

a) Within experimental error, the G-values of nitrogen coincide with the following relation. $G(N_2)=3.78\sqrt{[N_2O]}$.

Table 2. G-Values of phenol, biphenyl, and unspecified products[a)] from the γ-radiolysis of benzene solution of nitrous oxide at room temperature

N_2O mol/l	G-Value		
	Phenol	Biphenyl	Unspecified
0	0	0.08	0.06
0.366	1.50	0.51	0.11
0.568	1.48	0.33	0.09

51.3	7.26		

Table 4. G-Values of phenol, biphenyl, and unspecified products from the γ-radiolysis of benzene-nitrous oxide liquid mixtures at 0°C

N_2O mol/l	G-Value		
	Phenol	Biphenyl	Unspecified
19.4	2.07	0.40	0.05
21.8	2.30	0.38	0.05
28.8	2.26	0.49	0.04
41.6	2.91	0.55	0.05
45.9	3.01	0.54	0.05
52.3	2.92	0.50	0.03
54.7	3.01	0.48	0.02
61.1	2.94	0.48	0.02
66.9	2.78	0.48	0.02
68.7	2.96	0.48	0.02
70.9	2.96	0.41	0.02

In Fig. 1, the G-values of nitrogen and phenol are plotted as a function of the electron density of nitrous oxide. The G-value of nitrogen obtained at the temperature of dry ice-methanol is also plotted; it shows a linear dependence on the electron density of nitrous oxide.

Discussion

Formation of Phenol. In the study of the gas phase radiolysis of benzene-nitrous oxide mixtures, Rzad and Warman observed a very high yield of phenol formation ($G\sim40$).[9)] They proposed a chain mechanism involving the electron transfer from $C_6H_6O^-$ to nitrous oxide, a mechanism which corresponds

9) S. J. Rzad and J. M. Warman, *J. Phys. Chem.*, **72**, 3013 (1968).

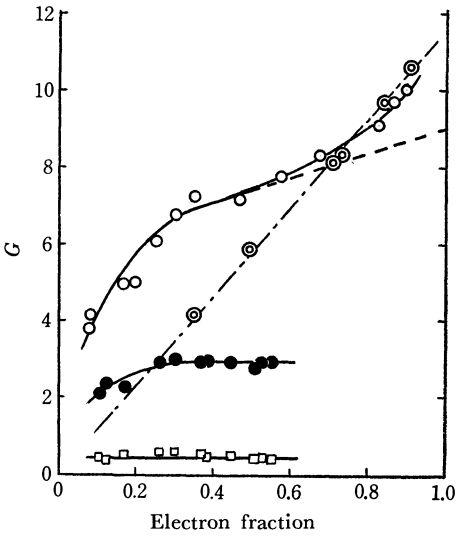

Fig. 1. G-Value of nitrogen (○), phenol (●), and biphenyl (□) obtained at 0°C and G-value of nitrogen (◎) at dry-ice temperature as a function of the electron density of nitrous oxide. Dashed line was tentatively drawn by connecting the G-value of nitrogen at around 0.5 in the electron density with $G_0=9$, which is the average used for the calculation of $g(N_2)$.

to the reaction (3) presented in the Introduction. To explain the present results, the chain mechanism is obviously not necessary. In place of the electron transfer, we tentatively assumed the following reactions:

$$C_6H_6O^- + N_2O \rightarrow N_2 + C_6H_6O_2^- \quad (3)$$

$$C_6H_6O_2^- + C_6H_6^+ \rightarrow C_6H_5OH + C_6H_6O \quad (4)$$

Here, C_6H_6O stands for the intermediate product of the reaction between benzene and an oxygen atom.

Boocock and Cvetanović investigated the reactions of oxygen atoms with benzene in the gas phase, using the mercury photosensitized decomposition of nitrous oxide as the source of oxygen atoms; they found that the yield of phenol formation is very much smaller than that expected from the yield of nitrogen.[10] The ratio in the yield of phenol to nitrogen formation was about 0.06. For the rest of the oxygen atoms, they found that carbon monoxide and polymers were formed. In the present study, carbon monoxide could not be observed. This may be attributed to the fact that the present experiment was performed in a liquid. The intermediate product, C_6H_6O, therefore, probably gives rise to only polymers. In fact, the formation of yellowish-white polymers was observed, though it was not analyzed.

As is shown in Tables 2 and 4, the yield of biphenyl increased with the increase in the concentration of nitrous oxide. This increase may be explained by the following reactions:

$$C_6H_6O^* \rightarrow C_6H_5 + OH \quad (5)$$

$$2\,C_6H_5 \rightarrow C_6H_5\text{-}C_6H_5 \quad (6)$$

Here, the asterisk denotes the excited state which is the precursor of C_6H_6O in the reaction (4).

10) G. Boocock and R. J. Cvetanović, *Can. J. Chem.*, **39**, 2436 (1961).

Formation of Nitrogen. The gas-phase radiolysis of nitrous oxide has been investigated by many groups of investigators, but the mechanism of the formation of nitrogen has not yet been established in detail.[11,12] For the liquid phase, only one report by Robinson and Freeman could be found in the literature.[13] According to their tentative reaction mechanism, the G-value of ionization is 3.0, and that of excitation, which results in the decomposition into N_2 and O, is 6.4. Our present results are compatible with their mechanism. As may be seen in Fig. 1, when the electron fraction of nitrous oxide is in the range from 0.6 to 0.9, the G-values of nitrogen obtained at 0°C are a little smaller than those obtained at the dry-ice temperature. At this temperature, benzene and nitrous oxide probably decompose independently, because the system is not homogeneous. The deviation of $G(N_2)$ from the linearity obtained at the dry-ice temperature may be explained by the charge-transfer reaction from N_2O^+ to benzene. The ionization potential of nitrous oxide in the gas phase has been reported to be 12.9 eV, and that of benzene, to be 9.5 eV. This type of charge transfer may be completed at electron densities down to 0.6 in Fig. 1. If this reasoning is correct, the formation of nitrogen below 0.6 in the electron density of nitrous oxide should be explained by the following two types of reactions. One is the reaction initiated by the electron scavenging of nitrous oxide, which has already been discussed in the Introduction; the other is the non-ionic reaction of nitrous oxide, which may be described as follows:

$$N_2O \rightsquigarrow N_2 + O \quad (7)$$

The oxygen atoms produced in this reaction may react with benzene and produce a polymer, as has been discussed. This mechanism matches the observation that the G-value of phenol becomes saturated as the concentration of nitrous oxide increases, while in the same range of nitrous oxide concentration the G-value of nitrogen still has a tendency to increase.

Another possible non-ionic reaction forming nitrogen is the benzene sensitized decomposition of nitrous oxide. In this respect, we have recently examined the benzene-photosensitized decomposition of nitrous oxide in a cyclohexane solution. The light source used was a low-pressure mercury lamp. The quantum yield of the decomposition was very small (about 0.005). This result does not necessarily mean that the benzene-sensitized decomposition is negligibly small in the radiolysis, because highly excited states of benzene, which may be formed in the radiolysis but not in the photolysis, might play a role in the decomposition of nitrous oxide. This possibility, therefore, cannot be completely ruled out by the present experiment.

Nitrogen Resulting from the Electron Scavenging of Nitrous Oxide. In order to apply the empirical equation

13) M. G. Robinson and G. R. Freeman, *J. Phys. Chem.*, **72**, 1394 (1968).

(II) to the present data, we have to discriminate the G-value of the nitrogen produced by the electron scavenging from the value of that produced by other processes. A tentative calculation has been made by using the following relation:

$$G(N_2) = \varepsilon_B g(N_2) + \varepsilon_{N_2O} G_0$$

Here, $g(N_2)$ is the G-value of nitrogen resulting from the reaction initiated by the energy absorbed by benzene, and G_0 is the G-value of nitrogen from pure liquid nitrous oxide, excluding the contribution of N_2O^+. ε_B and ε_{N_2O} are the electron densities of benzene and nitrous oxide respectively. As the value of G_0, we had to take a wide range of values, from 8 to 10, because of the inaccuracy of the data, as is shown in Fig. 1. However, the calculated $g(N_2)$ values were not so scattered, as is shown in Fig. 2. The asymptotic value obtained at high concentrations of nitrous oxide ranges from 6.2 to 6.8. If the contribution from the benzene-sensitized decomposition can be disregarded, this value should be equal to twice that of the G-value of the electrons from benzene.

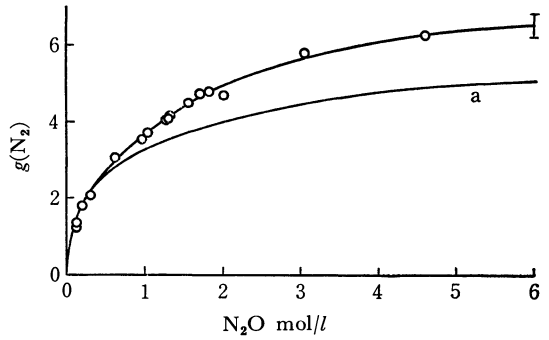

Fig. 2. G-Value of nitrogen formation initiated by the energy absorbed by benzene at room temperature as a function of the concentration of nitrous oxide. The curve a) is drawn by using Eq. (II).

The curve a) in Fig. 2 was drawn by using Eq. (II), with $G_{gi}=3.9$, $\alpha=0.7$ l/mol, and $\beta/\alpha=50$, according to the method of Hentz and Sherman.[7] The agreement was obviously very poor. We tried various combinations of the values for G_{gi}, α, and β, but as long as Eq. (II) was used, a successful adjustment could not be made. If Eq. (II) correctly expresses the result of the electron scavenging of nitrous oxide, the disagreement might be due to a neglect of the benzene-sensitized decomposition of nitrous oxide. However, the G-value of electrons estimated above, 3.2 ± 0.2, is a little smaller than that to be expected from the W-value of benzene in the gas phase ($\sim$25 eV); *i.e.*, as far as the G-value of nitrogen is concerned, it is not necessary to take the contribution of the benzene-sensitized decomposition of nitrous oxide into account.

In connection with the G-value of electrons from benzene, the G-value of phenol at 0°C is suggestive; it does not exceed 3, even at the highest concentration of nitrous oxide examined. If the mechanism of the formation of phenol is that proposed above, the G-value of phenol should be nearly equal to that of the electrons scavenged by nitrous oxide. This, however, is not conclusive, either, because of the uncertainty of the reaction mechanism.

Although the validity of Eq. (I) is evidenced by many experimental results,[14] this equation itself has shortcomings when it is applied to higher concentrations of scavengers; experimentally, the value of $[S]$ cannot exceed that of the pure state, which is usually less than 10 mol/l for most of the solutes. Therefore, since α is 0.7 l/mol in the case of benzene, the $\sqrt{\alpha S}(1+\sqrt{\alpha S})^{-1}$ fraction is less than 0.8. Even in the case of $\alpha=16$ l/mol, which has been reported in the study of the electron scavenging of methyl bromide in the radiolysis of cyclohexane[2], the above fraction is 0.93. In other words, the G_{gi} estimated by using Eq. (I) or (II) can never be observed experimentally.

In the formulation of the non-homogeneous kinetics of charge scavenging, it is usually assumed, for the convenience of the theoretical treatment, that only one ion pair exists in a spur. Even Eq. (I) is based on the same assumption, though it is very empirical.[4] However, it is well known that the formation of multi-ion pairs in a spur is not negligibly small.[15] Therefore, when a high concentration of scavenger is used, the contribution of such ion pairs cannot be ignored. The large deviation of the experimental data from the empirical equation shown in Fig. 2 might be due to such a neglect. For a complete interpretation, further investigation is obviously desired.

Test for Validity of Constant Ionic Medium Principle. Variation of the Activity Coefficient of Hydrogen Ion in Various Compositions of Medium Cations with 3 M Perchlorate Ions

Hitoshi OHTAKI and Georg BIEDERMANN*

Department of Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

* *Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm, Sweden*

(Received December 15, 1970)

Potential changes of cells with a glass electrode and a hydrogen electrode in combination with a reference half-cell were measured in solutions of various compositions of cations at constant concentrations of hydrogen and total perchlorate ions. Measurements were carried out for the systems $LiClO_4$-$NaClO_4$, $LiClO_4$-$AgClO_4$, $NaClO_4$-$AgClO_4$, $NaClO_4$-$TlClO_4$, $LiClO_4$-$Mg(ClO_4)_2$, $LiClO_4$-$Ba(ClO_4)_2$, $NaClO_4$-$Ba(ClO_4)_2$, $AgClO_4$-$Ba(ClO_4)_2$, and $LiClO_4$-$La(ClO_4)_3$. In some cases a remarkable potential change was observed. Part of the change was due to the variation of the liquid junction potential at the interface of a test solution and a solution in a salt bridge. However, the change was attributed in greater part to the electrostatic free energy change of the transfer of hydrogen ion from a ($3/m$ M A^{m+}, 3M ClO_4^-) solution to a (xM A^{m+}, yM B^{n+}, 3M ClO_4^-) solution (where $mx+ny=3$). Variation of the composition of electrolytes gives rise to a significant change of the dielectric constant of a solution, so that the activity coefficient of hydrogen ions varies in different solutions at a constant concentration of perchlorate ions. Potential changes are additive in $A_1(ClO_4)_{m_1}$-$B_1(ClO_4)_{n_1}$, $A_1(ClO_4)_{m_1}$-$B_2(ClO_4)_{n_2}$ and $B_2(ClO_4)_{n_2}$-$B_1(ClO_4)_{n_1}$ solutions for a given replacement of cations in solutions, where A_1, B_1, and B_2 denote cations with charges of m_1, n_1, and n_2, respectively.

When we apply the constant ionic medium principle to reactions in electrolyte solutions, it is essential to choose what variable must be kept constant in the course of the reactions. Often the formal ionic strength is taken as the variable. Sometimes the total equivalent concentration of all ions is chosen, and sometimes the concentration of "inert" cation or anions. A historical review on the application of ionic media and merits of the use of the high concentration of medium salts have been described by Biedermann and Sillén.[1] The assumption of constant ionic activities in a constant ionic medium, however, has not been rigorously tested. The present study was undertaken to examine this by testing the validity of the ionic medium principle by means of emf measurements of cells containing solutions in which concentrations of perchlorate and hydrogen ions were kept constantant and those of "inert" cations were varied.

Experimental

Reagents. All reagents used were prepared from relevant carbonates or oxides and perchloric acid. They have been used for studies of hydrolytic reactions of metal ions in the Laboratory of Inorganic Chemistry of the Royal Institute of Technology, Stockholm.

Apparatus. *Glass electrodes*: Beckman glass electrodes (No. 40498) were used.

Hydrogen electrodes were prepared by the method described by Bates.[2] Emf values obtained were corrected to those at one atmospheric pressure.[3]

Silver chloride electrodes were prepared by Brown's method.[4]

The "Wilhelm" type of half-cell described by Forsling, Hietanen, and Sillén[5] was used as the reference half-cell.

A Leeds and Northrup Type K-3 Universal Potentiometer for measurements with hydrogen electrodes and *a Radiometer PHM 4 pH Meter* with glass electrodes were used. Emf's were read to 0.01 mV with the former and 0.1 mV with the latter.

A Coulometric Analyzer (Leeds and Northrup Co., Philadelphia) was used for coulometric reduction of hydrogen ions.

Hydrogen gas, free from oxygen and carbon dioxide, was preequilibrated with a solution of 3 M perchlorate and was then introduced into a hydrogen electrode. A titration vessel was filled with nitrogen gas, free from carbon dioxide and preequilibrated with a 3 M perchlorate solution, instead of hydrogen gas when we used only glass electrodes for measurements. No essential difference has been found in results obtained with hydrogen and glass electrodes.

Procedure for Potentiometric Measurements. All potentiometric measurements were performed at 25.00±0.01°C in a paraffin oil thermostat which was placed in a room thermostated at 25±2°C. In the course of emf measurements the total concentration of perchlorate ion was kept constant at 3 M. The hydrogen ion concentration was also kept constant at 0.01 M except in the case of $NaClO_4$-$TlClO_4$ solutions in which the total concentration of perchlorate ion was 3 M but the concentrations of hydrogen ion were 0.01 and 0.1 M.

The titration procedure was as follows: Into a solution S_1 titrant S_2 was added. The composition of S_1 was ($3-0.01$)/m M A^{m+}, 0.01 M H^+, 3 M ClO_4^-, and that of S_2 was ($3-0.01$)/n M B^{n+}, 0.01 M H^+, 3 M ClO_4^-. All metal ions used were not hydrolyzed in such acid solutions. Titration was performed up to a point where A^{m+} ions of more than half of the total equivalent were replaced with B^{n+} ions, and then the reverse titration, *i.e.*, titration of the S_2 solution with the S_1 solution was carried out with the same set of electrodes. Data obtained with these two titrations were combined by the use of data in the overlapped region.

$$|x\text{M } A^{m+},\ y\text{M } B^{n+},\ 0.01000\text{ M } H^+,\ 3.000\text{ M } ClO_4^-|$$
$$(mx + ny + 0.01 = 3) \qquad (C)$$

and Ref denotes the reference half-cell

$$\text{Ag-AgCl}|(3-0.01)/m\text{ M } A(ClO_4)_m,$$
$$0.01\text{ M } AgClO_4|3/m\text{ M } A(ClO_4)_m| \qquad (D)$$

The value of the emf measured, E, may be given by the following equation at 25°C;

$$E = E^\circ + \frac{RT}{F}\ln a_H + E_j$$
$$= E^\circ + 59.15\log[H^+] + 59.15\log f_H + E_j(H, A, B) \qquad (1)$$

where E° is a constant and a_H and f_H denote the activity and the activity coefficient of hydrogen ion, respectively. E_j represents the liquid junction potential at the junction

$$3/m\text{ M } A(ClO_4)_m|\text{Solution} \qquad (E)$$

which is a function of concentrations of H^+, A^{m+}, and B^{n+} at the 3 M perchlorate ions, the junction potential at the junction, $(3-0.01)/m$ M $A(ClO_4)_m$, 0.01 M $AgClO_4/3/m$ M $A(ClO_4)_m$, in the salt bridge in the reference half-cell being assumed constant during the emf measurements.

Equation (1) can be rewritten as

$$E - 59.15\log[H^+] = E^\circ + 59.15\log f_H + E_j(H, A, B) \qquad (2)$$

Since E° is a constant ΔE, the difference of $E-59.15\log[H^+]$ values in a solution, $(3-0.01)/m$ M A^{m+}, 0.01 M H^+, 3 M ClO_4^-, and in a solution, xM A^{m+}, yM B^{n+}, 0.01 M H^+, $(mx+ny+0.01=3)$, depends on the variation of f_H and E_j with the composition of cations in a solution at the constnat perchlorate and hydrogen ion concentrations.

Results and Discussion

Variation of potentials with compositions of electrolytes in a solution can be given by

$$\Delta E = \frac{RT}{F}\Delta\ln f_H + \Delta E_j$$
$$= 59.15\Delta\log f_H + \Delta E_j(H, A, B) \qquad (3)$$

where $\Delta\log f_H$ and ΔE_j represent differences of $\log f_H$ and E_j, respectively, in solutions, $(3-0.01)/m$ M A^{m+}, 0.01 M H^+, 3 M ClO_4^- and xM A^{m+}, yM B^{n+}, 0.01 M H^+, 3 M ClO_4^- $(mx+ny+0.01=3)$. Values of ΔE were determined in nine sets of various combinations of $A(ClO_4)_m$ and $B(ClO_4)_n$. Results are graphically shown in Figs. 1 and 2.

Each ΔE could be expressed by an approximate linear function of $[B^{n+}]$, but in some cases in which ΔE varies markedly, it could be better described with a quadratic function of $[B^{n+}]$ than a linear function. Equations for variations of ΔE as a function of $[B^{n+}]$ in various systems of $A(ClO_4)_m$-$B(ClO_4)_n$ are summarized in Table 1. Solid lines in Figs. 1 and 2 show curves drawn on the basis of equations for ΔE in Table 1.

Liquid junction potentials have been determined in some solutions containing 3 M perchlorate as ionic media. In 3 M $LiClO_4$ solution, E_j has been evaluated as $-16[H^+]$ mV/M[6] and in 3 M $NaClO_4$, $E_j = -16[H^+]$ mV/M[1] or $-17[H^+]$ mV/M.[7] When the concentration of hydrogen ion increases, a quadratic function with respect to the hydrogen ion concentration may be more adequate to describe the variation of

$LiClO_4$-$NaClO_4$	$\Delta E=-6.8[Na^+]+0.2[Na^+]^2$	−6.6
$NaClO_4$-$TlClO_4$	$\Delta E=-7[Tl^+]$ $([Tl^+]\leq 0.1M]$	−7

E_j.[1] About −0.2 mV may be estimated for the liquid junction potential caused by the diffusion of hydrogen ions at the junction (E), which is in the same order of magnitude with the experimental uncertainty of a measurement with a pH meter.

Correction of the junction potential caused by migration of hydrogen ions in solutions were examined in the following way. From a solution containing 3 M $LiClO_4$ and a trace amount of hydrogen ions, the hydrogen ions were removed coulometrically and values of $E-59.15\log[H^+]$ were extrapolated to $[H^+]=0$.[8] The value obtained by extrapolation is denoted as E', which may be given by

$$E' = E^\circ + 59.15\log f_H + E_j(\mathrm{Li}, 0) \quad (4)$$

Since E' was determined in a solution in which concentrations of hydrogen and sodium ions ($Na^+=B^{n+}$ in this case) were zero, E_j is denoted as $E_j(0, \mathrm{Li}, 0)$ or simply $E_j(\mathrm{Li}, 0)$ as in Eq. (4). The composition of electrolytes in the solution was then changed by the addition of the solution S_2 (only a trace amount of hydrogen ions was contained without removing electrodes from the solution, and the value of E'

$$E' = E^\circ + 59.15\log f_H + E_j(\mathrm{Li}, \mathrm{Na}) \quad (5)$$

was determined with the same procedure as before. The current passed in the course of coulometric titrations was so small that variation of composition of the solution by electrolysis was negligible, $\Delta E'$, the difference of E' values in 3 M $LiClO_4$ and in 3 M $(Li^+, Na^+)ClO_4^-$ solutions, differed from ΔE by only negligible amounts in the whole range of compositions of solutions, as seen in Fig. 3.

Different mobilities of lithium and sodium ions give rise to a liquid junction potential, $E_j(\mathrm{Li}, \mathrm{Na})$ at the junction (E). The liquid junction potential may be estimated by Henderson's equation,[9] which can be simplified as[1]

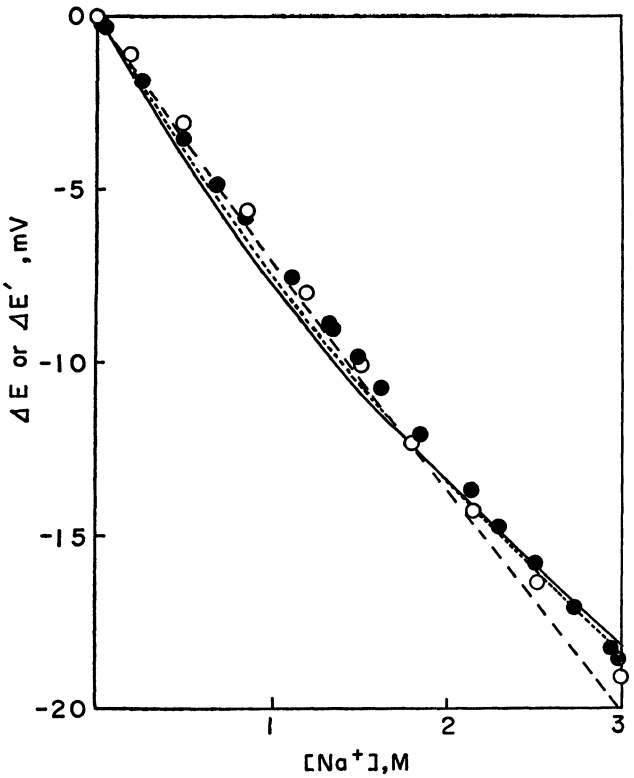

Fig. 3. Relationship between ΔE (●) or $\Delta E'$ (○) and $[Na^+]$. ----, calculated ΔE values by the use of Eq. (13); —— calculated ΔE values by the use of Eq. (13); calculated ΔE_{corr} values by the use of (16) with $r_H=7.0$Å and $\delta_{ClO_4}=-9.0$; ···, calculated ΔE_{corr} by Eq. (16) with $r_H=4.0$Å and $\delta_{ClO_4}=-6.7$.

$$E_j(\mathrm{A}, \mathrm{B}) = -59.15\log\left(1 + \frac{n d_{B(A)}[B^{n+}]}{3}\right) \quad (6)$$

in 3 equiv./l perchlorate solutions, where $d_{B(A)}$ denotes

$$d_{B(A)} = \frac{\Lambda_{B(ClO_4)_n} - \Lambda_{A(ClO_4)_m}}{\Lambda_{A(ClO_4)_m}} \quad (7)$$

and Λ represents the equivalent conductivity of the relevant electrolyte.

Equation (6) may be approximated as

$$E_i(\mathrm{A}, \mathrm{B}) \simeq -19.72 n d_{B(A)}[B^{n+}] \quad (8)$$

The value of $d_{B(A)}$ in a 3 M $(Li^+, Na^+)ClO_4^-$ solution may be evaluated from data of Λ in 3 M $LiClO_4$ and in 3 M $NaClO_4$. It can be estimated from data

$$-19.72 d_{H(Li)} \simeq -16^{6)} \text{ or } d_{H(Li)} = 0.81 \quad (9)$$

and

$$-19.72 d_{H(Na)} \simeq -17^{7)} \text{ or } d_{H(Na)} = 0.86 \quad (10)$$

Since $d_{Na(Li)}$ is derived from Eqs. (9) and (10) as

$$d_{Na(Li)} = \frac{\Lambda_{NaClO_4} - \Lambda_{LiClO_4}}{\Lambda_{LiClO_4}} = \frac{d_{H(Li)}+1}{d_{H(Na)}+1} - 1 = -0.027 \quad (11)$$

provided that Λ_{HClO_4} remains unchanged in 3 M $LiClO_4$ and 3 M $NaClO_4$ solutions, the liquid junction potential, $E_j(\mathrm{Li}, \mathrm{Na})$ is obtained as

$$E_j(\mathrm{Li}, \mathrm{Na}) = -19.72 d_{Na(Li)}[Na^+] = 0.53[Na^+] \quad (12)$$

Thus, ΔE values obtained experimentally may be corrected by the liquid junction potential $E_j(\mathrm{Li}, \mathrm{Na})$:

8) G. Gran, *Analyst*, **77**, 661 (1952).
9) P. Henderson, *Z. phys. Chem.* (Leipzig), **59**, 118 (1907); *ibid.*, **63**, 325 (1908).

$$\Delta E_{corr} = 59.15\Delta \log f_H = \Delta E - E_j(\mathrm{Li, Na})$$
$$\simeq -7.3[\mathrm{Na^+}] \quad (13)$$

Calculation of Eq. (8) may be oversimplified with neglection of higher terms of $[B^{n+}]$ and, therefore, the term with $[Na^+]^2$ is dropped in Eq. (13). The value -17 in Eq. (10) for E_j(H, Na) may be the upper limit of the $-19.72d_{H(Na)}$ value, so that ΔE_{corr} estimated by Eq. (13) may give the lower limit of ΔE_{corr}. Since no essential difference has been observed in the measurements with hydrogen and glass electrodes, the sodium effect on glass electrodes is negligible. In Fig. 3 values of ΔE_{corr} calculated by Eq. (13) are plotted by a broken line.

Liquid junction potentials have not been determined in other solutions but it can be expected that the liquid junction potentials may not be so large that the contribution of the variation of the potentials to ΔE values becomes significant, because most ions have similar equivalent conductivities in aqueous solutions except for hydrogen and hydroxyl ions. Thus, it is concluded that the change of the activity coefficient of hydrogen ion is attributed to ΔE with varying compositions of electrolytes in solutions.

Reactions of hydrogen ions with metal ions and perchlorate ions are denied from the fact that no association and hydrolytic reactions have been observed in these solutions. Association of lithium or sodium ions with perchlorate ions has not been detected in 3 M solutions. If no association reaction occurs in lithium perchlorate-sodium perchlorate solutions, variation of the activity coefficient of hydrogen ions may be caused by the free energy change of transfer of hydrogen ions from a 3 M $LiClO_4$ solution to a $LiClO_4$-$NaClO_4$ mixture.

According to Hasted, Ritson, and Collie,[10] the dielectric constant of a solution decreases with increasing concentration of an electrolyte. The variation of the dielectric constant is proportional to the concentration of an electrolyte and the contributions of a cation and an anion, δ, to the variation are additive.

$$\varepsilon = \varepsilon_0 + (\delta_c + \delta_a)C \quad (14)$$

where ε and ε_0 represent dielectric constants of a solution and the pure solvent, respectively, and C the molar concentration of an electrolyte, and values of δ are evaluated to be -11 ± 1 for Li^+ and -8 ± 1 for Na^+. However, no value has been given for δ_{ClO_4}. Equation (14) holds for solutions containing about 2—2.5 equiv./l cations and anions, and its application to 3 M solutions should not give rise to serious error making the following discussion worthless. Free energy changes of transfer of ions from one solution to another may be calculated by the simple Born's equation or, more adequately, by other equations with more realistic models of hydrated ions.[11,12] Stokes[11] has calculated hydration energies of various ions with models of hydrated ions taking into consideration the dielectric saturation effect of water in hydration shells. Ohtaki[13] has modified Stokes' model and applied it to hydrated hydronium ion in order to interprete variation of dissociation constants of acids in mixed solvents. Ohtaki assumed a "naked" hydronium ion having an ionic radius of 1.4 Å, the ion being surrounded by the first and the second hydration shells each with thickness of 2.8 Å. In the following considerations, a simple approximation is applicable where the dielectric constants in the first and second hydration shells of a hydronium ion in 3 M $LiClO_4$ solution are the same as those in 3 M $NaClO_4$ and 3 M (Li^+, Na^+)-ClO_4^- mixtures, and dielectric constants of bulk solutions are given by Eq. (14). With these approximations the electrostatic free energy changes of transfer of 1 mol of hydronium ion from 3 M $LiClO_4$ to a 3 M (Li^+, Na^+)ClO_4^- mixture can be given by

$$\mu_H^\circ(m) - \mu_H^\circ(s) = \boldsymbol{R}T\{\ln f_H(m) - \ln f_H(s)\} = \boldsymbol{R}T\Delta \ln f_H$$
$$= \frac{Ne^2}{2r_H}\left(\frac{1}{\varepsilon(m)} - \frac{1}{\varepsilon(s)}\right) \quad (15)$$

where μ_H^0 denotes the standard chemical potential of the hydronium ion and m and s in parentheses represent quantities in a 3 M (Li^+, Na^+) ClO_4^- mixture and 3 M $LiClO_4$, respectively as follows. Since ΔE_{corr} is given by $\boldsymbol{R}T\boldsymbol{F}^{-1}\Delta \ln f_H$, ΔE_{corr} can be represented

$$\Delta E_{corr} = \frac{Ne^2}{2\boldsymbol{F}r_H}\left(\frac{1}{\varepsilon(m)} - \frac{1}{\varepsilon(s)}\right) \quad (16)$$

$$\left.\begin{aligned} &\text{and} \quad \varepsilon(s) = \varepsilon_0 + 3(\delta_{Li} + \delta_{ClO_4}) \\ &\varepsilon(m) = \varepsilon_0 + x\delta_{Li} + y\delta_{Na} + 3\delta_{ClO_4} \quad (x+y=3) \end{aligned}\right\} \quad (17)$$

If we assume that the radius of the hydrated hydronium ion is 7.0 Å (1.4 Å for the naked hydronium ion and 2.8 Å for each hydration shell), satisfactory agreements were found between ΔE_{corr} (or even ΔE) values observed and calculated using Eq. (16) when we choose $\delta_{ClO_4} = -9$. Values of ΔE_{corr} in mV unit thus calculated were plotted by a solid line in Fig. 3. Application of the Hepler's model[12] gave similar results (shown by a dotted line in Fig. 3) with $r_H = 4$ Å and $\delta_{ClO_4} = -6.7$. $r_H = 7$ Å may be a better assumption than $r = 4$ Å in these calculations because Hasted *et al.*[10] estimated the minimum hydration number of 10 for a proton in their treatment and these hydrated water molecules may possibly be included in the first and second hydration shells.[14] The value $\delta_{ClO_4} = -9$ assumed in calculations with Stokes' model seems to be reasonable in comparison with values of $\delta_{Cl} = -3$, $\delta_I = -7$ and $\delta_{OH} = -13$, and the results show that electrostatic free energy changes caused by the variation of bulk dielectric constants of solutions may play the most important role in variation of the activity coefficient of hydrogen ions.

For magnesium, barium, and lanthanum ions, values of δ have been found to be -24, -22, and -35, respectively.[10] Application of the above arguments to (A^+, B^{n+})ClO_4^- solutions leads to the following conclusions. Replacement of lithium ions with corresponding equivalent quantities of these ions contributes to variation of dielectric constants of solu-

tions to a less extent than that with sodium ions. In Li^+–La^{3+} mixtures, the potential variation may be fairly small and in Na^+–Ba^{2+} solutions ΔE varies in the opposite direction with that found in Li^+–Na^+ solutions. Variation of ΔE in Li^+–Ba^{2+} and Li^+–Mg^{2+} solutions may be smaller than that in Li^+–Na^+ solutions.

Experimental results support these considerations. Thus, it can be said that the main part of the variation of potentials measured in this study is interpreted in terms of electrostatic free energy changes of transfer of hydrogen ions from one salt medium to another, the main factor of the variation being caused by the change of the bulk dielectric constant of solutions with varying compositions of medium salts.

This conclusion is supported by the fact that the variation of potential is additive. Potential variations occurring at 1 equivalent-ion replacement of a cation are shown in the last column of Table 1. The equivalent replacement of a highly hydrated cation, such as lithium ion, with strongly hydrated bi- or tervalent cations might be expected to introduce only a small violation of the ionic medium principle of the solution. Replacement of strongly hydrated cations with less hydrated cations, on the other hand, results in a larger variation of activity coefficients of reacting species in the medium. From the viewpoint of δ values, activity coefficients of reacting species may vary to a much larger extent when an anion such as ClO_4^- of a medium salt is replaced by another kind of anion, *e.g.*, Cl^- ion.

The Water Structure Model of Narten *et al.* and the Pressure Effect on Sound Absorption in Water

Otohiko NOMOTO*,** and Harumi ENDO*

**Department of Applied Physics, Defence Academy, Yokosuka*

***Kobayashi Institute of Physical Research, Kokubunji, Tokyo*

(Received December 18, 1970)

The mechanism of the temperature dependence of ultrasonic absorption in water under atmospheric pressure has hitherto been studied by means of the two-state-model theory of water. For an explanation of the pressure dependence of ultrasonic absorption by the two-state model, however, we are obliged to adopt the contradictory assumption that the open-packed structure of water has a higher energy than the more close-packed one. In order to avoid this contradictory assumption inherent in the two state-model theory, we have here employed the water model recently proposed by Narten *et al.* on the basis of X-ray scattering analysis. Although the calculation based on the Narten-model succeeds in explaining the pressure dependence of the ultrasonic absorption without the above-mentioned contradictory assumption, the structual compressibility (β_{st}) thus obtained is about two times larger than the most reasonable value. The origin of this discrepancy seems to be that the Narten model of water considers the framework of the ice-1 lattice to be of infinite extent, without any boundary. By assuming the cluster-structure to be of a finite size, we can reduce β_{st} to a reasonable value in agreement with the experimental results. The water cluster is found to be about eight molecules in diameter at 4°C.

The ultrasonic absorption (α) in water is known to be higher than the classical value (α_{cl}) due to the shear viscosity (η) and the heat conductivity (k). As α_{cl} is proportional to the square of frequency (f), it is usual to write:

$$\frac{\alpha_{cl}}{f^2} = \frac{(2\pi)^2}{\rho V^3}\left(\frac{2}{3}\eta + \frac{1}{2}\frac{\gamma-1}{\gamma}\frac{k}{C_v}\right) \tag{1}$$

Here, ρ is the density; V, the sound velocity; C_v, the specific heat at a constant volume, and $\gamma(=C_p/C_v)$, the ratio of the specific heats. As $\gamma \cong 1$ in water, the term due to heat conduction can be omitted in this case. The difference being ascribed to the bulk viscosity (κ), the total absorption (α/f^2) becomes:

$$\frac{\alpha}{f^2} = \frac{(2\pi)^2}{\rho V^3}\left(\frac{2}{3}\eta + \frac{1}{2}\kappa\right) \tag{2}$$

It is known, from hypersonic measurements, that (α/f^2) in water is independent of the frequency up to the GHz ($=10^9$ Hz) range. This means that, in the general formula of relaxational viscosity absorption:

$$\alpha = \frac{2}{3}\frac{\eta}{\rho V^3}\frac{\omega^2}{1+\omega^2\tau_1^2} + \frac{1}{2}\frac{\kappa}{\rho V^3}\frac{\omega^2}{1+\omega^2\tau_2^2} \tag{3}$$

and dispersion:

$$V^2 = V_0^2 + \frac{4}{3}\frac{G}{\rho}\frac{\omega^2\tau_1^2}{1+\omega^2\tau_1^2} + \frac{K'}{\rho}\frac{\omega^2\tau_2^2}{1+\omega^2\tau_2^2} \tag{4}$$

the relaxation time for the shear viscisity (τ_1) and that for the bulk viscosity (τ_2) are sufficiently small ($\omega\tau_1 \ll 1$, $\omega\tau_2 \ll 1$ where $\omega = 2\pi f$), even in the GHz range. Here, G is the shear modulus, and K', the relaxational part of the bulk modulus related to η and κ by Maxwell's relations:

$$\eta = G\tau_1 \text{ and } \kappa = K'\tau_2 \tag{5}$$

There being relations

$$\frac{1}{\beta_0} = K_0, \quad \frac{1}{\beta_\infty} = K_\infty \tag{6}$$

between the static and instantaneous compressibilities (β_0 and β_∞), and the corresponding bulk modulus (K_0 and K_∞), we obtain as the relaxational modulus, K',

and the structual (or relaxational) compressibility, β_{st}:

$$K = K_0 + K' \text{ and } \beta_0 = \beta_\infty + \beta_{st} \quad (7)$$

The mechanism of ultrasonic absorption in water has been studied by Hall,[1] by Smith and Lawson,[2] and by Davis and Litovitz.[3] They applied the two-state-model theory of water to explain the bulk viscosity and relaxational compressibility. Hall's theory, based on the monomer-dimer model, explained the temperature dependence of sound absorption using suitably adjusted parameters to fit the experimental results (*cf.* also Davis and Litovitz[3]). In Hall's paper, it is assumed that the open-packing state of water is the lower energy state. For the explanation of the pressure dependence of the ultrasonic absorption, however, Litovitz and Carnevale,[4] calculating by means of a modification of Hall's two-state-model theory, were obliged to adopt the assumption that the open-packing structure of water has a higher free energy than the close-packing state, in contradiction to the usual physico-chemical concepts as to the structure of liquid water (*cf.* also Herzfeld and Litovitz[5]). To interpret the pressure dependence of ultrasonic absorption in water without introducing these contradictory assumptions in the two-state-model theory, we employed the water model recently proposed by Narten *et al.*[6] on the basis of their X-ray scattering analysis.

Water Structure Model Proposed by Narten *et al.* (Interstitial Model)

Samoilov[7] has proposed an interstitial model of the liquid water structure so as to explain the radial distribution function obtained from the X-ray data. Narten *et al.*, building on Samoilov's idea, formulated a model, consisting of a framework of the extended ice-1 structure, with some non-hydrogen-bonded water molecules filling some of the cavities of the network. This framework structure is very open, with ample spaces or cavities to accommodate non-hydrogen-bonded water molecules. The positions to accommodate the water molecules in the interstices are on the triad axis. The accommodated water molecules in the cavity interact with the framework molecules with less specific, although by no means negligible, force. In this model, the ice-1 framework is anisotropically extended, and both vacant lattice sites and the occupancy of the interstices by water molecules are permitted, although the vacant lattice site of the framework is practically absent up to 100°C. Accordingly, liquid water can be said to consist of two species forming both the framework and the interstitial molecules. This model, however, considers the lattice of the extended ice-1 framework to be infinite, without boundary, no cluster-structure being taken into account. Narten *et al.* found that the calculated radial distribution functions agree with the experimental results up to very high temperatures (*ca.* 200°C).

Theoretical

Acoustic pressure in an associated liquid accompanies two sorts of compression: *a*) the compression of the intermolecular distance, and *b*) the breakdown of intermolecular bonds accompanying the destruction of the open structure. The former is represented by the instantaneous compressibility, β_∞, while the latter is the origin of the structual compressibility, β_{st}. In this calculation, we assume the volume of the liquid water to be proportional to the number of framework lattice sites. This means that the dimensions of the framework remain the same, independent of whether the cavity sites are vacant or not. On this assumption, the molar volume (v) can be given by the following relations:

$$v = \frac{W}{f_1} v_{fr} \quad (8)$$

$$W = \frac{f_1 + z f_2}{f_1} \quad (9)$$

where

v_{fr}: the volume per mole of H_2O of framework
W: the fraction of water molecules in the framework positions
f_1: the occupancy of the framework sites (f_1 is 100% up to 100°C; *cf.* Narten *et al.*[6])
f_2: the occupancy of the interstitial sites
z: the number of interstitial sites per framework site

In this calculation, we will limit the temperature range at up to 100°C. Then, we obtain $f_1=1$ in Eqs. (8) and (9) from the experimental results of Narten *et al.*[6]

By substituting Eq. (8) into

$$\beta_{st} = -\frac{1}{v}\left(\frac{\partial v}{\partial p}\right)_T \quad (10)$$

we obtain:

$$\beta_{st} = W z \left(\frac{\partial f_2}{\partial p}\right)_T \quad (11)$$

where z is kept constant.

On the other hand, Narten *et al.* found both the entropy of mixing and the molar Gibbs free energy of the model from their statical thermodynamic consideration of the interstitial water model. Further, they obtained, as the free-energy change associated with the transformation of the interstitial molecule into the framework:

$$\Delta G_I^0 = RT\left[\ln \frac{f_2}{1-f_2} - z \ln (1-f_2)\right] \quad (12)$$

We obtain from Eq. (11):

$$\left(\frac{\partial f_2}{\partial p}\right)_T = W f_2 (1-f_2) \Delta v_I^0 / RT \quad (13)$$

1) L. Hall, *Phys. Rev.*, **73**, 775 (1948).
2) A. Smith and A. Lawson, *J. Chem. Phys.*, **22**, 351 (1954).
3) C. Davis and T. Litovitz, *ibid.*, **42**, 2563 (1965).
4) T. Litovitz and E. Carnevale, *J. Appl. Phys.*, **26**, 816 (1955).
5) K. Herzfeld and T. Litovitz, "Absorption and Dispersion of Ultrasonic Waves," Academic Press, New York and London, (1959) p. 438.
6) H. Narten, M. Danford, and H. Levy, *Discuss. Faraday Soc.*, **43**, 97 (1967).
7) O. Samoilov, "Ion no Suiwa" (Translation from Russian by W. Uehira), Chijin Shokan, Tokyo (1967).

Then, the structural compressibility is given by

$$\beta_{st} = zW^2 f_2(1-f_2)\Delta v_I^0/RT \quad (14)$$

Here $\Delta v_I^0=(\partial G_I^0/\partial p)_T$ becomes v_{fr}, because we assume that the interstitial water molecule has no effective volume. Therefore, by substituting Eq. (10), we obtain the relation:

$$\beta_{st} = \frac{zv_{fr}}{RT}\frac{f_2(1-f_2)}{(1+zf_2)^2} \quad (15)$$

It is easy to show that Eq. (15) is equivalent to the result obtained by Frank and Quist[8] on Pauling's water model:[9]

$$\beta_{st} = \frac{v_{fr}}{RT}(1-W)[W-v(1-W)] \quad (16)$$

where $v=1/z$.

We can find the temperature (t) dependence of the parameters (f_2 and W) from the data of Narten *et al.*, represented as graphs in their paper:

$$W = -4.59\times10^{-4}\ (t-4) + 0.82$$

In their paper, however, f_2 is so random that we can not find any definite relation with the temperature. We calculated f_2 from Eq. (9), by assuming z (=1/2) to be independent of the temperature.

Results of Calculations

Figure 1 shows the temperature dependence of β_{st} as obtained from Eq. (15). The results of other authors[1-4] are also shown for the sake of comparison. As may be seen, the present result gives nearly the same slope of the $\beta_{st}(t)$-curve as in previous investigations, but the value of β_{st} is about two times any previous finding (such as that of Hall *et al.*).

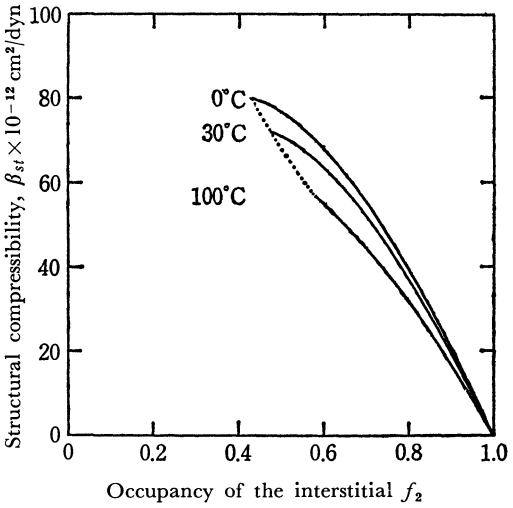

Fig. 2. β_{st} dependence of f_2 at various temperature.
---- Temperature dependence of f_2 under the atmospheric pressure.

Figure 2 shows the f_2 dependence of β_{st} at 0, 30, and 100°C. As the framework-structure part of water is destroyed with an increase in the pressure, we have to expect a monotonous increase in the occupancy of the cavity (f_2) with an increase in the pressure. On the other hand, the dotted line shows the temperature dependence of f_2 under atmospheric pressure.

Considerations and Discussion

Our results at 4°C are shown in Table 1, together with the previous ones. An obvious difference is that our value of $\beta_{st}=78.9\times10^{-12}$ cm²/dyne is much larger than that, $\beta_0(=\beta_\infty+\beta_{st})=50.2\times10^{-12}$ cm²/dyne, in water. It is necessary to remove this contradiction. If we assume a reasonable value (*cf.* Hall[1]) to be $\beta_{st}=32.2\times10^{-12}$ cm²/dyne at 4°C, which is in accordance with ultrasonic absorption measurements, we find from Eq. (16) that the apparent value, z', is 0.284 on the condition that $w=0.820$ remains the same (here we assume Eq. (17)). Then, we obtain from Eq. (9) $f_2=0.773$.

Table 1

Temp. 4°C	Present results: Narten model	Present results: Cluster model	Frank-Quist (Pauling model)	Two state model
V_{fr}	22.0	22.0	22.0	
W	0.820	0.820	0.818	
z	0.500	0.284	0.261	
f_2	0.439	0.773	(0.858)	
$\beta_{st}\times10^{-12}$	78.9	32.2	21.0	32.2[1]
				30.0[3]

The radial distribution function determined by Narten *et al.* from the X-ray scattering data is based on the lattice model up to a distance of about 10 Å,

further distances being averaged out. It is probable that water consists of clusters of finite sizes larger than 10 Å in radius.

Here we assume that the water structure consists of clusters containing n^3 water molecules, the structure inside the cluster being the same as the Narten model. As the number of interstitices are reduced to $[(n-1)/n]^3$ times, we find that z apparently becomes $[(n-1)/n]^3$ times as large as the infinite model. Further, we assume in this cluster model that the average intermolecular distance between clusters is not affected, so the density in this model does not change. The space between the clusters is assumed not to accommodate the non-hydrogen-bonded molecules. Considering the above conditions, we obtain the following relation:

$$\left(\frac{n-1}{n}\right)^3 z = z' \tag{18}$$

where z $(=1/2)$ is the number of interstitial sites per framework site, corresponding to the Narten model without considering the cluster. If we choose $z'=0.284$, so as to bring the calculated β_{st} value in Table 1 (column (2)) into agreement with the observed value, we obtain $n=5.81$ from Eq. (18). Assuming the cluster to be spherical, the diameter of the cluster becomes about eight molecules at 4°C. In performing the above calculations at various temperatures, we find the radius (n_r) of the spherical cluster (expressed in the number of water molecules) to be dependent on the temperature as is plotted in Fig. 3. As may be seen, n_r increases with an increase in the temperature. Although this is rather unexpected, we cannot place too much weight on it, considering the very approximate nature of our hypothesis.

ESR Measurement and Irradiation at Variable Temperatures below 77°K

Machio IWASAKI, Keichi NUNOME, Takahisa ICHIKAWA,* and Kazumi TORIYAMA

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya

(Received December 26, 1970)

An apparatus for irradiation and subsequent ESR measurements at variable temperatures below 77°K was constracted by combining an ESR spectrometer, and an X-ray irradiator, and a laboratory scale low temperature refrigerator operating at the temperature region between 77 and 4.2°K. A device for rotating the single crystal specimen was made to measure the angular dependence of the ESR spectra. The lowest specimen temperature achieved was estimated to be 6°K and the precision of the temperature control was less than ±0.5°K for a period of several hours. The apparatus makes it possible to irradiate samples and to measure ESR spectra at any temperature in the range between 77 and 6°K. Some applications for irradiation and ESR measurements at low temperatures are also described. An unstable radical which disappears at about 60°K was found in an irradiated single crystal of L-cystine dihydrochloride. Experimental evidence for the quantum tunnelling of the methyl group in polymethylmethacrylate radical was also found by the temperature dependence of the spectra observed at temperatures lower than 77°K.

ESR measurements at a temperature region lower than 77°K are usually carried out at 4.2°K by using liquid helium. In some cases, even lower temperatures can be achieved by rapid pumping of liquid helium. It is not easy, however, to maintain intermediate temperatures between 4.2 and 77°K (liquid nitrogen temperature), especially for a fairly long period. For example, in the measurements of the orientation dependence of the ESR spectra of single crystals, a constant temperature with a fairly high precision has to be maintained for at least several hours. In addition, for the study of the primary process of radiation-induced reactions, the irradiation is to be made at temperatures lower than 77°K, because of instability of the produced radicals. This kind of experiment can not be easily carried out by using liquid helium. Besides, liquid helium is not always available and is not easy to handle. If low temperatures could be obtained without the use of liquid helium, a number of laborious processes required for experiments at a temperature region lower than 77°K might be considerably reduced.

Recently a laboratory scale refrigerator which can be operated by using a compressed helium gas from commercial cylinders has been developed and it provides a fairly simple way to obtain any intermediate temperatures between 77 and 4.2°K. We have applied

* Present address: Department of Applied Chemistry, Faculty of Engineering, University of Hiroshima, Senda-cho, Hiroshima.

this sort of equipment for irradiation and subsequent ESR measurements at low temperature and obtained fairly successful results. This paper describes our apparatus built mainly for the measurements of the angular dependence of the ESR spectra of irradiated single crystals.

In this method the crystals are cooled by thermal conduction through the contact with a cryogenic tip of the refrigerator so that a number of checks have to be made to ascertain the real temperature of the specimens. Performance of our equipment will be described together with some results obtained for the NO radical in a single crystal of hydroxylamine hydrochloride, irradiated single crystals of *N*-acetylalanine and L-cystine dihydrochloride, and irradiated polymethylmethacrylate films.

Apparatus

The refrigerator is a Cryo-Tip system AC-3L-110 supplied by Air Products and Chemicals Inc. The alignment of an ESR spectrometer, X-ray irradiator, and the refrigerator is shown in Fig. 1. The movable mount of the refrigerator was designed and built to make it possible to shift the refrigerator horizontally from the X-ray irradiator to the sample cavity for prompt ESR measurements after irradiation. Besides this horizontal movement, the mount performs vertical movement for inserting the specimen holder into the X-ray irradiator or the sample cavity, and the rotational movement for changing the crystal orientations to the magnetic field. The mount has also a cross leader for the fine adjustment of the sample position in the cavity. A device for adjusting the vertical axis of the refrigerator is also added to make sure that the rotational axis of the crystal is perpendicular to the magnetic field. A sketch of the refrigeraaor mount is shown in Fig. 2.

Hydrogen and helium gases from cylinders are led to the liquid nitrogen dewar where the gases are precooled down to 77°K. Hydrogen and helium gases are then expanded successively and liquefied at the tip

The vertical axis for rotation is also adjustable.

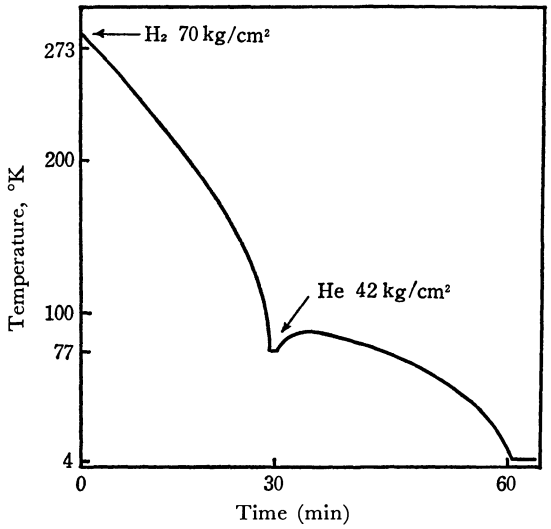

Fig. 3. Cooling curve for normal operation of the refrigerator.

of the refigerator. Figure 3 shows a cooling curve measured with a chromel-constantan thermocouple attached to the tip of the refrigerator. After the low pressure purge at 7—14 kg/cm² for 20 min, the hydrogen pressure was raised to 70 kg/cm². This is taken as an origin of the time scale in the abscissa of Fig. 3. After 30 min needed for liquefying hydrogen gases, the hedlium pressure was increased to 42 kg/cm² and another 30 min were required to liquefy helium gases. The tip temperature is easily controlled in the range from 77° to 4.2°K by adjusting the flow rate of the gases. It is easy to maintain any intermediate temperature, say 40°K, for several hours with an accuracy of less than ±0.5°K.

A vent pipe of the used hydrogen gas is led to the roof, while the helium gas is restored to the cylinders by a compressor through a liquid nitrogen trap with

active charcoal.

Specimens for ESR measurements are attached to the sample holder of a sapphire or a copper rod (3 mmϕ × 80mm) connected to the tip of the refrigerator surrounded by an aluminum vacuum shroud (Fig. 2). The length of the specimen holder depends on the dimension of the ESR cavity into which part of the specimen holder is inserted. The part of the specimen holder is surrounded by a Spectrosil tube of 10 mmϕ, the inside of which is evacuated through the vacuum shroud for maintaining thermal insulation. The ESR measurements are easily carried out by inserting the Spectrosil tube into a cavity with a TE_{011} mode. Adjustment of the orientation of the specimen to the magnetic field can be achieved by simply rotating the refrigerator mount around the vertical axis. This method is entirely free from the bubble noise inherent to the method using liquid coolants. Since the surface of the Spectrosil tube is maintained at room temperature, there is no variation of the Q-value of the sample cavity even though the temperature of specimen changes.

Irradiation of the specimen at low temperatures is also easily carried out by inserting the Spectrosil tube into the irradiation chamber in which an X-ray tube is installed The X-ray irradiator is placed in front of an ESR magnet at a distance of about 1 m to make it easier to transfer the refrigerator promptly to the ESR cavity right after irradiation. The ESR signal due to color centers produced at room temperature in the Spectrosil tube by X-irradiation is a sharp singlet having the g-factor close to the free spin value and its intensity is not so strong that the central part of the signal of the specimen is masked.

Temperature Measurements

Although the temperature of the tip of the refrigerator is maintained at 4.2°K when helium gas is liquefied, there should be thermal gradient along the rod of the specimen holder in such a way that the specimen is cooled by the thermal conduction through a long rod. The temperature difference between the tips of the refrigerator and the sapphire or copper rods measured by an Au doped Co–Pt thermocouple was about 6 and 4°K, respectively, when the Cryo-Tip system was operated with full power. The temperature rise through the rod is reduced to 2—1°K when the temperature of the tip of the refrigerator is raised to 70°K. Figure 4 shows the correction curve for the temperature rise at the sample position of the rod. The ordinate represents the temperature rise through the rod and the abscissa the temperature at the tip of the refrigerator.

The main cause of the temperature rise through the rod seems to be the radiation from the Spectrosil tube which is kept at room temperature. The vacuum in the Spectrosil tube is extremely high because the residual air is completely trapped on the surface of the heat exchanger, the temperature of which is very much lower than the freezing points of oxygen and nitrogen. Therefore, the conduction through the residual gases from the Spectrosil tube may be negligible. It is not possible, however, to use a radiation shield of silver mirror inside the Spectrosil tube as in the Dewar vessel because it lowers the Q-value of the sample cavity. When the Spectrosil tube was dipped into a liquid nitrogen dewar, the temperature rise became negligibly small and the liquid helium temperature was attained. Therefore, the cold nitrogen gas from the Dewar vessel of liquid nitrogen was introduced into the sample cavity to lower the temperature of the surface of the Spectrosil tube. By this device the temperature rise through the rod is reduced to about 2°K when the copper rod is used at the full operation of the refrigerator. The lowest possible specimen temperature obtained by our apparatus is about 6°K.

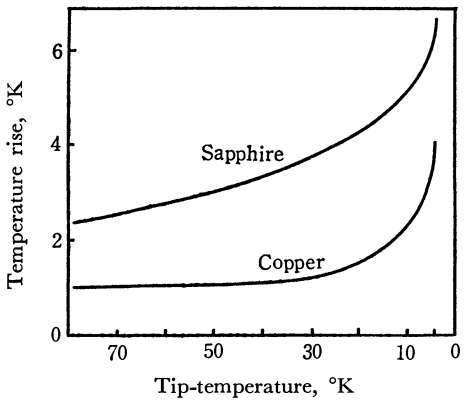

Fig. 4. Correction curve for the temperature rise along the sample rod *vs.* temperature of the cryogenic tip of the refrigerator.

The temperature rise during X-irradiation was found to be 2—3°K under operating conditions of 30 mA and 40 kV. The distance from the X-ray target to the specimen holder is about 30 mm.

The temperature of the sample itself attached to the rod is very difficult to measure, because of the small size of the crystal or film. In order to avoid the thermal gradient inside the specimen, it is necessary to use a very thin, say 0.1—0.2 mm, crystal or film. In this case, the temperature of the sample was confirmed by the ESR measurements.

ESR Measurements

According to Gamble and Miyagawa, the ESR spectrum of the radical CH_3–$\dot{C}R_1R_2$ formed in an irradiated single crystal of *N*-acetylalanine shows a remarkable temperature dependence in the region between 4—20°K due to the quantum mechanical effect on the hindered oscillation of methyl group.[1] Temperature changes of the spectral features they observed at 4.2, 12.5, and 17.5°K are so sensitive to the observed temperature that it may provide a good test sample for checking the real temperature of the specimen. We have also measured the temperature dependence of the same sample by using our apparatus with a copper rod as a sample holder. The spectra obtained at 12.5 and 17.5°K, which were estimated from the correction curve in Fig. 4, are in very good

1) W. L. Gamble and I. Miyagawa, *Phys. Rev. Lett.* **20**, 415 (1968).

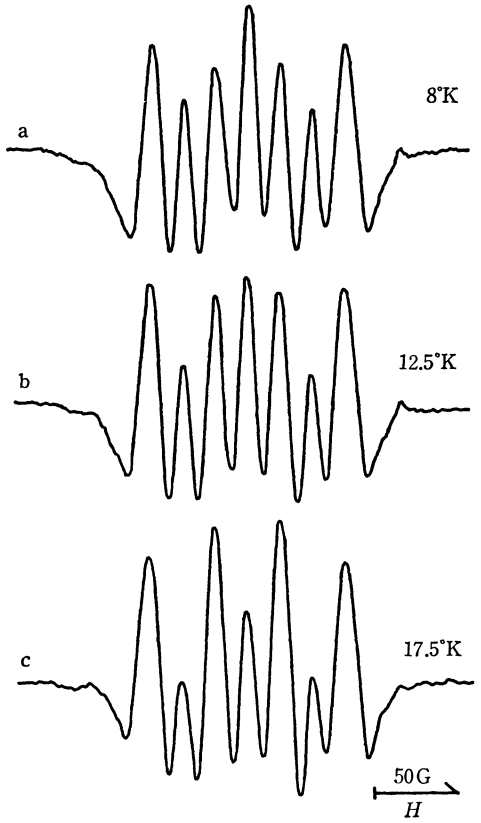

Fig. 5. ESR spectra of an irradiated single crystal of *N*-acetylalanine measured at (a) 8°K, (b) 12.5°K, and (c) 17.5°K. The magnetic field is applied along the *c*-axis.

agreement with their spectra as shown in Figs. 5(b) and (c). This means that the specimen temperature is practically the same as that of the copper rod. Figure 5(a) gives a spectrum observed at 8°K which is the lowest temperature obtained by our apparatus without aid of cold nitrogen gas flow into the sample cavity. The spectral feature of Fig. 5(a) is in between their spectra observed at 4.2 and 12.5°K. The splendid agreement between the two independent measurements may ensure the estimates of the specimen temperature in both the experiments.

In the temperature region higher than 20°K, the spectral change of this radical is so gradual that it is of no use to check the specimen temperature. Therefore another check was made by using the Curie law, *viz.*, the linear relation of the ESR intensity to reciprocal temperature. For this purpose one has to use the sample, the signal of which is hard to saturate at the low temperature region. The NO radical found by Ohigashi and Kurita[2] in an irradiated single crystal of hydroxylamine hydrochloride has extremely short T_1 and it may be expected that the signal is not saturated in a fairly wide range of low temperature. Figure 6 shows the relative intensity of the ESR spectra of the NO radical plotted against the reciprocal temperature estimated from the correction curve in Fig. 4. In this experiment, the sapphire rod was used for the specimen holder. As is seen in Fig. 6, a good linear relation was obtained in the temperature range between 25 and 60°K.

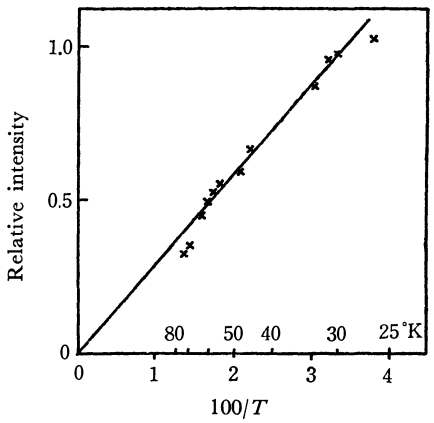

Fig. 6. Plots of the ESR intensities *vs.* reciprocal temperatures for the NO radical trapped single crystal of hydroxylamine hydrochloride.

It is concluded that the specimen temperature is practically the same as that of the sample rod in the wide range of low temperature achieved by our apparatus.

Applications

Irradiation at low Temperature. In some cases irradiation has to be made at temperature lower than 77°K, since the primary species produced by irradiation are sometimes unstable at 77°K. For example, the cation radical formed in an irradiated single crystal of L-cystine dihydrochloride[3] is known to be unstable at 77°K.[4] Irradiation at temperatures lower than

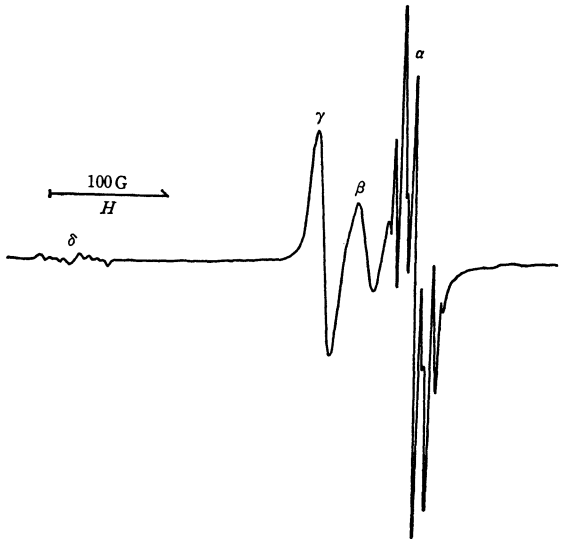

Fig. 7. ESR spectra of a single crystal of L-cystine dihydrochloride irradiated and measured with our system. The magnetic field is applied along the *c'*-axis.

2) H. Ohigashi and Y. Kurita, *J. Phys. Soc. Jap.* **24,** 654 (1968).

3) H. C. Box, H. G. Freund, K. T. Lilga, and E. E. Budzinski, *J. Phys. Chem.*, **74,** 40 (1970).

4) According to the recent study of Akasaka *et al.* (13th Symposium on Radiation Chemistry, Tokyo, Oct. 9, 1970), the spectrum of the cation is observable even at 77°K if the observation is made in the dark.

77°K is desirable for studying the primary process of radiation-induced reactions.

Our system was applied in the irradiation of a single crystal of L-cystine dihydrochloride. A typical spectrum measured right after irradiation is shown in Fig. 7. Both the cation (α in Fig. 7) and the anion (β in Fig. 7) are stably trapped. In addition, a new signal δ with an extremely large g-anisotropy and a small hyperfine structure was found at lower magnetic field side of the spectra due to the cation and anion. The signal disappeared irreversibly when the temperature was elevated to about 60°K. Figure 8 shows an angular dependence of this signal measured in the ac′ plane. The variation of the g-value in this plane is from 2.26 to the free spin value. Although the magnetically non-equivalent site of this signal is one in the ac' plane, there are two sites in both the ab and bc' planes. This means that the radical responsible to this signal does not possess symmetry of the mother molecule. From this together with the large positive g-shift the signal may be assigned to a sort of sulfur radical produced by the scission of the S–S bond.

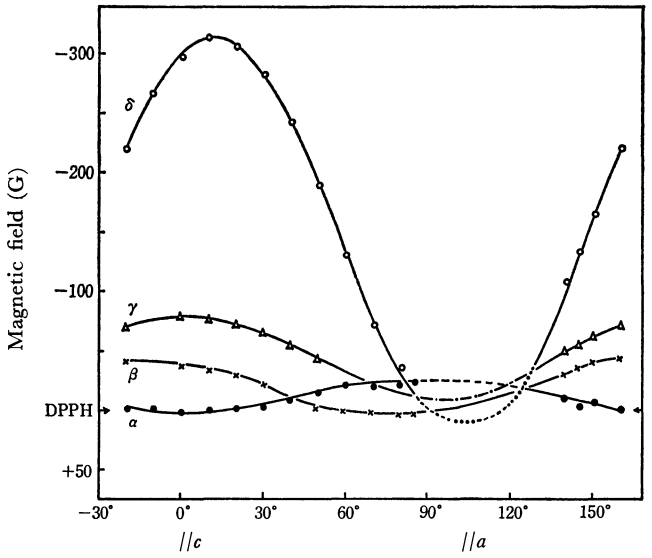

Fig. 8. Angular dependence of the ESR spectra of a single crystal of L-cystine dihydrocholide irradiated and measured with our system. The magnetic field is applied in the ac′ plane.

This experiment shows that our system is applicable to the irradiation at temperatures lower than 77°K and the subsequent ESR measurements.

Measurements of ESR Temperature Dependence. In some cases, the temperature dependence of the ESR spectra in a temperature region lower than 77°K is required to be measured. As an example, it is reported that the ESR spectrum of polymethylmethacrylate radical, RCH_2–$\dot{C}(CH_3)COOMe$ measured at 4.2°K exhibits a remarkable difference from that at 77°K.[5] Interpretation of this difference is not possible because of the lack of information on the spectral change at intermediate temperatures. By means of our system the temperature dependence of the spectra was successfully measured in the range between 77 and 6°K. The results are shown in Fig. 9. As described in our paper,[6] the spectrum observed at 77°K is interpreted on the assumptions of the freely rotating methyl group and the distribution of the conformational angle of the two C–H_β bonds to the half filled $2p$ orbital. The spectral change observed at temperatures lower than 77°K can be interpreted by the quantum mechanical effect on the hindered oscillation of the methyl group as is the case of the radical, CH_3–$\dot{C}R_1R_2$, in irradiated *N*-acetylalanine.[1] The spectra observed at 6°K is well reproduced by the seven-line spectrum due to the quantum tunnelling of the methyl group[7] and further splittings due to the two β-proton couplings. The temperature dependence observed by our system gave the experimental evidence for the quantum tunnelling of the methyl group in the polymethylmethacrylate radical. Details will be given elsewhere.

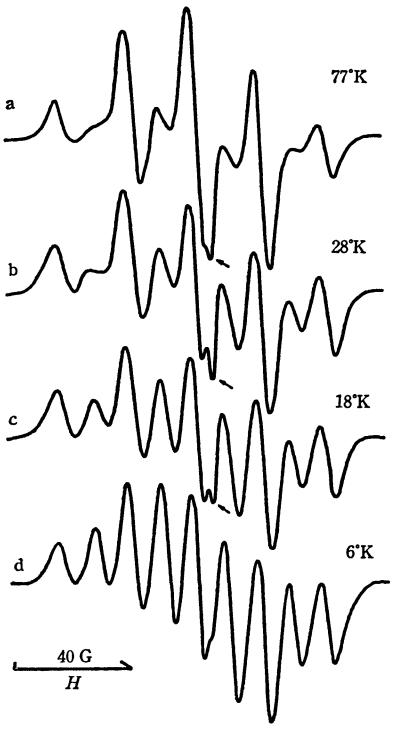

Fig. 9. Temperature dependence of the ESR spectra of polymethylmethacrylate radical measured at (a) 77°K, (b) 28°K, (c) 18°K, and (d) 6°K. The arrows indicate the signal due to the color center of the Spectrosil tube.

The authors wish to thank Drs. Y. Kurita and H. Ohigashi of Basic Research Laboratory, Toray Industries, Inc. for their helpful cooperation in measuring the ESR signal of the NO radical trapped in an irradiated single crystal of hydroxylamine hydrochloride.

Studies on Triplet Energy Transfer by Means of an Emission-Absorption Flash Technique. II. Mixed Triplet-Triplet Annihilation in Ethanol

Koichi KIKUCHI, Hiroshi KOKUBUN, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received December 28, 1970)

The mixed delayed fluorescence due to the processes, $A^T+B^T \xrightarrow{p_M{}^A k_{MTT}} A^*+B$ in the following systems in ethanol solutions have been quantitatively investigated. a) 1) 9-methylanthracene-anthracene, 2) 9-phenylanthracene-anthracene, 3) 9-methylanthracene-9-phenylanthracene, 4) anthracene-acridine, 5) 9-methylanthracene-acridine, 6) 9-phenylanthracene-acridine. b) 7) eosin-anthracene, 8) proflavine-anthracene, 9) eosin-acridine. It has been found that for class a) in which the separations of singlet excited levels of A and B are less than a few times of kT, the delayed fluorescence of both components occur and the value of $(p_M{}^A+p_M{}^B)$ is close to that of the efficiency of a simple p-type delayed fluorescence, p^A or p^B. The delayed mixed excimer fluorescence also occurs in most cases. For class b) in which the level differences largely exceed kT, only the delayed fluorescence of the lower level component occurs. It has also been established that the delayed excimer fluorescence in a single component system increases in intensity from anthracene through 9-methyl- to 9-phenylanthracene. The $p_M{}^A/p_M{}^B$ values are discussed for systems (1), (2), and (3).

Delayed fluorescence due to T–T annihilation has been studied extensively by Parker[1] and Birks[2] since its discovery by Parker and Hatchard.[3] It seems that the recent work of Birks *et al.*[4] has terminated the debates upon its mechanism. Their conclusion is that T–T annihilation occurs according to the dual paths

(I) $A^T+A^T \rightarrow A_2{}^{**} \rightarrow A_2{}^* \rightarrow 2A + h\nu$ (excimer fluorescence)
$\qquad\qquad\qquad\quad \rightarrow A^* + A \rightarrow 2A + h\nu'$ (monomer fluorescence)

(II) $A^T + A^T \rightarrow A^* + A$

in which process (I) goes through encounter whereas (II) proceeds by a long range interaction. This scheme is essentially the same as the one proposed earlier by Parker.[5] Birks *et al.* and Parker also agree on the point that process (I) is temperature dependent while (II) is not, the former predominating at room temperature.

One purpose of the present work is to compare the efficiency of *mixed T–T annihilation* with that of simple type T–T annihilation at room temperature assuming that process (I) is predominant. Since the discovery of mixed T–T annihilation by Parker,[6] no quantitative investigation seems to have been made. Although there is no doubt that in the anthracene (donor)-naphthacene (acceptor) system,[7] the delayed fluorescence of the latter is brought about by $D^T+A^T \rightarrow D+A^*$, there is some ambiguity as to the mechanism of the enhanced delayed fluorescence in the eosin-anthracene system.[8] Parker's observation gave no quantitative information as to what extent the enhanced delayed fluorescence of both eosin (D) and anthracene (A) occurs *via*

(III) $D^T + A^T \rightarrow D^* + A$ (M-type 1)
$\qquad\qquad\qquad\quad \rightarrow D + A^*$ (M-type 2)

or

$D^T + D^T \rightarrow D^* + D$
$A^T + A^T \rightarrow A^* + A$ (P-type)

We developed a method of separating M-type from P-type using the flash technique involving absorption and emission measurements.[9] By means of this method, we established that (M-1) occurs very efficiently and that (M-2) does not occur at all in the alcoholic solution of eosin and anthracene. In the present work, the proflavine-anthracene and eosin-acridine systems have been studied. They are similar with respect to the singlet energy separation between donor and acceptor. Further, systems consisting of donor and acceptor with almost the same singlet excited levels have been studied. As such compounds, we have chosen anthracene and its substituted compounds which are well known to give only very weak excimer fluorescence. It is expected that the dependence of the relative fluorescence yield of donor and acceptor (processes (M-1) and (M-2)) on the singlet energy levels of the two components can be studied more easily with such compounds. In connection with the mixed T–T annihilation, quantitative investigations on the simple type T–T annihilation of the component compounds and on the delayed excimer fluorescence have been performed. The intensities of the mixed delayed excimer fluorescence (MDE-Fl) have been compared with those of

the delayed excimer fluorescence (DE–Fl) of the components.

Figure 1 gives the energy levels of the lowest singlet excited states for the compounds studied, as evaluated from the 0–0 band of absorption and emission in ethanol.

Method of Analysis

Our method consists of the measurements of the time dependence of both T–T absorption and D–Fl under the same conditions by means of a flash apparatus.[10] For a solution containing a single component A or B which exhibits P-type D–Fl, the following relations

$$^3A + {}^3A \xrightarrow{p_A k_{TT}^A} {}^1A^* + A \quad \text{(i)}$$
$$\searrow^{q_A k_{TT}^A} (AA)^* \quad \text{(v)}$$
$$^3B + {}^3B \xrightarrow{p_B k_{TT}^B} {}^1B^* + B \quad \text{(ii)}$$
$$\searrow^{q_B k_{TT}^B} (BB)^* \quad \text{(vi)}$$

hold exactly between the measured D–Fl intensity I_{DF} and the measured optical density of the T–T absorption D_T.

$$I_{DF}^A(P, \lambda_1) = \alpha^A(\lambda_1)\phi_F^A(p^A k_{TT}^A[^3A]^2) = \alpha^A(\lambda_1)\phi_F^A p^A k_{TT}^A\left(\frac{D_T^A(\lambda_1')}{\varepsilon_T^A(\lambda_1')d}\right)^2 \quad (1)$$

$$I_{DF}^B(P, \lambda_2) = \alpha^B(\lambda_2)\phi_F^B(p^B k_{TT}^B[^3B]^2) = \alpha^B(\lambda_2)\phi_F^B p k_{TT}^B\left(\frac{D_T^B(\lambda_2')}{\varepsilon_T^B(\lambda_2')d}\right)^2 \quad (2)$$

where k_{TT} and p are respectively the rate constant for the encounter of two triplet molecules and the efficiency of T–T annihilation, and α is a parameter depending on the spectral distribution of the fluorescence and on the experimental conditions. ϕ_F is a quantum yield of fluorescence and d, the cell length, is 10 cm. The wavelengths λ_1 and λ_2 are chosen in a suitable way as described below in the region where DE–Fl is negligible.

For a solution containing both A and B, the mixed T–T annihilation, should be taken into account. In

$$^3A + {}^3B \xrightarrow{p_M^A k_{MT}} {}^1A^* + B \quad \text{(iii)}$$
$$\xrightarrow{p_M^B k_{MT}} {}^1B^* + A \quad \text{(iv)}$$
$$\xrightarrow{q_M k_{MT}} (AB)^* \quad \text{(vii)}$$

this case D–Fl intensity of A (or B) at given triplet concentrations of A and B, is a sum of P-type D–Fl given by (1) (or (2)) and MD–Fl, (3) (or (4)).

$$I_{DF}^A(M, \lambda_1) = \alpha^A(\lambda_1)\phi_F^A p_M^A k_{MT}[^3A][^3B] = \alpha^A(\lambda_1)\phi_F^A p_M^A k_{MT}\frac{D_T^A(\lambda_1')D_T^B(\lambda_2')}{\varepsilon_T^A(\lambda_1')\varepsilon_T^B(\lambda_2')d^2} \quad (3)$$

$$I_{DF}^B(M, \lambda_2) = \alpha^A(\lambda_2)\phi_F^B p_M^B k_{MT}[^3A][^3B] = \alpha^B(\lambda_2)\phi_F^B p_M^B k_{MT}\frac{D_T^A(\lambda_1')D_T^B(\lambda_2')}{\varepsilon_T^A(\lambda_1')\varepsilon_T^B(\lambda_2')d^2} \quad (4)$$

In most systems, however, both D–Fl and the T–T absorption of the components overlap each other. The measured D–Fl intensity at λ_1, for example, consists of the components due to A and B species. Thus

$$I_{DF}(\lambda_1) = I_{DF}^A(P, \lambda_1) + I_{DF}^A(M, \lambda_1) + I_{DF}^B(P, \lambda_1) + I_{DF}^B(M, \lambda_1) \quad (5)$$

A similar equation holds for $I_{DF}(\lambda_2)$. In an analogous way, the optical density for λ_1' is given by

$$D_T(\lambda_1') = D_T^A(\lambda_1') + D_T^B(\lambda_1') = \varepsilon_T^A(\lambda_1')[^3A]d + \varepsilon_T^B(\lambda_1')[^3B]d \quad (6)$$

Hence we have to divide the measured quantity $I_{DF}(\lambda_1)$ (or $I_{DF}(\lambda_2)$) into the components $I_{DF}^A(\lambda_1)$ and $I_{DF}^B(\lambda_1)$ (or $I_{DF}^A(\lambda_2)$ and $I_{DF}^B(\lambda_2)$) and similarly $D_T(\lambda_1')$ (or $D_T(\lambda_2')$) into $D_T^A(\lambda_1')$ and $D_T^B(\lambda_1')$ (or $D_T^A(\lambda_2')$ and $D_T^B(\lambda_2')$). This is done successfully by means of the following equations, if λ_1, λ_2 and λ_1', λ_2' are chosen properly.

$$D_T^A(\lambda_2') = \{D_T(\lambda_1') - [\varepsilon_T^B(\lambda_1')/\varepsilon_T^B(\lambda_2')] \times D_T(\lambda_2')\}/\{[\varepsilon_T^A(\lambda_1')/\varepsilon_T^A(\lambda_2')] - [\varepsilon_T^B(\lambda_1')/\varepsilon_T^B(\lambda_2')]\} \quad (7)$$

$$D_T^B(\lambda_1') = \{D_T(\lambda_2') - [\varepsilon_T^A(\lambda_2')/\varepsilon_T^B(\lambda_1')] \times D_T(\lambda_1')\}/\{[\varepsilon_T^B(\lambda_2')/\varepsilon_T^B(\lambda_1')] - [\varepsilon_T^A(\lambda_2')/\varepsilon_T^A(\lambda_1')]\} \quad (8)$$

$$I_{DF}^A(\lambda_1) = \{I_{DF}(\lambda_2) - [\alpha^B(\lambda_2)/\alpha^B(\lambda_1)] \times I_{DF}(\lambda_1)\}/\{[\alpha^A(\lambda_2)/\alpha^A(\lambda_1)] - [\alpha^B(\lambda_2)/\alpha^B(\lambda_1)]\} \quad (9)$$

$$I_{DF}^B(\lambda_2) = \{I_{DF}(\lambda_1) - [\alpha^A(\lambda_1)/\alpha^A(\lambda_2)] \times I_{DF}(\lambda_2)\}/\{\alpha^B(\lambda_1)/\alpha^B(\lambda_2) - \alpha^A(\lambda_1)/\alpha^A(\lambda_2)\} \quad (10)$$

In order to carry out the above procedure, it is necessary to measure ε_T at various wavelengths and also to know the shape of the delayed fluorescence.

The above analysis enables us to compare the magnitude of $I_{DF}^A(\lambda_1)$ in the mixed system with that of $I_{DF}^A(\lambda_1)$ in the solution containing only A, both at various $D_T^A(\lambda_2')$ values; then the excess of the former is attributed to the mixed T–T annihilation given by Eqs. (3) and (4). A similar analysis can be applied to MDE–Fl, at least in principle. In this case the wavelengths of emission have to be chosen in the region of excimer fluorescence. In practice, however, the dif-

ficulty in obtaining the exact spectrum of DE–Fl prohibits a complete analysis of the data.

Experimeutal

Details of the apparatus and manipulation have been reported.[10] All the reagents were purified by standard methods. For the studies on the mixed T–T annihilation, β-acetonaphthone was used as a triplet energy sensitizer in order to produce a large quantity of the two species in the triplet state to be investigated. The scattering light longer than 400 nm was removed by means of a Hoya-U2 filter. Ethanol solutions were used. The concentrations of the solutes were usually chosen for a species with a higher T-level as 10^{-5} M and for the other, 10^{-6} M. The concentration of β-acetonaphthone was always 5×10^{-4} M. A set of five deaerated solutions were prepared simultaneously and two of them were used for the measurement of T–T absorption at two wavelengths and the remaining for the measurement of D–Fl at three wavelengths. It was confirmed that the fluctuation in the flash intensity was less than a few percent.

The molar absorption coefficient of T–T absorption at a certain wavelength was determined in the following way. Using eosin or proflavine as a T-energy donor, the optical density of T–T absorption of a given substance (acceptor) directly after flashing (energy donor only, excited) was measured under conditions of a complete energy transfer. The concentration of T-state was evaluated from the decrease of the ground state donor immediately after flashing in the absence of an acceptor, taking into consideration a correction factor determined from the ratio between the fluorescence intensities of a donor in the presence and absence of an acceptor. (In the presence of an acceptor, triplet donor quickly returns to the ground state and causes a corresponding increase in the absorption of light.) It was confirmed that the optical-densities taken at time t on the decay curves measured at various wavelengths remain constant in ratio with each other irrespective of the choice of t. This implies the non-participation of intermediates other than the triplet state. The molar absorption coefficients obtained are in satisfactory agreement with the data in literature. Some necessary data are listed in Table 1.

Results

Studies on the Delayed Fluorescence of a Solution Containing One Species. In order to analyse the data of the two component systems according to the method described above, it is necessary to prepare beforehand some data of the single component systems. Among them the p-values and the intensities of the excimer fluorescence of anthracene derivatives are considered to be of value since they have not yet been reported.

Measurement of D–Fl was made by using β-acetonaphthone as a sensitizer. The spectral shape was determined by plotting the intensities at the same time-points on the decay curves measured at various wave lengths. It was confirmed that the shape remains constant irrespective of the time points on the intensity decay curves. The spectral shapes for anthracene, 9-methylanthracene, 9-phenylanthracene, and acridine are given in Figs. 2, 3, 4, and 5. They were corrected for the instrumental factors. The intensities of D–Fl are weaker than those of normal fluorescence in the 0–0 band region due to the reabsorption but appreciably stronger in the longer wavelength region.

The latter result is attributed to DE–Fl which increases in the order, anthracene<9-methylanthracene<9-phenylanthracene. It is notable that the DE–Fl of acridine is apparent. The plots of $\sqrt{I_{DF}(\lambda)}$

against D_T were found to be satisfactorily linear for anthracenes and acridine substantiating the view that the delayed fluorescence of these compounds are of P-type. These are the most important relations for the study of the mixed T–T annihilation. A few example for anthracene are shown in Fig. 6. The D–Fl spectra of eosin and proflavine both of E-type were not measured since the intensities were very weak. Some data necessary for the analysis of the mixed T–T annihilation are listed in Table 2.

From the results listed in Tables 1 and 2, we can evaluate the values of $\alpha(\lambda)\phi_F p k_{TT}$ by means of Eqs. (1) and (2). The values of p have been obtained by the method reported already.[10] k_{TT}-values can be evaluated from the decay curves of T–T absorption and the ε_T-values listed in Table 1. The values of ϕ_{ST}, p, and k_{TT} for anthracene, 9-methyl- and 9-phenyl-

anthracene, and acridine are compiled in Table 3.

A similar analysis can be carried out on the DE–Fl to the step of evaluating the $\beta\phi_{EF}qk_{TT}$ values, which are also listed in Table 3.

Studies on a Solution Dissolving Two Aromatic Compounds. In the studies of mixed T–T annihilation, it is most interesting to evaluate the $p_M{}^A$- and $p_M{}^B$-values (see processes (iii) and (iv)). The procedure both experimental and theoretical will be described in some detail for one system, anthracene (B) and 9-methylanthracene (A). For other systems, only significant findings will be described. All the data evaluated are listed in Table 4. A and B denote the species respectively with lower and higher 0–0 emission band. β-acetonaphthone was used as a sensitizer. For 9-methylanthracene(A)-anthracene(B), decays of T–T absorption were measured at 420 and 426 nm from 100 μsec after flashing because the triplet β-acetonaphthone was found to disappear almost completely during this time interval. The decays were analysed according to Eqs. (7) and (8).

Similarly the decays of D–Fl were measured at 400, 412, and 540 nm. The relation between D–Fl and T–T absorption for anthracene and for 9-methylanthracene obtained by the above analysis is shown in

Table 2. Relationship between delayed fluorescence and T-T absorption

Compound	Relation	Wavelength dependence of D-Fl intensity		
		400 nm	412 nm	540 nm

a) *cf.* This Bulletin, **43**, 3435 (1970).

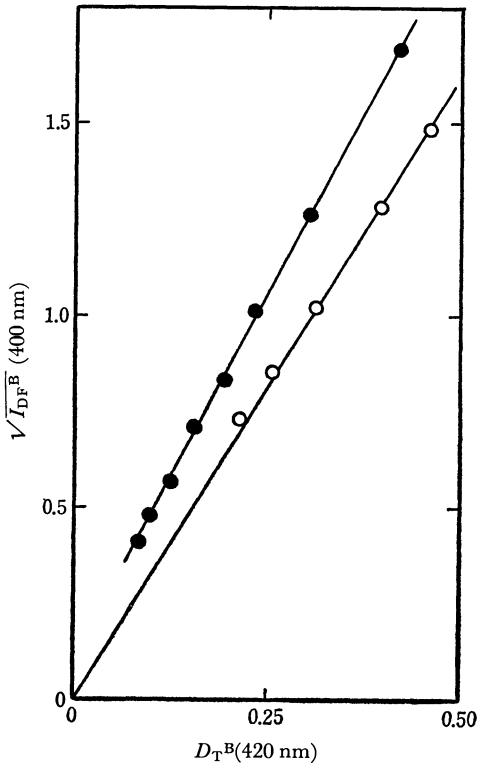

Fig. 7. The relation between D-Fl and T-T absorption for anthracene.

Figs. 7 and 8. Straight lines are the reference plots for the simple P-type delayed fluorescence corresponding to the relations in Table 2. The excesses over the reference lines are clearly due to the mixed T–T annihilation, I_{DF}^A(M, 412) and I_{DF}^B(M, 400). Figure 9 shows that these two quantities are in excellent proportionality to the product of D_T^B (420) and D_T^A (426) as is expected from Eqs. (3) and (4). Thus it is certain that the excess D–Fl is due to the mixed T–T annihilation. From the values of slope in Fig. 9 one can evaluate the value of $\alpha^B(400)\phi_F^B p_M^B k_{MT}/[\varepsilon_T^B(420)\varepsilon_T^A(426)d^2]$ and the corresponding value of A.

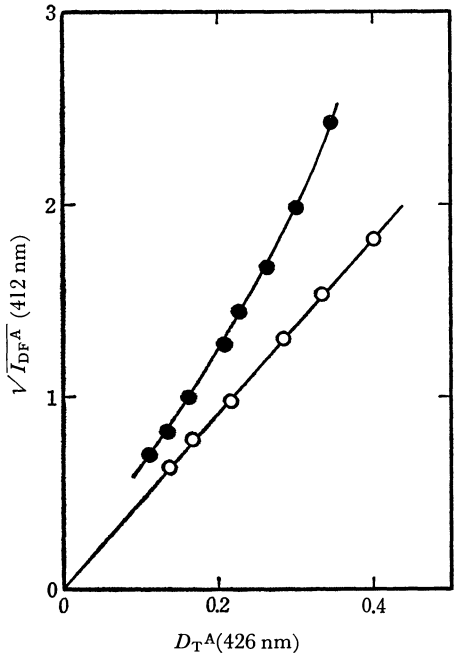

Fig. 8. The relation between D-Fl and T-T absorption for for 9-methylanthracene.

It is convenient to introduce a factor f defined as follows to compare the efficiency of the mixed type and pure P-type D–Fl.

$$f^A = p_M^A k_{MT}/p^A k_{TT}^A \qquad f^B = p_M^B k_{MT}/p^B k_{TT}^B \tag{11}$$

By combining Eqs. (1), (2) and Eqs. (3), (4) one can easily evaluate the f^A and f^B values as well as the $p_M^A k_{MT}$ and $p_M^B k_{MT}$ values given in Table 4.

As seen in Fig. 2 and Fig. 3, DE–Fl of anthracene and 9-methylanthracene exists although very weak.

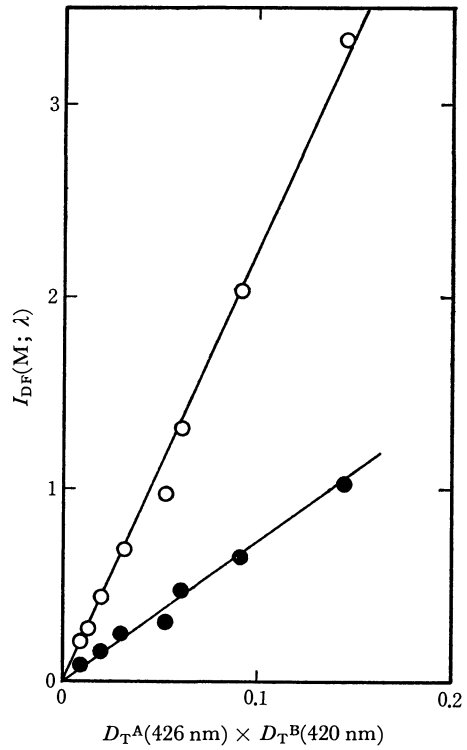

Fig. 9. The plots of $I_{DF}(M; \lambda)$ *vs.* $D_T^A(426) \times D_T^B(420)$ for 9-methylanthracene(A)-anthracene(B) system; ○ A at 412 nm, ● B at 400 nm.

Since D–Fl of monomer is negligible at 540 nm, D–Fl at this wavelength consists of the P-type and the mixed type DE–Fl, $I_{EF}(P, 540)$ and $I_{EF}(M, 540)$.

$$I_{DF}^A(P, 540) = I_{EF}^A(P, 540) + I_{EF}^A(M, 540)$$
$$= \beta^M \phi_{EF}^M q^M k_{MT} \frac{D_T^A(\lambda_1')D_T^B(\lambda_2')}{\varepsilon_T^A(\lambda_1')\varepsilon_T^B(\lambda_2')d^2}$$
$$+ \beta^A(540)\phi_{EF}^A q^A k_{TT}[D_T^A(\lambda)/\varepsilon_T^A(\lambda)d]^2 \quad (12)$$

The analysis can be made as in the case of monomer D–Fl, but in this case it was found that MDE–Fl is negligible.

For anthracene(B)-9-phenylanthracene(A), Fig. 10 shows the relation between the MDE-Fl intensity I_{DF}^E at 540 nm and the product of $D_T^A(440)$ and $D_T^B(421)$, obtained as a result of the above analysis. Although the linearity is not very good, there is no doubt that MDE–Fl occurs in this system.

System, 9-phenylanthracene(A) and 9-methylanthracene(B) also gives MDE–Fl.

In acridine(A)-anthracene(B), the fluorescence yield of acridine is one order less than that of anthracene derivatives and the triplet lifetime is much smaller; hence the measurement and analysis could not be performed accurately. However, the analysis clearly showed that both components exhibit MD–Fl as shown in Fig. 11. There is scarcely any doubt that MDE–Fl also occurs as seen from Fig. 12. For acridine(A)-9-methylanthracene(B), the results are qualitatively similar to those of the above system.

In acridine(A)-9-phenylanthracene(B), D–Fl spectra of the two components greatly resemble each other and

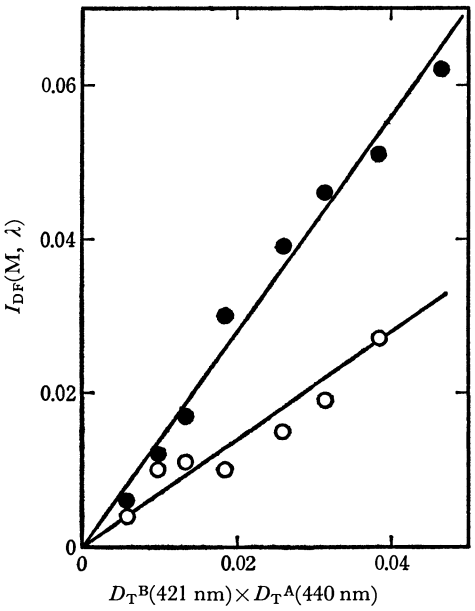

Fig. 11. The plots of $I_{DF}(M; \lambda)$ *vs.* $D_T^B(421) \times D_T^A(440)$ for acridine(A)-anthracene(B) system; ○ A at 400 nm, ● B at 412 nm.

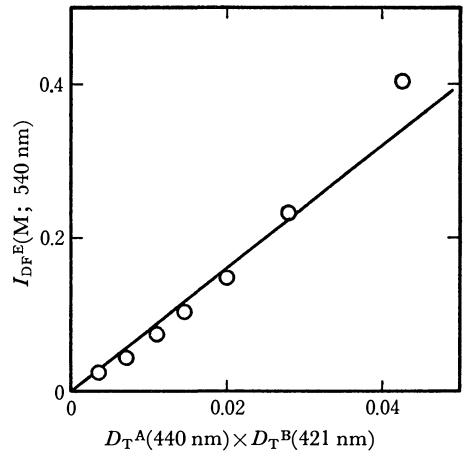

Fig. 10. The relation between $I_{DF}^E(M; 540)$ and $D_T^A(440) \times D_T^B(421)$ for anthracene(B)-9-phenylanthracene(A) system.

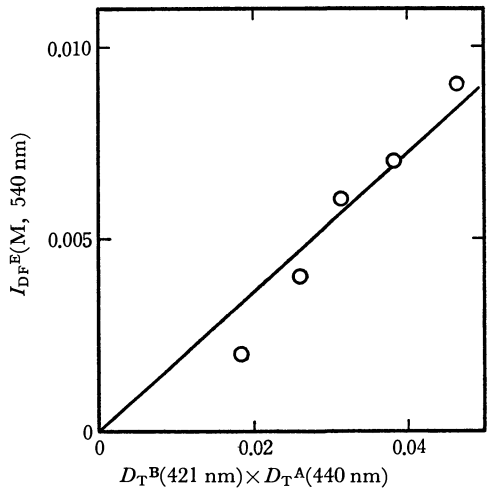

Fig. 12. The relation between $I_{DF}^E(M, 540)$ and $D_T^B(421) \times D_T^A(440)$ for acridine(A)-anthracene(B) system.

the fluorescence yield of the latter is considerably larger than that of the former. Therefore D–Fl could not be divided into two components. However, since D–Fl from acridine is very weak, the approximate values of f^B and $p_M{}^B k_{MT}$ could be estimated. The analysis at 540 nm also gave evidence for the occurrence of MDE–Fl.

Studies on Two Species with Quite Different Excited Singlet Levels. As is well known, D–Fl of eosin and of proflavine (both, A) is of E-type and is expressed by

$$I_{DF}{}^A(E, \lambda) = \alpha^A(\lambda)\phi_F{}^A k_T[{}^3A] \qquad (1')$$

of Eqs. (1) and (2). Accordingly, the expression for instead MD–Fl $I_{DF}(M, \lambda)$ has to be modified as follows.

$$I_{DF}{}^A(M, \lambda) = \alpha^A(\lambda)\phi_F{}^A p_M{}^A k_{MT}[{}^3A][{}^3B] + \alpha^A(\lambda)\phi_F{}^A k_T[{}^3A]$$

Apart from these two points, the method of analysis is essentially the same as in P-type D–Fl.[10] In eosin(A)-anthracene(B),[9] only D–Fl of eosin is increased remarkably by mixed T–T annihilation while that of anthracene scarcely shows any increase.

In proflavine(A)-anthracene(B), D–Fl of proflavine under ordinary conditions is of E-type and a similar analysis to that for the above system gave essentially the same result; D–Fl of proflavine largely increases by mixed T–T annihilation while that of anthracene is scarcely affected (Fig. 13).

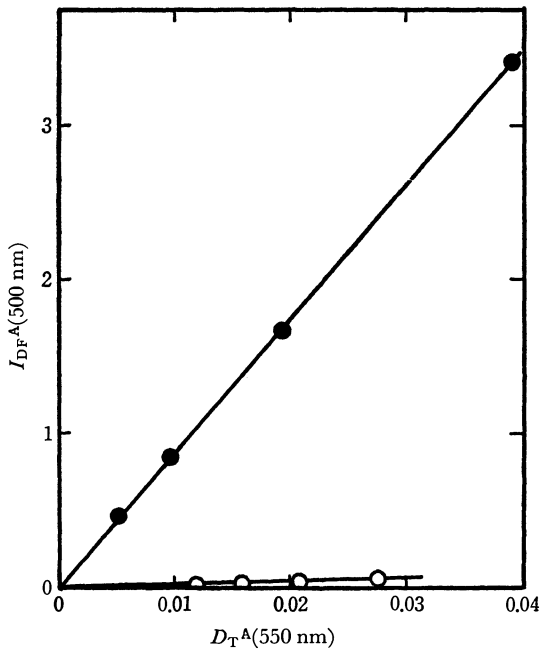

Fig. 13. The relation between $I_{DF}{}^A(500)$ and $D_T{}^A(550)$ for proflavine(A)-anthracene(B) system; ○[B]=0 M, ●[B]=2×10^{-6} M.

For eosin(A)-acridine(B), the results are similar to those of the above two systems.

For the last three systems MDE–Fl could not be investigated.

Discussion

In the present investigation, mixed T–T annihilation of anthracene derivatives have been studied quantitatively. Since the concentrations of both components are less than 10^{-5} M, no process in the initially excited singlet state participates, for instance, A*+B→A+B* and A*+B→(AB)*, *etc.* Accordingly the present results are concerned only with T–T annihilation of various types. The method of analysis leaves nothing doubtful at least in principle. Although errors may become considerable in some cases owing to experimental difficulties, the following general conclusions can be drawn.

1) When the singlet excited levels of A and B differ a few times of kT, D–Fl of both components occur.

2) When the level differences largely exceed kT, only D–Fl of the component with a lower level occurs.

3) MD-Fl occurs generally in case 1).

4) The efficiency of MDE–Fl ($p_M{}^A+p_M{}^B$) is equal to that of P-type D–Fl (p^A or p^B) at least in the order of magnitude.

For the mixed excimer fluorescence Birks and Christophorous[11] in classifying two types, stated that it occurs with a diffusion controlled rate in the systems composed of like compounds such as anthracene and its derivatives, while it does not occur at all in a pair of molecules with different aromatic cores. It has been established that similar situations hold also in mixed T–T annihilation.

It is very interesting that the value of $p_M{}^A/p_M{}^B$ is always larger than unity, *i.e.*, the component with a lower singlet excited level emits more efficiently when the 0–0 band of fluorescence is adopted as an excited level. Since the mixed T–T annihilation at room temperature occurs according to the following scheme as has been well established,[4]

$$B^T + A^T \rightarrow (B\cdots A)^{**} \xrightarrow{k_M{}^B} B^* + A$$
$$\xrightarrow{k_M{}^A} A^* + B$$
$$\rightarrow (B\cdots A)^* \text{ (mixed excimer)}$$

the value of $p_M{}^A/p_M{}^B$ is nothing but the ratio of the rate constants $k_M{}^A$ and $k_M{}^B$.

At present, the microscopic mechanism of a simple type delayed fluorescence as well as of a mixed one is unknown; $(B\cdots A)^{**}$ merely denotes an encounter state of unknown character. Birks suggested that the intermediate in the case of a simple type one may experience a quintet, triplet, or singlet state.[12] Such a change in spin states may occur in the early stage of encounter, but in mixed T–T annihilation, differing from the simple T–T annihilation, the two components A* and B or B* and A produced may still have a chance of transforming to each other. Thus it is necessary to take the following three possibilities into consideration as the molecular processes determining the $p_M{}^A/p_M{}^B$ value.

A) A^T and B^T approach close enough to interact and change their electronic states yielding ultimately (A*+B) or (B*+A) (bracket denotes that the two components still exist in the encounter state) in a certain proportion as determined by a specific electronic or vibronic interaction.

11) J. B. Birks and L. G. Christophorous, *Nature*, **196**, 33 (1962); p. 423 in Ref. 2.

12) J. B. Birks, *Chem. Phys. Letters*, **1**, 561 (1968).

B) The possibility may exist that in the encounter state, the Boltzmann distribution is approached between A* and B* due to electronic exchange interaction.

C) During the diffusion apart, there is another possibility that a long range dipole-dipole interaction causes a mutual transformation. This is thought to be possible because the distance to which the two components separate during the lifetime of the excited state $\sim 10^{-8}$ sec is estimated to be 10—100 Å. If the R_0-value in Förster's theory[13] is suitable, then $A+B^* \rightleftharpoons B+A^*$ may occur during the lifetime.

From the above viewpoint, the values of the Boltzmann factor $e^{-\Delta E/RT}$ (ΔE, difference of 0–0 band of fluorescence) and of R_0 for $B^*+A \rightleftarrows B+A^*$ are added in Table 4. The values of p_M^A/p_M^B change from 3 to 5 except for system (1). Putting aside the results for the systems involving acridine which are less reliable, only the p_M^A/p_M^B values for (1), (2), and (3) will be discussed. It is evident that these values are not well related with either the values of R_0 or of $e^{-\Delta E/RT}$. It may be said from the R_0 values that the energy transfer due to Förster's mechanism does not occur so efficiently in the present systems. Although the value of p_M^A/p_M^B for system (3) well agrees with the value of $e^{-\Delta E/RT}$, it may be judged that this is rather a mere coincidence in view of large discrepancies in (1) and (2). Thus in the present systems, it seems likely that the p_M^A/p_M^B values are determined mainly by the ratio of the two processes $(A\cdots B)^{**} \rightarrow (A^*\cdots B)$ and $(A\cdots B^*)$. The two components in the encounter state may then separate quickly with any noticiable chance of transforming to each other. When the levels of A* and B* are far apart, it is reasonable to consider that only the emission of the lower component occurs.

A few remarks will be added to the DE–Fl of anthracene derivatives. Birks and Aladekomo[14] reported that anthracene does not exhibit the excimer fluorescence while 9-methylanthracene does. He states[15] that anthracene with a great tendency of forming a stable photodimer does not give excimer fluorescence, while 9-methylanthracene with less tendency of dimerization due to a little steric hindrance will emit the excimer fluorescence. He expects that 9-phenylanthracene which does not dimerize will be more liable of forming excimer. However, no experimental data were given for the latter two compounds. The present results have verified his argument for the first time. Thus the values of $\beta\phi_{EF}q$ measured at 540 nm listed in Table 3 increase five times from anthracene to 9-methylanthracene and also from 9-methylanthracene to 9-phenylanthracene. In spite of some uncertainty in β-value, there is scarcely any doubt that these great differences reflect the differences in their excimer formation tendencies.

Nature of the Acid Sites on the Surface of Silica-alumina. II. The Relation between the Acid Property of the Sites and the Photo-ionization of Polyacenes Adsorbed on the Surfaces

Kazuto TAKIMOTO and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 8, 1971)

The ESR and diffuse reflection spectra of the polyacenes adsorbed on the surfaces of silica gel, alumina, and silica-alumina were measured. The amount of the cation radicals generated on the surfaces was enhanced upon irradiation with UV light. This was interpreted in terms of the photo-ionization accomplished *via* a charge-transfer state by an absorption of $h\nu_{CT}$, which was expected to vary with the strength of the Lewis-acid sites. The rate of the radical formation was not the first order, and that of the annihilation was the second order only in the initial stage. These phenomena are discussed in connection with the heterogeneity of the acid properties on the surfaces.

It is well known that such polyacenes as anthracene and perylene cause an electron transfer and a proton transfer on the surface of silica-alumina, even in the absence of ultraviolet (UV) irradiation. This phenomenon is interpreted in terms of the interaction of these polyacenes with the strong Lewis-acid sites and the Brönsted-acid sites on the surface of silica-alumina. A number of studies of the acidity, activity, and structure of the acid sites have been done in connection with catalysis by such techniques as infrared, ESR, diffuse reflection, and gas adsorption.[1-4] From these studies, we know that some strong acid sites on the surface interact with the polyacenes even in the ground state;

the cation radical is formed by an electron transfer from the polyacenes to the surface, and the carbonium ion is generated by a proton transfer from the surface to the polyacenes. Terenin and his co-workers have found that the formation of the cation radical on the surface is enhanced by UV irradiation.[5] This may show that the electron transfer occurs even on the weaker acid sites upon irradiation with UV light. As has previously been reported,[6] the acid properties of silica-alumina, alumina, and silica gel have been fairly well revealed. It is, therefore, of great interest to study the photo-ionization of polyacene adsorbed on the surfaces in connection with their acid properties.

The polyacene adsorbed on the surface can be regarded as a surface complex. We take into consideration the charge-transfer state in order to explain the transition from a nonbonding type, D···A, to a cation and anion type, $D^+ + A^-$, by UV irradiation, where D and A are a donor and an acceptor respectively. It is significant that the energy corresponding to the charge-transfer absorption band, $h\nu_{CT}$, caused by the interaction of the polyacene with the acid site varies with the strength of the acid site. The purpose of this work is to reveal; (1) the relation between the radical formation by UV irradiation and the acid property of the surface, and (2) the mechanism of the annihilation of the radical.

Experimental

Naphthalene and anthracene were purified by the sublimation method. Guaranteed perylene obtained from the Tokyo Kasei Co. was used without further purification. *n*-Hexane was purified by distillation, with several pieces of metallic sodium added to remove any moisture. The 12% silica-alumina, alumina, and silica gel were the same as those used in the preceding work.[6]

The polyacenes were adsorbed from their vapor phases or from the oxygen-free *n*-hexane solutions onto the surfaces of the silica-alumina, alumina, and silica gel. The source of UV light was an 1-kW high-pressure mercury arc. The ESR spectra were obtained by using a spectrometer described elsewhere.[7] The rate of the radical formation was determined from the increase in the relative intensity of the ESR signal on UV irradiation. The diffuse reflection spectra were measured by using a Hitachi-Perkin-Elmer 139 spectrophotometer, equipped with an attachment to measure diffuse reflection.

Results

ESR Spectra. When the surface coverage of polyacene was low and the coloration was just discernible, an ESR spectrum with nine well-resolved peaks was observed, as may be seen in Fig. 1; the hyperfine coupling constant and the *g*-value of the spectrum were 3.4 gauss and 2.0025 respectively. The spectrum was the same as that of the cation radical of polyacene, as was found by comparing the spectrum with that measured in a strongly oxidizing reagent.[8]

Figure 2 shows the rate of the radical formation from the naphthalene adsorbed on the surfaces of the silica-alumina, alumina, and silica gel which were treated at 300°C for 8 hr *in vacuo*. In the absence of UV irradiation, the cation radical of the naphthalene was formed only on the surface of the silica-alumina. Upon UV irradiation, the cation radical was generated also on the surface of the alumina, though it was not formed on the surface of the silica gel. The rates of radical formation by UV irradiation and its annihilation on the surface of the silica-alumina were faster than those on the alumina. The rate of the radical annihilation was considerably slower than that of the radical formation. The rates of the formation and annihilation of the radicals from the anthracene and perylene are

bands at 440 and about 530 mμ, and a feeble band at 760 mμ were observed. Upon UV irradiation for 30 min, the absorption band at 440 mμ was remarkably enhanced, while the bands at 530 and 760 mμ scarcely changed. According to several authors,[9] the band at 430 mμ, corresponding to that at 440 mμ in this work, is to be ascribed to the carbonium ion, naphthalene·H^+. On the other hand, the band at 530 mμ arises from the cation radical, naphthalene$^+$. The band at 760 mμ is attributable to the anion radical, naphthalene$^-$, which, in theory, must have the same band as that of the cation radical.[10] The structured bands below 320 mμ belong to physically-adsorbed naphthalene molecules. After the sample had been allowed to stand in a dark room for a day, the absorption maxima at 440 and 530 mμ increased a little, while the bands at wavelengths longer than 680 mμ slightly decreased.

The spectrum of the anthracene adsorbed on the surface of silica-alumina is shown in Fig. 6. The absorption bands appeared at 420, 560, 620, 660, and 720 mμ. The absorption maxima at 420 and 720 mμ may be assigned to the carbonium ion and the cation radical of the anthracene respectively.[9] The species for the weak absorption bands at 560, 620, and 660 mμ are not certain. The structured bands below 380 mμ arise from physically-adsorbed anthracene molecules. The absorption spectrum of the perylene adsorbed on the surface of the silica-alumina is shown in Fig. 7. The absorption bands are situated at 540, 610—620, and 730 mμ. After UV irradiation, the

maximum at 540 mμ increased significantly, while that at 730 mμ did so fairly much. These bands may be ascribed to the perylene cation radical. The bands below 450 mμ are due to physically-adsorbed perylene molecules.

Discussion

According to Mulliken's theory,[11] the wave functions of a surface complex may be represented by the following formulas:

$$\Psi_G^{(i)} = a^{(i)}\phi_{D\cdots A}^{(i)} + b^{(i)}\phi_{D^+\cdots A^-}^{(i)}$$
$$\Psi_E^{(i)} = a^{*(i)}\phi_{D\cdots A}^{(i)} + b^{*(i)}\phi_{D^+\cdots A^-}^{(i)}$$

where $\Psi_G^{(i)}$ and $\Psi_E^{(i)}$ are the ith wave functions in the ground state and the excited state respectively, and $\phi_{D\cdots A}^{(i)}$ and $\phi_{D^+\cdots A^-}^{(i)}$ are the ith wave functions of the nonbonding type and the charge-transfer type respectively, among many wave functions of the complex which result from the heterogeneity in the strength of the Lewis-acid site on the surface.

When a polyacene was adsorbed on the surface of silica-alumina, the cation radical was formed even in the absence of UV irradiation. This indicates the presence of a considerable amount of the surface complex, whose coefficient, $|b^{(i)}|$, in $\Psi_G^{(i)}$ is much larger than $|a^{(i)}|$. In other words, a large number of the strong Lewis-acid sites are present on the surface of silica-alumina. As the ionization potential of polyacene decreases, the amount of the cation radical generated on the surface in the ground state increases, as may be seen in Figs. 2, 3, and 4. This is due to an increase in the number of the charge-transfer-type functions, accompanied by a decrease in the ionization potential of polyacene.

The charge-transfer band corresponding to the transition from Ψ_G to Ψ_E could not be detected. This may be due to the band-broadening caused by the fact that the coefficients, $|a|$ and $|b|$, in Ψ_G can take various values. The energy of the charge transfer, $h\nu_{CT}$, decreases as the electron affinity of the Lewis-acid site increases and as the ionization potential of polyacene decreases. The photo-ionization of the polyacene adsorbed on the site, the electron affinity of which has a low value as compared with that of the ionization potential of the polyacene, may be accomplished *via* a charge-transfer state by the absorption of $h\nu_{CT}$. Thus, when polyacene adsorbed on the surface of silica-alumina was irradiated with UV light, the cation radical was formed even in the weak-acid site on the surface where it could not be produced in the absence of UV irradiation.

In the case of the alumina, the perylene and naphthalene adsorbed on the strong Lewis-acid sites are ionized by the transfer of the electron to the surface, while those adsorbed on the comparatively weak acid sites are also ionized *via* a charge-transfer state by means of UV irradiation. The amount of the radicals formed by the photo-ionization is, however, affected by the acid property of the surface. The difference between the amounts of the radicals produced on the surfaces of the alumina and the silica-alumina results not from the difference in the distribution of the acid sites, but from that in their number.[6,12] On the other hand, the naphthalene and perylene adsorbed on the surface of the silica gel were scarcely

ionized even with UV irradiation. This may be due to the lack of Lewis-acid sites on the surface.

When the energy level of a nonbonding type, D···A, rises to over the barrier or a charge-transfer state, the cation radical is generated. Its stability becomes higher as the electron affinity of the Lewis-acid site increases because the photo-ejected electron is stabilized on the site.

The rate of the radical formation was not the first order. However, the rate of the formation may be expected to be the first order, since the radical is formed by UV irradiation through the following process:

$$D\cdots A \xrightarrow{h\nu} D^+\cdots A^- \xrightarrow{\text{stabilization}} D^+ + A^-$$

The deviation of the formation rate from the first order may be caused by the heterogeneity of the surface. The sites on the surface have a wide range of acidity and acid strength. Such a distribution of the acid sites may complicate the rate of the radical formation.

On the other hand, when the UV light was put off, the annihilation of the radical occurred. Two mechanisms for the annihilation may be considered:

(1) $D^+ + A^- \xrightarrow{\text{reaction}}$ other products

(2) $D^+ + A^- \xrightarrow{\text{recombination}} D\cdots A + h\nu$

When the sample was kept for a day after UV irradiation and again irradiated, the amount of the radical was restored almost to the initial value. Hence, the (2) mechanism seems to be predominant. The rate of the annihilation was the second order in the initial stage, while it became the first order in the later stage. The annihilation rate seems to be the second order, since the recombination of the cation radical with the trapped electron predominantly contributes to the rate process. The fact that the rate of the radical annihilation in the later stage is apparently the first order may be due to the distribution of the Lewis-acid sites. That is, the rate constant of the recombination may be different according to the strength of the Lewis-acid sites; the rate of the recombination of the radical with the photo-ejected electron becomes faster as the Lewis-acid site is weaker, and also as the ionization potential of polyacene is higher. As a result, the rate of the annihilation seems to deviate from the second order as the reaction proceeds. This may also explain why the rate of the annihilation of the radical is slow in comparison with that of the formation, and why the ratio of the rate of the annihilation to that of the formation is least for perylene among these three polyacenes.

The authors wish to express their thanks to Dr. Akinori Hasegawa for his helpful discussions.

The Reactions of Photogenerated Solvated Electrons in Methanolic Solutions of Potassium Iodide

Hiroshi SEKI and Masashi IMAMURA

The Institute of Physical and Chemical Research, Wako, Saitama

(Received January 22, 1971)

Hydrogen formation from UV-irradiated potassium iodide solutions was studied using CH_3OH and CH_3OD as the solvents and nitrous oxide and acids as the solvated-electron scavengers. The maximum quantum yield of the solvated electron in CH_3OH was found to be 0.6 both in nitrous oxide and in acid solutions. It was concluded that the solvated electron produces hydrogen in pure methanol through Reaction (1), $e^-_{solv} \rightarrow H + CH_3O^-$, with a quantum yield of 0.35 at 25°. The rate constant of this reaction is 5.4×10^5 sec^{-1}, corresponding to a half-life of 1.3 μsec. From the results obtained with acid solutions, it was also concluded that nitrous oxide reacts with a solvated electron to produce one molecule of nitrogen in neutral methanol.

Solvated electrons are produced in aqueous solutions and many other polar liquids by the irradiation of ionizing radiations. The reactions of these solvated electrons, particularly of hydrated electrons, have been extensively studied by many investigators.[1] Solvated electrons have also been known to be produced by the UV irradiation of aqueous and alcoholic solutions of several inorganic[2] and organic compounds,[3] and, by the flash-photolysis technique, they have been shown to give an absorption spectra identical with those produced by ionizing radiations.[4-7]

Jortner *et al.*[8] studied the photochemical formation of solvated electrons using an electron scavenger in 0.15 M iodide solutions in methanol, ethanol, and isopropanol, and reported the quantum yields of 0.6—0.7 for the solvated electrons in these alcohols. Whereas they failed to observe the hydrogen formation from these solutions, Dainton *et al.*[9] observed it from an

UV-irradiated methanolic solution of lithium ferrocyanide.

In the γ-radiolysis of methanol, on the other hand, free solvated electrons are produced with $G=2.0$ and are believed to be a precursor of the product hydrogen.[10] Two possible pathways for the hydrogen formation from solvated electrons in radiation-irradiated methanol have been supposed:

$$e^-_{solv} \rightarrow H + CH_3O^- \quad (1)$$

$$CH_3OH_2^+ + e^-_{solv} \rightarrow H + CH_3OH \quad (2)$$

The pulse radiolysis studies showed that the decay of solvated electrons in alcohols is represented by the first-order kinetics,[11,12] indicating that they react principally with alcohol molecules. The rate constant of this decay reaction has been determined not only by the pulse-radiolysis technique, but also by steady-irradiation experiments.[13–15] However, there seem to be disagreements among these values larger than can be accounted for by experimental errors.

In contrast to the earlier result,[8] we observed the formation of hydrogen from UV-irradiated methanolic solutions of potassium iodide, and chose this system as an appropriate one for investigating the reaction of a solvated electron with a methanol molecule free from the interference of the competing reaction (Reaction (2)). This paper will report on the results of Reaction (1) as well as on the reaction of the solvated electron with nitrous oxide.

Experimental

Chemicals. Reagent-grade methanol supplied by the Wako Pure Chemical Co. was purified by distillation from a dinitrophenylhydrazine-H_2SO_4 solution. Deuterated methanol, CH_3OD(>99 atom%D), was obtained from CIBA, Ltd., and was purified similarly by using a small spinning-band distillation apparatus. The isotopic purity of the distilled CH_3OD was determined by NMR and was found to be usually ~99%.

The potassium iodide and hydrochloric and sulfuric acids were of a reagent grade from Wako and were used without further purification. Nitrous oxide and carbon dioxide, standard gases from the Takachiho Trading Co., were purified by distillation *in vacuo*.

Sample Preparation. A weighed amount of potassium iodide was degassed thoroughly in an irradiation ampoule before transferring degassed methanol into the ampoule by distillation on a vacuum line. When an acid solution was prepared, a small amount of acid was degassed beforehand and then added to the degassed methanolic solution through a break-seal. A such meticulous care was necessary to prevent the coloration due to iodine liberation in the solutions prepared.

Nitrous oxide and carbon dioxide were added to the solution volumetrically, their concentrations being calculated from the solubility data.[16]

Irradiation. The light source was an Ushio ULO-6DQ low-pressure mercury lamp, which was operated at 38V AC and 0.15 A with a voltage stabilizer. A 254-nm light was isolated by the use of an interference filter.[17] The methanolic solution of potassium iodide has a CT spectrum, with its peak at 220 nm extending to nearly 270 nm. The irradiation ampoule was a quartz cylinder, 2 cm in i.d. and 10 cm in length. All the photolyses were conducted at room temperature (~25°).

The light intensity and the quantum yields were determined by using a potassium ferrioxalate actinometer; the potassium ferrioxalate had been prepared according to the method described by Calvert and Pitts.[18] The concentration of the ferrous ions formed was determined by the *o*-phenanthroline method, and the quantum yield was taken to be $\Phi(Fe^{2+})=1.25$ at 254 nm.[18] The light intensity was in the range of $(2.7—8.3)\times10^{-9}$ einstein l^{-1} sec^{-1}.

Analytical Procedures. The hydrogen was determined by combustion on cuprous oxide using a micro gas-analyzer.[19] The amount of nitrogen produced from nitrous oxide solutions was determined from the residual gas volume after complete combustion, followed by absorption on magnesium perchlorate and Ascarite in the gas-analyzer. The formaldehyde was determined by the chromotropic-acid method.[19] The isotopic compositions of the hydrogen produced from CH_3OD samples were determined by mass-spectrometric analysis.[20]

Flash Photolysis. The details of the flash-photolysis apparatus have been described previously.[21] Briefly, the photolysis flash consisted of two Ushio xenon lamps. The operating characteristics of the lamps were 100 joule of energy per flash and 10 μsec for flash duration to a 50% peak. The reaction vessel was a quartz cylinder, 10 mm in i.d. and 10 cm in length, with flat plates sealed on either end.

Pulse Radiolysis. The rate constant of the reaction between solvated electron and nitrous oxide in methanol was determined by the pulse-radiolysis technique using a 3 MV Van de Graaff accelerator; the details will be published elsewhere.[22]

Results

Iodide Solutions in CH_3OH. Potassium iodide solutions (0.05—0.1 M) in CH_3OH produce hydrogen as a gaseous product upon UV irradiation. In the absence of potassium iodide, the UV irradiation produces no detectable hydrogen. A typical result is shown in Fig. 1, from which the quantum yield for hydrogen formation can be calculated to be 0.35 at 25°.

Another stable product from methanol is formalde-

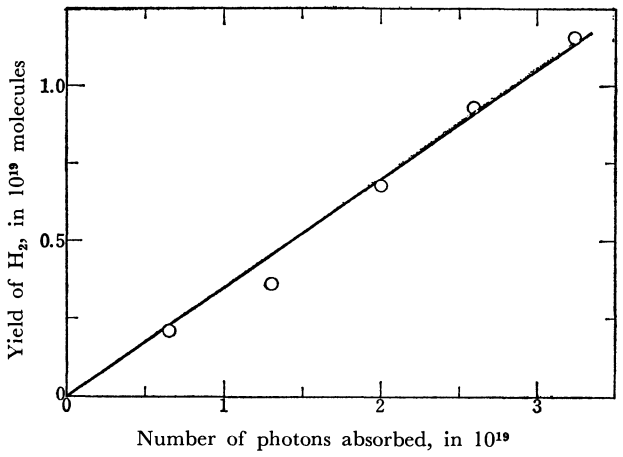

Fig. 1. Formation of hydrogen from UV-irradiated methanolic solution of potassium iodide. [KI]=0.1 M.
UV irradiation was carried out through an interference filter (see Ref. 17) at room temperature. $\Phi(H_2)$ is calculated to be 0.35.

hyde, which was determined after removing iodide from the irradiated solution by distillation *in vacuo*. The average quantum yield for formaldehyde is 0.3 at 25°, which is approximately the same as the value for $\Phi(H_2)$ from an iodide solution without a scavenger.

The quantum yields for hydrogen and formaldehyde were found to be independent of the iodide concentration within the range studied; most of the experiments were carried out at 0.1 M KI.

A flash photolysis study revealed the transient formation of I_2^-, which has absorption maxima at about 390 and 750 nm and which decays with a half-life of about 100 μsec at 420 nm; neither spectrum nor decay of the solvated electron could be observed because of the relatively long resolution time of the apparatus used. The absorption spectrum of I_2^- in methanol resembles those observed in aqueous[5] and ethanolic solutions.[7]

Effect of Electron Scavengers. N_2O. Nitrous oxide has been known as an effective solvated-electron scavenger, and its solution in methanol, in the absence of iodide, has been confirmed not to produce nitrogen upon UV irradiation. However, when nitrous oxide was added to the iodide solution in methanol, it produced nitrogen and the hydrogen yield was reduced. The quantum yields of nitrogen as well as hydrogen are plotted in Fig. 2 as a function of the nitrous oxide concentration.

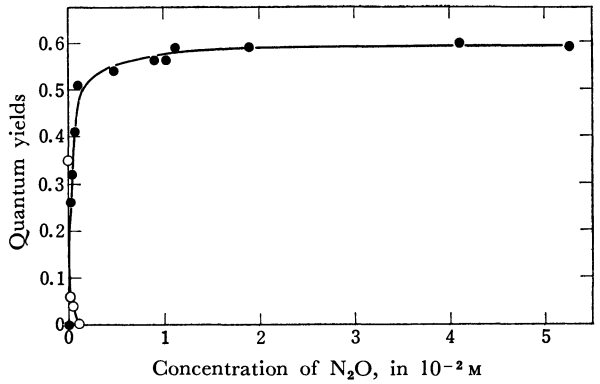

Fig. 2. Dependence of quantum yields for nitrogen and hydrogen on the concentration of nitrous oxide. [KI]=0.1 M.
●, N_2; ○, H_2

The quantum yield of nitrogen reaches a plateau value of 0.59 above 1.2×10^{-2} M N_2O, independent of the iodide concentration within the range investigated. This limiting yield is in good agreement with the value obtained by Jortner *et al.* (0.6).[8] With an increase in the concentration of nitrous oxide, the yield of hydrogen decreases rapidly, no hydrogen being detected at nitrous oxide concentrations as low as 5×10^{-4} M. In the presence of nitrous oxide, a small amount of I_3^- was found to be produced; this was not detected in the absence of nitrous oxide.

CO_2. Carbon dioxide, a solvated-electron scavenger, reduces $\Phi(H_2)$, no hydrogen being detected at concentrations as low as 10^{-3} M.

H^+. Hydrochloric or sulfuric acid was also added as a solvated-electron scavenger. As is shown in Fig. 3, the quantum yield for hydrogen increases with an increase in the concentration of acid, the plateau value being 0.57 for each acid. The plateau value of the quantum yield is in agreement with the plateau value of $\Phi(N_2)$ in nitrous oxide solutions.

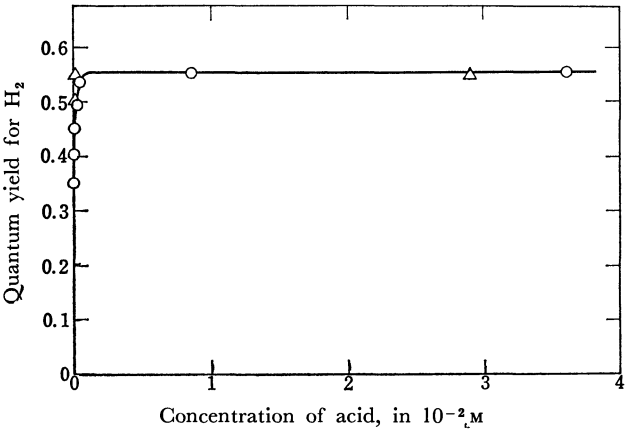

Fig. 3. Dependence of the quantum yield for hydrogen on the concentration of acids. [KI]=0.1 M.
○, H_2SO_4; △, HCl

Iodide Solutions in CH_3OD. Hydrogen was found to be produced by the UV irradiation also from iodide solutions in CH_3OD. The quantum yield for hydrogen, however, is considerably lower than that in CH_3OH, about 1/20 for the 0.1 M KI solution. The isotopic composition of hydrogen produced from 0.1 M KI solutions in CH_3OD was determined to be H_2: HD : D_2=16 : 84 : 0. As the purified CH_3OD contained ~1% CH_3OH, the observed isotopic compositions of hydrogen were subjected to corrections for the low rate of hydrogen production and the isotopic purity of the solvent. The result is that the fractions of HD should be very close to 100% if the 100% CH_3OD is used as a solvent. In the presence of nitrous oxide, however, the plateau value of $\Phi(N_2)$ (0.72) is substantially higher than that in CH_3OH (0.59). Similar

results have also been reported with H_2O and D_2O by Jortner *et al.*[8]

Although the quantum yield for hydrogen is very low in the 0.1 M KI solution in CH_3OD, it showed a steady increase with a decrease in the concentration of iodide, and, simultaneously, the fraction of H_2 in the product hydrogen was found to increase. However, the limiting quantum yield for nitrogen from CH_3OD solutions containing nitrous oxide is independent of the iodide concentration, as in the CH_3OH solutions. This apparently interesting phenomenon is being subjected to further study.

Rate Constant of the $e^-_{solv}+N_2O$ Reaction in Methanol. The rate constant of the reaction between the solvated electron and nitrous oxide in methanol was determined by the pulse-radiolysis technique. The decay of the solvated electron obeys the second-order kinetics, and its rate constant was found to be 1.3×10^{10} $M^{-1}sec^{-1}$, which is in fair agreement with the previous value (1.3×10^{10} $M^{-1}sec^{-1}$) obtained by us from the competition kinetics in the γ-radiolysis of methanol.[10] This value also agrees with that of $(1.4\pm0.4)\times10^{10}$ $M^{-1}sec^{-1}$ obtained by Dainton *et al.* from competition kinetics using nitrous oxide and benzyl chloride in methanol.[9]

Discussion

Photochemical studies of aqueous solutions of potassium iodide have been carried out extensively, and the primary processes seem to be relatively well understood.[2] Some difficulties in the interpretation of differences in the peak wavelengths of negatively-charged transients produced by the flash irradiation of several aqueous inorganic solutions[23] have been eliminated by the results from novel flash-photolysis experiments carried out by Devonshire and Weiss.[5] They succeeded in showing that the transient species produced from UV-irradiated aqueous solutions of several inorganic salts have absorption spectra identical with that of the hydrated electron obtained in the pulse radiolysis of aqueous systems.

Scavengers added to aqueous solutions react with hydrated electrons, not with the excited iodide ions,[24,25] and may compete with the secondary diffusive recombination. Recent results by Czapski, Ogdan, and Ottolenghi,[25] who investigated the photochemistry of aqueous solutions of iodide and bromide in the presence of high concentrations of nitrous oxide, have revealed that the "cage effect" takes place in the iodide system.

Similar results have been obtained for methanolic and ethanolic solutions of iodide,[6-8] no elaborate discussions of the primary processes taking place in UV-irradiated iodide solutions being required at the present stage. The primary processes for iodide ions are assumed here to be:

$$I^-_{solv} + h\nu \rightarrow I^-{}^*_{solv} \quad (3)$$

$$I^-{}^*_{solv} \rightarrow I^-_{solv} + \text{energy} \quad (4)$$

$$I^-{}^*_{solv} \rightarrow (I_{solv} + e^-_{solv}) \begin{cases} \nearrow I_{solv} + e^-_{solv} & (5a) \\ \searrow I^-_{solv} & (5b) \end{cases}$$

The parentheses in the above scheme mean that I_{solv} and e^-_{solv} are formed in a pair; Reaction (5b) represents the secondary recombination process.

In the present study, in the absence of an electron scavenger, the UV irradiation produces hydrogen with $\Phi(H_2)=0.35$ at 25°. Hydrogen may reasonably be assumed to form from the solvated electrons produced by Reaction (5a). The solvated electron has an absorption spectrum extending to short wavelengths.[1] We compared the quantum yield obtained by the use of an interference filter with that obtained by the use of a glass filter that transmits longer wavelengths, and found no significant difference in the $\Phi(H_2)$ between the two cases. This experiment may rule out the possibility of the participation of photo-excited solvated electrons in producing hydrogen, as has been suggested for rigid matrices at 77°K.[26]

The results on the isotopic composition of hydrogen from the UV-irradiated CH_3OD solutions indicate that hydrogen arises *via* Reaction (1), which results in the rupture of the hydroxyl hydrogen of methanol. Since the abstraction of the hydrogen atom by another hydrogen atom or by free radicals in liquid methanol takes place principally at the α-position,[27,28] the nearly 100% HD production after corrections for the isotopic purity of CH_3OD used and for the lower yield of hydrogen in the CH_3OD solution can be explained satisfactorily by assuming Reaction (1). It should be noted here that, in the nitrous oxide solutions in CH_3OD, the plateau value of $\Phi(N_2)$ is as high as 0.72, substantially higher than that in CH_3OH, indicating that most of the solvated electrons produced are recaptured, probably by iodine atoms, before forming hydrogen in CH_3OD.

The fact that, despite the higher $\Phi(N_2)$ in CH_3OD than in CH_3OH, the quantum yield for hydrogen is lower in CH_3OD than in CH_3OH, may be explained in terms of the isotope effect on the O–H (O–D) bond rupture. A similar isotope effect has been observed in the reactions of hydrated electron with H_2O[29] and D_2O:[30] $k(e^-_{aq}+H_2O)=16$ M^{-1} sec^{-1} and $k(e^-_{aq}+D_2O)=1.25$ M^{-1} sec^{-1}.

As a necessary consequence of the formation of solvated electrons, iodine atoms are produced (Reaction 5a), followed by the transient formation of I_2^-. Iodine atoms or I_2^- are expected to oxidize CH_2OH radicals produced by the $H+CH_3OH\rightarrow H_2+CH_2OH$ reaction to give formaldehyde:

$$I(\text{or } I_2^-) + CH_2OH \rightarrow CH_2O + I^-(2I^-) + H^+ \quad (6)$$

Some of the iodine atoms capture solvated electrons to form iodide ions. This reaction sequence is supported quantitatively by the experimental fact that the quantum yield for formaldehyde, $\Phi(CH_2O)$, is approximately the same as $\Phi(H_2)$. The second-order decay of the transiently-formed I_2^- and the non-formation of I_3^- as a stable product also support the above argument. Dobson and Grossweiner[7] have assumed similar reactions of I or I_2^- as well as the decay of solvated electrons in ethanolic solutions.

Upon the addition of nitrous oxide, solvated electrons are efficiently scavenged and nitrogen is formed:

$$e^-_{solv} + N_2O \rightarrow N_2 + O^- \quad (7)$$

As may be seen from Fig. 2, at the nitrous oxide concentration of 1×10^{-2} M, $\Phi(N_2)$ reaches a plateau value of 0.59, higher than $\Phi(H_2)$ in the absence of electron scavengers, and $\Phi(H_2)$ diminishes to zero at concentrations as low as 5×10^{-4} M N_2O. These facts indicate that hydrogen is not produced by the reaction between the photo-excited iodide ion and methanol, and that, in the concentration range studied, nitrous oxide competes not only with hydrogen formation and the reaction with iodine, but also with the secondary recombination for solvated electrons. Other modes of nitrogen formation by the $N_2O+O^-\rightarrow N_2+O_2^-$ reaction, sometimes assumed in the radiolysis of organic systems and by the reaction with the photo-excited iodide ion can be ruled out by the results with acid solutions, as will be mentioned below. It was shown previously[10] that reactions of nitrous oxide with H atoms or CH_2OH radicals do not give rise to nitrogen formation.

Carbon dioxide also scavenges the solvated electron efficiently. At the concentration of 10^{-3} M, the formation of neither hydrogen nor formaldehyde could be detected; a lack of information on the reaction of CO_2^- limits any realistic evaluation of the observation that formaldehyde is not formed.

The addition of acid increases $\Phi(H_2)$ to a plateau value that is equal to the plateau value of $\Phi(N_2)$ in the nitrous oxide solution (Fig. 3). This result can be explained in terms of the efficient reactivity of the hydrogen ion towards the solvated electron:

$$e^-_{solv} + CH_3OH_2^+ \rightarrow H + nCH_3OH \quad (8)$$

It also has an important implication for the reaction between nitrous oxide and solvated electrons. If, as has been mentioned above, nitrous oxide reacts also with O^- to form an additional nitrogen, the $\Phi(H_2)$ in the acid solution should be lower than $\Phi(N_2)$ in the nitrous oxide solution. The rate constants of Reactions (7) and (8) are both in the order of 10^{10} M^{-1} sec^{-1}, and no hydrogen-producing pathways other than Reaction (8) can be supposed for acid solutions. Therefore, we can conclude from the present results that nitrous oxide reacts with one solvated electron to produce one molecule of nitrogen in neutral methanolic solutions. The possibility of producing nitrogen by the reaction between the photo-excited ioide ion and nitrous oxide can also be ruled out from this viewpoint.

The same conclusion regarding the reaction between the solvated electron and nitrous oxide has been obtained by Jha and Freeman[13] from the radiolysis results with acid and nitrous oxide solutions in methanol and by Jortner *et al.*[8] from the photochemical study of aqueous iodide solutions as well. This has been assumed in our previous study carried out to determine the solvated-electron yield in methanol by the use of nitrous oxide as a solvated-electron scavenger.[10]

In the presence of nitrous oxide in low concentrations, the hydrogen formation will compete with the reactions of solvated electrons with nitrous oxide, iodine, and an impurity (if any), and hydrogen and nitrogen are produced simultaneously. Under these conditions, therefore, the ratio of $\Phi(N_2)$ to $\Phi(H_2)$ is expressed by:

$$\frac{\Phi(N_2)}{\Phi(H_2)} = \Phi(e^-_{solv}) \times \frac{k_7[N_2O]}{k_1 + k_7[N_2O] + k_x[X]} \Big/ \Phi(e^-_{solv}) \times \frac{k_1}{k_1 + k_7[N_2O] + k_x[X]} = k_7[N_2O]/k_1$$

Here, $\Phi(e^-_{solv})$ is the assumed quantum yield for the free solvated electron competing among the reactions mentioned above; its value is not determined experimentally, however. $k_x[X]$ is the overall expression for the reaction rate of the reactants other than nitrous oxide. As the two quantum yields were determined simultaneously from the same solution, the above conventional expression may be pertinent.

Figure 4 shows the linear relationship between $\Phi(N_2)/\Phi(H_2)$ and $[N_2O]$ in the concentration range of $(1—5)\times10^{-4}$ M. According to the above equation,

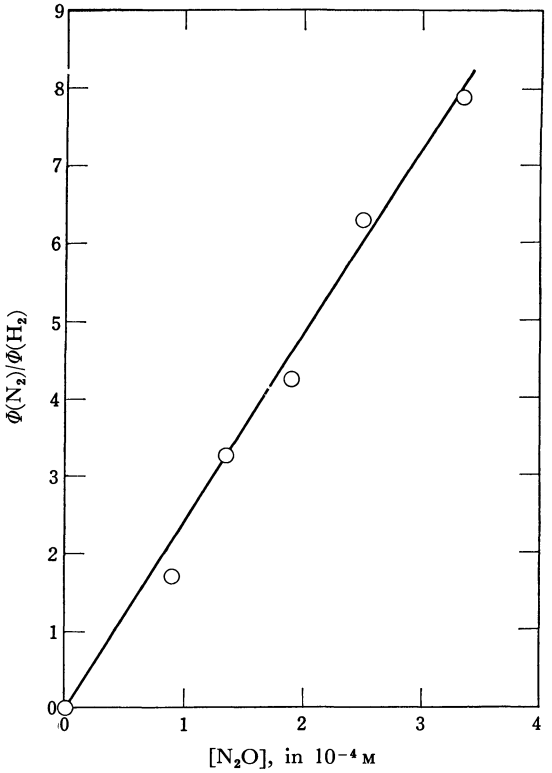

Fig. 4. A plot of $\Phi(N_2)/\Phi(H_2)$ *vs.* $[N_2O]$ for UV-irradiated solutions of low nitrous oxide concentrations. [KI]=0.1 M.

the slope of the straight line gives $k_7/k_1=2.4\times10^4$ M^{-1}. Taking $k_7=1.3\times10^{10}$ M^{-1} sec^{-1}, one can obtain a first-order rate constant of $k_1=5.4\times10^5$ sec^{-1}, which corresponds to a half-life of 1.3 μsec.

The present k_1-value of 5.4×10^5 sec^{-1} seems close to some literature values obtained directly by the pulse-radiolysis technique, 3.7×10^5 sec^{-1} (20°),[12] or indirectly by the competition kinetics, 4.6×10^5 sec^{-1} (25°),[13] with due consideration taken of the experimental errors involved in the preparation of samples of low nitrous oxide concentrations in this study; a much higher half-life of 7.5 μsec, corresponding to the lower rate constant of 0.9×10^5 sec^{-1}, has also been reported from a competition-kinetics study.[15]

Finally, it is interesting to compare the rate constant for Reaction (1) with that for the reaction of the hydrated electron with methanol in aqueous solutions. The rate constant for the latter reaction has recently been obtained by Hickel and Schmidt with photogenerated hydrated electrons in a hydrogen-saturated solution of sodium hydroxide as $k(e_{aq}^- + CH_3OH) \leq 400$ M^{-1} sec^{-1}.[31] Although this reaction is essentially different from Reaction (1) that is the decomposition of the solvated electron, the comparison of these rate constants may have some relevance to the structure and reactivity of solvated electrons; no discussion can be made here, however.

Conclusion. The photochemical formation of solvated electrons from aqueous or alcoholic solutions of potassium iodide is not a novel subject. However, this system has been shown, according to circumstances, to be convenient for studying the reactions of solvated electrons, which all play an important role in the radiation chemistry of polar liquids.

In this study, it was concluded that the solvated electron forms hydrogen in methanol through Reaction (1), in which the hydroxyl hydrogen is dissociated. The rate constant of this reaction was determined explicitly. We have assumed that hydrogen is formed in neutral solutions from solvated electrons, escaping the primary and secondary recombinations (geminate recombination),[32] and that the scavengers used compete with the hydrogen-formation process in the lower concentration range and can compete with the secondary recombination in the higher concentration range. Although it is not essential for the present study whether or not nitrous oxide competes with the secondary recombination at higher concentrations, the linear dependency of $\Phi(N_2)$ on the square root of the nitrous oxide concentration[25,32] observed at these concentrations may support the above assumption.

It has also been shown that the reaction of the solvated electron with nitrous oxide yields one molecule of nitrogen in neutral methanolic solutions.

The authors wish to acknowledge the assistance of Mr. Hiro Ishida in a part of this study of acid solutions. They also wish to express their thanks to Dr. Shigeyoshi Arai and Dr. Akira Kira for their helpful suggestions in carrying out the flash-photolysis and the pulse-radiolysis experiments.

The Activity of Dilute Sodium in Liquid Au-Na Alloy

Kazushi HIROTA and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received March 23, 1970)

The electromotive force of the cell;

Au–Na alloy $|Na_2CO_3|$ $CO_2 + O_2$, Pt-Rh,

was determined as a function of the temperature and the concentration of sodium in the alloy. The results were consistent with the activity values determined previously by the equilibrium method. The overpotential due to the current passing through the Au–Na alloy surface is less than 1 mV per mA/cm^2 of the current density at 1400°K. The activity of sodium, referred to the pure liquid standard state, was calculated from the electromotive force of this cell. The activity coefficient of sodium in Au–Na alloy is:

$$\log \gamma_{Na} = -2.55/T \cdot 10^{-3} + 0.39 \pm 0.05$$

in the temperature range from 1250°K to 1500°K and in the concentration range of less than 10 atom%Na.

In connection with construction of a sodium electrode adequate for use at high temperatures, the determination of the activity of sodium in an Au–Na alloy was undertaken. The large difference in ionization energies between Au and Na may result in the large negative value of the partial molar heat of mixing, and in the low value of the activity coefficient of the sodium in the alloy. Liquid metallic gold, therefore, is suitable as a solvent of sodium to reduce the vapor pressure and the reactivity of sodium.

Only a few thermochemical measurements have been performed on the Au–Na alloy. These are the calorimetric determination of the heat of the reaction of Au(s) with Na(l) at 403°K and at the concentration of 96.7 atom% Na by Oriani and Webb,[1] and the equilibrium determination among the Au-Na alloy, the Na_2CO_3 melt, and the CO_2+CO gas mixture at 1400°K.[2]

In the following, the electromotive force of the cell, Au–Na|Na_2CO_3|CO_2+O_2, Pt–Rh, will be determined. From the results of the measurements, the properties of the Au–Na electrode will be ascertained, and the activity coefficient of the sodium in the Au–Na alloy will be calculated by the use of the standard free energy of the formation of Na_2CO_3.

Experimental

The construction of the sodium electrode is given in Fig. 1. The Au–Na alloy was placed at the bottom of the alumina tube. The potential of this alloy was led to the outside of the furnace by an iridium wire, which was protected from gas and from the Na_2CO_3 melt with an alumina tube in order to prevent it from acting as a gas electrode.

The Au–Na alloy was made by means of an electrolysis of the Na_2CO_3 melt, *i.e.*, by the charge of the cell shown schematically in Fig. 1. At room temperature, the Au–Na alloy does not react with water when the concentration of sodium in the alloy is less than 20 atom%. The chemical composition of the alloy was determined by a method reported previously.[2]

The sodium carbonate melt dissolves alumina slightly under every set of experimental conditions. At the working conditions of 1400°K, about 5 mg/1 g Na_2CO_3 of alumina was found to dissolve in the sodium carbonate in the saturated state.

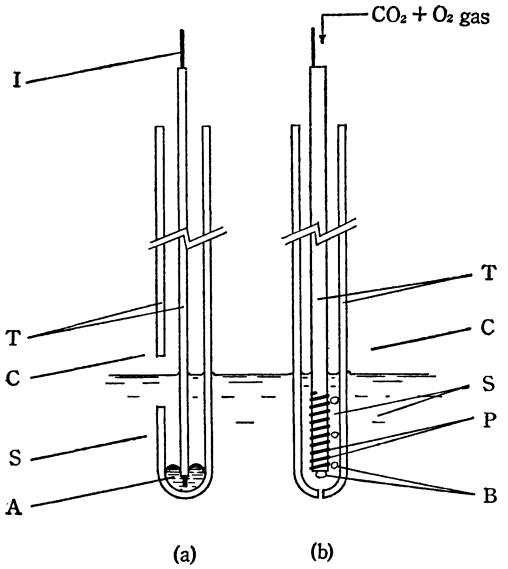

Fig. 1. Construction of the cell, Au-Na alloy|Na_2CO_3|CO_2 +O_2, Pt-Rh.
(a) Au-Na alloy electrode. (b) CO_2+O_2 gas electrode. A, Au-Na alloy; B, bubbles of CO_2+O_2 gas mixture; C, CO_2 gas; I, Iridium wire; P, platinum wire; S, sodium carbonate melt; T, alumina tubes.

Figure 1b shows the construction of the gas electrode used as the reference electrode. The composition of the gas was 80 vol%CO_2 and 20 vol%O_2, within an error of ±0.5 vol%.

These electrodes were immersed in the sodium carbonate in an alumina crucible placed in a vertical tube furnace. CO_2 gas flowed upward through the furnace. The temperature of the system was kept constant within ±5°C. The electromotive force obtained was corrected for the thermoelectromotive force.

Results and Discussion

The cell investigated has the following characteristics:

Au-Na|Na_2CO_3|CO_2(0.8 atm) + O_2(0.2 atm), Pt-Rh.

When every part of this cell is kept at sufficient equilibrium conditions, the electromotive force values are equal to that associated with the free energy change of the following reaction:

1) R. A. Oriani and M. B. Webb, *Acta Met.*, **7**, 63 (1959).
2) K. Hirota and T. Katsura, This Bulletin, **43**, 94 (1970).

$$CO_2(g) + (1/2)O_2(g) + 2Na(\text{in Au-Na alloy}) = Na_2CO_3(l) \quad (1)$$

The electromotive forces determined in the present experiment are given in Tables 1 and 2.

Comparison with the Equilibrium Experiment. The principal experimental criterion for the reliability of the electrode is that the potential is in agreement with the thermodynamic calculations. In a previous paper,[2] the activity coefficient of sodium in Au–Na alloy has been determined at 1400°K by the use of equilibrium between the Au–Na alloy and the Na_2CO_3 melt in contact with the CO_2+CO gas mixture.

The results for the $CO(g)+Na_2CO_3(l)=2Na(g)+2CO_2(g)$ reaction in the concentration range from 0.02 to 0.2 wt%Na are as follows at 1400°K:

$$\Delta G^\circ/4.606\,\boldsymbol{R}T + \log(P_{Na}/N_{Na}) = 2.44 \pm 0.03 \quad (2)$$

where $\Delta G^\circ = 2\Delta G_f^\circ(CO_2) - \Delta G_f^\circ(Na_2CO_3) - \Delta G_f^\circ(CO)$, where the ΔG_f°s are the standard free energies of the formation of each compound, and where N_{Na} and P_{Na} are the atom fraction of sodium in the alloy and the partial pressure of monatomic sodium in equilibrium with the alloy respectively.

The calculated electromotive force, E_{calc}, associated with the free energy change in Reaction (1) is given by;

$$E_{calc} = [\Delta G_f^\circ(CO_2) - \Delta G_f^\circ(Na_2CO_3)]/2\boldsymbol{F} - (\boldsymbol{R}T/2\boldsymbol{F}) \ln (a_{Na_2CO_3}/P^2_{Na} \cdot P_{CO_2} \cdot P_{O_2}{}^{1/2}) \quad (3)$$

where $\boldsymbol{F}$ is Faraday's constant and $a_{Na_2CO_3}$ is the activity of the liquid Na_2CO_3 referred to the pure liquid Na_2CO_3. From Eqs. (2) and (3), we obtain at 1400°K:

$$E_{calc} = [\Delta G_f^\circ(CO) - \Delta G_f^\circ(CO_2)]/2\boldsymbol{F} - (\boldsymbol{R}T/2\boldsymbol{F}) \ln (a_{Na_2CO_3}/N^2_{Na} \cdot P_{CO_2} \cdot P_{O_2}{}^{1/2}) + (11.24 \pm 0.14)\boldsymbol{R}T/2\boldsymbol{F} \quad (4)$$

When $a_{Na_2CO_3}=1$, $P_{CO_2}=0.8$, and $P_{O_2}=0.2$, i.e., under the working conditions of the cell, Eq. (4) yields:

$$E_{calc} = 277.8 \log N_{Na} + 1{,}451 \pm 9 \text{ (mV)} \quad (5)$$

where the values of the standard free energy of the formation of CO and CO_2 are taken from "JANAF Thermochemical Tables."[3]

3) The standard free energy of the formation values used in the present calculation are taken from "JANAF Thermochemical Tables" PB168 370, U. S. Department of Commerce/National Bureau of Standards (1965).

The experimental values found by electromotive force measurements of the cell were compared with the corresponding E_{calc} values calculated by Eq. (5), substituting the sodium concentration found in the alloy by chemical analysis. The values of the standard free energy of the formation of CO and CO_2 are known to be highly reliable. The accuracy of Eq. (5), therefore, depends only on that of the equilibrium experiment.

The values given in Table 1 exhibit an approximate agreement between the results of the equilibrium experiment and the present electromotive force measurement. The difference between these values, the calculated and the measured, is about 10 mV; this indicates the approximate magnitude of the error in the present method of electromotive force measurement.

The Overpotential at the Au–Na Alloy Electrode. The electrode potential as a function of current density was determined by this cell;

$$\begin{array}{lll} CO_2 + O_2 \mid & & \text{, Ir wire} \quad (1) \\ & Na_2CO_3 \mid \text{Au-Na alloy} & \\ CO_2 + O_2 \mid & & \text{, Ir wire} \quad (2) \end{array}$$

Two gas electrodes and one Au–Na alloy electrode were immersed in the same sodium carbonate melt, and two iridium wire were connected at the alloy electrode. The potential difference between one of the gas electrodes and an iridium wire was measured at 1400°K as a function of the current passed through the other gas-electrode iridium-wire pair. The results are shown in Fig. 2.

The overpotential determined by this method was 0.9 mV per mA/cm² of the current density at 0.5 atom% Na; this overpotential value decreased with an increase in the concentration of sodium in the alloy.

Estimation of Probable Error. The Au–Na alloy in the sodium electrode at working conditions slowly loses sodium even if the external current is zero. When the concentration of sodium in the alloy was low, the rate at zero external current was 1.0—0.5 mA/cm² in terms of the current density at the steady state of the system; it was almost independent of the sodium concentration.

However, when the partial pressure of sodium is about 10 mmHg or more, the escaping rate of sodium at zero external current increases rapidly with the concentration of sodium in the alloy. The rate, estimated by the time dependency of the electromotive force, was 20—10 mA in terms of the equivalent charging current at the concentration of about 30 atom%Na and at 1400°K. This rate depends also on the dimensions of the electrode tube and is a function of the convectional flow of the sodium carbonate melt.

The partial reduction of alumina in contact with Au–Na alloy results also in the loss of sodium. At a relatively high concentration of sodium, the alumina in contact with the alloy turned grey. Sodium is lost at a high rate at first, and then it slowly becomes a low rate as time elapses.

This loss of sodium results in the gradient of the sodium concentration at the surface of the Au–Na alloy, and leads to a depression of the electromotive force of the cell. The estimation of the magnitude of this depression in electromotive force can be obtained roughly by the use of Fig. 2.

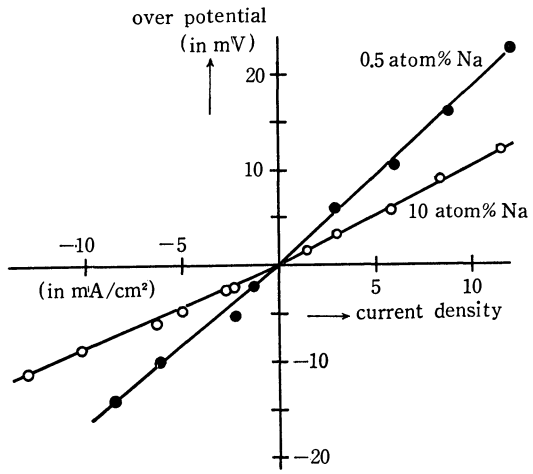

Fig. 2. Overpotential of Au-Na alloy electrode at 1400°K as a function of current density.

In the measurement of the electromotive force, the rate of the decrease in the sodium concentration was kept within 20 mA/cm². Therefore, the depression in the electromotive force values does not exceed about 20 mV in the present measurement. No correction was made for this depression in electromotive force values, since the phenomena have a complex nature.

The gas electrode used was highly reliable in spite of the fact that it has much kinetic resistance. The accuracy of this electrode in this temperature range seems to be better than that in the range from 800 to 600°C in which Borucka and Sugiyama made their measurements.[4]

It is known that Na_2CO_3 decomposes partly into Na_2O and CO_2 gas at a high temperature.[5] On the surface of the Au–Na alloy, a large part of the CO_2 molecules may be reduced to CO molecules by sodium, and the fugacity of CO_2 in the sodium carbonate melt may be low in comparison with that in the gas phase.

At the equilibrium of these reactions, it is obvious that:

$$-\boldsymbol{R}T \ln (a_{Na_2CO_3} \cdot P^2_{Na}/a^2_{Na_2O} \cdot P_{CO}) = \Delta G_f^\circ(Na_2CO_3) - 2\Delta G_f^\circ(Na_2O) - \Delta G_f^\circ(CO) \quad (6)$$

When the concentration of sodium in the alloy is high, it is also obvious that $a_{Na_2CO_3} < 1$ and that $P_{CO} \fallingdotseq 1$. Therefore, we obtain, for the temperature range between 1300°K and 1500°K:

$$\log a_{Na_2O} < \log P_{Na} - 1.9 \quad (7)$$

Therefore, the decomposition of the Na_2CO_3 melt may be disregarded under the present experimental conditions.

Activity Coefficient of Sodium at an Infinite Dilution. Equation (3) may be rearranged in the following form:

$$[\Delta G_f^\circ(CO_2) - \Delta G_f^\circ(Na_2CO_3)]/2.303\boldsymbol{R}T + \log(P_{Na}/N_{Na}) = \boldsymbol{F}E/2.303\boldsymbol{R}T - \log(N_{Na} \cdot P_{CO_2}^{1/2} \cdot P_{O_2}^{1/4}) \quad (8)$$

4) A. Borucka and C. M. Sugiyama, *Electrochim. Acta*, **14**, 871 (1969).

5) M. Schenke, G. H. J. Broers, and J. A. A. Ketelaar, *J. Electrochem. Soc.*, **113**, 404 (1966).

The right-hand side of Eq. (8) consists of directly measurable quantities in the present measurements. By the use of the right-hand side of Eq. (8), the left-hand side was calculated; the values thus obtained are given in Table 2.

When the concentration of sodium is lower than 10 atom%Na, the right-hand side of Eq. (8) does not depend on the sodium concentration within the range of experimental uncertainty. For this concentration range, the experimental values can be written in the form:

$$[\Delta G_f^\circ(CO_2) - \Delta G_f^\circ(Na_2CO_3)]/2\cdot2.303\boldsymbol{R}T + \log(P_{Na}/N_{Na}) = 15.0/T\cdot10^{-3} - 5.3 \pm 0.05 \quad (9)$$

By the use of the values of the standard free energy of formation[3] it is found that:

$$\log(P_{Na}/N_{Na}) = 7.5/T\cdot10^{-3} - 4.61 \pm 0.05 \quad (10)$$

When we choose pure liquid as the standard state for the activity of sodium, a_{Na}, the activity coefficient, $\gamma_{Na}=a_{Na}/N_{Na}$, can be obtained from Eq. (9), and the standard free energy of the condensation of monatomic sodium gas into the pure liquid sodium[3]:

$$\log \gamma_{Na} = -2.55/T\cdot10^{-3} + 0.39 \pm 0.05 \quad (11)$$

The relative partial molar excess free energy of sodium in the Au–Na alloy, referred to the pure liquid state defined by $\Delta\bar{G}^E_{Na}=\Delta\bar{G}_{Na}-\boldsymbol{R}T\ln N_{Na}=\boldsymbol{R}T\ln\gamma_{Na}$, is:

$$\Delta\bar{G}^E_{Na} = -11.7 + 1.78\cdot10^{-3}\cdot T \pm 0.15 \text{ (kcal/mole)} \quad (12)$$

From this value, the relative partial molar excess entropy and the relative partial molar heat of the mixing of sodium is obtained by the relation $\Delta\bar{G}^E_{Na}=\Delta\bar{H}^M_{Na}-T\cdot\Delta\bar{S}^E_{Na}$:

$$\Delta\bar{S}^E_{Na} = -1.8 \pm 1.0 \text{ (cal/mol·deg)},$$
$$\Delta\bar{H}^M_{Na} = -11.7 \pm 0.15 \text{ (kcal/mol)} \quad (13)$$

The values given in Eqs. (9), (10), (11), and (13) are valid in the concentration range lower than 10 atom%Na and in the temperature range between 1300° and 1500°K.

The Activity of Sodium as a Function of the Concentration up to 30 atom%Na. At concentrations of sodium higher than 10 atom%Na, the right-hand side of Eq. (8) does not remain constant, but increases with the sodium concentration. When we plot the right-hand side of Eq. (8) against $(1-N_{Na})^2$, a rather pronounced curvature is obtained. However, when we plot these values against N^2_{Na}, the values seems to fall on straight lines. The Au–Na alloy, therefore, is not a regular solution. The results are given in Fig. 3.

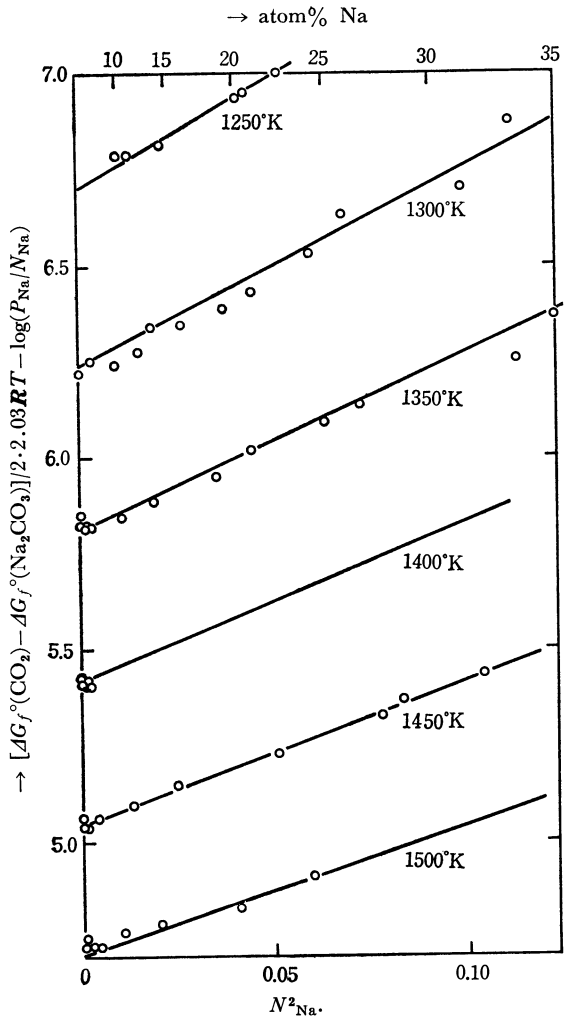

Fig. 3. A linear relation between the right hand side of Eq. (8) and N^2_{Na}. Eq. (14) is given as solid lines.

If we dare to give an algebraic expression for these results, we obtain the following equation, Eq. (14), for the range of sodium concentration lower than 30 atom%Na:

$$[\Delta G_f^\circ(CO_2) - \Delta G_f^\circ(Na_2CO_3)]/2\cdot2.303\boldsymbol{R}T + \log(P_{Na}/N_{Na}) = 15.0/T\cdot10^{-3} - 5.3 + 23\cdot N^2_{Na}/(T\cdot10^{-3})^3 \pm 0.1 \quad (14)$$

This equation is shown as solid lines in Fig. (3).

Preparation of Chromium(III) and Cobalt(III) Complexes with *d,l*-α-Phenylalanine-*N,N*-diacetic Acid[1]

Akira UEHARA, Eishin KYUNO, and Ryokichi TSUCHIYA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received April 28, 1970)

The following chromium(III) and cobalt(III) complexes with PADA (*d,l*-α-phenylalanine-*N,N*-diacetic acid) were prepared: $K[Cr(OH)pada(H_2O)]\cdot 5H_2O$ (violet) (I), $K[Cr(OH)pada(H_2O)_2]\cdot 3H_2O$ (green)(II), $(enH_2)_{1/2}[Cr(OH)pada(H_2O)_2]$ (green) (III), [Cr pada(*o*-phen)]·H_2O (brown) (IV), $K_2[Cr(ox)pada]\cdot 2H_2O$ (violet) (V), $K[Co(OH)pada(H_2O)]\cdot 5H_2O$ (blue-violet) (VI), and $K_2[Co_2(OH)_2(pada)_2]$ (brown-pink) (VII). On the basis of electronic spectra in both aqueous solution and solid state, it was found that PADA behaves toward central metal as a quadridentate ligand in complexes I, IV, V, VI, and VII; in other words, unlike the case of nitrilotriacetic acid (NTA), nitriloisopropionicdiacetic acid (NIPDA) and *l*-leucine-*N,N*-diacetic acid (LDA), PADA did not give different coordinating structures to the respective complexes in solid state and aqueous solution. From thermal analysis with derivatograph in the reaction processes of complex VI, it was found that the complex liberates one mole of coordinating water at about 170—180°C, resulting in the formation of the diol complex VII.

The authors have studied the preparation and properties of the chromium(III) and cobalt(III) complexes with NTA,[2,3] NIPDA,[4] LDA,[5] NPDA,[6] and AEDA.[7] Continuing these studies, we tried to prepare the corresponding complexes with PADA. The rational formulas of the chelating agents concerned are given in Table 1. In spite of a similar frame in these agents, the coordinating behaviors somewhat differ from each other due to differences in the fine structures and in the chemical properties such as acid dissociation constants. For instance, the ligands forming three five-membered chelate rings such as NTA, NIPDA, and LDA act toward metals as either $N\text{–}O_3$, $N\text{–}O_2$, or O_3 type, whereas the ligands forming two five- and one six-membered chelate rings such as NPDA and AEDA do not act as O_3 type.

If one of hydrogen atoms in a methylene group in NTA is substituted by a more bulky radical such as benzyl group, it is expected that the coordinating behaviors considerably differ from NTA, NIPDA, and LDA probably due to the stronger steric effect of the ligand substituted as above. The main purpose of the present work is to prepare PADA and the complexes therewith in order to confirm the above expectation.

When the ligands NTA and its analogues act as a quadridentate toward metal, the remaining *cis* sites are occupied by H_2O and OH^- in an aqueous medium. Therefore, an olation process expressed by the following scheme is expected in appropriate thermal conditions:

$$2[M(OH)L(H_2O)]^- \xrightarrow[-2H_2O]{} [L\ M(OH)_2M\ L]^{2-},$$

where M and L denote central metals such as chromium(III) or cobalt(III) and the quadridentate ligands, analogues of NTA, respectively. Another purpose of this study is to find a consistency between the diol complex thermally obtained as above and that directly prepared.

Table 1. Rational formula and abbreviation of chelating agents

Rational formula	Chelate ring	R	Chelating agent
N(CHRCOOH)(CH$_2$COOH)(CH$_2$COOH)	5, 5, 5	H	NTA[a]
		CH_3	NIPDA[a]
		$CH_2\cdot CH(CH_3)_2$	LDA[a]
		$CH_2\cdot C_6H_5$	PADA[a]
N(CH$_2$CH$_2$·R)(CH$_2$COOH)(CH$_2$COOH)	5, 5, 6	COOH	NPDA[a]
		SO_3H	AEDA[a]

a) NTA, Nitrilotriacetic Acid;[2] NIPDA, Nitriloisopropionicdiacetic Acid;[4] LDA, *l*-Leucine-*N,N*-diacetic Acid;[5] PADA, *d,l*-α-Phenylalanine-*N,N*-diacetic Acid; NPDA, Nitrilopropionicdiacetic Acid;[6] AEDA, β-Aminoethylsulfonic-*N,N*-diacetic Acid.[7]

Experimental

Preparation of d,l-α-*Phenylalanine*-N,N-*diacetic Acid.* Sixteen grams of *d,l*-α-phenylalanine was dissolved in 100 m*l* of water containing 7 g of potassium hydroxide, and 100 m*l* of aqueous solution containing 19 g of monochloroacetic acid was dropwise neutralized with 20 g of potassium hydrogen carbonate. The latter solution should be added gently and carefully, or else the deposition of *d,l*-α-phenylalanine takes place. The mixed solution was heated on a water bath, 30 m*l* of water containing 12 g of potassium hydroxide being added. Heating was continued for one hour in order to complete the condensation reaction. After the resulting solution was cooled to room temperature, the pH of the solution was adjusted to 2—3 by adding concentrated hydrochloric acid. White powdered crystals were easily obtained. Recrystallization of the crude product was carried out by dissolving it in potassium hydrogen carbonate solution and by adjusting the pH of the solution to 2—3. Yield 10 g.

Found: N, 4.99; C, 55.55; H, 5.85%. Calcd for N-$(CH(CH_2C_6H_5)COOH)(CH_2COOH)_2$: N, 4.80; C, 55.13; H, 5.89%.

Preparation of Complexes. Preparative procedures of the complexes are schematically shown in Table 2.

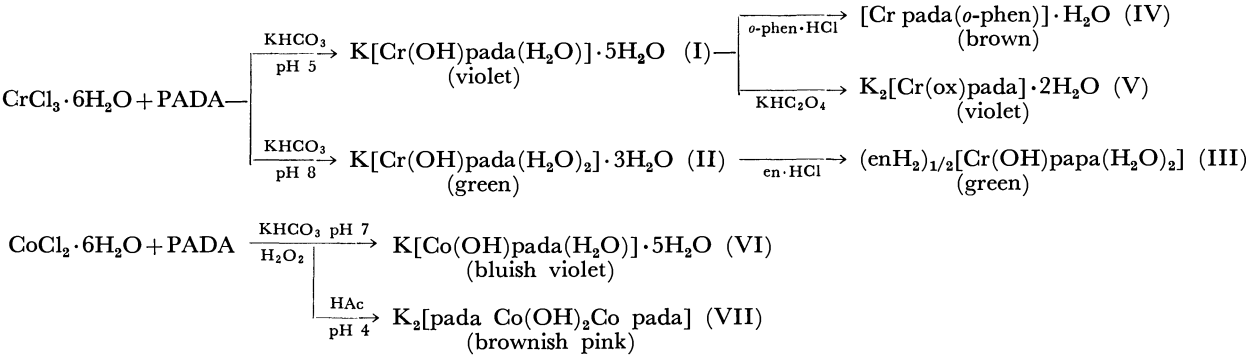
Table 2. Preparative scheme for chromium(III) and cobalt(III) PADA complexes



Potassium Hydroxo-d,l-*α-phenylalanine*-N,N-*diacetatoaquochromate(III) Pentahydrate, K[Cr(OH)pada(H$_2$O)]·5H$_2$O (I)*: Two hundred milliliters of water containing 14 g of PADA was neutralized with 6 g of potassium hydroxide. The solution was added to 100 m*l* of water containing 13 g of chromium(III) chloride hexahydrate, and the mixture was heated on a water bath until the color of the solution turned violet. After the pH of the solution was carefully adjusted to 5, the solution was concentrated to about 200 m*l* and left to stand in a refrigerator. Violet crystals were obtained which were recrystallized from water. Yield 4 g.

Found: N, 2.84; C, 31.60; H, 5.06%. Calcd for K-[Cr(OH)pada(H$_2$O)]·5H$_2$O: N, 2.96; C, 31.91; H, 4.83%.

Potassium Hydroxo-d,l-*α-Phenylalanine*-N,N-*diacetatodiaquochromate(III) Trihydrate, K[Cr(OH)pada(H$_2$O)$_2$]·3H$_2$O (green) (II)*: The preparative procedure was the same as for complex I until the violet solution was obtained. When the pH of the solution was carefully adjusted to 8, the color turned green. The resulting solution was left to stand in a refrigerator. Green crystals were obtained which were recrystallized from water. Yield 1.5 g.

Found: N, 2.94; C, 32.78; H, 4.83%. Calcd for K-[Cr(OH)pada(H$_2$O)$_2$]·3H$_2$O: N, 3.10; C, 32.90; H, 5.13%,

Ethylenediammonium Hydroxo-d,l-*α-phenylalanine*-N,N-*diacetatodiaquochromate(III), (enH$_2$)$_{1/2}$[Cr(OH)pada(H$_2$O)$_2$] (green) (III)*: Four and a half grams of complex II was dissolved in 100 m*l* of water containing 4 g of ethylenediamine hydrochloride. A gradual concentration on a water bath soon produced green crystals which were recrystallized from water. Yield 2.5 g.

Found: N, 3.39; C, 40.61; H, 5.31%. Calcd for (en-H$_2$)$_{1/2}$[Cr(OH)pada(H$_2$O)$_2$]: N, 3.12; C, 40.67; H, 5.72%.

d,l-*α-Phenylalanine*-N,N-*diacetato*-o-*phenanthrolinechromium(III) Monohydrate, [Cr pada(o-phen)]·H$_2$O (brown) (IV)*: Five grams of complex I was dissolved in a 200 m*l* of water, and then 2 g of *o*-phenanthroline was added to the solution. The pH of the solution was adjusted to *ca.* 5, and the solution was warmed on a water bath until the color turned brown. From the cooled solution brown crystals were obtained which were recrystallized from water. Yield 2 g.

Found: N, 7.96; C, 55.83; H, 4.10%. Calcd for [Cr pada(*o*-phen)]·H$_2$O: N, 7.61; C, 56.16; H, 3.92%.

Potassium Oxalato-d,l-*α-phenylalanine*-N,N-*diacetatochromium-(III) Dihydrate, K$_2$[Cr(ox)pada]·2H$_2$O (violet) (V)*: Five grams of complex I was dissolved in 100 m*l* of water containing 0.5 g of potassium hydroxide and 1.5 g of oxalic acid. When the solution was heated on a water bath, the color gradually turned from violet to bright violet. The solution was left to stand in a refrigerator for several days. Violet crystals were obtained which were recrystallized from water. Yield 1 g.

Found: N, 2.64; C, 33.83; H, 3.01%. Calcd for K$_2$-[Cr(ox)pada]·2H$_2$O: N, 2.83; C, 33.41; H, 2.82%.

Potassium Hydroxo-d,l-*α-phenylalanine*-N,N-*diacetatoaquocobaltate(III) Pentahydrate, K[Co(OH)pada(H$_2$O)]·5H$_2$O (blue-violet) (VI)*. Seven grams of PADA was dissolved in 200 m*l* of water containing 6 g of potassium hydroxide. Six grams of cobalt(II) chloride hexahydrate was dissolved in 50 m*l* of water. The latter was added little by little under magnetic stirring. The two solutions must not be mixed in the reverse order, otherwise the deposit of PADA is formed. The pH of the mixed solution was carefully adjusted to 6—7, and a few milliliters of hydrogen peroxide solution was added in order to oxidize cobalt(II) ion. As soon as the solution turned violet, it was stored in a refrigerator. Bluish-violet crystals were obtained. Since the solution sometimes turned from violet to brownish pink when the pH was not adequately adjusted, it had to be kept violet in order to obtain the desired complex. Recrystallization was carried out from water. Yield 1.5 g.

Found: N, 2.82; C, 30.11; H, 5.10%. Calcd for K-[Co(OH)pada(H$_2$O)]·5H$_2$O: N, 2.79; C, 31.17; H, 5.03%.

*Potassium μ-Dihydroxobis(*d,l-*α-phenylalanine)*-N,N-*diacetatodicobaltate(III), K$_2$[pada Co(OH)$_2$Co pada] (brown-pink) (VII)*: The compound was prepared from the filtrate after the crystals of complex VI were removed as precipitate. After the pH of the filtrate was adjusted to 3—4, the resulting solution was gently heated on a water bath until the color of the solution turned brownish pink. On cooling, brownish pink crystals were obtained. Purification of the crystals was carried out from water. Yield 1 g.

Found: N, 3.60; C, 39.84; H, 3.33%. Calcd for K$_2$-[pada Co(OH)$_2$Co pada]: N, 3.56; C, 39.73; H, 3.33%.

Instruments. The instruments used in the present work are the same as described previously.[6]

Results and Discussion

IR Spectra. IR spectra for the complexes were measured in a Nujol-mull state. It is known that characteristic bands for free and coordinated carboxylic acid generally appear at ~1750 and ~1640 cm^{-1}, respectively, in aminopolycarboxylic acid complexes.[8] Since the complexes prepared in the present work showed a band near ~1640 cm^{-1}, it is obvious that the carboxylate groups in the complexes are all coordinated.

Molar Conductivity and Magnetic Moment. Molar

8) D. H. Bush and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **75**, 4574 (1953).

conductivities were measured in an aqueous solution at 25°C in order to find the type of electrolytes for the complexes. Magnetic moments were evaluated from the magnetic susceptibilities measured by the Gouy method. The results are given in Table 3.

Table 3. Molar conductivity (λ), magnetic moment (μ_{eff}) and coagulation value (mF)

Complex	λ[a] mho cm^{-1}	mF[b]	μ_{eff} B.M. (°K)
I	125.6		3.83 (296)
II	121.3		3.86 (295)
III	148.9		3.78 (296)
IV	5.2		3.91 (296)
V	254.3		3.85 (296)
VI	121.2	5.7	dia. (295)
VII	154.8	0.5	dia. (295)

a) 10^{-3} mol/l aqueous solution was used at 25°C.
b) $Fe(OH)_3$ sol was used.

The values of the molar conductivities for the complexes I, II, III, and VI fairly support the view that they are 1 : 1 type electrolyte. The values for the complexes IV and V indicate that the former is a non-electrolyte and the latter, 1 : 2 type electrolyte, respectively. On the other hand, the value for complex VII may be somewhat smaller than that expected for 1 : 2 type electrolyte as $K_2[Co_2(OH)_2pada_2]$. However, the fact that the coagulation value for VII measured by using ferric oxide hydrosol was 0.5 milliformol will support 1 : 2 type for VII.

The values of the magnetic moments for complexes I—V were in the region of 3.8—3.9 B.M., while the magnetic susceptibilities for complexes VI and VII showed that they are diamagnetic. This indicates that the central metals chromium and cobalt in complexes are both tervalent.

Electronic Spectra. It has often been pointed out that the ligands NTA,[2] NIPDA,[4] and LDA,[5] forming three five-membered chelate rings can act as a terdentate ligand of O_3 and $N\text{–}O_2$ as well as a quadridentate ligand of $N\text{–}O_3$ type. Though PADA also has three five-membered chelate rings as in the above three ligands, how does it behave toward metals?

Figure 1 shows the spectra for complex I in aqueous solution and solid state together with those for the corresponding NTA complex $K[Cr(OH)nta(H_2O)]\cdot 2H_2O$. The former two spectra closely resemble that for NTA-complex in solid state but not in aqueous solution, indicating that the coordinating structure of complex I is the same as that for NTA-complex in solid state. It has been assigned that NTA, NIPDA, and LDA act as a quadridentate ($N\text{–}O_3$) in a solid and as a terdentate (O_3) in a solution. In the case of PADA, no such phenomenon could be detected.

Figure 2 contains the spectra for complexes II and III in aqueous solution, together with that for the corresponding NTA complex, $K[Cr(OH)nta(H_2O)_2]\cdot 3H_2O$. Since their spectra are substantially similar, it will be accepted that PADA acts as a terdentate ligand in complexes II and III. Though PADA can

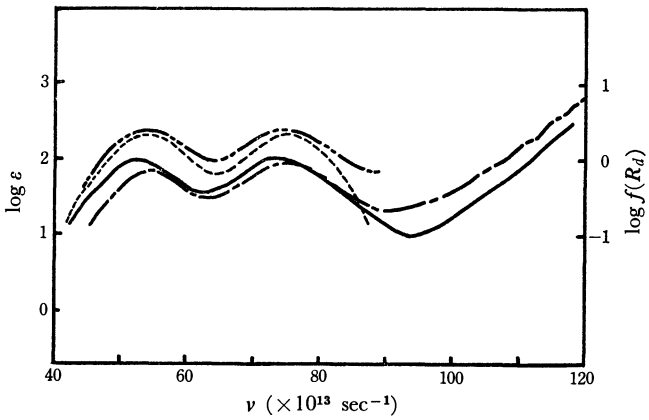


Fig. 1. Electronic spectra for complex I in an aqueous solution (———), in a solid state (– – –) and $K[Cr(OH)nta(H_2O)]\cdot 2H_2O$ in an aqueous solution (——), in a solid state (----).

act toward metals as both a quadridentate and terdentate, as seen in complexes I, II, and III, the coordinating manner does not change as extensively as that in NTA, NIPDA, or LDA. This may be due to the stronger steric hindrance by a large radical (benzyl radical) in PADA.

The absorption spectra for complexes VI and VII in aqueous solution are given in Fig. 3. Inamura

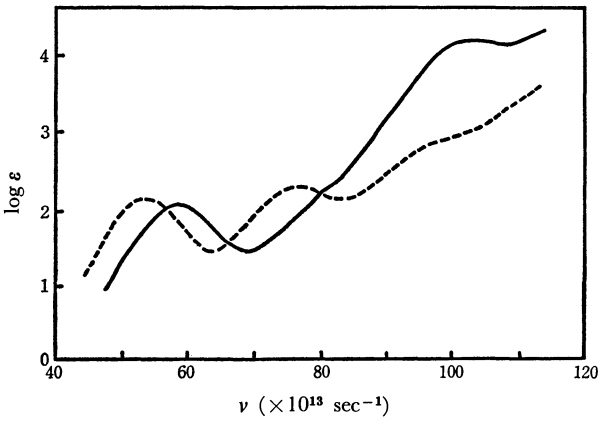

Fig. 3. Electronic spectra for complexes VI (----) and VII (——).

and Kondo[9] have reported that the spectra for the ol-ammine cobalt(III) complexes containing bridged OH groups show no distinct second d-d band, but a band due to bridged OH groups at $90—100\times10^{13}$ (c/s). As an example, it can be shown that K_2[nta-$Co(OH)_2Co$ nta] gives a band at near 100×10^{13} (c/s).[10] As seen from the figure, complex VII does now show such a distinct second band as in the case of complex VI, but a band at 100×10^{13} (c/s) appears predominantly. From these results, complex VII is considered to be a diol complex.

The derivatogram for complex VI is given in Fig. 4.[11] Two steps corresponding to the loss of 4 moles and one mole of water are observed in the temperature ranges of 40—90 and 90—110°C, respectively. The

VII	59.41 (2.09)	b)	~105 (~4.10)[c]

a) The specific bands due to the coordinating *o*-phenanthlorine.
b) The band can not be clearly detected because of the strong overlap owing to the specific band of the bridging OH groups.
c) The specific band due to the bridging OH groups. The band is not clearly detected because of its broadening.

DTA curve in the above two steps shows the endothermic reaction. Although the mass loss corresponding to one mole of water is also detected at 170—180°C, the reaction is shown to be exothermic in spite of liberation of water. At this step, the color of the sample turned from bluish violet to brownish pink. The spectrum for complex VI picked up at 180°C in the intermediate course of the derivatograph is given in Fig. 5, together with those for complexes VI and VII. The spectrum observed for the sample obtained in the thermal process is found to be similar to that of complex VII. It is also deduced from the results that the diol complex was formed by heating complex VI.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

Preparation of Hydroxoaquo- and Diol-Type Cobalt(III) Complexes with Analogues of Nitrilotriacetic Acid[1)]

Akira UEHARA, Eishin KYUNO, and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received April 30, 1970)

The following hydroxoaquo- and diol-type cobalt(III) complexes were prepared: K[Co(OH)(α-abda)-$(H_2O)]\cdot 2H_2O$ (I), K[Co(OH)(vda)$(H_2O)]\cdot 1.5\,H_2O$ (II), K[Co(OH)pgda(H_2O)] (III), K_2[nipda $Co(OH)_2$-Co nipda]$\cdot 2H_2O$ (IV), K_2[(α-abda) $Co(OH)_2$Co (α-abda)]$\cdot 3H_2O$ (V), K_2[vda $Co(OH)_2$Co vda]$\cdot 3H_2O$ (VI), K_2[*l*da $Co(OH)_2$Co *l*da]$\cdot 2H_2O$ (VII) and K_2[pgda $Co(OH)_2$Co pgda]$\cdot 2H_2O$ (VIII), where α-abda, vda, pgda, nipda and *l*da are the abbreviations of *d,l*-α-amino-*n*-butyric-*N,N*-diacetate, *l*-valine-*N,N*-diacetate, *d*-α-phenylglycine-*N,N*-diacetate, nitriloisopropionicdiacetate and *l*-leucine-*N,N*-diacetate ions, respectively. From the measurements of electronic spectra, conductivities and coagulation values and the results of derivatography, it was found that the diol complexes IV—VIII were also formed from the correspoindng hydroxoaquo complexes in the thermal reaction process.

Studies on the preparation and the properties of chromium(III) and cobalt(III) complexes with some analogues of nitrilotriacetic acid (NTA) have been reported.[2-4)] When these chelating agents coordinate to metals in the hydroxoaquo-type complexes, $[M(OH)L(H_2O)]^-$, where M is cobalt (III) or chromium(III) and L is a quadridentate analogue of NTA, the ligands, OH^- and H_2O, should inevitably be situated in *cis*-positions. It is well known that a hydroxoaquo complex may liberate the coordinating water, resulting in the formation of the corresponding diol complexes under certain conditions. Such examples were found in the complexes $[Co(OH)(NH_3)_4(H_2O)]X_2$[5,6)] and $[Cr(OH)en_2(H_2O)]Cl_2$[7)] for the first time. Studies[2,3)] concerning diol-formation from K[Co(OH)nipda$(H_2O)]\cdot 2H_2O$ and K[Co(OH)*l*da$(H_2O)]\cdot H_2O$ were recently carried out in our laboratory.

In order to extend the study on diol-formation, the present work was undertaken (1) to prepare several hydroxoaquo complexes as the starting material and their corresponding diol complexes, and (2) to find the consistency between the diol complexes thermally obtained and those directly prepared.

For the sake of convenience, the general, rational formula and the abbreviations of chelating agents used in the present work are given in Table 1.

Experimental

Preparation of Hydroxoaquo Complexes. The general paths for the preparation of the hydroxoaquo and the diol complexes are given in Table 2, where L denotes one of the analogues of nitrilotriacetate ion.

*1) Potassium Hydroxo-*d,l*-α-amino-*n*-butyric-*N,N*-diacetato-aquocobaltate(III) Dihydrate, K[Co(OH)(α-abda)$(H_2O)]\cdot 2H_2O$ (I)*: Ten grams of *d,l*-α-amino-*n*-butyric acid was dissolved in 30 m*l* of water containing 6 g of potassium hydroxide. 19 g of monochloroacetic acid was dissolved in 200 m*l* of water, and then gradually neutralized with 20 g of potassium hydrogen carbonate. The two solutions were mixed together and heated on a water bath. After the temperature of the solution reached 70—80°C, 12 g of potassium hydroxide was added. An exothermic reaction took place. Heating was continued for about one hour in order to complete the reaction. When the resulting solution was cooled in a refrigerator, potassium chloride was precipitated. After the precipitate was removed by filtration, the filtrate was used as the starting material.

To the filtrate, 300 m*l* of water containing 20 g of cobalt(II) chloride hexahydrate was gradually added under magnetic stirring, since rapid addition often produced undesirable sediments such as cobalt hydroxide. The pH of the solution was adjusted to 6—7 by means of potassium hydrogen carbonate or acetic acid, and then 5 m*l* of hydrogen peroxide solution was dropped in order to oxidize cobalt(II) salt. Bluish violet crystals were obtained from the cooled solution. The crude products were recrystallized from aqueous solution. Yield about 5 g.

Found: N, 3.55; C, 25.07; H, 4.31%. Calcd for K[Co(OH)(α-abda)$(H_2O)]\cdot 2H_2O$: N, 3.63; C, 24.96; H, 4.45%.

*2) Potassium Hydroxo-*l*-valine-N,N-diacetatoaquocobaltate(III) Sesquihydrate, K[Co(OH)vda$(H_2O)]\cdot 1.5H_2O$ (II)*: This

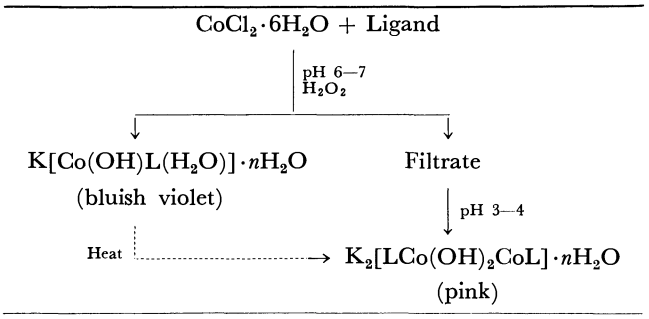
TABLE 2. A GENERAL PATH FOR PREPARATION OF COMPLEXES



complex was prepared by a similar procedure to that for α-ABDA except that 12 g of *l*-valine was used as the starting material in stead of *d,l*-α-amino-*n*-butyric acid. The crystals were also bluish violet. Recrystallization was carried out from water. Yield 7 g.

Found: N, 3.46; C, 27.81; H, 4.40%. Calcd for K-[Co(OH)vda(H_2O)]·1.5H_2O: N, 3.59; C, 27.72; H, 4.65%.

*3) Potassium Hydroxo-*d*-α-phenylglycine-*N,N*-diacetatoaquocobaltate(III), K[Co(OH)pgda(H_2O)] (III)*: Five grams of d-α-phenylglycine was dissolved in 10 m*l* of water containing 2 g of potassium hydroxide. Nine grams of monochloroacetic acid was dissolved in 30 m*l* of water and gradually neutralized with 20 g of potassium hydrogen carbonate. Further procedure for obtaining the solution containing the desired ligand material was the same as that for α-ABDA except that 4 g of potassium hydroxide was added to the warmed solution on a water bath.

6.5 g of cobalt(II) chloride hexahydrate was dissolved under magnetic stirring in the solution obtained after the above procedure. After the pH of the solution was adjusted to 7—7.5, a few milliliters of hydrogen peroxide solution was added. The solution turned violet. In this case, the violet solution often turns pink as a result of the partial formation of the diol complex, and it is important to take care to keep the pH value of the solution in the desired range as exact as possible. From the rapidly cooled solution, bluish violet crystals were obtained. Recrystallization was carried out from water. Yield about 0.5 g.

Found: N, 3.31; C, 34.31; H, 3.80%. Calcd for K-[Co(OH)pgda(H_2O)]: N, 3.37; C, 34.73; H, 3.64%.

Preparation of Diol Complexes. 4) Potassium μ-Dihydroxobis(nitriloisopropionicdiacetato)dicobaltate(III) Dihydrate, K_2[nipda Co(OH)$_2$Co nipda]·2H_2O (IV): Five grams of NIPDA[8] was dissolved in 100 m*l* of aqueous solution containing 6 g of cobalt(II) chloride hexahydrate. The solution was heated on a water bath and neutralized with 5 g of potassium hydrogen carbonate. After the pH of the solution was adjusted to 6—7, a few milliliters of hydrogen peroxide was dropped into the solution in order to oxidize cobalt(II) salt, when bluish violet crystals of K[Co(OH)nipda(H_2O)]·H_2O[3] were obtained. After the crystals were separated, the pH of the filtrate was adjusted to 3—4 with acetic acid. The solution was warmed gently until the color turned from violet to pink. Pink crystals were obtained from the cooled solution after several days. They were recrystallized from water. Yield 0.5 g.

Found: N, 4.14; C, 25.64; H, 3.45%. Calcd for K_2-[nipda Co(OH)$_2$Co nipda]·2H_2O: N, 4.18; C, 25.10; H, 3.31%.

*5) Potassium μ-Dihydroxobis(*d,l*-α-amino-*n*-butyric-*N,N*-diacetato)dicobaltate(III) Trihydrate. K_2[(α-abda) Co(OH)$_2$Co (α-abda)]·3H_2O*: This was crystallized from the filtrate after the removal of complex I in its preparation. After the pH of the filtrate was adjusted to 3—4 with acetic acid, the solution was warmed gently on a water bath until it turned pink. On cooling for several days, pink crystals were obtained which were recrystallized from water. Yield about 0.6 g.

Found: N, 3.92; C, 26.80; H, 3.77%. Calcd for K_2-[(α-abda) Co(OH)$_2$Co (α-abda)]·3H_2O: N, 3.91; C, 26.84; H, 3.94%.

*6) Potassium μ-Dihydroxobis(*l*-valine-*N,N*-diacetato)dicobaltate(III) Trihydrate, K_2[vda Co(OH)$_2$Co vda]·3H_2O (VI)*: This was crystallized from the filtrate in the preparation of complex II by a procedure similar to that for complex V. Pink crystals were recrystallized from water. Yield about 1 g.

Found: N, 3.71; C, 29.04; H, 4.61%. Calcd for K_2-[vda Co(OH)$_2$Co vda]·3H_2O: N, 3.76; C, 29.06; H, 4.33%.

*7) Potassium μ-Dihydroxobis(*l*-leucine-*N,N*-diacetato)dicobaltate(III) Dihydrate, K_2[lda Co(OH)$_2$Co lda]·2H_2O (VII)*: This complex was prepared by a similar procedure to that for complex IV except that six grams of *l*-leucine-*N,N*-diacetic acid (LDA)[2] was used as a starting ligand in place of NIPDA. The complex was pink as in the case of complex IV. Recrystallization was carried out from water. Yield 0.5 g.

Found: N, 3.65; C, 31.48; H, 4.31%. Calcd for K_2-[lda Co(OH)$_2$Co lda]·2H_2O; N, 3.71; C, 31.86; H, 4.54%.

*8) Potassium μ-Dihydroxobis(d-α-phenylglycine-*N,N*-diacetato)-dicobaltate(III) Dihydrate, K_2[pgda Co(OH)$_2$Co pgda]·2H_2O (VIII)*: This was prepared in a procedure similar to that for complex V except that the filtrate in the preparation of complex III was used. It was also recrystallized from water. In the preparation of the pgda-complex, the diol salt was more easily formed as compared with the corresponding hydroxoaquo salt, whereas in the case of the other complexes, hydroxoaquo salts were more readily produced than the corresponding diol salts. Yield 0.5 g.

Found: N, 3.61; C, 35.97; H, 3.19%. Calcd for K_2-[pgda Co(OH)$_2$Co pgda]·2H_2O: N, 3.53; C, 36.30; H, 3.30%.

Apparatus. The apparatus used in the present study is the same as reported previously.[9]

Results and Discussion

Electronic Spectra. A striking difference in features between the hydroxoaquo and the diol complexes is that the former is bluish violet, whereas the latter is pink. Spectra for all the complexes were obtained but only representative examples in a pair of VDA complexes, II and VI, are shown in Fig. 1. Complex II gives the first and the second bands at 53.57 and 76.53×10^{13} sec^{-1} respectively. Complex VI does not show the second band distinctly, but a new band at $\sim 100 \times 10^{13}$ sec^{-1}. All the complexes, IV, V, VII, and VIII exhibit the same features in their spectra as those of complex VI.

It is known[10] that the ol-ammine complexes show the specific band due to the bridged OH group at

Table 3. Absorption maxima

Complex	ν_1 (log ε_1)	ν_2 (log ε_2)[a]	Complement[b]
I	53.10 (2.15)	75.38 (2.35)	
II	53.38 (2.09)	76.34 (2.26)	
III	53.10 (2.13)	76.73 (2.29)	
IV	59.76 (2.11)		~100 (~4.2)
V	59.64 (2.13)		~100 (~4.3)
VI	59.06 (2.16)		~100 (~4.2)
VII	59.76 (2.18)		~100 (~4.3)
VIII	59.29 (2.18)		~105 (~4.6)

a) The second bands of complexes IV to VIII can not be clearly detected because of the overlap with the specific band due to the bridging OH groups.
b) These values show the specific bands due to the bridging OH groups. The band can not be clearly detected because of its broadening.

about 100×10^{13} sec^{-1}. In some cases the second band does not appear due to being concealed by the strong specific band. Such a difference[11] may propose one evidence that VI is a diol and II a hydroxoaquo complex. The numerical values of absorption maxima for all the complexes prepared in the present work are summarized in Table 3.

Conductivity and Coagulation Value. To determine the type of electrolytes for the complexes, the molar conductivities and coagulation values were measured in an aqueous solution at 25°C. The numerical data are shown in Table 4. All the complexes show a molar conductivity of the same order. Accordingly, no distinction could be detected between the hydroxoaquo and the diol complexes by this method. However, it is known that the average coagulation values for uni- and bivalent complex anions are 6.6 mF and 0.48 mF, respectively.[12] The values measured with an iron(III) hydroxide sol for the complexes I to III was 5—6 mF, while for complexes IV to VIII, 0.6—0.8 mF, indicating that the former three are 1 : 1 type (hydroxoaquo complex anion) and the latter four 1 : 2 type electrolytes (diol complex anion).

Change from Hydroxoaquo- to Diol-Complex in the Thermal Reaction Process. The hydroxoaquo complexes in the solid phase are expected to liberate the coordinating water upon heating, forming the corresponding diol complexes as suggested by a broken arrow in Table 2. The thermal reaction for the complexes was measured with a derivatograph.[13] Figure 2 shows the derivatograms for complexes I, II, and III. Five hundred milligrams of the samples was used in each run in a constant nitrogen stream with a heating rate of 1°C/min. As seen from TG and DTA curves, complexes I and II are observed to liberate two moles of water at 50—110 and one and a half moles of water at 80—130°C, respectively, with endothermic

13) R. Tsuchiya, Y. Kaji, A. Uehara, and E. Kyuno, This Bulletin, **42**, 1881 (1969).

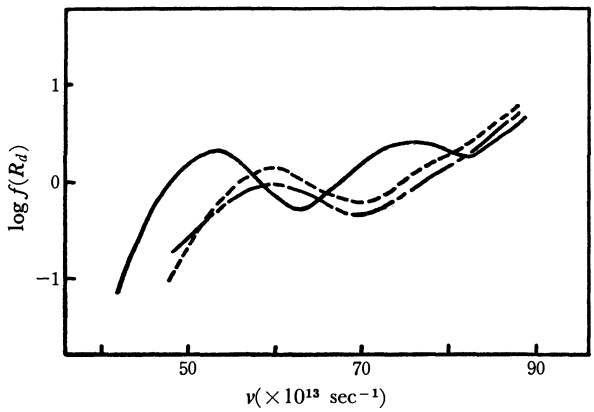

Fig. 3. Electronic spectra for complexes II (——), VI (----) and the sample II picked up at 190°C (—·—).

reactions. It is further found that one mole of coordinated water is liberated from the complexes I, II, and III at 185—200, 175—190, and 190—215°C, respectively, with exothermic reactions. At these steps, the color of the samples changed from bluish violet to pink as in the case of the corresponding NIPDA,[3] LDA,[2] and PADA (*d,l*-Phenylalanine-*N,N*-diacetic Acid)[4] complexes.

Figure 3 gives the electronic spectra measured by the diffuse reflectance method for complexes II, VI and for the sample of complex II picked up at this heating step (190°C). The spectrum for the last sample resembles that for complex VI, suggesting that the structure of the sample picked up at this step is similar to that of complex VI. Accordingly, the fact that the diol complex is formed by heating the corresponding hydroxoaquo complex may be successfully verified by the above experimental results.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1555—1560 (1971)

The Chromium(III) Complexes with Natural α-Amino Acids[1]

Hisayuki MIZUOCHI,[2] Akira UEHARA, Eishin KYUNO, and Ryokichi TSUCHIYA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received October 6, 1970)

The following chromium(III) complexes with natural α-amino acids were prepared: $[Cr(\alpha\text{-ambut})_3]\cdot 2H_2O$ (red) (I), $(-)_{546}$-$[Cr(l\text{-leu})_3]\cdot 2H_2O$ (red) (II), $(+)_{546}$-$[Cr(l\text{-leu})_3]\cdot 2H_2O$ (red) (III), $[Cr(l\text{-glu})_3]\cdot 2H_2O$ (red) (IV), $(+)_{546}$-$[Cr(l\text{-lys})_2(H_2O)_2]Cl\cdot 3H_2O$ (red) (V), $[Cr(OH)(\alpha\text{-ambut})_2(H_2O)]\cdot H_2O$ (light purple) (VI), $[Cr(OH)(l\text{-val})_2(H_2O)]\cdot H_2O$ (light purple) (VII), $[Cr(OH)(l\text{-leu})_2(H_2O)]\cdot H_2O$ (light purple) (VIII) and $[Cr(OH)(l\text{-glu})_2(H_2O)]\cdot H_2O$ (light purple) (IX), where α-ambut, *l*-leu, *l*-glu, *l*-lys, and *l*-val are the basic forms of α-amino-n-butyric acid, *l*-leucine, *l*-glutamine, *l*-lysine and *l*-valine, respectively. From the results of electronic and infrared absorption spectra, molar conductivities and behaviors toward ion exchangers, the composition and structures of the complexes were determined. The striking information obtained is that the complexes (I)—(IV) are considered to have all the β-form unlike the corresponding cobalt(III) complexes having both α- and β-forms. On the basis of ORD and CD measurements, the complexes (II), (III), and (V) were found to be optically active.

A number of transition metal complexes with various amino acids are already known. Within the limits of chromium(III) as a central metal ion, the complexes with synthetic amino acids such as NTA (nitrilotriacetic acid)[3] and IDA (iminodiacetic acid)[4] and their derivatives[5–8] have been prepared, their chemical properties and structures being investigated.

Of the natural amino acids, however, studies on the complexes are rare except for the tris-type complexes containing glycine[9,10] α-alanine,[11–15] asparagine[16], or *l*-aspartic acid.[17] In the present work, attempts were made to prepare chromium(III) complexes with various natural α-amino acids in tris- or bis-type and to investigate which type of complex can be successfully synthesized in each natural α-amino acid and which form of complex can be obtainable in two geometrically possible isomers.

Experimental

Preparation of Chromium(III) Complexes. Preparation of the chromium(III) complexes with natural α-amino acids carried out in the present work was classified into the following three methods depending upon the kinds of chromium(III) salts used as the starting material.

1. *Method using Chromium(III) Hydroxide*: This is essentially the same as the method by Ley and Winkler.[9] To a solution of *l*-glutamine (45 g, 0.3 mol) was added a slight excess of freshly prepared chromium(III) hydroxide (12 g, 0.12 mol), and the mixture was heated on a water bath until a reddish violet solution was obtained. This was filtered at once to remove unreacted hydroxide. The filtrate was evaporated to a half volume and cooled to room temperature. After adding a small amount of ethanol, the mixture was kept in a refrigerator overnight in order to precipitate the unreacted amino acid. After being filtered, the filtrate was kept to stand at room temperature for two or three days. Pink crystals were gradually precipitated.

The yield was about 10%. Found: C, 34.33; H, 6.03; N, 15.92%. Calcd for $[Cr(l\text{-glu})_3]\cdot 2H_2O$ (*l*-glu=*l*-glutamine): C, 34.38; H, 5.92; N, 16.05%.

By applying the same method as described above, the corresponding complexes with glycine, *d,l*,α-alanine and *l*-asparagine were prepared in better yields (about 30%) than in *l*-glutamine.

2. *Method using Chromium(III) Chloride*: This is similar to the method reported by Green and Ang,[15] and by Volshtein and Molosnova.[16] To a solution of α-amino-*n*-butyric acid (30 g, 0.3 mol), for example, was added an aqueous solution of chromium(III) chloride hexahydrate (27 g, 0.1 mol), and the mixture was heated on a water bath until it turned to violet. The color changed again to reddish violet by the dropwise addition of potassium hydrogen carbonate (30 g, 0.3 mol). On heating the solution, pink crystals began to appear on the wall of the evaporating dish. The filtrate was cooled to room temperature and kept standing overnight. Fine pink crystals were obtained.

The yield was about 10%. Found: C, 36.51; H, 7.10; N, 10.65%. Calcd for $[Cr(\alpha\text{-ambut})_3]\cdot 2H_2O$ (α-ambut=α-amino-*n*-butyric acid): C, 37.02; H, 6.90; N, 10.71%.

The yields for the complexes with glycine, *d,l*-α-alanine, and *l*-asparagine prepared by applying this method were all 30%.

The complex with *l*-lysine obtained by the same method was bis-type. Found: C, 30.79; H, 7.67; N, 12.52%. Calcd for $[Cr(l\text{-lys})_2(H_2O)_2]Cl\cdot 2H_2O$ *l*-lys=*l*-lysine: C, 30.80; H, 7.77; N, 11.98%.

By using a similar method except that 0.2 moles of the desired amino acid, instead of 0.3 moles, were employed as a starting material and the mixed solution was kept standing at room temperature for about one week instead of overnight after the addition of potassium hydrogen carbonate, the bis-type complexes with *l*-glutamine, α-amino-n-butyric acid, *l*-leucine, and *l*-valine were obtained as light purple crystals. For *l*-glutamine complex, Found: C, 31.21; H, 6.11; N; 13.49%. Calcd for $[Cr(OH)(l\text{-glu})_2(H_2O)]\cdot H_2O$: C, 30.36; H, 5.82; N, 14.17%. For α-amino-n-butyric acid complex, Found: C, 32.38; H, 6.63; N, 9.34%. Calcd for $[Cr(OH)(\alpha\text{-ambut})_2(H_2O)]\cdot H_2O$: C, 31.05; H, 6.79; N, 9.06%. For *l*-leucine complex, found: C, 41.39; H, 7.94; N, 7.91%. Calcd for $[Cr(OH)(l\text{-leu})_2(H_2O)]\cdot H_2O$ (*l*-leu=*l*-leucine): C, 40.75; H, 7.69; N, 7.92%. For *l*-valine complex, Found: C, 35.75; H, 6.81; N, 8.34%. Calcd for $[Cr(OH)(l\text{-val})_2(H_2O)]\cdot H_2O$ (*l*-val=*l*-valine): C, 35.60; H, 6.89; N, 8.31%.

The chromium(III) complex with leucine in tris-type was prepared by a different method from that mentioned above, though chromium(III) chloride was used as starting material in the same manner. 26.6 g (0.1 mol) of chromium(III) chloride hexahydrate in 200 m*l* of 80% methanol and 39.3 g (0.3 mol) of *l*-leucine were mixed and the mixture was heated in a round flask equipped with a reflux condenser. As the reaction proceeded, the color of the solution turned from green to violet. After the reaction was completed, a mixture of methanol and aqueous ammonia (0.3 mol) was gradually added dropwise to the solution, whereby its color became reddish. The solution was filtered and cooled to room temperature. A small amount of methanol having been added, the mixture was kept in a refrigerator for two days to let ammonium chloride precipitate. The filtrate was evaporated to half its volume under reduced pressure and was kept standing at room temperature after repeated filtration. Pink crystals were obtained, soluble in methanol. After removal of the crystals, the filtrate was kept at room temperature for a long time. Another crop of crystals was obtained, insoluble in methanol but soluble in *N,N*-dimethylformamide (DMF). In spite of this difference in solubility, the chemical composition of the two complexes obtained above is expressed by $[Cr(l\text{-leu})_3]\cdot 2H_2O$.

Soluble in methanol: Found: C, 44.09; H, 7.57; N, 8.45%.

Soluble in DMF: Found: C, 45.39; H, 8.73; N, 8.52%. Calcd for $[Cr(l\text{-leu})_3]\cdot 2H_2O$: C, 45.17; H, 8.42; N, 8.78%.

Preparation of Cobalt(III) Complexes. In order to compare the UV and IR spectra of the chromium(III) complexes with those of the corresponding cobalt(III) ones, the latter were also prepared by known methods.[18,19]

Apparatus. The molar conductivities and UV spectra were measured with a Yokogawa Universal Bridge BV-Z-12A and with a Hitachi EPS Spectrophotometer, respectively. The IR spectra were measured with a JASCO DS-301 and a JASCO Model IR-E Infrared Spectrophotometers both in KBr disk and in nujol mull. The optical rotatory dispersion (ORD) and circular dichroism (CD) curves were recorded with a JASCO Optical Rotatory Dispersion Recorder, Model UV-S attached with a CD recorder. The quantity of crystalline water contained in these compounds was estimated from the TG curve measured with a Shimadzu TM-1A Thermanobalance and a MOM Derivatograph Typ-OD-102.

Results and Discussion

UV Absorption Spectra. The UV absorption spectra of the chromium(III) complexes with amino acids in tris-type, together with those in bis-type with glycine or *l*-lysine, were measured in 20% perchloric acid solution except for that of tris-*l*-leucinatochromium(III) complexes measured in methanol and DMF and that of the corresponding cobalt(III) complexes measured in 60% perchloric acid solution. The numerical data of their maxima are summarized in Table 1. The spectra of tris(*l*-leucinato)chromium(III) and tris(*l*-glutaminato)chromium(III) are shown in Figs. 1 and 2, respectively, together with

a) Bis-type complexes. Others: tris-typecomplexes.

those of the corresponding cobalt(III) complexes of β-form.

It is known that there are two geometrical isomers in tris-type amino acid complexes, *i.e.*, *mer* (*cis*, *trans*) and *fac* (*cis*, *cis*) type with respect to the nitrogen or oxygen atoms coordinating to central metal, the former called α-form (violet) and the latter β-form (red).

It was pointed out[20] that the main difference between the absorption curves in these two isomers appears predominantly in the first band; *viz.*, the first band of the α-form isomer shows some splitting, while that of the β-form isomer does not. Although the positions giving the maximum absorbancies for these chromium(III) complexes are shifted to a somewhat lower frequency region compared with those for the corresponding cobalt(III) complexes, the shapes of the bands for the chromium(III) complexes prepared

in the present work are nearly the same as those for the corresponding cobalt(III) ones assigned to β-form. This suggests that the chromium(III) complexes in tris-type have also the β-form.

The spectra of bis(*l*-lysinato)- and bisglycinatodiaquochromium(III) complexes are shown in Fig. 3. In bis(*l*-aminato)diaquochromium(III) complexes, five geometrically possible isomers are considered, which are given in Fig. 4. It is obvious from Fig. 3 that the first absorption band not only gives a higher molar absorption coefficient than the second band but also shows no splitting. This leads us to presume the coordinating structure of these bisaminatodiaquo complexes to be (e) in Fig. 4, which is not trans structure with respect to nitrogen or oxygen atoms.

Since the absorption spectra could not be measured in aqueous solution owing to much smaller solubility in water, those for hydroxobisaminatoaquo complexes, $[Cr(OH)Am_2(H_2O)]\cdot H_2O$, where Am=*l*-

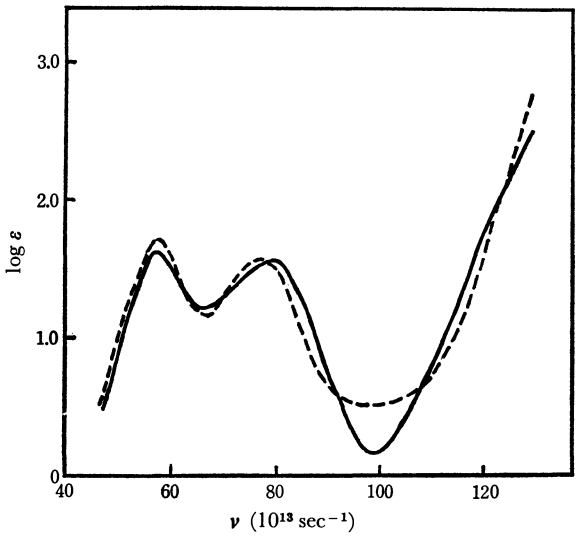

Fig. 3. Electronic absorption spectra of $[Cr(l\text{-lys})_2(H_2O)_2]Cl$ (——) and of $[Cr(gly)_2(H_2O)_2]NO_3$ (----) in aqueous solutions.

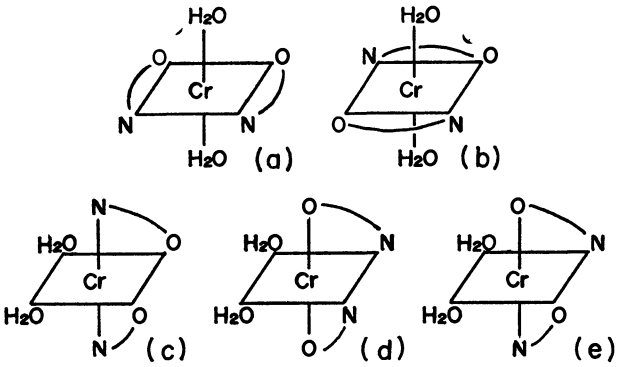

Fig. 4. Five geometrically possible isomers for $[CrL_2(H_2O)_2]^+$, where L denotes bidentate amino acid.

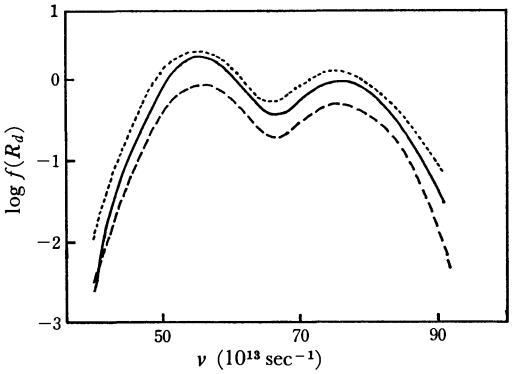

Fig. 5. Absorption spectra of $[Cr(OH)(\alpha\text{-ambut})_2(H_2O)]$ (——), $[Cr(OH)(l\text{-leu})_2(H_2O)]$ (— —) and $[Cr(OH)(l\text{-val})_2(H_2O)]$ (----) by the diffuse reflectance method.

glutamine, α-amino-*n*-butyric acid, *l*-leucine, or *l*-valine, were obtained by the diffuse reflectance method. The representative spectra for the chromium(III) complexes with α-amino-*n*-butyric acid, *l*-leucine and *l*-valine are shown in Fig. 5.

The first absorption peaks appear at 55, 56, and $55 \times 10^{13}\,sec^{-1}$ and the second peaks appear at 76, 75.5, and $75.5 \times 10^{13}\,sec^{-1}$ for α-amino-*n*-butyric acid, *l*-leucine and *l*-valine, respectively, as seen in Fig. 5. From the features of the absorption curves in this figure, where the first absorption bands do not show appreciable splitting, having higher absorption coefficients than the second bands, the hydroxobisaminato-aquochromium(III) complexes seem to have (e) structure in Fig. 4, containing OH and H_2O ligands in *cis* sites.

IR spectra. Infrared absorption spectra were measured over the range of 4000—700 cm^{-1}. The spectra of the chromium(III) complexes with glycine,

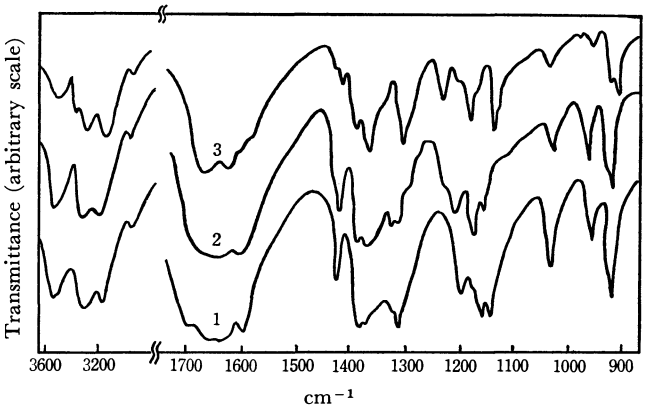

Fig. 6. IR spectra of $[Cr(gly)_3]$ (1), β-$[Co(gly)_3]$ (2), and α-$[Co(gly)_3]$ (3).

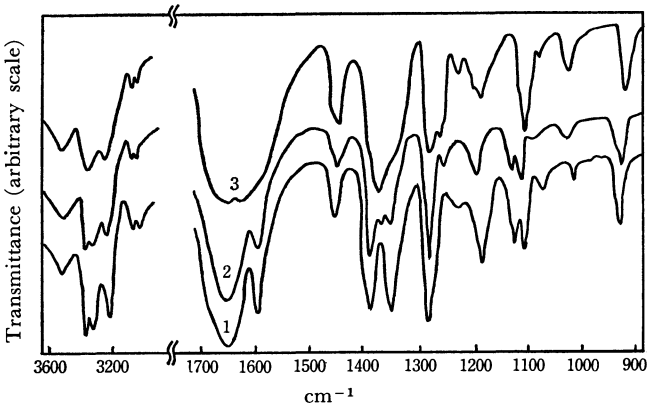

Fig. 7. IR spectra of $[Cr(\alpha\text{-ala})_3]$ (1), β-$[Co(\alpha\text{-ala})_3]$ (2), and α-$[Co(\alpha\text{-ala})_3]$ (3).

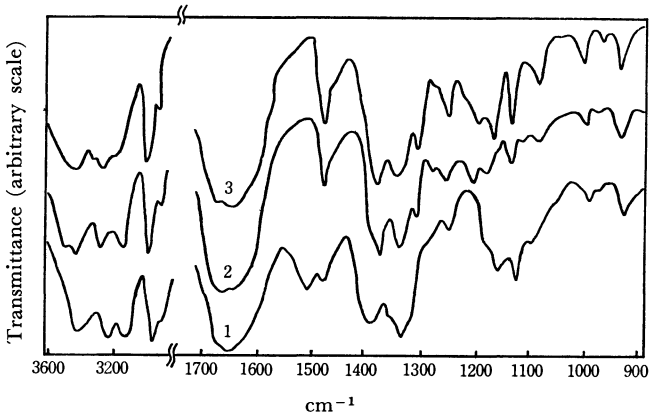

Fig. 8. IR spectra of $[Cr(l\text{-leu})_3]$ (1), β-$[Co(l\text{-leu})_3]$ (2), and α-$[Co(l\text{-leu})_3]$ (3).

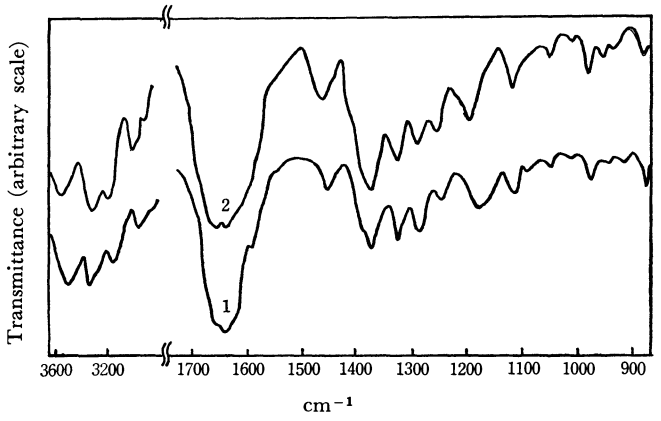

Fig. 9. IR spectra of [Cr(α-ambut)$_3$] (1) and β-[Co(α-ambut)$_3$] (2).

d,l-α-alanine, *l*-leucine, α-amino-*n*-butyric acid, and *l*-glutamine in tris-type are shown in Figs. 6—10, together with those of the corresponding cobalt(III) complexes in both α- and β-forms, though the α-forms of cobalt(III) complexes with α-amino-*n*-butyric acid and with *l*-glutamine could not be found.

The spectral curves for the chromium(III) complexes are extremely analogous to those for the corresponding cobalt(III) complexes in β-form rather than those in α-form, especially in several wave number regions, 3180—3400 cm^{-1} (NH_2 stretching), 1600—1650 cm^{-1} (NH_2 bending), 1350—1420 cm^{-1} (COO^- stretching) and 1100—1200 cm^{-1} (CH_2 deformation). It can be assumed from IR spectra that the tris-type of chromium(III) complexes have the same β-structure as the corresponding cobalt(III) complexes.

Behaviors toward Ion Exchangers and Molar Conductivity. Bisglycinatodiaquochromium(III) nitrate and bis(*l*-lysinato)diaquochromium(III) chloride were adsorbed by Cl^--form exchanger and their molar conductivity data measured in 1×10^{-3} mol/*l* were 69.5 and 202.4 mho cm^{-1}, respectively. This suggests that the above two complexes are 1 : 1 valency type, the complex cation being univalent as expected.

On the other hand, hydroxoaminatoaquochromium(III) complexes were adsorbed by neither cation nor anion exchangers and their conductivities could not be measured owing to insolubility in water. This is in line with the behavior of their non-electrolytes.

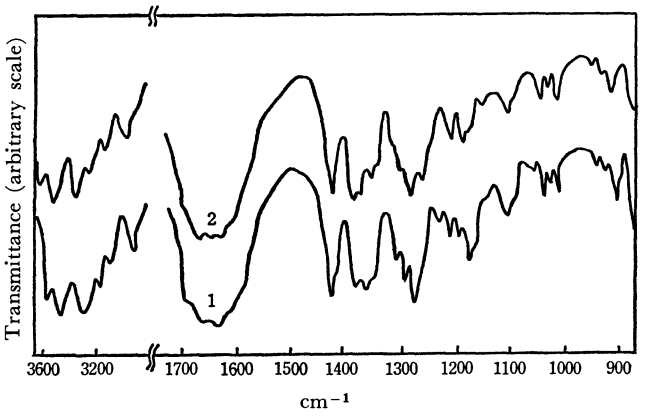

Fig. 10. IR spectra of [Cr(gly)$_3$] (1) and β-[Co(gly)$_3$] (2).

ORD and CD Spectra. The optical rotatory dispersion, circular dichroism, and absorption curves for tris(*l*-leucinato)chromium(III) soluble in methanol and in DMF and those for bis(*l*-lysinato)diaquochromium(III) chloride measured in water are given in Figs. 11 and 12, respectively. The molar rotations for two tris(*l*-leucinato)chromium(III) complexes were $[M]_{546}=-3496$ and $+5932$ respectively, and

◑: Complexes prepared in this work

that for bis(*l*-lysinato)diaquochromium(III) chloride was $[M]_{546}=+2867$.

The chromium(III) complexes with various amino acids in the types, $[CrL_3]$, $[CrL_2(H_2O)_2]X$ and $[Cr(OH)L_2(H_2O)]$, where L denotes amino acid and X denotes Cl^- or NO_3^-, were synthesized, and they are summarized in Table 2 together with those reported.

The tris-type chromium(III) complexes were all of β(*fac*)-structure, though in the corresponding cobalt(III) complexes both α- and β-forms have been found. The reason why α-form can not be obtained as crystals in the preparative conditions of the chromium(III) complexes with natural amino acids is not clear as yet.

An attempt to prepare the α-form of the chromium(III) complexes may be examined with the following ideals. Since the isomers (a) and (b), two of the bisaminatodiaquochromium(III) complexes depicted in Fig. 4, have *trans*-structure, the introduction of the third chelation of amino acid into them is impossible without the movement of chelating ligands already coordinated. On the contrary, in the *cis*-isomers (c), (d), and (e), the probability of the formation of the α-form complexes will amount to 5/6 by introducing the third chelation.

As an example, the preparation of a α-form chromium(III) complex in crystalline state was attempted by using *d,l*-α-alanine as the third bidentate ligand to be introduced into bisglycinatodiaquochromium(III) nitrate, and violet crystals were obtained. Taking account of the color of the crystals, the complexes are considered to have α-form structure and the starting bisglycinato complex to have cis-structure of either (c), (d), or (e).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1560—1562 (1971)

Spectrophotometric Determination of Benzethonium with Tetrabromophenolphthalein Ethyl Ester

Masahiro TSUBOUCHI

Faculty of Education, Tottori University, Tottori

(Received August 1, 1970)

A spectrophotometric method is proposed for the determination of benzethonium. The method is based on solvent extraction of the ion-pair formed between benzethonium and colored tetrabromophenolphthalein ethyl ester, into 1,2-dichloroethane. The extract has a maximum absorbance at 615 mμ, and follows Beer's law with good precision up to 4×10^{-6} M in aqueous solution. The absorbance of the extract is constant in the pH range 7—11. Organic cations interfere.

Tetrabromophenolphthalein ethyl ester (TBPE) has been used as a pH indicator. In a previous paper,[1] this reagent was shown to be useful for the colorimetry of diphenhydramine by solvent extraction. In the course of this study, various amines or organic cations were extracted with TBPE into dichloroethane. The colors of the extracts were found to be classified into the following three categories. (1) Red-violet which is developed by the presence of diphenhydramine, *N*,*N*-dimethylpiperazine, papaverine, triethanolamine, pilocarpine, or eserine. (2) Blue which is extracted by the presence of benzethonium, spartein, neostigmine, tetraethylammonium, acetylcholine, or thiamine. (3) Yellow which is the same color as reagent blank for the presence of aniline, acetonitrile, 3-aminoquinoline, pyridine, *N*,*N*-dimethylformamide, EDTA, or NTA.

This paper deals with the determination of benzethonium with TBPE. The proposed method has a very good reproducibility and a high sensitivity. The titrimetric method[2] has been used for the determination of benzethonium which is widely used as disinfectant.

Experimental

Apparatus. Spectrophotometric measurements were carried out with a Shimadzu QR-50 spectrophotometer, with 10-mm cuvettes. An Iwaki Model KM shaker with a time switch was used for the extraction. The pH measurements were carried out with a Toa Denpa Model HM-5 pH meter.

Reagents. *Tetrabromophenolphthalein Ethyl Ester (TBPE) Solution*: Weighed amounts of tetrabromophenolphthalein

1) M. Tsubouchi, This Bulletin, **43**, 3164 (1970).

2) Japanese Pharmacopoeia, VII-1, Part II, Nankodo (1965), p. 214.

ethyl ester potassium salt were dissolved in ethyl alcohol.

Standard Benzethonium Solution: A stock solution was prepared by dissolving 4.661 g of benzethonium chloride (dried at 105°C) and diluting to 1 *l* with water to make the solution 1.0×10^{-2} M. The stock solution was used to prepare the standard solution with desired concentration.

Buffer Solution: The pH 8.5 buffer was prepared by mixing 0.5 M potassium dihydrogen phosphate solution and 0.15 M sodium borate solution.

All the chemicals were of reagent grade and the water used was passed through an ion-exchange resin.

Procedure. Take 5 m*l* of benzethonium solution (less than 2×10^{-5} M), 2 m*l* of TBPE solution (10^{-3} M) and 5 m*l* of the buffer solution into a 10 -m*l* separating funnel. Dilute the mixture to 25 m*l* with water and shake the solution for 2 min with 10 m*l* of 1,2-dichloroethane. After separation of the two layers, run off the extract into a glass tube through a filter paper to remove droplets of water. Measure the absorbance of the extract at 615 mμ using a reagent blank as a reference.

Results and Discussion

Absorption Spectra. Figure 1 shows the visible absorption spectra of benzethonium extracts with TBPE. It can be seen that the presence of benzethonium in aqueous solution leads to a considerable increase in the extraction. The absorbance maximum of the extracts is at 615 mμ. The same absorption spectra as in Fig. 1 were obtained for spartein, tetraethylammonium, acetylchlorine, or thiamine. The blue color in the organic layer can be attributed to the ion pair formation between the TBPE and the cations.

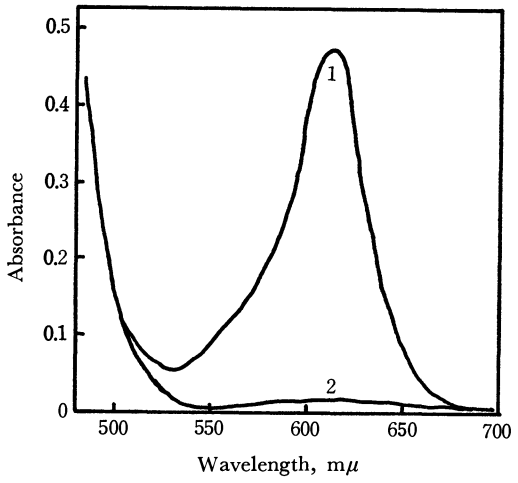

Fig. 1. Absorption spectra.
1: Spectrum of organic phase extracted from the aqueous solution (25 m*l*) containing 2×10^{-6} M of benzethonium, 8×10^{-5} M of TBPE and 5 m*l* of pH 8.5 buffer solution.
2: Spectrum of organic phase extracted from the aqueous solution (25 m*l*) containing the same component as that of curve 1 but benzethonium is absent.
Reference: Water

Effect of pH. The effect of pH on extraction was studied by extracting benzethonium from a series of aqueous solutions buffered at various pH values. As shown in Fig. 2, the absorbance of the extract was constant when the pH of the aqueous phase was in the range 7—11.

The extreme pH dependence was observed for the determination of quinine[3] or thiamine[4] with bromophenol blue or bromothymol blue. Similarly, no constant absorbance in any pH range could be obtained, when bromophenol blue or bromocresol green was used as extracting agent for benzethonium.

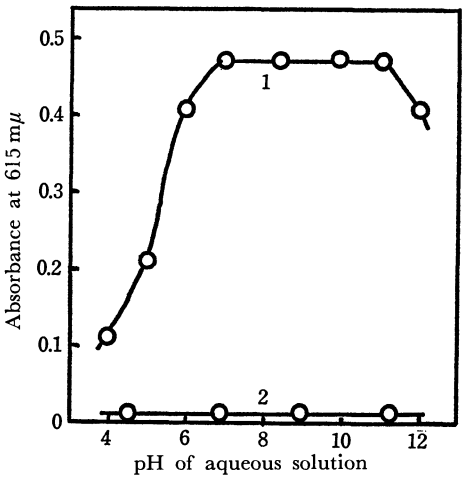

Fig. 2. Effect of pH.
1: Extract with 2×10^{-6} M benzethonium
2: Extract without benzethonium
Reference: Water

Effect of Reagents. The influence of TBPE concentration on extraction is illustrated in Fig. 3. It is apparent that the concentration of TBPE should be maintained greater than 10-fold molar excess over benzethonium to obtain a constant extraction. Excess amounts (2—10 m*l*) of the buffer solution used in the procedure had no influence on the absorbance of the

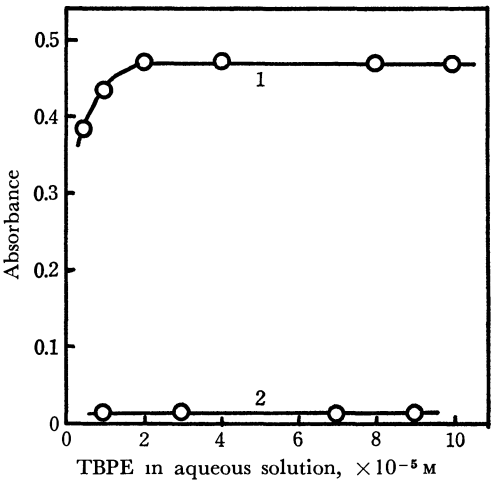

Fig. 3. Effect of the amount of TBPE.
1: Extract with 2×10^{-6} M benzethonium
2: Extract without benzethonium

3) M. Tatsuzawa, S. Nakayama, and A. Okawara, *Bunseki Kagaku*, **19**, 761 (1970).
4) V. D. Gupta and D. E. Cadwallader, *J. Pharm. Sci.*, **57**, 112 (1968).

extract. When the addition of the buffer solution was less than 2 m*l*, no effective separation of the two layers was observed.

Solvent for Extraction. The behavior of various solvents in the extraction was studied. Solvents were found to be classified into the following three categories. (1) Those with which the presence of benzethonium leads to a considerable increase in the extraction of blue TBPE: *e.g.* chloroform, 1,2-dichloroethane. (2) Those which do not extract the blue TBPE even in the presence of benzethonium: *e.g.* monochlorobenzene, toluene, *n*-hexane, cyclohexane, carbon tetrachloride. (3) Those with which the blue TBPE is extractable even without benzethonium: *e.g.* methyl isobutyl ketone, nitromethane, nitrobenzene, butyl acetate, ethyl acetate, ether, isoamylalcohol.

1,2-Dichloroethane was found to be most suitable for the extraction of a TBPE-benzethonium system.

Other Variables. Full color development required about 1 min shaking. Continued shaking up to 5 min produced no further change in absorbance. The color intensity of dichloroethane extracts remains constant for 1 hr. Fluctuation of room temperature (16—27°C) gave no measurable effect on absorbance.

Calibration and Precision. The system followed Beer's law up to 4×10^{-6} M of benzethonium in aqueous layer, with molar absorptivity of 9.00×10^{4} mol^{-1} cm^{-1} liter at 615 mμ.

The reproducibility of the proposed method was estimated from the results of ten sample solutions, each with a final benzethonium concentration of 2.0×10^{-6} M. The mean absorbance was 0.450 with a standard deviation of 0.005 absorbance unit.

Percentage of Extraction and Composition of the Colored Species. A sample (25 m*l*) containing 4.0×10^{-6} M of benzethonium was extracted with 10 m*l* of dichloroethane at pH 8.5. The amounts of benzethonium in the aqueous layer and organic layer were then determined according to the proposed method. The percentage of extraction was about 5% in the absence and 99% in the presence of TBPE.

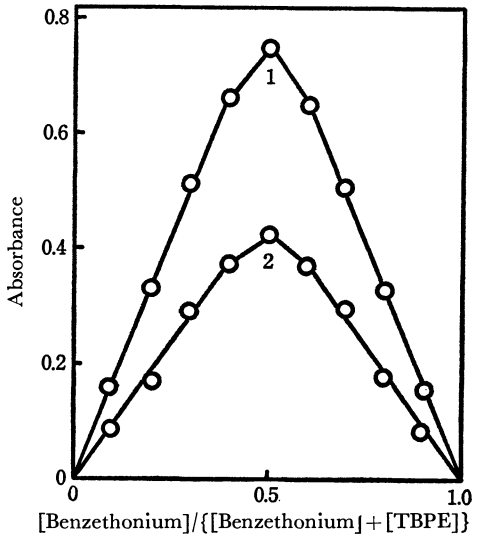

Fig. 4. Continuous variation curves.
Extraction was done from the aqueous solutions in which the total concentration of benzethonium plus TBPE was 8×10^{-6} M.
Reference: Reagent blank extracted from an aqueous solution without benzethonium
1: 615 mμ, 2: 590 mμ

Figure 4 shows the continuous variation curve for benzethonium. It might be suggested that a 1 : 1 ion-pair compound is formed in the dichloroethane phase between TBPE and benzethonium.

These results are characteristic of benzethonium as compared with diphenhydramine[1] in the extraction system.

Effect of Diverse Substances. Table 1 shows the effect of diverse substances on the determination of benzethonium. Organic cations interfere.

Table 1. Effect of diverse substances

Benzethonium taken: 2×10^{-6} M

Analysis of Practical Samples. Waste Water: The method was applied to a waste water containing benzethonium which had been used as a disinfectant solution for cupboard and plate basket. The sample solution was diluted or concentrated, and then analyzed by the proposed method or titrimetric method.[2] The result was 3.97×10^{-4} M of benzethonium by the proposed method, and 3.95×10^{-4} M by the titrimetric method.

Pharmaceutical Preparation: A commercially available disinfectant solution obtained was treated in the same manner as the waste water. The result was 0.220 M of benzethonium by the proposed method, and 0.218 M by the titrimetric method.

The author expresses appreciation to Professor Y. Yamamoto of Hiroshima University for valuable advice.

Studies on Cobaloxime Compounds. IV. The Polarography of Cobaloximes

Yorikatsu HOHOKABE and Noboru YAMAZAKI

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 19, 1970)

Various types of cobaloximes, *e.g.*, *Co*-alkyl derivatives with different bases as an axial ligand and polymeric cobaloximes with the general formula of $Co(OH)(DH)_2$(Copoly—AM-VPy) (DH: dimethylglyoximato monoanion) in which Copoly—AM-VPy is a low-molecular-weight copolymer of acrylamide and 4-vinylpyridine, were prepared, and their half-wave potentials in cathodic reduction were compared to each other and to those of a few vitamin B_{12} compounds. All of them showed a single irreversible cathodic wave. Methyl- and cyanocobaloximes were reduced at more negative potentials than the corresponding methylcobalamin and cyanocobalamin(vitamin B_{12}). The half-wave potential of methylcobaloxime shifted in the direction of the more negative potentials as the donating strength of the axial base increased. This was correlated with the charge-transfer transition energies of those cobaloximes as determined from their electronic spectra. The polymeric cobaloximes were reduced at less negative potentials than the others.

The cobaloxime compounds have properties quite similar to those of vitamin B_{12} compounds in their chemical reactivity, as have been established especially by Schrauzer *et al.*[1] The oxidation and reduction of cobalt in those complexes are the most important steps in many of the reactions. The polarographic reduction is a useful means inasmuch as the half-wave potentials can be considered as resulting solely from the ease of the reduction of each complex itself, since mercury cathode has a common reducing power which can be controlled in any way; this is different from the reduction with other chemical reducing reagents, that is, the result of two reactants, *i.e.*, the complex and a reagent.

The polarographic behavior of cobaloximes has been studied extensively by Maki[2] and by Schrauzer *et al.*[3] Maki reported that $K[Co(CN)_2(DH)_2]\cdot 3/2H_2O$[4] showed a single irreversible wave at −1.105 V *vs.* SCE in 0.5 M Na_2SO_4; they attributed this wave to a two-electron reduction from Co(III) to Co(I). Schrauzer *et al.* reported the half-wave potentials of several cobaloximes. For example, $CoCl(DH)_2$(py) yields three cathodic waves, at −0.10, −1.0, and −1.27 V, *vs.* the Ag/AgCl electrode at 25°C in a 50% aqueous ethanolic solution, while there were four waves, at −0.67, −1.44, −2.42, and −3.06 V *vs.* Ag/0.10 M $AgNO_3$ at 25°C in acetonitrile. The first wave corresponds to the reduction of Co(III) to Co(II); the second, to Co(II)—Co(I), and the third, to Co(I)—Co(0), whereas the fourth is due to the reduction of pyridine. They have also reported the polarographic reduction of some alkylcobaloximes, which show two irreversible waves in acetonitrile. For instance, $CH_3Co(DH)_2(H_2O)$ yields two cathodic waves, at −1.7 and −2.42 V *vs.* Ag/0.10 M $AgNO_3$. From a comparison between these alkylcobaloximes and $CoCl(DH)_2$(py), they have deduced that the organocobaloximes are complexes of Co(II).

In this work, various types of cobaloximes, *e.g.*, *Co*-methyl derivatives with different axial bases and *Co*-alkylcobaloximes with pyridine as a common axial base were synthesized. The half-wave potentials of these cobaloximes were determined under the same conditions and were compared to each other and also to those of other several cobaloximes and vitamin B_{12} derivatives. The dependence of the ease of reduction upon the kind of the axial ligand was discussed. The results will be described below.

Experimental

Materials. All the alkylcobaloximes were synthesized mostly by the methods of Schrauzer and have been reported in previous publications.[5-7] The cyanocobalamin and methylcobalamin were kindly supplied by the Eisai Co. All the other reagents used in the measurements were of a G. R. grade and were obtained from commercial sources.

Measurements. The polarographic measurements were made with a Yanagimoto potential-controlled Polarograph (model PA102) at 25°C. All the complexes were dissolved in a 0.1 N K_2SO_4 aqueous solution. Before each determination, nitrogen gas was bubbled through the solution for 10 min. Two ppm of a copolymer of acrylamide and 4-vinylpyridine (Copoly—AM-VPy, AM : VPy molar ratio= 14.5, M_n=1500) were added to each solution in order to diminish the maximum wave. The characteristics of the capillary used were as follows: m=0.684 mg/sec and t= 4.55 sec, the values of which were measured in a 0.1 N K_2SO_4 aqueous solution.

Results and Discussion

All the cobalt complexes examined in this work showed a single irreversible cathodic wave under these conditions. These results were in good agreement with those on $K[Co(CN)_2(DH)_2]\cdot 3/2H_2O$ obtained by Maki, and not with those on the cobaloxime derivatives obtained by Schrauzer. According to Maki's results, which were obtained under conditions more similar to ours, this wave can be attributed to Co(III)—

Co(I) reduction. Most of the cobaloximes were reduced at more negative potentials than $Co(H_2O)_6^{2+}$, probably as a result of a strong interaction of dimethylglyoxime ligands with cobalt.

Many alkyl derivatives, especially hydroxypropyl and methyl derivatives, have been synthesized as model vitamin B_{12} compounds,[6] and their electronic and infrared absorption spectra, and also the effect on a B_{12}-dependent enzymatic reaction, have been reported.[6-8]

The reduction waves of these analogs and vitamin B_{12} compounds under the same conditions are compared in Table 1. Methylcobalamin or cyanocobalamin was reduced at a less negative potential than the corresponding methyl- or cyanocobaloximes. For example, methyl(pyridine)cobaloxime was reduced at a potential more negative by −0.11 V than that of methylcobalamin. Planary-coordinating-dimethylglyoxime ligands in cobaloximes seem to charge more electrons to cobalt atoms than does corrin in cobalamin.

The half-wave potentials of *Co*-methylcobaloximes are affected by another axial ligand. As the electron-donating power of the axial base increases, the potential shifts to more negative potentials. The relationship between the pK_a of the axial base and the half-wave potential of the cobaloxime is shown in Fig. 1. The order of the ease of reduction coincided with that of the spectrochemical shift of methylcobaloximes;[7] *i.e.*, the charge-transfer transition energies of methylcobaloximes decreased in this order: (imidazole)-, (*γ*-picoline)-, (pyridine)-, (*p*-toluidine)-, (nicotinamide)-, and aquocobaloxime. Therefore, the half-wave potentials measured in this experiment are considered to be a measure of the reducibility of the Co atom in these complexes.

8) Y. Hohokabe and N. Yamazaki, This Bulletin, **44**, 798 (1971).

Generally, in the polarographic reduction, the electron from the mercury cathode is transferred to the lowest vacant orbital of the reductant. According to molecular orbital theory, non-bonding orbitals (d_{xy}, d_{yz}, d_{zx}) are filled with 6 electrons in the case of an octahedral Co(III) complex, and the antibonding orbital (σ^*) is the lowest vacant one which is formed with the formation of the corresponding bonding orbital (σ) by the interaction of the d_{z^2} orbital of the central metal with suitable orbitals of axial ligands. Therefore, the potential at which the reduction of the complex occurs probably depends directly upon the absolute energy level of the lowest vacant orbital, and not necessarily upon the energy difference between σ and σ^*. Since the stronger interaction of the axial-base component causes increasing negative potentials of the reduction, as has been mentioned above, it is considered that a strong interaction of the base results in raising the absolute energy level of σ^*. If the absolute energy level of σ is assumed to be less affected by the formation of molecular orbitals between cobalt and ligands than that of σ^*, the energy difference between σ and σ^*, *i.e.*, ν_I, which can be determined by studying the electronic spectrum, should increase with the interaction of the ligands in the complex.

B: 1, H_2O; 2, nicotinamide; 3, *p*-toluidine; 4, pyridine; 5, *γ*-picoline; 6, imidazole.

In short, $\Delta E_{1/2}$ which is the difference between a half-wave potential of methylcobaloxime and that of a given cobaloxime as a criterion, and $\Delta\nu_I$, which is the difference in charge-transfer transition energy between them, are expected to be correlated. Using as a criterion methylaquocobaloxime, in which coordinating water is considered to be the weakest ligand among the ligands examined in this work, we could obtain the correlation between $\Delta\nu_I$ and $\Delta E_{1/2}$; it is illustrated in Fig. 2. Methyl(imidazole)cobaloxime is not included here because its ν_I is obscurely shown as a shoulder band on its electronic spectrum. As is shown in Fig. 2, there is clearly a relationship between $\Delta\nu_I$ and $\Delta E_{1/2}$, supporting the argument just presented. In other words, as has been discussed above, a strongly-interacting ligand raises the σ^* orbital, while the level of σ is less affected, resulting in making the reduction potential more negative and in raising

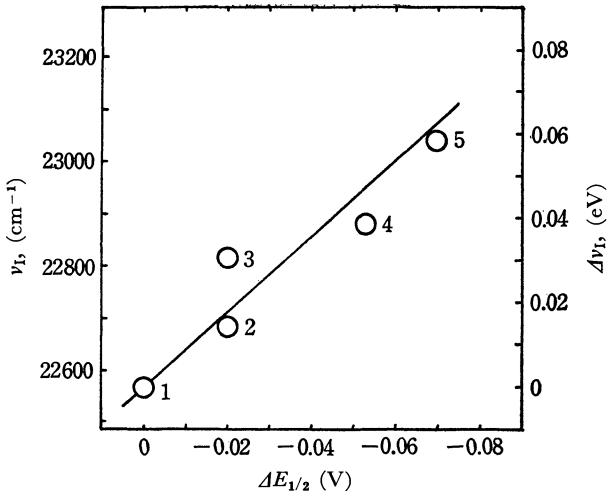

Fig. 2. The correlation between $\Delta\nu_I$ and $\Delta E_{1/2}$ of methylcobaloximes.
The data of methylaquocobaloxime were adopted as a standard for the calculation of $\Delta\nu_I$ and $\Delta E_{1/2}$. ν_I is the lowest charge-transfer transition energy which had been obtained directly from electronic spectral data.[7]
1, H_2O; 2, nicotinamide; 3, *p*-toluidine; 4, pyridine; 5, *γ*-picoline.

the charge-transfer transition energy ($\sigma\rightarrow\sigma^*$). This is well supported by the fact that the slope of the $\Delta\nu_I$ *vs.* $\Delta E_{1/2}$ plots is around 0.9; this shows that the differentiations are of the same degree in both series.

Many (pyridine)cobaloximes with various kinds of another axial ligand were also examined; the results are shown in Table 2. Simple alkyl derivatives were reduced at nearly the same potential, while benzyl and hydroxypropyl derivatives were at less negative potentials. The argument which has just described in the case of methylcobaloximes, *i.e.*, that a strongly coordinating ligand raises the level of the antibonding orbital, could not be ascertained in (pyridine)-cobaloximes with a different axial ligand, such as Cl, CN, and alkyl, because the low solubility of chloro- and cyano-cobaloximes in water prevented us from determining their spectrochemical sequences in those (pyridine)cobaloxime series. However, speaking only of alkyl derivatives, the relationship between ν_I and $E_{1/2}$ was not observed. Benzyl and hydroxyalkyl ligands have substituents of different natures, such as the aromatic ring and the hydroxy group respectively, so that the affinity of the complex to the electrode might differ from those of simple alkyl derivatives.

The ease of the reduction depends, of course, on the electron affinity of the cobalt atom in the complex. In addition, it is known that the half-wave potential is governed by the rate of the reduction reaction at the cathode in the irreversible reduction; *i.e.*, the higher the rate of reduction reaction, the less negative the potential. The higher rate of the reduction reaction will be attained by the larger value of the rate constant of the electrode reaction. This is probably the consequence of the closer distance between the cathode and the reactant (Co atom), and of the electron affinity of the cobalt atom in the complex.

It is expected that a strongly electron-attractive ligand facilitates the reduction of the complex. Since the Hammett σ constants are considered to be a measure of the electronic properties of the ligand, the half-wave potentials of (pyridine)cobaloximes are correlated with the constants of their axial ligands in Figs. 3 and

$Co(OH)(DH)_2(H_2O)$[c]	−1.26[d]	0.25

4. The complex with an electron-attractive ligand is reduced at a less negative potential, as has been expected. However, it was found, from an investigation of the infrared spectra of cobaloximes,[6] that the electron-attractive ligand in the sixth position causes stronger interaction between Co and the fifth ligand, *i.e.*, the axial base, in turn resulting in an increase in the electron density of the equatorial moiety in the cobaloxime. The observation of the polarographic behavior seems to be inconsistent with that of the infrared spectra. It is also expected, however, that the electron from the mercury cathode is transferred to Co through an electron-attractive ligand, such as CN or Cl; this facilitates the reduction of the central cobalt atom, irrespective of the electron density of the Co in the complex.

The polymeric cobaloximes have also been prepared and described previously.[5,9] They are reduced at less negative potentials than other, analogous monomeric cobaloximes, as is shown in Table 2. The half-wave potentials of polymeric cobaloximes were expected to be more negative than that of hydroxo-aquocobaloxime. Nevertheless, the reduction of the former was observed to take place at a less negative potential than that of the latter. This might be due to a polymer effect, by which the existence of amide groups in the neighborhood of the Co moiety facilitated the electron-transfer from the cathode to the complex. The addition of the same copolymer to the other monomeric cobaloximes did not change their half-wave potentials, but only diminished the maximum wave which was generally observed in the absence of a surface-active agent. Since polyacrylamide is known as a surface-active agent, the facilitating effect of the polymeric ligand on the reduction of the polymeric cobaloxime may be attributed to the strong adhesion of polymeric cobaloxime to the dropping mercury cathode, thus facilitating reduction reaction by the electron of mercury cathode. The half-wave potential was not affected by a change in the molecular weight of the polymeric ligand.

9) The half-wave potentials of polymeric cobaloximes reported previously had more negative values, but they may have been incorrectly standardized.

The Crystal Structure of κ'-Al_2O_3, the New Intermediate Phase

Masataro Okumiya and Goro Yamaguchi

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received August 24. 1970)

A structure model of κ'-Al_2O_3 has been obtained by means of X-ray powder diffraction data. An hexagonal unit cell with $a=5.544$ and $c=9.024$ Å and containing $5\frac{1}{3}$ Al_2O_3 was assumed. The oxygen arrangement is the same close packed structure as that of tohdite, and $10\frac{2}{3}$ aluminium atoms are statistically distributed over several octahedral and tetrahedral positions. The R factor for the reflection intensity is 0.13 for 115 reflections.

The first investigation of the dehydration of tohdite $5Al_2O_3 \cdot H_2O$ was performed by Krischner in 1966 using the electron diffraction method.[1] In 1970, a more detailed investigation[2] was performed by the present authors using electron diffraction, X-ray powder diffraction, thermogravimetric measurement, differential thermal analysis, and the measurement of the density; the following transformation series were thus established:

$$\text{tohdite} \xrightarrow{\text{dehyd.}} \kappa'\text{-}Al_2O_3 \rightarrow \kappa\text{-}Al_2O_3 \rightarrow \alpha\text{-}Al_2O_3$$

The κ'-Al_2O_3 was found to be a new unstable intermediate phase and was easily produced by heating tohdite(F)[2] in a high vacuum at just the dehydration temperature. It seems necessary, for a further discussion of the transformation series, to elucidate the atomic arrangement of this unstable phase. The present work has been performed in order to elucidate the atomic arrangement and to confirm the conclusion of the previous discussion. For this purpose, the structure analysis was made by the X-ray powder diffraction method.

Experimental Procedure

The specimen of κ'-Al_2O_3 (from tohdite) used in this work was prepared as follows. Tohdite obtained by treating gibbsite hydrothermally with AlF_3 was heated in a high vacuum (10^{-4} mmHg) up to the temperature of complete dehydration (750°C) and then cooled rapidly to room temperature. This was performed in a high-vacuum TGA instrument[2] in order to check the dehydration percentage. The κ'-Al_2O_3 (from tohdite) was obtained as hexagonal plates with a micron-order size and containing about 0.3% of fluorine as an impurity; this specimen was denoted as κ'-Al_2O_3 (from tohdite(F)) in the previous paper.[2] In the present X-ray intensity calculation, the small amount of fluorine was neglected.

The X-ray powder diffraction diagram was obtained by means of Ni-filtered Cu$K\alpha$ radiation using a Rigaku Denki diffractometer equipped with a scintillation counter and a pulse-height discriminator. The diffraction intensities relative to the (202) intensity were obtained by measuring the peak areas. 41 peaks were measured up to $\sin\theta/\lambda=0.621$ Å^{-1}. No correction was made for the preferred orientation effect on the intensity.

Structure Determination

In the previous paper,[2] κ'-Al_2O_3(from tohdite) was assumed to have a hexagonal unit cell of almost the same size as that of tohdite $5Al_2O_3 \cdot H_2O$. The cell dimensions calculated from the powder diffraction data are $a=5.544\pm0.001$ and $c=9.024\pm0.001$ Å. Density measurement showed that this unit cell contains about $5\frac{1}{3}$ of Al_2O_3, namely, 16 oxygen atoms and $10\frac{2}{3}$ aluminium atoms.

On the basis of this unit cell, the X-ray powder diffraction pattern can be indexed. The systematic absences among the observed reflections of κ'-Al_2O_3 (from tohdite) are the same as those of tohdite: *hhl* with $l=2n+1$. The possible space groups are $P\bar{3}1c$, $P31c$, $P6_3mc$, $P\bar{6}2c$, and $P6_3/mmc$.

It was found that the intensity distribution of the reflections of κ'-Al_2O_3 (from tohdite) resembles that of the corresponding reflections of tohdite (especially that of the reflections at $2\theta>40°$) (Fig. 1). Therefore, we considered κ'-Al_2O_3 (from tohdite) to have a structure similar to that of tohdite. We attempted to derive a structure model of κ'-Al_2O_3 (from tohdite) from the structure of tohdite as determined from the X-ray powder diffraction data.[3,4] The space group of κ'-Al_2O_3 (from tohdite) was assumed to be the same as that of tohdite, $P6_3mc$.

The structure factors are obtained from the X-ray powder diffraction intensities. The intensities of the overlapping peaks were separated into the ratio of the calculated intensities of the corresponding reflections of tohdite. A three-dimensional Fourier synthesis was made using these structure factors and the phases of the corresponding reflections of tohdite.

After a several-cycle refinement of Fourier synthesis, the outline of the structure of κ'-Al_2O_3 (from tohdite) was obtained as follows: The arrangement of oxygen atoms was revealed to be the same as that of tohdite, ABAC closed packing. As for the positions of the aluminium atoms, it was found that the aluminium atoms are distributed over several octahedral and tetrahedral positions, including aluminium positions in tohdite, and that some of their occupancies are less than 1. These occupancy factors were refined by the least-squares method. The least-squares analysis program was written for the HITAC 5020E computer, in which the occupancy factors of aluminium atoms were varied so as to minimize $R_I'=\sum(I_o-I_c)^2$, where:

I_o=integrated intensity

$I_c=K \cdot I_p \cdot \sum_i m_i \cdot |F_c|^2$, where:

$\sum_i$=the sum over overlapping peaks

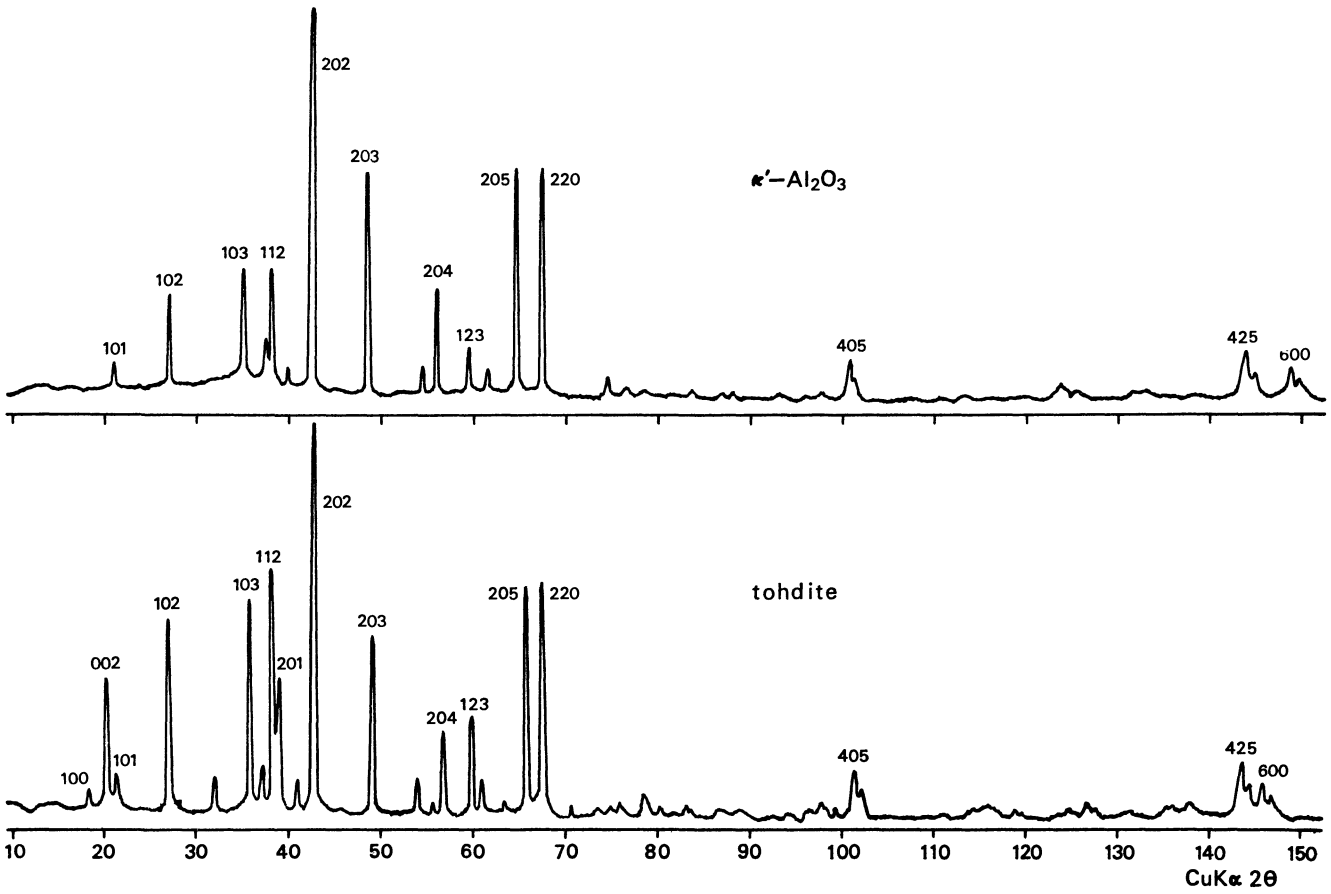

Fig. 1. X-Ray powder diffraction pattern of κ'-Al_2O_3 and tohdite.

K=scale factor
m_i=multiplicity
L_p=Lorentz and polarization factor

The structure factor, F_c, is presented as:
$F_c=\sum_j p_i \cdot f_j \cdot \exp 2\pi i(hx_j+ky_j+lz_j)$, where:
p_j=occupancy factor

In the calculation of the structure factor, an overall isotropic temperature factor was used. Six occupancy factors were varied independently, while the restrictive condition, $\Sigma p=10\frac{2}{3}$, was neglected. The occupancy factors of oxygen atoms were fixed as 1.0. The final occupancy factors and their standard deviations, as estimated from the diagonal element of the inverse to the least-squares matrix, are listed in Table 1, together with the atomic coordinates.

Table 1. Atomic coordinates and occupancy factors with their standard deviations ($\times 10^2$)

Position	x	y	z	p	Number of equivalent positions
O(1)	0	0	0	1.0	2
O(2)	0.500	$-x$	0.006	1.0	6
O(3)	0.832	$-x$	0.256	1.0	6
O(4)	1/3	2/3	0.254	1.0	2
Al(1)	1/3	2/3	0.056	0.51(2)	2
Al(2)	0.833	$-x$	0.061	0.08(1)	6
Al(3)	2/3	1/3	0.148	0.98(5)	2
Al(4)	0.156	$-x$	0.118	0.34(1)	6
Al(5)	0.169	$-x$	0.363	0.67(3)	6
Al(6)	0.884	$-x$	0.448	0.12(2)	6

Overall isotropic temperature factor 0.72 (0.05)Å^2

The calculated intensities for the parameter of Table 1 are listed in Table 2. The $R_I=\Sigma|I_o-I_c|/\Sigma I_o$ factor is 0.13.

Discussion

The results of this structure calculation confirmed the previous conclusions that the oxygen sub-lattice is preserved during the transformation from tohdite to κ'-Al_2O_3 (from tohdite) and that aluminium atoms are randomly distributed over the octahedral and tetrahedral positions. The distribution of the aluminium atoms of Table 1 is illustrated in Fig. 2. The total number of aluminium atoms in the unit cell is calculated as 10.2 ($\sigma=0.3$). This is in fairly good agreement with the ideal, $\Sigma p_j=10\frac{2}{3}$.

Between the second and the third layers of oxygen atoms, aluminium atoms are distributed over the octahedral positions, Al(5), and the tetrahedral positions, Al(6). The obtained occupancy factor for the Al(5) positions of 0.67 is considered to be 2/3; this means that three Al(5) positions are occupied randomly by two aluminium atoms, while in the structure of tohdite the corresponding positions are fully occupied by three aluminium atoms. The Al(6) positions are partly occupied, with an occupancy factor of 0.12, while the

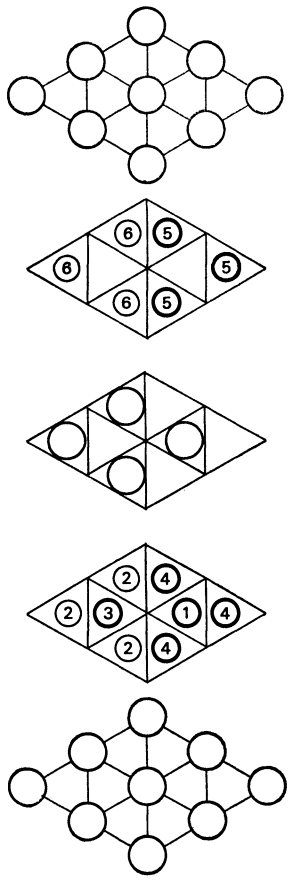

Fig. 2.

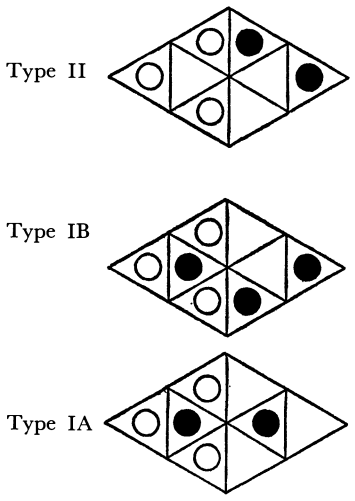

Fig. 3. Arrangement of aluminium atoms in the 1st (type IA, IB) and the 2nd (type II) aluminium layers of κ'-Al_2O_3 (from tohdite).

corresponding positions of tohdite are vacant. This type of cation arrangement is denoted as Type II; one of the three possible arrangements is illustrated in Fig. 3.

Between the first and the second oxygen layers aluminium atoms are distributed over octahedral, Al(3) and Al(4), and tetrahedral, Al(1) and Al(2), positions. The obtained occupancy factors, 0.98 for Al(3), 0.34 for Al(4), and 0.51 for Al(1), are considered to be 1, 1/3, and 1/2 respectively. The distribution of aluminium atoms between these oxygen layers could be explained as the average of two types of cation arrangement: Type IA: the Al(3) and Al(1) positions are fully occupied, and Al(2) is partly (12%) occupied. If we overlook the atoms in Al(2), this type is found in tohdite between the corresponding oxygen layers. Type IB: Al(3) is fully occupied, the three Al(4) positions are occupied by two aluminium atoms, and the Al(2) positions are partly (8%) occupied.

There are two types of combinations of adjacent aluminium layers, *i.e.*, IA-II and IB-II. In the former type, there is no face-shared contact between oxygen polyhedra around aluminium atoms. In the latter type, some of the oxygen octahedra have to share contact faces along the *c*-axis.

Considering that the occupancy factors for Al(6) and Al(2) are rather small and that the unstable κ'-Al_2O_3 (from tohdite) might not be described as a definite unit cell, but as a statistical structure average, it is possible that other octahedral and tetrahedral positions (Fig. 4) are also occupied by aluminium atoms with small occupancy factors. However, no other highly occupied aluminium positions should exist except those listed in Table 1, since the structure proposal of Table 1 is satisfactory enough to explain the X-ray powder pattern of κ'-Al_2O_3 (from tohdite).

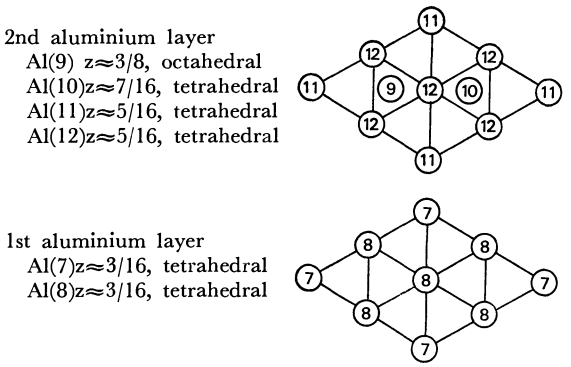

Fig. 4. Tetrahedral and octahedral positions of aluminium atoms which might be occupied with small occupancy.

According to the above-mentioned structure, κ'-Al_2O_3 (from tohdite) may be described as a partly cation-redistributed structure of tohdite and as an unstable intermediate phase in the transformation from tohdite to κ'-Al_2O_3 (from tohdite).

All the calculations were performed with HITAC 5020E computer of the Computation Center of the University of Tokyo. The calculation of the Fourier synthesis was done by the use of Universal Crystallographic Computation Program System 5020 UNICS.

Several Novel Ru(VI) and Ru(IV) Complexes Derived from [RuO_4bipy] and [RuO_3phen]$_2O$

Toshio ISHIYAMA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received August 31, 1970)

Five novel neutral complexes of ruthenium(VI) and ruthenium(IV) with 2,2′-bipyridine and 1,10-phenanthroline, [$RuO_2(OH)_2$bipy]·$3H_2O$, [$Ru(OH)_3$phen]$_2O$, [RuO_2bipy$_2$]·$3H_2O$, [RuO_2bipy·phen]·$3H_2O$ and [RuO_2phen$_2$], were prepared and characterized by a study of their infrared, visible and ultraviolet absorption spectra, and by polarographic measurements. [$RuO_2(OH)_2$bipy] and [$Ru(OH)_3$phen]$_2O$ were obtained by the reduction of previously-reported complexes, [RuO_4bipy] and [RuO_3phen]$_2O$ respectively, with methanol, and [RuO_2bipy$_2$], [RuO_2bipy·phen] and [RuO_2phen$_2$], by the reactions of [RuO_4bipy] and [RuO_3phen]$_2O$ in methanol with 2,2′-bipyridine and 1,10-phenanthroline respectively. [RuO_2bipy·phen] and [RuO_2phen$_2$] were also obtained in methanol by the substitution reactions of [RuO_2bipy$_2$] and [RuO_2bipy·phen] with 1,10-phenanthroline respectively. The five complexes were all diamagnetic. [$RuO_2(OH)_2$bipy] was assumed to be a "ruthenyl" complex with two oxide ions coordinated at the *trans* positions, like such well-known *trans*-dioxo-ruthenyl analogues as $Cs_2[RuO_2Cl_4]$ and [$RuO_2(OH)_2(NH_3)_2$], and [$Ru(OH)_3$phen]$_2O$ was assumed to be a binuclear complex with an oxygen-bridge between ruthenium atoms. [RuO_2bipy$_2$], [RuO_2bipy·phen], and [RuO_2phen$_2$] were assumed to be mononuclear complexes with two oxide ions coordinated at the *trans* positions, and their oxidation numbers were found polarographically, to be 4.

Organic chelate compounds of "ruthenyl" and oxo-bridged binuclear ruthenium(IV) species with coordinated hydroxy groups have not been reported, since most "ruthenyl" and hydroxoruthenium species are very unstable and are easily hydrolyzed. Wagnerova[1] attempted to prepare a "ruthenyl" oxalate, $[RuO_2ox_2]^{2-}$, by the reduction of ruthenium tetroxide with oxalate ions. He reported that there was no evidence of a "ruthenyl" oxalate, $[RuO_2ox_2]^{2-}$, although the corresponding osmium(VI) species was very stable, and that $[Ruox_3]^{2-}$ might be obtained. Lott and Symons[2] and Woodhead and Fletcher[3] obtained several ruthenyl complexes formulated as $[Ru^{VI}O_2X_4]^{2-}$. They suggested that the two oxygen atoms of "ruthenyl" complexes, like their osmium analogues, could all be presumed to be *trans*, and reported that the complexes were all diamagnetic, probably because of the low symmetry of the ligand field.

Bis(2,2′-bipyridine)- and bis(1,10-phenanthroline)-ruthenium(IV) chelates, with two oxide ions coordinated at the *trans* positions in either case, have not been reported. Dwyer and his co-workers[4] prepared dichlorobis(2,2′-bipyridine)- and dichlorobis(1,10-phenanthroline)-ruthenium(II) complexes, and they denoted them as $[Ru^{II}B_2Cl_2]^0$. They reported that these neutral complexes were spin-paired and showed no tendency of disproportionation to the tris complexes under normal experimental conditions, although the bis-iron(II) chelates rapidly disproportionate in aqueous solutions, and suggested that the Ru(II) complexes isolated had *cis*-configurations.

In the present paper five new complexes, [$RuO_2(OH)_2$bipy]·$3H_2O$, [$Ru(OH)_3$phen]$_2O$, [RuO_2bipy$_2$]·$3H_2O$, [RuO_2bipy·phen]·$3H_2O$, and [RuO_2phen$_2$], are reported, they were obtained by the reduction and substitution reactions of two previously-reported complexes,[5),6)] [RuO_4bipy]·$3H_2O$ and [RuO_3phen]$_2O$, with 2,2′-bipyridine and 1,10-phenanthroline in methanol.

Experimental

Materials. Ruthenium(III) chloride monohydrate (extra pure grade) supplied by Mitsuwa Chemicals & Co. was used without further treatment. Both 2,2′-bipyridine and 1,10-phenanthroline were supplied by Yoneyama Chemicals. The former was purified by recrystallization from distilled water, and the latter, from ethanol after it had been dried by heating at 115°C for 3 hr. Commercial methanol was dried by treatment with magnesium ribbon and iodine. Lithium perchlorate (extra pure grade) supplied by Mitsuwa Chemicals & Co. was purified by recrystallization from methanol after drying.

Syntheses. (1) Dioxodihydroxo(2,2′-bipyridine)-ruthenium(VI), [$RuO_2(OH)_2$bipy]·$3H_2O$, and μ-Oxo-bis[trihydroxo-(1,10-phenanthroline)ruthenium(IV)], [$Ru(OH)_3$phen]$_2O$: A solution of 1 g of [RuO_4bipy]·$3H_2O$ or [RuO_3phen]$_2O$ in 150 m*l* of methanol was refluxed and shaken on a hot-water bath until the solution turned dark-brown. The solution was then evaporated to dryness, and the residue was recrystallized from methanol and dried *in vacuo*. Yields: dioxodihydroxo(2,2′-bipyridine)ruthenium(VI), 93.85%, and μ-oxo-bis[trihydroxo(1,10-phenanthroline)ruthenium-(IV)], 95.15%, on the basis of the starting complexes. The product complexes are insoluble in carbon tetrachloride, benzene, ether, acetone, and dioxane, but are soluble in water, methanol, ethanol, acetic acid, and dimethyl formamide. Both complexes are stable in methanol, and [$RuO_2(OH)_2$bipy] is stable in water too. However, the aqueous solution of [$Ru(OH)_3$phen]$_2O$ slowly changes from dark-brown to green, probably because of air oxidation in water. The ruthenium and water contents and the molecular weights of the complexes were measured by methods reported previously.[5)]

Found: Ru, 26.58; C, 32.24; H, 4.03; N, 7.47; H_2O, 14.05%; mol wt, 330. Calcd for $[RuO_2(OH)_2(C_{10}H_8N_2)]\cdot 3H_2O$: Ru, 26.79; C, 31.83; H, 4.24; N, 7.43; H_2O, 14.24%; mol wt, 325(anhydride).

Found: Ru, 31.36; C, 41.47; H, 3.28; N, 8.24%; mol wt, 650. Calcd for $[Ru(OH)_3(C_{12}H_8N_2)]_2O$: Ru, 29.95; C, 42.28; H, 3.23; N, 8.22%; mol wt, 681.

(2) Dioxobis(2,2'-bipyridine)ruthenium(IV), $[RuO_2bipy_2]\cdot 3H_2O$, and *Dioxobis(1,10-phenanthroline)ruthenium(IV), $[RuO_2phen_2]$*: To a solution of 1 g of $[RuO_4bipy]\cdot 3H_2O$ or $[RuO_3phen]_2O$ in 15 m*l* of methanol, 5 g of 2,2'-bipyridine or 1,10-phenanthroline was added. The reaction mixture was refluxed under shaking on a hot-water bath until the solution turned orange-brown. The solution was then evaporated to dryness, and the residue was repeatedly washed with benzene and then dissolved in pure water. An insoluble product was filtered off. The solution was concentrated, and the crystals formed were recrystallized from pure water and dried *in vacuo*. Yield: dioxobis(2,2'-bipyridine)ruthenium(IV), 96.15%, and dioxobis(1,10-phenanthroline)-ruthenium(IV), 98.35%, on the basis of the starting complexes. Both complexes are insoluble in carbon tetrachloride, benzene, ether, ester, and dioxane, but are soluble in water, methanol, acetic acid, acetone, and dimethyl formamide.

Found: Ru, 20.16; C, 47.29; H, 4.22; N, 10.19; H_2O, 11.00%; mol wt, 450. Calcd for $[RuO_2(C_{10}H_8N_2)_2]\cdot 3H_2O$: Ru, 20.40; C, 48.00; H, 4.40; N, 11.20; H_2O, 10.80%; mol wt, 446(anhydride).

Found: Ru, 20.35; C, 58.43; H, 3.41; N, 11.51%; mol wt, 510. Calcd for $[RuO_2(C_{12}H_8N_2)_2]$: Ru, 20.65; C, 58.30; H, 3.25; N, 11.33%; mol wt, 494.

(3) Dioxo(2,2'-bipyridine)(1,10-phenanthroline)ruthenium(IV), $[RuO_2bipy\cdot phen]\cdot 3H_2O$: To a solution of 1 g of $[RuO_4bipy]\cdot 3H_2O$ in 150 m*l* of methanol, 5 g of 1,10-phenanthroline were added. The reaction mixture was refluxed under shaking on a hot-water bath until the solution turned orange-brown. Then we followed the procedure described in the proceding section. Yield: 84.42%, on the basis of $[RuO_4bipy]\cdot 3H_2O$. The complex is insoluble in carbon tetrachloride, benzene, ether, ester, and dioxane, but is soluble in water, methanol, ethanol, acetic acid, acetone, and dimethyl formamide.

Found: Ru, 19.14; C, 50.53; H, 4.37; N, 11.17; H_2O, 11.00%; mol wt, 510. Calcd for $[RuO_2(C_{10}H_8N_2)(C_{12}H_8N_2)]\cdot 3H_2O$: Ru, 19.16; C, 50.57; H, 4.19; N, 10.68; H_2O, 10.30%; mol wt, 470(anhydride).

(4) Tetraoxo(2,2'-bipyridine)ruthenium(VIII), $[RuO_4bipy]\cdot 3H_2O$, and μ-Oxo-bis[trioxo(1,10-phenanthroline)ruthenium(VII)], $[RuO_3phen]_2O$. These substances were synthesized according to the methods reported in previous papers.[5,6] The results of the elemental analyses and the molecular weights coincided with those reported previously.

Absorption Spectra. The infrared absorption spectra were obtained on an infrared spectrophotometer, Model IR-S of the Japan Spectroscopic Co., by the KBr disk method. The crystalline water of the complexes was removed by heating for 15 hr at 115°C. It was ascertained from the elemental analysis that the structure of the complexes is not altered by this treatment. The visible and ultraviolet absorption spectra were measured with a Beckmann Model D.U. spectrophotometer.

Magnetic Measurements. The magnetic susceptibility was measured at 25°C with a Cahn R.G. Electrobalance by the Faraday method. The five new complexes were all found to be diamagnetic.

Polarographic Measurements. The polarographic measurements were carried out with a Yanagimoto Automatic Recording Polarograph (Type PA 101). The characteristics of the capillary used were $m=0.648$ mg/sec and $t=4.63$ sec/drop in a 0.5 mol/*l* $LiClO_4$ methanol solution when the height of the mercury reservoir was 70.0 cm and when the applied potential was 0 volt *vs.* a saturated mercurous sulfate reference electrode at 25°C. A conventional H-type electrolytic cell with a potassium sulfate-saturated agar bridge and a sintered glass disk was used as the reference electrode. The experimental procedure was as follows: In order to make the solutions to be measured, four standard solutions were first prepared by dissolving crystals of $[RuO_2bipy_2]$, $[RuO_2bipy\cdot phen]$, $[RuO_2phen_2]$, and $[Ru(OH)_3phen]_2O$ in methanol; the concentrations of the complexes were all adjusted to 10^{-3} mol/*l*. Lithium perchlorate was used as the supporting electrolyte, and its concentration was adjusted to 1 mol/*l*. A 10-m*l* portions of each standard solution was transferred into a 50-m*l* Erlenmeyer flask, to which was then added 10 m*l* of a mol/*l* solution of lithium perchlorate in methanol. A part of the mixture was transferred into an electrolytic cell. The dissolved oxygen was removed by bubbling nitrogen gas in for about half an hour, and the polarograms were recorded in a flow of nitrogen gas through the surface of the solution in an electrolytic cell.

Results and Discussion

Oxidation States of the Complexes. Polarograms of the four new complexes are shown in Fig. 1. All the complexes measured are reduced polarographically in two steps. The half-wave potentials of the first waves of $[RuO_2bipy_2]$, $[RuO_2bipy\cdot phen]$, $[RuO_2phen_2]$, and $[Ru(OH)_3phen]_2O$ are −0.18, −0.19, −0.22, and −0.21 V *vs.* Hg, Hg_2SO_4 (satd.) elec. respectively in 0.5 mol/*l* $LiClO_4$ methanol solutions,

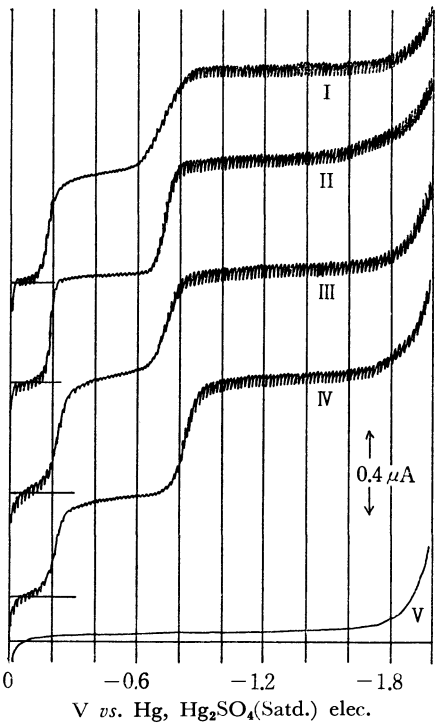

Fig. 1. Polarograms of the complexes.
I: 5×10^{-4} mol/*l* $[RuO_2bipy_2]$, II: 5×10^{-4} mol/*l* $[RuO_2bipy\cdot phen]$, III: 5×10^{-4} mol/*l* $[RuO_2phen_2]$, IV: 5×10^{-4} mol/*l* $[Ru(OH)_3phen]_2O$, V: 0.5 mol/*l* $LiClO_4$ in CH_3OH (the supporting electrolyte).

while those of the second waves are −0.71, −0.73, −0.74, and −0.82 volt respectively. The ratios of the height of the first wave to that of the second are approximately 1 : 1 for all the complexes. Consequently, the first and second waves correspond to a gain of one electron each, indicating the reduction from Ru(IV) to Ru(III), and from Ru(III) to Ru(II) states, respectively. A similar polarogram has also been reported by Niedrach and Tevebaugh[7] for ruthenium(IV) in a perchloric acid solution. They interpreted this as meaning that ruthenium(IV) was step-by-step reduced to Ru(III) and to Ru(II) states. As a result, the oxidation numbers of ruthenium in $[RuO_2bipy_2]$, $[RuO_2bipy\cdot phen]$, $[RuO_2phen_2]$, and $[Ru(OH)_3phen]_2O$ were all concluded to be 4.

Compositions of the Complexes. (1) Dioxodihydroxo(2,2'-bipyridine)ruthenium(VI) and μ-Oxo-bis[trihydroxo(1,10-phenanthroline)ruthenium(IV)]: From the results of the elemental analysis, the mole ratios of ruthenium to 2,2'-bipyridine or 1,10-phenanthroline were both found to be 1 : 1. The data of the molecular weight indicate that the oxohydroxoruthenium(VI) complex with 2,2'-bipyridine is mononuclear, and that the hydroxoruthenium(IV) complex with 1,10-phenanthroline is an oxo-bridged binuclear species.

(2) Dioxobis(2,2'-bipyridine)ruthenium(IV) and dioxobis(1,10-phenanthroline)ruthenium(IV): From the results of the elemental analysis, the mole ratios of ruthenium to 2,2'-bipyridine or 1,10-phenanthroline were both found to be 1 : 2. The data of the molecular weight indicate that both of the complexes, $[RuO_2bipy_2]$ and $[RuO_2phen_2]$, are mononuclear.

(3) Dioxo(2,2'-bipyridine)(1,10-phenanthroline)-ruthenium(IV): From the results of the elemental analysis, the mole ratio of ruthenium, 2,2'-bipyridine, and 1,10-phenanthroline seems to be 1 : 1 : 1. The observed molecular weight indicates that the complex is mononuclear, $[RuO_2bipy\cdot phen]$.

Reduction and Substitution Reactions of $[RuO_4bipy]$ and $[RuO_3phen]_2O$ with 2,2'-bipyridine and 1,10-phenanthroline in Methanol. The reactions of $[RuO_4bipy]$ and $[RuO_3phen]_2O$ are shown schematically in Fig. 2.

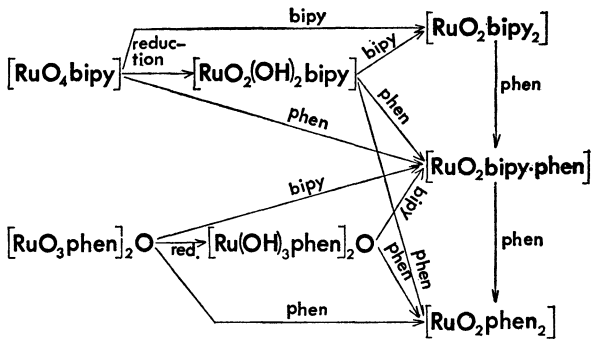

Fig. 2. Reduction and substitution reactions of $[RuO_4bipy]$ and $[RuO_3phen]_2O$ in methanol.

$[RuO_2(OH)_2bipy]$ and $[Ru(OH)_3phen]_2O$ are formed by the reduction of $[RuO_4bipy]$ and $[RuO_3phen]_2O$ respectively, with methanol. It was confirmed, by elemental analyses and by comparison of the spectra, that $[RuO_2bipy_2]$ was formed by the reactions of $[RuO_4bipy]$ or $[RuO_2(OH)_2bipy]$ with 2,2'-bipyridine, and that $[RuO_2phen_2]$ was produced by the reactions of $[RuO_3phen]_2O$ or $[Ru(OH)_3phen]_2O$ with 1,10-phenanthroline. It was also found that the mixed-ligand complex, $[RuO_2bipy\cdot phen]$, could be synthesized by the following reactions in mehtanol: (1) the reaction of $[RuO_4bipy]$ with 1,10-phenanthroline, (2) the reactions of $[RuO_3phen]_2O$ and $[Ru(OH)_3phen]_2O$ with 2,2'-bipyridine, and (3) the stoichiometric reaction between equimolar 1,10-phenanthroline and $[RuO_2(OH)_2bipy]$. In the third reaction, $[RuO_2phen_2]$ was formed if an excess of 1,10-phenanthroline was employed. $[RuO_2bipy\cdot phen]$ and $[RuO_2phen_2]$ were also obtained in methanol by the substitution reactions of $[RuO_2bipy_2]$ and $[RuO_2bipy\cdot phen]$ respectively with equimolar 1,10-phenanthroline. The structures of these bis-chelates of dioxoruthenium(IV) will be discussed later.

Air Oxidation of $[Ru(OH)_3phen]_2O$ in an Aqueous Solution. An aqueous solution of $[Ru(OH)_3phen]_2O$ changes slowly from dark-brown to green, probably because of air oxidation in water. It was confirmed from the spectral change that $[Ru(OH)_3phen]_2O$ was transformed to $[RuO_3phen]_2O$ in water.

Infrared Absorption Spectra. The main infrared absorption bands of the present complexes are shown in Table 1, together with those of free ligands. The C=N, C=C, and C–H stretching peaks are all shifted to the higher frequency side by ligation in a manner similar to the cases of $[RuO_4bipy]$ and $[RuO_3phen]_2O$.[5,6] The absorption bands at 3380 and 3390 cm^{-1} of oxo-hydroxoruthenium(VI) and oxo-bridged hydroxoruthenium(IV) complexes with 2,2'-bipyridine and 1,10-phenanthroline respectively were assigned to the O–H stretching. Similar observations have been reported for hydroxo-complexes of osmium,[8] hydroxonitrosyl ruthenium complexes,[9] and $[Re(OH)Cl_2(O\cdot COC_3H_7)]_2$.[10] The infrared spectra of the ruthenium(IV) oxide complexes with 2,2'-bipyridine and 1,10-phenanthroline contain no peaks which can be attributed to the O–H stretching frequencies, indicating that the hydroxo groups are not present in the ruthenium(IV) oxide complexes.

Electronic Absorption Spectra. The visible and ultraviolet absorption spectra of oxo-hydroxoruthenium(VI), oxoruthenium(IV), and oxo-bridged hydroxoruthenium(IV) complexes with 2,2'-bipyridine and 1,10-phenanthroline were measured in water and methanol. They are shown in Figs. 3 to 7, together with those of pure ligands in water.

Dioxodihydroxo(2,2'-bipyridine)ruthenium(VI) has six absorption bands, at 670, 560, 450, 364, 290, and 244 mμ (Fig. 3). Four of those peaks, those at 670, 560, 450, and 364 mμ, may all be assigned to the charge transfer from ligand to metal. Considerable data on the spectra of tetrahedral oxyanions, which

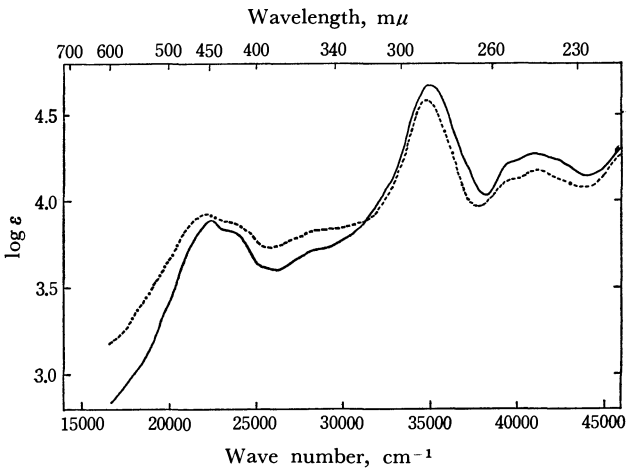

Fig. 4. Absorption spectra of $[RuO_2bipy_2]$ in water (——) and methanol (------).

have one or two *d* electrons in their ground states, were reported by Symons and his co-workers[11,12] and by Wolfsberg and Helmholz.[13] They suggested that the lowest transitions in such oxyanions as CrO_4^{3-}, MnO_4^{2-}, MnO_4^{3-}, and FeO_4^{2-} might also be interpreted as due to the charge transfer from oxygen to metal. The 290 and 244 mμ bands appear to be intraligand transitions corresponding to the two bands at 279 and 233 mμ in 2,2'-bipyridine.

Dioxobis(2,2'-bipyridine)ruthenium(IV) has five absorption bands and a shoulder at 450, 425, 350, 287, 244, and 255 mμ respectively (Fig. 4). A similar spectrum has also been reported by Fergusson and Harris[14] for tris(2,2'-bipyridine)ruthenium(II) chloride, which has six absorption bands at 452, 425, 348. 287, 250, and 245 mμ and which shows a close resemblance to those of the present complex, $[RuO_2bipy_2]$, in the intensity and the characteristic shape of each band. They suggested that the 452 and 425 mμ bands might be assigned to the charge transfer from metal to ligand ($t_{2g} \rightarrow \pi^*$ transitions), and the 348 mμ band, to the charge transfer from ligand to metal ($\pi \rightarrow e_g^*$ transition). The 450 and 425 mμ bands in the present complex, $[RuO_2bipy_2]$, may also be assigned to the charge transfer from metal to ligand, and the 350 mμ band, to the charge transfer from ligand to metal. The two peaks in the ultraviolet region appear to be intraligand transitions corresponding to the 279 and 233 mμ bands observed for free 2,2'-bipyridine.

Dioxobis(1,10-phenanthroline)ruthenium(IV) has four peaks and two shoulders at 450, 420, 265, 225, 310, and 290 mμ respectively (Fig. 5). A similar, spectrum has also been reported by Crosby, Perkins

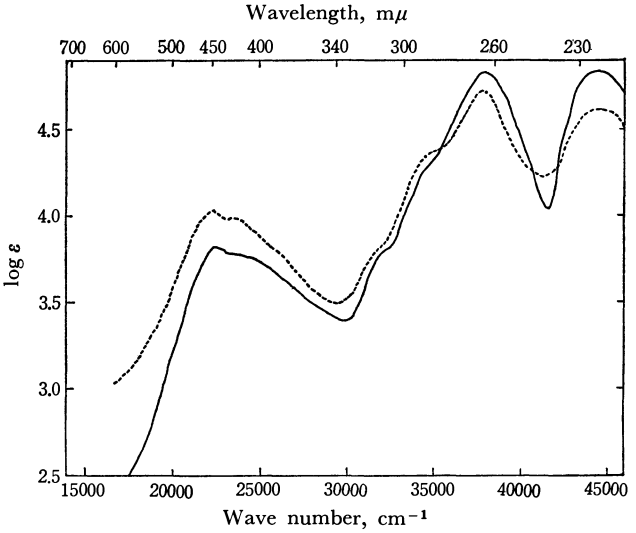

Fig. 5. Absorption spectra of $[RuO_2phen_2]$ in water (——) and methanol (------).

and Klassen[15] for tris(1,10-phenanthroline)ruthenium(II) chloride, which has six absorption bands at 450, 420, 315, 288, 265, and 223 mμ; this spectrum bears a remarkable resemblance to those of the present complex, $[RuO_2phen_2]$, in the intensity and the characteristic shape of each band. They suggested that the 450 and 420 mμ bands might be assigned to the charge transfer from metal to ligand. The 450 and 420 mμ bands in the present complex, $[RuO_2phen_2]$, may also be assigned to the charge transfer from metal to ligand. The two shoulders and the two peaks observed in the ultraviolet region appear to be intraligand transitions corresponding to the 320, 290, 265, and 230 mμ bands in free 1,10-phenanthroline.

Dioxo(2,2′-bipyridine)(1,10-phenanthroline)ruthenium(IV) has six peaks at 450, 425, 370, 290, 265, and 225 mμ (Fig. 6). The 450 and 425 mμ bands may both be assigned to the charge transfer from metal to ligand, and the 370 mμ band, to the charge transfer from ligand to metal. The latter charge-transfer transition (ligand-to-metal) is probably due to the coordination of the 2,2′-bipyridine molecule. A similar absorption band has been reported by Fergusson and Harris[14] for $[Ru^{II}Cl_2bipy_2]$ and $[Ru^{III}Cl_2bipy_2]Cl\cdot 3H_2O$. The three peaks observed in the ultraviolet region appear to be intraligand transitions corresponding to the 279 mμ band in 2,2′-bipyridine and to the 265 and 230 mμ bands in 1,10-phenanthroline respectively. The electronic absorption data show that this compound is a mixed-ligand complex of 2,2′-bipyridine and 1,10-phenanthroline.

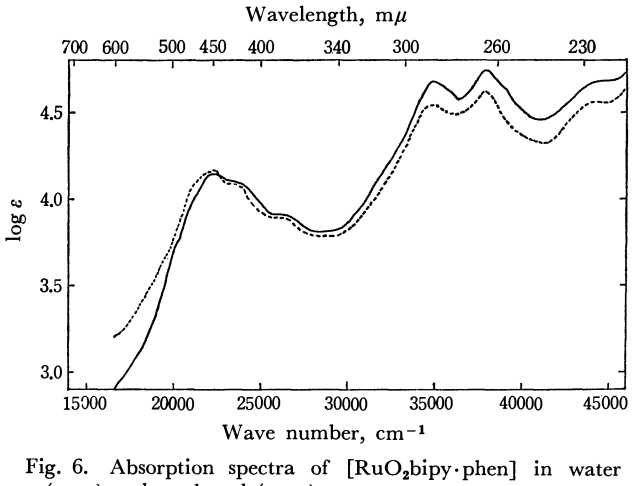

Fig. 6. Absorption spectra of $[RuO_2bipy\cdot phen]$ in water (——) and methanol (------).

μ-Oxo-bis[trihydroxo(1,10-phenanthroline)ruthenium(IV)] has four peaks and two shoulders at 450, 375, 265, 222, 315, and 290 mμ respectively (Fig. 7). The two peaks observed at 450 and 375 mμ may both be assigned to the charge transfer from metal to ligand, as in $[RuO_2phen_2]$. The charge-transfer bands for the present complex, $[Ru(OH)_3phen]_2O$, are observed in a shorter-wavelength region than those of the previous complex, $[RuO_3phen]_2O$. This fact shows that the charge-transfer transitions of $[Ru(OH)_3phen]_2O$ occur with a higher energy than those of $[RuO_3phen]_2O$. The two charge-transfer bands of $[Ru(OH)_3phen]_2O$ are diffusely observed in comparison with those of $[RuO_2phen_2]$, presumably due to an interaction between two ruthenium atoms or a low symmetry of the binuclear species. The two shoulders and two peaks observed in the ultraviolet region may all be assigned to the intraligand transitions of 1,10-phenanthroline. The spectrum of $[Ru(OH)_3phen]_2O$ which has been oxidized with air for a month in water coincides with that of the first complex, $[RuO_3phen]_2O$, showing that the present complex, $[Ru(OH)_3phen]_2O$, is transformed to $[RuO_3phen]_2O$ in water. This fact was also confirmed by the elemental analysis and by measurement of the molecular weight and the magnetic susceptibility.

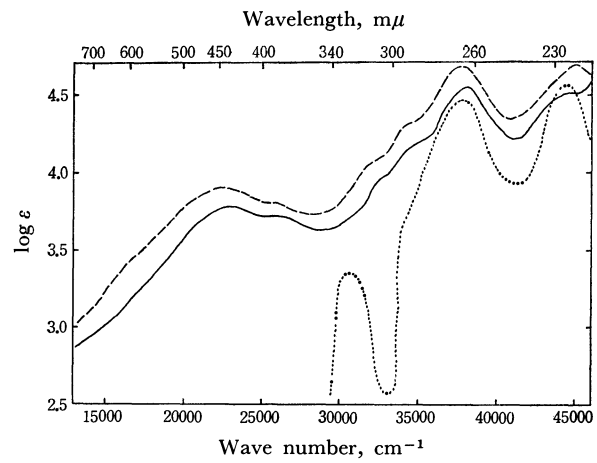

Fig. 7. Absorption spectra of $[Ru(OH)_3phen]_2O$ and 1,10-phenanthrolone.
—— $[Ru(OH)_3phen]_2O$ in H_2O, ---- $[Ru(OH)_3phen]_2O$ in CH_3OH, ------ phen in H_2O

Magnetic Properties. The observed diamagnetism of dioxodihydroxo(2,2′-bipyridine)ruthenium(VI) indicates the pairing of the two *d* electrons in Ru(VI). The complex contains the ruthenium atom octahedrally bonded one 2,2′-bipyridine, two oxide, and two hydroxide ligands. The molecular orbital treatments of $[RuO_2Cl_4]^{2-}$ and $[OsO_2(OH)_4]^{2-}$ which have been reported by Lott and Symons[2] may be applied to $[RuO_2(OH)_2bipy]$ just as to the asymmetrical "ruthenyl" complex, $[RuO_2(OH)_2(NH_3)_2]$.[16]

The diamagnetism of μ-oxo-bis[trihydroxo(1,10-phenanthroline)ruthenium(IV)] may be explained by applying the molecular orbital treatment of $K_4[Ru_2OCl_{10}]$ which has been reported by Dunitz and Orgel.[17]

The diamagnetism of dioxobis(2,2′-bipyridine)-, dioxobis(1,10-phenanthroline)-, and dioxo(2,2′-bipyridine)(1,10-phenanthroline)-ruthenium(IV) is especially interesting. Each of the present complexes, $[RuO_2bipy_2]$, $[RuO_2phen_2]$, and $[RuO_2bipy\cdot phen]$, contains the ruthenium atom octahedrally bonded to two oxide and two 2,2′-bipyridine or 1,10-phenanthroline ligands, and the four d electrons must exist as two pairs, assuming a *trans*-configuration with two

oxide ligands. It was reported by Deguchi[18] and Nakai for $[Cu(bipy)_2(ClO_4)]ClO_4$ and $[Cu(phen)_2(H_2O)](NO_3)_2$ that the steric interference between H-atoms linked to the 3- and 3'- or 2- and 9-carbon atoms might be removed by the tetrahedral distortion of the two 2,2'-bipyridine or 1,10-phenanthroline molecules respectively. This may be assumed to be a *trans*-configuration when the above consideration is applied to the present complexes, $[RuO_2bipy_2]$, $[RuO_2phen_2]$, and $[RuO_2bipy\cdot phen]$.

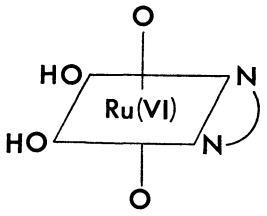

Fig. 8. The proposed structure of $[RuO_2(OH)_2bipy]$.

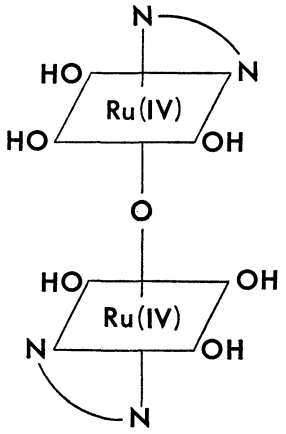

Fig. 9. The proposed structure of $[Ru(OH)_3phen]_2O$.

The structures shown in Figs. 8 and 9 seem clear possibilities for the two types of the present complexes. The oxidation number of $[RuO_2(OH)_2bipy]$ is assumed to be 6, and those of $[Ru(OH)_3phen]_2O$, $[RuO_2bipy_2]$, $[RuO_2phen_2]$ and $[RuO_2bipy\cdot phen]$, to be 4.

The author wishes to express his thanks to Professor Shinichi Kawaguchi of Osaka City University for his kind guidance and encouragement throughout this work, and to Professor Hideo Yamatera, the University of Nagoya, for his guidance in molecular orbital consideration. His thanks are also due to Dr. Tetsuo Mamuro, the chairman of the Department of Health Physics and Instrumentation of the Radiation Center of Osaka Prefecture, for his encouragement and support, to Dr. Toyokichi Kitagawa of Osaka City University for his guidance in the measurement of polarograph, and to Dr. Shichio Kawai, the University of Osaka, for his guidance in the measurement of the magnetic susceptibility.

The Chemical-transport Reaction of Spinel-type Oxides

Koichi NAGASAWA*, Yoshichika BANDO, and Toshio TAKADA
Institute for Chemical Research, Kyoto University, Uji
(Received September 29, 1970)

Single crystals and thin films of spinel-type oxides were prepared by a chemical-transport reaction in a closed system, using HCl gas as the transport agent. This paper will report on the preparation conditions and the reaction process of the chemical-transport reaction. The reaction process of Co_3O_4 was found to be different from that of other oxides, since Co_3O_4 was dissociated into CoO and O_2 in the closed tube. The reaction process was explained by the difference in the dissociated oxygen pressure between the source zone and the crystallization zone in the system. The chemical-transport reaction of $NiFe_2O_4$ was applied to the preparation of thin film. The single-crystal thin films were epitaxially grown on the (110) and (111) surfaces of MgO.

The growth of spinel-type oxides is very important for the fundamental investigation of their physical properties. Therefore, many investigations of the growing method, for instance, the growth from the melt or from the flux, have been made. The growing method from the melt is not suitable for the material dissociated below the melting point, and the method from the flux sometimes causes the flux to be included in the crystals.

The growing method from the gas phase has been expected not to have such defects, and so recently much interest has been directed toward this method. Takei and Takasu[1] prepared single-crystal films of $NiFe_2O_4$ $CoFe_2O_4$, and Fe_3O_4 on the MgO substrate by the decomposition of appropriate mixtures of the metal halides by water vapor. Sputtering in a glow-discharge system from a ceramic cathode of the ferrite also made it possible to prepare single-crystal films of nickel ferrite.[2] In addition, the chemical transport reaction method in a closed system, which was developed by Schäfer and his co-workers,[3] for the growth of single crystals of various solid substances, *e.g.*, Si, Ge, Cu_2O, and Fe_2O_3 is applicable to the growth of ferrite. Hauptmann[4] applied this chemical-transport reaction, using HCl gas as the transport agent, to the preparation of Fe_3O_4 single crystals. In this case, single crystals were presumably grown by this reaction:

$$Fe_3O_4(s) + 8HCl(g) \rightleftharpoons 2FeCl_3(g) + FeCl_2(g) + 4H_2O(g) \quad (1)$$

where (s) and (g) indicate the solid and gaseous states respectively. Moreover, Kleinert[5] reported the growth of $NiFe_2O_4$, $MnFe_2O_4$, and other spinel-type oxides by the same method. In these cases, the materials which were used as the sources were not dissociated in the system. As the cobaltite Co_3O_4 is dissociated into CoO and O_2 at high temperatures, the process of this chemical-transport reaction may be expected to be different from that of other oxides.

In the present investigation, single crystals of Co_3O_4 were synthesized by a chemical-transport reaction using HCl gas, and the reaction process of Co_3O_4 was compared with that of $NiFe_2O_4$. Moreover, $NiFe_2O_4$ thin films were epitaxially grown on the (110) and (111) surfaces of the MgO single crystal. Some parts of this investigation have been already reported in a short note.[6,7] This paper will present the results in detail and will discuss them.

Experimental

Source Materials and Substrates. The source materials for the chemical-transport reaction were Co_3O_4 powder, $NiFe_2O_4$ powder, and sintered $NiFe_2O_4$. The Co_3O_4 powder was obtained by the thermal decomposition of $CoCO_3$ at 700°C in air. α-Fe_2O_3 and NiO were weighed, mixed, and then calcined at 1000°C for 2 hr. Calcination was followed by crushing. This powder was pressed and fired in air at 1200°C for a day. The $NiFe_2O_4$ powder was obtained by crushing this sintered body. $CoCO_3$ and NiO were Wakoo guaranteed reagents, and α-Fe_2O_3 was a product of the Toda Industrial Co., Ltd. (99.9%). Single crystals of MgO were obtained from the New Metals Corp.; a polished (110) or (111) surface or a cleaved (100) surface was used as the substrate for the growth of $NiFe_2O_4$ thin film.

Method. The source material, Co_3O_4 or $NiFe_2O_4$

powder, was loaded into one end of a silica tube 18 cm in length and 1.4 cm in diameter. After the tube had then been evacuated to 10^{-6} mmHg, 40 mmHg of HCl gas was admitted and the other end of the tube was sealed off. The tube was heated for 2—3 days in a furnace with a temperature gradient, as is shown in Fig. 1, and then quenched in water within a minute. The temperatures of the source zone and crystallization zone were 1000°C and 800°C respectively. The tube was then broken, and the crystals obtained in the crystallization zone were removed from the wall of the tube.

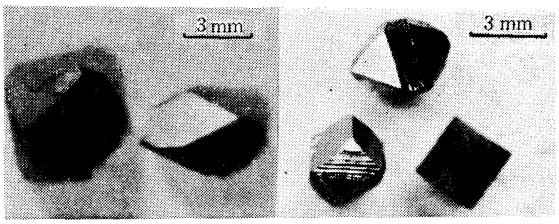
In the growth of $NiFe_2O_4$ thin films, the source material was sintered $NiFe_2O_4$, 8 mm in diameter and 3 mm thick. The silica tube used was 17 cm in length and 9 mm in diameter. In the crystallization zone, a substrate of MgO single crystal having a polished (110) or (111) surface or a cleaved (100) surface was mounted. The pressure of the HCl gas admitted was 50 mmHg. The temperature in the source zone was 1030°C, and at the substrate zone, 860°C, as is shown in Fig. 1. The tube was heated for two days, pulled out of the furnace, and cooled in air. The film grown on the surface of the substrate could be separated from the substrate by treating it in a hot 2—5% aqueous solution of nitric acid. The surface area and weight of the film were measured, and the film thickness was calculated from the density of $NiFe_2O_4$.

Analysis. The phases of the source material remaining in the source zone after the reaction, which will here after be called the "residue", and the single crystals obtained were identified by means of X-ray powder diffraction using Mn-filtered Fe-radiation. The lattice constants of the single crystals were measured by the X-ray powder pattern, using {721} reflection. A Laue photograph was taken of a face of a crystal obtained using copper radiation.

In the case of the $NiFe_2O_4$ thin film, a Laue photograph was taken by means of the transmitted diffracted lines. As an electron beam could pass through the edge of the film, the lattice constant of the films was measured by means of usual electron diffraction, using Au polycrystalline film as a standard sample. The atomic ratios of iron to nickel in the films were measured by chemical analysis.

Results and Discussion

Chemical-transport Reaction of Co_3O_4. The transport of Co_3O_4 and $NiFe_2O_4$ by HCl yielded some black and bright crystals 2—5 mm in size. Figure 2 shows photographs of representative crystals. The Laue photograph showed that the best developed faces were {111}. The {110} planes were also observed in some



(A) (B)

Fig. 2. Photographs of (A) Co_3O_4 single crystals and (B) $NiFe_2O_4$ single crystals.

$NiFe_2O_4$ single crystals. The X-ray powder diffraction of the single crystals indicated that they had a spinel structure and that the lattice constant was 8.080 Å in Co_3O_4 and 8.352 Å in $NiFe_2O_4$ respectively. These values agreed approximately with the A.S.T.M. value.

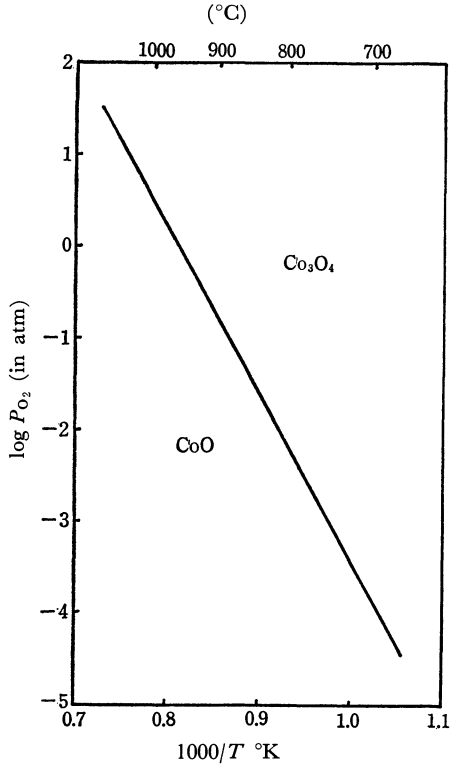


Fig. 3. Oxygen pressure in equilibrium with Co_3O_4 and CoO as a function of 1000/T°K.

TABLE 1. CONDITIONS EMPLOYED IN PREPARATION OF SPINEL-TYPE OXIDE SINGLE CRYSTALS BY CHEMICAL TRANSPORT REACTION AND RESULTS

Run No.	Source material	Weight of source material charged (g)	Phase of residues at the source zone	Phase of single crystals obtained	Admitted HCl gas (mmHg)	Reaction time (day)	Temperature gradient (°C)
1	Co_3O_4	0.40	CoO	Co_3O_4	40	2	1000—800
2	Co_3O_4	0.15	CoO	Co_3O_4	40	2	1000—800
3	Co_3O_4	0.70	Co_3O_4+CoO	Co_3O_4	40	3	1000—800
4	Co_3O_4	0.50	Co_3O_4+CoO	Co_3O_4	40	3	1000—800
5	$NiFe_2O_4$	0.15	$NiFe_2O_4$	$NiFe_2O_4$	40	3	1000—800
6	$NiFe_2O_4$	0.30	$NiFe_2O_4$	$NiFe_2O_4$	40	3	1000—800
7	$NiFe_2O_4$	0.50	$NiFe_2O_4$	$NiFe_2O_4$	40	3	1000—800

In the case of the chemical-transport reaction of Co_3O_4, the phases of the residue changed with the amount of the source material present before the reaction. Table 1 gives a survey of the growth experiments. Runs 1 and 2, in which the weights of the source material were 0.40 and 0.15 g respectively, gave only CoO as the residue. However, runs 3 and 4, in which these weights were 0.50 g and 0.70 g, gave two phases of CoO and Co_3O_4 as the residue. Such phenomena could be explained by the dissociation reaction of Co_3O_4, $Co_3O_4 \rightarrow 3CoO + 1/2O_2$. In this case, the dissociation oxygen pressure is given by the equation[8]: $\log P_{O_2} = -19150/T + 15.48$. Figure 3 shows the dissociation pressure *versus* the temperature. According to Fig. 3, the dissociation pressure of Co_3O_4 is 2.78 atm at 1000°C and 5.6×10^{-3} atm at 800°C. Co_3O_4 at the source zone is perhaps dissociated into CoO and O_2 at 1000°C until the oxygen pressure reaches 2.78 atm in the closed system. If the Co_3O_4 is assumed to be completely dissociated into CoO and O_2 in the system whose volume is estimated to be about 27 m*l*, the oxygen pressures of runs 1—4 can be calculated to be 3.2, 1.2, 4.0, and 5.5 atm respectively. The calculated dissociated pressure of run 2, 1.2 atm, is lower than the dissociation pressure, 2.78 atm, at 1000°C. Therefore, it is considered that, in run 2, the Co_3O_4 is completely dissociated into CoO and O_2, and that then $CoCl_2$ gas is prepared by the reaction of CoO and HCl in the source zone. However, in this experiment, Co_3O_4 crystals were prepared in the crystallization zone. As the oxygen pressure in the tube should be higher than the dissociation pressure of Co_3O_4 in the crystallization zone of 800°C, this reaction may occur as follows:
in the source zone of 1000°C:

$$Co_3O_4(s) \rightarrow 3CoO(s) + \frac{1}{2}O_2(g) \quad (2)$$

$$3CoO(s) + 6HCl(g) \rightarrow 3CoCl_2(g) + 3H_2O(g) \quad (3)$$

and in the crystallization zone of 800°C:

$$2CoCl_2(g) + 3H_2O(g) + \frac{1}{2}O_2(g) \rightarrow Co_3O_4(s) + 6HCl(g) \quad (4)$$

The calculated oxygen pressures of runs 3 and 4, 4.0 and 5.5 atm respectively, are much higher than 2.78 atm, and in the source zone Co_3O_4 should be partially dissociated into CoO and O_2 until the oxygen pressure amounts to 2.78 atm. Therefore, the reaction proceeds with a source material consisting of CoO and Co_3O_4. In runs 3 and 4 the following reaction may be added to the above-mentioned reaction in the source zone:

$$Co_3O_4(s) + 8HCl(g) \rightleftharpoons CoCl_2(g) + 2CoCl_3(g) + 4H_2O(g). \quad (5)$$

The reverse reaction may occur in the crystallization zone.

In run 1, the calculated oxygen pressure, 3.2 atm, is slightly higher than 2.78 atm. However, in this experiment, the residue was CoO. This can be explained by considering the following process. In the initial stage, the reaction should proceed with two phases of CoO and Co_3O_4 in the source zone, and the oxygen pressure seems to be kept at 2.78 atm in the tube. As the growth of Co_3O_4 single crystals consumes the O_2 gas in the crystallization zone, as is shown in Eq. (4), the Co_3O_4 at the source zone should be dissociated into CoO and O_2 by the quantity of Co_3O_4 prepared in the crystallization zone, thus keeping the oxygen pressure 2.78 atm. Therefore, the quantity of Co_3O_4 in the source zone should decrease with the growth of Co_3O_4 single crystals in the crystallization zone, and only CoO should come to exist as the residue in the source zone. In every case from run 1 to run 4, it is considered that Co_3O_4 single crystals grow under the oxygen pressure dissociated in the source zone.

In the case of $NiFe_2O_4$, the phases of single crystals and the residue did not change with the amount of the source before the reaction, as is shown in runs 5, 6, and 7. The chemical-transport reaction seems to proceed with source material of a single phase, according to this simple reversible reaction:

$$NiFe_2O_4(s) + 8HCl(g) \rightleftharpoons NiCl_2(g) + 2FeCl_3(g) + 4H_2O(g). \quad (6)$$

Preparation of Thin Film of $NiFe_2O_4$. Figure 4 shows the surfaces of the MgO (100), (110), and (111) substrates on which $NiFe_2O_4$ was deposited by the chemical-transport reaction. On the (100) MgO

(A) (B)

Fig. 5. Laue patterns of film using copper radiation. (A) film on (110) surface of MgO. (B) film on (111) surface of MgO.

substrate, many oriented pyramid-like microcrystals were observed, as is shown in Fig. 4(A). On the contrary, thin films were observed on the (110) and (111) MgO substrates. The film was shiny and opaque brown, and it overlaid the substrate. The films removed from the substrate was composed of a ferromagnetic material. The film thickness was about 5000 Å, and the growing speeds were about 100 Å/hour. Laue patterns obtained using copper radiation are shown in Fig. 5. The pattern of the film on the (110) surface of MgO consisted of reflections with a two-fold axis; the film was a (110) plane with a cubic structure. The pattern of the film on the (111) surface of MgO corresponded to that of the single crystal film with a (111) surface with a cubic structure. The electron diffraction of the film removed from the (111) surface of MgO gave spots with a six-fold axis. The lattice constant calculated by means of the diffraction spots was 8.38 Å. This value agrees within 0.5% with the A.S.T.M. value of $NiFe_2O_4$. The atomic ratio of iron to nickel in the film was determined to be 1.97 ± 0.04 from the chemical analysis. Therefore, it may be concluded that the film was nickel ferrite deposited epitaxially on the (110) and (111) planes of MgO.

When the $NiFe_2O_4$ powder was charged as the source, thin films were not grown, and many small crystals were found on the substrate. The rate of surface reaction may be much higher in the powdered source material than in the sintered one, as the surface area of the powdered material is larger than that of the sintered one. It is considered that the high rate of surface reaction results in much transport. In this case, the great deal of transport seems to cause the overgrowth of $NiFe_2O_4$ crystals on the substrate.

The authors wish to express their thanks to Dr. N. Yamamoto for his fruitful discussions.

The Effect of Axial Pyridine Ligands on the Charge Transfer Bands of *trans*-Bis(dimethylglyoximato)Cobalt(III) and -Iron(II) Complexes

Yukio YAMANO, Isao MASUDA, and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 16, 1970)

The electronic absorption spectra of $[Co^{III}(dmgH)_2B_2]^+$ and $[Fe^{II}(dmgH)_2B_2]$ (dmgH=dimethylglyoximate monoanion and B=pyridine derivatives) are inspected with respect to the effect of the axial pyridine ligands on the charge-transfer bands of the complexes. The characteristic bands observed in the 275—305 mμ region for the Co(III) complexes and in the 485—555 mμ region for the Fe(II) complexes, which have been assigned to a metal→oxime charge-transfer band, are shifted to shorter wavelengths with a decrease in the basicity of the pyridine derivatives. The results have been discussed by taking into account the π-interaction of the $d_\pi(d_{xz}, d_{yz})$ orbital of the central metal ion with the empty π-orbitals of both the dimethylglyoximate and the pyridine derivatives. It is suggested that the π-interaction is stronger in the Fe(II) complexes than in the Co(III) complexes, while the σ-bond is stronger in the latter. The infrared spectral evidence that the C=N stretching frequency is dependent on the axial pyridine derivatives, and that it is observed at a lower frequency in the Fe(II) than in the Co(III) complexes, is consistent with the above results.

It was thought to be informative to investigate the nature of the bonding between axial ligands and planar transition metal complexes in order to understand the transmission of the electronic effect of the axial ligands in the complexes. When ligands such as pyridine are coordinated axially to the planar complexes, a d_π-(metal)-π^*(py) bonding may be either taken into account[1-3] or may be omitted.[4,5] In previous works, the present authors postulated a π-interaction between the central cobalt ion and the pyridine ring in the *trans*-bis(1,2-dioximato)cobalt(III) complexes on the basis of the anomalous behavior of the pyridine ligands, extensively facilitating the deprotonation reaction of the intramolecular hydrogen bridges of the complexes.[6]

In earlier publications,[7] it was reported that the electronic absorption spectra of the *trans*-bis(1,2-dioximato)cobalt(III) complexes with aniline derivatives show characteristic C-I(340—400 mμ) and C-II(300—375 mμ) bands, which can be ascribed to the charge-transfer transitions from the axial aniline derivatives to the cobalt ion, and from the cobalt ion to the dioximate ligand, respectively. It seemed that it would be interesting to elucidate the effects of the axial pyridine analogues on the charge-transfer spectra of the complexes.

In this paper, the electronic spectra of *trans*-$[Co(dmgH)_2B_2]^+$ (dmgH=dimethylglyoximate monoanion and B=pyridine derivatives) have been inspected and compared with the spectra of $[Fe(dmgH)_2B_2]$, and the data have been discussed by taking into account the π-interaction between the axial ligands and the central metal ion.

Experimental

Preparations. The cobalt(III)-dimethylglyoxime complexes with the $[Co(dmgH)_2B_2]Cl$ formula, listed in Table 2, were prepared by a method described elsewhere.[6]

The iron(II)-dimethylglyoxime complexes with the $[Fe(dmgH)_2B_2]$ formula were prepared according to the method of Miwa *et al.*[8] The procedure was carried out under a nitrogen atmosphere. To an ethanol solution of $dmgH_2$ (1.5 g, 0.013 mol), $FeSO_4 \cdot 7H_2O$ (1.5 g, 0.0065 mol) in an aqueous solution was added at room temperature; this was followed by the stirring in of pyridine or its derivatives (3—4 g, 0.03—0.04 mol) in an ethanol solution. The pH value of the solution was adjusted to about 7 by adding aqueous HCl or NaOH. Fine crystals precipitated; they were collected on a filter and washed with water, ethanol, and then ether. The analytical data are summarized in Table 1.

Measurements. The electronic absorption spectra of $[Co(dmgH)_2B_2]Cl$ were measured in an aqueous-ethanol (1 : 1) solution. As to $[Fe(dmgH)_2B_2]$, the electronic absorption spectra were measured in an ethanol solution containing an excess of the free axial ligand under a nitrogen atmosphere, since the complexes in solution are known to change upon standing in the air due to the dissociation of the axial ligand and the concomitant oxidation of the central iron ion.[9] The complexes showed little spectral change under the above conditions, and they gave a spectrum quite close to that obtained for the solid sample. A Hitachi Spectrophotometer, Model EPS-3, and a Hitachi Infrared Spectrometer, Model EPI-2G, were used for recording the spectra.

Results and Discussion

Cobalt(III) Complexes. As may be seen in Fig. 1, the electronic absorption spectra of $[Co(dmgH)_2B_2]^+$ (B=pyridine derivatives) show three intense bands in the 250—400 mμ region, the band around 250 mμ may be assigned to the intraligand(dmgH) $\pi \rightarrow \pi^*$ transition.[10] The bands at 315—370 mμ and 275—305 mμ, which will hereafter be referred to as the α- and β-bands respectively, are not well defined and

have lower intensities than the C-I and C-II bands of $[Co(dmgH)_2A_2]^+$ (A=aniline derivatives). The lower intense band at about 450 mμ might be due to a *d*—*d* transition. The complexes of the same type with ammonia, benzylamine, and imidazole as axial ligands show a spectral pattern similar to that of the pyridine species.[7] The absorption maxima of the α- and β-bands have been determined by the method of parabolic approximation.[11] The results obtained for $[Co(dmgH)_2Py_2]^+$ are represented in Fig. 1, while the numerical data are given in Table 2.

By plotting the frequencies (ν_{max}) of the α- and β-bands against the basicities of the free pyridine derivatives,[12–14] linear correlations have been found, as is shown in Fig. 2-α and -β. The α- and β-bands are shifted to a longer wavelength with an increase in the basicity of the pyridine derivatives. The degree of the shifts for the α-band is 1.5 times larger than that for the β-band. These shifts for the α- and β-bands caused by the nature of the axial ligands seem to be qualitatively similar to those observed for the C-I and C-II bands of $[Co(dmgH)_2A_2]^+$. In the case of this complex, the C-I band has been assigned to the charge-transfer band from the axial aniline derivatives to the cobalt ion on the basis of the fact that, with an increase in the basicity of the aniline derivatives, this band is

shifted to a longer wavelength, although the C-II band is shifted only a little.[7] As to the C-II band, it has been assigned to the charge-transfer band from the cobalt ion to the dioximate ligand, since it is shifted to a longer wavelength with an increase in the electron-withdrawing property of the dioximate ligands for $[Co(DH)_2(p\text{-}CH_3OAn)_2]^+$ (DH=1,2-dioximate monoanion and An=aniline).[7] Judging from the above observations and the frequencies of these bands, it is reasonable to ascribe the α- and β-bands for $[Co(dmgH)_2B_2]^+$ to the charge-transfer bands from the axial pyridine derivatives to the cobalt ion, and from the cobalt ion to the dimethylglyoximate ligand, respectively.

It is significant to note that: i) the β-band in $[Co(dmgH)_2B_2]^+$ is considerably affected by the nature of the axial pyridine derivatives, whereas the C-II band in $[Co(dmgH)_2A_2]^+$ is only slightly affected, and ii) the β-band for the axial pyridine complexes is observed at a higher energy than the C-II band for the axial aniline complexes (the difference in the energies between these two bands becomes larger as the basicity of the bases decreases) (Fig. 2). In order to explain these facts, it will be necessary to consider the d_π(Co)–π*(Py) interaction in addition to the d_π-(Co)–π*(dmgH) bonding,[15] and the σ-bonding. As is shown in Fig. 5, it seems that the $d_\pi(d_{xz}, d_{yz})$–π*-(Py) interaction stabilizes the d_π-levels, thus weakening the $d_\pi(d_{xz}, d_{yz})$–π*(dmgH) bonding and stabilizing the π*(dmgH) level. The extent of the stabilization of the π*(dmgH) level would, in this case, be smaller than that of the d_π-levels. Therefore, the d_π(Co)→π*(dmgH) charge-transfer band is observed in a shorter wavelength region for the axial pyridine complexes than for the axial aniline complexes. The empty π-level of the pyridine derivatives is expected to be lowered in the order: 4-NH_2Py>Py>4-CNPy.[16,17] Therefore, the π-interaction described above will become stronger and the d_π(Co)→π*(dmgH) charge-transfer band will be shifted to a higher energy in the order; 4-NH_2Py<Py<4-CNPy. The intraligand-(dmgH)π→π* band tends to shift to a longer wavelength as the π-acceptor property of the pyridine derivatives increases. This seems to be consistent with the above considerations.

Iron(II) Complexes. $[Fe(dmgH)_2B_2]$ (B=pyridine derivatives) has often been characterized by two intense absorption bands at about 500 and 400 mμ (Fig. 3).[8,9,18,19] In this paper we will designate them as the γ- and δ-bands respectively. In the case of the complexes with axial ammine or hydrazine ligands, no absorption band corresponding to the above δ-band has been observed. The γ-band has been assigned to the d_π(Fe)→π*(dmgH) transition on

The frequency is given in 10^{13} sec^{-1}.

a) These numbers are referred in Figs. 3 and 4.

b) In the spectra of $[Fe(dmgH)_2(3\text{-}CH_3Py)_2]$ in ethanol solution, two $d\rightarrow d$ bands with lower intensity ($\log\varepsilon=2.16$ and 2.0) are observed at $\nu_{max}=46.13$ and 42.13. In the spectra of the other complexes in ethanol solution, similar bands were unsuccessfully observed for their lower solubility.

the basis of the fact that, with an increase in the electron-withdrawing property of the dioximate ligand, it is shifted to a longer wavelength, although the δ-band is shifted only a little.[19] In a recent theoretical treatment,[20] the band at 526 mμ for $[Fe(dmgH)_2(NH_3)_2]$ has been indicated to be the $d_\pi(Fe)\rightarrow\pi^*$(dmgH) charge-transfer band. As to the δ-band mentioned above, it has been proposed that it is due to the $d_\pi(Fe)\rightarrow\pi^*$(Py) charge-transfer transition, since it is shifted to a longer wavelength in the 4-cyanopyridine complex than in the pyridine complex.[9]

Our interest led us to inspect the shifts of both the γ- and δ-bands for a series of axial pyridine derivatives in connection with the shifts of the α- and β-bands for $[Co(dmgH)_2B_2]^+$. As is shown in Fig. 4, the δ-band is considerably shifted to a longer wavelength with a decrease in the basicity of the pyridine derivatives; this indicates an increase in the derivatives' π-acceptor property. Therefore, the δ-band is ascribed to the $d_\pi(Fe)\rightarrow\pi^*$(Py) charge-transfer transition. The γ-band is shifted to a shorter wavelength as the basicity of the pyridine derivatives decreases. The degree in the shift of the γ-band is almost the same as that of the β-band for $[Co(dmgH)_2B_2]^+$ (Figs. 2 and 4). This result is consistent with the above statement that the γ-band of the Fe(II) complexes, like the β-band of the Co(III) complexes, is due to the d_π(metal)$\rightarrow\pi^*$-(dmgH) charge-transfer transition.

Such an effect of the axial pyridine derivatives on the $d_\pi(Fe)\rightarrow\pi^*$(dmgH) charge-transfer band may, as has been discussed for the Co(III) complexes, reflect a contribution of the $d_\pi(Fe)$–π^*(Py) interaction to the bonding between the iron ion and the pyridine ring. That is, with an increase in the π-acceptor property of the pyridine derivatives, the $d_\pi(Fe)$–π^*(Py) bonding becomes stronger and the d_π-orbitals are further stabilized. Therefore, the $d_\pi(Fe)$–π^*(dmgH) bonding becomes weaker. The fact that the bands with lower intensities in the 610—740 mμ region, which may be attributed to $d\rightarrow d$ transitions, are shifted in the same way as the γ-band (Fig. 4) seems to support the above consideration.

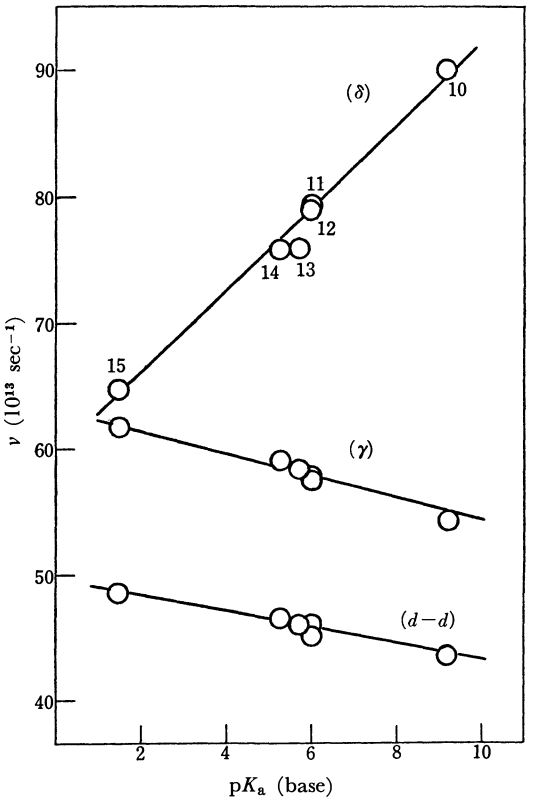

Fig. 4. Plots of the ν_{max} of $[Fe(dmgH)_2B_2]$ against the pK_a values of the conjugate acids of free bases.
(γ): γ-band, (δ): δ-band, and (d—d): $d\rightarrow d$ band.

Comparison of the Cobalt(III) and Iron(II) Complexes. The d_π(metal)$\rightarrow\pi^*$(dmgH) charge-transfer bands in the Co(III) complexes(β-band) and in the Fe(II) complexes(γ-band) are almost equally shifted to longer wavelengths as the basicity of the pyridine derivatives increases. The energy of the charge-transfer band for the Co(III) complexes is about twice that for the Fe(II) complexes (Figs. 2 and 4). One reason for this may be that, in these complexes, the ionization potential of the Fe(II) ion is lower than that of the Co(III) ion, as is shown in Fig. 5.[21] A lower ioni-

zation potential of the Fe(II) ion may also explain the different direction of the charge-transfer band between the axial ligands and the central metal ion for the Co(III) and Fe(II) complexes: from the pyridine derivatives to the cobalt ion, and from the iron ion to the pyridine derivatives, respectively.

The above facts suggest that the π-bonds between the central metal ion and the ligands are stronger in the Fe(II) complexes than in the Co(III) complexes and that the σ-bonds are stronger in the latter than in the former.

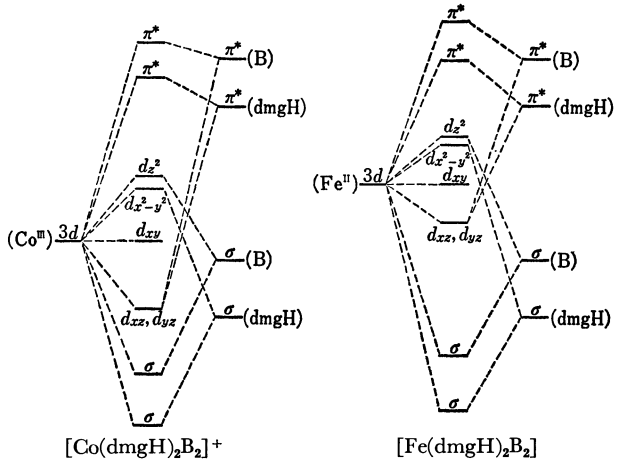

Fig. 5. Schematic orbital diagrams for $[Co(dmgH)_2B_2]^+$ and $[Fe(dmgH)_2B_2]$. By using the approximation of C_{4v} symmetry for the planar metal chelate of the complexes the axes were determined as follows; the nitrogen atoms of the dimethylglyoximate ligands lie on the x and y axes, and the cobalt ion lies on the intersection. The z axis is perpendicular to the xy plane.

IR Spectra. As is shown in Table 4, the IR spectra of the Co(III) and Fe(II) complexes show characteristic bands in the 1700—1800, 1510—1590, and 1060—1240 cm^{-1} regions; these are assigned to the O–H–O, C=N, and N–O stretching frequencies respectively.[15,22] The band observed at about 515 cm^{-1} might be attributed to the metal-N(oxime) stretching frequency on the basis of the assignment for $[Ni(dmgH)_2]$.[23] The C=N stretching frequencies of the complexes are shifted to much lower frequencies than for the free dimethylglyoxime($\nu_{C=N}=1750\ cm^{-1}$)[23] because of the existence of a d_π(metal)–π^*(dmgH) bonding.[15] The C=N stretching frequencies are dependent on the axial pyridine derivatives.

In the Co(III) complexes, it is obvious from Tables 2 and 4 that the C=N stretching frequencies are shifted to longer wavelengths as the β-band(d_π(Co)$\rightarrow\pi^*$-(dmgH)) is shifted to a longer wavelength. These results seem to suggest that, as the d_π(Co)–π^*(Py) interaction becomes stronger, the d_π(Co)–π^*(dmgH) bonding is more weakened and the C=N double bonding character is increased. The C=N stretching frequencies are lower in the Fe(II) complexes than in the Co(III) complexes, indicating that the d_π(metal)–π^*(dmgH) bonding is stronger in the former. The stretching frequency of the Co–N(oxime) is slightly lower than that of the Fe–N(oxime). This may be due to the facts that the π-bond is stronger in the Fe(II) complexes and that the σ-bond is stronger in the Co(III) complexes, as has been suggested before.

Kinetics and Mechanism of the Ligand Substitution Reaction of the Mercury(II)-4-(2-pyridylazo)resorcinol Complex with 1,2-Cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid

Shigenobu FUNAHASHI, Masaaki TABATA, and Motoharu TANAKA

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received December 7, 1970)

Kinetics and mechanism of the ligand substitution reaction of the mercury(II)-PAR complex with CyDTA were studied at 25°C in the presence of halogenide ion at an ionic strength of 0.1. The rate law can be written as

$$-\frac{d[Hg(par)_2^{2-}]}{dt} = (k_1'[H^+] + k_2' + k_{3,X}'[H^+][X^-])\frac{[Hg(par)_2^{2-}]}{[Hpar^-]}[Hcydta^{3-}]$$

where X^- refers to a halogenide ion (chloride, bromide, iodide). The rate constants k_1', k_2', and $k_{3,X}'$ were determined as: $k_1' = (2.4\pm0.1)\times10^7$ M^{-1} sec^{-1}, $k_2' = (1.9\pm0.1)\times10^{-2}$ sec^{-1}, $k_{3,Cl}' = (4.5\pm0.2)\times10^9$ M^{-2} sec^{-1}, $k_{3,Br}' = (3.2\pm0.1)\times10^{11}$ M^{-2} sec^{-1}, $k_{3,I}' = (5.6\pm0.2)\times10^{14}$ M^{-2} sec^{-1}. The rate constants for the paths involving mixed hydroxo and halogeno complexes (k_2' and $k_{3,X}'$) are quantitatively accounted for in terms of electron donation of ligands OH^- and X^-.

The ligand substitution reactions of metal complexes with multidentate ligands have been extensively studied by many authors.[1-9] Some of these studies have shown that ligands coordinated to a central metal ion affect the rate of substitution. In the reaction of monoacidopentaaquonickel(II) complex with 4-(2-pyridylazo)resorcinol (PAR) it has been shown that the ligand coordinated to nickel(II) labilizes coordinated water molecules.[7] Hunt *et al.*[8] reported that the rate of water exchange of some nickel(II) complexes became faster with increasing extent of substitution. In the ligand substitution of the Ni(II)-EDDA complex and the Ni(II)-NTA complex with PAR,[9] it has been revealed that EDDA and NTA coordinated to nickel(II) labilize water molecules attached to nickel(II).

In the present study, the kinetics and mechanism of the ligand substitution reaction of the mercury(II)-PAR complex with CyDTA (1,2-cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid) were studied in the presence of halogenide ion. The reaction system is

$$Hg(II)\text{-}PAR + CyDTA \rightleftarrows Hg(II)\text{-}CyDTA + PAR \quad (1)$$

Primary purpose of this study is to elucidate the effect of monodentate ligands on the reaction.

Experimental

Reagents. *Mercury(II) Perchlorate*: Commercial G. R. mercury(II) oxide was dissolved in perchloric acid. Twice recrystallized sodium bicarbonate was added to the solution to obtain mercury carbonate. The mercury(II) perchlorate solution was prepared by dissolving mercury carbonate in a perchloric acid solution. The concentration of the mercury(II) solution was determined by a standard EDTA solution using xylenol orange as an indicator.

CyDTA: The acid form of CyDTA obtained from Dojindo Co., Ltd., was dissolved in a sodium hydroxide solution. CyDTA was then precipitated by addition of perchloric acid. The purified CyDTA was dissolved in 2 eq. of sodium hydroxide. The CyDTA solution was standardized complexometrically by a zinc(II) standard solution using Erio T as an indicator.

Sodium Chloride: Sodium chloride was obtained by addition of reagent grade hydrochloric acid to a saturated sodium chloride solution. Sodium chloride obtained was heated by an infrared lamp in order to expel excess hydrochloric acid.

Sodium Bromide: G. R. sodium bromide was recrystallized three times from distilled water. The bromide solution was standardized by a standard silver nitrate solution using eosine as an indicator.

Sodium Iodide: G. R. sodium iodide was recrystallized twice from distilled water. The precipitated sodium iodide was washed with ether and benzene, and then dried *in vacuo* at room temperature. The sodium iodide solution was standardized in the same way as the bromide solution.

Methods of preparation of all other reagents (sodium perchlorate, sodium hydroxide, PAR, borax and boric acid) have been described previously.[4]

Apparatus: The following instruments were used: Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer, Hitachi Model QPD-53 recorder, Hirama Type 6 spectrophotometer, X-Y recorder Type UR-631 (Matsushita Communication Industrial Co., Yokohama), Radiometer PHM-4d (Copenhagen) with a Type G 202 B glass electrode and K 401 calomel electrode, Sharp Model TEB-10 thermoelectric circulating bath and a Coolnics circulator Type CTE-IB (Komatsu Solidate Co., Komatsu).

Procedure of Measurement of the Substitution Reaction Rate. Ionic strength was kept constant at 0.1 M with sodium perchlorate. A buffer solution of borate-boric acid was used. The mercury(II)-PAR solution containing PAR in excess was taken in a silica beaker with a light path of 5.3-cm or a quartz cell with a light path of 2.0-cm placed in the cell com-

partment thermostated at 25±0.2°C. The reaction was started by mixing the mercury(II)-PAR complex solution and the CyDTA solution. The reaction was followed automatically, the transmittance of the reaction system at 500 nm being recorded as a function of time. Molar absorption coefficients of $Hg(par)_2^{2-}$ and $Hpar^-$ at 500 nm are $\varepsilon_{Hg(par)_2}=6.50\times10^4$ and $\varepsilon_{Hpar}=1.31\times10^3$, respectively. All pH values were measured with a Radiometer PHM-4d which was carefully calibrated with a standard buffer solution (sodium borate 0.01 M) prepared as described by Bates.[10] All experiments were carried out at room temperature of 25±1°C.

Results

Substitution of the Mercury(II)-PAR Complex with CyDTA. The reaction of the mercury(II)-PAR complex with CyDTA was studied in the presence of a large excess of PAR over a pH range 8.5—9.1. Under the present experimental conditions the dominant species of CyDTA and PAR are the monoprotonated species $Hcydta^{3-}$ and $Hpar^-$, respectively, as apparent from stability constants: $K^H_{Hcydta}=10^{11.78}$, $K^H_{H2cydta}=10^{6.20}$, $K^H_{Hpar}=10^{12.31}$, $K^H_{H2par}=10^{5.48}$. The mercury(II)-PAR complex forms the 1 : 2 complex $Hg(par)_2^{2-}$. The mercury(II)-CyDTA complex is the 1 : 1 complex $Hg(cydta)^{2-}$ ($K_{Hg(cydta)}=10^{24.4}$ [11], $K^{OH}_{Hg(cydta)OH}=10^{3.2}$ [12]). Equilibrium (1) is much favored to the right so that the substitution reaction of the mercury(II)-PAR complex with CyDTA goes substantially to completion and the reverse reaction can be neglected. Thus the reaction system studied is described as

$$Hg(par)_2^{2-} + Hcydta^{3-} + H_2O \rightarrow Hg(cydta)^{2-} + 2\,Hpar^- + OH^-$$

From the measurements of the initial rate, the rate of decrease of the mercury(II)-PAR complex is found to be first-order with respect to mercury(II)-PAR and to CyDTA. Thus the rate equation can be expressed as

$$-\frac{d[Hg(par)_2^{2-}]}{dt} = k_{0(H,PAR)}[Hg(par)_2^{2-}][Hcydta^{3-}] \quad (2)$$

This equation is confirmed also from the linearity of the second order plots obtained by it. We have the following relationships

$$A_0 = \varepsilon_{Hg(par)_2}C_{Hg} + \varepsilon_{Hpar}(C_{PAR}-2C_{Hg}) \quad (3)$$

$$A_t = \varepsilon_{Hg(par)_2}[Hg(par)_2^{2-}] + \varepsilon_{Hpar}(C_{PAR}-2C_{Hg}+2[Hg(cydta)^{2-}]) \quad (4)$$

$$A_\infty = \varepsilon_{Hpar}C_{PAR} \quad (5)$$

where A_0, A_t, and A_∞ are the absorbances of the reaction system at reaction time 0, t and ∞, respectively, and C_{Hg} and C_{PAR} denote the total concentration of mercury(II) and of PAR, respectively. Substitution of Eqs. (3), (4) and (5) into the integrated form of Eq. (2) leads to

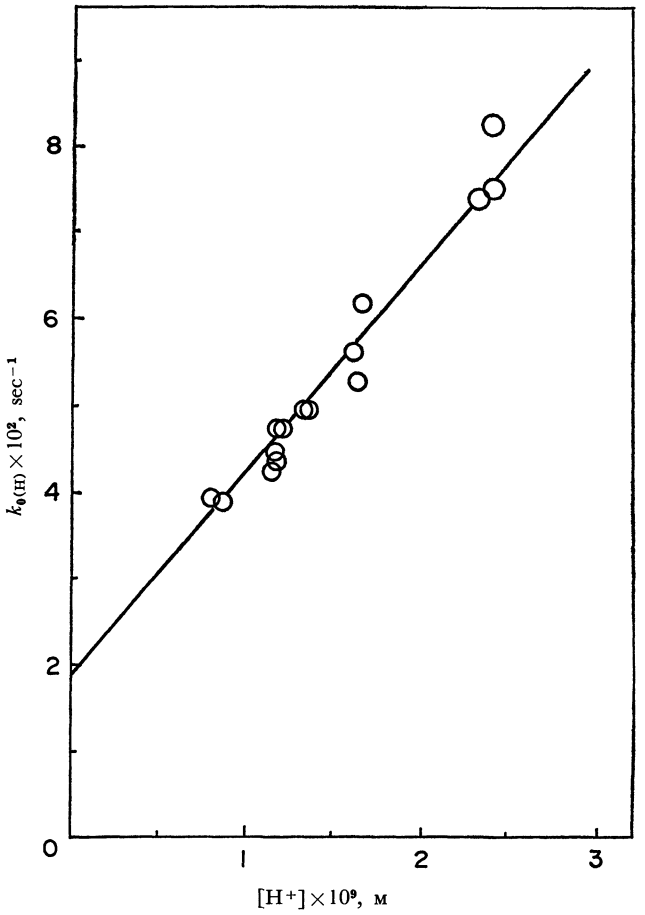

Fig. 1. Plot of $k_{0(H)}$ *vs.* $[H^+]$.
$C_{CyDTA}=(0.771-3.85)\times10^{-5}$ M, $C_{Hg}=(0.984-2.95)\times10^{-6}$ M, $C_{PAR}=(1.50-4.00)\times10^{-4}$ M, $\mu=0.1$ ($NaClO_4$), 25°C.

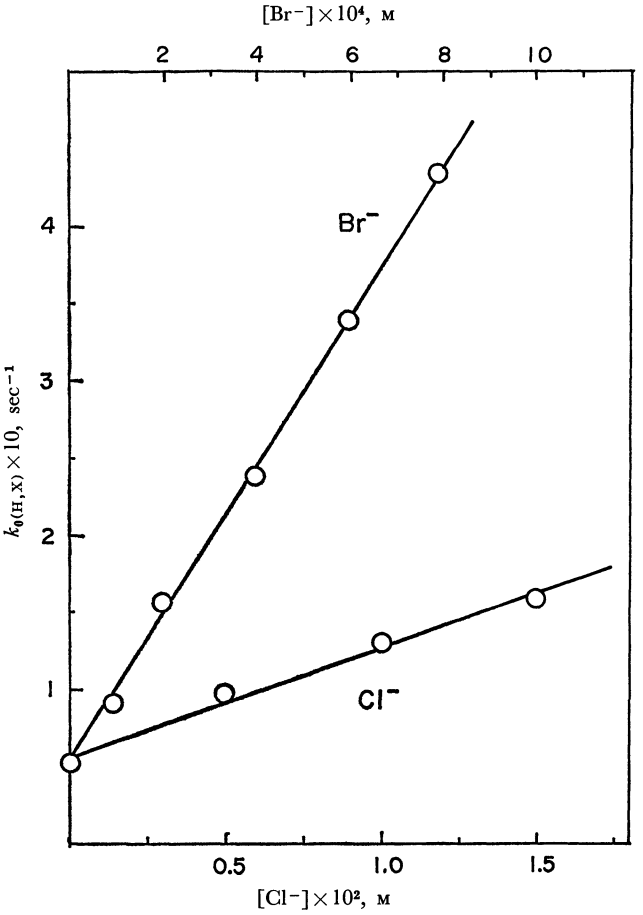

Fig. 2. Effect of the halogenide ion concentration on conditional rate constants.
$C_{Hg}=1.97\times10^{-6}$ M, $C_{CyDTA}=1.93\times10^{-5}$ M, $C_{PAR}=2.00\times10^{-4}$ M, pH=8.83±0.01, $\mu=0.1$ ($NaClO_4$), 25°C.

$$\frac{2.303}{C_{CyDTA}-C_{Hg}}\log\left\{\frac{A_0-A_\infty}{A_t-A_\infty}-\frac{C_{Hg}(A_0-A_t)}{C_{CyDTA}(A_t-A_\infty)}\right\}=k_{0(H,PAR)}t \quad (6)$$

Plots of the left-hand side of this equation *vs.* t give a straight line, of which the slope corresponds to the conditional rate constant $k_{0(H,PAR)}$. Conditional rate constants are summarized in Table 1. The data indicate the linear relationship between $k_{0(H,PAR)}$ and the reciprocal concentration of PAR with the zero intercept. Values of $k_{0(H,PAR)}[Hpar^-]$ (*i.e.* $k_{0(H)}$) are plotted against the concentration of hydrogen ion in Fig. 1, from which we can derive the following relationship:

$$k_{0(H,PAR)}[Hpar^-]=k_1'[H^+]+k_2' \quad (7)$$

The rate equation of the substitution of the mercury-(II)-PAR complex with CyDTA is

$$-\frac{d[Hg(par)_2^{2-}]}{dt}=(k_1'[H^+]+k_2')\frac{[Hg(par)_2^{2-}][Hcydta^{3-}]}{[Hpar^-]} \quad (8)$$

Substitution of the Mercury(II)-PAR Complex with CyDTA in the Presence of Halogenide Ions. A halogenide ion accelerates the substitution of the mercury(II)-PAR complex with CyDTA. Conditional rate constants $k_{0(H,PAR,X)}$ under various conditions are summarized in Table 2. The plot of $k_{0(H,X)}$ *vs.* $[X^-]$ gives a straight line with an intercept as shown in Fig. 2. The value of the intercept, corresponding to the reaction path independent of halogenide ions, is the same as that found in the reaction in the absence of halogenide at the same pH (*i.e.* $[H^+]=(1.5\pm0.1)\times10^{-9}$, see Fig. 1.). Hence, we have the following relationship:

$$k_{0(H,X)}=k_1'[H^+]+k_2'+k_{3(H)}'[X^-] \quad (9)$$

The values of conditional rate constants in the presence of iodide, bromide, and chloride are plotted against hydrogen ion concentrations in Fig. 3. It is evident that $k_{0(H,X)}$ is linearly related to the hydrogen ion concentration. Thus Eq. (9) can be written as

$$k_{0(H,X)}=k_1'[H^+]+k_2'+k_{3,X}'[H^+][X^-] \quad (10)$$

From these results we obtain the following rate equation for the ligand substitution reaction of the mercury(II)-PAR complex with CyDTA in the presence of halogenide ion:

$$-\frac{d[Hg(par)_2^{2-}]}{dt}=(k_1'[H^+]+k_2'+k_{3,X}'[H^+][X^-])\times\frac{[Hg(par)_2^{2-}][Hcydta^{3-}]}{[Hpar^-]} \quad (11)$$

The rate constants k_1', k_2', $k_{3,Cl}'$, $k_{3,Br}'$, and $k_{3,I}'$ at 25°C and $\mu=0.1$ are tabulated in Table 3.

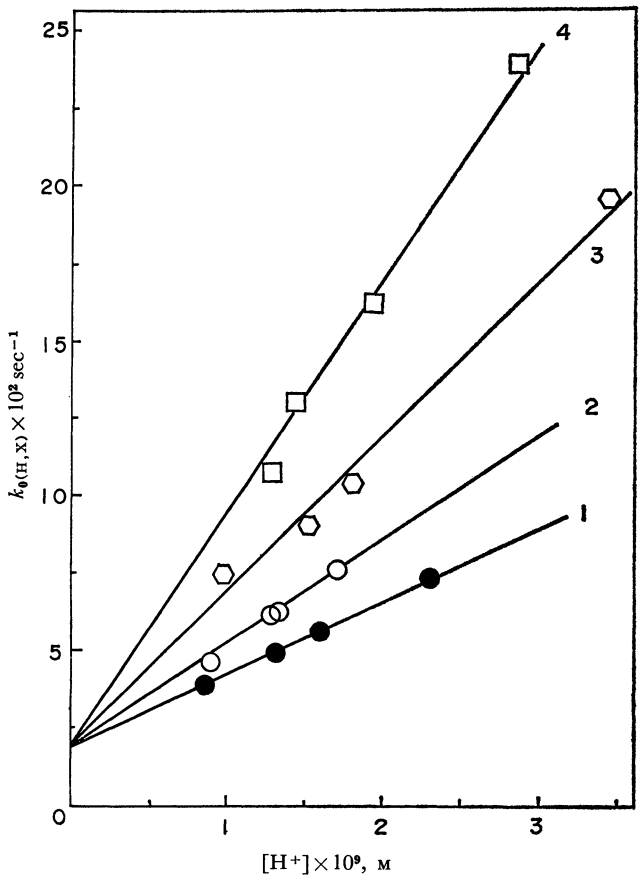

Fig. 3. Effect of the hydrogen ion concentration on conditional rate constants in the presence of halogenide ions. 1: $[X^-]=0$ M, 2: 2.16×10^{-8} M, 3: $[Br^-]=0.94\times10^{-4}$ M, 4: $[Cl^-]=1.00\times10^{-2}$ M, $C_{Hg}=1.97\times10^{-6}$ M, $C_{CyDTA}=1.93\times10^{-5}$ M, $C_{PAR}=2.00\times10^{-4}$ M, $\mu=0.1$ ($NaClO_4$), 25°C.

$k_{3,I}'$	$(5.6\pm0.2)\times10^{14}$ M^{-2} sec^{-1}

Discussion

The rate of the reaction of the mercury(II)-PAR complex with CyDTA is suppressed by the increased PAR concentration, and is first-order with respect to the hydrogen ion concentration. The predominant species of PAR is the mono-protonated form $Hpar^-$. CyDTA can not react directly with the 1 : 2 mercury-(II)-PAR complex $Hg(par)_2^{2-}$ but with the 1 : 1 mercury(II)-PAR complex Hg(par) formed by the dissociation of a PAR. Thus it seems reasonable to consider Equilibrium (12) to precede the rate-determining step (13).

$$Hg(par)_2^{2-} + H^+ \rightleftarrows Hg(par) + Hpar^- \quad (12)$$

$$Hg(par) + Hcydta^{3-} \rightarrow Hg(cydta)^{2-} + Hpar^- \quad (13)$$

Such a predissociation equilibrium has been observed also in the ligand substitution reactions of the zinc(II)-PAR complex[4] and the copper(II)-PAR complex[6] with (ethyleneglycol)bis(2-aminoethylether)-*N*,*N*,-*N*'-tetraacetic acid. When the equilibrium constant of Reaction (12) is taken into consideration, the following equation can be derived from Eq. (11).

$$-\frac{d[Hg(par)_2^{2-}]}{dt} = \left(\frac{k_1' K^{par}_{Hg(par)_2}}{K^H_{Hpar}} + \frac{k_2' K^{par}_{Hg(par)_2}}{K^H_{Hpar}}[H^+]^{-1} + \frac{k_{3,X}' K^{par}_{Hg(par)_2}}{K^H_{Hpar}}[X^-]\right)[Hg(par)][Hcydta^{3-}] \quad (14)$$

where $K^H_{Hpar}=[Hpar^-]/[par^{2-}][H^+]$ and $K^{par}_{Hg(par)_2}=[Hg(par)_2^{2-}]/[Hg(par)][par^{2-}]$.

In the presence of halogenide ions the following equilibrium should be operative in the present ligand substitution.

$$Hg(par) + X^- \rightleftarrows Hg(par)X^- \quad (15)$$

PAR has three coordinate sites (N in pyridine, N in azo and O in resorcinol). The 1 : 1 mercury(II)-PAR complex will accept another ligand. The third term on the right-hand side of Eq. (14) corresponds to the reaction path through the mixed halogeno complex. The second term on the right-hand side of Eq. (14) involves the reciprocal concentration of hydrogen ion. This suggests a reaction path through a mixed hydroxo complex similar to the mixed halogeno complex. Protolytic reaction of mercury(II) ion is sufficiently fast, and the following equilibrium precedes the rate-determining step.

$$Hg(par) \rightleftarrows Hg(par)OH^- + H^+ \quad (16)$$

With constants for Equilibria (15) and (16), Eq. (14) is rewritten as

$$-\frac{d[Hg(par)_2^{2-}]}{dt} = \frac{k_1' K^{par}_{Hg(par)_2}}{K^H_{Hpar}}[Hg(par)] + \frac{k_2'}{K_W}\frac{K^{par}_{Hg(par)_2}}{K^{OH}_{Hg(par)OH}K^H_{Hpar}}[Hg(par)OH^-] + \frac{k_{3,X}' K^{par}_{Hg(par)_2}}{K^X_{Hg(par)X}K^H_{Hpar}}[Hg(par)X^-])[Hcydta^{3-}] = (k_1[Hg(par)] + k^{OH}[Hg(par)OH^-] + k^X[Hg(par)X^-])[Hcydta^{3-}] \quad (17)$$

Some related constants are defined as follows:

$$K_W = [H^+][OH^-] \quad (18)$$

$$K^{OH}_{Hg(par)OH} = \frac{[Hg(par)OH^-]}{[Hg(par)][OH^-]} \quad (19)$$

$$K^X_{Hg(par)X} = \frac{[Hg(par)X^-]}{[Hg(par)][X^-]} \quad (20)$$

$$k_1 = k_1'\left(\frac{K^{par}_{Hg(par)_2}}{K^H_{Hpar}}\right) \quad (21)$$

$$k^{OH} = \frac{k_2'}{K_W}\frac{1}{K^{OH}_{Hg(par)OH}}\left(\frac{K^{par}_{Hg(par)_2}}{K^H_{Hpar}}\right) \quad (22)$$

$$k^X = k_{3,X}'\frac{1}{K^X_{Hg(par)X}}\left(\frac{K^{par}_{Hg(par)_2}}{K^H_{Hpar}}\right) \quad (23)$$

The proposed reaction mechanism of the mercury-(II)-PAR complex with CyDTA in the presence of

halogenide ions is as follows:

$$Hg(par)_2^{2-} + H^+ \rightleftarrows Hg(par) + Hpar^-$$

$$Hg(par)OH^- + Hcydta^{3-} \xrightarrow{k^{OH}} Hg(cydta)^{2-} + Hpar^- + OH^-$$

$$Hg(par) + Hcydta^{3-} \xrightarrow{k_1} Hg(cydta)^{2-} + Hpar^-$$

$$Hg(par)X^- + Hcydta^{3-} \xrightarrow{k^X} Hg(cydta)^{2-} + Hpar^- + X^-$$

The equilibria between $Hg(par)_2^{2-}$ and Hg(par), and between Hg(par) and $Hg(par)X^-$ precede the rate-determining steps. CyDTA reacts with Hg(par), $Hg(par)OH^-$, and $Hg(par)X^-$ formed through the equilibrium processes.

It is necessary to determine $K^{par}_{Hg(par)_2}$, $K^{OH}_{Hg(par)OH}$ and $K^X_{Hg(par)X}$ in order to estimate the values of k_1, k^{OH}, and k^X. Unfortunately, these stability constants could not be successfully determined because of hydrolysis and precipitation of complexes. As apparent from Fig. 4, the plot of $\log(k_{3,X}'/k_{3,H_2O}')$ *vs.* E_n values of ligands (halogenide and hydroxide ions) gives a good straight line with a slope of 6.1, where k_{3,H_2O}' corresponds to $k_1'/55.5$ and E_n refers to the electron donor constant of a ligand.[13] Since $k_{3,X}'/k_{3,H_2O}' = (55.5/k_1) \times k^X K^X_{Hg(par)X}$ from Eqs. (21)—(23), $\log k^X K^X_{Hg(par)X}$ has a linear relationship with E_n's of ligands. Therefore, either $\log k^X$ or $\log K^X_{Hg(par)X}$ or both are proportional to E_n of X. In fact, the following results have been reported in some systems. In the case of the reaction between $Ni(H_2O)A^+$ and PAR there is an excellent correlation between E_n values of ligands and formation rate constants (where A denotes F^-, N_3^-, CH_3COO^-, OH^-, and H_2O[7]). For the mixed complex of Hg(cydta)X^{3-}, log stability constant $\log K^X_{Hg(cydta)X}$ is related to E_n of X by a straight line with a slope of 4.[12] The plot of $\log K^X_{HgX_4}$ *vs.* E_n gives a straight line with a slope of 1.5,[14] $K^X_{HgX_4}$ being defined as follows: $K^X_{HgX_4} = [HgX_4^{2-}]/[HgX_3^-][X^-]$. For the mixed complex of the type $Hg(CN)_3X^{2-}$, the slope of the plot of $\log K^X_{Hg(CN)_3X}$ *vs.* E_n of X^- has been found to be 2.[15] These facts being taken into account, the slope of the plot of $\log K^X_{Hg(par)X}$ *vs.* E_n is expected to be smaller than 6.1. This suggests that the rate constant (k^X) also depends on the E_n value of a ligand (X^-) coordinated to the mercury(II)-PAR complex; a ligand having larger E_n value tends to weaken the bond of mercury(II) with PAR. When a ligand coordinated to a central metal donates to a greater extent, the bond of the central metal with the leaving ligand will be weakened and more easily broken.

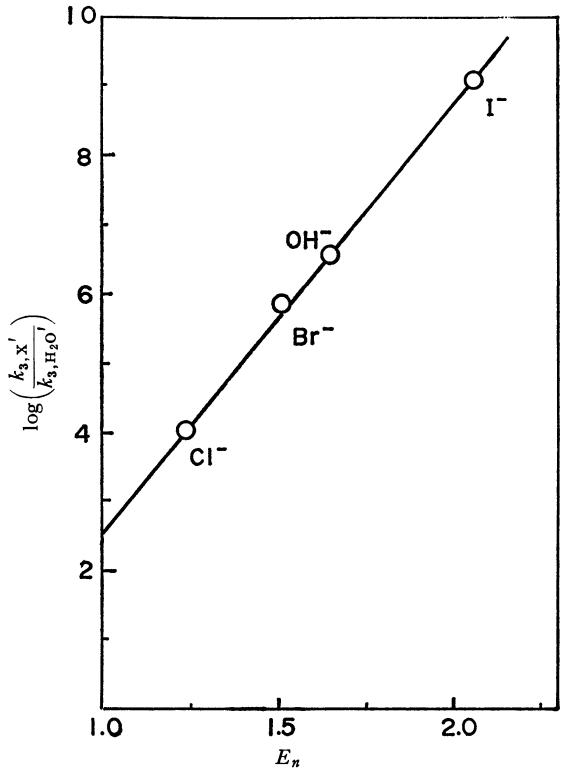

Fig. 4. Plot of $\log(k_{3,X}'/k_{3,H_2O}')$ *vs.* E_n.

The Extraction of the Cesium Ion with Some Nitrophenols into Nitrobenzene. I. Distribution Studies

Mutsuo KOYAMA, Osamu TOCHIYAMA, and Taitiro FUJINAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 19, 1970)

The liquid-liquid extraction of alkali-metal nitrophenolates was studied by using nitrobenzene as the extracting solvent. Nitrophenol derivatives such as *o*-, *m*-, *p*-nitrophenols, α-dinitrophenol, and picric acid were chosen here in order to examine the effect of their steric characters and pK values on the distribution equilibrid. It was concluded that: 1) all the cesium nitrophenolates extracted into nitrobenzene were mainly in the dissociated form; 2) the extraction of *m*- and *p*-nitrophenolates proceeds by the stepwise adduct formation with free phenols, whereas little tendency of adduct formation was observed with the picrate system; 3) α-dinitrophenolate has a character between the other two; 4) the distribution of *o*-nitrophenolate is negligible. A detailed discussion is given of the phenomena in terms of ionic equilibria in both the aqueous and organic phases.

The liquid-liquid extraction of alkali metal ions has received attention not only from the viewpoint of practical analysis, but also from that of a theoretical interest in solute-solvent interaction.

In a previous paper, the present authors reported on the extraction of cesium into nitrobenzene with chromium complexes.[1] Similar extractions have been investigated by many authors using various reagents, such as tetraphenylborate,[2,3] dipicrylamine[4,5] and polyiodide.[6] In all these cases, the subject species are dissociated completely into ions in both the organic and aqueous phases.

On the other hand, Horner *et al.*[7] have shown the possibility of extracting cesium with various phenols as the reagents. Later, many alkyl derivatives of phenol were examined by Konečný and Sistkóva[8] and the extraction equilibria were discussed by Zingaro *et al.*[9] In the extraction of alkali phenolate, the extracted species are tightly-bounded ion pairs sometimes adducted with reagent acids.

Although the extraction mechanisms and the equilibria are pretty well understood in the case of chelate-extraction systems, the interpretation of the ion-pair extraction has not been completed. The distribution coefficient in the ion-pair system depends not only upon the bulk character of the solvents, such as dielectric constants and/or the solubility parameters, but also upon the particular interactions between solute and solvent, or sometimes between solutes.

The present series of studies were undertaken in order to investigate the influence of the characteristics of reagent anions on the extraction of alkali-metal ions and to estimate the relative degree of solute-solvent interactions.

In these studies, nitrobenzene was chosen as the organic solvent and cesium ions were distributed into both phases, using nitrophenol derivatives as the reagents. The nitrophenol derivatives examined were *ortho*-, *meta*-, *para*-nitrophenol (*o*-NP, *m*-NP, *p*-NP), 2,4-dinitrophenol (α-DNP), and 2,4,6-trinitrophenol (picric acid, PA); they were chosen because they have different acid dissociation constants in water and different steric effects, and are expected to have characters intermediate between those of alkyl phenols and dipicrylamine, tetraphenylborate, and others. In nitrobenzene, which is a strongly ionizing solvent, only dissociated forms are expected, and a difference in anion solvations (homoconjugation) can be observed for each nitrophenol.

The present paper is confined to a study of the ionic equilibria in the extraction processes. In the next paper,[10] the role of anions and the solute-solvent interaction will be discussed with the results obtained through the distribution and conductivity studies.

Experimental

Reagents. All the reagents used were of a reagent-grade purity. The nitrobenzene was vacuum-distilled before use. Carrier-free ^{137}Cs was supplied by the Oak Ridge National Laboratory.

Apparatus. The γ-ray measurements were performed with a single-channel pulse-height analyser (Osaka Denpa-Model LA-3T) equipped with a 1.5″ x 1.5″ NaI(Tl) well-type crystal. The absorbance measurements were carried out with an automatic recording spectrophotometer (Shimadzu-Model SV-5 A) by the use of quartz cells with a 1-cm light path. A pH meter (Horiba Model P) was used for all the pH measurements.

Procedure. In the distribution studies of nitrophenols, the pH of the aqueous phase was controlled by the addition of either a hydrochloric acid or a sodium hydroxide solution. Each nitrophenol solution of a 0.1 M concentration was prepared by dissolving the phenol in nitrobenzene. Four milliliters of the aqueous solution and the same volume of

the nitrobenzene solution were brought into contact and shaken in a glass tube for 30—60 min. at 20±1°C. The distribution ratios of nitrophenols were obtained by measuring their concentrations in the aqueous phase according to the following procedure. An appropriate aliquot of the aqueous phase was taken in a volumetric flask and diluted with a 0.1 M sodium hydroxide solution. The absorbance (*p*-NP; 402 nm, *m*-NP; 392 nm, *o*-NP; 420 nm, α-DNP; 362 nm and PA; 358 nm) was measured in order to determine the concentration of the nitrophenols. The pH of the aqueous phase after the equilibration was also measured and used for the calculation of the distribution ratios. The glass electrode pH meter was found to show pH 0.00, 1.00, 2.00, and 3.00 within an error of ±0.1 in solutions of perchloric acid of 1.0, 0.10, 1.0×10^{-2}, and 1.0×10^{-3} M respectively.

Similar procedures were employed for the distribution studies of the cesium ion. The pH of the aqueous phase, however, was adjusted with lithium hydroxide or sodium hydroxide, and the ionic strength was controlled with lithium chloride or sodium chloride.

A cesium chloride solution of an adequate concentration was added to the aqueous phase, and the distribution ratio of the cesium ion was obtained by measuring the γ-ray activities of ^{137}Cs in both the aqueous and organic phases.

Theoretical

(1) Distribution of Nitrophenols. In the extraction of nitrophenol ROH, the following equilibria can be considered in both phases:

$$(RO^-)_a + (H^+)_a \rightleftarrows (ROH)_a \quad (1)$$

$$(ROH)_a \rightleftarrows (ROH)_o \quad (2)$$

$$(RO^-)_o + (H^+)_o \rightleftarrows (ROH)_o \quad (3)$$

where the a and o subscripts refer to the aqueous and organic phases respectively. The concentration constants are expressed by the following equations:

$$K_{a,ROH} = [RO^-]_a[H^+]_a/[ROH]_a \quad (4)$$

$$K_{D,ROH} = [ROH]_o/[ROH]_a \quad (5)$$

$$K_{0,ROH} = [RO^-]_o[H^+]_o/[ROH]_o \quad (6)$$

$K_{a,ROH}$ and $K_{0,ROH}$ are the dissociation constants of ROH in the aqueous and nitrobenzene phases respectively, and $K_{D,ROH}$, the distribution coefficient of the neutral ROH.

At the distribution equilibrium between the two phases, the distribution ratio of ROH, D_{ROH}, is written as:

$$D_{ROH} = \frac{[ROH]_o+[RO^-]_o}{[ROH]_a+[RO^-]_a} \quad (7)$$

Among these chemical species, $[RO^-]_0$ can be neglected, because the dissociation of ROH in nitrobenzene is very small. Therefore,

$$D_{ROH} = \frac{[ROH]_o}{[ROH]_a+[RO^-]_a} \quad (7')$$

By combining Eqs. (2), (4), (5), and (7'), D_{ROH} is expressed as Eq. (7''):

$$D_{ROH} = \frac{K_{D,ROH}}{1+K_{a,ROH}/[H^+]_a} \quad (7'')$$

In this equation, D_{ROH} is a function of pH, that is (i) in the lower pH region:

$$D_{ROH} = K_{D,ROH} \quad (7''\text{-i})$$

and (ii) in the higher pH region:

$$D_{ROH} = K_{D,ROH}[H^+]_a/K_{a,ROH} \quad (7''\text{-ii})$$

If the curve of $\log D_{ROH}$ *vs.* pH consists of two parts which are represented by Eqs. (7''-i) and (7''-ii), $K_{D,ROH}$ and $K_{a,ROH}$ can be calculated from these equations.

The following relationship is obtained between the total concentration of nitrophenol and the concentration of undissociated nitrophenol in nitrobenzene:

$$[ROH]_{total} = [ROH]_o + [ROH]_a + [RO^-]_a$$

$$b = [ROH]_o\left(1+\frac{1}{K_{D,ROH}}+\frac{K_{a,ROH}}{K_{D,ROH}[H^+]_a}\right) \quad (8)$$

(2) Distribution of the Cesium Ion. In the experiments on the distribution of the cesium ion, the following equilibria must be considered in both the aqueous and organic phases:

$$(Cs^+)_a + (OR^-)_a \rightleftarrows (CsOR)_a \quad (9)$$

$$(CsOR)_a \rightleftarrows (CsOR)_o \quad (10)$$

$$(Cs^+)_0 + (OR^-)_o \rightleftarrows (CsOR)_o \quad (11)$$

$$(OR^-)_0 + n(ROH) \rightleftarrows (OR\cdot nROH^-)_o \quad (12)$$

$$K_{a,CsOR} = [Cs^+]_a[OR^-]_a/[CsOR]_a \quad (13)$$

$$K_{D,CsOR} = [CsOR]_o/[CsOR]_a \quad (14)$$

$$K_{0,CsOR} = [Cs^+]_o[OR^-]_o/[CsOR]_o \quad (15)$$

$$K_{Cs}^* = K_{0,CsOR}K_{D,CsOR}/K_{a,CsOR}$$
$$= [Cs^+]_o[OR^-]_o/[Cs^+]_a[OR^-]_a \quad (16)$$

$$K_n^f = [OR\cdot nROH^-]_o/[OR^-]_o[ROH]_o^n \quad (17)$$

Here, $K_{a,CsOR}$ and $K_{O,CsOR}$ represent the dissociation constants in each phase; $K_{D,CsOR}$, the distribution coefficient of the neutral CsOR; K_{Cs}^*, the distribution coefficient of fully-dissociated Cs^+ and OR^-, and K_n^f, the homoconjugation constant or the adduct formation constant in the organic phase.

When the concentration of cesium ions is sufficiently large as compared with those of other cations in the organic phase, the electrical neutrality in the phase can be written as:

$$[Cs^+]_o = [OR^-]_o + [OR\cdot ROH^-]_o + [OR\cdot 2ROH^-]_o + \cdots$$
$$= [OR^-]_o(1+\sum_n K_n^f[ROH]_o^n) \quad (18)$$

On the other hand, the distribution ratio of the cesium ion is:

$$D_{Cs} = \frac{[Cs^+]_o+[CsOR]_o}{[Cs^+]_a+[CsOR]_a} \quad (19)$$

When free cesium ions are considered to be the only chemical species of cesium in both the organic and aqueous phases, Eq. (19) can be written as:

$$D_{Cs} = [Cs^+]_o/[Cs^+]_a \quad (19')$$

By combining Eqs. (13)—(19'), D_{Cs} can be transformed into:

$$D_{Cs} = K_{Cs}^{*1/2}(1+\sum_n K_n^f[ROH]_o^n)^{1/2}\frac{[OR^-]_a^{1/2}}{[Cs^+]_a^{1/2}} \quad (20\text{-i})$$

$$= K_{Cs}^{*1/2}(1+\sum_n K_n^f[ROH]_o^n)^{1/2} \times \frac{K_{a,ROH}^{1/2}[ROH]_o^{1/2}}{K_{D,ROH}^{1/2}[Cs^+]_a^{1/2}[H^+]_a^{1/2}} \quad (20\text{-ii})$$

When most of the cesium ions are present in the form of ion pairs in both phases,

$$D_{Cs} = \frac{K_{D,CsOR}}{K_{a,CsOR}}[OR^-]_a \quad (21\text{-i})$$

$$= \frac{K_{D,CsOR}K_{a,ROH}[ROH]_o}{K_{a,CsOR}K_{D,ROH}[H^+]_a} \quad (21\text{-ii})$$

Eqs. (20) and (21) predict the difference in the dependence of D_{Cs} on $[H^+]_a$ and $[Cs^+]_a$.

Therefore, from the experimental data, whether the chemical form $(Cs^+)_o$ or $(CsOR)_o$ stands in the nitrobenzene phase can be confirmed.

When a considerable amount of NaOR or LiOR is extracted, the electrical neutrality expressed in Eq. (18) is no longer valid; the following relationship must be considered instead:

$$[M^+]_0 = [OR^-]_0 + [OR\cdot ROH^-]_0 + [OR\cdot 2ROH^-]_0 + \cdots \quad (18')$$

where M^+ denotes the competing cation, such as Li^+ or Na^+, and where

$$K_{a,MOR} = \frac{[M^+]_a[OR^-]_a}{[MOR]_a} \quad (22)$$

$$K_{D,MOR} = \frac{[MOR]_o}{[MOR]_a} \quad (23)$$

$$K_{o,MOR} = \frac{[M^+]_0[OR^-]_o}{[MOR]_o} \quad (24)$$

$$K_M^* = \frac{[M^+]_0[OR^-]_o}{[M^+]_a[OR^-]_a} \quad (25)$$

From these equations, we obtain:

$$D_{Cs} = [Cs^+]_o/[Cs^+]_a = K_{Cs}^{*1/2}\left(\frac{K_{Cs}^*}{K_M^*}\right)^{1/2}\frac{[OR^-]_a^{1/2}}{[M^+]_a^{1/2}} \times (1+\sum K_n^f[ROH]_o^n)^{1/2} \quad (26)$$

This equation shows that the D_{Cs} values are no longer the function of $[Cs^+]_a$, but the function of $[M^+]_a$, when $[Cs^+]_a \ll [M^+]_a$.

Results and Discussion

(1) Distribution of Nitrophenols. Figure 1 presents the relationship between the distribution ratios of each nitrophenol at the concentration of 0.1 M and the pH of the aqueous phase after the partition equilibrium has been attained. In these studies, the aqueous ionic strength was not fixed, because the ex-extraction of sodium nitrophenolates could be neglected.

In the figure, there are two parts, representing Eqs. (7″-i) and (7″-ii). From these curves, the $K_{a,ROH}$ and $K_{D,ROH}$ values can be obtained; these values are shown in Table 1. The $K_{a,ROH}$ values are in good agreement with those measured by other method.[11]

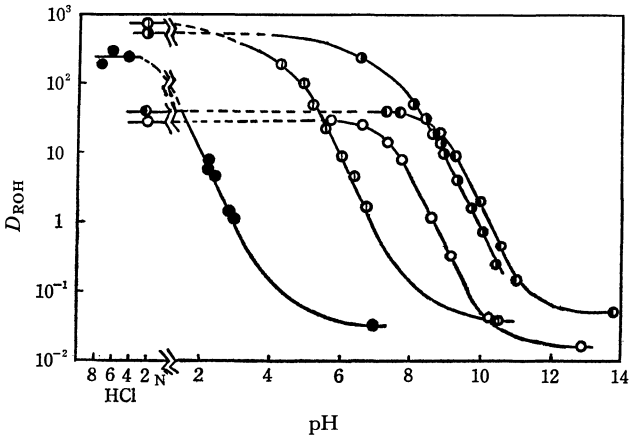

Fig. 1. Distribution of nitrophenols as the function of pH. $[ROH]_{total}=0.1$
○ *p*-NP ◐ *m*-NP ◑ *o*-NP ⓘ α-DNP ● PA

TABLE 1. DISTRIBUTION COEFFICIENTS AND DISSOCIATION CONSTANTS OBTAINED BY THE EXTRACTION METHOD

	$K_{D,ROH}$	$K_{a,ROH}$	$K_{a,ROH}$ other methods[11]
p-NP	28.4	6.1×10^{-8}	6.5×10^{-8}
m-NP	40.2	2.2×10^{-9}	5.2×10^{-9}
o-NP	599	1.1×10^{-7}	0.75×10^{-7}
α-DNP	746	0.89×10^{-4}	1.0×10^{-4}
PA	256	2.6×10^{-1}	3.8×10^{-1}

In the higher pH regions, the curves are not as linear as was expected from Eq. (7″-ii), because the extraction of NaOR can not be neglected in these regions.

From the experiment, the relationships between pH and $[ROH]_o$, which are represented by Eq. (8), were obtained and used in the calculation of the distribution of the cesium ion.

(2) Distribution of the Cesium Ion. (2-1) The Relationship between D_{Cs} and pH: In Fig. 2, the dependence of the distribution ratios of the cesium ion on the pH of the aqueous solution is presented. In this study, the total concentration of nitrophenol and the total concentration of the lithium ion were maintained at 0.4 M. However, the distribution of lithium ions in the organic phase was practically

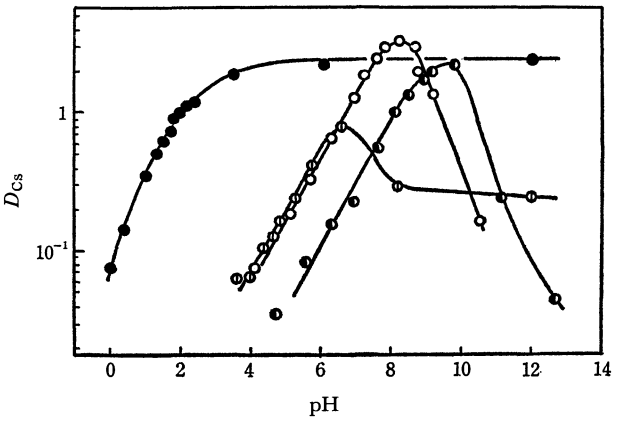

Fig. 2. Distribution of cesium ion as the function of pH. $[ROH]_{total}=0.4$, $[Li^+]_a=0.4$, $[Cs^+]_a=10^{-3}$.
○ *p*-NP ◐ *m*-NP ⓘ α-DNP ● PA

negligible, and the concentration of lithium ions in the aqueous phase was practically 0.4 M. The distribution ratios have been corrected for the constant aqueous cesium ion concentration (10^{-3} M) according to Eq. (27). This correction is based on Eq. (20), which is derived from the assumption that the chemical species in both organic and aqueous phases are fully dissociated:

$$D_{Cs}(\text{corrected}) = D_{Cs}(\text{raw})\left(\frac{10^{-3}}{[Cs^+]_a(\text{experimental})}\right)^{1/2} \quad (27)$$

Since, in the case of *o*-nitrophenol, the distribution ratios were found to be below 10^{-3} at all the pH values, no relationship is presented in the figures.

In Fig. 2, the slope of the ascending part of the curve is 1/2 in every case, and Eq. (20) applies well. In these parts, $[ROH]_o$ can be considered constant in Eq. (20-ii), because the third term in Eq. (8) can be neglected in the low pH regions, as is demonstrated in Fig. 1. In the case of picric acid, the slope deviates from 1/2 and approaches to 1 in the lower pH region. This deviation can be attributed to the increase of $[H^+]_o$ caused by the extraction of picric acid and/or of hydrochloric acid. If the hydrochloric acid is extracted and the electrical neutrality is expressed as $[H^+]_o=[Cl^-]_o$, the relation between D_{Cs} and $[H^+]_a$ can be represented by Eq. (27):

$$D_{Cs} = \frac{K_{Cs}^*}{K_H^*} K_{HCl}^{*1/2} \frac{[Cl^-]_a^{1/2}}{[H^+]_a^{1/2}} \quad (27)$$

where:

$$K_H^* = \frac{[H^+]_o[OR^-]_o}{[H^+]_a[OR^-]_a} \quad (25')$$

$$K_{HCl}^* = \frac{[H^+]_o[Cl^-]_o}{[H^+]_a[Cl^-]_a} \quad (28)$$

According to Eq. (27), the slope of the plot of log D_{Cs} *vs.* pH must remain 1/2, even in the lower pH region. If $[H^+]_o$ is mainly created by the dissociation of the picric acid extracted and if, therefore, the electrical neutrality is expressed as $[H^+]_o=[OR^-]_o$, Eq. (26'), which is derived from Eq. (26) by replacing $[M^+]$ by $[H^+]$, applies to the relation between D_{Cs} and $[H^+]_a$. This equation shows that the slope must be 1 in the lower pH region:

$$D_{Cs} = K_{Cs}^{*1/2}\left(\frac{K_{Cs}^*}{K_H^*}\right)^{1/2}(1 + \sum_n K_n^f[ROH]_o^n)^{1/2} \times \frac{K_{a,ROH}^{1/2}[ROH]_o^{1/2}}{K_{D,ROH}^{1/2}[H^+]_a} \quad (26')$$

Therefore, the increase of the slope which is observed in the lower pH region can be attributed to the extraction and dissociation of picric acid, and not to the extraction of hydrochloric acid.

The increase in pH also causes a loss of $[ROH]_o$ according to Eq. (8). In the high pH regions, the concentration of nitrophenol in nitrobenzene can be presented as:

$$[ROH]_o = [ROH]_{total}\left(1+\frac{1}{K_{D,ROH}}+\frac{K_{a,ROH}}{K_{D,ROH}[H^+]_a}\right)^{-1} = \frac{K_{D,ROH}}{K_{a,ROH}}[H^+]_a[ROH]_{total} \quad (8')$$

Therefore, Eq. (20) comes to Eq. (20'):

$$D_{Cs} = K_{Cs}^{*1/2}\frac{[ROH]_{total}^{1/2}}{[Cs^+]_a^{1/2}} \times \left\{1 + \sum_n K_n^f\left(\frac{K_{D,ROH}}{K_{a,ROH}}[H^+]_a[ROH]_{total}\right)^n\right\}^{1/2}$$

where $[ROH]_{total}$ and $[Cs^+]_a$ are constant. This equation shows that the slopes of log D_{Cs} *vs.* pH approach $-n/2$ in the high pH regions. Although few data are available for the high pH regions because the solution is not well-buffered in those regions, *p*- and *m*-nitrophenols show a decrease in D_{Cs} with an increase in the pH. In contrast, the system with picric acid shows no decrease in D_{Cs} with an increase in the pH. This means that the K_n^f value is negligibly small and that simple ion pairs are the predominant species in the extract. In the case of α-dinitrophenol, the slope of the descending part reaches zero as the pH increases. This can be explained by using Eq. (20'). In the region where D_{Cs} decreases as the pH increases, the second term:

$$\left(K_1^f\frac{K_{D,ROH}}{K_{a,ROH}}[H^+]_a[ROH]_{total}\right)$$

plays a more important role than the first term, 1. On the other hand, in the region where the slope reaches zero, the second term becomes less important. Thus with the system of α-dinitrophenol, non-conjugated ions are extracted in the higher pH region, and both conjugated and non-conjugated ions are extracted in the lower pH region.

(2-2) The Relationship between D_{Cs} and $[Cs^+]_a$: The relationship between the distribution ratios of cesium ions and the cesium-ion concentration in equilibrium is shown in Figs. 3—6. The aqueous ionic strength, which was adjusted with sodium or lithium chloride (before the equilibration), was considered to be unchanged during the extraction process. The pH of the aqueous phase was adjusted so as to be constant in each experiment.

The slope of log D_{Cs} *vs.* log $[Cs^+]_a$ is $-1/2$ unless the concentration of cesium ions is relatively small. This value shows that the cesium ion in the nitrobenzene phase is a free ion and that Eq. (20) holds quite well.

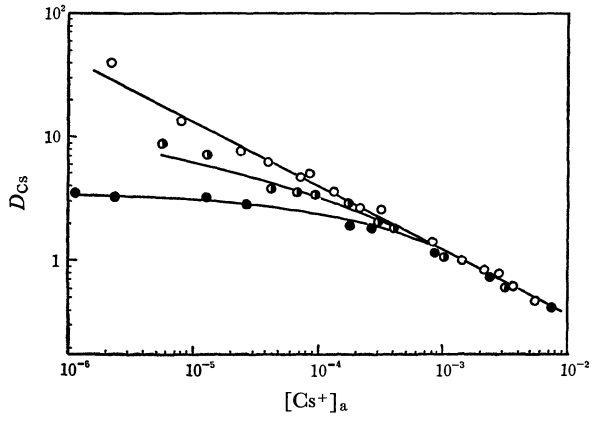

Fig. 3. Distribution of cesium ion as the function of cesium concentration (*p*-NP).

○ $[ROH]_{total}=0.4$, pH 1.6
● $[ROH]_{total}=0.2$, pH 12.3 $[Li^+]_a=0.25$

In Figs. 3—6, the effect of the aqueous ionic strength can be seen when the concentration of lithium or sodium ions is quite large. When the concentration of cesium ions is quite small, Eq. (26) shows the relationship between D_{Cs} and $[Cs^+]_a$. The equation indicates that D_{Cs} is no longer the function of $[Cs^+]_a$ but the function of $[M^+]_a$. The relationship between D_{Cs} and $[M^+]_a$ when the cesium-ion concentration is quite small is shown in Fig. 7. The slope of $\log D_{Cs}$ *vs.* $\log [M^+]_a$ is $-1/2$. This shows that Eqs. (18′) and (26) are valid in this case.

The extraction behavior with picric acid is shown in Fig. 6. The slope of $\log D_{Cs}$ *vs.* $\log [Cs^+]_a$ deviates a little from the slope of $-1/2$, although no metal ions are present except cesium ions. In this case, the cation competing against the cesium ion in the organic phase is a proton which is derived from the dissociation of picric acid in the organic phase (the dissociation constant, pK_o, of picric acid in nitrobenzene is 7.5[12]). From the assumption that $[H^+]_o=[OR^-]_o$ is valid, the concentration of protons in the organic phase can be calculated as *ca.* 10^{-4} M by using Eq. (6). Accordingly, in the region where the concentration of cesium ions in the organic phase is lower than 10^{-4} M, D_{Cs} is no longer dependent on $[Cs^+]_a$, but on $[H^+]_o$. With an increase in the concentration of cesium ions beyond 10^{-4} M, D_{Cs} becomes more dependent on the concentration of cesium ions.

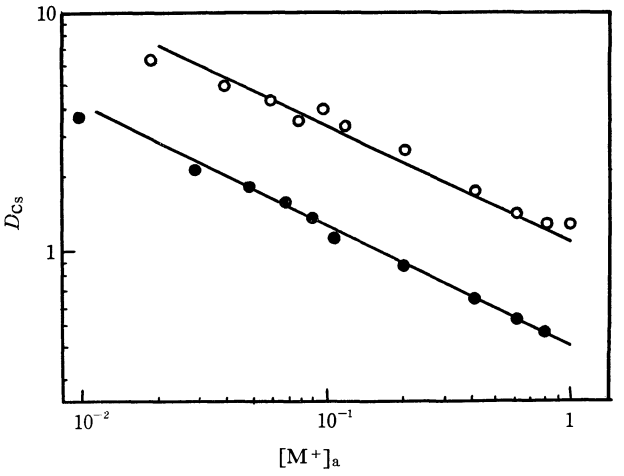

Fig. 7. Distribution of cesium ion as the function of sodium ion concentration or lithium ion concentration (*p*-NP).
$[ROH]_{total}=0.1$, $[Cs^+]_a=10^{-5}$
○ M=Li, pH 8.2, ● M=Na, pH 7.6

(2-3) The Relationship between D_{Cs} and $[ROH]_{total}$: Figure 8 shows the dependence of the distribution ratios of the cesium ion on the total concentration of nitrophenol. In this study, the experimental values have been corrected to the value at the constant pH and at the constant aqueous cesium-ion concentration. The correction has been made according to the following equation:

$$D_{Cs}(\text{corrected}) = D_{Cs}(\text{raw}) \times \left\{\frac{[Cs^+]_a(\text{corrected})[H^+]_a(\text{corrected})}{[Cs^+]_a(\text{raw})[H^+]_a(\text{raw})}\right\}^{1/2}$$

In this experiment, no cations were present in either the organic or aqueous phase except proton and cesium ions.

At a constant pH, the term

$$(1 + 1/K_{D,ROH} + K_{a,ROH}/K_{D,ROH}[H^+]_a)$$

is constant in Eq. (8). Therefore, the slope of log D_{Cs} *vs.* log $[ROH]_{total}$ is the same as that of log D_{Cs} *vs.* log $[ROH]_o$. The slopes correspond to $(n+1)/2$ in Eq. (20-ii). From the experiment shown in Fig. 8, the n values obtained were 0.3 with picric acid, 1 with α-dinitrophenol, 2 with *m*-nitrophenol, and 2.3 with *p*-nitrophenol. The number, n, of the adduct molecules increases as the number of substituted nitro-groups decreases. This observation is also supported by the results shown in the experiments on the relationship between D_{Cs} and pH.

(2-4) Conclusions: The results of the above experiments are summarized in Table 2. In this table, no clear relations can be found in the case of *o*-nitrophenol, because the distribution ratios were below 10^{-3} in every experiment. The reason for this difference from the cases of *p*- and *m*-nitrophenols can not be explained by these experiments alone, though the obstruction of the formation of the CsOR ion-pair, the difficully of the formation of the conjugated ion $(OR\cdot nROH^-)_0$, and some other causes can be considered.

In all cases, the chemical form of cesium ions is concluded to be dissociated ions. The participation of free nitrophenols was observed in the distribution of cesium ions. Through distribution studies, however, no information can be obtained on whether free nitrophenols interact with anions or with cations. Nevertheless, in the present study, we assumed that free nitrophenols interact only with anions. The reason for this assumption will be discussed in the next paper,[10] which will deal with the results of the conductivity measurements. The adduct formation (homoconjugation) of free nitrophenols with anions is seen in the cases of mono- and di-substituted nitrophenols. These cases correspond with the cases of other alkyl-substituted phenols. The extraction of picrate resembles those of dipicrylaminate, tetraphenylborate, reineckate, and other ion-pairs.

The extraction constants were calculated from the data; the values were obtained; as K_{Cs}* or $K_{Cs}*K_n^f$. In the cases of picric acid and α-dinitrophenol, both K_{Cs}* and $K_{Cs}K_1^f$ were obtained, K_{Cs}*, from the data when pH is very high, and $K_{Cs}*K_1^f$, from the data when pH is low. As can be seen from the slopes of the curves of log D_{Cs} *vs.* log $[ROH]_{total}$ in Table 2, the n values can not be determined exactly. Therefore, the extraction constants obtained in this experiment include some uncertainty.

The exchange constants, $K_{Cs}*/K_M*$, are also shown in Table 2. The values were obtained from the data when $[M^+]_a \gg [Cs^+]_a$ or from the log D_{Cs} *vs.* log$[Cs^+]_a$ curves, which are shown in Figs. 3—6.

In this paper, all the experimental data are plotted as a function of the concentration, and all the constants are calculated by using the concentration, no special attention being paid to the activity coefficients in the two phases. However, the ionic strength in the aqueous phase was maintained constant in most of the experiments. No meaningful deviation is noticeable in the explanation of the experimental results.

The relationship between these extraction constants and solubilities will be discussed in the next paper.[10]

The Crystal Structure of 2,2′-Bipyridinium Tetrabromocobaltate(II)

Shigetaka KODA, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 30, 1971)

The crystal structure of 2,2′-bipyridinium tetrabromocobaltate(II) has been established by successive Fourier analyses. The atomic parameters were refined by least-squares techniques, using the three-dimensional X-ray data, to an R factor of 0.127 for 1461 non-zero reflections. The complex crystallizes in the space group $P2_1/c$ with four formula units in the unit cell with dimensions of $a=8.42$, $b=14.00$, $c=12.88$ Å, and $\beta=98.7°$. The crystal consists of slightly distorted tetrahedral $[CoBr_4]^{2-}$ anions and 2,2′-bipyridinium cations, in which two pyridinium ring planes are inclined toward one another at an angle of 39°. The two N^+–H groups in the cation participate in N^+–H···Br^- type hydrogen bonds (N···Br=3.23 Å and 3.31 Å). The mean value of the four Co-Br bond lengths is 2.42 Å.

In the course of the preparation of the bromo-analogue of *trans*-$[CoCl_2(bipy)_2]Cl$,[1,2] (bipy=2,2′-bipyridine), we isolated green crystals whose color is quite similar to that of the *trans*-$[CoBr_2en_2]Br\cdot HBr\cdot 2H_2O$.[3] However, the absorption spectra and elemental analyses of the compound suggested that this salt does not contain a complex cation of *trans*-$[CoBr_2(bipy)_2]^+$, but is a novel compound with the chemical formula of $[bipyH_2]\cdot[CoBr_4]$. Subsequently, this salt could be prepared by the direct reaction of 2,2′-bipyridine with $CoBr_2\cdot 6H_2O$ in concentrated hydrobromic acid. The chloro-analogue of this compound, $[bipyH_2][CoCl_4]$, can also be obtained by a similar method. Instead of characterizing the compound by means of the usual methods, such as a study of the IR or electronic spectra, we have undertaken an X-ray crystal analysis of $[bipyH_2][CoBr_4]$. We have already presented preliminary accounts of our work;[4] here the crystal structure of this compound will be given in detail.

Experimental

1) Preparation of Complexes. a) $[bipyH_2][CoX_4]$ *(X=Cl, Br)*: Both compounds were prepared by mixing equivalent amounts of the appropriate metal halide and bipyridine in conc. hydrohalogenic acid. The products were then recrystallized from the hot conc. HX solution. They are moderately hygroscopic.

2,2′-Bipyridinium Tetrabromocobaltate(II),

Yellowish-green crystals were obtained from the deep blue solution as needles.

Found: C, 22.35; H, 1.98; N, 5.16%. Calcd for $C_{10}H_{10}N_2Br_4Co=[bipyH_2][CoBr_4]$: C, 22.35; H, 1.87; N, 5.21%.

2,2′-Bipyridinium Tetrachlorocobaltate(II),

Large blue crystals were obtained from a deep blue solution in the form of plates.

Found: C, 33.61; H, 2.93; N, 7.99%. Calcd for $C_{10}H_{10}N_2Cl_4Co=[bipyH_2][CoCl_4]$: C, 33.45; H, 2.79; N, 7.80%.

b) Pyridinium Tetrabromocobaltate(II), $[pyH]_2[CoBr_4]$ *(py=pyridine)*: This compound was prepared following the method of Percival and Wardlaw.[5]

Found: C, 23.67; H, 2.67; N, 5.65%. Calcd for $C_{10}H_{12}N_2Br_4Co=[pyH]_2[CoBr_4]$: C, 22.29; H, 2.25; N, 5.20%.

2) Electronic Spectra of Solids. Specimens of $[bipyH_2][CoBr_4]$ and $[pyH]_2[CoBr_4]$ were ground with nujol and placed between two plates of opal glass, and their transmission spectra were measured with a Hitachi EPU-2A photoelectric spectrophotometer.[6]

3) X-Ray Data Measurement. The specimens used in the present investigation were coated with vaseline in order to prevent decomposition caused by atmospheric moisture. Oscillation and Weissenberg photographs taken with Ni$K\alpha$ radiation exhibited a monoclinic symmetry with space group $P2_1/c$. The lattice parameters were obtained from ($hk0$) and ($h0l$) Weissenberg photographs on which Al wire patterns had been superimposed; then they were refined by a least-squares method. In order to collect the three-dimensional intensity data, equi-inclination Weissenberg photographs were taken with Co-filtered Ni$K\alpha$ radiation from $0kl$ to $5kl$ and from $hk0$ to $hk6$, using a multiple-film technique. The intensities were visually estimated by the use of a standard scale. Thus, 1461 independent non-zero reflections were observed. These relative intensities were corrected for Lorentz and polarization factors, a spot-shape correction being made for upper layers. An absorption correction was applied to the data around the c axis, using a cylindrical approximation, since μR is equal to about 3.5. All the intensities were then placed on a common scale by a least-squares method. The crystal data are summarized in Table 1.

Structure Determination

The coordinates of the three bromine atoms were determined by an elaborate examination of the twenty largest peaks in the three-dimensional Patterson function. The positions of all the remaining atoms (except hydrogen) were found by successive three-dimensional Fourier analyses,[7] all the atoms of the pyridine rings being assumed provisionally to be carbon atoms at this stage. The refinement of the crystal structure was carried out by a block-diagonal-matrix, least-squares method.[8] Three cycles of refinement using isotropic temperature factors for all the atoms reduced the conventional R factor to 0.16.

The atoms in the close vicinity of each bromine atom were thoroughly examined in order to pick out the nitrogen atoms among the pyridine ring atoms, for it is quite reasonable to suppose that there must be N^+–H···Br^--type hydrogen bonds in the crystal. We found two ring atoms which are in close contact, 3.23 Å and 3.31 Å, with Br(1) and Br(4) respectively. They were identified as the nitrogen atoms on the basis of close contacts as well as the favorable directions of the hydrogen atoms.

In the further refinement, the anisotropic thermal parameters were applied to the heavy atoms. Four cycles of the least-squares calculation resulted in a convergence, with R=0.127, for all the 1461 non-zero reflections.

The atomic scattering factors used were taken from the International Tables for X-ray Crystallography. The final atomic coordinates and thermal parameters are given in Tables 2(a) and (b). All the numerical calculations were carried out on a FACOM 270-30 computer of our university. Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.[9]

Results and Discussion

The crystal consists of 2,2′-bipyridinium cations and tetrahedral $[CoBr_4]^{2-}$anions. Figures 1 and 2 show the crystal structure viewed along the a and c axes respectively. As is shown in the figures, the structure is composed of regions of anions and cations, both elongated along the c axis. The arrangement of these ions

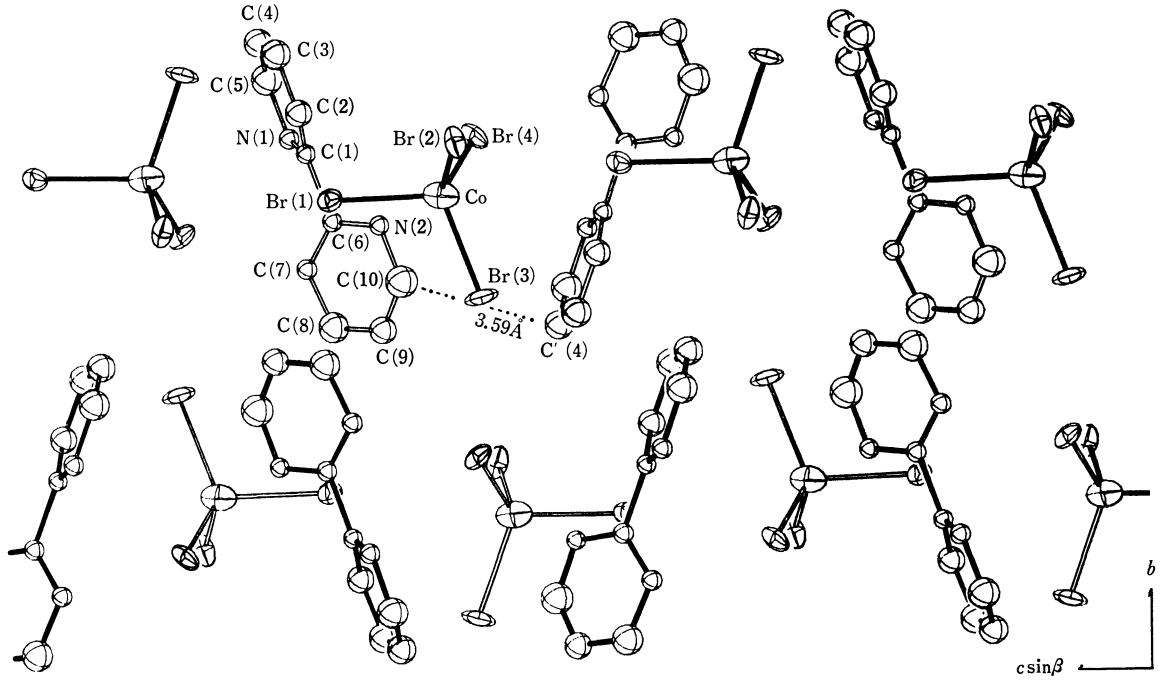

Fig. 1. The crystal structure viewed along the *a* axis.

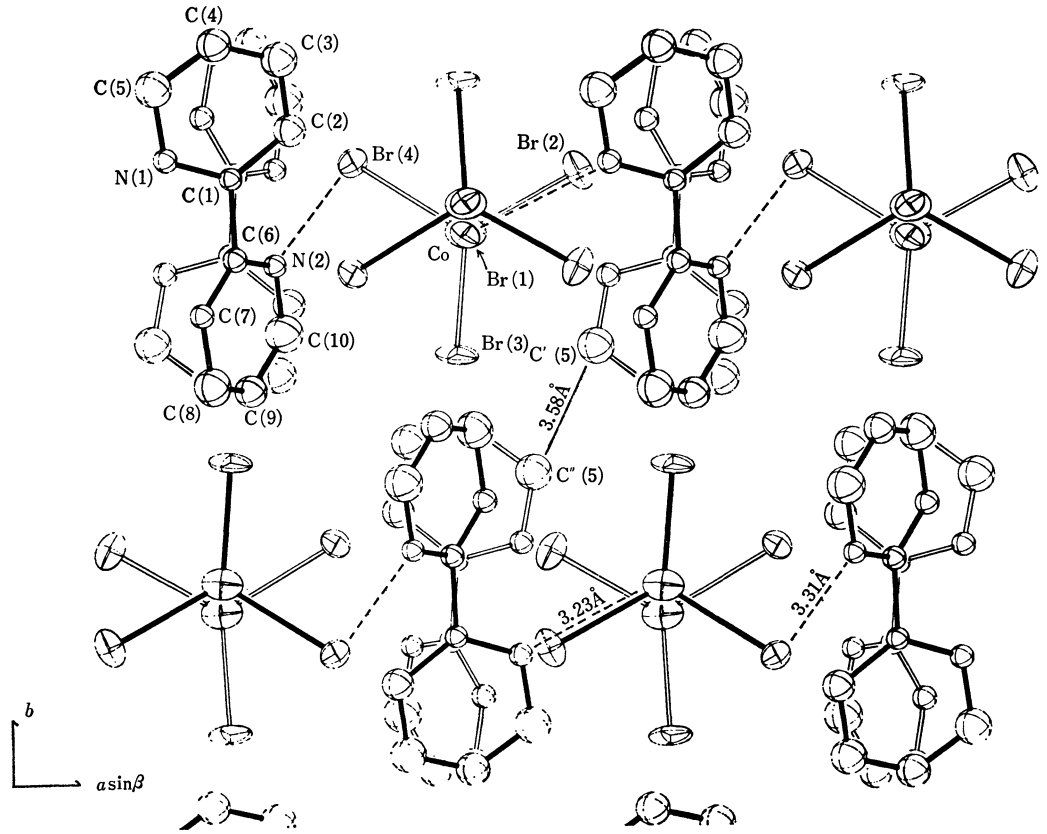

Fig. 2. The crystal structure viewed along the *c* axis.

in a checkered pattern is clearly illustrated in Fig. 2. Two-dimensional linkages are also formed by a N^+—H··· Br^--type hydrogen bonding extended along the *a* axis. These linkages are indicated by dashed lines in Fig. 2. The distances of the hydrogen bonds, 3.23 Å and 3.31Å, are in the range expected for this type. Apart from these, the closest intermolecular contacts are C′(5)··· C″(5) (=3.58 Å) and C′(4)···C(10) (=3.59 Å) (see Figs. 1 and 2). The interatomic distances and angles are listed in Tables 3(a) and (b).

It is known that the conformation of the 2,2′-bipyridine molecule is coplanar in the crystalline state, the

two nitrogen atoms being in the *trans* positions with respect to the C–C bond connecting the two pyridine rings.[10] However, this is not the case with our bipyridinium cation. As may be seen in Figs. 1 and 2, the bipyridinium cation lacks planarity. The individual pyridinium moiety is planar; the equation of the best plane through the six atoms N(1), C(1), C(2), C(3), C(4), and C(5), is:

$$0.162X + 0.332\,Y + 0.929\,Z = 3.99,$$

and that of the plane of the six atoms N(2), C(6), C(7), C(8), C(9), and C(10) is:

$$0.742\,X + 0.140\,Y + 0.655\,Z = 3.17,$$

where X, Y, and Z are the rectangular coordinates in Å units, X standing for $x+z\cos\beta$; Y, for y, and Z, for $z\sin\beta$. C(1) shows the maximum deviation of 0.04 Å from the former plane, and both C(9) and C(10) are in the maximum deviation from the latter plane by 0.04 Å. These two ring planes are inclined at an angle of 39° to each other. This dihedral angle is comparable with those found in (bipyH$_2$)SeOCl$_4$,[11] within the accuracy of the standard deviations.

The coordination around the cobalt atom is almost a regular tetrahedron. However, in the four Co–Br bonds, two of them (Co–Br(1)=2.436 Å and Co–Br(4) =2.452 Å) are longer than the other two (Co–Br(2)= 2.409 Å and Co–Br(3)=2.382 Å). The differences in the bond lengths between these two groups are possibly significant in view of the e.s.d.'s. The elongation in the former group must result from the hydrogen bonding in which the corresponding bromine atoms participate.

In the solid state, the color of [bipyH$_2$][CoBr$_4$] is green, while that of the analogous complex, [pyH]$_2$·[CoBr$_4$], is blue. As can be seen from Fig. 3, in which

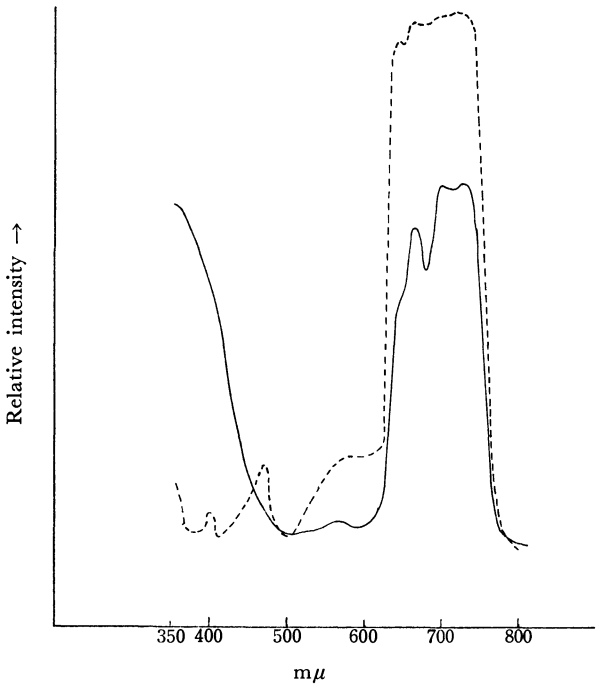

Fig. 3. Transmission spectra of [bipyH$_2$][CoBr$_4$]: —— and [pyH]$_2$[CoBr$_4$]: ----.

their transmission spectra are shown, the remarkable color difference between them is attributable to the absorption bands in the higher frequency region; a detailed discussion will be given in subsequent papers.

The authors are grateful to Dr. Akio Takenaka of Kwansei Gakuin University for providing them with the computer program for crystal structure illustration. Thanks are also due to Mr. Jun-ichi Gohda for his organic elemental analyses.

Preparation and Circular Dichroism of Six Isomers of Bis(L-alaninate-*N*-monoacetato)cobaltate(III) Complexes

Ken-ichi OKAMOTO, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 1, 1971)

Six isomers, two *trans(N)* and four *cis(N)*, of bis(L-alaninate-*N*-monoacetato)cobaltate(III) ions have been synthesized as their sodium or potassium salts. The isomers have been separated by ion-exchange column chromatography and their geometrical and chiral configurations determined on the basis of their absorption and circular dichroism spectra in visible and near ultraviolet regions and of proton magnetic resonance spectra. The corresponding L-prolinate-*N*-monoacetate complex has also been studied. The asymmetry of the coordinated imino nitrogen has been discussed from the analysis of the CD curves.

L-Alanine-*N*-monoacetic acid is a derivative of iminodiacetic acid and a typical O,N,O-tridentate ligand of linear type which contains one asymmetric carbon atom. The nitrogen atom of this ligand, however, becomes asymmetric by coordination to a metal ion; the circular dichroism (CD) spectrum of the complex will then be supplied from two vicinal contributions produced by the asymmetric carbon and the asymmetric nitrogen. Some isomers of cobalt(III) complexes with iminodiacetate or *N*-methyliminodiacetate, which have neither asymmetric carbon nor nitrogen atom, have been prepared and characterized by their electronic absorption[1,2] and CD spectra[3] in visible and ultraviolet regions and by PMR spectra.[2,4] Of these complexes, *cis(N)* isomer of bis(iminodiacetato) complex has a chiral configuration, and the absolute configurations of the optical isomers have been determined from comparison of their CD bands with those of a stereospecifically formed complex ion, $(+)_{546}$-[Co{$(-)_{589}$-pdta}]$^-$.[5]

In the present paper, the preparation and separation of isomers of bis(L-alaninate-*N*-monoacetato)cobaltate (III) complex will be reported with those of the corresponding L-prolinate-*N*-monoacetate complex; the geometrical and chiral configurations of these complexes will be determined by their electronic absorption, CD, and PMR spectra. The additivity of three kinds of CD contributions, one from the configurational chirality and the other two from the vicinal chiralities of the asymmetric carbon and nitrogen atoms, will be discussed.

Experimental

(1) Preparation of Ligands. A solution of 45 g of L-alanine in 125 m*l* of 4 N lithium hydroxide was added to a solution of 47.3 g of monochloroacetic acid in 125 m*l* of 4 N lithium hydroxide. To this mixture 125 m*l* of 4 N lithium hydroxide was added drop by drop with vigorous stirring at 70—80°C. The pH of the mixture was maintained in the range 8—9 during the reaction. After the addition, the mixture was heated at 90°C for about 10 min. The reaction mixture was cooled to room temperature and 120 m*l* of concentrated hydrochloric acid was added to it. The solution was concentrated in a vacuum evaporator until it became syrupy. When it was kept in a refrigerator for 24 hr, white crystals were separated out, which were collected by filtration and then washed well with ethanol. These white crystals, the desired acid hydrochloride, were contaminated with a small amount of lithium chloride. They were recrystallized from warm water. The pure crystals were washed with ethanol and ether, and then dried in a vacuum desiccator. The yield was approximately 23 g. $[\alpha]_D^{25} = +3.0°$ (*c* 5.4, water).

Found: C, 31.84; H, 5.53; N, 7.41%. Calcd for L-alamaH$_2$·HCl·1/4H$_2$O=C$_5$H$_{10}$NO$_4$Cl·1/4H$_2$O: C, 31.93; H, 5.63; N, 7.45%.

L-Proline-*N*-monoacetic acid was also prepared by a similar procedure using L-proline instead of L-alanine. $[\alpha]_D^{17} = -54°$ (*c* 1.0, water).

Found: C, 48.66; H, 6.46; N, 7.98%. Calcd for L-promaH$_2$=C$_7$H$_{11}$NO$_4$: C, 48.55; H, 6.40; N, 8.09%.

(2) Preparation of Isomeric Mixture of Lithium Bis(L-alaninate-N-monoacetato)cobaltate(III): *Li*[*Co*(L-*alama*)$_2$]·nH_2O. A solution of 8.4 g of cobalt(II) chloride hexahydrate in 10 m*l* of water was added to a solution containing 13.6 g of L-alamaH$_2$·HCl·1/4H$_2$O whose pH had been previously adjusted to 7.3 with 4 N lithium hydroxide. To this solution 10 g of lead dioxide was added and the resulting mixture was mechanically stirred at about 30°C for 2 hr. The color of the solution turned from dark red to bluish violet. Thereafter the pH was adjusted to 6.5 with 4 N lithium hydroxide and the mixture was kept for 90 min at room temperature. An excess of lead dioxide was filtered off. A large amount of methanol-ether (1 : 2) mixture was added to the filtrate. The bluish violet deposit was filtered and washed with methanol-ether (1 : 2) mixture and ether, and then dried in a vacuum desiccator. The yield was approximately 11 g.

(3) Separation of the Isomers of [*Co*(L-*alama*)$_2$]$^-$. About 8 g of the lithium salt obtained in (2) was dissolved in an appropriate amount of water and passed through a column (25 mm × 1500 mm) containing strong anion exchange resin, Dowex 1×8 (200—400 mesh, chloride form). After the column had been swept with water, the adsorbed band was eluted with 0.07 N aqueous solution of potassium chloride or sodium perchlorate at a rate of 2.5 m*l* per min. Six colored bands, a brownish red one (i), a reddish purple one (ii), and four violet ones (iii), (iv), (v) and (vi), were eluted in this order. Isomers i and ii were confirmed to be *trans(N)* ones and iii, iv, v and vi the *cis(N)* ones, by measurement of their absorption spectra. Each eluate was concentrated to dryness in a vacuum evaporator. The resulting solid isomers were contaminated with a small amount of potassium chlo-

—	*trans*(*N*)-RR-K[Co(L-proma)$_2$]·3H$_2$O	(+)0.06	33.92	34.01	4.88	4.89	5.66	5.67

ride, and were treated as follows. An aqueous solution of silver perchlorate was added drop by drop to the solution containing the crude complex and the precipitated silver chloride was filtered off. The complex desired was obtained by adding ethanol to the filtrate. The complex crystals were washed with water-ethanol (1 : 2) mixture and ethanol, and then dried in a vacuun desiccator. Isomers i and ii were isolated as sodium salts, while iii∼vi as potassium salts. Analytical results are given in Table 1.

*(4) Preparation and Separation of Potassium Bis(*L*-prolinate-*N*-monoacetato)cobaltate(III):* *K[Co(*L*-proma)$_2$]·nH_2O.* This was prepared and separated by a similar procedure to that for L-alama complex, using L-promaH$_2$ instead of L-alamaH$_2$·HCl·1/4H$_2$O. Two colored bands, a violet one and a brownish red one, were eluted in this order with 0.07 N aqueous solution of potassium chloride. The violet isomer was unstable in solution; the CD of the violet eluate decayed out with time. The violet isomer was not obtained in solid state, but the absorption and CD spectra of the solution suggested that this is the *cis(N)* isomer. The brownish red isomer was isolated as potassium salt trihydrate (Table 1), and was confirmed to be the *trans(N)* isomer by measurement of the absorption spectrum.

(5) Measurements. The electronic absorption spectra of the complexes were measured with a Beckman DU spectrophotometer. The CD spectra were recorded with a Roussel-Jouan dichrograph and a JASCO Model ORD/UV-5 spectrophotometer. All measurements were made in aqueous solutions at room temperature. The PMR spectra of the complexes in deuterium oxide were measured with a Japan Electron Optics 3H-60 spectrometer.

Results and Discussion

It has veen well established that the *trans(N)* and *cis(N)* isomers of a [Co^{III}(O)$_4$(N)$_2$]$^-$ type complexes can be identified from the splitting pattern of their first absorption bands in the visible region.[6,7] As is seen in Fig. 1 and Table 2, the first absorption bands of the two earlier eluates (isomers i and ii) of [Co(L-alama)$_2$]$^-$ and of the stable eluate of [Co(L-proma)$_2$]$^-$ exhibit a sub-peak (or shoulder) at the longer wavelength side of the major peak. On the contrary, on the absorption curves of the four later eluates (isomers iii, iv, v and vi) of [Co(L-alama)$_2$]$^-$, a vague shoulder is observed at the shorter wavelength side of the major peak. This indicates that the former group is *trans(N)* isomer and the latter *cis(N)*.

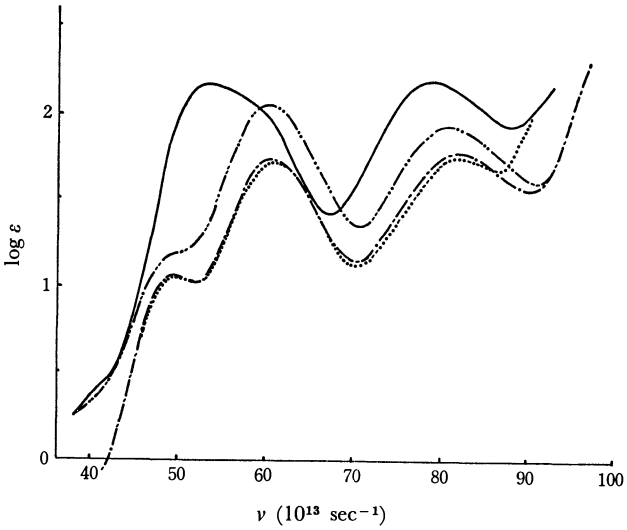

Fig. 1. Absorption curves of *trans(N)*-RR-[Co(L-alama)$_2$]$^-$ (———), *trans(N)*-RS-[Co(L-alama)$_2$]$^-$ (— — —), *trans(N)*-[Co(ida)$_2$]$^-$ (----) and *Δ-cis-(N)*-RR-[Co(L-alama)$_2$]$^-$ (——).

The *cis(N)* isomers of [Co(L-alama)$_2$]$^-$ exhibit two CD extrema in the first absorption band region as shown in Table 3. Of the four isomers the earlier eluted two isomers (iii and iv)show a negative and a positive CD band listing from longer wavelength side, whereas isomers v and vi show a positive and a negative band in the corresponding region. The absolute configuration of the isomer of *cis(N)*-[Co(ida)$_2$]$^-$, which was obtained from the less soluble diastereoisomer with (−)$_{546}$-[Co·(en)$_2$(ox)]$^+$, has been assigned to be *Λ*[8] by Van Saun and Douglas,[3] and the first absorption band of this complex shows a positive and a negative CD band listing from longer wavelength side. The *Λ*-(−)$_{546}$ isomer of [Co(edta)]$^-$ also shows a similar Cotton effect pattern in this region.[3,9] Since each of the *cis(N)* isomers in the present work has a C_2 or pseudo-C_2 symmetry, it is expected that the effective crystal field in these complexes is quite similar to those in the ida and edta complexes. Therefore it is concluded that the *cis(N)* isomers iii and iv have a *Δ* configuration and the isomers v and vi a *Λ* configuration.

In the parent complex, [Co(ida)$_2$]$^-$, four isomers are

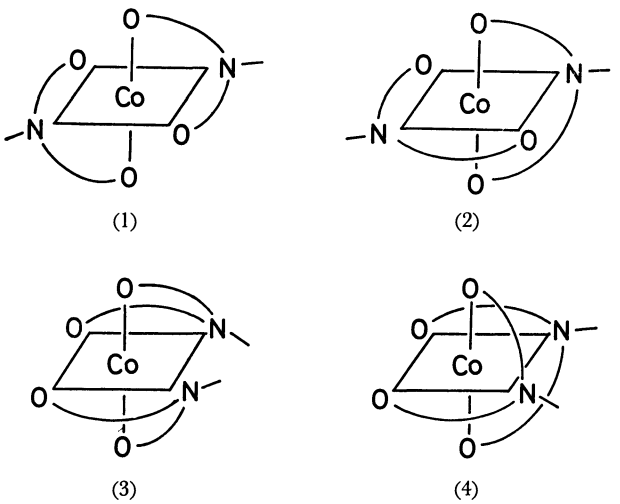

Fig. 2. Four possible isomers for a [Co(O,N,O-tridentate)$_2$] type complex: (1) facial-*trans*(*N*), (2) meridional-*trans*(*N*), (3) *Λ-cis*(*N*) and (4) *Δ-cis*(*N*).

possible as is seen in Fig. 2; so far the meridionally coordinating *trans*(*N*) isomer (2) is unknown. Such a meridional form of ida has been found only in a mixed complex with diethylenetriamine, [Co(ida)(dien)]$^+$.[4] A molecular model examination shows that the *Δ-cis*(*N*) isomer of L-proma complex can not exist because of serious steric hindrance between two pyrrolidine rings in the complex. We obtained an unstable violet colored eluate, which shows an absorption spectrum of *cis*(*N*)-[Co(O)$_4$(N)$_2$]$^-$ type and a CD spectrum similar to those of isomers v and vi of L-alama complex (with *Λ* configuration). The molecular model of the *Λ* isomer of [Co(L-proma)$_2$]$^-$ shows that the pyrrolidine ring of one ligand makes a rather short contact to the acetate methylene in another ligand, and that this may be the reason for the instability of this isomer. The stable *trans*(*N*)-[Co(L-proma)$_2$]$^-$ may be type (1) isomer in Fig. 2.

When L-alama coordinates to a cobalt(III) ion, the nitrogen atom of the ligand is optically activated (as

having R or S configuration). Accordingly three isomers, RR, RS, and SS, are possible for each of the bis(L-alama) complexes of *trans(N)*, *Δ-cis(N)* and *Λ-cis(N)* form. In the case of L-proma complex, the ligand cannot coordinate to take the S configuration of nitrogen atom; then only the RR isomer is expected for each of the *trans(N)* and *Δ-cis(N)* L-proma complexes. In fact, only one isomer was obtained by ion-exchange column chromatography for each of the *trans(N)* and *cis(N)* complexes. It has already been established that L-prolinate shows a complete stereospecific coordination of this kind; L-prolinate itself fixes the absolute configuration of the asymmetric nitrogen center to the S configuration.[10,11]

Experimentally only two isomers of possible three isomers were obtained for the *trans(N)* bis(L-alama) complex by ion-exchange column chromatography. If the nitrogen center takes S configuration, a repulsion exists between an alaninate methyl group of a coordinated L-alama ligand and a proton of the glycinate ring of the same ligand as is seen in Fig. 3(b). There is no such a repulsion in the R-form coordination (Fig. 3(a)). From this viewpoint, it is possible to assume tentatively that the two *trans(N)* isomers of bis(L-alama) complex obtained are the RR and RS forms of the type (1) isomer in Fig. 2.

The PMR spectra of the *trans(N)* bis(L-alama) complexes, i and ii, are shown in Fig. 4. The proton signals of *trans(N)* bis(L-alama) complexes consist of a group of AX_3 pattern due to $>CH-CH_3$ and another group of AB pattern due to $-CH_2-$. Only one set of AX_3 and AB patterns is expected for the RR or SS isomer and two sets for the RS isomer, since the former has C_2 symmetry and the latter C_1. As shown in Fig. 4, isomer i showed a doublet (at 1.73 ppm) in the region of methyl protons, whereas isomer ii showed two doublets (at 1.65 and 1.78 ppm) in this region. This behavior supports the view that isomer i is RR and isomer ii RS form. This was also confirmed by the result in the region of methylene and methine protons (3—5 ppm): the PMR spectrum of isomer i exhibited a pair of quartets, whereas that of isomer ii was complicated.

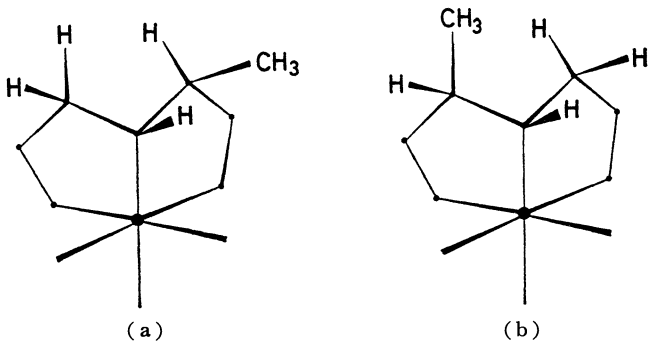

Fig. 3. Two possible configurations of the L-alama^{2-} ligand facially coordinated to a cobalt atom: (a) R from with regard to the asymmetric nitrogen atom, and (b) S form.

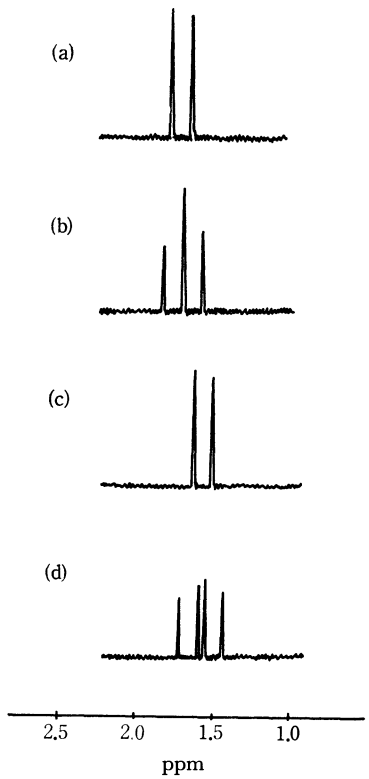

Fig. 4. The PMR spectra of bis(L-alama) complexes in D_2O. (a) isomer i (RR), (b) isomer ii (RS), (c) isomer v (RR) and (d) isomer iv (RS).

A similar conclusion was also obtained for the PMR spectra of the isomers of *cis(N)* bis(L-alama) complex. Isomer iv showed two doublets (at 1.48 and 1.66 ppm) due to two methyl groups and isomer v a doublet (at 1.56 ppm) (Fig. 4). The poor yields of isomers iii and vi did not allow measurement of the PMR spectra. However, the absorption maximum and CD extremum data in Tables 2 and 3 suggest that isomer iii corresponds to isomer v (RR) and isomer vi to iv (RS). Thus, if the possibility of the SS configuration is excluded, the four isomers obtained of *cis(N)*-[Co(L-alama)$_2$]$^-$ are assigned as follows: iii to *Δ*-RR, iv to *Δ*-RS, v to *Λ*-RR, and vi to *Λ*-RS.

It has been reported for several cobalt(III) complexes that the configurational and vicinal contributions to CD are separable and almost additive.[6b,12-14] The CD data and curves of the present complexes are shown in Table 3 and Figs. 5 and 6. The CD curve of a *cis(N)* isomer consists of a configurational contribution (*Δ* or *Λ*) and two vicinal ones due to the asymmetric nitrogen (R or S) and carbon (L) atoms. This assumption leads to the following additivity formulas:

$$\Delta\varepsilon(\text{iii}) = \Delta + 2\text{R} + 2\text{L} \qquad (1)$$

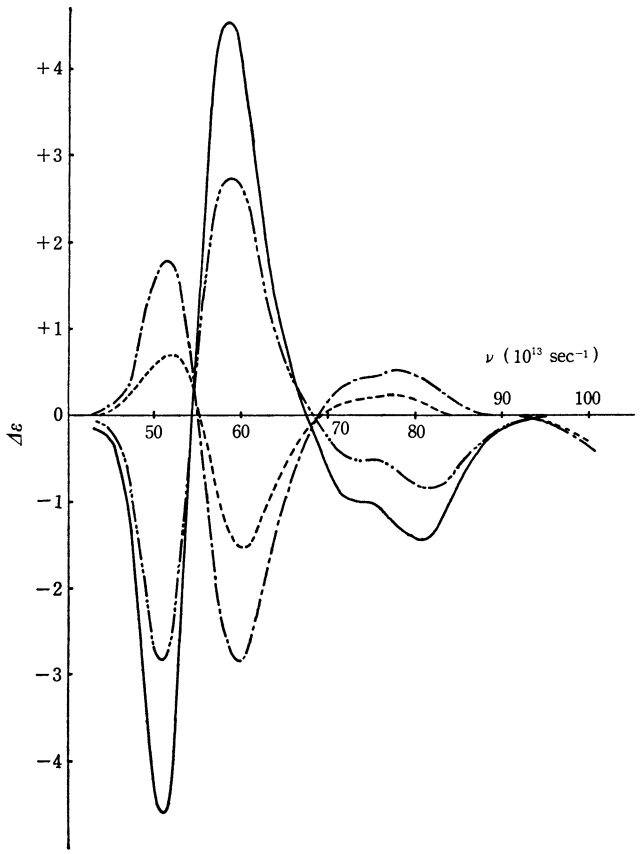

Fig. 5. CD curves of *cis(N)*-[Co(L-alama)$_2$]$^-$ isomers: *Δ-cis(N)*-RR (——), *Δ-cis(N)*-RS (— — —), *Λ-cis(N)*-RR (----) and *Λ-cis(N)*-RS (— — —).

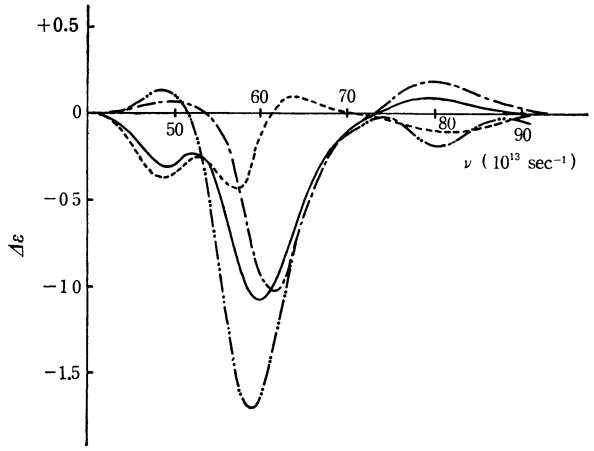

Fig. 6. CD curves of *trans(N)*-[Co(O,N,O-tridentate)$_2$] type complexes: (1) RR-[Co(L-alama)$_2$]$^-$ (——), (2) RS-[Co(L-alama)$_2$]$^-$ (— — —), (3) RR-[Co(L-proma)$_2$]$^-$ (— — — —), and (4) calculated curve (1)−(2) (----).

$$\Delta\varepsilon(\text{iv}) = \Delta + 2\text{L} \tag{2}$$

$$\Delta\varepsilon(\text{v}) = \Delta + 2\text{R} + 2\text{L} \tag{3}$$

$$\Delta\varepsilon(\text{vi}) = \Delta + 2\text{L} \tag{4}$$

where, of course, there exists the relation, $\Delta = -\Lambda$. Thus we have

$$\Delta = 1/2 \times \{\Delta\varepsilon(\text{v}) - \Delta\varepsilon(\text{iii})\} = 1/2 \times \{\Delta\varepsilon(\text{vi}) - \Delta\varepsilon(\text{iv})\} \tag{5}$$

$$2\text{R} = \Delta\varepsilon(\text{iii}) - \Delta\varepsilon(\text{iv}) = \Delta\varepsilon(\text{v}) - \Delta\varepsilon(\text{vi}) \tag{6}$$

$$2\text{L} = 1/2 \times \{\Delta\varepsilon(\text{iv}) + \Delta\varepsilon(\text{vi})\} \tag{7}$$

The curves of configurational Δ, vicinal 2R, and vicinal 2L can be calculated by applying Eqs. (5)—(7) to the observed CD curves of *cis(N)* isomers. The calculated curves are shown in Fig. 7.

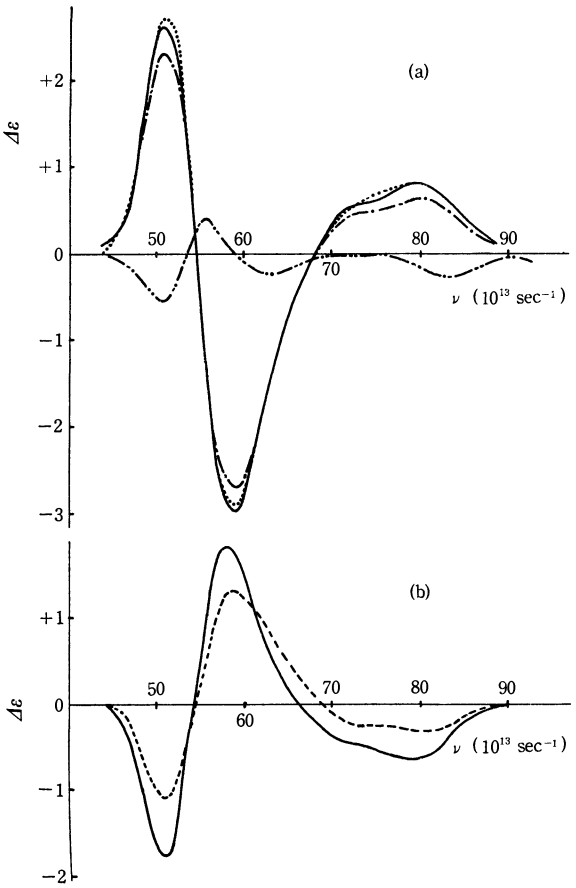

Fig. 7. Curve analyses of *cis(N)*-[Co(L-alama)$_2$]$^-$ complexes: (a) Δ configurational and 2L vicinal (carbon atom) curves; $1/2\times\{\Delta\varepsilon(\text{v})-\Delta\varepsilon(\text{iii})\}$ (——), $1/2\times\{\Delta\varepsilon(\text{vi})-\Delta\varepsilon(\text{iv})\}$ (— — —) and $1/2\times\{\Delta\varepsilon(\text{iv})+\Delta\varepsilon(\text{vi})\}$ (— — — —). Observed CD curve of *Λ-cis(N)*-[Co(ida)$_2$]$^-$ (----). (b) 2R vicinal curves (nitrogen atom); $\Delta\varepsilon(\text{iii})-\Delta\varepsilon(\text{iv})$ (——) and $\Delta\varepsilon(\text{v})-\Delta\varepsilon(\text{vi})$ (----).

The calculated configurational curve Δ (Fig. 7a), agrees well with the curve of *Δ-cis(N)*-[Co(ida)$_2$]$^-$ by Van Saun and Douglas.[3] As shown in Fig. 7b, there is also a rather good correspondence between the vicinal 2R curve which was calculated from a pair of *Δ-cis(N)* isomers and that from a pair of *Λ-cis(N)* isomers. This also supports the assignment of the configurations of the nitrogen atoms, which was made from the visible absorption and PMR spectra.

The CD spectra of the *trans(N)* bis(L-alama) isomers are also treated in a similar manner. In this case, however, there is no configurational contribution. Therefore the calculated curve, $\Delta\varepsilon(\text{i})-\Delta\varepsilon(\text{ii})$, represents the vicinal contribution 2R (Fig. 6).

Studies of the Pyrolysis of Triglycerides

Kazuo KITAMURA

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto

(Received April 16, 1970)

The pyrolysis of triglycerides (trilaurin and tripalmitin) in an atmosphere of nitrogen at 300—700°C has been attempted. Fatty acids, acrolein, ketones, and olefins have been identified as pyrolysis products. As intermediates of the pyrolysis, unsaturated glycol difatty acid esters and acid anhydrides were also detected. These results suggest a reaction mechanism of the pyrolysis involving the above compounds.

Numerous studies of the thermal oxidation of glycerides have been reported, but only a few papers have dealt with the pyrolysis of glycerides in the absence of air. The pyrolysis of glycerides may be expected to be different in the absence of and in the presence of air.

Crossley[1] has reported studies of the pyrolysis of glycerides with and without air, but he has not described in detail the mechanism of pyrolysis in the absence of air.

The present author has prepared pure trilaurin and tripalmitin and then pyrolyzed them in an atmosphere of nitrogen at 300—700°C. The pyrolysis products have been analyzed and indentified, and the mechanism of a series of pyrolysis reactions has elucidated.

Experimental

Pyrolysis Apparatus and Procedure. The pyrolysis apparatus used was the same as that illustrated in a previous paper.[2] When the temperature in the quartz tube reached a fixed temperature, a throughly-dried sample (about 0.5 g) in a porcelain boat was introduced to the center of the tube by means of a steel rod driven by a magnet. A slow stream of purified nitrogen (20 ml/min) was passed through the quartz tube during the pyrolysis. The products of the pyrolysis were collected in the N_1 trap (cooled by ice and salt) and in the N_2 and N_3 traps (cooled by dry ice and acetone), and were then submitted to analysis.

Preparation of Samples. Purified fatty acids were converted to acid chlorides,[3] and these were then treated with glycerol in chloroform and pyridine to give the triglycerides.[4] After repeated recrystallization from acetone, thin-layer chromatography (tlc) (coating material : silica gel G; developing solvents : petroleum ether : diethyl ether : acetic acid, 70 : 30 : 2) showed no impurities. The melting points and saponification values (S.V.) of the samples are shown in Table 1.

TABLE 1. MELTING POINTS AND SAPONIFICATION VALUES OF THE SAMPLES

Sample	Mp (°C)	S.V.
Trilaurin	45.0—45.8	263.0
Tripalmitin	65.5—65.7	207.7

Analysis of Pyrolysis Products. The pyrolysis products were dissolved in carbon tetrachloride, and were then separated into acidic and neutral fractions with 10% K_2CO_3. After the methylation of the acidic fractions, the methyl esters were analyzed by gas-liquid chromatography (glc).[5] The neutral fractions were analyzed by column chromatography, by tlc, by a study of the infrared spectrum (IR),[6] and by chemical analysis.

Results and Discussion

Acidic and Neutral Fractions. Using a 0.5-g sample each time, a series of ten pyrolyses was performed. The total weights of the acidic and neutral fractions are shown in Table 2.

TABLE 2. ACIDIC FRACTIONS AND NEUTRAL FRACTIONS

Sample	Pyrolysis temperature (°C)	Acidic fraction (g)	Acidic fraction (%)	Neutral fraction (g)	Neutral fraction (%)
Trilaurin	550	1.50	30.0	1.90	38.0
Tripalmitin	450	2.22	44.3	1.63	32.5

Fatty Acids. A part of the carbon tetrachloride solutions of the pyrolysis products were titrated with with standard alkali; the acid values (A.V.) thus obtained are shown in Fig. 1. The A.V. were most in the pyrolysis products at 550°C(trilaurin) and at 450°C (tripalmitin). At these temperature, the fatty acid yields were 46.9% (trilaurin) and 54.8% (tripalmitin).

The pyrolysis temperatures, 450°C and 550°C, are considered to be favorable for the most effective performance of the pyrolysis. Tlc showed also that no pyrolysis took place at 300°C, that at 450—550°C the spots of the pyrolysis products appeared most clearly, and that at 700°C the spots were not clear and that carbonization probably took place. Accordingly, pyrolysis can best be performed at 450—550°C.

Glc analysis of the acidic fractions in pyrolysis products showed that the main parts are the component fatty acids of the samples. In addition to these, many saturated and unsaturated lower acids were found to be present in very small amounts.

Unsaturated Glycol Difatty Acid Esters. In previous reports on the pyrolysis of ethylene glycol fatty acid esters,[2] monoglycerides[7] and diglycerides[8] in an atmosphere of nitrogen, the main decomposition

1) A. Crossley, T. D. Heyes, and B. J. F. Hudson, *J. Amer. Oil Chemists' Soc.*, **39**, 9 (1962).

2) K. Kitamura and N. Tachikawa, *J. Japan Oil Chemists' Soc.*, **14**, 250 (1965).

3) I. Imai and T. Wakabayashi, *ibid.*, **10**, 435 (1961).

4) B. F. Daubert and A. R. Baldwin, *J. Amer. Chem. Soc.*, **66**, 997 (1944).

5) A Yanagimoto GCG-2 Gas Chromatograph with a thermal-conductivity detector was used.

6) A Hitachi EPI-S_2 Infrared Spectrophotometer was used.

7) K. Kitamura, S. Kajita, A. Sasaki, and Y. Inoue, *Memoirs of the Res. Inst. of Sci. and Eng., Ritsumeikan Univ.*, **15**, 53 (1966).

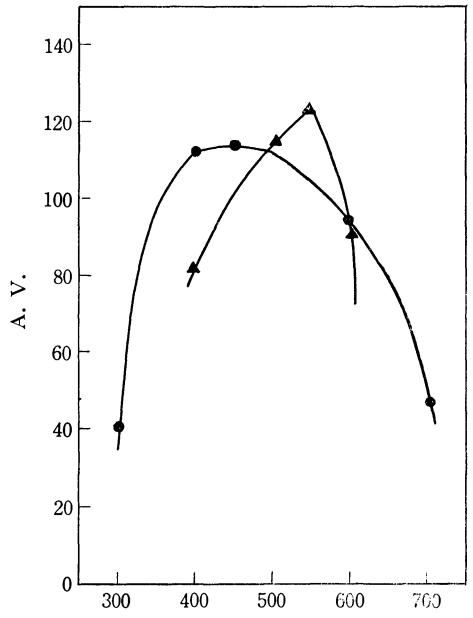

Fig. 1. Effect of the pyrolysis temperature on A.V. of the pyrolysis products.
▲: Trilaurin; ●: Tripalmitin

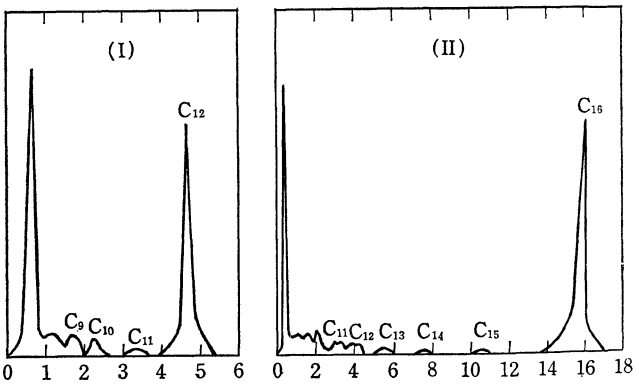

Fig. 2. Gas chromatograms of the acidic fractions (methyl esters).
(I): Trilaurin, (II): Tripalmitin, Column: Apiezon grease L, Column temperature (I): 230°C, (II): 235°C, Carrier gas: He, 40 ml/min.

reactions were the same as in the pyrolysis of fatty acid esters:

$$RCOOCH_2CH_2R' \rightarrow RC(=O\cdots H)(O\text{-}CH_2)\text{-}C(R')\text{-}H \rightarrow RCOOH + \underset{\underset{H_2}{|}}{\overset{R'}{\overset{\diagdown}{CH}}}\overset{\diagup}{C}\ ^{9)} \quad (1)$$

In the pyrolysis of ethylene glycol fatty acid esters, the pyrolysis products were obtained purely and were identified:[2]

$$\begin{matrix}CH_2OCOR\\|\\CH_2OCOR\end{matrix} \rightarrow RCOOH + \begin{matrix}CH_2\\\|\\CHOCOR\end{matrix} \quad (2)$$

8) K. Kitamura, *ibid.*, **17**, 85 (1968).

Therefore, in the pyrolysis of triglycerides (trilaurin and tripalmitin), the first decomposition process should proceed by means of the formation of fatty acids and unsaturated glycol difatty acid esters (UGDE), as is shown in the following equations:

$$\begin{matrix}CH_2OCOR\\|\\CHOCOR\\|\\CH_2OCOR\end{matrix} \rightarrow RCOOH + \begin{matrix}CH_2\\\|\\COCOR\\|\\CH_2OCOR\end{matrix} \quad (3)$$

$$\begin{matrix}CH_2OCOR\\|\\CHOCOR\\|\\CH_2OCOR\end{matrix} \rightarrow RCOOH + \begin{matrix}CHOCOR\\\|\\CH\\|\\CH_2OCOR\end{matrix} \quad (3')$$

$R = C_{11}H_{23}$ or $C_{15}H_{31}$

About 1 g of the neutral fraction of the pyrolysis product (tripalmitin) was separated by column chromatography with silica gel (50 g) as the adsorbent and with petroleum ether and ether (7:3) as developers. A substance (0.06—0.1 g), the I.V. of which was about 20.0 (halogen addition hindrance by carbonyl), was obtained from the middle part of the column. The S.V. of this substance was 170.4 (84% of the theoretical).

This substance shows IR adsorption peaks at 1780 and 1680 cm^{-1} ($-\overset{O}{\overset{\|}{C}}-O-C=C-$); 1740 cm^{-1} ($-C=O$); 1180 and 1110 cm^{-1} ($=C-O-C-$);[10] 1160 and 1110 cm^{-1} ($=C-O-C=$);[11] 870 cm^{-1} ($CH_2=C\langle$).[12]

From these results, it can be deduced that this substance has the structure of UGDE shown in Eq. (3).

In the case of trilaurin, the results obtained were almost the same.

Acid Anhydrides. In Eq. (4), because of the resonance of (iii), the pushing-out of the electron to

$$R\text{-}C(=O)\text{-}O\text{-}C=C- \ \text{(i)} \leftrightarrow R\text{-}C(=O^{\ominus})\text{-}O^{\oplus}\text{-}C=C- \ \text{(ii)} \quad (4)$$
$$\updownarrow$$
$$R\text{-}C(=O)\text{-}O^{\oplus}=C\text{-}C^{\ominus}- \ \text{(iii)}$$

the carbonyl oxygen of (ii) is considered to decrease. For this reason, the (1)-type decomposition of UGDE in Eq. (3) cannot be considered to proceed. Accordingly, the decomposition of Eq. (5) seems plausible.

$$\begin{matrix}CH_2\\\|\\COCOR\\|\\CH_2OCOR\end{matrix} \rightarrow \begin{matrix}CH_2\\\|\\C\text{-}O\\|\\CH_2\end{matrix} + \begin{matrix}RC=O\\\diagup\ O\\RC=O\end{matrix}$$
$$\searrow \quad \begin{matrix}CH_2\\\|\\C\\\|\\CHOH\end{matrix} \rightarrow \begin{matrix}CH_2\\\|\\CH\\|\\CHO\end{matrix} \quad (5)$$

$R = C_{11}H_{23}$ or $C_{15}H_{31}$

On the contrary, UGDE in Eq. (3)'seems clearly not to decompose to acid anhydride and acrolein; this is supported by the fact that the yield of acrolein does not exceed about 50% of the theory.

The detection of the acid anhydrides in the neutral fractions was attempted in three ways. First, the IR spectra of the neutral fractions (pyrolysis temperature: 550°C) showed strong bands at 1810 cm^{-1} and 1740 cm^{-1}; these bands are characteristic of acid anhydrides. Secondly, the neutral fractions were analyzed quantitatively by the morpholine method;[13] the results are shown in Table 3.

Table 3. Acid anhydrides formation

Sample	Pyrolysis temperature (°C)	Acid anhydride (%)	From free acid
Trilaurin	450	4.3	
	550	6.0	2.2
Tripalmitin	450	2.7	0.8
	550	6.4	4.1

Acid anhydrides are also formed on the pyrolysis of free acids—on, for instance, the pyrolysis of lauric and palmitic acid at 550°C and 450°C respectively; the acid anhydrides from each acid are also listed in Table 3

Finally, tlc was carried out and the acid anhydrides were identified by comparing them with authentic samples.

Acrolein. In a series of ten experiments, about 0.3 m*l* of liquid was collected in the N_2 and N_3 traps; the major part of the liquid was acrolein, which was detected by glc in comparison with an authentic sample. In these cases, however, the pyrolysis products were passed directly into the 2,4-dinitrophenylhydrazine hydrochloride solution to form hydrazones (2,4-DNPH). Ketones (see below) were condensed in the N_1 trap; a small amount of acrolein was also obtained from the N_1 trap by the distillation of the carbon tetrachloride solution. This was converted to 2,4-DNPH and then added to the 2,4-DNPH obtained from the N_2 and N_3 traps. One example of these results is shown in Table 4.

Table 4. Acrolein formation

Sample (g)	2,4-DNPH (g)	Acrolein (g)	Yield (%) Found	Yield (%) Theoretical
Trilaurin 0.490	0.073	0.017	3.5	8.8
Tripalmitin 0.500	0.076	0.018	3.6	6.9

α-Olefins. Authentic samples of lauric and palmitic anhydride were pyrolyzed; they gave the corresponding acids in almost quantitative yields, which can be accounted for by the following reaction equation:

$$\begin{matrix} RCH_2C{=}O \\ \quad\quad\diagdown\!\!\diagup O \\ RCH_2C{=}O \end{matrix} \rightarrow RCH_2COOH + RCH{=}C{=}O \qquad (6)$$

$$R = C_{10}H_{21} \text{ or } C_{14}H_{29}$$

Thus, it was confirmed that acid anhydrides decomposed to acids and aldoketenes. However, as the ketenes formed seemed to be less volatile because of the long alkyl radical, and also not to be so stable because of the ketene group, they are thought to decompose during the pyrolysis as follows:[14]

$$RCH_2CH{=}C{=}O \rightarrow RCH_2CH{:} + CO \qquad (7)$$
$$\downarrow$$
$$RCH{=}CH_2$$

Using alumina as an adsorbent, the column chromatography of the pyrolysis products of triglycerides was carried out; the fractions eluted by petroleum ether showed IR spectra identical with α-olefins (1810,1645, 1420, 990, and 910 cm^{-1}).

The tlc of the pyrolysis products of triglycerides, using the pyrolysis products of alkyl ketene dimers (next paragraph) as the standard, also indicated the existence of α-olefins ($Rf \fallingdotseq 1$).

Because of the unstability of ketene, these ketene monomers have not yet been isolated.[15] Therefore, the decyl ketene dimer and the tetradecyl ketene dimer were prepared from acid chlorides and triethylamine[16] respectively: they were pyrolyzed, and the IR of the expected ketenes were measured. In these cases, however, the IR spectra were the same as those of α-olefins.

Ketones. Laurone and palmitone were detected in the pyrolysis products by tlc, and were identified by using authentic samples as the standard. Oximes of laurone (mp 36—37°C) and palmitone (mp 59—60 °C) were also obtained. In addition to these ketones, various other ketones seemed to be formed.[2]

In this experiment, laurone (from trilaurin) and palmitone (from tripalmitin) have been identified, although they were present in small amounts. Accordingly, it seems that these ketones were not formed directly from triglycerides, but that they were formed secondarily from fatty acids which were themselves originated by the decomposition of triglycerides.[2] Supposing that the ketones are formed from the triglycerides directly, Eq. (8) (Crossley[1]) has to hold:

$$\begin{matrix} CH_2OCOR \\ | \\ CHOCOR \\ | \\ CH_2OCOR \end{matrix} \rightarrow RCOOH + RCOR + CO_2 + CH_2{=}CHCHO \qquad (8)$$

$$R = C_{11}H_{23} \text{ or } C_{15}H_{31}$$

The fatty acids obtained in this experiment account for about 50%, but their the oretical yields, as calculated from Eq. (8), are about 30%. This difference is fairly

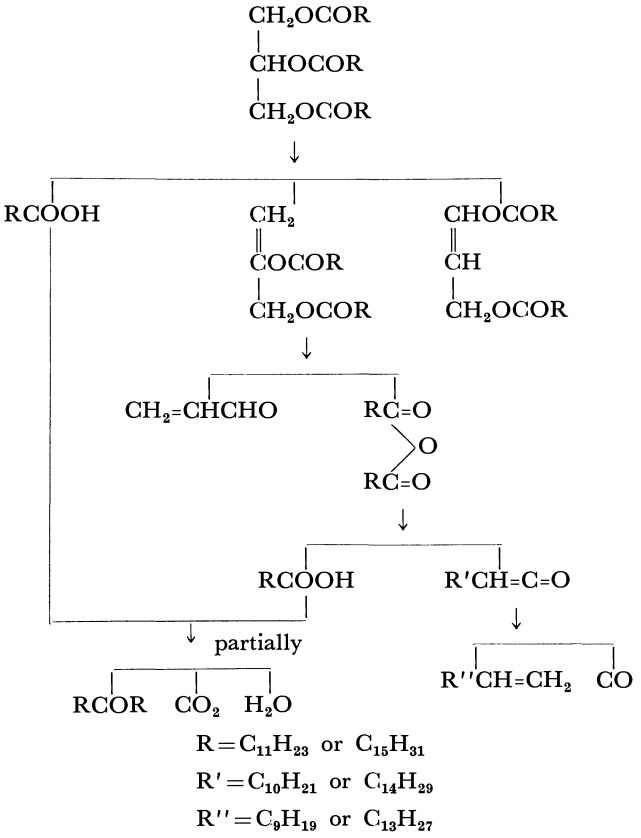
1: α-Olefins (from ketenes)
2: Ketones 3: Triglycerides
4: UGDE 5: Acid anhydrides
Coating material: Silica gel G
Developing solvents: Petroleum ether, ether and acetic acid (70 : 30 : 2)
Indicator: Sulfuric acid and charring

Conclusion

The main pyrolysis products and pyrolysis intermediate products, *etc.* discussed above, are summarized in Table 5. According to these experimental results and the discussion, the reaction mechanism of the pyrolysis of triglycerides in an atmoshere of nitrogen may be postulated to be as follows:



$R = C_{11}H_{23}$ or $C_{15}H_{31}$

$R' = C_{10}H_{21}$ or $C_{14}H_{29}$

$R'' = C_9H_{19}$ or $C_{13}H_{27}$

A Novel Synthesis of 4*H*-1,3-Thiazin-4-one Derivatives

Masataka YOKOYAMA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba

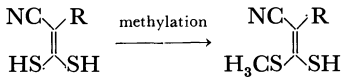
(Received July 20, 1970)

4*H*-2,5,6-Substituted-2,3-dihydro-1,3-thiazin-4-ones were synthesized by the condensation reaction of β-alkylthio-β-mercapto-α-cyanoacrylamide with a variety of ketones and aldehydes in an acidic medium.

The monomethyl ether of enedithiols **1** proved to display different nature according to the R groups (Scheme 1). When R was carbamoyl, the resulting β-methylthio-β-mercapto-α-cyanoacrylamide (**2d**$_1$) was stable colorless needles. When R was alkoxycarbonyl, methyl β-methylthio-β-mercapto-α-cyanoacrylate (**2b**) and ethyl β-methylthio-β-mercapto-α-cyanoacrylate (**2c**) which were obtained as colorless needles, upon heating at 35—40°C, easily changed into stable yellow materials ($C_{12}H_{14}N_2S_5O_4$ for **2b** and $C_{14}H_{18}N_2S_5O_4$ for **2c**). The yellow materials were not examined in the present work. When R was cyano, a dialkyl enedithiol was obtained instead of **2a**. The ease of the complete methylation of **2a** may be due mainly to the less steric hindrance of cyano as the R group.

In view of the NMR and IR spectra of **2d**$_1$, the structure of **2d**$_1$ is probably "zwitterion"; **2d**$_1$ may be more stable than **2b** and **2c** because of this zwitterion structure.

Using the nucleophilic character of the mercapto group of β-alkylthio-β-mercapto-α-cyanoacrylamide (**2d**), the present investigation was directed to exploring the reaction of **2d** with ketones and aldehydes (**3**). Compound **2d**, in the presence of sulfuric acid, easily reacted with a series of ketones and aldehydes to give 4*H*-2,2-disubstituted-6-alkylthio-5-cyano-2,3-dihydro-1,3-thiazin-4-ones.



1 **2**

1a, **2a**: R=CN; **1b**, **2b**: R=CO_2CH_3;
1c, **2c**: R=$CO_2C_2H_5$; **1d**, **2d**$_1$: R=$CONH_2$

Scheme 1

The formation of **5** was considered to proceed through an intermediate **4** in the reaction of **2d** with **3**, because β,β-bis(methylthio)-α-cyanoacrylamide and **3** did not react in the presence of sulfuric acid to give *N*-addition

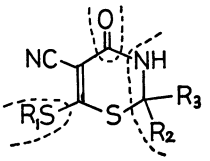
a) Mass spectra were measured with a Nihon Denshi JMS-01 SG mass spectrometer. Ionizing energy was maintained at 75 eV and the total ionizing current was 200 μA.

derivatives (Scheme 2).

Table 1 shows the appearance, melting points, and yields of **5** of the present method. The structure of **5** was determined by studying the reaction process and the results of elemental analysis (Table 6) and the IR, NMR and mass spectra. In this reaction, β-ethoxycarbonylmethylthio-β-mercapto-α-cyanoacrylamide (**2d$_3$**) was treated with methanol using as solvent in the presence of acidic catalyst and converted into 4*H*-2,2-disubstituted-5-cyano-2,3-dihydro-6-methoxycarbonylthio-1,3-thiazin-4-one (**5o**—**r**) by the ester interchange.

The NMR spectra of **5m** revealed a broad peak at δ8.30 characteristic for NH, and a peak of R_2 at δ6.20 was split by the effect of NH. The mass spectra of **5** showed four characteristic fragments (Table 2); (M—NHR_2R_3), (M—CO), (M—NHR_2R_3—SR_1), and (M—NHR_2R_3—SR_1—CO). The fragments were considered to be formed by the following fragmentation.



The derivatives of 4*H*-1,3-thiazin-4-one have previously been synthesized through the reaction of methyl β-thiocarbamoylthiopropionate with sulfuric acid,[1] of substituted thiosemicarbazides with dimethyl acetylenedicarboxylate,[2] and of *N*-substituted dithiocarbamic acid with propionic acid.[3] The 4*H*-1,3-thiazin-4-one derivatives hitherto reported have been 4*H*-5,6-dihydro-1,3-thiazin-4-ones. This is a new preparative method leading to 4*H*-2,3-dihydro-1,3-thiazin-4-one derivatives, which have not yet been reported. The UV spectra showed the absorption near 225 mμ corresponding to the π—π^* of the carbonyl group and near 275 mμ corresponding to the π—π^* of the double bond (Table 3).

order of multiplicity (s=singlet, d=doublet, t=triplet, q=quartet, and m=multiplet), integration, and assignment.

Preparation of β,β-Dimercapto-α-cyanoacrylonitrile (1a), Methyl β,β-Dimercapto-α-cyanoacrylate (1b), Ethyl β,β-Dimercapto-α-cyanoacrylate (1c), and β,β-Dimercapto-α-cyanoacrylamide (1d). Sodium salts of **1a**, **1b**, and **1c** were prepared by Gompper's method.[4] Ammonium salt of **1d** was prepared from the reaction of ethyl cyanoacetate, carbon disulfide, and aqueous ammonia.[5]

The alkylation of **1a**, **1b**, **1c**, and **1d** was worked up with dimethyl sulfate and diethyl sulfate in the usual way.

Conversion of 1d into β-Alkylthio-β-mercaptoacrylamide (2d). To a mixture of diammonium salt of **1d** (21 g, 0.11 mol) and methanol (100 m*l*) was added dimethyl sulfate (10 m*l*, 0.11 mol) slowly under stirring below 20°C. The reaction mixture was allowed to stand for 8 hr and poured into water (500 m*l*). The yellow solution was acidified with concentrated hydrochloric acid (30 m*l*). The colorless material was collected by filtration, washed with dilute hydrochloric acid, dried, and recrystallized from methanol to give ca. 18 g of colorless needles (β-methylthio-β-mercapto-α-cyanoacrylamide, **2d**$_1$): yield 95%; mp 149—150°C (dec) (reported mp 145—146°C (dec)[4]). The IR spectrum coincided with that of the compound which was prepared from potassium hydroxide, cyanoacetamide, carbon disulfide, and methyl iodide by Gompper's method.[4]

The ethylation of **1d** was worked up as mentioned in the methylation of **1d**. The crude material was recrystallized from methanol-water to give colorless needles (β-ethylthio-β-mercapto-α-cyanoacrylamide, **2d**$_2$): yield 98%; mp 116—117°C (dec); UV_{max} (99% EtOH): 227 mμ (log ε 4.16), 292.5 (3.97), 343 (4.01); Mass spectrum (75 eV) *m/e* (rel. intensity): 188 (100, M^+), 171 (20, $-NH_3$), 160 (13, –CO), 127 (73, $-SC_2H_5$); IR (KBr): 3420, 3280, 3180 (NH_3^+), 2980, 2920 (CH), 2200 (conj. CN), 1650 (CO), 1550 (conj. C=C), 1450 cm^{-1} (CH); NMR (DMSO-d_6) δ: 7.75 (broad, 3H, NH_3^+), 3.15 (q, 2H, CH_2, J=7 Hz), 1.42 (t, 3H, CH_3, J=7 Hz). Found: C, 38.19; H, 3.99; N, 14.93; S, 33.98%; mol wt (mass), 188. Calcd for $C_6H_8N_2S_2O$: C, 38.29; H, 4.25; N, 14.88; S, 34.07%; mol wt, 188.18.

The preparation of β-ethoxycarbonylmethylthio-β-mercapto-α-cyanoacrylamide (**2d**$_3$) was worked up as follows. To a mixture of potassium hydroxide (22.4 g, 0.4 mol) and methanol (120 m*l*) was added cyanoacetamide (16.8 g, 0.2 mol) and then carbon disulfide (12 m*l*) under cooling below 20°C. Ethyl bromoacetate (22 m*l*, 0.2 mol) was added slowly to the reaction mixture under cooling below 20°C. The mixture was allowed to stand for 5 min at 0°C, poured into water (500 m*l*), and acidified with concentrated hydrochloric acid (30 m*l*) to give a colorless precipitation. The crude product was collected by filtration, washed with dilute hydrochloric acid, dried, and recrystallized from methanol to give 30 g of colorless prisms: yield 65%; mp 138—139°C (dec); UV_{max} (99% EtOH): 220 mμ (sh, log ε 4.02), 277.5 (3.78), 334 (3.87); Mass spectrum (75 eV) *m/e* (rel. intensity): 246 (27, M^+), 232 (40, $-CH_2$), 215 (8, $-NH_3$), 200 (50, $-C_2H_5$, $-NH_3$), 127 (100, $-SCH_2CO_2C_2H_5$); IR (KBr): 3320, 3240, 316 (NH_3^+), 2960 (CH), 2200 (conj. CN), 1730 ($COOC_2H_5$), 1655 (CO), 1530 (conj. C=C), 1485 (CH), 1298 cm^{-1} (C–O–C). Found: C, 38.91; H, 4.04; N, 11.11; S, 26.20%; mol wt (mass), 246. Calcd for $C_8H_{10}N_2S_2O_3$; C, 39.03; T, 4.06; N, 11.37; S, 26.04%; mol wt, 246.20.

Preparation of 4H-5-*cyano*-2,3-*dihydro*-6-*methylthio*-1,3-*thiazin*-4-*one*-2-*spirocyclohexane (5a).* A mixture of cyclohexanone (5 g, 0.05 mol), β-methylthio-β-mercapto-α-cyanoacrylamide (3 g, 0.02 mol), 2% sulfuric acid (10 m*l*), and methanol (50 m*l*) was refluxed for 10 min. The crude material was collected by filtration, washed with methanol, dried, and recrystallized from acetic acid to give 4 g of colorless plates (**5a**); IR (KBr): 3280, 3160, 3040 (NH), 2900 (CH), 2220 (conj. CN), 1650 (CO), 1470 cm^{-1} (CH); NMR (CF_3CO_2H)δ: 8.30 (broad, 1H, NH), 2.78 (s, 3H, SCH_3), 2.20 (m, 4H, $2CH_2$), 1.75 (m, 6H, $3CH_2$). Found: C, 51.74; H, 5.48; N, 10.95; S, 25.19%; mol wt (mass), 254. Calcd for $C_{11}H_{14}N_2S_2O$: C, 51.96; H, 5.50; N, 11.01; S, 25.22%; mol wt, 254.23.

The preparations of **5b** to **5r** were worked up as mentioned in the isolation of **5a**. The appearance, melting

The Michael Reaction of Fluoro-substituted-9,9′-Bifluorenylidenes and -Fluorenes, and the Syntheses of Some Related Compounds[1]

Masahiro MINABE, Akio TANAKA,* Masahiro WAKUI,** and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya

(Received September 3, 1970)

The Michael reaction of fluoro-substituted 9,9′-bifluorenylidenes and fluorenes was carried out; the normal addition products, fluoro-substituted tribiphenylenepropanes, were obtained, but no abnormal product was isolated. Some new fluoro-substituted-fluorenes, -9,9′-bifluorenylidenes, -9,9′-bifluorenyls and -α,δ-dibiphenylenebutadienes, were synthesized. The structures of the fluoro-substituted tribiphenylenepropanes were confirmed by the lithium-halogen interconversion reaction of 9-lithiofluorenes and 9-bromo-9,9′-bifluorenyls. The pyrolyses of fluoro-substituted tribiphenylenepropanes afforded fluoro-substituted or nonfluoro-substituted-9,9′-bifluorenylidenes, -9,9′-bifluorenyls, -fluorenes, and -fluorenones. Differential scanning calorimetry was applied to fluoro-substituted-9,9′-bifluorenyls and -tribiphenylenepropanes.

The Michael reaction[2] of 9,9′-bifluorenylidene (**4**) with 2,7-dibromofluorene gave the normal product, 2′,7′-dibromotribiphenylenepropane, together with the abnormal 2′,7′,2″,7″-tetrabromotribiphenylenepropane and tribiphenylenepropane. Also, normal 2,7,2′,7′-tetrabromotribiphenylenepropane and the abnormal 2′,7′-dibromotribiphenylenepropane, 2′,7′,2″,7″-tetrabromotribiphenylenepropane and tribiphenylenepropane were similarly obtained from 2,7,2′,7′-tetrabromo-9,9′-bifluorenylidene and fluorene (**1**). The formation of these abnormal products was explained by a combination of addition, elimination, and protonation processes in the presence of sodium hydroxide-pyridine solution. The normal products were primarily obtained in the presence of sodium ethoxide, as has previously been reported in this series.[2,3]

The present paper will deal with another Michael reaction, that of fluoro-substituted 9,9′-bifluorenylidenes and fluorenes. The experiments were designed primarily to clarify any effects due to the difference between fluoro-substitution. Secondly, the new fluoro-substituted compounds were synthesized in order to compare their properties with those of other, corresponding halogeno compounds.

The Michael reaction of **4**[4] and 2-fluorofluorene (**2**)[5] with potassium hydroxide in pyridine or with sodium ethoxide in ethanol gave 2′-fluorotribiphenylenepropane (**12**), 2-fluorofluorenone (**10**),[5] and recovered materials. The yield of **12** increased with an increase in the base concentration (see Table 1, Runs 1—6.)

When the reaction of 2,2′-difluoro-9,9′-bifluorenylidene (**6**)[5,6] with **1** was carried out under similar base conditions, 2,2′-difluorotribiphenylenepropane (**13**) and **10** were obtained (see Table 1, Runs 7—9).

An analogous reaction between **4** and 2,7-difluorofluorene (**3**)[7] yielded 2′,7′-difluorotribiphenylenepropane (**16**) exclusively (see Table 2, Runs 1—4). Further the condensation of 2,7,2′,7′-tetrafluoro-9,9′-bifluorenylidene (**8**) with **1** led to 2,7,2′,7′-tetrafluorotribiphenylenepropane (**17**) in a good yield (see Table 2, Runs 5—7).

The sequence for the formation of these addition products is shown in Scheme I. While a 9-fluorenyl carbanion (A′) is generated from (A) in the presence of a base, a new bond in carbanion (C′) can be formed by the attack of (A′) on the highly-polarized central double bond of (B). Then, (C′) may be transformed to the normal addition product (C) by protonation.

From 2- or 2,7-di-bromo-,[2] -iodo-, and -chloro-[8] derivatives, the normal and abnormal compounds were produced; however, in the corresponding fluoro derivatives, only the normal compounds were formed under the same conditions. These results can be explained in terms of the inductive effect of the fluorine atoms, which may operate on the 9′-methine carbon atom in the ion (C′); the 9′-hydrogen atom causes an increase in electron availability, and, consequently, the 9″-carbon is protonated in preference to the removal of a 9′-proton (*i.e.*, examples **12** and **16**). Likewise affected is the 9″-carbon (*i.e.*, examples **13** and **17**), so that the fission of the 9-9″ carbon-carbon bond is controlled; therefore, the 9″-carbon can be protonated with ease to form the normal compounds.

It can be assumed that the (C′) and (C″) ions could hardly attain equilibrium under such reaction conditions, so that the ions can be subjected to protonation with a fairly rapid formation of the corresponding tribiphenylenepropanes.

2,2′,2″-Trifluorotribiphenylenepropane (**15**) and 2,7,2′,7′,2″,7″-hexafluorotribiphenylenepropane (**19**) were obtained by the reaction of **6** and **2**, and by that

of **8** and **3**, respectively (see Table 1, Run 10 and Table 2, Run 8). These Michael products could be expected as normal products, but the stereoisomeric tribiphenylenepropanes[3b,9] were not isolated. The reactions of 2-fluoro-9,9′-bifluorenylidene (**5**) with **2** or **1** gave 2′,2″-difluoro-9,9′-bifluorotribiphenylenepropane (**14**) or **12** (see Table 1, Runs 11 and 12). Similarly, the reactions of 2,7-difluoro-9,9′-bifluorenylidene (**7**) with **3** or **1** afforded 2′,7′,2″,7″-tetrafluorotribiphenylenepropane (**18**) or **16** respectively (see Table 2, Runs 9 and 10).

Four fluoro-substituted 9,9′-bifluorenyls, *i.e.*, 2-fluoro- (**21**) (mp 243—244°C), 2,2′-difluoro- (**22**)[5] (mp 241—242°C), 2,7-difluoro- (**23**) (mp 241.5—242.5°C), and 2,7,2′,7′-tetrafluoro-9,9′-bifluorenyl (**24**) (mp 241—242°C), were obtained by the reduction of the corresponding 9,9′-bifluorenylidenes. Interestingly, these melting points are very close to that of 9,9′-bifluorenyl (**20**)[10] (mp 244—245°C).

The related fluoro-substituted 9-hydroxy-9,9′-bifluorenyls and 9-bromo-9,9′-bifluorenyls were synthesized in the usual way, as is shown in Table 4. Ten fluoro-substituted tribiphenylenepropanes were prepared and confirmed by the reaction of 9-lithiofluorenes and 9-bromo-9,9′-bifluorenyls, as is summarized in Table 5.

The pyrolyses of **19**, **17**, **13**, and **12** were also carried out. The carbon-fluorine bonds being stable under such thermal conditions, fluoro-substituted- or non-fluoro-substituted- 9,9′-bifluorenylidenes, -9,9′-bifluorenyls, -fluorenes, -fluorenones, and recovered tribiphenylenepropanes were obtained. The thermal behavior was analogous to that proposed previously.[1,3a]

The thermal behavior of the 9,9′-bifluorenyls (**20**, **21**, **22**, **23**, and **24**) and the fluoro-substituted tribiphenylenepropanes (**12**, **13**, **15**, **16**, **17**, and **19**) was studied. Typical thermograms of **13** and **24** are shown in Fig. 1.

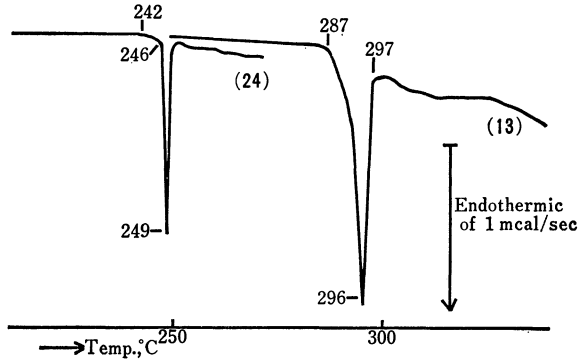

Fig. 1. Differential scanning calorimeter thermograms of **13** and **24**.

In the (**24**) thermogram, the sharp, first single peak curved slowly at 242°C and then steeply at 246°C to reach the inflection point, 249°C, of the melting endotherm, which corresponds to the melting point (241—242°C) of **24**. The peak indicates that **24** is thermally "unreactive."

The second major endothermic peak, centering at 287°C and 297°C in the thermogram (**13**), corresponds to the melting point (289—290°C (dec)), but it is relatively broader than that of **24**. This may be due to its being thermally "reactive" at the melting point. The further endothermal tendency of **13** after the melting peak indicates the formation of pyrolysates and their secondary pyrolyses. In addition, an analogous thermal behavior was observed for other compounds.

Experimental[11]

The IR spectra were recorded on KBr pellets using a JASCO model IR-G spectrophotometer (Japan Spectroscopic Co., Ltd.).

Measurements of DSC Thermograms. The instrument used in this series was a differential scanning calorimeter, Model DSC-1B (Perkin-Elmer Corp.). The experiments were run with a sensitivity of ±4 mcal/sec under an atmosphere of nitrogen, at a scan time of 8°C/min and a chart speed of 0.5 inch/min. Each sample, **24** (0.63 mg) and **13** (3.27 mg), was packed in aluminum pans with a volatile sample sealer.

Syntheses of 9-Bromofluorenes. 2-Fluoro-9-bromofluorene: a) A mixture of 2.0 g of **2**, 2.0 g of *N*-bromosuccinimide (NBS), and 10 m*l* of anhydrous benzene was refluxed for 3 hr to afford 2.1 g (75%) of colorless 2-fluoro-9-bromofluorene (mp 112—113°C) from cyclohexane. Found: C, 59.33; H, 2.69. Calcd for $C_{13}H_8FBr$: C, 59.35; H, 3.06%.

b) 2-Fluorofluoren-9-ol[12] (0.40 g; 0.002 mol) in 10 m*l* of acetic acid was saturated with hydrogen bromide at room temperature, after which the mixture was allowed to stand overnight. The removal of the solvent under reduced pressure, washing with water, and extraction with 10 m*l* of cyclohexane yielded 0.40 g (76%) of colorless needles, mp 113—114°C, identical in all respects with the product obtained by Method a.

2-Fluoro-7-nitrofluoren-9-one: A 0.92-g (0.004 mol) portion of 2-fluoro-7-nitrofluorene[7b,13] was oxidized by sodium bichromate and recrystallized from benzene; 0.79 g (86%) of ketone was obtained as yellow needles, mp 201—202.5°C. IR (>C=O): 1716 cm^{-1}.

Found: C, 64.17; H, 2.52; N, 5.55%. Calcd for $C_{13}H_6NO_3F$: C, 64.21; H, 2.49; N, 5.76%.

2,7-Difluorofluoren-9-ol: The foregoing 2,7-difluorofluorenone (**11**)[14] was subjected to reduction with zinc dust and aqueous ammonium hydroxide in ethanol, and recrystallized from aqueous methanol (25%); it gave a quantitative yield of 2,7-difluorofluoren-9-ol, mp 165.5—166°C, as fine, colorless needles. IR (-OH): 3190—3290 cm^{-1}.

2,7-Difluoro-9-bromofluorene: a) The bromination of 2,7-difluorofluoren-9-ol (5.0 g) with dry hydrogen bromide yielded 5.8 g (90%) of 2,7-difluoro-9-bromofluorene, mp 136—138°C. Found: C, 55.94; H, 2.34. Calcd for $C_{13}H_7F_2Br$: C, 55.55; H, 2.51%.

b) A 3.0-g portion of **3** was worked up with NBS; it formed 3.3 g (79%) of 2,7-difluoro-9-bromofluorene, identical in all respects with the product obtained by Method a.

*Syntheses of 9,9′-Bifluorenylidenes. 2-Fluoro-9,9′-bifluorenylidene (**5**)*: A mixture of 10.2 g of 2-fluoro-9′-hydroxy-9,9′-bifluorenyl, 400 m*l* of acetic acid, and 5 m*l* of concentrated sulfuric acid was refluxed for 30 min. The reaction mixtures was then evaporated to 50 m*l* under reduced pressure, and the precipitate was filtered off, washed with water, and extracted with 100 m*l* of acetone. Red needles (4.1 g) of **5**, mp 208—209°C, formed, while the concentration of the mother liquor yielded an additional 2.6 g of **5** (total: 6.7 g, 69%). Found: C, 90.40; H, 4.20%. Calcd for $C_{26}H_{15}F$: C, 90.15; H, 4.36%.

*2,7-Difluoro-9,9′-bifluorenylidene (**7**)*: A 0.8-g portion of 2,7-difluoro-9′-hydroxy-9,9′-bifluorenyl was worked up as in the synthesis of **5**; **7** was thus obtained (0.45 g; 59%) as red needles, mp 224—225°C.

Found: C, 86.00; H, 3.53%. Calcd for $C_{26}H_{14}F_2$: C, 85.70; H, 3.87%.

*2,2′-Difluoro-9,9′-bifluorenylidene (**6**)*. a) **6** was prepared from 2-fluoro-9-bromofluorene (1.32 g; 0.005 mol), as in the case of **4**; 0.7 g (84%); mp 226—227°C.

Found: C, 86.04; H, 3.54%. Calcd for $C_{26}H_{14}F_2$: C, 85.70; H, 3.87%.

b) A benzene (20 m*l*) solution of 1.11 g (0.0025 mol) of 2,2′-difluoro-9-bromo-9,9′-bifluorenyl was percolated through an alumina column (45 g of activated alumina: for chromatography, 300 mesh, Wako Pure Chemical Ind. Ltd.; column: 1.8 cmϕ × 18 cm). The colorless solution immediately turned red over alumina, and the red band formed was eluted with benzene. The red solution was evaporated

11) All the melting points are uncorrected.

12) G. G. Smith and R. P. Bayer, *Tetrahedron*, **18**, 323 (1962) (*Chem. Abstr.*, **57**, 8515 (1962)).

13) J. A. Miller, R. B. Sandin, E. C. Miller, and H. P. Rusch, *Cancer Res.*, **15**, 188 (1955) (*Chem. Abstr.*, **49**, 16178 (1955)).

14) H. L. Pan and T. L. Fletcher, *J. Med. Chem.*, **8**, 491 (1965).

to dryness under reduced pressure; subsequent recrystallization from acetic acid gave 0.78 g (86%) of **6** (mp 226.5—227°C).

*2,7,2',7'-Tetrafluoro-9,9'-bifluorenylidene (**8**).* An acetone (34 m*l*) solution of 3.2 g of 2,7-difluoro-9-bromofluorene was treated with potassium hydroxide-methanol (0.64 g/14 m*l*) to give 2.1 g (92%) of red **8**, mp 337—338°C (dec).

Found: C, 78.06; H, 3.10%. Calcd for $C_{26}H_{12}F_4$: C, 78.00; H, 3.02%.

Syntheses of 9,9'-Bifluorenyls. Typical Procedure: A mixture of 0.10 g of **5**, 20 m*l* of acetic acid, 1 g of zinc dust, and 1 m*l* of hydrochloric acid was refluxed for 2 hr. The reaction mixture was filtered, the filtrate was poured into cold water, and the precipritate was recrystalized from a mixture of benzene and ethanol (1 : 1) to give 0.10 g of colorless needles, **21**, mp 243—244°C.

Formation of 2,2'-Difluoro-α,δ-dibiphenylenebutadiene and 2,7,2',7'-Tetrafluoro-α,δ-dibiphenylenebutadiene. A mixture of 0.5 g of **2**, 45 m*l* of ethanol, and 2.5 g of potassium hydroxide in 5 m*l* of water was refluxed under a gentle stream of air for 24 hr. The precipitate was recrystallized from pyridine to give 0.14 g (26%) of 2,2'-difluoro-α,δ-dibiphenylenebutadiene as orange needles with a mp of 392—393°C (dec). Found: C, 86.21; H, 4.30%. Calcd for $C_{28}H_{16}F_2$: C, 86.14; H, 4.13%. In addition, 0.10 g (20%) of **2** and 0.21 g (39%) of **10** were isolated from the ethanol mother solution.

2,7,2',7'-Tetrafluoro-α,δ-dibiphenylenebutadiene was prepared by the same procedure as before. Yield, 23% of fine orange-red needles, mp 398°C (dec). Found: C, 78.85; H, 3.23%. Calcd for $C_{28}H_{14}F_4$: C, 78.87; H, 3.31%.

The Michael Reaction of 9,9'-Bifluorenylidenes and Fluorenes. Typical Procedure: A Mixture of 1.34 g (1/300 mol) of **8**, 1.11 g (1/150 mol) of **1**, 28 m*l* of pyridine, and 3 g of potassium hydroxide in 2 m*l* of water was placed in a sealed tube and heated at 93—95°C for 2 hr. During this period, the color turned from red to dark green.

The reaction mixture was poured into 40 m*l* of methanol, and the precipitate was filtered off, washed with water, recrystallized from ethyl acetate, and from a mixture of benzene and ethanol to give 1.37 g of **17**, mp 286—287°C (dec.).

The pyridine-methanol mother solution was poured into 500 m*l* of water, and the precipitate was sublimed *in vacuo* at 150°C to yield an additional 0.23 g (total 1.60 g; 85%) of **17** from the sublimation residue.

The sublimed part was extracted with 50 m*l* of cyclohexane, and the extract was chromatographed on alumina; 0.58 g of **1**, mp 110—112°C, and 0.04 g of **11**, mp 200—201°C, were thus isolated. Further, 0.06 g (total 0.10 g) of **11** was obtained from the insoluble portion.

The identities of the compounds in this series were confirmed by mixed-melting-point determinations and by a comparison of the IR absorption spectra with those of authentic samples.

Syntheses of 9-Hydroxy-9,9'-bifluorenyls and 9-Bromo-9,9'-bifluorenyls. General Procedure: The reaction was carried out in the usual way. *n*-Butyllithium was prepared from 2.8 g of *n*-butyl bromide in 20 m*l* of anhydrous ether and 0.4 g of lithium chips in 40 m*l* of anhydrous ether. 2,7-Difluoro-9-lithiofluorene was prepared by adding 3.2 g of **3** in 40 m*l* of anhydrous benzene to the *n*-butyllithium solution. To this mixture we then added 150 m*l* of anhydrous benzene containing 3.0 g of **11**. Then, the reaction mixture was worked up as usual. 2,7,2',7'-Tetrafluoro-9-hydroxy-9,9'-bifluorenyl was prepared in a good yield (5.3 g; 91%), mp 188—189°C, from cyclohexane.

A 4.6-g portion of 2,7,2',7'-tetrafluoro-9-hydroxy-9,9'-bifluorenyl in 50 m*l* of acetic acid was saturated with dry hydrogen bromide at room temperature, after which the reaction mixture was allowed to stand overnight. Crystals of 2,7,2',7'-tetrafluoro-9-bromo-9,9'-bifluorenyl (4.8 g) were thus obtained, mp 175—176°C (dec), from cyclohexane.

*Formation of 2',2''-Difluorotribiphenylenepropane (**14**) by a Lithium-halogen Interconversion Reaction.* *n*-Butyllithium was prepared from 0.69 g of *n*-butyl bromide in 10 m*l* of anhydrous ether and 0.08 g of lithium chips in 20 m*l* of anhydrous ether. Then 2-fluoro-9-lithiofluorene was formed by adding 0.74 g of **2** in 15 m*l* of anhydrous benzene to the *n*-butyllithium solution. Into this resulting mixture there were slowly stirred 40 m*l* of anhydrous benzene containing 1.28 g of 2-fluoro-9'-bromo-9,9'-bifluorenyl. After standing overnight, the reaction mixture was treated as usual to give 0.18 g (12%) of **14** from ethyl acetate, mp 282—283°C (dec).

All the syntheses of this series were carried out in a similar manner.

*Pyrolysis of 2,7,2',7',2'',7''-Hexafluorotribiphenylenepropane (**19**).* Finely-powdered **19** (2.41 g; 0.004 mol) was heated at 310—320°C for 3.5 min in a 200-m*l* Erlenmeyer flask. The red molten product was extracted with 50 m*l* of boiling cyclohexane. The extract was allowed to stand overnight, and the deposit was combined with the insoluble portion. Upon fractional crystallization from benzene and ethyl acetate, *0.28* g of **8**, mp 336—338°C (dec), *0.76* g of **24**, mp 238—239°C, and 0.84 g of recovered **19**, mp 303—304°C (dec) were separated.

The cyclohexane mother solution was chromatographed on an alumina column; 0.02 g of **3**, mp 79—81°C, and 0.05 g of **11**, mp 203—205°C, were thus obtained.

*Pyrolysis of 2,7,2',7'-Tetrafluorotribiphenylenepropane (**17**).* A 2.84-g portion of **17** was heated at 310°C for 3 min. The following compounds were separated: 0.02 g of **8**, mp 335°C (dec), 0.20 g of **24**, mp 239—241°C, 0.28 g of **23**, mp 238—240°C, 0.05 g of **11**, mp 199—201°C, and recovered **17**, mp 285—286°C (dec).

*Pyrolysis of 2,2'-Difluorotribiphenylenepropane (**13**).* A 2.66-g portion of **13** was heated at 310—320°C for 2 min. Consequently, 0.37 g of **22**, mp 239—241°C, 0.80 g of **21**, mp 240—241.5°C, 0.12 g of **20**, mp 241—243°C, 0.16 g of **6**, mp 224—226°C, 0.23 g of **5**, mp 206—207°C, 0.02 g of **4**, mp 181—182.5°C, 0.09 g of **10**, mp 112—114°C, and 0.03 g of fluorenone (**9**), mp 80—81°C, were obtained. Further, 0.15 g of **13**, mp 288—289.5°C (dec) was recovered.

*Pyrolysis of 2'-Fluorotribiphenylenepropane (**12**).* The heating of 5.13 g of **12** at 300—305°C for 3 min gave 0.48 g of **21**, mp 239—241°C, 0.80 g of **20**, mp 239—240°C, 0.02 g of **6**, mp 219—222°C, 0.26 g of **5**, mp 205—207°C, 0.23 g of **4**, mp 181—182°C, 0.004 g of **10**, mp 113—114°C, 0.02 g of **9**, mp 81—81.5°C, 0.01 g of **1**, mp 113—115°C, and 1.73 g of recovered **12**, mp 280—281.5°C (dec).

The identities of the compounds in this series were confirmed by a comparison of their melting points and IR spectra with those of authentic samples.

The authors wish to express their gratitude to Professor S. Mitsui, of Tohoku University, for his helpful discussions. They are also grateful to Drs. John and Elizabeth Weisburger of the National Institutes of Health, U.S.A., for supplying editorial assistance.

Substituents Effects on the Azo-Hydrazone Tautomerism of 4-Arylazo-2,6-di-*t*-butylphenols

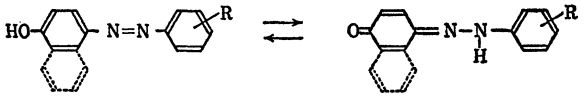
Eiichiro MANDA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

(Received September 14, 1970)

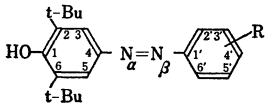
The substituents effects on the azo-hydrazone tautomerism of 4-arylazo-2,6-di-*t*-butylphenols in carbon tetrachloride were studied by means of infrared and visible spectra. The substituents effects on their absorption spectra were discussed. The azo tautomers are predominant in the tautomeric equilibria of 3'- and 4'-substituted derivatives. Considerable participations of the hydrazone tautomers are found in the equilibria of the 2'-substituted derivatives having substituents capable of forming intramolecular hydrogen bonding with hydrazone-hydrogen atom. In the equilibria of 2',6'-disubstituted derivatives, the positions of the equilibria move somewhat to the azo side from those of the corresponding 2'-substituted derivatives.

It is well known that the hydroxyazo dyes (I) show the azo-hydrazone tautomerism:



(I) - azo tautomer (I) - hydrazone tautomer

Many papers have been given on the naphthol derivatives of the dyes (I) since their tautomeric equilibria were found to show remarkable changes with their substituents and the solvents.[1-10] It has been observed that the electron-releasing substituents and the non-polar solvents favor the azo tautomers in equilibria. There are few papers on the phenol derivatives of (I). This might be due to the fact that the azo tautomers have been found predominant in equilibria. 4-Arylazo-2,6-di-*t*-butylphenols (II), which are the derivatives of hydroxyazo dyes (I), were prepared. The infrared and visible spectra of the phenols (II) in carbon tetrachloride solution showed interesting substituent effects on the tautomerism.



(II)

Results and Discussion

The results are summarised in Table 1.

Infrared Spectra. It has been pointed out that the dyes (I) show significant differences in their infrared spectra and that, among many absorption bands, the characteristic bands are the ν_{OH} band of the azo tautomer and the ν_{NH} and ν_{CO} bands of the hydrazone tautomer.[5,6] In this paper, each tautomer was studied by means of the ν_{OH} and the ν_{NH} bands, respectively, since the ν_{CO} bands appeared in the absorption region of the solvent.

ν_{OH} Bands: It has been reported that the ν_{OH} bands of (I) were sometimes found in the region of the ν_{NH} bands as a result of the hydrogen bondings, and some difficulties were encountered to distinguish the respective bands.[5] The infrared spectra of the azo tautomers of the phenols (II) always show sharp, monomeric ν_{OH} bands.[11] The bands are located nearly always at *ca.* 3640 cm^{-1}, while ν_{OH} bands of 4-substituted-2,6-di-*t*-butylphenols have been reported to shift within the region 3649—3626 cm^{-1} with their substituents.[12] The intensities vary with the substituents and tend to become smaller when the substituents displace the positions of the equilibria towards the hydrazone side.

ν_{NH} Bands: The bands are found in the region 3380—3280 cm^{-1} and the locations and the intensities vary not only with the substituents but also with substituting positions. Of 3'- and 4'-substituted derivatives, 4'-nitro derivative has a trace of ν_{NH} band, but no other derivative has it. Of 2'-substituted derivatives, methoxy, halogen and nitro derivatives have ν_{NH} bands, but not methyl derivative. The bands are due to the hydrazone tautomers which are favored in the equilibria by the additional stabilisation of the intramolecular hydrogen bonding between 2'-substituent and hydrazone-hydrogen atom.[6] The bands are also found in the spectra of 2',6'-dichloro, 2',6'-dibromo, 2',6'-dinitro, 2',4'-dinitro, and 2',4',6'-trinitro derivatives, in which intramolecular hydrogen bondings are also possible. The wave numbers of the ν_{NH} bands give the following order of locations:

$$2',4',6'\text{-}(NO_2)_3 - 2',6'\text{-}(NO_2)_2 - 2',4'\text{-}(NO_2)_2 - 2'\text{-}NO_2$$
$$- 2',6'\text{-}Cl_2 - 2',6'\text{-}Br_2 - 2'\text{-}Br_2 - 2'\text{-}Cl - 2'\text{-}MeO - 2'\text{-}F$$

The order might not be the order of the strengths of the intramolecular hydrogen bondings since the locations of the ν_{NH} bands have been observed to shift towards lower wave numbers with electron-attracting substituents in the unassociated 4-arylazo-1-naphthols

vw, w, m, s; relative intensities

ε_a, ε_h; molar extinction coefficients of azo and hydrazone bands, respectively.

in which the intramolecular hydrogen bondings are impossible.[6] Besides, the hydrogen bondings in 2',6'-disubstitted derivatives can be disturbed by the twisting of aryl nuclei. The molecular model inspections for the hydrazone tautomers of such geometries that the quinone nuclei and the aryl nuclei are in the same plane show that the distance between α-nitrogen atom and 2'-chlorine atom is *ca.* 2.3 Å, and the distance between α-nitrogen atom and the oxygen atom of 2'-nitro group is *ca.* 1.4 Å. Thus, it is very likely that aryl nuclei are twisted as a result of large steric repulsions.

Visible Spectra. The phenols (II) have two absorption maxima in the region 340—460 mμ and substituents change their locations and the molar extinction coefficients (ε) of the absorption maxima. It is well known that the hydroxyazo dyes (I) have two absorption maxima in the region 320—480 mμ, and the absorptions at shorter wavelengths originate from azo tautomers and the absorptions at longer wavelengths from hydrazone tautomers.[1-10,13,14] It is concluded from a comparison between infrared and visible spectra that the phenols (II) follow this relation. This is also supported by the fact that untautomerising 2,6-di-*t*-butyl-*p*-benzoquinone-*N*-methylphenylhydrazone has its absorption maximum at 437 mμ.

Azo Bands: Figure 1 gives the correlation of the Hammett substitution constants[15] and the wavelengths of the absorption maxima of the azo bands of 3'- and 4'-substituted derivatives. It is observed that the substituents of larger electron-releasing or -attracting powers show larger bathochromic effects, in which an anomalously large shift is caused by 4'-nitro group, and the shift by 3'-substituents are smaller than those by 4'-substituents. The absorptions may be due to π–π^* transitions of the completely conjugated π-electron systems of azo tautomers.[16] 2'-Substituted derivatives show bathochromic shifts to 3'- and 4'-isomers although hypsochromic shifts are expected because of the steric interaction between 2'-substituents and azo group. Thus, the observed bathochromic shifts might be due to the electronic effects of 2'-substituents stronger than 3'- and 4'-substituents. 2', 6'-Disubstituted derivatives, except for dinitro derivative, have their absorption maxima at wavelengths shorter than the corresponding 3'- and 4'-substituted derivatives. The planer conformations of 2',6'-disubstituted derivatives are impossible because of the steric repulsion between azo group and substituents. The molecular model inspection for the co-planer azo tautomer of 2',6'-dichloro derivative show that the distance between α-nitrogen atom and 2'-

chlorine atom is *ca.* 2.5 Å and that between β-nitrogen atom and 6′-chlorine atom is *ca.* 2.9 Å. Thus, the twist of the aryl nuclei may exist in the actual molecules and give rise to hypsochromic shifts. The bathochromic shift of 2′,6′-dinitro derivative may be due to the overwhelming electronic effects of two nitro groups.

Hydrazone Bands: Figure 2 gives the correlation

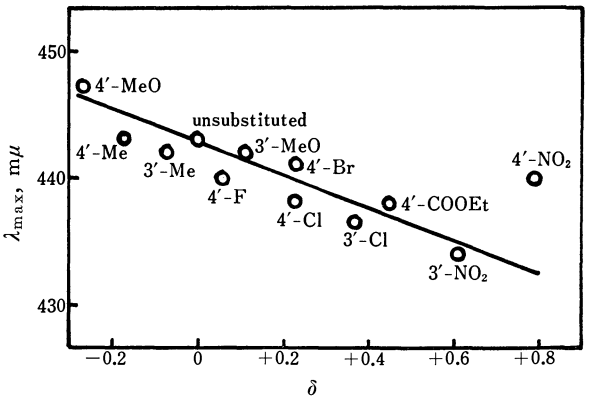

Fig. 2. The correlation of the Hammett substitution constants with the wavelength of the hydrazone bands of 3′- and 4′-substituted phenols(II).

of the Hammett substitution constants and the wavelengths of the absorption maxima of the hydrazone bands of 3′- and 4′-substituted derivatives. The electron-releasing substituents have the trend to shift the absorption maxima towards longer wavelengths and the electron-attracting substituents have the opposite trend. The same trend is observed in 2′-substituted derivatives except for 2′-nitro derivative. The bathochromic shift in 2′-nitro derivative is due to the strong intramolecular hydrogen bonding. 2′,6′-Disubstituted derivatives have the same trend as in 3′- and 4′-derivatives. But the locations of the absorption maxima are displaced to wavelengths shorter than those of the corresponding 2′-substituted derivatives owing to the twist of the aryl nuclei.

Tautomeric Equilibria. The position of the tautomeric equilibrium can be estimated with molar extinction coefficients ε at the absorption peaks in the infrared or visible spectra. The visible spectra, however, show that the disappearance of the ν_{NH} bands in the infrared spectra does not mean the absence of hydrazone tautomers. The small amount of the hydrazone tautomer will erase the weak ν_{NH} band. The position of the equilibria should be discussed by means of the molar extinction coefficients in the visible spectra when the true molar extinction coefficients of the individual tautomers are known and the location of the absorption maxima are separated sufficiently from each other.[3] On account of the above restrictions, the tautomeric equilibria of the phenols (II) can not be discussed quantitatively. The values of the ratio $\varepsilon_{\text{azo band}}/\varepsilon_{\text{azo band}} + \varepsilon_{\text{hydrazone band}}$ are caluculated in Table 1 since the values should indicate the positions of the tautomeric equilibria indirectly. The conclusions from these values and the infrared spectra are as follows. The azo tautomers are predominant in the tautomeric equilibria of 3′- and 4′-substituted derivatives. The electron-releasing substituents favor the hydrazone tautomers in equilibria. Considerable participation of the hydrazone tautomers is found in the equilibria of 2′-substituted derivatives having substituents which can form the intramolecular hydrogen bondings with the hydrazone-hydrogen atoms since the hydrazone tautomers are stabilised by intramolecular hydrogen bonding. In the equilibria of 2′,6′-disubstituted derivatives, the positions of the equilibria move somewhat to the azo side from those of the corresponding 2′-substituted derivatives. The disubstitution at 2′- and 6′-positions may disturb the intramolecular hydrogen bonding and diminish the stabilisation for hydrazone tautomers. In the equilibrium of 2′,4′,6′-trinitro derivative, however, the electronic effect is so large that the hydrazone tautomer is completely predominant.

Experimental

Phenols (II) were prepared through the condensation of 2,6-di-*t*-butyl-*p*-benzoquinone with arylhydrazine hydrochlorides or arylhydrazines (in case of dinitro and trinitro derivatives). Preparation of 4′-methyl derivative gives a typical example as follows: 2,6-di-*t*-butyl-*p*-benzoquinone (1.67 g, 0.0076 mol) was added to the ethanol solution (100 m*l*) of *p*-tolylhydrazine hydrochloride (1.45 g, 0.0091 mol), containing concentrated hydrochloric acid (5 m*l*). After the reaction mixture was kept standing for one week at room temperature, yellow crystals of 4-(4′-tolylazo)-2,6-di-*t*-butylphenol were precipitated by careful addition of water (*ca.* 30 m*l*) to the reaction mixture. The prepared phenols (II) were purified with recrystalisations from ethanol and silica gel column chromatography. The following melting points (°C) were observed for each crystal; 2′-MeO: orange plates, 163.4—164.0. 3′-MeO: yellow needles, 126.6—128.6.

Results of elementary analyses for the prepared compounds were in good agreement with theoritical values. The infrared spectra of the phenols (II) in carbon tetrachloride solution of 4.00×10^{-3} M in 1 mm NaCl cell were recorded with Shimadzu IR-27G Grating Spectrophotometer. The visible spectra of the phenols (II) in carbon tetrachloride solution of 2.00×10^{-3} M in 0.11 mm quartz cell were recorded with Hitachi EPS-2U Recording Spectrophotometer. Be0r's law was valid for the concentration higher than 5.00×10^{-3} M.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1623—1627 (1971)

The Radical Polymerization and Copolymerization of Triallylidene Sorbitol with Styrene or Acrylonitrile

Tatsuro Ouchi, Yoshikazu Yaguchi, and Masayoshi Oiwa

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received September 16, 1970)

The polymerization of triallylidene sorbitol (TAS) and the copolymerization of TAS with styrene (St) or acrylonitrile (AN) have been carried out, using benzoyl peroxide as an initiator at 80°C. They were kinetically investigated in relation to the degradative or effective chain transfer by the allylidene group, and by the cyclization by three double bonds. The results can be summarized as follows: 1) the relation among the rate of polymerization, R_p, the initiator concentration, (I), and the monomer concentration, (M), can be expressed by the following equation: $((I)/R_p-a)^{-1}=A(M)+B$, where a, A, and B are constant; 2) the ratio of the rate of unimolecular cyclization to the total rate of bimolecular propagation and the chain transfer of uncyclized radical was estimated to be 0.291; 3) the degree of polymerization depends on the monomer concentration, but not on the initiator concentration; 4) the rates of copolymerization decrease markedly with an increase in the TAS or tricrotylidene sorbitol (TCS) mole fraction in monomer mixtures; and 5) the following monomer reactivity ratios were ascertained: St(M_1)-TAS(M_2) $r_1=4.60$, $r_2=0.13$, AN(M_1)-TAS(M_2) $r_1=0.70$, $r_2=0.26$, St(M_1)-TCS(M_2) $r_1=2.31$, $r_2=0.39$, AN(M_1)-TCS(M_2) $r_1=0.30$, $r_2=0.36$. The Q and e values for the functional group were calculated from the above values as 0.05 and −0.08 (TAS), and 0.10 and −0.25 (TCS) respectively.

In a previous paper,[1] the polymerization of diallylidene pentaerythritol (DAPE) was kinetically investigated in relation to the degradative or effective chain transfer by the allylidene group, and by the cyclization by two double bonds in DAPE. The monomer reactivities have also been reported in the copolymerizations of DAPE or dicrotyridene pentaerythritol (DCPE) with various monomers.[2,3]

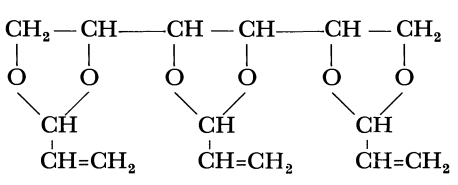
The present paper will deal with the polymerization of triallylidene sorbitol (TAS), and the difference between triallylidene and diallylidene cyclic acetal compounds will be kinetically discussed.

The copolymeizations of TAS and triallylidene pentaerythritol (TCS) with styrene (St) or acrylonitrile (AN) were carried out; they will be discussed by using the Gibbs equation.[4]

Experimental

Monomers. The TAS was prepared from D-sorbitol and acrolein by the procedure of Fisher and Smith;[5] bp 194—196°C/8 mmHg (lit,[5] bp 149—151°C/0.9 mmHg).

Found: C, 60.82; H, 6.88%; bromine value, 159; molecular weight, 296. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%; bromine value, 161; molecular weight, 296.



TAS

The TCS was synthesized with D-sorbitol and crotonaldehyde,[6] and was purified by extraction with light oil.

Found: C, 63.49; H, 7.78%; bromine value, 140; molecular weight, 340. Calcd for $C_{18}H_{26}O_6$: C, 63.89,

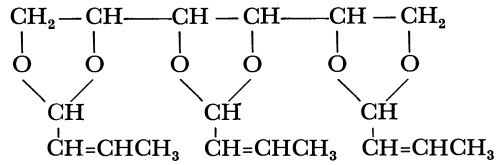
H, 7.75%; bromine value, 140; molecular weight, 338.



TCS

The St, AN, benzoyl peroxide (BPO), benzene, and dimethylformamide (DMF) were purified by the usual methods.

Polymerization Procedure. The polymerization was carried out using BPO as a radical initiator. Measured amounts of each monomer, initiator, and solvent were placed in an ampoule, which was then degassed twice in the usual manner and flushed with nitrogen. The ampoule was sealed under a vacuum and then set into a thermostat. After a definite reaction time, the ampoule was removed from the thermostat; the polymer was then separated by pouring the contents into a large amount of petroleum ether, followed by centrifuging.

The polymer thus obtained was then washed repeatedly with petroleum ether and dried *in vacuo* to a constant weight. The conversion of the polymer was less than 10%.

Analyses of the Polymer. The composition of the copolymer was determined by elementary analysis. The residual unsaturation of the polymer was calculated from the composition and the bromine value (BV) obtained by the bromite-bromate method.[7] The molecular weight of the polymer was measured with a vapor-pressure osmometer (Hewlett Packard Model-302), using benzene as the solvent at 37°C.

Kinetics of Homopolymerization

The initial polymerization of triallylidene cyclic acetal compounds is treated in a manner similar to that described in previous papers,[1,8] including the chain transfer and the cyclization. The kinetic equations are derived by assuming the following elementary reactions:

Decomposition of initiator	$I \rightarrow 2R\cdot$	$2k_d(I)$
Initiation	$R\cdot + M \rightarrow M\cdot$	$3k_i(R\cdot)(M)$
Cyclization	$M\cdot \rightarrow M_c\cdot$	$k_c(M\cdot)$
Propagation	$M\cdot + M \rightarrow M\cdot$	$3k_p(M\cdot)(M)$
	$M_c\cdot + M \rightarrow M\cdot$	$3k_{cp}(M_c\cdot)(M)$
Effective chain transfer	$R\cdot + M \rightarrow R' + M\cdot$	$3k_i'(R\cdot)(M)$
	$M\cdot + M \rightarrow P + M\cdot$	$3k_{tr}(M\cdot)(M)$
	$M_c\cdot + M \rightarrow P + M\cdot$	$3k_{ct}(M_c\cdot)(M)$
Degradative chain transfer	$R\cdot + M \rightarrow R' + M^*$	$3k_i^*(R\cdot)(M)$
	$M\cdot + M \rightarrow P + M^*$	$3k_{tr}^*(M\cdot)(M)$
	$M_c\cdot + M \rightarrow P + M^*$	$3k_{ct}^*(M_c\cdot)(M)$

where I denotes an initiator; R·, an initiator radical; M, a monomer; M· the uncyclized radical; $M_c\cdot$, the cyclized radical; R′, the inactive product; M*, the stable radical, and P, a polymer.

7) I. P. Losev and O. Y. Fedotoba, "Praktikum po Khimii Vysokopolimernykh Soedinenii," Gosudarstvennoe Nauchno-Tekhnicheskoe Izdatelstvo Khimicheskoi Literatury, Moskova.

8) T. Ouchi, S. Tatsuno, T. Nakayama, and M. Oiwa, This Bulletin, **43**, 2241 (1970).

The following equations can be obtained by assuming steady-state conditions.

The rate of polymerization, R_p, is given by:

$$R_p = \left(\frac{3(M) + c}{3a(M) + bc}\right)(I) \tag{1}$$

which, on rearrangement, gives:

$$(3(M) + c)(I)/R_p = 3a(M) + bc \tag{2}$$

$$\frac{1}{(I)/R_p - a} = \left(\frac{3}{b - a}\right)\left(\frac{(M)}{c} + \frac{1}{3}\right) \tag{3}$$

The residual unsaturation of the polymer, $3R_{us}$, is shown by:

$$\frac{1}{3R_{us}} - 1 = \frac{c}{3(M)} \tag{4}$$

The relation among the degree of polymerization, $\bar{P}_n$, and the monomer and initiator concentrations is represented by:

$$\frac{R_p(3a(M) + bc}{\bar{P}_n(I)} = 6a\gamma_t(k_t' + k_d/\gamma_t + k_{tr}/k_{tr})^*(M) + 3ab\gamma_t(k_i' + k_d/\gamma_t + k_{ct}/k_{ct}^*) \tag{5}$$

where: $\gamma_t = k_d(k_t + k_t')/(k_t + k_t' + k_t^*)$

$a_{tr}^* = k_{tr}^*/(k_p + k_{tr} + k_{tr}^*)$

$b_{ct}^* = k_{ct}^*/(k_{cp} + k_{ct} + k_{ct}^*)$

$a = a_{tr}^*/2\gamma_t,\ b = b_{ct}^*/2\gamma_t$

$c = k_c/(k_p + k_{tr} + k_{tr}^*)$

Results and Discussion

Polymerization of TAS. The polymerization of TAS was investigated under different initiator and monomer concentrations at 80°C. The results are given in Table 1, in which the values of the residual unsaturation and the molecular weight are estimated by extrapolating to zero for conversion.

The Residual Unsaturation. As can be seen from Table 1, the residual unsaturation is independent of the initiator concentration, but decreases with a decrease in the monomer concentration.

The plots of $(1/3R_{us}—1)$ against $1/(M)$ are shown in Fig. 1. A straight line through the point of origin was obtained, as predicted by Eq. (4). By using this slope, c was obtained as 0.873 mol/*l*.

The Rate of Polymerization. When the monomer concentration is kept constant and the initiator concentration is varied, it may be expected from Eq. (1) that R_p will give a straight line with (I). The result is shown in Fig. 2, in which the experimental data are very close to the calculated linear relationship.

By using the c value thus obtained, the a and b values were calculated by applying the method of least-squares to Eq. (2); a and b were 4.73×10^3 sec and 9.73×10^4 sec respectively (Fig. 3).

By using the a value thus obtained the plots of $((I)/R_p—a)^{-1}$ against (M) according Eq. (3) shown in Fig. 4 were obtained; they show a good linear relationship. Therefore, the a value seems to be proper.

The Degree of Polymerization. As can be seen in Table 1, the degree of polymerization, $\bar{P}_n$, is very small;

Table 1. Polymerization of TAS at 80°C

(BPO) ($\times 10^{-1}$ mol/l)	(TAS) (mol/l)	R_p ($\times 10^{-6}$ mol/l·sec)	BV	$3R_{us}$	Molecular weight
3.30	1.35	19.5	88.0	0.816	859
2.48	1.35	15.0	88.9	0.824	804
1.65	1.35	7.80	88.5	0.820	850
0.826	1.35	5.63	87.9	0.815	827
1.65	0.676	5.04	75.2	0.697	837
1.65	0.542	4.49	70.5	0.653	813
1.65	0.452	4.03	67.0	0.621	808

it is independent of the initiator concentration, but increases with an increase in the monomer concentration. A similar tendency has been found on the polymerization of DAPE.[1] The plots of $R_p/\overline{P}_n$ against (I) and $(3a(M)+bc)R_p/\overline{P}_n(I)$ against (M) are shown in Fig. 5; they have a good linear relationship and satisfy Eq. (5). Accordingly, these results suggest that the a, b, and c values obtained here are justifiable on the polymerization of TAS.

Generally, k_d is of the order of about 10^{-5}—10^{-6} in

the case of a radical polymerization, as is well known.[9] Consequently, a_{tr}^* and b_{tr}^* were estimated to be of the order of about 10^{-2}—10^{-3} and 10^{-1}—10^{-2}; the degradative chain transfer may preferentially occur rather than the propagation.

Comparison of Parameters. The polymerization parameters for TAS and DAPE are summarized in Table 2.

It was found that the a and b of TAS were larger than those of DAPE. Consequently, the degradative chain transfer is found to occur more readily on TAS than on DAPE. This may result from the difference in the probablity of collision between diallylidene and triallylidene compounds.

On the other hand, the ratios of the rate of cyclization to the total rates of propagation and chain transfer for TAS polymerization were larger than those for DAPE; triallylidene compounds were cyclized more easily than diallylidene compounds. The difference in steric hindrance between tri- and diallylidene cyclic acetals may cause such tendency.

For investigating the effect of the temperature on polymerization, the polymerization was carried out at 60, 70, and 80°C. The overall activation energy, as calculated from the Arrhenius plot, was 17.3 kcal/mol, which was nearly equal to that of the usual radical polymerization.

Copolymerization. The dependence of the monomer composition on the rate of copolymerization at 80°C is shown in Fig. 6. The rates of copolymerization decrease markedly with an increase in the mole fraction of TAS in the monomer mixtures. This tendency may be ascribed to the degradative chain transfer by the allylidene group and to the steric hindrance by the cyclic acetal.

Monomer Reactivity Ratios. Figure 7 shows the polymer composition as a function of the monomer composition. Figure 8 shows the residual unsaturation as a function of the copolymer composition. These results mean that the residual unsaturations of the copolymers obtained decreased slightly with an increase in the TAS or TCS, and were nearly equal to 1.0. Accordingly, the cyclization may be approximately negligible on these systems of copolymerization.

The functional group reactivity ratios, r_1' and r_2', determined according to a modification of the Gibbs copolymerization equation,[4] are summarized in Table 3.

In Fig. 7 the theoretical solid curves calculated from the resulting reactivity ratios are shown to agree very closely with the experimental measurements.

The Q' and e' values for TAS and TCS, as calculated from the r_1' and r_2' values, are shown in Table 3.

The average values of Q' and e' for TAS, TCS, DAPE, and DCPE were estimated to be as follows: TAS $Q'=0.05$, $e'=-0.08$; TCS $Q'=0.10$, $e'=-0.25$; DAPE $Q'=0.03$,[2] $e'=0.0$;[2] DCPE $Q'=0.01$,[3] $e'=-0.32$.[3]

No difference in Q' and e' values between tri- and diallylidene cyclic compounds could be recognized. This suggests that the TAS are unconjugate and neutral monomers just the same as the DAPE.

The Q' values for TCS were slightly larger than those for TAS; they might be influence by the hyperconjugation of the methyl group. On the other hand, the e' values of TCS were more negative than those of TAS; they must be contributed to the methyl group, which is a proton donor.

Elimination Reactions Promoted by Fluoride Ion in Acetonitrile. Elimination Reaction from 2-Arylethyl Derivatives[1]

Jun-ichi HAYAMI,[2] Noboru ONO, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto
(Received September 21, 1970)

Rates of bimolecular elimination have been determined for the reaction of 2-arylethyl bromides, chlorides, and tosylates with anhydrous tetraethylammonium fluoride in acetonitrile. The rates of elimination reactions in this new base system were much faster than those in conventional base systems (alkoxide-alcohol). The Hammett ρ values were found to be $\rho=2.033$ (X=Cl) at 25.0°C and $\rho=1.879$ (X=Br) at 5.0°C for *p*-Y-$C_6H_4CH_2$-CH_2X. Kinetic deuterium isotope effects were determined using 2-phenylethyl-2,2-d_2 bromide and chloride to be $k_H/k_D=3.99$ (X=Cl) and 5.03 (X=Br). These data and the low k_{OTs}/k_{Br} ratio suggest that fluoride-ion-promoted elimination reaction proceeds through a very tight transition state where β-proton is less than half transferred to the base.

Recent works on the transition state of the bimolecular elimination invoked interesting problems. Bunnett proposed the theory of the variable E2 transition state—a continuous spectrum between pane-carbonium extreme through central to pane-carbanion extreme of the transition state.[3] Parker and co-workers proposed the theory of a variable transition state in the spectrum between E2C—E2H extreme with the concept of variable "looseness" or "tightness".[4] Hoffmann's view[5] may be in close agreement with the latter interpretation.

Some examples of the halide ion promoted bimolecular elimination reactions were explored to establish a criterion of the theory. Halide ion, especially the halide ion in a dipolar aprotic solvent, is a weak hydrogen but a strong carbon nucleophile. A study of the bimolecular elimination in a dipolar aprotic solvent promoted by a strong hydrogen nucleophile might be of use in order to establish a better understanding of the reaction.

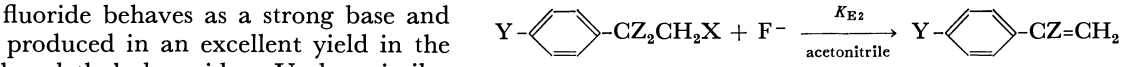
In previous papers[6] the authors reported that tetraethylammonium fluoride behaves as a strong base and that styrene was produced in an excellent yield in the reaction of 2-phenylethyl bromide. Under similar conditions tetraethylammonium chloride and bromide underwent solely the substitution reaction.

Substitution reactions and elimination reactions by chloride, bromide, and iodide ion are well-known and the mechanism of these reactions have been studied extensively.[4] However, there are few reports on fluoride ion promoted bimolecular reactions, and no quantitative kinetic data are available.[7] This may be due to the difficulty in finding the electrolyte soluble in pure dipolar aprotic solvents to secure fluoride anion in a homogeneous reaction system. This difficulty has been overcome by use of tetraethylammonium fluoride in a dipolar aprotic solvent.

In the present communication the authors report the characteristics of the elimination reaction from 2-phenylethyl derivatives promoted by the new base system and suggest a structure for the transition state.

Results and Discussion

Kinetic measurements of the elimination reactions of the series of the para-substituted 2-phenylethyl bromide and chloride were undertaken using the base system of tetraethylammonium fluoride in acetonitrile. Similar experiments with several of the para-substituted 2-phenylethyl tosylates were undertaken. The general formula is as follows.



$$Y\text{-}C_6H_4\text{-}CZ_2CH_2X + F^- \xrightarrow[\text{acetonitrile}]{k_{E2}} Y\text{-}C_6H_4\text{-}CZ{=}CH_2 \quad (1)$$

Y = CH_3O, CH_3, H, Cl
Z = H, D
X = Cl, Br, OTs

Reaction rates were determined by following the appearance of styrene or substituted styrenes spectrophotometrically. With a large excess of the base, first order (pseudo-first-order) kinetics held for every run. A typical example is given in Table 5. Second order rate constants were calculated by dividing the pseudo-first-order rate coefficients by the pertinent tetraethylammonium fluoride concentrations. The concentration of the fluoride ion was determined by titration with thorium nitrate.[8] The results are given in Table 1. The olefin-forming elimination was accompanied by the bimolecular substitution to some extent,[6] and olefin was obtained in the yield of 75% for the elimination from tosylates. In other cases olefin was obtained almost quantitatively as is shown in Table 1 (see Experimental).

A four-fold variation in base concentration caused no

CH_3O	22.4	−0.2

a) $\Delta H^{\neq}$, $\Delta S^{\neq}$: at 25°C

The Hammett ρ-values were derived by the least-squares procedure of Jaffé[9] from the rate constants of the 2-phenylethyl derivatives with para substituents, methoxy, methyl, hydrogen and chlorine. These calculations together with results of elimination reactions in ethanol and t-butyl alcohol are summarized in Table 3. The kinetic deuterium isotope effects with 2-phenylethyl-2,2-d_2 bromide and chloride were determined, the results are also given.

9) H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

Kinetic data show that tetraethylammonium fluoride in acetonitrile is about 800 times as effective as sodium ethoxide in ethanol in promoting the E2 reaction from 2-phenylethyl chloride, k_{E2} being 3.89×10^{-3} and 4.5×10^{-6} l/mol sec at 25°C.[10] The activation parameters in Table 2 fall in a reasonable range for typical E2 reactions.

Second order kinetics and the activation parameters show that the E1 mechanism can be excluded for the present cases. Of the two mechanisms E2 and E1cB, compatible with the kinetics, E1cB should be excluded since the ρ-values and the k_H/k_D ratios, both obtained in the present communication, are against criteria for E1cB.

Recently, McLennan[3c] and also Rappoport[3d] reviewed the criteia for E1cB. They suggested that E1cB should show a very high positive value of ρ (which should be greater than 3.7 obtained in the E2 reaction of 2-arylethyl-trimethylammonium salt) and the k_H/k_D ratio of unity. In certain cases of "Type II" E1cB, E1cB with negative ρ-values are suggested.

In the present cases, the ρ-values are positive but the values in the neighborhood of 2 seem to be too small and the k_H/k_D ratios of more than 3 are too high for the

10) The value for sodium ethoxide was calculated by extrapolation from other temperatures, using the experimental data of DePuy *et al.*[11] They have reported that k_{E2} is 24.1×10^{-5} at 60°C and 185×10^{-5} at 80°C.

E1cB mechanism to be operative (Table 3).

Interesting features of the fluoride promoted elimination from substituted 2-phenylethyl derivatives can be characterized by the small ρ values, low k_H/k_D ratios and very diminished ratios of k_{OTs}/k_{Br} although they are not at all out of the range of the expected magnitude for the E2 reaction.

As is shown in Table 3, the k_H/k_D ratio of 5 for 2-phenylethyl bromide at 5°C is smaller than the k_H/k_D ratios for the same compound with a conventional base, which gives the k_H/k_D ratios sometimes exceeding 7. The k_H/k_D ratios for the E2 reaction generally decrease with the increase in reaction temperature. An example can be found in reports by Saunders[13,15] as well as in Table 3. This implies that the k_H/k_D ratio for the 2-phenylethyl bromide might decrease to a certain amount and more diminished ratios would be anticipated at higher temperatures. Smaller k_H/k_D ratios were also obtained for 2-phenylethyl chloride.

The positive ρ value with k_H/k_D less than the theoretical maxima (*ca.* 7)[16] may suggest the pane-carbanion transition state in which the proton is more than half transferred.

The other characteristics of the fluoride promoted E2 reaction, however, are strongly against the pane-carbanion interpretation. According to Hoffmann,[5] the small value of the leaving group selectivity coefficient, the rate ratio k_{OTs}/k_{Br}, is a good criterion for the little C-X (C_α-leaving group) bond-breaking together with the little C–H (C_β-hydrogen) bond-breaking in the bimolecular reaction. The k_{OTs}/k_{Br} ratio of 0.027 obtained is one of the smallest values (Table 4).[17] Rho (ρ) value of 1.8 or less (anticipated at higher temperatures) for the 2-arylethyl bromide seems too low for a pane-carbanion transition state but may be compatible with the "central" synchronous process.

TABLE 4. RATIOS k_{OTs}/k_{Br} FOR ELIMINATIONS FROM p-Y-$C_6H_4CH_2CH_2X$

Y	Base	Solvent	k_{OTs}/k_{Br}
CH_3	F^-	CH_3CN	0.027

CH_3O	t-BuO^-	t-BuOH	0.15[a]
H	EtO^-	EtOH	0.1[a]
NO_2	t-BuO^-	t-BuOH	1.57[a]

a) Ref. 5.

Taking into account the very low k_{OTs}/k_{Br} ratio and the diminished Hammett ρ value, the present authors suggest that in the fluoride promoted E2 reaction, β-proton is less than half transferred in the transition state. In other words, a very tight and reactant-like transition state should be ascribed to this E2 reaction where both the C–H and C–X bond-breaking are not far advanced.

It might be interesting to discuss a plausible mechanism in the light of E2C—E2H spectrum. As Parker[4] has pointed out, the tight transition state such as proposed in the present study is against the E2C mechanism. Another kinetic result in authors' laboratory[18] is also against the E2C mechanism. The E2C transition state should be much like an SN2 transition state, and the ρ value for the E2C reaction of 2-arylethyl chloride may be expected to be similar or slightly higher than the ρ value for the SN2 reaction of the same compounds. The ρ value (*ca.* 2) obtained in the present study is substantially higher than the ρ value found in the SN2 reaction of 2-arylethyl chloride with radioactive chloride ion in acetonitrile ($\rho=0.57$)[18] and is in a reasonable range for normal E2H reactions. This conclusion is consistent with the "principle of hard and soft acids and bases" which predicts that hard fluoride ion is liable to attack a hard proton while the soft halide ion (Cl^-, Br^-, or I^-) can attack relatively soft carbon.[19]

17) The smaller k_{OTs}/k_{Br} for the reaction in acetonitrile compared to the one in the protic solvent may be rationalized in terms of the lack of the solvation stabilization of the leaving group (anion) in a dipolar aprotic solvent. In a protic solvent, assistance by the solvation may give rise to a relatively looser transition state that reflects upon slightly enhanced k_{OTs}/k_{Br} ratios.

18) J. Hayami, N. Tanaka, S. Kurabayashi, Y. Kotani, and A. Kaji, Abstracts of Papers, III-1323, 23rd Annual Meeting of Chemical Society of Japan, Tokyo, April 1970.
19) R. G. Pearson and J. Songstad, *J. Amer. Chem. Soc.*, **89**, 1827 (1967).

The idea of the tight transition state is not incompatible with the Swain-Thornton rule,[20] which postulates a more reactant-like transition state for a more reactive base. The tight transition state in the fluoride promoted elimination can be rationalized in terms of the very small steric requirement of the fluoride ion in a dipolar aprotic solvent and the high proton affinity of the fluoride which is the reflection of the intrinsically high electronegativity of fluorine.

The results clearly show that the fluoride promoted elimination from 2-arylethyl derivatives is a typical E2 reaction, and the characteristics of the reaction suggest features of the tight transition state. Utility of the fluoride ion in a dipolar aprotic solvent is promising. Features of the elimination reaction including the orientation rule in the olefin-formation from secondary alkyl derivatives were given in a previous paper.[21]

Experimental[22]

Materials. 2-Arylethyl *p*-toluenesulfonates were prepared in the usual way from the corresponding 2-arylethanols and were recrystallized from ethanol.

2-Phenylethyl tosylate, mp 38.5—39.0°C (lit,[23] 38.5—39.0°C); 2-*p*-chlorophenylethyl tosylate, mp 79.0—79.3°C (lit,[24] 79.5—80.1°C); *p*-tolylethyl tosylate, mp 68.0—69.0°C (lit,[24] 68.6—69.3°C); *p*-anisylethyl tosylate, mp 58.5—59.0°C (lit,[24] 58.3—59. °C); 2-phenylethyl-2,2-d_2 tosylate, mp 38.5—39. °C (lit,[13] 37.4—38.0°C).

2-Arylethyl Chlorides: 2-Arylethyl chlorides were prepared by heating to reflux arylethyl tosylates with excess of tetraethylammonium chloride in acetonitrile. In a typical example, 2-phenylethyl-2,2-d_2 tosylate (12.0 g, 0.044 mol) and tetraethylammonium chloride (16.5 g, 0.1 mol) were dissolved in 100 m*l* of acetonitrile and the solution was heated under gentle reflux for 24 hr. The solution was cooled and poured into 100 m*l* of water and the organic layer was taken out with pentane. After washing and drying the extracts, pentane was carefully removed and the product was distilled to give 4.8 g (86%) of 2-phenylethyl-2,2-d_2 chloride, bp 84.0°C/16 mmHg. On the NMR spectra of the deuterated compound, the signal due to β hydrogen (7.1 τ) completely vanished. Boiling points of the chlorides are as follows; 2-phenylethyl chloride, bp 90°C/25 mmHg;[11] 2-*p*-chlorophenylethyl chloride, bp 84°C/4 mmHg[11]; 2-*p*-anisylethyl chloride, bp 95°C/4 mmHg; 2-*p*-tolylethyl chloride, bp 67°C/4 mmHg.

2-Arylethyl Bromide: 2-Arylethyl bromides were prepared in a procedure analogous to that for the preparation of the 2-arylethyl chlorides using sufficient acetonitrile to dissolve tetraethylammonium bromide at a reflux temperature. Boiling points of the bromides are as follows: 2-phenylethyl bromide, bp 90°C/11 mmHg[12]; 2-phenylethyl-2,2-d_2 bromide, bp 95°C/16 mmHg[13]; 2-*p*-anisylethyl bromide, bp 124°C/4 mmHg[12]; 2-*p*-tolylethyl bromide, bp 101°C/10 mmHg.

Solvent and Base. Acetonitrile was purified as previously reported.[25] Preparation of tetraethylammonium fluoride was reported.[6] Fluoride reagent should be prepared freshly before use, as it is very hygroscopic and liable to decompose slowly to form triethylamine and ethylene even at room temperature. Hydrogen fluoride evolved seemed to deteriorate the specimen by forming tetraethylammonium acid fluoride. Tetraethylammonium fluoride stored for a month in a vacuum desiccator showed a greatly diminished rate of elimination reactions, sometimes about one hundredth of a fresh specimen.

Determination of Amount of Substitution Reactions. The amount of 2-arylethyl fluorides arising from substitution reactions of 2-arylethyl chlorides, bromides, and tosylates with fluoride in acetonitrile was determined by glc analysis. A solution in acetonitrile containing 0.2 M of tetraethylammonium fluoride and 0.1 M of a 2-phenylethyl derivative was allowed to react to completion. The resulting solution was poured into water and extracted with pentane. The extracts were dried and concentrated by careful fractionation of pentane. The concentrate was analyzed on a column of TG-3000 on Celite 545 at 110°C. Glc analysis showed that the fluorides were formed from the corresponding halides in 4% yield while the tosylates gave fluorides in 25% yield.

Kinetic Measurements. The reactions in acetonitrile were carried out in a thermostat kept within ±0.1°C of the stated temperature. Reaction rates were followed by analysis of styrene or substituted styrene spectrophotometrically. The reaction mixture was placed in a 50 m*l* volumetric flask, and after an appropriate time 1 m*l* aliquots of the solution were withdrawn at intervals and the reaction was quenched by the addition of 0.05 N nitric acid. The time of the first withdrawal was taken as "time-zero". Thus $\log A_\infty/(A_\infty - A_t)$ *vs.* t plot gave a good straight line with a negative time intercept. About 20-fold excess of fluoride was used and pseudo-first-order rate constants were determined from the slope of a plot of $\log A_\infty(A_\infty - A_t)$ against time, where A_t is the absorbance at time t and A_∞ is the absorbance after at least ten half-lives. The last values, A_∞, showed that the olefins were produced essentially in quantitative yield except for tosylates where a fair amount of the substitution was accompanied by elimination. The absorbance was meas-

The Hofmann Rearrangement. I. Kinetic Substituent Effects of *ortho*-, *meta*-, and *para*-Substituted *N*-Bromobenzamides[1]

Tsuneo IMAMOTO, Yuho TSUNO, and Yasuhide YUKAWA

The Institute of Scientific and Industrial Research, Osaka Univervity, Yamadakami, Suita, Osaka

(Received September 25, 1970)

The kinetic substituent effects on the Hofmann rearrangements of *ortho*-, *meta*-, and *para*-substituted *N*-bromobenzamides were studied in an aqueous sodium hydroxide solution. The rate constants of the *meta*- and *para*-derivatives were correlated by means of our equation:

$$\log k/k_0 = -2.39(\sigma^0+0.41\Delta\bar{\sigma}_R^+) + 0.002$$

The reaction rates of *ortho*-derivatives were found to be 2—20 times faster than those of the corresponding *para*-derivatives. The reaction mechanism of this rearrangement was discussed in terms of LFER, the *ortho*/*para* rate ratios, and the activation parameters; as a result, the concerted mechanism (the participation of the phenyl group in electron-deficient nitrogen at the transition state) was favored rather than the two-step mechanism. The similarity of the reaction mechanism of the Hofmann to the Lossen rearrangement was also shown on the basis of LFER.

The Hofmann reaction, the conversion of amide into primary amine uncontaminated with secondary amine, is one of the most useful reactions for organic syntheses.[2] The course of this reaction has already been demonstrated, as in the following scheme by isolating reaction intermediates:

$$R\text{-}CONH_2 \xrightarrow{OX^-} R\text{-}CO\bar{N}^-\text{-}X \xrightarrow{-X^-} R\text{-}NCO \xrightarrow{H_2O} R\text{-}NH_2$$

The rearrangement step, where the conjugate base of *N*-haloamide is converted accompanying the release of the halide ion into isocyanate, is the most important stage in the course of the Hofmann reaction. This rearrangement is well-known to be intramolecular from the results of many stereo-chemical and isotopic studies.[2,3] As for further details of the mechanism, however, only a few kinetic studies have been reported. Hauser and his co-worker,[4,5] in their kinetic study of substituted *N*-bromobenzamides, showed that electron-releasing substituents in the phenyl group accelerated the rate of the rearrangement and that electron-attracting substituents retarded it. Joshi *et al.*[6] reported the kinetic results of the rearrangements of three aliphatic *N*-bromoamides. In spite of these insufficient data, it has been formally speculated that the rearrangement proceeds through a two-step mechanism;[7] the release of the halide ion from the conjugate base of *N*-haloamide takes place in the first step, and the unstable univalent nitrogeneous intermediate thus formed rearranges immediately into isocyanate. Wright and Fry[8] recently investigated the isotope effect of this rearrangement using phenyl-1-^{14}C labeled *N*-bromobenzamide and suggested a concerted mechanism; the release of the halide ion and the migration of the phenyl group to nitrogen took place simultaneously. Joshi *et al.* also presented a similar mechanism in their paper. It appears, however, that the amount of data reported hitherto is not sufficient to support strongly the concerted mechanism, and the two-step mechanism has not yet been definitely excluded.

In order to elucidate the reaction mechanism more precisely, we have extensively studied kinetic substituent effects on the Hofmann rearrangement of substituted *N*-bromobenzamides.

Experimental

Materials. Various substituted *N*-bromobenzamides were prepared by a modification of Hauser's method.[4]

Finely-pulverized amide (0.1 mol) was added to an ice-cold hypobromite solution, freshly prepared from 0.2 mol of bromine, 0.5 mol of sodium hydroxide, and 300—800 m*l*

of water. After vigorous stirring for 2—15 min, the reaction mixture was filtered rapidly with a suction into a solution of 30 m*l* of acetic acid in 70 m*l* of ice water. The *N*-bromoamide thus precipitated was collected, washed successively with 5% aqueous acetic acid and water, and dried at room temperature. The yields of the crude products were generally 80—90%. Unsubstituted, *p*-methyl, *p*-fluoro, *p*-phenyl, and *m*-chloro derivatives were recrystallized from dichloroethane; *m*-nitro and *p*-nitro derivatives, from acetic acid; *p*-chloro and *p*-bromo derivatives, from methanol; the *o*-nitro derivative, from dichloroethane-DMF (4 : 1), and the *m*-trifluoromethyl derivative, from dichloroethane-*n*-hexane (5 : 1). Better results were obtained in every case by recrystallization at a temperature lower than 60°C.

However, the acidification of the reaction mixture in the cases of *m*-methyl, *o*-methyl, *p*-methoxy, *p*-ethyl, and *p*-*t*-butyl derivatives did not give the precipitates, but a pasty mass. This was redissolved in a 3% sodium hydroxide solution at −5—0°C and filtered into cold aqueous acetic acid containing ice to give almost colorless precipitates of the corresponding *N*-bromoamide. This solid material was collected, washed with water, pressed to dry, and dissolved in chloroform or dichloroethane. Into this saturated solution, *n*-hexane was added until turbidity just appeared, and then the solution was cooled. *N*-Bromoamides containing more than 96% of the theoretical amount of active bromine could be obtained by this method.

These *N*-bromoamides were kept cold, away from the light.

The analytical data and melting points for *N*-bromoamides are listed in Table 1.

The *o*-methoxy- and *m*-methoxy-*N*-bromobenzamides were very unstable compounds, and the corresponding pure materials could not be obtained. In the cases of *p*-ethoxy- and *p*-phenoxybenzamides, because of accompanying bromination on the benzene ring, the compounds isolated were not the expected ones, but *m*-bromo-*p*-ethoxy- and *p*-(*p*′-bromophenoxy)-*N*-bromobenzamides.

Kinetic Measurements. The reaction rates were measured by titrating the residual amount of unrearranged *N*-bromoamide with a standardized sodium thiosulfate solution.[9] In a measuring flask we placed 200 m*l* of a standardized aqueous sodium hydroxide solution and immersed in a constant-temperature water bath (accuracy ±0.01°). A

9) Van Dam, *Rec. Trav. Chim. Pays-Bas*, **18**, 408 (1899); Van Dam and J. H. Aberson, *ibid.*, **19**, 318 (1900).

certain amount of *N*-bromoamide was weighed accurately into a 300-m*l* Erlenmeyer flask and immersed in the bath. After standing for one hour, the sodium hydroxide solution was transferred into the Erlenmeyer flask, and shaken vigorously until all of the *N*-bromobenzamide had been dissolved. The course of the reaction was followed by titrating a residual amount of active bromine with a sodium thiosulfate solution at moderate intervals; a 10-m*l* portion of the solution was pipetted out and transferred into 100 m*l* of an ice-cold 0.5 N HCl solution to which 2 m*l* of 20% aqueous solution of potassium iodide had been added just before; the iodine thus liberated was titrated with a 0.025 N $Na_2S_2O_3$ solution to the starch-iodide end-point.

In the cases of *m*-methoxy- and *o*-methoxy-benzamides, from which corresponding *N*-bromoamides could not be isolated, the kinetic measurements were carried out as follows. A hypobromite solution (0.025 mol/*l*, $f=0.996$) was prepared by the drop-by-drop addition of bromine to an ice-cold 0.5 N NaOH solution ($f=1.000$). Finely-pulverized pure amide (0.0055 mol) was added to 200 m*l* of this hypobromite solution at the reaction temperature, the mixture was shaken vigorously for a few minutes, and then the reaction was followed by the above procedure.

Results and Discussion

Effect of the Concentration. In order to examine the effects of the concentrations of *N*-bromoamide and sodium hydroxide on the reactivity, kinetic measurements of unsubstituted- and *m*-chloro-*N*-bromobenzamides were made in respect to:

A. Changing the concentration of *N*-bromoamide in a 1 N NaOH solution;

B. Changing the concentration of sodium hydroxide, but keeping that of *N*-bromoamide constant (0.05 mol/); and

C. Changing the overall concentration, with the concentration ratio of *N*-bromoamide to sodium hydroxide kept at 1 : 20.

a) Extrapolated value.

The concentration factor for *N*-bromoamide and sodium hydroxide was 1.000±0.003 in every case. The reaction temperatures were 20.00±0.01°C for unsubstituted amide and 30.00±0.01°C for *m*-chloro amide. The first-order rate constants were calculated by the least-squares method according to Eq. (1):

$$k \times t = 2.303 \times \log (a/a-x) \quad (1)$$

where t is the reaction time and where $a-x$ is the concentration of *N*-bromoamide at time t. Almost all the cases obeyed first-order kinetics, at least to 80% completion of the reaction (see Fig. 1). The observed rate constants are listed in Table 2.

In the case A, a very small rate enhancement was observed despite the increase in the concentration of *N*-bromoamide from 0.00625 to 0.1 mol/*l*. On the other hand, in the case B, the rate constant considerably depended on the concentration of sodium hydroxide, but tended to converge to a constant value as it approached an infinite dilution. The extremely small concentration of sodium hydroxide, however, gave an anomaly. In the case B with 0.1 N NaOH, the solution was gradually darkened as the reaction proceeded, and the dark brown precipitates appeared after the reaction was about half completed. The reaction rate increased with the progress of reaction (see Fig. 2).[10] The reaction involves a preequilibrium between *N*-bromoamide and its conjugate base, as is indicated by the following scheme. The relatively low concentration

$$X\text{-}C_6H_4\text{-}CONHBr + OH^- \rightleftharpoons X\text{-}C_6H_4\text{-}CON^-\text{-}Br + H_2O$$

ratio of sodium hydroxide to *N*-bromoamide releases a small amount of the *N*-bromoamide reactant, which then reacts rapidly with the rearranged products to lose its active bromine. The dark brown precipitates are considered to be the reaction products of *N*-bromoamide with amine or isocyanate.

From the above observations, it appears necessary to keep the initial concentration ratio [NaOH]/[Amide] at least *ca.* 10 to obtain a good kinetic result. The case C indicates the rates measured under reaction conditions in which the concentration ratio of *N*-bromo-

a) Measured by using sodium hypobromite solution.

10) The rate constant under this reaction conditions was calculated from the first-order plots of the initial stage of the reaction.

amide to sodium hydroxide kept at 1:20. The observed rate constants appeared to be given by the combined results of the concentration effects of *N*-bromoamide (case A) and sodium hydroxide (case B).

The rate constants independent of the initial concentration can be obtained by the extrapolation of the observed rate constants to an infinite dilution. However, they are only approximate and are not as precise as those measured directly. It is very noticeable that the rate ratios of the unsubstituted derivative to the *m*-chloro derivative are almost the same under these conditions. This indicates that any reaction conditions within the limits examined may be employed to ascertain the relative change in the rates of various substituted *N*-bromobenzamides. Practically, fixed conditions with the respective concentrations of *N*-bromoamide and sodium hydroxide being 0.025 mol/*l* and 0.5 N were employed throughout the series of runs as the most suitable standard from the experimental point of view.

Substituent Effects. The rates of the release of the bromide ion from the conjugate bases of various substituted *N*-bromobenzamides were determined at various temperatures. The initial concentrations of *N*-bromoamides and sodium hydroxide were maintained at 0.025 mol/*l* and 0.5 N (f=1.000±0.003) respectively throughout the series. Plots of the log $(a-x)$ against time t gave an excellent straight line, covering over 75% of the reaction, for almost all derivatives. In the cases of *p*-phenyl, *p*-fluoro, *p*-*t*-butyl, and *o*-nitro derivatives, the reaction rates were gradually increased as the reaction proceeded; thus, the rate constants were calculated from the plots of the initial state of the reaction. The *m*-nitro and *p*-nitro derivatives behaved peculiarly; the first-order plots provided a good straight line at temperatures over 45°C, but not at 30°C. Rate measurements of unsubstituted and *p*-methoxy derivatives were made not only by the general method but also by the conventional modification used for *o*-methoxy and *m*-methoxy derivatives (see the Experimental section). The disagreement between the two methods did not exceed *ca.* 2% of the rate constant. The obtained rate constants are listed in Table 3. The rate constants at 30.00°C and the activation parameters derived are also shown in Table 4.

a) Extrapolated from data at other temperatures.

The present authors[11] have previously pointed out that the Linear Aromatic Substituent-Reactivity relationship (LArSR relationship, Eq. (21)) is one of the most useful tools for speculating on the reaction mechanism:

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \qquad (2)$$

where σ^0 is the normal substituent constant, where r is a constant depending on the resonance requirement in the reaction, and where $\Delta\bar{\sigma}_R^+$ measures the capacities of the substituents to supply electrons by resonance. It is of interest to discuss the reaction mechamism of the Hofmann rearrangement in terms of the above equation. First, the logarithms of the rate constants have been plotted against Hammett's σ constants in order to examine the applicability of the original Hammett equation, $\log k/k_0=\rho\sigma$ to our data. A good overall linear relation with a ρ-value of −2.52 is observed with the correlation coefficient of 0.994, while *p*-methoxy and *p*-*t*-butyl derivatives deviate a little. There is no reason to consider that the deviation of the *p*-methoxy group

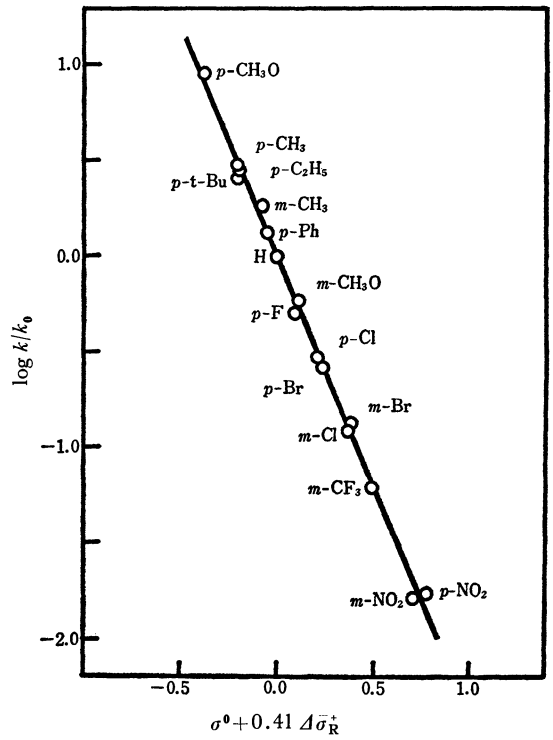

Fig. 3. Application of the LArSR relationship.

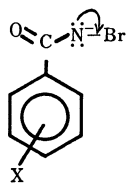
11) Y. Yukawa, Y. Tsuno, and M. Sawada, This Bulletin, **39**, 2274 (1966); Y. Yukawa and Y. Tsuno, *Nippon Kagaku Zasshi*, **86**, 873 (1965).

is attributable to the experimental error. It would be more reasonable to refer the deviation to the strongly electron-releasing conjugative ability of the methoxy group. That is, the Hofmann rearrangement may be considered to be a slightly more σ^+-characteristic reaction than the dissociation of benzoic acids, from which the Hammett's σ constants are derived. The use of Eq. (2) gives a better linearity, including the *p*-methoxy group, with a correlation coefficient of 0.997, as is shown in Fig. 3.

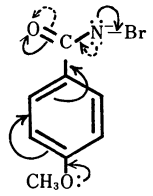
$$\log k/k_0 = -2.39(\sigma^0 + 0.41\,\Delta\bar{\sigma}_R^+) + 0.002 \qquad (3)$$

For the interpretation of the above derived parameters, especially of the resonance parameter, *r*, it will be very useful to consider the effect of the conjugation in the initial and the transition states.

In the conjugations applicable for the initial state, the *dπ–pπ* conjugation on the N–Br bond (I) may be considered to be important as the factor influencing the reactivity; the contribution of this conjugation leads to an increase in the bond-order of the N–Br bond and makes it more difficult to release the bromide ion from the reactant molecule (the Bond-energy Effect). The degree of this conjugation can be affected by the substituent on the migrating phenyl group, especially by electron-releasing conjugative groups at the *para*-position, For instance, the *p*-methoxy group, a typical electron-releasing conjugative group, will produce a considerable increase in the above conjugation effect through the cross conjugation of the carbonyl group. As is indicated by Formula (II), the methoxy group particularly strengthens the conjugation of the carbonyl group with the phenyl group, while it weakens the conjugation of the carbonyl group with the nitrogen orbital, resulting in a relative increase in the *dπ–pπ* conjugation on the N–Br bond. Therefore, if the present reaction is controlled solely by the *dπ–pπ* conjugation effect at the initial state, the resonance parameter, *r*, in the LArSR relationship Eq. (2) may be expected to be negative, as has been observed in the Curtius rearrangement



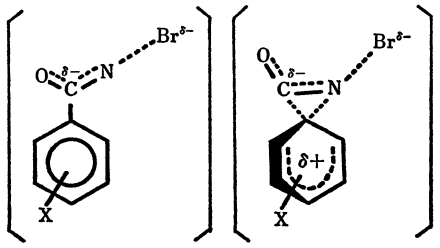
(I)



(II)

in toluene ($r=-1.04$)[12] and in the Wolff rearrangement ($r=-1.7$).[13] In the present Hofmann rearrangement, however, comparatively large positive *r*-value (0.41) has been obtained. This result clearly indicates that the bond-energy effect mentioned above is not necessarily a predominant factor in influencing the reactivity of the Hofmann rearrangement.

On the other hand, the following two models may be assumed as probable structures of the transition state. The (III) model corresponds to the two-step mechanism,



(III) (IV)

where the release of the bromide ion takes place at the first step and the univalent nitrogeneous intermediate formed rearranges immediately into isocyanate. The other model (IV) corresponds to the concerted mechanism (or the one-step mechanism), where the release of the bromide ion and the migration of the phenyl group to the nitrogen are simultaneous processes. In the former model, the substituent effect on the stabilization of this state is expected to afford a small positive *r*-value (a value of the same order as for σ, $r=0.27$), since its electronic nature resembles closely that of the benzoate anion. On the other hand, in the latter model, a strongly electron-releasing conjugation is required for the partial bond formation between the phenyl group and nitrogen, and thus a large positive *r*-value should be observed, as in the Beckmann rearrangement of acetophenone oximes ($r=0.60$—0.65). The observed *r*-value (0.41), however, appears too large for the (III) model and, on the contrary, too small for the (IV) model. Its *r*-value does not entirely support either of the above two models without considering the effect of the conjugation at the initial state. It is a rather plausible explanation for the present data that the large positive *r*-value due to the electrophilic conjugative effect at the transition state (IV) may be somewhat compensated for by the negative *r*-value resulting from the *dπ–pπ* conjugation on the N–Br bond at the initial state.

It is also of interest to discuss the effect of *ortho*-substituents with regard to the reaction mechanism. The polar effect of the *ortho*-substituent is generally recognized to be nearly equal to that of *para*-substituent;[14] thus, the rate ratio and the relative value of the activation parameters of *ortho*- to *para*-substituent can be taken as

Table 5. Effects of *ortho*-substituents

measures of *ortho* effects reflecting the reaction mechanism. The *ortho*/*para* rate ratios and relative value of activation parameters are summarized in Table 5. It may be noted that comparatively large *ortho*/*para* rate ratios are observed, and that these values depend mainly on the difference in the entropy of activation, except for the case of the nitro group. The introduction of an *ortho*-substituent restricts the rotation of the phenyl ring and lessens the entropy in the initial state more than dose that of the corresponding *para*-substituent. If the reaction proceeds by the two-step mechanism, the difference in the entropy of the *ortho*- and *para*-derivatives in the initial state will not have any effect on the relative value of the entropy of activation. However, in the case of the concerted mechanism, the entropy of activation of the *para*-derivative is lowered below that of corresponding *ortho*-derivative by the restriction of the motion of the phenyl ring on proceeding from the reactant to the transition state; therefore, it can be expected that the relative value of the entropy of activation, $\Delta\Delta S^{\neq}$, depends considerably on the difference in entropy in the initial state. The observed value of $\Delta\Delta S^{\neq}$ can be qualitatively interpreted by the above considerations. On the other hand, the following explanation of the *ortho* rate effects is also probable. The through-conjugation between carbonyl and phenyl groups is weakened by reduced co-planarity due to the introduction of the *ortho* group. This effect increases the conjugation of the carbonyl group with the nitrogen orbital, but decreases the $d\pi$–$p\pi$ conjugation on the N–Br bond. The smaller $d\pi$–$p\pi$ conjugation may play a role in bringing about the rate acceleration.

Hauser and Renflow had measured the rates of eight *meta*-, *para*-, and two *ortho*-substituted *N*-bromobenzamides in a 1N aqueous sodium hydroxide solution at 30°C. Logarithms of our rate constants have been plotted against theirs. An excellent correlation results, with a correlation coefficient of 0.9999 and a slope of 1.000 except for nitro and *p*-methoxy derivatives, which are attended with large experimental uncertainty in Hauser's data. This fact indicates that the mechanism of this reaction is little affected by a minor change in the reaction conditions.

The Lossen rearrangement, of which the leaving group is carboxylates as a substitute for halide, is expected to be analogous to the Hofmann rearrangement with respect to the reaction mechanism. Hauser and his co-worker[15] had reported the kinetic results of the decomposition of potassium dihydroxamates (R–CON–OCOR′)$^-$K$^+$, where R and R′ were various substituted phenyl groups. As is shown in Table 6, the

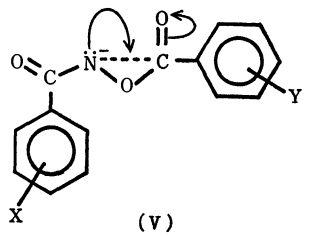
a) The number of the species of substituent X.

LFER between the Lossen rearrangement and the Hofmann rearrangement is excellent regardless of the different leaving groups. These satisfactory linear relationships suggest that the mechanisms of the two reactions are almost the same. It is conceivable that the contribution of the homo-conjugation (Formula V), which may be compared with the $d\pi$–$p\pi$ conjugation in the Hofmann rearrangement, on the depression of the reactivity should not be neglected.



(V)

The Hofmann Rearrangement. II. Kinetic Substituent Effects of *ortho-*, *meta-*, and *para*-Substituted *N*-Chlorobenzamides

Tsuneo IMAMOTO, Yuho TSUNO, and Yasuhide YUKAWA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received September 25, 1970)

The reaction rates of the Hofmann rearrangement of *ortho-*, *meta-*, and *para*-substituted *N*-chlorobenzamides were measured under the same reaction conditions as were used for the preceding *N*-bromo series. The rate constants of the *N*-chloroamides were found to be slightly larger than those of the *N*-bromoamides. The relative values of the activation entropy and the activation enthalpy of *N*-chloro- and *N*-bromo-derivatives were approximately −4 e.u. and −1.3 kcal/mol respectively. The LFER between the two series was excellent, indicating that the reaction mechanism was almost the same for both series. The effects of the leaving group on the reactivity of *ortho*-substituents were discussed in terms of the *ortho/para* rate ratios and the relative values of the activation parameters of *ortho-* and *para*-substituents.

As has been described in the preceding paper,[1] the kinetic substituent effects on the Hofmann rearrangement of substituted *N*-bromobenzamides were studied in order to elucidate the mechanism precisely. The results appeared to suggest that this rearrangement proceeded through a concerted-type transition state; the dissociation of the nitrogen-bromine bond and the migration of the phenyl group to nitrogen took place simultaneously. Furthermore, the results indicated that the contribution of the $d\pi$–$p\pi$ conjugation to the nitrogen-bromine bond in the initial state was also an important factor in depressing the reactivity.

It remained necessary to examine whether or not these qualities of the rearrangement are changed by the substitution of the leaving group, bromide, for chloride. In the present study, the substituent effects of substituted *N*-chlorobenzamides have thus been determined, and the results are discussed in terms of the effects of the leaving group on the reactivity.

Experimental

Materials. Various substituted *N*-chlorobenzamides, but not *m-* and *p*-methoxy and *p*-ethoxy derivatives, were prepared by a modification of Elliott's method.[2] Ten grams of pure amide was dissolved in 10% hydrochloric acid, and chlorine gas was passed into this solution for one hour. The *N*-chloroamide thus precipitated was collected, washed with water, and dried *in vacuo*. The yields of the crude products were generally 70—80% of the theoretical amounts.

In the cases of *m-* and *p*-methoxy and *p*-ethoxy benzamides, chlorination on the benzene ring was also present and the corresponding pure *N*-chloroamides could not be isolated by the above method. However, these *N*-chloroamides could be obtained by the application of the method of Altenkirk and Israelstam.[3] Ten grams of pure amide and 0.4 g of borax were dissolved in methanol, and into this solution an equimolar quantity of *t*-butyl hypochlorite was added at room temperature. After standing in the dark for *ca.* 15 hr, the reaction mixture was diluted with water to twice the original volume. The *N*-chloroamide thus precipitated was collected, washed with water, and dried *in vacuo* (yield 50—70%).

The crude *N*-chloroamides were recrystallized from dichloroethane or from a mixed solvent of methanol and dichloroethane. The analytical data and melting points for *N*-chlorobenzamides are listed in Table 1.

Kinetic Measurements. The rates of the rearrangement of the substituted *N*-chlorobenzamides except those of the *m*-methyl derivative were measured by the same method as was previously used for *N*-bromobenzamides.[1] The initial concentrations of *N*-chloroamide and sodium hydroxide were 0.025 mol/*l* and 0.5 N respectively.

In the case of *m*-methyl benzamide, from which the corresponding *N*-chloro derivative could not be isolated,[4] the kinetic measurements were carried out as follows. Finely-pulverized amide (0.0055 mol) was added at the reaction temperature to 200 m*l* of a hypochlorite solution (0.025 mol/*l*, $f=1.000$), freshly prepared by passing chlorine gas into an ice-cold 0.5 N ($f=1.000$) NaOH solution. The mixture was shaken vigorously for a few minutes, and then the reaction was followed by titrating the residual active chlorine with a 0.025 N $Na_2S_2O_3$ solution.

In order to compare the two rate constants, that obtained by the usual method and that obtained by the conventional modification applied to the *m*-methyl derivative, the rates of the *m*-chloro derivative were measured at 30°C by both the above methods. The rate constant obtained by the latter method was, at most, *ca.* 2% smaller than the constant obtained by the former method.

Results and Discussion

The rates of the release of the chloride ion from the conjugate bases of substituted *N*-chlorobenzamides were measured under the same reaction conditions as were used for the previous *N*-bromo series. All the runs strictly obeyed first-order kinetics, at least to 75% completion of the reaction, except for those of the *m*-methyl derivative. Some examples of first-order plots are shown in Fig. 1. In the case of the *m*-methyl derivative, the rates of which were measured by using a hypochlorite solution, a short induction period was observed when the reaction was about 15% complete (see Fig. 1),[5] and the rate constants were calculated from the first-order plots, excluding the induction period. The reproducibility of the rate constant obtained from repeated runs was within 0.7%, and the plots of $\log k/T$ *vs.* $1/T$ gave an excellent straight line in every case. The ob-

1) T. Imamoto, Y. Tsuno, and Y. Yukawa, This Bulletin, **44**, 1632 (1971).

2) G. R. Elliott, *J. Chem. Soc.*, **121**, 203 (1922).

3) B. Altenkirk and S. S. Israelstam, *J. Org. Chem.*, **27**, 4532 (1962).

4) Chlorination with chlorine gas gave solely a pasty mass.

5) The induction period may be caused by the *N*-chlorination of the amide with hypochlorite at the initial stage of the reaction.

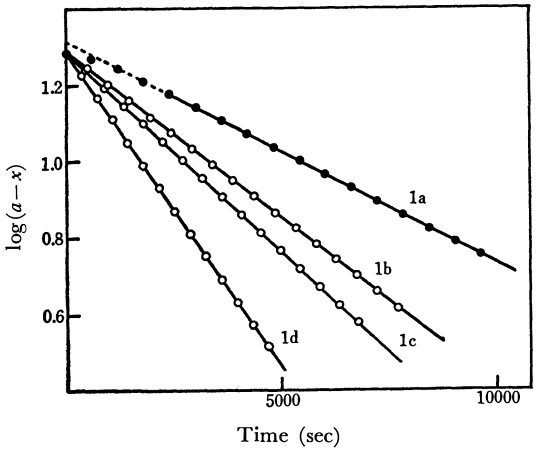

Fig. 1. Typical first-order plots.
1a: *m*-CH_3, at 15°C; 1b: *p*-F, at 25°C
1c: *p*-Cl, at 30°C; 1d: H, at 25°C.

served rate constants are listed in Table 2. The rate constants at 30°C and the derived activation parameters are summarized in Table 3.

The rate constant at 30°C is found to be slightly larger than that of the corresponding *N*-bromoamide, and the chloride/bromide rate-ratio is calculated to be *ca.* 1.2 in every substituent. It should be noted that the observed rate-ratio is considerably different from that of the usual alkyl halide reported hitherto in various nucleophilic substitution reactions and elimination reactions. That is, an alkyl chloride reacts 10—1000 times slower than the corresponding bromide,[6] whereas in the Hofmann rearrangement the *N*-chloroamide is slightly more reactive than the *N*-bromoamide. This result might possibly be referred to the fact that the bond-breaking of the nitrogen-halogen bond does not take place in the rate-determining step, but this possibility is entirely obviated by the kinetic results on the Lossen rearrangement. Hauser *et al.*[7] had studied the kinetic substituent effect on the Lossen rearrangement of dihydroxamates (I), and obtained a comparatively large positive ρ-value (+1.0). This result evidently indicates that the rate-determining step involves the bond-cleavage of the nitrogen-oxygen bond. From the similarity of the reaction mechanism of the Lossen

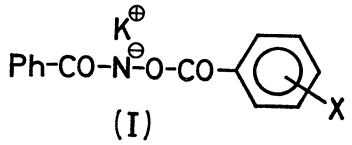
a) Extrapolated from data at other temperatures.



(I)

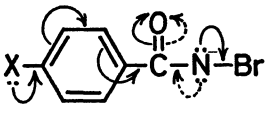
to that of the Hofmann rearrangement, it is also clear that the dissociation of the nitrogen-halogen bond in the Hofmann rearrangement takes place in the rate-determining step. The data on the relative reactivities of the *N*-chloro and *N*-bromo derivatives can be rather reasonably interpreted by considering the effect of solvation at the initial and the transition states. The reactant molecule, the conjugate base of *N*-haloamide, is strongly solvated by the hydrogen bond with the amide group, at which a large negative charge is acquired. Both *N*-chloro and *N*-bromo derivatives, however, will be subjected to almost the same degree of the solvation, since this solvation is controlled for the most part by the large acquired negative charge at the amide group, with a minor influence by the halogen atom. On the other hand, at the transition state the solvent water molecule is strongly hydrogen-bonded with a large negative charge on the halogen atom. Therefore, the degree of the solvation is proportional

to the ion potential of the halide ion itself; the *N*-chloro derivative is more solvated than the *N*-bromo derivative. The difference in the solvation effect in the transition state can be estimated to be one of the main factors in increasing the reactivity of *N*-chloroamide relative to that of *N*-bromoamide. This consideration is supported by the fact that the relative values of the activation entropy and the activation enthalpy have been found to be approximately −4 e.u. and −1.3 kcal/mol respectively.

In addition to the solvation effect, the effect of the $d\pi$–$p\pi$ conjugation on the relative rate effect can not be neglected. As has been described in the preceding paper, the $d\pi$–$p\pi$ conjugation on the nitrogen-halogen bond seems to be an important factor in depressing the reactivity. Therefore, if the $d\pi$–$p\pi$ conjugation on the N–Br bond is stronger than that of the N–Cl bond, the reactivity of the *N*-bromoamide will be relatively more depressed than that of the *N*-chloroamide. The above assumption regarding the relative strength of the $d\pi$–$p\pi$ conjugation on the nitrogen-halogen bond may be supported by the data on the $d\pi$–$p\pi$ conjugation of the carbon-halogen bond.[8] This might lead to a subsequent conclusion that, in the Hofmann rearrangement, the effects of the solvation and the $d\pi$–$p\pi$ conjugation on the relative reactivity are so important as to overcome the effects of the polarization and the σ-bond strength of the nitrogen-halogen bond.

The application of LFER to the present data will provide valuable information on the effect of the leaving group on the reactivity as well as on the more precise reaction mechanism of this rearrangement. In a preceding study of the substituent effect of the *N*-bromoamides, it has been inferred that the most important factors characterizing the Hofmann rearrangement are the $d\pi$–$p\pi$ conjugation on the N–Br bond in the initial state and the participation of the phenyl group migrating to electron-deficient nitrogen in the transition state.

These two factors can be influenced by the substituent on the migrating phenyl group, especially by the electron-releasing conjugative substituent at the para-position. In the initial state, such a substituent increases the $d\pi$–$p\pi$ conjugation on the nitrogen-bromine bond by the aid of the cross conjugation effect of the carbonyl group, as is indicated in Formula (II), and



(II)

makes it more difficult to release the bromide ion from the reactant molecule. On the other hand, in the transition state, the same electron-releasing conjugative substituent facilitates the additional conjugation of the phenyl group with electron-deficient nitrogen, with a considerable stabilization of the transition state, and promotes the rate acceleration.

It is one of the purposes of the present study to examine the effect of the leaving group on the conjugation effects mentioned above. The logarithms of the relative rate constants of *meta*- and *para*-substituted *N*-chlorobenzamides have been plotted against those of *N*-bromoamides. An excellent linear relation has been observed except for the nitro group,[9] as shown in Fig. 2. The slope of the correlation line and its correlation coefficient are calculated as 0.97 and 0.9999 respectively.

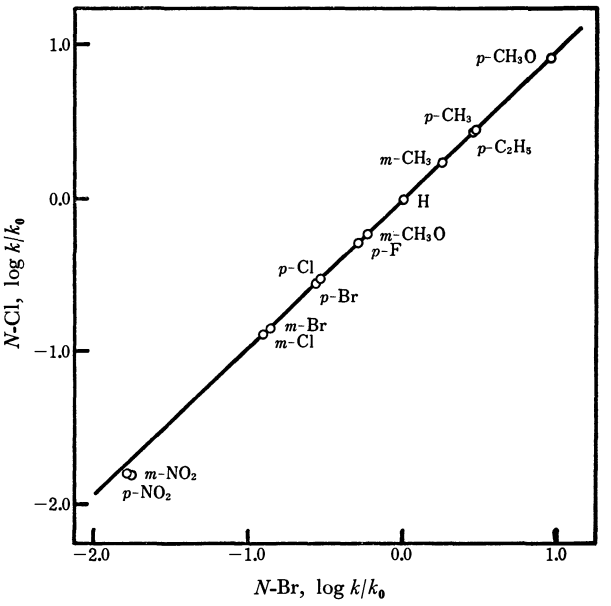


Fig. 2. Comparison of *N*-chloro with *N*-bromo derivatives.

Furthermore, as may be anticipated from the above results, the application of the Linear Aromatic Substituent-Reactivity relationship (LArSR relationship; $\log k/k_0=(\sigma^0+r\Delta\bar{\sigma}_R^+)$) to the present data gives almost the same values of the reaction constant, ρ, and of the resonance parameter, r, as those of the *N*-bromo series.

$$\log k/k_0 = -2.43(\sigma^0+0.41\Delta\bar{\sigma}_R^+) + 0.02$$

These results obviously indicate that the conjugation effects in both the initial and the transition states are also important factors for the reaction of *N*-chloroamides; furthermore, it may be concluded that the substituent effect for each conjugation effect is almost the same for both the *N*-chloro and *N*-bromo series. This conclusion does not conflict with the earlier estimation of the relative strength of the $d\pi$–$p\pi$ conjugation of N–Cl and N–Br bonds; such a small difference in the strength of the $d\pi$–$p\pi$ conjugation will not be so sensitively reflected in the substituent effect as to give a certain trend to the correlation plots.

It is also of interest to discuss the effect of the leaving group on the *ortho* effect. The *ortho*/*para* rate ratios for several substituents observed in Hofmann, Lossen and Curtius rearrangements are listed in Table 4. In

8) Although the data on the relative strength of the $d\pi$-$p\pi$ conjugation on the nitrogen-halogen bond have not yet been reported, its relative strength may be presumed to be the order, F$\ll$Cl$<$Br$<$I, from that of $d\pi$-$p\pi$ conjugation on the carbon-halogen bond; J. Hine and P. D. Langford, *J. Amer. Chem. Soc.*, **78**, 5002 (1956); J. Hine, N. W. Burske, M. Hine, and P. D. Langford, *ibid.*, **79**, 1406 (1957).

9) The deviations of the nitro groups are attributable to the uncertainty of the rate constants of the nitro-*N*-bromobenzamides.

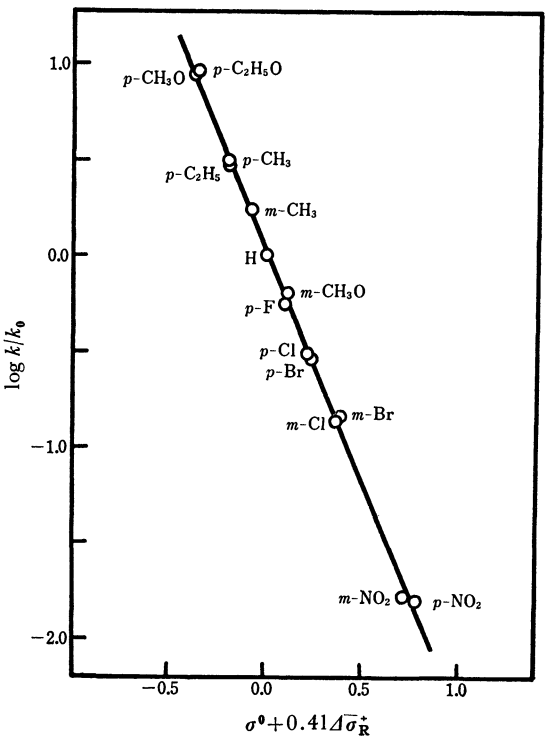

Fig. 3. Application of the LArSR relationship.

the case of the *N*-bromo series, the *ortho/para* rate ratio varies over a considerably wide range, depending on the substituent, but it tends to decrease with an increase of the electron-attracting character of the substituent except for the methoxy group. This tendency appears also in the present *N*-chloro series and in the Lossen rearrangement. Another noticeable fact is the relative value of the activation parameters of *ortho-* and *para*-substituents. In both the *N*-chloro and *N*-bromo series, similar values of $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ are observed in a given substituent except for nitro groups,[10] as is shown in Table 5. These facts apparently indicate that the *ortho* effects in the Hofmann and the Lossen rearrangements are almost the same in every leaving group.

On the other hand, the Curtius rearrangement, of which leaving group is a nitrogen molecule, is expected to be considerably different from the Hofmann and the Lossen rearrangements with respect to the reaction mechanism. The structure of the transition state of the Curtius rearrangement is considerably closer to that of the initial state, since, in this rearrangement, a stable nitrogen molecule is released in the rate-determining step. The reactivity, therefore, depends greatly on the strength of the $N\text{-}N_2$ bond.[11] In the case of an *ortho*-substituent, the bond-order of the $N\text{-}N_2$ bond is reduced by the steric restriction of the through conjugation of the phenyl group with the carbonyl group with an elevation in the reactivity. The exclusive significancy of this bond-energy effect on the Curtius rearrangement is evidently reflected in the *ortho* effects—the quite large *ortho/para* rate ratios and the enthalpy dependency of their rate ratios (see Tables 4 and 5). It is especially to be noted that the *ortho* effects on the Curtius rearrangement are in marked contrast to those on the Hofmann and the Lossen rearrangements, which are caused both by the bond-energy effect in the initial state and by the participation of the phenyl group migrating to nitrogen in the transition state.

10) The comparatively large disagreement of the nitro groups is caused by the uncertainty of the activation parameters of *N*-bromoamides. The *p*-nitro-*N*-bromobenzamide did not obey first-order kinetics at 30°C due to accompanying hydrolysis of the reactant molecule itself, and the reaction rates were measured at 45—55°C where satisfactory first-order plots were obtained. The narrow temperature range and the side reaction may afford considerable uncertainty to the derived values of activation parameters. In the case of *o*-nitro-*N*-bromobenzamide the reaction rate gradually increased as the reaction proceeded, and the rate constants were calculated from the initial stage of the reaction. Therefore, the activation parameters of this derivative may be also attended with large uncertainty.

11) Y. Yukawa and Y. Tsuno, *J. Amer. Chem. Soc.*, **79**, 5530 (1957); Y. Yukawa and Y. Tsuno, *ibid.*, **80**, 6346 (1958).

The Hofmann Rearrangement. III. Kinetic Substituent Effects of 4- and 5-Substituted 2-Chloro-*N*-chlorobenzamides

Tsuneo IMAMOTO, Yuho TSUNO, and Yasuhide YUKAWA

The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka

(Received September 25, 1970)

The kinetic measurements of the Hofmann rearrangement of 2,4-, 2,5- 2,6-, and 3,5-disubstituted *N*-chlorobenzamides were carried out. The rate constants of 4- and 5-substituted 2-chloro-*N*-chlorobenzamides were applicable to the LArSR relationship:

$$\log k/k_0 = -2.21(\sigma^0+0.69\Delta\bar{\sigma}_R^+) + 0.03$$

indicating that the reactivity of the 2-chloro series was subjected to a larger additional conjugation effect than that of the 2-unsubstituted series. The detailed discussion of the reaction mechanism on the basis of these results supported strongly the concerted mechanism.

As has been described in the preceding papers,[1,2] kinetic studies of the Hofmann rearrangement of *mono*-substituted *N*-bromo- and *N*-chloro-benzamides were carried out with a view to elucidating its precise reaction mechanism. From the results, we concluded that both the bond-energy effect in the initial state and the participation of the migrating phenyl group in electron-deficient nitrogen in the transition state were important factors in characterizing the rearrangement.

In order to establish the existence of the above two factors, a kinetic study of the rearrangement of 4- and 5-substituted 2-chloro-*N*-chlorobenzamides has undertaken, and a further attempt has been made to evaluate each of them semi-quantitatively on the basis of LFER.

In this paper we will report these kinetic results, along with those of a few other disubstituted *N*-chlorobenzamides, and will discuss the reaction mechanism of the Hofmann rearrangement.

Experimental

Materials. *Disubstituted benzamides* were prepared by the usual methods and were identified by elementary analysis. The melting points of these amides are listed in Table 1.

Disubstituted N-chlorobenzamides were prepared by the methods described in the preceding paper. The melting points and the analytical data of these *N*-chloroamides are listed in Table 1.

Kinetic Measurements. The reaction rates were deter-

mined according to the procedure described in the preceding paper. The initial concentrations of *N*-chloroamide and sodium hydroxide employed were 0.025 mol/*l* and 0.5 N respectively.

Results and Discussion

The rates of the release of the chloride ion from the conjugate bases of *multi*-substituted *N*-chlorobenzamides were measured under the same reaction conditions as those used in connection with the preceding kinetics of *mono*-substituted *N*-chlorobenzamides. All the runs except those of the 3,5-dinitro derivative strictly obeyed first-order kinetics, at least to 75% completion of the reaction.[3] The reproducibility of the rate constant from repeated runs was within 0.7%, and the plots of log k/T *vs.* $1/T$ gave an excellent straight line in every case. The observed first-order rate constants are listed in Table 2. The rate constants at 30.00°C and the derived activation parameters are summarized in Table 3.

a) Extrapolated from data at other temperatures.

As a result of the previous kinetic studies of the Hofmann rearrangement of *mono*-substituted *N*-bromo- and *N*-chloro-benzamides, it was suggested that the bond-energy effect in the initial state and the participation of the phenyl group in electron-deficient nitrogen were important factors in controlling the reactivity. The most interesting point in connection with these two factors consists in the effects of the *para*-substituted electron-releasing conjugative groups on the reactivity. In the transition state these substituents facilitate the additional conjugation of the phenyl group with electron-deficient nitrogen, with a considerable stabilization of its state. In the inital state, however, such substituents increase the bond-order of the nitrogen-halogen bond through the cross-conjugation of the carbonyl group with the phenyl group and with the nitrogen orbital, and lead to a rate retardation with a stabilization of the initial state. The former conjugation effect is expected to give a comparatively large positive value of the reasonance parameter, r, of the LArSR relationship, whereas the latter effect will rather afford a negative r-value. The resonance parameter (r=0.41) for the rearrangement of *mono*-substituted *N*-chlorobenzamides can be qualitatively interpreted in terms of the mutual compensation of the conjugation effects in the initial and the transition states.

In order to establish these theories, it is necessary to ascertain the substituent effect in a system where the amide group is sufficiently hindered from conjugating with the phenyl group in the initial state, and so the kinetic study of 4- and 5-substituted 2-chloro-*N*-chlorobenzamides has been undertaken. The chloro group at the *ortho*-position has been chosen as the most suitable group in satisfying the following requirements: sufficient steric effect to restrict the through-conjugation of the amide group with the phenyl group in the initial state, measurable rates, and the easily-

3) In the case of 3,5-dinitro derivative excellent first-order plots were not obtained especially at the temperature lower than 45°C. This anomaly is presumably caused by accompanying the hydrolysis of the reactant conjugate base of *N*-chloroamide.

available amides.

The logarithms of the relative rate constants of the present 2-chloro series have been plotted against those of the preceding 2-unsubstituted series. As is illustrated in Fig. 1, all the *meta*-substituents and the *para*-nitro substituent form an excellent strainght line with a slope of 0.930 and a correlation coefficient of 0.9999, whereas the electron-releasing conjugative substituents at the *para*-position deviate upward from the correlation line. Each deviation, however, appears to be proportional to electron-releasing conjugative ability of its substituent. In fact, the least-mean-square calculation using the values of the electron-releasing conjugative ability ($\Delta\bar{\sigma}_R^+$)[4] gives an excellent straight line with a correlation coefficient of 0.9999, including all the *para*-substituents, as is shown in Fig. 2. The slope of the correlation line is 0.930, which is the same as that calculated from all the *meta*-substituents and the *para*-nitro substituent. This fact evidently indicates that the reactivity of the 2-chloro series is subjected to a larger additional conjugation effect than that of the 2-unsubstituted series. The application of the LArSR relationship to the present data gives a good linearity, as is shown in Fig. 3. Although the calculated reaction

$$\log k/k_0 = -2.21(\sigma^0+0.69\Delta\bar{\sigma}_R^+) + 0.03$$

constant ($\rho=-2.21$) is nearly equal to the value of the 2-unsubstituted series ($\rho=-2.43$), the resonance parameter ($r=0.69$) is considerably larger than that of the 2-unsubstituted series ($r=0.41$).

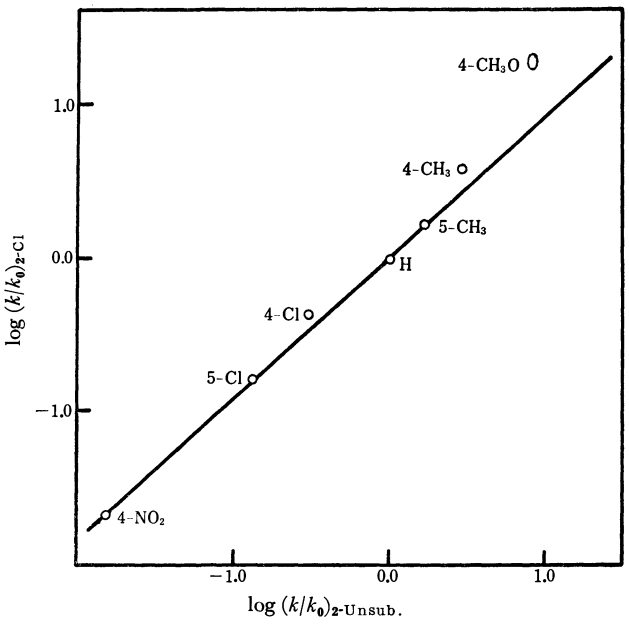

Fig. 1. Comparison with 2-unsubstituted derivatives.

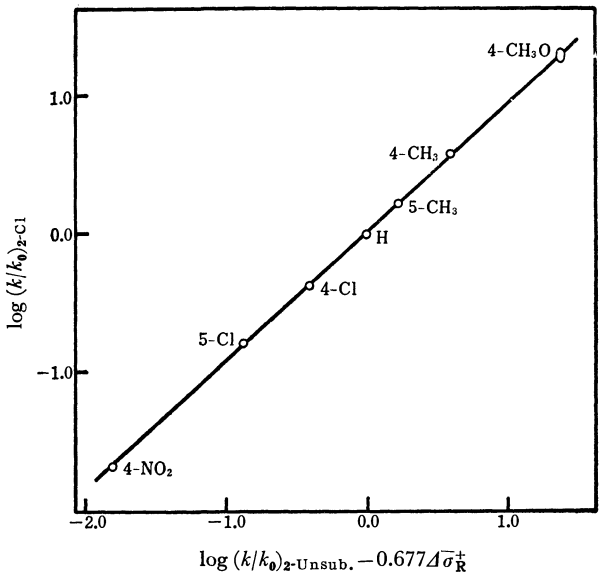

Fig. 2. Comparison with 2-unsubstituted derivatives with the application of the LArSR relationship.

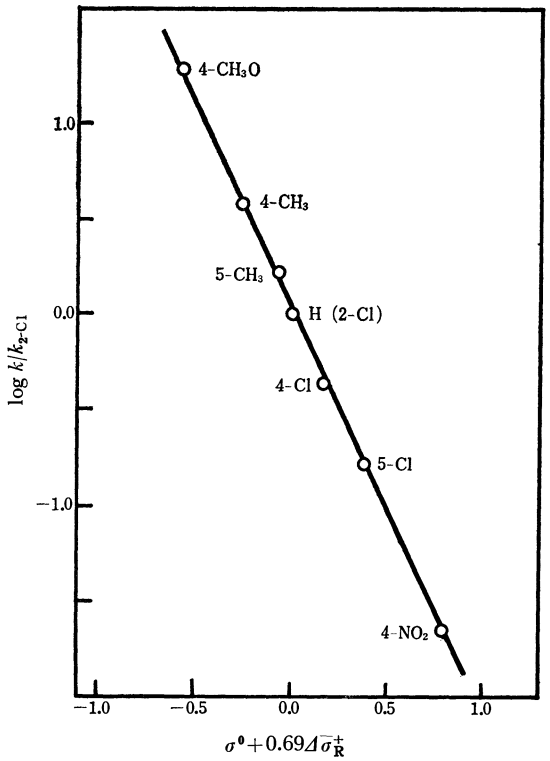

Fig. 3. Application of the LArSR relationship.

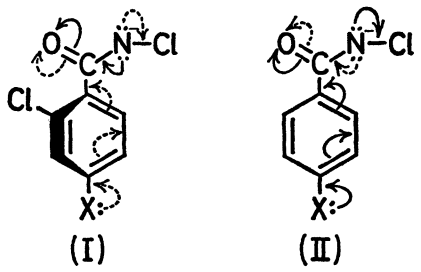
The conjugations applicable to the initial state are visualized in Formulae (I) and (II). The through-conjugation of the carbonyl group with the phenyl

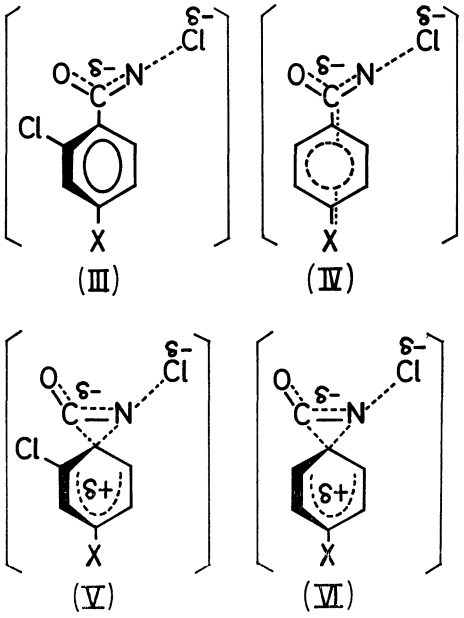


group is remarkably restricted in the 2-chloro system (I), while it is not in the 2-unsubstituted system (II). The substituent effect on this conjugation *effect* in the 2-chloro series, therefore, is expected to be

4) Y. Yukawa, Y. Tsuno, and M. Sawada, This Bulletin, **39**, 2274 (1966).

smaller than that in the 2-unsubstituted series.

On the other hand, in the transition state the degree of the conjugation in both series depends on the reaction mechanism (or on the structure of the transition state). In the two-step mechanism, the conjugation of phenyl group with the amide group is restricted in the 2-chloro system (III), but not in the 2-unsubstituted system (IV). On the contrary, in the concerted mechanism the degree of the conjugation may be expected to be almost the same for both the 2-chloro and 2-unsubstituted systems (V and VI), since in this state the phenyl ring is twisted almost at a right angle to the amide group due to the effective overlap of orbitals.



If the reaction proceeds through the two-step mechanism, the reactivity of the 2-chloro series should be considerably affected by the steric restriction of the conjugation in both the initial and transition states. The substituent effect of the conjugation effect on the 2-chloro series is expected to be smaller than that on the 2-unsubstituted series; the r-value of the 2-chloro series should be smaller than the value (0.41) of the 2-unsubstituted series. On the other hand, if the reaction proceeds through the concerted mechanism, the r-value to be observed on the 2-chloro series will be larger than the value of the 2-unsubstituted series, since the effect of the conjugation in the transition state is almost the same for both the 2-chloro and 2-unsubstituted series; further, the substituent effect on the conjugation effect in the initial state is reduced for the 2-chloro series more than for the 2-unsubstituted series. The comparatively large positive r-value (0.69) resulting in the 2-chloro series strongly supports the concerted mechanism rather than the two-step mechanism.

It is of interest to discuss the effect of the introduction of the chlorine atom into the *ortho*-position in relation to the above discussion of the substituent effect of

Table 4.

k_{2-Cl}/k_H	= 1.6
$k_{2,6\text{-di-Cl}}/k_H$	= 0.35
$k_{2,6\text{-di-Cl}}/k_{2\text{-Cl}}$	= 0.22
$k_{2\text{-Cl}}/k_{4\text{-Cl}}$	= 5.3
$k_{2,6\text{-di-Cl}}/k_{2,4\text{-di-Cl}}$	= 0.52

4- and 5-substituted 2-chloro-*N*-chlorobenzamides. The relative reactivities among unsubstituted, 2-chloro, 4-chloro, 2,4-dichloro, and 2,6-dichloro derivatives are listed in Table 4. The first introduction of the chlorine atom at the *ortho*-position effects a small rate acceleration ($k_{2-Cl}/k_H=1.6$), where as the second one at another *ortho*-position effects rather a rate retardation ($k_{2,6-diCl}/k_{2-Cl}=0.22$). The steric rate effect of the *ortho*-substituent can be qualitatively evaluated by means of the *ortho*/*para* rate ratios, since the polar effect of the *ortho*-substituent is generally recognized to be nearly equal to that of the corresponding *para*-substituent. The k_{2-Cl}/k_{4-Cl} value of the present reaction is calculated to be 5.3, indicating considerable steric rate acceleration due to the first introduction of the *ortho*-chloro substituent. The value of $k_{2,6-diCl}/k_{2,4-diCl}$, which corresponds to the steric rate effect due to the other *o*-chloro substituent, is calculated to be 0.52, indicating that the steric effect of the other *o*-chloro substituent affords a rather small rate retardation.

From these results, it would be reasonable to consider that the first introduction of the chloro substituent at the *ortho*-position effects a large steric effect to restrict the conjugation of the phenyl group with the carbonyl group considerably. The observed value of the resonance parameter of the 2-chloro series, therefore, may be attributed for the most part to the conjugation effect in the transition state. This value can be compared with the r-value of the Beckmann rearrangement, the reaction mechanism of which is estimated to be a concerted one. The r-value of the Beckmann rearrangement under various conditions has been calculated to be *ca.* 0.65. If the substituent effect on the conjugation in the transition state of the Hofmann rearrangement has an r-value of about 0.7, the effect of the $d\pi$-$p\pi$ conjugation in the initial state in the 2-unsubstituted series might be estimated to be *ca.* −0.3 as a resonance parameter by the subtraction of the value of 0.7 from the observed r-value (0.41) of the 2-unsubstituted series. This estimated r-value of the bond-energy effect due to the $d\pi$-$p\pi$ conjugation of the nitrogen-chlorine bond is reasonable as compared with the observed r-values of the Curtius and the Wolff rearrangements, which are characterized exclusively by the bond-energy effect of the $N-N_2$ bond.[5]

It is also of interest to discuss the substituent effects on the Hofmann rearrangement in terms of the derived activation parameters. The plots of $\Delta H^{\neq}$ *vs.* $\Delta S^{\neq}$ are

5) The r-values of the Curtius rearrangement in toluene and of the Wolff rearrangement in toluene are −1.04 and −1.7, respectively; Y. Yukawa and Y. Tsuno, *J. Amer. Chem. Soc.*, **79**, 5530 (1957); Y. Yukawa and Y. Tsuno, *ibid.*, **80**, 6346 (1958); Y. Yukawa, Y. Tsuno, and T. Ibata, This Bulletin, **40**, 2613 (1967); Y. Yukawa, Y. Tsuno, and T. Ibata, *ibid.*, **40**, 2618 (1967).

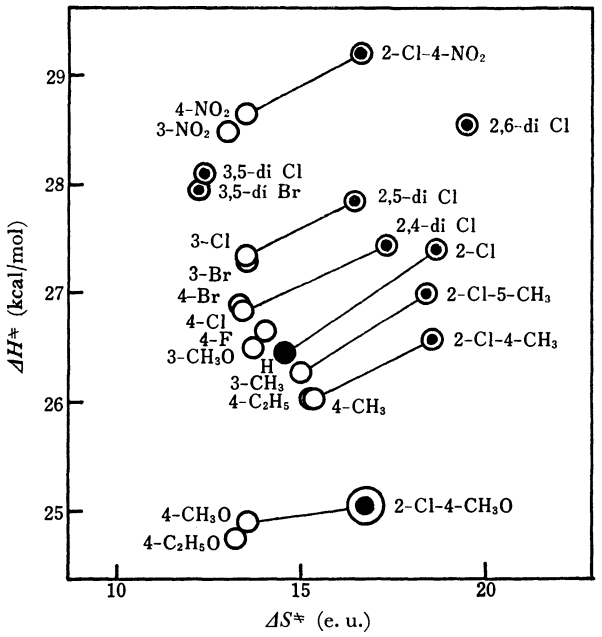


Fig. 4. $\Delta H^{\ddagger}$ *vs.* $\Delta S^{\ddagger}$ for the Hofmann rearrangement.

shown in Fig. 4, along with those of the *meta*- and *para*-substituents of the 2-unsubstituted series studied previously. In the case of the 2-unsubstituted series the enthalpy of activation varies from *ca.* 24.5 to *ca.* 28.5 kcal, although the entropy of activation varies merely from *ca.* 13 to *ca.* 15 e.u. This enthalpy dependency of the substituent effect on the reactivity is presumably caused both by the bond-energy effect in the initial state and by the additional conjugation effect of the phenyl group in the transition state, rather than by the solvation effect. The solvation effect is surely considered to play an important role in the reactivity; however, the substituent effect on it appears to be almost the same throughout the series. Another noticeable fact is shown by the plots of the 2-chloro series, which form a pattern similar to that of the 2-unsubstituted series, though they deviate in parallel fashion by *ca.* 3 e.u. and *ca.* 0.5 kcal from the corresponding plots of the 2-unsubstituted series. This fact shows that the reaction mechanism of the 2-unsubstituted and 2-chloro series are substantially the same. In the 3,5-dichloro and 3,5-dibromo derivatives, excellent additivities are found not only in the free energy of activation but also in the entropy and the enthalpy of activation. These additivities also indicate that the reaction mechanism of this rearrangement does not change with the change in the polar effect, at least not in the cases examined. The 2,6-dichloro derivative, however, does not retain any additivity. The failure of the additivity in the free energy of activation may be attributed to the entropy of activation, as is indicated in Fig. 4. The entropy gain caused by the concerted mechanism is perhaps saturated by the first introduction of the chlorine atom. The second introduction will afford rather rate retardation because of the additional polar effect.

Synthesis and Spectral Properties of Chloro-substituted Triptycenes

Ikuko MORI, Tadao KADOSAKA,* Yoshiteru SAKATA, and Soichi MISUMI

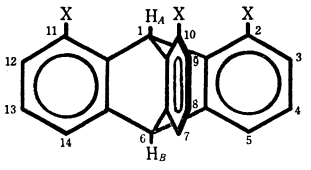
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received October 22, 1970)

A series of 2-, 7-, 10-, and 11-chloro-substituted triptycenes were prepared by means of the addition of benzyne or 3-chlorobenzyne to anthracene and its derivatives for studying the effect of chloro-substituent on electronic and NMR spectra. It was found that the intensity of the longest wavelength bands in the chlorotriptycenes could be explained in terms of superposition of three benzenoid chromophores, and that the calculated value of chloro-group on magnetic anisotropy was in good agreement with the values reported.

Owing to its rigid cage structure which enables σ-type overlap between three isolated π-electron systems, triptycene has been given much attention since the first synthesis by Bartlett *et al.*[1] Thereafter many derivatives have been synthesized[2] for the investigation of electronic, NMR, and CD spectral properties.

A stepwise introduction of a particular substituent at 2-, 10-, and 11-positions of triptycene (I) is interesting



I

for the study of the effect of the substituent on the electronic absorption spectrum of triptycene. Such derivatives are suitable for exploring the magnetic anisotropy of the substituent by comparison of the chemical shift of bridgehead proton H_A with that of the other one H_B.

In the present paper we will report on the synthesis and the spectral, electronic and NMR properties of several chlorotriptycenes.

Results and Discussion

Synthesis The synthesis of mono-, di-, and trichlorotriptycenes was carried out according to the reaction sequence shown in Chart 1. Chloro-substituted anthracenes, III, IV, and V, were prepared from the corresponding anthraquinone derivatives by reduction with zinc and aqueous ammonia.[3] The mono- and di-chlorotriptycenes were obtained in two ways, by the reaction of the corresponding chloroanthracenes with benzyne generated from anthranilic acid according to the procedure of Friedman,[4] and by the reaction of anthracene and 1-chloroanthracene with 3-chlorobenzyne generated from 6-chloroanthranilic acid. The fact that both methods give identical products, 2-chloro-

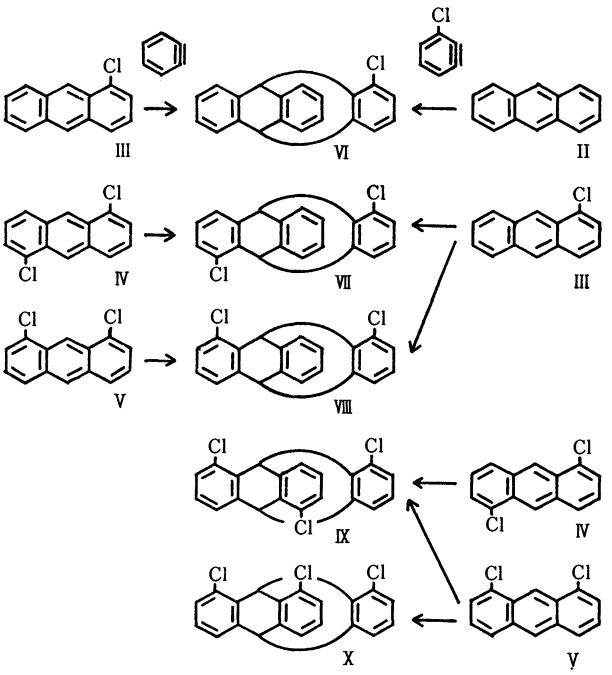


Chart 1

triptycene (VI) and dichlorotriptycenes (VII and VIII), indicates intermediary formation of 3-chlorobenzyne from 6-chloroanthranilic acid. 2,7,11-Trichlorotriptycene (IX) was prepared by the addition of 3-chlorobenzyne to 1,5-dichloroanthracene (IV), while an isomer, 2,10,11-trichlorotriptycene (X) was obtained along with IX by use of 1,8-dichloroanthracene (V) in place of IV. The properties and yields of the above chlorotriptycenes are summarized in Table 5.

In general, a mixture of two isomeric triptycenes, quasi-*trans* and quasi-*cis*, is obtained by the reaction of 3-chlorobenzyne with the substituted anthracenes devoid of center of symmetry, *i.e.*, III, V, and XI; for example, a mixture of quasi-*trans* (XII) and quasi-*cis* (XIII) from XI as follows.

As the isomers are distinguishable from the chemical shifts (Table 4) of the bridgehead protons in NMR spectra, the ratio of the isomers can be determined by comparison of their peak areas. The ratios obtained are shown together with those of 9-substituted anthracenes in Table 1. It is difficult to attribute these ratios to steric requirement of substituents. The inductive effect of the substituents would be mainly operative in determining the ratios.

Table 1. Ratios of isomeric triptycenes yielded by the reaction with 3-chlorobenzyne

Anthracene	Triptycene derivative quasi-*trans*/quasi-*cis*
1-Chloro- (III)	1
1,8-Dichloro- (V)	1.9
9-Chloro- (XI)	1.9
9-Methyl- (XI)	1
9-Ethyl- (XI)	1
9-*i*-Propyl- (XI)	0.8

Electronic Spectra Two different interpretations have been given on the electronic spectra of triptycene and its derivatives up to the present. On the basis of appreciable spectral difference between triptycene and triphenylmethane, Bartlett and Lewis ascribed the difference to the intramolecular charge transfer in the former.[5] On the other hand, Wilcox, Jr., and Craig gave the explanation that the electronic spectrum of triptycene could be regarded as the superposition of three benzenoid chromophores on the ground of crude MO calculation.[6]

The spectra of chloro-substituted triptycenes are shown along with those of the parent compound triptycene in Fig. 1 and Table 2. They show that all the longest wavelength bands of chlorotriptycenes appear at the same position, but the intensity of the bands at 260—280 mμ decreases with the increase of the number of chloro-substituent. It seems that this phenomenon can be explained by Platt's quantitative approach to the intensities of the ^1L_b band in polysubstituted benzenes.[7] He assigned to each substituent a quantity

called the spectroscopic moment m, which has units of (centimeter moles/liter)$^{1/2}$ and from which the increase or the decrease in the maximum extinction ε can be calculated by the following vector-addition formula for two substituents.

$$\varepsilon - \varepsilon_0 \sim m_i^2 + m_j^2 - 2m_i m_j \cos\theta \qquad (1)$$

where ε_0 is the vibrational intensity of benzene itself and θ is the angle between the axes through each substituent and bisecting the ring.

To calculate the intensity, triptycene is divided into three *o*-xylene chromophores, and 2-chlorotriptycene is divided into one 3-chloro-*o*-xylene and two *o*-xylene chromophores in the same manner. Then the relative intensities of *o*-xylene and 3-chloro-*o*-xylene are res-

Table 3. Calculated and observed values for the intensity of the longest wavelength absorption bands of chlorotriptycenes

2,10,11-Cl_3- (X)	537	975

5) P. D. Bartlett and E. S. Lewis, *J. Amer. Chem. Soc.*, **72**, 1011 (1950).
6) C. F. Wilcox, Jr., *J. Chem. Phys.*, **33**, 1874 (1960); C. F. Wilcox, Jr., and A. C. Craig, *J. Org. Chem.*, **26**, 2491 (1961).
7) J. R. Platt, *J. Chem. Phys.*, **19**, 263 (1951).

pectively 49 and 1, estimated by Eq. (1) and the moments of methyl and chlorine groups (7 and 6).[7] Assuming the ε-values of *o*-xylene chromophore is one third of ε-value of triptycene (ε=4740) and ε_0 is 150,[7] $\varepsilon-\varepsilon_0$ value of 3-chloro-*o*-xylene is $(4740/3-150)\times 1/49$. Thus the ε-value of the longest wavelength bands of chlorotriptycenes were calculated as shown in Table 3.

The calculated values also show the decreasing tendency of the intensities with the number of chloro-substituent. A moderately good agreement between observed and calculated values was obtained. The small difference between both values is possibly due to the replacement of the spectroscopic moment of bridgehead carbon simply by that of methyl group.

Consequently, we suppose that the intensity of ^1L_b bands of chlorotriptycenes can be accounted for in terms of the superposition of three benzenoid chromophores, which supports Wilcox, Jr.'s interpretation on the UV spectra of triptycene.

NMR Spectra The NMR spectra of triptycene and its derivatives were first reported by Theilacker *et al.*[8] and later analyzed in detail by Smith and Shoulders,[9] and Kidd *et al.*[10] The spectrum of triptycene in carbon disulfide reveals an $A'_2B'_2$ pattern of aromatic protons centered at 2.96 τ and a singlet of two bridgehead tertiary protons at rather low field of 4.79 τ. Supposing that a substituent is introduced at 2- or 3-position of triptycene, bridgehead proton should shift to higher or lower field owing to the anisotropy of the substituent. Thus the magnitude of such shifts will allow us to estimate the shielding effect of the substituent by comparison with the other bridgehead proton as in structure (I). Table 4 shows the chemical shifts of bridgehead

Table 4. Chemical shifts (δ) of bridgehead protons of chlorotriptycenes in $AsCl_3$ and average internal chemical shift per chlorine atom

protons of chlorotriptycenes. The spectra of chlorotriptycenes (VI—X) were all measured in arsenic trichloride because of poor solubility of trichloroderivatives (IX and X) in the usual organic solvents. The table reveals that with the increase of the number of chlorine atoms the resonance position of the bridgehead proton regularly shifts to lower field by average 0.43 ppm.[11]

A difference in net shielding, or the internal chemical shift $\Delta\sigma$, between two protons H_A and H_B in a molecule can generally be expressed by the equation

$$\Delta\sigma = \sigma_A - \sigma_B = \Delta\sigma_d + \Delta\sigma_w + \Delta\sigma_e \quad (2)$$

where $\Delta\sigma_d$ is magnetic anisotropy effect, $\Delta\sigma_w$ is the van der Waals effect and $\Delta\sigma_e$ is electric field effect. In reference to the X-ray analysis[12] the geometry of chlorotriptycenes was drawn from which the distance r between a bridgehead proton nearer to chlorine atom and the midpoint of C–Cl bond, the distance R between the proton and the chlorine atom, and the angle θ given by the line represented as r and C–Cl bond axis were measured, as shown in Fig. 2.

The electric field effect $\Delta\sigma_e$ in Eq. (2) is calculated by the equation of Buckingham[13]

$$\Delta\sigma_e = -2\times 10^{-12}E_z - 10^{-18}E^2, \quad (3)$$

and the electric field term E is estimated by the following equation, assuming the point charge.

$$E = \mu/R^2\cdot l, \quad (4)$$

where μ is the dipolemoment of chlorobenzene (1.56 D) and l is the distance between chlorine atom and the center of the benzene ring (Fig. 2).

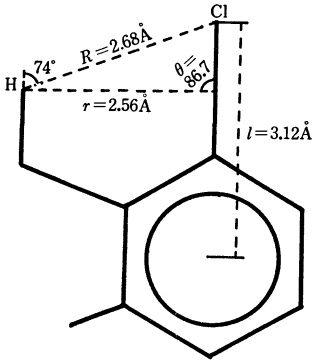

Fig. 2. Measured distances (R, r, and l) and angles in chlorotriptycenes.

The steric compression effect $\Delta\sigma_w$ is estimated from the following equation which was presented by Bothner-By and modified by Nakagawa.[14]

$$\Delta\sigma_w = (-[R]/R^6)\times 7 \quad (5)$$

where [R] is atomic refraction. The value $\Delta\sigma_d$ (−0.03 ppm) which is left in substracting $\Delta\sigma_e$ (−0.29 ppm) and $\Delta\sigma_w$ (−0.11 ppm) from the observed value $\Delta\sigma$ may be ascribed to the long range shielding due to the magnetic anisotropy of the substituent. $\Delta\sigma_d$ is related with the measured values of θ and r by the following McConnell equation.[15]

1) benzyne method. 2) chlorobenzyne method.

$$\Delta\sigma_d = (1/3r^3)\Delta\chi(1-3\cos^2\theta) \quad (6)$$

A calculated value of $\Delta\chi$, -1.6×10^{-30} cm^3/molecule, is in good agreement with the values reported by Schaeffer and Yonemoto[16] (5×10^{-30} cm^3/molecule) and by Flautt[17] (1.5×10^{-30} cm^3/molecule).

Two bridgehead protons of 3-chlorotriptycene show a singlet peak, or no internal chemical shift, probably due to the smaller difference of distances between both protons and the substituent in 3-substituted triptycene than in 2-substituted one.

These results imply that our assumption is reasonable, and that the triptycene derivatives are fairly suitable compounds for the study of magnetic anisotropy, due to the presence of appropriate reference proton in the rigid molecular structure.

Experimental

All melting points are uncorrected. The IR and UV spectra were measured on a Jasco autorecording spectrometer DS-402G and on a Hitachi EPS-3T, respectively. The NMR spectra were measured on a Hitachi Perkin-Elmer R-20 spectrometer (60 MHz) using TMS as an internal standard. A frequency counter was used to measure the frequency separation between signals.

Mono-, Di-, and Tri-chlorotriptycenes. Preparation of mono-, di-, and tri-chlorotriptycenes was carried out using the Diels-Alder reaction of anthracene derivatives with benzyne or 3-chlorobenzyne, generated from anthranilic or 6-chloroanthranilic acid respectively (Chart 1). All the reactions were carried out according to the procedure of Friedman and Logullo.[4] 3-Chlorotriptycene was synthesized by the reaction of anthracene with 4-chlorobenzyne generated from 5-chloroanthranilic acid.

2-Chlorotriptycene (VI) obtained by two methods shows an identical melting point and spectral properties. The reaction of 1-chloroanthracene with 3-chlorobenzyne gave a mixture of dichlorotriptycenes, VII and VIII. Attempts to separate VII and VIII from the mixture were unsuccessful. However, the chromatography on alumina of the reaction mixture of 1,8-dichloroanthracene (V) with 3-chlorobenzyne resulted in the separation of the trichlorotriptycenes, IX and X. An early benzene fraction was evaporated and recrystallized from alcohol to give 2,7,11-trichlorotriptycene (IX). Crystals obtained from the latter fraction were treated with cyclohexane to remove IX from slightly soluble isomer, 2,10,11-trichlorotriptycene (X) and were recrystallized from cyclohexane to give pure X.

The analytical data, melting points and yields of several chlorotriptycenes obtained are summarized in Table 5.

Reaction of 3-Chlorobenzyne with 9-Alkyl- and 9-Chloro-anthracenes. All reactions of 3-chlorobenzyne with 9-alkyl- and 9-chloro-anthracenes were undertaken according to the general procedure[18] described in the following case of 9-methylanthracene.

To a solution of 9-methylanthracene[19] (2.0 g, 10 mmol) and *i*-amyl nitrite (2.0 m*l*, 15 mmol) in dimethoxyethane (20 m*l*) was dropwise added a solution of 6-chloroanthranilic acid (2.6 g, 15 mmol) in dimethoxyethane (10 m*l*) for 30 min under refluxing and stirring. After further reflux for 10 min and addition of *i*-amyl nitrite (2 m*l*), an additional solution of 6-chloroanthranilic acid (2.6 g) in dimethoxyethane (10 m*l*) was added dropwise to the mixture for 30 min under reflux. The mixture was refluxed for 20 min with stirring to complete the reaction and cooled, and the solvent was removed *in vacuo*. The residue obtained was treated with maleic anhydride (2.0 g) in xylene (25 m*l*) under reflux for 1 hr. After evaporation of xylene the residue was chromatographed on alumina (50 g) with benzene. A part (150 m*l*) of the effluent (700 m*l*) was evaporated to dryness in a vacuum and the residue was dissolved in deuterochloroform to measure NMR spectrum. The ratio of quasi-*trans*/quasi-*cis* in the product was determined from half-width of bridgehead proton signals in both isomers.

The authors wish to express their appreciation to Professor Masazumi Nakagawa of Osaka University for his continued encouragement through this work.

The Cyclization Products from Acetone with Cyanoacetic Esters

Minoru IGARASHI*,** and Hiroshi MIDORIKAWA**

*Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Ibaraki

**The Institute of Physical and Chemical Research, Wako, Saitama

(Received October 28, 1970)

The structure of the cyclization product from acetone with the cyanoacetic ester has been established as 3-alkoxycarbonyl(cyano)methylene-6-cyano-5,5-dimethyl-1-cyclohexene-1-ol by means of infrared and NMR spectroscopic determinations and by successive degradations.

A cyclic compound, $C_{14}H_{16}O_3N_2$, regarded as 4,6-dicyano-4-ethoxycarbonyl-3,5,5-trimethyl-$\Delta^{2,6}$-cyclohexadien-1-ol (I), was first obtained by Gardner and Haworth[1] by the condensatioln of acetone with a sodium derivative of ethyl cyanoacetate. The reaction course was inferred to be as follows.

$$(CH_3)_2CO + 2CH_2(CN)COOC_2H_5 \xrightarrow{NaOC_2H_5}$$

$$(CH_3)_2C(CH(CN)COOC_2H_5)_2 \xrightarrow{(CH_3)_2CO}$$

$$(CH_3)_2C\begin{matrix}\diagup CH(CN)COCH_2COCH_3 \\ \diagdown CH(CN)COOC_2H_5\end{matrix} \xrightarrow{(HCl)}$$

$$(CH_3)_2C\begin{matrix}\diagup C(CN)=\!=\!=\!=\!=C(OH)\diagdown \\ \diagdown CH(CN)COOC_2H_5 \quad HO(CH_3)C\diagup\end{matrix}CH \xrightarrow{-H_2O}$$

$$(CH_3)_2C\begin{matrix}\diagup C(CN)=\!=\!=\!=\!=C(OH)\diagdown \\ \diagdown C(CN)(COOC_2H_5)\text{-}C(CH_3)\diagup\end{matrix}CH \qquad (I)$$

They claimed that the product afforded a benzoyl derivative, but no rigorous proof for the structure was presented. The same product was obtained by us from acetone with ethyl cyanoacetate in the presence of potassium fluoride.[2] In view of the existing uncertainty of the structure of the product and our interest in the analogous cyclization reaction, it seemed worth while to reinvestigate the condensation product of acetone and cyanoacetic ester.

We prepared a compound, $C_{13}H_{14}O_3N_2$, by the condensation of acetone with methyl cyanoacetate in the presence of anhydrous potassium fluoride. After purification by recrystallizations, the product was obtained as pale yellow plates, mp 175°C, which were turned green by the action of ferric chloride in an alcoholic solution and which dissolved readily in an aqueous sodium carbonate solution. The reaction of the product with an excess of alcoholic 2,4-dinitrophenylhydrazine gave no precipitates, but the product became slightly reddish-yellow after standing for several days. These results indicated the structure of the product to be the enol-form rather than the tautomeric keto-form.

The infrared spectrum (Nujol) (Fig. 1) of the product showed an OH stretching band at 3110 cm^{-1} and a band located at 3530 cm^{-1} in an acetone solution. Other prominent bands were observed at 2270 cm^{-1} (very weak) and 2220 cm^{-1} (strong), corresponding to the presence of unconjugated and conjugated nitrile groups respectively. Absorption bands characteristic of the carbonyl group (1720 cm^{-1}) and the C=C group (1590 cm^{-1}) were observed. These infrared spectrum data render the formula I untenable and suggest that formula II or III is more plausible:

$$NC\diagdown \overset{4}{C}H_2\text{-}\overset{5}{C}(CH_3)_2\diagdown{}^{6} \quad \text{(II)}$$
$$\quad {}^{3}C=C \qquad\qquad CHCN$$
$$CH_3OOC\diagup \quad \diagdown CH=C(OH)\diagup$$
$$\qquad\qquad {}_{2} \quad {}_{1}$$

$$CH_3OOC\diagdown \quad \diagup CH_2\text{-}C(CH_3)_2\diagdown \quad \text{(III)}$$
$$\quad C=C \qquad\qquad CHCN$$
$$NC\diagup \quad \diagdown CH=C(OH)\diagup$$

The structure could also be deduced from the NMR spectrum, and a complete assignment could be made in terms of a mixture of two geometrical isomers, II and III.

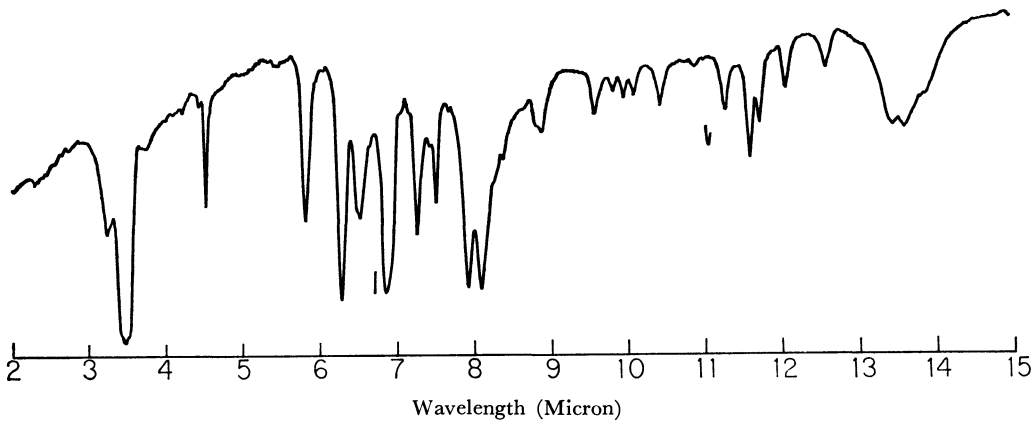

Fig. 1. The IR spectrum of 6-cyano-5,5-dimethyl-3-methoxycarbonyl(cyano)methylene-1-cyclohexene-1-ol.

1) H. D. Gardner, Jr., and W. N. Haworth, *J. Chem. Soc.*, **95**, 1955 (1909).

2) M. Igarashi, H. Midorikawa, and S. Aoyama, *J. Sci. Res. Inst.*, **52**, 105 (1958).

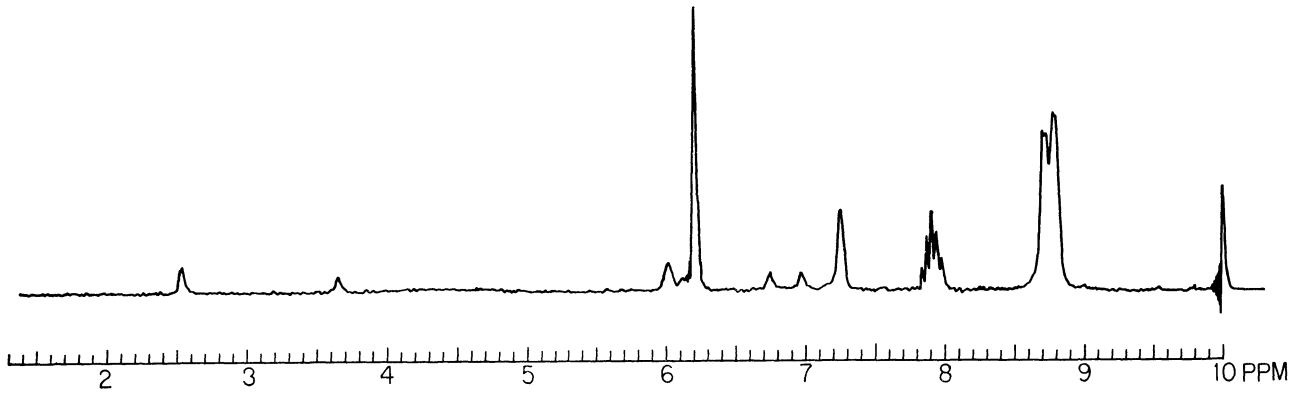

Fig. 2. The NMR spectrum of 6-cyano-5,5-dimethyl-3-methoxycarbonyl(cyano)methylene-1-cyclohexene-1-ol.

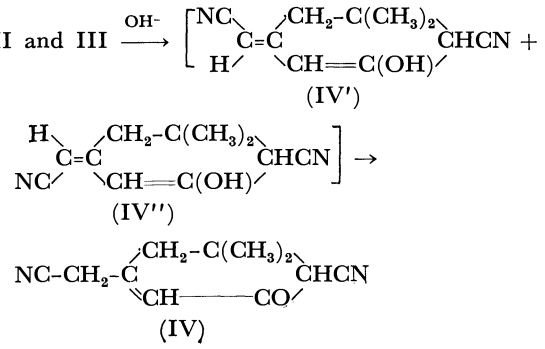
The spectrum (deuterioacetone) (Fig. 2) contained two doublets, (each 3H) at 1.22 and 1.29 ppm, which can be ascribed to the C5–dimethyl groups. The methylene group gave rise to a singlet and a doublet at 2.75 and 3.14 ppm respectively. C4–(axial)H and (equatorial)H of the III isomer would be expected to give more separated signals than those of the II isomer because of the marked interaction with the ester carbonyl group. Molecular-model considerations supported this effectation. On the basis of this assumption, the singlet was assigned to the C4–H_2 protons of the II isomer, and the doublet, to those of the III isomer. In both isomers, the O–CH_3 signal of the ester group appeared at 3.80 ppm as a sharp singlet. The singlet (1H) at 4.00 ppm was assignable to the C6–H since it would be expected to appear at a higher field than the olefinic C2–H. Two signals (1H), at 6.35 and 7.46 ppm, were assigned to the C2–H proton. One of these (7.46 ppm) was indicative of C2–H in the II isomer, since the isomeric composition estimated on the basis of the integration of the area under this signal was consistent with that estimated on the basis of a signal at 2.75 ppm, which has been assigned to C4–H_2 of the II isomer. From the NMR spectrum, the composition of the mixture was estimated to be: II isomer, 60%, and III isomer, 40%.

Substantially the same result was obtained from the condensation product, $C_{14}H_{16}O_3N_2$, mp 135°C, of acetone with ethyl cyanoacetate under similar conditions. In this case, the isomer ratio was 50:50.

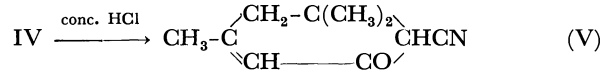
6-Cyano-5,5-dimethyl-3-methoxycarbonyl(cyano)-methylene-1-cyclohexene-1-ol (containing the II and III isomers) was hydrolyzed with aqueous sodium hydroxide for 3 hr to give 6-cyano-3-cyanomethyl-5, 5-dimethyl-2-cyclohexene-1-one (IV) (85% yield).



We had expected to obtain a mixture of two isomeric compounds, IV′ and IV″. However, the product obtained gave no evidence of being a mixture (tlc, IR, and NMR). The structure of IV was confirmed as follows.

The product readily afforded the corresponding hydrazone, in contrast to the case when the starting materials were II and III, when it was treated with 2, 4-dinitrophenylhydrazine in ethanol. The infrared spectrum of the product revealed a band at 2270 cm^{-1} characteristic of the unconjugated nitrile group, and none due to the conjugated one. Other prominent bands observed at 1680 and 1640 cm^{-1}, which may be assigned to the stretchings of C=O (conjugated) and C=C (conjugated) groups respectively, suggest the presence of the keto-form structure, IV.

The NMR spectrum (deuteriochloroform) showed signals at 1.19 and 1.33 ppm (singlets) due to the two methyl groups. The singlet at 2.45 ppm (2H) was assignable to the ring methylene protons (C4–H_2), and the singlet at 3.35 ppm (2H), to the side-chain protons (C3–CH_2–CN), because the latter disappeared completely when IV was converted into V. Two signals were observed for the methine protons. We attribute the signal at 3.45 ppm to the C6–H proton, and the signal at 6.30 ppm to the C2–H proton, on the general ground that the olefinic proton is more deshielded than the paraffinic proton.



(V)

The hydrolysis and subsequent decarboxylation of IV yielded a ketone (yield 80%). Microanalysis supported the formula of $C_{10}H_{13}ON$. The infrared spectrum revealed a band at 2270 cm^{-1} attributable to a unconjugated nitrile group, a strong carbonyl band at 1675 cm^{-1}, and a conjugated C=C band at 1635 cm^{-1}.

The NMR spectrum (Fig. 3) of the product showed three singlets (each 3H), at 1.08, 1.23, and 1.98 ppm. The two higher-field singlets were ascribed to the C5–dimethyl groups by analogy with those of compounds II—IV. Then, the remaining lower field singlet was ascribed to the C3–methyl group. The methylene protons in the ring (C4–H_2) gave a singlet at 2.35 ppm; this was consistent with that of the compound IV. The singlets at 3.38 (1H) and 5.88 (1H) ppm were

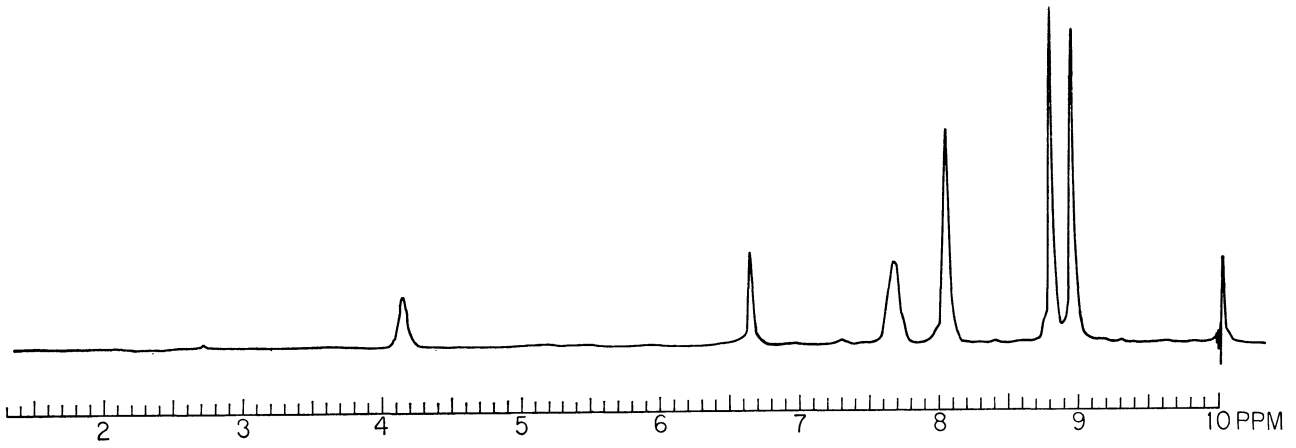


Fig. 3. The NMR spectrum of 6-cyanoisophorone.

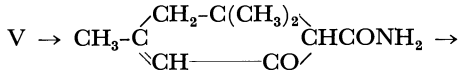
assigned to the C6–H and C2–H protons respectively by a comparison with those of the other, known 2-cyclohexene-1-one systems.[3]

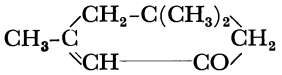
From the above data, we assign the product to the V structure, 6-cyanoisophorone.

6-Cyanoisophorone (V) was converted into 6-carbamoylisophorone (VI) with 75% sulfuric acid at 70—80°C for 2 hr. The infrared spectrum of the product showed the two bands at 3355 and 3135 cm^{-1} characteristic of the NH_2 group. The remainder of the spectrum was consistent with the presence of a $CONH_2$ group. These bands disappeared from the spectrum when the compound was hydrolyzed and subjected to decarboxylation.

Finally, the hydrolysis of the amide VI with 75% sulfuric acid at 130—150°C for 3 hr yielded isophorone (VII). The infrared spectrum and the mp (144°C) of its 2,4-dinitrophenylhydrazone were identical with those of an authentic sample.



(VI)



(VII)

From the facts that the cyclic products (II and III) were obtained from only the isopropylidenecyanoacetic ester and that its dimer was isolated as the intermediate,[2] the reaction course may be concluded to be as shown in Scheme I.

Experimental

The infrared spectra were recorded on a Shimadzu model IR-27G infrared spectrophotometer. The NMR spectra were measured on a JNM-60 high-resolution NMR spectrometer operating at 60 MHz. The chemical shifts are given as ppm downfield from tetramethylsilane as the internal standard.

6-Cyano-5,5-dimethyl-3-methoxycarbonyl(cyano)methylene-1-cyclohexene-1-ol. The condensation was carried out according to the method previously used.[2]

Acetone (11.6 g) and methyl cyanoacetate (9.9 g) were mixed, and then anhydrous potassium fluoride (5.8 g) was added to the mixture. After refluxing for 10 hr on a water bath, the reaction mixture was cooled, dissolved in water, acidified with hydrochloric acid, and extracted with ether. The ethereal solution was washed several times with water and shaken with an aqueous sodium carbonate solution. When the alkaline solution was acidified with hydrochloric acid, a yellowish oil separated. After a while, the oil solidified to a hard cake. The yield was 13.6 g (55%). It was crystallized from acetone - water to slight yellow needles melting at 177—178°C (decomp).

The compound dissolved readily in an aqueous sodium carbonate solution, and it gave a green coloration with ferric

chloride in an alcoholic solution. The reaction of the product with 2,4-dinitrophenylhydrazine in an ethanolic solution gave no crystalline material; it only turned slightly reddish-yellow after standing for several days.

Found: C, 63.60; H, 5.72; N, 11.48%; mol wt, 242. Calcd for $C_{13}H_{14}O_3N_2$: C, 63.40; H, 5.73; N, 11.38%; mol wt, 246.

IR(Nujol): 3110 (OH), 2270 (very weak) (unconjugated CN), 2220 (strong) (conjugated CN), 1725 (CO), 1590 (side chain C=C), 1540 (ring C=C) cm^{-1}.

NMR (deuterioacetone): 1.22 (doublet) (CH_3), 1.29 (doublet) (CH_3), 2.75 (singlet) and 3.15 (doublet) (CH_2), 4.00 (singlet) (C6–H), 6.35 (singlet) and 7.46 (singlet) (C2-H) ppm.

6-Cyano-3-cyanomethyl-5,5-dimethyl-2-cyclohexene-1-one (IV). A mixture of the unsaturated ester (II and III) (0.1 mol) and a 0.2 N sodium hydroxide solution (0.2 mol) was allowed to saponify for 3 hr on a water bath. The alkaline solution was cooled. When it was acidified with dilute hydrochloric acid, a yellowish oil separated from the aqueous solution. The oil solidified when it was allowed to stand in an ice-box. The yield was 83%. Recrystallizations from water gave slightly yellow needles; mp 111—113°C.

Found: C, 69.85; H, 6.56; N, 14.93%. Calcd for $C_{11}H_{12}ON_2$: C, 70.18; H, 6.43; N, 14.88%.

IR (Nujol): 2270 (CN), 1680 (C=O), 1640 (C=C) cm^{-1}.

NMR (deuteriochloroform): 1.19 (singlet) (CH_3), 1.33 (singlet) (CH_3), 2.45 (singlet) (C4–H_2), 3.35 (singlet) (C3–CH_2–CN), 3.45 (singlet) (C6–H), 6.30 (singlet) (C2–H) ppm.

2,4-Dinitrophenylhydrazone. Mp 212°C.

Found: C, 55.44; H, 4.06; N, 22.99%. Calcd for $C_{17}H_{16}O_4N_6$: C, 55.43; H, 4.38; N, 22.82%.

6-Cyanoisophorone (V). A mixture of IV (4.2 g) and concentrated hydrochloric acid was refluxed for one hour. The reaction mixture was then dissolved in water and extracted with ether. The ether extract on evaporation left an oil distilling at 163—164°C/12 mmHg. The oil solidified when it was allowed to stand overnight in an ice-box. The yield was 2.8 g (77%). Recrystallizations from chloroform-petroleum ether gave colorless plates; mp 56—57°C.

Found: C, 73.51; H, 7.90; N, 8.56%. Calcd for $C_{10}H_{13}ON$: C, 73.59; H, 8.03; N, 8.58%.

IR (Nujol): 2270 (CN), 1670 (C=O), 1635 (C=C) cm^{-1}.

NMR (carbon tetrachloride): 1.08 (singlet) (C5–CH_3), 1.23 (singlet) (C5–CH_3), 1.98 (singlet) (C3–CH_3), 2.35 (singlet) (C4–H_2), 3.38 (singlet) (C6–H), 5.88 (singlet) (C2–H) ppm.

2,4-Dinitrophenylhydrazone. Mp 230°C.

Found: N, 20.24%. Calcd for $C_{16}H_{17}O_4N_5$: N, 20.40%.

6-Carbamoylisophorone (VI). To a solution of 95% sulfuric acid (10 g) and water (2 g), 6-cyanoisophorone (3 g) was added, and then the mixture was heated at 70—80°C for 2 hr. After being cooled, the solution was poured into ice water and extracted with ether. The ethereal solution was repeatedly washed with water, and then the ether was removed. The oily residue solidified when it was allowed to stand overnight in an ice-box. Recrystallizations from methanol gave colorless plates; mp 139—140°C (yield, 75%).

Found: C, 66.05; H, 8.09; N, 7.68%. Calcd for $C_{10}H_{15}O_2N$: C, 66.27; H, 8.34; N, 7.73%.

Isophorone VII. A mixture of 75% sulfuric acid (2 m*l*) and 6-carbamoylisophorone (0.6 g) was heated at 150—160°C for 3 hr. After cooling, the reaction mixture was poured into ice water and extracted with ether. The ethereal solution was washed, dried, and then evaporated. The distillation of the residue gave isophorone; bp 95—100°C/2 mmHg (lit,[4] bp 109°C/32 mmHg).

IR: 1670 (C=O), 1640 (C=C) cm^{-1}.

2,4-Dinitrophenylhydrazone. Mp 144—145°C (lit,[4] mp 146°C).

Found: N, 17.70 %. Calcd for $C_{15}H_{18}O_4N_4$: N, 17.60%.

The authors wish to express their hearty thanks to Professors Taro Hayashi and Tatsuo Takeshima for their kind advice and encouragement, and to Dr. Haruo Homma and his staff for their microanalyses.

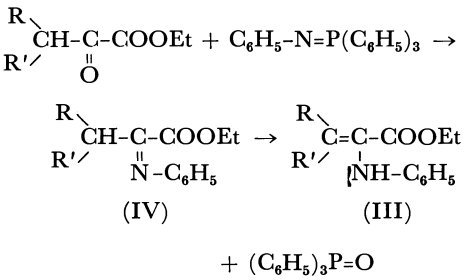
(Received October 30, 1970)

Isolation of a primary enamine and its tautomeric imine has been described and their dimerization discussed. Reduction of ethyl 3-methyl-2-nitro-2-butenoate with aluminum amalgam afforded ethyl 2-amino-3-methyl-2-butenoate (I) (enamine form), while treatment of ethyl 3-methyl-2-oxobutanoate with triphenylphosphinimine gave ethyl 2-imino-3-methylbutanoate (II) (imino form). The enamine and its tautomeric imine dimerized to give 3,6-diisopropylidene-2,5-dioxopiperazine (VII) and 2-ethoxycarbonyl-2,5-diisopropylimidazolid-4-one (IX), respectively. However, individual acylation of both the enamine and the imine gave the same acyl compound.

It has been postulated that α-imino acids are important intermediates in the transformation between α-amino acids and α-keto acids.[2] However, there has been no report on the tautomerism between imino acid and enamino acid. Previous investigations on the enamine had dealt almost exclusively with secondary and tertiary enamines.[3]

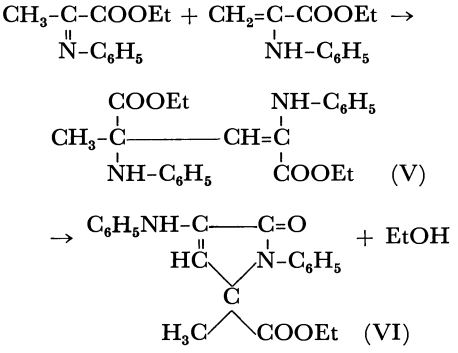
In a previous paper,[4] the authors reported briefly that a primary enamine (ethyl 2-amino-3-methyl-2-butenoate: I) could be isolated as a reduction product of the corresponding α,β-unsaturated α-nitrocarboxylic ester, and the tautomeric imine (ethyl 2-imino-3-methylbutanoate: II) from a reaction mixture of the corresponding α-oxocarboxylic ester with triphenylphosphinimine. The acylation of both I and II, however, gave the same acyl enamine derivative and the dimerization of I and II gave dioxopiperazine (VII) and imidazolidone derivative (IX), respectively. The isomerization between I and II, however, was unsuccessful.

On the other hand, in the case of the reaction of α-oxocarboxylic esters with *N*-phenyltriphenylphosphinimine, secondary enamine (III) and the tautomeric imine (IV) were obtained as an equilibrium mixture.



Scheme 1

On the basis of the IR and NMR data, it has been found that the isomerization of IV to III occurred and the composition of the reaction mixture was evaluated.[5] So far, however, a complete enamine-imine interconversion between III and IV has been unsuccessful.[5] In the case of ethyl pyruvate, the reaction mixture (III and IV; R=R′=H) dimerized to give 3-anilino-5-ethoxycarbonyl-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (VI) *via* ethyl 2,4-dianilino-4-ethoxycarbonyl-2-pentenoate (V) as an intermediate.[5]



Scheme 2

This paper reports the synthesis of ethyl 2-imino-3-methylbutanoate (II) through the reaction of ethyl 3-methyl-2-oxobutanoate with triphenylphosphinimine by the method of Appel and Hauss,[6] as well as the dimerization and chloroacetylation of I and II, respectively.

Results and Discussion

According to the method of Tatsuoka *et al.*[7] ethyl 2-amino-3-methyl-2-butenoate (I) was prepared in a 56% yield as a pale yellow oil from ethyl 3-methyl-2-nitro-2-butenoate with aluminum amalgam in ether under reflux.[8] Appel and Hauss reported the reaction of methyl pyruvate with triphenylphosphinimine to give methyl 2-iminopropionate, though the structure of the

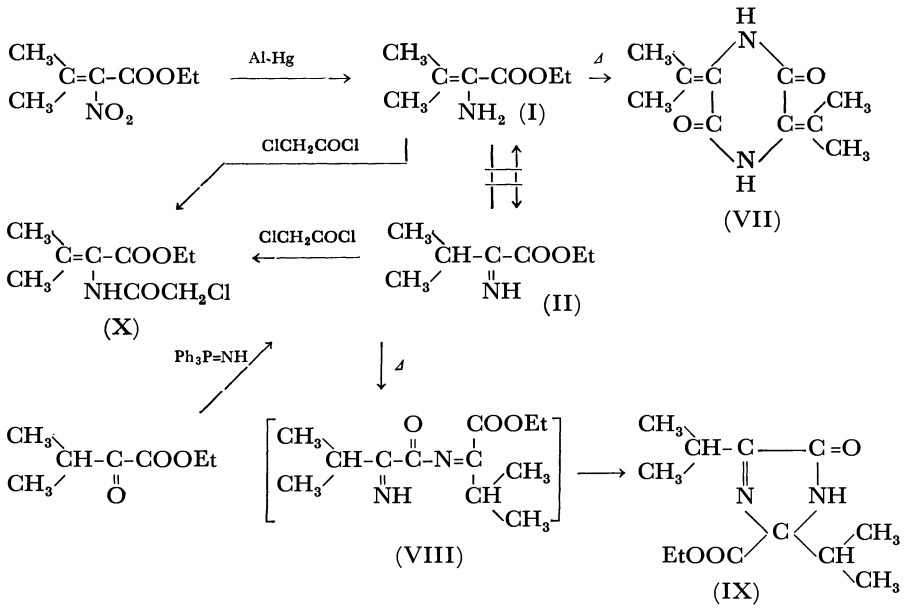

Scheme 3

product was not clarified since the product could not be isolated and its characterization was deduced only by hydrogenation into (±)-alanine.[6] However, treatment of ethyl 3-methyl-2-oxobutanoate with triphenylphosphinimine in anhydrous acetonitrile for 2 hr under reflux afforded a pale yellow oil as an analytical pure product in a 40% yield, and the product was identified as ethyl 2-imino-3-methylbutanoate (II), the tautometric isomer of I. The infrared spectrum of II showed an intense ester carbonyl band at 1730 cm^{-1} and a medium band attributable to C=N stretching vibration at 1640 cm^{-1}, while that of I showed two intense absorption bands at 1730 cm^{-1} and 1690 cm^{-1} and medium bands at 1640 and 1600 cm^{-1} as shown in Figs. 1A and 1B.

The NMR spectrum of I showed peaks at τ 5.72 (q, $-C\underline{H}_2CH_3$, 2H), 6.82 (broad s, $-NH_2$, 2H), 7.91 (s, $-CH_3$, 3H), 8.22 (s, $-CH_3$, 3H), and 8.67 (t, $-CH_2C\underline{H}_3$, 3H), while that of II showed peaks at τ 0.00 (broad s,

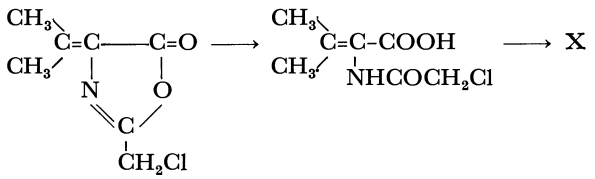
one imino proton), 5.67 (q, $-C\underline{H}_2CH_3$, 2H), 6.87 (m, methine proton, 1H), 8.65 (t, $-CH_2C\underline{H}_3$, 3H), and 8.80 (d, two $-CH_3$, 6H) as shown in Figs. 2B and 2C. The pattern is essentially the same as that of parent α-keto ester except that, in the latter, no signal lower than 5.0 was observed and the one proton multiplet shifted to τ6.72 (Fig 2A). The NMR spectrum of I showed no signal lower than τ5.0 (Fig 2C).

When enamine (I) was treated with chloroacetyl chloride in aqueous sodium hydrogencarbonate with vigorous stirring at room temperature, ethyl 2-(2-chloroacetamido)-3-methyl-2-butenoate (X) was obtained in a 47% yield, which was also obtained in a 30% yield from II by reaction with chloroacetyl chloride in ether in the presence of triethylamine. The ester (X) was synthesized by the hydrolysis of 2-chloromethyl-4-isopropylideneoxazol-5-one followed by the esterification of the resulting *N*-(chloroacetyl) dehydrovaline, and the acetyl enamine structure (X) was confirmed with NMR spectrum by Kurita *et al.*[9]



When α-imino ester (II) was allowed to stand for a week at room temperature and then redistilled, 2-ethoxycarbonyl-2,5-diisopropylimidazolid-4-one (IX) was obtained in a 79% yield. α-Amino ester (I) was heated in a sealed tube at 180—190°C for 48 hr to give the dioxopiperazine (VII). The structure of X was derived from its elemental and spectroscopic analyses (see Experimental). It has been found that the above three dimerization courses (Schemes 2 and 3) were different. Thus it seems that the interconversion between I and II can not be carried out under the experimental conditions mentioned above, although the conversion of III to IV occurred at room temperature. Attempt to isomerize enamine or imine conversely by alkali was unsuccessful.

Experimental

All boiling and melting points are uncorrected. The IR spectrum was recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectrum was measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 MHz.

Materials. Triphenylphosphinimine hydrobromide was prepared by the reaction of triphenylphosphine dibromide with ammonia in the presence of triethylamine by the method of Horner and Oediger[10] Mp 240—242°C (decomp.). The acetonitrile used was distilled from phosphorous pentoxide and dried over calcium hydride.

Ethyl 2-Amino-3-methyl-2-butenoate (I). The procedure was modified from the method of Tatsuoka *et al.*[7] A solution of ethyl 3-methyl-2-nitro-2-butenoate (22 g) in ether (150 m*l*) was added drop by drop to aluminum amalgam (from 13 g of aluminum) placed in ether (300 m*l*) with vigorous stirring at room temperature. After a few minutes, the ether began to reflux. During the addition of the above solution, a few drops of water was added at 10-min intervals to maintain refluxing. After addition of the solution was completed, the stirring was continued for 2 hr. The mixture was extracted thoroughly several times with ether. The combined ethereal extract was dried over anhydrous sodium sulfate and then evaporated. Distillation of the residual oil afforded a pale yellow oil (6.9 g, 56%), bp 65—72°C/9 mmHg.

Found: C, 58.51; H, 9.03; N, 9.79%. Calcd for $C_7H_{13}NO_2$: C, 58.72; H, 9.15; N, 9.78%.

Ethyl 2-Imino-3-methylbutanoate (II). To a solution of triphenylphosphinimine (from triphenylphosphinimine hydrobromide (10.74 g) and sodium hydride (1.3 g)) in acetonitrile (150 m*l*), ethyl 3-methyl-2-oxobutanoate (4 g) was added and heated on a steam bath with stirring. After 30 min, the solution began to reflux. After stirring was continued for more 5—10 min, the solution was allowed to stand at room temperature with stirring and then acetonitrile was evaporated. Dry ether was added to the residual oil and then substance precipitated was filtered off. The ethereal solution was concentrated again, and then the residual oil was extracted with dry petroleum ether three times (each 50 m*l*). After concentrating the solution, the resulting oil was distilled under reduced pressure to afford a pale yellow oil (1.6 g, 40%), bp 65—67°C/15 mmHg.

Found: C, 58.68; H, 9.37; N, 9.56%. Calcd for $C_7H_{13}NO_2$; C, 58.72; H, 9.15; N, 9.78%.

3,6-Diisopropylidene-2,5-piperazinedione (VII). The reaction was carried out using the technique of Fischer for 3,6-dialkyl-2,5-piperazinedione.[11] Compound I (0.5 g) was heated in a sealed tube at 180—190°C for 48 hr. Into the reaction mixture was added a small quantity of ethanol. The crystalline product was collected and recrystallized from ethanol to afford colorless needles (0.14 g, 20.5%), mp 264—265°C (decomp.), undepressed on admixture with the authentic sample.[8]

2-Ethoxycarbonyl-2,5-diisopropylimidazolid-4-one (IX). Compound II (1.2 g) was allowed to stand for a week at room temperature. Distillation under reduced pressure, was unsuccessful. The residual syrup gradually crystallized at room temperature. Redistillation of the crystalline syrup gave a pale yellow oil (0.8 g, 80%), bp 116—117°C/0.07 mmHg (mp 48—49°C). NMR ($CDCl_3$): τ 0.77 (broad s, NH), 5.71 (q, $-C\underline{H}_2CH_3$, 2H), 6.94 (m, methine proton, 1H), 7.22 (m, methine proton, 1H), 8.71 (t, $-CH_2C\underline{H}_3$, 3H), 8.72 (d, two $-CH_3$, 6H), 8.96 (d, $-CH_3$, 3H), 9.26 (d, $-CH_3$, 3H). IR (KBr): 3107, 1750, 1630, 1275, 1200 cm^{-1}.

11) E. Fischer, *Ber.*, **34**, 433 (1901).

Found: C, 59.85; H, 8.21; N, 11.76%. Calcd for $C_{12}H_{20}N_2O_3$: C, 59.98; H, 8.39; N, 11.66%.

Ethyl 2-(2-Chloroacetamido)-3-methyl-2-butenoate (X).

A) From I: Chloroacetyl chloride (0.8 g) was added drop by drop, with vigorous stirring, to I (1 g) suspended in a solution of sodium hydrogencarbonate (0.6 g) in water (15 m*l*) at room temperature. After stirring for 30 min, a crystalline product precipitated. The crystals were collected, washed well with water, and recrystallized from 50% ethanol to afford colorless needles (0.7 g, 47%), mp 117—118°C, undepressed on admixture with the authentic sample.[9] NMR ($CDCl_3$): τ 2.07 (broad s, NH), 5.77 (q, $-C\underline{H}_2CH_3$, 2H), 5.86 (s, $-COCH_2-$, 2H), 7.80 (s, $-CH_3$, 3H), 8.15 (s, $-CH_3$, 3H), 8.72 (t, $-CH_2C\underline{H}_3$, 3H). IR (KBr): 3200, 1720, 1665, 1535 cm^{-1}.

B) From II: A solution of chloroacetyl chloride (0.58 g) in dry ether (30 m*l*) was added drop by drop, with stirring, to a solution of II (0.7 g) in dry ether (30 m*l*) in the presence of triethylamine (0.5 g) in an ice-salt bath. After stirring overnight at room temperature, triethylamine hydrochloride precipitated was filtered off, and then the ethereal solution was concentrated to give residual oil. Heated at 70°C under reduced pressure (2 mmHg), the oil immediately converted into crystals. Recrystallization from di-*n*-butyl ether afforded colorless needles (0.32 g, 30%), mp 118.5—119°C, undepressed on admixture with the sample obtained by procedure *A*.

Further Studies of the Chemical Cleavage of the Tryptophyl Bond by Ozonization-hydrazine Treatment[1,2]

Fumio SAKIYAMA and Shin-ichiro SAKAI*

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received November 2, 1970)

The second step (hydrazine treatment) in the chemical cleavage of the tryptophyl bond according to the scheme proposed previously was further studied under mild conditions using a model *N'*-formylkynurenyl peptide, carbobenzoxy-L-alanyl-*N'*-formyl-L-kynurenyl-L-leucine. The reaction of the model compound with an excess of hydrazine acetate at 25—30°C for 24—48 hr gave rise to the selective cleavage of the kynurenyl bond together with a concomitant tetrahydropyridazone formation. The maximum cleavage was 80—90%. It was then suggested that the incomplete cleavage of the tryptophyl bond in synthetic oligopeptides by means of ozonization-hydrazine treatment was mainly due to insufficient conversion of the indole nucleus into *N'*-formylanthranyl grouping in the first step (ozonization).

A new principle for the chemical cleavage of the tryptophyl bond has previously been proposed.[3,4] According to the reaction scheme, the tryptophyl residue in the peptide chain is first oxidized selectively by ozone to the *N'*-formylkynurenyl residue, which serves the γ-carbonyl function: a subsequent reaction with hydrazine results in 2,3,4,5-tetrahydropyridazone formation, with a concomitant cleavage of the peptide bond acylated by the tryptophyl residue (Fig. 1). On the basis of the experiments performed on model compounds, the cleavage reaction of several synthetic tryptophyl peptide derivatives was carried out, and fairly good results were obtained.[1] However, on the reaction of the ozonized hen's egg-white lysozyme with hydrazine under the same conditions, the expected cleavage reaction was accompanied by a considerable non-selective hydrolysis of other peptide bonds.[5]

Sin e the oxidation step is free from such hydrolytic cleavage, it was quite obvious that the reaction temperature in the second step with hydrazine was too high to exclude undesirable hydrolysis. A similar disadvantage is expected in other chemical reactions reported in the literature aiming at effecting the cleavage of a kynurenyl bond.[6-8] For instance, the intramolecular participation of the γ-carbonyl or the γ-hydroxy group in the preferential hydrolysis of the peptide linkage involving the kynurenine is effectively accomplished only on heating at 100°C in a weakly alkaline or a diluted hydrochloric acid solution. Thus, it is desirable to establish milder conditions for the selective cleavage of the kynurenyl bond with hydrazine. In the present report, the authors will deal

with the preparation of a model peptide derivative containing *N'*-formylkynurenine and its reaction with hydrazine, and with the application of the improved method to the cleavage of the tryptophyl bond in several oligopeptides and gramicidin A.

Results and Discussion

Synthesis of a Model Peptide Derivative. The synthesis of peptide derivatives containing *N'*-formylkynurenine has previously been reported by Previero and his colleagues,[9] who utilized the ozonolysis of the corresponding tryptophyl peptide derivatives in the presence of resorcinol.[10] As a model peptide derivative, the carbobenzoxy derivative of alanyl-*N'*-formylkynurenylleucine was chosen. Two routes of synthesizing the tripeptide derivative were examined; one was a step-by-step elongation of the peptide chain, starting from the carboxyl-terminal leucine, while the other was a direct ozonization of carbobenzoxyalanyltryptophylleucine or its methyl ester (Fig. 2).

For the step-by-step procedure, it was necessary to prepare the *N*-α-protected derivative of *N'*-formylkynurenine. Since a conventional *t*-butyloxycarbonyl substituent was not suitable for the present purpose,[11] the classical carbobenzoxy residue was used. The *N*-α-carbobenzoxy derivative of tryptophan was ozonized without resorcinol; in order to isolate crystalline carbobenzoxy-*N'*-formylkynurenine, the crude material had to be purified by chromatography on a silicic-acid column. The formation of the kynurenyl bond was then attempted either by the *p*-nitrophenyl-ester method or by the dicyclohexylcarbodiimide (DCC) method.[12] The conversion of carbobenzoxy-*N'*-formylkynurenine into its *p*-nitrophenyl-ester was performed by means of interesterification with trifluoracetyl *p*-nitrophenolate;[13] though the active ester thus obtained was subjected to reaction with the leucine methyl ester, no fruitful results were obtained. Then, the carbobenzoxy-*N'*-formylkynurenylleucine methyl ester was prepared by the DCC method without any considerable difficulties. The formation of the alanyl bond was similarly achieved by the coupling of carbobenzoxy alanine with the *N'*-formylkynurenylleucine methyl ester which had been prepared by the catalytic hydrogenation of its carbobenzoxy derivative. By a comparison of the melting points and by a study of the infrared spectrum and the chromatographic behavior, the carbobenzoxy tripeptide ester was found to be identical with that prepared by the direct ozonization of the carbobenzoxyalanyltryptophylleucine methyl ester.[14]

The protected tripeptide ester was then submitted to usual hydrolysis in aqueous alkaline media. However, the ester group was not quantitatively hydrolyzed, and the ultraviolet spectrum of the reaction mixture revealed an anomalous absorption at 332 mμ, indicating that a certain unexpected reaction occurred during this treatment.[15] On the other hand, the alkaline hydrolysis in an aqueous pyridine solution reduced such an unfavorable side reaction; finally, the repeated recrystallization of the hydrolysate yielded the pure carbobenzoxytripeptide, which reverted to the parental tripeptide methyl ester on esterification by diazomethane.

The direct ozonization of the carbobenzoxy derivative of alanyltryptophylleucine into the corresponding *N'*-formylkynurenyl derivative was a less favorable procedure for the present purpose because it was difficult to purify the ozonization product, as is also observed in the preparation of carbobenzoxy *N'*-formylkynurenine.

Reaction of Carbobenzoxy-L-Alanyl-N'-Formyl-L-Kynurenyl-L-Leucine with Hydrazine. The results of the experiments on the cleavage of the tryptophyl bond in lysozyme under the conditions reported in a previous paper[1] suggested that one of the major defects to be improved was the non-specific hydrolysis of the peptide bonds during the reaction of the ozonized protein with hydrazine. From this point of view, the cleavage reaction was again investigated at room temperature using

14) For preparation of the methyl ester of the model peptide, the ozonization method of the corresponding tryptophyl peptide derivative was more useful than the stepwise method involving the protected *N'*-formylkynurenine.
15) As one of possible side reactions, a heteroring formation such as 4-quinolone might be suggested from the spectroscopic data, but no further study was carried out.

the model peptide derivative. However, on the reaction of carbobenzoxy-L-alanyl-*N'*-formyl-L-kynurenyl-L-leucine in an aqueous hydrazine-acetate buffer at pH 4.0, neither leucine nor alanine was released, even after 72 hr. On the other hand, on the incubation of the above reaction mixture at 100°C for 3.5 hr, leucine was detected with an apparent increase in the absorption around 350 mμ due to the formation of the expected tetrahydropyridazone derivative.

When the reaction scheme presented in Fig. 1 is considered, it is rational to assume that, if the hydrazone is once formed, the intramolecular condensation of the amino group in it with the adjacent α-carbonyl function takes place and that the cleavage of the peptide linkage concerned is accomplished by a concomitant heterocyclic ring formation. Therefore, the formation of the hydrazone of the (*N'*-formyl-) kynurenine must be a key reaction in the present cleavage of the peptide bond. Since the hydrazone is formed by an equilibrium reaction through an intermediate tetrahedral hydroxyhydrazino (carbinolamine) derivative (Fig. 1), the higher the hydrazine concentration, the more efficient the formation of the hydrazone. In addition, it must be noted that the hydrazone formation consists of a successive reaction, addition of hydrazine, and subsequent elimination of water, which is usually catalyzed with either an acid or a base. Therefore, the reaction of the tripeptide derivative with 80% hydrazine hydrate was attempted in order to convert quantitatively its carbonyl function into hydrazone. In fact, a marked decrease in the characteristic absorption at 322 mμ due to the *N'*-formylkynurenyl residue was observed within five minutes of mixing the *N'*-formylkynurenyl peptide derivative and hydrazine base at room temperature. This fact indicates that the addition of hydrazine to the carbon-oxygen double bond in the kynurenyl residue takes place effectively.

When the hydrazine-treated tripeptide derivative was incubated in aqueous media at pH 4.0 at room temperature after the excess of hydrazine hydrate had been removed, leucine could be liberated in a 30% yield after 72 hr. During this reaction, white precipitates were separated and identified as 4-carbobenzoxyalanylamino-6-(*o*-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one. This fact shows that, in an aqueous solution, the hydroxyhydrazino (carbinolamine) intermediate was dehydrated to the hydrazone, and that the intramolecular hydrazinolysis of the peptide bond subsequently took place on the carboxyl side of the kynurenyl residue.

The release of leucine from the hydrazine-treated model peptide derivative under various conditions was determined; the results are summarized in Table 1. In the reaction in aqueous media, the extent of the cleavage was estimated to be 30—45%. When dioxane was added in the reaction media, more leucine was released and the course of the cleavage could also be followed by means of ultraviolet spectroscopy. On the other hand, when the reaction solvent was replaced by glacial acetic acid, the leucine released was similar in extent with that released in aqueous media.[16] Even after treatment with hydrazine hydrate, the cleavage reaction with a large excess of hydrazine was more effective than that without the cleaving reagent. This finding suggests that, under those conditions, the retro-reactions of the hydroxyhydrazino (carbinolamine) derivative and the hydrazone by equilibrium are prevented, and that enough hydrazone for the effective cleavage of the kynurenyl bond is always produced during the reaction.

Table 1. Release of leucine by the reaction of carbobenzoxy-L-alanyl-*N'*-formyl-L-kynurenyl-L-leucine with hydrazine after pretreatment with the binucleophile

Concentration of the model peptide derivative (mM)	Concentration of hydrazine (M)	Reaction: Media	Reaction: Temp.	Reaction: Period (hr)	Yield of leucine released (%)	Yield of tetrahydropyridazone formed (%)
2.00[a]	0	aq. soln (pH. 3.8)	r.t.	72	30	—
2.00[a]	0	aq. soln (pH. 3.8)	r.t. then 100°C	72 3	47	—

1.38[b]	1.6	gl. acetic acid	r.t.	47 120	— 77	79 81
1.15[b,e]	1.6	gl. acetic acid	r.t.	47 120	— 55	45 56

a,b) The pre-treatmet with 80% hydrazine hydrate was carried out at room temperature for 2 min (a) or for half an hour (b).
c) The residual material after evaporation of hydrazine and water was allowed to stand overnight at room temperature.
d) Distinct absorption maximum at 353 mμ was not obtained, but a shoulder was observed.
e) After treatment with hydrazine, removal of the excess reagent was omitted.

The cleavage reaction was subsequently simplified into a single procedure because the hydrazone formation and subsequent cleavage of the peptide bond could then be achieved under the same circumstances as in the present case. When the model peptide derivative was subjected to a reaction with a large excess of hydrazine in glacial acetic acid at room temperature, the absorption at 322 mμ was gradually decreased and a new absorption at 353 mμ emerged. The ninhydrin assay of the reaction mixture showed the liberation of the amino acid, which increased parallel with the increase in the absorption at 353 mμ (Fig. 3). As is shown in Table 2, the extent of the cleavage reaction for 48—50 hr at room temperature was estimated to be 73—92% on the basis of the absorbance of the tetrahydropyridazone derivative formed. By amino acid analysis,

16) Incubation of the hydrazine-treated tripeptide derivative in glacial acetic acid brought about liberation of leucine without the heteroring formation (see Table 1). This liberation of the amino acid may be due to a different mechanism from the present scheme.

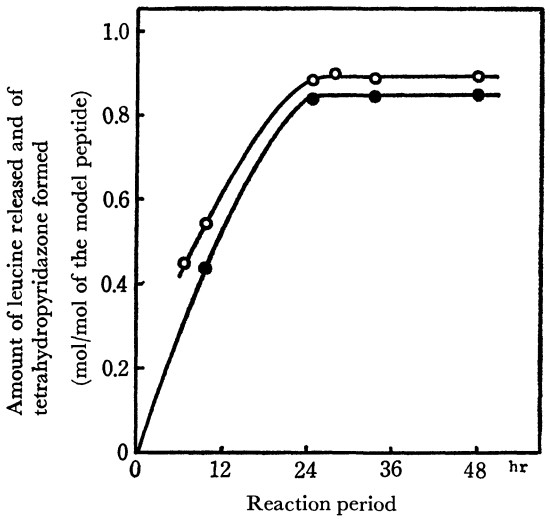

Fig. 3. Relationship between the tetrahydropyridazone formation (—○—) and liberation of leucine (—●—) by the reaction of the model *N'*-formyl-kynurenyl peptide (IV, 1.32 mM) with hydrazine (0.66M) in glacial acetic acid at room temperature.

TABLE 2. RELEASE OF LEUCINE BY THE DIRECT REACTION OF CARBOBENZOXY-L-ALANYL-*N'*-FORMYL-L-KYNURENYL-L-LEUCINE WITH HYDRAZINE ACETATE IN GLACIAL ACETIC ACID[a]

Concentration of		Yield of	
the model peptide derivative(mM)	hydrazine (M)	leucine released	tetrahydropyridazone derivative
6.18	5.0	—	74
2.41	2.0	—	91
1.60	1.6	81(81)	91(84)
1.19–1.39	0.5–1.2	78–87	82–90
0.59	1.6	78(80)	92(86)
0.57	0.5	—	84
0.27	1.6	113[b](86)	73(67)
0.12	0.1	—	no maximum

a) The formation of the tetrahydropyridazone derivative was estimated after 48—50 hr at room temperature and analysis of the amino acid was done after 120 hr. The yield after 24 hr was presented in parentheses.
b) See b) in Table 4.

it was also confirmed that leucine was the sole amino acid liberated during the cleavage reaction for 120 hr and that about 78—87% of the theoretical amount of the amino acid was present.[17] A study of the ultraviolet spectrum showed another reaction product to be identical with the expected 4-L-(*N*-carbobenzoxy-L-alanylamino)-6-(*o*-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (Table 3). Table 4 shows the results of the cleavage reaction of the tryptophyl bond by ozonization and subsequent hydrazine treatment under the same conditions. The over-all reaction yielded the corresponding amino acid in a 30—50% yield on the basis of the parent peptide, but the second step directly causing the cleavage of the peptide chain could be

17) Removal of the β-benzoylpropionyl grouping as a substituent in the nucleotide synthesis was carried out with 0.5 M hydrazine in pyridine-water (R. L. Letsinger and P. S. Miller, *J. Amer. Chem. Soc.*, **91**, 3356 (1969)).

TABLE 3. SPECTRAL IDENTIFICATION OF THE TETRAHYDROPYRIDAZONE DERIVATIVE OBTAINED IN THE REACTION OF Z-ALA-*N'*-FORMYLKYN-LEU-OH WITH HYDRAZINE.

	Ratio of the absorbance against that at 283 mμ		
	250 mμ	283 mμ	353 mμ
4-L-(*N*-carbobenzoxy-L-alanyl-amino)-6-(*o*-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one[a]	1.50	1.0	0.76
A sample obtained by base treatment and subsequent reaction in aq. media[b]	1.46	1.0	0.67
A sample obtained by direct cleavage reaction in glacial acetic acid[c]	1.44	1.0	0.71

a) Part II, p. 530 in Ref. 1).
b) Compound V in Experimental part.
c) The sample was isolated on reaction of carbobenzoxy-L-alanyl-*N'*-formyl-L-kynurenyl-L-leucine (1.91 mM) with hydrazine acetate (1.2 M) in glacial acetic acid at room temperature for 48 hr.

TABLE 4. THE CHEMICAL CLEAVAGE OF THE TRYPTOPHYL BOND IN SEVERAL SYNTHETIC PEPTIDES AND GRAMICIDIN A[a]

Peptide derivative	Ozonization yield determined as		Yield of the over-all cleavage reaction determined by	
	N'-formyl-Kyn	Kyn	tetrahydro-pyridazone formation	amino acid analysis
Z·Trp·Gly·OH	47	41	42	34
Z·Trp·Leu·OH	45	51	50	65[b]
Z·Trp·Phe·OH	47	57	56	40
Z·Gly·Trp·Gly·OH	49	39	38	30
Z·Ala·Trp·Leu·OH	48	54	44	56[b]
Gramicidin A	86	43	46	—

a) The data presented were given by duplicate experiments except ozonization of gramicidin.
b) These yields were probably over-estimated according to low resolution between the leucine and a byproduct (possibly acetylhydrazine, eluted just before leucine in analysis on a Mitamura Amino Acid Analyzer (a column used for analysis, 0.9×50 cm, Aminex A-4)). Flow rate of the developing buffer (0.2 N citrate buffer, pH 3.25) was 50 ml/hr.

carried out to an extent similar to that in case of the model compound. From this result it must again be emphasized that, in the cleavage of the tryptophyl bond, the complete conversion of the tryptophan into the (*N'*-formyl-) kynurenine is necessary for the quantitative scission of the peptide linkage.

Propionic or butyric acid can be utilized as a reaction solvent in place of the glacial acetic acid, but formic acid, which is a good solvent for proteins, can not. Moreover, hydrazine acetate only must be used as the cleaving reagent; it is not replaceable by hydrazine dihydrochloride or sulfate.

In conclusion, the cleavage of the kynurenyl bond can be achieved by the aid of hydrazine under such mild conditions that no other peptide bond is affected. The hydrazine treatment can be carried out by two methods; one is the direct reaction of the kynurenyl

residue with hydrazine, while the other involves the preformation of the carbinolamine intermediate by treatment with the binucleophile in basic media. Though the cleavage of the tryptophyl bond in oligopeptides is possible to a similar extent by either procedure, the latter method may also be useful for that of the peptide bonds in proteins.

Experimental

All the melting points were uncorrected. The amino-acid analyses were performed on a Beckman amino acid analyzer model MS unless otherwise specified. The absorption spectra were measured by a Beckman spectrophotometer, type DB. The examination of the synthetic peptide by mass spectrometry was done by means of a Hitachi Mass Spectrograph, type RMU-6D. Ozone was generated from oxygen by a generator manufactured by the Nippon Ozone Co., Ltd., type 0-3-2. The formic acid (98—100%) was purchased from Merck AG and was used without purification.

The Cleavage Reaction of the N′-Formylkynurenyl Bond in the Model Peptide by Hydrazine. A typical procedure for the present reaction will be described below. About 2.8 mg (5 μmol) of carbobenzoxy-L-alanyl-*N′*-formyl-L-kynurenyl-L-leucine was dissolved in 80% or 100% hydrazine hydrate (0.2 m*l*); after this mixture had stood at room temperature for half an hour, the hydrazine and water were evaporated *in vacuo* by the same procedure as was used with lyophilization.[18] The residual substance was then dissolved in glacial acetic acid containing hydrazine acetate (1.6 M) (3 m*l*), and the reaction vessel, equipped with a stopper, was kept at 25—27°C on a water bath equipped with a thermostat. Portions (0.2 m*l*) of the acetic acid solution were withdrawn at suitable intervals and diluted with ethanol (3 m*l*). The ethanol solution was submitted to spectrometry at ranges from 450/400 mμ to 300 mμ or from 400 mμ to 230 mμ, with dilution to a suitable concentration, if necessary. The progress of the cleavage reaction could be followed in terms of the tetrahydropyridazone formation, and the extent of the cleavage reaction was determined from the absorbance at 353 mμ ($\varepsilon_{353m\mu}=8.13\times10^3$).

When the pretreatment by hydrazine was omitted, the model peptide was directly subjected to the reaction with hydrazine acetate in glacial acetic acid.

For the determination of the amino acid released, about 0.1 μmol (a theoretical amount when the reaction occurred quantitatively) was pipetted, diluted immediately with a 0.2 M citrate buffer at pH 2.2, frozen, and kept in a freezer (−20°C) until analysis has been performed by means of an amino-acid analyzer.

Isolation and Characterization of the 4-L-(N-Carbobenzoxy-L-alanylamino)-6-(o-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (V) Formed on the Reaction of the Model Peptide with Hydrazine. The carbobenzoxy-L-alanyl-*N′*-formyl-L-kynurenyl-L-leucine (113 mg, 0.2 mmol), dissolved in 80% hydrazine hydrate (2 m*l*), was allowed to stand at room temperature for 5 min; then, the excess hydrazine was evaporated *in vacuo* to dryness over concentrated sulfuric acid (overnight). The residue was dissolved in water (15 m*l*), and the pH of the aqueous solution was adjusted to 3.8 with 4M acetic acid. At this stage, a large amount of an insoluble material was separated, but the suspension, after dilution to 100 m*l* with water, changed to an almost clear solution on standing at room temperature for 2 hr. After 24 hr, white precipitates which had separated were collected; they amounted to 23 mg. Additional precipitates (6 mg) were obtained after 72 hr. The white precipitates were combined and crystallized from methanol-water. Mp 200—204°C (lit,[1] 197.5—198°C). Molecular weight (mass spectrometry), Found: 409. Calcd for $C_{21}H_{23}O_4N_5$: 409. R_f (TLC, SiO_2) 0.69 (ethyl acetate: acetic acid= 5:1 by volume). λ_{max}; 353 mμ, 283 mμ and 250 mμ (in ethanol).

Cleavage Reaction of the Tryptophyl Bond in Several Tryptophyl Peptide Derivatives and Gramicidin. The tryptophyl peptide derivative (10 μmol) was dissolved in 98—100% formic acid (2 m*l*) and oxidized by approximately 0.01% ozone at 7—8°C until the increase of the absorption at 320 mμ reached its maximum. An aliquot (0.1 m*l*) was withdrawn, evaporated to dryness *in vacuo* over sodium hydroxide pellets, and used for amino-acid analysis after acid hydrolysis. Another portion (0.5 m*l*) was similarly evaporated and then dissolved in a glacial acetic acid (2 m*l*) containing hydrazine acetate (1.6 M). The acetic acid solution was kept at 25—27°C on a water bath for 48—50 hr, and then the liberated amino acid was determined. The progress of the cleavage was also followed by the spectrometric method, which has been described previously.

Carbobenzoxy-N′-formyl-L-kynurenine (I). Carbobenzoxy-L-tryptophan (1.38 g) was dissolved in a 98—100% formic acid (50 m*l*), and ozone in oxygen was bubbled at 5—10°C into the formic acid solution until a maximal absorption at 320 mμ was obtained. The solvent was then replaced by chloroform, and the insoluble materials were filtered off. The clear chloroform solution was shaken with 1N sodium carbonate, and the aqueous alkaline solution was acidified to pH about 1 after mixing with chloroform. The acidified solution was shaken with chloroform, and the sirupy ozonization product (854 mg) obtained on the evaporation of the chloroform was purified by chromatography on a silicic-acid (20 g) column. On the concentration of the first fraction from the column (300 m*l*, developing with chloroform containing 5—10% methanol), an amorphous substance (669 mg)[19] resulted. The crude carbobenzoxy-*N′*-formyl-L-kynurenine was obtained by repeating extraction and back-extraction between chloroform and aqueous acid or an alkaline solution as has been described above. The pure sample (246 mg, 16%) was obtained by recrystallization from methanol; mp 145—146°C. $[\alpha]_D^{25}=+23.1$ (*c* 0.73, in methanol). R_f (TLC, SiO_2) 0.85 (ethyl acetate: acetic acid=10:1 by volume). Molecular weight (mass spectrometry), Found: 370. Calcd: 370. λ_{max} (ethanol): 320 mμ and 258 mμ. ν(KBr): 3320, 3200, 1748, 1685, 1642, 1598, 1580, 1520, 1442 and 1407 cm^{-1}.

Found: C, 61.46; H, 4.68; N, 7.73%. Calcd for $C_{19}H_{18}O_6N_2$: C, 61.61; H, 4.90; N, 7.56%.

Carbobenzoxy-N′-formyl-L-kynurenyl-L-leucine Methyl Ester (II). Carbobenzoxy-*N′*-formyl-L-kynurenine (222 mg) and L-leucine methyl ester (88 mg) were dissolved in chloroform (2 m*l*), and dicyclohexylcarbodiimide (124 mg) was added to the chloroform solution under cooling with ice water. After 2 hr at 0°C and then 1 hr at 20°C, the insoluble dicyclohexylurea was filtered off. A crystalline material (280 mg) resulted on the evaporation of the chloroform; it was recrystallized from methanol. Yield, 205 mg

18) If evaporation of the aqueous hydrazine was omitted, the cleavage took place less effectively.

19) In another experiment, a crystalline material (mp 177—184°C, browning with gas evolution) was isolated. λ_{max} (methanol) 263 mμ and 325 mμ. Found: C, 58.03: H, 4.16; N, 7.14; ash 8.1%. Since this compound showed identical properties with the *N′*-formylkynurenine derivative after alkali-acid treatment, the crystalline sample was throught to be an adduct with silicic-acid used for chromatography.

(69%); mp 146—147°C (sintered at 139°C). $[\alpha]_D^{25} = -15.2$ (*c* 0.94, in methanol). Molecular weight (mass spectrometry), Found; 497. Calcd; 497.

Found: C, 62.67; H, 6.46; N, 8.35%. Calcd for $C_{26}H_{31}O_7N_3$: C, 62.76; H, 6.28; N, 8.45%.

Carbobenzoxy-L-alanyl-N′-formyl-L-kynurenyl-L-leucine Methyl Ester (III). *i) By Step-by-step Synthesis from the Leucine Methyl Ester*: The carbobenzoxy-*N′*-formyl-L-kynurenyl-L-leucine methyl ester (876 mg) was dissolved in methanol (70 m*l*) containing glacial acetic acid (106 mg) and hydrogenated on palladium-charcoal for 5 hr at room temperature. After the filtration of the catalyst, the clear methanol solution was passed through a Dowex 1 (OH-form) column and the effluent was evaporated to dryness. The residue (676 mg), solidified in crystals, was coupled with carbobenzoxy-L-alanine (394 mg) by dicyclohexylcarbodiimide (363 mg) in chloroform (10 m*l*) for 2 hr under cooling with ice water. After the chloroform solution freed from the resulting urea derivative was washed with diluted alkali, diluted acid, and water successively, the crude tripeptide derivative (863 mg) was obtained on the evaporation of the solvent. The crude product was then purified by silicic-acid chromatography. The fraction (60 m*l*) eluted with 5% methanol in chloroform after the column had been washed with chloroform (300 m*l*) was evaporated. Pure crystals (320 mg, mp 142—144°C) resulted on treatment with methanol. From the mother liquor, an additional product (130 mg, mp 143°C) was isolated by chromatographic purification. Total yield, 450 mg; 45%. The sample for analysis was further purified by recrystallization from methanol; mp 143—144°C (sintered at 140°C). By admixing with the carbobenzoxy-*N′*-formyl-L-kynurenyl-L-leucine methyl ester (II), the melting temperature dropped to 134—144°C. $[\alpha]_D^{18} = +27.1$ (*c* 1.4, in chloroform). λ_{max} (ethanol), 322 mμ. Molecular weight (mass spectrometry), Found, 568. Calcd: 568.

Found: C, 61.47; H, 6.33; N, 9.76%. Calcd for $C_{29}H_{30}O_8N_4$: C, 61.25; H, 6.38; N, 9.85%.

ii) By the Ozonization of the Carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine Methyl Ester. The carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine methyl ester[1] (5.37 g) was dissolved in formic acid (30 m*l*) and oxidized by ozone for 70 min under cooling with ice water. Then the solvent was replaced with chloroform, and the chloroform solution was washed with a diluted sodium carbonate solution. On the evaporation of the solvent, a neutral substance (5.35 g) was obtained; it was similarly chromatographed on a silicic-acid column. From the fraction eluted with chloroform containing 2—3% methanol, the crystalline, protected tripeptide derivative (1.84 g) was obtained by the evaporation of the solvent and by subsequent treatment with methanol. An additional ozonization product was obtained by repeated chromatography of the mother liquor after the first crystalline materials had been collected. The total yield of the crude products (2.22 g, mp 139—141°C) was 39%. The sample for analysis was again recrystallized from methanol; mp 143—144°C (after sintered at 139°C). $[\alpha]_D^{18} = +26.8$ (*c* 1.4, in chloroform). No depression of the melting point of the pure sample was observed after admixing with the sample obtained by the (i) procedure.

Carbobenzoxy-L-alanyl-N′-formyl-L-kynurenyl-L-leucine (IV). The protected tripeptide ester (III) (142 mg) was dissolved in pyridine (3 m*l*), and after 1N sodium hydroxide (0.5 m*l*) had been added to the pyridine solution, the aqueous pyridine solution was stirred for 40 min under cooling with ice water. After the methyl ester (III) was no longer detected (thin layer chromatography), dry ice and water were added successively. The hydrolysate was then shaken twice with chloroform (30 m*l* each), and the chloroform solution was dried with anhydrous sodium sulfate and concentrated under reduced pressure. The resulting crystalline material was washed with ether and recrystallized from methanol-water. Yield, 100 mg (70%). Mp 138—140°C (sintered at 136°C). The ultraviolet spectrum showed a small shoulder at 332 mμ. Recrystallization from the same solvent was repeated. The pure crystals thus prepared showed no absorption at 332 mμ; mp 140°C (foam after sintered at 136°C). $[\alpha]_D^{25} = -29.7$ (*c* 0.77, in methanol). The crystals showed a higher melting point at 159—162°C (dec., sintered at 132°C) after having been dried at 50°C for 5 hr under reduced pressure (10 mmHg) for analysis.

Found: C, 59.40, 59.34; H, 6.20, 6.28; N, 9.98, 9.90%. Calcd for $C_{28}H_{34}O_8N_4 \cdot 1/2H_2O$; C, 59.67; H, 6.26; N, 9.94%. The protected *N′*-formylkynurenyl peptide (IV) (87 mg), dissolved in methanol (1 m*l*), was treated with an excess of diazomethane in an ethereal solution. The methylation was continued for half an hour at room temperature, and the solution was concentrated to a sirup giving a crystalline product by treatment with methanol. The pure esterification product (55 mg, mp 140—142°C) obtained by recrystallization from methanol showed no depression of the melting point after admixture with compound (III).

The infrared absorption spectrum of the esterification product also showed a good agreement with that of compound (III).

The authors wish to express their thanks to Professor Kozo Narita for his advice during the present investigation. They also wish to thank Misses Yoshiko Yagi and Yuriko Sako for carrying out the amino-acid analyses.

Photochemical Reaction of 3,4-Diphenylsydnone[1]

Yoshiharu HUSEYA, Akiko CHINONE, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 6, 1970)

In a recent communication,[2] we proposed 1*H*-1,3-diphenyldiazirine for the photolysis product of 3,4-diphenylsydnone. However, it was found later that the product was identical with the already known 2,4,5-triphenyl-1,2,3-triazole. In this paper, details of the photolysis of 3,4-diphenylsydnone and identification of the product are described. The formation of triazole derivative by the photolysis of 3,4-diphenylsydnone seems to be interesting. The reaction mechanisms are discussed.

Recently, much interest has been focussed upon the photolysis of mesoionic compounds due to their peculiar structures and 1,3-dipolar character. Krauch *et al.*[3] reported that the photolysis of 3-phenylsydone gave 4-phenyl-1,3,4-oxadiazoline-5-one, presumably *via* fused three-membered intermediate, 1*H*-diazirine derivative or nitrile imine. Kato[4] is working on photolysis of various mesoionic compounds with a view to investigating their photolysis in terms of a fused three-membered intermediate. In anticipation of the isolation of the intermediate having three-membered ring structure, we have been studying the photolysis of 3,4-disubstituted sydnone.

We reported that photolysis of 3,4-diphenylsydnone **(1)** gave a product of mp 119—120°C, which was considered, though not conclusively, to be 1,3-diphenyl-2-azirine **(3)**, on the basis of elementary analysis and mass spectroscopic analysis. However, on further examination, it was found that several behaviors of the compound could not be explained satisfactorily by the proposed structure.

Molecular weight determination of photolysis product (A) by the Rast method or by vapor pressure osmometer gave the value 310 and as an alternative formula, $C_{20}H_{15}N_3$ is possible which is consistent with this molecular weight and elementary analysis. For this empirical formula, three isomers of triphenyltriazoles are possible. It was found that 2,4,5-triphenyl-1,2,3-triazole **(6)** synthesized by Auwers *et al.*[5] has the same melting point and chemical properties as (A). Comparison with authentic sample revealed that (A) was identical with (**6**).

The mass spectroscopic results which caused us to deduce an incorrect structure can be explained by considering that the major peak at *m/e* 194 was due to a fragment $C_6H_5CNNC_6H_5$ derived from **6**. Both **3** and **6** have no proton except that of phenyl. Thus, NMR data are not sufficiently informative for determination of the structure, and some ambiguity was encountered in analyzing the NMR absorption spectrum due to phenyl proton. However, the results can be explained by means of both **3** and **6**.

Further evidence for excluding the diazirine structure (**3**) for A is provided by the fact that product A shows no infrared absorption at about 1740 cm^{-1} due to strained C=N linkage, and that attempts to reduce A by lithium aluminum hydride or catalytic hydrogenation with palladium-charcoal were unsuccessful.

The photolyses of 3-*p*-chlorophenyl-4-phenylsydnone and 4-phenyl-3-*p*-tolylsydnone were carried out under the same conditions to give corresponding 1,2,3-triazole derivatives.

The unexpected formation of **6** is unusual and some considerations are given on the mechanism of this

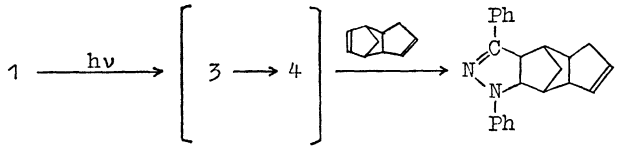
reaction. Similar to the photolysis of 3-phenylsydnone, the intermediacy of 1*H*-1,3-diphenyldiazirine (**3**) or diphenylnitrile imine (**4**) is probable in the photolysis of **1**. It was reported that diphenylnitrile imine produced from 2,5-diphenyltetrazole by thermolysis gave 1,3,4,6-tetraphenyl-1,2,4,5-tetrazine (**7**) by head-to-tail dimerization.[6] On the contrary, Scheiner and Dinda[7] stated that the formation of **6** from 2,5-diphenyltetrazole by photolysis proceeds *via* 1,2-bisphenylazo-1,2-diphenylethylene (**5**), and suggested that **5** is formed by photodimerization involving tetrazole-tetrazole association and not by head-to-head dimerization of 1,3-dipolar nitrile imine (**4**). The head-to-tail thermal dimerization of **4** should afford 1,2,4,5-tetrazine (**7**). As it is known that irradiation of some heterocyclic five membered rings yields rearranged products,[8] the formation of **6** from **7** *via* 1,3,5-triphenyl-1,2,4-triazole (**8**) seems to be probable. However, photolysis of authentic sample of **8**[9] resulted in the recovery of starting material. Thus, if the formation of **6** by photolysis of **1** proceeds *via* **5**, it would be unreasonable to consider that **6** is derived exclusively from nitrile imine.

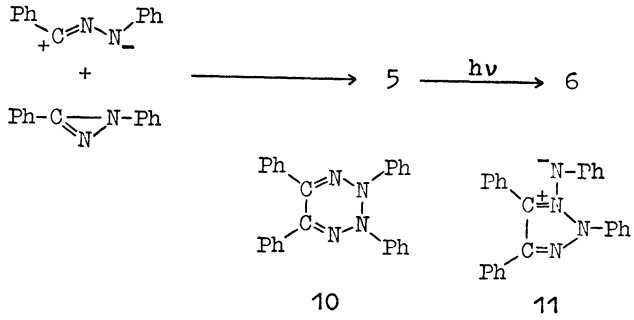
Krauch *et al.*[3] reported that 1,3-dipolar cycloaddition of 3-phenylsydnone did not take place by photolysis. Our attempt on this reaction using dicyclopentadiene as a dienophile was also unsuccessful. While thermal 1,3-dipolar cycloaddition to 3-phenylsydnone is well known,[10] the same reaction by photolysis has not been realized. For the purpose of intercepting the intermediate nitrile imine, we have attempted the photolysis of 3,4-diphenylsydnone in the presence



9

of dicyclopentadiene as a dipolarophile. The irradiation of a suspension of 3,4-diphenylsydnone in dicyclopentadiene gave a product to which tetracyclic structure (**9**) may be assigned, on the basis of elementary analysis, the same melting point as reported by Huisgen *et al.*[11] and spectroscopic data, indicating that the cycloaddition of dicyclopentadiene to **4** (or 1,3-position of **3**) occurred and addition of dicyclopentadiene to 2,3-position of **3** did not occur. These results show that the photolysis of 3,4-diphenylsydnone is not similar to thermal 1,3-dipolar cycloaddition observed in sydnone, which occurs at 2,4-position of sydnone. The thermal 1,3-dipolar cycloaddition of **1** was tried in dicyclopentadiene at 165°C to give intractable oil.

Thus, it is most likely that the reaction may proceed through the sequence indicated below.[12,13]



10 11

Experimental

All melting points were determined on a hot stage, and were not corrected.

Photolysis of 3,4-diphenylsydnone. A solution of 3.0 g of 3,4-diphenylsydnone[15,16] in 300 m*l* of dioxane was placed in a Pyrex vessel, purged with nitrogen for 0.5 hr, and irradiated with a high-pressure mercury lamp (100W) under nitrogen. The reaction ended after 30 hr. The solvent was evaporated under reduced pressure, and the residue was chromatographed over alumina. Elution with benzene gave 0.45 g (24%) of **6**, mp 119—120°C, IR ν(KBr) 3050, 1595, 1493, 970, 775, 700 cm^{-1}. The identity of **6** was established by comparison (IR and mixed mp) with an authentic sample. The same procedures were employed with two other sydnones.

Irradiation of 4-phenyl-3-*p*-tolysylsydnone[16] gave 4,5-diphenyl-2-*p*-tolyl-1,2,3-triazole (23%), mp 114—116°C, IR ν(KBr) 3050, 1510, 975, 825, 770 cm^{-1}.

Found: N, 13.32%. Calcd for $C_{21}H_{17}N_3$: N, 13.50%.

Irradiation of 3-*p*-chlorophenyl-4-phenylsydnone[16] gave 2-*p*-chlorphenyl-4,5-diphenyl-1,2,3-triazole (21%), mp 99—101°C, IR ν(KBr) 3050, 1490, 975, 825, 770, 700 cm^{-1}.

Found: N, 12.64%. Calcd for $C_{21}H_{17}N_3Cl$: N, 12.86%.

Photolysis of 3,4-diphenylsydnone with dicyclopentadiene. A suspension of 2.0 g of **1** in 300 m*l* of commercial dicyclopentadiene was irradiated with a high-pressure mercury lamp for 20 hr. Removal of the solvent under reduced pressure and recrystallization of the residue from ethanol gave 0.55 g of 1,3-diphenyl-4,8-methane-3a,4,4a,7a,8,8a-hexahydroindeno[5,6-*c*]pyrazole, mp 178—179°C (lit,[11] mp 173—174°C).

Mechanism and Reactivity of Hydrolysis of Aliphatic Sulfonate Esters

Akira MORI, Masuzo NAGAYAMA, and Hiroshi MANDAI

Research Department, Lion Fat & Oil Co., Ltd., Hirai, Edogawa-ku, Tokyo

(Received November 7, 1970)

It was shown with a five-membered sultone that the hydrolysis of aliphatic sultones in water proceeds substantially by $B_{AL}1$-E1 mechanism, and that it is a nucleophilic substitution reaction caused by hydroxyl ion and water. We carried out a kinetic experiment on the hydrolysis of 1,4-butanesultone and ethyl ethanesulfonate, both in water and in water - acetone mixed solvent. It was found that these aliphatic sulfonate esters were hydrolyzed substantially by $B_{AL}1$-E1 mechanism as in the case of a five-membered sultone, and in particular, ethyl ethanesulfonate was hydrolyzed by complete $B_{AL}1$-E1 mechanism. The results seem to be justified by a tracer experiment with $H_2{}^{18}O$. Namely, the ratios of the C–O fission to the S–O fission in 1,3-propanesultone and ethyl ethanesulfonate were 85.6:14.4 and 100:0, respectively. In strong alkaline solutions and approtic solvent - water systems, the S_N2 reaction involving attack of the nucleophile on sulfur atom took place partly in sultones, but practically not in linear sulfonate esters. On the other hand, the ratio of relative reaction rates of a five-membered sultone, a six-membered sultone, and a linear sulfonate ester in water is 37:1:7. Since E_a is nearly the same for these three compounds, the contribution of strain in the molecular structure to the reactivity is small, and in consequence the above ratio seems to be attributed to ΔS^*.

We reported[1,2] that aliphatic five-membered and six-membered sultones are obtained from sulfonation of long chain alpha olefins with sulfur trioxide and that these sultones are converted into an useful detergent by hydrolysis the mechanism of which is ascribed substantially to $B_{AL}1$-E1. Kinetic data of the hydrolysis in D_2O suggested that the reaction is a nucleophilic substitution reaction by hydroxyl ion and water ($k_H/k_D=1.03$).[2] However, the sultones used in the tracer experiments on the hydrolysis with $H_2{}^{18}O$ were long chain aliphatic sultones, which gave a mixture of hydroxy alkane sulfonates and alkene sulfonates by hydrolysis, and in consequence, an accurate result could not be expected because of difficulty in purification of the products. In this study, therefore, 1,3-propanesultone which yields only one product by hydrolysis was used in the $H_2{}^{18}O$ tracer experiment, and the previous results were reinvestigated.

Sulfonation of long chain alpha-olefins with sulfur trioxide gives six-membered sultones in addition to five-membered sultones which seem to differ from each other. Studies were thus made on the structural effect on the mechanism of hydrolysis and the reactivity of aliphatic sulfonate esters.

Hydrolysis of linear alkyl sulfonate esters was carried out in $H_2{}^{18}O$, and the results were compared with those obtained in the kinetic study.

Experimental

Materials. Commercial *1,3-propanesultone* (c.p.grade) was distilled under reduced pressure before use:bp 113.0—114.5°C/3 mmHg.

1,4-butanesultone was prepared from tetrahydrofuran according to the method of Truce and Hoerger.[3]: bp 112°C/1.5 mmHg, n_D^{25}1.437.

Found: C, 35.27; H, 5.64; S, 23.33%. Calcd for $C_4H_8SO_3$; C, 35.28; H, 5.92; S, 23.55%.

Ethyl ethanesulfonate was prepared from ethylsulfonyl chloride and ethyl alcohol according to the method of Sekera and Marvel[4]: bp 43°C/1 mmHg and n_D^{25}1.4229.

Found: C, 34.90; H, 7.40; S, 23.11%. Calcd for $C_4H_{10}SO_3$: C, 34.77; H, 7.29; S, 23.20%.

All the solvents used in kinetic experiments were purified by distillation.

Commercial *sodium perchlorate* (c.p.grade) was used.

Water enriched with ^{18}O was obtained from the Yeda Research and Development Co., Ltd. (Israel) and the atomic percentage of ^{18}O was 1.742.

Sodium hydroxide enriched with ^{18}O was prepared in an authentic manner from sodium ethoxide and water enriched with ^{18}O.

Measurement of the Rate of Hydrolysis. 1,4-Butanesultone and ethyl ethanesulfonate were hydrolyzed in water and in 65 vol% of aqueous acetone at room temperature under the following conditions, the pH being kept constant with a pH-stat (manufactured by Toa Electronic Ltd., Model HS-1B). The amount of sultones decomposed was calculated from that of sodium hydroxide required for counterbalancing the decrease of the pH by sulfonic acids formed by the decomposition of sultones.

Hydrolysis was carried out in an atmosphere of nitrogen to eliminate the effect of carbon dioxide in air. Sodium perchlorate was added to maintain the ionic strength of the reaction system constant.

Conditions of Hydrolysis. Concentration of the samples: 0.04 mol/*l*; Solvents: Water and aqueous acetone (65 vol%); Ionic strength: 0, 0.5 and 0.8; Temperatures: 25.0—55.0°C; pH: 3.0—11.3.

Determination of the Reaction Rate Constant (k_1). Using a linear equation, logs $S/(S-S')$ was plotted *versus* time t(sec), where S is the initial amount of sultone and S' is amount of sultone decomposed in time t(sec). k_1 was obtained from the slope of the plots.

Hydrolysis in $H_2{}^{18}O$. Hydrolysis of 1,3-Propanesultone: 1,3-Propanesultone (1.954 g, 1.6×10^{-2} mol) was dissolved in a solution containing 750 mg (1.8×10^{-2} mol) of $Na^{18}OH$ in 10 m*l* of $H_2{}^{18}O$, and the solution was heated on a water bath at 70°C for 2.5 hr. The pH of the reaction mixture was greater than 12 at the end of the reaction. The unreacted sultone was removed by extraction with 5 m*l* of petroleum

1) M. Nagayama, H. Okada, and S. Tomiyama, *Kogyo Kagaku Zasshi*, **72**, 2248 (1969).

3) W. E. Truce and F. D. Hoerger, *J. Amer. Chem. Soc.*, **76**, 5357 (1954).

4) V. C. Sekera and C. S. Marvel, *ibid.*, **55**, 345 (1933).

ether carried out four times. The aqueous layer was neutralized with N/10 HCl, and the solvent was evaporated to leave crude sulfonate behind. Recrystallization from 95% ethyl alcohol gave 1.80 g of needles of pure sulfonate. NMR spectral analysis showed that the sulfonate thus obtained contained only sodium 3-hydroxypropanesulfonate.

Pure sulfonate (1 g) was treated with 3 m*l* of dimethylformamide and 40 m*l* of thionyl chloride to give chlorosulfonyl chloride according to the method of Bosshard *et al.*[5] The product was purified by distillation under reduced pressure: yield, 100 mg, bp 65.0°C/3 mmHg; IR spectra, strong SO_2–Cl absorption was observed at 1380 and 1165 cm^{-1}.

The atomic percentage of excess ^{18}O in the sulfonate and chlorosulfonyl chloride was measured according to the method of Rittenberg and Ponticorvo[6] and the ratio of the C–O fission to the S–O fission was determined.

Hydrolysis of Ethyl Ethanesulfonate: To a solution of 750 mg (1.8×10^{-2} mol) of $Na^{18}OH$ in 10 m*l* of $H_2{}^{18}O$ was added 2.211 g (1.6×10^{-2} mol) of ethyl ethanesulfonate, and the hydrolysis was carried out with stirring at 80°C for 2 hr on a water bath. The pH of the reaction mixture at the end of the reaction was greater than 12. The unreacted ethyl ethanesulfonate was extracted with ethyl ether, the aqueous layer was neutralized with N/10 hydrochloric acid, the solvent was removed, and NaCl was separated to yield crude sulfonate. Recrystallization from 95% ethanol gave 1.50 g of needles of pure sulfonate. The ratio of the C–O fission to the S–O fission was determined from the atomic percentage of excess ^{18}O in the sulfonate thus obtained and ^{18}O enriched aqueous sodium hydroxide solution used for the hydrolysis.

Results and Discussion

Kinetic Studies of Hydrolysis. Hydrolysis of 1,4-Butanesultone: The relationship between log K_1 and pH in the hydrolysis of 1,4-butanesultone in 65 vol % of aqueous acetone and in water is shown in Fig 1. It is apparent that a six-membered sultone undergoes exactly the same type of reaction as a five-membered sultone. A first-order reaction takes place in water, but in a mixed system consisting of an aprotic solvent and water, a rise is observed in the curve and this tendency becomes slightly less pronounced than in the case of the five-membered sultone on the alkaline side. However, from the rise observed in the curve, it seems that an S_N2-E2 reaction takes place to some extent, although a $B_{AL}1$-E1 reaction predominates.

The effect of the ionic strength in 65 vol % of aqueous acetone on the alkaline side, where the reactivity of the S_N2-E2 reaction is large, is shown in Table 1. Here again, the positive salt effect is observed as before, and the increase of electron charge in the transition state, namely the cause of the monomolecular reaction, is detected.

Table 1. Effect of ionic strength on the K_1 value of hydrolysis of C_4 1,4-sultone (at 50°C, pH 9 in 65 vol % Acetone)

Ionic strength	$6+\log K_1$
0	0.629
0.5	0.696
0.8	0.788

Hydrolysis of Ethyl Ethanesulfonate: The relationship between log K_1 and pH in the hydrolysis of ethyl ethanesulfonate in 65 vol % of aqueous acetone and in water is shown in Fig. 2. A clean first-order reaction is observed both in the aqueous acetone and in water. This suggests that, in contrast to sultones, ethyl ethanesulfonate is hydrolyzed completely by the $B_{AL}1$-E1 reaction to the exclusion of the S_N2-E2 reaction. This will be examined later with reference to the analysis of ^{18}O contained in the products of the hydrolysis of ethyl ethanesulfonate in ^{18}O enriched water.

As shown in Fig. 2, the effect of the ionic strength was partly at pH 4 and 10, but only a weak salt effect was observed.

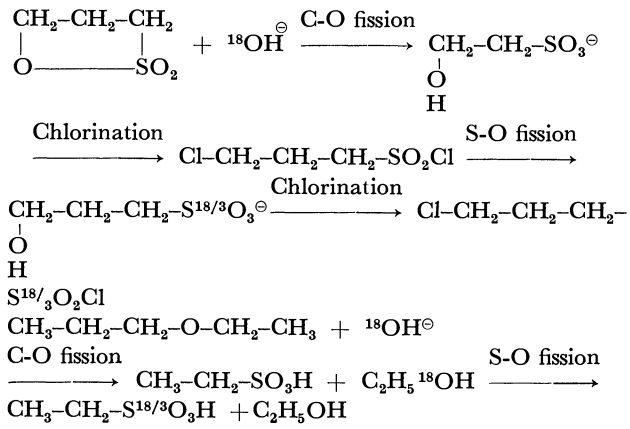
a) in water
b) Bordwell's Data[7] in water

7) F.G. Bordwell, C.E. Osborne, and R.D. Chapman, *J. Amer. Chem. Soc.*, **81**, 2698 (1959).

As shown in Table 2, the ratio of relative reaction rates of a five-membered sultone, a six-membered sultone, and a linear alkyl sulfonate ester in water at pH 7 is 37:1:7. This ratio seems to be the relative rate *via* $B_{AL}1$-E1 mechanism, because in the relationship between log K_1 and pH the values of log K_1 are constant below pH 10. Since E_a is nearly the same, these compounds can be regarded to undergo practically the same type of reaction. On the other hand, the strain in the ring should depend on the enthalpy term.[8,9] This term, however, is nearly the same, *viz.*, the difference in free energy of strain between a five-membered ring and a six-membered ring is slight. Consequently, contribution of the strain to the reactivity in the hydrolysis of sultones seems to be small and the reactivity is controlled practically by the entropy term (ΔS^*) alone.

Hydrolysis in $H_2{}^{18}O$. The hydrolysis of sultones and ethyl ethanesulfonate proceed mostly by $B_{AL}1$-E1 mechanism, but the results of kinetic studies suggest that S_N2-E2 reaction also occurs in the case of sultones. For the sake of confirmation, hydrolysis was carried out in $H_2{}^{18}O$ in a strongly alkaline medium (pH>12), and the atomic percentage of excess ^{18}O in the aqueous sodium hydroxide, hydrolysis products and its chlorinated compound were measured to determine the ratios of the C–O fission to the S–O fission in sultones and ethyl ethanesulfonate.

A previous kinetic study[2] indicates that both long chain substituted 1,3-sultones and unsubstituted 1,3-sultones undergo the same types of reactions and the ratios of the C–O fission to the S–O fission are nearly the same for the two groups. The samples of long chain substituted sultones for the analysis of ^{18}O present technical problems with respect to purification. Unsubstituted sultones which yield a single component, and are easily purified, seem to give more accurate values for the C–O and S–O fission. Thus, the ratio of the C–O fission to the S–O fission in 1,3-propanesultone seems to be applicable to aliphatic five-membered sultones.



The ratios of the C–O fission to the S–O fission in 1,3-propanesultone and ethyl ethanesulfonate are shown in Table 3.

8) F.S. Dainton, T.R.E. Devlin, and P.A. Small, *Trans. Faraday Soc.*, **51**, 1710 (1955).
9) P. A. Small, *ibid.*, **51**, 1717 (1955).

Table 3. Atomic percentage of excess ^{18}O and the ratios of the C-O fission to the S-O fission in the hydrolysis of 1,3-propanesultone and ethyl ethanesulfonate

Condition of Hydrolysis / Sample	1,3-propanesultone at 70°C, for 2.5 hr above pH 12	Ethyl ethanesulfonate at 80°C, for 2 hr above pH 12
$Na^{18}OH$-$H_2{}^{18}O$	1.459 (atom %)	1.503 (atom %)
Resulted Sulfonate	0.351	0.002
Chlorosulfonyl-chloride	0.101	—
C-O fission	85.6 (%)	100 (%)
S-O fission	14.4	0

The hydrolysis of a five-membered sultone occurs *via* scission of the S–O linkage even in water in a strongly alkaline medium. Since the S–O fission *via* monomolecular cleavage is difficult to conceive, the S_N2 reaction seems to be possible. This is reasonable if one considers that $OH^{\ominus}$, a hard base, tends to attack $-^{\oplus}SO_2$ more readily than $C^{\oplus}$ since $-^{\oplus}SO_2$ is a harder acid.

The S_N2 reaction tends to occur in aliphatic sultones when the activity of hydroxyl ion is increased such as in a strong alkaline medium or in a system consisting of an aprotic solvent and water.

On the other hand, in the hydrolysis of ethyl ethanesulfonate not the S_N2 reaction but the $B_{AL}1$-E1 reaction *via* the C–O fission occurs exclusively, both in a strong alkaline medium and in an aprotic solvent-water system. This result agrees with the kinetic results.

The S_N2 reaction seems to occur in six-membered sultones to a slightly less extent than in five-membered sultones, since a rise in the plot of log K_1 *versus* pH in the former sultone in 65 vol % of aqueous acetone is slightly less pronounced.

It is obvious that the hydrolysis of sultones proceeds by $B_{AL}1$-E1 mechanism. It is considered that in ordinary hydrolysis systems, where the activity of hydroxyl ion is not very high, only the $B_{AL}1$-E1 reaction occurs as in the case of ethyl ethanesulfonate.

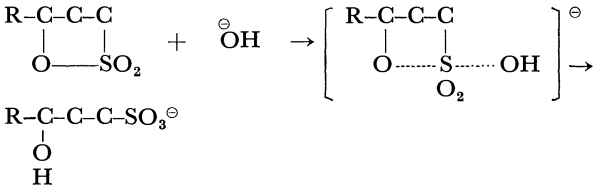
Consequently, the ratio of K_1 of a five-membered sultone, a six-membered sultone, and ethyl ethanesulfonate in water at pH 7 shows the relative reactivity of hydrolysis by the $B_{AL}1$-E1 reaction.

We thus conclude that in the reactions of hydrolysis of aliphatic alkyl sulfonate esters which proceed by the $B_{AL}1$-E1 reaction *via* the cleavage of C–O bond, the contribution of a ring strain to reactivity is very small, and the reactivity seems to be decided essentially by the entropy term ($\Delta S^{\neq}$).

The S_N2 reaction which follows a fission of S–O bond only occurs when the sultones are reacted in a solvent where the activity of hydroxyl ion is very high. This reaction seems to occur more easily in a five-membered sultone than a six-membered sultone.

However, in straight chain alkyl sulfonate ester which has no ring strain, the S_N2 reaction was not observed. It is obvious that in this reaction, contribution of the ring strain to the reactivity is very large. This tendency is consistent with the observation by Kaiser *et al.*[10] on aliphatic five-membered, six-membered and straight chain alkyl sulfates.

It is very interesting to compare these observations with the study by Müller *et al.*[11] with regard to the reactions of hydrolysis of aromatic sultones, in which only the S_N2 reaction can occur. Even in this case, contribution of the ring strain is also very large.



The authors are grateful to Dr. Shinichi Tomiyama, the Senior Managing Director of Lion Fat & Oil Co., Ltd. They also wish to express their thanks to Professer Dr. Shigeru Oae, Osaka City University and Professor Dr. Waichiro Tagaki, Gunma University, for many helpful discussions and suggestions during this work.

The Preparation of Deoxyguanosine Oligomers on an Insoluble Polymer Support

Takeo SHIMIDZU and Robert L. LETSINGER*

Faculty of Engineering, Kyoto University, Kyoto

**Department of Chemistry, Northwestern University, Evanston, Illinois, U.S.A.*

(Received December 4, 1970)

The syntheses of deoxyguanosine-containing oligonucleotides, deoxyguanylyldeoxyguanylyldeoxyguanosine (d-GpGpG), deoxyguanylyldeoxyguanylyldeoxyguanylyldeoxyguanosine (d-GpGpGpG) and deoxyguanylyldeoxyguanylyldeoxyguanylylthymidine (d-GpGpGpT) have been described. Those nucleotidic materials were synthetized on an insoluble polymer support; the polymer was a copolymer of styrene, *p*-vinylbenzoic acid, and divinylbenzene. The blocking group used at the *N*-position of deoxyguanosine was di-*p*-methoxytrityl.

Since Letsinger and his co-worker[1] used a polymer support technique to synthetize an oligonucleotide, many similar investigations have been made.[2-9] The most striking characteristic of the polymer support technique is the simplicity of its treatment and reaction-controlling of the intermediary products of nucleotidic materials, as in the Merrifield method[10] used in the synthesis of oligopeptide. However, in polymer support techniques used to synthetize a polypeptide with a higher molecular weight at a higher degree of condensation reaction, there is a limitation which results from a failure of sequence in the synthetized polypeptide, which can not be isolated from the desired product.[11] That is, in the polymer support techniques in polypeptide and polynucleotide syntheses, by-products resulting from an incompleteness of condensation steps accumulate until there is a cleavage of the product from the polymer support. Still, this technique is useful for the synthesis of a oligonucleotide unless the separation and isolation of the desired oligonulceotide is impossible. Table 1 shows the results of several syntheses of oligonucleotides by the polymer support technique. These procedures give higher yields than would a conventional homogeneous method.

In a preceding paper,[9] we described the synthesis of deoxyguanylyldeoxyguanosine on an insoluble polymer support; on it the 5'-OH of deoxyguanosine was bound as an anchor group. In this paper, the application of this method to the syntheses of trinucleotide, tetranucleotides, and their derivatives will be described. That is, deoxyguanylyldeoxyguanylyldeoxyguanosine (d-GpGpG), deoxyguanylyldeoxyguanylyldeoxyguanyl-

yldeoxyguanosine (d-GpGpGpG), deoxyguanylyldeoxyguanylyldeoxyguanylylthymidine (d-GpGpGpT), and their *N'*-di-*p*-methoxytrityl-substituted derivatives are synthetized. As the blocking group at the *N*-position[13] of deoxyguanosine, di-*p*-methoxytrityl (DMTr) is used.

These nucleotides were synthetized by the phosphodiester route on insoluble polymer supports like those described in the preceding paper.[9] The course of the synthesis is shown in Fig. 1.

The polymer supports used are tabulated in Table 2. The selectivity in the position of the anchorage of the hydroxy group in *N*-di-*p*-methoxytrityl deoxyguanosine[14] ((DMTr)d-G) depends on the crosslinkage of the polymer. A lower degree of crosslinkage gave a low selectivity of the 5'–0 anchorage, although the reac-

tion rate was faster. When the COCl content in the polymer support reaches 20%, the yield of the oligonucleotide decreases. These results are tabulated in Tables 3 and 4.

The synthetized *N*-substituted oligonucleotides were finally separated using a Sephadex LH-20 column. When gel filtration with Sephadex LH-20, for example, is used, the limited separation capacity of the column must be considered. It can be seen from Fig. 2 that the upper limit of the molecular size of water-insoluble nucleotidic material which can be applied to the Sephadex LH-20 column is between five and six in the degree of condensation. In general, the separation and purification of oligonucleotide using an ion-exchange cellulose or an ion-exchange gel column is easier than that using a gelfiltration column when the oligonucleotide is soluble in water.

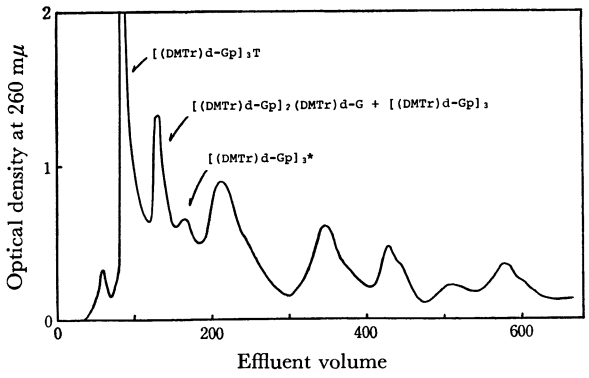

Fig. 2. Isolation of [(DMTr)d-Gp]$_3$T, VI, by sephadex LH 20 column.
*) (DMTr) is partly cloven.

The overall yields of these nucleotides were 22% (for d-GpGpG), 7% (for d-GpGpGpG *via* (b)), 17.5% (for d-GpGpGpG *via* (c)), and 18% (for d-GpGpGpT).

Experimental

Polymer Support, p–*COCl*. As is shown in Table 2, definnite amounts of freshly-distilled styrene, *p*-divinylbenzene, and *p*-vinylbenzoic acid[15] were placed, with a few seeds of the popcorn polymer and 0.5 mg of benzoyl peroxide, in an Erlenmeyer flask which had been well purged with nitrogen. Polymerization and chlorination were performed by the method described in the preceding paper.[9]

Di-p-*methoxytrityldeoxyguanosine*. Prepared by the procedure of Schaller *et al.*,[14] mp 167—168°C.

Paperchromatography was performed by the descending technique using Toyo Roshi No. 53 paper. The solvents were: A, isopropyl alcohol - concentrated ammonia - water (7:1:2); C, ethyl alcohol - 1M ammonium acetate at pH 7.35 (7:3). The phosphate buffer solution used in the electrophoreses was a mixture of 1/15M KH_2PO_4 and 1/15M Na_2HPO_4 (1:17).

The selectivity in the position of the anchorage of the hydroxy group in (DMTr)d-G was determined after the first phosphorylation of the anchored (DMTr)d-G. The selectivity (5′-0 linkage) was defined as [d-Gp/(d-Gp+pd-G)]×100.

N-*Di*-p-*methoxytrityldeoxyguanosine Trimer* (*IV*). *N*-Di-*p*-methoxytrityldeoxyguanosine (1.2 g) was treated with 1.0 g of the polymer support (I) in 20 ml of dry pyridine for 48 hr. Then, 10 ml of methanol was added to esterify any remaining acid chloride groups, and the mixture was stirred for 12 hr. Then, the polymer was collected by filtration and washed completely with methanol in an Soxhlet extractor until no residual *N*-di-*p*-metoxytrityldeoxyguanosine was found in the extract. The polymer was then dried under a vacuum over phosphorus pentoxide. The weight of the polymer was 1.170 g, from which value the amount of the *N*-di-*p*-methoxytrityldeoxyguanosine bound to the polymer support was estimated to be about 0.170 g.

The polymer-deoxyguanosine derivative (II) was added to a mixture of *β*-cyanoethylphosphate[16,17] (1 mmol) and mesitylenesulfonyl chloride[18] (2 mmol) in 20 ml of dry pyridine, and the mixture was stirred for 50 hr. Then, the solids were separated and kept at 50° with a 50% aqueous solution of pyridine for 30—40 min in order to hydrolyze a condensed phosphate. Finally, the solids, consisting of the polymer (III), were washed with methanol and dried under a vacuum over phosphorus pentoxide.

Prior to the addition of the second nucleosidic material, the activation of the terminal phosphate was achieved with mesitylenesulfonyl chloride. The polymer (III) was suspended in 20 ml of dry pyridine, after which a 2 mmol portion of mesitylenesulfonyl chloride was added. The reaction mixture was stirred for 24 hr. Then a solid was allowed to settle and the supernatant liquid was withdrawn. The solid was washed three times with dry pyridine to remove the major portion of mesitylenesulfonyl chloride, moisture being

kept off meanwhile. Then 1.0 g of *N*-di-*p*-methoxytrityldeoxyguanosine was added to the solid along with 20 m*l* of dry pyridine. The reaction was carried out under stirring for 3 days. Then, 20 m*l* of methanol were added. After 3 hr's stirring, the mixture was filtered, and the solid was washed with pyridine, methanol, and ether successively.

With the 1.0 g portion of the solid, such phosphorylation and the addition of nucleosidic material were repeated using appropriate amounts of the reagents.

After the addition of the third nucleosidic material, *N*-di-*p*-methoxytrityldeoxyguanosine, 0.2 g of the resulting solid was treated with a mixture of 1 m*l* of 2N NaOH, 2 m*l* of ethanol, and 2 m*l* of dioxane for 12 hr in order to cleave a nucleotide from the polymer support. The polymer was collected by filtration and washed with ethanol several times. The alkaline filtrate, together with ethanol washes of the polymer, was neutralized with Dowex 50 resin (pyridinium form). After the removal of the Dowex resin, the addition of ethanol to the solution and evaporation were repeated 2 times; the resulting material was made up with 1 m*l* of an ethanol solution. The solution was placed in a Sephadex LH-20 column (1 cm × 70 cm) and eluted with 90% ethanol at the rate of 0.5 m*l*/min. After a small peak, the major peak (160—220 m*l*) appeared. The third peak partly overlapped the second. The major elution part, the second peak, was concentrated and was then placed in the column again. A major peak (168—260 m*l*) was found just after a small peak (158—167 m*l*). The elution of the major peak was concentrated and kept in a refrigerator after a small amount of ether had been added. A pale yellow precipitate was collected and dried under reduced pressure over phosphorus pentoxide. A soft powdery material was thus obtained (13 mg). This material was homogeneous in the solvent A (R_f 0.75—78). The ultraviolet characteristics in an ethanol solution were: λ_{max}, 278 mμ (55,000), 263 mμ (56,200), 237 mμ (78,400); λ_{min}, 274 mμ (51,700), 252 mμ (53,400), 225 mμ (70,900).

Found: C, 60.50; H, 5.01; N, 11.29%. Calcd for $C_{93}H_{89}O_{22}N_{15}P_2$: C, 61.01; H, 4.90; N, 11.48%; for $C_{93}H_{91}O_{23}N_{15}P_2$ (monohydrate): C, 60.42; H, 4.96; N, 11.36%; for $C_{93}H_{93}O_{24}N_{15}P_2$ (dihydrate): C, 59.84; H, 5.02; N, 11.26%.

Deoxyguanylyldeoxyguanylyldeoxyguanosine (d-GpGpG). From 0.2 g of the solid, the nucleotidic materials were cloven as has been described above. The neutralized solution was made up to 1 m*l*. Then 3 m*l* of 80% acetic acid was added to the solution, and the mixture was kept for 5 hr. The acetic acid was evaporated under reduced pressure at room temperature. Then 20 m*l* of dilute ammonium hydroxide was added, the mixture was centrifuged, and the supernatant was concentrated to 5 m*l*. The supernatant solution was then adjusted to pH 9.5 with a very small amount of acetic acid. The supernatant was applied to the top of a DEAE-cellulose (carbonate form) column (2 cm × 20 cm). The column was washed with 0.02M NH_4HCO_3 until no ultraviolet-absorbing material was eluted. Further elution was carried out using a linear gradient of ammonium bicarbonate. The mixing vessel and the reservoir contained 1 *l* of 0.02M salt and an equal volume of 0.3M salt. The main peak ranged from the elution volume of 700 to that of 1120 m*l*. The total optical density was 240 O.D. The elution was repeated to dryness by adding water, and finally lyophilized.

Thus, 11.2 mg of the desired product, d-GpGpG, was obtained. The material was homogeneous in electrophoresis at pH 8.0 (1/15M phosphate buffer). The electrophoretic mobility, compared with that of deoxyguanosine 5′-phosphate, was 0.15. The ultraviolet absorption characteristics in water were: λ_{max}, 255 mμ (23,900); λ_{min}, 224 mμ (10,100); $\lambda_{shoulder}$, 268 mμ. R_f in the solvent A was 0.01. A venom phosphodiesterase preparation[19] was added to a small amount of the product, and the mixture was incubated at 37° for 12 hr. When paper electrophoresis was then carried out at pH 8.0, three spots were obtained: mobility 0 (2.4 O.D.), mobility 0.15 (0.1 O.D.), and mobility 1.0 (5.1 O.D.). Those spots corresponded to deoxyguanosine, an undegraded material, and deoxyguanosine 5′-phosphate. The optical densities were determined from the differences between the absorbances of the eluted solutions of the spots and those of the elutions of the appropriate blanks. From these results, the material was identified as deoxyguanylyldeoxyguanylyldeoxyguanosine, d-GpGpG.
