As a possible route towards a synthesis of mesoionic 3,4-dihydro-4-iminoimidazole (anhydro-4-aminoimidazolium hydroxide), we tried the reaction of *N*-methyl-*N'*-phenylbenzamidine (Ia) with bromoacetonitrile (IIa) anticipating the formation of an intermediate V. When the reaction was carried out in toluene, V was not isolated, but 4-amino-3-methyl-1,2-diphenylimidazolium bromide (IVa) was obtained. Attempts to isolate the intermediate, *N*-cyanomethyl-*N*-phenyl-*N'*-methylbenzamidine, were unsuccessful even in the presence of triethylamine or sodium acetate. The structure of the salt of mesoionic compound is most likely to be IVa instead of IVa', since the alkylation of amidine occurs preferentially at the doubly-linked nitrogen atom. It is known that *N*-methyl-*N'*-phenylbenzamidine reacts preferably in form A rather than in form B.[3,4] When the diphenylbenzamidine (Ib) was treated with IIa in xylene, corresponding triphenyl substituted derivative (IVb) was obtained. By the same method, *N*-phenyl-*N'*-*p*-tolylbenzamidine (Ic) was reacted with IIa to give IVc. Considering the influence of the groups R_1 and R_3 in Ic on the basicity of the nitrogen atom, IVc seems to be preferable to IVc'.[3] In the reaction of *N*-*p*-nitrophenyl-*N'*-phenylbenzamidine (Id) with IIa, it was found that the influence of the nitro group in Id was such that no reaction occurred with IIa under the same conditions. Although the isolation of the salt III was not successful, these ring formations seem to proceed through salts III, followed by interaction of two groups, with a mechanism similar to that of sydnone imine salts formation.[5] The structure of these products was established by elementary analyses and infrared spectra, which showed bands at 3380—3100 cm^{-1} corresponding to N–H stretching vibration, and at 1650—1645 cm^{-1} due to imidazole ring.

The reaction of amidines (Ia—Ic) with chloroacetonitrile (IIb) did not take place. However, amidines (Ia—Ic) reacted with IIb and equimolar amount of potassium iodide to give corresponding imidazolium iodides (IVd—IVf) in an ethanol solution. The mechanism of formation of the imidazolium iodides seems to proceed *via* halogen exchange followed by nucleophilic attack as mentioned above. Treatment of IVa with sodium bicarbonate or triethylamine did not give free base, but resulted in recovery of starting material. This indicates that the free base of IVa is stronger than the bases. No reaction was observed also in the treatment of IVb with sodium bicarbonate or triethylamine. Treatment of IVb with sodium hydroxide did not give the free base but afforded the intermediate Va, IR spectrum of which did not show C≡N stretching vibration as in the case of *O*-cyanomethyl-*N*-phenylbenzimidate.[6] On treating Va with dry hydrogen bromide, IVb was obtained. Treatment of IVa or IVc with sodium hydroxide gave oily substance which could not be purified. Treatment of IVa with acetic anhydride gave the *N*-acetyl derivative VI. The infrared spectrum was consistent with that expected for VI, showing a weak band at 3190 cm^{-1} resulting from N–H stretching vibration, and a strong band at 1697 cm^{-1} resulting from carbonyl group. On the other hand, treatment of IVb with acetic anhydride gave hygroscopic product which could not be identified. On treating IVa or IVb with picric acid, the picrates VIIa and VIIb were obtained respectively. On treating the iodides IVd—IVf with silver perchlorate, stable perchlorates VIIIa—VIIIc were obtained in good yield. Treatment of the perchlorate with acetic anhydride resulted in the recovery of starting material instead of acetylated product.

Diaryl substituted imidazolium salts (IVa, IVd, and VIIIa) show absorption maxima at about 290 mμ and triaryl substituted imidazolium salts (IVb, IVc, IVe, IVf, VIIIb, and VIIIc) show absorption maxima at about 300 mμ irrespective of the anion, which are suggestive of their heteroaromatic system. The NMR spectrum of IVd in $CDCl_3$–CD_3CN exhibits two singlets at τ 6.40 (3H, methyl protons at 3-position) and at τ 3.03 (1H, a proton at 5-position) and multiplet at τ 2.4—2.8 (10H, protons of phenyl groups). Methyl protons of IVd are shielded to a greater extent as compared with those attached to sydnone and sydnone imine ring.[7,8] The proton at 5-position is deshielded

Experimental

All melting points were determined on a micro hot stage and are not corrected. Infrared spectra were taken on KBr tablet.

4-Amino-3-methyl-1,2-diphenylimidazolium Bromide (IVa). A solution of 2.1 g of *N*-methyl-*N*′-phenylbenzamidine and 1.2 g of bromoacetonitrile (IIa) in 30 m*l* of toluene was refluxed for 3 hr. After cooling, the precipitates were collected and washed with benzene, and recrystallized from acetonitrile to give colorless prisms with a mp of 280—285°C.

Found: C, 58.24; H, 4.71; N, 12.50%. Calcd for $C_{16}H_{16}N_3Br$: C, 58.12; H, 4.85; N, 12.73%. IR: 3440, 3275, 3140, 1660, 1647 cm^{-1}. λ_{max}^{EtOH} 290 mμ (ε 7500).

4-Amino-1,2,3-triphenylimidazolium Bromide (IVb). (i) A solution of 2.7 g of diphenylbenzamidine and 1.2 g of IIa in 30 m*l* of xylene was refluxed for 4 hr. After cooling, the precipitates which separated out were collected and recrystallized from ethanol to give colorless prisms with a mp of 282—284°C (yield 60%).

Found: C, 64.05; H, 4.88; N, 10.60%. Calcd for $C_{21}H_{18}N_3Br$: C, 64.29; H, 4.59; N, 10.71%. IR: 3380, 3110, 1646 cm^{-1}. λ_{max}^{EtOH} 302 mμ (ε 7000).

(ii) To a solution of 0.1 g of *N*-cyanomethyl-*N*,*N*′-diphenylbenzamidine in 10 m*l* of benzene, 20 m*l* of benzene containing 0.05 g of gaseous hydrogen bromide was added dropwise. Precipitates which separated out were collected and recrystallized from ethanol. No depression of the melting point was observed on admixture with the product obtained by method (i).

*4-Amino-1,2-diphenyl-3-*p*-tolylimidazolium Bromide (IVc).* A solution of 2.86 g of *N*-phenyl-*N*′-*p*-tolylbenzamidine an 1.2 g of IIa in 30 m*l* of xylene for 40 min. After cooling, the precipitates were collected and reprecipitated from and ethanol solution with ether to give colorless prisms with a mp of 267—268°C (yield 58%).

Found: C, 64.88; H, 5.12; N, 10.52%. Calcd for $C_{22}H_{20}N_3Br$: C, 65.04; H, 4.93; N, 10.35%. IR: 3400, 3100, 1650 cm^{-1}. λ_{max}^{EtOH} 298 mμ (ε 6700).

4-Amino-3-methyl-1,2-diphenylimidazolium Iodide (IVd). A suspension of 2.1 g of *N*-methyl-*N*′-phenylbenzamidine and 0.8 g of chloroacetonitrile (IIb) and 1.7 g of potassium iodide in 50 m*l* of ethanol was refluxed for 5 hr, and after cooling the precipitates were filtered off. The filtrate was treated with activated charcoal and concentrated in a vacuum to give crude product, which was reprecipitated from an ethanol solution with ether to give colorless prisms with a mp of 205—206°C (yield 24%).

Found: C, 51.02; H, 4.48; N, 11.02%. Calcd for $C_{16}H_{16}N_3I$: C, 50.94; H, 4.25: N, 11.14%. IR: 3255, 3130, 1645 cm^{-1}. λ_{max}^{EtOH} 292 mμ (ε 7100).

4-Amino-1,2,3-triphenylimidazolium Iodide (IVe). A suspension of 1.36 g of diphenylbenzamidine and 0.38 g of IIb and 0.83 g of potassium iodide in 20 m*l* of ethanol was refluxed for 7 hr. After cooling, precipitates were collected and recrystallized from ethanol to give colorless needles with a mp of 280—283°C (yield 44%).

Found: C, 57.12; H, 4.33; N, 9.73%. Calcd for $C_{21}H_{18}N_3I$: C, 57.42; H, 4.10; N, 9.57%. IR: 3400, 3140, 1645 cm^{-1}. λ_{max}^{EtOH} 300 mμ (ε 6300).

*4-Amino-1,2-diphenyl-3-*p*-tolylimidazolium Iodide (IVf).* This compound was prepared by a method analogous to that of IVd. Reprecipitation from an ethanol solution with ether gave colorless needles with a mp of 272—274°C (yield 36%).

Found: C, 58.04; H, 4.66; N, 9.34%. Calcd for $C_{22}H_{20}N_3I$: C, 58.29; H, 4.42; N, 9.27%. IR: 3400, 3150, 1650 cm^{-1}. λ_{max}^{EtOH} 300 mμ (ε 6600).

N-Cyanomethyl-N,N′-diphenylbenzamidine (Va). To a solution of 1 g of IVb in 20 m*l* of ethanol, 2 m*l* of 8% aqueous sodium hydroxide solution was added. Precipitates were collected and recrystallized from ethanol to give colorless prisms with a mp of 128—130°C (yield 60%).

Found: C, 80.96; H, 5.56; N, 13.40%. Calcd for $C_{21}H_{17}N_3$: C, 81.00; H, 5.50; N, 13.50%. IR: 1615 cm^{-1}. NMR:

τ_{Me_4Si} ($CDCl_3$) 5.2 (2H, singlet), 2.7—3.4 (15H, multiplet).

N-Acetyl-4-amino-3-methyl-1,2-diphenylimidazolium Bromide (VI). A solution of 1 g of IVa in acetic anhydride was heated at 100°C for 5 min. After cooling, ether was added to the solution, and the precipitates were collected and recrystallized from acetonitrile to give colorless prisms with a mp of 270—273°C (yield 62%).

Found: C, 57.94; H, 4.72; N, 11.18%. Calcd for $C_{18}H_{18}N_3OBr$: C, 58.07; H, 4.83; N, 11.29%. IR: 3190, 3100, 1697, 1618 cm^{-1}.

Reaction of IVa or IVb with Picric Acid. To a solution of IVa in ethanol, a solution of picric acid in ethanol was added and refluxed for 2 min. After cooling the precipitates were collected and recrystallized from ethanol-ethyl acetate to give VIIa with a mp of 193—194°C.

Found: C, 54.96; H, 3.54; N, 17.71%. Calcd for $C_{22}H_{18}N_6O_7$: C, 55.23; H, 3.79; N, 17.57%.

By the same method as mentioned above, VIIb was obtained from IVb as yellow needles with a mp of 180—182°C.

Found: C, 59.46; H, 3.95; N, 15.27%. Calcd for $C_{27}H_{20}N_6O_7$: C, 60.00; H, 3.73; N, 15.55%.

1,2,3-Trisubstituted 4-Aminoimidazolium Perchlorates (VIIIa—VIIIc). To a solution of IVd (0.33 g) in acetonitrile-chloroform, a solution of 0.21 g of silver perchlorate in chloroform-ethanol was added dropwise. The precipitates were filtered off and filtrate was concentrated in a vacuum to give crude product, which was reprecipitated from a chloroform solution with ether to give VIIIa as colorless needles with a mp of 145—146°C (yield 69%).

Found: C, 54.73; H, 4.39; N, 12.06%. Calcd for $C_{16}H_{16}N_3O_4Cl$: C, 54.94; H, 4.61; N, 12.01%. IR: 3400, 3330, 1655 cm^{-1}. λ_{max}^{EtOH} 292 mμ (ε 6500).

By the same method as mentioned above, VIIIb was obtained from IVe as colorless needles with a mp of 254—256°C (yield 75%).

Found: C, 60.94; H, 4.60; N, 10.18%. Calcd for $C_{21}H_{18}N_3O_4Cl$: C, 61.22; H, 4.40; N, 10.21%. IR: 3425, 3330, 1650 cm^{-1}. λ_{max}^{EtOH} 302 mμ (ε 6600).

By the same method as mentioned above, VIIIc was obtained from IVf as colorless needles with a mp of 204—205°C (yield 59%).

Found: C, 62.14; H, 4.97; N, 9.89%. Calcd for $C_{22}H_{20}N_3O_4Cl$: C, 62.03; H, 4.73; N, 9.87%. IR: 3410, 3325, 1650 cm^{-1}. λ_{max}^{EtOH} 300 mμ (ε 6400).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 828—832 (1971)

The Reaction of α-Carbonyl Sulfides with Bases. I. The Reaction between α-Carbonyl Sulfides with Thiolates

Michinori Ōki, Wataru Funakoshi, and Atsuko Nakamura
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
(Received September 29, 1970)

It is found that carbonyl compounds, such as ketones and esters, bearing an alkyl(or aryl)thio group at the α-position, are smoothly reduced to the parent carbonyl compounds by the action of the thiolate anion. α-Halo or α,α-dihalo ketones are similarly reduced with the thiolate, probably *via* the corresponding sulfides. The mechanism of the reaction is discussed.

Since oxygen and sulfur belong to the same group in the periodic table, many similar reactions occur with the oxygen-sulfur analogs. However, there are also some dissimilarities, mainly because of the ability of the sulfur atom to expand its valence shell. The formations of the quadrivalent and sexivalent sulfur compounds are typical examples. As another dissimilarity of the two elements, the behavior toward bases may be cited; elemental sulfur itself and other polysulfides are known to undergo electrophilic cleavage,[1] whereas the dialkyl peroxides have seldom been reported to be cleaved by the bases.[2]

During the course of another study, we have encountered a rather curious reaction: the treatment of α-chlorodeoxybenzoin (**1**) with sodium methanethiolate (**2**) in ethanol gave rise to the formation of deoxybenzoin (**3**) instead of the expected α-(methylthio)deoxybenzoin (**4**). This finding of an unexpected reaction allured us to investigate the scope and the mechanism of the reaction. The purpose of this paper is to present the results of these studies and our conclusion that this unexpected reaction probably occurs *via* a nucleophilic attack of the thiolate ion on sulfur:

$$\underset{\text{(1)}}{C_6H_5\text{-}\underset{Cl}{CH}\text{-}\overset{O}{C}\text{-}C_6H_5} \xrightarrow[\text{(2)}]{CH_3SNa} \underset{\text{(3)}}{C_6H_5\text{-}CH_2\text{-}\overset{O}{C}\text{-}C_6H_5}$$

Results and Discussion

The cautious treatment of **1** with one equivalent of **2** in ethanol at 0°C resulted in the formation of **4** in a good yield, whereas the heating of an equimolar mixture of **1** and **2** in ethanol afforded a mixture of **3** and **4**. Thus, it is possible that the formation of **4** is the intervening process in the reduction of **1** to **3**.

$$\mathbf{1} \xrightarrow{CH_3SNa} \underset{\text{(4)}}{C_6H_5\text{-}\underset{CH_3S}{CH}\text{-}\overset{O}{C}\text{-}C_6H_5} \xrightarrow{CH_3SNa} \mathbf{3}$$

1) A. J. Parker and N. Kharasch, *Chem. Rev.*, **59**, 583 (1959).
2) Oxidation of olefins and amines with peroxy acid and Baeyer-Villiger oxidation may be considered to involve the nucleophilic cleavage of the O–O bonds. For cleavage of hydrogen peroxide with various bases, see J. O. Edwards and R. G. Pearson, *J. Amer. Chem. Soc.*, **84**, 16 (1962).

Table 1. Reduction of α-alkylthio carbonyl compounds with thiolates

Run No.	Substrate	Thiol	Molar ratio[a)]	Reaction period (hr)	Yield (%)	Products

a) Molar ratio is expressed by dividing number of moles of the thiolates by that of the substrates.

Indeed, treating **4** with **2** also afforded **3** in a good yield; in order to reduce **1** to **3** in a good yield, it was necessary to use two molar portions of **2** for each mole of **1**.

In order to test the generality of the reaction, various α-halo or α-alkylthio carbonyl compounds were treated with various thiolates: the results are shown in Tables 1 and 2. It may now be said that the reduction with thiolate is a fairly general reaction. A few of the interesting points to be pointed out are as follows: 1) even α,α-dihalo ketone can be reduced to the parent ketone with thiolate (run 12); 2) α-alkylthio and α-halo esters are also reduced with thiolate (runs 7 and 17); 3) benzenethiolate is a weaker reducing agent than the alkanethiolates (run 4). It seems that the solvent must be fairly polar in order to effect the reaction, since treating α-(methylthio)acetophenone with ethanethiolate in benzene gave only a trace of the reduced material.

It is now necessary, for studying the mechanism of the reaction further, to know the fate of the sulfur compounds: it was found that dimethyl disulfide was formed when **1** was treated with **2**. Although the treatment of **4** with sodium ethanethiolate afforded dimethyl disulfide and diethyl disulfide in addition to ethyl methyl disulfide, the formations of the symmetric disulfides could be attributed to the scrambling of the ethyl methyl disulfide because of the presence of ethanethiolate anion:[1,3)]

$$RSSR' + RS^- \longrightarrow RSSR + R'S^-$$

$$RSSR' + R'S^- \longrightarrow R'SSR' + RS^-$$

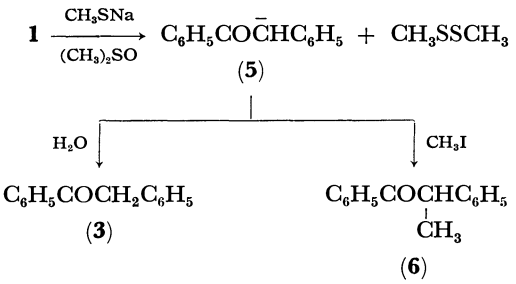
Other combinations of thioethers and thiolates which could give asymmetric disulfides also afforded symmetric sulfides.

The formation of disulfides might be interpreted as indicating that the reaction proceeded *via* a radical intermediate. However, the idea is rather inconsistent with the solvent effects and the fact that the conditions

3) S. Oae and H. Tanaka, *Yukigosei Kagaku Kyokaishi*, **27**, 793 (1969).

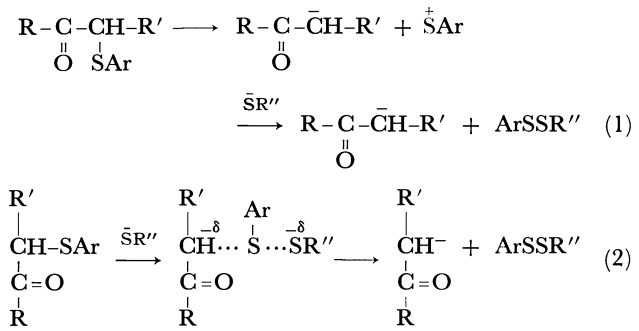
are strongly ionic. Another fact may be added as a proof against the radical intermediate; the reduction with benzenethiolate is slow compared with that with ethanethiolate. Trapping the intermediate was thus attempted in order to ascertain the nature of this reaction.

1 was treated with sodium methanethiolate in dimethyl sulfoxide to form a deep red-orange solution. The solution was quenched with water to give **3**, whereas quenching with methyl iodide gave α-methyldeoxybenzoin (**6**). Thus, the reaction clearly proceeds *via* an ionic intermediate; otherwise it is difficult to explain the products. It is most probable to assume the intermediacy of the deprotonated anion of deoxybenzoin (**5**). Then, in ethanol and other protic solvents, **5** picks up a proton to form **3**, whereas it survives in dimethyl sulfoxide until quenched.



In view of the above discussion, thiolate must attack the sulfur atom of the thioethers as a nucleophile. That is, this reaction involves a nucleophilic attack at the sulfur atom of the thioether. If this mechanism is assumed, it is easy to explain the slow reaction with benzenethiolate, since benzenethiolate is a more stable anion than ethanethiolate[4] and may thus be a poorer nucleophile.

Two possibilities may be considered as the reaction mechanism: S_N1- and S_N2-type reactions at the sulfur atom of the thioether. These mechanisms may be expressed by Eqs. (1) and (2) respectively:



(1)

(2)

However, the possibility of the S_N1-type reaction can be ruled out for the following reason: if it were an S_N1-type reaction, there would be no reason for the alkoxide ion to fail to cause a similar reaction, but it actually is the case as will be demonstrated in the following paper.[5]

4) p*Ka* values of benzenethiol and ethanethiol are 12.0 and 8.3, respectively. M. Ōki, "San to Enki (Acids and Bases)," Baifūkan, Tokyo (1967), p. 66.

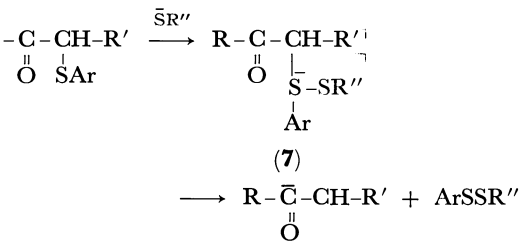
5) M. Ōki and W. Funakoshi, This Bulletin, **44**, 832 (1971).

Information about the transition state of the reaction can be obtained by measuring the substituent effects on the rates of the reaction. The pseudo-first-order rates of the reaction of α-(phenylthio)acetophenone and α-(*p*-bromophenylthio)acetophenone with sodium benzenethiolate were thus obtained using an excess of thiophenol and a reasonable amount of sodium in order to keep the concentration of the thiolate constant, while the second-order rates were calculated by using the concentration of the thiolate ion. The results are listed in Table 3. The rates are slightly diminished when the substituent is electron-withdrawing. Thus, the results may be taken as favoring the S_N2-type transition state rather than the S_N1-type, since, if it were an S_N1-type reaction, the decrease in ratio would be much larger.

Table 3. Rates of reaction of α-(arylthio)-acetophenone ($ArSCH_2COC_6H_5$) with sodium benzenethiolate in ethanol (65°C)

Ar	$k_1 \times 10^2$ hr^{-1}	$k_2 \times 10^5$ *l*·mol^{-1}·hr^{-1}
C_6H_5	2.65	1.15
p-BrC_6H_4	1.4	0.7

Another alternative may be postulated as a rate-determining step: the electron pair is donated by the anion to the sulfur *d*-orbital to form **7**:



This possibility can, however, be ruled out also: if it were the case, the electron-withdrawing substituent would enhance the reaction rate.

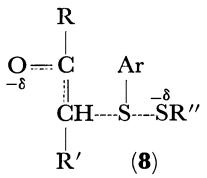
It may be argued that reduction may not be directly caused by the thiolate anion, but by the hydride shift from either alkoxide or the thiolate anion, as many reductions are known to occur by the action of alkoxide through the hydride shift. However, this possibility can be discarded for two reasons. First, as will be discussed in the following paper,[5] ethoxide is not capable of reducing the α-alkylthio ketone. The second reason is that benzenethiolate can reduce α-alkyl(or aryl)-thio ketone in ethanol. In the latter reaction, the reducing agent must be the benzenethiolate ion, which has no α-hydrogen, since ethoxide, which may exist because of an equilibrium and also as a reaction product, has no power to reduce the alkylthio ketone.

Having established the nucleophilic nature of the reaction, the next problem is to clarify the role of the carbonyl group. The role of the carbonyl group may be considered to be two-fold. First, it acts as an anion-stabilizing substituent because of its intrinsic mesomeric and inductive nature **8**. Second, the attacking base may add to the carbonyl group first, and then within the adduct **9** a nucleophilic reaction may take place, as is indicated by the arrows:

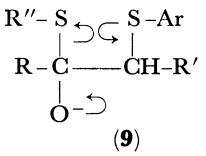
Table 4. Reactions of some α-substituted ketones with thiolates in ethanol

Substrate	Thiol	Molar ratio[a)]	Reaction period (hr)	Yield of parent ketone (%)
$C_6H_5CH(SCN)C_6H_5$	C_2H_5SH	6.0	2	quantitative
$C_6H_5COCH_2SCN$	C_2H_5SH	2.5	7	45
$C_6H_5COCH_2Cl$	H_2S	20	5	10
$C_6H_5COCH_2SCOCH_3$	C_2H_5SH	8.0	1	84

a) Molar ratio was calculated on the basis of sodium used for making thiolates. Thiols were used always in excess relative to sodium.



(8)

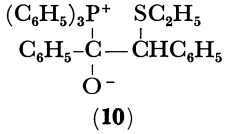


(9)

The data are rather contradictory and confusing. Triphenylmethyl chloride, ethyl triphenylmethyl thioether, phenyl trichloromethyl thioether, and *p*-benzoylbenzyl ethyl thioether gave no sign of reduction when treated with thiolate either in ethanol or in dimethyl sulfoxide-ethanol, although triphenylmethyl, trichloromethyl, and *p*-benzoylbenzyl groups are supposed to stabilize the anion to a considerable extent. These results suggest that the presence of the anion-stabilizing substituent is not good enough to cause the reaction, thus favoring the intermediate **9**. Failure of methyl *p*-tolyl sulfone to be formed from phenylthiomethyl *p*-tolyl sulfone may be added as another proof for the intermediacy of **9**, since bromomethyl *p*-tolyl sulfone is reported to be reduced by a thiolate to methyl *p*-tolyl sulfone.[6)] However, it may be argued that this is not direct proof of the importance of the carbonyl group in the reduction with thiolate, because deprotonation may compete with the nucleophilic attack at the sulfur atom.

$$p\text{-}CH_3C_6H_4SO_2CH_2Br \xrightarrow{\bar{S}C_6H_5} p\text{-}CH_3C_6H_4SO_2CH_3$$

On the other hand, there is a fact which cannot be explained by the intermediate **9**: α-(ethylthio)deoxybenzoin is smoothly reduced with triphenylphosphine. The details of the reaction will be discussed in the next paper.[5)] If the adduct **10**, which itself will be of high energy because of the charge separation and the steric effect, is formed, it has to be assumed that the positively-charged phosphorus behaves as a nucleophile: this is, though, highly unlikely.



(10)

The mechanism of the reaction could be different according to the structure of the substrate and the attacking base. This point must be explored further.

6) F. G. Bordwell and B. B. Jarvis, *J. Org. Chem.*, **33**, 1182 (1968).

Finally, we wish to point out that the reaction of α-carbonyl sulfide with thiolate is not limited to α-carbonyl thioethers; some other sulfur compounds are also cleaved at the C–S bond to produce the parent carbonyl compounds. Some of the results are shown in Table 4. It will be seen that thiocyano and acetylthio ketones are smoothly reduced to the parent ketones.[7)] The isolation of acetophenone in a low yield on the treatment of α-chloroacetophenone with sodium hydrogen sulfide may be attributed to the presence of an equilibrium of ionization such as is expressed by the following equation (negative charge on the sulfur atom should certainly reduce the possibility of the nucleophilic attack):

$$C_6H_5COCH_2SH + HS^- \rightleftharpoons C_6H_5COCH_2S^- + H_2S$$

It has been well established that disulfides are cleaved at the S–S bond by various bases, and excellent reviews have been published.[1,3)] However, thioethers are known to be fairly inert toward bases, and under forcing conditions a proton alpha to the sulfur atom is removed because of the stabilization due to the sulfur atom.[8)] The reaction discovered here occurs under rather mild conditions and is a unique one in a sense mentioned above.

Experimental

Materials. The following new thioethers were identified.

α-(Methylthio)deoxybenzoin. α-Chlorodeoxybenzoin (26.5 g or 0.115 mol) was allowed to react with sodium methanethiolate in ethanol prepared from 27 g (0.56 mol) of methanethiol at −15°C. The reaction mixture was poured into water after 30 min at 0°C and extracted with ether to afford α-(methylthio)deoxybenzoin, mp 73—73.5°C, in almost quantitative yield. Found: C, 74.36; H, 5.70%. Calcd for $C_{15}H_{14}OS$: C, 74.36; H, 5.80%.

Similarly the following compounds were prepared.

α-(Ethylthio)deoxybenzoin: mp 74.1—75.5°C. Found: C, 75.29; H, 6.30%. Calcd for $C_{16}H_{16}OS$: C, 74.98; H, 6.29%.

α-(Ethylthio)cyclohexanone: bp 119—121°C/30 mmHg. Found: C, 60.70; H, 8.66%. Calcd for $C_8H_{14}OS$: C, 60.74; H, 8.92%.

7) Incidentally, this makes a very interesting contrast with the reaction between some nucleophiles and methyl α-thiocyanoacetate in that the latter yields $^-SCH_2CO_2CH_3$ anion. See R. G. Hiskey, W. H. Bower, and D. N. Harpp, *J. Amer. Chem. Soc.*, **86**, 2010 (1964); R. G. Hiskey and D. N. Harpp, *ibid.*, **86**, 2014 (1964).

8) Hydrogen atoms of the methylene group which is placed between two sulfur atoms are easily exchanged by deuterium under the influence of the basic catalyst. See for example: S. Oae, W. Takagi, and A. Ohno, *Tetrahedron*, **20**, 427 (1964).

α,α-Bis(methylthio)acetophenone: mp 65.5—66.5°C. Found: C, 56.80; H, 5.58%. Calcd for $C_{10}H_{12}OS_2$: C, 56.60; H. 5.70%.

The Reaction of Thiolates with Sulfides and Halogen Compounds. As an example of the general procedure, the reduction of α-chlorodeoxybenzoin with methanethiolate will be described. The reduction of the sulfides proceeded smoothly with equimolar thiolate, whereas the halides needed at least 2 molar portions of thiolate to produce the parent ketone in a good yield. Sometimes an excess of thiol was used to cover the loss by vaporization.

To a solution prepared from 0.3 mol of sodium and 150 m*l* of ethanol, was added 0.4 mol of methanethiol and then 0.126 mol of α-chlorodeoxybenzoin. The solution was heated under reflux and poured into water after 30 min. The subsequent extraction of the mixture gave deoxybenzoin, mp 56—57°C, in an almost quantitative yield.

The other products were analyzed by vapor-phase chromatography.

Reaction of α-(Methylthio)deoxybenzoin with Methanethiolate in Dimethyl Sulfoxide. A solution prepared from 0.958 g (0.04 mol) of sodium and 60 m*l* of ethanol was treated with an excess of methanethiol and then evaporated. The residue was taken up in 60 m*l* of dimethyl sulfoxide and mixed with a solution of 4.808 g (0.02 mol) of α-(methylthio)deoxybenzoin in 20 m*l* of dimethyl sulfoxide. The mixed solution was heated for 45 min at 85°C to produce a deep red-orange color, Quenching the solution with water gave deoxybenzoin, whereas treating the solution with methyl iodide yielded α-methyldeoxybenzoin (NMR, δ from TMS in CCl_4 4.51 (q) and 1.50 (d)).

Determination of the Reaction Rates. A solution was prepared containing *ca* 7×10^{-2} mol of α-(arylthio)acetophenone, *ca* 5 mol of thiophenol, and *ca* 2×10^{-2} mol of sodium in 200 m*l* of ethanol. Di-*p*-methoxyphenyl ketone was added to the solution for use as an internal standard of analysis. Ten-mililiter portions of the solution were sealed in separate tubes, and the decrease in the quantity of the α-keto sulfides was determined by means of NMR.

The cost of this study has been defrayed in part by the Grant-in-Aid for Fundamental Research from the Ministry of Education, to which the author's thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 832—835 (1971)

The Reaction of α-Carbonyl Sulfides with Bases. II. The Effect of Variation in the Nucleophiles

Michinori Ōki and Wataru Funakoshi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 29, 1970)

The reactions of α-alkylthio ketones with various nucleophiles were examined. It was found that such "strong bases" as ethoxide did not cause any cleavage of the C–S bond, whereas such "weak bases" as thiourea could cause the cleavage. The phenomena may be explained by the concept of soft-and-hard acids and bases. Discussions are given of some reactions of the nucleophilic attack on sulfur, which have previously been reported, in the light of this new reaction.

Since α-carbonyl sulfides were found to produce the parent keones and esters on treatment with the thiolate anion, it seemed that it would be interesting to study how widely this reaction is applicable. In the preceding paper[1] we have reported that this kind of reactions occurs not only with the α-carbonyl thioethers but also with α-thiocyano ketones and α-mercapto or α-acetylthio ketones. The purpose of this paper is to report on the effect of the kind of nucleophiles on the reaction of α-carbonyl sulfides. As examples of the latter compounds, α-alkylthio ketones were chosen because of their high reactivity.

Results and Discussion

Since thiolate was able to reduce α-alkylthio ketones, it is natural to examine the reaction of the oxygen analogs. Thus sodium ethoxide was allowed to react with α-(ethylthio)acetophenone in boiling ethanol for 1.5 hr. This treatment ended in the recovery of the starting material. One of the reasons for the recovery of this compound could be the enolization of the ketone, which might compete favorably with the nucleophilic attack on the sulfur atom. α-Methyl-α-(methylthio)-deoxybenzoin (**1**) was chosen as an example to be treated with ethoxide, because this compound has no α-hydrogen and the anion expected to be produced should be stable. The formation of the anion should thus be favored.

a) The substrate is α-methyl-α-(methylthio)deoxybenzoin.
b) The substrate is α-(ethylthio)deoxybenzoin.

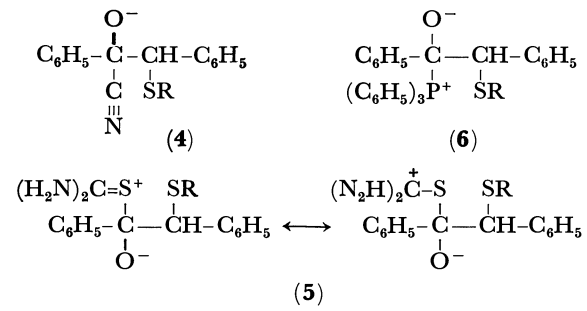
deoxybenzoin and other sulfur compounds; rather, ethyl benzoate and methyl 1-phenylethyl sulfide (**3**) were detected by means of vapor-phase chromatography. Indeed, benzoic acid was isolated after hydrolysis. It is clear that the attack by the ethoxide ion on sulfur is very slow and that the usual ketone cleavage by the base takes place *via* the adduct **2**.

Similarly, α-(methylthio)acetophenone did not give acetophenone on treament with sodium amide, although the amide anion is known to be a stronger base than ethoxide. Thus, it seemed that the capability of causing the C–S scission is not dependent on the base strength expressed by the pK_a values of the conjugate acids. This was experienced in many reactions of carbonium ions[2] and sulfur compounds;[3] the term "thiophilicity" has been proposed to express the nucleophilicity of bases when the site to be attacked is the sulfur atom. Thus, α-(methylthio)deoxybenzoin and its homologs were treated with various bases; the results are given in Table 1.

It can be pointed out that phosphine, cyanide ion, and thiourea are favorable for cleaving the C–S bond to produce deoxybenzoin. Some bases yielded benzil, which must be a product of the simultaneous desulfurization and oxidation; this tendency is clear with the iodide ion. However, in the absence of oxygen, the formation of benzil is not observed, indicating that the reaction is very probably of a radical nature. Support for this idea is given by the reaction of α-methyl-α-(methylthio)deoxybenzoin (**1**), which is not affected under similar conditions. Thus α-hydrogen is necessary to induce the change.

It seems that the higher polarity of the solvents is also a necessary condition for inducing this kind of reaction, for α-(ethylthio)acetophenone failed to give acetophenone when treated with triphenylphosphine in tetrahydrofuran.

The successful cleavage of the C–S bond of α-(alkylthio)deoxybenzoin with the cyanide ion, thiourea, and triphenylphosphine may be taken as support for the direct attack of the nucleophile on the sulfur atom, since, if the adducts **4**, **5**, and **6** are formed, neutral carbon, neutral sulfur which is next to the positive site, or positively-charged phosphorus must be the attacking base. The possibility is, however, very unlikely.



(**4**) (**6**)

(**5**)

The rough order of the reactivities of the bases is thus obtained as follows:

$$RS^- > C_6H_5S^- \sim (C_6H_5)_3P > CN^- > (H_2N)_2C{=}S > SCN^- \sim I^- \sim Br^-$$

Many papers[4,5] have been published dealing with the nucleophilicities of the bases in reactions with polysulfides and disulfides. The main difference between the nucleophilicity of the bases in relation to the polysulfides and that in relation to α-carbonyl sulfides is that hydroxide and ethoxide ions act as effective agents to cleave the S–S bond on the polysulfides, whereas,

2) C. G. Swain and C. B. Scott, *J. Amer. Chem. Soc.*, **75**, 141 (1953).
3) J. O. Edwards and R. G. Pearson, *ibid.*, **84**, 16 (1962).
4) A. J. Parker and N. Kharasch, *Chem. Rev.*, **59**, 583 (1959).
5) S. Oae and H. Tanaka, *Yukigosei Kagaku Kyokaishi*, **27**, 793 (1969).

they are ineffective in the cleavage of the C–S bond. There have been many attempts to explain the nucleophilicity of the base. Some representative theories will be discussed in an attempt to explain the above results.

Parker and Kharasch obtained the order of nucleophilicity in relation to the bivalent sulfur atom by determining the equilibrium point of the following equation:[4,6]

$$RSSR + Y^- \rightleftharpoons RS^- + RSY$$

The result was:

$$(C_2H_5O)_3P > -\overset{|}{C}^- \sim RS^- > ArS^- > (C_6H_5)_3P \sim CN^- >$$
$$SO_3^{2-} > OH^- > S_2O_3^{2-} > (H_2N)_2C{=}S > SCN^- > Br^- > Cl^-$$

An insufficient agreement of this order with the data presented here is, of course, to be expected, since those results were based on the equilibrium point and ours, on the product distribution, which is in turn determined by the one-way reaction rate.

On the other hand, Swain and Scott obtained the following order of nucleophilic constants as a fundamental characteristic of the bases:[2]

$$S_2O_3^{2-} > SO_3^{2-} \sim SH^- \sim CN^- > I^- >$$
$$SCN^- > OH^- > (H_2N)_2C{=}S$$

It may be pointed out that the placement of thiourea does not explain our results at all.

Pearson *et al.* presented the idea of the softness and hardness of the acids and bases and explained some S_N2-type organic reactions by assuming that a soft acid reacts more effectively with the soft bases. The softness is generally understood to express the higher polarizability of the acids and bases and has been obtained from the rates of the reactions of methyl iodide and *trans*-$[Pt(py)_2Cl_2]$ with various bases.[7] The order of softness thus obtained with the platinum complex is as follows:

$$(C_2H_5O)_3P > (C_6H_5)_3P \gg S_2O_3^{2-} > C_6H_5S^- \sim (H_2N)_2C{=}S >$$
$$(CH_3O)_3P > CN^- \gg SCN^- > I^- > Br^- > CH_3O^-$$

In this view of soft-and-hard acids and bases, sulfur of thioether must be one of the softest acids. Therefore, the cleavage of the C–S bond in α-carbonyl thioethers must be fast with the soft bases. The results presented here may be said to be generally in agreement with Pearson's theory, but the theory cannot explain some of the detailed results; for example, triphenylphosphine is much less reactive than predicted, and the reactivity of thiourea is less than that expected.

It may be necessary to modify the presently-proposed theories or to invent another theory to explain the results obtained with the α-carbonyl sulfides. This is also a rather expected results, since the orders of the rates of reactions of the bases with methyl iodide and the platinum complex do not agree with each other in some details.[7]

In view of the above-mentioned results, some of the points in the literature are worthy of comment. It was found that the treatment of α-(carboxymethylthio)-deoxybenzoin (**7**) with the hydroxide ion gave deoxybenzoin and glyoxylic acid in addition to hydrogen sulfide.

$$C_6H_5{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{SCH_2CO_2H}{|}}{CH}{-}C_6H_5 \xrightarrow{OH^-}$$

(**7**)

$$C_6H_5COCH_2C_6H_5 + CHOCO_2H + H_2S$$

In order to explain these results, Iskander *et al.*[8] have assumed an attack by the hydroxide ion on sulfur, followed by cleavage to carbanion and sulfenic acid; finally, there was decomposition to glycolic acid and hydrogen sulfide.

$$-\underset{\underset{O}{\|}}{C}-\underset{|}{C}-S-\underset{|}{C}-CO_2Na \xrightarrow{OH^-} -\underset{\underset{O}{\|}}{C}-\underset{|}{C}-\underset{\underset{OH}{|}}{\bar{S}}-\underset{|}{C}-CO_2Na$$

$$\longrightarrow -\underset{\underset{O}{\|}}{C}-\underset{|}{\bar{C}}^- + \underset{\underset{OH}{|}}{S}-CH_2CO_2Na \longrightarrow$$

$$-\underset{\underset{O}{\|}}{C}-\underset{|}{CH} + CHOCO_2Na + S^{2-}$$

However, these mechanisms involve some points which are still to be clarified; especially, it is very hard to explain why carboxymethanesulfenic acid changes to glyoxylic acid and hydrogen sulfide. Since, in our experiments, proton abstraction occurs with the ethoxide, and, since the hydroxide ion is known to be a typical hard base, we favor the route of the formation of carbanion which has been proposed by Teich and Curtin:[9]

$$-\underset{\underset{O}{\|}}{C}-\underset{|}{C}-S-\underset{|}{\underset{H}{C}}-CO_2Na \xrightarrow{OH^-} -\underset{\underset{O}{\|}}{C}-\underset{|}{C}-S-\underset{|}{\bar{C}}-CO_2Na$$

$$\longrightarrow -\underset{\underset{O}{\|}}{C}-\underset{|}{\bar{C}}^- + S{=}\underset{|}{C}-CO_2Na \xrightarrow{H_2O}$$

$$-\underset{\underset{O}{\|}}{C}-\underset{|}{C}-H + O{=}\underset{|}{C}-CO_2Na + H_2S$$

We believe the similar reaction of *p*-nitrobenzylthioacetic acid in an alkaline solution reported by Schönberg and Iskander[10] can be similarly explained instead of considering the hydroxide attack on sulfur:

$$NO_2-C_6H_4-CH_2SCH_2CO_2Na \xrightarrow{OH^-}$$

$$HC(=O)-C_6H_4-N{=}N-C_6H_4-CH(=O) + CHOCO_2Na + H_2S$$

Experimental

The general procedure for the reaction was essentially the same as that reported in the preceding paper.[1] The pertinent

p-Toluenesulfonylation of 1,2-*O*-Cyclohexylidene-*myo*-inositol[1]

Tetsuo SUAMI, Seiichiro OGAWA, Takatoshi TANAKA, and Toshiki OTAKE*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

* *Nippon Electric Varian Co., Ltd., Azabu Iigura-cho, Minato-ku, Tokyo*

(Received October 15, 1970)

p-Toluenesulfonylation of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**) afforded one mono (1), three di (1,4, 1,5, and 1,6), three tri (1,4,5, 1,4,6, and 1,5,6), and one tetra (1,4,5,6)-*O*-*p*-toluenesulfonyl derivatives of *myo*-inositol, and all the structures have been established by way of their proton magnetic resonance (PMR) spectra and the reaction sequences.

The sulfonate esters of carbohydrates are useful precursors for a wide variety of their derivatives.[2a,b] Therefore, selective sulfonylation at hydroxyl groups of sugars has been extensively studied.[2b] On the other hand, little information is, so far, known about the reactivities of the hydroxyl groups of cyclitols toward sulfonylation. Thus it seemed of interest to investigate a sulfonylation of inositols. In the present paper, we wish to report the *p*-toluenesulfonylation of 1,2-*O*-cyclohexylidene-*myo*-inositol (**1a**).[3]

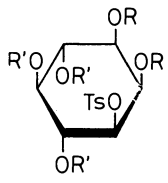
a: R=H
b: R=Ac



2

a: R=cyclohexylidene, R′=H
b: R=cyclohexylidene, R′=Ac
c: R=R′=H
d: R=R′=Ac

When **1a** was treated with 2 equivalents of *p*-toluenesulfonyl chloride in dry pyridine at 0—5°C for 24 hr and then at room temperature for 6 days, almost exclusively one isomer of the mono sulfonyl derivative (**2a**) was obtained in 41% yield. Acetylation of **2a** with acetic anhydride and pyridine gave tri-*O*-acetyl derivative (**2b**). Removal of cyclohexylidene group by refluxing of **2a** in 80% aqueous acetic acid afforded 1-*O*-*p*-toluenenesulfonyl-*myo*-inositol (**2c**),[4] and further acetylation of **2c** gave 1,2,4,5,6-penta-*O*-acetyl-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2d**), which was identified with anauthentic sample.[5] Consequently, **2a** was assigned to1, 2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol. Although the same reaction was carried out with 1.5 or 3 equivalents of *p*-toluenesulfonyl chloride, **2a** was obtained in 39 or 36% yield, respectively. These results indicated that the hydroxyl group on C-3 was the most reactive one among four hydroxyl groups in **1a**, and were in accordance with the observed facilitation of acylation or sulfonylation by neighboring oxygen atoms in a cis position.[3] Other instance of this effect is the preferential *p*-toluenesulfonylation of 1,2:3,4-di-*O*-isopropylidene-*epi*-inositol in the 5-position.[6]

Then an isolation of the di-*O*-*p*-toluenesulfonyl esters was attempted. Compound **1a** was treated with

2 equivalents of *p*-toluenesulfonyl chloride similarly a described before. After **2a** was obtained in 33% yield, its mother liquor was, then, subjected to a fractional crystallization to give a crystalline mixture of three di-esters in 41% yield. Further fractionations by a column chromatography using silica gel and recrystallization afforded chromatographically homogeneous three isomers of the di-esters (**3a**, **4a**, and **5a**). In another run, after isolating **2a** in 22% yield, the mixture was fractionated to give practically pure **3a**, **4a**, and **5a** in 20, 16 and 2.6% yield, respectively. Acetylation of **3a**, **4a**, and **5a** with acetic anhydride and pyridine gave the di-*O*-acetyl derivatives (**3b**), (**4b**), and (**5b**). Three isomers, (**3c**), (**4c**), and (**5c**), of di-*O*-*p*-toluenesulfonyl-*myo*-inositol were obtained by removal of cyclohexylidene group from **3b**, **4b**, and **5b**. On acetylation, **3c**, **4c**, and **5c** afforded tetra-*O*-acetyl derivatives (**3d**), (**4d**), and (**5d**), respectively.

In order to establish a configuration of the di-*O*-*p*-toluenesulfonyl derivatives, **2a** was further sulfonylated. When a course of the reaction with 1.5 equivalent of *p*-toluenesulfonyl chloride upon **2a**, as well as 2 equivalent upon **1a**, were monitored by a thin layer chromatography (TLC), both chromatograms were shown to be almost identical, except some traces of minor components. These results indicated that the three di-esters obtained must be derived from **2a**, and, accordingly, they should be either the 3,4-, 3,5- or 3,6-disulfonyl derivative. Also periodate oxidation was applied to an elucidation of the position of the sulfonyloxy groups in the di-esters. Compound **4a** was observed to react with periodate solution, however, neither **3a** nor **5a** would consume the reagent. So it might have been considered that the conformational rigidity of 1,2-*O*-cyclohexylidene-3,4 (or 3,6)-di-*O*-*p*-toluenesulfonyl-*myo*-inositol prevented a formation of the five membered periodate ester.[7]

Partial PMR spectrum of 3,4,5,6-tetra-*O*-acetyl-1,2-*O*-cyclohexylidene-*myo*-inositol (**1b**), as a reference compound, was shown in Fig. 1. The signals for the protons on C-1 and C-2, to which the cyclohexylidene group attached, are well upshifted and are separated

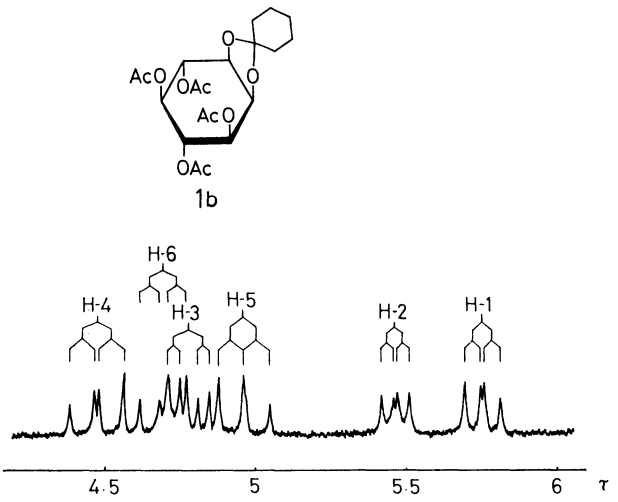

Fig. 1. Partial PMR spectrum of 3,4,5,6-tetra-*O*-acetyl-1,2-*O*-cyclohexylidene-*myo*-inositol (**1b**) (100 MHz, $CDCl_3$).

7) J. Corse and R. E. Lundin, *J. Org. Chem.*, **35**, 1904 (1970).

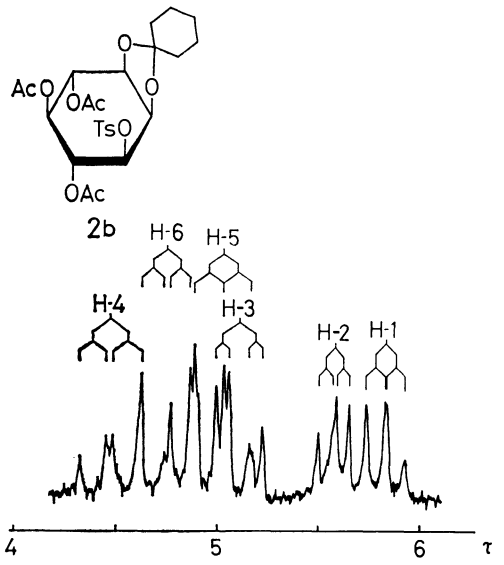

Fig. 2. Partial PMR spectrum of 4,5,6-tri- *O*-acetyl-1,2-*O*-cyclohexylidene-3-*O*-*p*-toluenesulfonyl-*myo*-inositol (**2b**) (60 MHz, $CDCl_3$).

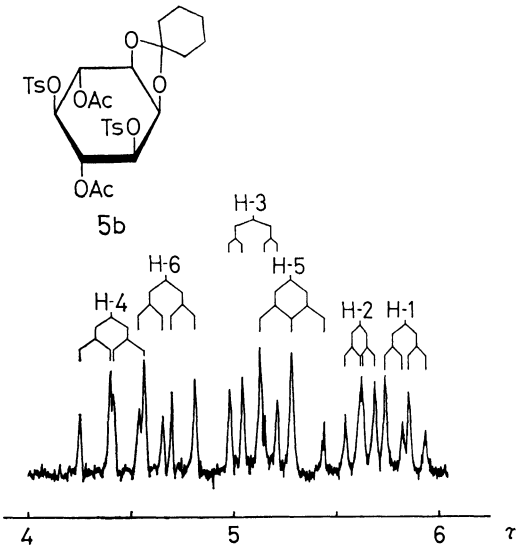

Fig. 3. Partial PMR spectrum of 4,6-di-*O*-acetyl-1,2-*O*-cyclohexylidene-3,5-di-*O*-p-toluenesulfonyl-*myo*-inositol (**5b**) (60 MHz, $CDCl_3$).

from those of the protons on the remaining carbon atoms. This simplified the assignment of signals. If it is assumed that the signal for H-1 (pseudoaxial) appears higher than that for H-2 (pseudoequatorial), all remaining signals could be adequately resolved by first-order method and assigned unambiguously to each proton, as listed in Tables 1 and 2. This assignment was further supported by the PMR spectrum of **2b** (Fig. 2). The spectral pattern is similar to that of **1b**, except that the signal for the H-3 proton is upshifted by 0.32 ppm. This can be easily understood by the fact that, in the case of **1b**, the acetoxy group on C-3 is substituted by a *p*-toluensulfonyloxy group. In the well resolved PMR spectrum of **5b** (Fig. 3), both signals for the H-3 and H-5 protons are upshifted by 0.32 ppm, comparing with those in the spectrum of **1b**. By analogy, these results might suggest that two

p-toluenesulfonyloxy groups are located at C-3 and C-5. While, in the PMR spectrum of **3b**, the quartet for the H-4 proton appears at τ 4.50, and this means that the *p*-toluenesulfonyloxy group is not located at C-4. Therefore, according to the observations of periodate oxidation and PMR spectra, **3a**, **4a**, and **5a** could be assigned to 1,2-*O*-cyclohexylidene-3,6-, 3,4- and 3,5-di-*O*-*p*-toluenesulfonyl-*myo*-inositol, respectively.

Table 1. Chemical shifts of methine protons[a)]

Compound	Chemical shifts (τ)					
	H-1	H-2	H-3	H-4	H-5	H-6
1b[b)]	5.75 q	5.46 q	4.78 q	4.47 q	4.96 t	4.69 q
2b	5.80 t	5.55 q	5.10 q	4.47 q	5.00 t	4.73 q
3b	5.84 t	5.59 q	5.14 q	4.50 q		
5b	5.83 q	5.61 t	5.10 q	4.41 t	5.28 t	4.67 q
5d	4.98 q	4.42 t	5.21 q	4.45 t	5.13 t	4.41 t
7b	5.81 t	5.59 q	5.21 q	4.54 q		

a) Measured at 60 MHz in $CDCl_3$, unless otherwise stated.
b) Measured at 100 MHz in $CDCl_3$. This compound should be named 1,4,5,6-tetra-*O*-acetyl-2,3-*O*-cyclohexylidene-*myo*-inositol, but it is not convenient for discussing the PMR spectrum.

Table 2. First-order coupling constants of methine protons

Compound	coupling constants (Hz)					
	$J_{1,2}$	$J_{2,3}$	$J_{3,4}$	$J_{4,5}$	$J_{5,6}$	$J_{6,1}$
1b	5.5	3.8	9.9	8.3	8.9	6.6
2b	5.5	4.0	10.0	8.0	8.0	6.5
3b	5.5	3.5	9.5	8.0		6.5
5b	5.0	3.5	10.0	9.0	9.0	7.0
5d	2.7	3.0	10.5	9.5	9.5	10.5
7b	6.0	3.2	10.0	6.0		5.0

It is interesting to note that the coupling constants between H-1 and H-2 are of the order of 5.0—5.5 Hz, indicating the angle between the bridgehead hydrogen atoms of a cyclohexylidene ring of approximately 35—40° on the basis of Karplus equation.[8)] Judging from the other coupling constants observed, the six-membered ring was only slightly flattened from the chair conformation by the introduction of 1,2-*O*-cyclohexylidene group into *myo*-inositol derivatives.

When a reaction mixture of **1a** and 7 equivalents of *p*-toluenesulfonyl chloride in dry pyridine was kept at room temperature until its TLC indicated an absence of the di-esters, two tri-esters (**6a** and **7a**) were obtained in a pure state by fractional crystallizations in 28 and 6% yield, respectively. The TLC of its mother liquor showed a presence of considerable amount of the tetra-ester. On acetylation, **6a** and **7a** gave di-*O*-acetyl derivatives (**6b**) and (**7b**). On acid hydrolysis with aqueous acetic acid, **6a** and **7a** gave two isomers, (**6c**) and (**7c**), of tri-*O*-*p*-toluenesulfonyl-*myo*-inositol, which, on acetylation, afforded tri-*O*-acetyl derivatives (**6d**) and (**7d**), respectively. In another run, after **6a** was crystallized out in 24% yield, the mother liquor was evaporated and the residue was subjected to an acid hydrolysis with aqueous acetic acid. From the hydrolyzate, 1,4,5,6-tetra-*O*-*p*-toluenesulfonyl-*myo*-inositol (**9a**) was recovered in 21% yield, which was converted into di-*O*-acetyl derivative (**9b**). Then the mother liquor was evaporated and the residual oil was treated with a mixture of acetic anhydride and pyridine to afford, in addition to **7d** (5%), hitherto unknown tri-*O*-acetyl-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol (**8**) in 11% yield.

Now, sulfonylation of the three isomers of di-*O*-*p*-toluenesulfonyl derivative, **3a**, **4a**, and **5a**, were attempted for the purpose of obtaining informations on a position of sulfonyloxy groups in the tri-esters. By the TLC studies of sulfonylation products of the di-esters, it is apparent that both **6a** and **7a** were derived from **3a**, while, **6a** and **7a** were formed from **4a** and **5a**, respectively. In addition to each major component, an unidentified minor component was found in the reaction mixtures of **4a** and **5a**. Accordingly, **6a** and **7a** should be 1,2-*O*-cyclohexylidene-3,4,6- and -3,5,6-tri-*O*-*p*-toluenesulfonyl-*myo*-inositol, respectively, while, the unidentified compound might be considered to be the 3,4,5-tri-ester. These structural assignments were also confirmed by PMR spectra, and the nucleophilic displacement reaction with an azide ion, which will be described later.

The PMR spectrum of **7b** reveals a quartet at τ 4.54, which is assigned to the signal for H-4 proton. Therefore the acetoxy group is located at C-4 in **7b** and **7b** must be the 3,5,6-tri-ester. On the other hand, the absence of a quartet in a lower field in the PMR spectrum of **6b** indicated that the sulfonyloxy group is in C-4 position, and ascertained the structural assignment of **6b**.

Theoretically, four tri-esters can be derived from **1a**: the 3,4,5-, 3,4,6-, 3,5,6-, and 4,5,6-esters. So that the unidentified tri-ester (**8**) must be either the 3,4,5-

a) Measured at 60 MHz in $CDCl_3$.
b) Signal of two acetyl methyl protons.

or 4,5,6-tri-ester. Had **8** been the 4,5,6-tri-ester, two acetoxy groups on C-1 and C-3 should be spectroscopically equivalent and their signals should appear as one singlet. However, **8** shows three peaks at τ 8 region: τ 7.92, 8.02 and 8.08 (Table 3). Therefore, **8** should be 1,2,6-tri-*O*-acetyl-3,4,5-*O*-*p*-toluenesulfonyl-*myo*-inositol.

The remarkable facilitation of sulfonylation have not been observed among the hydroxyl groups of **1a** other than that on C-3. Some differences in the relative proportions of the isomeric sulfonyl esters obtained are seemed to be explained by a steric and an electronic effects on a hydroxyl group toward sulfonylation.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. Infrared (IR) spectra were taken in KBr disks. PMR spectra were measured on a Varian Associate A-60D (60 MHz) or HA-100D (100 MHz) spectrometer at a concentration of *ca.* 10% deuteriochloroform with tetramethylsilane as an internal standard. Chemical shifts are expressed in τ-values and signals are described as s (singlet), t (triplet), q (quartet), or m (complex multiplet). Values given for coupling constants are first-order. Thin layer chromatography (TLC) was done with silica gel (Wakogel B-10, Wako pure chemical industries Ltd.) using toluene-methyl ethyl ketone (4 : 1 or 3 : 1 volume) as the solvent system. The compounds were detected by exposing the plates to iodine vapor; the relative proportions of the compounds were estimated visually. All solutions were concentrated by a rotary evaporator at 40—50°C under reduced pressure. Whenever pyridine was employed in a reaction, the residual pyridine was removed by repeated codistillation with dry toluene.

1,2-O-*Cyclohexylidene*-myo-*inositol* (***1a***). This compound was prepared from *myo*-inositol following the method of Angyal and his coworkers[3] and purified by recrystallization two times from ethanol, mp 178—179°C (lit,[3] 179°C).

3,4,5,6-Tetra-O-*acetyl-1,2*-O-*cyclohexylidene*-myo-*inositol* (***1b***). This compound was prepared from **1a** following the method of Angyal and his coworkers,[3] mp 117—118°C (lit,[3] 118°C).

1,2-O-*Cyclohexylidene-3*-O-p-*toluenesulfonyl*-myo-*inositol* (***2a***). A solution of **1a** (5.2 g) in dry pyridine (80 m*l*) was externally cooled to 0—5°C. *p*-Toluenesulfonyl chloride (7.6 g, 2.0 equiv.) was added in one portion and dissolved under stirring, and the temperature was maintained below 5°C for 24 hr. Then the reaction mixture was stored at room temperature (15—20°C) for 6 days. The mixture was, then, poured onto ice and water (500 m*l*), and, after 24 hr at room temperature, the resulting gum was collected by decantation. The crude product was dissolved in chloroform (150 m*l*) and washed with N hydrochloric acid, 10% aqueous sodium carbonate and water successively. After drying over anhydrous sodium sulfate, the solution was evaporated to yield a semisolid, which was recrystallized from ethanol to give colorless needles (3.4 g, 41%) of **2a**, mp 225—227°C (dec.). Two recrystallization from methanol afforded an analytical sample, mp 229—230.5°C (dec.).

Found: C, 54.80; H, 6.39; S, 7.41%. Calcd for $C_{19}H_{26}O_8S$: C, 55.06; H, 6.32; S, 7.74%.

Although TLC showed the presence of considerable amounts of di- and tri-esters in the mother liquor of **2a**, further isolation was not attempted in this experiment.

In another run, the sulfonylation was carried out with 1.5 equiv. of *p*-toluenesulfonyl chloride, and the reaction mixture was kept at 0—5°C for 3 days, followed by 2 days at room temperature. The yield of **2a** was 39%. When 3.0 equiv. of *p*-toluenesulfonyl chloride was used, the yield of **2a** was 36%.

4,5,6-Tri-O-*acetyl-1,2*-O-*cyclohexylidene-3*-O-p-*toluenesulfonyl*-myo-*inositol* (***2b***). Compound **2a** (0.20 g) was treated with a mixture of acetic anhydride (2 m*l*) and pyridine (2 m*l*) at room temperature overnight. Then the reaction mixture was poured onto ice and water (20 m*l*) and the resulting crystals were collected by filtration; yield 0.23 g (88%), mp 158—160.5°C. Two recrystallization from ethanol gave fine needles (0.20 g) of **2b**, which showed the same melting point. PMR: τ 7.54 (3, s, OTs C–CH_3).

Found: C, 55.78; H, 6.05; S, 5.74%. Calcd for $C_{25}H_{32}O_{11}S$: C, 55.54; H, 5.97; S, 5.93%.

1-O-p-*Toluenesulfonyl*-myo-*inositol* (***2c***). A mixture of **2a** (1.2 g) and 80% aqueous acetic acid (20 m*l*) was refluxed for 2 hr. After cooling, the resulting precipitates were collected by filtration, washed with ethanol and dried; yield 0.74 g (77%), mp 222.5—225°C (dec.). Recrystallization from acetic acid and water gave colorless needles of **2c**, which was identified with an authentic sample (lit,[4] mp 224°C) by a mixed melting point and comparing with IR spectra.

1,2,4,5,6-Penta-O-*acetyl-3*-O-p-*toluenesulfonyl*-myo-*inositol* (***2d***). Compound **2c** (0.10 g) was treated with a mixture of acetic anhydride (2 m*l*) and pyridine (2 m*l*) at room temperature overnight. Then the reaction mixture poured onto ice and water to give colorless crystals (0.15 g, 92%) of **2d**, mp 149.5—151°C. It was identified with an authentic sample (lit,[4] mp 151°C) by a mixed melting point and comparing with IR spectra.

1,2-O-*Cyclohexylidene-3,6-di*-O-p-*toluenesulfonyl*-myo-*inositol* (***3a***), *1,2*-O-*Cyclohexylidene-3,4-di*-O-p-*toluenesulfonyl*-myo-*inositol* (***4a***) *and 1,2*-O-*Cyclohexylidene-3,5-di*-O-p-*toluenesulfonyl*-myo-*inositol* (***5a***). (a) A solution of **1a** (26.0 g) in dry pyridine (340 m*l*) was cooled to 0—5°C. *p*-Toluenesulfonyl chloride (38.0 g, 2.0 equiv.) was added in one portion and the solution was kept for 24 hr at 0—5°C, followed by 9 days at room temperature (15—20°C). Then the reaction mixture was poured onto ice and water (500 m*l*), and, after 2 days at room temperature, the water layer was separated from the resulting gum with decantation and extracted with chloroform

(2×200 ml). The extracts were washed with N hydrochloric acid, 10% aqueous sodium carbonate and water successively, and allowed to stand at room temperature overnight. The resulting crystals were collected and washed with ethanol; yield 13.9 g (33.4%), mp 225°C (dec.). Recrystallization from ethanol gave colorless needles (10.3 g, 24.7%) of **2a**, mp 229—230.5°C (dec.).

Then the gum (*ca.* 26 g) was dissolved in hot ethanol (150 ml) and kept at room temperature to give colorless crystals (10.4 g, 18.3%), which were shown to be a mixture of **3a** and **4a** by TLC. The mother liquor was evaporated and the residue was again dissolved in ethyl acetate (30 ml). Addition of benzene (60 ml) afforded the second crystals (8.45 g, 14.9%), which were composed of mainly **3a**. After 2 weeks, the third crystals (1.72 g, 3.0%) were obtained from the mother liquor and shown to be a mixture of **4a** and **5a** by TLC. Then the oily product which was obtained by evaporation of the filtrate was applied to the top of a column of silica gel (50 g, Wakogel C-200, Wako pure chemical industries Ltd.) packed in toluene-methyl ethyl ketone (5 : 1 volume). The column was eluted with the same solvent system, and the fractions were collected and combined according to the results of TLC. Evaporation of the eluates gave chromatographically pure crystals of **3a** (0.31 g), **4a** (0.53 g) and **5a** (0.78 g).

Further fractional crystallization of the first, second, and third crystals from methyl ethyl ketone and toluene gave **3a** (2.3 g), **4a** (3.6 g), and **5a** (0.9 g).

An analytical sample of **3a** was obtained by recrystallization from methyl ethyl ketone and toluene, and dried over phosphorus pentoxide *in vacuo* at 120°C; colorless granular crystals, mp 175—177.5°C.

Found: C, 55.05; H, 5.73; S, 11.41%. Calcd for $C_{26}H_{32}O_{10}S_2$: C, 54.91; H, 5.68; S, 11.28%.

Two recrystallization from methyl ethyl ketone and toluene afforded an analytical sample of **4a** as colorless cubic crystals, mp 173—175°C.

Found: C, 54.66; H, 5.63; S, 10.73%.

Recrystallization from methyl ethyl ketone and toluene gave an analytical sample of **5a** as colorless tiny needles, mp 182.5—184°C.

Found: C, 54.71; H, 5.65; S, 11.06%.

(b) Compound **1a** (26.0 g) was treated with *p*-toluenesulfonyl chloride (38.0 g) in dry pyridine (260 ml) similarly as described in (a). From the water layer, **2a** (9.3 g, 23%) was isolated. The gum was fractionally crystallized from ethyl acetate (45 ml) and benzene (100 ml) to give crystals (11.2 g, 19.6%) of **3a**, which were shown to be sufficiently pure for use in further synthetic experiment by TLC. The mother liquor was evaporated to give an oil which was crystallized from ethyl acetate and benzene to yield practically pure crystals (9.1 g, 16%) of **4a**, and, after long storage at room temperature, a crystalline mixture (8.5 g, 15%) of **3a**, **4a** and **5a** was obtained. Then the filtrate was evaporated and the resulting oil was subjected to a column chromatography similarly as described in (a). Four main components were obtained: a mixture of the tri-esters (0.59 g), **3a** (0.57 g), a mixture of **3a** and **4a** (2.92 g), and **5a** (0.43 g).

*Periodate Oxidation of **3a**, **4a**, and **5a**.* To a solution of 30 mg of 1,2-*O*-cyclohexylidene-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3a**, **4a**, and **5a**) in 2 ml of methanol, a 1 ml portion of 50% aqueous methanolic solution of sodium metaperiodate (50 mg/ml) was added and the solution was kept for 2 days at room temperature in a dark place. The reaction mixture was analyzed directly by TLC. Judging from the results of TLC, both **3a** and **5a** did not react with periodate, and only **4a** was shown to react with periodate giving rise to another compound.

p-*Toluenesulfonylation of **2a**.* To a solution of **2a** (0.10 g) in dry pyridine (2 ml) was added *p*-toluenesulfonyl chloride (0.09 g, 1.5 equiv.) and the mixture was allowed to stand at room temperature for 4 days. The reaction mixture was analyzed directly by TLC. Monitoring by TLC, the chromatograms were found to be almost identical, except some traces of minor components, with that of the reaction mixture of **1a** and 2 equiv. of *p*-toluenesulfonyl chloride in pyridine prepared under the same condition. Even when an additional amount of *p*-toluenesulfonyl chloride was added to the mixture, both the chromatograms were identical, except some traces of minor components somewhat increased.

*4,5-Di-O-acetyl-1,2-O-cyclohexylidene-3,6-di-*O-p-*toluenesulfonyl-*myo-*inositol (**3b**).* Compound **3a** (0.20 g) was treated with a mixture of acetic anhydride (2 ml) and pyridine (3 ml) at 80°C for 1 hr. Then the reaction mixture was poured onto ice and water (10 ml) and the resulting precipitates were collected by filtration; yield 0.24 g (100%), mp 157—159°C. Two recrystallization from ethanol gave colorless needles (0.18 g, 78%) of **3b**, mp 158—160.5°C. PMR: τ 7.55 (6, s, OTs C–CH_3).

Found: C, 55.33; H, 5.39; S, 9.58%. Calcd for $C_{30}H_{36}O_{12}S_2$: C, 55.21; H, 5.56; S, 9.83%.

*5,6-Di-*O-*acetyl-1,2-*O-*cyclohexylidene-3,4-di-*O-p-*toluenesulfonyl-*myo-*inositol (**4b**).* Compound **4a** (0.45 g) was acetylated similarly as described under the preparation of **3b** to give crude crystals (0.45 g, 87%) of **4b**, mp 169—171.5°C. Two recrystallization from ethanol afforded colorless granular crystals (0.34 g, 66%), mp 170—170.5°C. PMR: τ 7.58 (6, s, OTs C–CH_3), 5.91 (1, t, H-1, J=5.5 Hz), 5.64 (1, q, H-2, J=3.5 and 5.5 Hz).

Found: C, 55.36; H, 5.66; S, 9.88%. Calcd for $C_{30}H_{36}O_{12}S_2$: C, 55.21; H, 5.56; S, 9.83%.

*4,6-Di-*O-*acetyl-1,2-*O-*cyclohexylidene-3,5-di-*O-p-*toluenesulfonyl-*myo-*inositol (**5b**).* Compound **5a** (0.13 g) was acetylated similarly as described under the preparation of **3b** to give crude crystals (0.15 g, 99%) of **5b**, mp 178.5—180°C. Two recrystallization from ethanol gave colorless needles (0.10 g, 67%), mp 166.5—168°C. Compound **5b** crystallized from ethanol in two allotropic forms: needles, mp 166.5—168°C, and rectangular plates, mp 179—180.5°C. PMR: τ 7.55 (6, s, OTs C–CH_3).

Found: C, 55.03; H, 5.61; S, 9.52%. Calcd for $C_{30}H_{36}O_{12}S_2$: C, 55.21; H, 5.56; S, 9.83%.

*1,4-Di-*O-p-*toluenesulfonyl-*myo-*inositol (**3c**).* A mixture of **3a** (0.20 g) and 80% aqueous acetic acid (10 ml) was refluxed for 2 hr. The reaction mixture was evaporated to give a crystalline residue, which was triturated with water and collected by filtration; yield 0.16 g (93%), mp 196—199°C. Recrystallization from acetic acid and water afforded colorless needles of **3c**, mp 198—200°C.

Found: C, 48.92; H, 5.02; S, 12.61%. Calcd for $C_{20}H_{24}O_{10}S_2$: C, 49.18; H, 4.95; S, 13.13%.

*1,6-Di-*O-p-*toluenesulfonyl-*myo-*inositol (**4c**).* A mixture of **4a** (0.25 g) and 80% aqueous acetic acid (10 ml) was refluxed for 2 hr. The reaction mixture was evaporated and the residue was dried by repeated codistillation with dry ethanol. Several attempts to crystallize amorphous glassy product of **4c** failed. Then it was dried over phosphorus pentoxide *in vacuo* at 110°C and analyzed; yield 0.22 g (76%), mp 155—160°C.

Found: C, 49.47; H, 5.41%. Calcd for $C_{20}H_{24}O_{10}S_2$: C, 49.18; H, 4.95%.

*1,5-Di-*O-p-*toluenesulfonyl-*myo-*inositol (**5c**).* Compound **5a** (0.29 g) was refluxed with 80% aqueous acetic acid (30 ml) for 2 hr. The reaction mixture was evaporated to dryness

and the residue was crystallized from ethanol to give colorless tiny needles (0.18 g, 71%) of **5c**, mp 211—212.5°C (dec.). Recrystallization from acetic acid and water afforded an analytical sample, mp 212—214°C (dec.).

Found: C, 48.99; H, 4.97; S, 12.85%. Calcd for $C_{20}H_{24}O_{10}S_2$: C, 49.18; H, 4.95; S, 13.13%.

1,2,4,5-Tetra-O-*acetyl-3,6-di*-O-p-*toluenesulfonyl*-myo-*inositol (**3d**).* Compound **3c** (0.24 g) was treated with a mixture of acetic anhydride (3 m*l*) and pyridine (4 m*l*) at 80°C for 1 hr. The the mixture was poured onto ice and water (20 m*l*) and the resulting precipitates were collected by filtration; yield 0.32 g (99%), mp 214—217°C. Recrystallization from chloroform and ethanol gave plates and needles (0.27 g, 84%) of **3d**, mp 216.5—217.5°C. PMR: τ 7.56 (6, s, OTs C–CH_3), 5.20 (1, q, H-3, J=3 and 10 Hz), 4.40 (1, t, H-2, J=*ca.* 3 Hz).

Found: C, 50.85; H, 5.13; S, 10.16%. Calcd for $C_{28}H_{32}O_{14}S_2$: C, 51.20; H, 4.91; S, 9.77%.

1,2,5,6-Tetra-O-*acetyl-3,4-di*-O-p-*toluenesulfonyl*-myo-*inositol (**4d**).* Crude **4c**, which was obtained from **4a** (1.01 g), was treated with a mixture of acetic anhydride (8 m*l*) and pyridine (10 m*l*) at room temperature overnight. Then the mixture was poured onto ice and water (20 m*l*) and the crystals were collected by filtration; yield 1.02 g (87%), mp 190—193°C. Recrystallization from ethyl acetate and ethanol gave colorless granular crystals of **4d**, mp 196—197.5°C. PMR: τ 7.54 (6, s, OTs C–CH_3), 5.40 (1, m, H-3), 5.07 (1, q, H-1, J=2.8 and 10 Hz).

Found: C, 51.07; H, 4.89; S, 9.64%. Calcd for $C_{28}H_{32}O_{14}S_2$: C, 51.20; H, 4.91; S, 9.77%.

1,2,4,6-Tetra-O-*acetyl-3,5-di*-O-p-*toluenesulfonyl*-myo-*inositol (**5d**).* Compound **5c** (47 mg) was treated with a mixture of acetic anhydride (0.5 m*l*) and pyridine (0.5 m*l*) at room temperature overnight. The mixture was poured onto ice and water and the resulting gum was crystallized from ethanol and water; yield 60 mg (95%), mp 160.5—162°C. Recrystallization from ethanol and water gave an analytical sample of **5d** as colorless needles, which showed the same melting point. PMR: τ 7.54 (6, s, OTs C–CH_3).

Found: C, 50.93; H, 4.88; S, 9.60%. Calcd for $C_{28}H_{32}O_{14}S_2$: C, 51.20; H, 4.91; S, 9.77%.

1,2-O-Cyclohexylidene-3,4,6-tri-O-p-*toluenesulfonyl*-myo-*inositol (**6a**) and 1,2-O-Cyclohexylidene-3,5,6-tri*-O-p-*toluenesulfonyl*-myo-*inositol (**7a**).* To a cooled solution of **1a** (26.0 g) in dry pyridine (380 m*l*), *p*-toluenesulfonyl chloride (133.5 g, 7.0 equiv.) was added in one portion, and the reaction mixture was stored at room temperature (10—15°C) for 10 days. Then any pyridine hydrochloride was removed by decantation and the solution was poured onto ice and water (1 *l*). After 2 days, the resulting gum was collected by filtration and dissolved in chloroform (300 m*l*). The chloroform solution was washed with N hydrochloric acid, 10% aqueous sodium carbonate, and water successively, and then, dried over anhydrous sodium sulfate. Then the solution was evaporated to yield a partly crystalline residue, which was triturated with chloroform and ethanol, and collected by filtration; yield 19.9 g (27.6%), mp 170—175°C. Recrystallization from chloroform and ethanol gave practically pure crystals (18.0 g) of **6a**, mp 173—177°C. An analytical sample was obtained by two recrystallizations from ethanol and dried over phosphorus pentoxide *in vacuo* at 120°C, mp 175—177.5°C.

Found: C, 54.93; H, 5.54; S, 12.70%. Calcd for $C_{33}H_{38}O_{12}S_3$: C, 54.83; H, 5.30; S, 13.30%.

From the mother liquor of **6a**, colorless plates were obtained after 1 week; yield 3.95 g (5.5%), mp 176—181°C. Two recrystallizations from chloroform and ethanol afforded an analytical sample of **7a** as colorless tiny plates, mp 183—184.5°C.

Found: C, 54.60; H, 5.27; S, 12.83%.

In another run, starting from **1a** (26.0 g), **6a** (18.2 g, (25.2%), and **7a** (2.67 g, 3.7%) were obtained from the reaction product. Then the mother liquor was evaporated and the residual oil was crystallized from methyl ethyl ketone and toluene to give a crystalline mixture (19.5 g) of mono- and di-esters. According to the result of TLC, considerable amount of tri- and tetra-esters were shown to be present in the mother liquor, but, further isolation of the isomer was not attempted.

p-*Toluenesulfonylation of **3a**, **4a**, and **5a**.* To a solution of 50 mg of 1,2-*O*-cyclohexylidene-di-*O*-*p*-toluenesulfonyl-*myo*-inositol (**3a**, **4a**, and **5a**) in 1 m*l* of dry pyridine was added 70 mg (4.0 equiv.) of *p*-toluenesulfonyl chloride and the mixture was allowed to stand at room temperature for 4 days. Then the reaction mixture was analyzed directly by TLC using toluene-methyl ethyl ketone (3:1) and benzene-ethyl acetate (9 : 4) as the solvent systems. Judging from the results of TLC, **3a** gave rise to **6a** and **7a**, while, **6a** and **7a** were formed from **4a** and **5a**, respectively. In addition to the major component, an unidentified product was found in the reaction mixture of **4a** and **5a**, which might be considered to be *1,2-O*-cyclohexylidene-*3,4,5*-tri-*O-p*-toluenesulfonyl-*myo*-inositol.

5-O-Acetyl-1,2-O-cyclohexylidene-3,4,6-tri-O-p-*toluenesulfonyl*-myo-*inositol (**6b**).* Compound **6a** (1.0 g) was treated with a mixture of acetic anhydride (5 m*l*) and pyridine (5 m*l*) at room temperature overnight. Then the reaction mixture was poured onto ice and water (30 m*l*) and the precipitates were collected by filtration; yield 1.0 g (95%), mp 177.5—179°C. Recrystallization from chloroform and ethanol afforded colorless cubic crystals (0.91 g) of **6b**, mp 179—180.5°C. PMR: τ 7.58 (9, s, OTs C–CH_3), 5.91 (1, t, H-1, J=5.5 Hz), 5.63 (1, q, H-2, J=3.5 and 5.5 Hz).

Found: C, 55.14; H, 5.47; S, 12.85%. Calcd for $C_{35}H_{36}O_{15}S_3$: C, 54.84; H, 5.27; S, 12.58%.

4-O-Acetyl-1,2-O-cyclohexylidene-3,5,6-tri-O-p-*toluenesulfonyl*-myo-*inositol (**7b**).* Compound **7a** (0.10 g) was acetylated similarly as described under the preparation of **6b** to give crystals (0.10 g, 95%) of **7b**, mp 194—195°C. Recrystallization from ethanol afforded colorless cubic crystals (0.09 g), mp 195.5—196°C. PMR: τ 7.59 (9, s, OTs C–CH_3).

Found: C, 55.05; H, 5.22; S, 12.79%. Calcd for $C_{35}H_{36}O_{15}S_3$: C, 54.84; H, 5.27; S, 12.58%.

1,4,6-Tri-O-p-*toluenesulfonyl*-myo-*inositol (**6c**).* A mixture of **6a** (2.0 g) and 80% aqueous acetic acid (40 m*l*) was refluxed for 2 hr. After cooling, the reaction mixture was poured into water (200 m*l*) and the resulting crystals were collected by filtration; yield 1.5 g (84%), mp 217—220°C. Recrystallization from ethanol gave two allotropic forms of crystals; needles and plates, mp 223—225.5°C. The melting point of the former is slightly lower than that of the latter. When the crystals were dissolved in 2-methoxyethanol and a crystallization was induced by addition of ethanol, colorless plates of **6c** were obtained homogeneously, mp 225.5—226.5°C.

Found: C, 50.68; H, 4.95; S, 14.92%. Calcd for $C_{27}H_{30}O_{12}S_3$: C, 50.47; H, 4.71; S, 14.97%.

1,4,5-Tri-O-p-*toluenesulfonyl*-myo-*inositol (**7c**).* A mixture of **7a** (0.51 g) and 80% aqueous acetic acid (10 m*l*) was refluxed for 2 hr. The reaction mixture was evaporated to dryness and the residue was digested with ethanol to give crystals (0.36 g, 81%) of **7c**, mp 205—211°C. Recrystallization from ethanol afforded colorless granular crystals, mp 208.5—210°C.

Found: C, 50.68; H, 4.87; S, 14.70%. Calcd for $C_{27}H_{30}O_{12}S_3$: C, 50.47; H, 4.71; S, 14.97%.

1,2,5-Tri-O-*acetyl-3,4,6-tri*-O-p-*toluenesulfonyl*-myo-*inositol*

(6d). Compound **6c** (0.10 g) was acetylated similarly as described under the preparation of **4d** to give crystal (0.12 g, 97%) of **6d**, mp 218.5—221°C. Recrystallization from chloroform and ethanol afforded colorless cubic crystals, which showed the same melting point. PMR: τ 7.56 (9, s, OTs C-CH_3), 5.49 (1, m, H-3), 4.48 (1, t, H-2, J=2.5 Hz).

Found: C, 51.40; H, 4.89; S, 12.69%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.56; H, 4.72; S, 12.49%.

1,2,4-Tri-O-*acetyl-3,5,6-tri*-O-p-*toluenesulfonyl*-myo-*inositol* ***(7d)***. Compound **7c** (0.10 g) was acetylated similarly as described under the preparation of **4d** to give crystals (0.11 g, 92%) of **7d**, mp 207—209°C (after melting and resolidifying at 180—185°C). Recrystallization from chloroform and ethanol afforded small needles, mp 210.5—212.5°C (after partly melting and showing a transition at 194—196°C). PMR: τ 7.56 (9, s, OTs C-CH_3), 5.27 (1, q, H-3, J=3 and 10 Hz).

Found: C, 51.57; H, 4.75; S, 12.30%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.56; H, 4.72; S, 12.49%.

1,2,6-Tri-O-*acetyl-3,4,6-tri*-O-p-*toluenesulfonyl*-myo-*inositol* ***(8)*** *and 1,4,5,6-Tetra*-O-p-*toluenesulfonyl*-myo-*inositol* ***(9a)***. A compound **1a** (5.0 g) was treated with *p*-toluenesulfonyl chloride (25.6 g, 7.0 equiv.) in dry pyridine (60 m*l*) and the reaction mixture was worked up similarly as described under the preparation of **6a** and **7a**. After **6a** (3.3 g, 24%) had been isolated by crystallization from chloroform and ethanol, the mother liquor was evaporated to dryness and the oily residue was refluxed with 80% aqueous acetic acid (50 m*l*) for 2 hr. The reaction mixture was kept for 2 days at room temperature and the resulting precipitates were collected by filtration. Then the mother liquor was again refluxed for additional 3 hr and the second crystals were obtained. The first and second crystals were combined and recrystallized two times from methyl ethyl ketone and ethanol to give colorless plates (3.3 g, 21%) of **9a**, mp 142—152°C (after sintering at 138°C). An analytical sample was obtained by recrystallization from methyl ethyl ketone and ethanol, mp 145—153°C.

Found: C, 51.59; H, 5.16; S, 15.54%. Calcd for $C_{34}H_{36}O_{14}S_4 \cdot C_2H_5OH$: C, 51.30; H, 5.03; S, 15.22%.

Then the mother liquor of **9a** was evaporated to dryness and the residue was treated with a mixture of acetic anhydride (10 m*l*) and pyridine (15 m*l*) overnight at room temperature. The reaction mixture was poured onto ice and water (100 m*l*) and, after 2 days, the resulting gum was filtered by suction. The gum was digested with chloroform and ethanol to give colorless needles (1.97 g), mp 173—177°C. Recrystallization from chloroform and ethanol afforded needles (1.6 g, 11%) of **8**, mp 194—194.5°C. PMR: τ 7.56 (9, s, OTs C-CH_3), 5.40 (1, q, H-3, J=3 and 9 Hz).

Found: C, 51.45; H, 4.53; S, 12.13%. Calcd for $C_{33}H_{36}O_{15}S_3$: C, 51.56; H, 4.72; S, 12.49%.

On addition of ethanol, the mother liquor gave plates (0.78 g, 5.3%) of **7d**, mp 202.5—206°C.

1,2-Di-O-*acetyl-3,4,5,6-tetra*-O-p-*toluenesulfonyl*-myo-*inositol* ***(9b)***. Compound **9a** (0.20 g) was acetylated as similarly as described under the preparation of **3d** to give crystals (0.23 g) of **9b**, mp 188.5—190.5°C. Recrystallization from ethanol afforded colorless needles (0.20 g, 91%), mp 189.5—190.5°C. PMR: τ 7.54 (12, s, OTs C-CH_3), 5.34 (1, q, H-3, J=3 and 8 Hz), 4.67 (1, t, H-2, J=*ca.* 3 Hz).

Found: C, 52.02; H, 4.77; S, 14.94%. Calcd for $C_{38}H_{40}O_{16}S_4$: C, 51.82; H, 4.58; S, 14.57%.

The authors are grateful to Professor Sumio Umezawa for his kind advice, to Mr. Saburo Nakada for his elementary analyses, and to Mr. Shigeyuki Itabashi and Mr. Shuichi Oki for their assistance in the preparative experiments. The financial support from the Ministry of Education for this work is gratefully acknowledged.

Iminodithiocarbonates. IV. Pyrolyses of *N*-Acyl Immonium Salts of Iminodithiocarbonates

Yoshio Ueno, Takeshi Nakai, and Makoto Okawara

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received October 20, 1970)

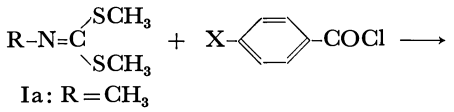
The pyrolyses of *N*-acyl immonium salts of *S,S'*-dimethyl *N*-methyl- (II) and *N*-phenyl-iminodithiocarbonates (III) were studied. *N*-Methyl-immonium salt II gave *S*-methyl *N*-acyl-*N*-methyl-dithiocarbamate (V) at 100°C, but *N*-phenyl derivatives (III) gave phenyl isothiocyanate and *S*-methyl thiolbenzoate (VI) at 140°C. On the other hand, cyclic immonium salt, 2-(*N*-benzoyl-*N*-methyl)-1,3-dithiolanylium chloride (IV) gave 2-benzoylimino-1,3-dithiolane(VII) with elimination of *N*-methyl group at 200°C. It was found that *N*-acyldithiocarbamate V isolated was further decomposed to methyl isothiocyanate and thiolbenzoate at 200°C. Independent syntheses of *N*-acyldithiocarbamates V were performed on the reaction of *N*-monosubstituted dithiocarbamates and acyl chloride.

During the course of our study[1] on the reactivity of *N*-substitued iminodithiocarbonates, we found that the unusually stable *N*-acyl immonium salts were formed on the reaction of iminodithiocarbonates with various acid chlorides at room temperature. In the present paper, studies on the pyrolyses of these *N*-acyl immonium salts (II,III and IV) and the resulting formation of *N*-acyldithiocarbamates (V), isothiocyanates, thiolbenzoate (VI) and 2-benzoylimino-1,3-dithiolane (VII) are reported.

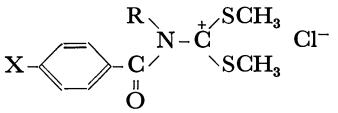
1) Y. Ueno, T. Nakai, and M. Okawara, Submitted, This Bulletin.

Results and Discussion

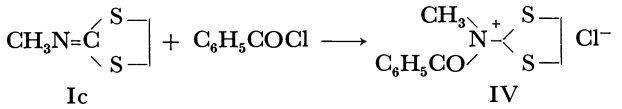
Pyrolysis of N-*Benzoyl Immonium Chloride of* S,S-*Di-*



Ia: R=CH_3
Ib: R=C_6H_5

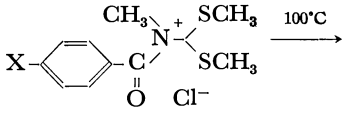


IIa: R=CH_3, X=H
IIb: R=CH_3, X=Cl
IIIa: R=C_6H_5, X=OCH_3
IIIb: R=C_6H_5, X=H

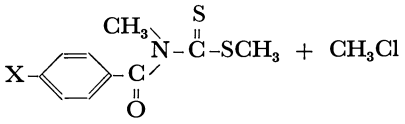


Ic IV

methyl N-*Methyl-Iminodithiocarbonate,II.* Pyrolysis of IIa at 100°C for 9 hr gave methyl *N*-benzoyl-*N*-methyl-dithiocarbamate (Va) in 90% yield. Similarly, the pyrolysis of *N-p*-chlorobenzoyl immonium chloride (IIb) gave methyl *N-p*-chlorobenzoyl-*N*-methyl-dithiocarbamate (Vb) in 79% yield.



IIa: R=H
IIb: R=Cl



Va: R=H
Vb: R=Cl

The structure of V was established by IR, UV and NMR spectra and elemental analysis. The IR spectra showed a band at 1655—1665 cm^{-1} due to the amide-carbonyl group. The UV spectra showed two maximum absorption bands at around 240—260 mμ and 270 mμ which characterized the S–C(=S)– and N–C(=S)– resonance, respectively, in the dithiocarbamate structure. The NMR spectrum of Va fully confirmed the structure (Fig. 1). Thus signals due to S-methyl and *N*-methyl groups appeared as singlets at δ 2.58 and δ 3.66, respectively, and those due to aromatic groups as a multiplet centered at δ 7.50.

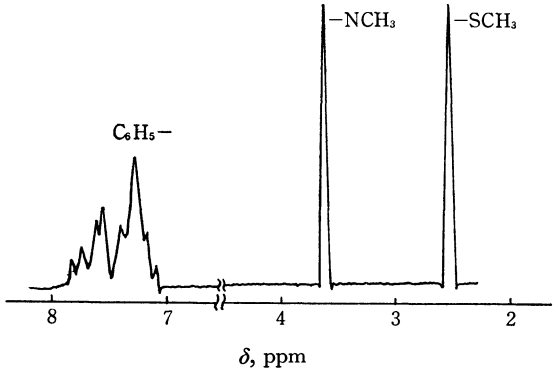


Fig. 1. The NMR spectrum of Methyl *N*-benzoyl-*N*-methyl-dithiocarbamate (Va) in $CDCl_3$.

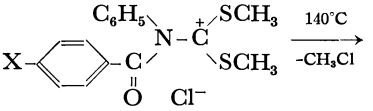
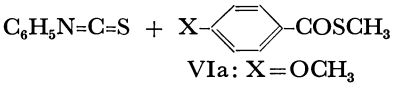
Pyrolysis of N-*Benzoyl Immonium Chlorides of* S,S'-*Dimethyl* N-*Phenyl-Iminodithiocarbonates, III.* Pyrolysis of IIIa at 140—150°C for 7 hr gave phenyl isothiocyanate and methyl *p*-methoxythiolbenzoate (VIa) in 75 and 65% yield, respectively. Similarly, pyrolysis of the *N*-benzoyl immonium chloride (IIIb) gave phenyl isothiocyanate and methyl thiolbenzoate (VIb). In both cases, at lower temperature such as 100°C decomposition of III did not take place and the *N*-benzoyl dithiocarbamates corresponding to V were not obtained. The structures of phenylis othiocyanate and thiolbenzoate were confirmed by the spectral data and the results of elemental analysis.

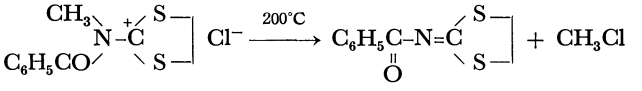


IIIa: X=OCH_3
IIIb: X=H



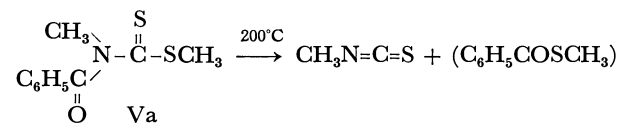
VIa: X=OCH_3
VIb: X=H

Pyrolysis of N-*Benzoyl Immonium Chloride of 2-Methyl-imino-1,3-dithiolane, IV.* Immonium chloride IV was prepared by mixing 2-methylimino-1,3-dithiolane and benzoyl chloride at room temperarture. On being heated, IV melted at about 140°C and then started to decompose at about 190°C. The reaction vessel was kept at 190—200°C for 5.5 hr. The product, 2-benzoylimino-1,3-dithiolane (VII) was obtained in 50% yield. The structure of VII was established by elemental analysis and by comparison of its IR and melting point with the data in literature.[2] The IR spectrum of VII showed a band at 1640 cm^{-1} due to the carbonyl group.



IV VII

Pyrolysis of Methyl N-*Benzoyl*-N-*Methyl-Dithiocarbamate (Va).* Although different types of products were obtained in the pyrolyses of II and III, dithiocarbamate V isolated from II seems to be an intermediate for the formation of isothiocyanate and thiolbenzoate from III. Thus the pyrolysis of *N*-benzoyl dithiocarbamate (Va) was examined. The dithiocarbamate Va was pyrolyzed at 200—220°C for 0.5 hr and resulted in the formation of methyl isothiocyanate in over 54% yield.

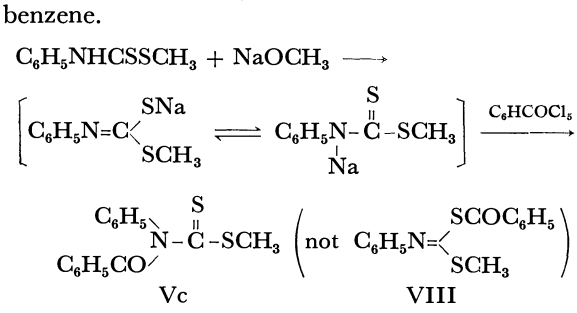


Va

Independent Synthesis of Methyl N-*Benzoyl*-N-*Phenyl-Dithiocarbamate (Vc).* Methyl *N*-benzoyl-*N*-phenyl-dithiocarbamate (Vc) was synthesized by the reaction of methyl *N*-phenyl dithiocarbamate with benzoyl chloride.

2) J. Burkhardt, R. Feinauer, E. Gulbins, and K. Hamann, *Chem. Ber.*, **99**, 1912 (1966).

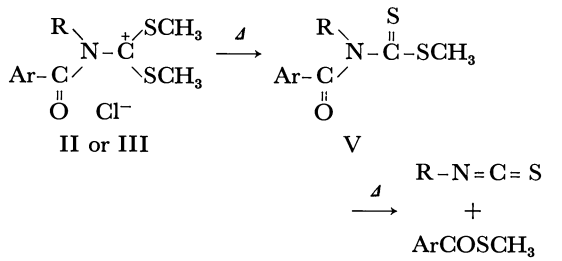
Methyl *N*-phenyl dithiocarbamate was converted into the sodium salt by treating with sodium methoxide in methanol followed by treating with benzoyl chloride in benzene.



The product was assigned as *N*-benzoyl derivative Vc and the isomeric structure of *S*-benzoyl derivative VIII was eliminated by the following facts. (1). The IR spectrum showed a characteristic band of amide-carbonyl group at 1680 cm^{-1} and no band due to the ester carbonyl or imino group. (2). The UV spectrum showed two characteristic absorption at 240 mμ and 270—280 mμ due to S–C(=S)– and –N–C(=S)– resonance, respectively. (3). Formation of no picrate by the addition of picric acid indicates the absence of imino basic group. (4). The product on the reaction of methyl *N*-methyldithiocarbamate with benzoyl chloride was identical in all respects with the methyl *N*-benzoyl-*N*-methyldithiocarbamate (Va).

The structure of phenyl isothiocyanate obtained by pyrolysis of *N*-benzoyldithiocarbamate Vc at 140—150°C was confirmed by its IR spectrum. A new band at 2150 cm^{-1} due to the –N=C=S group in phenyl isothiocyanate appeared.

Pyrolytic Scheme of N-*Acyl Immonium Chloride of Iminodithiocarbonates.* From the result obtained above, the formation of isothiocyanate from *N*-phenylimmonium chloride III can be interpreted by the following scheme involving the intermediacy of the *N*-acyl dithiocarbamate V.



Immonium chloride II or III are pyrolyzed initially to give the dithiocarbamate V with elimination of methyl chloride. Dithiocarbamate V is further decomposed to isothiocyanate and thiolbenzoate. When R is alkyl group, the intermediate dithiocarbamate V was isolated. However, phenyl-substituted dithiocarbamate (Vc) was not isolated and spontaneously decomposed to phenyl isothiocyanate and thiolbenzoate. This indicates the less thermal stability of *N*-phenyl derivative than *N*-alkyl in compound V. While several reactions, RNX–C(=S)Y→RN=C=S+XY, are known for the formation of isothiocyanate with elimination of simple molecule, this is the first example for the formation of isothiocyanate with elimination of thiolbenzoate moiety. In contrast with the open-chain immonium salts (II or III), cyclic immonium salt IV resists the breaking at S–C bond and elimination of *N*-methyl group predominates to produce the 2-benzoylimino-1,3-dithiolane (VII).

Experimental

All melting and boiling points were uncorrected. Infrared and ultraviolet spectra were recorded on a Hitachi infrared EPI-S2 and EPS-2 spectrophotometer, respectively. The NMR spectrum was obtained with a Japan Electron Optics JNL-100 spectrophotometer in a deuteriochloroform solution using tetramethylsilane as an internal standard.

Materials. The immonium chlorides II, III, and IV were prepared by mixing the corresponding iminodithiocarbonates with benzoyl chloride derivatives at room temperature.[1] The acyl immonium chlorides thus obtained were subjected to pyrolyses without isolation.

Pyrolysis of N-*Benzoyl Immonium Chloride of* S,S-*Dimethyl*-N-*Methyl-Iminodithiocarbonate (IIa).* Immonium chloride IIa prepared from Ia (2.7 g, 0.02 mol) and benzoyl chloride (2.8 g, 0.02 mol) were heated at 100°C for 9 hr. By cooling the reaction mixture in a dry ice - acetone bath after the reaction, methyl *N*-benzoyl-*N*-methyl-dithiocarbamate (Va) was obtained (4.0 g, 90%). mp 71.5—72.0°C (recrystallized from *n*-hexane); UV: $\lambda_{max}^{cyclohexane}$ 243.5, 275 mμ, IR: (KBr): $\nu_{C=O}$ 1665 cm^{-1}.

Found: C, 53.73; H, 5.05; N, 6.26%. Calcd for $C_{10}H_{11}NOS_2$: C, 53.33; H, 4.92; N, 6.32%.

Similarly, methyl *N*-*p*-chlorobenzoyl-*N*-methyl-dithiocarbamate Vb was obtained in 79% yield: mp 64.5—65.5°C (recrystallized from *n*-hexane); UV λ_{max}^{EtOH} 260, 276 mμ, IR: $\nu_{C=O}$ 1655 cm^{-1}.

Found: C, 47.05; H, 3.74; N, 4.97%. Calcd for $C_{10}H_{10}NOS_2Cl$: C, 46.25; H, 3.88; N, 5.39%.

Pyrolysis of N-p-*Methoxybenzoyl Immonium Chloride of* S,S'-*Dimethyl*-N-*Phenyl-Iminodithiocarbonate (IIIa).* Immonium chloride IIIa prepared from *N*-phenyl iminodithiocarbonate Ib (4.0 g, 0.02 mol) and *p*-methoxybenzoyl chloride (2.9 g, 0.0017 mol) were heated at 140—150°C for 7 hr. Gas evolution was observed at about 150°C. After decomposition the reaction mixture was subjected to distillation in a vacuum, giving two fractions with a boiling point of 58—69°C/1 mmHg, (1.7 g) and 107—117°C/1 mmHg, (2.0 g). The lower-boiling fraction (74%) was identical in its infrared spectrum (2110 cm^{-1}, N=C=S) and boiling point with those of authentic phenyl isothiocyanate. The higher boiling fraction crystallized after distillation. It was recrystallized from *n*-hexane to give methyl *p*-methoxythiolbenzoate (VIa) with a melting point 41.5—42.0°C (65%); IR (KBr); $\nu_{C=O}$ 1642 cm^{-1}.

Found: C, 59.22; H, 5.30; N, 0.00%. Calcd for $C_9H_{10}O_2S$: C, 59.33; H, 5.53; N, 0.00%.

Similarly, the pyrolysis of *N*-benzoyl immonium chloride IIIb at 140—160°C for 6.5 hr gave a mixture of phenyl isothiocyanate and methyl thiolbenzoate with a boiling point of 56—75°C/4 mmHg. The IR spectrum showed a band at 2110 cm^{-1} (N=C=S) and at 1665 cm^{-1} (C=O). The close boiling point of the two products makes it difficult to separate each component by distillation. The small amount of residue on distillation was recrystallized, and was tentatively assigned as benzanilide by its IR spectrum and melting point (164.5°C). Pyrolysis of IIIb did not take place noticeably at 100°C after 8 hr.

Pyrolysis of N-*Benzoyl Immonium Chloride of 2-Methylimino-1,3-dithiolane, (IV).* 2-Methylimino-1,3-dithiolane (Ic)

(1.33 g, 0.01 mol) was mixed with benzoyl chloride (1.4 g, 0.01 mol) at room temperature. Immonium chloride IV was formed with a slight heat evolution, and which was kept at 190—200°C for 5.5 hr. Cooling the reaction mixture in a dry ice-acetone bath gave 2-benzoylimino-1,3-dithiolane (VII) (1.2 g, 50%): mp 76—77°C (recrystallized from the mixture of ether and petroleum ether) (lit,[2] 79°C): IR (KBr): $\nu_{C=O}$ 1640 cm^{-1} (lit,[2] 1640 cm^{-1}).

Found: C, 53.62; H, 3.78; N, 6.33%. Calcd for $C_{10}H_9NOS_2$: C, 53.78; H, 4.06; N, 6.28%.

Pyrolysis of Methyl N-*Benzoyl*-N-*Methyl-Dithiocarbamate (Va).* Va was heated at 200—220°C for 0.5 hr. Distillation of the reaction mixture gave two fractions with boiling points 70—80°C (0.3 g) and 120°C (0.9 g). Lower boiling fraction was identical in its IR spectrum with an authentic sample of methyl isothiocyanate. Identification of methyl isothiocyanate by transformation into thiourea derivative was carried out using *p*-methoxyaniline in ethanol solution. Recrystallization of the resulting thiourea derivative several times from ethanol gave needles of *N*-methyl-*N*-*p*-methoxyphenyl thiourea: mp 171.0—172.0°C; Found: C, 54.75; H, 5.74; C, 13.99%. Calcd for $C_9H_{12}N_2OS$: C, 55.09; H, 5.17; N, 14.28%.

Higher boiling fraction was assumed to be a mixture of methyl isothiocyanate and methyl thiolbenzoate based on its IR spectrum, at 1670 cm^{-1} (C=O) and 2130, 2240 cm^{-1} (N=C=S), but was not further investigated.

Independent Synthesis of Methyl N-*Benzoyl*-N-*Phenyl-Dithiocarbamate, (Vc).* To a solution of methyl *N*-phenyl-dithiocarbamate (3.7 g, 0.02 mol) in 20 m*l* of methanol, was added sodium methoxide (1.2 g, 0.02 mol). After stirring for 1 hr at room temperature, evaporation of methanol under reduced pressure gave white sodium dithiocarbamate. To a suspension of the sodium dithiocarbamate in 20 m*l* of dry benzene was added benzoyl chloride (2.8 g, 0.02 mol). After refluxing the mixture for 0.5 hr, filtration and evaporation of the solvent gave a yellow solid of methyl *N*-benzoyl-*N*-phenyl-dithiocarbamate (Vc) (2.5 g, 44%): mp 99—100°C (recrystallized twice from *n*-hexane); IR (KBr): $\nu_{C=O}$ 1680 cm^{-1}; UV λ_{max}^{EtOH} 244, 278 mμ.

Found: C, 62.80; H, 4.36; N, 4.90%. Calcd for $C_{15}H_{13}NOS_2$: C, 62.71; H, 4.56; N, 4.88%.

Similarly, methyl *N*-benzoyl-*N*-methyl-dithiocarbamate (Va) was synthesized on the reaction of methyl *N*-methyl-dithiocarbamate and benzoyl chloride. Thus, to a mixture of methyl *N*-methyl-dithiocarbamate (3.0 g, 0.025 mol) and sodium hydroxide (1 g, 0.025 mol) in 12 m*l* of water, was added dropwise benzoyl chloride (3.5 g, 0.025 mol) with stirring and external cooling at 7—10°C. The yellow oil separated was extracted with ether. After drying the etheral solution with anhydrous sodium sulfate, cooling the solution gave crude Va (3.3 g, 59%); mp 68—70°C. The product completely agreed with the pyrolyzed product Va in all respects in the IR and UV spectra.

Long Spacings of ω-Cyclohexyl Alkanoic Acids

Akio Ishizawa

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 15, 1970)

In almost all the long chain compounds studied the chain ends are either both methyl or one of the ends is substituted with a group different in nature but similar in size with the chain constituent.[1] Studies of the long chain compounds substituted with a bulky group at the chain end in comparison with the results from such compounds as long chain *n*-paraffins or *n*-alkanoic acids will clarify the influence of the end groups on the properties of these long chain crystals. Reported here are some results from the examination of solid ω-cyclohexyl alkanoic acids $\langle\overline{\text{H}}\rangle$-$(CH_2)_n$COOH ($n$=13 to 33)[2] by X-ray powder method.

The specimens crystallized from solution (acetic acid) and those from melt gave essentially the same diffraction patterns except that in some of those obtained from solution two or more crystalline forms were observed concomitantly. The odd (n=even) and even (n=odd) members of the acids crystallized from melt, like many long chain compounds studied, differed not only in the general appearance of the diffraction patterns but also in the relation between the long spacing and the chain length.[3] Examination of the specimens crystallized from melt at temperatures just below their melting points gave the long spacings identical with those obtained at room temperature within experimental error.[4] In the thermal analysis of the specimens, the time-temperature curves increased monotonously with temperature until the temperature reached about 1°C below their melting points, where the slope of the curves became gradual. Thus, the crystalline forms obtained from melt seems stable in the range from room temperature to near their melting points.

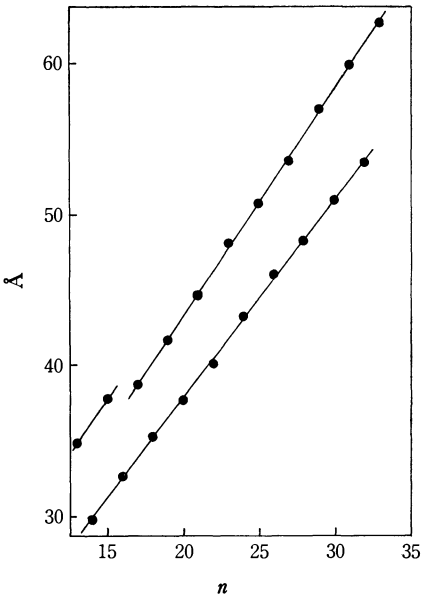

Fig. 1. Dependence of the long spacings on the chain length in $\langle\overline{\text{H}}\rangle$-$(CH_2)_n$COOH.

The effect of a bulky end group is evidently demonstrated in the long spacings. The values obtained are considerably smaller than the calculated length of the hydrogen-bonded dimeric molecule in which the chain is stretched in a straight zig-zag form. The tilt angle which refers to the angle between the chain axis and the basal plane is estimated to be about 30°

from the increment of the value of the long spacing with the two additional chain units divided by twice the theoretical increase in the chain length, 2×2.515 Å. Almost all the long chain compounds studied are known to pack themselves in crystals with the chain axis inclined about 60° at most to the basal plane.[1] The marked inclination of the hydrocarbon chain of these acids seems to show the intrinsic importance of the packing of the large end groups on the arrangement of the chain molecules in crystals.

Long Spacings of ω-Cyclohexyl Alkanols

Akio ISHIZAWA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 15, 1970)

It has been found that substitution of a bulky cyclohexyl group at the end of long chain alkanoic acids caused a marked change in the arrangement of the hydrocarbon chain in crystals.[1] Reported here is another similar observation on the effect of a bulky group which is introduced at the end of normal alkanols.

ω-Cyclohexyl alkanols $\langle\overline{\text{H}}\rangle$-$(CH_2)_n$OH($n$=14 to 34)

were synthesized by the reduction of ethyl (or methyl) ω-cyclohexyl alkanoates with excess lithium aluminum hydride in refluxing ether. After treatment with boiling ethanolic potassium hydroxide solution, the resulting mixture was evaporated to dryness under reduced pressure, extracted with anhydrous benzene, and the products were repeatedly recrystallized from benzene or toluene solution.

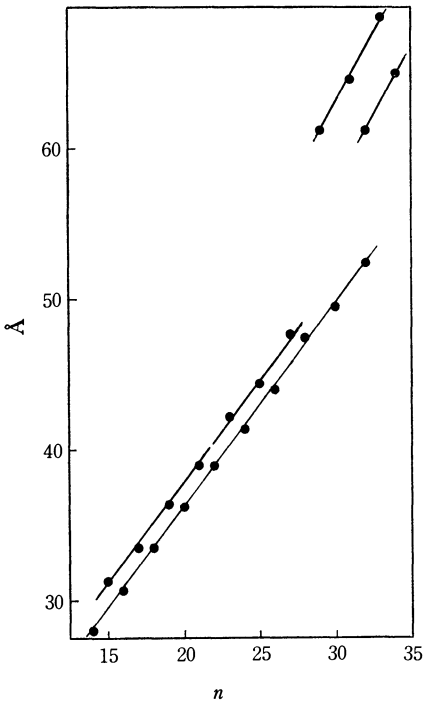

Fig. 1. Dependence of the long spacings on the chain length in $\langle\overline{\text{H}}\rangle$-$(CH_2)_n$OH.

1) A. Ishizawa, This Bulletin, **44**, 845 (1971).

As in the case of ω-cyclohexyl alkanoic acids[1] and many other long chain crystals,[2] the odd (n=odd) and even (n=even) alkanols crystallized from melt differed not only in the general appearance of the powder patterns but also in the variation of the long spacings with the chain length. As is evident from the values of long spacings, the crystalline forms of the alkanols changed at n=29 in the odd series and at n=

32 in the even. Formation of a crystalline form with $n=32$ was found to be sensitive to the method of preparation. Rapid cooling, in general, gave the form with larger long spacing. In the other members no such behavior was observed. When the specimens were examined at temperatures immediately below their melting points,[3] those with $n\leqq 28$ gave essentially the same diffraction patterns and long spacings as were obtained at room temperature, but with the higher members ($n\geqq 29$), though the reflections at higher angles were similar to those obtained at lower temperatures, the intensity of the reflections corresponding to the long spacings became too weak to be measured. In thermal analysis, the time-temperature curves of these specimens increased linearly with temperature until the temperature reached about 1°C below their melting points, where the slope of the curves became gradual. Thus, the crystalline forms of the alkanols seemed stable in the range from room temperature to just below their melting points.

The effect of a bulky cyclohexyl end group on the chain arrangement was clearly seen in the values of the long spacings of the alkanols. The long spacings are considerably shorter than the theoretical length of the hydrogen-bonded dimeric molecule in which the chain is stretched in a zig-zag form and the tilt angle of the chain axis to the basal plane is estimated to be about 30°. The effect is similar to that observed in ω-cyclohexyl alkanoic acids and the packing of the bulky end group seems to be responsible for the change in the arrangement of the hydrocarbon chains in crystals.

3) All the measurements at high temperature were carried out within 1°C below the melting points.

Long Spacings of α,ω-Dicyclohexyl Alkanes and α, ω-Diphenyl Alkanes

Akio ISHIZAWA, Chihito FUNAYAMA, and Masao KOSAKA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 15, 1970)

A bulky cyclohexyl group substituted at the chain terminal of *n*-alkanols or *n*-alkanoic acids has been found to cause a marked change in the arrangement of the hydrocarbon chains in crystals.[1] Here we report studies on α,ω-diphenyl alkanes  (I_n) and α,ω-dicyclohexyl alkanes  (II_n) (n=15 to 24) which are substituted with bulky groups at either ends of the chain.[2]

Like many other long chain compounds.[3] the odd (n=odd) and even (n=even) series of both I_n and II_n, crystallized from melt, gave different diffraction patterns. The long spacings also varied in different ways with chain length in the odd and even members.

At temperatures just below melting points the I_n specimens crystallized from melt gave essentially the same diffraction patterns and long spacings as those at room temperature, so that the crystalline forms seemed stable in the temperature range studied.

In II_{even} members a change in the crystalline form took place at II_{20} where the change displayed itself in the diffraction patterns as well as in the value of the long spacing. The II_{20} specimen, obtained by a similar method of preparation as for the lower members, gave two sets of long spacings. The feature of the diffraction patterns of this specimen showed no change up to a few degrees below its melting point, but at just below melting point, the crystalline form with the larger long spacing disappeared. On the other hand, the specimen obtained from melt by very rapid cooling consisted essentially of the form with the larger long spacing, the same as that was obtained for II_{22} and for II_{24}. No such behavior like that of II_{20} was ob-

24	34.91	34.85	27.76	27.90

served for any other II members and the crystalline forms once formed seemed stable even at temperature just below melting point.

As is evident from the long spacings of I_n and II_n, the values obtained are considerably shorter than the calculated length of the molecules in which the hydrocarbon chains are stretched in a straight zig-zag form. In crystals, II_n compounds may be considered an analogue to ω-cyclohexyl alkanoic acids and ω-cyclohexyl alkanols which exist in dimeric form by hydrogen bonding between the polar groups. The tilt angle of the hydrocarbon chain in II crystals is found unaffected by the absence of any polar groups and is calculated to be about 30° which is similar to the value obtained for ω-cyclohexyl alaknoic acids and ω-cyclohexyl alkanols.[1] The decrease of the tilt angle of I_n is less marked than that of II_n but is somewhat smaller than those which are not substituted with bulky groups.[3] These observations appear to indicate the importance of the shape and the packing of the end groups on the arrangement of the chain molecules in crystals.

Kinetic Studies of Lead Acetate Complex Formation in Aqueous Solutions

Tatsuya YASUNAGA and Shoji HARADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received June 26, 1970)

It is well known[1] that the rate constant of complex formation depends on the nature of the metal ion, *e.g.*, on the charge, the electric configuration, the ionic radius, and the coordination number. The Pb^{2+} ion has a noble gas electronic configuration and a large ionic radius; therefore, the rate of water substitution, which is the rate-determining step of the complex formation reaction, is expected to be very fast. The purpose of the present work is to perform kinetic studies of lead acetate complex formation with the help of the ultrasonic relaxation method.

Experimental

Reagent-grade lead acetate, lead nitrate, sodium acetate, and perchloric acid were used. Ultrasonic absorption measurements were carried out at 25°C by the pulse method over the frequency range from 15 to 95 MHz. Details of the apparatus have been described elsewhere.[2]

Theoretical

The metal ion and the ligand are hydrated in an aqueous solution. In the case of complex formation, therefore, two or three-step mechanisms, the rate-determining step of which is the release of a water molecule from the metal ion, have been proposed.[3,4] If the substitution rate of the water molecule is fast, however, the distinction of the steps is obscured. The complex formation reaction can, then, be approximately expressed by:

$$M_{aq}^{m+} + L_{aq}^{n-} \underset{k_f}{\overset{k_b}{\rightleftarrows}} ML_{aq}^{m-n} \qquad (1)$$

where M is the metal ion, L is the ligand, and ML is the complex, and where the subscript means that the ions are hydrated. The rate constants are related to the relaxation frequency, f_r, by the following form:

$$2\pi f_r = k_f + k_b(C_M + C_L) \qquad (2)$$

where C_M and C_L are the concentrations of M and L respectively. The relaxation frequency is expressed by the single relaxation equation:

$$\alpha/f^2 = A\{1 + (f/f_r)^2\}^{-1} + B \qquad (3)$$

where α is the absorption coefficient, f is the frequency, and A and B are constants.

Results and Discussion

The concentrations of the species, which were calculated by the use of the formation constants of lead acetate[5,6] and acetic acid,[7] are summarized in Table

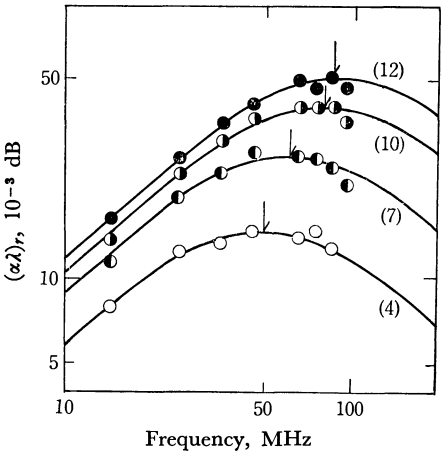

Fig. 1. Ultrasonic absorption in lead acetate solutions. $(\alpha\lambda)_r$ means the excess absorption per wavelength and the arrows indicate the relaxation frequencies. Numeral shows the sample number.

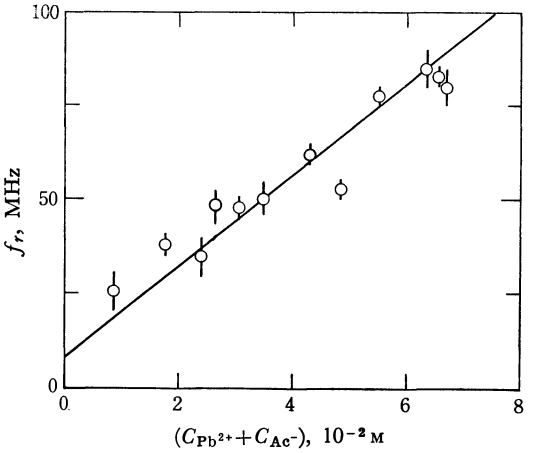

Fig. 2. Plot of relaxation frequency (f_r) *vs.* $(C_{Pb^{2+}}+C_{Ac^-})$.

1. The ionic strengths of the solutions were 0.1—0.3, but the formation constant of lead acetate at $\mu=0.2$ was used, for the change in ionic strength by an addition of $NaClO_4$ did not have a serious effect on the absorption curves. Therefore, no special care was taken with regard to the ionic strength. Representative absorption curves are shown in Fig. 1. The relaxation frequencies obtained are also listed in Table 1.

The principal equilibria between lead and acetate ions at low concentrations are:

$$Pb^{2+} + Ac^- \underset{k_{f1}}{\overset{k_{b1}}{\rightleftarrows}} PbAc^+ \qquad (4)$$

$$PbAc^+ + Ac^- \underset{k_{f2}}{\overset{k_{b2}}{\rightleftarrows}} Pb(Ac)_2 \qquad (5)$$

$Pb(Ac)_3^-$ and higher-order complexes may exist, but the concentrations are very low. Therefore, the present absorption can be attributed to one of the above two equilibria. Both of the equations have been investigated in trying to correlate the experimental data.

Equation (2) can, then, be rewritten for Eq. (4):

$$2\pi f_r = k_{f1} + k_{b1}(C_{Pb^{2+}} + C_{Ac^-}) \qquad (6)$$

With the data in Table 1, f_r is plotted against $(C_{Pb^{2+}}+C_{Ac^-})$ in Fig. 2. From the slope and the intercept of the line in Fig. 2, k_{b1} and k_{f1} were obtained; $k_{b1}=7.5\times10^9$ M^{-1} sec^{-1}, and $k_{f1}=5.7\times10^7$ sec^{-1}. The equilibrium constant of Eq. (4) is also given by $K=k_{b1}/k_{f1}=133$ M^{-1}. The equilibrium constant obtained is in good agreement with the literature value,[5,6] which had been previously used in the calculation of the ionic concentrations. On the other hand, the same plots for Eq. (5) show a linear relation, but yield a different equilibrium constant from that used before. Along with the fact that the excess ultrasonic absorption was observed in the solution where the concentration of $PbAc_2$ was very low, these results suggest that Eq. (4) is responsible for the present absorption.

The formation rate constant of Eq. (4), k_{b1}, is interesting in relation to the nature of the metal ion. Eigen and Eyring[8] obtained the rate constant of complex formation, $k_b=7\times10^9$ M^{-1} sec^{-1}, for the reaction:

$$HgCl^+ + Cl^- \underset{k_f}{\overset{k_b}{\rightleftarrows}} HgCl_2 \qquad (7)$$

They said that the value is close to the rate constants of water substitution of Pb^{2+} and Ba^{2+} ions. In this

8) M. Eigen and E. M. Eyring, *Inorg. Chem.*, **2**, 636 (1963).

work, we obtained 7.5×10^9 M^{-1} sec^{-1} for the rate constant of the complex formation of lead acetate. Considering that the Pb^{2+} ion has a large ionic radius[9] (1.32 Å) and the filled outer orbitals and, moreover, considering that the coordination number of the water molecule is larger than those of ordinary ions,[10] the above value seems to be reasonable.

Acylation of Aluminum Trisacetylacetonate with *n*-Butyryl Chloride in the Presence of Aluminum Chloride[1]

Tetsuro NOJIRI,* Masatoshi MOTOI, and Iwao HASHIMOTO**

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received September 5, 1970)

It was reported[2] that acetylacetone reacts with *n*-butyryl chloride to give *n*-butyrylacetone (I) and di-*n*-butyrylmethane (II) in the presence of more than 2 equivalents of aluminum chloride in nitrobenzene at 45°C. These products can be rationalized by assuming initial formation of dichloroaluminum enolate of the β-diketones, acetylacetone and I, followed by butyrylation leading to the respective deacetylated products, I and II. Murdoch *et al.* and Barry reported that the metal chelates (excluding aluminum chelate) of β-diketones react with acyl chlorides in refluxing toluene or cyclohexane,[3,4] or in chloroform at room temperature[5] to afford initially triacylated methanes. Doolan and Gore[6] pointed out that aluminum trisacetylacetonate (III) or acetylacetone (regarded as converting into III during the reaction) reacts as in aromatic acylation with acetyl chloride to give diacetylated III in the presence of the excess of aluminum chloride in boiling carbon disulfide. This paper deals with the problem of deciding how the reaction of III with *n*-butyryl chloride proceeds under conditions similar to those of the above butyrylation of acetylacetone.[2]

The conditions of the present reactions and the product yields based on acetylacetone to be formed from III are given in Table 1. All the experimental procedures are similar to those for acetylacetone.[2]

The non-catalyzed reaction of III with 3 equivalents of *n*-butyryl chloride afforded I as a single product in a low yield only when the temperature was raised to 65°C. This shows that there is some difficulty at 45°C in acylating through coordination of *n*-butyryl chloride with the central metal atom of the chelate as with the mechanism proposed by Murdoch *et al.*[3,4] Even at low temperature, however, the addition of 1.5 equivalent of aluminum chloride gave II as well as I. The formation of II suggests that III can be acylated through its ring-opening during the reaction.

In the presence of 3 equivalents of aluminum chloride (1 equivalent for each acetylacetone component in III) the yields of both I and II obtained using 6 equivalents of *n*-butyryl chloride (2 equivalents for each acetylacetone component in III) increased to

near maximum and were almost unaffected even when the reaction time was extended from 0.5 to 1 hr, but the extension of time to 24 hr allowed II to increase at the expense of I. Although the total yields increased somewhat, these findings are similar to those observed in the butyrylation reactions of acetylacetone under analogous conditions.

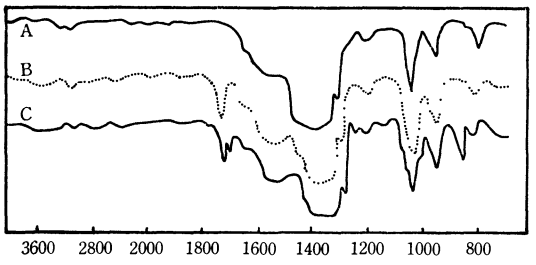

Fig. 1. Infrared spectrum of aluminum trisacetylacetonate in nitrobenzene (A); with 0.5 (B); and with 1.5 equivalent of $AlCl_3$ (C).

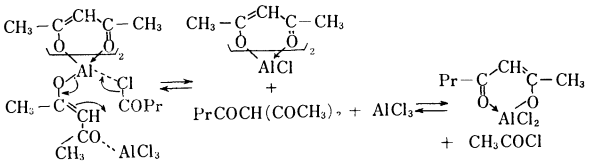
The infrared spectra of III in nitrobenzene solutions containing 0.5 and 1.5 equivalent of aluminum chloride show medium absorption peaks at 1688, and 1715 and 1688 cm^{-1} due to carbonyl group, respectively, which cannot be observed with the spectrum of III in nitrobenzene, as shown in Fig. 1. It can be seen that, concurrent with the ring-opening of III, a carbonyl group appears and leaves a site capable of coordinating with *n*-butyryl chloride on the central aluminum so that the butyrylation reaction proceeds easily as follows:



The chloroaluminum bisacetylacetonate and dichloroaluminum *n*-butyrylacetonate which were formed must be further butyrylated and then deacetylated in the same way as illustrated in the above equation. Although not produced from acetylacetone by using 0.5 equivalent of aluminum chloride,[2] II was provided from III in a nearly maximum yield of 16% even under the corresponding conditions. This high yield seems to be ascribable to the easier enolate formation of III by its ring-opening as compared with that of acetylacetone.

The authors wish to express their hearty thanks to Professor Kiyotaka Matsui for his kind guidance and encouragement.

On the Ratio of A_N to $A_{H(NH)}$ for Some Phenyl Nitric Oxide Radicals

Toshio NISHIKAWA and Kazuo SOMENO

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received September 14, 1970)

In an ESR study on monophenyl nitric oxide radicals (phenyl NOR) in solution, it has been suggested by Chapelet-Letourneux *et al.*[1] that the ratio of hf splitting of nitrogen to that of hydrogen attached to it, $A_N/A_{H(NH)}$, has an almost constant value of about 0.77.

TABLE 1. $A_N/A_{H(NH)}$ OF PHENYL NOR PREPARED FROM VARIOUS STARTING MATERIALS

Starting materials	$A_N/A_{H(NH)}$	Ref.
Ph-NH_2+PBA-NO_2	0.762	1
Ph-N(H)OH	0.764	1
Ph-NO_2+$LiAlH_4$	0.752	2
Ph-N(H)OH+PbO_2	0.759	3
Ph-NO+Ph-N(H)OH	0.753	4
Ph-NH_2+PBA	0.756	Present work

In the present note, some experimental results are reported in order to ascertain this constancy of the ratio, and it is also shown that phenyl NOR having intramolecular hydrogen bond (IH-bond) has another constant value of the ratio.

Well resolved ESR spectra were obtained from the radicals produced in oxidation of aniline derivatives with perbenzoic acid (PBA) at room temperature. The molecular structures of radicals were determined

from analysis of the spectra. The phenyl NOR was very stable in many organic solvents at room temperature. All the spectra were obtained in dioxane at room temperature unless otherwise noted. The IH-bond is formed between amino proton and carboxyl group in *o*-aminobenzoic acid and its esters. Thus phenyl NOR produced from these compounds may also have the IH-bond because of the remaining one of amino proton.

Table 4. $A_N/A_{H(NH)}$ of R–Ph–N(H)O having IH-bond

R	$A_N/A_{H(NH)}$
o-COOH	0.705
$-COOCH_3$	0.713
$-COOC_2H_5$	0.688
$-COOC_4H_9$	0.687
$-COCH_3$	0.679
-CHO [a]	0.687

a) Toluene was used as a solvent.

The ratios were obtained for some phenyl NOR under various conditions as shown in Tables 1 to 4. It may be concluded from these data (Tables 1 to 3) that the values of the ratios are in the range of 0.74—0.76 and all the effects of solvent species, substituents and steric hindrance give only less than 1% change on the ratio. This is because about 70—80% of spin density is on the nitrogen and the oxygen atoms. On other hand, as shown in Table 4, the ratio decreases to 0.71—0.68 when the radicals have the IH-bond. The only exception was in the case of *p*-acetylphenyl NOR, where the ratio decreases below the range 0.74—0.76. The ambiguity of hf splitting determination due to the complexity of the spectrum might make the ratio questionable. The effect of IH-bond seems to make a predominant contribution to the ratio. The decrement of the ratio may be used to check the IH-bond formation of phenyl NOR.

The Carbon Dioxide-Catalyzed Ester Exchange Reaction

Yoshio Otsuji, Noboru Matsumura, and Eiji Imoto

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received September 18, 1970)

Carbon dioxide has long been recognized as an inert gas for most neutral organic compounds. However, we have reported in a previous communication[1] that, contrary to the above view, CO_2 catalyzes the transacylation reaction from acid amides to amines. We now wish to report that CO_2 can also catalyze the ester-exchange reaction between carboxylic esters and alcohols.

Results and Discussion

A solution of butyl formate in an excess of ethanol was agitated by a stream of dry CO_2 at room temperature for 5 hr. The vpc analysis of the reaction mixture revealed that this simple treatment gave rise to an ester-exchange reaction affording ethyl formate in a 30% yield. A similar exchange reaction was also observed between other carboxylic esters and alcohols. The results are summarized in Table 1.

$$RCO_2R' + R''OH \xrightarrow{CO_2} RCO_2R'' + R'OH$$

In the controlled experiments, mixtures of butyl formate and *n*-octyl alcohol and of ethyl butyrate and butyl alcohol were allowed to stand, or were agitated by a stream of N_2, for 5 hr at room temperature. No exchange reaction was observed in any of these treatments, confirming that CO_2 must be a catalyst for the reaction.

The ester-exchange reaction was also conducted in an autoclave under the pressure of CO_2. The results are summarized in Table 2. The controlled experiments, which were carried out under the pressure of N_2, confirmed that the exchange reaction is always CO_2-catalyzed reaction, except for the reaction of butyl formate at elevated temperatures (see runs 14 and 18). The reason for this exception was clarified

a) The "rt" indicates the room temperature, which was ~20°C.
b) The controlled experiments were conducted under the pressure of N_2.

when the reaction products were carefully analyzed. The vpc analysis of the reaction mixture obtained after the treatment of butyl formate with octyl alcohol under the pressure of N_2 at 100—110°C showed that the mixture contained formic acid and butene-1. Both products could be formed by the thermal decomposition of butyl formate. The formic acid thus produced would react with octyl alcohol to give octyl formate. The formation of the ester from formic acid under the experimental conditions was in fact verified by a separate experiment.

$$HCO_2C_4H_9 \xrightarrow{\Delta} HCO_2H + CH_3CH_2CH{=}CH_2$$

$$HCO_2H + n\text{-}C_8H_{17}OH \rightarrow HCO_2C_8H_{17}$$

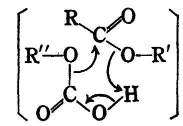
Thus, the striking features of this study can be summarized by the following four items; (i) the reactivities of esters decrease in the order of; butyl formate > ethyl butyrate > ethyl benzoate (runs 5, 8, and 10), implying that the increase in the positive charge on the carbonyl carbon of the esters makes the progress of the reaction profitable; (ii) the reactivities of the alcohols decrease in the order of; primary > secondary tertiary > (runs 1, 2, 3, and 5); (iii) the yield of the exchanged esters increases with the decrease in the reaction temperature (runs 4, 5; and 6, 7, 8, and 9); and (iv) the increase in the reaction time increases the yield of the exchanged esters (runs 11, 12, and 13).

On the basis of these observations, together with those described in the previous paper,[1)] we tentatively propose the mechanism shown in Scheme 1 for the ester-exchange reaction:

$$R''OH + CO_2 \rightleftharpoons R''OCO_2H \quad (1)$$

I

$I + RCO_2R' \rightarrow$ (2)



II

$$II \rightarrow RCO_2R'' + R'OH + CO_2 \quad (3)$$

Scheme 1

The reversible reaction (1) has been postulated by Hempel and Seidel,[2)] mainly on the basis of the freez-

2) W. Hempel and J. Seidel, *Ber.*, **31**, 2997 (1898).

ing-point elevation of an alcohol containing CO_2 and the molecular composition of the isolated product. However, the equilibrium constant for this reaction has not yet been determined. Nevertheless, it is reasonable to assume that the equilibrium constant for the reaction (1) in various alcohols is proportional to the solubility of CO_2 in the alcohols. The solubility data[3] of CO_2 in alcohols suggest that the equilibrium constants would decrease in the order of; primary> secondary>tertiary alcohols, an order which is in accordance with the reactivity order of the alcohols for the ester-exchange reaction. This fact and the effect of the temperature on the yield of the exchanged esters are consistent with the assumptions that reaction (1) is involved in the initial stage of the reaction and that the monoalkyl carbonate (I) is a reactive species; the concentration of I would increase with a lowering of the temperature by means of the increase in the solubility of CO_2; and accordingly, the yield of the exchanged esters would increase with a lowering of the temperature.

The monoalkyl carbonate I would then react with an ester to form a six-membered transition state (II), which would spontaneously collapse to give the exchanged ester, accompanied by the elimination of the alcohol (R'OH) and CO_2. At this stage, the nucleophilic reactivity of the alcohol may be enhanced to some extent, since the temporary formation of an alkoxide ion ($R''O^-$) would be expected at the moment of the elimination of CO_2.

3) H. Stephen and T. Stephen, "Solubilities of Inorganic and Organic Compounds," Vol. 1, Pergamon Press, Oxford, London (1963), pp. 1058—1076.

Experimental

The vpc analyses were preformed with a Yanagimoto GCG-5DH gas chromatograph, employing a stainless steel column (1.5 m × 3 mm o.d.) packed with 30% PEG-20 M on Chromosorb (80 mesh) and using helium as the carrier gas. For quantitative analyses, the respective authentic samples were used as the internal standards.

All the compounds used were purchased or prepared by the standard methods, and they were purified by distillation before use. CO_2 was generated from dry ice and was dried by passing it through concentrated H_2SO_4 and then a column packed with $CaCl_2$.

Ester-exchange Reaction in a Stream of CO_2. A solution of an ester (~0.05 mol) in an alcohol (0.1—0.2 mol) was placed in a flask equipped with a gas inlet and outlet tubes, to which a tube packed with $CaCl_2$ was connected. Dry CO_2 was then passed into the solution. The passing rate was so adjusted as to maintain the rate as constant as possible throughout the whole series of experimental runs. After an appropriate period of time, an aliquot taken up from the reaction mixture was subjected to vpc analysis.

Control experiments were carried out under conditions similar to those employed above except that the passing gas was changed from CO_2 to N_2. In these experiments, the exchanged esters were not obtained in a detectable yield, but the starting materials were recovered.

Ester-exchange Reaction under the Pressure of CO_2. To a solution of an ester (~0.03 mol) in an alcohol (0.1—0.2 mol) placed in a 300-m*l* autoclave, we added small pieces of dry ice. The autoclave was then closed and warmed to the reaction temperature. After checking the pressure, the autoclave was shaken for an appropriate period of time. An aliquot was pipetted out from the reaction mixture and then subjected to vpc analysis.

Control experiments were carried out under conditions similar to those employed above except that N_2 was used in place of CO_2.

A Spectroscopic Study on Hydrogen Bonding and Proton Transfer in Photo-Excited *p*-Hydroxybenzophenone

Akio MATSUYAMA* and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received October 6, 1970)

In a previous paper,[1] one of us (H.B.) showed that, in contrast to the case of the usual phenolic compounds,[2-4] proton transfer does not occur from *p*-hydroxybenzaldehyde to triethylamine, a strong proton acceptor, in the excited state in spite of its occurrence in the ground state. This was attributed to the fact that the lowest excited singlet of the *p*-hydroxybenzaldehyde molecule is an (n, π^*) state, where the proton-donating power of the molecule is relatively weak. In their discussion on the photochemical behavior of *p*-hydroxybenzophenone, an analogue of *p*-hydroxybenzaldehyde, Godfrey, Porter, and Suppan[5] assumed that the proton transfer would take place in the excited singlet state. In this study, the emission properties of *p*-hydroxybenzophenone coupled with proton-accepting substances have been examined to get an insight into the validity of these contradictory views.

Figure 1 shows the absorption and phosphorescence spectra of *p*-hydroxybenzophenone at 77°K in the presence of proton acceptors. The absorption spectrum of *p*-hydroxybenzophenone at 77°K in a mixture of hydrocarbons containing ether is obviously

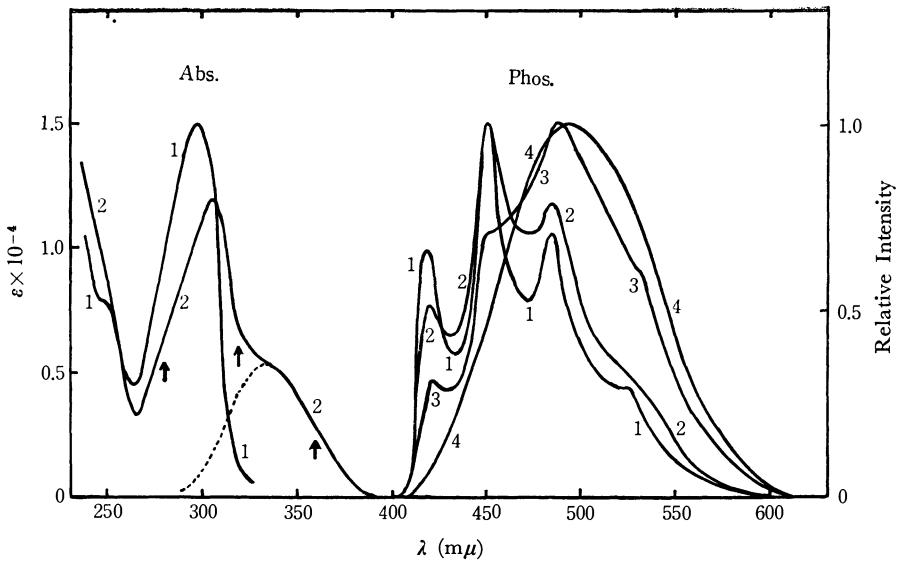

Fig. 1. Absorption (Abs.) and phosphorescence (Phos.) spectra of *p*-hydroxybenzophenone (3.03×10^{-5} mol/*l*) at 77°K.
Absorption: 1, in methylcyclohexane and isopentane (volume ratio, 1:1) containing ethyl ether (0.4 mol/*l*) as a proton acceptor; 2, in methylcyclohexane, isopentane and ethyl ether (4 : 4 : 1) containing triethylamine (4.0×10^{-3} mol/*l*).
Phosphorescence: 1, in methylcyclohexane and isopentane (1 : 1) containing ethyl ether (0.4 mol/*l*), excitation at 290 mμ; 2, 3 and 4, in methylcyclohexane, isopentane and ethyl ether (4 : 4 : 1) containing triethylamine (4.0×10^{-3} mol/*l*), excitation at 280, 320 and 360 mμ, respectively, as indicated by arrows.

ascribable to the simple hydrogen-bonded complex between *p*-hydroxybenzophenone and ether. This complex has at about 350 mμ another absorption band, which is weak and is assigned to an $n\rightarrow\pi^*$ transition. When triethylamine is added as a proton acceptor besides ether, an additional absorption band appears at 77°K in the longer wavelength region. It can be shown that in the latter case the solute molecules are associated with triethylamine owing to the much stronger basicity of the amine compared with ether. Thus, hydrogen bonding occurs between the solute and amine molecules to give a simple hydrogen-bonded complex, followed by proton transfer from the solute to the amine to yield a hydrogen-bonded ion pair. The additional absorption band can be attributed to the proton-transferred complex, *i.e.*, the hydrogen-bonded ion pair, as in the case of previous studies.[1,6,7] In the ground state of the solute molecule, an equilibrium is to be established at 77°K between the simple hydrogen-bonded complex and the ion pair.

It should be noted that in the absence of ether the *p*-hydroxybenzophenone-triethylamine system in the hydrocarbon mixture gives almost exclusively the simple hydrogen-bonded complex. This shows that the degree of proton transfer is sensitive to the polarity of the solvent.

The hydrogen-bonded complex between *p*-hydroxybenzophenone and ether gives an emission spectrum with a vibrational structure (Fig. 1). The emission has a lifetime of the order of millisecond and is assigned to the phosphorescence from the lowest triplet state of an (n, π^*) type.[8,9]

The system containing triethylamine as a proton acceptor exhibits different phosphorescence spectra, depending on the wavelengths of exciting light. Thus, excitation at 280 mμ is largely related to the hydrogen-bonded complex, the observed spectrum being essentially the same as that found in the *p*-hydroxybenzophenone molecule hydrogen-bonded with ether, whereas excitation at 360 mμ leads to a broad, long-lived ($\approx$1 sec) and red-shifted phosphorescence spectrum which is entirely different from the spectrum of the simple hydrogen-bonded complex. The broad spectrum resulting from the 360 mμ excitation may be assigned to the $\pi\leftarrow\pi^*$ phosphorescence originating in the proton-transferred complex. In this way, excitation at shorter and longer wavelengths induces phosphorescence from the simple hydrogen-bonded complex and from the proton-transferred complex, respectively. The emission obtained by excitation at intermediate wavelengths (*e.g.*, 320 mμ) is found to be a superposition of phosphorescence emissions from both complexes.

These absorption and emission characteristics of *p*-hydroxybenzophenone in relation to hydrogen bonding and proton transfer are very similar to those of *p*-hydroxybenzaldehyde,[1] except that in the former the lowest triplet is of (n, π^*) type and the proton-transferred complex gives no fluorescence. In the

simple hydrogen-bonded complexes (*i.e.*, the protonated forms) of the two compounds, the lowest excited singlet (S_1) is an (n, π^*) state and the next lowest singlet (S_2) is a (π, π^*) state of charge-transfer nature. On exciting the *p*-hydroxybenzophenone-triethylamine system at shorter wavelengths (*e.g.*, 280 mμ), the protonated form is raised to its S_2 level. By the same reasoning as in the case of *p*-hydroxybenzaldehyde,[1] it is concluded that the state S_2 of the protonated form of *p*-hydroxybenzophenone is deactivated by rapid radiationless processes to the lower singlet and triplet states, phosphorescence being emitted from the protonated form itself, and that no proton transfer takes place throughout the deactivation processes.

Godfrey *et al.*[5] found that the photo-excited *p*-hydroxybenzophenone shows an anomalously low reactivity toward abstraction of a hydrogen atom from solvents. In order to interpret this phenomenon, they assumed that the proton transfer would occur in the excited singlet state of the protonated form, in marked contrast to our conclusion. It would be desirable to re-examine the anomalous photochemical behavior of *p*-hydroxybenzophenone in the light of the results of the present spectroscopic investigation.

Experimental

p-Hydroxybenzophenone was recrystallized from a mixture of water and ethanol. Methylcyclohexane of spectroscopic quality was used without further purification. Isopentane was passed through a silica-gel column. Ethyl ether was distilled over metallic sodium. Triethylamine was fractionally distilled over phosphorus pentoxide. Absorption spectra were obtained with a Hitachi EPS-3 spectrophotometer at 77°K. Emission spectra were measured at 77°K with an apparatus which was constructed using a Hitachi G-3 grating monochromator and a Hitachi EPU-2A prism monochromator.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 856—857 (1971)

The Spatial Distribution of Secondary Electrons Produced in the γ-Radiolysis of Cyclohexane

Shin SATO and Takefumi OKA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 13, 1970)

In order to analyze the reactions of charged species produced in liquid-phase radiolysis, it is important to know the spatial distribution of secondary electrons, even if it is qualitative. Recently, Warman, Asmus, and Schuler proposed an empirical equation for the charge scavenging[1] from which they derived a distribution function for the lifetime of the charged species produced in the radiolysis of hydrocarbon solutions.[2] On the other hand, we ourselves have previously discussed the kinetics of the electron scavenging of nitrous oxide in the radiolysis of several hydrocarbons by assuming a Gauss function as the spatial distribution of secondary electrons.[3] By combining these two procedures, we have realized that it is possible to derive a spatial distribution of secondary electrons in the γ-radiolysis of cyclohexane. The present note will report the procedure of deriving the distribution function and will discuss the implications of this function.

Procedure[4]

The G-value of the electrons scavenged by an electron scavenger is expressed by the following equation, based on an appropriate assumption:[3]

$$G_s = G_{fi} + G_{gi}\left\{1-\int_0^\infty \phi(r)\ (1-N_s)^{nz}\ 4\pi r^2\ \mathrm{d}r\right\}. \qquad (1)$$

Here, G_{fi} and G_{gi} are the G-values of free and geminate electrons respectively. $\phi(r)$ is the distribution function of the distance between a thermalized electron and its parent positive ion. N_s is the mole fraction of the electron scavenger, n is the number of jumps which an electron makes before neutralization, and z is the number of new neighboring molecules when an electron makes a jump. As has been established by Williams,[5] the following relation exists between n and r: $n=r^3/3\sigma^2 r_c$. Here, r_c is the Onsager length and σ is the mean distance of a jump made by the electron.

When the concentration of the electron scavenger is not large, $(1-N_s)^{nz}$ may be replaced by $\exp(-nzN_s)$. Then, by changing a variable from r to x ($x=r^3$), we can obtain the following equation:

$$G_s = G_{fi} + G_{gi}\left\{1-\frac{4\pi}{3}\int_0^\infty \phi(x^{1/3})\ \exp(-kSx)\mathrm{d}x\right\}. \qquad (2)$$

Here, S is the concentration of the scavenger in mol l^{-1}, k is a constant $(2z/\sigma^2 r_c)(M/10^3\rho)$, M is the molecular weight of cyclohexane, and ρ is the density.

So far, two empirical equations have been proposed for expressing the relation between the G-value of scavenged electrons and the concentration of the electron scavenger. One of them has been proposed by

1) J. M. Warman, K.-D. Asmus, and R. H. Schuler, *Adv. Chem. Ser.*, **82**, 25 (1968).

2) S. J. Rzad, P. P. Infelta, J. M. Warman, and R. H. Schuler, *J. Chem. Phys.*, **52**, 3971 (1970).

3) S. Sato, T. Terao, M. Kono, and S. Shida, This Bulletin, **40**, 1818 (1967); S. Sato, *ibid.*, **41**, 304 (1968).

4) A similar treatment was proposed by M. Tatsuya at the 13th Conference of Radiation Chemistry at Tokyo, Oct., 1970, though there are small differences in details.

5) F. Williams, *J. Amer. Chem. Soc.*, **86**, 3954 (1964).

Warman, Asmus, and Schuler:[1]

$$G_s = G_{fi} + G_{gi}\frac{\sqrt{\alpha S}}{1+\sqrt{\alpha S}}. \quad (3)$$

The other has been proposed by Hummel:[6]

$$G_s = G_{fi} + G_{gi}\{1-\exp(-\sqrt{\alpha S})\}. \quad (4)$$

Here, α is a parameter which can be determined experimentally. According to Warman *et al.*, the value of α is 16 $l\,mol^{-1}$ for most of the effective electron scavengers. Now, utilizing the table of the Laplace transformation, we can derive the following two spatial distribution functions by combining Eqs. (2) and (3), and Eqs. (2) and (4):

$$\phi(r) = \frac{3k}{4\pi\alpha}\left\{\left(\frac{\alpha}{\pi kr^3}\right)^{1/2} - e^{kr^3/\alpha}\,\mathrm{erfc}\left(\frac{kr^3}{\alpha}\right)^{1/2}\right\} \quad (5)[7]$$

and

$$\phi(r) = \frac{3}{8\pi}\left(\frac{\alpha}{\pi k}\right)^{1/2} r^{-9/2}\exp\left(-\frac{\alpha}{4kr^3}\right). \quad (6)$$

Numerical calculations can easily be made by substituting the following values: r_c=280 Å (Onsager length in cyclohexane at 25°C), σ=5.4 Å (diameter of a cyclohexane molecule), and z=6. The results are shown in Fig. 1. A Gauss function used for our calculations in previous papers is also plotted.

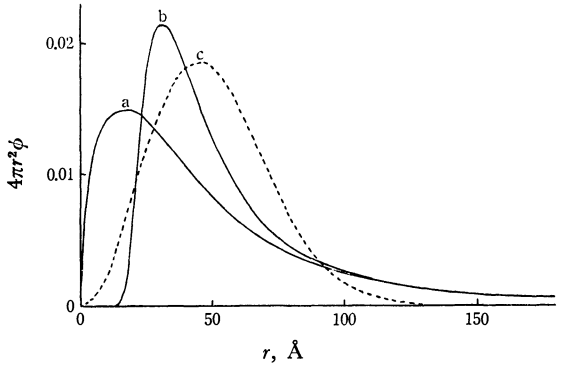

Fig. 1. Spatial distributions of secondary electron. a, Eq. (5); b, Eq. (6); c, the Gauss function (r_{av}=50 Å).

Discussion

A few years ago, Freeman and Fayadh estimated the spatial distribution of the secondary electrons produced in the γ-radiolysis of liquids[8] by using the tables proposed by Lea for the range of high-energy electron.[9] The distribution function, which is expressed by a step function, is quite similar in its form to curve b in Fig. 1. Judging from the many successful calculations made by Freeman and his collaborators,[10] the function (6) may be useful for the approximate calculation of the kinetics of the reactions of the charged species produced in the liquid-phase radiolysis because of its rather simple form.

According to Warman *et al.*, Eq. (3) is better than (4) for expressing the concentration dependence of G_s observed in the radiolysis of cyclohexane. They plotted $1/(G_s-G_{fi})$ as a function of $1/\sqrt{\alpha S}$ and estimated the value of G_{gi} by extrapolating the linear relationship to $S\to\infty$.[1] However, judging from the form of the distribution function (5), this procedure is questionable. As is shown in Fig. 1, the curve a has a large contribution at smaller values of r. Such a state, for example, at r=3 Å, would not be an ionized state, but a highly excited state, because of the strong interaction with the parent positive ion. Therefore, their procedure may include such a contribution of the reaction as the following:

$$\text{cyclo-}C_6H_{12}^* + S \rightarrow C_6H_{12}^+ + S^-$$

In other words, the value of G_{gi} estimated by their procedure may be a little larger than that of the so-called geminate ions.

Syntheses of Fused Heterocycles *via* Cycloaddition of Hetaryne. Studies on Heteroaromaticity. Part XLVII[1]

Tadashi SASAKI, Ken KANEMATSU, and Masayuki UCHIDE

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received October 14, 1970)

In comparison with abundant examples for the cycloaddition reactions of dehydrobenzene (benzyne), only occasional reports have been made concerning the same reactions of dehydroaromatic heterocycles (hetarynes).[2] Recently, the electronic structures of hetarynes have been discussed using the extended Hückel theory,[3] by which the larger relative stability is predicted for 3-pyridyne compared with other pyridyne isomers.

These facts prompted us to report one-step syntheses of the fused bicyclic heteroaromatic ring system by the cycloaddition reactions of this hetaryne.

Expecting that the intermediate 3-pyridyne (II) might be trapped with dipolarophiles or dienophiles, the lead tetraacetate oxidation of 1-aminotriazolo-[4,5-*c*]pyridine (I)[4] was carried out in the presence of dienophilic five-membered heterocycles or some dipolarophiles.

These results are described in this note.

Results and Discussion

Only one example of 1,2-cycloaddition of dehydroheterocycle is recorded;[5] cyclopentadiene adds to 3-pyridyne in a 1,2-fashion rather than in a 1,4-fashion of Diels-Alder reaction. On the other hand, attempts to add 3-pyridyne to anthracene remain unsuccessful.[6]

In contrast, lead tetraacetate oxidation of compound I was carried out in the presence of dimethylfulvene, norbornadiene, and furan at room temperature for 1 hr. Only the *endo*-oxide III (picrate, mp 178°C) was obtained from furan in a 74% yield, which was identified by the IR and NMR spectral comparison with those of an authentic sample prepared by heating 3-pyridinediazonium-4-carboxylate in furan.[7] A recent report described the lead tetraacetate oxidation of I in the presence of tetracyclone which affords 5,6,-7,8-tetraphenylisoquinoline.[4] Neither 1,2-cycloadducts nor 1,4-Diels-Alder adducts could be isolated from the reaction of 3-pyridyne with dimethylfulvene or norbornadiene.

Similarly, 1,3-dipolar cycloaddition reactions of 3-pyridyne with dipolarophiles were also attempted.

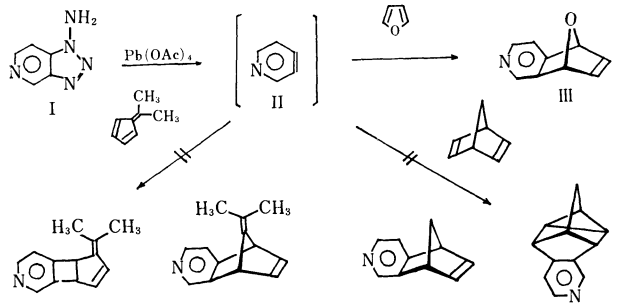

Chart 1.

There is only one example[2] known for a 1,3-addition of azide to a dehydroheterocyclic intermediate as shown by the following scheme.

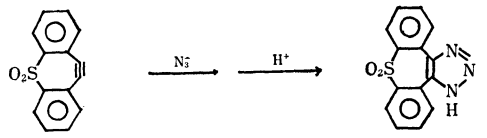

Chart 2.

Treatment of a mixture of I and *N*-phenylsydnone in 1 : 1.3 mol ratio with lead tetraacetate in tetrahydrofuran at room temperature led to the formation of 1,3-dipolar cycloadduct IV, mp 132—133°C, in a 30% yield. The NMR spectrum of IV shows signals of the ring protons at τ 0.60 (1*H*, s), 1.52 (1*H*, s), 1.77 (1*H*, d, J=7.0 Hz), and overlapping signals at τ 1.96—2.51 (1*H*-ring proton and 5*H*-phenyl protons, m). Similar oxidation of a mixture of compound I and benzaldehyde phenylhydrazone[8,9] in 1 : 1.1 mol ratio with an excess of lead tetraacetate afforded the expected cycloadduct V as pale yellow oil (picrate, mp 234—237°C) in a 15% yield. However, attempted cycloaddition of diphenyldiazomethane or benzonitrile oxide with 3-pyridyne was unsuccessful.

The orientation in the addition reaction of 1,3-dipolar *N*-phenylsydnone or diphenylnitrilimine with 3-pyridyne is not clear at present. However, the nucleophilic attack of the dipolar on 3-pyridyne might occur preferentially at the C-4 position as a consequence of its lower total electron density (3.97 against 4.35 electrons)[3] as shown by the following chart.

The structures of the 1,3-dipolar cycloadducts IV and V were tentatively assigned as 2-phenyl-2*H*-pyrazolo[4,3-*c*]pyridine and 1,3-diphenyl-1*H*-pyrazolo-

8) The nitrilimines have been trapped during the oxidation of aldehyde hydrazones; W. A. F. Gladstone, J. B. Aylward, and R. O. C. Norman, *J. Chem. Soc., C*, **1969**, 2587.

9) T. Sasaki and T. Yoshioka, This Bulletin, **43**, 1254 (1970).

[4,3-*c*]pyridine, respectively. Such a fused ring system as pyrazolo[4,3-*c*]pyridine is the first in the fused heterocyclic series.

Attempted 1,3-dipolar cycloaddition reactions of 3-pyridinediazonium-4-carboxylate with dipolarophilic nitrilimines were unsuccessful.

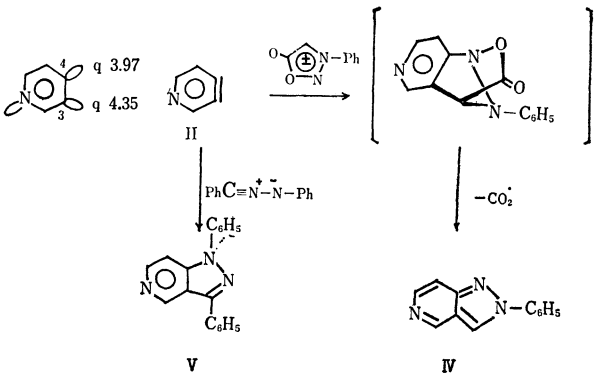

Chart 3.

Thus, it can be concluded that the cycloaddition reactivity of 3-pyridyne is generally much lower than that of benzyne, since the stereospecific 2+4 cycloaddition, the 2+2 nonconcerted cycloaddition, and the 1,3-cycloaddition for benzyne have been reported to give the corresponding cycloadducts in excellent yields.[2,10]

Experimental[11]

Lead Tetraacetate Oxidation of 1-Aminotriazolo[4,5-c]pyridine in the Presence of Furan. Compound I (390 mg) was dissolved in furan (5.1 g) and this solution was dropwise added to a stirred suspension of lead tetraacetate (1.4 g) in dichloromethane (20 m*l*) at 20°C. The reaction was always instantaneous and exothermic with evolution of nitrogen. Work-up involved filtration, evaporation of the solution, and chromatography (silicic acid, 100 mesh, Mallinckrodt) of the residue using benzene as an eluent.

Colorless oil of an *endo*-oxide III (317 mg, 75%) was obtained from the eluent; picrate, mp 178°C (lit,[7] mp 178°C).

Found: C, 48.28; H, 2.69; N, 14.97%. Calcd for $C_{15}H_{10}O_8N_4$ (picrate): C, 48.13; H, 2.69; N, 14.97%.

Reaction of 3-Pyridyne with N-Phenylsydnone. A solution of compound I (400 mg) and *N*-phenylsydnone (670 mg) in tetrahydrofuran (40 m*l*) was added dropwise to a stirred suspension of lead tetraacetate (1.2 g) in tetrahydrofuran (20 m*l*) at 20—25°C. After 1 hr, work-up as described above afforded an adduct IV (168 mg, 30%) as colorless prisms, mp 132—133°C.

Found: C, 73.56; H, 4.71; N, 21.74%. Calcd for $C_{12}H_9N_3$: C, 73.83; H, 4.65; N, 21.53%.

Reaction of 3-Pyridyne with 1,3-Diphenylnitrilimine. A solution of benzaldehyde phenylhydrazone (226 mg) and I (135 mg) in dichloromethane (20 m*l*) was added during 50 min to a stirred suspension of lead tetraacetate (1.5 g) in dichloromethane (50 m*l*) at below 10°C. The resulting thick suspension was further stirred at room temperature for 1 hr. Work-up as above afforded an adduct V (80 mg) as pale yellow oil; picrate, mp 234—237°C.

Found: C, 57.86; H, 3.29; N, 16.51%. Calcd for $C_{24}H_{16}N_6O_7$ (picrate): C, 57.60; H, 3.22; N, 16.80%.

Conformations of Low-molecular-weight Poly-γ-Benzyl-L-Glutamate Films

Takayoshi Iio

Department of Physics, Faculty of Science. Nagoya University, Chikusa-ku, Nagoya

(Received October 20, 1970)

We wish to report here our infrared (IR) studies of the conformations of low-molecular-weight poly-γ-benzyl-L-glutamate (PBLG) films cast from various helix-forming solvents, such as *N,N'*-dimethylformamide (DMF), *m*-cresol, dioxane, 1,2-dichloroethane (DCE), benzene, and chloroform.[1] We adopted five kinds of low-molecular-weight PBLG samples with different degrees of polymerization (DP), the DP values being 8, 13, 21, 28, and 49, and one high-molecular-weight PBLG (DP=250). The characters of the samples are shown in Table 1.

Table 1. The characters of the polymers

Sample	Initiator	A/I[a]	DP
PBLG-5	*n*-hexylamine	5	8[b]
PBLG-10	*n*-hexylamine	10	13[b]
PBLG-20	*n*-hexylamine	20	21[b]
PBLG-30	*n*-hexylamine	30	28[b]
PBLG-50	*n*-hexylamine	50	49[b]
PBLG-100	triethylamine	100	250[c]

a) Molar ratio of the anhydride to the initiator.
b) Determined by the method (1).
c) Determined by the method (2).

The IR spectra of the PBLG films are shown in Fig. 1. The high-molecular-weight PBLG exhibits the amide I band at about 1650 cm^{-1} and the amide II band at about 1548 cm^{-1}, these bands are due to the α-helix.[2]

1) S. J. Singer, *Advances in Protein Chemistry*, **14**, 1 (1959).

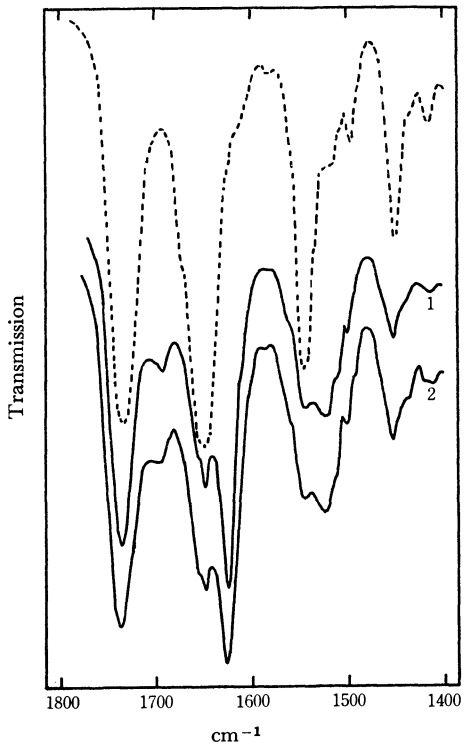

Fig. 1(a). IR spectra of PBLG-5 films cast from DMF (1) and chloroform (2) solutions. Dashed curve is that of PBLG-100 film cast from chloroform solution.

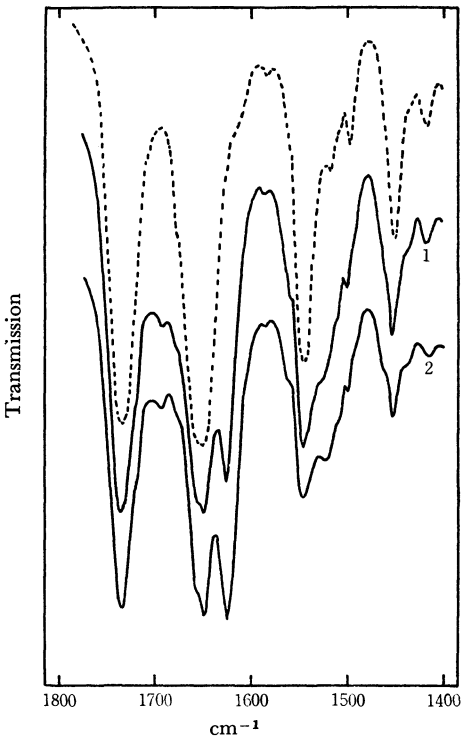

Fig. 1(b). IR spectra of PBLG-10 films.

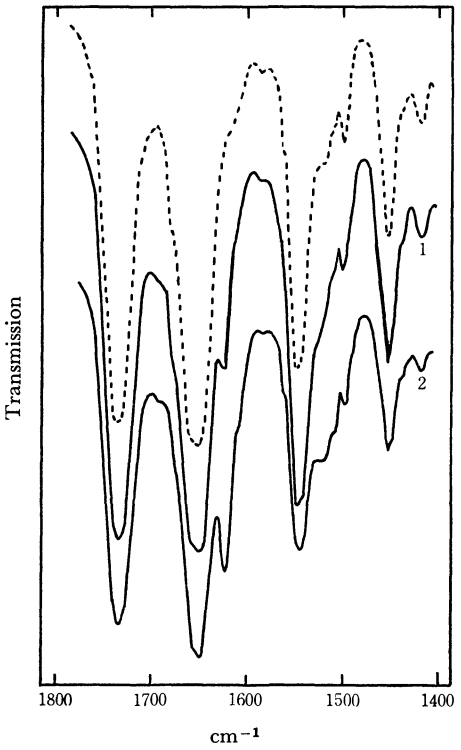

Fig. 1(c). IR spectra of PBLG-20 films.

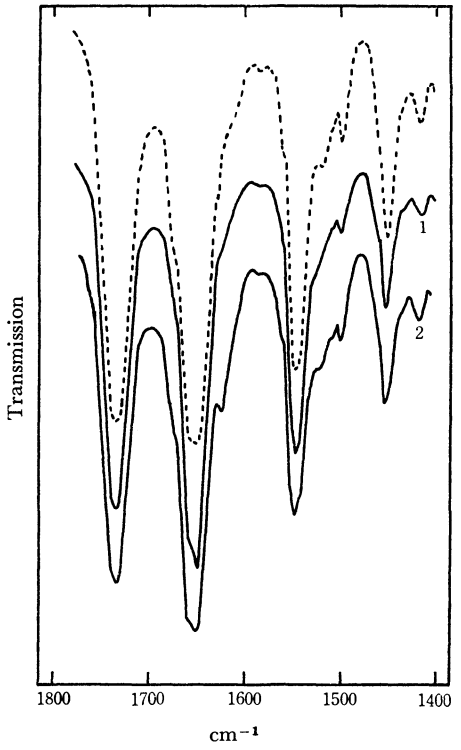

Fig. 1(d). IR spectra of PBLG-30 films.

On the other hand, the low-molecular-weight PBLG samples exhibit the amide I bands at about 1690 and 1625 cm^{-1}, positions which are attributable to the anti-parallel pleated sheet or the β-form, and at about 1650 cm^{-1}, a position which is due to the α-helix.[2] It is remarkable that the intensity of the 1625-cm^{-1} component depends not only on the value of DP, but also on the solvents from which the PBLG film was cast. This solvent effect on the degree of the β-formation is a new finding in this experiment.

2) T. Miyazawa and E. R. Blout, *J. Amer. Chem. Soc.*, **83**, 712 (1961).

The extinction coefficient of the 1625-cm^{-1} component of the amide I in the β-form is believed to be similar to that of the 1650-cm^{-1} component of the α-helix,[3] therefore, the apparent value of the β-form content, f_β, of the PBLG film may be obtained from the IR spectrum by using this equation:

$$f_\beta = \frac{OD_{1625}}{OD_{1625} + OD_{1650}}$$

where OD is the optical density of each component, calculated from the value of the transmission by the usual method.[4] The content of the α-helix equals $(1\text{-}f_\beta)$.

The f_β values are plotted in Fig. 2 as a function of the DP value. As may be seen in Fig. 2, the content of the β-form decreases as the DP value increases up to 49. The PBLG films cast from DMF and *m*-cresol solutions have smaller f_β values than have those cast from chloroform, DCE, and benzene solutions; the films from the dioxane solution have values of f_β intermediate between these two classes. Thus, it is found in this experiment that the helix-forming solvents make the low-molecular-weight PBLG films take not only the α-helix but also the β-form, and that the content of the β-form of the film depends on the solvent as follows: chloroform-benzene-DCE > dioxane > *m*-cresol-DMF.

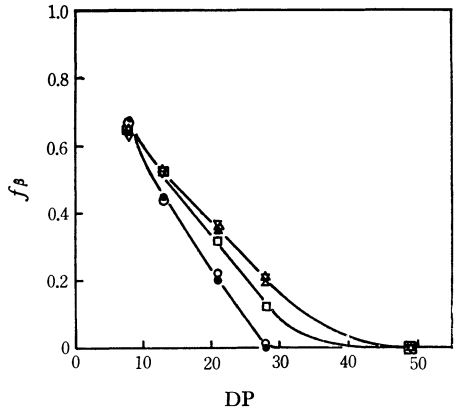

Fig. 2. Variation of the β-form content, f_β, of the PBLG films cast from the chloroform (▽), benzene (▲), DCE (△), dioxane (□), DMF (●), and *m*-cresol (○) solutions.

Experimental

Preparation of the Polymer. The low-molecular-weight PBLG samples, with different values of DP were obtained by polymerizing γ-benzyl-L-glutamate-*N*-carboxyanhydride in dioxane, using *n*-hexylamine as the initiator; the molar ratios of the anhydride to the initiator were 5, 10, 20, 30, and 50. The high-molecular-weight PBLG was obtained by using triethylamine as the initiator. The polymer was precipitated with ether from the dioxane solution, and dried under a vacuum. The DP value was determined by one of the following two methods: (1) we measured the nuclear magnetic resonance (NMR) spectra of the polymer in a chloroform and trifluoroacetic acid mixture,[5] and determined the number average DP value by calculating the ratio of the areas of the $C_\beta H_2$–$C_\gamma H_2$ proton resonances of the PBLG side-chain and the $(CH_2)_4$ proton resonances of the *n*-hexylamine bound to the C-terminal of the PBLG[6]; (2) we measured the intrinsic viscosity of the polymer in dichloroacetic acid at 25.0°C, and then applied the intrinsic viscosity *vs.* DP value relationship of Bradbury and Fenn to determine the DP value.[7] The results are summarized in Table 1.

IR Study. The dried polymer was dissolved into each helix-forming solvent, the solution was spread on a NaCl plate, and then the solvent was evaporated under a vacuum at room temperature. The IR spectrum of each unoriented film on the NaCl plate was measured with an infrared spectrophotometer, IR-G, made by the Japan Spectroscopic Co., Ltd.

The author wishes to thank Dr. Akira Minakata for his helpful advice and discussions, and Dr. Akira Warashina for his help in determining the DP values of the polymers by the NMR method.

Syntheses of Alkyl *p*-Toluenesulfinates by Use of *N,N'*-Dicyclohexylcarbodiimide[1]

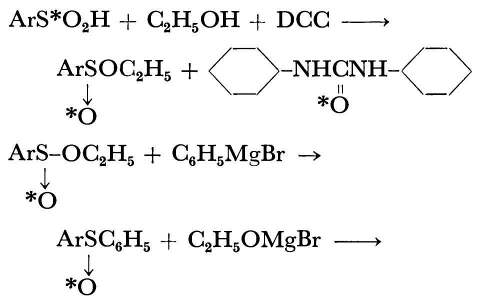
Yoshiko Miyaji, Hiroshi Minato, and Michio Kobayashi
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo
(Received October 23, 1970)

In contrast with the case of carboxylic acids, sulfinic acids cannot be converted to their esters by the reaction with alcohols in the presence of acid catalysts, since they readily undergo disproportionation to yield thiosulfonates and sulfonic acids under acid conditions. Ordinary procedures for synthesizing sulfinates utilize reactions between sulfinyl chlorides and anhydrous alcohols[2,3] or reactions between sodium sulfinates and chlorocarbonates in alcohols.[4] Investigations in our laboratories revealed that when an equimolar amount of dicyclohexylcarbodiimide (DCC) was present a sulfinic acid and an anhydrous alcohol were converted to a sulfinate in good yields. Results will be described in this paper.

Results and Discussion

The results are shown in Table 1. The procedure is very simple, and yet the yields are very good; 64—75% for ordinary sulfinates and 30% for unstable *t*-alkyl sulfinates. This method does not require sulfinyl chlorides which are thermally unstable and sensitive to moisture. This one-step synthesis of sulfinates at lower temperatures will be very effective for preparation of rather unstable sulfinates or isotope-labeled sulfinates.

When ^{18}O-labeled *p*-toluenesulfinic acid and ethanol were let to react, the ethyl ester formed contained a half of the oxygen-18 present in the acid as shown in Table 2. When this ethyl ester was made to react with phenylmagnesium bromide, the ^{18}O % of phenyl *p*-tolyl sulfoxide was the same as that of the original acid. Therefore, only one of the oxygen-18 of the sulfinic acid is contained in the sulfinate as the sulfinyl oxygen.



These findings suggest that the following mechanism is plausible for this reaction. Further investigation is necessary in order to determine whether the intermediate is I or II.

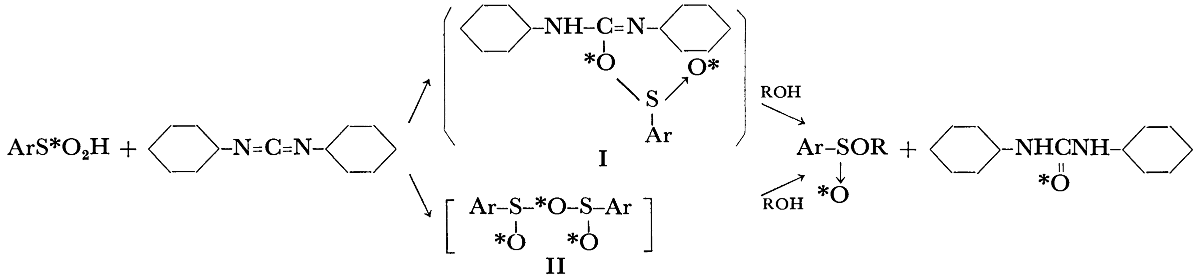


Table 1. Yields of alkyl *p*-toluenesulfinates by use of DCC

Experimental

Alkyl p-*toluenesulfinates. Method A*: *p*-Toluenesulfinic acid was dissolved in large excess of an anhydrous alcohol, and 0.9—0.95 mol of DCC per mol of the sulfinic acid was slowly stirred into the solution cooled with ice. The solution immediately became turbid, and in some cases some heat was evolved. Stirring was continued for several hours or overnight. White precipitates formed were filtered off, water was added to the filtrate, and oil-soluble products were extracted with *n*-hexane. The hexane extracts were washed with a sodium carbonate solution and water, dried and then distilled. A pure alkyl sulfinate was obtained by distillation under reduced pressure or recrystallization.

Method B: To a dichloromethane solution of *p*-toluenesulfinic acid an equimolar or a little excess amount of an alcohol was added. A dichloromethane solution of DCC was slowly stirred into the sulfinic acid solution cooled with ice, and the stirring was continued for several hours or overnight. White precipitates formed were filtered off, the solvent was removed by evaporation, and the residue was dissolved in hexane. When white precipitates were formed they were removed by filtration. The rest of the procedure was the same as described in method A.

The reason why the amount of DCC used as less than equimolar is that the unreacted DCC cannot be easily separated from sulfinates by distillation. The DCC reacted can be easily removed as dicyclohexylurea. Method B is suitable for these alcohols which are solid or do not dissolve sulfinic acids readily. In this case DCC or dicyclohexylurea dissolves in dichloromethane to some extent, and these compounds must be removed by reprecipitation by addition of *n*-hexane to the residue of distillation.

Oxygen-18 Labeled Compounds. p-*Toluenesulfinic Acid-*^{18}O: Eleven grams of *p*-toluenesulfinic acid was dissolved in a mixture of 20 m*l* of $D_2{}^{18}O$ (^{18}O: 1.5 atom%) and 8.5 m*l* of dioxane. The solution was kept at 84°C for 1 hr, during which the exchange of ^{18}O is expected to be complete. After neutralization with a sodium carbonate solution and evaporation of solvent, the residue was dissolved in water. Acidification of the solution by addition of sulfuric acid yielded 8.7 g of *p*-toluenesulfinic acid-^{18}O.

Benzyl p-*Tolyl Sulfone-*^{18}O: The *p*-toluenesulfinic acid-^{18}O prepared as described above was neutralized by an aqueous sodium carbonate solution, and evaporation of the solvent yielded sodium *p*-toluenesulfinate-^{18}O. A mixture of 1 g of this sulfinate and 2 m*l* of benzyl bromide was heated at 118°C for 5 hr in a sealed tube. Benzyl *p*-tolyl sulfone produced was extracted with ether, washed with a sodium carbonate solution and water, and then dried. The ether was evaporated, and the residue was recrystallized from *n*-hexane.

The ^{18}O analyses were carried out according to the method of Rittenberg and Ponticorvo.[5)]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 863—865 (1971)

Unperturbed Dimensions of Poly-*o*-chlorostyrene

Kimiyoshi MATSUMURA, Keisuke MIZUNO, Masamichi FUKAYA, Takahiro KAMIYA, and Yasunobu SATO

Department of Chemistry, Aichi Kyoiku University, Kariya, Aichi

(Received October 30, 1970)

In a previous paper,[1] one of the present authors reported that the K_θ value of the butanone solution of poly-*o*-chlorostyrene (the theta solution at 25°C) is fairly small compared with that found from the viscosity plot for the toluene solutions; the solvent effect is considered to be the cause of the difference between these K_θ values.

In this paper, in order to examine the effect of the solvent on the K_θ value and to find the temperature dependence of the K_θ values, the viscosity measurements of poly-*o*-chlorostyrene in critical consolute solvents, which were mixtures of benzene (solvent)-cyclohexane (nonsolvent) at three ratios of mixing, were made.

Experimental

Material. The preparation and fractionation of poly-*o*-chlorostyrene were done according to the method described in a previous paper.[1] The molecular weights of the polymer fractions were determined by viscosity measurements of the toluene solutions at 25°C, with an intrinsic viscosity-molecular weight relationship of $[\eta]=1.15\times10^{-4}\cdot M^{0.66}$.[1] The molecular weights of the fractions used for the determination of the theta temperature were 141.7×10^4, 89.0×10^4, 52.5×10^4, and 23.3×10^4, while those of the fractions used for the viscosity measurements were 72.0×10^4, 59.9×10^4, 47.6×10^4, 35.8×10^4, 25.9×10^4, and 14.3×10^4.

The benzene and cyclohexane used as the solvents were purified by the methods described in a previous paper.[2] The critical consolute solvent mixtures were prepared by mixing benzene and cyclohexane by volume at 25°C; the ratios of benzene *vs.* cyclohexane were (A) 1/2.2, (B) 1/2.4,

2) K. Matsumura, M. Fukaya, and K. Mizuno, This Bulletin, **43**, 1881 (1970).

and (C) 1/2.6.

Measurements. The methods used for the determination of the temperature and for the measurements of the viscosities of the solutions were the same as those in a previous paper.[2]

Results and Discussion

The Determination of the Theta Temperatures. An example of the measurements of the precipitation temperatures, T_p, and the determination of the theta temperature for poly-*o*-chlorostyrene in one critical consolute solvent mixture (A) is shown in Fig. 1. After the same procedures as that shown in Fig. 1, the theta temperatures were determined to be as follows: 31±2°C in solvent (A), 38±2°C in (B), and 45±3°C in (C).

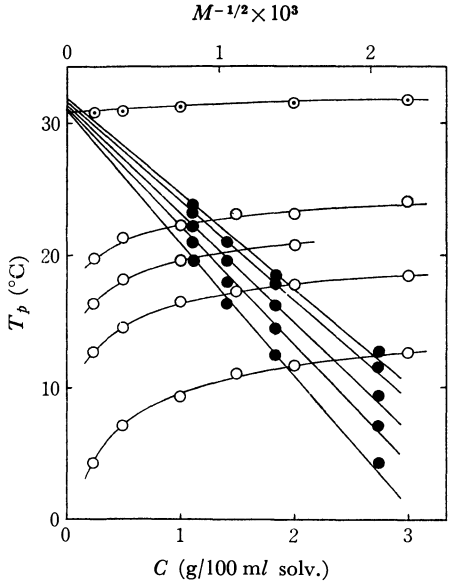

Fig. 1. The determination of the theta temperature for poly-*o*-chlorostyrene in solvent (A): ○, T_p-C for each fraction; ⊙, T_p-C for $M=\infty$; ●, T_p-$M^{-1/2}$ for several concentrations corresponding to those of ⊙.

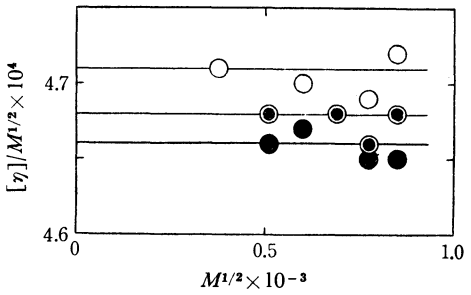

Fig. 2. Viscosity plots for poly-*o*-chlorostyrene in the critical consolute solvents: ○ (31°C), ⊙ (38°C), ● (45°C).

Viscosity. The intrinsic viscosity, $[\eta]$, and the Huggins constant, k', of poly-*o*-chlorostyrene in the critical consolute solvents are summarized in Table 1.

Discussion. As is shown in Fig. 2, the values of $[\eta]/M^{1/2}$, $(=K_\theta)$, were independent of $M^{1/2}$, as is known to be generally true for a theta solution. The K_θ values of the critical consolute solution found from Fig. 2 are shown in Table 2, together with the values of $\{\langle L^2\rangle_0/M\}^{1/2}$, $(=\{K_\theta/\Phi_0\}^{1/3})$, and σ, $(=\{\langle L^2\rangle_0/\langle L^2\rangle_{0f}\}^{1/2})$, calculated from the K_θ values, in which the value of Φ_0, the Flory parameter, was assumed to be 2.55×10^{21}, the same as that found in a previous paper.[1]

The K_θ values are in fair agreement with that of the butanone solution at 25°C (the theta solution), 4.60×10^{-4};[1] they are smaller the higher the temperature, much as with the temperature dependencies of K_θ for polystyrene and for poly-*p*-chlorostyrene.[2,3]

It was previously reported that the K_θ value of poly-*o*-chlorostyrene in butanone at 25°C is fairly small compared with that found from the viscosity plot of the toluene solution, and that this difference in K_θ values proves that the solvent effect may depend on the fact that the butanone solution gives a lower consolute temperature.

However, the results in this paper show no difference between the K_θ value of poly-*o*-chlorostyrene in a theta

Table 1. The experimental results of the viscosity measurements for poly-*o*-chlorostyrene in the critical consolute solvent mixtures

solvent, which gives a lower consolute temperature, and that in a solvent, which gives a higher one. This suggests that the large value of K_θ in the toluene solution may not be caused by the solvent effect but, rather, by the downwards curvature of the viscosity plot, as was shown in a previous paper.[1] Therefore, there is difficulty in finding the value of K_θ from the viscosity plot of poly-*o*-chlorostyrene in toluene (a good solvent).

Some Benzylidene and Cyclohexylidene Derivatives of 3-Deoxy-3-nitro-α-D-glucopyranose[1]

Tohru SAKAKIBARA, Tetsuyoshi TAKAMOTO, and Toshio NAKAGAWA*

Department of Chemistry, Tokyo Institute of Technology, Ō-okayama, Meguro-ku, Tokyo

(Received October 30, 1970)

In a previous paper[2] we reported that methyl 2-*O*-acetyl-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-glucopyranoside reacts smoothly with theophylline and 2,6-dichloropurine in the presence of sodium hydrogen carbonate to give, *via* 3-nitro-2-enoside, the corresponding 2-purinyl-glucosides in excellent yields. This finding urged us to attempt the similar reaction with 2-nitro sugars. To our knowledge, the only example belonging to this class of compounds, except 2-nitro-alditols, has been described by Lemieux *et al.*[3], *i.e.* per-*O*-acetyl-2-nitro-D-glucal, -galactal and -xylal, derived from the corresponding acetylated glycals with dinitrogen tetraoxide. But all attempts to obtain 2'-nitro nucleosides from the reaction mixtures of these compounds with some purine homologues have been hitherto unsuccessful in our laboratory.

On the other hand, we have studied on the oxidative C^1-C^2 fission of 3-deoxy-3-nitro-D-glucose (**2**) with periodate or lead tetraacetate with the aim of preparing and characterizing 2-nitro sugars, but the desired product (**7**) is likely too unstable to isolate, giving only the degradated product (**8**). In this paper, we wish to present thereof and some acetal derivatives of **2** obtained throughout this work.

Phenyl 3-deoxy-3-nitro-β-D-glycopyranoside (**1**), almost selectively prepared by successive oxidation and nitromethane condensation of phenyl β-D-glucopyranoside,[4] was hydrolyzed (4 N HCl, 100°C, 2 hr) to give the reducing 3-deoxy-3-nitro-D-glucose (**2**).[5] Treatment of **2** with benzaldehyde and zinc chloride yielded the 4,6-*O*-benzylidene derivative (**3**). Compounds **2** and **3** were isolated in high yields as an α-form (downward-mutarotating). Acetylation of **3** with acetic anhydride in pyridine gave the 1,2-di-*O*-acetate (**4**), which was deduced to be an α-anomer on the basis of its NMR spectra: (1) a relatively small value of $J_{1,2}$ (3.8 Hz)[6]; (2) an axial *O*-acetyl signal resonating at 7.84 τ($CDCl_3$).[6,7]

On an acetal exchange reaction[8] with 1,1-diethoxycyclohexane in the presence of *p*-toluenesulfonic acid (50°C/~20 mmHg), **2** gave the 1,2;4,6-di-*O*-cyclohexylidene derivative (**5**). The *α-pyranose* structure of **5** was proved by comparison of the chemical shifts and coupling constants of its ring protons[9] with those of 4,6-*O*-benzylidene-1,2-*O*-cyclohexylidene derivative (**6**), prepared by the analogous treatment of **3** (*cf.*

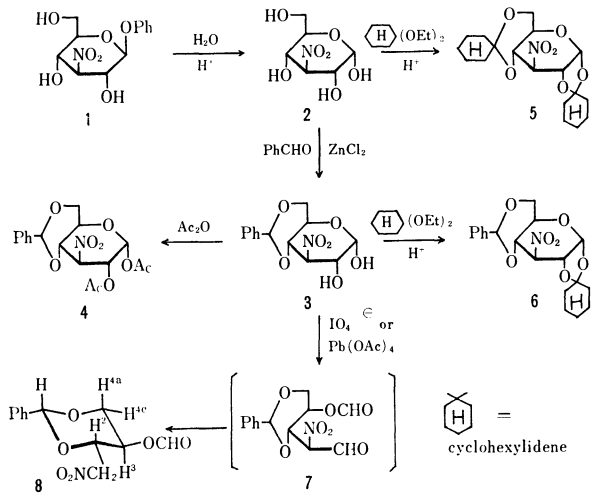
9) Moreover, if compound **5** had a *furanose* structure, $J_{2,3}$ should be ≥0.5 Hz. *Cf.* R. J. Abraham, L. D. Hall, L. Hough, and K. A. McLauchlan, *Chem. Ind.* (London), **1962**, 213; *J. Chem, Soc.*, **1962**. 3699.

Table 1).

Oxidation of **3** with periodate or lead tetraacetate gave no 2-nitro sugar **7** but a successive de-*C*-formylation occurred to form 2,4-*O*-benzylidene-1-deoxy-3-*O*-formyl-1-nitro-D-erythritol (**8**), whose structure was confirmed by its NMR spectra (Table 1).



Experimental

Melting points were determined in capillaries and are uncorrected. IR spectra were obtained with a Hitachi EPI-S2 instrument. NMR spectra were taken with a JEOLCO JNM-4H-100 spectrometer, using an internal TMS standard. Optical rotations were measured with a Carl Zeiss photoelectric polarimeter.

3-Deoxy-3-nitro-α-D-glucose (2). A mixture of phenyl 3-deoxy-3-nitro-β-D-glucopyranoside[4] (10.0 g) and 4 N hydrochloric acid was refluxed for 2 hr and the resulting solution was evaporated. The residue was dissolved in hot water (*ca.* 50 m*l*), treated with active charcoal and filtered. The filtrate was evaporated, and the residue was coevaporated several times with water and then crystallized from ethanol. After washing with ethyl acetate, the crystals (colorless, 5.5 g, 75%) may be used for a synthetic purpose without further purification. A sample for analysis was recrystallized from methanol/ethyl acetate: mp 174—174.5°C (decomp.) [*lit*,[5] 176—177°C (decomp.)]; $[\alpha]_D^{20}$ +114° (*t*=0 min) → +108.5° (5 min) → +93.2° (30 min) → +79.5° (22 hr; const.) (*c* 1, H_2O)[*lit*,[5] $[\alpha]_D$ +99.6° (6 min) → +73.9° (130 min, const.) (*c* 1, H_2O)].

Found: C, 34.44; H, 5.10; N, 6.72%. Calcd for $C_6H_{11}O_7N$: C, 34.45; H, 5.30; N, 6.70%.

4,6-O-Benzylidene-3-deoxy-3-nitro-α-D-glucopyranose (3). A mixture of **2** (2.7 g), zinc chloride (4 g), and benzaldehyde (13 m*l*) was stirred for 2 days and then poured into a mixture of ice water and petroleum ether with vigorous stirring. The precipitates were collected by filtration, washed well with water and petroleum ether, and recrystallized from ethanol/water: Yield 2.9 g (76%); mp 149.5—150.5°C; $[\alpha]_D^{20}$ +34.3° (*t*=0 min) → +31.0° (2 hr 15 min) → +22.6° (24 hr) → +15.8° (3 days) → +12.2° (7 days) → +8.9° (15 days, const.)(*c* 1, dioxane). IR(KBr): 3400 cm^{-1} (OH); 1565 cm^{-1} (NO_2).

Found: C, 52.47; H, 4.81; N, 4.72%. Calcd for $C_{13}H_{15}O_7N$: C, 52.52; H, 5.09; N, 4.71%.

1,2-Di-O-acetyl-4,6-O-benzylidene-3-deoxy-3-nitro-α-D-glucopyranose (4). To a solution of **3** (0.89 g) in pyridine (9 m*l*) was added acetic anhydride (6 m*l*) under ice cooling. The reaction mixture was allowed to stand for 2 hr at room temperature and then poured into ice water. The precipitates were collected by filtration, washed well with water, and recrystallized from acetone/ethanol: Yield 1.13 g (99.2%); mp 220°C (decomp.); $[\alpha]_D^{20}$ +65.9° (*c* 1, $CHCl_3$). IR (KBr): 1755 cm^{-1} (C=O); 1565 cm^{-1} (NO_2). NMR ($CDCl_3$): 7.84 τ (3H-*s*, *ax. O*-Ac on *C*[1]); 7.99 τ (3H-*s*, *eq. O*-Ac on *C*[2]).[6,7]

Found: C, 53.39; H, 4.93; N, 3.71%. Calcd for $C_{17}H_{19}O_9N$: C, 53.54; H, 5.02; N, 3.67%.

1,2;4,6-Di-O-cyclohexylidene-3-deoxy-3-nitro-α-D-glucopyranose (5). A solution of **2** (0.63 g), 1,1-diethoxycyclohexane[10] (2 m*l*), and *p*-toluenesulfonic acid (0.01 g) in DMF (6 m*l*) was boiled at 50°C/~20 mmHg, with use of a fine stream of dry air to promote steady ebullition.[8] After 1.5 hr, the reaction mixture was neutralized with sodium hydrogencarbonate, the undissolved material was filtered off, the filtrate was evaporated *in vacuo*, and the residue was recrystallized from ethanol/petroleum ether: Yield 0.5 g (45%); mp 121—123.5°C; $[\alpha]_D^{20}$ +122° (*c* 1, $CHCl_3$). IR (KBr): 1560 cm^{-1} (NO_2).

Found: C, 58.36; H, 7.09; N, 3.78%. Calcd for $C_{18}H_{27}O_7N$: C, 58.52; H, 7.37; N, 3.79%.

4,6-O-Benzylidene-1,2-O-cyclohexylidene-3-deoxy-3-nitro-α-D-glucopyranose (6). A solution of **3** (0.89 g), 1,1-diethoxycyclohexane[10] (12 m*l*), and *p*-toluenesulfonic acid (0.01 g) in dioxane (20 m*l*) was treated for 5 hr similarly as described above. The product was recrystallized from acetone/ethanol: 0.69 g (61%); mp 155.5—156.5°C; $[\alpha]_D^{20}$ +95.5° (*c* 1, $CHCl_3$). IR (KBr): 1550 cm^{-1} (NO_2).

Found: C, 60.18; H, 5.87; N, 3.82%. Calcd for $C_{19}H_{23}O_7N$: C, 60.47; H, 6.14; N, 3.71%.

2,4-O-Benzylidene-1-deoxy-3-O-formyl-1-nitro-D-erythritol (8). a) Periodate Oxidation: Into a solution of sodium metaperiodate (0.70 g) in water (50 m*l*) was added **3** (0.89 g) and stirred at room temperature. After 6 hr, sodium hydrogencarbonate (0.25 g) was added to it and them ixture was stirred for 3 days. The precipitates were collected by filtration, washed with water, and recrystallized from ethanol/petroleum ether: colorless needles (0.404 g, 50.5%); mp 113°C; $[\alpha]_D^{20}$ −47.2° (*c* 1, EtOAc). IR (KBr): 1725 cm^{-1} (C=O); 1560 cm^{-1} (NO_2); no absorption of OH.

Found: C, 53.93; H, 4.76; N, 5.23%. Calcd for $C_{12}H_{13}O_6N$: C, 53.93; H, 4.90; N, 5.24%.

b) Lead Tetraacetate Oxidation: In a solution of lead tetraacetate (1.46 g) in dry benzene (30 m*l*) was stirred **3** (0.89 g) at room temperature for 2 hr, the precipitates were filtered off, the filtrate was evaporated, and the residue was recrystallized from ethanol/petroleum ether to give over 70% yield of colorless needles, mp and mixed mp 113°C. IR and NMR spectra were identical with those of the product obtained under (*a*).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 867—869 (1971)

Chemical Studies of Minerals Containing Rarer Elements from the Far East District. LXIV.[1] Abukumalite from Fusamata, Kawamata-machi, Fukushima Prefecture, Japan

Kozo Nagashima, Kazuso Nakao, Hisanobu Wakita, and Akira Kato*

* *Department of Chemistry, Tokyo Kyoiku University, Tokyo*

* *Department of Geology, National Science Museum, Ueno Park, Tokyo*

(Received November 2, 1970)

Abukumalite was first described by Hata(1938)[2] from a granite pegmatite at Suishoyama, Kawamata-machi (formerly called Iisaka Village), Fukushima Prefecture, Japan. In 1939, Machatschki[3] pointed out the isostructural relation between abukumalite and apatite due to the isomorphous coupled substitution of CaP by YSi, this being later confirmed by Omori and Hasegawa.[4] Recently, Ito(1968)[5] synthesized the intermediate members between $Ca_{10}P_6O_{24}(OH)_2$ and $Ca_6Y_4Si_6O_{24}(OH)_2$ to suggest the presence of continuous solid solution series between them, though not fully substantiated by natural materials, but partially by such a yttrian apatite as that from Naegi, Gifu Prefecture, Japan, containing 10.65% Y_2O_3 (Omori and Konno, 1962)[6] and abukumalites. Also a rare-earth ($\Sigma Ce > \Sigma Y$) silicatian apatite is reported from the Adirondack Mountains, New York.[7]

The localities of abukumalite reported thereafter include Shinden, Gifu Prefecture, Japan,[8] Hiradani, Shiga Prefecture, Japan,[9] northwestern U.S.S.R.,[10] and Pyörönmaa, Finland.[11] An aluminian variety has been reported from Siberia[12] and a cerian variety, an intermediate of abukumalite and britholite has been reported from Kola Peninsula.[13] Those from the last three foreign localities are in thermally recoverable metamict state.

The pegmatite at Fusamata, Kawamata-machi, Fukushima Prefecture, is located about 2 kilometers north of Suishoyama pegmatite, the original locality of abukumalite. In the former are known such rare earth minerals as gadolinite,[14] allanite, yttrialite, iimorite,[15] thorogummite, fergusonite, xenotime, and rare-earth-bearing zircon. The studied abukumalite was found in the dump as dark reddish brown masses up to 1 cm across and superficially coated by thorogummite.

The present report deals with the chemical analysis to specify the abukumalite from Fusamata as a fluorine dominant variety of abukumalite, and also with the determination of distribution patterns of lanthanoids in this abukumalite and that from the original locality to designate them as the members of thalenite-type (Goldschmidt and Thomassen, 1924).[16]

Chemical Composition

Chemical analysis was carried out on hand-picked material of about 3 g adopting the usual procedure for the rare earth-bearing silicates. The average atomic weight of the rare earths was determined by titrating the weighed mixed oxides with EDTA after dissolving them in hydrochloric acid. Fluorine was determined by the method proposed by Ellestad (1964).[17]

The result of chemical analysis is given in Table 1 in which that of the original abukumalite (Hata, 1938)[2] is also tabulated for comparison. The calculation of the analysis based on O+OH+F=13 gives $(\Sigma Y_{2.905}Ca_{1.388}Mn_{0.424}Fe^{3+}_{0.115}Fe^{2+}_{0.100}Al_{0.040}Na_{0.023}K_{0.015})_{5.010}(Si_{2.694}P_{0.204}Al_{0.102})_{3.000}O_{12.000}(F_{0.581}(OH)_{0.279}O_{0.140})_{1.000}$, well accounting for the ideal formula $Ca_2Y_3(SiO_4)_3(F, OH)_2$ with minor substitution of Ca by Mn, Fe, *etc.*, and the relation F>OH, differing from the original abukumalite in which OH>F.

X-Ray Studies

The precession photographs show it to be hexagonal with $a_0=9.44_1$ Å and $c_0=6.79_0$ Å, respectively, with the systematic extinction rule as: no condition for *hkil* and $l=2$ n for $000l$. Thus the possible space group is C_6^2, C_{6h}^2, or D_6^2. Though the preference should be due to its structural study, it is very probable that

1. Abukumalite. Suishoyama, Kawamata-machi, Fukushima Prefecture, Japan. Cu/Ni radiation. Diffractometer method. After Sakurai and Kato (1962).
2. Synthetic $Ca_4Y_6Si_6O_{24}(OH)_2$. After Ito (1968).
3. Abukumalite. Fusamata, Kawamata-machi, Fukushima Prefecture, Japan. Cu/Ni radiation. Diffractometer method. The present study.

abukumalite has the same space group as ordinary apatite, C_{6h}^2.

X-ray powder data are obtained by diffractometer method employing Cu/Ni radiation. They are well coincident with those of abukumalite from the original locality, Suishoyama neighbouring to Fusamata and synthetic $Ca_{10}(PO_4)_6(OH)_2$ (Ito, 1968)[5] as shown in Table 2.

Optical Propertites

Though nearly colorless in thin section, the studied abukumalite is light brown in thick spinters with very weak dichroism: O=colorless to light brown, E= light brown; O<E.

It is uniaxial positive and the refractive indices measured by immersion method are: $\omega=1.773$, $\varepsilon=1.777$, $\varepsilon-\omega=0.004$. These values are within the variation range of those of abukumalites[8]: $\omega=$ 1.750—1.780, $\varepsilon=1.752$—1.783.

The Distribution Pattern of Lanthanoids

The distribution of lanthanoids in two abukumalites from Fusamata and Suishoyama was studied adopting about 0.5 g extracted rare earth oxides by x-ray fluorescent method, and Y, La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er, Tm, and Yb were detected. The result of the quantitative analysis of the elements including relative error of less than 10% are plotted *versus* atomic numbers (Fig. 1). The patterns obtained show a close resemblance between Fusamata and Suishoyama abukumalites, both belonging to thalenite-type as defined by Goldschmidt and Thomassen (1924).[16] The same tendency is also found in abukumalites from Shinden,[8] Hiradani,[9] and Pyörönmaa.[11]

The authors express their thanks to Dr. Kin-ichi Sakurai and late Mr. Otokichi Nagashima for their kind offering of the abukumalite specimens to the authors.

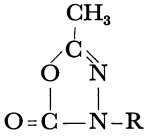
SHORT COMMUNICATIONS

Ring-opening Polymerization of 2-Methyl-1,3,4-oxadiazolin-5-one

Takeshi ENDO, Takeshi INOUE, and Makoto OKAWARA
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

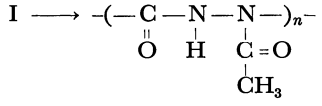
(Received December 8, 1970)

2-Methyl-1,3,4-oxadiazolin-5-ones (I—III) were obtained easily by the reaction of corresponding hydrazides with phosgene in good yield.[1] They were confirmed by elementary analysis and IR spectrum.



I, R=H (mp 112°C)
II, R=CH_3 (bp 70—72°C/10mmHg)
III, R=C_6H_5 (mp 92—93°C)

It is known that these derivatives are important as antibacterial compounds. The reactions of these compounds with primary amines[2] or water[3] have been reported. We found that a new type polymer IV could be synthesized by the ring-opening polymerization of 2-methyl-1,3,4-oxadiazolin-5-one (I), using tertiary amines or Lewis acids as catalysts. However, 2,4-dimethyl-1,3,4-oxadiazolin-5-one (II) and 2-methyl-4-phenyl-1,3,4-oxadiazolin-5-one (III) did not polymerize.



(IV)

Polymerization was carried out in sealed tubes in the absence of oxygen. The conditions for polymerization are given in Table 1. The polymer was purified by means of reprecipitation with *N,N*-dimethylformamide (DMF) and ether. The results are given in Table 1. The yield increases with the increase of the basicity of amines, although the molecular weight of the resulting polymer is low. It was found that a higher concentration of the catalyst is necessary for obtaining high yield. Compound I could also be polymerized by use of Lewis acids such as BF_3OEt_2 and $TiCl_4$, but the molecular weight and yield of the polymer obtained were low. The polymer obtained in the form of white powder is soluble in DMF, dimethyl sulfoxide (DMSO) and water, but insoluble in common organic solvents such as alcohol, acetone, and benzene. The structure of the polymer was confirmed by IR and NMR. The IR spectrum (in DMSO) indicated the three characteristic absorption bands at 3100 (N–H), 1720 (–C(=O)–CH_3) and 1690 cm^{-1} (–C(=O)–N). The absorptions attributable to carbonyl group (1770 cm^{-1}) and double bond (C=N) (1630 cm^{-1}) in the monomer disappeared. NMR spectrum of the polymer shows the two peaks at $\tau=7.35$ (singlet) and −1.15 ppm (singlet) assigned to methyl proton and N–H proton, respectively (NMR spectrum of monomer; methyl proton 7.80 ppm, N–H proton −0.55 ppm).

Liquid Adducts Consisting of Ammonia and Aliphatic Acid

Shizuo NAKAMURA
Sagami Chemical Research Center, Sagamihara, Kanagawa
(Received October 24, 1970)

A curious phenomenon is described herewith which takes place when a certain solid compound is added to liquid ammonia in a sealed glass tube. The compound turns liquid and remains at the bottom without being mixed with the liquid ammonia. The phenomenon does not seem to have been reported.

The following four compounds show the phenomenon: imino diacetic acid (IDA), glutaric acid (GLA), glutamic acid (GMA) and aspartic acid (ASP).

The liquid is viscous and sticky like the solution of a high molecular compound. It is not a compound in the usual sense. The ammonia content of the liquid varies with temperature. In the case of IDA the molar ratio of NH_3/IDA is 8 at dry ice temperature, and 6.5 at room temperature. The liquid becomes stiffer with the fall of temperature. At −78°C the liquid turns transparent, colorless caramel which does not flow; at −196°C it turns glassy, while liquid ammonia solidifies into a white mass. With the rise of temperature the liquid becomes turbid, but becomes transparent when left to stand for some time. The turbid liquid turns clear at once if temperature falls. This takes place at temperatures −30°C—+100°C. The phenomenon above 100°C was not studied.

The liquid is stable at room temperature under the pressure of saturated ammonia. In the case of IDA, the decomposition pressure is 2.1—2.4 atm at 22°C.

TABLE 1. TUBE SIZE AND EXPERIMENTAL CONDITIONS

Tube size			Maximum temp. °C	Maximum pressure atm.
Inner dia. mm	Outer dia. mm	Length cm		
12	17.5	28	37	14
3[a)]	8[a)]	17	100	62
2.5	9	17		
20	26	13	37	14
2.3	5	15	35	13

a) The tube burst after being kept at 100°C for one hour.

When the pressure is reduced, ammonia gas bubbles out from the viscous liquid giving rise to the formation of a white foamed mass (in the case of GLA, the mass is less sticky than in other cases, the foam being smaller). The mass is sticky at first, but turns brittle after complete separation of ammonia. It is an ammonium salt of the acid which is also dissolved forming a liquid phase like its free acid.

The liquid obtained from the four dibasic acids differ in their ammonium contents. Rough estimate at room temperature gives the results: IDA-6.5NH_3, GLA-7NH_3, GMA-6NH_3 and ASP-5NH_3.

NMR spectra of IDA-NH_3 and GLA-NH_3 at 35°C show that there is no ammonia molecule of ordinary liquid ammonia, *viz.*, NMR signal of the ammonia proton shifts from $\delta=9.88$ (ordinary liquid ammonia) to $\delta=4.74$ in the case of IDA, and to $\delta=4.26$ in the case of GLA.

The facts that the liquid does not mix with liquid ammonia, it is viscous and sticky, it exists between −196°C and +100°C, and its NMR signal of ammonia proton shifts largely from that of liquid ammonia, suggest that ammonia molecules are surrounded by atoms of acid molecules forming clathrate-like liquid structure.

Experimental. Thick glass tubes were used in order to prevent explosion. Tube size and experimental conditions are shown in Table 1.

Decomposition pressure was estimated by reading the temperature of liquid ammonia, whose vapor pressure balanced with that of the viscous liquid. The temperature range was −15°C (2.33 atm) to −17°C (2.14 atm).

In order to measure the ammonia content in the liquid, the liquid ammonia (upper phase) was made to volatilize gradually at room temperature. With the disappearance of upper phase, the tube was sealed off immediately, and weighed. The pressure was then reduced for the formation of foamed mass, and the vessel was evacuated and weighed. The results are given in Table 2. The accuracy of weighing is ±0.01 g.

TABLE 2. MASS BALANCE OF THE VISCOUS LIQUID

	Acid used g	Viscous liquid g	Ammonia content g	Molar NH_3/acid ratio	Remaining solid	
					g	Formula
IDA-NH_3	0.50	0.91	0.41	6.4	0.57	NH_4-$C_4H_6O_4N$

On the Structure of Ethyl Mercaptan

Michiro HAYASHI, Hisae IMAISHI, Keiichi OHNO, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima
(Received November 16, 1970)

Recently, Kadzhar, Abbasov, and Imanov[1] have published a paper on the microwave spectra of trans ethyl mercaptan and its ^{34}S isotopically-substituted species. We have also independently worked on the same molecule and five isotopically-substituted species, in both the trans and gauche molecular forms.

For the trans isomer, since we have not yet finished the measurements of two ^{13}C isotopic species, the r_s structure of the molecule can not be obtained at present. A preliminary survey has shown us, however, that too many weak spectra crowd around the expected regions for the ^{13}C species, and careful measurements will be necessary for the assignment of the spectra due to two ^{13}C species in natural abundance. Therefore, we have obtained only a tentative structure which reasonably reproduces the observed rotational constants.

For the gauche isomer, we could assign the spectra only to "a"-type transitions. For "b"- and "c"-type spectra, the splittings due to the internal rotation of the SH group seem to be too large for us to get the reasonable assignments without information from theoretical treatments of the splittings, on which we are now working.

The "a" type spectra of the $J_{0J}\rightarrow(J+1)_{0J+1}$ type show no splitting, while the spectra of the $J_{1J}\rightarrow(J+1)_{1J+1}$ and $J_{1J-1}\rightarrow(J+1)_{1J}$ types are split into doublets, with separations of several mega-Hertz.

The "B" and "C" rotational constants shown in the table can be obtained by taking the average frequencies of the components of the doublets for the latter types of the spectra.

As for the "A" rotational constants, we cannot obtain them from the "a"-type spectra alone since the molecule is so close to the symmetric top. The observed rotational constants of the gauche isomer are not reproduced by simply changing the dihedral angle CCSH, while keeping the other structural parameters the same as those of the trans form; the discrepancies amount to about 5% for all isotopic species. However, reasonable agreements are obtained if we change the dihedral angle CCSH after exchanging the values of the CCS and one of the CCH angles in the CH_2 group. The CCH angle to be exchanged is the one situated at the trans position against the SH bond in the gauche isomer.

This is understandable if we have a tilted CH_2 group toward the SH bond; it is similar to the CH_3 group found, for example, in methyl mercaptan.[2]

trans isomer (MHz)	A	B	C

Water Formation in the Gas Phase Radiolysis of Nitrous Oxide-Hydrocarbon Mixtures

Satoshi TAKAO, Yoshihiko HATANO, and Shoji SHIDA
Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 14, 1970)

The determination of water formation in the radiolysis of nitrous oxide - hydrocarbon systems is important for the elucidation of radiolytic mechanism of pure nitrous oxide, as well as the electron-scavenging process of nitrous oxide in hydrocarbons.[1] However, information is scanty and inaccurate. In previous papers,[2] an ionic mechanism in the gas-phase radiolysis of nitrous oxide was proposed and the importance of processes other than the ionic process was suggested. In the present study, the effect of hydrocarbons on the gas-phase radiolysis of nitrous oxide has been examined.

A sample containing about 90 cmHg of N_2O with small amounts of the hydrocarbons, C_2H_6, C_3H_8, C_2H_4, or C_3H_6, was irradiated by ^{60}Co-γ rays at room temperature to a total dose of 2.1×10^{20} eV/g. The products were analyzed by gaschromatography using a molecular sieve-5A column at 60°C for N_2 and CO and a polyethyleneglycol-200 column at 70°C for other oxygen-containing products. Special care was taken in the analysis of the main product H_2O.

The addition of small amounts of hydrocarbons to N_2O caused a sudden decrease in the nitrogen yield and a large increase in the yield of oxygen-containing products, giving respective plateau values. In all cases, H_2O is the major product with small amounts of alcohols or CO. A typical result for C_2H_6 is given in Fig. 1. Decrease of the observed nitrogen yield was 2.5 in G unit for C_2H_6 and C_3H_8, 2.6 for C_2H_4, and 2.7 for C_3H_6. The total yields of oxygen-containing products were 6.8 for C_2H_6, 6.9 for C_3H_8, 6.8 for C_2H_4 and 6.4 for C_3H_6. They are roughly three times, as much as the decrements of the nitrogen yield. In the presence of the hydrocarbons, NO and O_2 were not detected.

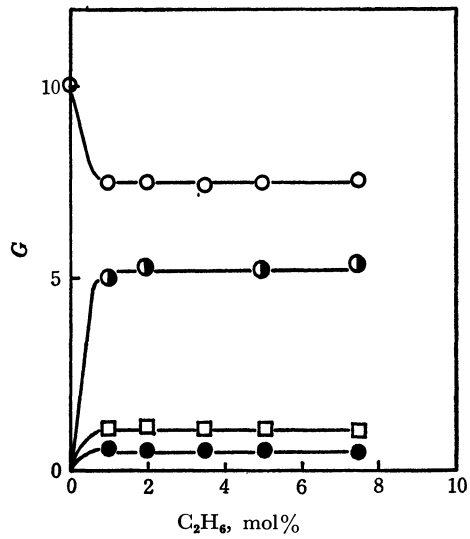

Fig. 1. The effect of C_2H_6 addition to N_2O.
○ N_2, ◑ H_2O, □ i-C_4H_9OH, ● C_2H_5OH.

From the results, the contribution from ionic processes is considered, for which the following schemes are assumed;[3]

$$N_2O \rightsquigarrow N_2O^+ + e^-,\quad N_2O^+ + RH \rightarrow N_2O + RH^+,$$

$$N_2O + e^- \rightarrow N_2O^-,$$

$$N_2O^- + RH \text{ (or } RH^+) \rightarrow N_2 + OH^- \text{ (or OH)} + R,$$

$$OH^- + RH^+ \rightarrow H_2O + R, \text{ or}$$

$$OH^- + N_2O^+ \rightarrow N_2O + OH,\quad OH + RH \rightarrow H_2O + R.$$

According to these schemes, however, nitrogen should be produced as much as H_2O and the nitrogen yield should not decrease by the addition of a hydrocarbon. The observed decrease of the nitrogen yield, then, must be ascribed to some other processes. The total yield of the oxygen-containing products is much larger than the decrease of the nitrogen yield. It seems reasonable to assume the following non-ionic processes involving two kinds of oxygen atoms; one can contribute to the decomposition of N_2O but not the other,[4] both reacting with hydrocarbons to form oxygen-containing products. On the basis of the observed decrements of the nitrogen yields in the presence of hydrocarbons, combined with the total G(NO) value and that contributed from ionic processes obtained in the radiolysis of pure N_2O,[2] it can be concluded that O* plays a major role in the non-ionic decomposition of N_2O. From the consideration of photochemical studies[5] on the reactivities of oxygen atoms, it may be inferred that O and O* are the ground $O(^3P)$ and the excited $O(^1D)$ or $O(^1S)$ atoms, respectively.

$$N_2O \rightsquigarrow \begin{cases} N_2 + O, & O + N_2O \not\rightarrow \\ N_2 + O^*, & O^* + N_2O \rightarrow N_2 + O_2,\ 2NO. \end{cases}$$

On the Structure of Poly-L-lysine-metal Complexes in Aqueous Solution

Michio NAKAI, Michio YONEYAMA, and Masahiro HATANO

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received November 16, 1970)

Poly-L-lysine-copper(II) complex has been prepared as a model compound of a metalloenzyme and found to oxidize D-3,4-dihydroxyphenylalanine faster than L-enantiomorph at pH 10.5, where the polymer chain has helical structure to some extent.[1] It has been estimated that the cupric ion in the helical poly-L-lysine-copper(II) complex is coordinated by four amino nitrogens in the side chains of poly-L-lysine and, in addition, by a deprotonated nitrogen in the peptide bond of the polymer.[2]

We report herewith on the structures of the complexes prepared from poly-L-lysine and several metal salts, *i.e.*, nickel(II) nitrate, cobalt(II) nitrate, zinc(II) nitrate and potassium tetrachloropalladate(II). The pH titration and the measurements of circular dichroism (CD) and infrared absorption spectra were carried out for the polymer complexes formed in aqueous media.

The order of the stability constants of the complexes were estimated as $-Pd(II) > -Cu(II) > -Zn(II) \approx -Ni(II) \approx -Co(II)$ from modified Bjerrum plots[3] of the pH titration data obtained for the solution, with a ratio 0.15 of molar concentration of the metal ion to residual molar concentration of poly-L-lysine C_M/C_R. The Bjerrum formation functions, $\bar{n}$'s, were found to approach *ca.* 4 for all the complexes examined, which shows that each metal ion is coordinated by four amino nitrogens.

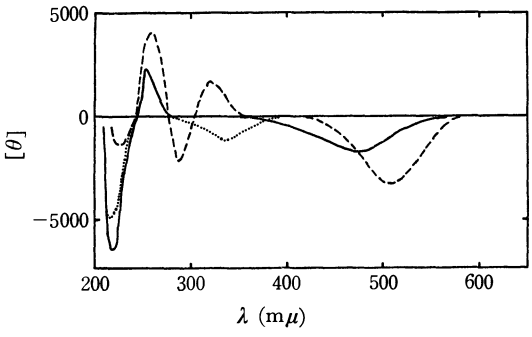

Fig. 1. CD spectra of poly-L-lysine-metal complexes (C_R= 0.005 M, C_M/C_R=0.15, pH 10.5); ---- Cu, —— Ni, ... Pd.

CD measurements were carried out at room temperature with a JASCO Model ORD/UV-5 optical rotatory dispersion recorder. The residual concentration of poly-L-lysine C_R and the ratio C_M/C_R were 0.005 mol/*l* and 0.15, respectively. All the polymer complexes showed n–π^* transition band due to helical structure at 222 mμ at pH 10.5. As in the case of poly-L-lysine-copper complex, only the poly-L-lysine-nickel and the poly-L-lysine-palladium complexes were found to show *d*–*d* transition and charge-transfer bands in addition to the band at 222 mμ (Fig. 1). The *d*–*d* transition bands are considered to be due to the vicinal effect of the asymmetric carbon of the poly-L-lysine through the coordination of the peptide group to the metal ion.

In order to ascertain the coordination of the peptide group in the cases of the nickel and the palladium complexes as done with the copper complex, the infrared absorption spectra in D_2O solutions at pD *ca.* 11 were recorded on a Hitachi Model EPI-G2 grating infrared spectrophotometer with small bags made of polyethylene film held between NaCl plates.[4] C_R and C_M/C_R were *ca.* 0.5 mol/*l* and 0.15, respectively. The amide I band of poly-L-lysine at pD *ca.* 11 shifts from 1640 cm^{-1} to 1610 cm^{-1} on the coordination of the peptide nitrogen to copper ion.[2] The band shifted to 1635 cm^{-1} and 1625 cm^{-1} for the nickel and the palladium complexes, respectively. No shift occurred in the case of the cobalt complex. The amide I band of glycylglycinate at 1632 cm^{-1} is known to shift to 1610 cm^{-1} and 1620 cm^{-1} when its deprotonated peptide nitrogen is coordinated to copper ion and nickel ion, respectively.[5] Thus the results seem to support the coordination of the peptide nitrogen to nickel and palladium ions as in the case of copper ion. They agree with those by CD measurement. In either of the nickel and the palladium complexes the metal ion seems to be coordinated by four amino nitrogens in the side chains of the helical poly-L-lysine and by a peptide nitrogen in the main chain of the polymer, which is similar to the case of poly-L-lysine-copper complex.

The Synthesis and Absolute Configurations of Lilac Alcohols

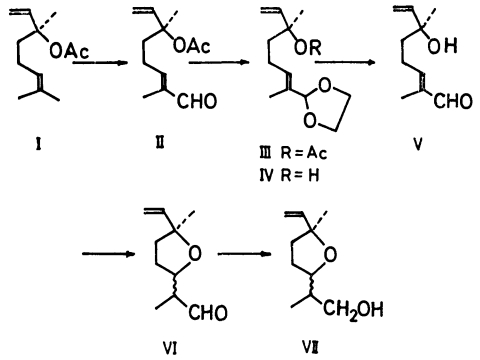
Seiji WAKAYAMA, Satoshi NAMBA, Kazuo HOSOI,* and Masaji OHNO*

Chemical Laboratory, Hokkaido University of Education, Sapporo

** Basic Research Laboratories, Toray Industries, Inc., Kamakura*

(Received January 11, 1971)

Lilac alcohols have recently been isolated and assigned to the diastereomers of β,5-dimethyl-5-vinyl-2-tetrahydrofuranethanol.[1,2] We now wish to describe a total synthesis of lilac alcohols with sufficient samples for the assignment of absolute and stereochemical configurations.



d-Linalyl acetate (I)[3] $[\alpha]_D^{25}$ +2.9 was treated with SeO_2 to afford α,β-unsaturated aldehyde II in 38% yield. Treatment of II with ethyleneglycol in the presence of *p*-toluenesulfonic acid in benzene gave ethyleneacetal III, which was hydrolysed with 5 N NaOH to afford IV. Column chromatography of IV on silica gel gave V (77% overall-yield from II to V).[4,5] The intramolecular Michael addition of alcohol to the α,β-unsaturated aldehyde was effected with NEt_3 to give VI in 43% yield. Reduction of VI with $LiAlH_4$ afforded a diastereomeric mixture (VII) of *d*-lilac alcohols in 75% yield. The mixture was separated completely by vpc to afford four diastereomers with R_t 7.1 $[\alpha]_D^{25}$ −1.4, 7.3 $[\alpha]_D^{25}$ +1.4, 8.8 $[\alpha]_D^{25}$ +6.7, and 10.1 $[\alpha]_D^{25}$ −0.5, which were shown to correspond to lilac alcohol-b, -d, -a, and -c, respectively, based on NMR, IR and optical rotations. *l*-Lilac alcohol-a $[\alpha]_D^{25}$ −11.6, -b $[\alpha]_D^{25}$ +3.0, -c $[\alpha]_D^{25}$ +2.5, and -d $[\alpha]_D^{25}$ −2.9 were synthesized from *l*-linalyl acetate[3] $[\alpha]_D^{25}$ −5.0 in a similar way, showing a contrary $[\alpha]_D$ to natural lilac alcohols. By combining the absolute configuration of *d*-linalool,[6] chemical relation to *trans*-linalool oxide,[1] and a detailed IR and NMR study of the intramolecular hydrogen bonding between the primary alcohol and ether linkage,[7] the absolute configurational assignments of lilac alcohol-a, -b, -c, and -d have been shown to be (βS, 2S, 5S), (βR, 2S, 5S), (βR, 2R, 5S), and (βS, 2R, 5S), respectively.

Chronology of the Addition of 1-Cyano-1-methylethyl Radicals to 9-Bromoanthracene Studied by CIDNP

Hiizu IWAMURA, Michiko IWAMURA,* Shiro SATO,** and Katsuhiko KUSHIDA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

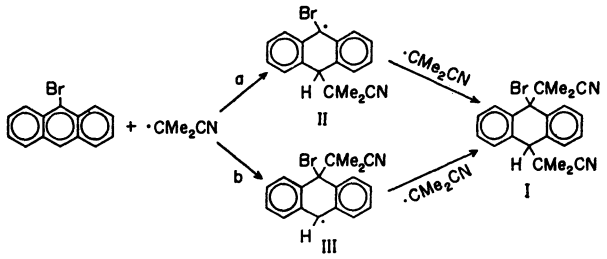
* *Department of Chemistry, Faculty of Science, Toho University, Narashino-shi, Chiba*

** *Nippon Electric Varian, Ltd., Azabu, Tokyo*

(Received January 21, 1971)

In previous papers we suggested a possible application of chemically induced dynamic nuclear polarization (CIDNP) for the determination of chronology of free radical addition reactions.[1] A typical example has now been found in the addition reaction of 1-cyano-1-methylethyl radicals to the *meso* positions of 9-substituted anthracenes.

The NMR spectrum of adduct I of 9-bromoanthracene, for example, has a doublet for the C-methyl protons at 0.86 and 0.78 ppm from the internal hexamethyldisiloxane. When 0.4 m*l* aliquot of a solution of 85 mg of 9-bromoanthracene and 112 mg of α,α'-azobisisobutyronitrile in 1.3 m*l* of tetrachloroethane was heated at 120°C in an NMR probe of a Varian HA-100 D spectrometer, it was the signal at the lower applied magnetic field (0.86 ppm) which showed an emission pattern. On the contrary, the intensity of the absorption peak at 0.78 ppm increased smoothly as expected for a normal growth of I as the reaction proceeded (see Fig. 1). Based on the empirical rule that the electronegative β-bromo substitution shifts the methyl proton resonance to the lower field by *ca.* 0.1 ppm,[2] it can be assumed that the emission signal corresponds to the methyl protons of $C_{(9)}$-CMe_2CN in I. Since the nuclear spin relaxation time T_1 of the intermediate radicals is usually short compared to their life-time, it is more probable that the nuclear spin polarization which was developed in the last step of the radical addition was detected in I. Thus the observation provides direct evidence for path a in Scheme 1 as the sequence of the addition reaction. The chronology is compatible with the knowledge that the addition proceeds through formation of a more stable intermediate radical in free radical chemistry. In the present case, II is considered to be more stable than III by additional resonance contribution of the bromine atom.



Scheme 1

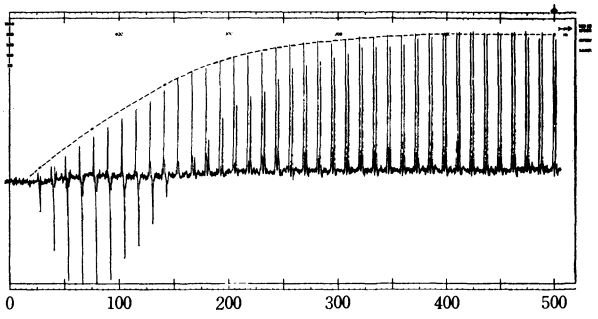


Fig. 1. Time dependence of the amplitude of the two C-methyl signals at 0.86 ppm (the upper envelope) and 0.78 ppm (the lower envelope) of I during the reaction. The dotted curve represents a theoretical increase in the concentration of I.[3]

A closer examination of the time dependence curve of the amplitude of the two C-methyl signals (Fig. 1) revealed, however, that the upper envelope representing the absorption peak at δ 0.78 ppm is not simply convex as expected for normal increase in the concentration of I as the reaction proceeds, but deviates slightly from the theoretical curve[3] in the 0—150 sec interval. The phenomenon seems to indicate that the curve could be an overlap between the normal exponential curve and a sigmoidal curve characteristic of the emission signals. The anomaly can be interpreted as a manifestation of the dual pathway of the addition reaction in which path b also contributes slightly.[4] The conclusion is consistent with that derived from the kinetic study of the reaction by Kooyman;[3] the partial rate factors at $C_{(10)}$ and $C_{(9)}$ of 9-bromoanthracene at 70°C are given as 1.37 and 0.07, respectively.[5]

4) This effect is less conspicuous for the lower envelope representing the emission signals at 0.86 ppm in Fig. 1.

5) Reactivity at $C_{(9)}$ is calculated to be *ca.* 10% at 120°C of the present experimental conditions.

The NMR Spectra of Molten Polyethylene

Kojitsu Goto and Atsuo Nishioka*

Japan Electron Optics Lab. Co., Ltd., Akishima, Tokyo

** Tokyo Institute of Technology, Ookayama, Meguro, Tokyo*

(Received January 16, 1970)

Quantitative analyses of methyl groups and olefinic double bonds (vinyl, vinylidene, and vinylene) are usually performed by the infrared (IR) absorption method, but it can also be done by the high-resolution nuclear-magnetic-resonance (NMR) method.[1,2] The latter method has the advantage of providing an absolute measurement method if the saturation effect can be neglected. However, the analysis of the double-bond content is more difficult than that of the methyl group because of their small quantity of the order 10^{-4}/carbon atoms. To improve the signal-to-noise ratio, a molten sample was used with the NMR accumulation method at 60 MHz by Ferguson,[2] but the details were not presented.

We have obtained better results on molten polyethylene without any accumulation at 180°C by using a 100 MHz NMR spectrometer (JEOL 4H-100) with higher sensitivity than in the early studies.[1,2] The careful preparation of the sample tube is necessary to avoid the formation of voids, which disturb the homogeneity of the magnetic field. At the early stage of our experiment, polyethylene, in either pellet or powdered form, was put into the sample tube and melted on the flame of a Bunsen burner for a relatively short time (about three minutes). Figure 1 shows the NMR spectra of these samples; they consist of very sharp lines similar to those of low-molecular-weight model compounds. The double-bond signals in polyethylene were assigned by comparing them with those of the model compounds: (a) octadecene-1 ($CH_3(CH_2)_{15}CH{=}CH_2$, δ=4.72—4.98 and 5.48—5.92) for the vinyl group, (b) 2-ethyl-butene-1 ($(CH_3CH_2)_2C{=}CH_2$, δ=4.56—4.63) for vinylidene, (c) elaidic acid $(CH_3(CH_2)_7C{=}C(CH_2)_7COOH$ (H), δ=5.22—5.37) for *trans*-vinylene, and (d) oleic acid $(CH_3(CH_2)_7C{=}C(CH_2)_7COOH$ (H H), δ=5.15—5.36) for *cis*-vinylene.

However, the IR measurement of these samples showed some increase in the double-bond content compared with that of the original pellets; attributable to the dissociation by overheating during the above operation.

We then tried to prepare the sample tube under milder conditions with an oil bath maintained at 180—200°C. Figure 2 shows the spectra of these samples, which give the same kinds of signals as are shown in Fig. 1, but with some broadening and weaker intensities. It was found that the half-height widths of the methylene proton signals of both normal and dissociated samples are not very different from each other, but that the tailing part of the signal is very broad in the normal sample, corresponding to the broad molecular-weight distribution in the original sample.

Thus, the NMR spectra of molten polyethylene is very useful in determining the contents of various types of olefinic double bonds in a relatively short time without any accumulation, that is, in a single scan; moreover, this method provides a broad line width which gives us new information about the molecular motion and the molecular-weight distribution of polyethylene chains.

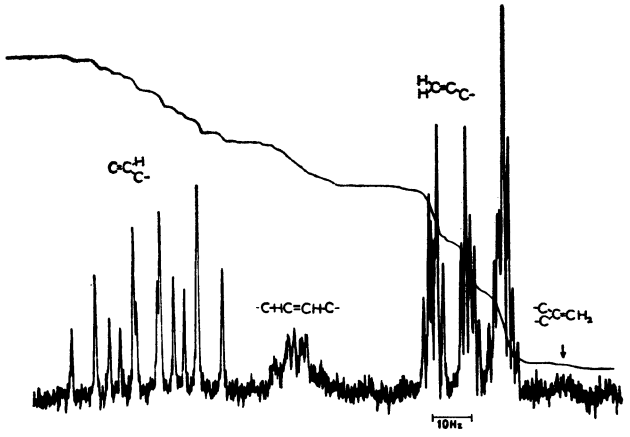

Fig. 1. Expanded spectrum of olefinic double bonds in molten high density polyethylene at 180°C.

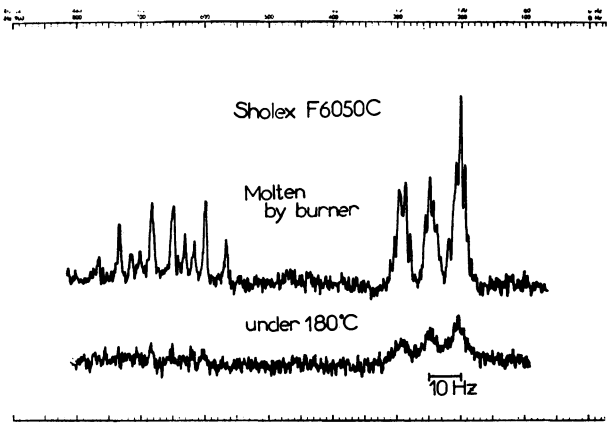

Fig. 2. Double bond spectra of molten high density polyethylene prepared by gas burner (upper) and oil bath (lower).

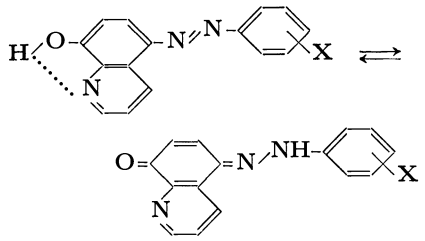
Thermochromism in 5-Arylazo-8-quinolinols Diluted with Sodium Chloride

Yoshio MATSUNAGA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received January 25, 1971)

Our earlier work on the diffuse reflection spectra of 1-arylazo-2-naphthols diluted with sodium chloride disclosed that the compounds in this solid two-component system exist as mixtures of the azo and hydrazone tautomers.[1] The movement of the equilibrium upon an elevation of the temperature was well demonstrated by the change in the spectrum. However, no appreciable thermochromism was noted, because the absorption bands of the two tautomers are rather coalescent. Here, we wish to report that 5-arylazo-8-quinolinols;



the synthesis of which was described as early as 1888 by Matheus,[2] are distinctly thermochromic when diluted with sodium chloride.

The compounds were prepared by the usual diazo-coupling reactions with 8-quinolinol. The derivatives carrying one of the following substituents in the *o*-, *m*-, or *p*-position on the phenyl ring were synthesized: methyl, chloro, methoxy, and nitro. They were easily purified by vacuum sublimation. The method of measuring the reflection spectra was the same as that described in our previous paper.[1]

For example, pure 5-(*m*-anisylazo)-8-quinolinol is orange. It turns yellowish orange upon dilution with sodium chloride. As is shown in Fig. 1, the spectrum consists of three bands, located at about 360—70 mμ, 430—40 mμ, and 540 mμ; among those, the band at 440 mμ dominates at room temperature. Upon the elevation of the temperature, the relative intensity of this band is markedly diminished at a concentration of 0.01%. The mixture is red-colored at 100°C. The direction of the spectral change upon heating in 5-phenylazo-8-quinolinol and all the *m*- and *p*-substituted compounds examined is the same as has been mentioned above. Nevertheless, various spectral features are observed because of the large difference in the relative intensities of the bands. Among the *o*-substituted compounds, only 5-(*o*-anisylazo)-8-quinolinol shows an appreciable spectral change upon the elevation of the temperature. Here, the direction of the change is the opposite of that observed in the others.

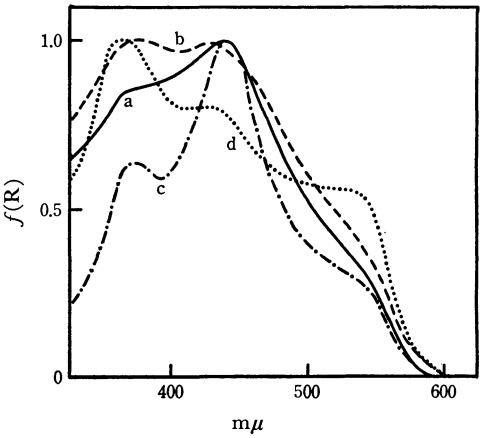


Fig. 1. Spectra of 5-(*m*-anisylazo)-8-quinolinol diluted with sodium chloride; (a) 1% at room temperature, (b) 1% at 100°C, (c) 0.01% at room temperature, and (d) 0.01% at 100°C. The maximum is arbitrarily taken as 1.00 in each spectrum.

It is likely that the azo tautomer is favored by the intramolecular hydrogen bond in the quinolinol part, the presence of which is suggested by the ease of vacuum sublimation. Therefore, the band outstanding in most of the room-temperature spectra may be ascribed to the azo tautomer. Further work is being planned to attempt a more conclusive assignment of the absorption bands to the possible tautomers.

Calorimetric Study of Polystyrenes of Low Molecular Weight

Satoshi MORIMOTO

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama

(Received February 5, 1970)

Heats of mixing ΔH^M at infinite dilution and integral heats of dilution ΔH_d were directly measured for the systems of atactic polystyrenes (PSt: MW$\leqq 10^4$, prepared by Pressure Chemical Co.) with benzene, toluene, and chloroform. The results are summarized as follows: (1) ΔH^M and ΔH_d decrease remarkably with the molecular weight of PSt in all solvents used. (2) The glass energies of the samples treated under the same thermal conditions were investigated and the large difference of heat capacities between liquid and glassy state of PSt was observed in the low molecular weight region. (3) Schulz's theory of osmotic second virial coefficient of athermal polymer solutions was found to agree, to a good approximation, with the differential heat $\overline{\Delta H}_1$ of dilution in toluene in the molecular weight region between 10^3 and 10^4. (4) The NMR and the X-ray diffraction analyses were performed for the PSt oligomer liquid (MW 600). All alkyl end group of molecules and an order formation in the liquid were observed. They are discussed in terms of calorimetric data.

The present study is concerned with the heats of solution and dilution in low molecular weight polystyrene-solvent systems. The heat of solution of a polymeric glass-solvent system arises partly from the glass energy of the polymer solid.[1] For atactic polystyrene (PSt), calorimetric studies[2,3] have confirmed the glass energy content, glass enthalpy which varies with the packing conditions of the polymer molecules under the glassy state. However, when polymeric glass samples of various molecular weights are treated under the same conditions, the heats of solution in the liquid polymer-solvent systems and the glass energy contents of the polymer glasses should change with their molecular weights. The heats of dilution of PSt solutions have been directly measured by several workers. In particular, studies on the low molecular weight PSt or the oligomer solutions have revealed remarkable changes of the solution properties with molecular weights in the oligomer region.[4,5]

In this work, the heats of mixing (ΔH^M) of PSt samples (prepared by Pressure Chemical Co., average molecular weight $\bar{M}\leqq 10^4$), treated under the same thermal conditions in benzene, toluene and chloroform at infinite dilution, and the heats of dilution of the solutions have been measured. Dependence of the values on molecular weight was examined and information on the polymer and the solution was obtained from the results.

Experimental

Materials. PSt polymers of narrow molecular weight distribution, $\overline{M_w}/\overline{M_n}\leqq 1.10$, products of the Pressure Chemical Co., were used. For the measurement of the ΔH^M, the polymers were subjected to the same thermal treatment with the exception of the polymer of $\bar{M}=600$, a viscous liquid. After removing air in a vacuum 10^{-5} mmHg, PSt samples were heat-treated at 130°C for 10 min in N_2 gas current and were annealed at room temperature. The liquid solute ethylbenzene and the solvents benzene, toluene, and chloroform were commercial products of the highest quality. All but chloroform were dried with sodium wire and fractionally distilled over phosphorus pentoxide before use. Chloroform was washed repeatedly with distilled water, dried over calcium sulfate and fractionally distilled before use.

Calorimetry. For the measurement of ΔH^M, a rotational twin conduction calorimeter[6] in which a mixing cell similar to that described by Malcolm and Rowlinson[7] was used. The principle of the detection of heat is similar to that reported previously.[8] Almost all ΔH^M values at infinite dilution were obtained from the measurements for final concentration of 0.7—1.3% using 20—30 mg of the solute and about 3 m*l* of the solvent. Measurements were performed within ±4% of standard deviation. For the determination of the integral heat of dilution (ΔH_d), a revised type of calorimeter[9] with multiple modules[10] was used. The ΔH_d values were obtained by diluting 1—7 m*l* of 5—10% solution to about 2×10^{-3} % concentration, *i.e.*, almost infinite dilution. The values were obtained with a maximum error of ±20%.

Density Measurements. Measurement of the change in density Δd between pure solvent and PSt dilute solution was carried out by means of Cahn electromagnetic balance RG using a density cell at 25°C. The measurement is entirely similar to that reported by Elgret *et al.*[11] The apparent specific valumes v_2^* of PSt oligomers in dilute solution were found from the equation[12]

$$v_2^* = d^{-1}(1+\Delta d/c) \qquad (1)$$

where d is the density of pure solvent and c is polymer concentration. The PSt concentrations were about 2% in benzene and in toluene, and about 1% in chloroform. Reproducibility of the values of v_2^* derived from the value of Δd was within ±0.1% on an average. The densities measured were 0.87405 for benzene, 0.86273 for toluene,

0.4753 for chloroform, and 0.86281 g/ml for ethylbenzene.

Other Measurements. NMR spectra were taken with a Nihon Denshi C-60 HL spectrometer using about 5% solution of the sample in $CDCl_3$. X-ray diffraction diagrams and photographs were obtained with a Rigaku Denki X-ray diffraction apparatus.

Results and Discussion

Heats of Solution. The results are given in Figs. 1 and 2. In Fig. 1, the values of ΔH^M of the low molecular weight PSt samples, subjected to the same thermal treatment in three solvents at 18 and 45°C are plotted against the molecular weights. The values of ΔH^M of ethylbenzene which can be regarded as the monomeric substance of PSt were endothermic for benzene, athermal for toluene and exothermic for chloroform. The larger exothermic change in ΔH^M suggests the larger exothermic contribution from the glass enthalpies which increase with the molecular weight of PSt. This tendency is made clear by the study of Schulz *et al.*[1] and also by the relation between the heat capacity C_p and the temperature of the

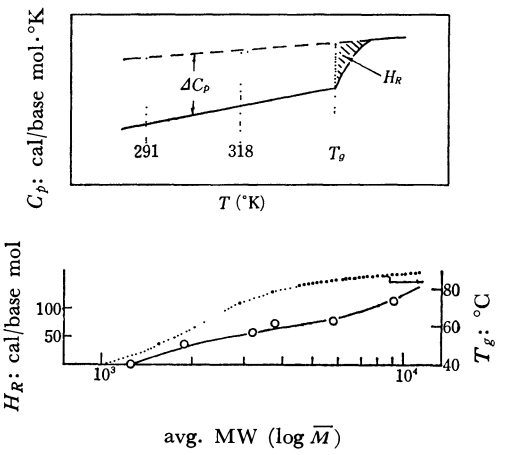

Fig. 3. Correlation of heat capacity with temperature, and the values of H_R[13] and T_g[13] *vs.* the molecular weight of PSt.

glass transition of PSt as shown in Fig. 3. The relation between the glass enthalpy and the heat of mixing ΔH_l^M of liquid polymer at infinite dilution is given by

$$\Delta H^M = \Delta H_l^M - \Delta H_g^M \tag{2}$$

$$\Delta H_g^M = \int_T^{T_g} \Delta C_p \, dT + H_R \,, \tag{3}$$

where $-\Delta H_g^M$ is the contribution due to glass enthalpy, T temperature, T_g glass temperature, ΔC_p the difference in C_p between glass polymer and liquid polymer to be assumed at the same temperature as shown in Fig. 3, H_R the rest enthalpy arising from the transition which takes place slowly from the glassy state to liquid phase, and shown as the shaded portion in Fig. 3. This relation can be used to estimate the contributions either of ΔH_l^M or ΔH_g^M to the ΔH^M values. Another approach to the estimation of the value of ΔH^M is from the apparent specific volume of the PSt in dilute solution. Horth *et al.*[14] found that the difference between v_2^* and the specific volume v_2^0 of the pure liquid polymer is approximately proportional to the ΔH_l^M, *viz.*,

$$v_2^* - v_2^0 = \beta \boldsymbol{R} T \kappa_1 v_2^0 \varphi_1 / V_1 (1+\alpha T)$$
$$= [\beta/(1+\alpha T)] \Delta H_l^M / M_0 \,, \tag{4}$$

where α and β are the coefficients of thermal expansion and the compressibility of the solution, φ_1 and V_1 the volume fraction and the molar volume of the solvent, $\boldsymbol{R}$ gas constant, κ_1 Flory's enthalpy parameter, and M_0 the molecular weight of the repeating unit of the polymer. Using the empirical v-T-M equation,[15] we obtained a relative relation between v_2^*-v_2^0 and $\overline{M}$ for the oligomers as shown in Fig. 2. Although not presented here, a similar figure is obtained using the other v-T-M relation.[16] The specific volume v_2^0 of ethylbenzene measured was 1.15900 which was used for the calculation. In the high molecular weight

region, the partial specific volume of PSt is almost constant and has been reported[11] to be 0.911 in benzene and 0.917 in toluene solution. These values agree fairly well with our results, 0.911 and 0.914, respectively, obtained as the apparent specific volumes v_2*. Calculated values $(1+\alpha T)/\beta$ were 316 for benzene, 330 for toluene, and 363 cal/cm^3 for chloroform system by using the values[17] of pure solvents instead of the solutions for α and β. These values are almost the same for the three solvent systems. It is understood that the behavior shown in Fig. 2 is consistent with the one obtained from direct calorimetric measurements.

In Figs. 1 and 2, the values ΔH_l^M for all solvent systems show a similar tendency for the change of molecular weight. However, the tendency slightly differed with the characteristics of the solvents. In the case of monomeric solute-ethylbenzene, ΔH^M of toluene system showed lower values than those of other systems. However, this relation was reversed when the molecular weight increased. This reversal was observed in the molecular weight region between 10^3 and 10^4, which shifted lower when the temperature was lowered.

The value of ΔH_l^M in PSt ($\overline{M}$: 3,980)-toluene system at 25°C has been obtained as 60 cal/base mol from the ΔH_l^M and C_p measurements by Schulz.[1] According to this scheme, the ΔH_l^M at the higher molecular weight region in benzene and chloroform systems should be constant, *i.e.*, about −100 and −300 cal/base mol for benzene and chloroform systems respectively. This exothermic effect in benzene or chloroform system is attributable to the interactions between the solvent molecules and the phenyl components in PSt molecules, although the slightly exothermic factor can not be ignored when the solute chain length increases.[5,18] The interaction between the solvent and the constituent of polymer molecule is introduced to interpreted ΔH_l^M qualitatively.[5,18,19] The values of ΔH^M of benzene and *n*-heptane both with chloroform were directly measured and the values −398 and 719 cal/mol were obtained, respectively. A considerably large exothermic value of ΔH^M in the chloroform system, as compared with PSt-benzene system, reflects the interactions between the chloroform and the phenyl group in PSt molecule.

A characteristic feature throughout this experiment is that the difference of the glass energies at different temperatures can be estimated from the measurements. In Fig. 4, the difference of the measured ΔH^M values at 18°C and 45°C are plotted against the molecular weight of PSt, although the temperature dependence of ΔH_l^M values are not completely negligible. The differences in the ΔH^M values thus obtained in this molecular weight region were somewhat scattered, but the large difference of glass energies is evident in the range $\overline{M}=10^3$—10^4. The magnitude of the difference in glass energy, when compared for a constant difference in temperature, corresponds to the mean values of ΔC_p between the measured temperatures

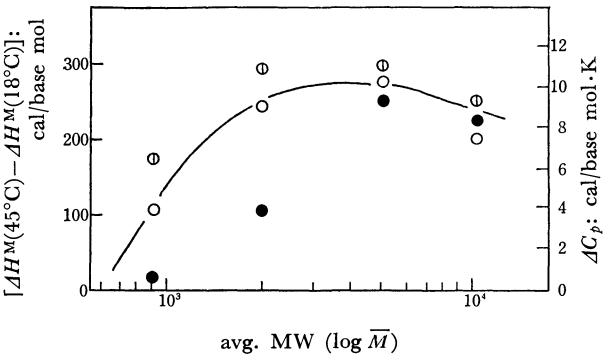

Fig. 4. The difference of glass energies between two measured temperatures and concluded ΔC_p value plotted against the avg. molecular weight of PSt.
○ Benzene ● Toluene ⓘ Chloroform

as shown in Fig. 4. The ΔC_p, or more exactly the ΔC_v at constant volume (generally at T_g), is the contribution of the conformational change of the polymer chains between the rubber and glassy states to the value of C_p, and is called conformational heat capacity.[20] Conversion of ΔC_p to ΔC_v might clarify this behavior, but the constants in the low molecular weight region have not been obtained. In connection with the movement of molecular chains,[21] the larger ΔC_p values may be explained as caused by the increase of the molecular cohesion in the glass of this molecular weight region or by the larger mobility of shorter chains in the liquid state, even though the cohesion might be independent of molecular weight. The sudden increase and the partially higher ΔC_p values were observed in the PSt oligomer region. The ΔC_p value of the higher molecular weight PSt agreed well with the reported value 0.09 cal/g. K[1,3] in this region.

Heats of Dilution. Measurement of the heats of dilution in the three solvent systems was performed at 25°C by diluting about 5 m*l* solution of the concentration 5—10% to infinite dilution for the toluene and the benzene systems and by diluting about 1 m*l* solution of the concentration 10% to infinite for the chloroform system. In order to obtain the differential heat $\Delta\overline{H}_1$ of dilution per mol solvent and the enthalpy term $B_H(=\boldsymbol{R}TA_{2,H})$ of the second virial coefficient $B(=\boldsymbol{R}TA_2)$ from the heats of dilution ΔH_d measured, the following equations were used.[4,22]

$$B_H = (\Delta H_d/w_2)/(c_e-c_a) \quad (5)$$

$$B_H = \boldsymbol{R}TA_{2,H} = -\Delta\overline{H}_1/\overline{V}_1c^2 \quad (6)$$

where A_2 and $A_{2,H}$ are the second virial coefficient and the enthalpy term of A_2, w_2 the weight of the solute to be diluted, c_a and c_e the initial and the final concentration of the solution. The value of B_H was found to depend on the concentration[4,23] and molecular weight,[24] but the dependence was neglected here for the sake of simplicity. The results are given in Fig. 5.

○ Benzene ● Toluene ⓘ Chloroform.

The values of ΔH_d were calculated from the B values according to the above equations, assuming that the c_a and $(c_a - c_e)$ are both 7.0×10^{-2} g/cm^3. The ΔH_d value corresponds to the heat arising from the dilution of 5 m*l* solution from 7% to infinite dilution. In Fig. 5, the molecular weight dependence is similar to that of ΔH_l^M at infinite dilution obtained from the heat of solution.

A characteristic feature of this experiment is the behavior of the toluene system which can be considered as an athermal solution. Theories of the second virial coefficient A_2^{ath} for athermal solutions have been given by several authors. From the equation derived by Schulz for A_2^{ath}[25] and by Schulz, Inagaki, and Kirste[26] for the relation between A_2 and $A_{2,H}$, the following equations are derived approximately for the value of B_H^{ath}.

$$B_H^{ath} = \boldsymbol{R}T^2\alpha\bar{v}_2(\pi^3 a^3 \boldsymbol{N}_A)^{1/2}/M_0(4^3 M_0\bar{v}_2)^{1/2} \quad (7)$$

$$B_H^{ath} = \boldsymbol{R}T^2\alpha\bar{v}_2(\pi^3 a^3 \boldsymbol{N}_A)^{1/2}/M_0(4^3 M_0\bar{v}_2)^{1/2}h(z)\,, \quad (8)$$

where α is the thermal expansion coefficient of the solution, $\bar{v}_2$ the partial specific volume of PSt, a the length of monomer unit, $\boldsymbol{N}_A$ the Avogadro number. With regard to the flexibility of polymer molecules, Schulz, Baumann, and Darskus[27] tried to combine the effect of coiling of long chain molecules. Miltiplying $A_{2,H}^{ath}$ by function $h(z)$ derived by Casassa,[28] they obtained good agreement with the experimental A_2 of athermal high polymer solutions. Equation (8) was thus derived and its applicability was examined. As seen in Fig. 5, our results show good agreement with the calculated values and the theory expresses the molecular weight dependence of the heat of dilution fairly well. Definite changes in the solution properties of the oligomers ($\overline{M}$: 10^3—10^4) have been observed by the measurements of the second virial coefficient,[5] the intrinsic viscosity,[29] and the partial specific compressibility.[30] The behavior can be explained as due to the flexibility of molecular chains in the solution (*i.e.*, rigid nature of the short chain molecule). This effect was observed in the direct measurement at the molecular weights between 10^3 and 10^4.

The enthalpy parameters χ_H and the $z\Delta w/\boldsymbol{k}T$ values[31] both involved in the Van Laar equation were calculated as a function of the molecular weight as shown in Fig. 6.

$$\chi_H = \overline{\Delta H}_1/\boldsymbol{R}T\varphi_2^2 \quad (9)$$

$$\chi_H = (\bar{V}_1/\bar{V}_2)z\Delta w/\boldsymbol{k}T\,, \quad (10)$$

Where φ_2 is the volume fraction of the solute PSt, z the coordination number, Δw the interchange energy, $\boldsymbol{k}$ the Bolzmann constant, $\bar{V}_2$ the partial molar volume of PSt. The $z\Delta w/\boldsymbol{k}T$ values of the benzene system for the higher molecular weight PSt ($\overline{M} \geqq 3000$) coincide with those for the toluene system. The comparatively higher χ_H values were observed in the low oligomer region as shown in Figs. 5 and 6. The con-

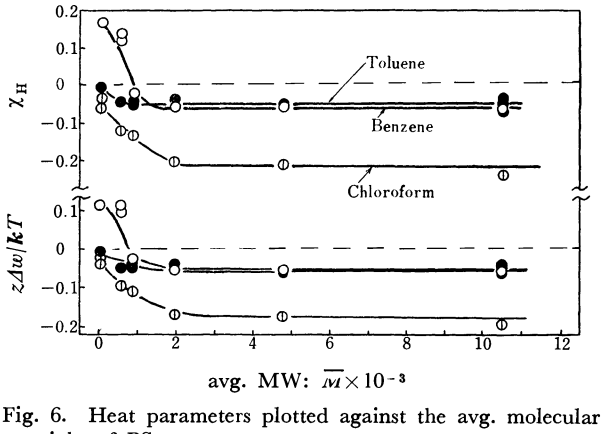

Fig. 6. Heat parameters plotted against the avg. molecular weight of PSt.

centration dependence of the enthalpy parameter was calculated on the basis of the quasi-chemical approximation for polymer solutions,[32,33]

$$\chi_H \equiv -T\left(\frac{\partial\chi_1}{\partial T}\right)$$
$$= [4\theta^2\Delta w(1-\theta)/\beta\varphi_2^2\boldsymbol{k}T(\beta+1-2\theta)(\beta+1)]$$
$$\times \exp(2\Delta w/z\boldsymbol{k}T) \quad (11)$$
$$\theta = \varphi_2(z-2)/(z-2\varphi_2)$$
$$\beta^2 = 1 + 4\theta(1-\theta)[\exp(2\Delta w/z\boldsymbol{k}T) - 1]\,.$$

The concentration dependence of the enthalpy parameter in the three solvent systems is shown in Fig. 7. The parameters χ_H were calculated on the basis of the $z\Delta w/\boldsymbol{k}T$ values, Eq. (11), and the ΔH_l^M values were obtained from Eq. (9) at $\varphi_2 = 1$ and the following

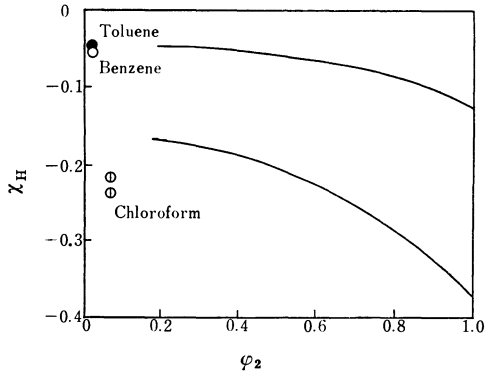

Fig. 7. Concentration dependences of the values of χ_H calculated on the basis of the quasi-chemical approximation. The avg. MW of PSt in toluene and in benzene are both 10500 and those in chloroform are 4800 and 10500.

equation which is expressed by the Van Laar equation.[31]

$$\Delta H_l^M \simeq (\bar{V}_2/\bar{V}_1)RT\chi_H \quad (12)$$

The ΔH_l^M values were −60, −80, and −300 cal/base mol for toluene, benzene, and chloroform solvent systems, respectively, and agreed well with the ΔH_l^M obtained from the direct measurements of the ΔH^M in the glassy PSt-solvent systems. From the results, the glass enthalpies of the higher molecular weight PSt can be calculated to be about 300 cal at 45°C and about 600 cal/base mol at 18°C.

An Order formation in the Oligomer Liquid. In examining the molecular weight dependence of ΔH^M and $\overline{\Delta H_1}$, we came across some problems concerning the behavior of low oligomers, in particular, the oligomer liquid ($\bar{M}$: 600, T_g: −18——20°C). First, the integral heat of dilution ΔH_d of the benzene solution at 25°C has a larger positive value than that reported.[4] Secondly, the heat of mixing ΔH^M at infinite dilution in the system, on the contrary, is exothermic, *i.e.*, of negative value. This suggested some questions on the chemical composition and ordering structures of the PSt oligomer sample.

The NMR spectrum of the oligomer showed the existence of long alkyl group, possibly *n*-butyl group, to the end as expected from the method of polymerization.[34] The NMR spectra of PSt and the oligomer are shown in Fig. 8. From the integral curves given by the dotted lines, the ratios of the number of protons from the phenyl groups of PSt molecule at the lower magnetic field to that from the methylene and methyne group at the higher field were compared. The ratio of 5 to 3 which is equal to the theoretical value was obtained for the high molecular weight PSt sample of the $\bar{M}$: 10500. For the oligomer sample, the ratio was 1 to 1. This shows that the oligomer molecule has an additional alkyl group, *i.e.* the *n*-butyl end group. Taking this fact into account, we can explain the larger heat of dilution by the endothermic interactions with solvent benzene.

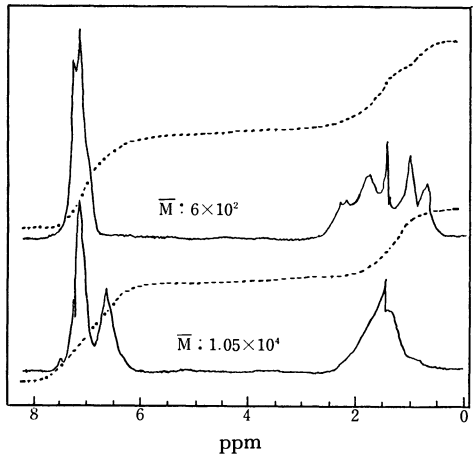

Fig. 8. NMR spectra of PSt and it's oligomer: dotted lines are the integral curves.

In order to check the possible existence of some ordered structure in the oligomer liquid, X-ray diffraction analysis was carried out at room temperature. The results are shown in Figs. 9 and 10. The diffracted amorphous halo of which 2θ is about 5° was found from both the X-ray diffraction intensity curve and photograph. On the other hand, the amorphous haloes ($2\theta \approx 10°$ and 20°) have been observed for the atactic PSt glass. The period calculated according to the Bragg equation was 17 Å, almost equal to the extended molecular chain length.

Such extended chain molecules which have a lower intramolecular energy than the coiled one, should bring an endothermic contribution to ΔH^M. This contribution is contrary to our result. Thus some exothermic contributions corresponding to the state of higher energy such as glass should be considered even in liquid state. If not, some strong rotational restriction of the side phenyl group in the ordered molecules is attributable to the endothermic effect. It has not been made clear, however, how such arrangements of chain molecules in general contribute thermally to the ΔH^M when dissolved. However, results suggest the existence of a smectic phase of short and rigid PSt oligomer molecules which are arranged parallel to each other in the liquid state. An exothermic contribution to ΔH^M was found in this oligomer liquid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 884—887 (1971)

An Interpretation of Mass Spectra of Disubstituted Benzenes by Simple LCAO MO Calculation. I

Susumu TAJIMA, Nobuhide WASADA, and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

(Received April 13, 1970)

A part of the mass spectra for derivatives of aniline and anisole was interpreted using the results of MO calculation. Compounds studied were: aniline derivatives: *o*-, *m*-, and *p*-compounds of anisidine, aminophenol, chloroaniline, nitroaniline, aminobenzoic acid, and aminoacetophenone; and anisole derivatives: *o*-, *m*-, and *p*-compounds of anisidine, methoxyphenol, chloroanisole, nitroanisole, methoxybenzoic acid, and methoxybenzaldehyde. The intensities of certain fragment ions in the mass spectra of these compounds were compared with the results of simple LCAO MO calculation for these compounds. A simple relation was found between the intensity and the partial bond order for a frontier electron of the bond ruptured.

Other than the well known quasi-equilibrium theory[1] (Q.E.T.), a method for theoretical interpretation of mass spectra of larger organic compounds has been reported by Hirota *et al.*[2,3] In this method, it is assumed that the scission probability of each of the skeletal bonds of the parent ion is proportional to the positive charge density of the highest occupied molecular orbital localized at the bond. Though the method has been applied successfully to paraffins[2] including cycloparaffins,[3] the basis for the interpretation has not yet been scrutinized as thoroughly as has been done for Q.E.T. The fundamental idea of Q.E.T. is generally accepted now, and the mass spectra of various aliphatic compounds[4-7] have been interpreted by the theory. The calculations involved, however, are rather tedious even for such a simple compound as propane. Nounou[8] has applied Q.E.T. to large aromatic compounds and successfully interpreted the mass spectra of substituted phenanthrenes. Recently, Dougherty[9] reported an interpretation of the decomposition of parent ions caused by electron impact with the perturbation MO method. Difference of mass spectra between aromatic isomers has been elucidated by Tatematsu *et al.*[10] on the basis of the difference of radical electron density, calculated by simple LCAO MO method, on the atoms in the isomers.

The purpose of the present paper is to find an approach to interpret the mass spectra of some aromatic compounds and to clarify the fragmentation mechanism by the results of simple LCAO MO calculation. In the procedure, various factors such as electron density, bond order *etc.* have been calculated by the method on a series of disubstituted benzenes and were compared with the intensity of certain fragment ions in their mass spectra.

Experimental

Mass spectra were obtained with a CEC 21—103C mass spectrometer. Conditions of measurement were: magnetic field, 4100 gauss; ion accelerating voltage, 3500—500 V; electron accelerating voltage, 70 eV; trap current, 10 μA; temperature of ion source, 250°C; temperature of sample manifold, 125—130°C.

The following derivatives of aniline and anisole were investigated: Aniline derivatives—*o*-, *m*-, and *p*-compounds

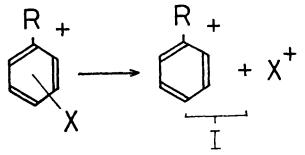

Fig. 1. Fragment ions investigated.

In Fig. 1, R denotes the common substituent, NH_2 or OCH_3, in the derivatives of aniline or anisole, respectively, and X denotes the other substituent, such as Cl, NO_2 *etc.* The summation of the intensity of ions shown in the right side of Fig. 1, *i.e.*, the ions inferred to be produced directly by a rupture of the bond between the aromatic moiety and the substituent X, was investigated. *I* desotes the summation of intensity of the ions mentioned above, normalized by the total ion intensity of the compound, *i.e.*, for aniline derivatives, *I* desotes the normalized ion intensity of $C_6H_4NH_2^+$ (*m/e* 92) plus X^+, and for anisole derivatives, *I* denotes that of $C_6H_4OCH_3^+$ (*m/e* 107) plus X^+. As shall be described, a simple correlation was found to be valid between log *I* and the partial bond order P^h for the frontier electron of the bond mentioned above.

Table 1. Partial bond order (P^h) of frontier electron

Aniline derivatives X	P^h *o*-	P^h *m*-	P^h *p*-
OCH_3	−0.136	−0.017	−0.134
OH	−0.126	−0.012	−0.126
Cl	−0.043	−0.002	−0.046
COOH	0.020	0.001	0.023
NO_2	0.024	0.001	0.028
$COCH_3$	0.037	0.001	0.046
Anisole derivatives X	P^h *o*-	P^h *m*-	P^h *p*-
NH_2	−0.154	−0.107	−0.151
OH	−0.146	−0.049	−0.143
Cl	−0.049	−0.002	−0.054
COOH	0.017	0.001	0.020
NO_2	0.021	0.001	0.026
CHO	0.035	0.002	0.045

A FACOM 270—30 computer was used for calculation. The parameters used in the calculation were quoted from the accepted values in the literature[11,12]. The results are shown in Table 1, where P^h is the partial bond order for a frontier electron of the bond between the substituent X and the aromatic moiety containing amino or methoxy group.

Results and Discussion

Correlation between the ion intensity *I*, described above, and various calculated quantities, such as electron density, free valence, and bond order for the molecules, were scrutinized. As a consequence of the investigation, a simple relation was found to be valid between the partial bond order P^h (shown in Table 1) for a frontier electron of the bond ruptured and log *I*. In Figs. 2, 3, and 4, log *I versus* P^h relation for each of *o*-, *m*-, and *p*-aniline derivatives, respectively, is plotted. The same plot for anisole derivatives is shown

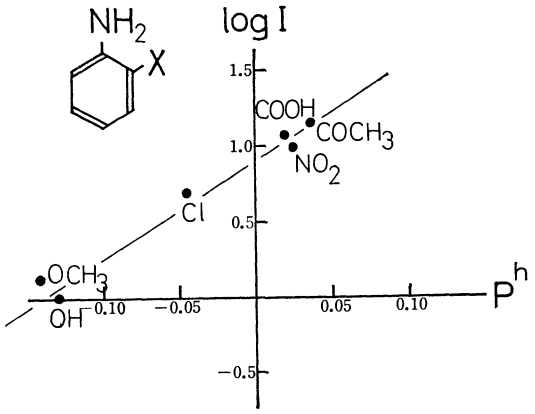

Fig. 2. log *I versus* partial bond order of the frontier electron for *o*-aniline derivatives.

in Figs. 5, 6, and 7.

Almost every compound studied exhibited a metastable peak corresponding to decomposition of M^+ into the aromatic moiety of interest, *i.e.*, into $C_6H_4NH_2^+$ for aniline derivatives, and $C_6H_4OCH_3^+$ for anisole derivatives, suggesting that at least a part of the process proceeds according to Q.E.T. mechanism. The implication is that the half life of parent ions is about 10^{-5} sec. The life time of an ion in its excited states is considered to be nearly 10^{-8} sec[13,14]. A molecular ion in its excited states does not decompose immediately after it is produced by electron impact, but rather undergoes many vibrations. During these vibrations there is a high probability of radiationless transitions among the many potential surfaces for the molecular ion, and the ion falls into its ground state or its low lying electronic states before it eventually decomposes.[1]

A linear relation was found between the vertical ionization potential measured by electron impact and H.M.O. coefficient of π-electron obtained by simple LCAO MO calculation for anisidines and chloroanilines. From the results it has been inferred that the first three ionizations of these compounds correspond to removal of a π-electron.[15] Similar conclusion has been obtained for other compounds under consideration in the present study.[16] Thus it is legitimately assumed that the low lying electronic states for the molecular ions in the present investigation are those produced by loss of a π-electron.

In view of the results so far achieved, the experimental results of the present study can be explained by Q.E.T. mechanism as follows. According to the theory, the excited molecular ion produced by electron impact does not decompose immediately into the various fragment ions, but the excited molecular ion falls into its ground or low lying electronic states by radiationless transition in less than 10^{-8} sec. Then the molecular ion decomposes by unimolecular decomposition into fragment ions mentioned above, *i.e.*, $C_6H_4NH_2^+$ and X^+ in the case of aniline derivatives or $C_6H_4OCH_3^+$ and X^+ in the case of anisole derivatives. If these fragment ions are produced from the molecular ion in its electronic ground state, as is assumed in Q.E.T., close correlation would be expected between some of the characteristic quantities of the molecular ion in its electronic ground state and the ion intensity of fragment ions inferred to be produced from the ion. A molecular ion in its electronic ground state is produced when a frontier electron is lost by the molecule. Figures 2—7 illustrate simple relations between the partial bond order for the frontier electron and the summation of the intensity of the fragment ions concerning the bond, normalized by the total ion intensity, and show considerable parts of the fragment ions referred are produced by this mechanism.

In simple LCAO MO calculation, the following expression is derived for the energy E_i of the ith molecular orbital,[17]

$$E_i = \alpha + 2\sum P_j^i \beta$$

where P_j^i is the partial bond order of an electron in the

ith MO for the jth bond, α is the Coulomb integral and β is the resonance integral, respectively. One can see that the larger the value of P_j^i for an electron is, the more the electron contributes to the stabilization of the bond. When a molecular ion M^+ in its ground state decomposes into the fragment ions mentioned above by unimolecular decomposition, the larger the partial bond order between the aromatic moiety and the substituent X of the frontier electron removed from the molecule is, the more the strength of the bond decreases by the removal of the electron and the more easily the bond ruptures. The results shown in Figs. 2—7 can be explained qualitatively by the rationalization.

We have not considered on ortho effect in our calculation. If there are appreciable ortho effects, the points in Figs. 2 and 5 will not lie close to a straight line, because the ortho effects may be different as the substituents differ.

For m-compounds for aniline derivatives, the partial bond order for the frontier electron in the bond under consideration is very small (Table 1), and the influence of the loss of a frontier electron on the bond strength is considered to be very small, though a trend similar to Figs. 2 and 4 manifests itself as is seen in Fig. 3. For m-compounds, when log I is compared with the partial bond order for the second highest occupied molecular orbital P' instead of that for the highest occupied molecular orbital, a relation similar to Fig. 2 and Fig. 4 is obtained as is shown in Fig. 8, except for chloroaniline. From the result, the molecular ions in the state which corresponds to the loss of an electron in the second highest occupied orbital appear to be mainly responsible for the rupture of the bond under consideration in this case. For o-, p-compounds for

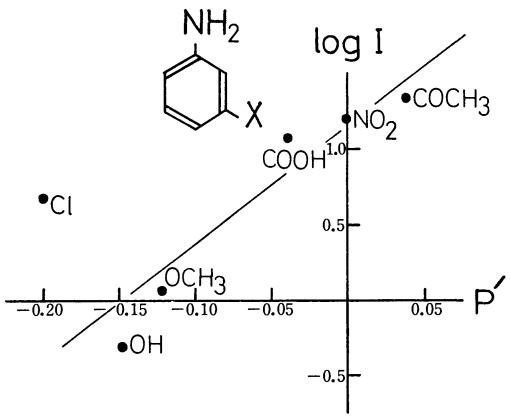

Fig. 8. log I *versus* partial bond order of an electron in the second highest occupied molecular orbital for m-aniline derivatives.

aniline derivatives, the partial bond order of the bond for the second highest occupied orbital is very small. For meta anisole derivatives, however, the loss of a frontier electron from the bond under consideration seems to decrease the stability of the bond more effectively than for meta aniline derivatives, since the partial bond order of the frontier electron in the m-compounds are larger for anisole derivatives than for aniline derivatives, as is seen in Table 1.

Studies on more numerous compounds are desirable, and a quantitative rationalization of the current phenomena and explanation for the abnormal behavior of m-chloroaniline, *etc.* deserve further investigation.

The authors wish to thank Dr. Akira Kuboyama of this Institute for his valuable discussions.

Purity Determination of Organic Compounds by a Newly Designed DTA Apparatus[1)]

Yo-ichiro MASHIKO, Takako SHINODA, and Hisae ENOKIDO*

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received May 21, 1970)

An apparatus of differential thermal analysis has been designed and constructed for the purpose of determining the purity of organic compounds with as small an amount of sample as possible, within a short time and yet with an accuracy of better than ±0.001 mol%. Degussa platinum thermometers were used. They were calibrated with a precision of better than ±0.004° against a standard platinum resistance thermometer. Methods for determining the impurities in samples on the basis of irreversible thermodynamics have been developed. The results were compared with those obtained by using an adiabatic calorimeter of our laboratory and by the National Bureau of Standards. The apparatus proved to be useful in determining the purity of about 1 m*l* of samples, whose melting points lie in the temperature range −200°C—+200°C within an accuracy of ±0.004 mol% in about 1.5 hr.

Differential thermal analysis (DTA) is widely used as a dynamic method of thermal analysis in various fields. However, in order to apply it to purity determination, the apparatus and procedure should be designed taking the following facts into consideration.

The accuracy of evaluation of impurities in the sample is dependent upon the precision of the thermometer. Thermocouples are used for DTA measurements, but it is difficult to calibrate them with a precision better than ±0.01°. In the DTA apparatus reported here, platinum thermometers calibrated against a standard platinum thermometer were employed. The temperature of the sample and the temperature difference between the sample and reference substance were recorded simultaneously as functions of time.

The DTA method is a dynamic one and the observed temperature is not measured at equilibrium. It is necessary therefore to analyze the resulting curves on the basis of irreversible thermodynamics instead of reversible thermodynamics.

Before testing the DTA apparatus with the NBS Standard Sample 217b 2,2,4-trimethylpentane, a comparison of the purity obtained by the NBS and that by our adiabatic calorimeter[2)] was made.

An extrapolation method as well as comparative methods for purity determination by the DTA measurements were developed.

Experimental

Apparatus. An apparatus was constructed to obtain DTA and total thermal analysis (TTA) curves simultaneously at temperatures from −200°C to 200°C. The cryostat of the apparatus was so designed that the amount of the sample can be as small as possible. The general assembly is illustrated in Fig. 1. A copper block A with two holes drilled symmetrically with respect to the center, is hung inside jacket E by means of three constantan cords. A heating wire is wound around A. In operation, the cryostat is sealed at the top plate F with Wood's metal or solder and mounted in a glass Dewar vessel containing coolant. All electric lead wires (#38 copper) come from the top of the cryostat through a stainless steel pipe at the center and are connected at the terminal D. They are then wound around A so as to secure good thermal contact. The inside of E is evacuated, and the cooling and heating rates are controlled by adjusting the amount of helium gas in it.

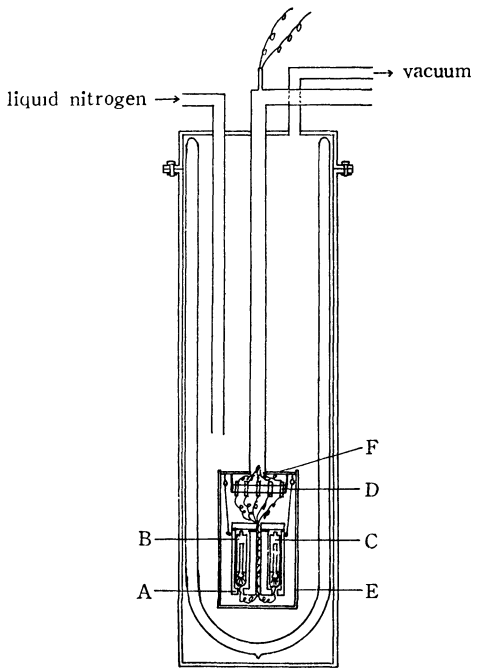

Fig. 1. Cross-section of the cryostat.
(A) copper block; (B) sample cell; (C) reference cell; (D) terminal of lead wires; (E) jacket; (F) top plate of the container

The details of sample or reference cell are shown in Fig. 2. Cell a is made of silver-plated copper (0.2 mm thick) with internal volume about 1 m*l*. Four vanes are soldered to the inside wall of the cell. The cap of the cell has a copper capillary tube c through which the inside can be evacuated. The platinum thermometer b is cast into a re-entrant well of the cell with indium alloy. Sample and reference cells, to which are attached silver-plated copper sheaths d, are set in the holes of A.

Since the cells are too small to fit standard platinum thermo-

meters, small platinum-in-glass thermometers (Degussa-Hanau Model P4) are employed. The Degussa thermometer was originally supplied with two nickel lead wires. It was modified by fixing four platinum lead wires instead of two nickel wires. The thermometers were then calibrated against a Leeds & Northrup platinum thermometer certified by the National Bureau of Standards. For the intercomparison of resistance values, two kinds of thermometers were cast with indium alloy into three re-entrant wells drilled in a copper block. The copper block was placed within an adiabatic shield of the adiabatic calorimeter assembly.[2] Some 50 comparisons of each Degussa thermometer with the standard thermometer were made in the temperature range from −180°C to 70°C under practically adiabatic conditions. Attempts were made to find coefficients which would fit the following formula separately in the temperature regions above and below 0°C to the observed resistance-temperature data for each Degussa thermometer.

$$R_t/R_0 = 1+\alpha t[1+\delta(1-t\cdot 10^{-2})10^{-2} + \beta t^2(1-t\gamma 10^{-2})10^{-6}] \quad (1)$$

Here t is the temperature in degrees Celsius, and R_t and R_0 are the resistances of the Degussa thermometer at t°C and 0°C, respectively. Coefficients determined are given in Table 1. Deviations of the observed resistances from the calculated resistances, obtained by means of Eq. (1) are within ±0.004° as shown in Fig. 3.

The temperature of a given sample and the difference in temperature between the sample and reference substance are simultaneously recorded on a Shimadzu Precision Recording Thermometer Type CT3 whose precision is 0.01° or 0.001° according to its two ranges.

Material. 2,2,4-trimethylpentane used in this experiment was the Standard Sample 217b which was purified and certified as 99.993±0.003 mol% by the National Bureau of Standards. Commercial 2,2,4-trimethylpentane and *n*-pentadecane of Extra Pure Grade were also obtained from Tokyo Kasei Kogyo Co., Ltd. α-Al_2O_3 which was supplied by Shimadzu Co. was used as a reference substance.

Results and Discussion

Principle of Purity Determination from the Freezing or Melting Point Measurement. For impurities that are completely soluble in the liquid phase but insoluble in the solid phase, a thermodynamic relation between the amount of impurities N in mole fraction and the equilibrium temperature T, for an ideal or sufficiently dilute solution, is given by

$$-\ln(1-N)/r = (T^*_{m0}-T)\Delta H_m/\boldsymbol{R}(T^*_{m0})^2 \quad (2)$$

where T_{m0} is the melting point of pure compound, r the fraction melted or crystallized, ΔH_m the heat of fusion at T_{m0} of the pure compound, and $\boldsymbol{R}$ the gas constant. When the temperature T given by a time-temperature curve is not measured at equilibrium, the equation for the amount of impurities should be derived from irreversible thermodynamics as follows[3]:

$$-\ln(1-N)/r = (\Delta H_m/\boldsymbol{R})(1/T-1/T_{m0}^*) + (\Delta C_p/\boldsymbol{R})[\ln(T_{m0}^*/T) + 1 - (T_{m0}^*/T)] + A(T,r)/\boldsymbol{RT}. \quad (3)[4]$$

Here ΔC_p denotes the difference of the heat capacity between liquid and solid state of a pure compound,

3) I. Prigogin and R. Defay, "Chemical Thermodynamics," Longmans, Green and Co., Ltd, (1954) p. 373.

4) For samples of purity above 99 mol% the approximate equation $-\ln(1-N)\simeq N$ may be used in Eqs. (2) and (3).

and $A(T, r)$ the affinity. The value of A changes as a function of given temperature or time. If A can be neglected, Eq. (3) is reduced to Eq. (2).

When $A=0$ for a specific sample, the values of temperature obtained and the fraction melted or crystallized can be used for the determination of purity by means of Eq. (2). Usually, it is however not possible to find the point at which $A=0$ in the time-temperature curve of DTA measurements. Attempts were made, therefore, to develop methods of evaluating the purity by means of Eq. (3) from the DTA and TTA curves. The methods are divided into two procedures as follows.

(a) Melting Point Depression Method Using Extrapolation: When the melting point (or freezing point[5]) of a pure compound T^*_{m0} and that of a given sample T^*_m at $r=1$ are known, it is possible to give the amount of impurities in the sample from the melting point depression $T^*_{m0}-T^*_m$. In the first place, the purity of NBS Standard Sample 217b 2,2,4-trimethylpentane was reexamined using the precision adiabatic calorimeter.[2] The result, $99.991_2\pm0.0014$ mol%, is in excellent agreement with the given purity, 99.993 ± 0.003 mol% by the NBS within probable error. The melting point T^*_{m0} of pure compound was found to be 165.821_5°K as shown in Fig. 4. Two measurements of

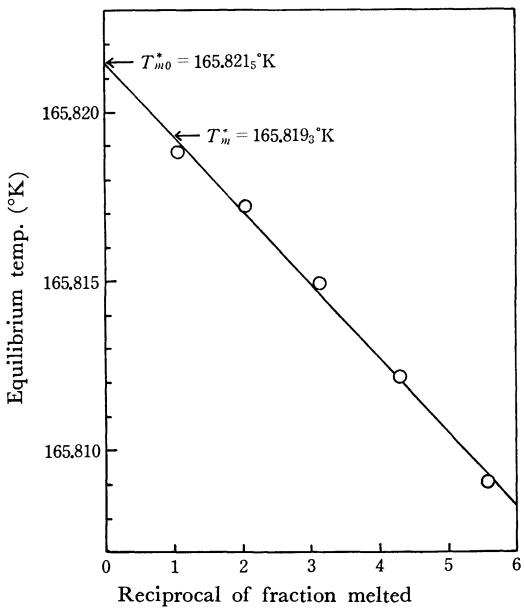

Fig. 4. Relationship between equilibrium temperatures and reciprocal of fraction melted for NBS Standard Sample 2,2,4-trimethylpentane.

TABLE 2. HEAT OF FUSION OF 2,2,4-TRIMETHYLPENTANE
mol wt 114.223; 0.208706 mol

Temperature Interval(°K)	Heat Input (cal/mol)	$\int C_p dT$ (cal/mol)	ΔH_m (cal/mol)
165.027–166.219	2285.8	86.4	2199.4
165.080–166.453	2296.8	98.6	2198.2
		average	2198.8±0.6

5) The melting point is exactly equal to the freezing point under an equilibrium condition.

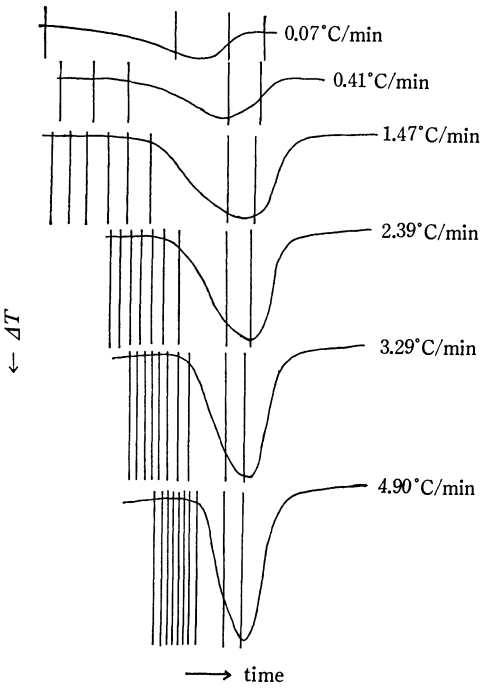

Fig. 5. DTA curves observed at various heating rates of commercial sample of 2,2,4-trimethylpentane.

the heat of fusion ΔH_m were also made, and the result is in good agreement with the literature value,[6] 2198 cal/mol, as summarized in Table 2.

DTA measurements at several heating rates were made using the NBS and commercial 2,2,4-trimethylpentane. Fig. 5 shows some examples of the DTA curves obtained.

As a matter of principle, the temperature at a peak maximum in a DTA curve obtained by this apparatus can be assumed to be equal to a quasi-melting point and depends upon the heating rate. The plots of temperatures at peak maxima (T_{max}) of DTA curve *versus* heating rates (a) for two samples of 2,2,4-trimethylpentane are shown in Fig. 6. Extrapolation of the curves obtained for two samples to $a=0$ gives the values of T_{max} $(a=0)$. We may assume that at T_{max} $(a=0)$ melting is complete under equilibrium condition, *viz.*, T_{max} $(a=0)$ agrees with the true melting point T^*_m of a given sample. We can then estimate the purity of sample by means of Eq. (2), where $r=1$ (complete melting) for T_{max} $(a=0)$. The values of T_{max} $(a=0)$ for the NBS and commercial samples were found to be 165.819°K and 165.334°K, and the purities 99.990 ± 0.004 mol% and 98.054 ± 0.004 mol%, respectively.

(b) Comparative Method: (i) If the affinity A in Eq. (3) at $T=T_{max}$ is denoted by A_{max}, it may be assumed that the value of A_{max} for the same material is dependent only upon heating rate a as shown in Fig. 6 for a highly purified sample. Since highly accurate result has been given for the purity of the NBS standard sample by adiabatic calorimetry, the value of A_{max} for 2,2,4-trimethylpentane can be calculated as a function of the heating rate by means of Eq. (3). The plotted result shows a smooth curve as in Fig. 7. The

6) American Petroleum Institute Research Project 6.

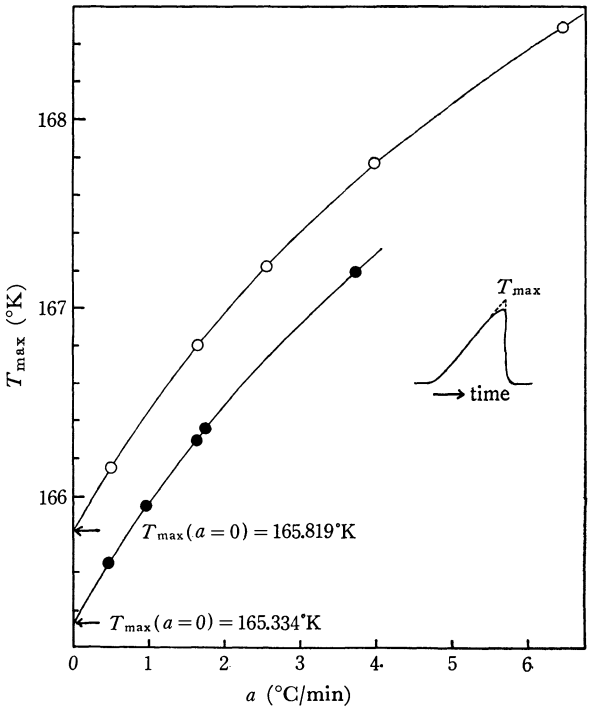

Fig. 6. Relationships between T_{max} and heating rate a for two samples of 2,2,4-trimethylpentane of different purity.
○ NBS sample ● commercial sample

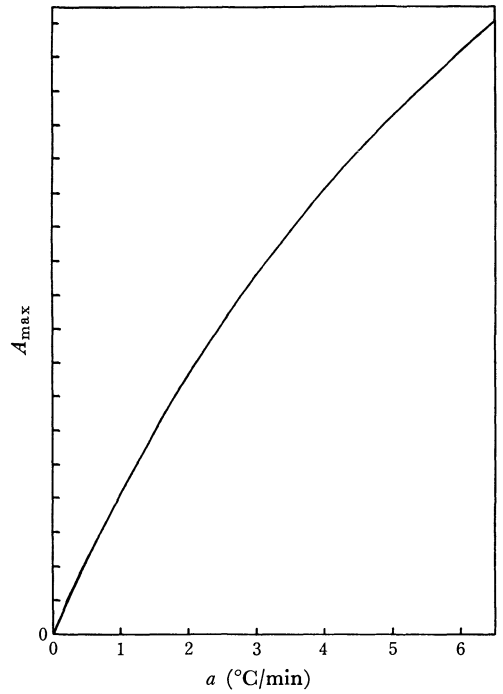

Fig. 7. Relationship between A_{max} and heating rate a for 2,2,4-trimethylpentane.

figure obtained on the NBS sample can be assumed to be applicable to the commercial sample, since the purity difference between the samples is small. Thus, from the values of T_{max} for the commercial sample observed at five different heating rates and the values of A_{max} obtained from the graph of A_{max} *versus* a of Fig. 7, the purity of the commercial sample was calculated by means of Eq. (3). The results are summarized in Table 3, and are in good agreement with that obtained by the melting point depression method (Fig. 6).

TABLE 3. RESULTS OF PURITY DETERMINATION BY COMPARATIVE METHOD (i) FROM THE DATA OBTAINED AT FIVE DIFFERENT HEATING RATES FOR COMMERCIAL SAMPLE OF 2,2,4-TRIMETHYLPENTANE

a (°C/min)	T_{max} (°K)	A_{max}/R	N (mol%)
0.47_2	165.644	2.068	98.05_4
0.96_8	165.949	4.111	98.05_4
1.61_1	166.295	6.443	98.04_8
1.73_7	166.354	6.830	98.05_0
3.72_1	167.193	12.459	98.05_6
		average	$98.05_2 \pm 0.004$

(ii) Indices 1 and 2 will be used in the following to denote two samples of different purity for DTA measurement. We will compare the purities at $T_1 = T_2 = T_{2,max}$ ($r_2 = 1$) with a fixed heating rate (a=const.). Then from Eq. (3) we obtain the relation

$$-\ln(1-N_1)/r_1 + \ln(1-N_2)/r_2 = (1/T_{2,max})(1/R)(A_1 - A_2), \quad (4)$$

where r_1 is the fraction melted at $T_1 = T_{2,max}$ for sample 1. In principle, a peak area of a DTA curve is proportional to the heat of fusion of the compound.[7] We can thus estimate the value of r by making use of the ratio of the peak area against time, *i.e.*, the value of $r(t')$ at time $t=t'$ is given by

$$r(t') = \left[\int_{t_i}^{t'} (y-y_s)dt + \int_{t''}^{t_f} (y-y_s)dt\right] \Big/ \left[\int_{t_i}^{t_f} (y-y_s)dt\right] \quad (5)$$

Here t_i and t_f are the times at which melting begins and finishes, t'' the time when $y=y(t')$ after the peak maximum, and y_s a steady state value of the differential temperature. Thus, if the amount of impurities N_1 for sample 1 is known, and the values of r_1, A_1, and A_2 ($=A_{max}$) in Eq. (4) are obtained from the $1/r_1$—$1/T$ relation, Eq. (3) and Fig. 7, respectively, then the amount of impurities N_2 for sample 2 can be calculated by means of Eq. (4). Here, sample 1 must be a substance with higher purity than the sample 2 ($N_1 < N_2$).

We employed the NBS and commercial 2,2,4-trimethylpentane as samples 1 and 2. Comparison of DTA data was made at the heating rate of 1.64_5°C/min for the NBS sample and 1.61_1°C/min for the commercial sample. The purity of the commercial sample was 98.04_8 mol% which is in good agreement with those obtained previously. Though the heating rates were adjusted to be as close as possible, it was difficult to obtain exactly the same heating rate for both samples. Method (ii) is therefore inferior to method (i) in accuracy.

Conventional Melting Point Method. In a melting curve the temperature which is given by the intersection of an extrapolated solid warming line with the extended backward liquid warming line, as shown in

7) M. J. Vold, *Anal. Chem.*, **21**, 683 (1949).

Fig. 8, has been regarded as an equilibrium point ($A=0$) of the melting curve.[8] The behavior of affinity A during the melting was investigated on two samples of 2,2,4-trimethylpentane to check whether $A=0$ is actually established at this point. Fig. 9 shows plots of A *versus* $1/r$ obtained from the peak area for the NBS and commercial samples. It is seen in Fig. 9 that an equilibrium point ($A=0$) not always realized in the melting curve, and the plots of the two samples differ largely in the $1/r<2$ region but are in agreement in the $1/r<2$ region. Although it is thought that the point of half melting ($1/r=2$) is mostly at equilibrium during the melting, the closest points to equilibrium for the NBS and commercial samples give the values of 2.13 and 1.65 for $1/r$, respectively, as shown in Fig. 9. It is therefore concluded that the well-known method of thermal analysis shown in Fig. 8 can not give a highly accurate result. It is desirable to make use of the comparative methods described previously in the region of the melting curve where $1/r<2$.

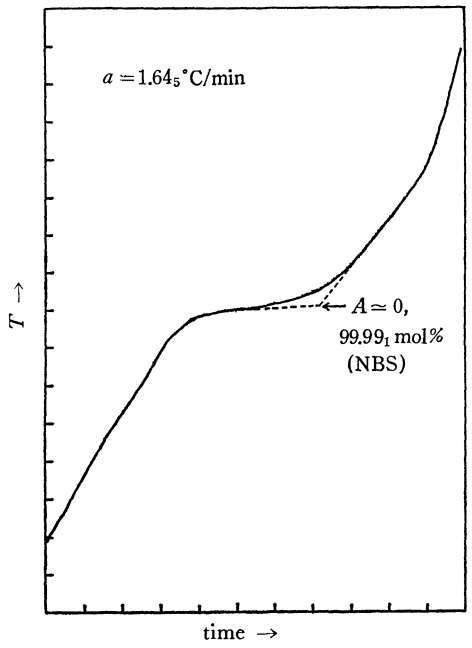

Fig. 8. Time-temperature melting curve for NBS sample of 2,2,4-trimethylpentane.

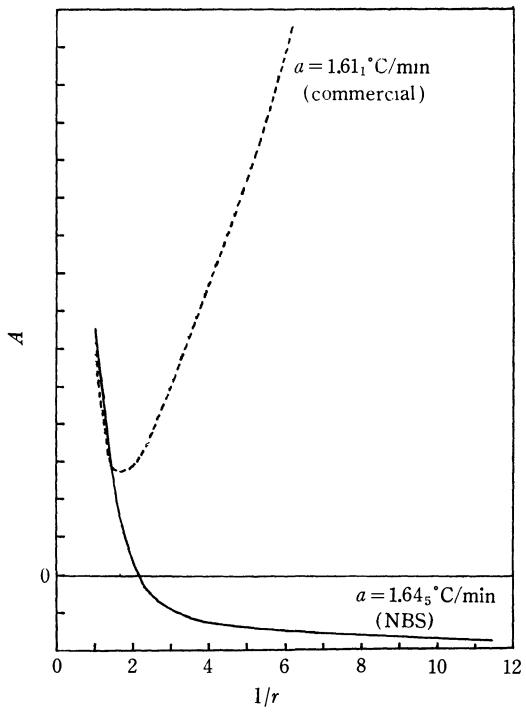

Fig. 9. Relationships between affinity A and reciprocal of fraction melted $1/r$ for NBS and commercial samples of 2,2,4-trimethylpentane.

The purity of two samples of 2,2,4-trimethylpentane determined by the methods described above are summarized in Table 4.

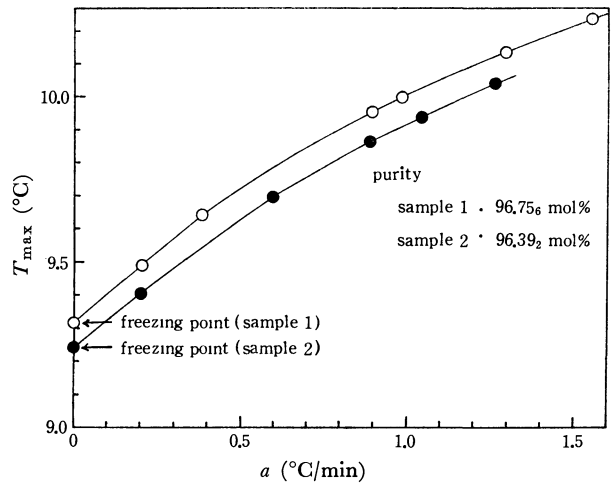

Fig. 11. Relationships between T_{max} and heating rate a for two samples of *n*-pentadecane of different purity.

Freezing DTA Measurement. The DTA data for two commercial *n*-pentadecane samples of different purity are given in Fig. 10. The freezing points of the samples were obtained by the well-known method[7] from the time-temperature cooling curves. The T_{max} ($a=0$) of the samples was obtained by the melting point depression method using extrapolation, as shown in Fig. 11. T_{max} ($a=0$) values are in excellent agreement with freezing points obtained from the freezing curves, and give the purity of each sample in terms of Eq. (2), as given in Fig. 11.

It can therefore be pointed out that when the sample is successfully supercooled, the freezing point obtained from the cooling curve is nearly at a temperature under equilibrium condition.

The authors wish to thank Dr. W. Wayne Meinke of the National Bureau of Standards for the supply of the Standard Sample 217b 2,2,4-trimethylpentane.

Brönsted and Lewis Acidity of Solid Nickel Sulfate

Hideshi HATTORI, Shun-itsu MIYASHITA, and Kozo TANABE
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received June 2, 1970)

The distribution of Brönsted and Lewis acidities of nickel sulfates heat-treated at various temperatures in air or in a vacuum has been determined by observing the infrared spectra of pyridine adsorbed on the sulfates in the range 1300—1600 cm^{-1}. It has been found that the Brönsted acidity increases with the rise of temperature of heat treatment in air, attains a maximum value at 250°C and then decreases, while the maximum of the Lewis acidity appears at a higher temperature (about 400°C), the sum of both acidities giving the total acidity measured by *n*-butylamine titration method. An experiment in a vacuum showed that Lewis acid is converted into Brönsted acid by the addition of water. The structural nature and the catalytic activity of the Brönsted and Lewis acid sites on nickel sulfate are discussed.

Solid nickel sulfate shows remarkable acidic property on being subjected to heat treatment[1] and is used as a new type of effective catalysts in a number of acid-catalyzed reactions.[2] It was found that the total acidity[3] (Brönsted plus Lewis acidity) of the sulfate heat-treated at various temperatures measured by *n*-butylamine titration method correlates well with the catalytic activity of the depolymerization of paraldehyde,[1] polymerization of propylene[4] and aldehydes,[5] hydration of propylene,[6] exchange reaction of chlorine between benzyl chloride and hydrogen chloride,[7] *etc.* However, no good correlation was found for the isomerization of α-pinene[8] and the hydrolysis of methylene chloride.[9] This was tentatively interpreted as due to the fact that isomerization depends on Brönsted acidity and hydrolysis on Lewis acidity,[2] on the basis of the structural study of acid sites.[10] However, since we have no experimental evidence for each type of acid site, we have attempted to measure Brönsted and Lewis acidities separately, by employing the infrared spectroscopic method[11] of pyridine adsorbed on the solid acid catalyst. The results are discussed in connection with the nature and the activity of acid sites of nickel sulfate catalyst.

Experimental

Infrared spectra of adsorbed pyridine were measured for nickel sulfate heat-treated in air or in a vacuum *in situ* cell. Heptahydrate of nickel sulfate was heat-treated in a glass

tube at various temperatures in the range 200—500°C for 3 hr in air and the glass tube was sealed off. Immediately after the tube was opened, it was connected to vacuum apparatus and evacuated to 10^{-6} mmHg for 30 min at room temperature and then pyridine (about 2 mmHg) was introduced and adsorbed for 10 min. After removing excess pyridine by evacuating for 30 min at room temperature, 5 mg of the sample was mixed with 200 mg of KBr powder and pressed into a tablet 12 mm in diameter by means of a pressure approximately 3000 kg/cm^2. The spectrum range in the 1300—1700 cm^{-1} was observed with an infrared spectrophotometer (Hitachi EPI-2).

In an *in situ* cell experiment, nickel sulfate mounted on silica gel (35 wt% as anhydride) was used. The sample discs were placed in the cell and heat-treated at various temperatures in a vacuum for 3 hr. After cooling to room temperature, pyridine (about 2 mmHg) was introduced and adsorbed for 15 min. After evacuation for 30 min at 50°C and further evacuation for 30 min at 100°C, the spectra were recorded on a Hitachi EPI-G2 double beam grating spectrophotometer. In some experiments, the effect of water on the spectrum of chemisorbed pyridine was examined to see whether Lewis acid can be converted into a Brönsted one. Weight loss of heptahydrate of nickel sulfate by dehydration in air or in a vacuum with the rise of temperature of heat treatment was also measured by weighing the samples treated for 3 hr at various temperatures.

Pyridine was purified by dehydration over molecular sieve 4A and by distillation in a vacuum. Heptahydrate of nickel sulfate was a guaranteed reagent of Kanto Chemical Co. Tokyo. Silica gel used was prepared by the hydrolysis of ethylorthosilicate, which had little acidity on the surface.

Results and Discussion

The spectra of pyridine adsorbed on nickel sulfate heat-treated at various temperatures in air are shown in Fig. 1, where two main absorption bands (1520 and 1425 cm^{-1}) are observed. Since the band of higher frequency disappears when the sample was heat-treated at 350°C, while the band of lower frequency still remains even by heat treatment at 450°C, both the bands seem to be those of different species of adsorbed pyridine. It is known that the band of coordinately bonded pyridine appears at 1445—1460 cm^{-1} on the surface of η-alumina,[11] silica-alumina,[11,12] and cation exchanged zeolites,[13–15] while the band of pyridinium ion or salts at 1530—1540 cm^{-1} on silica-alumina,[11,12] cation exchanged zeolites[13–15] or in various pyridine complexes.[16] Therefore, the band near 1520 cm^{-1} in Fig. 1 has been assigned to the band due to pyridinium ion and that at 1425 cm^{-1} due to coordinately bonded pyridine. Since the acid strength of the sulfate is lower than those of the solid acids mentioned above,[2] and it is known that the band of pyridine adsorbed on weaker acid site appears at lower frequency,[15] it seems likely that the species responsible for the bands at 1520 and 1425 cm^{-1} were adsorbed on much weaker Brönsted and Lewis acids respectively. Thus, the bands at 1520 and 1425 cm^{-1} in Fig. 1 can be respectively taken as those corresponding to Brönsted and Lewis acid. Figure 2 shows the changes in intensities of these two bands with change of temperature of heat treatment. It is seen that Brönsted acidity shows its maximum when the sample was heat-treated at 250°C, whereas Lewis acidity attains its maximum at about 400°C.

served for the samples heat-treated in air, though both spectra are essentially the same. The difference is considered due to the fact that the absorption bands of pyridine[11] adsorbed on silica which was used as a carrier in a vacuum experiment are superposed near 1600 cm^{-1} and 1440 cm^{-1}. Thus, the bands at 1490—1550 cm^{-1} become broader and those at 1440 cm^{-1} become sharper in the case of vacuum experiment (Fig. 3). The bands at 1490—1550 cm^{-1} for the samples heat-treated at 150°C seem to be large compared with those at 200°C (compare b and c with e and f in Fig. 3; the relative strength of the absorption at 1490—1540 cm^{-1} to that at 1440 cm^{-1} is larger for the samples heat-treated at 150°C than for those at 200°C). This indicates that Brönsted acidity decreases with the rise of temperature of heat treatment from 150 to 200°C in a vacuum. Dehydration curves in air and in a vacuum shown in Fig. 4 reveal that the temperature of heat treatment required for a definite extent of dehydration is about 100°C lower in a vacuum than in air. Thus, Brönsted acidity is expected to show its maximum value when heat-treated at about 150°C in a vacuum. The addition of water resulted in a decrease in the intensities of the 1440 cm^{-1} band and in a slight increase in the intensities of the 1490—1550 cm^{-1} band (Fig. 3, curves f and g). This indicates that Lewis acid is converted into Brönsted acid to some extent by the addition of water.

We shall now give some explanation on the Brönsted and Lewis acidity curves in Fig. 2, by taking into account the structural nature of acid sites of nickel sulfate. According to our studies with infrared, X-ray, electron spin resonance, *etc.*,[10] the acid center of nickel sulfate is considered to be an empty orbital on the nickel ion which appears in an incompletely dehydrated, metastable transition structure. Intermediate configuration is formed between the monohydrate and anhydrous form. The vacant orbital, and the resulting affinity for an electron pair, explains the Lewis acid nature of nickel sulfate. The Brönsted acidity arises from two sources. One is the water coordinated directly with a nickel ion. The nickel ion tends to attract the oxygen atom, thus setting a hydrogen ion free. The other is the surface water acidified by the inductive effect of neighboring cationic Lewis acid centers. Thus, Brönsted acid appears when the vacant orbital of nickel ion is formed by dehydration and its acidity increases with the rise of dehydration temperature. However, since the amount of hydrated water decreases as the temperature of heat treatment is increased, the Brönsted acidity begins to decrease at 250°C (Fig. 2). The Lewis acidity also increases with the rise of dehydration temperature, but does not decrease until the metastable structure having the vacant orbital collapses and changes to a stable structure at 450°C. Therefore, the maximum of Brönsted acidity appears at a lower temperature (250°C) and that of Lewis acidity at a higher temperature (400°C). The sum of both acidity curves gives the total acidity which was measured by *n*-butylamine titration method[1] (Fig. 2).

We reported that the rate maxima of the isomerization of α-pinene to camphene[8] and the formation of formaldehyde by the hydrolysis of methylene chloride[9] with nickel sulfates heat-treated in air at various temperatures were observed respectively at 250°C and 400°C, which do not coincide with the maximum of total acidity measured by *n*-butylamine titration method. The rate maxima coincide respectively with the maxima of Brönsted and Lewis acidity observed in the present experiment, and the activity curves for isomerization and hydrolysis plotted against the temperature of heat treatment of nickel sulfate correlate well with Brönsted and Lewis acidity curves shown in Fig. 2. This confirms our conclusions[2,9] that the isomerization of α-pinene is catalyzed by Brönsted acid, and the hydrolysis of methylene chloride by Lewis acid.

Group Interactions in Polyelectrolytes. V. The Kinetics of the Amination of Chloromethylated Polystyrene with 2-Aminobutanol

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received August 7, 1970)

The amination of chloromethylated polystyrene with 2-aminobutanol in dioxane was studied. The apparent rate constatns, k_{app}, as computed by the simple second-order equation, were found to increase linearly with the degree of amination; this was in contrast with the amination with *n*-butylamine, in which the k_{app} decreased as the amination proceeded. By assuming that the reactivity of the chloromethyl group is enhanced when it is situated next to the already-aminated group as a result of the "hydrophilic effect" of the hydroxyl group, rate equations which give the elementary rate constants were derived. In the presence of a large excess of amine, the over-all kinetics can be expressed by:

$$dx/dt = [ab/(3k_1-k_2)][3k_1(k_1-k_2)e^{-3k_1at} + 2k_1k_2e^{-k_2at}]$$

where x is the concentration of chloride ions at time t; where a is the initial concentration of amine, and b, that of the chloromethyl group, and where k_1 and k_2 are the rate constants of the elementary reactions which are independent of the neighboring group and under the influence of it respectively. The values of k_{app} calculated on the basis of k_1 and k_2 were also found to agree with the observed values.

Amination kinetics of chloromethylated polystyrene with *n*-butylamine or di-*n*-butylamine in dioxane was reported previously.[1] The apparent rate constant, as calculated by the simple second-order rate equation, k_{app}, decreased as the amination proceeded. The results were interpreted in terms of the two-step amination resulting from the steric effect of already-aminated neighboring groups, and the over-all kinetics in the presence of a large excess of amine could be expressed by an equation containing two rate constants.

In the present study, the amination of chloromethylated polystyrene with 2-aminobutanol has been carried out in dioxane, and k_{app} has been found to increase linearly with the degree of amination. The difference between the kinetic behavior in the amination of chloromethylated polystyrene with *n*-butylamine and with 2-aminobutanol is considered to arise from the different position of the amino group in the amines and the presence of the hydroxyl group in 2-aminobutanol. Analysis of the experimental data reveals that the amination proceeds in two steps. Rate equations for this reaction are derived on the basis of the kinetic data.

Experimental

Materials. Polystyrene and chloromethylated polystyrene were prepared by the procedure described in the previous paper;[1] their molecular weights were determined, by means of osmometry in toluene, to be 5.44×10^4 and 7.33×10^4 respectively. These results indicate that neither cross-linking nor degradation of the polymer occurred in the chloromethylation process. The chlorine content of the chloromethylated polystyrene, which was purified by reprecipitation with dioxane and methanol, was 22.87%, corresponding to the degree of chloromethylation of 97.8%. (−)-2-aminobutanol was prepared from its tartaric acid salt by the use of an ion-exchange resin column (Dowex-50, X-8, 20—50 mesh) according to the procedure reported by Tsuboyama *et al.*[2] It had a bp of 86—87°C/15 mmHg; n^{20} 1.4532; $[\alpha]_D^{20}$ −10.23. All the other chemicals were of a reagent grade, and de-ionized, de-carbonized water was used throughout the experiments.

Kinetic Measurement of the Amination. Fifty milliliters of a dioxane solution containing one gram of chloromethylated polystyrene, benzyl chloride, or ethylene bromide was throughly mixed with 100 m*l* of a dioxane solution containing a large excess of 2-aminobutanol (about twenty times as many moles as the chloromethyl group). The solution thus obtained was stirred during the reaction, and its temperature was maintained within ±0.1°C by means of a thermostat. Throughout the reaction, the system was kept homogeneous. At appropriate intervals, aliquots were taken out; each of them was poured into dilute nitric acid and titrated potentiometrically with 0.1 N silver nitrate. The experimental conditions are listed in Table 1.

given by the second-order equation:

$$k = \frac{1}{(a-b)t} \ln \frac{b(a-x)}{a(b-x)} \quad (1)$$

where a is the initial concentration of the amine and b, that of benzyl chloride, while x is the concentration of chloride ions at time t. Although chloromethylated polystyrene was also quantitatively aminated with 2-aminobutanol in dioxane without any separation of the polymer, the rate constant computed by Eq. (1) increased as the reaction proceeded. The experimental results are summarized in Figs. 1 and 2, where t is the time and $\overline{kt}$ is the term defined as follows:

$$\overline{kt} \equiv \frac{1}{a-b} \ln \frac{b(a-x)}{a(b-x)} \quad (2)$$

In the case of benzyl chloride (Fig. 1), the plot of $\overline{kt}$ against t is represented by a single line, while in the case of chloromethylated polystyrene (Fig. 2), the plot is divided into two lines which intersect at one-third of the amination. These results may be explained by assuming that the chloromethyl group of the polymer

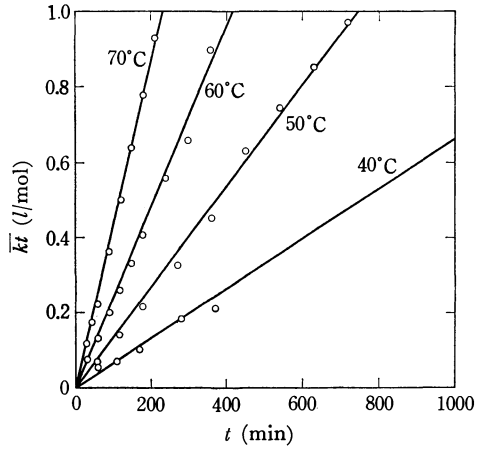

Fig. 1. Amination of benzyl chloride.

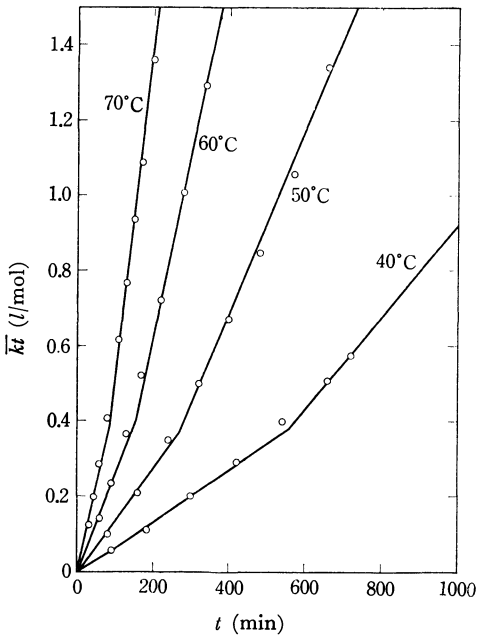

Fig. 2. Amination of chloromethylated polystyrene.

is aminated at a normal rate unless its neighboring group is changed, while the amination is accelerated when one of the nearest-neighbors is aminated. This assumption is partly supported by the amination of ethylene bromide shown in Fig. 3, where $\beta(=x/b)$

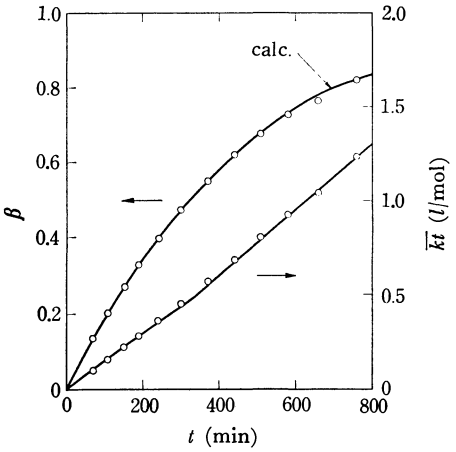

Fig. 3. Amination of ethylene bromide.

denotes the degree of amination. Acceleration, as expected, is observed in this reaction, though it is not very remarkable and the $\overline{kt}$ *vs.* t plot intersects nearly at half-amination. These results are in contrast with those of the amination of ethylene bromide with *n*-butylamine and di-*n*-butylamine, which is controlled by a single rate constant.[1)]

Sakurada[3)] reported that the rate of the alkaline hydrolysis of polyvinyl acetate in an aqueous acetone solution increased as indicated in the following relation:

$$dx/dt = k_0(1 + m\beta)(a - x)(b - x) \quad (3)$$

where k_0 and m are constants and where $\beta=x/b$. On the other hand, we may express the rate of bimolecular polymer reaction by:

$$dx/dt = k_{app}(a - x)(b - x) \quad (4)$$

where k_{app} is the apparent rate constant. On the basis of Eqs. (3) and (4), we obtain the relation:

$$k_{app} = k_0(1 + m\beta) \quad (5)$$

which means that k_{app} is a linear function of β.

The above relation has also been found in the present study to be applicable to the amination of chloromethylated polystyrene, as is shown in Fig. 4. The values of k_0 and m thus determined are listed in Table 2. Although k_0 increases with an increase in the tem-

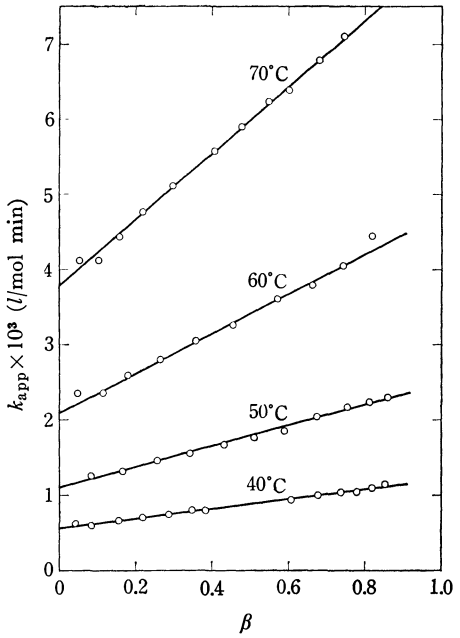

Fig. 4. Dependence of apparent rate constant on fractional conversion in the amination of chloromethylated polystyrene.

perature, m has an almost constant value irrespective of the temperature. It is interesting that these different kinds of reaction can be expressed by such a simple linear relation. It should be noted that k_{app} in the amination with n-butylamine or di-n-butylamine is not a linear function of β, but decreases markedly beyond half-amination.

Sakurada[3] ascribed the acceleration of the alkaline hydrolysis of polyvinyl acetate to the adsorption of alkali by the hydroxyl group formed in the polymer. He suggested the designation of "hydrophilic effect" for this phenomenon. It also seems possible that aminated groups in chloromethylated polystyrene adsorb 2-aminobutanol in dioxane because of the hydroxyl groups.

Rate Equations

The amination of chloromethylated polystyrene, as described in the preceding section, is a two-step reaction composed of two elementary reactions, one of which is independent of the neighbors and the other of which is accelerated by the neighboring aminated group. The rate equations for this reaction are derived on the model of low-molecular compounds to be described below.

Bifunctional Compound Model (Model I). The rate equation for a bifunctional compound, whose reactivity alters when one of the groups is changed, has previously been described.[1] It is given by:

$$dx/dt = (a-x)[k_1 b - 2(k_2 - k_1)x_1 - k_2 x] \quad (6)$$

$$k_1 = \frac{1}{[(2 - k_2/k_1)a - b]t} \ln \frac{1-\alpha}{1-(2-k_2/k_1)\beta} \quad (7)$$

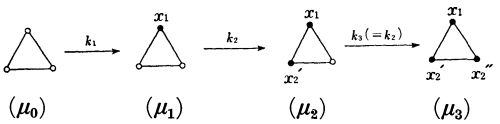
$$k_2 = \frac{1}{(a-b)(t-\tau)}\left(\ln \frac{1-\alpha}{1-\beta} - \ln \frac{1-\chi/a}{1-\chi/b}\right) \quad (8)$$

where x_1 is the concentration of the first changed group; τ and χ are the values of t and x when $x_1 \simeq b/2$; $\alpha = x/a$ and $\beta = x/b$. When a large excess of a reagent is used ($a \gg b$), the over-all kinetics is expressed by this equation:

$$\beta = 1 - \frac{k_1 - k_2}{2k_1 - k_2} e^{-2k_1 at} - \frac{k_1}{2k_1 - k_2} e^{-k_2 at} \quad (9)$$

The amination of ethylene bromide can properly be expressed by this equation. These rate equations were found to be useful in describing the amination kinetics of chloromethylated polystyrene with n-butylamine or di-n-butylamine, in which the amination of a chloromethyl group placed between two already-aminated neighbors is sterically hindered and the $\overline{kt}$ *vs.* t plot is divided into two lines intersecting nearly at $\beta = 0.5$.[1]

Trifunctional Cyclic Compound Model (Model II). In the reaction of chloromethylated polystyrene with 2-aminobutanol, in which the intersection lies nearly at $\beta = 1/3$, the amination of a chloromethyl group is assumed to be accelerated when one of its neighbors is aminated. Accordingly, the chloromethyl groups may be classified into three groups depending upon their environment; one is situated between unchanged neighbors, another is situated next to an aminated neighbor, while a third is situated between two aminated neighbors. In this case, the trifunctional cyclic compound model, shown below, is considered to be more suitable than Model I:



In the above figure illustrating the reaction of a trifunctional compound and a reagent, the white circles represent unchanged groups, and the black circles, changed groups. The relationships among the concentrations are:

$$\mu_0 = M - x_1 = (b/3) - x_1 \quad (10)$$

$$\mu_1 = x_1 - x_2, \ \mu_2 = x'_2 - x_2'' \quad (11)$$

$$x = x_1 + x_2, \ x_2 = x_2' + x_2'' \quad (12)$$

where M is the initial concentration of the compound and b, that of the reactive group of the compound; $\mu_n (n=0, 1, 2, \text{and } 3)$ is the concentration of the compound, n groups of which are changed at time t; x_1, x_2', and x_2'' are the concentrations of the first, secondary and last changed group respectively at time t. Since only two steps are observed in the amination of chloromethylated polystyrene with 2-aminobutanol, k_3 is simply assumed to be equal to k_2 in this case.

The over-all rate of the above reaction with the two rate constants of k_1 and k_2 is given by:

$$dx/dt = (a-x)[3k_1\mu_0 + k_2(2\mu_1 + \mu_2)]$$
$$= (a-x)[k_1 b - 3(k_1 - k_2)x_1 - k_2 x] \quad (13)$$

where a is the initial concentration of a reagent. On the assumption that $x \simeq x_1$ in the initial stage of reaction ($\beta < 1/3$) and that $x_1 \simeq b/3$ in the final stage ($\beta > 1/3$), the integration of Eq. (13) yields:

$$k_1 = \frac{1}{[(3 - 2k_2/k_1)a - b]t} \ln \frac{1-\alpha}{1-(3-2k_2/k_1)\beta} \quad (14)$$

$$k_2 = \frac{1}{(a-b)(t-\tau')}\left[\ln\frac{1-\alpha}{1-\beta} - \ln\frac{1-\chi'/a}{1-\chi'/b}\right] \quad (15)$$

where τ' is a time when $x_1 \simeq b/3$ and χ' is a value of x at this time. When a large excess of reagent is used ($a \gg b$), the term ($a-x$) in Eq. (13) can be replaced by a, and x_1 is given by:

$$x_1 = b(1 - e^{-3k_1 at})/3 \quad (16)$$

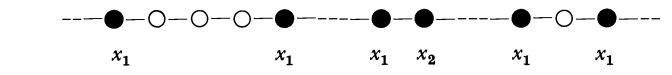
Hence, by integrating Eq. (13), we obtain;

$$x = b\left[1 - \frac{k_1 - k_2}{3k_1 - k_2}e^{-3k_1 at} - \frac{2k_1}{3k_1 - k_2}e^{-k_2 at}\right] \quad (17)$$

and the over-all rate is given by:

$$dx/dt = \frac{ab}{2k_1 - k_2}[2k_1(k_1 - k_2)e^{-2k_1 at} + k_1 k_2 e^{-k_2 at}] \quad (18)$$

Equations (14) and (15) can also be derived by considering the polymer reaction itself. The relative position of changed groups on a polymer molecule may be illustrated as follows:



Two groups may be situated independently (I), side by side (II), or with an unchanged group between them (III). In the initial stage of the reaction, the situation [III] can be neglected; the rate is then given by:

$$dx/dt = dx_1/dt + dx_2/dt$$
$$= (a-x)[k_1\{(b-x) - 2x_1\} + 2k_2 x_1] \quad (19)$$

On the assumption that $x \simeq x_1$ in the initial stage, we obtain;

$$dx/dt = (a-x)[k_1 b - (3k_1 - 2k_2)x] \quad (20)$$

In the final stage of the reaction, only reactive groups next to the changed group are left and the rate is given by:

$$dx/dt = k_2(a-x)(b-x) \quad (21)$$

By integrating Eqs. (20) and (21), we obtain Eqs. (14) and (15) respectively.

Discussion

The rate constants of the amination of ethylene bromide at 70°C were calculated on the basis of Eqs. (7) and (8) for Model I (bifunctional compound model) to give $k_1 = 1.39 \times 10^{-3}$ ($k_1' = 1.45 \times 10^{-3}$) and $k_2 = 1.91 \times 10^{-3}$ l/mol min respectively; k_1' is an approximate value of k_1 which is obtained from the slope of the $\overline{kt}$ *vs.* t plot according to:

$$k_1' = \Delta\overline{kt}/\Delta t \quad (22)$$

The values of β calculated on the basis of Eq. (9) by using the above values of k_1 and k_2 are plotted against t in Fig. 3, in which a solid line show this calculated plot. The experimental values, which are represented by white circles, fall excellently on this plot.

In the case of chloromethylated polystyrene, the rate constants were calculated on the basis of Eqs. (7) and (8), on the one side, and on the basis of Eqs. (14) and (15) for Model II (the trifunctional compound model), on the other side. The results are summarized in Table 3, where the rate constants of benzyl chloride are also listed. The over-all kinetics expressed by Eq. (9) for Model I and by Eq. (17) for Model II were evaluated by using the respective values of k_1 and k_2. In Fig. 5, the broken and solid lines are the calculated plots for Model I and II respectively, and the white circles represent observed values. The agreement of the calculated and observed values are not so excellent as in the case of ethylene bromide, though Model II expresses the experimental results more closely than does Model I.

---- calculated for Model I
—— calculated for Model II
○ observed values

Equation (6) for Model I can be expressed in the form of Eq. (3) as follows:

$$dx/dt = k_1\left[1 + (k_2/k_1 - 1)\left(\frac{2\beta_1/\beta - 1}{1-\beta}\right)\beta\right](a-x)(b-x)) \quad (23)$$

where β_1 is given by the following equation when $a \gg b$:

$$\beta_1 = x_1/b = (1 - e^{-2k_1 at})/2 \quad (24)$$

By comparing Eqs. (23) with (4), we obtain:

$$k_{app}/k_1 = 1 + (k_2/k_1 - 1)(2\beta_1 - \beta)/(1-\beta) \quad (25)$$

Equation (13) for Model II can also be transformed to:

$$dx/dt = k_1\left[1 + (k_2/k_1 - 1)\left(\frac{3\beta_1/\beta - 1}{1-\beta}\right)\beta\right] \quad (26)$$

and:

$$k_{app}/k_1 = 1 + (k_2/k_1 - 1)(3\beta_1 - \beta)/(1 - \beta) \quad (27)$$

where β_1 is given by Eq. (16) when $a \gg b$.

The value of k_{app} at a given time can be calculated as a function of k_1, k_2, and t on the basis of Eqs. (25) and (27) respectively; the calculated values are compared with the observed values in Fig. 6. The agreement of the two sets of values is better in Model II than in Model I.

On the other hand, k_{app}/k_1 in Eqs. (25) and (27) has the same meaning as k_{app}/k_0 in Eq. (5), since the values of k_0 and k_1 are almost the same, as is shown in Tables 2 and 3. The plots of k_{app}/k_0 against β for Model I, Model II, and the original data are shown in Fig. 7. The plot for Model II is closer to the observed one than is that for Model I.

It may be concluded, on the basis of the facts to be summarized below, that Model II is better for such a self-accelerated reaction as that shown in the present study: (i) the intersection in the $\overline{kt}$ *vs.* t plot lies near $\beta=1/3$; (ii) the amination of ethylene bromide is also self-accelerated; (iii) the rate equations for Model II which give k_1 and k_2 can be derived in terms of the polymer reaction; (iv) the calculated plot of β *vs.* t for Model II is closer to the observed one than is that for Model I, and (v) the k_{app} values calculated for Model II are almost the same as the observed values.

The Arrhenius plots of the rate constants listed in Table 3 are shown in Fig. 8, where the plot for k_1 is the one calculated on the basis of Model II. The values of E_a, the activation energy, which were calculated by the least-squares method, are listed in Table 4, where the mean values of A, the frequency factor, have been computed by means of:

$$k = A\exp(-E_a/\boldsymbol{R}T)\ l/\text{mol min}$$

In the table are also listed the mean value of $\Delta S_0^{\neq}$, the entropy of activation, which was calculated by:

$$A/60 = e(\boldsymbol{k}T/\boldsymbol{h})\exp(\Delta S_0^{\neq}/\boldsymbol{R})$$

TABLE 4. ACTIVATION ENERGIES, FREQUENCY FACTORS, AND ACTIVATION ENTROPIES OF AMINATION

Halide	Amine		E_a kcal/mol	A l/mol min	$\Delta S_0^{\neq}$ cal/deg mol
Chloromethylated polystyrene	2-Aminobutanol	k_1	13.6±0.2	1.57×10^6	−40.5
		k_2	13.6±0.1	4.50×10^6	−38.4
Benzyl chloride	2-Aminobutanol		13.4±0.1	1.60×10^6	−40.5
Benzyl chloride	*n*-Butylamine		12.5±0.2	7.88×10^5	−41.8

where $e=2.713$, k is the Boltzmann constant, and h, the Planck constant; the standard state refers to a unit concentration of one mole per liter.

The same value of E_a is obtained for k_1 and k_2; this value is comparable to that of the monomeric one, benzyl chloride. The value of A or $\Delta S_0^{\neq}$ for k_2 is slightly higher than that for k_1, whereas the latter is consistent with the values for benzyl chloride. This suggests that the amination of chloromethylated polystyrene proceeds normally in the initial stage.

The above-described facts also support the assumption that the self-acceleration in the amination is due to the adsorption of 2-aminobutanol by the hydroxyl group in the nearest-neighbor. In addition, the stronger self-acceleration has been observed in the amination with diethanolamine in dioxane.[4] On the other hand, such a steric hindrance of the neighboring groups as is observed in the amination with *n*-butylamine has not been found in the amination with 2-aminobutane in dioxane.[4] The "hydrophilic effect" of the hydroxyl group can, therefore, be considered to be the predominant factor in the amination of chloromethylated polystyrene with 2-aminobutanol in dioxane.

The authors wish to express their thanks to Mr. M. Takahashi for his technical assistance in preparing the polymer and in carrying out the measurement.

Excitation of Sodium Atoms by Collisions with Vibrationally Excited Molecules behind Shock Waves

Soji TSUCHIYA and Isao H. SUZUKI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo

(Received August 20, 1970)

Simultaneous measurements of Na D and CO fundamental emissions have been made behind a shock wave in CO–Ar or CO–N_2–Ar mixture containing a trace of Na vapor. The relaxation of a population in each vibrational level is calculated by use of Montroll-Shuler equation. The Na D emission intensity behind the shock wave in the 1.5% CO+Ar mixture nearly follows the relaxation of CO molecules excited to a vibrational level $v=3$ or 4, which is energetically lower than the 3^2P state of Na. This means that most Na atoms are excited by collisions with CO molecules in a level higher than $v=3$, and that the Na D reversal temperature exceeds the vibrational temperature of CO molecules behind the shock wave. In contrast to this, excitation of Na behind the shock wave in the 1.7% CO+49.3% N_2+49.0% Ar mixture is due to collisions with N_2 molecules in a level higher than $v=6$, and a nearly resonant vibrational-to-electronic energy transfer is realized. The relative values of the exciting rate k_v^e by collisions with CO or N_2 in a level v are determined to be $k_1^e : k_2^e : k_3^e : k_4^e : k_5^e = <0.01 : 0.04 : 1 : 1.6 : <2$ for Na–CO and $k_4^e : k_5^e : k_6^e : k_7^e : k_8^e = <0.03 : 0.21 : 1 : 1.4 : <2$ for Na–N_2 collisions at about 2600°K.

It is well known that the collision cross-section of an inert monoatomic gas for quenching the Na D fluorescence is very small or zero, while those of molecular gases are of the same order of magnitude as the gas kinetic ones. This is one of the evidences of the efficient energy transfer from the electronic to vibrational modes of molecules and the very poor coupling between the electronic and translational motions. Gaydon and Hurle[1,2] proposed that the Na D reversal temperature behind a shock wave in N_2 or other molecular gases was the same as the vibrational temperature of molecules, and they determined the vibrational relaxation times of some diatomic gases from the profiles of Na D reversal temperature behind shock waves. This means that Na atoms are excited by collisions with molecules in a vibrational level nearly resonant to the 3^2P state of Na. Other results in line with the above idea have been reported on the electronic excitation of Na atoms by collisions with vibrationally excited N_2 molecules in an electrical discharge[3] and in thermal beams.[4] However, these experiments could not give direct information on a vibrational state of N_2 whose energy was transferred to the electronic state of Na. To clarify this point, two experiments concerning the quenching process of excited atoms were carried out. Polanyi and coworkers observed the infrared emission induced in CO[5] and NO[6] through the quenching of Hg(6^3P), and concluded that less than half of the electronic energy was transferred to vibrations of CO and NO. Burrow and Davidovits[7] examined the vibrational state of N_2 which quenched Rb(5^2P) by the superelastic electron impact method, and found the vibrational state of a certain quantity of N_2 to be $v=5$ which was

nearly resonant to the 5^2P state.

In this work, we have measured the emissions of CO fundamental and Na D line at the same position behind shock waves in CO–Ar and CO–N_2–Ar mixtures containing a trace of Na vapor, and found a correlation between vibrational relaxation and electronic relaxation. The purpose of this experiment is to examine whether the electronic excitation temperature of Na is the same as the vibrational temperature or not, and to determine vibrational levels of diatomic molecules that can excite Na atoms most efficiently.

Experimental

The shock tube used is a stainless steel pipe of 10 cm i.d. with the test section of 460 cm and the driver section of 100 cm in length. The test section was evacuated to less than 10^{-4} Torr, and the leak rate was about 10^{-2} Torr/hr. Mylar film was used as a diaphragm which was ruptured spontaneously by the accumulating pressure of H_2 gas. Three windows are placed 400 cm away from the diaphragm; two quartz windows for measurement of the Na D doublet lines and calibration of a glass prism monochromator by passing a light beam across the tube from an appropriate light source, and the other CaF_2 window perpendicular to the light path of Na D line for the infrared emission. An infrared filter (Optical Coating Lab., LO-04260) and an Au-doped Ge detector (Philco, GPC-201A) were used to isolate and detect the CO fundamental emission. The time constant of the detector and an amplifier system was about 2 μsec. The Na D doublet was measured by a monochromator with a photomultiplier 1P21. The shock velocity was determined by two Pt film gauges placed 30 cm in front of and behind the observation windows.

The sample gases Ar, N_2, and CO were commercially available ones, and their nominal purities were 99.99% for Ar, 99.98% for N_2, and 99.5% for CO. The CO gas was purified by successive distillation using molecular sieve 5A at liquid nitrogen temperatare, and other gases were introduced into a mixing tank through a trap cooled by liquid nitrogen. A trace of Na vapor was added to the sample gas as fine dust by feeding the gas into the shock tube through a trap filled with Na vapor at 10^{-2}—10^{-3} Torr. By this method, a roughly controlled quantity of Na vapor could be mixed in the shock-heated gas, and the time required for colloidal Na to vaporize was very short. This was ascertained by measurement of the absorption of Na D line. No Na D emission was observed in a shock-heated gas without introduction of Na vapor by the above procedure.

Results

Figure 1(a) shows an example of emission profiles of CO fundamental and Na D line behind a shock wave in the 1.5% CO+Ar mixture. The intensity of CO fundamental increases exponentially with a time lapse after the shock arrival, and that of Na D line rises gradually toward its equilibrium value. The latter phenomenon is explained by the fact that Na atoms are excited by collisions with vibrationally excited CO molecules. Previously,[8] we ascertained that the collision cross-section of Ar atom for quenching Na(3^2P) was less than 10^{-3}Å^2. A similar conclusion for a Cs(6^2P)–He collision was reported by Dodd, Enemark, and Gallagher.[9] Thus, Ar atoms have no role in the excitation of Na atoms in a shock-heated CO–Ar mixture.

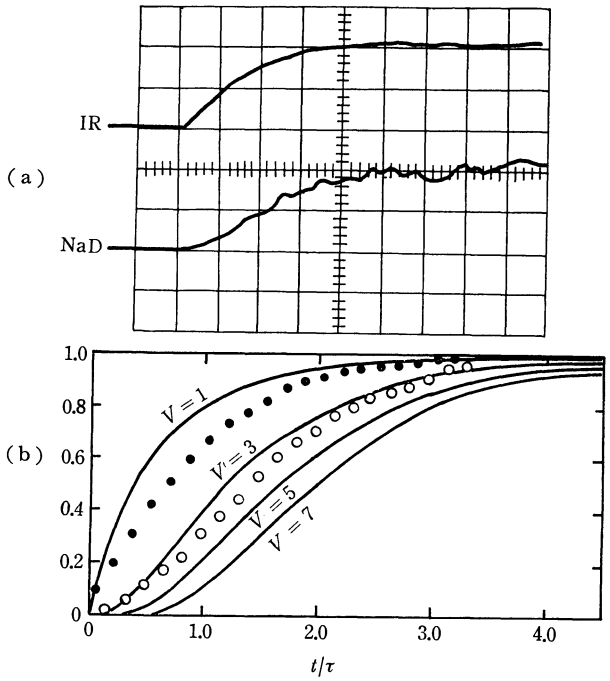

Fig. 1. (a) Emission profiles of CO fundamental and Na D line behind a shock wave in the 1.5% CO+Ar mixture.
(b) Vibrational relaxation of CO molecules in level v calculated from the above result and the excitation relaxation of Na atoms. Shock condition: $U_s=1.63$ mm/μsec, $p_2=518$ Torr, $T_2=2620$°K, $p_2\tau=74.0$ atm. μsec, and sweep velocity=20 μsec/division. #332.
– $\frac{x_v(t)}{x_v(\infty)}$, ● $\frac{I_{CO}(t)}{I_{CO}(\infty)}$, ○ $\frac{I_{Na}(t)}{I_{Na}(\infty)}$

The vibrational relaxation of CO in the CO–Ar mixture can be followed by the CO fundamental emission. Here, we make three assumptions: (1) the vibration of CO is harmonic, (2) only single quantum transitions are possible, and (3) the transition probability from $v=i$ to $v=i-1$ and that from $v=i$ to $v=i+1$ obey the relations, $P(i;-1)=iP(1;-1)$ and $P(i;+1)=(i+1)P(1;+1)$. For this case, Montroll and Shuler[10] showed that the vibrational distribution in each level was of the Boltzmann type, and the vibrational temperature T_v could be defined throughout the relaxation process. Thus, the concentration of CO in the v-th vibrational level should be given by

$$x_v = M(1 - e^{-\Theta})e^{-v\Theta}, \quad (1)$$

where $\Theta=\boldsymbol{hc}\omega/\boldsymbol{k}T_v$ (ω=vibrational frequency in cm^{-1}) and M is the total concentration of CO, *i.e.*, $M=\sum_v x_v$. The relaxation of the vibrational energy $E(T_v)$ is formulated to be

8) S. Tsuchiya and K. Kuratani, *Combustion and Flame*, **8**, 299 (1964).

9) J. N. Dodd, E. Enemark, and A. Gallagher, *J. Chem. Phys.*, **50**, 4838 (1969).

10) E. W. Montroll and K. E. Shuler, *ibid.*, **26**, 454 (1957).

$$1 - E(T_v)/E(T) = e^{-t/\tau}, \quad (2)$$

where $E(T)$ is the vibrational energy in equilibrium with the translational temperature T and τ the vibrational relaxation time. Since the vibrational energy is proportional to the intensity of the fundamental vibration, the relaxation time is determined experimentally by use of Eq. (2), and the vibrational temperature during the course of the relaxation can be expressed as a function of t/τ considering the relation $E(T_v) = Mhc\omega e^{-\theta}/(1-e^{-\theta})$. The concentration in each vibrational level during the relaxation can then be calculated as shown in Fig. 1(b). Applicability of the Montroll-Shuler equation to the present problem will be discussed later.

The Na D emission intensity can be assumed as a thermal emission under optically thick conditions, since the concentration of Na atoms is about 10^{11}—10^{12} atoms/cc, which is estimated from absorption measurement. Hence, the imprisonment of the Na D resonance line is effective for the present system, and the intensity is given by

$$I_{Na} = E_D B^\circ(\omega_D, T_{exc})\overline{\Delta\omega}\cdot\Delta\Omega\cdot\Delta s, \quad (3)$$

where B° is a steradiancy from the black body at a temperature T_{exc}, ω_D the wavenumber of Na D line, $\overline{\Delta\omega}$ a spectral slit width of the monochromator, $\Delta\Omega$ a solid angle of a light flux incident on the monochromator, Δs an area of the slit, and E_D an effective emissivity defined by

$$E_D = \int g(\omega', \omega_D)\{1 - \exp[-k(\omega')L]\}d\omega' \Big/ \int g(\omega', \omega_D)d\omega', \quad (4)$$

where $g(\omega',\omega_D)$ is a slit function of the monochromator set at the wavenumber of ω_D, $k(\omega)$ absorption coefficient, and L the optical depth of gaseous emitter. The emissivity depends only on the concentration of Na atoms, and is assumed to be constant in the flowing gas behind a shock wave. Therefore, the ratio of the intensity at time t to that at an equilibrium region far from a shock front is

$$\begin{aligned} I_{Na}(t)/I_{Na}(\infty) &= B^\circ(\omega_D, T_{exc})/B^\circ(\omega_D, T_2) \\ &= \exp[-(hc\omega_D/k)(1/T_{exc} - 1/T_2)] \\ &= [Na^*]_t/[Na^*]_\infty, \end{aligned} \quad (5)$$

where T_2 is the translational temperature behind a shock wave, and Na* denotes Na(3^2P) atom. Thus, the relative concentration of Na(3^2P) or the excitation temperature T_{exc} can be obtained from the Na D emission measurement.

The energy exchange process between the electronic and vibrational states of Na and CO is represented by

$$Na + CO(v) \rightleftarrows Na^* + CO(v - \Delta), \quad (6)$$

where the vibrational quanta Δ of CO is transferred to or from the electronic state of Na, and the exciting and quencing rates are denoted by $k^e_{v,\Delta}$ and $k^q_{v-\Delta,\Delta}$. The quenching process occurs efficiently in every gas kinetic collision, and the exciting probability is very large in a collision with a CO molecule in a particular vibrational level. Thus, the quasi-equilibrium between the electronic and vibrational states of Na and CO can be assumed, *viz.*, the relation,

$$[Na^*]/[Na] = (\sum_v k_v^e x_v)/[(\sum_v k_v^q x_v) + k_r], \quad (7)$$

holds during the relaxation process behind a shock wave. In this equation

$$k_v^e = \sum_{0\le\Delta\le v} k^e_{v,\Delta} \text{ and } k_v^q = \sum_{0\le\Delta\le v^*} k^q_{v,\Delta},$$

where v^* is the nearly resonant level to the 3^2P state of Na; $v=8$ for CO and $v=7$ or 8 for N_2, and k_r is a rate of radiative loss. In the present experimental condition, the radiative loss of Na(3^2P) can be neglected as shown previously,[8] and the denominator on the right-hand side of Eq. (7) is close to $k_0^q x_0 + k_1^q x_1$, which is nearly constant throughout the relaxation process. Reasons for this are: (1) a very poor population in a vibrational level higher than $v=2$ in the temperature range of the present experiment, and (2) it is reasonable to assume that the quenching rate of molecules in the vibrationally ground state does not differ from that of first excited molecules (Ref. 17 and Discussion). The emission intensity relative to that at the equilibrium region far after the shock arrival is then represented by

$$\begin{aligned} I_{Na}(t)/I_{Na}(\infty) &= \sum_v k_v^e x_v(t)/\sum_v k_v^e x_v(\infty) \\ &= \text{const.} \sum_v k_v^e[e^{-v\theta}(1 - e^{-\theta})], \end{aligned} \quad (8)$$

and the relative values of k_v^e's can be estimated by comparing the profile of I_{Na} with the calculated ones of x_v's.

It is seen from Fig. 1(b) that the experimental plots of $I_{Na}(t)/I_{Na}(\infty)$ nearly agree with those of $x_v(t)/x_v(\infty)$ when $v=3$ or 4. This seems that Na atoms are excited mainly by collisions with CO molecules in the vibrational level $v=3$ or 4, *i.e.*, the contribution of terms with $v=3$ or 4 to the right-hand side of Eq. (8) is very large as compared with that of a term with another v. Hence, the relative values of k_v^e's may be calculated by the least square method using the equation

$$\begin{aligned} y(\equiv I_{Na}(t)/I_{Na}(\infty)(1 - \chi)^{-1}) &= \sum_v k_v'\chi^v \\ &\approx k_2'\chi^2 + k_3'\chi^3 + k_4'\chi^4, \end{aligned}$$

where $\chi = e^{-\theta}$ and $k_v' = \text{const. } k_v^e$. The calculation was made by using observed values of y and χ at an interval of 0.1 of t/τ in the range that $t/\tau = 0.3$—3.0. The maximum value of k_1' was estimated by the assumption that $y = k_1'\chi$ when $t/\tau = 0$—0.3, and that of k_5' by the equation

$$\sum[y - (k_2'\chi^2 + k_3'\chi^3 + k_4'\chi^4) = k_5'\sum\chi^5,$$

where the notation $\sum$ means to sum up the experimental values at an interval of 0.1 of t/τ. In order to ascertain the reliability of the result obtained by the above method, the same procedure was applied to a case of contribution from other vibrational states, *e.g.*, $v=1$, 2, and 3 or $v=4$, 5, and 6. However, the result was physically untenable, since the conditions $k_v^e \ge 0$ and $k_v^e \ge k_{v-1}^e$ were not satisfied. The relative values of k_v^e's thus calculated are summarized in Table 1, from which we can conclude that most Na atoms are excited by collilions with CO molecules in a level higher than $v=3$. The experimental accuracy of Na D emission intensity is not enough to determine the

relative values of k_v^e's more than three, and the error is large for k_v^e at high vibrational levels owing to poor population.

The observed emission profiles of Na D and CO fundamental behind a shock wave in the 1.7% CO+49.3% N_2+49.0% Ar mixture are shown in Fig. 2(a). In a previous paper,[11] we proposed the vibrational relaxation equation for a diatomic gas mixture, and obtained the collision probability of the vibration-vibration energy exchange between CO and N_2. According to the result, the vibrational relaxation of CO should closely follow that of N_2. Since the concentration of CO is much smaller than that of N_2, and the collision cross-sections of CO and N_2 for quenching Na(3^2P) are of a similar magnitude,[12] the exciting or quenching collisions of CO molecules with Na atoms scarcely contribute to the whole intensity of Na D line. Analysis for the determination of relative values of k_v^e's is the same as that for the case of CO. As seen from Fig. 2(b), the excitation of Na atoms is made mainly by collisions with N_2 molecules in vibrational levels $v=5$—7. The calculated results are shown in Table 2. A nearly resonant vibrational-to-electronic energy transfer between N_2 and Na can be concluded. This is in line with Gaydon and Hurle's postulate.[1]

Discussion

The relaxation of the population in each vibrational level has been calculated by use of the Montroll-Shuler equation, based on the foregoing three assumptions.

11) Y. Sato, S. Tsuchiya, and K. Kuratani, *J. Chem. Phys.*, **50**, 1911 (1969).
12) D. R. Jenkins, *Proc. Roy. Soc.* (London), **A303**, 453 (1968).

Appropriateness of this procedure should be discussed. The vibrational excitation of CO in a CO–Ar mixture proceeds by two processes (this is the same for a N_2–Ar mixture). One is a gain or loss of vibrational quanta Δ by collision with Ar or CO through the translation-vibration (T-V) energy transfer

$$\text{(i)}\quad \mathrm{CO}(i) + \mathrm{M} \rightleftarrows \mathrm{CO}(i+\Delta) + \mathrm{M}.$$

The other is a resonant or near-resonant vibration-vibration (V-V) energy transfer process

$$\text{(ii)}\quad \mathrm{CO}(i) + \mathrm{CO}(j) \rightleftarrows \mathrm{CO}(i+\Delta) + \mathrm{CO}(j-\Delta).$$

According to this mechanism, the relaxation of population x_i in the i-th vibrational level is given by

$$\begin{aligned} dx_i/dt = {} & Z\sum_{\Delta\geq 1}\{[P(i-\Delta;\ \Delta)x_{i-\Delta} + P(i+\Delta;-\Delta)x_{i+\Delta}] \\ & - [P(i;\ -\Delta) + P(i;\ \Delta)]x_i\}N \\ & + Z\sum_{j}\sum_{\Delta\geq 1}\{[Q(i-\Delta, j;\ \Delta)x_{i-\Delta}x_j + Q(i+\Delta, j;\ -\Delta)x_{i+\Delta}x_j] \\ & - [Q(i, j;\ -\Delta) + Q(i, j;\ \Delta)]x_i x_j\}, \end{aligned} \tag{9}$$

where Z is the collision frequency, N the concentration of whole particles CO and Ar, and the probabilities for the forward processes of (i) and (ii) are represented respectively by $P(i;\ \Delta)=\phi_{\mathrm{A}}P_{\mathrm{A}}(i;\ \Delta)+\phi_{\mathrm{CO}}P_{\mathrm{CO}}(i;\ \Delta)$ and $Q(i,j;\ \Delta)$, in which ϕ_{A} and ϕ_{CO} are mole fractions of Ar and CO, and P_{A} and P_{CO} are the corresponding T-V probabilities by collisions with Ar and CO, respectively. Since $Q \gg P$, a quasi-equilibrium in the distribution of population in each vibrational level can be assumed during the relaxation process as proposed by Treanor, Rich, and Rhem.[13] That is, the vibrational relaxation proceeds keeping the second term in Eq. (9) equal to zero.

If we can assume that a CO molecule is a harmonic oscillator, the quasi-equilibrium condition results in the Boltzmann distribution, and the vibrational temperature can be defined. Then, Eq. (9) is reduced to

$$\begin{aligned} dx_i/dt = {} & ZN\sum_{\Delta\geq 1}[P(i;\ -\Delta)(\rho^{\Delta}x_{i-\Delta} - x_i) \\ & - P(i+\Delta;\ -\Delta)(\rho^{\Delta}x_i - x_{i+\Delta})], \end{aligned} \tag{10}$$

where $\rho=\exp(-\boldsymbol{hc}\omega/\boldsymbol{k}T)$ and $P(i-\Delta;\ \Delta)=\rho^{\Delta}P(i;\ -\Delta)$ from the detailed balancing. Here, we will take a first momentum $V=\sum_i ix_i$ from Eq. (10). The result is

$$dV/dt = ZN\sum_{\Delta\geq 1}\Delta\sum_{i}P(i+\Delta;\ -\Delta)(\rho^{\Delta}x_i - x_{i+\Delta}). \tag{11}$$

By assuming the Landau-Teller rule of transitions,

$$\begin{aligned} P(i+\Delta;\ -\Delta) = {} & (1/\Delta!)(i+1)(i+2) \\ & \cdots\cdots(i+\Delta)P(\Delta;\ -\Delta), \end{aligned} \tag{12}$$

Eq. (11) can be written as

$$\begin{aligned} dV/dt = {} & ZNM\sum_{\Delta\geq 1}\Delta P(\Delta;\ -\Delta)\{\rho^{\Delta}[1 + (V/M)]^{\Delta} \\ & - (V/M)^{\Delta}\}, \end{aligned} \tag{13}$$

where $M=\sum_i x_i$. If the quantity, $X=1-E/E(T)$ is defined to represent the departure of vibrational energy E from $E(T)$ in equilibrium with translational temperature T, the relaxation of vibrational energy can be written as

$$\begin{aligned} -dX/dt = {} & ZN\sum_{\Delta\geq 1}\Delta(\rho/1-\rho)^{\Delta-1}P(\Delta;\ -\Delta)[(1-\rho X)^{\Delta} \\ & - (1-X)^{\Delta}], \end{aligned} \tag{14}$$

where the relations $M=E(T)(1-\rho)/\rho\boldsymbol{hc}\omega$ and $V=E(T_v)/\boldsymbol{hc}\omega$ are used to derive the above equation from Eq. (13). This shows that the multiple quanta transitions cause non-linearity in the relaxation equation, and that the relaxation cannot be described as a simple exponential approach toward the equilibrium state. If all the terms higher than X in Eq. (14) are neglected, the equation should be similar to that of Landau-Teller, and an apparent relaxation time τ can be defined as

$$1/\tau = ZN\sum_{\Delta\geq 1}\Delta^2\rho^{\Delta-1}/(1-\rho)^{\Delta-2}P(\Delta;\ -\Delta). \tag{15}$$

In Fig. 3, the exact calculation for the system, where both the single and double quanta transitions contribute to relaxation, is compared with the above approximate solution, and the diference between the relaxing vibrational energies in both models is only 10% even if $P(2;\ -2)/P(1;\ -1)=0.1$. Therefore, to apply the Landau-Teller relaxation equation to the experimental analysis means to automatically take into account to a certain extent the contribution from multiple quanta transitions.

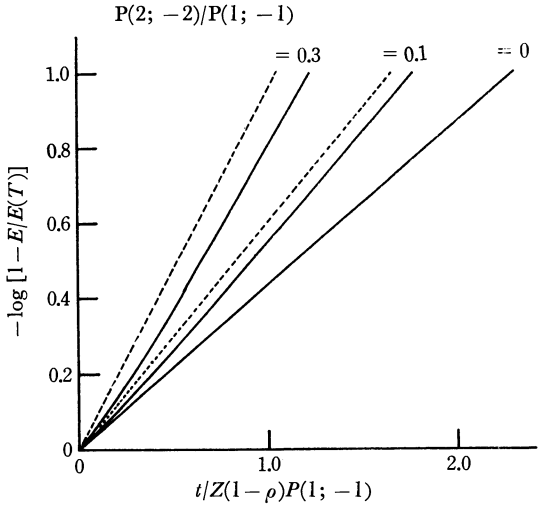

Fig. 3. Relaxation profile of CO behind a shock wave of 2000°K with single and double quanta transitions.
Solid line: exact solution, dotted line: approximate solution neglecting X^2 term.

It is probable that the real vibrational relaxation deviates from that of the Landau-Teller-Montroll-Shuler equation due to anharmonicity, especially for molecules in a high vibrational level. The quasi-equilibrium condition for a system of anharmonic oscillators results in a non-Boltzmann distribution.[13] In the shock-tube experiment, the translational temperature is higher than the vibrational one, though the latter cannot be uniquely defined. For this case, an effective vibrational temperature θ_v^* for a vibrational level v is lower than θ_1^* for the level $v=1$. Calculation of θ_v^*/θ_1^* as a function of θ_1^*/T shows that θ_v^*/θ_1^* is 0.97 for CO in a level $v=8$ when $\theta_1^*/T=0.3$. This value of θ_v^*/θ_1^* is for the initial stage of the relaxation where the population of highly excited molecules which contribute to the excitation of Na is very small.

13) C. E. Treanor, C. W. Rich, and R. G. Rhem, *J. Chem. Phys.*, **48**, 1798 (1968).

Table 3. Relative values of the exciting and quenching rates k_{Δ}^{e} and k_{Δ}^{q} of Na atom in Na–CO and Na–N_2 collisions at about 2600°K

vib. quanta transferred, Δ		1	2	3	4	5	6	7	8

	k_{Δ}^{q}	—	—	—	<0.5	1.0	1	0.1	<0.06
	k_{Δ}^{q} (calcd)[a]	0	0.35	0.62	0.97	1.30	1	0.32	0

a) Relative values of k_{Δ}^{q} (calcd) at 0.1 and 0.2 eV of initial kinetic energies for Na–N_2 and Na–CO collisions, repectively, are those calculated by Bauer *et al.*[17]

Thus, a large deviation from the Boltzmann distribution cannot be expected in the present experimental condition. The remaining effects of the anharmonicity are the enhancement of the multiple quanta transitions and the difference in values of $\exp(-E_v/\boldsymbol{k}T_v)$ (E_v is a real energy level) and $\exp(-v\boldsymbol{hc}\omega/\boldsymbol{k}T_v)$. The former can be rejected from the preceding discussion, and the latter effect causes little change in curves of $x_v(t)/x_v(\infty)$ in Figs. 1 and 2. The absolute values of x_v must be corrected by a factor $\exp[(v\boldsymbol{hc}\omega-E_v)/\boldsymbol{k}T_v]$, which does not produce a serious effect on the present conclusion.

The uncertainty in the population distribution can be eliminated by a direct measurement of the vibrational relaxation of highly excited molecules, especially in a level energetically near the 3^2P state. Lack of this experiment is the weakest point in this kind of work. However, we can say at least that the excitation temperature of Na atoms does not agree strictly with the the vibrational temperature of CO, while it nearly agrees with that of N_2 if the molecules are assumed to undergo relaxation of the Landau-Teller type.

The detailed balancing equation for process (6) is

$$k^{e}_{v,\Delta}/k^{q}_{v-\Delta,\Delta} = (g^*/g)\exp[-(E^* - \Delta\boldsymbol{hc}\omega)/\boldsymbol{k}T], \quad (16)$$

where g is the degeneracy of Na(3^2S), g^* the combined degeneracies of the two 3^2P states, E^* the electronic energy of Na(3^2P), and T a translational or rotational temperature. If it is possible to suppose that the exciting or quenching rate is only dependent on the vibrational quanta Δ transferred to or from the electronic state of Na and independent of vibrational states of colliding molecules, the exciting rate k_{Δ}^{e} and consequently the quenching rate k_{Δ}^{q} can be estimated as shown in Table 3. This means that the energy transfers of vibrational quanta $\Delta=3$—4 in Na–CO collisions and $\Delta=5$—6 in Na–N_2 collisions are most effective. Thus, about half of the electronic energy must be supplied from the translational or rotational motion to excite Na(3^2S) by collision with CO.

The relation between the excitation temperature of Na and the vibrational temperature of molecules may be discussed by Eqs. (7) and (16). Equation (7) can be simplified by the aforementioned assumption that $k^{e}_{v,\Delta}=k_{\Delta}^{e}$ and $k^{q}_{v,\Delta}=k_{\Delta}^{q}$ for all v, and is written as

$$[Na^*]/[Na] = \sum_{0\le\Delta\le v^*} k_{\Delta}^{e}\exp(-\Delta\boldsymbol{hc}\omega/\boldsymbol{k}T_v)/\sum_{0\le\Delta\le v^*} k_{\Delta}^{q},$$

where the radiative process is neglected. Combining the above equation with the equation of detailed balancing Eq. (16), the following relation can be derived.

$$\exp(-E^*/\boldsymbol{k}T_{exc}) = \sum_{0\le\Delta\le v^*} k_{\Delta}^{q}\exp[-(E^*/\boldsymbol{k}T) + (\Delta\boldsymbol{hc}\omega/\boldsymbol{k})(1/T - 1/T_v)]/\sum_{0\le\Delta\le v^*} k_{\Delta}^{q}. \quad (17)$$

In a thermal equilibrium system in which $T=T_v$, Eq. (17) shows that $T_{exc}=T$, while $T_{exc}\neq T$ in the system of $T\neq T_v$. For the latter, the relation of T_{exc} to T_v can be clarified by assuming that only the vibrational energy of $\Delta^*\boldsymbol{hc}\omega$ is exchanged with the electronic state of Na, where Δ^* means the most effective vibrational quanta transferred in the vibrational-to-electronic energy transfer, that is, $k_{\Delta q}=0$ when $\Delta\neq\Delta^*$. Then, we have

$$1/T_{exc} = (\Delta^*\boldsymbol{hc}\omega/E^*)/T_v + [1 - (\Delta^*\boldsymbol{hc}\omega/E^*)]/T. \quad (18)$$

In the case of resonant vibrational-to-electronic energy transfer, we get

$$\Delta^* = v^*,\ T_{exc} = T_v.$$

On the other hand, in a non-resonant case, $\Delta^*<v^*$, we obtain

$$T < T_{exc} < T_v \quad \text{or} \quad T > T_{exc} > T_v.$$

The vibrational relaxation time obtained by measuring the Na D emission behind a shock wave in CO should be shorter than that determined from the CO fundamental emission, since $T_{exc}>T_v$. Figure 4(a) represents the relaxation of the vibrational energy calculated from the emission profiles of CO fundamental and Na D emissions, for which the assumption $T_v=T_{exc}$ is made. The vibrational energy defined by the Na excitation is nearer to its equilibrium value than the real energy observed by the infrared emission. This may be referred to the fact that the main contribution to the excitation of Na is caused from CO molecules in a level $v=3$ or 4. However, an apparent relaxation time which is determined from a slope of linear plots, $\log(1-E/E(T))$ *vs.* t, does not differ so much from the true one. The difference between the two slopes is less than 10%, which is of a magnitude comparable to an experimental error of the Na D emission measurement. Thus, vibrational relaxation times in CO or CO–Ar mixture observed by separate measurements of the Na D and CO fundamental emissions appear to agree with each other as Russo has found.[14] The same analysis for a CO–N_2–Ar mixture is shown in Fig. 4(b), and the vibrational relaxations measured

by both methods agree quite well. This indicates the resonant mechanism in the vibrational-to-electronic energy transfer, and is in line with Hurle's experiment.[2]

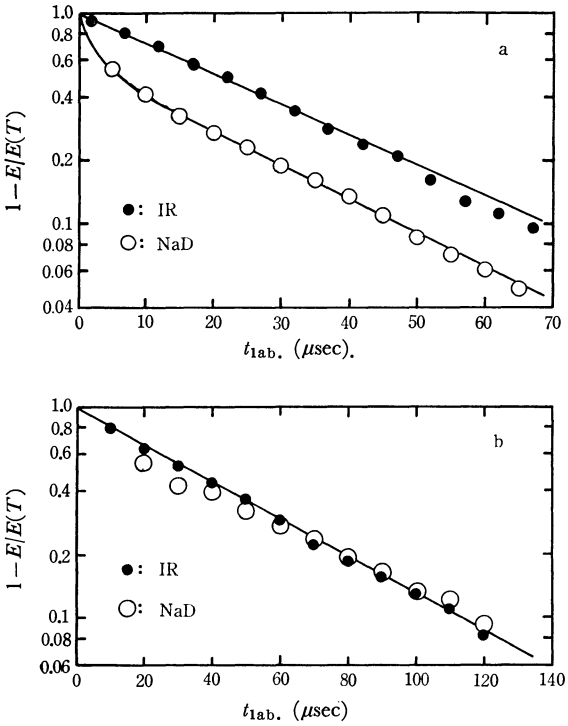

Fig. 4. (a) Relaxation of the vibrational energy of CO behind a shock wave in the 1.5% CO+Ar mixture.
(b) Relaxation of the vibrational energy of N_2 behind a shock wave in the 1.7% CO+49.3% N_2 +49.0% Ar mixture. Two values of $E/E(T)$ are determined from infrared emission measurement, $I_{CO}(t)/I_{CO}(\infty)$, and from the NaD emission by assuming that $T_v=T_{exc}$.

Russo[14] also observed the vibrational relaxation in the expanding flow of the 5%CO+Ar mixture by measuring the Na D reversal and CO vibrational temperatures, and found that the ratio of the relaxation time τ_e to that of the shock-wave experiment τ_s is 10^{-2}—10^{-3} for the infrared method, and 10^{-1}—10^{-2} for the Na D method. Since $T_v>T$ in the expanding flow and $\Delta^*=3$—4, T_{exc} must be lower than T_v if a non-Boltzmann distribution is not taken into account. This suggests a smaller value of τ_e/τ_s for the Na D method than that for the infrared method, while a non-Boltzmann distribution caused by the V-V coupling of anharmonic oscillators has a reverse effect. However, it seems impossible to explain the difference in values of τ_e/τ_s observed by two methods in terms of the latter effect. A later experiment by Rosenberg, Taylor, and Teare[15] shows that H atoms as an impurity reduce considerably the relaxation time of CO in the expanding flow. Hence, the Na excitation temperature observed by Russo might be abnormally high by the chemi-excitation mechanism $H+H+Na\rightarrow H_2+Na^*$.

Theoretical calculation for the quenching process, $Na(3^2P)+N_2(0)\rightarrow Na(3^2S)+N_2(v)$, was made by Bjerre and Nikitin[16] and by Bauer, Fisher, and Gilmore.[17] They proposed that the adiabatic potentials of $Na(3^2P)+N_2(^1\Sigma_g^+)$ and $Na(3^2S)+N_2(^1\Sigma_g^+)$ were crossed by the surface $Na^++N_2^-$, and that the non-adiabatic transitions occurred at these crossing points. This model explains well the large quenching cross-section of N_2, though the collision process without crossing or approaching of initial and final potential surfaces results in a very small cross-section.[18] Bjerre and Nikitin calculated the classical trajectories on the potential surfaces by applying the Landau-Zener formula to the transitions at crossing points, and obtained the final classical vibrational energies of N_2 and quenching probabilities. Their result shows the vibrational states of N_2 molecules, to which the energy of $Na(3^2P)$ is transferred, to be mostly in $v=1$—4. This is incompatible with our results. Bauer *et al.* treated the process in terms of a diffusion of the probability flux through a two-dimensional network of potential curves characterized by the electronic and the vibrational states of N_2 and N_2^-. The transition probability at each crossing point is given by the Landau-Zener formula, in which the transition matrix element is the product of an electronic interaction function and a Franck-Condon factor between the vibrational states of N_2 and N_2^-. In Table 3, their results are compared with ours in order to show qualitative agreement.

Conclusion

The excitation of Na atoms to the 3^2P state behind the shock wave in a CO–Ar mixture follows the vibrational excitation of CO molecules to levels $v=3$—4 rather than to a level $v=8$ which is energetically resonant to the 3^2P state of Na. The result is derived with the assumption that the vibrational relaxation of CO proceeds under the condition of Landau-Teller. Analysis of this result shows that most Na atoms are excited by collisions with CO molecules in a vibrational level higher than $v=3$, and the remaining energy to excite Na atoms is supplied from the translational or rotational motion of the colliding atom and molecule. In contrast to this, the excitation of Na atoms is made by collisions with vibrationally excited N_2 molecules in levels $v=5$—7, and the process is a nearly resonant vibrational-to-electronic energy transfer. Thus, the Na excitation temperature behind the shock wave in a N_2–Ar mixture is nearly in agreement with the vibrational temperature of N_2. The results are compatible with the theoretical calculation based on the mechanism that a Na atom is excited *via* an ionic state $Na^+\cdots CO^-$ or $Na^+\cdots N_2^-$ in the process of molecular collision.

The authors thank Mr. Yukinori Sato for his valuable discussion on the analysis of vibrational relaxation.

Studies on Salt Solution Aerosols. V.[1] The Effect of Surface Active Substance upon the Droplet Size of an Aqueous NaCl Solution Aerosol

Yasuo Ueno and Isamu Sano

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 25, 1970)

An aqueous NaCl solution (10%) containing a surface active substance was dispersed to a mist with a Dautrebande type atomizer. The influence of the surface active substance on the droplet size and mass concentration of the mist during aging was studied. We examined ethyl alcohol, acetic acid, ethyl acetate, acetone, glycerine, and a commercial nonionic surfactant. From the results it was found that at an early stage of aging, the droplet number present in mist was inversely proportional to the fourth power of droplet size.

In a previous study,[2] we carried out an experiment on the production of aqueous NaCl solution aerosols by atomizing an aqueous NaCl solution containing or not containing a surfactant with an atomizer. We found that the droplet size decreases with the increase of the concentration of the surfactant or with the decrease of the surface tension of the dispersing solution. Surfactants used were commercial products of polyoxyethylene nonylphenyl ether, $C_9H_{19}C_6H_4O(CH_2CH_2O)_nH$ with $n=6$, 9, and 21.

In the present study we worked with a Dautrebande's baffle type atomizer, which is superior to the intercepting glove type used earlier as it produces droplets finer than 1.2 μ diameter.

Unlike the above-mentioned polymeric surfactants with the c.m.c. ranging from 10^{-1} to 10^{-2}% by weight, almost all the surface active substances examined in the present work are of much higher solubility so that they enabled us to conduct the experiment over a wider range of concentration to gain knowledge of the role of surface active substance in the production of mist and, moreover, of the correlation between the size and number of the droplets present in mist immediately after its formation.

Various methods[3] of measuring the size of droplets of a mist have been presented, but they are laborious and troublesome on account of the volatility of the droplets causing alteration in their size. For example, in the chemical spot method,[3] it involves preparation of a series of calibration curves. The method adopted in the present study takes advantage of the volatility and is of significance as being applicable and available to much the same extent as the other methods.

Experimental

Materials. Ethyl alcohol, acetic acid, ethyl acetate, acetone, and glycerine used were of the extra pure grade. Commercial surfactant, EA-80 (polyoxyethylene nonylphenyl ether, $n=9$), was used as obtained from a chemical supply house.

Apparatus and Procedure. The over-all experimental

3) Y. Ueno and I. Sano, This Bulletin, **44**, 637 (1971).

arrangement is illustrated in Fig. 1. The compressed air at 5 kg/cm² (1) was driven through an air cleaner (2) and its pressure was reduced to 3 kg/cm² by a pressure regulator (3). The air was passed through filter tubes of glass fibers (4) and of absorbent cotton (5) for elimination of air-borne dust and then, it was humidified by bubbling through the same solution (6) as that to be dispersed and released from gustiness of flow with the aid of two large bottles (7). Finally, the pressure was adjusted and maintained constant at 2 kg/cm² by regulators (8) and (9). The mist thus generated with an atomizer (17) was introduced for 10 min into a mist chamber which had previously been saturated with water vapor of the dispersing solution. The humidity and temperature in the chamber were measured by means of an electrical resistance type hygrometer (12) and a glass thermometer (13) before and after the run. The temperature was kept at 20.0°±0.5°C throughout all the runs of experiment. The mist was subjected to aging with a constant rate stirrer (50 rev/min) (19) for an hour. The recorded time was reckoned from the moment of stopping the introduction of mist. At frequent intervals, portions of the mist were drawn for determination of mass concentration and particle size. The total amount of the portions of mist drawn from the chamber, so that it would scarcely affected the accuracy of the determination.

The solution to be dispersed was an aqueous NaCl solution (10%) or that containing a surface active substance in such an amount that the diminution of NaCl was within 0.05%.

Mist Generator. The mist generator employed is a modification of the Dautrebande type[4] and is illustrated in Fig. 2. The amount of the dispersing solution present in the generator is maintained constant by feeding fresh solution from the bottom of a cylindrical reservior (7) of 7 cm diameter, and the excess leaves the generator to a sink through a level tube (not shown in Fig. 2) whose height is adjustable as one wishes. The solution is drawn up by virture of the Venturi effect through the annular channel between the nozzle (3) and the filtering column (4). The atomized droplets impinge against the upper part of the filtering cap (5); the coarser ones are unstable to precipitate and run down into the dispersing solution (10), while those surviving are driven to pass through about fifty, small holes of 1.0 mm diameter (8) in the filtering column (4) and some of them encounter one another and coalesce. The stabilized and finer mist is thus generated through a mouthpiece (6).

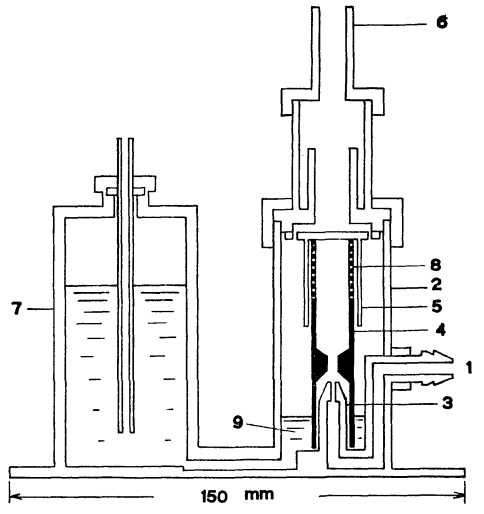

Fig. 2. Aerosol generator equipped with a constant feeding reservior.
1) compressed air tubing 2) plastic cylinder 3) air nozzle 4) filtering column topped by filtering holes 5) filtering cap 6) mouthpiece 7) reservior 8) small holes of 1.0 mm diameter in filtering column 9) dispersing solution

It is well known that this device can favourably be utilized for generation of submicronic droplets on account of its merit that size selection is effectively made through a liquid filtration mechanism, whereby coarser droplets are obligatory removed from the mist in the inner column.

Mass Concentration Analysis. Portions of the mist were periodically drawn with a constant rate air pump and passed through an electrical precipitator under a voltage of 7200 V/cm. The deposit in it was dissolved in 20 cc of distilled water and the weight was determined by electrical conductivity measurement with an error of less than 5%. With the volume of the mist drawn, which was recorded on the flowmeter, the concentration was calculated as milligrams of NaCl per cubic centimeter.

Particle Size Analysis. Portions of the mist were drawn into a silica gel holding syringe and dried, and they were passed to a precipitator at a rate of 15 cc/min. The precipitator used was that of Shibata Scientific Instrument Co. Estimates of the particle size were made on the thermal precipitator samples with a Hitachi HU-11DS electron microscope at a magnification of 3000 X. Electron microscope collodion mesh grids were mounted on a circular cover glass which was fitted close to a heated wire of the thermal precipitator. The sodium chloride particles were cubic crystals, and the number averaged width of their one crystal face was regarded as the representative size. From the average width (L) thus found, we calculated the radius (R) of the sphere corresponding to a 10% solution droplet.

Results and Discussion

Time Variation of Mass Concentration. Figure 3 shows that the mass concentration decreases with the

elapse of time and markedly with the addition of a surface active substance to the dispersing solution. It will be seen that if the reciprocal of the mass concentration is plotted against the time, a linear relation holds in the early stages of nearly all the runs, revealing that the rate of the decrease in mass concentration follows the rate law of a second order reaction.

Time Variation of Particle Size Distribution and Number Concentration. The variation in particle size distribution with time is given in Fig. 4. It is evident in the figure that the size of a sodium chloride particle as represented by the width of one crystal face increases with time and, with the particles obtained from the solution droplets containing ethyl acetate, the size gets smaller as the surface active substance is more concentrated. The similar results were found for another surface active substances such as ethyl alcohol, acetic acid, acetane, glycerine, and polyoxyethylene nonylphenyl ether.

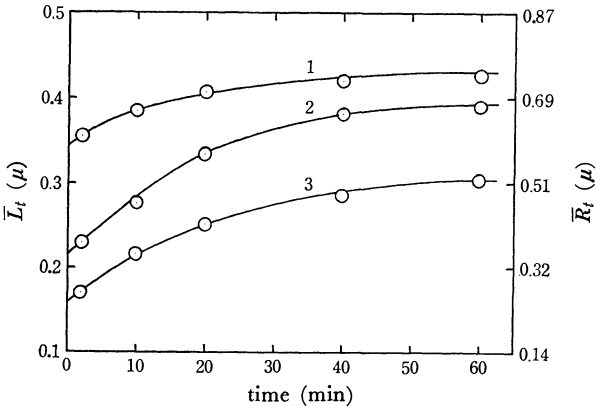

Fig. 4. Time variation of particle size distribution.
(1) with no surface active substance (2) ethyl acetate, 0.20 mol/l (3) ethyl acetate, 0.45 mol/l

We calculate the average droplet radius ($\bar{R}_t$) from the average crystal size ($\bar{L}_t$) by use of the relation

$$4/3\cdot\pi\bar{R}_t^3\cdot\rho_1\cdot W/100 = \rho_2\bar{L}_t^3 \qquad (1)$$

where W is the NaCl concentration of dispersing solution, ρ_1 and ρ_2 are the densities of the solution and NaCl crystal, respectively, and the subscript t is the time elapsed, while the bar over a letter signifies the average. On the right axis in Fig. 4 is shown the radius (R_t).

Size Distribution and Number Concentration Immediately after Atomization. Let us express the average of crystal size, droplet radius, mass concentration, and number concentration at zero time by L_0, R_0, C_0, and N_0, respectively. The value of L_0 or R_0 is found by extrapolation of the plot of L_t or R_t *vs.* t to the intercept in Fig. 4 and similarly the value of C_0 in Fig. 3. The number concentration N_0 can be estimated by

$$N_0 = C_0/(L_0^3\rho_2) = C_0/(4/3\cdot\pi R_0^3\rho_1\cdot W/100) \qquad (2)$$

Figure 5 indicates the relationship between the droplet radius (R_0) or number concentration (N_0) and the surface tension of dispersing solution. From the figure, it will be noted that as the surface tension is decreased, the smaller radius and the higher concentration are attained except the case of glycerine which exhibits that the plotted points deviate largely from the curves for the radius as well as the concentration probably because of comparatively high viscosity of the solution. Figure 6 shows the relationship of R_0 or N_0 and the viscosity, with the exception of the solutions of EA-80 and ethyl acetate which are of low viscosity. Remark should be made, here, of the fact that the relation of R_0 to the viscosity is in the reverse to that in the previous paper;[5] the reason may be possibly be that the working mechanism of the present atomizer is different from that of the atomizer employed previously. We will later report the effect of viscosity in more detail with particular reference to the experiments using glycerine, ethylene glycol and so on as a surface active substance.

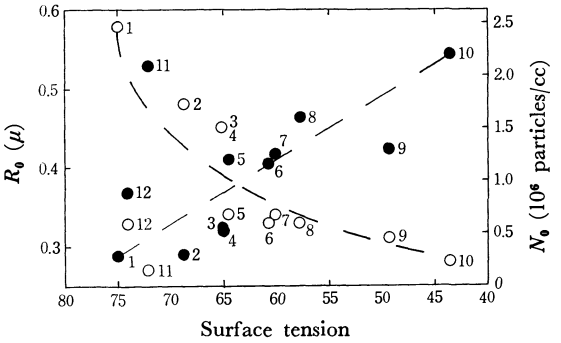

Fig. 5. Relation between R_0 or N_0 and the surface tension of dispersing solution.

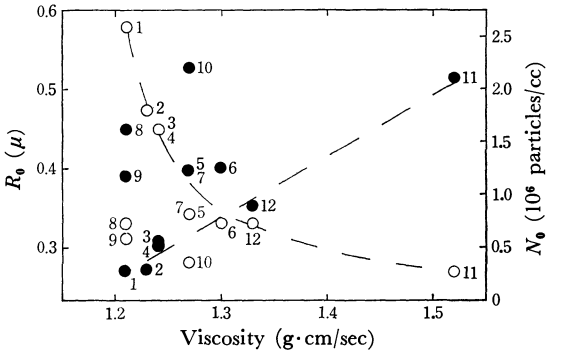

Fig. 6. Relation between R_0 or N_0 and the viscosity of dispersing solution.
With regard to the legends, confer Fig. 5. (○ : R_0, ● : N_0)

If it is assumed that a mechanical W is required for a large number of droplets, whose surface area taken together runs up to A_2, to be formed from a bulk solution of surface area A_1, then

$$W = \gamma\Delta A = \gamma(A_2 - A_1) \qquad (3)$$

where γ is the surface tension. Neglecting A_1 in comparison with A_2 and denoting the surface active substance containing NaCl solution by a prime,

$$\gamma A_2 = \gamma' A_2' \qquad (4)$$

5) I. Sano and Y. Ueno, *Nippon Kagaku Zasshi*, **90**, 47 (1969).

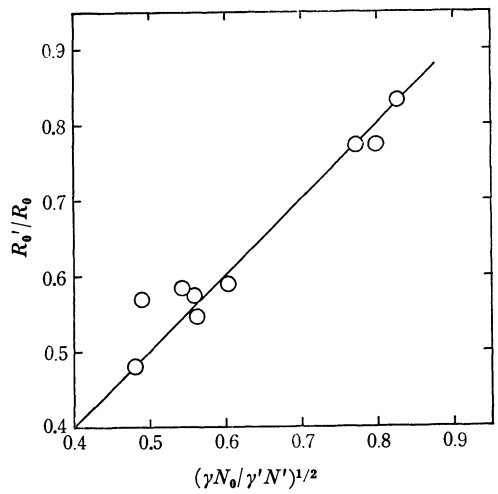

Fig. 7. Plot of R_0'/R_0 against $(\gamma N_0/\gamma' N_0')^{1/2}$.

and

$$\gamma'/\gamma = A_2/A_2' = N_0 S_0/N_0' S_0' \tag{5}$$

where N_0 and S_0 represent the number concentration of the droplets present in the mist chamber and the average area per droplet, respectively. Since S_0 is equal to $4\pi R_0^2$, it follows from Eq. (5) that

$$R_0'/R_0 = (\gamma N_0/\gamma' N_0')^{1/2} \tag{6}$$

The validity of Eq. (6) is as given in Fig. 7.

According to the results previously reported,[2]

$$R_0'/R_0 = (a\gamma'^{1/2} - b)(a\gamma^{1/2} - b) \tag{7}$$

where a and b are empirical constants. From Eqs. (6) and (7), we get

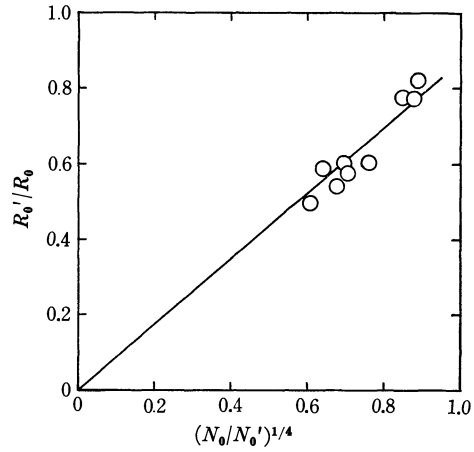

Fig. 8. Plot of R_0'/R_0 against $(N_0/N_0')^{1/4}$.

$$R_0'/R_0 = (N_0/N'_0)^{1/4}[(1 - b/a \cdot \gamma'^{-1/2})/(1 - b/a \cdot \gamma^{-1/2})]^{1/2} \tag{8}$$

The magnitude of the 1/2-power term of the right side is clearly less than unity as γ' is smaller than γ, and would be supposed to remain nearly constant for the range studied. Experimental verification of Eq. (8) is presented in Fig. 8; there is a straight line of a slope slightly lower than 45° which is in conformity with expectation. This reveals that the Eq. (8) might be approximated to

$$R_0'/R_0 = (N_0/N_0')^{1/4} \tag{9}$$

It will be a useful relation for the estimation of the droplet size or the number concentration in aerosol at zero time without knowledge of the surface tension of the solution to be dispersed.

The Catalytic Oxidation of Hydrogen on Titanium Dioxide; Anatase and Rutile

Yoshito ONISHI

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received August 26, 1970)

To clarify the reaction mechanism of catalytic oxidation of hydrogen on titanium dioxide, the rate of catalytic oxidation of hydrogen by oxygen and the reduction rate of titanium dioxide by hydrogen have been measured by a static method in temperature range of 400—650°C at 10^{-2} mmHg. The results were compared with those of carbon monoxide which were reported in the previous papers. The oxidation reactions of hydrogen on anatase and rutile were first order with respect to hydrogen and independent of the oxygen pressure. The oxidation rate was almost the same as the reduction rate of titanium dioxide by hydrogen. The activation energy was 29.2 kcal/mol for anatase and 17.8 kcal/mol for rutile, and the difference between these values for two crystal forms was nearly equal to that of the oxidation of carbon monoxide. Therefore, it may be considered that the mechanism of oxidation of hydrogen is analogous to that of carbon monoxide. The electric conductivity of the catalyst during the oxidation of hydrogen was larger than that in oxygen at the same temperature, and was still larger than that during the oxidation of carbon monoxide except for a few cases on anatase. There were close correlations between the electric conductivity and the amount of active oxygen of the catalyst and the reduction rate constant of titanium dioxide by both hydrogen and carbon monoxide.

As a series of investigations of the catalytic action of titanium dioxide, the catalytic oxidation of carbon monoxide[1,2] and the catalytic decomposition of nitrous oxide[3] have been carried out. It was confirmed from the results that the difference between anatase and rutile in the catalytic action is owing to the difference in the desorption rates of the active oxygen from the catalysts. Furthermore, in order to examine whether the reaction mechanism of carbon monoxide is applied to other reactions, the catalytic oxidation of hydrogen was examined because hydrogen is a reducing gas analogous to carbon monoxide.

There have been published several papers concerning the oxidation of hydrogen on the metallic oxide catalysts,[4-12] and some of them [4-7,10] compared the reaction mechanisms of the oxidation of hydrogen with those of carbon monoxide. But except for a few papers on the adsorption of hydrogen on titanium dioxide,[13] there is none which treated systematically the catalytic oxidation of hydrogen on titanium dioxide.

Experimental

The catalysts[1] used in the present investigation were anatase (A) and rutile (R) which was obtained from the sample A by heating it at 1150°C for 3 hr. The specific surface areas of anatase and rutile estimated by B.E.T. method using nitrogen as the adsorbate were 10.3 m^2/g and 1.0 m^2/g, respectively. Polymorphic forms of two samples were confirmed by X-ray diffraction. Hydrogen, oxygen, and carbon monoxide from the commercial cylinders were purified by passing through a liquid nitrogen cooled trap. The apparatus had a trap, a Pirani gauge, a McLeod gauge, and a sample tube of fused quartz. Pressure of gas was usually measured by the Pirani gauge but sometimes by the McLeod gauge. The trap in the apparatus was cooled by liquid nitrogen in order to protect the sample from grease and mercury vapors and also to catch the oxidation product of hydrogen, H_2O.

The catalyst heated to 600°C for 3 hr in oxygen under a pressure of about 70 mmHg was called to be in its starting state.[2] After this treatment, the catalytic oxidation of hydrogen was measured at a definite temperature and under pressure of about 10^{-2} mmHg by using a mixed gas with a composition of $H_2/O_2=2/1$. The reaction product H_2O is condensed in the liquid nitrogen trap, and the oxidation rate of hydrogen can be determined by measuring the rate of decrease of the pressure. The distance between the trap and the sample tube was so small and the pressure in the reaction system was so low that the reaction product was caught rapidly in the trap. Therefore, even without a circulating pump, there was no trouble for the measurement. For the purpose of estimating the order of reaction, the reaction rate was also determined by using a mixed gas with a composition of $H_2/O_2=3/1$. The electric conductivity of the catalyst was measured by using the apparatus for the experiment under gas pressures of 10 mmHg and above, which was described in the previous paper.[1]

Results and Discussion

Dependence of Catalytic Activity on Specific Surface Area and Crystal Form. The rates of the catalytic oxidation of hydrogen on two crystal forms were determined in temperature range of 400—650°C and under pressure of about 10^{-2} mmHg. The reaction was first order with respect to the total pressure of the reac-

tant gas P, and its rate can be expressed as follows:

$$d(H_2O)dt = 2/3k \cdot P \quad (1)$$

where k is a constant. The Arrhenius plots on two crystal forms are shown in Fig. 1 by △. As shown in this figure the experimental points of k are linear for both anatase and rutile, and activation energies were calculated to be 29.2 kcal/mol and 17.8 kcal/mol, respectively.

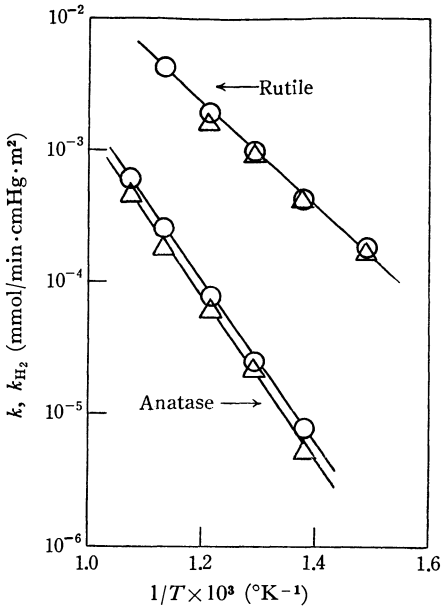

Fig. 1. Effect of temperature on the rate constant of oxidation of hydrogen.
△: k ○: k_{H_2}

Dependence of Reaction Rate and Partial Pressures of Hydrogen and Oxygen. To examine the effect of the partial pressures of hydrogen and oxygen on the reaction rate, the oxidation rate of hydrogen was measured in temperature range of 400—650°C and under pressure of about 10^{-2} mmHg keeping the initial partial pressure of oxygen constant and changing the partial pressure of hydrogen, or *vice versa*. The results are shown in Figs. 2 and 3. It is found from the figures that the oxidation rate of hydrogen is first order with

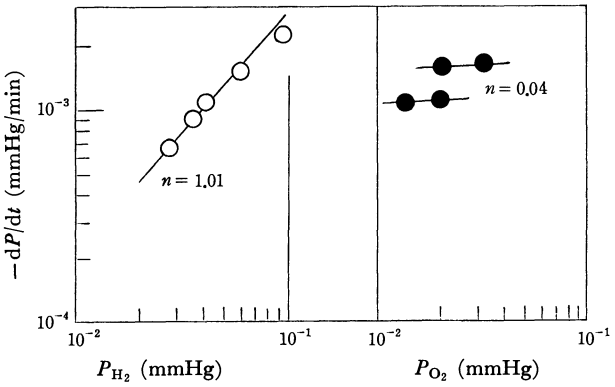

Fig. 2. Kinetics of the oxidation of hydrogen for anatase at 600°C. Open circles refer to constant O_2 partial pressure and changing H_2 pressures. Filled circles refer to constant H_2 partial pressure and changing O_2 pressures. n is the order of reaction.

respect to the hydrogen pressure P_{H_2} and independent of the oxygen pressure P_{O_2}, therefore, the following equation is obtained:

$$d(H_2O)/dt = k \cdot P_{H_2} \quad (2)$$

Reaction of Active Oxygen of Catalyst with Hydrogen. When the catalyst in the starting state was exposed to hydrogen under pressure of about 10^{-2} mmHg at a definite temperature, hydrogen reacted slowly with the active oxygen of the catalyst and water vapor thus formed was condensed in the trap and the pressure of hydrogen decreased. It was found from the results that the formation rate of water depends upon P_{H_2} and is expressed as follows:

$$d(H_2O)/dt = k_{H_2} \cdot P_{H_2} \quad (3)$$

where k_{H_2} is a rate constant of reduction of titanium dioxide by hydrogen. The Arrhenius plots on two crystal forms are shown in Fig. 1 by ○, and the value k_{H_2} is almost the same as the rate constant of the catalytic oxidation of hydrogen k above mentioned.

Electric Conductivity of the Catalyst. The temperature-dependence of electric conductivities for the catalysts of two crystal forms measured in various conditions are shown in Figs. 4 and 5. It is seen that the values in $H_2/O_2=2/1$ are larger than those in oxygen in the measured temperature range and are still larger than those in $CO/O_2=2/1$ except for the values at the temperatures lower than 450°C on anatase. From the results, it is considered that the catalyst during the oxidation of hydrogen would be in more reduced state than in the case of the oxidation of carbon monoxide except for the case at the lower temperatures mentioned above for anatase. As is listed in Table 1, the trend in conductivity coincides well with the trend in the rate constants k_{H_2} and k_{CO}.

As the slopes of the temperature-dependence of electric conductivity in oxygen and in vacuum are parallel to each other for two crystal forms, as shown in Figs. 4 and 5, it is probable that the surface state of titanium dioxide preheated at 600°C in oxygen is stable under the experimental temperatures. In the previous papers,[1,2] it is mentioned that the electric conductivity of the catalyst during the oxidation of carbon monoxide is larger than that in oxygen be-

●: in O_2 (70 mmHg)
□: in vacuum (10^{-6} mmHg)

cause a part of active oxygen on the catalyst is removed by the reaction with the carbon monoxide in the mixed gas. Therefore, from the same reason, the electric conductivity of the catalyst during the oxidation of hydrogen is larger than that in oxygen and, in narrow conductivity range, the amount of increase of conductivity will depend upon the number of the active oxygen defect. By utilizing this relation, the deficiency of active oxygen during the oxidation of hydrogen

TABLE 1. RATE CONSTANTS OF REDUCTION OF CATALYSTS BY HYDROGEN AND CARBON MONOXIDE

Temp. (°C)	650	600	550	500	450	400
$k_{H_2}\times10^4$ (H_2O mmol/min·cmHg·m²)						
Anatase	5.8	2.5	0.88	0.27	0.074	—
Rutile	—	41.0	21.5	10.8	4.6	1.9
$k_{CO}\times10^4$ (CO_2 mmol/min·cmHg·m²)						
Anatase	—	0.75	0.396	0.176	0.0896	—
Rutile	—	3.01	2.24	1.83	1.36	—

can be estimated from the electric conductivities in oxygen and in $CO/O_2=2/1$.

On the other hand, it was mentioned in the previous paper[2] that when titanium dioxide in the starting state is exposed to carbon monoxide under pressure of 10—150 mmHg at a definite temperature, after a certain period, all the surface oxygen which reacts easily with carbon monoxide is used up and the decrease of CO pressure stops. The reactive surface oxygen is called active oxygen on the oxidation of carbon monoxide. Similarly an amount of active oxygen for the oxidation of hydrogen can be determined. When the catalyst in the starting state was exposed to a circulating hydrogen under pressure of about 50 mmHg, hydrogen reacted with the surface oxygen of the catalyst to form water which was condensed in the trap, and H_2 pressure decreased. But the decrease stopped after a definite period as is the case of carbon monoxide. Thus the amount of active oxygen for the oxidation of hydrogen was estimated from the total decrease of the H_2 pressure. The amounts for two catalysts at various temperatures agreed within the experimental error with those of carbon monoxide. Therefore, the amount of active oxygen for the oxidation of hydrogen seems to be approximately equal to that for carbon monoxide at the same temperature. Therefore, the values of active oxygen listed in the previous paper[2] are also applicable to the oxidation of hydrogen. In Table 2, the deficiency of active oxygen on the oxidati on o hydrogen $(1-\theta)$, the rate constant of oxidation of the reduced titanium dioxide by oxygen k_{O_2} listed in the previous paper,[2] and the values of $k_{O_2}\cdot(1-\theta)^2$ are shown, where θ is the fraction of coverage of active oxygen. θ is equal to 1 at the starting state. The value $k_{O_2}\cdot(1-\theta)^2$ agrees almost with k_{H_2} which is listed in

TABLE 2. CALCULATED VALUES OF $(1-\theta)$, k_{O_2}, AND $k_{O_2}\cdot(1-\theta)^2$

k_{O_2} and $k_{O_2}\cdot(1-\theta)^2$ ($-O_2$ mmol/min·cmHg·m²)				
Temp. (°C)	600	550	500	450
Anatase				
$(1-\theta)\times10^2$	3.27	2.80	2.14	1.54
$k_{O_2}\times10$	2.35	1.20	0.55	0.25
$k_{O_2}\cdot(1-\theta)^2\times10^4$	2.5	0.93	0.25	0.059
Rutile				
$(1-\theta)\times10^2$	4.90	5.83	5.43	5.70
$k_{O_2}\times10$	18.0	7.50	3.40	1.33
$k_{O_2}\cdot(1-\theta)^2\times10^4$	43	26	10	4.2

Table 1, and from these values, the following equation may be satisfied approximately because the value θ is nearly equal to 1 during the oxidation of hydrogen:

$$P_{H_2} \cdot k_{H_2} \cdot \theta = 2P_{O_2} \cdot k_{O_2} \cdot (1-\theta)^2 \quad (4)$$

The above equation is entirely similar with that for the oxidation of carbon monoxide. Therefore, the catalytic oxidation of hydrogen seems to proceed with the same mechanism as that of the oxidation of carbon monoxide, as will be mentioned below.

Reaction Mechanism of Oxidation of Hydrogen. It has been described in the previous paper[1] that the electric conductivities of the catalysts of two crystal forms in oxygen at a definite temperature are constant independently of oxygen pressure. This shows that the surface of the catalyst is saturated with oxygen under pressure above 10^{-2} mmHg. It seems from this fact that the oxidation rate of the reduced catalyst by oxygen is extremely fast. In fact, these values are 920—4400 times as large as the reduction rates of the catalyst by hydrogen in temperature range of 450—600°C. Therefore, from Eqs. (1), (2), and (3), and from the results shown in Fig. 1, the reaction of the oxidation of hydrogen may consist of two steps; 1) the active oxygen of the catalyst reacts with hydrogen which is physisorbed or has just collided with the surface from the gas phase, and water thus formed is desorbed leaving an oxygen defect on the surface, and 2) the oxygen defect is quickly refilled with oxygen from the gas phase. The reaction steps are expressed by the following equations:

$$H_2(g) + O(s) \not\rightarrow H_2O(g) + (s) \quad (5)$$

$$(s) + 1/2\, O_2(g) \rightarrow O(s) \quad (6)$$

where O(s) refers to the active oxygen of the catalyst and (s) the oxygen defect on the surface. The rate of step (6) is extremely faster than that of step (5), therefore, the rate of water formation depends upon only P_{H_2}.

For the oxide catalysts other than titanium dioxide, there are several papers[4-8] which state that the rate of catalytic oxidation of hydrogen depends upon only P_{H_2}, and some papers[4-7,10] compared the reaction mechanism with that of carbon monoxide and found the similar mechanism for both gases. For titanium dioxide, the mechanism of oxidation of hydrogen is entirely similar to that of carbon monoxide, and the electric conductivities of the catalysts during the oxidation of both gases are larger than those in oxygen at the same temperatures. Moreover, the effect of crystal form for the oxidation of hydrogen and carbon monoxide is similar, *i.e.*, the activation energy of the oxidation of hydrogen on anatase is larger about 10 kcal/mol than that on rutile, as is the case for carbon monoxide. The reason of this agreement is explained by the fact that the rate-determining steps of two oxidation reactions are considered to be the reaction between the active oxygen of the catalyst and hydrogen or carbon monoxide. Therefore, the difference of 10 kcal/mol comes from the difference in the readiness of reaction between the gases and the active oxygen of the two forms, *i.e.*, the readiness of desorption of the active oxygen from the catalysts, and has almost no correlation with the kinds of the reactant gases. The activation energy of the thermal desorption of the active oxygen atoms of anatase is about 10 kcal/mol larger than that of rutile[1] and this difference can be compared with the difference in activation energies of the oxidation of hydrogen by two crystal forms.

The author wishes to express their deep thanks to Professor Takuya Hamamura of Kyoto Technical University and Professor Kumasaburo Kodera of Kyoto University for their kind advices and discussions.

Electron Donor-acceptor Complexes between Group IV Tetrahalides and Methylbenzenes

Masahiro HATANO and Osamu ITO

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received August 27, 1970)

The charge-transfer bands of the loose complexes between Group IV tetrahalides (chlorides and bromides) and methylbenzenes were observed, and the electron affinities of these tetrahalides were systematically evaluated from these observed charge-transfer bands. The semi-empirical molecular orbital calculations (the extended Hückel method) for these tetrahalides revealed that the tetrahalides interact with the benzene ring using the vacant molecular orbital involving the empty *d* atomic orbital of the halogen atom in the tetrahalides. Moreover, the meanings of the electron affinities estimated in this study were discussed in terms of the molecular orbitals, by comparing them with the values of the electron affinities evaluated by other methods.

Extensive studies have been made of the complexes between Group IV tetrahalides and *n*-donors by means of the thermodynamic[1] and the spectroscopic measurements, such as IR[2] and NMR.[3] Since Mulliken developed the theory of the donor-acceptor complex,[4] it has been reported that these tetrahalides form not only stable complexes with *n*-donors, but also loose complexes with aromatic π-donors.

As for the carbon tetrachloride and carbon tetrabromide, many workers have studied the formation of loose complexes with π-donors.[5-8] The formation of loose complexes between tin tetrachloride and aromatic hydrocarbons has been studied by Tsubomura[9] and by Myher and Russell.[10] By the spectroscopic measurements, Krauss and his co-workers have found that the titanium tetrachloride and vanadium tetrachloride form loose complexes with π-donors.[11]

Although there have been many investigations of the tetrahalide complexes, many essential problems have not yet been solved. Some of them are as follows:

i) What are the structures of these complexes?

ii) What is the order of the electron affinities of the tetrahalides, which are evaluated from the charge-transfer bands, and what are the meanings of these electron affinities?

iii) What are the molecular orbitals of the tetrahalides which are used to accept the aromatic π-electrons of the donors?

The aim of the present study is to settle some of these problems as definitely as possible. In order to accomplish this purpose, we undertook to measure the UV and visible spectra and to carry out some molecular orbital calculations on these tetrahalides.

Experimental

Materials. Cyclohexane of a spectral-use grade was refluxed over calcium hydride and was distilled and stored under nitrogen gas. The hexamethylbenzene (HMB) and pentamethylbenzene (PMB) were recrystallized and sublimated twice, whereas durene purified by zone-refining was used without further purification. The Mesitylene was refluxed, distilled, and stored in a sealed vessel under nitrogen gas. All the tetrachlorides and tetrabromides, of an extra pure grade, were distilled *in vacuo* and then were immediately used.

Procedure. After the glass apparatus had been dried in a high vaccum and baked to a high temperature, the donor and acceptor solutions were made separately, with air excluded, in glass apparatus, and then degassed in a high vaccum to follow the mixing of both solutions. The concentrations of the solutions were varied over a wide range to obtain the new absorption bands clearly. The absorption spectra were measured by a Cary model 14M recording spectrophotometer, and fused quartz cells with a light-path length of 0.1—10 mm were used.

Experimental Results and Discussion

Electron Donor-acceptor Complexes between Tin Tetrachloride and Methylbenzenes. The mixed solutions of tin tetrachloride and methylbenzenes, *i.e.*, mesitylene, durene, PMB, and HMB, in cyclohexane showed significant absorption bands in the UV and visible regions, where solutions of the individual components show negligible absorption; only in the appropriate concentrations of the donor (0.050—0.075 mol/*l*) and those of the acceptor (0.025—0.050 mol/*l*) solutions were new absorption maxima clearly separated, as is shown in Fig. 1.

The plotting of the transition energies of the new absorption bands ($h\nu_{CT}$) against the ionization potentials(I_P)[12] of the corresponding donors exhibits a linear relationship, as is shown in Fig. 2-I. A similar linear relationship has been established in the iodine molecular

A,D: concentrations of acceptor and donor, respectively, d: absorbance, ε: molar extinction coefficient, K: formation constant, (1) 340 nm, (2) 320 nm, (3) 300 nm

Continuous variation plots for the absorbance of the solutions of tin tetrachloride and HMB in cyclohexane are given in Fig. 3. At both 300 nm (a maximum of the charge-transfer absorption) and 320 nm, these plottings indicate that a 1 : 1 complex is formed in this system; this finding is consistent with that of Myher and Russell.[10] Since the formation of a 1 : 1 complex was confirmed, the Benesi-Hildebrand plots for this system were attempted, as is shown in Fig. 4, which shows straight lines. The formation constant and molar extinction coefficient of this complex were estimated to be as shown in Table 1, in which the formation constants varied greatly with the wavelength. It has been reported that the dependence of the formation constants on the wavelength occur, when a contact charge-transfer complex or another com-

position is included in the system,[18,19] but we could not determine which case is more likely in this system. However, when the formation constant of one system is compared with that of another system, only the values obtained at or near the maxima of the charge-transfer absorptions may be suitable. The estimated values of the formation constants at the absorption maxima are shown in Table 2, together with the literature values for the carbon tetrachloride complexes, which were measured near the maxima of the charge-transfer bands.[7] Moreover, from the temperature changes of the formation constants, the formation enthalpy for this system was estimated to be −2.8 kcal/mol; this value was comparable with the previously reported values.[9,10]

The Charge-transfer Bands of the Other Tetrahalide Complexes with HMB. As for the other tetrachloride complexes and tetrabromide complexes with HMB, all the spectra except the carbon tetrahalide complex were measured (Fig. 5—10); the absorption maxima of the newly-appearing absorption bands are summarized in Table 3, together with the reported charge-transfer bands. The shapes and positions of these absorption spectra are characteristic of the charge-transfer bands. In the case of silicon tetrahalides, the approximate values are shown in Table 3, since the new absorptions seemed to overlap with those of the donor.

In the systems of titanium tetrahalides and methylbenzenes (Figs. 8 and 9), two absorption peaks appeared, as had been reported by Dijkgraaf[20] and by Ott and his co-workers.[21] Since a peak at a shorter wavelength changed its position with a variation in the concentrations of the donor and the acceptor, this

peak was deduced to be an apparent absorption peak which emerged from the difference between the absorption of titanium tetrahalide in the complex system and that of titanium tetrahalide itself in cyclohexane. Therefore, only the absorptions at longer wavelengths were deduced to be the charge-transfer bands which correspond to the values reported by Krauss and his co-workers.[11]

On the basis of these measurements, it may be pointed out that the charge-transfer bands of the tetrabromides appear in a longer-wavelength region than those of the corresponding tetrachlorides and the charge-transfer bands of tetrahalides including the transition elements appear in a longer-wavelength region than those of tetrahalides including non-transition elements.

of electron acceptors have been evaluated on the basis of the charge-transfer bands by many investigators.[22,23] Using the same donor, neglecting the differences in the coulombic interaction energies between the components in the complexes, and neglecting the contributions of the local excitations to the charge-transfer transition, the following approximate equation can be derived:

$$(E_A)_i - (E_A)_0 = (h\nu_{CT})_0 - (h\nu_{CT})_i \quad (1)$$

Here, the suffixes o and i indicate the standard and any given acceptor respectively. Since the "vertical" ionization potential and electron affinity should be involved in the charge-transfer transition according to Mulliken's theory,[4] the values used here and evaluated on the basis of Eq. (1) are not "adiabatic"

22) M. Batley and L. E. Lyons, *Nature*, **196**, 573 (1962).
23) G. Briegleb, *Angew. Chem.*, **76**, 326 (1964).

but "vertical." Here, choosing the iodine molecule and HMB as the standard system, and assuming the electron affinity of the iodine molecule to be 1.8_0 eV[22] and the charge-transfer transition energy of this system to be 3.4_7 eV,[13] the electron affinities of all the tetrachlorides and tetrabromides could be evaluated systematically, as is shown in Table 3.

The electron affinities of titanium tetrachloride and vanadium tetrachloride evaluated by Krauss and his co-workers[11] are smaller by 1 eV than the values evaluated in this study, because they evaluated them assuming the electron affinity of iodine molecule to be 0.8 eV[23] and used that value as the standard in Eq. (1). Therefore, these electron affinities are meaningful only as relative values. As was expected from the transition energies of the charge-transfer bands, the electron affinities of transition-element tetrahalides are larger than those of non-transition element tetrahalides, and the electron affinities of bromides are larger than those of chlorides.

c) Ref. 21, d) Refs. 24 and 25, e) Ref. 8, f) Ref. 13.

Moreover, it was pointed out by Davis and Farmer[8] that the electron affinity of carbon tetrachloride as evaluated from the charge-transfer band was smaller than the corresponding values of *p*-benzoquinone; on the other hand, this order was reversed when the electron affinity was evaluated by the magnetron method (Table 4).[24,25] In the following section we will attempt to explain this anomaly in terms of the molecular orbital.

Structure of the Loose Complexes between Tetrahalides and Methylbenzenes. In general, tetrahalides form 1 : 2 stable complexes with *n*-donors, the structures being as shown in Fig. 11-A,[26] while, with aromatic π-donors, tetrahalides form loose complexes, whose structures have not yet been made clear except a carbon tetrabromide complex with *p*-xylene (Fig. 11-B).[5] If tetrahalides form A-type complexes, some spectral changes might occur accompanying a conformational change from the T_d to the D_{4h} of tetrahalides. These changes in the electronic spectra were indicated by Bridgland and McGregor in their study of vanadium tetrachloride complexes with *N*-oxides;[27] that is, in a ligand field with a D_{4h} symmetry of vanadium tetrachloride in the

[A] a stable complex toward *n*-donors
[B] a loose complex between CBr_4 and *p*-xylene proposed by Striter and Templeton[5]
[C] a possible structure between $SnCl_4$ and methylbenzene

A-type complex, the $2T_{2g}-2E_g$ intramolecular charge transition of the T_d symmetry split into two transitions. However, in the case of the vanadium tetrachloride-HMB complex, the spectral change was not observed, as is shown in Fig. 10; this indicates that vanadium tetrachloride retains the T_d symmetry even in the complex with methylbenzenes. As for the tetrachlorides, since the order of the atomic distance between the central atom and the halogen atom of tetrachlorides is $CCl_4<SiCl_4<GeCl_4<TiCl_4<VCl_4<SnCl_4$ (Table 3), it may be presumed that tetrachlorides, whose distance are smaller than vanadium tetrachloride, will tend to form a structure similar to that of the vanadium tetrachloride complex with methylbenzenes, that is, a B-type structure (Fig. 11).

The only remaining problem here is, then, the analysis for the tin tetrachloride complex, for which Tsubomura[9] assumed that the tin atom may be coordinated directly to either one or two benzene rings. On the other hand, it has been reported that, although the stable complexes show a 1 : 2 composition, the loose complexes show a 1 : 1 composition. Even in the case of the tin tetrachloride complexes with methylbenzenes, the formation of 1 : 1 complexes was confirmed (Fig. 3); this suggests that the tetrachlorides composed of a relatively large-sized central atom such as tin tetrachloride also form B-type complexes. This suggestion was supported by the order of the formation constants, which increase in the same order as those of the carbon tetrachloride complexes (Table 2), whose structures were presumed to be B-type.[5]

Since the unstability accompanying the conformational change from the T_d to the D_{4h} or from the T_d to the "Pyramidal" of tetrachloride is too large to form a complex between the central atom and the benzene ring, the A- and C-type structures may be excluded. The same discussions may be extended to the tetrabromide complexes.

Theoretical Considerations and Discussions

It has been presumed by some workers that the carbon tetrahalides accept the π-electron of the benzene ring using the empty *d* atomic orbitals of halogen

atoms (3*d* for chlorides and 4*d* for bromides).[28] To ascertain the truth of this assumption for all tetrahalide complexes, molecular orbital calculations were carried out by an extended Hückel method for tetrachlorides and tetrabromides.[29] In these calculations, in addition to *s* and *p* atomic orbitals, empty *d* atomic orbitals of halogen atoms were considered. All the valence state ionization potentials used in this study are summarized in Table 5, together with the literatures.

The distances between the central atoms and the halogen atoms are shown in Table 3.[30] The overlap integrals were calculated using the Slater-type atomic orbitals by means of the method of Roothaan,[31] whose program was reported by Offenhartz.[32,33]

c) Energy level of the lowest vacant orbital.
d) Overlap integral in complex.

Some of the results of the calculations are shown in Table 6. The calculated ionization potentials of tetrachlorides may be compared with the measured values;[34] the agreement is as good as is generally achieved for this quantity. On the other hand, the electron affinity calculated by the extended Hückel method could not be compared directly with the measured values, but it may be possible to compare them relatively. However, no correlation, not even a relative one, could be found between the lowest vacant orbital energies and the electron affinities evaluated from the charge-transfer bands. As for the non-transition element tetrahalides, when the vacant molecular orbitals (E_V) involving the *d* atomic orbital of the halogen atom, which appeared at a higher energy level than those of the lowest vacant orbital, are plotted against

the electron affinities evaluated from the charge-transfer bands, the molecular orbitals involving the $3d_{z^2}$ and $3d_{yz}$ of chlorides or the $4d_{z^2}$ of bromides all satisfy a linear relationship, as is shown in Figs. 12 and 13 respectively. The corresponding vacant molecular orbitals of the transition-element tetrahalides, which could be found by extrapolating the plots for the non-transition-element halides, do not always involve empty *d* atomic orbitals on the halogen atoms. These molecular orbitals are summarized in Tables 7 and 8 for the chlorides and in Table 9 for the bromides. From the geometry of the empty *d* atomic orbitals, some structures of the complexes with benzene rings could be presumed, as is illustrated in Fig. 14.

Since it has been accepted that the charge-transfer force is determined mainly by the electron affinity and the overlap integral (S_{AD}) between the donor and the acceptor orbital, these overlap integrals were evaluated approximately, assuming an a_{2u} molecular orbital of benzene as the donor orbital and using the coordination system shown in Fig. 14-B_1. These results are shown in Tables 6 and 7. Since the overlap integrals for the lowest vacant orbitals are very small compared with that of the iodine-benzene complex, which was evaluated by Aono to be 0.11,[35] it is not considered that these molecular orbitals of tetrachlorides accept the π-electrons of the donor. However, the overlap integrals of the molecular orbitals in Table 7 are suitable values for explaining the formations of the weak complexes. Since the electron affinities of titanium tetrachloride and vanadium tetrachloride are larger than these of tin tetrachloride and carbon tetrachloride, and since the order of the overlap integrals are reversed, the compensation between the electron affinity and the overlap integral might induce the lack of variation in the formation enthalpies in the complexes.

On the basis of these results, we could explain the anomaly in the meaning of the electron affinity shown in Table 4. That is, although carbon tetrachloride accepts the free electron by using the lowest vacant orbital, and although the result of this process might correspond to the value measured by the magnetron method, the π-electrons of the benzene ring are accepted by the molecular orbital involving the empty *d* orbital of the chlorine atom in carbon tetrachloride; this process corresponds to the charge-transfer transition. On the other hand, an organic π-acceptor such as *p*-benzoquinone accepts both the free electron and the π-electrons of the donor by using the lowest vacant orbital, for this orbital expands outside of the acceptor molecule.

As has been discussed above, the results on the struc-

35) S. Aono, *Progress Theor. Phys.*, **22**, 313 (1959).

tures of the complexes and on the molecular orbitals of tetrahalides permit the explanation of many phenomena, such as the order of the electron affinities and formation enthalpies; therefore, it may safely be concluded that the tetrahalides interact with the benzene ring using the vacant molecular orbitals involving empty *d* atomic orbitals on halogen atoms of tetrahalides. Moreover, this conclusion suggests that the weak other charge-transfer bands from the donor orbital to the lowest vacant orbital of tetrahalide may appear in a wavelength region longer than those observed in this study. However, more detailed studies of the shapes of the charge-transfer bands, especially of their tails, are needed.

The authors wish to thank to Professor T. Nakajima and Dr. A. Tajiri of Tohoku University and Dr. M. Okuda of the University of California for their useful discussions and for making extended Hückel programs. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 923—928 (1971)

An Infrared Spectroscopic Study of Hydrogen Bonds. The Liquid-Liquid Interaction of Solvents with Trimethylsilanol

Tsutomu KAGIYA, Yūzō SUMIDA, Takeshi WATANABE, and Toshihiro TACHI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 7, 1970)

An infrared spectroscopic study of the hydrogen-bonding interaction of binary solvents (S_1–S_2) with trimethylsilanol has been made, where CCl_4 is used as S_1 and the aromatic hydrocarbons and the O- and N-containing solvents, as S_2. On the basis of the findings on the O–H frequency shifts ($\Delta\nu_{OH}$) of trimethylsilanol, the equilibrium constants (K) and the preferential coordination constants (α_{1-2}) of hydrogen-bond formation, the difference in the O–H···π and the O–H···n hydrogen-bonding interactions has been discussed. The free-energy changes ($-\Delta G$) were found to be better related to the apparent half-widths ($\Delta\nu_{1/2}$) of the O–H bands than the $\Delta\nu_{OH}$. The $\Delta\nu_{OH}$ of trimethylsilanol caused by the interaction with the solvent was in good correlation with the donor number defined as the heat of mixing of the solvent with antimony(V) chloride. From the linear relationship between the $\Delta\nu_{OH}$ of trimethylsilanol and the $\Delta\nu^{S}_{OH}$ of the surface silanol caused by the gas-phase adsorption on silica gel, it was also found that the proton-donating power of the surface silanol was considerably larger than that of trimethylsilanol and was nearly equal to that of *p*-nitrophenol. There existed a linear relationship through the point of origin between the α_{1-2} and the separation factors (α^{S}_{1-2}) in the liquid-phase adsorption on the silica gel surface.

Many interesting studies of the intramolecular and the intermolecular hydrogen bonds have been made by using such analytical instruments as IR, NMR, and Raman spectrometers.[1] Especially, the O–H···π hydrogen-bonding interactions between the proton donors and the solvents containing π-electrons have been systematically studied with the IR technique.[2-4] On the other hand, the spectroscopic studies of the O–H···n interactions of the proton donors with the solvents containing hetero atoms have been mainly focussed on the O–H frequency shifts, the equilibrium constants, and the enthalpy changes of hydrogen-bond formations.[5-10] Many investigations of the hydrogen bond have, in any case, been made in very dilute solutions of such inert solvents as CCl_4. Little attention has been paid to the quantitative difference or to the correlation between the O–H···π and the O–H···n interactions.[1] Moreover, few systematic studies of hydrogen-bonding interactions in correlation with the gas-phase and/or the liquid-phase adsorption phenomena on a solid surface have been reported, except for the gas-phase adsorption on silica gel.[11,12] On the other hand, despite the vastness of the literature on intermolecular interactions in solution, the correlation between the nucleophilic coordinations of solvents to the Brönsted acids and the Lewis acids has never been discussed because of the different types of interactions

1) The studies of the hydrogen bonds were summarized in G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman & Co., San Francisco, Calif., (1960).

involved.[13]

In this paper, the hydrogen-bonding interaction has been studied by means of the IR technique between various proton-acceptor solvents (S_2) in carbon tetrachloride (S_1) solutions and trimethylsilanol, which has a partial structure (SiO–H bond) analogous to the silanol group on the silica gel surface.[14] The objectives of the present work are; (1) to discuss the different types of hydrogen bonds, *i.e.*, the O–H···π and the O–H···n interactions; (2) to compare the hydrogen-bonding interaction with trimethylsilanol with the nucleophilic coordination to antimony(V) chloride as a Lewis acid, and (3) to ascertain the relationship between the liquid-liquid interaction with trimethylsilanol and the gas-phase adsorption (solid-gas interaction) or the liquid-phase adsorption (solid-liquid interaction) on silica gel.

Experimental

Materials. All the solvents were obtained commercially and were purified by the usual methods. The trimethylsilanol was synthesized by the method of Sommer.[15]

Spectra Measurements. The composition of the binary mixture of carbon tetrachloride (S_1) and the second solvent (S_2) was cautiously determined by weighing and was varied over quite a wide concentration range. A small quantity of trimethylsilanol was added to a weighing bottle containing the binary mixture to make a solution of 0.004—0.015 mol/*l*. The KBr cell, with an optical thickness of 0.20 cm and filled with the solution, was placed in the irradiation path of infrared light, controlled at 28±3°C, and then allowed to equilibrate before scanning. All the spectral measurements were made by using a Japan Spectroscopic Co., Ltd., Model DS-403G infrared spectrophotometer. The spectral slit width was 1.7 cm^{-1} in the O–H fundamental regions (3400—3700 cm^{-1}).

Analysis of Spectra. The O–H frequency shifts ($\Delta\nu_{OH}$) of trimethylsilanol caused by the S_2 were expressed as the difference from the free O–H absorption frequency in CCl_4 ($\nu_{OH}(CCl_4)=3702$ cm^{-1});

$$\Delta\nu_{OH} = \nu_{OH}(CCl_4) - \nu_{OH}(S_2) \quad (1)$$

In the following equilibrium reaction;

$$SiOH\cdots S_1 + S_2 \rightleftarrows SiO\text{–}H\cdots S_2 + S_1 \quad (2)$$

the concentration ([SiOH···S_1] or [SiO–H···S_2]) of trimethylsilanol solvated by S_1 or S_2 in the binary mixture was estimated from the calibration curve of the trimethylsilanol concentration in each solvent against the absorbance, which had been drawn in advance. However, the O–H absorption band of trimethylsilanol in the polar solvent differed considerably in frequency, in intensity, and in shape from that caused by the solvent in the binary mixture. The concentration [SiO–H···S_2] of trimethylsilanol solvated by such solvents as ethyl acetate (EA), acetonitrile (AN), dioxane (DOX), and tetrahydrofuran (THF) was replaced by [SiOH]$_0$−[SiOH···S_1], where [SiOH]$_0$ was the initial concentration. Moreover, in order to evaluate the apparent molar absorption coefficients (κ_2) of hydrogen-bonded complexes with the hetero atoms, the check for the Lambert-Beer rule was made in such dilute solutions of CCl_4 that the free O–H band disappeared, that is, in solutions with volume ratios of CCl_4 : EA=1 : 1, CCl_4 : AN=1 : 1, CC_4 : DOX=2 : 1, and CCl_4 : THF=2 : 1. The concentration [SiO–H···S_2] estimated by using the apparent molar absorption coefficients agreed, within the limits of experimental error (3—5%), with [SiOH]$_0$−[SiOH···S_1]. The equilibrium constant (α_{1-2}) in Eq. (2), which we called the preferential coordination constant, was calculated by the use of Eq. (3);

$$\alpha_{1-2} = \frac{[SiO\text{–}H\cdots S_2]([S_1]_0 - [SiOH\cdots S_1])}{[SiOH\cdots S_1]([S_2] - [SiO\text{–}H\cdots S_2])} \quad (3)$$

The equilibrium constant (K) of hydrogen-bond formation in very dilute solutions of CCl_4 was estimated from the α_{1-2}.

Results and Discussion

Figures 1 and 2 show typical examples of O–H···π and O–H···n spectra observed in CCl_4-benzene and CCl_4-tetrahydrofuran solutions respectively. The

Lambert-Beer rule held fairly well over a wide concentration range of trimethylsilanol in CCl_4 and in the aromatic hydrocarbons, but not in solvents containing oxygen and nitrogen atoms diluted by CCl_4, as has been described in the experimental section (Fig. 3). This may be due to the large polarity of the hydrogen-bonded complex with the hetero atom. As is shown in Figs. 1 and 2, the isosbestic points were observed in every binary solution studied in the present work except the CCl_4-acetonitrile solution.[16] This fact leads to the conclusion that all hydrogen-bonded complexes have compositions of 1 : 1.[4c] Moreover, the fact that the preferential coordination constants, calculated on the basis of the 1 : 1 complex, are reasonably constant over the wide concentration range of the S_2 provides indirect support for the 1 : 1 assumption.

In Table 1, the apparent molar absorption coefficients (κ_2) and the apparent half-widths ($\Delta\nu_{1/2}$) of the O–H bands bonded by the solvents, the equilibrium constants (K) of the hydrogen-bond formation in very dilute CCl_4 solutions, and the preferential coordination constants (α_{1-2}) of the binary mixtures are summarized, together with the O–H frequency shifts ($\Delta\nu_{OH}$) of trimethylsilanol caused by the S_2. The error limits in Table 1 are believed to be within about 5%.[4c]

Difference in the O–H···π and O–H···n Hydrogen Bonds. It should be noted in Table 1 that the apparent molar absorption coefficients which are characteristic of the hydrogen-bonded complexes are nearly equal within 230—300 l/mol·cm, even though the O–H···π and O–H···n hydrogen bonds are of different types.[17] On the other hand, the half-widths, expressing the relaxation phenomenon of the complexes, changed markedly with different forms of hydrogen-bonding interaction, *i.e.*, ~50 cm^{-1} for O–H···π and 120—160 cm^{-1} for O–H···n complexes.[18] Moreover, the $\Delta\nu_{OH}$, α_{1-2}, and K values of solvents containing the oxygen and nitrogen atoms are large in comparison with those of the aromatic hydrocarbons. These results suggest the stronger nucleophilic coordination of the lone-pair-electrons of the hetero atom to trimethylsilanol than that of the π-electrons of the benzene nuclei. A major difference in the two types of hydrogen-bonding interactions is considered to appear more conspicuously in the entropy effect than in the enthalpy effect.

In order to confirm this theory, the free-energy changes ($-\Delta G$) of hydrogen-bond formation were plotted against the $\Delta\nu_{OH}$ values, which were propor-

tional to the enthalpy changes of hydrogen-bond formation, as had been pointed out in the earlier papers.[1,8] As is shown in Fig. 4, a linear relationship is apparently obtained between them. However, further observation indicates different straight lines for the aromatic hydrocarbons and the solvents containing the hetero atoms, whose slopes are nearly equal to each other. This can be explained as resulting from the remarkable difference in the entropy effects of π- and n-hydrogen bonds. A similar result had been reported for the phenol adducts with π-electron and lone-electron donors.[4b,c]

On the other hand, the $\Delta\nu_{1/2}$ value should be an overall value expressing the molecular movement of the O–H group in solutions, including the enthalpy and the entropy changes. Therefore, the ΔG value may be expected to have a better correlation with the $\Delta\nu_{1/2}$ value than with the $\Delta\nu_{OH}$. As is confirmed in Fig. 5, the ΔG *vs.* $\Delta\nu_{1/2}$ relationship is satisfied in various binary solutions, regardless of the form of the hydrogen bond.

Interaction Forces of Solvents toward the Brönsted and Lewis Acids. As has been mentioned in the previous papers,[10a,d] the $\Delta\nu_{OH}$ can be regarded as a measure of the proton-accepting (the electron-donating) properties of S_2 toward the Brönsted acid. On the other hand, Gutmann *et al.* have made quantitative calorimetric measurements of the interactions of a number of solvents containing the hetero atoms with antimony(V) chloride and have proposed a donor number for each of the solvents toward the Lewis acid.[13] A comparison of the electron-donating properties of the solvents toward the different kinds of acids, *e.g.*, the Brönsted and Lewis acids, is shown in Fig. 6, where the $\Delta\nu_{OH}$ values of pyridine, dimethyl sulfoxide, dimethylformamide, and *N*,*N*-dimethylacetamide have been approximated from the data for deuteromethanol as a proton donor.[10a] The $\Delta\nu_{OH}$ increased linearly with the increase in the donor numbers. It seems that it can be concluded from this fact that there exists a certain physicochemical rule between the intermolecular interactions toward the Brönsted acid and the Lewis acid, despite the different types of interactions.

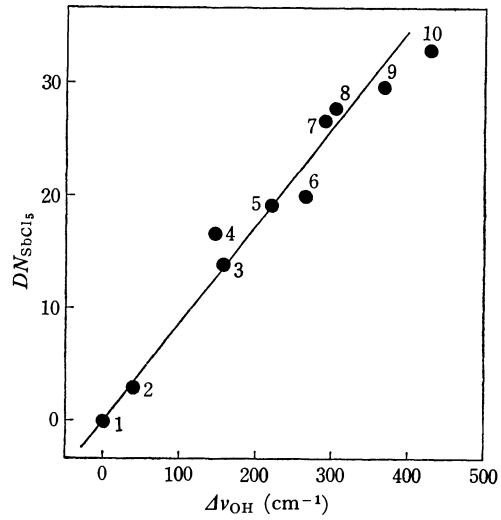

Fig. 6. Relationship between the donor numbers (DN_{SbCl_5}) and the O-H frequency shifts ($\Delta\nu_{OH}$).

The $\Delta\nu_{OH}$ values of solvents (7—10) were estimated from the data for deuteromethanol.
The DN_{SbCl_5} of CCl_4 was approximated by that of 1,2-dichloroethane.

Liquid-liquid Interaction with Trimethylsilanol and Solid-gas and Solid-liquid Interaction with the Silica Gel Surface. It is well known that the silanol group on the silica gel surface plays an effective role in the catalytic reactions. In order to make clear the intermolecular interactions on the silica gel surface, the liquid-liquid interaction with trimethylsilanol was compared with the gas-phase adsorption (solid-gas interaction) and

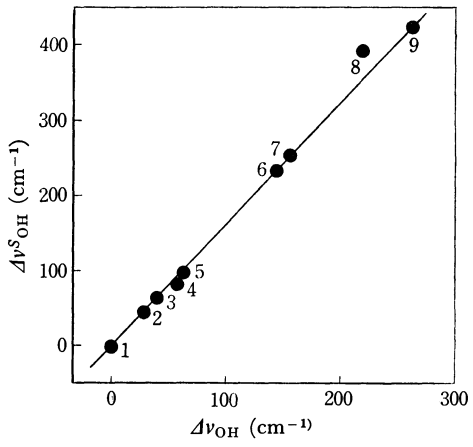

Fig. 7. Relationship between the O-H frequency shifts ($\Delta\nu^S_{OH}$) of silica gel surface silanol by gas-phase adsorption and the O-H frequency shifts ($\Delta\nu_{OH}$) of trimethylsilanol.

the liquid-phase adsorption (solid-liquid interaction) on silica gel.

The $\Delta\nu_{OH}$ values of trimethylsilanol were plotted against the $\Delta\nu^S_{OH}$ values, which were the O–H frequency shifts of the surface silanol caused by the monolayer adsorption of gases on silica gel,[12,19] where the O–H absorption frequency by CCl_4 vapor was taken to be 3704 cm^{-1}. As is shown in Fig. 7, a good linear relationship, with a slope of 1.60 was obtained between them. The value of this slope indicates that the O–H group of the surface silanol is more acidic than that of trimethylsilanol; that is, the ionic dissociation energy

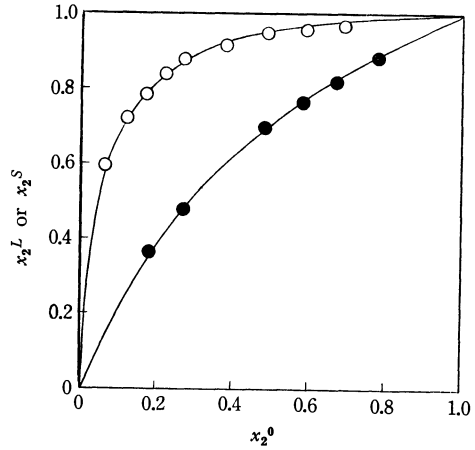

Fig. 8. Plots of the mole fractions (x_2^L) of trimethylsilanol bonded by S_2 or the mole fractions (x_2^S) of S_2 adsorbed on silica gel against the mole fractions (x_2^0) of non-bonded S_2.
●; Carbon tetrachloride-Toluene (Trimethylsilanol), $\alpha_{1-2}=2.36$
○; Cyclohexane-Toluene (Silica gel), $\alpha^S_{1-2}=18.6$.

19) The silanol O–H frequency shifts on the silica gel surface depend slightly on the surface coverage; they grow considerably with the surface coverage up to a monolayer, while on further adsorption they change very slowly.
20) For such a homologous series of adsorbates as the aromatic hydrocarbons, the $\Delta\nu_{OH}$ increases as the differential heat of adsorption becomes larger.

of the surface O–H bond is smaller than that of the trimethylsilanol O–H bond.[10d] This may correspond to the fact that the O–H fundamental frequency of silica gel is 3749 cm^{-1} in the gas-phase,[12] considerably larger than that (*ca.* 3710 cm^{-1}) of trimethylsilanol.[10d] In a previous paper,[10d] we defined the proton-donating power (Φ_D) of the donor, independent of the kind of proton acceptor, as the ratio of the O–H frequency shift of the proton donor in a certain acceptor to that of methanol as a standard proton donor;

$$\Phi_D = \frac{\Delta\nu_{RO-H}(\text{proton acceptor})}{\Delta\nu_{MeO-H}(\text{proton acceptor})} \quad (4)$$

This definition rests on the fact that there exists a linear relationship, through the point of origin, between $\Delta\nu_{RO-H}$ and $\Delta\nu_{MeO-H}$ in the same proton acceptor.[8d,10d] According to our definition, the Φ_D of the trimethylsilanol and the silica gel surface silanol were determined to be 1.65 and 2.65 respectively. The value of

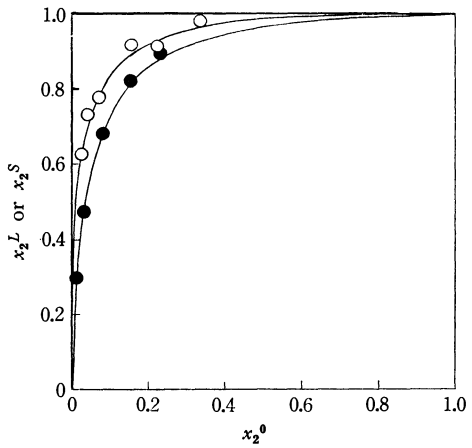

Fig. 9. Plots of the mole fractions (x_2^L) of trimethylsilanol bonded by S_2 or the mole fractions (x_2^S) of S_2 adsorbed on silica gel against the mole fractions (x_2^0) of non-bonded S_2.
●; Carbon tetrachloride-Dioxane (Trimethylsilanol), $\alpha_{1-2}=30.6$
○; Cyclohexane-dioxane (silica gel), $\alpha^S_{1-2}=63.3$.

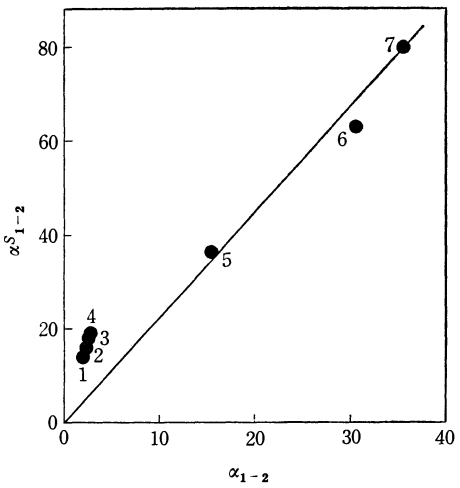

Fig. 10. Relationship between the preferential coordination constants (α_{1-2}) of trimethylsilanol and the separation factors (α^S_{1-2}) of silica gel.

surface silanol is nearly equal to that (2.92) of *p*-nitrophenol. On the other hand, the $\Delta\nu_{OH}$ is not related to the differential heat of adsorption, expressing the total energy of the complicated interaction with the surface at a given coverage.[20] However, from a comparison of the homogeneous and heterogeneous hydrogen-bonding interactions, it can be concluded that there is a difference in the Φ_D, namely, the sensitivity to proton acceptors, but no essential difference in the nucleophilic coordination phenomena.

In order to compare the liquid-liquid interaction with trimethylsilanol with the solid-liquid interaction with the silica gel surface, we examined the relationship between the preferential coordination constants (α_{1-2}) to trimethylsilanol and those ($\alpha^S{}_{1-2}$) on silica gel, that is, the separation factors. The latter was obtained from the data on the preferential adsorption from the binary solution of cyclohexane(S_1)-second solvent(S_2) on silica gel.[11] In Fig. 8 and 9, the mole fractions ($x_2{}^L$) of trimethylsilanol bonded by the S_2 or those ($x_2{}^S$) of the S_2 adsorbed on the silica gel are plotted against the mole fractions ($x_2{}^0$) of the non-bonded S_2 in the equilibrium solution. It should be noted in Figs. 8 and 9 that the binary mixtures are better separated on the silica gel surface than in trimethylsilanol. The separation power of silica gel or trimethylsilanol is characterized by the $\alpha^S{}_{1-2}$ or the α_{1-2}. A quantitative relationship between the α_{1-2} and the $\alpha^S{}_{1-2}$ is illustrated in Fig. 10. A straight line, though not good, is drawn with a slope of 2.2 through the point of origin. This may correspond to the fact that the Φ_D of surface silanol is larger than that (1.65) of trimethylsilanol.[10d] It can be said from the above considerations that the separation powers of proton donors in the same binary mixture become larger as the Φ_D values of the donors increase.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 928—933 (1971)

The Molecular and Crystal Structure of 3,4-Furandicarboxylic Acid Dimethylester

Yasuyoshi OKADA,* Kazumi NAKATSU,** and Akira SHIMADA

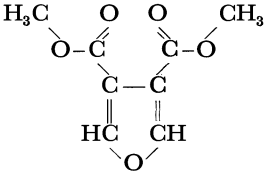
Department of Chemistry, Faculty of Science, Osaka City University, Sugimotocho, Osaka

(Received September 9, 1970)

The crystals of 3,4-furandicarboxylic acid dimethylester are monoclinic of the space group $P2_1/a$, with unit cell dimensions $a=12.64$, $b=8.16$, $c=7.97$ Å, and $\beta=100.0°$. An approximate structure was determined by application of the symbolic addition phase determining procedure. After several cycles of least-squares refinement, the discrepancy index for the 901 observed reflections was reduced to 14%. In the molecule the furan ring is planar, and one carbomethoxy group is almost on the same plane as the furan ring, while the other makes an angle of 10.5° with the ring. The bond lengths and angles do not differ appreciably from the values found in the other compounds, except for those of C(3)–C(4)=1.41 Å, C(4)–C(3)–C(6)=131° and C(3)–C(4)–C(7)=132°, the latter two being larger than normal values probably because of interaction between the carbonyl-oxygens. The mode of packing of the molecules and a scheme of twinning found in this crystal is discussed.

3,4-Furandicarboxylic acid dimethylester (I) (MW 184, mp 47°C) was studied by means of X-ray crystal analysis to elucidate its molecular structure and the mode of packing in the crystal. Several structures similar to that of the present molecule were studied. They include 3,4-furandicarboxylic acid,[1] furan-α,α'-dicarboxylic acid[2] (or 2,5-furandicarboxylic acid), and 3,4-thiophendicarboxylic acid dimethylester.[3] It would be of interest to compare the present structure with the others, especially about the configurations of the two substituents with respect to the furan ring and the bond distances and angles inside it.

(I)



Experimental

Specimens of suitable size for X-ray work were crystallized from the aqueous solution in the form of a transparent, colorless column elongated along the c axis.[4] The crystals have a cleavage plane normal to the a^* axis.

The compound crystallizes always in a twinned form; the twinning is found to be such that the twins have common a^* and b^* but different c^* direction. Twinning made the accurate intensity determinations difficult, for partial or heavy overlappings of the reflections from the twins occurred in some zones.

Since the crystals sublime readily in the air at room temperature, the specimen was enclosed in a capillary tube during exposure to X-rays. Multiple Weissenberg intensity data were collected with Ni-filtered Cu $K\alpha$ radiation along axis c from zeroth to fifth layer and along axes a and b for zeroth layer only. The intensities were estimated visually with the use of a calibrated scale. Altogether 1239 independent reflections were observed, and 338 of them were too weak to be

measured. No correction was made for absorption and extinction. After the Lorentz and the polarization corrections were made, intensities were placed on a same relative scale.

The crystal data are as follows:

Monoclinic,

$a=12.64\pm0.04$ Å

$b=8.16\pm0.02$

$c=7.97\pm0.02$

$\beta=100.0\pm0.1°$

Systematic Absences, $h0l$ with h odd and $0k0$ with k odd

Space Group, $P2_1/a$

Density, $D_m=1.50$ g cm^{-3}, $D_x=1.51$ g cm^{-3}

Z 4

Absorption Coefficient, $\mu=12.7$ cm^{-1} (for Cu $K\alpha$).

Structure Determination

Since attempts to solve the Patterson map were not successful, the direct phase determining method, or so-called symbolic addition method[5] by Karle *et al.*, was applied. Professor Y. Okaya of State University of New York kindly supplied us with a copy of his program.[6]

In this procedure normalized structure factors may be used, being defined as

$$E_h^2 = F_h^2/\varepsilon \sum_{j=1}^{N} f^2{}_j h^2, \qquad (1)$$

where F_h is the observed structure factor for the reflection $\boldsymbol{h}$, and N is the number of atoms in the unit cell. ε is a factor that depends on the space group extinctions, and $\varepsilon=1$ in the space group $P2_1/a$ except for the $h0l$ and $0k0$ reflections, where $\varepsilon=2$. The distribution and the statistical averages of the normalized structure factor are given in Table 1. The experimental values imply that the crystal is centrosymmetric.

To initiate the symbolic addition procedure, three linearly independent reflections were chosen to specify the origin. The signs of two other reflections were specified symbolically by letters. These five reflections forming the basic starting set are as follows:

Table 1. Statistical averages and distribution of the normalized structure factors

	Experimental	Theoretical	
		Centric	Acentric
$\langle\|E^2\|\rangle$	1.000[a]	1.000	1.000

3 4 1	2.67	+			

These reflections were chosen on the basis of the large number of interactions obtained from application of the Σ_2 formula and on their relatively high $|E|$ values. The Σ_2 formula is

$$sE_h \approx s\sum_{k} E_k \cdot E_{h-k}, \qquad (2)$$

where s means "sign of". The probability $P_s(E_h)$ that a symbolic phase s determined by the Σ_2 formula is valid is given by[6]

$$P_s(E_h) = 1/2 + 1/2 \tanh\left(\frac{\sigma_3}{\sigma_2^{3/2}}|E_h|\cdot R_s\right), \qquad (3)$$

where $\sigma_n=\sum_{j=1}^{N} Z_j{}^n$, Z_j is the atomic number of the jth atom and R_s is the difference between the sum of the products $E_k \cdot E_{h-k}$ associated with the dominant symbol(s) and the sum of the products of all other symbols.

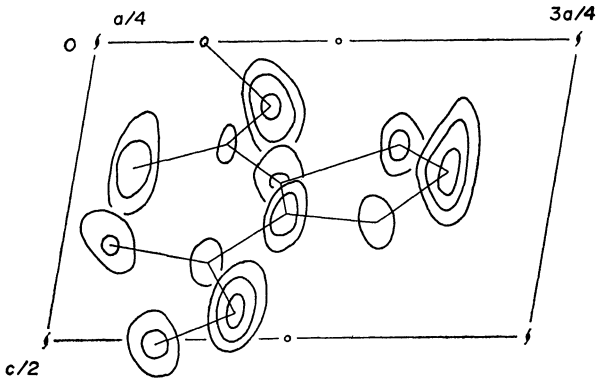
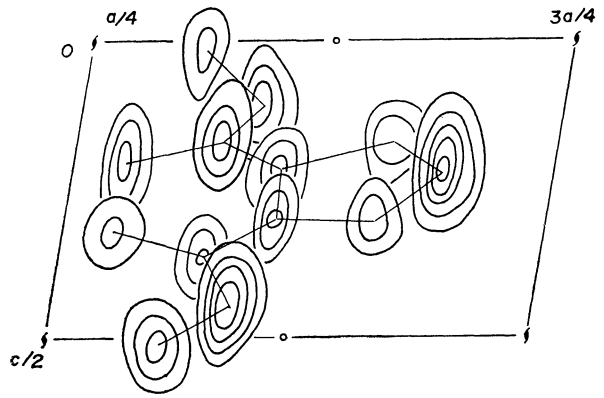
6) Y. Okaya and A. Bednowitz, *ibid.*, **22**, 111 (1967).

Only 220 reflections with $|E|$ greater than 1.5 were considered. As many terms in Σ_2 as possible were used to determine each phase. An example of Σ_2 list is given in Table 2, which contains all the interaction pairs giving the index triplet for which a phase should be assigned. Some of these terms seem to indicate a relationship between the unknown symbols. After four cycles of iterations, the phases for 138 reflections were expressed by the combinations of A and B. Inspection of all the Σ_2 interaction lists showed that there was only one possible assignment for the unknown A and B, that is, A=+ and B=+. Any other assignment would have resulted in discrepancies in a number of contributors to Σ_2. This relation was taken into account and 29 additional phases of the reflections were determined. Thus 167 phases were settled.

E maps (Fourier map with E rather than F values for coefficients) were computed with both the 138 and 167 reflections. All the thirteen non-hydrogen atoms in the asymmetric unit were resolved. Sections from these maps are illustrated in Figs. 1(a) and (b). On the E map shown in Fig. 1(b), the peak values for all the atoms exceeded 220 (on an arbitrary scale), while the maximum value of the rapidly varying background was 193.



(a)



(b)

Fig. 1. E maps computed with 138 terms (a) and 167 terms (b).

Coordinates for the thirteen non-hydrogen atoms as read from the E map were subjected to a least-squares refinement, using all the reflection data. After three cycles of diagonal least-squares calculations, the discrepancy index $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$ was reduced to 0.21 for the non-zero reflections only. Successive two cycles of block-diagonal calculations lowered R only by 2%.

Electron density and difference Fourier syntheses were calculated at this stage of refinement. Sections of the three-dimensional electron density map projected on (010) are given in Fig. 2. Since remarkable anisotropic thermal vibration of the atoms were implied from the difference Fourier map, further refinement was carried out with the anisotropic temperature factors applied to the thirteen non-hydrogen atoms. Two more cycles of block-diagonal least-squares calculations improved R to 0.135. The peaks of hydrogen atoms did not appear in the difference map even at this stage.

Results and Discussion

The final coordinates and temperature factors of the atoms are listed in Table 3(a) and (b), respectively, and the intramolecular distances and angles are given in Table 4 and Fig. 3. In Table 5 the bond distances and angles inside the furan ring found in the several similar molecules are compared with the mean values in the present one, where the furan ring has approximately a mirror symmetry through O(1) and the midpoint of C(3)–C(4) bond.

The ring C–O lengths of 1.36 and 1.35 Å are very close to the values found in various compounds. The double bond lengths of 1.37 and 1.38 Å in the ring are nearly equal to the value of 1.361 Å found in furan, but greater than the values 1.351 and 1.35$_4$ Å found in 3,4-acid and α,α'-acid, respectively. The single bond distance 1.41 Å in the ring appears to be significantly shorter than the value 1.462 Å found in 3,4-acid. The single bonds between the ring and the carbonyl group are 1.45 and 1.47 Å long, the former

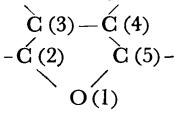

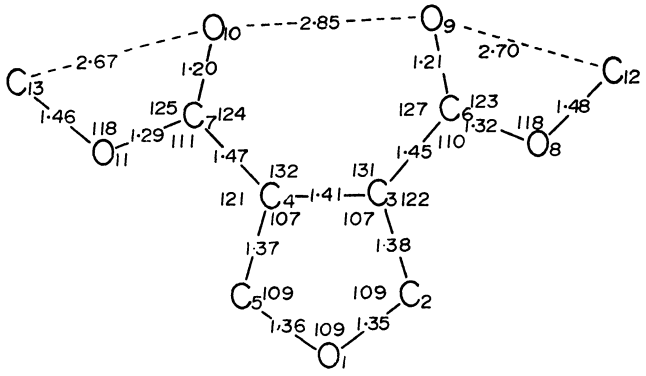

Fig. 3. The molecular structure projected on the plane of furan rin . Standard deviations are about 0.016Å and 1.0°.

is slightly shorter than the usual value.

The furan ring is accurately planar, and the equation of the mean plane and the deviations of the atoms from this plane are given in Table 6, in which the planes of carbonyl groups are also described. The oxygen atoms in one of the carboxyl group, O(10) and O(11), are markedly out of the plane of furan ring; the twist angle of the carboxyl group with respect to the ring plane is 10.5°. The other carboxyl oxygen atoms, O(8) and O(9), on the other hand, are almost completely on the same plane as the ring.

The distance between the two carboxyl oxygen atoms is 2.85 Å, which is just the twice of the van der Waals radius of oxygen atom and should be compared to the value of 2.91 Å found in 3,4-thiophendicarboxylic acid dimethylester.[3] The angles C(4)–C(3)–C(6)= 131° and C(3)–C(4)–C(7)=132° deviate considerably from the ideal value 126°. This would be due to the steric hindrance between the two substituents. The interaction would also cause the distortion of the bond angles around C(6) and C(7), *viz.*, C(3)–C(6)–O(9) and C(4)–C(7)–O(10) are increased, while C(3)–C(6)–O(8) and C(4)–C(7)–O(11) are reduced by several degrees each.

The mode of packing of the molecules in the crystal can be seen in Figs. 4 and 5. The furan rings incline

7, in which several close approaches are found between the carbonyl oxygen atom and the methyl group, and between the furan ring carbon atoms.

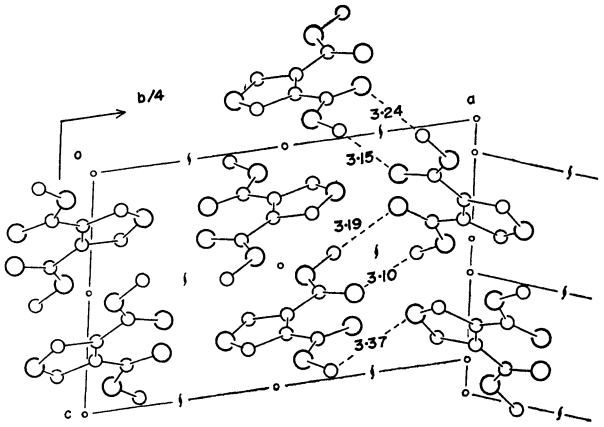

Fig. 6. Proposed scheme of twinning.

A submicroscopic scheme of twinning is proposed, as shown in Fig. 6. The boundary surface of the twin components is assumed on the crevice that lies between the molecular layers parallel to the bc plane, and the layer on $x=a$ is inverted and translated along axes b and c so that the twins have common a^* and b^* directions but different c^* direction. Thus, the resultant intermolecular distances across the crevice on $x=a/2$ and $x=a$ take reasonable values as shown in the figure.

The authors wish to express their sincere thanks to Professor Yoshiharu Okaya of State University of New York and Professor Tamaichi Ashida of Osaka University who kindly gave us computing facilities.

Effect of Phase on Excitation Transfer in the Radiolysis of Isobutane

Tetsuo MIYAZAKI, Takahisa YAMADA, Terunobu WAKAYAMA, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 10, 1970)

The effects of CCl_4 on the formation of H_2 and C_4H_9 radicals in the radiolysis of i-C_4H_{10} have been studied in glass at 77°K and the liquid at 195°K. The yield of H_2, which is not affected by the addition of N_2O or SF_6, decreases sharply upon the addition of CCl_4 in the glass, as in the crystal (This Bulletin, **42**, 1164 (1969); **43**, 1017 (1970).), while it does not so sharply decrease in the liquid as in the solid. The effects of CCl_4 on the yields of H_2 correspond fairly well to those on the yields of the C_4H_9 radicals. The effects of CCl_4 in the glass are explained by the excitation transfer from the excited butane molecule to CCl_4, as in the radiolysis of i-C_4H_{10} in the crystal. A kinetic treatment suggests that its mechanism may be the exciton transfer. Some remarks on the primary process of ionization in the radiolysis of solid hydrocarbons are given from the viewpoint of exciton transfer.

We have studied the radiolysis of isobutane in the crystalline state at 77°K by ESR spectroscopy and product analysis. Though the yields of C_4H_9 radicals and hydrogen do not decrease in the presence of conventional electron scavengers, they decrease remarkably upon the addition of CCl_4.[1] The characteristic effects of CCl_4 have been ascribed to exciton transfer from a kinetic consideration. Recently it has been found that the radiolysis of solid isobutane is affected appreciably by its state, by whether it is glass or polycrystal.[2] Although the isobutyl radical is formed in the crystalline state by γ-irradiation, the t-C_4H_9 radical is formed in the glassy state. The yields of CH_4 and C_3H_6 in the radiolysis of solid isobutane are much higher in the polycrystalline state than in the glassy state. It has been suggested that a plausible explanation of the phase effect is in terms of the difference between the efficiency of energy transfer in the glass and that in the polycrystal.

Here we have studied the effects of the phase on the excitation transfer to CCl_4 in the radiolysis of isobutane.

Experimental

The isobutane, methylcyclohexane (MCH), nitrous oxide, and carbon tetrachloride were all the same as those which had been used before.[1,2] The sulfur hexafluoride (Matheson Co.) was of a high purity. The samples were irradiated with Co-60 γ-rays at a dose rate of 4.2×10^5 rad/hr. The ESR measurements were made on a JES-3BX ESR spectrometer. The gaseous products not condensable at the temperature of liquid nitrogen were analyzed by a gas burette connected to a Toepler pump and a copper oxide furnace kept at 240°C.

Pure isobutane forms a polycrystalline solid at 77°K. When a sample of isobutane containing a small amount of MCH is plunged into liquid nitrogen, it forms a clear glass. The concentration of MCH in the radiolysis of glass for the product analysis is different from that for the ESR measurement. This is because the state of the glass depends upon the concentration of MCH. The glass at a high concentration of MCH is unfavourable for the detection of radicals by ESR, because the matrix is so soft that the radicals are not trapped. Therefore, the concentration of MCH chosen for the measurement of the C_4H_9 radical is 4 mol/100 mol of i-C_4H_{10}. The glass at a low concentration of MCH is, however, so unstable that it becomes crystalline during a long γ-irradiation time. Therefore, when the yield of H_2 is measured in the radiolysis in the glassy state, the chosen concentration of MCH is 10 mol/100 mol of i-C_4H_{10}.

Results

Formation of Hydrogen. In the radiolysis of i-C_4H_{10}-MCH(10 mol/100 mol of i-C_4H_{10}) system, N_2O and SF_6 are added in the glassy state in order to suppress the formation of hydrogen by a neutralization reaction (reactions (1) and (2)), if any should occur:

$$C_4H_{10} \rightsquigarrow C_4H_{10}^+ + e^- \quad (1)$$

$$C_4H_{10}^+ + e^- \rightarrow H,\ H_2,\ P \quad (2)$$

where P represents some radicals or molecules. As is shown in Table 1, the yield of hydrogen does not decrease at all upon the addition of electron scavengers, such as N_2O and SF_6. Since $G(N_2)$ amounts to 1.4—1.6 in the radiolysis of i-C_4H_{10}-MCH(10 mol/100 mol of the i-C_4H_{10})-N_2O(3 mol/100 mol of i-C_4H_{10}) system, N_2O captures electrons efficiently to produce N_2, as

Table 1. Radiolysis of i-C_4H_{10}—MCH(10[a]) system in the glassy state at 77°K
Total dose: 4.3×10^6 rad

	$G(H_2)$	$G(CH_4)$	$G(N_2)$

in the radiolysis of liquid cyclohexane.[3] Therefore, it can be concluded that hydrogen is not formed by the neutralization reaction in the radiolysis of isobutane in the glassy state as it is in the crystalline state.[1]

The effect of CCl_4 on the yield of hydrogen in the radiolysis of isobutane in the liquid, glass, and polycrystal are shown in Fig. 1. Since a part of the hydrogen formation in the radiolysis of liquid isobutane[4] is due to the neutralization reaction of cation and an electron, SF_6 was added in order to suppress the formation of hydrogen by the ionic process. Since the hydrogen is not formed in the radiolysis of the glassy and polycrystalline states by the neutralization reaction, the effect of CCl_4 is not influenced by the presence of an electron scavenger such as N_2O.

Formation of C_4H_9 Radical. The effects of CCl_4 on the yields of t-C_4H_9 radicals in the radiolysis of the i-C_4H_{10}-MCH (4 mol/100 mol of i-C_4H_{10}) system in the glass are shown in Fig. 2. The correlation between the yields of H_2 and those of the C_4H_9 radicals, as plotted against the concentration of CCl_4, is also shown in Fig. 2. Since the effect of CCl_4 on the yields of H_2 is completed at 5 mol of CCl_4/100 mol of i-C_4H_{10}, the yield of hydrogen $G'(H_2)$, which is affected by the addition of CCl_4, can be estimated by the following equation: $G'(H_2)=G(H_2)-G(H_2)_c$. $G(H_2)_c$ is $G(H_2)$ at 5 mol of CCl_4/100 mol of i-C_4H_{10}, and $G'(H_2)$ and $G(C_4H_9)$ are, in the absence of CCl_4, both normalized to unity. The fact that the yields of the C_4H_9 radicals coincide fairly well with $G'(H_2)$ indicates that the formation of the C_4H_9 radical is closely related to the formation of H_2.

Discussion

Excitation Transfer. It can be considered that the C_4H_9 radical and H_2 are formed mainly by the decomposition of excited molecules produced directly by the γ-irradiation of solid isobutane. This conclusion is based on the following observations, made both here and in a previous study:[1]

1) The yields of the C_4H_9 radical in the radiolysis of polycrystalline isobutane are not changed by the presence of conventional electron scavengers, such as phenyl iodide, ethyl iodide, nitrous oxide, and sulfur hexafluoride.[1]

2) The yields of the C_4H_9 radical do not increase upon the photobleaching of toluene anions in the γ-irradiated isobutane-toluene(5 mol/100 mol of i-C_4H_{10}) system in the polycrystalline state.[1]

3) The yields of the C_4H_9 radical do not increase upon the photobleaching of electrons trapped in the γ-irradiated isobutane-MCH(4 mol/100 mol of i-C_4H_{10}) system in the glassy state or the photobleaching of benzene anions in the γ-irradiated isobutane-MCH (4 mol/100 mol of i-C_4H_{10})-benzene(5 mol/100 mol of i-C_4H_{10}) system in the glassy state.

4) The yields of H_2 in the radiolysis of glassy isobutane are not changed at all by the presence of conventional electron scavengers, such as nitrous oxide and sulfur hexafluoride.

The yields of the C_4H_9 radical and H_2 decrease sharply, however, upon the addition of CCl_4 in the radiolysis of solid isobutane (Figs. 1 and 2). Let us ascribe this effect to excitation transfer from the excited isobutane molecule to CCl_4 and the suppression of the decomposition of the excited isobutane:

$$C_4H_{10} \xrightarrow{I} C_4H_{10}^* \quad (3)$$

$$C_4H_{10}^* \xrightarrow{k_d} C_4H_9 + H \quad (4)$$

$$H + H \longrightarrow H_2 \quad (5)$$

$$H + C_4H_{10} \longrightarrow C_4H_9 + H_2 \quad (6)$$

3) S. Sato, R. Yugeta, K. Shinsaka, and T. Terao, *ibid.*, **39**, 156 (1966).
4) K. Tanno, S. Shida, and T. Miyazaki, *J. Phys. Chem.*, **72**, 3496 (1968).

$$C_4H_{10}^* + CCl_4 \xrightarrow{k_q} C_4H_{10} + CCl_4^* \quad (7)$$

where I is the rate of reaction (3) and where k is the rate constant. The yield of the thermal hydrogen atom captured by ethylene is measured by ESR and found to be rather small in the radiolysis of i-C_4H_{10} containing C_2H_4.[1] Therefore, it is likely that some of the H atoms in reaction (4) are hot atoms.

As is shown in Fig. 1, the efficiency of excitation transfer depends upon the phases; its order in this system is as follows:

glass > crystal > liquid

The reason why the excitation transfer is more efficient in the glass than in the crystal is not clear at present. It is noted that the yields of hydrogen do not decrease upon the addition of CCl_4 in the liquid phase (Fig. 1).

The C–H bond rupture of the excited butane molecule in reaction (4) may occur in the period of one vibration ($\sim 10^{-13}$ sec). Since the excitation transfer in reaction (7) competes with reaction (4), the rate of excitation transfer is probably extremely high. Therefore, the mechanism of the excitation transfer may be exciton transfer.

Now let us consider the excitation transfer in the glass by the kinetic treatment on hydrogen formation. The formation of hydrogen may be expressed as in reactions (3)—(7). The rate of excitation transfer (reaction (7)) cannot be expressed a priori, as that of the bimolecular reaction. Therefore, the following expression is adopted:[5]

$$R_q = k_q[C_4H_{10}^*][CCl_4]^{n/3} \quad (I)$$

where R_q is the rate of reaction (7). Since the rate of excitation transfer is usually expressed as some integral power function of the distance between two interacting molecules, it is assumed here that $R_q \propto [CCl_4]^{n/3}$, where n is an integer. $[CCl_4]^{1/3}$ is proportional to the reciprocal of the average distance between the molecules of carbon tetrachloride and excited butane. The rate of excitation transfer for various theoretical models is expressed as follows:[6]

a) Exciton transfer:

$$R_q \propto \frac{1}{r^3}$$

b) Vibrational-relaxation resonance transfer:

$$R_q \propto \frac{1}{r^6}$$

where r is the distance between interacting molecules. The steady-state treatment leads to:

$$\frac{1}{G'(H_2)} = \frac{1}{I} + \frac{k_q}{Ik_d}[CCl_4]^{n/3} \quad (II)$$

where n is taken to be 3 or 6, depending upon the models. Kinetic plots of our data for (a) and (b) are shown in Fig. 3. The experimental points fall reasonably well

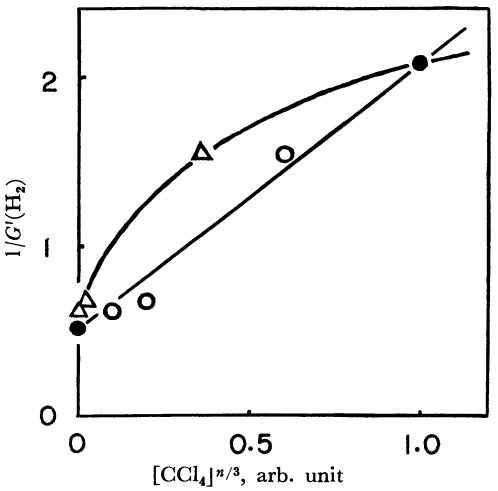

Fig. 3. Relations between $1/G'(H_2)$ and $[CCl_4]^{n/3}$ in the radiolysis of i-C_4H_{10}—MCH(10[a])—N_2O(3[a]) system at 77°K. When $[CCl_4]=0.5$[a], $[CCl_4]^{n/3}$ is nomalized to be 1.
○—○: $n=3$
△—△: $n=6$
a) Unit, mol/100 mol of i-C_4H_{10}

on a straight line for $n=3$; thus,

$$R_q \propto [CCl_4] \propto \frac{1}{r^3}$$

The kinetic treatment suggests that the mechanism of excitation transfer in the glass is exciton transfer. The same conclusion was previously obtained for the butyl-radical formation in the crystalline state.[1]

Primary Process of Ionization in the Radiolysis of Solid Hydrocarbons. There are some peculiar phenomena in the solid-state radiolysis, as compared with the radiolysis in the liquid phase.

First, the fragmentation of an excited isobutane ion is negligible in the radiolysis of isobutane in the polycrystal and glass,[1,2b] while it plays an important role in the radiolysis of liquid isobutane.[4] The excited isobutane ion has an electronic excitation energy of more than 1.8 eV and decomposes instantaneously in one vibration to form the $C_3H_7^+$ ion and the CH_3 radical.[7] When the excited isobutane ion is produced by the charge-transfer reaction from Kr^+ in the γ-irradiated Kr-i-C_4H_{10} system at 77°K, it has an excitation energy of more than 1.8 eV and decomposes even in the solid matrix of Kr.[8] Since it seems that the matrix of the i-C_4H_{19}-MCH (10 mol/100 mol of i-C_4H_{10}) system is softer than that of solid Kr at 77°K, we cannot ascribe the depression of the fragmentation of excited ion in the γ-irradiated glassy isobutane to the cage effect by the matrix. Therefore, it is conceivable that the yields of the excited ion are lower in the solid state than in the liquid state.

Second, the yields of hydrogen, which are not affected by the addition of N_2O and which correspond to those from nonionic processes, are much higher in the γ-irradiated glassy isobutane than in the liquid state. Therefore, it is conceivable that the yields of

8) T. Wakayama, A. Miwa, T. Miyazaki, K. Fueki, and Z. Kuri, unpublished results.

the nonionic species are higher in the solid state than in the liquid state.

Third, it has been reported by several investigators that the yields of the electrons which can be captured by electron scavengers are 1.5—2.0 G-units in the radiolysis of hydrocarbon glasses at 77°K. They used biphenyl,[9] alkyl disulfide,[10] benzene,[11] iodobenzene,[12] and nitrous oxide[12] as electron scavengers. The yields of the electrons captured by these scavengers were determined by measurements of the optical[9,10] or ESR absorption[11] of the anions, or by product analysis.[12] It is very interesting that G(e) values obtained by different scavengers and measurements are 1.5—2.0 in the γ-irradiated hydrocarbon glasses, while the G(e) values amount to 3—4 in γ-irradiated liquid hydrocarbon. Therefore, it is conceivable that the yields of ionization may be smaller in the solid state than in the liquid state.

One possible explanation of these characteristic phenomena of solid radiolysis will be given here from the viewpoint of the formation of the exciton. It may be said, from the above considerations, that the exciton plays an important role in the γ-irradiated solid, though it plays only a minor role in the liquid phase. When the exciton is formed by γ-irradiation in the solid hydrocarbon, the electronic absorption spectrum of the solid can be expected to differ from that of the liquid; that is to say, Davydov splitting can be expected to occur.[13] If a fraction of the ionization occurs from superexcited states, as proposed by Platzman,[14] and if the state of the exciton corresponds to the superexcited state, the following schemes may represent the ionization of i-C_4H_{10}: In the liquid state:[4]

$$i\text{-}C_4H_{10} \rightsquigarrow C_4H_{10}^{**} \quad (8)$$

$$C_4H_{10}^{**} \longrightarrow C_4H_{10}^{+*} + e^- \quad (9)$$
$$\longrightarrow C_4H_{10}^{+} + e^- \quad (10)$$

$$C_4H_{10}^{+*} \longrightarrow C_3H_7^{+} + CH_3 \quad (11)$$

where $C_4H_{10}^{**}$ represents isobutane in the superexcited states and where $C_4H_{10}^{+*}$ represents the excited isobutane ion. In the solid state:

$$i\text{-}C_4H_{10} \rightsquigarrow C_4H_{10}^{*} \quad (3)$$

$$C_4H_{10}^{*} \longrightarrow C_4H_9 + H \quad (4)$$
$$\longrightarrow C_4H_{10}^{+} + e^- \quad (12)$$

where $C_4H_{10}^{*}$ represents the exciton which produces mainly a butyl radical, a hydrogen atom, a butane ion, and an electron. A mechanism by which the exciton may be related to the ionization was also suggested in the solid radiolyses of polyethylene[15] and succinic acid.[16]

It can be understood from the above reaction scheme that the fragmentation of the excited ion occurs only in the radiolysis of liquid isobutane. The yields of hydrogen from nonionic processes may be larger in the radiolysis of solid isobutane than in that of the liquid phase, because reaction (4) is involved. Since the exciton produces mainly neutral fragments in the radiolysis of glass (reaction (4)), the yields of electrons may be rather low in γ-irradiated glass as compared with those in the liquid phase.

The authors wish to thank Dr. Kanji Katsuura of the Kurashiki Rayon Company for his helpful discussions.

Electronic Absorption Spectra of Crystals of Thymine, Uracil, and Their Derivatives

Masashi TANAKA and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya

(Received September 21, 1970)

The electronic structures and spectra of thymine, uracil, and their derivatives have been studied by measuring the electronic absorption spectra of the single crystals. In the polarized absorption spectra of the crystal, an unusual absorption band appears at about 285 mμ in the tail of the usual $\pi\rightarrow\pi^*$ transition when the crystal has the C=O···H–N-type hydrogen bond. The direction of the transition moment of this band is found to be along the direction of the hydrogen bond between a pair of C=O···H–N-groups, the nature of which is discussed from several viewpoints. The direction of the transition moment of the first and second $\pi\rightarrow\pi^*$ bands is determined to be inclined at about $+38°$ and $+86°$ from the $C_4\cdots N_1$ line toward the C_5 atom. The result for the first band is not in perfect agreement with the finding of Stewart and Davidson regarding 1-methylthymine, who regarded this angle as either $-14°$ or $+19°$.

Thymine and uracil are important base components of DNA and RNA molecules. The electronic structures and spectra of these molecules are significant in studying the conformation and optical properties of poly-nucleotide, since the hypochromic and circular dichroic effects are governed mainly by the nature of the electronic transitions and the interaction of excited states of these base pairs. Although many investigations have appeared on the spectra of DNA bases and these derivatives in solution,[1-5] little work has been done with the polarization of the transition moments. Stewart and Davidson[6] reported on the absorption spectra of single crystals of 9-methyladenine and 1-methylthymine. Chen and Clark[7] measured the polarized reflection spectra of the purine crystal. The present research was undertaken in order to find the polarization of each band by measurements of the absorptions on the single crystals of several of these base components. The polarized crystal absorption spectra of several kinds of crystals of thymine, uracil, and these derivatives were measured; these bases all have the same π-electron framework and, to a first approximation, may have the same polarization property if we disregard the effect of substituent methyl groups. The exciton-type interaction between different excited states (second-order exciton effects) will be disregarded because the transition moments are not very large. The dichroic ratios are used with the oriented gas model to find the directions of two $\pi\rightarrow\pi^*$ transitions in the 220 and 280 mμ regions.

In the crystalline spectra, we have noticed a particular kind of absorption band which is accompanied by a C=O···H–N-type hydrogen bond: The polarization character of this band is rather specific, and its nature will be discussed from several points of view.

Experimental

Materials. The 5-ethyl-6-methyluracil was kindly supplied by Dr. Marsh of the California Institute of Technology, while the 1,3-dimethyl thymine and 1,3-dimethyluracil were synthesized by Dr. Sakabe of our laboratory. All the other compounds were obtained from the Sigma Chemical Company, the California Corporation for Biochemical Research, or the Nakarai Chemical Company. All these compounds were recrystallized from water or ethanol before measurement.

Apparatus. The crystal spectra were recorded at room temperature on a specially-designed microspectrophotometer consisting of: (i) an Olympus polarizing microscope with Zeiss Ultrafluar objectives and a quartz Rochon polarizer, (ii) a Zeiss PMQII monochromater with tungsten and hydrogen sources, and (iii) a 1P28 photomultiplier tube with a standard Zeiss detection system.

Results

1,3-Dimethylthymine. The absorption spectrum of the single crystal of 1,3-dimethylthymine is shown in Fig. 1. The crystal absorption spectrum is similar to that of the solution spectrum, and the $\pi\rightarrow\pi^*$ band is observed at about 270 mμ. The direction of the transition moment can not be discussed with this crystal since the crystal structure has not yet been analyzed.

Calcium Thymidylate. The absorption spectrum of the single crystal of calcium thymidylate has been measured and is shown in Fig. 2-a. The crystal structure analysis has been carried out by Trueblood, Horn, and Luzzati,[8] who showed that the crystal belongs to the space group of C_{2h}-$P2_1$ and that two molecules are included in a unit-cell. The unit-cell dimensions are $a=14.40$, $b=6.87$, $c=9.81$ Å, and $\beta=90°58'$. On the basis of this finding, the projection of molecules onto the developed plane (100) is pictured in Fig. 2-b. A thymine ring is found nearly perpendicular to the bc plane; it is related to another ring with a two-fold screw axis parallel to the *b* axis. The distance between the two thymine rings is 3.43 Å, and no hydrogen bonding of the C=O···H–N-type is involved between the base rings. The crystalline absorption spectrum

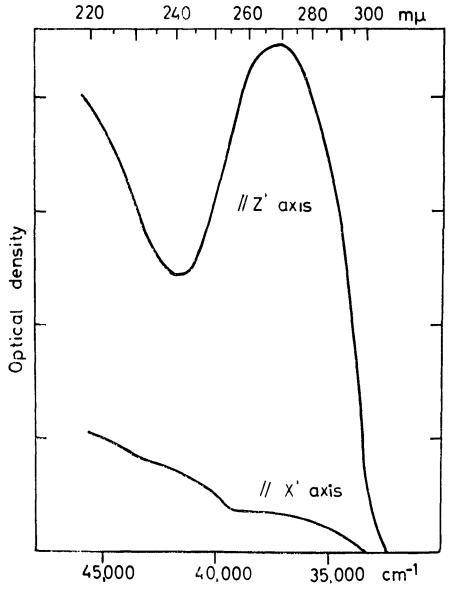

Fig. 1. The polarized absorption spectrum of the single crystal of 1,3-dimethylthymine.

is measured on the bc plane. In the *c* axis spectrum, two peaks are observed at 275 and 220 mμ but the *b*-axis spectrum has only a peak at 280 mμ in the region between 330 and 220 mμ. Each peak shifts to a longer wavelength as compared with the solution spectrum, but no extra band is observed. The dichroic ratio for the first $\pi\rightarrow\pi^*$ band in the vicinity of 280 mμ is determined from the areas under two perpendicularly-polarized absorption curves and it gives $I_c : I_b = 10 : 1$. If θ is the angle which the transition moment projected onto the bc plane makes with the *c* axis, then the polarization ratio ($I_c : I_b$) is equal to $\cot^2\theta$. From the crystal structure data, we may be able to find the relation of the molecular frame to the *b* axis and, finally,

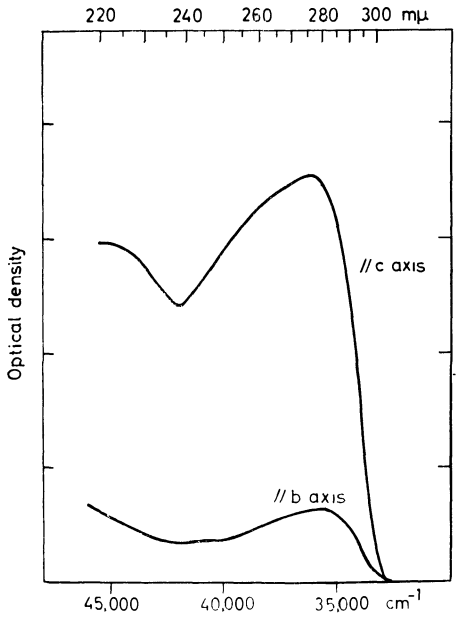

Fig. 2-a. The polarized absorption spectrum in the (100) plane of the single crystal of calcium thymidylate.

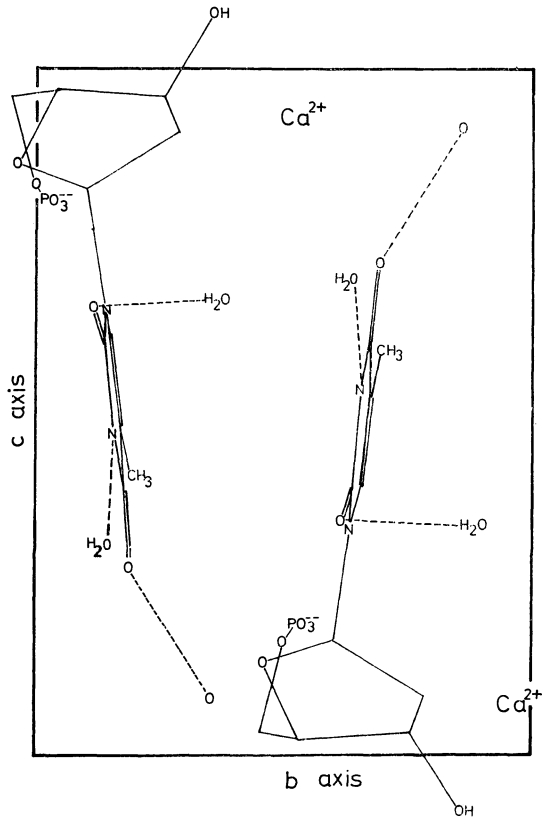

Fig. 2-b. Projection of calcium thymidylate molecules onto the (100) plane.

to determine the direction of the transition moment in the molecular plane. By this method, the transition moment of this band is determined to lie at either +79° or +97° inclined to the reference axis, which is settled along the line joining the C_4 atom and its para partner (N_1) as is shown in Fig. 3. Here, the positive sign of the angle indicates clockwise rotation around the center of the ring. The dichroic ratio of the second $\pi\rightarrow\pi^*$ band is about 6 : 1 ($I_c : I_b$) as measured from the observed band intensities. From these results, the transition moment to the reference axis is estimated as being inclined to +82° or +94°. These angles are found to be more or less likely for the first and second bands, but this result is not reasonable from a theoretical point of view. The accuracy of the measurement is poor, because the molecular plane is sharply tilted to the developed crystalline plane. In such a configuration an accurate determination will be rather difficult, but it will provide some auxiliary information.

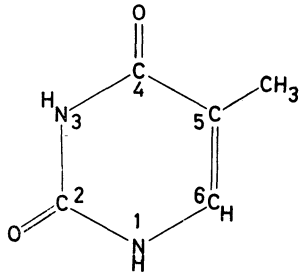

Fig. 3. Numbering of the atoms of thymine molecule.

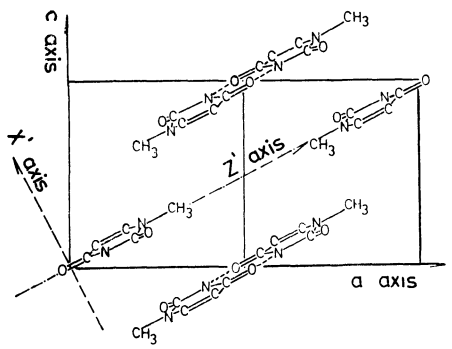

Fig. 4-a. Projection of 1-methylthymine molecules onto the (010) plane.

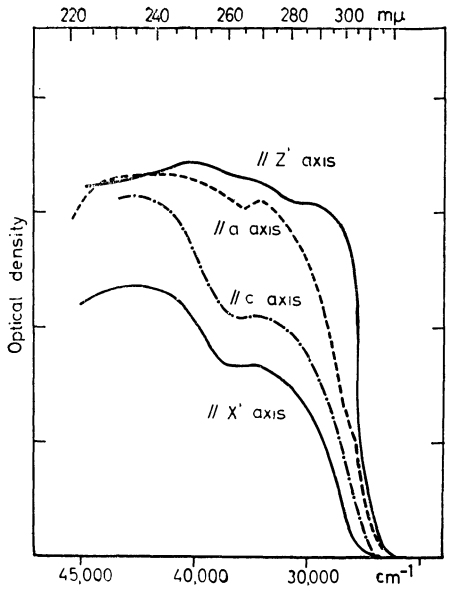

Fig. 4-b. The polarized absorption spectrum in the (010) plane of the single crystal of 1-methylthymine.

1-Methylthymine. Hoogsteen[9] analyzed the crystal structure of 1-methylthymine and showed that the crystal belongs to the space group of C_{2h}-$P2_1/c$, including four molecules in a unit-cell. The unit-cell dimensions are $a=7.53$, $b=12.09$, $c=7.60$ Å, and $\beta=89°58'$. The projection of molecules onto the developed cleavage plane (010) is pictured in Fig. 4-a. The molecules are arranged in layers closely parallel to the (102) plane and nearly perpendicular to the ac plane. The molecules are joined together in pairs by two C=O···H–N-type hydrogen bonds around a center of symmetry. The absorption spectra have been measured along the a and c crystal axes as well as along the Z' and X' optical axes, as is shown in Fig. 4-b. Here, the optical axis Z' is placed within the (102) plane and the X' axis is normal to its plane. Stewart and Davidson[6] measured the polarized absorption spectrum with the (102) plane, in which they used a crystal cut by a diamond knife of ultramicrotome. Our spectra are different from their spectrum in that an extra peak appears in the vicinity of 310 mμ. This band is nearly perfectly polarized along the Z' axis. Therefore, the direction of the transition moment must be along the direction of the hydrogen bond. Accordingly, the origin of this band might be intimately connected with the existence of the hydrogen bond of a C=O···H–N-type. This absorption characteristic is also found with other types of crystals containing the C=O···H–N-hydrogen bond between the base rings; we will discuss its nature in a later section. The next peak is found in the 270 mμ region; this peak may be assigned to the first $\pi\rightarrow\pi^*$ band. In the determination of the dichroic ratio of these bands, two methods are employed. One is to subtract the extra band from the observed spectral curve, regarding it as of different electronic origin. The other method is to include it into a single $\pi\rightarrow\pi^*$-type transition. By the first method the observed dichroic ratio is about 6 : 1 ($I_{z'}$: $I_{x'}$) and the direction of the transition moment

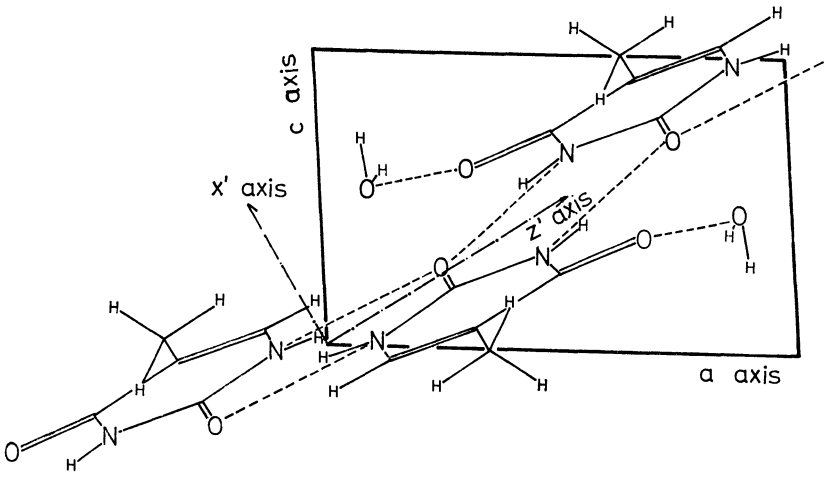

Fig. 6-a. Projection of thymine monohydrate molecules onto the (010) plane.

is deduced to be either +84° or +103° to the C_4-N_1 reference axis. By the latter method, the angle is found to be +80° or +110°. The second $\pi\rightarrow\pi^*$ band exists in the region of 235 mμ, with the dichroic ratio of 1.5 : 1 ($I_{z'} : I_{x'}$). From this value, the transition moment is determined to lie at +87° or +96° inclined to the reference axis. In this case also, the first and the second bands show similar polarizations; this must be due to the conditions of the developed plane being unfavourable for the measurement of the first band.

Thymine. The crystal structure of thymine anhydrate has been analyzed by Ozeki, Sakabe, and Tanaka[10] in our laboratory. The crystal belongs to the space group of C_{2h}–$P2_1/c$ and includes four molecules in a unit-cell. The unit-cell dimensions have been found to be as follows; a=12.87, b=6.83, c=6.70 Å, and β=105°. The projection of molecules onto the cleavage plane (100) is pictured in Fig. 5-a. The plane of the molecule is nearly parallel to the (001) plane and is included at 3.3° and 4.1° to the a and b axes respectively. The molecules are connected by two hydrogen bonds of the C=O···H–N-type. The crystalline absorption spectrum has been measured on the (100) plane; it is shown in Fig. 5-b. In the spectrum parallel to the b axis, an extra hump is observed at about 285 mμ and no component is detected along the c axis. Accordingly, this band may be related to the hydrogen bond of the C=O···H–N-type; it will be discussed in a later section, The peak of the first $\pi\rightarrow\pi^*$ band exists at 255 mμ in both the b- and c-axes spectra, and the observed dichroic ratio is about 3.6 : 1 ($I_b : I_c$). The direction of the transition moment is determined to be either +50° or +68° (or, alternatively, +52° or +66°) to the C_4–N_1 axis. In the second $\pi\rightarrow\pi^*$ band, a maximum is observed at 220 mμ in the b axis spectrum, but no peak is found in the c-axis spectrum down to 220 mμ. The dichroic ratio is determined to be 2 : 1 ($I_b : I_c$), and the transition moment is estimated to be either +55° or +63° for the reference axis.

Thymine Monohydrate. The crystal structure of thymine monohydrate was analyzed by Gerdil.[11] The crystal belongs to the space group of C_{2h}–$P2_1/c$ and includes four molecules in a unit-cell. The unit-cell dimensions are a=6.08, b=27.76, c=3.82 Å, and β=94°19′. The projection of molecules onto the developed plane (010) is pictured in Fig. 6-a. The hydrogen bonds of the C=O···H–N-type extend along the direction of the Z' optical axis. The polarized absorption spectrum was measured in the (010) plane; it is shown in Fig. 6-b. The spectrum has an extra band at about 285 mμ in addition to two $\pi\rightarrow\pi^*$ bands at 265 and 220 mμ. The extra band is polarized along the direction of the Z' axis, which is the direction of the maximum refractive index. The observed dichroic ratios for two $\pi\rightarrow\pi^*$ bands at 265 and 220 mμ are about 3.4 : 1 and 1.4 : 1 ($I_{z'} : I_{x'}$) respectively. The angles between the transition moment and reference axes are determined to be +24° or +81° (or,

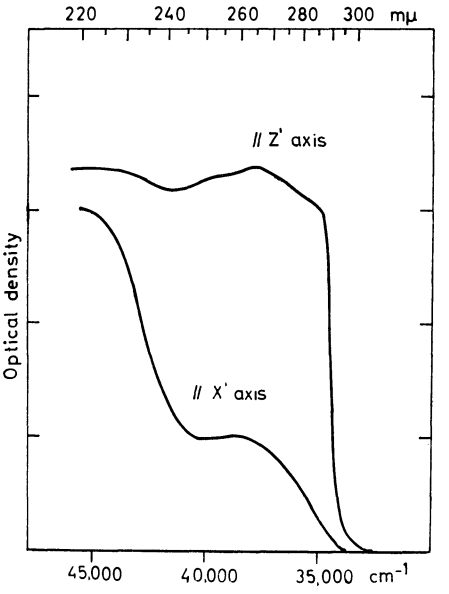

Fig. 6-b. The polarized absorption spectrum in the (010) plane of the single crystal of thymine monohydrate.

alternatively, +35° or +78°) for the first band and +43° or +76° for the second band.

1,3-Dimethyluracil. The absorption spectrum of the single crystal of 1,3-dimethylthymine is shown in Fig. 7. The crystal absorption spectrum is similar to the solution spectrum, and the first $\pi\rightarrow\pi^*$ band is observed at about 265 mμ. The peak of the second $\pi\rightarrow\pi^*$ band exists below 220 mμ. The direction of the transition moments of these two bands can not be discussed on the basis of the crystal spectra, since the crystal structures have not yet been analyzed.

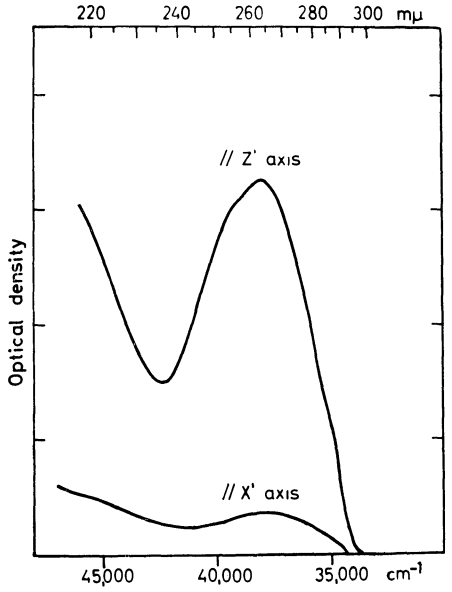

Fig. 7. The polarized absorption spectrum of the single crystal of 1,3-dimethyl uracil.

Sodium Uridine-5'-phosphate. The absorption spectrum of the single crystal of sodium uridine-5'-phosphate has been measured; it is shown in Fig. 8. The crystal structure is not known, but there seems to be

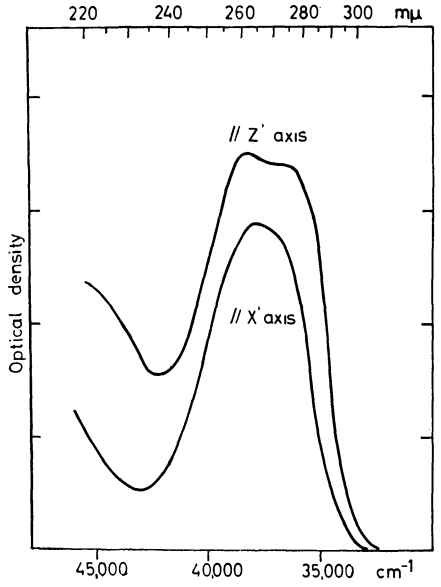

Fig. 8. The polarized absorption spectrum of the single crystal of sodium uridine-5'-phosphate.

no hydrogen bond of the C=O···H–N-type between the bases. The absorption spectrum is similar to that in solution, as expected, and no anomalous extra band is observed.

Uracil. The optical property of this crystal was studied by Gilpin and McCrone,[12] while the crystal structure was analyzed by Parry.[13] The crystal belongs to the space group of C_{2h}–$P2_1/a$ and includes four molecules in a unit-cell. The cell dimensions are $a=11.82$, $b=12.35$, $c=3.62$ Å, and $\beta=120°$. The projection of molecules onto the ac plane is pictured in Fig. 9-a. The molecules are arranged in a hydrogen-bonded layer parallel to the (001) plane. In this crystal, one oxygen atom (O_8) forms two hydrogen bonds with nitrogen atoms in the neighbouring molecules. The crystalline absorption spectrum was measured on the ac plane by means of a polarized light; the results are shown in Fig. 9-b. For the spectrum on the ac plane, an extra peak is observed along the direction of the Z' optical axis, which is related to the hydrogen bond of the C=O···H–N-type. The peak of the first $\pi\rightarrow\pi^*$ band exists at 255 mμ, and the dichroic ratio is about 1.4 : 1 ($I_{z'} : I_{x'}$). Accordingly, the angle between the transition moment and the reference axis is estimated to be +19° or +23° for this plane. For the second $\pi\rightarrow\pi^*$ band, a peak

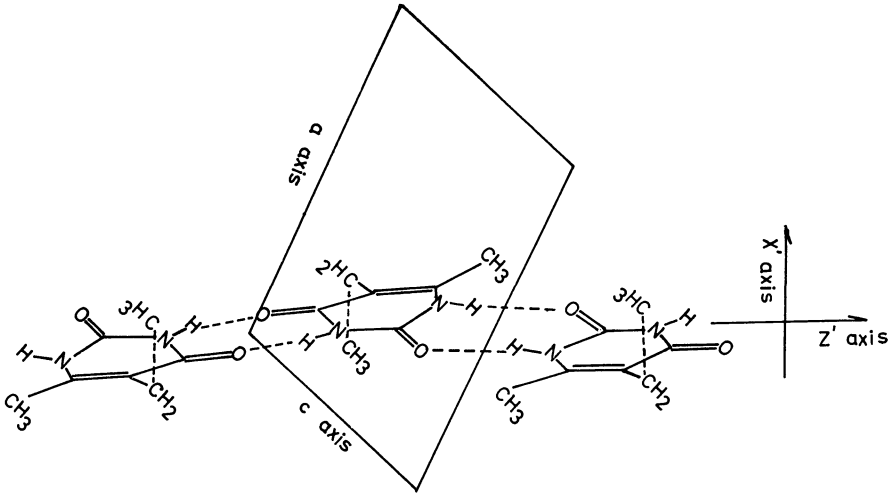

Fig. 10-a. Projection of 2-ethyl-5-methyluracil onto the (010) plane.

was not observed and so it would be difficult to obtain the dichroic ratio and to determine the direction of the transition moment.

2-Ethyl-5-methyluracil. Reeke and Marsh[14] had analyzed the crystal structure of 5-ethyl-6-methyluracil and had shown that the crystal belongs to the space group of $P\bar{1}$ and includes two molecules in a unit-cell. The projection of molecules onto the developed cleavage plane (010) is pictured in Fig. 10-a. Molecules are held together by C=O···H–N-type hydrogen bonds to form chains along the [102] direction. The absorption spectrum has been measured on the ac plane; it is shown in Fig. 10-b. In the polarized absorption spectra parallel to the Z' optical axis, an extra peak has been observed at about 290 mμ, and it has no component along the X' axis. Therefore, this band may be connected with the hydrogen bond

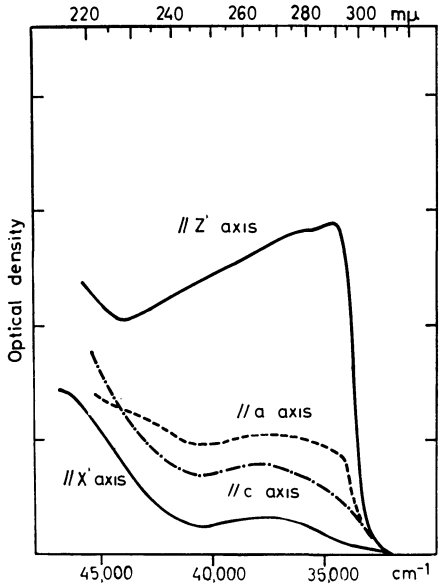

Fig. 10-b. The polarized absorption spectrum in the (010) plane of the single crystal of 2-ethyl-5-methyluracil.

14) G. N. Reeke, Jr., and R. E. Marsh, *Acta Crystallogr.*, **20**, 703 (1966).

of the C=O···H–N-type. The peak of the first $\pi\rightarrow\pi^*$ band is supposed to lie at 265 mμ; the observed dichroic ratio is about 9 : 1 ($I_{z'} : I_{x'}$), and it gives the direction of the transition moment to be either $+45°$ or $-60°$ to the reference axis. In the second $\pi\rightarrow\pi^*$ band, no peak is observed down to 220 mμ, but the dichroic ratio may be determined to be 3 : 1 ($I_{z'} : I_{x'}$) from the intensities in the measured region. Therefore. the transition moment is estimated to be either $+35°$ or $+100°$ for the C_4–N_1 axis.

Discussion

The directions of the transition moments obtained from these measurements are tabulated in Table 1. The values for the first and the second $\pi\rightarrow\pi^*$ bands are rather scattered, and a careful consideration is needed to determine the average angle. First of all, the accuracy of the dichroic measurement with each crystalline plane is not sufficient enough to decide the angle within an error of $\pm10°$, because several bands overlap in this region. Secondly, the estimation of the angle is particularly difficult when the molecular plane is sharply tilted to the developed crystalline plane and the transition moment projected on the crystalline plane is placed nearly parallel to the line at which the molecular plane intersects the crystalline plane. For this reason, the results on calcium thymidylate and 1-methyl thymine are disregarded for the determination of the direction of the transition moment of the first $\pi\rightarrow\pi^*$ band; the results with four other crystals yielded the average value of $+38°$, with a probable error of $\pm14°$. This value is not in exact agreement with the value obtained by Stewart and Davidson,[6] who regarded this angle as $-14°$ or $+19°$ on 1-methylthymine. The second $\pi\rightarrow\pi^*$ band will be perpendicular to the first $\pi\rightarrow\pi^*$ band because of the orthogonal relation, and the transition moment of the second band is placed perpendicularly to the intersecting line in the cases of calcium thymidylate and 1-methylthymine. Therefore, the results with five crystals are estimated to be $+86°$. The above-mentioned results are shown in Fig. 11. The deviations

TABLE 1. DIRECTION OF THE TRANSITION MOMENTS DETERMINED FROM THE OBSERVED DICHROIC RATIOS

Compound	First $\pi\rightarrow\pi^*$ band (I)[a]		First $\pi\rightarrow\pi^*$ band (II)[b]		Second $\pi\rightarrow\pi^*$ band	
		angle[c]		angle[c]		angle[c]
Calcium thymidylate	$I_c : I_b$ 10 : 1	+79° or + 97°			6 : 1	+82° or + 92°
1-Methyl thymine	$I_{z'} : I_{x'}$ 6 : 1	+84° or +103°	7 : 1	+80° or +110°	1.5 : 1	+87° or + 96°
Thymine	$I_b : I_c$ 3 : 1	+52° or + 66°	3.6 : 1	+50° or + 68°	2 : 1	+55° or + 63°

a) The hump in the vicinity of 285 mμ is thought as another extra band which is assumed to have a line shape of gaussian type.
b) The hump in the vicinity of 285 mμ is thought as part of the same band.
c) The angle which the transition moment makes with the line joining the nitogen (N_1) and its para partner (C_4) (clockwise rotation denoted as positive in Fig. 3)

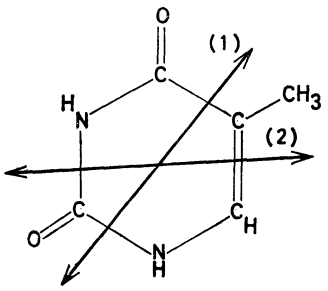

Fig. 11. Directions of the transition moments of the two $\pi\rightarrow\pi^*$ bands in the vicinity of 260 mμ (1) and 220 mμ (2).

between the observed values and average values may be interpreted by the mixing effect of the crystal field. It is now necessary to develop the experimental and theoretical studies of this effect.

Finally, let us discuss the nature of the additional band. Two prominent characteristics are noticed with this extra band; one is its polarization parallel to the direction of the hydrogen bonding, and the second is that it is observed as a hump on the tail of the first π—π^* band. We can imagine several explanations for this band; a charge-transfer point of view associated with a strong hydrogen bonding is stressed in a previous short communication.[15] Another explanation, which seems much more reasonable, is based on the consideration of the potential curve for the excited and the ground states. It is well known that the potential function of the hydrogen bonding has two minima along the direction of the hydrogen-stretching coordinate. It is very probable that the excited state has a displaced potential minimum relative to that of the ground state, as is shown in Fig. 12, because the N–H bond of the excited molecule may have a stronger acidity or hydrogen-donating power than the normal molecule, or the carbonyl group may

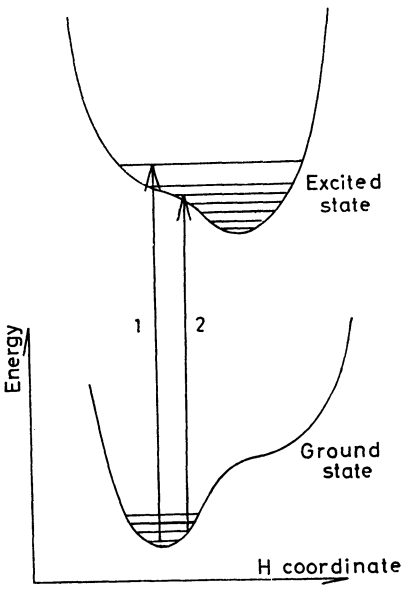

Fig. 12. The potential curve along the hydrogen bond.

have a stronger accepting power. For this particular potential problem, the vibrational structure of the electronic transition must be greatly modified. Specifically, the lower energy transitions are accompanied by a large displacement of the hydrogen coordinate and a large vibrational Frank-Condon factor, which causes the polarization to be along the direction of the hydrogen bonding. An alternative idea to explain this pattern is that the energy of the first $\pi\rightarrow\pi^*$ excited configuration is modified by the perturbation of the charge-transfer excited configuration; this may be regarded as a kind of vibronic perturbation in the excited state. These considerations are really suggestive of the shape and the electronic structures of the excited hydrogen bonding system in connection with the photochemical changes and mutations induced by ultraviolet light and radiation in DNA bases.

The Hydrogenation of Butadiene Catalyzed by Pentacyanocobaltate(II) in Aqueous and Non-aqueous Solvents

Takuzo FUNABIKI and Kimio TARAMA
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received September 21, 1970)

The hydrogenation of butadiene catalyzed by pentacyanocobaltate(II) was studied in water and in glycerol-methanol-water and ethylene glycol-methanol solutions. The amount of hydrogen absorbed, and the rate of hydrogen absorption, in the water solvent were much greater than in the other solvents. The composition of the butenes produced by the hydrogenation in the water solution was *trans*-2-≫1->*cis*-2-butene at CN/Co<5.1, and 1-≫*trans*-2->*cis*-2-butene at CN/Co>5.1; this composition was affected by the concentration of the complex. The composition of the butenes produced in the glycerol-methanol solution was *trans*-2-≫1->*cis*-2-butene at CN/Co<5.4 and 1->*cis*-2-≫*trans*-2-butene at CN/Co>5.4; a concentration effect similar to that in the water solution was observed. The composition of butenes in the glycerol-methanol-water solution at CN/Co=6.0 was remarkably affected by the composition of the solvent. In the ethylene glycol-methanol solution, *cis*-2-butene was much more producible than in the glycerol-methanol solution. The mechanism of the hydrogenation of butadiene by pentacyanocobaltate(II) was discussed on the basis of these solvent effects on the composition of products, and on the basis of the kinetical behavior of this hydrogenation reaction.

Pentacyanocobaltate(II) is a typical and interesting complex in the areas of both coordination chemistry and catalysis,[1] and its typical nature has been made clear in recent years as part of development of the chemistry of homogeneous catalysis, but our understanding of this complex can still be said to be inadequate. Recently, the present authors investigated this complex with two objects; one was to find organic solvents to increase the reactivity of this complex, and the other was to make sure of the radical mechanism proposed for the reaction of this complex. We found that pentacyanocobaltate(II) easily initiates the halomethylation of olefin in the glycerol-methanol solvent.[2] In a study related to this interesting solvent effect, we have found that the hydrogenation of butadiene catalyzed by pentacyanocobaltate(II) in the glycerol-methanol solvent gives very different results from those in water, as has already reported briefly.[3] It has been also found that butadiene is hydrogenated in the absence of hydrogen in these solvents,[3] but the results are somewhat different from those in the presence of hydrogen. In this paper, we will report more detailed results of the hydrogenation of butadiene in these solvents in the presence of hydrogen.

Experimental

Reagents. The glycerol and ethylene glycol (Nakarai Chemicals, LTD., Guaranteed Pure Grade) were distilled *in vacuo*. The methanol (Nakarai Chemicals, LTD., Guaranteed Pure Grade) was dried by the use of magnesium methoxide. The KCN (Nakarai Chemicals, LTD., Guaranteed Pure Grade) was dried in a vacuum desicator containing P_2O_5. Anhydrous $CoCl_2$ (Nakarai Chemical, Extra Pure Grade), butadiene (Takachiho Chemicals, containing 0.5—0.7% 1-butene), and hydrogen and nitrogen gases (Teikoku-Sanso) in commercial cylinders were all used without further purification.

Apparatus. The reaction vessel was 100-m*l*, three-necked flask equipped with a 50-m*l* dropping funnel; it was connected to two gas burets for hydrogen and butadiene, a mercury manometer, a gas-flow meter, and a stroke pump (Rigo-sha), which was used to circulate the gases in the reaction vessel through the solution at a flow rate of about 500 m*l* per minute. The solution was stirred magnetically and maintained at 20°C by means of a thermostat.

Procedure. The procedure consisted of two steps: the first step was hydrogen absorption by pentacyanocobaltate(II), and the second step was butadiene hydrogenation by the solution obtained in the first step.

(a) Hydrogen Absorption: In a hydrogen atmosphere, 10 m*l* of the $CoCl_2$ solution in the dropping funnel was added to 40 m*l* of the KCN solution in the reaction vessel while the solution was stirred vigorously and the gas was circulated, the volume of hydrogen absorbed at a constant atmospheric pressure was recorded as a function of the time for 1 hr in the case of the water solution and for 2 hr in the case of the glycerol-methanol solution. (When a mixture of 35 m*l* of glycerol and 15 m*l* of methanol was used as the solvent, the $CoCl_2$ was dissolved in 10 m*l* of methanol.) 10 mmol of $CoCl_2$ was used, except in examining the effect of the concentration of the complex.

(b) Hydrogenation of Butadiene: After the hydrogen-absorption procedure (a), about 130 m*l* of butadiene was introduced into the reaction vessel in such a way as replacing the hydrogen in the gas phase by butadiene as completely as possible. Stirring and circulation were started again after the above procedure. (This is the start of the hydrogenation.) While butadiene was supplied to maintain a constant atmospheric pressure, 2-m*l* gas samples were picked out by an injection-syringe at 10- or 20-min intervals for 4 hr; these samples were analyzed by means of a gas chromatograph (Shimadzu, Type GC-2B), using a 3.5-m column of DMS at room temperature. The moles of each butene produced were calculated, assuming that the sums of the relative amounts of butene and butadiene on the gas chromatograph correspond to the total moles of butadiene introduced into the reaction vessel until the sampling time.

Results

Hydrogen Absorption. Figure 1 shows typical examples of the hydrogen absorption by pentacyano-

cobaltate(II) in water and the glycerol-methanol solution respectively. In the water, an initial rapid absorption of hydrogen was observed and the amount of hydrogen absorbed was nearly equal to the expected value (from the concentration of the complex), but in the glycerol-methanol solution, the rate of absorption was much slower and the amount of it was much less. (In the latter case, an initial increase in the gas volume was observed during the addition of the $CoCl_2$ solution to the KCN solution.) The amount of hydrogen absorbed tended to decrease with an increase in the CN/Co ratio; this tendency was more remarkable in the glycerol-methanol solution than in the water.

Hydrogenation of Butadiene in Water Solution. The Effect of the CN/Co Ratio: As is shown in Fig. 2,[4] a result similar to those obtained by other authors[5,6] was obtained: *trans*-2-butene is selectively produced in the low CN/Co region, and 1-butene in the high CN/Co region, while *cis*-2-butene is always negligible. The variation in the total yield of butenes was not remarkable. Figure 3 shows the time courses of the formation of each butene at several CN/Co ratios; it is known that the hydrogenation almost stops within 1 hr.

Effect of the Concentration of the Complex: Figure 4 shows the results of the experiments in which the concentration of the complex was varied between 0.05 M and 0.25 M at CN/Co=5.0 (Fig. 4-a), and between 0.10 M and 0.20 M at CN/Co=6.0 (Fig. 4-b). At CN/Co=5.0, the mole fraction of *trans*-2-butene in the product decreased, while those of 1- and *cis*-2-butene increased with a decrease in the cobalt concentration[7]: at CN/Co=6.0, that of 1-butene decreased with the cobalt concentration. The total yield of butenes decreased linearly with the cobalt concentration.

4) The data for the composition and yield of each butene in Figures 2, 4, 5, 7, 8, and 10 are those obtained 3 hr after the start of the hydrogenation of butadiene. The data for the amount of hydrogen absorbed are those obtained by the procedure (a).

results of the hydrogenation in the glycerol (35 m*l*)-methanol (15 m*l*) solution were remarkably different from those in the water, as is shown in Fig. 5 (*cf.* Fig. 2). *trans*-2-Butene was exclusively produced in the low CN/Co region, as in the water, while *cis*-2-butene was produced as much as 1-butene in the high CN/Co region. That is to say, the composition of the products was *trans*-2-≫1->*cis*-2-butene at CN/Co<5.4, and 1->*cis*-2-≫*trans*-2-butene at CN/Co>5.4. The total yield of butenes and the amount of hydrogen absorbed decreased with an increase in the CN/Co ratio. The results in water and in glycerol-methanol are compared in Table 1.

a) Water (50 m*l*), Glycerol (35 m*l*)+Methanol(15 m*l*), $CoCl_2$=10 mmol, 20°C
b) Composition after 3 hr from the start of the hydrogenation

Figure 6 shows the time courses of the formation of butenes at several CN/Co ratios in the glycerol-methanol solvent. Although almost all the *trans*-2-butene was formed within the initial hour at a rapid rate, *cis*-2-butene and 1-butene were formed gradually at rather slow rates. In comparison with the formation of *cis*-2-butene, an initial rapid formation was observed in the case of 1-butene.

Effect of the Concentration of the Complex. Figure 7 shows the results when the concentration of the complex was varied between 0.05 M and 0.20 M at CN/Co=5.0 and 6.0 in the glycerol (35 m*l*)-methanol (15 m*l*) solution. At CN/Co=5.0, the mole fraction of *trans*-

2-butene in the products decreased, and those of 1- and *cis*-2-butene increased, with a decrease in the cobalt concentration (Fig. 7-a). At CN/Co=6.0, the mole fraction of 1-butene decreased and that of *cis*-2-butene increased with a decrease in the cobalt concentration (Fig. 7-b). The total yield of butenes decreased linearly with the cobalt concentration, but this tendency was greater at CN/Co=5.0 than at CN/Co=6.0.

Effect of Solvent Composition in the Glycerol-Methanol-water Solutions: Figure 8 shows the results at CN/Co=6.0 in the solvents with a total volume of 50 m*l*, containing glycerol (35 m*l*), methanol (15→0 m*l*), and water (0→15 m*l*). The increase in the water content (which involves, at the same time, the decrease in the methanol content) resulted in a great increase in the mole fraction of 1-butene and a decrease in that of *cis*-2-butene. The amount of hydrogen absorbed and the total yield of the butenes showed little change. Figure 9 shows the time courses of the formation of butenes in these solvents; it indicates that, although the initial rate of the formation of 1-butene changes little, that of *cis*-2-butene greatly decreases as the content of water increases.

Figure 10 shows the results at CN/Co=6.0 in the solvents containing glycerol (35 m*l*), methanol (15 m*l*),

and water (0→15 m*l*). Remarkably different from the results shown in Fig. 8, the composition and the total yield of butenes did not vary in spite of the increase in the water content, although the amount of hydrogen absorbed increased with the water content. Figure 11 shows the time courses of the formation of butenes in these solvents; it indicates that, although the initial rate of the formation of 1-butene increases with the water content, that of *cis*-2-butene is little affected.

Color of the Solution: The aqueous solution of pentacyanocobaltate(II) was dark green and clear just after its preparation so long as CN/Co>4.8 ([Co]=0.2 M). After the hydrogen absorption, the color of the solution changed from dark green to a greenish yellow. Upon the introduction of butadiene to the solution, the solution became dark green within about 5 min, but it turned yellow green or yellow as the reaction proceeded. During the hydrogen absorption and the hydrogenation processes, a precipitate was formed at CN/Co<5.0. In the case of the glycerol (35 m*l*)-methanol (15 m*l*) solvent ([Co]=0.2 M), the solution was always clear, even in the low CN/Co region. At CN/Co<5.2, the dark green which was found just after the preparation of the complex soon turned dark brown and changed to red brown in the process of the hydrogen absorption. When butadiene was introduced, the red brown rapidly changed to dark brown, but it became red brown again during the process of the hydrogenation. At CN/Co>5.7, a color change similar to that in the water solution was observed, except that the yellow color was generally deeper in this solvent. In the region of CN/Co=5.2—5.7, a color change intermediate between the above two typical cases was observed.

Hydrogenation of Butadiene in the Ethylene Glycol-Methanol Solution. The preliminary experiment of the

hydrogenation of butadiene in the ethylene glycol (35 m*l*)-methanol (15 m*l*) solution showed rather different features from that in the glycerol-methanol solution. At CN/Co=6.0, the solution of the complex, just after having been prepared in a hydrogen atmosphere, was dark green and contained a precipitate, although the KCN and $CoCl_2$ solutions were both clear before mixing. After the hydrogen absorption (47 m*l* of hydrogen was absorbed), the solution remained dark green and contained a precipitate. When butadiene was introduced, a rapid absorption of butadiene was observed for the initial 10 min; the solution immediately became clear and yellow in its color within 5 min. The composition of butenes was *cis*-2->1-≫*trans*-2-butene even in the initial stage; after 3 hr, it was *cis*-2-(50%)>1-(45%)≫*trans*-2-butene (5%).

At CN/Co=5.0, the solution after the hydrogen absorption (41 m*l* of hydrogen was absorbed) was also dark green and contained many precipitates. When hydrogenation was started, a rapid absorption of butadiene was observed, but the change in color (to orange) and disappearance of the precipitate was slow. The composition of butenes was *trans*-2->*cis*-2->1-butene in the initial stage, but it became *cis*-2-(44%)>1-(36%)>*trans*-2-butene(20%) after 3 hr. The time courses of the formation of butenes at CN/Co=5.0 and 6.0 are shown in Fig. 12.

Discussion

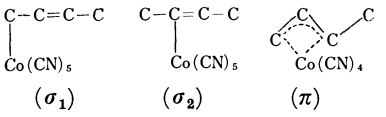
The hydrogenation of butadiene by pentacyanocobaltate(II) was first reported by Spencer and Dowden,[5] who described that 1-butene was produced at a high CN/Co ratio and *trans*-2-butene, at a low ratio. Kwiatek *et al.*[6] studied this reaction in detail, varying the CN/Co ratio, changing the order of the introduction of hydrogen and butadiene into the complex solution, and using deuterium instead of hydrogen; they reported that the composition of butenes varies at CN/Co=5.5—6.0,[8] that the active species of the reaction is the hydrido-complex $HCo(CN)_5^{3-}$, and that the reaction intermediates are fairly stable organocyanocobaltates(III). They have proposed the following mechanism (Eqs. (1)—(3)), in which the rate-determining step is (3):

$$2\,Co(CN)_5^{3-} + H_2 \rightleftarrows 2\,Co(CN)_5H^{3-} \quad (1)$$

$$Co(CN)_5H^{3-} + C_4H_6 \rightleftarrows Co(CN)_5(C_4H_7)^{3-} \quad (2)$$

$$Co(CN)_5H^{3-} + Co(CN)_5(C_4H_7)^{3-} \rightarrow 2\,Co(CN)_5^{3-} + C_4H_8 \quad (3)$$

As the structure of the intermediate complex, $Co(CN)_5(C_4H_7)^{3-}$, the following three types have been proposed:[9,10] two σ-type complexes (σ_1 and σ_2) and one π-allyl-type complex (π), and it has been considered that the composition of butenes depends on the concentration of each intermediate. Kwiatek and Seyler considered that, in the high CN/Co region, (σ_1) is the most stable and 1-butene is produced exclusively from it, while in the low CN/Co region, (π) is the most stable and 2-butene (*trans*≫*cis*) is produced exclusively from it. On the other hand, Burnett *et al.*,[11] who studied this butadiene hydrogenation kinetically, proposed a mechanism in which 1-butene is produced from (σ_2); *trans*- and *cis*-2-butene, from (σ_1), and *trans*-2- and 1-butene, from (π). The basic difference between the two mechanisms is in the way of the



attack of the hydrido-complex $HCo(CN)_5^{3-}$ on butadiene and on the intermediate complexes; in the former mechanism, it is a 1,4-addition and γ-attack, while in the latter, it is a 1,2-addition and α-attack. Although Jackman *et al.*[12] reported that the reaction of conjugated olefin with hydridopentacyanocobaltate occurs in the *cis*-1,2-addition, the present authors consider that the hydrogenation of a conjugated diene such as butadiene must be a special case.

In discussing the mechanism of the hydrogenation of butadiene by pentacyanocobaltate(II), it should be noticed that the results which have been obtained by other authors were obtained in water and so the proportion of *cis*-2-butene to *trans*-2- and 1-butene was always negligible. The most characteristic result which was obtained in the glycerol-methanol solution was that *cis*-2-butene is produced in the high CN/Co region, and the time course of its formation is very different from that of *trans*-2-butene; in the case of *trans*-2-butene, a rapid initial formation, followed by

8) Suzuki reported later that the composition varies very sharply at CN/Co=5.1—5.2 (*cf.* T. Suzuki and T. Kwan, *Nippon Kagaku Zasshi*, **86**, 713 (1965)).

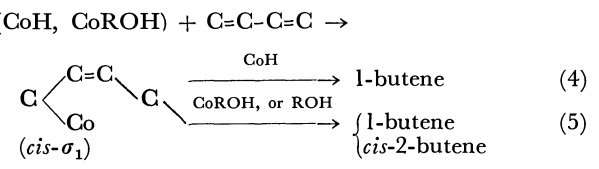
a slow formation or none at all, is observed, while *cis*-2-butene is produced gradually and successively. Therefore it is reasonable to assume that the structure of the intermediate for the *cis*-2-butene formation resembles that for 1-butene rather than that for *trans*-2-butene. If it is supposed that such organocyano-complexes as (σ_1), (σ_2), and (π) are the intermediates for the butadiene hydrogenation by pentacyanocobaltate(II),[13] and that σ complex is stable in the high CN/Co region, it is natural to consider that the (σ_1) of the *cis* configuration (*cis*-σ_1) is probably an intermediate for the *cis*-2-butene formation, because with other σ complexes such as the (σ_1) with a *trans* configuration and the (σ_2), there is the great probability of the formation of *trans*-2-butene besides *cis*-2-butene.

As an intermediate for 1-butene formation, two complexes (σ_1 and σ_2), should be considered, because either complex may produce 1-butene, by the γ- or the α-attack of the hydrido-complex. Although it is difficult to decide which is the proper intermediate, at this stage we prefer *cis*-σ_1, because it seems to be more appropriate to consider a common intermediate for the two butenes (1- and *cis*-2-butene) rather than different intermediates. Hence, in the mechanism here proposed, butadiene and the hydro-complex react in the 1,4-addition to form a *cis*-butenyl complex at first.

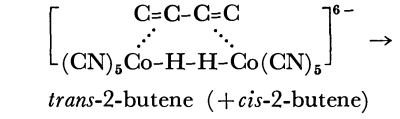
The present authors observed a difference in the time courses of the formation of 1- and *cis*-2-butene in the glycerol-methanol and the glycerol-methanol-water solutions. The rate of the formation of 1-butene in the initial stage is greater than that of *cis*-2-butene; this difference becomes more obvious with an increase in the water content in the solvent. This result may be explained in terms of the difference in the reactivity of the two active reducing species, provided that there exists another reactive reducing species besides the hydrido-complex: The reaction of the hydrido-complex with *cis*-σ_1 is rapid and produces exclusively 1-butene in the initial stage (the quantity of 1-butene produced by this reaction may be rather small, because the amount of hydrogen absorbed in this solvent is generally small), but another reactive reducing species, which may be a solvent molecule or a cyanocobalt-complex coordinated by the solvent, reacts to produce nearly equal amounts of 1- and *cis*-2-butene at a relatively slower rate than the hydrido-complex. This may be written schematically as in Scheme 1, where CoH, CoROH and ROH denote the hydrido-com-



Scheme 1

plex, the cyanocobalt complex coordinated by an alcoholic solvent, and the alcoholic solvent respectively. If there is enough CoH for the second step in Scheme 1, an initial rapid formation of 1-butene will be observed, and *vice versa*. This proposal may well be supported by the following facts: 1) In the water solution, 1-butene is selectively formed in the high CN/Co region; this can be ascribed to the selective performance of reaction (4). 2) In the glycerol-methanol solution in the high CN/Co region in the absence of hydrogen, the composition of butenes is *cis*-2->1-$\gg$*trans*-2-butene;[3] this can be ascribed to the absence of the hydrido-complex. 3) In the ethylene glycol-methanol solution at CN/Co=6.0, the composition of butenes is also *cis*-2->1-$\gg$*trans*-2-butene, even in the initial stage; this can be ascribed to the rapid reaction of butadiene with hydrido-complex to produce the intermediate complex (*cis*-σ_1) without saving the hydrido-complex for the second step. (This may be connected with the rate of the dissolution of butadiene into the solvent or with the precipitate formation.)

The probable intermediate for the *trans*-2-butene formation may well be a π-methallyl-complex (π), as was proposed by Kwiatek,[9] but it seems to be rather difficult to explain the initial rapid formation of *trans*-2-butene from the (π) complex, for the rate of isomerization between σ-allyl and π-allyl complexes presumed from the NMR spectra with an allyl-pentacyanocobaltate(III)[10] is not very great. We wish here to propose another route for the formation of *trans*-2-butene, in which *trans*-2-butene is produced in one step via a butadiene-bridged transition state which is produced by one molecule of butadiene and a dimeric-type hydrido-complex, such as proposed by Piringer and Farcas;[14] the mechanism may be shematically written as in Scheme 2:



trans-2-butene (+*cis*-2-butene)

Scheme 2

In these mechanisms, the selectivity of the hydrogenation of butadiene by pentacyanocobaltate(II) largely depends on the type of hydrido-complexes which are in equilibrium in the solution and whose equilibrium constant is affected by the CN/Co ratio and the concentration of the complex. It is supposed that the monomeric form exists selectively in the high CN/Co region, and that the monomeric form increases with the a decrease in the concentration in the low CN/Co region (*cf.* Figs. 4 and 7).

The color change of the solution suggests a variation of the structure of the complexes in solution, but we should be careful in discussing these data. At this stage, it cannot be decided whether or not the brown color observed in the glycerol-methanol solution in the low CN/Co region is connected with the structure of the complex which produces *trans*-2-butene.

13) Although the present authors have proposed another possible mechanism of the formation of 1- and *cis*-2-butene in the high CN/Co region, supposing that the *cis*-2-buteneyl radical is the intermediate, this radical mechanism will not be discussed further in this paper (*cf.* K. Tarama, T. Funabiki, and M. Mohri, *Shokubai*, **11**, 35 (1969)).

14) O. Piringer and A. Farcas, *Z. Phys. Chem. N.F.*, **46**, 190 (1965).

The solvent effect on the hydrogenation by pentacyanocobaltate(II) is rather complicated. The presence of water is surely important in 1-butene formation (Fig. 8), but it is not decisive (Fig. 9). The presence of methanol seems to be important for the *cis*-2-butene formation, but the role of methanol cannot be discussed in detail before the effect of glycerol becomes clear. At this stage, the results in the solvent containing glycerol-methanol-water (Figs. 8—11) may be explained as follows, on the basis of the proposed mechanism: the constancy of the initial rate of the formation of 1-butene in the solvents of Figs. 8 and 9 may be ascribed to the constancy of the concentration of the hydridocomplex (the amount of hydrogen absorbed in each solvent was nearly constant), and the great decrease in the rate of formation of *cis*-2-butene may be ascribed to the decrease in the methanol content. The increase in the initial rate of formation of 1-butene with the increase in the water content in the solvents of Figs. 10 and 11 may be ascribed to the increase in the concentration of the hydrido-complex (the amount of hydrogen absorbed increases with an increase in the water content), and the constancy of the rate of the formation of *cis*-2-butene may be ascribed to the nearly constant content of methanol. The present authors consider that the difference in the reactivity of pentacyanocobaltate(II) between that in water and that in these alcoholic solvents is due partly to the difference in the structures of the reactive species, to for example, the difference between the free ion in water and the ion-pair in alcoholic solvents, and partly to the difference of the solvating ability of the solvents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 951—957 (1971)

Optical Activity of Nucleic Acid-Thionine Complexes[1)]

Yasumasa J. I'HAYA and Tomoyasu NAKAMURA

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo

(Received October 1, 1970)

The absorption spectra, optical rotatory dispersion, and circular dichroism (CD) of the DNA- and RNA-thionine complexes were measured at the nucleic acid phosphate to dye ratios (P/D) 0.01—50 and at the temperature range 20—85°C. The Cotton effects of P/D >3 complexes were observed in the wavelength region 520—680 nm, being resolved at least into four partial Cotton effects. From their transient profiles with changing P/D values and the observed temperature effect, they were interpreted to be induced from the dye monomers bound near the asymmetric environment of nucleic acids. The Cotton effects of P/D <2 complexes in the wavelength region 450—580 nm are new and have not been reported for other DNA-dye systems. The trough of these Cotton effects completely disappeared at 50°C and the decreasing profile of its relative rotation with increasing temperature was roughly parallel to that of the dimer fraction. The newly developed Cotton effects are inferred to result from an interaction between the dye dimers aggregated in a helical fashion along the nucleic acid helices. The negative sign CD maximum observed in the wavelength region 300—330 nm is probably due to DNA-dye interactions, but its origin is not clear.

It is well known that some basic dyes show photodynamic and mutagenic actions for microorganisms.[2,3)] Binding of such dyes to biological macromolecules, such as nucleic acids and polysaccarides, induces the bathochromic and hypochromic effects in the visible electronic absorption region of the dyes.[4-7)] Concerning the nucleic acid-aminoacridine dye complexes, the binding mechanism and conformations have been studied extensively by many investigators using the optical rotatory dispersion (ORD) and circular dichroism (CD) methods.[8-11)] Acridine orange (AO) and/or proflavine is an optically inactive molecule. When either dye binds to a biological helical polymer, anomalous optical rotation (Cotton effect) is observed in the spectral region of the dye. Blake and Peacocke[9)] observed this "extrinsic Cotton effect" by means of ORD measurement, and Gardner and Mason[11)] by CD measurement under various experimental conditions, *viz.*, by changing the nucleic acid phosphate to dye ratio (P/D), pH, and ionic strength. In order to explain the induced anomalous optical rotations for nucleic acid-dye complexes, particularly for the DNA-AO complexes, the following models have been proposed: for their conformations, helical arrangement of the dye along the macromolecule or helical tangential extension of the dye hanging on the anionic residue of the macromolecule, and for their

interaction mechanism, dipole-dipole interaction between the stacked and/or intercalated dyes or asymmetric environment of the binding sites.

Much has been said for and against these models. In the DNA-AO complexes, there appear two or three negative CD maxima in the visible absorption region of the dye, in addition to the positive CD maximum in the longer wavelength region. However, the primary source of the Cotton effects, *i.e.*, whether they are induced from monomerically bound AO or from dimerically bound AO, has not been established.

Thionine forms molecular complexes with nucleic acids. In this paper we report results of the measurement of the induced Cotton effects and absorption spectra resulting from the interaction of thionine with native DNA and RNA. We show how Cotton effects change their profiles with P/D and temperature. Comparing the results with those obtained for the DNA-AO complexes, we will discuss the origin of the induced Cotton effects, in particular the contribution of the thionine dimer. Certain inferences will be made as to the binding conformations of the nucleic acid-thionine complexes.

Experimental

Commercial calf-thymus DNA (Sigma Type 1) was used without further purification. Unfractioned RNA was prepared from rat-liver according to Kirby's method.[12] Stock solutions of nucleic acids (30 mg/25 m*l*) were stored in the cold and diluted just prior to use. Thionine (3,7-diaminophenothiazonium chloride; Lauth's violet) (Tokyo Kasei) was purified by recrystallization twice from aqueous solution. In this purified dye, no detectable impurity was found through Sephadex LH-20 column chromatography. Stock solutions of the dye were stored in the dark in order to avoid photosensitized reactions.

Stock aqueous solutions of the dye and nucleic acids were dissolved in 0.01 M phosphate buffer (pH 6.84). The concentration of nucleic acids, expressed in terms of phosphate residues, was determined as usual by the measurement of the absorbance at 260 nm and using the known molar extinction coefficients $\varepsilon_P^{260}=6{,}650$ and $\varepsilon_P^{260}=8{,}190$ for DNA and RNA, respectively. Within the concentration range of $(1—3)\times10^{-5}$ M, $\varepsilon^{598}=54{,}200$ was obtained for thionine in the phosphate buffer. This value is nearly in accord with that given by Rabinowitch and Epstein.[13]

Total concentration of the dye in the complexes was selected to be from 1.0×10^{-5} M to 3.3×10^{-5} M, since the observed extrinsic Cotton effects of the complexes strongly depended upon the concentration of the dye. Using a Jasco ORD/UV-5 recording spectrophotometer, absorption, ORD, and CD spectra were measured at various temperatures (20—85°C). Temperature studies were carried out with a specially designed variable temperature cell. Sample temperatures were measured with a copper-constantan thermocouple while spectra were being taken.

Results

Morthland *et al.*[4] reported that the absorption spectrum of thionine shifts to the red, losing its intensity, upon formation of the complex with nucleic acids. Although our experimental conditions differ somewhat from theirs, analogous bathochromism and hypochromism are observed except for extremely low P/D complexes (Fig. 1). When P/D exceeds 10, a new absorption maximum appears at about 610 nm, while the absorption maximum at 598 nm is diminished in intensity and remains as a shoulder in this region. In contrast to such high P/D complexes, the extremely low P/D ones show slight broadening of the shorter wavelength limb together with slight depression of the absorption maximum at 598 nm. The absorption spectrum of the dye alone, when the concentration

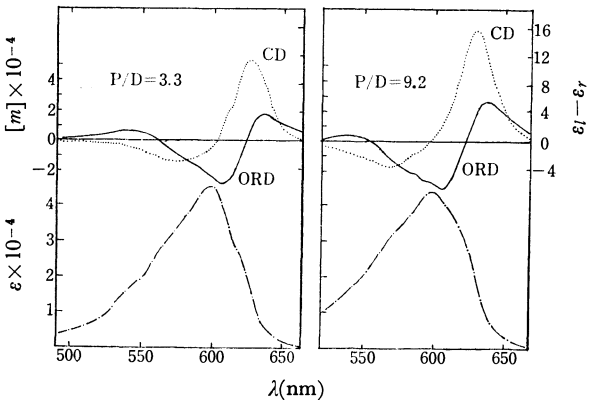

Fig. 2. ORD, CD (upper), and absorption (lower) spectra of DNA-thionine (left) and RNA-thionine (right) complexes at high P/D values. Total concentration of thionine, 1×10^{-5} M.

of the dye is sufficiently high (about 10^{-3} M), shows another maximum at 560 nm. This has been assigned to a dimer band of thionine.[13] The 610 nm (monomer) band of the high P/D and the 560 nm (dimer) band of the low P/D DNA-thionine complexes seem to correspond to the α-(or complex II) and β-(or complex I) bands of the DNA-AO complexes, respectively. At further increased P/D values, two isosbestic points are obtained at 608 nm and 602 nm. The former can be observed even when the concentration of DNA is not very high. The latter, however, can be observed only in the complexes of P/D values greater than 20. Metachromatic properties of the RNA-thionine complex are almost the same as those of the DNA-thionine complex described above.

Figures 2 and 3 show the representative ORD and CD spectra of the DNA- and RNA-thionine complexes. These data together with those for the absorption spectra are summarized in Table 1. At relatively high P/D values, the general shapes of these ORD and CD spectra resemble those of the DNA-AO complex.[9-11] It is apparent that there are one positive (*ca.* 626 nm) and one negative (*ca.* 576 nm) Cotton effect in the visible absorption spectral region of these complexes, as seen in Fig. 2 and Table 1. When P/D decreases to less than 2, new Cotton effects are observed in the region of 450—580 nm (Fig. 3). These types of Cotton effects have not been observed in other DNA-dye complexes. It should be noted that even in the DNA-thionine system the following conditions are required for observation: low P/D value (less than 2), high total concentration of the dye (at least, more than 2×10^{-5} M), and moderate temperature (below 50°C).

The decrease in P/D gives rise to the decrease in molar rotation of the peak at 636 nm and the trough at 606 nm and the increase in that of the trough at 525 nm. After passing intermediate P/D values where all these peaks and troughs are detected, only the trough

at 525 nm can be observed clearly even at extremely low P/D values. These variations in the ORD profile are illustrated in Fig. 4, together with those of the RNA-thionine complexes.

Figure 5 shows the effect of temperature on the ORD curves. The relative amplitudes (or relative molar rotations) at various temperatures are plotted in Fig. 6 where the value of the amplitude (or molar rotation) at 20°C is taken to be unity. The relative amplitude of the P/D=2.6 complex begins to decrease at about 40°C, reaches a value 0.5 at 60°C, but is still observable even at 85°C, beyond which the measurements become impossible to be carried out (Fig. 6a). This trend is quite similar to that of the DNA-AO complex.[14] For the P/D=0.36 complex, the effect of temperature is more drastic. At about 35°C the re-

14) M. Zama and S. Ichimura, *Biopolymers*, **9**, 53 (1970).

lative molar rotation of this complex reaches a value 0.5 and vanishes completely at temperatures higher than 50°C (Fig. 6b).

Thionine shows absorption also in the ultraviolet absorption region of nucleic acids. A negative CD band, which seems to correspond to the absorption shoulder of the dye at 310 nm, appears in the DNA-thionine complex. Figure 7 shows the Cotton effects of the complex and DNA alone developing in this spectral region, together with the absorption spectra of the complex and thionine alone. These CD spectra

are corrected in magnitude in order that the negative CD maximum of the complex around at 250 nm coincides with the corresponding maximum of DNA. Similar effects are observed in the RNA-thionine complex. No quantitative measurements with respect to these Cotton effects developing in the ultraviolet absorption region of the complexes have been carried out.

Discussion

Interactions between nucleic acids and dyes have been a subject of both experimental and theoretical

studies concerning the effect on the electronic spectra, the change in the thermodynamic parameters, hydrodynamic characters and other physical and chemical properties of complexes.[15] A problem of current interest in chemistry of macromolecule-dye complexes is the study of the induced optical activity of these systems. Many workers have studied the Cotton effects of complexes such as DNA-aminoacridine dyes,[8-11] DNA-actinomycine,[16] and polysaccaride-various dyes complexes by means of ORD and CD measurements.[17]

Yamaoka and Resnik[10] and Gardner and Mason[11] independently suggested the existence of the four partial Cotton effects observable in the visible absorption spectral region of the DNA-AO complex. Their concepts, however, are not in accord with each other with respect to the signs of Cotton effects. Yamaoka and Resnik resolved the resultant CD curves, derived from the experimental ORD spectrum by the Kroning-Kramers transform, into four components (partial CD bands) *viz.*, a positive CD band located at the longest wavelength and three successive negative CD bands. Gardner and Mason, on the contrary, directly measured the CD spectrum and concluded that there are one positive and two negative Cotton effects, of which the longer wavelength positive CD band possesses two positive components. Yamaoka and Resnik ascribed the interaction mechanism to the asymmetric environment due to the asymmetric carbon atoms of the macromolecule, in accordance with model I proposed and rejected by Stryer and Blout.[18] According to their interpretation these four CD bands correspond to four monomer transitions. The positive CD maximum is assigned to the ^1L_a forbidden transition of the free AO molecule and the other three negatives to the 0–0, 0–1, and 0–2 vibrational transitions of the ^1L_b allowed band.

The ORD and CD spectra of the DNA-thionine P/D=3.3 complex (Fig. 2) resemble very closely those of the DNA-AO complex (for example the P/D=5 complex given in Fig. 4 of Ref. 9). The binding conformation of the DNA-thionine complex is supposed to be quite similar to that of the DNA-AO complex, being supported by the flow dichroism experiment of Nagata *et al.*[19] on the complexes of DNA-phenothiazine dyes, such as methylene blue and toluidine blue, and of DNA-acridine dyes. From these similarities, the observed Cotton effects of the DNA-thionine P/D>3 complexes are inferred to be resolved into at least four components, all of them being due to monomer dye-asymmetric site and/or monomer dye-monomer dye interactions (vide post).

The Cotton effects newly developed at low P/D values (Fig. 3) seem to be caused by an interaction between the dimerically bound or more aggregated dyes in view of the following results experimental findings. (1) The Cotton effects are found near the dimer band. (2) Occurrence of this phenomenon strongly depends upon the total concentration of the dye. (3) At low P/D values, the visible absorption spectrum of the complex shows a slight blue shift (Fig. 1). (4) The Cotton effects of low P/D complexes undergo more rapid and more drastic temperature effect than those of high P/D complexes.

A question arises with respect to items (1) and (2). Is the existence of two CD maxima, a positive one at 555 nm and a negative one at 494 nm, consistent with the assumption that the Cotton effects of the low P/D complexes are due to the 560 nm dimer band of the dye? This can be answered by the concept of exciton splitting. The dimer transition may split into two transitions through interaction between the dimerically bound dyes. In the present case, an absorption spectrum corresponding to the negative CD maximum is uncertain, but it should be observed under some optimum experimental conditions, for example at lower temperature.

At extremely low P/D values, it appears that the amount of the dye dimers greatly increases since the dye monomers will closely bind to almost all possible binding sites of nucleic acids. This is confirmed by the fact that the longer wavelength Cotton effects, assigned to the monomerically bound dye molecules, disappear at extremely low P/D values (Fig. 4). From item (3), the bound dye dimer may form a face-to-face arrangement, the so-called stacking model, along the helix of nucleic acid.

The Cotton effects developing in the spectral region of 450—580 nm at low P/D values are ascribable to the dimer or higher aggregates of thionine. This is supported more strongly by the transient profiles of these Cotton effects accompanied with increasing temperature (item (4)). The decrease in the relative amplitude with increasing temperature, for the Cotton effects of the DNA-thionine P/D=2.6 complexes (Fig. 6a), appears to be due to the detachment of the bound dye from DNA and/or to a relatively mild structural change not so drastic as to induce the denaturation of DNA. Since the melting temperature of calf-thymus DNA is 85.2°C (in 0.15 M NaCl+0.05 M Na citrate solution),[20] we may infer that the decomposition of the DNA helices in the complex occurs at temperatures higher than 85°C, although the accurate melting temperature of the complex is not known. The fact that the relative amplitude is still non-zero even at this limiting temperature suggests that the Cotton effects of the P/D=2.6 complexes may be induced not from an interaction between the dye molecules aggregated in a helical fashion but to the dye bound near the asymmetric carbon atoms of nucleic acids. The bound dye is supposed to be primarily of the monomeric form, since there may exist quite a small amount of dye dimers at such high temperatures. This conclusion is also supported by Yamaoka and Resnik's experiment on the sodium poly-α, L-glutamate-AO complexes which shows optical activity

even at very high P/D values (P/D $\sim 10^4$).

In the case of the P/D=0.36 complex, the trough of the newly developed Cotton effects at 520—525 nm completely disappears at about 50°C (Fig. 6b). This critical temperature becomes lower with the decrease of the total concentration of dye. Using the data for the dimerization constants of thionine in aqueous solution,[13] the dimer fraction for the 3.3×10^{-5} M solution is calculated and plotted in Fig. 8 against temperature. The dimer fraction of the dye undergoes rapid reduction with increasing temperature. The trend resembles quite well the decrease in relative molar rotations. Since the dimerization constants used are of pure thionine in aqueous solution, there remains the question whether it is correct to use these values to estimate the dimer fraction of the dye in the DNA-thionine complex. We may suppose that the amount of the dimeric dyes bound to DNA in the complex is roughly proportional to the amount of the dye dimers in aqueous solution of the dye alone.

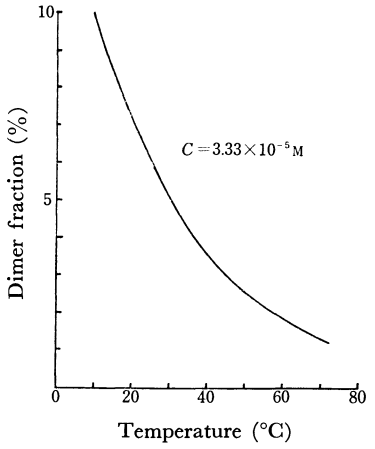

Fig. 8. Plot of dimer fraction of thionine in aqueous solution against temperature.

It appears reasonable therefore, to conclude that these newly developed Cotton effects for the low P/D complexes are ascribable to the dye dimer and that the disappearance of optical activity at about 50°C is due to the absence of dye dimer bound to DNA. Since DNA may still possess their helical structures at 50°C, there is possibly a model in which the dye dimers are bound in a repetitive fashion along the DNA helix to interact with each other. This model is supported by the general shapes of the ORD and CD curves of the low P/D complexes. We tentatively conclude, therefore, that the primary source of the optical activity newly found at 450—580 nm may be an electrostatic interaction between the dye dimers bound to DNA probably in a repetitive fashion to form a dye dimer super-helix. Vicinal disymmetry might play a sufficient role to induce optical activity, just as the case of the 520—650 nm Cotton effects.

A negative CD maximum appearing at 300—330 nm for the P/D=3.2 complex may be assigned to the absorption shoulder of thionine (Fig. 7). This has not been observed in the DNA-AO system. It was reported that DNA has a negative CD maximum in the same spectral region,[21] but we did not observe this. However, if it could be observed, it should be as small as one-tenth of the CD maximum of the complex. Therefore, the latter is undoubtedly due to an interaction between DNA and thionine. Our data are insufficient to estimate its origin, however.

It should be added that all of the foregoing discussion on the DNA-thionine complexes equally applies to the RNA-thionine complexes.

Conclusion

The results on the optical activity of the DNA- and RNA-thionine complexes are summarized as follows:

(a) The Cotton effects of the high P/D complexes are observed in the wavelength region 520—680 nm (Optical Activity I), both of them being resolved at least into four components.

(b) The Cotton effects of the low P/D complexes are observed in the wavelength region 450—580 nm (Optical Activity II). These are new types of Cotton effects which have not been observed in other DNA (or RNA)-dye systems.

(c) Optical Activity I which is predominant at the P/D values 4—5 diminishes rapidly with decreasing P/D values and Optical Activity II develops at about P/D=2.

(d) The effect of temperature on Optical Activity I differs from that on Optical Activity II. The former is observed even at 85°C, the latter completely disappears at 50°C.

(e) Unlike the DNA-AO complex, a negative CD maximum appears in the wavelength region 300—330 nm.

Interpretation of the results is summarized as follows:

(1) Optical Activity I is induced from the dye monomers bound near the asymmetric carbon atoms of nucleic acids.

(2) Optical Activity II results from an interaction between the dye dimers aggregated probably in a helical fashion along the nucleic acid helices.

(3) A negative CD maximum developing at 300—330 nm is probably due to DNA-dye interactions, but its origin is uncertain.

Electronic Spectra and Electrical Resistivities of the Molecular Complexes of Benzidine and Its Derivatives

Yoshio MATSUNAGA and Gunzi SAITO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 6, 1970)

The electronic structures of about sixty polycrystalline molecular complexes of benzidine and its derivatives have been examined on the basis of the vibrational and electronic spectra. The complexes show a strong tendency to be non-ionic, in spite of the low ionization potentials of the electron donors. Several non-ionic complexes exhibiting resistivities of the order of 10^3—10^5 ohm cm have been found. The optical and electrical properties of the complexes consisting of donor molecules with amino groups and of acceptor molecules with carbonyl groups are distinctly different from those of the others. The first charge-transfer absorption band of the solid complex in the former group appears at an energy considerably lower than that of the corresponding complex in chloroform. Moreover, the activation energy for semiconduction seems to be appreciably reduced by the formation of a hydrogen bond.

On the basis of the electronic and vibrational spectra, it has been established that the crystal charge-transfer complexes can be rather sharply divided into two groups, namely, those having essentially non-bonding ground states (hereafter to be called "non-ionic complexes") and those having dative ground states("ionic complexes").[1-3] In general, an ionic complex may be formed when a donor molecule with a low ionization potential is combined with an acceptor molecule with a high electron affinity. However, one of the present authors has demonstrated that the electrostatic energy of the charged lattice is as important as the energy needed to charge the constituent molecules in governing the formation of an ionic crystal complex.[4] Among the donor compounds examined in our previous paper, tetramethylbenzidine was found to show a very strong tendency to form non-ionic complexes in spite of its low ionization potential, which has been estimated to be as low as 6.8 eV.[5] In connection with this observation, it is noteworthy that most of the noticeably semiconducting quinone complexes are ionic.[6] Furthermore, non-ionic complexes display relatively low resistivities only when the charge-transfer absorptions are located in an exceptionally low-energy region. The tetramethylbenzidine-*p*-chloranil complex, which has a resistivity of 10^7 ohm cm, is known to be such an example. Therefore, one may hope to have a good chance of examining the physical properties of a large number of non-ionic complexes exhibiting charge-transfer absorptions at unusually low energies by studying the crystal complexes of benzidine and its derivatives.

Experimental

Materials. The following five compounds, the ionization potentials of which are supposed to increase in the order of numbering, were used as donors: *N,N,N',N'*-tetramethylbenzidine (I), *o*-tolidine (II), benzidine (III), *o,o'*-dibromo-*o*-tolidine (IV), and *o,o'*-dichloro-*o*-tolidine (V). The first three compounds were commercially obtained. They were purified by recrystallization and then by sublimation in a vacuum. The last two were prepared by the halogenation of compound II, as has been reported by Schlenk.[7] The fifteen acceptors used in this work were as follows: 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) (a), tetracyano-*p*-benzoquinodimethane (TCNQ) (b),[8] tetracyanoethylene (TCNE) (c), 2,3-dicyano-*p*-benzoquinone (d),[9] 2,3-dicyano-α-naphthoquinone (e),[10] 9-dicyanomethylene-2,4,7-trinitrofluorene (f), *p*-chloranil (g), 2,5-dichloro-3,6-dibromo-*p*-benzoquinone (h),[11] *p*-bromanil (i),[12] *p*-fluoranil (j), 2,5-dichloro-*p*-benzoquinone (k), 2,3-dichloro-*p*-benzoquinone (l),[13] 2,6-dichloro-*p*-benzoquinone (m), dichloro-*p*-xyloquinone (n),[14] and *s*-trinitrobenzene (TNB) (o). Their electron affinities decrease in approximately the above order. These compounds were obtained from commercial sources unless references are cited.

The molecular complexes were prepared by mixing the component compounds, previously separately dissolved in a hot solvent, usually benzene, chloroform, or dichloroethane. They were crystallized upon cooling or were precipitated immediately. Some ion-radical salts, the vibrational and electronic spectra of which were to be compared with those of the molecular complexes, were also prepared. The oxidation of the donor compounds was carried out with bromine according to the procedure of Hughes and Hush.[15] The acceptor compounds, a, b, d, and f, were reduced with the iodide ion following the methods reported by various workers.[2,16,17]

Measurements. The vibrational spectra of the crystal complexes were determined as Nujol mineral oil mulls with a Jasco IR-G infrared spectrophotometer, and the electronic spectra, with a Beckman DK-2A spectrophotometer with the

aid of a reflectance attachment. The procedure in the latter measurements was similar to that described in our previous paper.[18] The charge-transfer absorption spectra were also examined in solution. The solvent used throughout was chloroform, Wako Special Reagent. As the present donor compounds dissolved in chloroform are easily oxidized with air, sample solutions were prepared immediately before measurements by dissolving appropriate amounts of the component compounds.

The resistivities up to 10^8 ohm cm were examined by a voltage-current method employing a cell similar to that designed by LaFlamme.[19] The temperature was adjusted in the range from 20 to 60°C using a heating tape wrapped around the cell and connected to a variable transformer.

Results and Discussion

Characterization of Complexes. The complexes were classified into two groups, namely, non-ionic and ionic complexes, on the basis of the vibrational spectra. This method was described in detail in a previous paper.[2] In short, when the vibrational spectrum of a complex is well approximated by a superposition of the spectra of the component compounds, the complex is considered to be non-ionic. If the spectrum consists of the spectra of the ionized components, namely, D^+ and A^- free-radical ions, the complex is characterized as ionic. The vibrational spectrum of the A^- ion is usually readily distinguishable from that of the A molecule; therefore, it is not difficult to characterize the complexes by this technique. The results of the characterization are presented in Fig. 1. In this diagram the complexes have been arranged by placing the ionization potentials of the donors on the abscissa and the electron affinities of the acceptors on the ordinate. As had been proposed earlier,[4] the energy of the charge-transfer absorption in the TNB

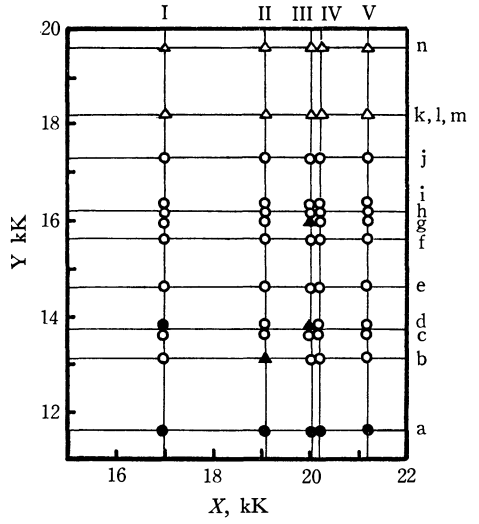

Fig. 1. Electronic structures of molecular complexes as revealed by the vibrational spectra. Non-ionic complexes are indicated by open circles and ionic ones by shaded circles. As to notations I—V, a—o and X and Y, see text.

complex, X, as determined in a chloroform solution, was taken as a measure of the former quantity, and that in the pyrene complex, Y, as a measure of the latter (see Eq. (1) in next section). The complexes which were found to be non-ionic are indicated by open circles, and those found to be ionic, by shaded circles. The following three, shown by shaded triangles, are of a complicated nature or are unstable: IIb, IIIc, and IIIg; therefore, they could not be well characterized. The complex IIb has a composition different from that calculated for 1 : 1, and it gives a vibrational spectrum which is too complicated to be considered as simply either non-ionic or ionic. A similar phenomenon has been disclosed by Ohmasa *et al.* in a closely related complex, benzidine-TCNQ, IIIb, when solvent molecules are occluded.[20] It has been known for a long time that benzidine forms a very unstable complex with *p*-chloranil.[21] Furthermore, this complex, IIIg, has been reported to be non-stoichiometric.[22]

For the combinations expressed by open triangles, no solid complex could be isolated. As may be seen in Fig. 1, most of the complexes examined in this work are non-ionic. The only exceptions are the DDQ complexes of I—V and the complex Id. These observations are in good accordance with our earlier view that the remarkably strong tendency to be non-ionic found in the tetramethylbenzidine complexes arises from the size and shape of this donor molecule, factors which are unfavorable to strong electrostatic interaction with acceptors.

Electronic Spectra. The energy of the charge-transfer absorption, $h\nu_{CT}$, in a non-ionic, 1 : 1 single complex may be written, as a good approximation:[23]

$$h\nu_{CT} = I_D - A_A - C' , \qquad (1)$$

where I_D is the ionization potential of the donor molecule and where A_A is the electron affinity of the acceptor molecule. The term C', the magnitude of which is known to be relatively insensitive to the kinds of donor and acceptor, arises largely from the electrostatic energy in the dative-bond structure. The complexes on the $Y=-X+$ constant line in Fig. 1 should all exhibit charge-transfer absorptions at nearly the same energy. The values of $h\nu_{CT}$, as estimated by the use of Fig. 1, are equal to:

$$\begin{aligned} &h\nu_{CT}(\mathrm{D\cdot TNB}) + h\nu_{CT}(\mathrm{pyrene\cdot A}) - h\nu_{CT}(\mathrm{pyrene\cdot TNB}) \\ &\quad = I_D - A_A - C'(\mathrm{D\cdot TNB}) - C'(\mathrm{pyrene\cdot A}) \\ &\quad + C'(\mathrm{pyrene\cdot TNB}) . \end{aligned} \qquad (2)$$

In Fig. 2, the $h\nu_{CT}$ values observed in chloroform solutions are plotted against the $h\nu_{CT}$ values estimated by the use of Eq. (2). The agreement is generally excellent; this confirms the assumption that the observed low-energy absorption is due to the charge-transfer from the donor molecule to the acceptor molecule. Double charge-transfer absorptions were recorded in

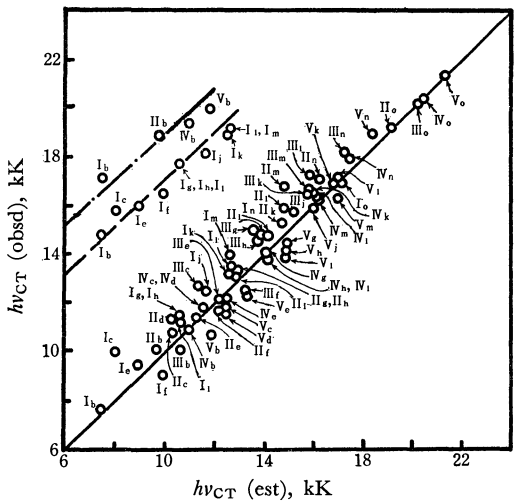

Fig. 2. Comparison between the observed energies of charge-transfer bands measured in solutions and the energies estimated by Fig. 1.

some combinations. The plot of the energy of the second absorption against the above-mentioned estimated $h\nu_{CT}$ values indicates that the second absorptions may be classified into two different classes. As one of them is characteristic of the complexes of tetramethylbenzidine, the absorption is apparently to be assigned to the charge-transfer from the second highest occupied orbital of the donor to the lowest vacant orbital of the acceptor. The absorption bands characteristic of the complexes of TCNQ form the other class. In this instance, the appearance of the second absorption is due to the charge-transfer from the highest occupied orbital of the donor to the second lowest vacant orbital of TCNQ. The average difference of 9.3 kK between the first and second bands in the TCNQ complexes is in agreement with the difference between the first and second transition energies in the TCNQ molecule as calculated by means of the molecular orbital method.[24] The existence of two classes in the second absorptions leads to the appearance of triple charge-transfer bands in the TCNQ complex of tetramethylbenzidine, as is shown in Fig. 3. The first band in the crystal complex is shifted to the low-energy side, and the second and third bands, to the high-energy side, compared to the corresponding bands observed in chloroform. An examination of Fig. 2 indicates that the third band is associated with the second lowest vacant orbital of TCNQ.

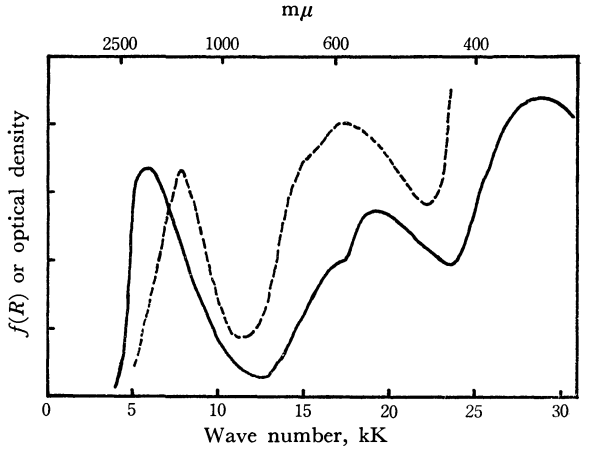

Fig. 3. Electronic spectra of tetramethylbenzidine-TCNQ in the solid state (——) and in a chloroform solution (----).

In Table 1 the energies of the charge-transfer absorptions of the solid complexes are summarized, along with the amounts of the shifts compared to the energies observed for the complexes in chloroform. As was noted in Fig. 1, the complexes with the acceptors, k, l, m, and n, could not be crystallized from the solution. For some of them, the charge-transfer absorptions in the solid phase could be measured with samples made by grinding together mixtures of the solid components. The energies obtained in this way are also presented in Table 1. Amano *et al.* have examined the polarized absorption spectra using single crystals of several complexes of benzidine and its tetramethyl derivative.[5,25] Their compounds include the following seven: Ib, Ig, Io, IIIb, IIIg, IIIk, and IIIo. The results given by Amano, which are cited for the sake of comparison in the footnote in Table 1, are in essential agreement with ours.

The first charge-transfer bands in all the solid complexes but Ij are shifted to the low-energy side if compared with those of the complexes in chloroform. A closer consideration of the amounts of the shifts shows that these non-ionic complexes must be further classified into two subgroups. With the donor I, the shifts are no more than 3.0 kK. Secondly, when the acceptor is not a quinone, the largest shift observed is 2.9 kK in the complexes Ic and IIb. Thus, the red-shifts found in this subgroup are usually small, and they may be explained in terms of a change in the surrounding molecules acting as a dielectric medium or by a change in the relative arrangement of the donor and acceptor molecules.[26,27] The second subgroup comprises complexes of quinones combined with the donors II—V, which bear unsubstituted amino groups. The red-shifts are quite substantial, ranging from 2.7 kK in the complex Vd to 6.0 kK in the complex Vn. In this respect, the complexes with *p*-fluoranil are quite exceptional; even a blue-shift was found in the complex Ij. The presence of amino groups in the donor molecules and carbonyl groups in the acceptor molecules induces the formation of hydrogen bonds in the crystal complexes. As it is a common feature that the donor and acceptor molecules are alternatively stacked, face-to-face, on each other along one of the crystal axes, the donor molecules linked to the acceptor molecules by hydrogen bonds should belong to different stacks. Thus, the effects of the hydrogen-bond formation, if any, must be observable only in the crystal complexes. A large red-shift of the charge-transfer absorption in quinhydrone as a result of the crystal-

lization has also been ascribed to the intermolecular hydrogen bond.[28]

The location of the second charge-transfer bands in the complexes of tetramethylbenzidine is only slightly affected by a change in the state. The nature of these absorptions has been speculated upon by Amano *et al.* on the basis of their measurements of the polarized absorption spectra.[5]

A striking resemblance between the spectra of the ionic DDQ complexes and the solid cation-radical salts derived from the donors should be mentioned. For example, the spectrum of the complex IVa is compared with that of solid *o,o'*-dichloro-*o*-tolidine bromide in Fig. 4. The latter is very similar to those of the solid bromides of benzidine, *o*-tolidine, and tetramethylbenzidine described in our earlier papers.[29,30]

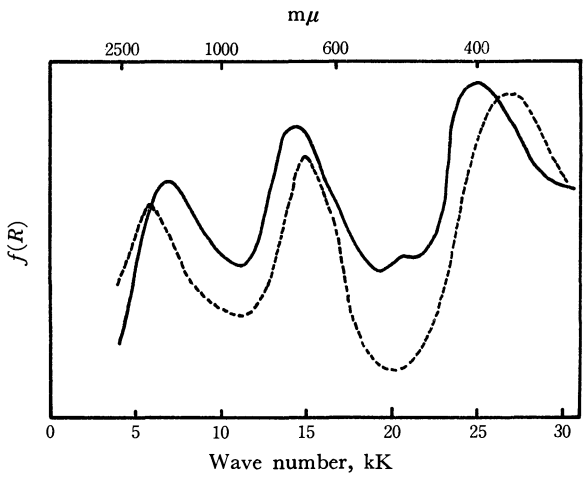

Fig. 4. Diffuse reflection spectra of dichloro-*o*-tolidine-DDQ (——) and dichloro-*o*-tolidine bromide (----).

The electronic spectra of ion-radical salts have been known to depend considerably upon the mode of intermolecular interaction. The spectrum shown in Fig.

4, which bears no resemblance to either the monomer or dimer spectrum and which is extended into a lower-energy region, is assigned to the cation-radicals in a strong more-than-by-pairs interaction. Consequently, we may conclude that the ionized donor molecules in these DDQ complexes strongly interact with each other. Such an interaction is possible, even if the donor and acceptor molecules are alternately stacked, because of the rather large difference in the size and shape of the component molecules.

Electrical Properties. The electrical resistivities, ρ, at room temperature and the activation energies for semiconduction, E_a, as defined by

$$\rho = \rho_0 \exp(E_a/kT) \tag{3}$$

are presented in Table 2, along with the values appearing in the literature.[6,22,26,31,32] The ionic DDQ complexes exhibiting resistivities of the order of 10^3 ohm cm are the most conductive ones in the present series of complexes. Nevertheless, it must be noted that the non-ionic complexes can be as conductive as the ionic ones if the component molecules are properly chosen. Their resistivities are continuously distributed from 10^3 ohm cm on upward; one in the order of 10^3, IId, three in the order of 10^4, IIb, IVd, and Vd, and two in the order of 10^5, IIe and IIIe. Thus, the resistivity of a complex seems to be very much determined by the acceptor. The complexes of the acceptors d and e tend to exhibit low resistivities. On the other hand, the TCNE complexes have resistivities of the order of 10^7 or 10^8 ohm cm, and the complexes of the acceptors f and j—o have resistivities higher than our upper limit, 10^8 ohm cm.

The electronic spectra and electrical resistivities in the series of the TCNE complexes and also the TNB complexes have been examined by Kuroda *et al.*[26,33] They have pointed out that $2E_a$, the energy gap if the conduction is intrinsic, is approximately equal to the energy of the charge-transfer absorption in the crystal complex. The empirical relation between these two quantities may be expressed, in general, by this equation:

$$2E_a = h\nu_{CT}(\text{solid}) - \Delta\,, \tag{4}$$

where Δ is nearly constant in a series of molecular complexes with a given acceptor if the donor molecules are of the same type. The magnitude of Δ varies within a rather narrow range, *e.g.*, 0.2 eV for the TNB complexes of aromatic amines. In Fig. 5, we plotted twice the activation energy for semiconduction against the energy of the first charge-transfer absorption given in Table 1. The complexes in the first subgroup are indicated by open circles, and those in the second, by shaded circles.

Another result which seems to be the consequence of the hydrogen bonding is clearly demonstrated here; that is, considerable deviations from Eq. (4) are observed with the complexes in the latter subgroup. The direction of the deviation is in accordance with the conclusion by Gravatt and Gross that an extended intermolecular overlap resulting from the hydrogen bonding produces a decrease in the activation energy for semiconduction.[34] However, their resistivities are close to those of the corresponding complexes of

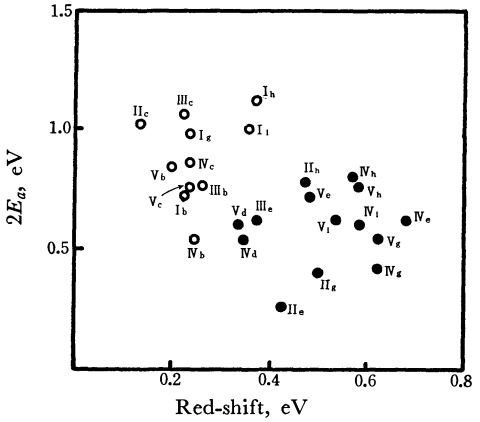

Fig. 6. Classification of molecular complexes on the basis of twice the activation energy for semiconduction and the amount of red-shift in the first charge-transfer band caused by crystallization.

tetramethylbenzidine. The decrease in the activation energy is apparently compensated for by an increase in the preexponential factor in Eq. (4), ρ_0. As the hydrogen bonding causes; (i) a large red-shift in the first charge-transfer band by crystallization and (ii) a substantial decrease in the activation energy for semiconduction, the molecular complexes can be quite distinctly divided into the two subgroups in a diagram such as that shown in Fig. 6. However, the mechanisms involved in these electronic processes are yet unknown.

The Preparation and Nonstoichiometry of Samarium Hexaboride

Koichi NIIHARA
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received October 7, 1970)

Samarium hexaboride was prepared by the borothermal reaction; $2\,Sm_2O_3+(6+4x)B=4\,SmB_x+3\,B_2O_2$. The residual oxygen content amounted to less than 0.03 w/o under optimum reaction conditions heating at 1650°C for 2 hr under a high vacuum. It was found by X-ray intensity and density measurements that the samarium hexaboride stayed stable over a large nonstoichiometric region from $Sm_{0.68}B_6$ to SmB_6. These extensive nonstoichiometric properties of samarium hexaboride can be explained in terms of the required electron numbers of the SmB_6 network in hexaboride.

In recent years the rare earth elements and their high-temperature compounds have been intensively investigated since their applications range over an extensive area of new technology, including radio engineering, electronics, metallurgy, machine construction, and electrical engineering. In particular, the hexaborides of the rare earth elements have become a subject of increasing importance and interest because of their high melting points, low electric resistivities, low values of the electron work function, high emission-current densities, and thermal stabilities.

All the rare earth metals, as well as scandium, strontium, barium, and plutonium, form isostructural hexaborides. The crystal structure of hexaborides was first determined by Stackelberg and Neuman.[1] According to them, the crystal structure is cubic and of the cesium chloride type, in which the metal atom is held in the center of a cage of boron atoms (just as the cesium atom is held in the CsCl crystal); six boron atoms in the octahedral form are located at the corners of the cell, in the same position as the chloride ion in cesium chloride.

The theoretical treatments by Longuet-Higgins and Roberts,[2] Eberhardt[3] and Yamazaki[4] have led to the conclusion that each boron octahedron requires 20 electrons, of which 18 come from the boron atoms and 2 from the metal atom. Out of the total of 20 electrons, 14 supposedly form bonds within the octahedron, and 6 enter into the external two-electron covalent bonds connected with neighboring octahedra. Therefore, it is possible that the rare earth hexaborides have a

relatively wide range of homogeneity, for the rare earth metals have three valence electrons.

The present study has been carried out so as to investigate the nonstoichiometric properties of pure samarium hexaboride. The results show that the study of nonstoichiometric propeties of the hexaboride will also provide useful information on the electronic configuration.

Experimental

Materials. Samarium sesquioxide, Sm_2O_3,[5] was separated from a crude rare earth mixture at this laboratory by replacement chlomatography, using the EDTA solution as the solvent. The Sm_2O_3 obtained by this method was over 99.9% pure, and other rare earth elements were found to be negligible in quantity by mass spectrography and radioactivation analysis.

The crystal boron, 99.9% pure and containing 0.11% oxygen. was obtained from Wako Pure Chemical Industries, Ltd, Tokyo.

Preparation of Samples. The hexaboride was prepared by the borothermal reduction[6-10] of samarium oxide, Sm_2O_3, according to the following equation:

$$2Sm_2O_3 + (6 + 4x)B = 4SmB_x + 3B_2O_2 \quad (1)$$

The lower volatile suboxide of the boron, B_2O_2, was removed upon reduction under a vacuum.

The samarium sesquioxide and boron were mixed in the desired mole proportions and ground carefully in a sardonyx mortar for complete homogenization. Samples weighing 4—5 g were heated at 1650°C in a tantalum crucible placed in an electric-resistance heater in a vacuum of 10^{-4}—10^{-6} mmHg at several temperatures for different times. The temperature was read with a W-WRe thermocupple and an optical pyrometer, corrected for window and prism absorptions.

X-Ray Diffraction. X-ray photographs of the products were taken using CuK_α and FeK_α radiations and a Debye-Scherrer X-ray powder camera (114.8 mm diameter). The precise lattice constants for the cubic hexaboride samples were calculated by extrapolating a plot of lattice constants *vs.* $\cos^2\theta$ to $\theta=90°$. The X-ray intensity ratio between the particular diffraction planes for the hexaboride was measured using an X-ray diffractometer equipped with a monochrometer.

Chemical Analysis. The boride samples were dissolved in Na_2CO_3 aq., and then their pH values were adjusted to 5.2 with $(CH_2)_6N_4$. After adding the XO indicator, analyses of the samarium were performed by titration with a 1/100 mol EDTA standard aquasolution. Boron analyses were performed by titration with a 1/10 N NaOH aquasolution after dissolving the samples in Na_2CO_3, adjusting their pH to 6.9, and adding Mannitol. Oxygen analyses were performed by the inert-gas-fusion coulonic titration method.

Density Measurements. The powdered specimens of 325—400 mesh were prepared by grinding them carefully in the sardonyx mortar. The density was determined at 20.5°C by a flotation technique using CCl_4.

Resistivity Measurements. For the resistivity measurements, a current of about 0.04 to 0.5 A was passed through the specimens and a standard resistance connected in series. A simple two-point apparatus and a standard potentiometric method were used. The resistivity measurements were carried out from the temperature of liquid nitrogen to 1000°K. The specimens used were $3\times5\times16$ mm blocks which were cut from annealed pellets using a diamond cutter.

Results and Discussion

Determination of Reaction Conditions. The samarium sesquioxide-boron compacts mixed at a 1 : 15 mol ratio were heated in a vacuum at 900—1900°C for 30 min. A loss weight results from the vaporization of the lower volatile oxide of boron, B_2O_2. The loss weight percentage after the heating reaction is plotted against the reaction temperature in Fig. 1. The dotted line indicates the theoretical loss weight percentage when the reaction is performed according to Equation (1).

Figure 1 shows that the borothermal reaction begins at about 1350°C and exceeds the theoretical weight loss at 1600°C. Figure 2 shows the oxygen content *vs.* the reaction time when the samarium sesquioxide-boron compact was reacted in a vacuum at 1650°C for different times. From Fig. 2 it is clear that the products contain only 300 ppm oxygen when reacted at 1650°C for 2 hr in a high vacuum.

From the results shown in Fig. 1 and Fig. 2, it can

be seen that the borothermal reaction is almost completed by heating at 1650°C for 2 hr in a vacuum.

Preparation of Samarium Hexaboride. The samarium sesquioxide-boron compacts mixed at various ratios were heated under a vacuum of 10^{-4}—10^{-6} mmHg at 1650°C for 2 hr. The results of chemical and X-ray analyses are summarized in Table 1. In the regions of 13—21 and 9—12 in the nominal composition ratio, B/Sm_2O_3, only samarium hexaboride, SmB_6, and both samarium tetraboride, SmB_4, and samarium hexaboride, SmB_6, were observed, respectively. In the region of 22—26 in the nominal composition, SmB_6 and a trace of boron were observed. In this region, samarium dodecaboride, SmB_{12}, was not detected at all. If the borothermal reaction takes place according to Eq. (1), the boron-samarium atomic ratio, B/Sm, must agree with the theoretical values shown in the second column in Table 1. Felten *et al.*[6] have reported that boric anhydride, B_2O_3, vaporizes during the reaction. If the boric anhydride, B_2O_3, vaporizes during the reaction, the B/Sm ratio in the region of 14—26 in the nominal composition is in good agreement with the theoretical values shown in the third column. However, the observed values coincide well with the theoretical values in the second column. From this fact, it may be concluded that, during the reaction, not boric anhydride, B_2O_3, but a volatile suboxide of the B_2O_2 boron is formed in the region of 15—26 in the nominal composition. In the region of 9—14, the analytical values of B/Sm are considerably different from the theoretical values. It is reasonable to think the borothermal reaction takes place in this region following these equations.

$$Sm_2O_3 + (15 - 2x)B = (2 - x)SmB_6 + xSmB_4 + (3/2)B_2O_2(g) \quad (2)$$

$$SmB_4 = SmB_6 + Sm(g) \quad (3)$$

Samsonov[11,12] has reported that an approximate thermodynamic calculation of either the suboxide of the B_2O_2 boron or boric anhydride, B_2O_3, but that SmB_4 is decomposed into SmB_6 and Sm(g) according to Eq. (3).

Nonstoichiometric Properties. As can be seen from Table 1, the samarium hexaboride is stable in the nonstoichiometric composition of 5.96—9.27 at the boron-samarium atomic ratio. The variation in the lattice parameter of the cubic hexaboride *vs.* B/Sm is shown in Fig. 3. The lattice parameter decreases with an increase in the B/Sm ratio in the region of the monophase hexaboride.

If the nonstoichiometric properties of samarium hexaboride are related to the position of samarium metal, the X-ray diffraction intensity will vary considerably because the magnitude of the atomic scattering factor of samarium is much larger than that of boron. The diffraction of the 100 and 110 planes is sensible for the position of samarium metal. The variation in the X-ray intensity ratio of the 100 diffraction plane *vs.* the 110 plane is plotted against the B/Sm ratio in Fig. 4. The dotted line shows the value of the calculated X-ray intensity ratio. These calculated values are obtained according to Eq. (4), supposing that is the formation of $Sm_{1-x}B_6$, the excess boron does not enter into interstitial sites in unit cells, but vacancies form at random in the sites of the samarium metal:

$$I \propto |F|^2 p \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta}$$

$$\frac{I_{100}}{I_{110}} \propto \frac{|F_2|^2 p_2 \dfrac{1 + \cos^2 2\theta_2}{\sin^2 \theta_2 \cos \theta_2}}{|F_1|^2 p_1 \dfrac{1 + \cos^2 2\theta_1}{\sin^2 \theta_1 \cos \theta_1}} \quad (4)$$

where p is the permutation factor.

The variation in the density against B/Sm=1+y in SmB_{1+y} or 1−x in $Sm_{1-x}B_6$ is plotted in Fig. 5. The solid line (a) shows the experimental values, both the closed circles (b) and the open circles (c) being the theoretical values. The values of the closed circles and open circles are calculated on the assumption that the nonstoichiometric composition can be indicated by the $Sm_{1-x}B_6$ formula or the SmB_{6+y} formula respectively. The experimental results are in good

agreement with the values of the closed circles. From the variations in the lattice parameter, the X-ray intensity ratio, and the density, it seems probable that the samarium hexaboride phase is stable from SmB_6 to $Sm_{0.68}B_6$. Johnson and Daane[13] have found that the lantanum hexaboride phase is stable from LaB_6 to $LaB_{7.8}$. It is probably more exact to refer to the latter as $La_{0.76}B_6$.

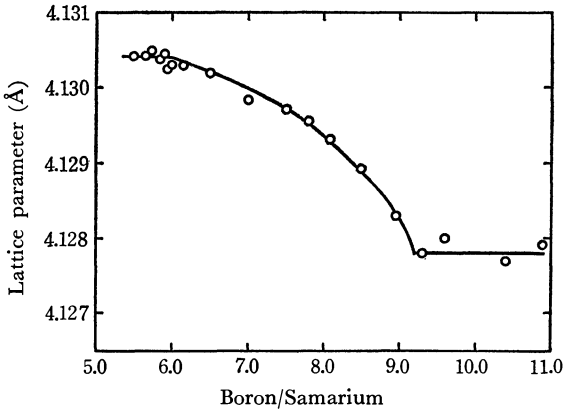

Fig. 3. The variation in the lattice parameter of samarium hexaboride.

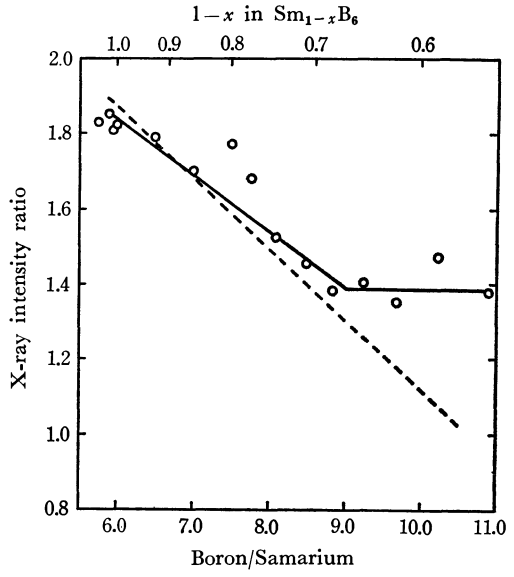

Fig. 4. The variation in the X-ray intensity ratio, $I(100)/I(110)$, against nonstoichiometric composition of samarium hexaboride.
-○-: experimental values, ----: calculated values.

Relationship between a Wide Homogeneity Range and Bonding. The wide range of homogeneity in samarium hexaboride can be explained in terms of the required electron numbers of the boron network and the availability of such electrons in the valence band of the metal atom. Calculations by Longuet-Higgins and Roberts[2] and Lipscomb and Britton[3] indicate that two electrons must be transferred to each boron octahedron in the hexaboride structure to ensure its

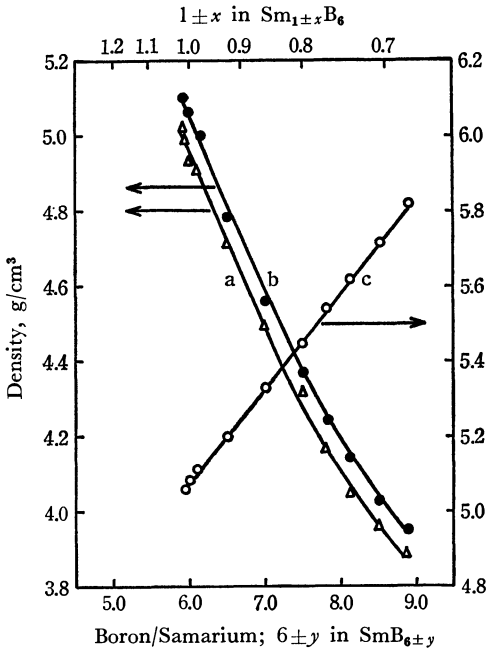

Fig. 5. The variation of density against nonstoichiometric composition of samarium hexaboride.
a(-Δ-): experimental values, b(-●-) and c(-○-) are X-Ray density calculated on the assumption that $Sm_{1-x}B_6$ or SmB_{6+y} respectively.

stability. In stoichiometric SmB_6 there is, therefore, one excess valence electron for each samarium atom because the rare earth metals generally have three valence electrons. This excess metal valence electron is responsible for the metallic properties. The lower limit of $Sm_{0.67}B_6$ is theoretically possible, with each samarium atom contributing all three valence electrons to the boron net; at that composition, the phase is presumably an electrical insulator.

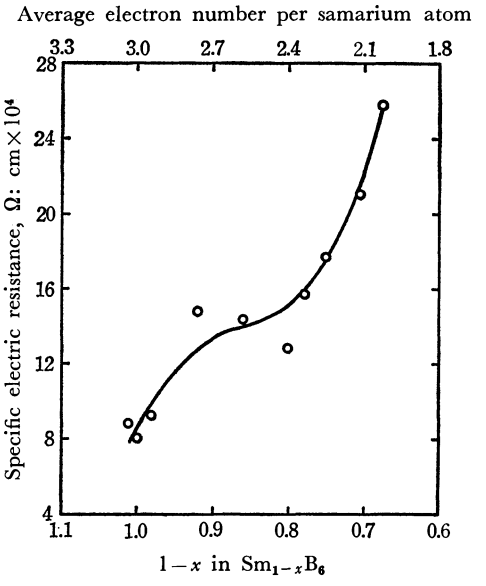

Fig. 6. The plot of specific electric resistivity *vs.* $1-x$ in $Sm_{1-x}B_6$ or average electron number per samarium metal atom.

Generally the temperature dependence of the electric resistance of a number of hexaborides of the rare

13) R. W. Johnson and A. H. Danne, *J. Phys. Chem.*, **65**, 909 (1961).

earth metals[12,14,15] showed a positive value of the temperature coefficient of the resistance, just as we should have expected for a substance with metallic conductivity. An exception is the hexaboride of samarium, which possesses a negative value of the thermal coefficient of the resistance. This fact can be explained by the change in the ratio of divalent and trivalent samarium with the temperature.[16-18] In the present work, $Sm_{1-x}B_6$ possessed a negative value of the temperature coefficient of resistance, very small in absolute magnitude at temperatures above 500°C. The variation in the electrical resistivity at 25°C against the electron number to be transfered to each boron octahedron is shown in Fig. 6. The electrical resistivity varies from 8×10^{-4} to 26×10^{-4} $\Omega\cdot$cm with an increase in the number of samarium-metal atom vacancies. At the lower limit of the homogeneity range, $Sm_{0.68}B_6$ (electron number, 2.04), the electrical conductivity is relatively large, probably due to: (a) impurities, (b) the effect of the d band of samarium metal, and (c) more few electrons being required to form the B_6 net.

Referring to (c) among these three factors, $Ba_{0.57}Na_{0.43}B_6$ and $Th_{0.23}Na_{0.77}B_6$ are stable in the $(NaMe)B_6$ system[19,20] and correspond to 1.60 electrons per metal atom. If the formation of the bond of boron in the SmB_6 phase requires 1.60 electrons, a somewhat smaller electron number per metal atom than two, the remaining electrons ($2.04-1.60=0.44$) per samarium atom in $Sm_{0.68}B_6$ can enter into the conduction band and its electrons can be responsible for the comparatively high electroconductivity at the lower limit of the nonstoichiometric composition.

From this standpoint, the limit of the homogeneity range existing between SmB_6 and $Sm_{0.53}B_6$ can be explained theoretically. The lower limit observed in this study was $Sm_{0.68}B_6$. It seems that the lower limit may be determined by the onset of mechanical instability in the boron lattice due to the large number of metal-atom vacancies. This point is still open to question, though, and further work is called for.

The author would like to thank Professor Seishi Yajima for his guidance and encouragement, and Mr. Masahiko Sase for his chemical analyses.

The Effect of Pressure on the Association of Dye Molecules in an Aqueous Solution[1)]

Keizo SUZUKI and Masao TSUCHIYA[2)]

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto

(Received October 12, 1970)

The effect of pressure on the association of rhodamine B (RB) and methylene blue (MB) in water has been investigated on the basis of their absorption spectra under hydrostatic pressures up to 4500 atm at room temperatures. Pressure increases the association of these dyes. The volume changes accompanying the 2 monomer$\rightleftarrows$ dimer process are calculated. The values are -10.4 cc/mol and -10.6 cc/mol in RB and MB respectively. These negative values are inconsistent with the suggestions by Rohatgi and Singhal and by Mukerjee and Ghosh that hydrophobic bonds are responsible for the associations of RB and MB. It is more plausible to assume that the hydrogen bond is the main binding force in the dye associations. London's dispersion force and the increase in the dielectric constant of water with the increase in the pressure may also assist the dye associations.

Dye association in an aqueous solution has, in general, been deduced from nonconformity with Beer's law. Various mechanisms have been advanced for the association of dyes. However, no definite mechanism has been put forward to explain the forces holding the dye molecules together. Mukerjee and Ghosh[3)] have recently suggested the contribution of the hydrophobic bond in the formation of the dimer from the fact that urea decreases the association of methylene blue. Rohatgi and Singhal[4)] also considered the hydrophobic bond as responsible for the association of rhodamine B because of the positive entropy change (+5.3 eu). If the hydrophobic bond is responsible for dye association, as they suggested, it could be expected that the equilibrium would shift to the monomer side under a high pressure, because the formation of the hydrophobic bond accompanies a positive volume

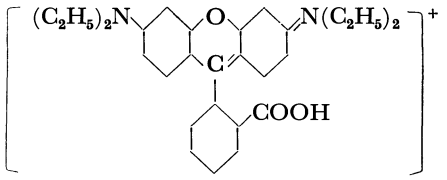
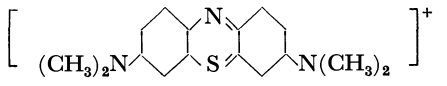
change.[5,6]

In this communication we will attempt to interpret the nature of bonding in the association of two dyes, rhodamine B and methylene blue, by measuring the absorption spectra of these aqueous dye solutions under high pressure. No study of the effects of applied pressure on the dye association has yet been reported. The molecular formulas of these dyes may be represented as follows:



Rhodamine B (RB)



Methylene blue (MB)

Experimental

Methods. High-pressure optical equipment of the Drickamer type[7] was used, along with a Hitachi-Perkin Elmer 139 type spectrophotometer. The absorption cell used is shown in Fig. 1, and the dye solution was sealed with mercury. Silicone oil was used as a pressure medium. The concentration of the dye solution under pressure was corrected by using the compressibility data of water.[8] The concentration of the solutions was limited to below *ca.* 10^{-3} mol/*l* in such a manner so as to form an isosbestic point, indicating that primarily there are present only two absorbing species (monomer and dimer) at 1 atm.

Materials. The rhodamine B (RB, Sumitomo Chemical Co.) and the methylene blue (MB, Nakarai Chemical Co.) were recrystallized twice, from acetone and ethanol respectively, and then dried at 110°C. The purity of the samples was judged from the values of their peak wavelengths at the monomer band. These values are tabulated in Table 1, along with the values for reference.

Results and Discussion

Figure 2 shows the spectra of aqueous RB solutions at concentrations from 10^{-3} to 10^{-5} mol/*l* at 1 atm. The absorption bands at 554 and 524 m*μ* correspond to those of the monomer (M) and the dimer (D) respectively, and an isosbestic point appears at 533 *mμ*. These spectra coincide well with those in the literature.[9]

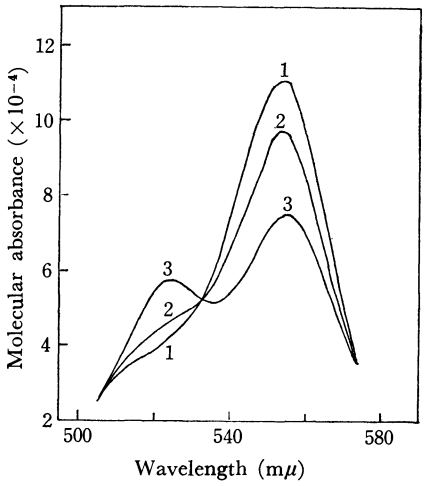

Fig. 2. Effect of concentration on absorption spectra of RB in aqueous solution at 1 atm and 30°C.
Concn. of RB (mol/*l*)
1 1×10^{-5}
2 1×10^{-4}
3 1×10^{-3}

Figure 3 shows the absorption spectra of RB (5.00×10^{-5} mol/*l*) under pressures of up to 4500 atm. It can be found from this figure that both the absorption bands shift to the red and that the absorption of the M-band decreases, while the absorption of the D-band increases, with an increase in the pressure. That is, the influence of the pressure is similar to the increase in the concentration, as is shown in Fig. 2, with the exception of the band shift. Such a band shift is a general phenomena observed in the absorption spec-

trum under high pressure; it may be attributed to a solvent effect deduced from the increase in the dielectric constant of the solvent.[10,11] If the shift at each pressure is restored to 1 atm, an isosbestic point can be demonstrated at 533 mμ, as in Fig. 2. We can, then, assume that only the dimer is formed in the experimental ranges of pressure and concentration.

The equilibrium constant, K, of 2 monomer $\rightleftarrows$ dimer was calculated according to the method of Rohatgi and Singhal.[4] The values of K from 1 to 4500 atm are tabulated in Table 2. The volume change accompanying the dimerization, ΔV, is calculated from the following relation;

$$\Delta V = -RT\left(\frac{\partial \ln K}{\partial P}\right)_T$$

Table 2. Effect of pressure on the equilibrium constant K of 2 monomer $\rightleftarrows$ dimer of RB (30°C) and MB (20°)

Pressure (atm)	Equilibrium constant K (l/mol)[a]	
	RB ($\times10^3$)	MB($\times10^4$)
1	6.01	5.56
900	7.48	8.52
1800	10.1	10.7
2700	14.8	15.1
3600	23.2	27.7
4500	39.8	42.2

a) The volume change accompanying association calculated from the above data is −10.4 cc/mol in RB and −10.6 cc/mol in MB.

10) F. G. Wick, *Proc. Amer. Acad. Arts and Sci.*, **58**, 555 (1923).
11) W. W. Robertson, S. E. Babb, and F. A. Matson, *J. Chem. Phys.*, **26**, 367 (1957).

The value of ΔV thus calculated is −10.4 cc/mol.

If the dimer is formed by a hydrophobic bond, as has been suggested by Rohatgi and Singhal,[4] the volume change accompanying the dimerization should be positive, because the formation of the hydrophobic bond is accompanying by a positive volume change, as has been reported by Kauzmann[5] and Scheraga *et al.*[6] Even if the participation of hydrophobic interaction in the dimerization process can not be neglected, another interaction, such as a hydrogen bond, should be predominant. The structure of the RB molecule fully admits the possibility of hydrogen-bond formation by the carboxyl group. It is plausible to assume that the hydrogen bond is concerned in the dimerization process of RB, because the formation of the hydrogen bond is accompanied by a negative volume change.[12-15]

Figure 4 represents the pressure effect on the absorption spectrum of MB in an aqueous solution. Absorption peaks appear at about 665 and 610 mμ; they correspond to the M-band and the D-band respectively, as has been reported by Rabinowitch and Epstein[16] and by others.[3,17-23] Both the absorption

bands decrease with an increase in the pressure, and no isosbestic point appears. It has been known that the absorption decreases under high pressure in other cases.[11] It should be mentioned, however, that the ratio of the optical density at the D-band (D_d) to that of the M-band (D_m), D_d/D_m, increases with the pressure. Moreover, no other absorption band besides the M-band and the D-band can be found at the shorter wavelengths 600 mμ to 400 mμ. The equilibrium constant, K, can be calculated according to the method of Rohatgi and Singhal,[4] as in RB. The values are tabulated in Table 2. The volume change accompanying the dimerization, ΔV, is calculated to be -10.6 cc/mol from Eq. (1).

The MB results also show that the dye association is promoted by compression, as in the case of RB. It has been found that the presence of urea and alcohol decreases the self-association of MB.[3] Therefore, the effect of the pressure on the association of MB is the opposite of the effects of urea and alcohol. From the viewpoint of the value of ΔV (negative sign), the association of MB can not be interpreted in terms of a hydrophobic bond, as has been suggested by Mukerjee and Ghosh.[3]

If the value of ΔV is taken into account, hydrogen bonding may be concerned in the self-association of MB. The structure of MB, however, does not admit the possibility of direct hydrogen bonding. A hydrogen bond through sandwiched water molecules may be involved in this phenomenon, as has been suggested by previous investigators.[23,24]

London's dispersion force could also cause a stacking of dye molecules so as to decrease the volume when the monomer units are in a sandwich with the principal molecular axes parallel, as has been suggested by Förster[25] and by Bergmann and O'Konski.[22] The increase in the dielectric constant with an increase in the pressure[26] may assist the association of dye ions, for an increase in the dielectric constant reduces the coulombic repulsive forces between the ionic parts of the dye ion.[27]

The authors wish to express their thanks to Professor W. Kauzmann of Princeton University for his valuable suggestions. The financial support given by the Ministry of Education is also gratefully acknowledged.

An MO-theoretical Interpretation of the Origin of the Orienting Effect in Aliphatic Systems

Hiroshi FUJIMOTO, Shinichi YAMABE, and Kenichi FUKUI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 14, 1970)

The importance of the charge-transfer interaction from the highest occupied (HO) molecular orbital (MO) of a donor to the lowest unoccupied (LU) MO of an acceptor molecule has been stressed on the basis of the numerical results of the calculation on a model of the S_N2 reaction of methyl chloride. The effect of a counter ion on the frontier orbitals has been discussed. For the E2 reaction of ethyl chloride, it has been discussed how the orienting effect of the leaving nucleophile is transmitted to the *trans*-β-hydrogen by means of the frontier electron density. The influence of the rotation about the C_α–C_β bond upon the reactivity of β-hydrogen has also been discussed.

In one of our previous papers, we have discussed the interaction energy between two reactant systems, *A* and *B*, partitioning it into four terms: the Coulomb, exchange, delocalization, and polarization interaction terms.[1] A succinct expression for each of these four terms has also been derived. On the basis of the three principles which govern the orientation and the spatial direction of chemical reactions, it has also been pointed out that the cooperation of the change in the molecular shape in the neighborhood of the reaction center with the charge-transfer interaction can be a driving force in a majority of chemical reactions.[2]

In this paper, we will present a further discussion of the physical meaning of the charge-transfer interaction and the orienting effect in the chemical reactions of aliphatic systems. To save space, the same notations as the previous paper[1] will be used, and no explanation will be repeated here.

The Delocalization Interaction

First of all, let us briefly mention the delocalization interaction terms in order to clarify the later discussion of the numerical computations. The delocalization interaction energy, *D*, is generally given by:

$$D = \sum_{i}^{occ}\sum_{l}^{uno} \frac{|H_{0,i\to l} - S_{0,i\to l}H_{0,0}|^2}{H_{i\to l,i\to l} - H_{0,0}} + \sum_{k}^{occ}\sum_{j}^{uno} \frac{|H_{0,k\to j} - S_{0,k\to j}H_{0,0}|^2}{H_{k\to j,k\to j} - H_{0,0}} \quad (1)$$

The denominator, $H_{i\to l,i\to l} - H_{0,0}$, can be expressed in terms of the ionization potential and the electron affinity:

$$H_{i\to l,i\to l} - H_{0,0} = I_{Ai}^{(B)} - E_{Bl}^{(A-i)} = I_{Ai}^{(B+l)} - E_{Bl}^{(A)} \quad (2)$$

in which:

I_{Ai}: the vertical ionization potential of the electron in the *i*th MO of the reactant *A*, and

E_{Bl}: the vertical electron affinity of the reactant *B* with respect to the *l*th MO.

$I_{Ai}^{(B+l)}$ is the value of I_{Ai} in the case of the approach of the system *B* with an additional electron occupying the *l*th originally unoccupied MO, and where $E_{Bl}^{(A-i)}$ is the value of E_{Bl} in the case of the approach of the system *A*, in which one electron occupying the *i*th MO is subtracted. The relations given in Eq. (2) can be easily visualized by means of a schematic diagram of the electron configurations without any formalism, as has been shown in one of our previous papers.[1]

The Delocalization Interaction and the Frontier Orbitals

Let us first consider the case in which two electronically neutral molecules interact with each other. The denominator of Eq. (1) is not simply expressed as $I_{Ai}-E_{Bl}$. The quantity $I_{Ai}^{(B)}$ represents the ionization potential of the *i*th MO of the reactant *A* under the influence of the reactant *B*. Since *B* is electronically neutral, $I_{Ai}^{(B)}$ may not differ very much from I_{Ai}. On the other hand, $E_{Bl}^{(A-i)}$ is the electron affinity of the *l*th MO of the reactant *B* in the cationic field of the reactant *A*, in which an electron in the *i*th MO is subtracted. Therefore, $E_{Bl}^{(A-i)}$ may be much greater than E_{Bl}. This implies that the denominator of Eq. (1) can be small enough in comparison with $I_{Ai}-E_{Bl}$.

Secondly, let us consider the case in which the reactant *A* is an anion and the reagent *B* is a neutral molecule. In this case, $E_{Bl}^{(A-i)}$ may be close to E_{Bl}, since the system *A* in which an electron in the *i*th MO is subtracted, is electronically neutral, while $I_{Ai}^{(B)}$ may be much smaller than those in neutral systems.

Lastly, let us consider the case where *A* is neutral and *B* is cationic. In this case, the $E_{Bl}^{(A)}$ may be greater than those in neutral systems, although $I_{Ai}^{(B+l)}$ may rather be close to I_{Ai}. Thus, we may come to the conclusion that the denominator of Eq. (1) is small enough when *i* denotes the HO MO of the donor, and *l*, the LU MO of the acceptor, among the various terms in *D*, in comparison with those simply expected from the $I_{Ai}-E_{Bl}$ of neutral molecules. In the interaction between an anion, *A*, and a cation, *B*, there may be cases in which $I_{Ai}^{(B)}-E_{Bl}^{(A-i)}$ is zero.

Even in not exactly degenerate case, the one-term approximation of *D*, such as Eqs. (4) and (5) in Ref. 2, may be valid for a majority of chemical interactions between the two reactant systems.

To exemplify these circumstances, we have carried out a numerical calculation on a model of the S_N2 reaction shown in Fig. 1. The MO's of the isolated species were obtained by means of an all-valence-shell ASMO SCF method which was similar to the one developed by Yonezawa *et al.*[3] The Coulomb electron repulsion integrals were estimated by point-charge approximation for intermolecular AO pairs. The

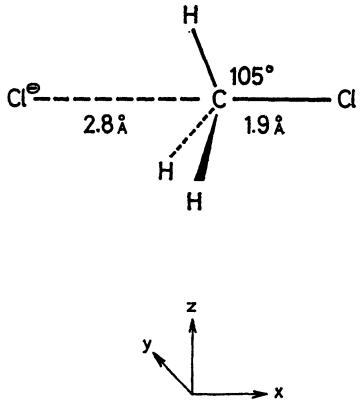

Fig. 1. The model of S_N2 reaction employed in this calculation.

integral, $\int t(1)(Z_\alpha e^2/r_{\alpha 1})t(1)dv(1)$, was taken to be equal to $Z_\alpha e^2/R_{\alpha\gamma}$ if the AO t belongs to the γ ($\gamma \neq \alpha$) nucleus, while, when t belongs to α, it was estimated using the Slater AO's. The other multi-center integrals were all calculated by the use of the Mulliken approximation.[4] The results of the calculation on various $(H_{i\to l,i\to l}-H_{0,0})$ are given in Table 1. We can see that the terms corresponding to the charge-transfer configurations from the p_x, p_y, and p_z of the attacking chloride ion to the LU MO of methyl chloride are relatively small in comparison with the other terms. Three p orbitals in the attacking chloride ion are degenerate in the isolated state, while this degeneracy is removed in the event of interaction with methyl chloride.

Table 1. The values of $H_{i\to l,i\to l}-H_{0,0}$ (in eV) for the various charge-transfer configurations of $CH_3Cl\cdots Cl\ominus$ system

i	l			
	LU	LU+1	LU+2	LU+3
s	15.4819	27.9199	27.9199	33.2388
x	3.2279	16.3913	16.3913	22.7129
y	6.3149	17.5828	17.9707	24.9383
z	6.3149	17.9706	17.5828	24.9383

Orienting Effect

The numerator of Eq. (1) may be supposed to be proportional to the overlap integral between the wave function of a charge-transfer configuration and that of the zero configuration. Moreover, we have a relation:

$$S_{0,i\to l} \cong \sqrt{2}\, s_{il} \tag{3}$$

This implies that the ease of the mixing of the charge-transfer configuration from the ith occupied MO of the system A to the lth unoccupied MO of the system B is proportional to the overlapping of these specific MO's. Table 2 shows the values of s_{il} calculated with respect to the nuclear configuration shown in Fig. 1.

3) T. Yonezawa, K. Yamaguchi, and H. Kato, This Bulletin, **40**, 535 (1967).

4) R. S. Mulliken, *J. Chim. Phys.*, **46**, 497 (1949).

Table 2. The values of $|s_{il}|$ for the various charge-transfer configurations of $CH_3Cl\cdots Cl\ominus$ system

i	l			
	LU	LU+1	LU+2	LU+3
s	0.0434	0	0	0.0740
x	0.0608	0	0	0.0504
y	0	0.0346	0.0008	0
z	0	0.0008	0.0346	0

We can see that the p_y and p_z orbitals are orthogonal to the LU MO of methyl chloride, while p_x has the largest overlap with the LU MO. This is due to the symmetry of the LU MO of methyl chloride, which has its maximum extension in the direction of the x-axis. Here it should be noted that the attack of the chloride ion and the departure of the chlorine of methyl chloride take place in the direction parallel with the x-axis. As we have previously discussed,[2] the LU MO of methyl chloride has the largest partial electron population at the carbon atom and antibonding character in the region of the carbon-chlorine bond, supplying a cause of inversion in the event of a S_N2 reaction. Although the values of $(H_{i\to l,i\to l}-H_{0,0})$ for the $i=s$ of the chloride ion and the $l=$LU+3 of the methyl chloride are large, the overlap integral, s_{il}, corresponding to this charge-transfer configuration is quite large, also. However, according to the second principle in our previous paper,[2] the contribution of this configuration becomes less and less important as the nuclear configuration change takes place along with the chemical reaction. Moreover, the importance of the charge-transfer term from the HO MO of the donor to the LU MO of the acceptor is accentuated by the aid of the cationic species which are present in the environment of the electron-acceptor molecule and by the aid of the anionic species which exist in the neighbor of the electron-donor molecule. We have made a calculation of the system composed of methyl chloride and the lithium cation, as is shown in Fig. 2. The

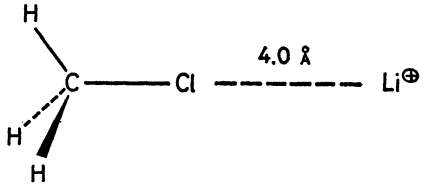

Fig. 2. The model employed for the calculation of the effect of a counter ion.

energy of the LU MO of methyl chloride is calculated to be 2.9570 eV, while that of the system shown in Fig. 2 is −4.5212 eV. In this case, the LU MO of the system comes to be almost degenerate with the HO MO of the chloride ion, which is calculated to be −3.4667 eV in our calculation. In real chemical MD of the chloride ion, which is calculated to be reactions, a reactant may hardly be exposed to the positive field of a bare nucleus. However, the one-term approximation of D, represented by Eqs. (4) and (5) in Ref. 2, might be valid in a majority of electron donor-acceptor interactions. Such an effect on MO's as to change their energy levels is an important role

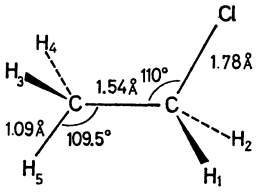
of counter ions, catalysts, solvents, and so on. This point will be discussed elsewhere.

Thus, we can conclude, as has already been discussed in our previous papers,[1,2] that the chemical reaction takes place at the position and in the direction where the overlapping of the HO MO of the electron-donor and the LU MO of the electron-acceptor is at its maximum; the present results support the conclusion fully.

Next, let us consider how the orienting effect of a nucleophile is transmitted to the *trans*-β-hydrogen, taking the case of the E2 reaction of ethyl chloride as an example. The partial valence-inactive population (C_r^2) and the partial valence-active population (v_r)[5] of β-hydrogen in the LU MO are given in Table 3.

Table 3. The partial valence-inactive and partial valence-active populations of hydrogens in LU of ethyl chloride

		Model I	Model II $F_{rs}\}=0$ s_{rs} $r=\mathrm{Cl}_{s,x,y,z}$ $s=\mathrm{H}_3,\mathrm{H}_4,\mathrm{H}_5$	Model III $F_{rs}\}=0$ s_{rs} $r=\mathrm{Cl}_{s,x,y,z}$ $\mathrm{H}_1,\mathrm{H}_2$ $s=\mathrm{H}_3,\mathrm{H}_4,\mathrm{H}_5$
$(C_r^{LU})^2$	3	0.0058	0.0058	0.0115
	5	0.0447	0.0453	0.0529
$v_r^{(LU)}$	3	−0.0027	−0.0030	−0.0065
	5	−0.0282	−0.0256	−0.0305



Model I is ethyl chloride, with the valence-angles and bond-lengths shown in the table, while Model II corresponds to the one in which the integrals between the chlorine and the 3, 4, and 5 hydrogens are put equal to zero in the secular equations and Model III is obtained by removing further the integrals between the 1 and 2 α-hydrogens and the 3, 4, and 5 β-hydrogens from Model II. We can see that the β-hydrogen *trans* to the chlorine has the largest frontier electron density ($(C_r^{(LU)})^2$) and anti-bonding character ($(v_r^{(LU)})^2$) among the three β-hydrogens in all of the three models presented in Table 3. This implies that the orienting effect of the nucleophile is transmitted to the *trans*-β-hydrogen mainly through the bonds having their maximum extension in the plane defined by chlorine, α,β-carbons, and *trans*-β-hydrogen.

Next, let us examine the change in the partial valence-inactive population and the partial valence-active population of hydrogens in the LU MO in the case of the rotation about the carbon α and carbon β bond axis. The results of the calculations on *n*-propyl chloride are shown in Table 4. It can be seen that the partial valence-inactive population of hydrogen in the LU MO is at its minimum when the plane involving the hydrogen and the α, β-carbons is perpendicular

to the one determined by the chlorine and the α, β-carbons, while it is at its maximum when the former is identified as the latter. When the methyl group is located *trans* to chlorine, the partial valence-inactive population of hydrogen in the LU MO is 0.0063. If the hydrogen comes to the *trans* position with respect to chlorine, the partial valence-inactive population increases to 0.0461. We have calculated the total energy of the system composed of *n*-propyl chloride and chloride ion in Fig. 3. The results shown in Fig. 3 have been obtained with reference to the approximation employed by Del Re and Parr in estimating

the nuclear repulsion energy.[6] We can see that the *gauche* form ($\theta=180°$) with respect to methyl and chlorine has a lower total energy than the *trans* form ($\theta=60°$) separated by a relatively low rotation barrier. A distinct parallelism has been shown to exist between the experimentally-observed rate constant of the E2 reaction and $(C_r^{(LU)})^2$, an approximate form of D, for a variety of alkyl halides.[7] *n*-Propyl bromide is found to be more reactive than ethyl bromide.[8] This also seems to indicate that hydrogen in *n*-propyl chloride is liable to be abstracted at the *trans* position to chlorine. This is conceivable, since the partial valence-inactive population of *trans*-β-hydrogen of ethyl chloride in the *staggered* form is 0.0447. Similar considerations may hold for other alkyl chlorides.

The results in Table 4 show that the β-hydrogen at the *cis* position to chlorine in an *eclipsed* *n*-propyl chloride ($\theta=0°$) has a larger reactivity toward a nucleophile than the other β-hydrogen ($\theta=120°$). This implies that if a molecule is rigidly fixed to the *eclipsed* form, selective *cis* elimination may take place. This may be a principal reason for the preferential *cis-exo* elimination of hydrogen bromide in *exo*-2-bromonorbornane.[9] Such an orienting effect of the leaving nucleophile should always be kept in mind in discussing the chemical reactivity of hydrogens in cyclic systems.

We have discussed the important role of the charge-transfer between the frontier orbitals and the origin of the orienting effect in terms of the frontier electron density for several chemical reactions of aliphatic systems, demonstrating how the so-called "anti-coplanar" selectivity in E2 reactions could arise.

The authors wish to express their appreciation to the Data Processing Center of Kyoto University for its generous permission to use the FACOM 230.60 computer.

Semiconductivity and Photoconductivity of TCNQ Crystal

Shoji HIROMA,* Haruo KURODA, and Hideo AKAMATU**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received October 24, 1970)

The results of a preliminary investigation on the semiconductive and photoconductive behaviors of the TCNQ crystal are described. The single crystal of TCNQ shows a resistivity of the order $10^{11}\ \Omega\cdot$cm at room temperature with an activation energy of about 0.6 eV. The photoconductive sensitivity of a TCNQ crystal is comparatively high. There are two types of crystal with respect to sensitivity to visible light. In both cases, the low-energy tail is extended up to about 1.5 eV. It is shown that both the activation energy of photoconduction and the light-intensity dependence of photocurrent differ appreciably in visible and ultraviolet regions.

Although extensive investigations have been carried out on the electrical properties of anion radical salts of 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ),[1] a good organic semiconductor, little is known on the properties of a TCNQ crystal itself. We could expect some interesting aspects on the electrical conduction in a TCNQ crystal. First, a low energy for the conduction state could be expected as will be discussed later. If this is the case, a TCNQ crystal will show a relatively good conductivity as well as some characteristic photoconductive behaviors. Secondly, we could easily inject electrons into a TCNQ crystal because of its high electron affinity.

In a previous paper,[2] we reported the polarized absorption spectra of the single crystal of TCNQ. We will report the results of a preliminary experiment on the semiconductivity and photoconductivity of a TCNQ crystal.

Experimental

TCNQ was synthesized by the method described by Acker and Hartler,[3] and purified first by recrystallization and then by repeated sublimation *in vacuo*. Because of the high electron affinity of TCNQ, it is apt to take donor-type impurities to form TCNQ ion radical. The purified specimen was checked with ESR, and confirmed to show no detectable signal. This means that the concentration of TCNQ ions, if present at all, might be less than $8\times10^{-16}\ g^{-1}$.

Single crystals were prepared by slow sublimation *in vacuo*, or by crystallization from ethylacetate solution. Most crystals thus obtained were a parallelepiped bounded with (001), (110). The developed face was usually (001). The size of a typical crystal used for the measurement was 0.5 cm × 0.5 cm × 0.05 cm.

For electrical measurements, electrodes were put on the

developed face of the crystal to form a sandwich-type arrangement. Although several different electrode materials were tested, most photoconductivity experiments were carried out by using a vacuum-deposited gold film as an illuminating electrode and carbon-paint electrode as another one.

DC currents were measured with a Toa Dempa Microvolt-ammeter Model PM-18. For illumination with a monochromatic light, a quartz-prism monochrometer was used with a Ushio 500 W Xe-lamp, or a tungsten lamp as the light source. The light intensity was measured with a calibrated germanium phototransistor, or a photomultiplier tube. Most measurements were carried out by placing the crystal in a vacuum of 10^{-4}—10^{-5} mmHg.

Results and Discussion

Dark Conduction. A TCNQ crystal shows a relatively high dark conduction. The single crystal showed a resistivity of 5×10^{11} Ω·cm at room temperature. The resistivity measured with a powder sample under compression of 116 kg/cm^2 was 1×10^{11} Ω·cm. These values are considerably low in comparison with the resistivity reported for polycyclic aromatic hydrocarbons of comparative molecular size, such as pyrene[4] and perylene.[5]

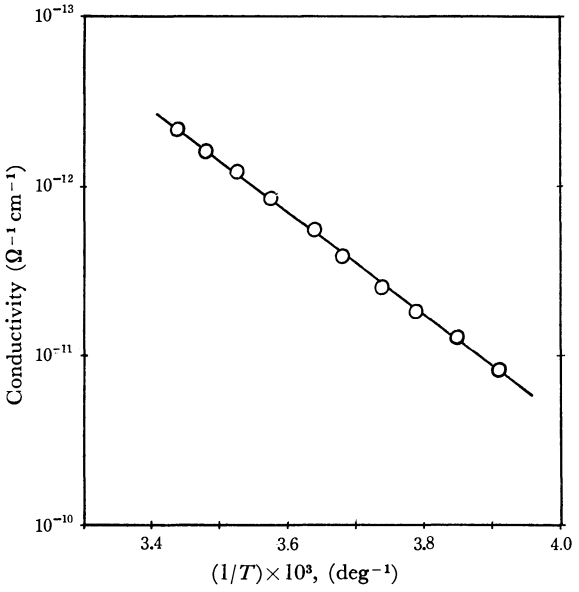

Fig. 1. Temperature dependence of conductivity of TCNQ crystal.

The temperature dependence of dark conduction was measured in the temperature range 200—290°K. An example is shown in Fig. 1. The results can be well described with the exponential equation

$$i = i_0 \exp(-\Delta E/kT) \quad (1)$$

The values of activation energy, ΔE, were found to differ a little with different crystals, but all of them fall in the range 0.45—0.6 eV. The highest value obtained in the present experiment was 0.6 eV.

Thus, if we assume that the carriers are formed by the intrinsic mechanism, not from impurity, the energy gap can be taken to be about 1.2 eV. The energy gap ε can be related to the ionization potential I and the electron affinity A of the component molecule by the relation

$$\varepsilon = I - A - 2P \quad (2)$$

where P is the polarization energy. From the magnetron experiment, Farragher and Page[7] have determined the electron affinity of TCNQ to be 2.88 eV. No experimental value is known for the ionization potential. From a molecular orbital calculation,[8] we predicted that $I=7.83$ eV and $A=2.35$ eV. Thus, the difference $I-A$ will be 5.48 eV if we take our theoretical values, and 4.95 eV if we take Page's value for A.[9] Although we have not estimated the polarization energy in a TCNQ crystal, it does not seem unreasonable to assume it to be about 2 eV according to the known data for various organic crystals.[7] Thus, we can predict that the energy gap in a TCNQ crystal might be in the range 1—1.5 eV. Hence the energy gap determined from the temperature dependence of dark conduction is not inconsistent with this estimation. Naturally, we can not exclude the possibility that the observed dark current is due to the impurity effect or the injection from electrode. The observed variation of the activation energy from crystal to crystal suggests that such extrinsic effects are not negligible. We only wish to point out that our highest experimental value, 1.2 eV, is not unreasonable for the true energy gap.

Spectral Response of Photoconduction. A TCNQ crystal exhibits a rather high photoconductive sensitivity as compared with usual polycyclic aromatic hydrocarbons. The photocurrent was found to be proportional to the applied field up to 10^3 V/cm.

The photocurrent *vs.* wavelength curve directly obtained with our experimental set-up is shown in Fig. 2(a). On examining a number of crystals, we found that TCNQ crystals can be classified into at least two types with respect to their spectral response of photoconduction, one which shows a lower sensitivity (*curve A*), and the other a higher sensitivity (*curve B*) in the visible region. We shall denote these two types by A and B, respectively.[11]

If we normalize the observed photocurrent to a constant light intensity, we obtain the curves shown in

11) At present, we do not know the reason for their appearance. Both types were found among crystals prepared by the same procedure. They can not be distinguished either from appearance or from the crystallographic character of the prominent face of the crystal.

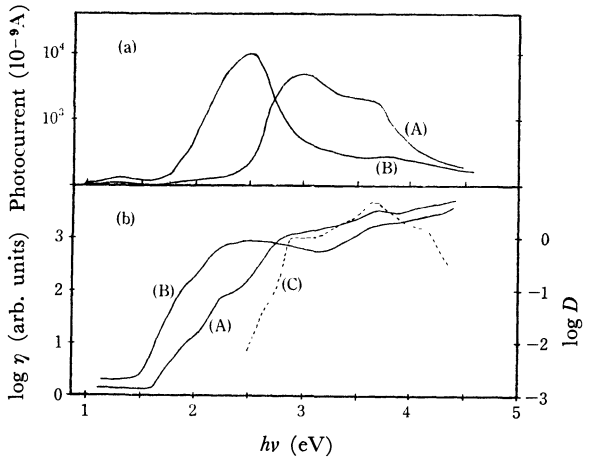

Fig. 2. Spectral response of photoconduction of crystal of A (*Curve A*), and crystal of B (*Curve B*). In Fig. 2(a), the photocurrent directly obtained without any correction for light intensity is plotted against the photon energy ($h\nu$). In Fig. 2(b), the logarithm of the apparent photoconductive sensitivity (η) is plotted against $h\nu$, together with the logarithm of the optical density (D) of the absorption spectrum of the crystal (*Curve C*).

Fig. 2(b), where the logarithm of η(Photocurrent/light intensity) is plotted against photon energy. The absorption spectrum of a TCNQ crystal is also shown. It can be seen that the spectral response curve of the A-type crystal corresponds to the absorption spectrum as regards the locations of the maxima, whereas there is an extra band in the 20—25 kK region in the case of the B-type crystal. It should be noted also that, in both cases, the tail of spectral response curve is extended into the lower energy region well outside the absorption edge. Such a tail seems to have a threshold at about 1.5 eV, which nearly coincides with the energy gap experimentally estimated from the temperature dependence of dark current.

We have examined the presence of electrode effect by using evaporated-film electrodes of different kinds of metal, *i.e.*, Au, Al, Pb, and Mg and a conducting glass electrode. But no specific effect of electrode material was found as far as the spectral response curve is concerned.

At present we do not know the reason for the difference in spectral response between A and B. It could be associated with the defect concentration of crystal. Another possibility might be the effect of impurity, or that of TCNQ ions which are produced either by impurity or the injection from electrodes. However, we have found that no marked change is produced in the spectral response curve, even if a large amount of TCNQ ions are introduced into the crystal by the doping of Li or ammonia.

Effects of Temperature and Light Intensity on Photocurrent. Photocurrent increases exponentially with temperature. An example of the experimental results obtained for crystal of A is shown in Fig. 3. From the results, the activation energy for photoconduction is estimated to be 0.15 and 0.03 eV for the wavelength of light 400 mμ and 500 mμ, respectively. The same results were obtained also for crystal of B.

The logarithm of the observed photocurrent against

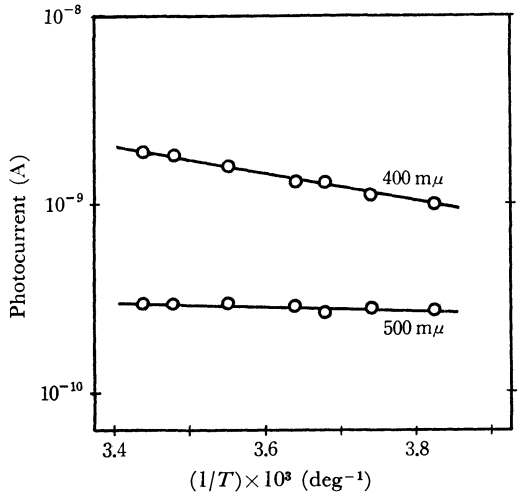

Fig. 3. Temperature dependence of photocurrent. (Crystal of A of TCNQ)

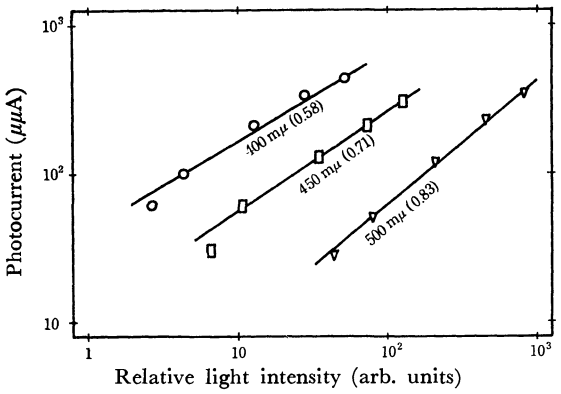

Fig. 4. Dependence of photocurrent (i_p) on the light intensity (L). (Crystal of A of TCNQ); the wavelength of the light is indicated in the figure, the number in the parentheses is the value of n obtained by assuming that $i_p \propto L^n$.

that of relative light intensity is plotted in Fig. 4. The data shown here were measured on crystal of A, but essentially the same results were obtained also for B type crystals. We can thus conclude that in both A and B types, the photocurrent is nearly proportional to the light intensity in the visible region, whereas it is almost proportional to the square root of the light intensity in the ultraviolet region. It is well known that photocurrent becomes proportional to the square root of light intensity when the concentration of charge carrier is controlled by the recombination of photogenerated carriers.[12] Such an effect is usually observed at very high light intensity. In the present experiments, the intensity of monochromatized light is not high, and is considerably lower in the ultraviolet region than in the visible region. It should be noted, however, that the absorption coefficient of a TCNQ crystal is quite high in the ultraviolet region, so that the incident light is strongly absorbed in a very thin region near the illuminated surface of the crystal, while the light in the visible region can penetrate deep into

12) N. Almeleh and S. E. Harrison, *J. Phys. Chem. Solids*, **26**, 1571 (1965).

the bulk of the crystal. Thus, it is most likely that an ultraviolet light produces a considerably high carrier concentration near the illuminated surface, where recombination could play an important role.

If this is actually the case, the temperature dependence of the steady-state photocurrent with an ultraviolet light will be dependent, not only on the carrier trapping in the bulk, but also on the recombination process. This could be the reason for the difference in activation energy between the visible and ultraviolet regions.

Effect of Electron Donor. We prepared a Li-doped polycrystalline film from a melt of TCNQ containing 1—2 weight percent of Li(TCNQ). The pale-green film thus obtained showed a considerably higher dark current, and the ratio of photocurrent to dark current was markedly reduced. However, no specific change was found in the shape of the spectral response curve of photoconduction. Similarly, a TCNQ crystal showed a pale green color when it was kept for a long period in ammonia vapor. The dark current in TCNQ crystal gradually increased with time on exposure to ammonia vapor. In the case of crystal of A, the photocurrent was lowered to about half of the original value throughout the spectral region after exposure to 15 mmHg ammonia vapor for 22 hr. Again, no specific change was found in the spectral response curve.

These results suggest that the doping of an electron donor, or the introduction of TCNQ ion into the crystal, markedly affects the dark conduction, but does not give rise to additional mechanism of charge carrier formation in photoconduction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 977—984 (1971)

Observation and Interpretation of Triplet-Triplet Absorption Spectra of Substituted Naphthalenes[1)]

Takeshi TAKEMURA, Kiyoaki HARA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received October 30, 1970)

Triplet-triplet (T-T) absorption spectra of naphthalene, α- and β-naphthol, and α- and β-methoxynaphthalene have been observed in rigid-glass solutions at 77°K by the rapid-scan spectrophotometric method and in fluid solutions at room temperature by the flash spectroscopic method. Hydrogenbonding effects on the T-T absorption spectra were examined for α- and β-naphthol. α-Naphthol was found to give different absorption spectra, depending upon the solvents employed. In a certain case the spectrum is attributed to a photoproduct rather than to the triplet state of α-naphthol. Analysis of the spectral data leads to the conclusion that the T-T absorption spectra in α-derivatives involve two different electronic transitions, and those in β-derivatives are due to a single electronic transition which is analogous to the transition in naphthalene. In agreement with these observations, calculations performed by the Pariser-Parr-Pople method predict that in the low-energy region, α-naphthol should have two allowed and detectable transitions, ${}^3\Psi_1 \rightarrow {}^3\Psi_7$ and ${}^3\Psi_1 \rightarrow {}^3\Psi_8$, and naphthalene and β-naphthol have only one such transition, ${}^3\Psi_1 \rightarrow {}^3\Psi_9$. The wave functions of triplet states are subjected to configuration analysis, with the result that ${}^3\Psi_7$ and ${}^3\Psi_8$ of α-naphthol are related predominantly to ${}^3\Psi_8$ and ${}^3\Psi_9$ of naphthalene, respectively.

Triplet-triplet (T–T) absorption spectra give useful information concerning the electronic structure of higher triplet states as well as of the lowest triplet of molecules. Until now a number of studies have been made both experimentally and theoretically on the T–T transitions in aromatic hydrocarbons such as naphthalene.[2,3)] It is to be expected that we get a deeper insight into the nature of triplet states by investigating the effect of substitution on the T–T transitions. There have been, however, relatively few systematic studies of T–T absorption for substituted aromatic hydrocarbons.

The present paper deals with T–T absorption spectra of some substituted naphthalenes. The parent hydrocarbon, naphthalene, is one of the molecules whose T–T transitions have attracted much attention.[2,3)] The naphthalene molecule shows at about 400 mμ a T–T absorption consisting of three sharp peaks. Recent studies including polarization measurements[4–6)] and molecular orbital calculations[7,8)] have demonstrated that this T–T absorption is due to a single electronic transition which has three peaks as vibrational components. In their theoretical study on T–T absorption spectra of substituted naphthalenes, Kla-

sinc and Sommer[9] paid attention to the experimental fact that the β-derivatives of naphthalene give an absorption spectrum similar to the spectrum of the parent molecule, but the α-derivatives show one or more new absorption bands.[10]

In this study, α- and β-naphthol and α- and β-methoxynaphthalene were treated as substituted naphthalenes. Our particular attention was directed to the distinction between the absorption arising from the triplet state and that possibly from a photoproduct, as well as to the distinction between individual transitions when different electronic transitions were involved in a T–T absorption. For naphthols, hydrogen-bonding effects were investigated on the T–T absorption spectra to obtain information on the origin of the spectra and also on the electronic properties of the triplet states concerned. In addition to these experimental investigations, calculations have been made for the triplet states of naphthols by the Pariser-Parr-Pople method,[11,12] and the resulting wavefunctions have been subjected to the configuration analysis proposed by Baba, Suzuki, and Takemura[13] with a view to revealing the electronic structure of the triplet states and making a reasonable assignment of the observed spectra.

Experimental

Materials. Naphthalene was purified by vacuum sublimation. α-Naphthol was recrystallized from ligroin, and β-naphthol from water and ligroin; both were further purified by vacuum sublimation. α-Methoxynaphthalene was purified by high-vacuum distillation over metallic sodium, and was then passed through an activated alumina column with a mixture of petroleum ether and ethyl ether as the solvent. After eliminating the solvent by distillation in an atmosphere of nitrogen, the α-methoxynaphthalene was again subjected to high-vacuum distillation. β-Methoxynaphthalene was recrystallized from ethanol and from *n*-heptane and was sublimed *in vacuo*.

Isopentane was distilled over phosphorus pentoxide. Methylcyclohexane and *n*-hexane of spectroscopic quality were used without further purification. Ethyl ether was treated with 10% sodium bisulfite solution, dried with calcium chloride and finally distilled over metallic sodium. Triethylamine was refluxed with phosphorus pentoxide and then fractionally distilled.

Apparatus and Procedure. Triplet-triplet absorption spectra were measured by two different methods. In the first method, the spectra were obtained with a rapid-scan spectrophotometer (Hitachi Model RSP-2[14]) in rigid-glass solutions at 77°K, as shown in Fig. 1. The spectrophotometer is a double-beam instrument, and scans from 220 to 700 mμ in 150 msec at a rate of 3 scans/sec. It is suitable for use in the present experiment since all the compounds studied have triplet lifetimes of about 2 sec.

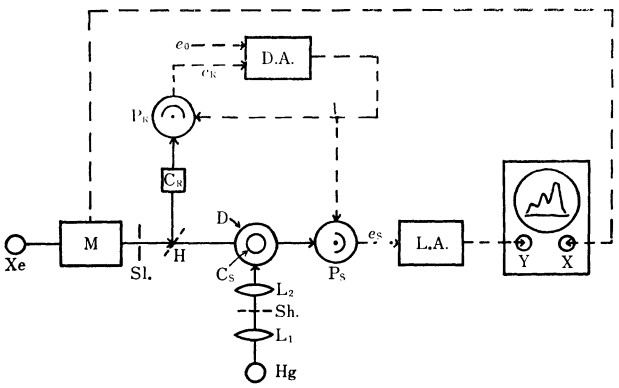

Fig. 1. A schematic diagram of the rapid-scan spectrophotometer as used for measuring T–T absorption spectra at 77°K. Xe, xenon light source; M, monochromator; Sl., slit; H, half-mirror; D, quartz Dewar; Hg, high-pressure mercury lamp for excitation; L_1 and L_2, lenses; Sh., shutter; D.A., differential amplifier; L.A., logarithmic amplifier; see text for other symbols.

Light from a 150-W xenon lamp, the source, is dispersed by a grating monochromator, and the resulting monochromatic light is divided into two beams which pass through the reference cell C_R and sample cell C_S, and then fall on the reference photomultiplier P_R and sample photomultiplier P_S, respectively. The difference between the output voltage e_R of P_R and a standard voltage e_0 is amplified, and the resulting voltage V is fed back to the cathode of P_R. By making the degree of amplification sufficiently great, e_R is held at a constant level (e_0) even if the wavelength of the monochromatic light is changed according to scanning. The voltage V is also applied to the photomultiplier P_S, so that the output voltage e_S of P_S becomes proportional to the transmittance of the sample. The output e_S is fed into a logarithmic amplifier to produce a voltage proportional to the absorbance of the sample. Absorption spectra corresponding to desired scans can be obtained on a storage oscilloscope for a desired wavelength range, with a linear wavelength scale which is calibrated with reference to the absorption spectrum of holmium.

In the T–T absorption measurements, the sample solution in a quartz cell of test-tube type was placed in a quartz Dewar and was cooled down to 77°K. An Osram HBO 100-W high-pressure mercury lamp was used for excitation. Several T–T absorption spectra were obtained in each measure-

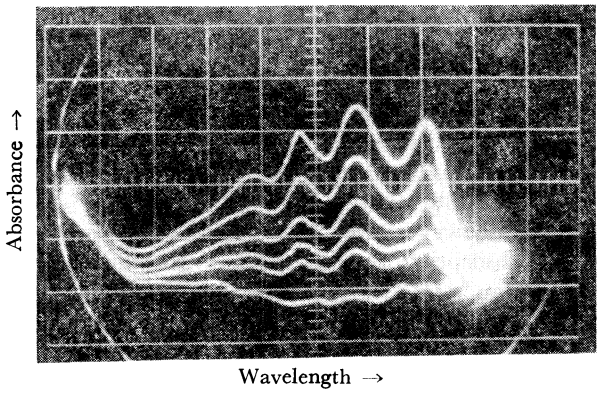

Fig. 2. T–T absorption spectra of α-naphthol in PME containing triethylamine at 77°K, measured by the rapid-scan spectrophotometer. The region of scanning is from 335 mμ to 535 mμ; the scan time is about 60 msec for this region.

ment. They included the spectrum corresponding to the scan immediately after shutting off the exciting light and also the spectrum (or base line) after completion of the triplet decay; allowance was made for the base line in determination of the true absorption. An example of the measurement by the rapid-scan method is shown in Fig. 2.

In the second method, T–T absorption spectra were obtained by means of flash spectroscopy. The technique and procedure were similar to those described by Porter and Windsor.[15,16] Two xenon flash tubes for excitation were mounted parallel to a sample quartz cell, 10 mm in diameter and 10 cm in length. The cell, was connected to a reservoir where the sample solution was degassed by repeated freeze-thaw cycles. The energy of the excitation flash was about 100 J. Another xenon flash tube was used to take the T–T absorption spectrum on the X-ray film set on a Shimadzu plane-grating spectrograph, Model GE-100. The density of the film was measured by a microphotometer.

Theoretical

Calculations on the Triplet States. Molecular orbital (MO) calculations have been made for the π-electronic triplet states of naphthalene and α- and β-naphthol by the semiempirical LCAO-SCF MO method including configuration interaction (CI), the Pariser-Parr-Pople method, to obtain the excitation energies and oscillator strengths of their T–T absorption transitions.

It is assumed that all the C–C distances are 1.40 Å, all the bond angles 120°, and the C–O distance is 1.37 Å. The valence-state ionization potentials I, valence-state electron affinities A, and resonance integrals β are taken to be as follows:

$$I_C = 11.16\,\text{eV}, \qquad I_O = 32.9\,\text{eV}$$
$$A_C = 0.03\,\text{eV}, \qquad A_O = 11.7\,\text{eV}$$
$$\beta_{CC} = -2.48\,\text{eV}, \qquad \beta_{CO} = -2.30\,\text{eV}$$

The Coulomb repulsion integrals γ_{pq} are calculated in units of eV by the formula

$$\gamma_{pq} = 14.40/[a \exp(-0.3\,r^2) + r] \qquad (1)$$

where r is the distance in units of Å between a pair of atoms p and q, and

$$a = 14.40/\{(1/2)[(I_p - A_p) + (I_q - A_q)]\}$$

with I and A expressed in units of eV. Atoms p and q may include both carbon and oxygen atoms, and Eq. (1) is used for $p=q$ as well as for $p \neq q$.

The values of I_C and A_C are taken from the data presented by Hinze and Jaffé.[17] In the derivation of Eq. (1), we first assumed a general formula

$$\gamma_{pq} = 14.40/[a \exp(-br^n) + r]$$

where b and n are adjustable parameters. (The formula proposed by Nishimoto and Mataga[18] is obtained by taking b as zero, while the formula by Knowlton and Carper[19] corresponds to $n=1$.) The values of b and n adopted here, together with the integral β_{CC}, are so chosen that the calculated excitation energies for the $^1B_{2u}$, $^1B_{1u}$, $^1E_{1u}$, and $^3B_{1u}$ states of benzene are in best agreement with the observed ones as measured at the maximum of the whole absorption band corresponding to each of the electronic transitions from the ground state to these singlet and triplet states. The values of I_O, A_O, and β_{CO} are determined so that the results of calculation and experiment may agree well as to the energy shifts of the lower singlet and triplet levels which are produced on going from benzene to phenol.

Twelve singly excited triplet configurations of lower energy are included in the CI calculations. If the SCF MO's of naphthalene and naphthols are numbered from 1 to 10 and from 1 to 11, respectively, in order of increasing orbital energy, the twelve configurations concerned are represented by the following one-electron transitions: for naphthalene 5→6, 7, 8, 9; 4→6, 7, 8, 9; 3→6, 7; 2→6, 7; and for naphthols 6→7, 8, 9, 10; 5→7, 8, 9, 10; 4→7, 8; 3→7, 8.

Configuration Analysis. The general procedure for configuration analysis has been described in a previous paper.[13] The wavefunctions $^3\Psi_1$, $^3\Psi_2$, ⋯ for the triplet states of α- or β-naphthol are collected in a row vector $^3\boldsymbol{\Psi}$. Each of these wavefunctions is expressed in terms of the reference state wavefunctions $^3\Psi_1{}^0$, $^3\Psi_2{}^0$, ⋯ that are built up from the MO's localized either on the naphthalene or on the substituent. The reference state wavefunctions collected in a row vector $^3\boldsymbol{\Psi}^0$ involve locally excited states and charge-transfer states. By introducing a matrix $^3\mathbf{M}$, $^3\boldsymbol{\Psi}$ is written as

$$^3\boldsymbol{\Psi} = {}^3\boldsymbol{\Psi}^0({}^3\mathbf{M}) \qquad (2)$$

The matrix $^3\mathbf{M}$ can be determined by the method developed previously.[13]

Results and Discussion

Figure 3 shows transient absorption spectra obtained by the rapid-scan method for naphthalene, α- and β-naphthol in a mixture of isopentane, methylcyclohexane and ether (PME; volume ratio, 6 : 1 :

0.7)[20] at 77°K, and Fig. 4 those obtained by the flash method in *n*-hexane at room temperature. In this paper all the spectra are given in such a way that the intensity of the maximum of the whole absorption spectrum is normalized to unity, since we are not concerned with the absolute absorption intensities. The numerical data on band maxima are presented in Table 1.

As has been mentioned, the absorption spectrum of naphthalene consists of three vibrational bands which belong to a single T–T electronic transition. In Figs. 3, 4 and Table 1, the absorption bands for naphthalene and its derivatives are denoted in the following way. The bands observed in the PME rigid glass are written in capital letters, while those observed in *n*-hexane by the flash method are written in small letters; the prime and double prime refer to α- and β-naphthol, respectively. As will be seen, bands of the same type are represented by letters of the same kind.

20) Ether was added to eliminate the possibility of association of the naphthol molecules.

Confirmation of T–T Absorption. The lifetimes of the transient absorption spectra in PME at 77°K shown in Fig. 3 were measured and found to be equal to the respective phosphorescence lifetimes of naphthalene, α- and β-naphthol observed under the same conditions. All the absorption spectra in Fig. 3 are therefore regarded as due to T–T transitions.

The T–T absorption spectra of naphthalene in Figs. 3 and 4 agree in their features, though a slight frequency shift is found. The corresponding spectra of β-naphthol also agree with each other and with the naphthalene spectra except for an additional band appearing in the spectrum of Fig. 4. Thus, on changing the solvent from the PME rigid glass to the fluid *n*-hexane, bands A'', B'', and C'' show a shift to higher frequencies, resulting in a'', b'', and c'', respectively. On the other hand, a new band referred to as r'' appears in the β-naphthol spectrum obtained by the flash method (Fig. 4). This band cannot be due to β-naphthol itself, but should be assigned to a certain molecular species produced by flash photolysis. In fact, r'' is identical with the absorption band at 21500 cm^{-1} which was found by Jackson and Porter[21] in flash photolysis of β-naphthol in viscous paraffin and assigned to the β-naphthoxyl radical.

The absorption spectrum of α-naphthol shown in Fig. 4 is similar to the spectrum attributed to a T–T transition in α-naphthol by Porter and Windsor.[22] However, the spectrum of α-naphthol in Fig. 4 differs entirely from the spectrum in Fig. 3, so that the former should not be identified with the T–T absorption. This is also supported by the following.

A rapid-scan measurement of the transient absorption spectrum was made for α-naphthol at 77°K in a hydrocarbon solvent of isopentane-methylcyclohexane (PM) mixture. In contrast to the case of Fig. 3, this did not contain ether. The spectrum thus obtained was very different from the T–T spectrum of α-naphthol in Fig. 3, and was analogous to the spectrum in Fig. 4. It was found that the absorption spectrum obtained in this way did not vanish so long as the sample was kept at low temperature, and disappeared on warming. This clearly shows that the spectrum in question, and hence the spectrum of α-naphthol in Fig. 4, cannot be due to a T–T transition, and should be attributed to a free radical produced by flash photolysis. The spectral behavior of α-naphthol thus changes with the constituent of the solvent employed, and it does not depend on the temperature or rigidity of the solvent.

In PME, the naphthol must form a hydrogen bond with ether. We assume that formation of a hydrogen bond between α-naphthol and a proton-accepting substance like ether gives rise to stabilization of the triplet state of the α-naphthol molecule and leads to the normal T–T absorption spectrum. It might be noted that a solution of α-naphthol in PME containing triethylamine as a proton acceptor also gives the T–T absorption at 77°K (*vide infra*).

Analysis of T–T Absorption Spectra. The three absorption bands of naphthalene (Fig. 3) belong to one and the same electronic transition and constitute a vibrational progression. Thus all these bands are known to be polarized along the long axis of the molecule,[4–6] and the spacings A···B and B···C are equally $\sim$1400 cm^{-1}, which can be assigned to a totally symmetric vibration of naphthalene. Similarly, the three absorption bands of β-naphthol are considered to constitute an analogous vibrational progression. The T–T absorption spectrum of α-naphthol (Fig. 3) involves five bands, which are not likely to belong to a single electronic transition. In connection with this problem, we will refer to additional experimental results.

The T–T absorption spectra at 77°K of α-naphthol in PME containing triethylamine as a proton acceptor and of α-methoxynaphthalene in PME are shown in Fig. 5, and the corresponding spectra of the β-derivatives in Fig. 6. In these figures the spectra of the naphthols in PME at 77°K are also given for comparison.

As regards the hydrogen bonding effects on electronic transitions, a thorough investigation has been carried out on the usual singlet transitions of hydroxylic compounds including α- and β-naphthol.[23] It was concluded that frequency shifts accompanying the formation of hydrogen bond differ in magnitude among different electronic transitions in a given molecule, and all the vibrational components for a given transition show a uniform shift. Intensity changes accompanying the formation of hydrogen bond also differ. These conclusions may be applied to the case of T–T transitions.

It is expected that triethylamine produces far greater hydrogen bonding effects on the T–T transitions of naphthols than does ether, since the former is known to have a much stronger proton-accepting power.[24,25]

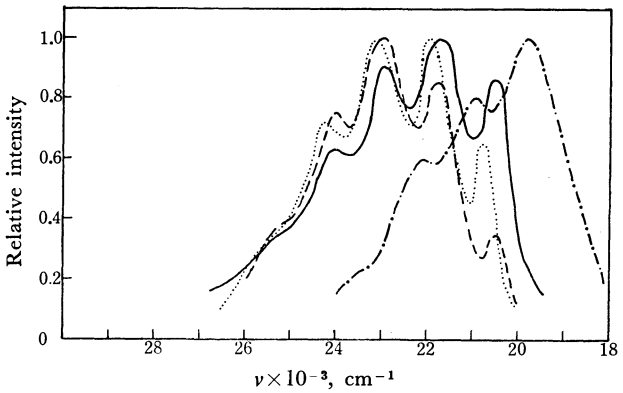

Fig. 5. T–T absorption spectra of α-substituted naphthalenes at 77°K: ·····, α-naphthol in PME; ——, α-naphthol in PME containing triethylamine (0.2 mol/*l*); —·—·, α-naphthol in an ethanol-methanol mixture containing potassium hydroxide (0.11 mol/*l*); – – –, α-methoxynaphthalene in PME. Concentrations of solutes: α-naphthol, 1.8×10^{-4} mol/*l* in all cases; α-methoxynaphthalene, 1.7×10^{-4} mol/*l*.

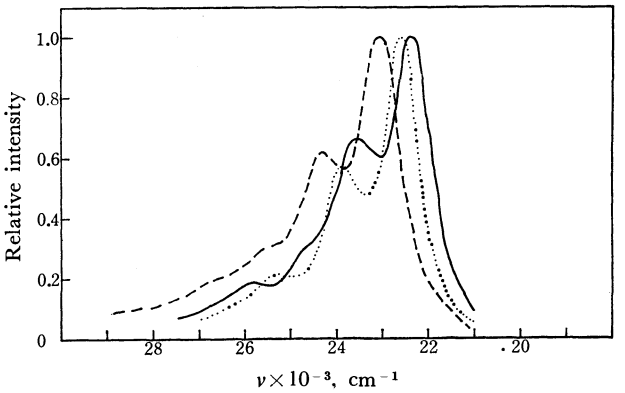

Fig. 6. T–T absorption spectra of β-substituted naphthalenes at 77°K: ·····, β-naphthol in PME; ——, β-naphthol in PME containing triethylamine (0.2 mol/*l*); – – –, β-methoxynaphthalene in PME. Concentrations of solutes: β-naphthol, 1.7×10^{-4} mol/*l* in all cases; β-methoxynaphthalene, 1.6×10^{-4} mol/*l*.

For β-naphthol (Fig. 6), the three bands show a uniform red shift on changing the proton acceptor from ether to triethylamine. Furthermore, the absorption spectrum of β-methoxynaphthalene resembles the spectrum of β-naphthol. These observations confirm the view that the absorption bands of β-naphthol or of β-methoxynaphthalene are to be associated with a single T–T transition.

In the case of α-naphthol (Fig. 5), when the proton acceptor is changed from ether to triethylamine, the two bands at lower frequencies, D′ and E′ (*cf.* Fig. 3), are red-shifted and intensified to a greater extent than the remaining three bands, A′, B′, and C′, suggesting that D′ and E′ belong to a different T–T transition from that to which A′, B′, and C′ belong. α-Methoxynaphthalene gives a spectrum which is, as a whole, similar to the α-naphthol spectrum. It is seen, however, that the bands corresponding to D′ and E′ are of lower intensity in α-methoxynaphthalene than in α-naphthol. In Fig. 5 is also shown the T–T absorption spectrum at 77°K of α-naphthol in an alkaline ethanol-methanol mixture (volume ratio, 5 : 1), where the naphthol molecule is converted to the naphtholate ion. Owing to the highly electron-donating character of the $-O^-$ group, the absorption spectrum of the α-naphtholate ion is markedly displaced to the red with a considerable change in appearance as compared with the spectrum of α-naphthol. It can be assumed here that in the naphtholate ion the bands D′ and E′ coalesce into one broad band with the maximum at 19800 cm^{-1}, and that the three bands at the higher frequencies correspond to A′, B′, and C′, with the band at 21000 cm^{-1} assigned as A′.

Thus, all the observations for the α-derivatives of naphthalene indicate that the absorption spectrum of α-naphthol or of α-methoxynaphthalene originates in two different T–T transitions, one leading to the bands A′, B′, and C′ and the other to D′ and E′. It is to be noted that the relative intensity of the T–T transition with which D′ and E′ are associated increases

in the order: α-methoxynaphthalene<α-naphthol hydrogen-bonded with ether<α-naphthol hydrogen-bonded with triethylamine<α-naphtholate ion.

In general the frequency shift of an electronic transition produced by hydrogen bonding is due to the difference between the energies of hydrogen bond for the electronic states which are concerned in that transition.[23] All the T–T absorption transitions in α- and β-naphthol treated in this study are found to be shifted to the red upon formation of the hydrogen bond. This means that in all cases the proton-donating power of the naphthols is stronger in the higher triplet state than in the lowest triplet. It should be noted that the frequency shifts for the T–T transitions of α- and β-naphthol are comparable in magnitude to those for the transitions from the ground state to excited singlet states of the naphthols.[23,24]

Theoretical Interpretation of T–T Transitions. The calculated energies for triplet states, relative to the ground state, and the oscillator strengths (f) for transitions from the lowest triplet state to higher triplet states are summarized in Table 2. In all cases, the triplet state wavefunctions are numbered from 1 to 12 in order of increasing energy. For naphthalene, the results of calculation by Pariser[26] are also given in the same table. It should be noted that Pariser included all singly excited configurations in his CI calculation. Of the resulting twenty-five state wavefunctions twelve are given in Table 2. The symmetry types are shown for the wavefunctions of the naphthalene molecule (symmetry group, D_{2h}). The long and short molecular axes are chosen as x and y coordinate axes, respectively, and the plus and minus signs have the same meaning as those used by Pariser.[26]

In Fig. 7 the results of calculations are compared with the spectral data obtained at 77°K in rigid-glass solution. The magnitudes of the calculated oscillator strengths f are represented by the lengths of solid lines in such a way that the largest f value for each of the molecules is normalized to unity. However, for the triplet states with f values less than one-tenth of the largest f, only their energy levels are shown in the figure by dotted lines. In each of the molecules, the experimental energy level for $^3\Psi_1$ represents the position of the 0–0 band of the phosphorescence spectrum measured in PME at 77°K; the spacing between the experimental level for $^3\Psi_1$ and the absorption curve given in the figure corresponds to the observed T–T transition energy.

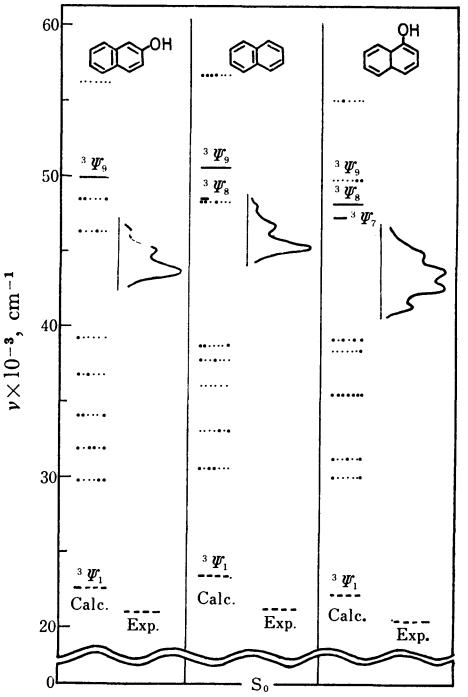

Fig. 7. Calculated and experimental energies of triplet states in naphthalene, α- and β-naphthol. Energies are expressed in wavenumbers relative to the ground state (S_0). The intensities of T–T transitions from the lowest triplet to higher triplet states are represented by solid lines of different lengths or by dotted lines according to the magnitudes of the calculated oscillator strengths; see text for the details.

Since the lowest triplet of naphthalene is a $^3B_{2u}^+$

26) R. Pariser, *J. Chem. Phys.*, **24**, 250 (1956).

state, only the transitions to the triplet states characterized by g and minus are to be allowed. From a comparison of the f values, it follows that the T–T absorption in β-naphthol as well as in naphthalene is due to $^3\Psi_1 \rightarrow {}^3\Psi_9$ transition, the adjacent transition $^3\Psi_1 \rightarrow {}^3\Psi_8$ being assumed to be too weak to be observed. In the case of α-naphthol, there is no large difference between the f values for $^3\Psi_1 \rightarrow {}^3\Psi_7$ and $^3\Psi_1 \rightarrow {}^3\Psi_8$, so that these transitions are expected to appear in the T–T absorption spectrum. Thus, of the two transitions observed for α-naphthol, the one of lower energy is assigned to $^3\Psi_1 \rightarrow {}^3\Psi_7$ and the other to $^3\Psi_1 \rightarrow {}^3\Psi_8$.

The triplet-state energies obtained from our calculations should in principle be related to the Franck-Condon maxima of absorption transitions which might be supposed to occur from the ground state to the triplet states concerned. If allowance is made for this fact, it might be said that the calculated energies are in general agreement with the experimental ones, at least with respect to the relative positions of the triplet levels

for naphthalene and its two derivatives.

In the T–T absorption spectrum of α-naphthol in PME at 77°K, the two transitions have almost the same intensities, whereas theory predicts that the intensity of the first transition should be about two-fifths of that of the second (Table 2). In PME, however, naphthol is linked to ether through a hydrogen bond, which will result in an increase in the relative intensity of the first transition. In fact, α-methoxynaphthalene, which is expected to have a π-electronic structure similar to that of α-naphthol and has no possibility of forming a hydrogen bond with ether, gives in PME a T–T absorption spectrum in which the first transition is weak compared with the second (see Fig. 5).

Recently Klasinc and Sommer[9] have made calculations on the T–T transitions of naphthalene and naphthols by the Pariser-Parr-Pople method. Their results differ in detail from the results of the present calculations, but they also reached the conclusion that one new transition should appear in the T–T absorption spectrum of α-naphthol.

Tables 3 and 4 give the results of configuration analysis. The triplet-state wavefunctions ${}^3\Psi_1$, ${}^3\Psi_2$, ⋯, ${}^3\Psi_{10}$ for the naphthols are analyzed into the wavefunctions for reference triplet states, *viz.*, the locally excited states related to naphthalene ${}^3\Psi_1{}^0$, ${}^3\Psi_2{}^0$, ⋯, ${}^3\Psi_{12}{}^0$, charge-transfer (CT) configurations ${}^3\Psi^0{}_{\mathrm{CTO}\to k}$, formed by transferring an electron from the orbital localized on the oxygen atom to the kth MO of naphthalene, and some other singly locally excited configurations ${}^3\Psi^0{}_{i\to k}$. The numbering of the MO's localized on naphthalene is the same as described previously. In the columns of Tables 3 and 4, the weights in percent of the ${}^3\Psi^0$'s obtained as the squares of the elements of the matrix ${}^3\mathbf{M}$ in Eq. (2), are shown for each of the ${}^3\Psi$'s, the weights less than 0.1% being omitted.[27]

It is seen from the tables that in β-naphthol the wavefunction ${}^3\Psi_9$ consists mainly of ${}^3\Psi_9{}^0$, while in α-naphthol ${}^3\Psi_7$ and ${}^3\Psi_8$ consist predominantly of ${}^3\Psi_8{}^0$ and ${}^3\Psi_9{}^0$, respectively. The lowest triplet state ${}^3\Psi_1$ is largely due to ${}^3\Psi_1{}^0$ in both α- and β-naphthol. Thus, ${}^3\Psi_1\to{}^3\Psi_7$ and ${}^3\Psi_1\to{}^3\Psi_8$ transitions in α-naphthol are to be related, respectively, to local transitions ${}^3\Psi_1{}^0(B_{2u}{}^+)\to{}^3\Psi_8{}^0(A_{1g}{}^-)$ and ${}^3\Psi_1{}^0(B_{2u}{}^+)\to{}^3\Psi_9{}^0(B_{1g}{}^-)$, and ${}^3\Psi_1\to{}^3\Psi_9$ in β-naphthol to ${}^3\Psi_1{}^0(B_{2u}{}^+)\to{}^3\Psi_9{}^0(B_{1g}{}^-)$. It will be found, on closer inspection of Table 3, that the appearance of a new transition in the α-derivative of naphthalene is due to the fact that ${}^3\Psi_7$ involves the characters ${}^3\Psi_9{}^0(B_{1g}{}^-)$ and CT configurations to an appreciable extent. The total weight of CT configurations amounts to as much as 18.7%.

We wish to express our thanks to Dr. Satoshi Suzuki for his co-operation and discussion in carrying out the calculations, and to Mr. Yoshio Shindo and Mr. Masahisa Fujita for their help in constructing the apparatus for flash spectroscopy.

27) Numbers written in boldface represent the largest weights.

The Role of Reaction Sites in the Radiolysis of Solid Succinic Acid

Tetsuo MIYAZAKI, Yoshiteru FUJITANI, Terunobu WAKAYAMA, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 2, 1970)

The main gaseous products in the radiolysis of solid succinic acid are CO_2, CO, and H_2. It was found that the $G(CO+H_2)$ from the powder is much higher than that from the single crystal, while there is no difference in $G(CO_2)$ between the powder and the single crystal, indicating that CO_2 is produced homogeneously in the solid. The clear difference in the $G(CO+H_2)$ between the powder and the single crystal cannot be attributed to the analytical procedure, the secondary reaction of CO, or the presence of H_2O as an impurity. It may be due to the difference in the primary process of the radiolysis. It is conceivable that the mobile active entity formed by the γ-irradiation of the crystal migrates to the special reaction sites and produces CO and H_2. The difference in $G(CO+H_2)$ may also be due to the different numbers of the sites between the powder and the single crystal. It is discussed whether the mobile entity is a cation, an electron, or an exciton.

We have previously studied the radiolysis in the solid state in order to elucidate the primary process of radiolysis in the solid state and in order to obtain information about reaction kinetics in the solid state. In the previous studies, some peculiar phenomena in solid-state radiolysis have been reported.[1,2] The formation of the exciton may play an important role in the radiolysis of solid isobutane, while it plays only a minor role in the liquid phase.[1] When solid isobutane is γ-irradiated, an isobutyl radical is formed in the crystalline state, while a tertiary butyl radical is formed in the glassy state.[2] This result cannot be

explained by the ordinary theory of a unimolecular reaction in the gas phase.

In a previous communication, the preliminary findings on the effect of crystal size on the radiolysis of succinic acid have been reported. In this work we will study this effect in more detail in order to get a better understudying of solid-state radiolysis.

Experimental

The succinic acid was supplied by the Katayama Chemical Co. and was more than 99.8% pure. The acid was in the form of a single crystal 0.5—1.0 cm long, and its melting point was 185°C. The single crystal was ground into powder with an agate mortar. The diameter of the powder was measured with a microscope and found to be about 2×10^5 Å.

After the samples of the single crystal or the powder had been degassing for more than 3 hours on a vacuum line, they were irradiated with γ-rays from Co-60 at a dose rate of 4.4×10^{19} eV/g hr. After irradiation, the sample was melted at 185°C, and then the gaseous products were analyzed as follows: the gaseous products (mixtures of CO and H_2) not condensable at the temperature of liquid nitrogen were analyzed by a gas burette connected to a Toepler pump and a cupric oxide furnace kept at 240°C, while another gaseous product (CO_2) not condensable at the temperature of dry ice was measured by means of the gas burette alone.

Results and Discussion

Gaseous Products in the Radiolysis of Solid Succinic Acid. The main gaseous products in the radiolysis of solid succinic acid are shown in Table 1. When succinic acid is γ-irradiated at −196°C in the powdered form or in the single crystal, the $G(CO+H_2)$ values are about 0.3 and 0.04 respectively at a dose of 6.6×10^{20} eV/g. The fact that the $G(CO+H_2)$ value is different from the previously-reported value[3] may be due to the difference in dose between the two cases. On the contrary, there is no clear difference in the yield of CO_2 between the powder and the single crystal. The yield of CO is about four times that of H_2. It should be noted that the $G(CO+H_2)$ value from the powder is much higher than that from the single crystal.

Table 1. Radiolysis of solid succinic acid

State	Irrad. Temp.	Method of Analysis	$G(CO+H_2)$	$G(CO_2)$
Powder	−196°C	Melting	0.20[a]+0.11[b]	2.01
Powder	−196°C	Melting	0.20[a]+0.10[b]	1.90
Single Crystal	−196°C	Melting	0.06	1.89
Single Crystal	−196°C	Melting	0.02	1.60
Powder	−196°C	Dissolved in ethanol	0.24	
Single Crystal	−196°C	Dissolved in ethanol	0	
Powder	30°C	Melting	0.92	4.92
Single Crystal	30°C	Melting	0.24	4.60

a) Yield before melting the sample

Dose: 6.6×10^{20} eV/g

3) T. Miyazaki, S. Okada, T. Wakayama, K. Fueki, and Z. Kuri, This Bulletin, **43**, 1907 (1970).

The possibility that the difference in $G(CO+H_2)$ value may be attributed to thermal decomposition during the analysis can be excluded for the following two reasons. First, two-thirds of the total yields of $CO+H_2$ could be measured at room temperature without melting the irradiated powder at 185°C, and the yields are much higher than the total yields from the single crystal. Second, when the CO and H_2 were measured after the γ-irradiated sample had been dissolved in ethanol at room temperature, the clear difference in $G(CO+H_2)$ value between the powder and the single crystal was also observed.

Does the CO produced in the single crystal react with the trapped radicals to result in the low yield of CO, while CO in the powder diffuses to the surface without the reaction? The yields of $CO+H_2$ trapped in the powder at the irradiation temperature of −196°C and 30°C are 0.1 and 0.5 respectively. These values are higher than the total yields from the single crystal at each temperature. The difference in $G(CO+H_2)$ value between the powder and the single crystal cannot be ascribed to this cause.

Therefore, the difference in $G(CO+H_2)$ may represent the difference in the yields of products in the radiolysis of succinic acid.

Effect of H_2O on the Radiolysis of Succinic Acid. Solid succinic acid contains a small amount of water in its crystal. When a solid succinic acid is melted at 185—190°C, the water is vaporized from the acid; then the vapor pressure of water can be measured after the sample has been rapidly cooled to room temperature. In order to examine whether or not water was produced by the thermal decomposition of succinic acid at 185—190°C, the samples were held at this temperature for different times and then the amounts of water were measured. As is shown in Table 2, the amounts of water do not depend upon the time the substances are kept at 185—190°C; therefore, they represent the amounts of water present in the crystal as an impurity.

Table 2. Amounts of H_2O as an impurity in the succinic acid

State	Time held at 185—190°C	H_2O (mol%)
Single Crystal	0.3 hr	10
Single Crystal	1.5 hr	8
Single Crystal	3.0 hr	13
Powder	0.3 hr	13

Since the water usually acts as an effective cation scavenger in the radiolysis, there is a possibility that the amount of water in the powder is smaller than that in the crystal and that the difference in $G(CO+H_2)$ value between the powder and the single crystal is due to this effect. Table 2 shows, however, that the amount of water in the powder is approximately equal to that in the single crystal. When the polycrystalline sample from which water has been completely removed

TABLE 3. EFFECT OF H_2O ON THE RADIOLYSIS OF SUCCINIC ACID AT $-196°C$

State	$G(CO+H_2)$	$G(CO_2)$
Sample A	0.22	2.01
Sample B	0.19	1.83
Powder	0.31	1.96

Sample A: Polycrystal, from which H_2O is removed completely by melting the powder.
Sample B: Polycrystal, from which H_2O is removed completely by melting the single crystal.
Dose: 6.6×10^{20} eV/g

by melting and degassing, is γ-irradiated, the yield of $CO+H_2$ is rather smaller than that from the powder (Table 3). Therefore, the difference in $G(CO+H_2)$ value between the powder and the single crystal cannot be ascribed to the effect of water, but must be ascribed to a difference in the physical state, such as the surface area or the defects in the crystal.

Effect of Total Dose. The dependence of gaseous products on the total dose is shown in Figs. 1 and 2. The rate of the production of $CO+H_2$ decreases gradually with an increase in the dose, while the yield of CO_2 increases linearly with an increase in the dose. These results suggest that the mechanism of the formation of CO and H_2 differs from that of CO_2. If it is supposed that CO and H_2 are produced at special active sites of the crystal, the sites may be gradually consumed with an increase in the dose, resulting in a decrease in the rate of the formation of $CO+H_2$. The yields of $CO+H_2$ in the radiolysis of the single crystal at $-196°C$ seem to be negligibly small at a low dose. This is because the analysis of a small amount of $CO+H_2$ with Toepler pump is very difficult. On the contrary, CO_2 may be produced homogeneously in the crystal.

Yield Measured at Room Temperature without Melting. A fraction of the gaseous products can be measured at room temperature without melting the irradiated sample; the measurable yields depend upon the storage time at room temperature (Fig. 3). When the powdered succinic acid is irradiated at $-196°C$, the

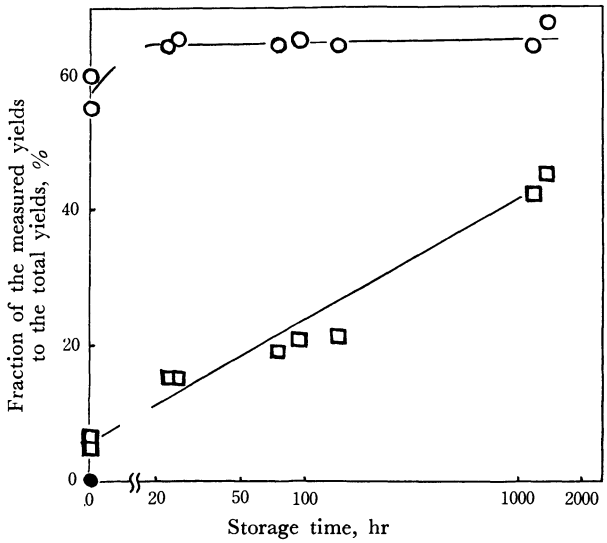

Fig. 3. Effect of storage time on the yields measured at room temperature before melting the irradiated sample.
○: Yields of $CO+H_2$ measured at room temperature before melting the irradiated sample.
□: Yields of CO_2 measured at room temperature before melting the irradiated sample.

$CO+H_2$ cannot be measured at $-196°C$, but two-thirds of the total yield can be measured immediately after warming up to room temperature. The measurable amount of $CO+H_2$ does not increase even if the sample is stored for longer than 1000 hr at room temperature. On the contrary, the amount of CO_2 measurable at room temperature gradually increases with the passage of the storage time. As will be discussed in the next section, the gaseous products may be formed mainly by warming the irradiated sample to room temperature. Two-thirds of CO and H_2 may be formed at some sites such as the surface and may come out easily from the crystal. The residue may be formed at another type of site, such as defects of the crystal, and be tightly trapped in the crystal. The results indicate that CO_2 may be formed uniformly in the crystal and may gradually diffuse to the surface during storage at room temperature.

Mechanism of Reaction. Since the effect of reaction sites on the radiolysis has not been reported previously, and since our information about the solid-state kinetics of molecular compounds is very scanty at present, it is not possible to explain this effect in a satisfactory way. We will discuss here a possible mechanism for this effect. Several investigators have proposed the following mechanism for explaining the ESR results on succinic acid:[4]

$$HOOCCH_2CH_2COOH \rightsquigarrow HOOCCH_2CH_2COOH^+ + e^- \quad (1$$

$$HOOCCH_2CH_2COOH^+ + HOOCCH_2CH_2COOH \rightarrow HOOCCH_2CH_2COO\cdot + HOOCCH_2CH_2COOH_2^+ \quad (2)$$

$$HOOCCH_2CH_2COO\cdot \rightarrow HOOCCH_2CH_3\cdot + CO_2 \quad (3)$$

$$e^- + HOOCCH_2CH_2COOH \rightarrow HOOCCH_2CH_2COOH^- \quad (4)$$

$$HOOCCH_2CH_2COOH^- \rightarrow HOOCCH_2CH_2 + CO_2^- \quad (5)$$

$$HOOCCH_2CH_2\cdot + HOOCCH_2CH_2COOH \rightarrow HOOCCH_2CH_3 + HOOCCH_2\dot{C}HCOOH \quad (6)$$

$$HOOCCH_2CH_2\cdot \rightarrow HOO\dot{C}CHCH_3 \quad (7)$$

Reactions (1), (2), and (4) take place at $-196°C$ by γ-irradiation. Reactions (3), (5), (6), and (7) represent the reactions which occur when the irradiated sample is warmed from $-196°C$ to room temperature. The facts that CO_2 is the main gaseous product in the radiolysis of succinic acid and that it is formed homogeneously in the crystal can be explained by the above reaction mechanism.

On the other hand, it is conceivable that CO and H_2 may be produced when the mobile active entity formed by γ-irradiation migrates to the reaction sites, such as the surface and defects in the crystal. We will now discuss whether the mobile entity is a cation, an electron, or an exciton.

(a) Cation: A crystal of succinic acid is a monoclinic plate; its structure was determined by Broadley *et al.* (Fig. 4).[5] Two nearest neighbor molecules of succinic acid are tightly combined by two hydrogen bonds between their carboxyl groups. Once a succinic acid cation is formed in reaction (1), its proton may be transferred easily to the second molecule by a quantum-tunneling process in a hydrogen bond (reaction (2)).[6] It is, however, difficult for the proton transfer to the third molecule to occur by this process, since there is no hydrogen bond between the protonated second molecule and the third molecule which is not depicted in Fig. 4.

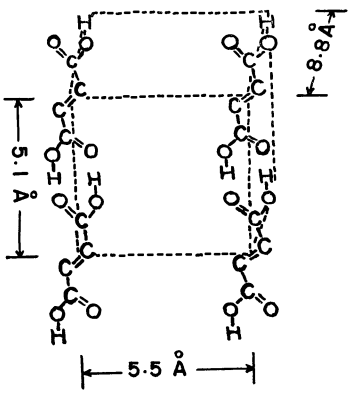

Fig. 4. Structure of the crystal of succinic acid in the unit cell.

The interaction between the protonated second molecule and the third molecule can roughly expressed by a charge-induced dipole interaction:

$$E = -\frac{e^2\alpha}{2r^4} \quad (I)$$

where E is the energy of interaction, and r, the distance between a charge and an induced dipole. α is the effective polarizability and is taken as 2×19^{-24} cc for a carbonyl group. Assuming that the charge of the protonated second molecule is localized on the oxygen atom, the distance (r) between the charge and a carbonyl group of the third molecule is 3.14 Å. From Eq. (I), we get $E\sim-1$ Kcal, which is rather less than the energy of the hydrogen bond, suggesting that the ion-molecule reaction would not occur easily.

Since water is an effective proton scavenger in the radiolysis, the fact that water does not affect the yields of CO and H_2 suggests that the proton does not move in the crystal.

(b) Electron: When 2-methyltetrahydrofuran (MTHF) glass containing a small amount of succinic acid is γ-irradiated at $-196°C$, the electrons are completely captured by the acid.[7] Since the efficiency of electron capture by maleic acid (HOOCCHCHCOOH) is 5—10 times as great as that of biphenyl in MTHF glass at $-196°C$,[8] succinic acid also may cap-

ture electrons efficiently in the solid state.

Since the absorption spectrum of the succinic-acid anion is not observed in the visible region, it is expected that the acid may possess a high electron affinity and that the anion, once it is formed, does not release an electron easily. Therefore, it seems that an electron does not move a long distance in the crystal of succinic acid.

(c) Exciton: In the previous studies of the radiolysis of solid isobutane,[1] it has been suggested that an exciton may play an important role in the solid-state radiolysis and that it will migrate to a distance of 20—30 Å. Since all the molecules of succinic acid in the crystal are combined by hydrogen bonds in one direction, an exciton, if it is formed, can migrate to a farther distance in the succinic acid than in saturated hydrocarbons. If it is supposed that the exciton migrates to the surface of succinic acid and is ionized there (reaction (9)), CO and H_2 may be formed by the neutralization of the succinic-acid ion by warming the sample up to room temperature (reaction (10)). This opinion is based on the findings that CO and H_2 are not observed at −196°C, and that CO is not adsorbed on the surface of succinic acid at −196°C. The reaction scheme may be represented as follows:

$$HOOCCH_2CH_2COOH \rightsquigarrow (HOOCCH_2CH_2COOH)_n^* \quad (8)$$

(in the crystal)

$$(HOOCCH_2CH_2COOH)_n^* \rightarrow HOOCCH_2CH_2COOH^+ + HOOCCH_2CH_2COOH^- \quad (9)$$

(at the surface)

$$HOOCCH_2CH_2COOH^+ + HOOCCH_2CH_2COOH \rightarrow HOOCCH_2CH_2COO\cdot + HOOCCH_2CH_2COOH_2^+ \quad (2)$$

$$HOOCCH_2CH_2COOH_2^+ + HOOCCH_2CH_2COOH^- \rightarrow CO,\ H_2,\ \text{other products} \quad (10)$$

(warming up to room temperature)

where $(HOOCCH_2CH_2COOH)_n^*$ is an exciton. The possibility that the exciton state in the solid may correspond to the superexcited state and be related to the ionization of the solid has also been suggested for the radiolysis of solid isobutane.[1c]

The authors wish to express their appreciation to Dr. Machio Iwasaki of the Government Industrial Research Institute of Nagoya for many fruitful discussions, and to Dr. Nobuo Tagusagawa of Nagoya University for his measurement of the crystal size of the powder.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 988—992 (1971)

Dielectric Relaxation and Molecular Structure. V. Application of the Single Frequency Method to Systems with two Debye Dispersions

Keniti HIGASI, Yoshinori KOGA, and Masahiko NAKAMURA
School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received November 28, 1970)

There are four Debye equations for dilute solutions which can be used to determine the relaxation time of a polar solute molecule. This paper offers a critical examination of these equations, especially two representative formulas which are mutually independent. If the solute molecule has a non-rigid configuration and has two relaxation times, τ_1 and τ_2, for overall and internal rotations, respectively, average relaxation times will be obtained from these equations based on measurements at a single frequency. However, the analysis of this paper shows that under a certain condition (if a proper frequency for the measurement and a suitable equation for the calculation are employed) one may make a crude estimate regarding one of the two relaxation times. Further, the ratio of two relaxation times seems to afford a clue for investigating the mechanism of internal rotation. In addition, Cole-Cole dispersion and atomic polarization problems are also discussed.

The dielectric constant ε' and loss ε'' of the dilute solution are represented by the following equations

$$\left.\begin{aligned} \varepsilon' &= \varepsilon_1' + a'w_2 \\ \varepsilon_0 &= \varepsilon_{10} + a_0 w_2, \quad \varepsilon_\infty = \varepsilon_{1\infty} + a_\infty w_2 \\ \varepsilon'' &= \varepsilon_1'' + a''w_2 \end{aligned}\right\} \tag{1}$$

in which subscript 1 refers to the pure solvent and 2 refers to the solute, while subscript 0 refers to the zero frequency measurement in the static field and ∞ to the infinite frequency measurement (at a very high frequency). The concentration w_2 in the present work is the weight fraction but any concentration units (*e.g.*, mole fraction) can be used instead.

The Debye equations for dilute solutions are[1)]

$$\frac{a' - a_\infty}{a_0 - a_\infty} = \frac{1}{1 + \omega^2\tau^2} \tag{2}$$

and

$$\frac{a''}{a_0 - a_\infty} = \frac{\omega\tau}{1 + \omega^2\tau^2} \tag{3}$$

where a', a_0, a_∞, and a'' are the so-called "slopes" defined by Eq. (1), ω is the angular frequency and τ the relaxation time. The relaxation time τ is obtained from Eq. (2)

$$\tau = \frac{1}{\omega}\sqrt{\frac{a_0 - a'}{a' - a_\infty}} \tag{4}$$

1) K. Higasi, This Bulletin, **39**, 2157 (1966).

And from Eq. (3)

$$\tau = \frac{1}{\omega}[A \pm \sqrt{A^2 - 1}] \tag{5}$$

where

$$A = \frac{a_0 - a_\infty}{2a''}$$

Combination of Eqs. (2) and (3) gives two independent equations

$$\tau = \frac{1}{\omega}\frac{a''}{a' - a_\infty} \tag{6}$$

and

$$\tau = \frac{1}{\omega}\frac{a_0 - a'}{a''} \tag{7}$$

If the solute molecule is provided not with one relaxation time but with two relaxation times, τ_1 and τ_2, Eqs. (2) and (3) will lead to the following expressions:

$$\frac{a' - a_\infty}{a_0 - a_\infty} = \frac{1 - C_2}{1 + \omega^2\tau_1^2} + \frac{C_2}{1 + \omega^2\tau_2^2} \tag{8}$$

$$\frac{a''}{a_0 - a_\infty} = \frac{(1 - C_2)\omega\tau_1}{1 + \omega^2\tau_1^2} + \frac{C_2\omega\tau_2}{1 + \omega^2\tau_2^2} \tag{9}$$

The coefficients, $C_1 \equiv 1 - C_2$ and C_2 are the weight factors of the two Debye processes defined by τ_1 and τ_2 respectively. The purpose of this paper is to make a critical examination of the average τ values obtained from a_0, a', a'', and a_∞ by the use of Eqs. (6) and (7) when the dielectric system actually does follow Eqs. (8) and (9).

Results

(I) $\tau(1)$ from Eq. (6). By dividing Eq. (9) by Eq. (8) we get

$$\frac{a''}{a_0' - a_\infty} = \frac{\dfrac{(1 - C_2)\omega\tau_1}{1 + \omega^2\tau_1^2} + \dfrac{C_2\omega\tau_2}{1 + \omega^2\tau_2^2}}{\dfrac{1 - C_2}{1 + \omega^2\tau_1^2} + \dfrac{C_2}{1 + \omega^2\tau_2^2}}$$

Consequently, the relaxation time τ defined by Eq. (6) will become

$$\tau(1) = \frac{1}{\omega}\frac{a''}{a' - a_\infty}$$

$$= \frac{(1 - C_2)\tau_1 + C_2\tau_2 + \omega^2\tau_1\tau_2[(1 - C_2)\tau_2 + C_2\tau_1]}{1 + [(1 - C_2)\tau_2^2 + C_2\tau_1^2]\omega^2} \tag{10}$$

Put $$\tau_1 = m\tau_2: \quad \omega\tau_2 = x \tag{11}$$

and we get

$$\tau(1) = A\tau_2 \tag{12}$$

where

$$A = \frac{[m - (m - 1)C_2] + mx^2[1 + (m - 1)C_2]}{1 + [1 + (m^2 - 1)C_2]x^2} \tag{13}$$

Eq. (13) contains a term m which was defined in Eq. (11) as the ratio of τ_1 to τ_2. The molecular relaxation time, τ_1, for overall rotation has been well investigated over the past twenty years. The relation between τ_1 and the molecular size and shape has been fairly well established so that one may be able to make a good guess for any polar molecule under given conditions,[2] although opinions may differ as to the accuracy of such an estimation.[3]

More recently extensive investigation have been made concerning the second relaxation time, τ_2, which arises from internal rotation of a polar group in the molecule.[2] The magnitude of τ_2 for a given polar group varies according to the investigator. For instance, German workers[4] find τ_2 in the range of 0.5—3 psec, mostly 1—2 psec, while American[2] and British[5] scientists give somewhat higher τ_2 values for the same group often in the range of 2—4 psec. Accuracy for the determination of τ_2 from the measurement is considered to be lower than that for τ_1. The value of τ_1,[2,3] the relaxation time for overall rotation is much larger and depends on the viscosity of the solvent. Perhaps τ_1 for a benzene derivative in benzene solution would be around 8—15 psec and those for molecules with two benzene rings in the same solvent would be 16—30 psec. According to the above estimates of τ_1 and τ_2 one may consider

$$1 < m \simeq 2 - 30$$

At the frequency of 100 GHz ($\omega = 0.6282 \times 10^{12}$), the condition $\omega\tau = 1$ gives $\tau = 1.59$ psec which corresponds to an average value of $\tau_2 \simeq 1$—2 psec estimated by Knobloch[4] and other German workers: $x = 1 (\omega\tau_2 = 1)$. And $x = 2 (\omega\tau_2 = 2)$ at 100 GHz will be in accordance with other estimate for τ_2.[2,5]

From Eq. (13) it follows:

Overall rotation only:

$$C_2 = 0: \quad A = \frac{m + mx^2}{1 + x^2} = m \quad \tau(1) \to \tau_1$$

Internal rotation only:

$$C_2 = 1: \quad A = \frac{1 + mx^2}{1 + mx^2} = 1 \quad \tau(1) \to \tau_2$$

Further $$m \to \infty \quad A \to \frac{C_2x^2}{C_2x^2} = 1 \qquad \tau(1) \to \tau_2$$

In Fig. 1 the relation of A *versus* C_2 is plotted for four cases, viz., $m = 10$ $x = 1$, $x = 0.3$; $m = 5$ $x = 1$, $x = 0.3$. It will be seen that with increase in m and x the curve becomes flat, A approaching to unity in the region of large C_2 values. For example, $1 < A \leq 1.2$ if $C_2 \geq 0.5$, $m \geq 10$ and $x \geq 1$. This will imply that the average relaxation time, $\tau(1)$, obtained at 100 GHz by use of the Eq. (6) would be larger by only 20% than the smaller relaxation time τ_2, if the absorption intensity due to the internal rotation is significant and two absorption peaks are fairly separated. However, at lower frequencies such as $x \to 0$, Eq. (13) gives $A \to (1/2)(m+1)$ at $C_2 = 1/2$, i.e.,

$$\tau(1) \to (1/2)(\tau_1 + \tau_2) \quad \text{at } C_2 = 0.5.$$

(II) $\tau(2)$ from Eq. (7). We may denote the relaxation time defined by Eq. (7) as $\tau(2)$ and will obtain

4) For instance, P. Knobloch, *Z. Naturforsch.*, **20a**, 580 (1965).
5) S. W. Tucker and S. Walker, *Can. J. Chem.*, **47**, 681 (1969).

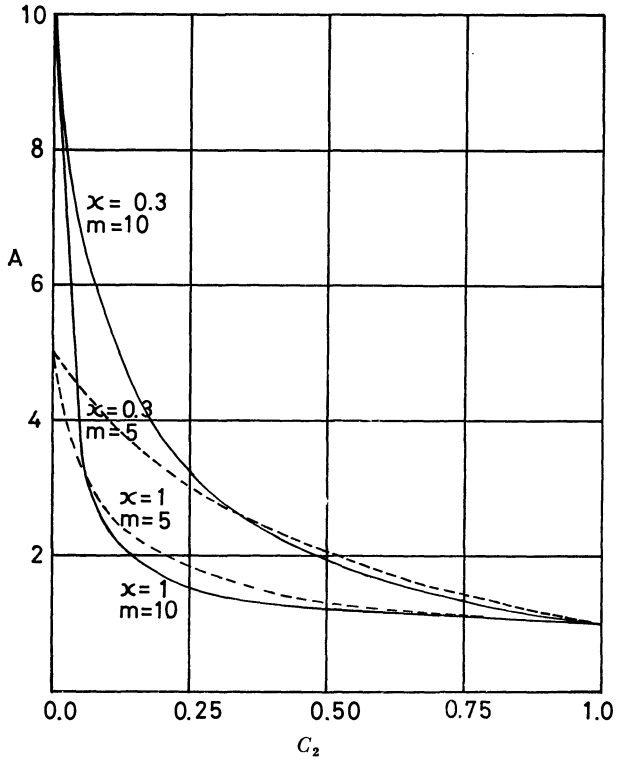

Fig. 1. Graphs relating ratio $\tau(1)/\tau_2 \equiv \boldsymbol{A}$ to the weight factor for internal rotation C_2, when $\tau_1/\tau_2 \equiv m = 5$, 10 and $\omega\tau_2 \equiv x = 0.3$, 1. The plots are based on Eq. (13).

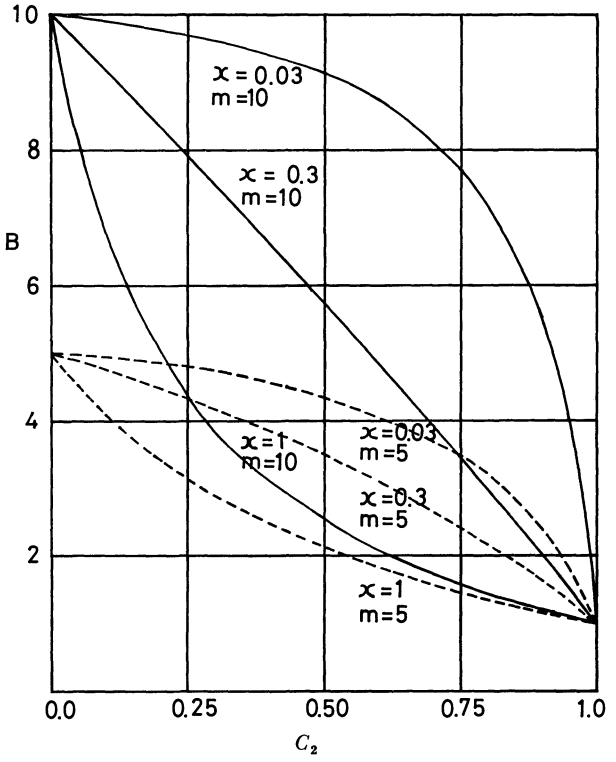

Fig. 2. Graphs relating ratio $\tau(2)/\tau_2 \equiv \boldsymbol{B}$ to the weight factor for internal rotation C_2, when $\tau_1/\tau_2 \equiv m = 5$, 10 and $x = \omega\tau_2 = 0.03$, 0.3, 1. Plots are based on Eq. (15).

$$\tau(2) = \frac{1}{\omega}\frac{a_0 - a'}{a''} = \boldsymbol{B}\tau_2 \tag{14}$$

where

$$\boldsymbol{B} = \frac{m^2 - (m^2 - 1)C_2 + m^2x^2}{m - (m - 1)C_2 + mx^2[1 + (m - 1)C_2]} \tag{15}$$

Overall rotation only:

$$C_2 = 0: \quad \boldsymbol{B} = \frac{m^2 + m^2x^2}{m + mx^2} = m, \quad \tau(2) \to \tau_1$$

Internal rotation only:

$$C_2 = 1: \quad \boldsymbol{B} = \frac{1 + m^2x^2}{1 + m^2x^2} = 1, \quad \tau(2) \to \tau_2$$

Further at lower frequencies ($x \to 0$)

$$\boldsymbol{B} \to m, \quad \tau(2) \to \tau_1$$

In Fig. 2 the relation of $\boldsymbol{B}$ to C_2 is plotted for six cases, $m = 10$, 5 and $x = 1$, 0.3, 0.03. It will be seen $\tau(2)$ gives a larger relaxation time than $\tau(1)$ for the dielectric system consisting in two Debye dispersions.

Gopala Krishna's equation[6] is based essentially on the same principle[1] with Eq. (7); recently, Vij and Srivastava[7] made a critical analysis of these equations. The relaxation times of non-rigid molecules[7,8] calculated by Gopala Krishna's procedure as well as by Eq. (7) would correspond to $\tau(2)$ for a given frequency.

(III) $\boldsymbol{B}/\boldsymbol{A}$ and C_2. We have $\tau(1) = \boldsymbol{A}\tau_2$ and $\tau(2) = \boldsymbol{B}\tau_2$. The ratio $\boldsymbol{B}/\boldsymbol{A}$ is unity at $C_2 = 0$ and $C_2 = 1$ and varies with m, x and C_2. In Fig. 3 are shown curves of $\boldsymbol{B}/\boldsymbol{A}$ *vs.* C_2 for $m = 5$ and 10 and $x = 1$ and 3. The maximum of $\boldsymbol{B}/\boldsymbol{A}$ becomes larger with increase in m.

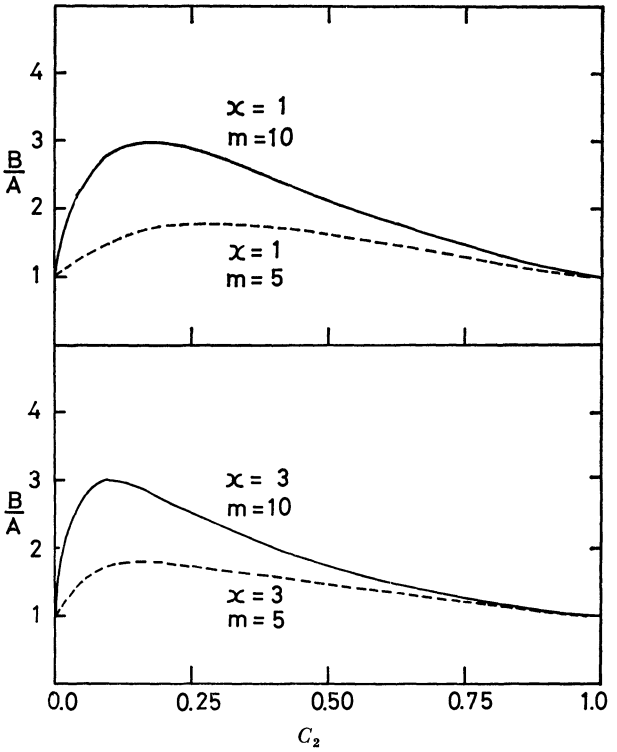

Fig. 3. Graphs relating ratio $\tau(2)/\tau(1) \equiv \boldsymbol{B}/\boldsymbol{A}$ to the weight factor C_2, when $\tau_1/\tau_2 \equiv m = 5$, 10, $\omega\tau_2 \equiv x = 3$, 1.

7) J. K. Vij and K. K. Srivastava, *ibid.*, **66**, 1087 (1970).
8) K. K. Srivastava and J. K. Vij, This Bulletin, **43**, 2307, 2313 (1970).

The literature[2,4] gives values of τ_2 to be 1—4 psec and almost independent of solvent. This would imply $x \rightarrow 1$—3 for $\omega \simeq 0.6 \times 10^{12}$ (100 GHz). Regarding τ_1 for overall rotation we might make a good guess[2,9] for a molecule with known molecular size and shape if the solvent and temperature are known. For given m and x the weight factor C_2 will be found to be associated with $\boldsymbol{B}/\boldsymbol{A}$.

(IV) $\tau(3)$ and $\tau(4)$ from Eqs. (4) and (5). We may call the relaxation time from Eq. (4) as $\tau(3)$.

$$\tau(3) = \frac{1}{\omega}\sqrt{\frac{a_0 - a'}{a' - a_\infty}} = \frac{1}{\omega}\sqrt{\frac{a''}{a' - a_\infty} \cdot \frac{a_0 - a'}{a''}}$$

from Eqs. (6) and (7)

$$\tau(3) = \sqrt{\tau(1) \cdot \tau(2)} \tag{16}$$

Thus, $\tau(3)$ is a geometric mean of $\tau(1)$ and $\tau(2)$.

$\tau(4)$ is the relaxation time which follows from Eq. (5) and is not independent of $\tau(1)$ and $\tau(2)$. Since Debye introduced a variation of Eq. (3) first in estimating the relaxation time of a polar molecule by the dilute solution method, Eq. (3) as well as its variations have been employed by many workers.[10,11] Figure 4 provides $\tau(4)$ *vs.* C_2 curves for systems with two Debye dispersions.

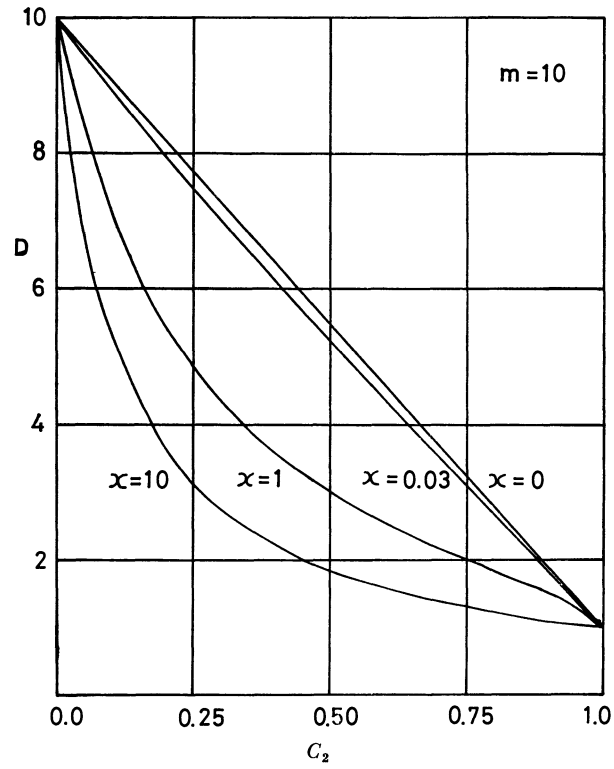

Fig. 4. Graphs relating ratio $\tau(4)/\tau_2 \equiv \boldsymbol{D}$ to the weight factor C_2 when $\tau_1/\tau_2 \equiv m = 10$ and $\omega\tau_2 \equiv x = 0$, 0.03, 1 and 10.

One will find from the upper curve in Fig. 4 that if $x = \omega\tau_2 \rightarrow 0$

$$\tau(4) = \tau_2[m - (m-1)C_2] = (1 - C_2)\tau_1 + C_2\tau_2 \tag{17}$$

This is an equation for internal rotation often utilized in the measurements at lower frequencies.[12]

$$\tau_{\text{eff}} = \left(\frac{\mu_1}{\mu}\right)^2 \tau_1 + \left(\frac{\mu_2}{\mu}\right)^2 \tau_2 \tag{18}$$

in which μ_1 and μ_2 are the two components of the molecular dipole μ.

(V) Problem of a_∞ and α. Equations for evaluating the relaxation time, Eqs. (4), (5), and (6) have a common weakness; they have uncertainty as to the choice of a_∞. Studies on chlorobenzene and other polar molecules by Smyth and his co-workers[13] seems to suggest $a_\infty \simeq a_D$—certainly this approximation, if true, would be very convenient. In most cases, however, $a_\infty \geq a_D$ would be more likely. The values $\tau(1)$ estimated based on $a_\infty \simeq a_D$ will be too small if actually a_∞ is larger than a_D.

If the dielectric system of dilute solution of a polar substance in non-polar solvent happens to obey the Cole-Cole empirical rule,[14] the following expression[1] will become valid.

$$\frac{a' - ja'' - a_\infty}{a_0 - a_\infty} = \frac{1}{1 + (j\omega\tau_0)^{1-\alpha}} \tag{19}$$

τ_0 is the most probable relaxation time, and α is the distribution parameter. From Eq. (19) $\tau(1)$ and $\tau(2)$ become

$$\tau(1) = \frac{1}{\omega} \frac{(\omega\tau_0)^{1-\alpha} \cos(\pi\alpha/2)}{1 + (\omega\tau_0)^{1-\alpha} \sin(\pi\alpha/2)} \tag{20}$$

$$\tau(2) = \frac{1}{\omega} \frac{(\omega\tau_0)^{1-\alpha} + \sin(\pi\alpha/2)}{\cos(\pi\alpha/2)} \tag{21}$$

Both $\tau(1)$ and $\tau(2)$ have smaller values than τ_0 for $\alpha \neq 0$. For example, at 100 GHz $\tau(1) = 4.3$ psec, $\tau(2) = 7.9$ psec for $\alpha = 0.1$ and $\tau_0 = 9$ psec; $\tau(1) = 3.1$ psec, $\tau(2) = 7.4$ psec for $\alpha = 0.17$ and $\tau_0 = 9$ psec.

Concluding Remarks

1. For the study of dielectric behavior of polar molecules it would be most desirable to obtain the complete spectrum of dielectric constants and losses in the whole frequency range where the dispersion takes place. However, this is an almost impossible task, unless the dispersion occurs only in the lower frequencies, say, below 7 GHz. Unfortunately the dipole dispersions due to group rotation in non-rigid molecules appear in much higher frequency range than this. In fact the single frequency method has been employed[6,7] in spite of all its theoretical defects for studies in the microwave frequencies.

2. If one uses Gopala Krishna's method[6] for determining the relaxation time of a non-rigid molecule, it should be noted that this equation provides a *mean* values. Its value, *i.e.* $\tau(2)$ is given by Eqs. (14) and (15) if the system is a superposition of two Debye dispersions.

3. The analysis of $\tau(1)$ shows that the relaxation time for internal rotation τ_2 may be estimated from high frequency measurements if we could have a true a_∞ value. In fact, τ_2 is closely associated with a_∞. Both quantities are of extreme importance in molecular science. They might be estimated with some accuracy but at present we do not have any absolutely reliable method to determine them.

We thank Professor H. Takahashi for helpful discussion. We are also grateful to the Toray Science Foundation for the financial aid.

School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received November 28, 1970)

This paper gives details of the equipment and the method of the measurement at 100 GHz. Dielectric constants and losses are measured at this frequency for ten organic molecules in benzene and four (aniline, phenol, and its derivatives) both in benzene and in dioxane. A majority of the molecules studied are of non-rigid configuration. Discussion is given of the relaxation times and the mechanism of internal rotation involved. Hydrogen bonding effects in aniline, phenol, and its derivatives are also discussed.

For many years a number of dielectric measurements have been carried out using a variety of frequency ranges. However, there are few dielectric data obtained in the range of very high frequency above 60 GHz, *i.e.*, below five millimeters in the wavelength. And this range of frequencies is a field which is still unexplored and need careful investigations.[1] For example, non-polar liquids such as benzene or carbon tetrachloride are found to show dielectric absorption in this frequency range[1] in a sharp contrast to the old belief that all the non-polar liquids should show no appreciable absorption in any range of frequencies.

According to Poley[2] polar liquids consisting of rigid molecules such as chlorobenzene and nitrobenzene are provided with an additional absorption at the high frequency end of millimeter band. This novel absorption became an object of intensive research.[3,4]

For a non-rigid molecule having a rotatable polar group or groups one finds two or more absorption peaks. The absorption due to internal rotation takes place in the millimeter range. For these reasons the dielectric measurements at a frequency of the wavelength less than 5 millimeters are of considerable interest.

In the present paper the writers wish to report on the millimeter wave apparatus for 100 GHz (3 mm), the method of measurements, the experimental results, and the dielectric relaxation times of the organic molecules obtained in dilute solution. Most of the substances chosen for the solute are of non-rigid configuration; and benzene was employed as solvent and for some solutes with hydrogen bonding capacity, *p*-dioxane was also used for comparison.

Apparatus

The experimental technique is based on the free space method.[5] For measuring dielectric constants and losses at 100 GHz the usual transmission line (wave guide) method is not much use since its upper limit is estimated to be about 75 GHz.[5] The apparatus is the microwave equivalent of Michelson interferometer and is of the same type with that of Garg, Kilp, and

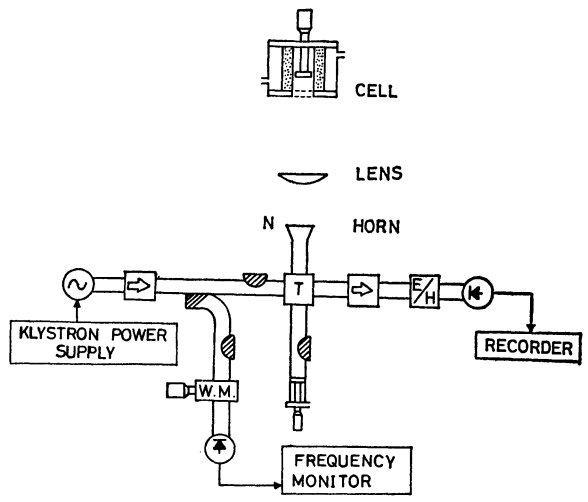

Fig. 1. Schematic of 100 GHz apparatus, microwave analog of the Michelson interferometer.

Smyth.[6,7] The schematic diagram of the apparatus is shown in Fig. 1.

The klystron (Oki 100 V 10 A) generates millimeter waves of about 3 mm in wavelength and its frequency is monitored by a cavity resonator (W 2203). The microwave energy is divided by a hybrid ring T (W 3701) in equal parts. Half passes through the transmitting horn N out into free space. A dielectric lens (TRGW 986) is used to produce a well-collimated beam, which traversed the liquid in the cell, reflected by the plunger, retraverses the liquid and finally is focussed by the lens back into the horn. In the reference arm the other half of the microwave energy from the hybrid is reflected by an adjustable plunger. The interference of the two beams takes place in the wave guide leading to the detective device and finally to the recorder (QPD 53).

Calculation of n and k

The complex index of refraction (n^*) of the material is defined as

$$n^* = n - jk \tag{1}$$

and the dielectric constant (ε') and the loss (ε'') of the same material are related to the above quantities according to

$$\left.\begin{aligned} \varepsilon' &= n^2 - k^2 \\ \varepsilon'' &= 2nk \end{aligned}\right\} \tag{2}$$

The evaluation of n and k values are essentially the same as employed by Garg, Kilp, and Smyth.[6] The final equation for obtaining k is

$$\begin{aligned} \frac{I_{max}(1)-I_{min}(1)}{I_{max}(2)-I_{min}(2)} &= \exp\left(-2\beta_0 k[h_1-h_2]\right) \\ &\times\left[\frac{(1+n)-(1-n)\exp\left(-4\beta_0 kh_1\right)}{(1+n)-(1-n)\exp\left(-4\beta_0 kh_2\right)}\right] \\ &\times\left[\frac{(1+n)^2-(1-n)^2\exp\left(-4\beta_0 kh_2\right)}{(1+n)^2-(1-n)^2\exp\left(-4\beta_0 kh_1\right)}\right]^2 \end{aligned} \tag{3}$$

The final electric intensity (I) at the detector has maxima and minima with the change of liquid thickness (h). The relative maximum (I_{max}) and the adjacent relative minimum (I_{min}) corresponding to a given liquid thickness h are observed; they are denoted by $I_{max}(1)$, $I_{min}(1)$ for h_1 and $I_{max}(2)$ and $I_{min}(2)$ for h_2, *etc.*. The phase constant β_0 is given by $\beta_0=2\pi/\lambda_0$ where λ_0 is the wavelength in air.

Smyth *et al.*[6] used an electronic computer to find n and k to fit the experimental curve. In the present work this formidable task of fitting was successfully replaced by a simple procedure which is based on a least-square method. (See Appendix.)

Purification of Materials

The organic compounds studied were all commercially available. Purchased materials of best grade were fractionally distilled before use. Solvents, benzene and *p*-dioxane, were carefully purified in the usual way.

Results

Measurements of ε' and ε'' for three to four dilute solutions for each solute were made and the so-called "slopes" a', a'', *etc.* were obtained on the assumption that the linear relationship of ε' and ε'' with the concentration (weight fraction) w_2 exists.

$$\left.\begin{aligned} \varepsilon' &= \varepsilon_1' + a'w_2 \\ \varepsilon'' &= \varepsilon_1'' + a''w_2\ ;\ \varepsilon_1'' \simeq 0 \\ \varepsilon_0 &= \varepsilon_{10} + a_0 w_2 \\ n_D^2 &= n_{1D}^2 + a_D w_2 \end{aligned}\right\} \tag{4}$$

in which subscript 1 refers to the pure solvent and 2 to the solute and the symbols have the usual meaning.

The relaxation time of a polar solute is obtained by the use of two equations.[8] We shall denote them by $\tau(1)$ and $\tau(2)$ in the following manner.

$$\left.\begin{aligned} \tau(1) &= \frac{1}{\omega}\cdot\frac{a''}{a'-a_\infty} \\ \tau(2) &= \frac{1}{\omega}\cdot\frac{a_0-a'}{a''} \end{aligned}\right\} \tag{5}$$

There is no reliable method to evaluate a_∞. The most common approximation is to assume a_∞ to be equal to a_D. This may be equivalent to say that both atomic polarization term and correction due to Poley's absorption[2] can be neglected.

Grant[9] suggests the use of the following equation in evaluating ε_∞ (*viz.*, a_∞ in this case)

$$a_\infty(\equiv a_G) = a' - \frac{(a'')^2}{a_0-a'} \tag{6}$$

We shall write the value given by Eq. (6) as a_G. The two values for relaxation times, $\tau(1)$ and $\tau(2)$, become identical with the use of this a_G value—the condition of $a_\infty=a_G$ may be a criterion for the pure Debye system with a single relaxation time. Contrary to this, $\tau(1)$ and $\tau(2)$ should have different vafues for a system with two Debye dispersions. They differ also for a system which obeys Cole-Cole's empirical rule.[8] Experimental values of a' and a'' obtained at about 100 GHz, *viz.*, 96.027 GHz are collected in Table 1. (See Eqs. (4) for the definition of a' and a''.) In the same table a_0 and a_D defined by Eqs. (4) are given together with a_G which is obtained from a', a'', and a_0 (see Eq. (6)).

Magee and Walker[10] proposed a new method for evaluating ε_∞ (hence a_∞) from the Cole-Cole arc for systems which really have two Debye dispersions. Their method was employed when sufficient data were available for the plot. When there are no reliable data, a tentative choice was made with the condition in mind that $a_D \leq a_\infty \leq a_G$.

In Table 2 a collection is given of experimental re-

laxation times in the units of psec (10^{-12} sec). Solvent is benzene if not stated; and temperature is 20°C for the present work and 15°—25° for the literature values. $\tau(1)$ and $\tau(2)$ are calculated by the use of a', a'', a_0, and a_D values recorded in Table 1. Since a_D is used instead of a_∞ throughout, $\tau(1)$ calculated from Eq. (5) is too low in general. Regarding the literature values τ_0 denotes the average relaxation time, τ_1 the relaxation time for overall rotation and τ_2 the relaxation time for internal rotation.

Discussion

Table 2 shows that diphenyl ether has two close values for the relaxation time $\tau(1)=3.2$ psec and $\tau(2)=3.6$ psec and according to Table 1 a_G is found to be near a_D. In contrast to this benzophenone has $\tau(1)=2.8$ psec and $\tau(2)=16.2$ psec and a_G is much larger than a_D. If an intermediate value 0.51 between a_D and a_G is taken for a_∞, $\tau(1)$ will become larger, *viz.*, 9.5 psec. Assuming that diphenyl ether and benzophenone have the same relaxation mechanism associated with $\tau_1=19.9$ psec and $\tau_2=3.31$ psec one will find the weight factor for internal rotation to be very big, *viz.*, $C_2=0.92$, in diphenyl ether, while the same factor is very small in benzophenone, *viz.*, $C_2=0.06$ for $\tau(1)=9.5$ psec and $\tau(2)=16.2$ psec.—The method of the analysis is given in the preceding paper.[8] These findings are in good agreement with the experimental results in the liquid state[35] and with the internal rotation mechanism based on the mesomeric effects.[36]

Two opposite views are available in connection with the dielectric anomaly of diphenyl ether.[37] One is based on the belief that the molecular moment of diphenyl ether lies in the direction of the line dividing the C–O–C angle of the molecule in two equal parts. This makes overall rotation, rotation of the whole molecules, to be the only cause of dielectric absorption. This is because rotation of two rings will not produce any change in the direction of the molecular moment. The other view[36] is based on the assumption that there might be a dipole component perpendicular to the line dividing the C–O–C angle equally and if so, this component (due to mesomerism) would be appreciable in diphenyl ether and very small in benzophenone. The advantage of the second view is that rotation of two rings alone can produce a change in the orientation of the molecular moment.

According to the former view one has to assume a special kind of overall rotation coupled with rotation of two rings[38] which would not occur so frequently. The weakness of the second mechanism is the lack of direct evidence for it[39]—although there is no reliable evidence against it[12,40,41] either.

Introduction of two CH_2 groups between O or C=O and two aromatic rings in the molecule of diphenyl ether or benzophenone will reduce the mesomeric effect and at the same time it will give a greater flexibility to the molecule.[42] It is interesting to find in this connection that $\tau(2)$ in Table 2 increases with the order: diphenyl ether, dibenzyl ether, dibenzyl ketone, and benzophenone.

Relaxation times for chlorobenzene (Table 2) are $\tau(1)=3.9$ psec and $\tau(2)=7.4$ psec, these being obtained on the assumption $a_\infty=a_D=0.05$. Contrary to this, or better a_∞ is estimated from the Cole-Cole plot, —we shall call it a_{CC}; Garg, Kilp, and Smyth[6] provided $a_{CC}=0.15$ which happens to be equal to a_G (Table 1). If this a_{CC} is used as a_∞, $\tau(1)=\tau(2)=7.4$ psec and Poley's absorption[2] will not exist or will be too weak to be detected at 100 GHz.

If a little smaller value $a_\infty=0.11$ is tentatively chosen, one would reach a conclusion that such an absorption does exist at the shorter end of millimeter band. For example, a weak absorption with $\tau_2=0.5$ psec, $C_2=0.1$ with the molecular rotation $\tau_1=8.5$ psec will be expected[8] on the assumption of two Debye processes. One of us (Takahashi)[43] confirmed Poley's absorption at about 2000 GHz (60 cm^{-1}) by a far infra-red spectrometer (FIS-3).

Dielectric relaxation of benzyl chloride has been analysed by Knobloch[22] and Purcell *et al.*[23]; the former gives $\tau_1=14.0$ psec, $\tau_2=1.4$ psec, $C_2=0.30$ while the latter gives two sets of $\tau_1=18.7$, $\tau_2=2.9$, and $\tau_1=23.7$, $\tau_2=2.3$ (all in psec). The present data lead to $\tau_1=12.4$ psec, $\tau_2=2.48$ psec and $C_2=0.24$[8] with the use of $a_{CC}=0.31$.[23] It appears fairly certain that there exist two dispersion regions in this molecule.

It is not clear, however, whether *p*-xylene chloride has such two relaxation processes or not. If $a_\infty=a_G=0.573$ is true, $\tau(2)=5.2$ psec will be the intramolecular relaxation time. On the other hand if the group rotation has a shorter relaxation time 1—2 psec,[22] we shall have to assume some contribution from overall rotation. An analysis[8] of the present data gives $\tau_1=11.6$ psec, $\tau_2=1.65$ psec, $C_2=0.25$ with $a_\infty=0.25$; or $\tau_1=11.6$ psec, $\tau_2=3.31$ psec, $C_2=0.55$ with $a_\infty=0.48$.

It is possible that both *p*-dimethoxy benzene and *p*-diethoxy benzene have two distinct relaxation processes, *viz.*, due to overall rotation as well as to internal rotation.[44] This is because if two methoxy or two ethoxy groups have freedom of rotation around the C–O axes, the components of the two mesomeric moments along the direction of the molecular axis would not cancel each other.

Now, consider the mesomeric moment arising from the upper OCH_3 group (see Fig. 2). The mesomeric moment depends upon the angle of rotation, φ_1, measured from the plane of the benzene ring.[45]

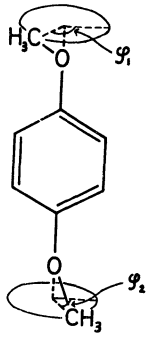

Fig. 2. Internal rotation in *p*-dimethoxybenzene and two angles of rotation, φ_1 and φ_2.

$$\mu_m(\text{upper}) = \mu_{max} \cos^2 \varphi_1$$

Similarly for the lower OCH_3 group

$$\mu_m(\text{lower}) = \mu_{max} \cos^2 \varphi_2$$

where φ_2 is the angle of rotation of the lower group. The component along the molecular axis is

$$\mu_m(\text{upper}) - \mu_m(\text{lower}) = \mu_{max}(\cos^2 \varphi_1 - \cos^2 \varphi_2)$$

The average $<\cos^2 \varphi_1 - \cos^2 \varphi_2>$ is 1/4 for free rotation and is not equal to zero in general. Contributions from overall rotation would be appreciable unless the maximum mesomeric moment μ_{max} of a methoxy group attached to a benzene ring is very small.[44]

The present data of $\tau(1)$ and $\tau(2)$ seem to support the above view, since the weight factor for molecular rotation $1-C_2$ is found to be quite large in several analyses[8] of the data. For example, for *p*-dimethoxy benzene $\tau_1=11.55$ psec, $\tau_2=1.65$ psec, $C_2=0.20$ with $a_\infty=0.30$ and for *p*-diethoxybenzene $\tau_1=11.55$ psec, $\tau_2=1.65$ psec, $C_2=0.20$ with $a_\infty=0.25$. These data can well be compared with the result of Klages and Knobloch's[22] analysis on *p*-dimethoxybenzene, or with Klages and Zenteks[46] $C_2=0.17$, $\tau_1=8.8$ psec, $\tau_2=(0.4)$ psec. More recently Vaughan *et al.*[47] give $C_2=0.13$ with $\tau_1=6.2$ psec and $\tau_2=0.9$ psec for liquid. However, there is uncertainty regarding the choice of a_∞. Anisole is in accord with $\tau_1=9.90$ psec, $\tau_2=1.65$ psec, $C_2=0.16$ with $a_\infty=0.21$. Again, it would be most desirable to have a reliable a_∞ value in order to find how important is the contribution of overall rotation.

Last group of four molecules are studied by the use of two solvents, benzene and dioxane, with a view to examining the hydrogen bonding effects of the solute with the solvent. According to the previous method of analysis[8] of two mean relaxation times $\tau(1)$ and $\tau(2)$ obtained at this high frequency one can make a very crude estimate of τ_1 and τ_2. The relaxation time τ_1 for overall rotation is closer $\tau(2)$ than to $\tau(1)$ and the relaxation time for internal rotation τ_2 is near to the observed $\tau(1)$ value. Recorded $\tau(1)$ values of these molecules are about 1—3 psec which is in good agreement with τ_2 for the OH and also for the NH_2 groups given by Knobloch.[48] In contrast to $\tau(1)$, $\tau(2)$ varies greatly with solutes and solvents and has values 4—20 psec. The ratio of $\tau(2)$ obtained in dioxane to that in benzene, τ_D/τ_B, is 2.48 (aniline), 1.81 (phenol), 2.36 (2,6-dimethyl phenol) and 1.16 (2,6-di-*t*-butyl phenol). The ratio of viscosities of two solvents is 1.2836 : 0.6466=1.99 : 1, while τ_D/τ_B for chlorobenzene and nitrobenzene are 1.57 and 1.51 respectively. The observed high increase of τ values from benzene to dioxane in aniline, phenol, and 2,6-dimethyl phenol is an indication that an oxygen atom of dioxane forms a hydrogen bond with amino-hydrogen atoms in aniline or with the hydrogen atom in phenol or of its derivative.[31] However, on account of the steric hindrance of the bulky substituents the OH group in 2,6-di-*t*-butyl phenol is not able to form a hydrogen bond with the solvent molecule. It is impressive to find small $\tau(2)$ values for this molecule both in benzene and dioxane. The group rotation seems to predominate in this molecule, as is the case of 2,4,6-tri-*t*-butyl phenol in decalin.[49] Further, the solute molecules tend to associate through hydrogen bonds. This association seems to take place in case of phenol in benzene.[50] Without such an effect the ratio τ_D/τ_B of phenol would possibly be much larger than the observed.

Appendix

1. *Calculation of n.* The real part of the refractive index n is expressed as

$$n = \sqrt{\frac{\left(\frac{\lambda_0}{\lambda_d}\right)^2+\left(\frac{\lambda_0}{\lambda_c}\right)^2}{1+\left(\frac{\lambda_0}{\lambda_c}\right)^2}} \qquad \text{(A-1)}$$

where λ_0, λ_d, and λ_c are the wavelength in air, the wavelength in the sample and the cut-off wavelength, respectively.

2. *Calculation of k.* The imaginary part of the refractive index k is calculated according to Eq. (3) by a least square method. Eq. (3) can be replaced in the following integrated form (A-2) using the relation:

$$h_m = \frac{1}{2} m\lambda_d$$

and

$$\beta_0 = 2\pi/\lambda_0$$

where $m=1, 2, \cdots, t$.

$$Y_m = -A_m k - B_m(k) + C \qquad \text{(A-2)}$$

where

$$Y_m = \ln[I_{max}(m) - I_{min}(m)]$$

$$A_m = \frac{2\pi\lambda_d}{\lambda_0} m$$

$$B_m(k) = \ln \frac{\left[(1+n)^2-(1-n)^2\exp\left(-\frac{4\pi\lambda_d km}{\lambda_0}\right)\right]^2}{\left[(1+n)-(1-n)\exp\left(-\frac{4\pi\lambda_d km}{\lambda_0}\right)\right]}$$

C is an integration constant.

The observed values of Y_m are expressed in a matrix form.

$$\tilde{\mathbf{Y}}^\circ = (Y_1^\circ, Y_2^\circ, \cdots, Y_t^\circ)$$

The unknown parameters in Eq. (A-2) are k and C. Therefore it is desired to obtain the values of k and C which give the calculated values of $\tilde{\mathbf{Y}}=(Y_1, Y_2, \cdots, Y_t)$ closest to $\tilde{\mathbf{Y}}^\circ$.

This may be done by the following procedure. Let k^{I} and C^{I} be the first guessed values of k and C and $\tilde{\mathbf{Y}}^{\mathrm{I}}=(Y_1^{\mathrm{I}}, Y_2^{\mathrm{I}}, \cdots, Y_t^{\mathrm{I}})$ be the calculated values of $\tilde{\mathbf{Y}}$ using k^{I} and C^{I}. To get the corrections Δk^{I} and ΔC^{I} from the difference $\Delta\mathbf{Y}=\mathbf{Y}^\circ-\mathbf{Y}^{\mathrm{I}}$, let us assume the corrected values to be k^{II} and C^{II} and the calculated values to be $\tilde{\mathbf{Y}}^{\mathrm{II}}=(Y_1^{\mathrm{II}}, Y_2^{\mathrm{II}}, \cdots, Y_t^{\mathrm{II}})$. The purpose of the least square method is to minimize the value of S which is expressed as:

$$S = (\tilde{\mathbf{Y}}^\circ-\tilde{\mathbf{Y}}^{\mathrm{II}})\mathbf{W}(\mathbf{Y}^\circ-\mathbf{Y}^{\mathrm{II}})$$

where $\mathbf{W}$ is a diagonal matrix whose element w_i is the weight factor of Y_i°.

An assumption is made that the variation of $\mathbf{Y}$ is linearly proportional to Δk and ΔC when they are very small. That is:

$$\mathbf{Y}^{\mathrm{II}} - \mathbf{Y}^{\mathrm{I}} = \mathbf{J}^{\mathrm{I}}\Delta\mathbf{K}^{\mathrm{I}}$$

where $\mathbf{J}^{\mathrm{I}}$ is a Jacobian matrix expressed as:

$$\mathbf{J}^{\mathrm{I}} = \begin{pmatrix} \frac{\partial Y_1^{\mathrm{I}}}{\partial k^{\mathrm{I}}} & \frac{\partial Y_1^{\mathrm{I}}}{\partial C^{\mathrm{I}}} \\ \frac{\partial Y_2^{\mathrm{I}}}{\partial k^{\mathrm{I}}} & \frac{\partial Y_2^{\mathrm{I}}}{\partial C^{\mathrm{I}}} \\ \vdots & \vdots \\ \frac{\partial Y_t^{\mathrm{I}}}{\partial k^{\mathrm{I}}} & \frac{\partial Y_t^{\mathrm{I}}}{\partial C^{\mathrm{I}}} \end{pmatrix}$$

and

$$\Delta\mathbf{K}^{\mathrm{I}} = \begin{pmatrix} \Delta k^{\mathrm{I}} \\ \Delta C^{\mathrm{I}} \end{pmatrix}$$

then

$$S = (\Delta\tilde{\mathbf{Y}}^{\mathrm{I}}-\Delta\tilde{\mathbf{K}}^{\mathrm{I}}\tilde{\mathbf{J}}^{\mathrm{I}})\mathbf{W}(\Delta\mathbf{Y}^{\mathrm{I}}-\mathbf{J}^{\mathrm{I}}\Delta\mathbf{K}^{\mathrm{I}}) \tag{A-3}$$

In order to mimimize S, the differenciation of S by $\Delta\mathbf{K}^{\mathrm{I}}$ must be zero. One obtains the following simultaneous linear equation

$$\tilde{\mathbf{J}}^{\mathrm{I}}\mathbf{W}\mathbf{J}^{\mathrm{I}}\Delta\mathbf{K}^{\mathrm{I}} = \tilde{\mathbf{J}}^{\mathrm{I}}\mathbf{W}\Delta\mathbf{Y}^{\mathrm{I}} \tag{A-4}$$

This equation may be solved if $|\tilde{\mathbf{J}}^{\mathrm{I}}\mathbf{W}\mathbf{J}^{\mathrm{I}}|\neq 0$ which is usually satisfied. Using the above calculated values of $\Delta\tilde{\mathbf{K}}^{\mathrm{I}}=(\Delta k^{\mathrm{I}}. \Delta C^{\mathrm{I}})$ the most appropriate second guessed values k^{II} and C^{II} are obtained.

$$k^{\mathrm{II}} = k^{\mathrm{I}} + \Delta k^{\mathrm{I}}$$
$$C^{\mathrm{II}} = C^{\mathrm{I}} + \Delta C^{\mathrm{I}}$$

The final values of k and C which give the best fit between observed and calculated values of $\mathbf{Y}$ can be obtained by repeating this process until S cannot be reduced any further.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 997—1000 (1971)

Osmotic Pressures of Polystyrene, Poly-*p*-chlorostyrene and Poly-*o*-chlorostyrene Solutions

Kenji KUBO and Kazuyoshi OGINO

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Tokyo

(Received November 30, 1970)

Second virial coefficients for polystyrene (PS), poly-*p*-chlorostyrene (PPCS), and poly-*o*-chlorostyrene (POCS) were determined in various solvents by osmotic-pressure measurements. Free-energy parameters, χ, were estimated from the values of the second virial coefficients. It was shown that the values of χ in each solvent at 30°C became larger in the following order: PS, POCS, PPCS in toluene; PS, PPCS, POCS in chlorobenzene; PPCS, PS, POCS in *n*-butyl acetate. It was indicated that, in addition to the effect of intermolecular forces, another parameter related to the stiffness of the polymer chains should be considered in order to discuss the thermodynamic properties of polymer solutions. It was shown that the values of χ for two polychlorostyrenes in *n*-butyl acetate increased with an increase in the temperatures, unlike the behavior of PS in the same solvent.

In a preceding paper,[1] it was shown that the thermodynamic properties of solutions of poly-*p*-chlorostyrene (PPCS) were markedly different from those of polystyrene (PS) because of the effect of the polar substituent at the para position.

In this paper, the variation in the thermodynamic properties due to the various positions of substituent was examined by osmotic-pressure measurements for PS, PPCS, and poly-*o*-chlorostyrene (POCS) in different solvents.

Experimental

Materials. *o*-Chlorostyrene, a monomer, was prepared from commercial *o*-chlorobenzaldehyde by the following process: *o*-chlorophenylmethylcarbinol was synthesized by a Grignard reaction and was then dehydrated by potassium bisulfate.[2] The monomer was polymerized in bulk at 60°C, in the presence of azo-bis-isobutyronitrile as an

2) L. A. Brooks, *J. Amer. Chem. Soc.*, **66**, 1295 (1944).

initiator, under nitrogen gas. The polymer was fractionated from a dilute benzene solution by a successive precipitation procedure using methanol. One separate from nine fractions was used for the osmotic-pressure measurements.

Each fraction of PPCS was the same as has been described in the previous paper.[1] The monodispersed polystyrene used in this experiment was from the Pressure Chemical Company; we assumed that this will not be of the isotactic type, for it was soluble in 2-butanone.

The solvents were dried, toluene and chlorobenzene with calcium chloride, and *n*-butyl acetate with magnesium sulfate, and were freshly distilled before each measurement.

Measurements. The osmotic pressures were determined using a Hewlett-Packard High Speed Membrane Osmometer (Model 503) and Schleicher & Schuell membranes (Type 08) at various temperatures; in toluene and chlorobenzene at 30°C and in *n*-butyl acetate at 5, 30, and 55°C. Pycnometer was used in determining the partial specific volumes in benzene at 30°C; these volumes were found to be 0.797 for PPCS and 0.792 (cc/g) for POCS.

Results

The second virial coefficient, A_2, was obtained from the osmotic pressure by the use of the following equation;

$$\pi/c = \boldsymbol{R}T(1/M_n + A_2c) \tag{1}$$

or;

$$(\pi/c)^{1/2} = (\boldsymbol{R}T/M_n)^{1/2}(1 + M_nA_2c/2) \tag{2}$$

where π is the osmotic pressure; c, the concentration; M_n, the number-average molecular weight; $\boldsymbol{R}$, the gas constant, and T, the absolute temperature. The data observed in toluene and chlorobenzene fit Eq. (2), and those in *n*-butyl acetate fit Eq. (1); several examples are shown in Figs. 1 and 2. The results for M_n and A_2 are summarized in Table 1.

According to the lattice theory of polymer solutions by Flory and Huggins, the free-energy parameter, χ, is related to A_2 by the following relation;

$$A_2 = (1/2 - \chi)\bar{v}_2^2/V_1 \tag{3}$$

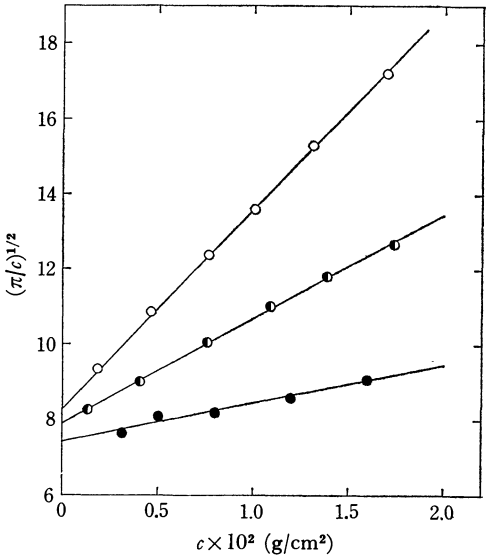

Fig. 1. Plots of $(\pi/c)^{1/2}$ against c in toluene at 30°C.
○ for PS, ◐ for POCS, and ● for PPCS-f6

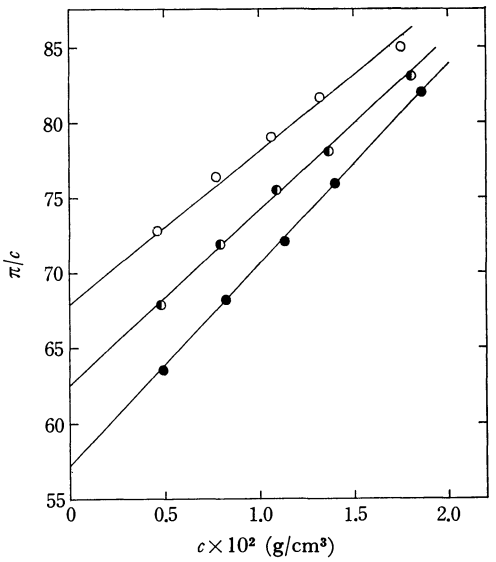

Fig. 2. Plots of π/c against c for POCS in *n*-butyl acetate.
● at 5°C, ◐ at 30°C, and ○ at 55°C

where $\bar{v}_2$ is the partial specific volume of the polymer and where V_1 is the molar volume of the solvent. Since a strong molecular-weight dependence of A_2 in dilute solutions has been observed, especially in good solvents, it is not reasonable, in a strict sense, to discuss the thermodynamic properties of polymer solutions in terms of χ values estimated from Eq. (3). In dilute polymer solutions, A_2 is generally given by the relation using Flory's notation:

$$A_2 = (1/2-\chi)(\bar{v}_2^2/V_1)h(z/\alpha_s^3) \tag{4}$$

with:

$$z = 2(3/2\pi)^{3/2}(\bar{v}_2^2/N_AV_1)(\overline{r^2}_0/M)^{-3/2}M^{1/2}(1/2-\chi). \tag{5}$$

Here, N_A is Avogadro's number, $\overline{r^2}_0$ is the unperturbed mean-square end-to-end distance of the polymer, and the latter is proportional to the molecular weight, M. The α_s quantity is the expansion factor related to the statistical radius. Several forms of $\alpha_s(z)$ consistent with $h(z/\alpha_s^3)$ have been reported. Recently, it has been shown by Fujita *et al.* that their experimental results can be explained well[3] by a combination of $\alpha_s(z)$ and $h(z/\alpha_s^3)$, which Yamakawa and his coworkers presented.[4,5] Therefore, employing their results we estimated χ as:

$$\alpha_s^2 = 0.541 + 0.459(1+6.04z)^{0.46} \tag{6}$$

and:

$$h(z/\alpha_s^3) = \{1-(1+4.454z/\alpha_s^3)^{-0.2867}\}/1.277(z/\alpha_s^3). \tag{7}$$

The value of χ is obtained as follows: by combining Eqs. (4)—(7), $A_2M^{1/2}(\overline{r^2}_0/M)^{-3/2}$ can be represented, and plotted, as a function of z only. The value of z, which corresponds to the A_2 and M_n values obtained from the osmotic-pressure measurements, can be found on the graph when we know the value of $(r_0^2/M)^{1/2}$.

a) Estimated from Eq. (3).
b) Estimated from Eqs. (4)—(7).

Then, the value of χ corresponding to the z can be readily obtained from Eq. (5). The values of χ, summarized in Table 1, are estimated, using the values of $\bar{v}_2$ in cc/g and $(\overline{r^2}_0/M)^{1/2}$ in cm·mol$^{1/2}$/g$^{1/2}$, to be as follows:

	$\bar{v}_2$	$(\overline{r^2}_0/M)^{1/2} \times 10^{11}$
PS	0.920[6]	670[7]
PPCS	0.797	584[1]
POCS	0.792	633[8]

The values of χ obtained from Eq. (3) are also summarized in Table 1.

Discussion

A free-energy parameter, χ, is resolved into an enthalpy term, χ_h, and an entropy term, χ_s. The enthalpy term is represented by Hildebrand's expression:[9]

$$\chi = V_1(\delta_s - \delta_p)^2/RT. \quad (8)$$

Here, the solubility parameter, δ, is given by $(\Delta E/V)^{1/2}$, where ΔE is the molar energy of vaporization, and the suffix s or p represents the solvent or the polymer respectively. It was shown by Huggins that χ_s is expressed as $1/z$ (z: coordination number); thus, χ should increase in accordance with $|\delta_s - \delta_p|$. From the results in toluene, taking account of δ_s (toluene)$=$ 8.9 and δ_p (PS)$=$9.3,[10] it seems to be reasonable to assume that δ_p increases in the order of PS, POCS, and PPCS. The assumption that the δ_p of POCS is smaller than that of PPCS suggests that the effect of the *o*-chlorine atom on an intermolecular force is not so large as that of the *p*-chlorine atom because of the screening effect by a main chain for the *o*-chlorine atom.

If the order of δ_p shown above can be used, and in view of δ_s (chlorobenzene)$=$9.50, the increase in χ does not correspond to the order of $|\delta_s - \delta_p|$ in chlorobenzene. Therefore, in addition to the effect of intermolecular forces, another parameter may be introduced so as to represent the difference in the thermodynamic properties of polymer solutions. Thus, it is reasonable to take into account a theory of the average-potential method proposed by Prigogine and his co-workers.[11] In this theory, external degrees of freedom of r-mer are defined as the remainder left by internal degrees associated with intramolecular valence forces from a total of $3r$ degrees of freedom; they are taken to be $3c$ in number. With a sufficiently large r, c/r tends to 0 for a "perfect rigid r-mer" and to 2/3 for a "perfect flexible r-mer." The parameter c has a value which decreases with an increase in the "stiffness' of the polymer chain. The intermolecular potential energy between elements of i and j is taken to be a Lennard-Jones 6-12 potential-energy type with characteristic parameters for the pair, ε^*_{ij} and r^*_{ij}, where r^*_{ij} is the distance between the centers of the elements, at a minimum potential energy of ε^*_{ij}. The element of the monomer is the monomer itself, and the submolecule of the polymer is treated as an element. If the "sizes" of the elements of A (monomer) and B

(r-mer) are equal,

$$r^*_{AA} = r^*_{BB} = r^*_{AB}. \quad (9)$$

If the minima of potential energies are also equal,

$$\varepsilon^*_{AA} = \varepsilon^*_{BB} = \varepsilon^*_{AB}. \quad (10)$$

The free-energy parameter in the (r-mer)-monomer system can, then, be approximately represented by this theory by the relation:

$$\chi = 1/z + (C_{P,A}/2R)(1 - c_B/q_B)^2 \quad (11)$$

where $C_{P,A}$ is the molar configurational heat capacity of the monomer and where q_B is given by $(rz-2r+2)/z$. Using the parameters assumed by Eqs. (9) and (10) along with Eq. (11), it can readily be understood that χ is larger in positive value the stiffer the polymer. The systems of polychlorostyrenes-chlorobenzene are treated as such cases in a crude sense. On the basis of this crude assumption, the χ values for these systems are not worth discussing quantitatively, but the finding that the value of χ for POCS in chlorobenzene is larger than the corresponding value for PPCS may be qualitatively attributed to the enlarged chain stiffness of POCS, which in turn may be due to the steric hindrance of the rotation of the main chain by the chlorine atom at the ortho position.

The second virial coefficients for PPCS and POCS in n-butyl acetate decrease with an increase in the temperature. This behavior is different from that of PS in the same solvent, and it is equivalent to a decrease in the intrinsic viscosity with an increase in the temperature, as has been reported previously for PPCS in n-butyl acetate.[1] In view of an inappreciable temperature coefficient of $\bar{r}_0^2$ for PPCS in the same solvent,[12] it seems reasonable to conclude that the values of χ for PPCS, and perhaps for POCS in n-butyl acetate, increase with an increase in the temperatures. This fact may suggest the existence of a strong interaction between the chlorine atom in the polymer and the solvent molecule. The solubility of POCS in n-butyl acetate in poorer than that of PPCS. This fact may be attributed to the difference in stiffness between the two polychlorostyrenes.

From the relations for A_2 and M_n reported in the literature, the values of A_2 can be estimated for polymers with the same molecular weights as those of the polymer fractions employed in this work. The values of A_2 thus obtained are 3.67[13] and 3.54×10^{-4} [14] for atactic PS in toluene; a value of 3.45×10^{-4} ($cm^3\cdot mol/g^2$) is obtained by us, which is slightly smaller than the former and is nearly equal to the latter. The values of A_2 for PPCS in toluene, 0.80[15] and 1.00×10^{-4},[16] are slightly larger than our corresponding value, 0.625×10^{-4} ($cm^3\cdot mol/g^2$). These discrepancies may be partly attributed to the difference in the molecular-weight distributions of the polymers; the deduced conclusion seems not to be affected by these discrepancies. The results for A_2 obtained from light scattering for poly-m-chlorostyrene in toluene[17] were not taken into account of our present discussion, because a value of A_2 obtained from such a measurement is not essentially equivalent to that obtained from osmotic pressure for a polymer fraction with a molecular-weight distribution.

The difference in solubility between PS and various polychlorostyrenes in toluene has been represented by Matsumura[8] on the basis of the data of the polymer-coil dimensions as measured by light scattering. The order of the solubilities of PS and PPCS among these polymers is the reverse of that estimated from our osmotic-pressure measurements. From the fact that our results on osmotic pressure for PS and PPCS in toluene are essentially identical with the corresponding data in the literature cited here, we have some question about the results of light scattering which have been referred to by Matsumura.[18,19]

We intend to proceed with our studies in concentrated polymer solutions by means of vapor-pressure measurements, by which a free-energy parameter is directly estimated; it seems that it will be interesting to discuss quantitatively the effect of the stiffness of a polymer chain on the thermodynamic properties, basing our discussion on the average-potential method or on Flory's method, presented lately.[20]

Non-Equilibrium Thermodynamics: Steady State Thermodynamic Relations in the Non-Linear Current-Affinity Region

R. J. Tykodi

Department of Chemistry, Southeastern Massachusetts University, North Dartmouth, Massachusetts, 02747, U. S. A.

(Received June 6, 1969)

A simple heat conduction example is used to show that the choice of boundary conditions for describing a steady process, although of no consequence in the linear current-affinity region, governs the applicability (or the lack thereof) of various thermodynamic assertions to the non-linear current-affinity region. The need for a whole family of classificatory principles to aid us in organizing our knowledge about steady processes is pointed out.

Steady state non-equilibrium situations can be described in thermodynamic terms;[1] the rate of entropy production $\theta \equiv \dot{S}(\text{system}) + \dot{S}(\text{surroundings})$ normally plays a central role in such descriptions. By combined use of the First and Second Laws of thermodynamics it is always possible to resolve the rate of entropy production in a steady state into a set of *currents* Y_i and *affinities* Ω_i, with the currents being time derivatives of extensive thermodynamic variables:

$$\theta = \sum_i Y_i \Omega_i \geqq 0. \tag{1}$$

In a neighborhood of a thermodynamic equilibrium state σ, we can express each current Y_i as a Taylor's series in the affinities Ω_j:

$$Y_i = Y_i(\Omega_j, \sigma) = \sum_j L_{ij}(\sigma)\Omega_j + 1/2\sum_{j,k} L_{ijk}(\sigma)\Omega_j\Omega_k + \cdots ; \tag{2}$$

the coefficients are functions of the parameters describing the thermodynamic equilibrium state σ. If we stop with the linear terms in the expansion in Eq. (2), we define a *linear* current-affinity *neighborhood* of the thermodynamic reference state σ. In such a linear neighborhood of a reference state σ, many interesting theorems hold for situations not involving magnetic or centrifugal fields:[1-3]

a) The matrix of the coefficients L_{ij} is symmetric: $L_{ij}=L_{ji}$.

b) The determinant of the coefficients L_{ij} and all principal minors of that determinant are positive: $L_{ii}>0$, $L_{ii}L_{jj}-L_{ij}L_{ji}>0$ $(i \neq j), \cdots$.

c) For a given reference state σ and a set of affinities Ω_j and currents Y_j $(j \neq i)$, the following relations hold:

$$(\partial Y_i/\partial \Omega_i)_{\Omega_j,\sigma} \geqq (\partial Y_i/\partial \Omega_i)_{Y_j,\sigma} > 0.$$

d) For a given reference state σ and a constant set of affinities Ω_j $(j \neq i)$, the rate of entropy production has a minimum at the point $Y_i=0$;

$$0 = (\partial\theta/\partial Y_i)_{\Omega_j,\sigma}|_{Y_i=0}, \quad 0 < (\partial^2\theta/\partial Y_i^2)_{\Omega_j,\sigma}|_{Y_i=0}.$$

e) For any given expression involving only the rate of entropy production, the currents Y_i, and the affinities Ω_i (in any combination), consider whether the expression equals zero or does not equal zero—*i.e.*, consider the *mystic properties* (the vanishing or non-vanishing) of the expression. Generate from the given expression a *dual* expression by everywhere exchanging the roles of currents and affinities, and examine the mystic properties of the dual expression. In the linear neighborhood of a reference state σ, a given expression of the appropriate type and its dual expression have the same mystic properties.

Let

$$B_{ij}(\sigma) \equiv (\partial Y_i/\partial \Omega_j)_{\Omega',\sigma}, \quad D_{ij} \equiv (\partial Y_i/\partial \Omega_j)_{Y',\sigma},$$

$$(\delta/\tilde{\delta}Y_j)_{\Omega',\sigma} \equiv (\partial/\partial Y_j)_{\Omega',\sigma}|_{Y_j=0},$$

$$(\delta/\tilde{\delta}\Omega_j)_{Y',\sigma} \equiv (\partial/\partial \Omega_j)_{Y',\sigma}|_{\Omega_j=0},$$

where the subscript $\Omega'(Y')$ means constant $\Omega_k(Y_k)$ for each $k \neq j$. Then in the linear current-affinity neighborhood of σ, the relations a)—e) take the forms

$$B_{ij}(\sigma) = B_{ji}(\sigma), \tag{3}$$

$$B_{ii}(\sigma) > 0, \quad B_{ii}(\sigma)B_{jj}(\sigma) - B_{ij}(\sigma)B_{ji}(\sigma) > 0 \quad (i \neq j), \cdots, \tag{4}$$

$$B_{ii}(\sigma) \geqq D_{ii}(\sigma) > 0, \tag{5}$$

$$(\delta\theta/\tilde{\delta}Y_i)_{\Omega',\sigma}, \quad (\delta^2\theta/\tilde{\delta}Y_i^2)_{\Omega',\sigma} > 0, \tag{6a, b}$$

$$0 = (\delta\theta/\tilde{\delta}Y_i)_{\Omega',\sigma=0} \leftrightarrow (\delta\theta/\tilde{\delta}\Omega_i)_{Y',\sigma=0}, \text{ etc.} \tag{7}$$

The question of interest is; Are there any general relations of the form (3)—(7) that hold *outside* the linear current-affinity neighborhood of reference state σ?

I shall now describe a simple heat conduction example that yields non-linear current-affinity relations and which is particularly rich in counter-examples for relations of the type (3)—(7).

Heat Conduction Example

Stretch a homogeneous metallic wire between two heat reservoirs (thermostats) α, β; cut the wire at its mid point and let the two thereby exposed faces of the wire communicate with a thermostat (heat reservoir) x; insulate the wire so that there are no lateral heat losses. Consider the case of a wire of constant thermal conductivity κ, and choose the dimensions of the wire so that $2\mathcal{B}\kappa/\mathcal{A}=1$, where $\mathcal{A}$ is the length and $\mathcal{B}$ is the cross sectional area of the wire. Let $\dot{Q}_\alpha{}^{(r)}$, $\dot{Q}_\beta{}^{(r)}$, $\dot{Q}_x{}^{(r)}$ represent the rate of influx of heat into the appropriate reservoir (of temperature T_α, T_β, or T_x). In the steady state we have the following relations:

$$\dot{Q}_\alpha{}^{(r)} + \dot{Q}_\beta{}^{(r)} + \dot{Q}_x{}^{(r)} = 0, \tag{8}$$

1) R. J. Tykodi, "Thermodynamics of Steady States," The Macmillan Company, New York (1967).

2) S. de Groot, "Thermodynamics of Irreversible Processes," North-Holland Publishing Company, Amsterdam (1951).

3) I. Prigogine, "Introduction to the Thermodynamics of Irreversible Processes," John Wiley & Sons, New York (1968).

$$\dot{Q}_\alpha^{(r)} = T_x - T_\alpha, \quad \dot{Q}_\beta^{(r)} = T_x - T_\beta,$$
$$\dot{Q}_x^{(r)} = T_\alpha + T_\beta - 2T_x, \tag{9}$$
$$\theta = \dot{Q}_\alpha^{(r)}\left(\frac{1}{T_\alpha} - \frac{1}{T_x}\right) + \dot{Q}_\beta^{(r)}\left(\frac{1}{T_\beta} - \frac{1}{T_x}\right)$$
$$\equiv Y_1\Omega_1 + Y_2\Omega_2, \tag{10}$$
$$= \dot{Q}_\alpha^{(r)}\left(\frac{1}{T_\alpha} - \frac{1}{T_\beta}\right) + \dot{Q}_X^{(r)}\left(\frac{1}{T_X} - \frac{1}{T_\beta}\right)$$
$$\equiv y_1\omega_1 + y_2\omega_2. \tag{11}$$

For a given thermodynamic state σ the linear current-affinity neighborhood is infinitesimal; it is thus easy to investigate relations such as (3)—(7) in the non-linear current-affinity region. By way of example, note that at constant T_β (let the state at β play the role of a reference state σ, *i.e.*, $\sigma=\beta$)

$$\dot{Q}_\alpha^{(r)} = Y_1 = Y_1(\Omega_1, \Omega_2, \sigma) = T_x - T_\alpha$$
$$= T_\beta(1 - T_\beta\Omega_2)^{-1} - T_\beta(1 + T_\beta\Omega_1 - T_\beta\Omega_2)^{-1}$$
$$= T_\beta\{T_\beta\Omega_1 - (T_\beta\Omega_1)^2 + 2T_\beta^2\Omega_1\Omega_2$$
$$+ (T_\beta\Omega_1)^3 + \cdots\}. \tag{12}$$

Let us now check the validity of relations (3)—(7) in the non-linear current-affinity region for various choices of reference state σ: $\sigma=\alpha, \beta, x$; a subscript σ in an equation means that the thermodynamic state at σ is being held constant, *i.e.*, subscript σ means constant T_σ.

Relations (3). The validity of relations (3) varies with the choice of reference state σ; thus (*e.g.*)

$$B_{12}(x) = B_{21}(x) = 0, \quad b_{12}(x) = b_{21}(x) = -T_\alpha^2, \tag{13}$$

but

$$B_{12}(\beta) \neq B_{21}(\beta), \quad b_{12}(\beta) \neq b_{21}(\beta), \tag{14}$$

except in the limit $T_\alpha \to T_\beta$, $T_x \to T_\beta$. (The upper and lower case convention introduced in Eqs. (10) and (11) applies throughout the paper.)

Relations (4). Relations (4) remain valid for either choice of currents and affinities—Eq. (10) or (11)—and for all choices of reference state.

Relations (5). The validity of relations (5) varies with the choice of reference state; thus (*e.g.*)

$$B_{ii}(\sigma) = D_{ii}(\sigma) > 0, \quad \sigma = \alpha, \beta, x, \quad i = 1, 2 \tag{15}$$

and

$$b_{11}(\beta) > d_{11}(\beta) > 0, \tag{16}$$

but

$$b_{11}(\alpha) = T_x^2, \quad d_{11}(\alpha) = T_\beta^2/2. \tag{17}$$

There is, consequently, no necessary ordering relation between $b_{11}(\alpha)$ and $d_{11}(\alpha)$, except in the limit $T_x \to T_\alpha$, $T_\beta \to T_\alpha$.

Relations (6). The relations

$$(\partial^2\theta/\partial Y_i^2)_{\Omega',\sigma} > 0, \quad (\partial^2\theta/\partial y_i^2)_{\omega',\sigma} > 0,$$
$$\sigma = \alpha, \beta, x, \quad i = 1, 2, \tag{18}$$

hold for all choices of reference state, but the validity of the relations

$$(\delta\theta/\tilde{\delta}Y_i)_{\Omega',\sigma} = 0, \quad (\delta\theta/\tilde{\delta}y_i)_{\omega',\sigma} = 0$$

varies with the choice of reference state; thus (*e.g.*)

$$(\delta\theta/\tilde{\delta}Y_1)_{\Omega_2,\beta} = 0, \quad (\delta\theta/\tilde{\delta}y_1)_{\omega_2,\beta} = 0, \tag{19}$$

but

$$(\delta\theta/\tilde{\delta}Y_1)_{\Omega_2,\alpha} \neq 0, \quad (\delta\theta/\tilde{\delta}y_1)_{\omega_2,\alpha} \neq 0, \tag{20}$$

and

$$(\delta\theta/\tilde{\delta}y_2)_{\omega_1,\sigma} \neq 0 \quad \sigma = \alpha, \beta, x, \tag{21}$$

except in the appropriate limit.

Relations (7). A given expression and its dual expression need not have the same mystic properties outside the linear current-affinity region; thus (*e.g.*)

$$(\delta\theta/\tilde{\delta}y_1)_{\omega_2,x} = 0 \text{ and } (\delta\theta/\tilde{\delta}\omega_1)_{y_2,x} = 0, \tag{22}$$

$$(\delta\theta/\tilde{\delta}y_2)_{\omega_1,\beta} \neq 0 \text{ and } (\delta\theta/\tilde{\delta}\omega_2)_{y_1,\beta} \neq 0, \tag{23}$$

but

$$(\delta\theta/\tilde{\delta}y_1)_{\omega_2,\beta} = 0 \text{ whereas } (\delta\theta/\tilde{\delta}\omega_1)_{y_2,\beta} \neq 0, \tag{24}$$

$$(\delta\theta/\tilde{\delta}y_2)_{\omega_1,\alpha} \neq 0 \text{ whereas } (\delta\theta/\tilde{\delta}\omega_2)_{y_1,\alpha} = 0, \tag{25}$$

except, of course, in the appropriate limit.

Observations

The relations (3)—(7) form an interrelated, compact set in the linear neighborhood of any arbitrary thermodynamic reference state σ. As we move outside the linear current-affinity region, we find that relations (4) and (6b) remain generally valid, but that the other relations become sensitive to the choice of reference state and cannot be counted on to remain valid for any arbitrary choice of reference state. Outside the linear current-affinity region, then, we can expect to find [with the exception of relations (4) and (6b)] only a series of special thermodynamic relations, relations that hold only for special choices of current-affinity representation and for special sets of reference states. We are thus faced with the task of categorizing steady states in such a way that we can immediately tell which of relations (3)—(7) is applicable to a given situation.

Consider, for example, the following situation: for an arbitrary reference state σ and fixed affinities Ω_j $(j\neq k)$ make a plot of θ *versus* Y_k; such a plot will always be concave upward—relation (6b)— and will always show a minimum. Now, start from an equilibrium configuration, the entire system being in state σ, and make θ *vs.* Y_k plots for various choices of the affinities Ω_j, moving (with each successive plot) farther and farther away from reference state σ. Let us examine the locus of the minima in the θ *vs.* Y_k plots as we move away from the equilibrium state; we observe one of two patterns: i) either the locus of the minima lies on the line $Y_k=0$ (Fig. 1), or ii) the locus of the minima lies off the line $Y_k=0$ (Fig. 2). We can accordingly categorize steady state situations by noting whether they follow the pattern of Fig. 1 or whether they follow that of Fig. 2—the thermoelectric effect[1] (*e.g.*), with Y_k being the electric current, follows the Fig. 1 pattern, whereas our heat conduction example, with $Y_k=\dot{Q}_x^{(r)}$ [Eq. (21)], follows the Fig. 2 pattern. What we would very much like to have is a criterion for recognizing a Fig. 1 situation *without* actually having to compute θ as a function of Y_k.

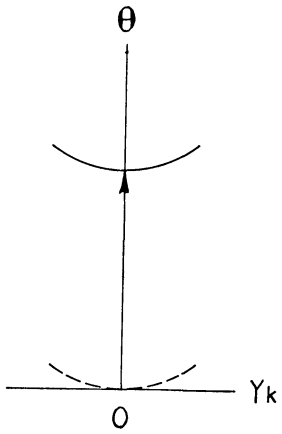

Fig. 1

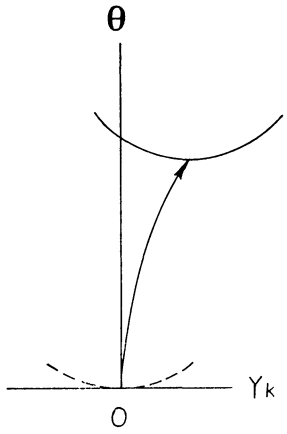

Fig. 2

A fruitful field for further effort, then, is the search for classificatory principles, *a la* Mendeleeff, for steady state situations so that we can treat such situations in groups according to their thermodynamic deserts.

Appendix

In this appendix I offer a tentative criterion for a situation of the Fig. 1 type. From the various steady-state currents Y_k, I single out a class of *conservative currents* Y_k^*: a conservative current (i) flows in a closed loop or (ii) flows from a source (χ) to a sink (ψ) without loss or branching, *i.e.* $Y_k^*(\chi)+Y_k^*(\psi)=0$, or (iii) is the rate of change of the degree of reaction variable ($\dot{\xi}$) for a chemical reaction. In considering the flow of a given current, I single out a class of *associated fundamental reference states* σ^*: an associated fundamental reference state for a current Y_k is a reference state such that the condition of constant Ω', σ implies that all the intensive variables in each Ω' are kept constant. To illustrate these ideas in terms of the heat conduction example of this paper, note that none of the currents $\dot{Q}_\alpha^{(r)}$, $\dot{Q}_\beta^{(r)}$, $\dot{Q}_x^{(r)}$ are conservative currents since they satisfy the three-term relation (8) instead of the two-term relation [(ii) above] required of a conservative current. Note also that in Eq. (10) with respect to current Y_1 reference state x is an associated fundamental reference state since constant Ω_2, x implies constant T_β, T_x; on the other hand reference state α is not an associated fundamental reference state for Y_1 since constant Ω_2, α implies only that the combination $T_\beta^{-1}-T_x^{-1}$ is to remain constant whereas the separate temperatures T_β, T_x may change.

The criterion that I tentatively propose is the following: A situation involving both a conservative current Y_k^* and an associated fundamental reference state σ^* follows the pattern of Fig. 1, *i.e.*

$$(\delta\theta/\tilde{\delta}Y_k^*)_{\Omega',\sigma^*}=0. \tag{26}$$

Of the four possible combinations of current type (Y_k^* or Y_k) and reference state type (σ^* or σ)$-(\delta\theta/\tilde{\delta}Y_k^*)_{\Omega',\sigma^*}$, $(\delta\theta/\tilde{\delta}Y_k^*)_{\Omega',\sigma}$, $(\delta\theta/\tilde{\delta}Y_k)_{\Omega',\sigma^*}$, $(\delta\theta/\tilde{\delta}Y_k)_{\Omega',\sigma}$—we know that each of the four expressions vanishes in a linear neighborhood of the appropriate thermodynamic reference state; I am now suggesting that it is only the Y_k^*,σ^* combination that unfailingly continues to vanish outside the appropriate linear neighborhood.

In considering the behavior of θ as a current Y_k vanishes, let the residual currents (the non-vanishing currents) be indicated by Y_i. If any of the Y_i are mass currents involving sensible amounts of kinetic energy, it is generally impossible to find an associated fundamental reference state σ^* for the vanishing current Y_k. This observation means that relation (26) can only be tested in the case of a vanishing current (Y_i) of mass or electricity or chemical reaction ($\dot{\xi}$) in the presence of a residual current (or currents) Y_i of heat or electricity. The various steady-state non-equilibrium effects that could conceivably meet the requirements of Eq. (26) are some of the electrokinetic effects, the thermomolecular pressure effect, thermoösmosis, thermal diffusion, thermoelectricity, and effects involving a stationary chemical reaction ($\dot{\xi}=0$) in the presence of residual flows of heat or electricity; see Ref. 1 for a full discussion of these non-equilibrium effects.

Salt and Medium Effects on H_ Indicators

N. CHATTANATHAN and C. KALIDAS

Department of Chemistry, Indian Institute of Technology, Madras, India

(Received September 29, 1970)

The activity coefficients of the molecular forms of a few nitrodiphenylamine indicators were determined by a solubility method in basic solutions of ethylene and propylene glycols. The medium effects on the ions of these indicators were also obtained by determination of the medium effects of their molecular forms separately by solubility measurements. Variation of the activity coefficients and the medium effects on the ions of the indicators are discussed.

In earlier papers on this subject,[1,2] it was shown that the validity of the acidity function concept is based on two conditions. For a pair of successive indicators B and B_1 in the overlapping range, the equality of the activity coefficient ratios

$$\frac{f_{B^{0,-}}}{f_{A^{+,0}}} = \frac{f_{B_1{}^{0,-}}}{f_{A_1{}^{+,0}}} \quad (1)$$

must be satisfied where A, B and A_1, B_1 are the indicator acid-base pairs. The superscripts $B^{0,-}$ indicate an uncharged or a negatively charged basic indicator used in H_0 or H_- measurements, respectively. The charges on the other species can be explained in a similar manner. The relative strengths of a pair of indicators must remain unchanged on changing the medium. Although the equality of the ratios of the above type has approximately been shown to hold by indirect methods for indicators of similar structure in water and some non-aqueous solvents of fairly high dielectric constant, the recent work of Boyd[3] has clearly established that there are quite large variations in the individual values of the activity coefficient for both the neutral bases and their conjugate acids. A direct determination of the activity coefficients of the indicators is, therefore, necessary not only for an evaluation of the relative contributions of the various terms in the appropriate acidity function but also to understand[4] the dependence of the acidity function on the indicator structure and in particular on the site of ionisation. Although several classes of indicators have been employed[5-7] for H_- measurements in aqueous and non-aqueous solutions of bases, no data are hitherto available on the variation of their activity coefficients with changing medium. The present work deals with the determination of the activity coefficients of the molecular forms of a few nitrodiphenylamines (which have earlier been employed for H_- measurements in glycols[2]) in sodium glycollate solutions of ethylene and propylene glycols and also their medium effects.

Experimental

Preparation of Solvents, Indicators, and Base. The purification of ethylene and propylene glycols has been described elsewhere.[2] The indicators 2,4,3′-trinitrodiphenylamine (2,4,3′-TNDA), 2,4-dinitrodiphenylamine (2,4-DNDA), and 2,4-dinitro-4′-aminodiphenylamine (2,4-DN-4′-amino-DA) were employed. They were prepared and purified according to standard methods in literature.[8] The preparation and standardization of sodium glycollate in ethylene and propylene glycols has been described.[2]

Solubility Measurements. The solubility measurements of the indicators at various concentrations of the base in the two glycol were carried out at 30±0.5°C. Their saturated solutions were obtained by shaking mixtures of the solid with the appropriate base solution for about 48 hr in a thermostat maintained at a fixed temperature. Known volume of the saturated solution was diluted suitably with the appropriate solvent (the pure solvent or a base solution of the desired concentration) to get convenient values of optical density. The optical densities were measured at the wavelength of maximum absorption of the molecular forms in a P.M.Q. II Carl Zeiss Spectrophotometer and the concentrations were calculated using the known extinction coefficients of the indicators in these solvents at this wavelength. In addition, solubility measurements of the various indicators in water at the same temperature were carried out to compute the medium effects. All solubility measurements were carried out at least in duplicate to confirm the reproducibility of results.

Results

The activity coefficients were calculated from

$$f_{HA} = \frac{S_0}{S}\left(1+\frac{K_{HA}}{h_-}\right) \quad (2)$$

where S_0 and S refer to the solubilities of the given indicator in the pure glycol and the base solution, respectively. K_{HA} is the thermodynamic dissociation constant of the indicator, the activity coefficients being referred to a value of unity at infinite dilution in the given solvent and $\log h_- = -H_-$ on the solvent standard state.

Table 1 gives the solubility and activity coefficient data for different indicators in the two solvents. The medium effects on the molecular and ionic forms of these indicators are presented in Table 2. The medium effect on the ions was calculated by adding the medium effect of the corresponding molecular acids to the overall medium effect which is given by pK^s_{HA}—pK^w_{HA} where pK^s_{HA} and pK^w_{HA} refer to the negative logarithm of thermodynamic ionisation constants of a given indicator in solvent "S" and water, respectively.

b) 2,4,2',4'-tetranitrodiphenylamine

The medium effect of the molecular acid was calculated from

$$\log f^o_{HA} = \log \frac{S_w}{S_g} \qquad (3)$$

where S_w and S_g are the solubilities of the indicator in water and the glycol, respectively. The results of Table 1 are plotted in Fig. 1.

Discussion of the Activity Coefficients. We see from Table 1 as well as from Fig. 1 that the activity coefficients of all the indicators vary considerably in the range of base concentrations employed contrary to general assumption. Generally, the indicator molecules are 'salted in' in the presence of the base except in the case of 2,4-DN-4'-amino-DA. There is, however, a tendency for the activity coefficients to increase *i.e.* show a 'salting out effect' at low base concentrations as well as at higher base concentrations.

A similar variation of the activity coefficients of some nitroanilines and amides was noted by others[3,4,9)] in acid solutions although no attempt was made to explain the variation. Qualitatively this can be explained in terms of three types of hydrogen bonded interactions when base concentration is increased. At low concentrations, the base, being a strong hydrogen bond acceptor, removes the solvent molecules bonded to the indicator thus decreasing its solubility. At intermediate concentrations, the increased indicator ionization coupled with the solvation of the indicator ion increases its solubility. At higher concentrations, this is opposed by hydrogen bonding between the base molecules, the effect being less on the sol-

9) M. I. Vinnik and N. Librovich, *Tetrahedron*, **22**, 2945 (1966).

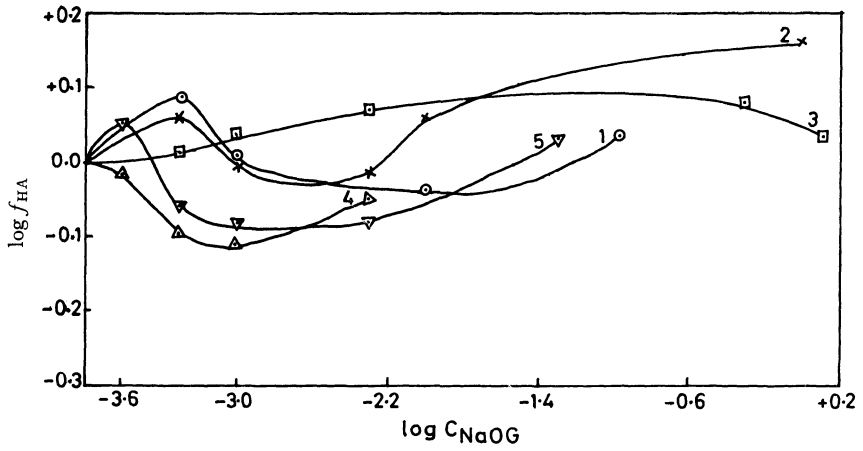

Fig. 1. Plot of $\log f_{HA}$ against $\log C_{NaOG}$ for various indicators in ethylene and propylene glycols.

⊙,△ refer to 2,4,3′-TNDA. ×,▽ refer to 2,4-DNDA. ▣ refers to 2,4-DN-4′-amino-DA.

vation of the indicator ion thus decreasing its solubility. In the case of 2,4-DN-4′-amino-DA the ionization of the indicator being much less, predominantly salting out effect is observed.

Our results show that the ratio of the activity coefficients of two successive indicators in the overlap region decreases from unity at higher base concentrations in ethylene glycol while it increases in propylene glycol. Since it was shown[2] that Eq. (1) is applicable for nitrodiphenylamines in basic solutions of ethylene and propylene glycols, a similar variation should be expected in the case of the activity coefficient ratio of the anionic forms of the indicators. An increase in the number of nitro groups leads to a greater "salting in" effect presumably due to the strong hydrogen bond interactions between these groups and the solvent, the effect being much more pronounced in propylene glycol than in ethylene glycol.

Discussion of Medium Effects. The medium effects for the ions of the various indicators in ethylene glycol are smaller than those in propylene glycol, and the free energy change for the transfer of the ions from water to ethylene glycol is negative while it is positive for propylene glycol.

Application of the Born equation reveals that the free energy change associated with the transfer of the indicator ions (the proton and the indicator anion) from a solvent of high to a low dielectric constant should be positive. Although the results in propylene glycol are in qualitative agreement with that predicted by the Born equation, the results in ethylene glycol are contradictory. This is not surprising since the Born equation takes into account only the electrostatic contribution to the free energy change of transfer while other factors, such as ion-solvent interactions, which depend on solvent basicity and contribute to the non-electrostatic part of the free energy change are ignored. The opposite signs of the medium effects of the indicator ions in the two solvents are undoubtedly due to the differences[2,10] in their solvent basicities. The differences in the medium effects of the ions of the various indicators in a given solvent most possibly arise from the changes in the delocalization of charge caused by the introduction of nitro or amino groups in various positions in the benzene ring. Such differences in charge delocalization affect the ion-solvent interactions considerably.

Grateful thanks are due to Professor M.V.C. Sastri, Head of the Department, for his constant encouragement throughout the work.

Corrosion Reaction of Iron in Phosphatizing Solution

Ryokai SHIRAKAWA,* Shiro TAKEDA,** Takao UMEGAKI,*** and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received June 3, 1970)

An electrochemical investigation was made on the corrosion reaction of iron in phosphatizing solution to clarify the mechanism of the formation of phosphate coating. Polarization characteristic curves revealed the corrosion of iron to be under cathodic control implying that the formation of phosphate coating occurs thus under cathodic control. The corrosion rate increased considerably by the addition of KNO_3 or KNO_2 which is used as an accelerator in phosphatization. The formation of phosphate coating was much accelerated by cathodic polarization of iron, but repressed by anodic polarization and rotation of the iron electrode.

The rate of phosphate coating formation is believed to be controlled by the corrosion rate of metal surface phosphatized. The corrosion reaction is divided into two electrochemical reactions, anodic and cathodic.

It was suggested by Machu[1-3] that the rate of phosphate coating formation is controlled by the anodic reaction at the anodic area, occupying more than 99% of metal surface and shows first order dependency on the anodic area. However, the relation between this rate and the anodic area fails by the addition of an accelerator to the phosphatizing solution because of its depolarization effect.

We found that the phosphate coating formation is basically under cathodic control which seems quite reasonable since the corrosion reaction of metal is usually under cathodic control.

Measurement of polarization characteristic and the rate of dissolution of iron in phosphatizing solutions of various compositions were made to decide the rate-determining step and the rate of corrosion reaction. The influence of the cathodic polarization of iron in the phosphate coating formation was examined.

Experimental

Polarization Characteristic. Solutions having the compositions shown in Table 1 were prepared by dissolving guaranteed pure chemical reagents in redistilled water (electroconductivity 2.2×10^{-6} mho·cm). Because of complications that may arise due to the formation of zinc phosphate coating on iron electrode, no zinc was added to the solution.

Iron electrode, 5 mm in diameter, was cut out from a commercial mild steel whose composition is given in Table 2. The bottom was polished with 0/5 emery paper, degreased with benzene just before the measurement and the other end was inserted into a glass tube support to be rotated in the solution. The rest of the electrode surface was covered with epoxy resin for the sake of insulation from solution. The rotation speed of the iron electrode was changed from 200 to 800 rpm.

Influence of Polarization on Phosphate Coating Formation. The composition of the solution is given in Table 4. The solution was prepared by dissolving ZnO in H_3PO_4 and HNO_3 and diluting with distilled water. The pH of the solution was controlled by addition of K_2CO_3.

TABLE 4. COMPOSITION OF PHOSPHATIZING SOLUTION

H_3PO_4	ZnO	HNO_3	pH
0.20 M	0.10 M	0.07 M	2.6

The same iron electrode and apparatus as those used in the experiment for polarization characteristic were used, except for the replacement of the potentiostat with a galvanostat.

A constant current was applied on the iron electrode in the phosphatizing solution and the change of iron electrode potential with time against SCE was recorded. The phosphate coating formed on the electrode was observed with a microscope.

Results and Discussion

Typical polarization characteristic curves of iron in solutions of various compositions at 600 rpm are shown in Fig. 2.

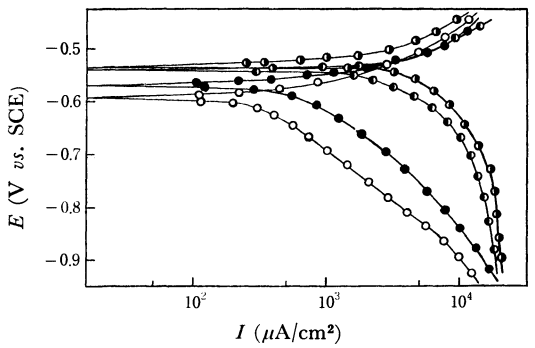

Fig. 2. Polarization characteristic of iron.
○: 0.23 M H_3PO_4 in N_2, ●: 0.23 M H_3PO_4 in air,
◐: 0.23 M H_3PO_4 + 0.10 M KNO_3 in N_2,
◑: 0.23 M H_3PO_4 + 0.10 M KNO_3 + 5 mM KNO_2 in N_2

The anodic polarization curves are smooth in all cases indicating the anodic reactions to be under diffusion control.

On the other hand, the cathodic polarization curves change appreciably with the composition of solution.

In pure H_3PO_4 under nitrogen atmosphere, a straight line called "Tafel slope" is observed on the cathodic polarization curve between the apparent current density of 500 and 5000 $\mu A/cm^2$ indicating the reaction to be under activation control. The intersection of extrapolated line of the Tafel slope and the corrosion potential gives an approximately 300 $\mu A/cm^2$ estimation of the corrosion current.

The polarization curves and the corrosion currents in this condition are not affected by the increase of rotation speed of iron electrode from 200 to 800 rpm except when current density is greater than 5000 $\mu A/cm^2$ where the cathodic polarization becomes slightly smaller with the increase of rotation speed. This could also be explained by the activation control of the corrosion reaction of iron.

In the air, the cathodic polarization curves are smooth for all rotation speeds throughout the range of current density. This indicates the cathodic reaction to be under diffusion control. In this case the corrosion potential becomes more noble than that under nitrogen atmosphere, as the rotation speed increases.

By addition of accelerators such as KNO_3 or KNO_2, the cathodic polarization curves show limiting currents and reactions proceed under diffusion control. The influence of dissolved oxygen is negligible in the presence of the accelerator.

It should be noted that in all cases, the polarization characteristic indicates that the corrosion reaction of iron in the phosphatizing solution namely the phosphate coating formation, is under cathodic control.

Figure 3 shows the corrosion current of iron in pure H_3PO_4 calculated from the amount of dissolved iron, assuming that the reaction is $Fe \rightarrow Fe^{2+} + 2e$, and applying the Faraday rule.

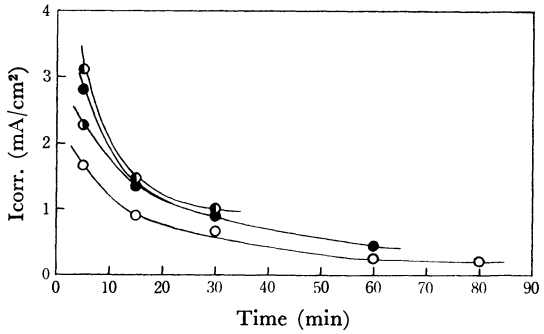

Fig. 3. Corrosion current of iron in H_3PO_4.
H_3PO_4 concn. ◐: 0.10 M Atmosphere ○: N_2
●○: 0.23 ●◐◑: air
◑: 0.50

The corrosion current diminishes exponentially with time and approaches a constant value under nitrogen or air atmosphere because of inactivation of iron surface. In the air, the corrosion rate is always greater than that under nitrogen atmosphere, while the difference of concentration of H_3PO_4 shows no influence on corrosion current. This shows that the reaction is mainly due to the oxygen dissolved in solution.

The corrosion current 300 $\mu A/cm^2$ obtained from the polarization characteristic corresponds to the value shown at 60—80 min in this case.

Figure 4 shows the corrosion rate of iron expressed by the dissolution rate of iron in H_3PO_4 containing various amounts of KNO_3 and KNO_2. Each plot is an average of three values obtained at 5, 15, and 30 min except those in pure H_3PO_4 which was taken only at 15 min. This is because when either KNO_3 or KNO_2 is present in the solution, the dissolved iron increases linearly with time showing constant corrosion rate within a deviation ±10%, while the corrosion rate changes considerably in the case of pure H_3PO_4. The corrosion rate increases with the increase of the concentration of added KNO_3. An increase of KNO_3 concentration from 0.05 to 0.50 M accelerates the corrosion rate by a factor of 4. KNO_2 has 30—70 times greater accelerating effect on the corrosion rate than

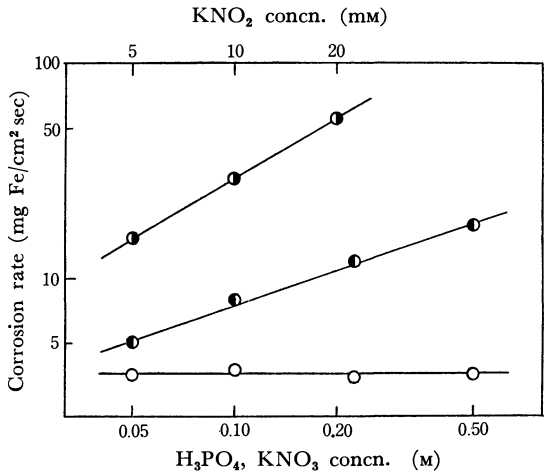

Fig. 4. Corrosion rate of iron in H_3PO_4 with KNO_3 or KNO_2.
○: pure H_3PO_4, ◐: 0.23 M H_3PO_4 + KNO_3,
◑: 0.23 M H_3PO_4+KNO_2

KNO_3.

It has also been found that the corrosion rate is not affected at all by the change of pH of the solution from 1.5 to 4.5 in pure H_3PO_4 but decreases to almost 1/6 by the same pH elevation when KNO_3 or KNO_2 is present in the solution. The increase of rotation speed of iron electrode from 100 to 600 rpm increases the corrosion rate by a factor of 2 in H_3PO_4 containing 0.1 M of KNO_3. This indicates that the corrosion rate is approximately proportional to the square root of the rotation speed of iron electrode.

When a cathodic current is applied to the iron electrode, active area on the iron surface decreases with the formation of phosphate coating, the iron electrode potential falling gradually, suddenly drops to the potential of electrodeposition of zinc. The time lap between the application of cathodic current and the sudden change of potential was measured as a phosphatizing time τ of iron electrode. Reproducibility of τ was examined and the deviation was found to be within ±20%.

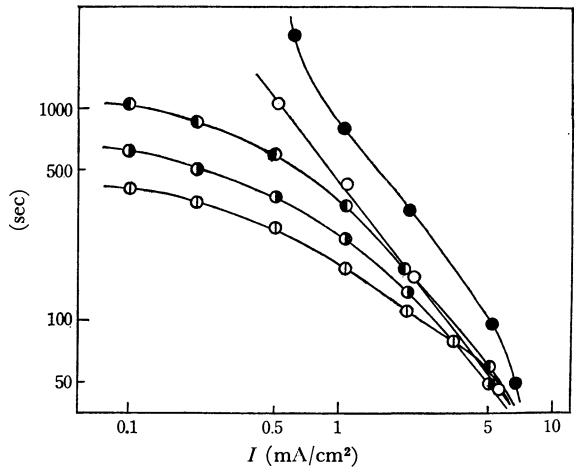

Fig. 5. Influence of cathodic polarization.
KNO_2 concn. ○●: 0 mM Rotation speed ○: 0 rpm
◐: 2.5 ●◐◑◌: 600
◑: 5
◌: 10

It is obvious from Fig. 5 that the cathodic polarization accelerates the coating formation considerably, but the rotation of electrode at 600 rpm represses it. This is due to the excessively large corrosion rate of iron surface caused by the rotation of the electrode. Coating formation is accelerated to a greater extent with the concentration of added KNO_2. The influence of cathodic polarization of iron electrode on

Fig. 6. Phosphate coating on buff-polished iron. (5 min, ×160)

Fig. 8. Phosphate coating on buff polished iron.
(5 min, ×160)
Without cathodic current, rotation at 600 rpm.

the coating formation is clearly seen in Figs. 6 and 7. This shows the phosphate coating formed on the buff-polished iron electrode.

The cathodic polarization increases the number and growth rate of phosphate crystals (Fig. 6) in comparison with that which is not polarized (Fig. 7). The rotation represses the phosphate coating and increases the corrosion of iron surface as seen in Fig. 8.

On the other hand, the anodic polarization of iron electrode shows no comparable effect on the coating formation as observed with the cathodic polarization when polarization is small. As the polarization is increased, the coating formation is repressed and the dissolution of iron electrode increases.

Conclusions

The corrosion reaction of iron which is the first step of phosphate coating formation was investigated from an electrochemical viewpoint and the following conclusions were obtained.

1) The corrosion reaction of iron in the phosphatizing solution is under cathodic control. Thus, the phosphate coating formation is also under cathodic control. The influence of diffusion rate can not be neglected.

2) The corrosion rate of iron is increased by KNO_3 and KNO_2, the latter being more effective.

3) The cathodic polarization of iron accelerates the phosphate coating formation considerably, while anodic polarization and rotation of the iron electrode represses it.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1010—1013 (1971)

The Spectroscopic Observation of the Selective Volatilization of Metal Solid Samples in a Nitrogen Plasma Flame[1)]

Masaoki Oku and Kichinosuke Hirokawa

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received June 5, 1970)

Some metal solid samples were burned in a nitrogen plasma flame, and the spectrum intensity-time curves were spectrographically observed. The curves indicated that the fractional distillation of alloying elements was caused by the reactions of the solid-alloy sample and nitrogen gas. The fractional distillation was explained in terms of the difference in the stabilities of the metal nitrides. The distribution of the emission species and the temperature of the flame suggested that there were few chemical reactions in the flame or that the chemical reactions in the flame had little effect on the spectrum intensities. In an appendix, the method of line-pair selections for obtaining the correct temperature is considered.

Many molecular species, such as MO, OH, and CN, are produced by the introduction of solution samples into a plasma flame; they cause the high background spectra. The use of a metal solid sample instead of the solution may eliminate some of them, but the difficulties of the use of a solid sample are present in the complications of sample charging, high-temperature physicochemical reactions in an electrode, and the evaporation process of electrode materials. Several excellent discussions of fractional distillation or selective vaporization have already been reported.[2-4)] However, few papers have discussed the fractional distillation resulting from the reactions of elements in a metal electrode with gases which produce plasmas. In a previous report,[5)] a burner which produced a current-free nitrogen plasma jet flame was used for the spectrographic analysis of metal solid samples. With it, satisfactory calibration curves were obtained

for the determination of some alloying elements in iron alloys, but for the alloying elements in aluminum alloy the precision was not satisfactory because of the sputtering of aluminum as aluminum nitride. In this report, the evaporation process of aluminum alloy and iron alloy, the emission profiles for metallic species in the nitrogen plasma flame, and the flame temperature will be investigated.

Experimental

The apparatus was the same as that described in the previous report.[5] The spectra were photographed under the following conditions: sample, 15 mm in length and 5 mm in diameter; polarity, anode; condenser voltage, 230—250 V; arc current, 13—15 A; tangentially-introduced gas-flow rate, 1.4 *l*/min; atomizer gas-flow rate, 4.2 *l*/min; slit width of spectrograph, 30 μ. Fuji spectrographic plates were developed with F.D. 131 at 20°C for 5 min. In order to measure the distribution of spectrum intensities along the vertical axis of the nitrogen plasma flame, the flames were imaged on the spectrographic slit with a 10-sec exposure after a predischarge of 120 sec. The intensity-time curves were obtained by a focused image of the flames on a condenser lens and by repeating a 10-sec exposure and a 20-sec interval after a predischarge of 5 sec. A Shimadzu ARL electron X-ray microprobe analyser was used for microanalysis; it had an accelerating voltage of 20 kV.

Results and Discussion

The vertical emission profiles for metallic species in the nitrogen plasma flames produced by an aluminum alloy (Si, 0.75; Cu, 0.90; Mg, 2.32; Zn, 3.06; Fe, 0.09; Mn, 0.274; Pb, 0.40; Bi, 0.58; Cr, 0.177; Ti, 0.266%) and by an iron alloy (V, 1.72%) are shown in Figs. 1 and 2 respectively. The spectrum intensities are normalized to the intensity of the part, 0.3 to 0.9 mm above the top of the burner. There were no proper two lines for measuring the temperature for the aluminum alloy flame. Therefore, the temperature was measured only for the iron alloy flame with the line-pair of FeI 3214.40 and FeI 3219.59. The method of selecting line-pairs for obtaining the correct temperature will be considered in an appendix. The temperature distribution curve along the vertical axis of the plasma flame is shown in Fig. 3. The higher a position in the flame, the lower the temperature. This suggests that the flame is cooled by the surrounding air and has no exothermic reactions at least. Moreover, the monotonous and nearly uniform decrease in the spectrum intensities with the height of the flame indicates that there are few reactions in the flame or that the chemical reactions have little effect on the

spectrum intensities.

For some elements in aluminum alloy, the intensity-time curves are shown in Figs. 4 and 5. Aluminum, magnesium, silicon, chromium, nickel, zinc, and lead make one group. Their intensities decreased with the time, though the rates of decrease were small. However, the intensity of manganese had risen in the early stage, and then, after a diminution, increased gradually again. The spectral intensity of titanium had decreased at first and then after an increase, decreased again. The intensity-time curve of a solid sample was not, of course, the same in each discharge, but the patterns of the curves appeared similar.

For some elements in iron alloys, the intensity-time curves are shown in Figs. 6 and 7. Nearly constant spectral line-intensity ratios with time were obtained for manganese, molybdenum, and vanadium in iron. On the other hand, the spectrum intensity ratios aluminum and titanium to iron decreased with the time. These patterns were also similarly maintained in each discharge.

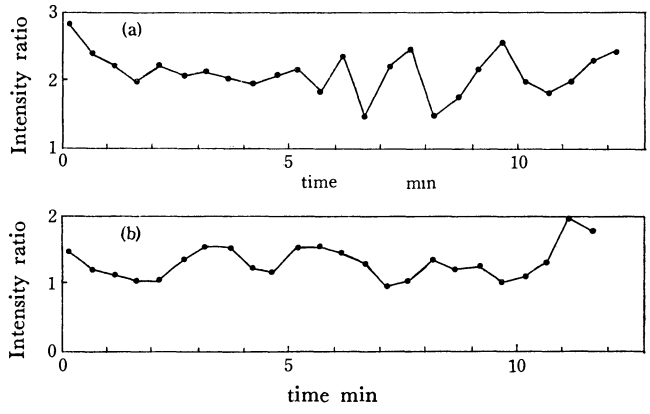

Fig. 6. Intensity-time curve for Mn in Al-Mn-Steel, MnI 2801.06/FeI 2840.42 (a); and Mo in Mo-Steel, MoI 3864.11/FeI 3805.34 (b).

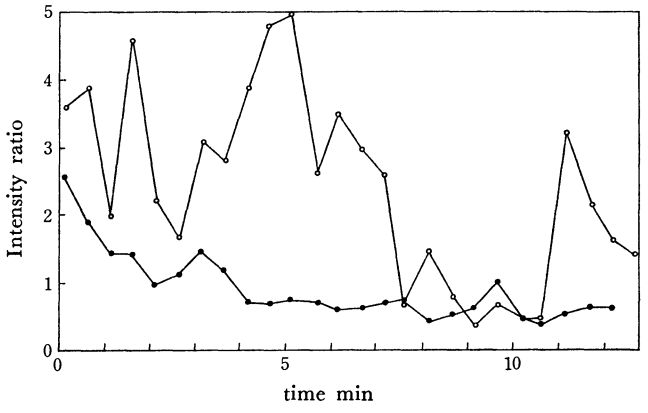

Fig. 7. Intensity-time curve for Ti, in Ti-Steel, and Al in Al-Mn-Steel.
○, TiI 3653.50/FeI 3451.92; ●, AlI 3092.71/FeI 3142.45

The flame temperature of titanium-iron alloy was around 4600—4900°K during the burning period. The flame used was current-free, so that violent change in the excitation conditions of the plasma during the burning period is not considered. Since the emission-spectral-line intensities from the flame under constant conditions are proportional to the concentration of the elements in the flame, the intensity-time curves are considered to be equivalent to the evaporation rate-time curves. The evaporation rates may depend to a considerable degree upon the chemical reactions on the electrode. Figures 4 to 7 may, consequently, indicate that there is a relationship between the intensity-time curves and the reactions on the electrode. The equilibrium between metals and the corresponding nitrides have been represented graphically by Darken and Garry.[6] The equilibrium is represented:

$$x\mathrm{M}_{(\mathrm{solid})} + \mathrm{N}_{2(\mathrm{gas})} = \mathrm{M}_x\mathrm{N}_{2(\mathrm{solid})}$$

Iron nitride decomposes at a low temperature, and titanium nitride is more stable at a high temperature. The partial pressure of the nitrogen of other metal system comes between the partial pressure of the iron system and that of the titanium system at the same temperature, as in Darken and Garry's graph. In the case of the aluminum matrix, the evaporation-rate ratio of aluminum to metal, which forms not so stably as aluminum, is nearly constant. Titanium is concentrated on the electrode surface of the electrode, titanium may intermittently evaporate in large quantities; then a second decrease is observed. In the case of the iron matrix, aluminum and titanium behave similarly. In electron-microprobe analysis, the intensity of Ti$K\alpha$ on the discharged surface of the sample was higher than that of other parts, and N$K\alpha$ was observed in the same places. These findings indicated that titanium was concentrated as titanium nitride there. Titanium nitride was observed even in the heated area of the bulk sample. However, the behavior of manganese could not be explained.

Conclusion

The reactions of solid-sample metal with nitrogen gas, which produces an arc plasma, cause a fractional distillation of the elements in samples. It indicates that a nitrogen plasma flame may not be adequate for the determination of titanium and zirconium in some alloys because of the higher stabilities of their nitrides. The differences in the stabilities of metal nitrides cause a fluctuation in the emission spectral intensity ratios.

Appendix

The fundamental equation for temperature measurement according to the two-line procedure is:

$$I_a/I_b = (gA)_a/(gA)_b \cdot \nu_a/\nu_b \cdot \exp(-(V_a - V_b)/kT).$$

if the lines are labelled a and b (I, relative intensity; g, statistical weight; A, relative transition probability; ν, frequency; V, excitation potential). Boumans[7] discussed the effect of $V_a - V_b$ and the $(gA)_a/(gA)_b$ ratio upon the relative error ($\Delta T/T$) of the temperature. The error, however, depends not only on them but also on the value of the I_a/I_b ratio.

a) In lines A and B the ratio $\Delta I/I$ ($I=I_a/I_b$) is larger than 4% and 10% respectively when the ratio $\Delta T/T$ is 2%. The combinations were made by atomic spectra line-pairs of iron expect Table 4. +, CuI; ++, ZnI; +++, CrI.

In experiments, especially with photographic plates, the range of the intensity ratio, $I(I_a/I_b)$, may be restricted to that between 0.1 and 10.0. The usual relative standard deviation of the spectrum intensity is larger than 2 per cent. Thus, if the $\Delta I/I$ is smaller than 4 per cent when I varies from I to $I+\Delta I$, the calculated temperature is not reliable. Since the small standard deviation in the temperature by the plotting method is 110°K at 5100°K,[8)] temperature ranges where where determination errors are within 2 per cent are presented in the tables. Tables 1—4 show the combination of $V_a - V_b$, $(gA)_a/(gA)_b$, the corresponding temperature ranges. The values of gA are based on the measurement of Corliss and Bozman.[9)] In the A and B lines, the $\Delta I/I$ ratios are larger than 4 per cent and 10 per cent respectively when the $\Delta T/T$ ratios are 2 per cent.

Thermal Annealing Behavior of the Recoil ^{57}Co Formed by the Decay of ^{57}Ni-Labeled Hexamminenickel(II) Complexes

Takashi Omori, Shaw-Chii Wu, and Takanobu Shiokawa
Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai
(Received August 26, 1970)

Thermal annealing reactions of ^{57}Co formed by the EC and β^+-decay of the ^{57}Ni-labeled hexamminenickel(II) halide complexes were investigated in detail by means of ion-exchange techniques. When the annealing is carried out at high temperatures, the chemical behavior of ^{57}Co is remarkably affected by the thermal decomposition of the parent and daughter complexes. In the intrinsic annealing, however, the annealing curves have characteristic shapes and the plateau yields of $^{57}Co(NH_3)_6^{3+}$ ion are independent of the temperature, depending on the nature of the outer-sphere anion. The unusual oxidation reaction of the recoil ^{57}Co(II) species is explained by the action of the crystal defects in the near-neighborhood of the recoil site.

Since Collins and Harbottle[1] found that the annealing reaction can take place in the hexabromoethane even if the γ-dose is negligibly small, there have appeared several studies of the intrinsic annealing of the recoil atom in the decay-atom system. For instance, Andersen *et al.*[2,3] have reported that, in the β^--decay process of $K_2{}^{125}SnCl_6$, the distribution of ^{125}Sb is strongly affected by the inherent crystal defects in the crystal, while in the IT process of $^{127m}Te(OH)_6$, the influence of crystal defects introduced prior to the decay event on the initial distribution of ^{127}Te and on the thermal annealing reaction can be ignored. In the IT process of $K^{80m}BrO_3$, it has also been found that the thermal annealing might be promoted by the inherent crystal defects.[4]

Studies of the intrinsic annealing process, therefore, would seem to provide very important information on the recombination mechanism in the solid phase. In a previous paper,[5] the chemical behavior of the ^{57}Co produced by the EC and β^+-decay of the ^{57}Ni-labeled hexamminenickel(II) complex was reported. The results showed that a fairly large amount of the ^{57}Co(III) species is produced, depending on the nature of the outer-sphere anion. Moreover, the heating of the sample at 60°C generally increases the yield of the cobalt(III) species. The present study has been carried out in order to clarify the thermal-annealing behavior of ^{57}Co in the hexamminenickel(II) halide complexes.

Experimental

All the reagents used were of a guaranteed-reagent grade.

Nickel-57 was produced by a (γ, n) reaction using an electron linear accelerator of Tohoku University. Nickel oxide which had been irradiated by bremsstrahlung with a maximum energy of 40 MeV was dissolved in concentrated hydrochloric acid, and then the solution was passed through an anion-exchange resin in order to separate the ^{57}Co produced by the EC and β^+-decay of ^{57}Ni and that produced by the (γ, p) reaction.[6] The ^{57}Ni-labeled hexamminenickel(II) halides were synthesized by ordinary methods[7] and were then stored in the dark at the temperature of dry ice. After the complete decay of the ^{57}Ni, the ^{57}Co-labeled species were separated by means of a cation-exchange resin method, with reference to the procedure previously reported by Ikeda *et al.*[8]

The thermal-annealing procedure was carried out in a constant boiling bath or in an electric oven. Crystals were placed in brown glass tubes in air unless otherwise stated. The macroscopic thermal decomposition of the hexamminenickel(II) complexes was studied under the same conditions as was the thermal annealing.

The radioactivity of ^{57}Co was measured with a 100-channel pulse-height analyzer equipped with an NaI(Tl) well crystal.

Results and Discussion

In the present investigation, the following ^{57}Co recoil species were separated by means of a cation-exchange resin method: $^{57}Co^{2+}$, $^{57}CoX(NH_3)_5^{2+}$, and $^{57}Co(NH_3)_6^{3+}$, where X denotes Cl, Br, or I. The experimental results for the initial distribution of ^{57}Co-labeled species in the hexamminenickel(II) complexes are summarized in Table 1. The yields shown are average values of at least five determinations.

Table 1. Initial yield of ^{57}Co-labeled species in hexamminenickel(II) halides

Compound	Yield of ^{57}Co-labeled species (%)		
	Co^{2+}	$CoX(NH_3)_5^{2+}$	$Co(NH_3)_6^{3+}$
$[^{57}Ni(NH_3)_6]Cl_2$	72.6±1.5	2.3±0.5	24.7±0.8
$[^{57}Ni(NH_3)_6]Br_2$	72.8±1.7	1.6±0.4	25.7±1.6
$[^{57}Ni(NH_3)_6]I_2$	70.3±2.0	2.7±0.6	26.9±1.5

Although the initial yields of the radioactive ^{57}Co species in the hexamminenickel(II) halides are nearly all equal, there appears a remarkable difference among the isothermal annealing curves, as is shown in Figs.

1—3. In all cases, an increase in the $^{57}Co(NH_3)_6^{3+}$ yields corresponds substantially to a decrease in the $^{57}Co^{2+}$ yield, and the yield of the ^{57}Co-labeled halopentamminecobalt(III) fraction is almost independent of the heating time and the temperature. Thus changes in the $^{57}CoX(NH_3)_5^{2+}$ yield are not plotted in the figures.

Figure 1 shows the annealing curves for the chloride complex. For temperatures below 80°C, the annealing isotherms exhibit normal kinetic patterns. At 119°C, the yield of the $^{57}Co(NH_3)_6^{3+}$ fraction increases at first, then reaches a maximum after 2 hrs' heating and subsequently decreases. This kind of annealing pattern is presumably due to the thermal decomposition of the reformed complex.

In the bromide complex, the annealing isotherms at various temperatures are shown in Fig. 2. Up to 100°C, the annealing curves possess characteristic shapes; that is, they show the inflection near the point

○, △, □: $^{57}Co^{2+}$; ●, ▲, ■: $^{57}Co(NH_3)_6^{3+}$

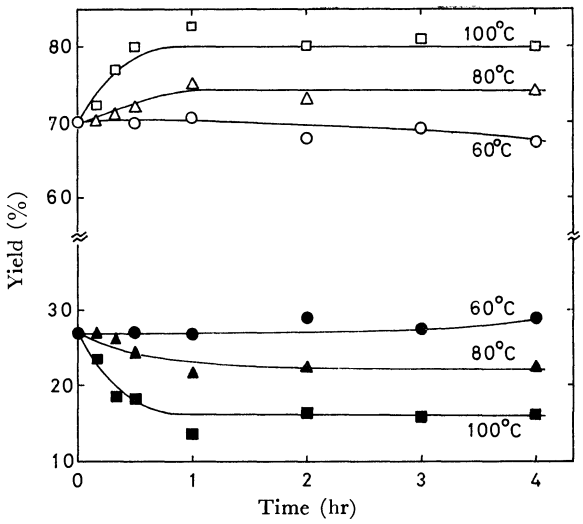

Fig. 3. Isothermal annealing curves of ^{57}Co in $[^{57}Ni(NH_3)_6]I_2$.
○, △, □: $^{57}Co^{2+}$; ●, ▲, ■: $^{57}Co(NH_3)_6^{3+}$

of origin. However, the curve at 119°C shows a normal kinetic pattern.

In the iodide complex, the annealing isotherms differ appreciably from those of the chloride and bromide complexes, as is shown in Fig. 3. The $^{57}Co(NH_3)_6^{3+}$ yield decreases gradually at 80°C, though it increases slightly at 60°C after 4 hrs' heating.

These experimental results suggest that the chemical behavior of the recoil ^{57}Co atoms in the nickel(II) complexes is influenced by the thermal decomposition of the daughter cobalt complexes. It is necessary to study also the effect of the thermal decomposition of the parent complexes, because the hexamminenickel(II) chloride decomposes at a lower temperature than does the hexamminecobalt(III) chloride.[9]

The macroscopic thermal decomposition of the hexamminenickel(II) chloride was noticeable after heating for 4 hr at 80°C, where it amounted to 6.2 per cent, while at 70°C no appreciable decomposition was observed after 20 hrs' heating. In the bromide and iodide complexes, no macroscopic decomposition of the crystal took place after 4 hrs' heating at 80°C, but the decomposition began at 100°C.

On the basis of the data for the thermal decomposition of the parent nickel(II) complexes, the chemical behavior of the recoil ^{57}Co atoms can be explained as follows: when the parent complex is thermally stable, the annealing reaction does not proceed essentially after 4 hrs' heating. On the contrary, when the parent complex, $[Ni(NH_3)_6]Cl_2$, begins to decompose, the $^{57}Co(NH_3)_6^{3+}$ yield increases remarkably. This suggests that freely-available ammonia molecules will participate in the formation reaction of the hexamminecobalt(III) complex. In the iodide, however, the decrease in the $^{57}Co(NH_3)_6^{3+}$ yield at 80°C is possibly to be ascribed to low thermal stability of hexamminecobalt(III) iodide, since the thermal

9) W. W. Wendlandt and J. P. Smith, "Thermal Properties of Transition-Metal Ammine Complexes," Elsevier, Amsterdam (1967).

decomposition of the hexamminenickel(II) iodide can be ignored.

In the (n, γ) process of the hexamminecobalt(III) complexes, Yasukawa and Saito[10,11] have also found that the thermal annealing reaction of ^{60}Co to reform the parent is promoted by the atmosphere of ammonia gas. This effect was interpreted in terms of the diffusion of ammonia, penetrating into the interior of the crystal and reacting with fragments to reform the parent.

Extensive kinetic studies of the thermal decomposition of the hexamminecobalt(III) complexes have been carried out by Tanaka and Nagase.[12] They proposed that the decomposition of $[Co(NH_3)_6]Cl_3$ *in vacuo* proceeds as follows:

$$[Co(NH_3)_6]Cl_3 \rightarrow [Co(NH_3)_6]Cl_2 + Cl \rightarrow CoCl_2 + 6NH_3 + (1/2)Cl_2 \quad (1)$$

The first step, which is rate-determining, is the electron-transfer process from the outer-sphere chloride ion to the central cobalt(III) ion. The reaction of the second step is very fast, because hexamminecobalt(II) chloride is thermally unstable. On the other hand, when the samples were treated in a sealed system or in air, the reaction was complicated:

$$[Co(NH_3)_6]Cl_3 \overset{A}{\rightleftharpoons} [Co(NH_3)_6]Cl_2 + (1/2)Cl_2 \rightleftharpoons R$$
$$\overset{B}{\longrightarrow} [CoCl(NH_3)_5]Cl_2 + NH_3 \overset{A'}{\rightleftharpoons}$$
$$[Co(NH_3)_5]Cl_2 + (1/2)Cl_2 + NH_3 \rightleftharpoons R \quad (2)$$

where R represents the mixture of the decomposition products. The B process takes place when the electron-transfer reaction is strongly interfered with. It should be noticed that the A process of Eq. (2) is a reversible electron-transfer reaction, in which oxygen in the air can oxidize the cobalt(II) to cobalt(III) complexes instead of halogen molecules. In both systems, the order of the increase in the rate of the electron-transfer reaction is expressed as follows: $[Co(NH_3)_6]Cl_3 < [Co(NH_3)_6]Br_3 < [Co(NH_3)_6]I_3$.

In the present system, the apparent annealing reaction is the oxidation of the cobalt(II) ion to the cobalt(III) ion. Since the yield of the halopentammine-cobalt(III) ion does not vary during the annealing reaction, the oxidation reaction seems to proceed as the reverse of the reaction expressed in the A process of Eq. (2). Furthermore, the fact that, when the ammonia molecules produced by the thermal decomposition of the parent complex are available, the formation of the hexamminecobalt(III) ion proceeds rapidly and extensively, suggests that the reformation of $^{57}Co(NH_3)_6^{2+}$ is also a rate-determining step in the thermal annealing.

In order to study further the effect of the ammonia molecules, a thermal annealing reaction in air was compared with that in a vacuum-sealed tube. After heating for 12 hr at 80°C, the $^{57}Co(NH_3)_6^{3+}$ yield increases to 24.9 per cent in the sealed system, but only to 15.1 per cent in air. In the sealed system, the ammonia molecules formed by the decomposition of the hexamminenickel(II) ion cannot escape from the system and participate in the reformation reaction.

In Mössbauer studies, the formation of $^{57}Fe(III)$ species is often observed in the EC process of the ^{57}Co-(II) compound.[13] In the hot-atom chemistry of the solid state, however, few examples have been reported of the oxidative reaction in the recoil process.[14] In other words, the recoil species other than the parent are, as a general rule, found, partly or entirely, in an oxidation state lower than their original condition. On annealing, the parent compound is reformed, even if the recoil species is found in a higher oxidation state than is the parent. These trends suggest that the chemical behavior of the recoil species is influenced mostly by the crystal matrix of the parent compound and secondarily by the chemical nature of the recoil species.

The present results contrast strongly with the general trends and indicate that the chemical property of the daughter species plays an important role in determining the chemical fate of the recoil atom in the foreign matrix. As an extension of this discussion, further study of the chemical behavior of the recoil ^{57}Co was designed in the temperature region where the effect of the thermal decomposition could be ignored. The experimental results are summarized in Fig. 4.

Table 2. Thermal annealing of ^{57}Co-doped hexamminenickel(II) complexes

Compound	Thermal treatment	Yield of ^{57}Co-labeled species (%)		
		Co^{2+}	$CoX(NH_3)_5^{2+}$	$Co(NH_3)_6^{3+}$
$[Ni(NH_3)_6]Cl_2$	None	51.8	0.1	48.2
	100°C, 4 hr	50.6	0.5	48.9
$[Ni(NH_3)_6]Br_2$	None	57.5	0.1	42.4
	100°C, 4 hr	57.3	0.2	42.5

The shape of these annealing curves is similar to that in the bromide complex at 100°C. However, some interesting features can be found: the characteristic plateau values are dependent on the nature of the outer-sphere anions, but independent of the temperature, and the order of the increase in the rate of the annealing reaction is expressed as follows: chloride> bromide>iodide.

Mathematical analyses showed that a composite annealing curve for the present data is incompatible with a single first- or second-order rate process, nor does it fit error-function kinetics. However, some qualitative explanation would be possible on the supposition that, in this temperature region, the annealing reaction could be considered to be stoichiometrically the same as that taking place at higher temperatures.

About 53 per cent of the decay events of ^{57}Ni is the EC process, and the remainder is the β^+-decay.[15] The recoil energy (max. 34 eV) is too low for the ^{57}Co atoms to allow displacement into the interstitial site.[16] However, the electronic excitation following the decay will affect the chemical behavior of the daughter species.

The emission of a positron from the nucleus of a constituent atom should produce a negatively-charged species. Accordingly, the immediate effect of the decay of the $^{57}Ni(II)$ complex would be the formation of the univalent cobalt complex, and this cobalt complex would be found in the cobalt(II) species upon dissolution. On the other hand, the decrease in nuclear charge by electron capture is balanced by the decrease in the number of electrons. However, the vacancy created in the K shell is followed by the Auger cascade, which results in a multiply charged daughter species.[17] The neutralization of the charged ion causes the decomposition of the compound and creates the crystal defects surrounding the recoil atom. In this case, the recoil species will be found in the oxidation states of Co(II) and Co(III).[13]

The electron-transfer reaction is also affected by the oxidative power of the outer-sphere anion.[5] In the halide complexes, the driving force for the oxidation seems to be electron trapping by positive holes produced during the neutralization of multiply-charged recoil species. In fact, the annealing rates increase with an increase in the electron affinity of the halogen atom. A thermal ionization mechanism for the thermal annealing of ^{60}Co in the hexamminecobalt(III) bromide has been proposed by Yoshihara and Harbottle.[18] This explanation was further confirmed by the ^{57}Co-doping experiment. The ^{57}Co-doped hexamminenickel(II) complexes which were synthesized from a solution of the nickel(II) ion containing carrier-free ^{57}Co were subjected to thermal treatment. In this case, all the ^{57}Co may exist in the form of the hexammine complex. The experimental results are listed in Table 2. The fairl large $^{57}Co(NH_3)_6^{3+}$ yield is due to the air-oxidation of the cobalt(II) ion during synthesis. No appreciable change in the $^{57}Co(NH_3)_6^{3+}$ yield is observed at 100°C, where the annealing behavior of the recoil ^{57}Co is noticeable, as may be seen in Fig. 1. This fact indicates that, when the crystal defects are absent in the near-neighborhood of the ^{57}Co atom, the oxidation reaction of the cobalt(II) species does not take place.

The temperature-independent plateau value of the $^{57}Co(NH_3)_6^{3+}$ yield suggests that the intrinsic annealing takes place in a small region affected by the recoil. If the damage to the crystal lattice is extensive, synthetic reaction such as the formation of the pentamminecobalt(III) complex will occur simultaneously, as has been pointed out by Yoshihara.[19]

We wish to express our thanks to Dr. M. Yagi and the operating group of LINAC for their kind arrangements for the irradiation and to Dr. K. Yoshihara for his valuable discussion. We are also very grateful to the Ministry of Education for a grant to T. O., and to the Atomic Energy Council, Republic of China, for a grant to S. C. W.

Kinetic Studies of the Electron Transfer Reaction in Iron(II) and Iron(III) Systems. III. Complex Formation and Catalytic Action with Thiocyanate Ion in Dimethyl Sulfoxide[1]

Goro WADA, Noriko YOSHIZAWA, and Yoko SAKAMOTO

Department of Chemistry, Nara Women's University, Nara

(Received August 28, 1970)

The formation constants K_1 and K_2 of the complexes $Fe(NCS)^{2+}$ and $Fe(NCS)_2^+$ in dimethyl sulfoxide (DMSO) and the rate constants and the activation parameters of the electron transfer reaction between Fe(II) and Fe(III) in DMSO catalyzed by thiocyanate ion were measured. K_1 and K_2 are $(8.4\pm0.9)\times10^2$ M^{-1} and $(0.97\pm0.10)\times10^2$ M^{-1} at $\mu=0.1$ M and 25°C, respectively. The apparent rate constant k_{app} is nearly independent of acid concentrations and increases markedly with total thiocyanate ion concentration. The rate constants k_1 and k_2 of Fe^{2+}-$Fe(NCS)^{2+}$ and Fe^{2+}-$Fe(NCS)_2^+$ systems are $(2.24\pm0.35)\times10^2$ M^{-1}sec^{-1} and $(2.96\pm0.64)\times10^3$ M^{-1}sec^{-1} at $\mu=0.2$ M and 25°C, respectively. $\Delta H_1^{\neq}=8.9\pm1.0$ kcal/mol and $\Delta S_1^{\neq}=-17\pm3$ cal/deg·mol are obtained from the temperature dependence of k_{app}. From a comparison with the data of cases catalyzed by Cl^- and SCN^- ions in water and DMSO, the present electron transfer reaction is deduced to proceed probably *via* the inner-sphere mechanism with the SCN^- ion as a bridging ligand, similar to the Cl^- ion-catalyzed reaction in DMSO.

In the electron transfer reaction between iron(II) and iron(III) species in aqueous solutions, the hydrogen atom transfer mechanism seemed to prevail because the hydrogen atoms of water molecules played an important role.[2] This was proved directly and indirectly by further evidence that the reaction still proceeded at a considerable rate even in the solid state[3] or in the very concentrated perchloric acid media[4] and that the reaction rate decreased with the addition of certain substances, such as nitromethane,[5] 2-propanol,[6] and some other alcohols,[7] because no or less exchangeable hydrogen atoms attached to the molecules of these substances. However, dimethyl sulfoxide (DMSO) was found to be not a substance making the reaction proceed slower but rather to be a medium better than water for the reaction, although DMSO seems to have no such exchangeable hydrogen atoms through which long chains of molecules are formed by hydrogen bondings, as water molecules easily do.[8] Moreover, the rate constants of the electron transfer reaction catalyzed by the chloride ion in this solvent are much larger than those in water.[9] Thus, there must be a reaction path other than the path *via* the hydrogen atom transfer mechanism.

According to recent more precise investigations, the electron transfer reactions of both the Fe^{2+}-$FeCl^{2+}$ [10] and Fe^{2+}-$FeNCS^{2+}$ [11] systems proceed predominantly even in aqueous solutions, *via* the inner-sphere mechanism and not *via* hydrogen atom transfer mechanism.

The present work was undertaken to see what effect thiocyanate ion has on the rate of the electron transfer reaction in DMSO, as compared with the case in which chloride ion was used in the same solvent.[9] In order to obtain the individual rate constants of the elementary reactions, the formation constants for the complexes between the existing species in DMSO had to be determined first. This was performed by the methods used in our previous investigation in the iron(III)-chloride ion-DMSO system.[12]

Experimental

Materials. Commercial DMSO of guaranteed reagent grade was distilled under a reduced nitrogen atmosphere of 3—4 mmHg, dried by shaking with activated alumina, and redistilled under the same condition. Iron(II) perchlorate crystal was prepared by dissolving pure iron wire in dilute perchloric acid and recrystallizing under an atmosphere of nitrogen. Iron(III) perchlorate was, then, easily prepared by oxidation of the iron(II) salt by hydrogen peroxide and the following recrystallization. Both crystals were not anhydrous but contained some lattice water. This did not matter at all, since the crystals were used only at very dilute concentrations and it was confirmed that a small amount of water does not seriously influence the results. Anhydrous sodium perchlorate was obtained by drying monohydrous salt recrystallized from water at 300°C. Anhydrous ammonium thiocyanate was obtained by storing wet crystal in a desiccator at room temperature, after recrystallization twice. The perchloric acid in DMSO was prepared by means of cation exchange resin. Dowex 50 w×8 resin of 50—100 mesh was treated with 6 N hydrochloric acid to transform it into H-type, washed with water to eliminate chloride ion completely, dried in an electric oven at a temperature not over 100°C, allowed to swell in DMSO, filled in a column, and then made to pass through a DMSO solution of 0.7 M ammonium perchlorate, until ammonium ion became detectable by the Nessler reagent in the eluent. The ammonium-free perchloric acid in DMSO obtained

was titrated with sodium hydroxide.

The stock solution of the radioactive tracer of ^{59}Fe was manufactured as follows: The radioactive $*FeCl_3$ in hydrochloric aqueous solution was heated in an evaporating dish, and a few drops of perchloric acid were added just before dryness. After repeating the procedure several times, the final perchloric salt was dissolved in DMSO and stored in the cold.

Photometry. For determination of optical densities of sample solutions, a Hitachi-Perkin-Elmer UV-VIS spectrophotometer Model 139 was used with a thermostated cell compartment and 1-cm silica cells.

Rate Measurements of Electron Transfer Reactions. The reaction was started by mixing two solutions, A and B, in a reaction vessel in a thermostat. Contents of solution A were $Fe(ClO_4)_3$ (labeled with ^{59}Fe), NH_4SCN, $HClO_4$, and $NaClO_4$. Those of solution B were the same as solution A except for $Fe(ClO_4)_2$ in place of $Fe(ClO_4)_3$. Nitrogen gas saturated with DMSO vapor was continuously bubbled through the reaction solution before and after the initiation of the reaction. Nitrogen bubbling was carried out not only for stirring but also for preventing oxidation. At certain intervals, an aliquot of the reaction solution was quickly taken out by a syringe or a thermostated pipet, into a quenching solution containing 2,2′-bipyridyl which immediately stopped the reaction because of quick formation of $Fe(bipy)_3^{2+}$. The quenching solution also contained aluminum nitrate. By addition of ammonia, aluminum ion was coprecipitated with iron(III) ion as hydroxide. The precipitate was filtered from the solution and the radioactivity of a definite portion of the filtrate was measured with a well-type scintillation counter. The rest of the filtrate was used for optical determination of the concentration of iron(II) in the form of $Fe(bipy)_3^{2+}$ at 522 nm. The sample of the reaction solution at infinite time was taken at least ten half lives of the reaction after the initiation. In order to determine the total concentration of iron species in the system, the iron(III) was reduced to iron(II) by hydroxylamine. A more detailed procedure of the rate measurement was described previously.[8,9]

Results and Discussion

Absorption Spectra and Formation Constants of Fe^{3+}-SCN^- *Complexes in DMSO.* The absorption spectra of $Fe(ClO_4)_3$ and of $Fe(ClO_4)_3$–NH_4SCN in DMSO at $HClO_4$ concentration of 0.02 M are shown in Fig. 1. Curves A and B show respectively the spectrum of the simply solvated Fe^{3+}, and that of a mixture of Fe^{3+} and SCN^-, which partly form monothiocyanato complex. By combining both curves and the value of K_1 which will be obtained later, curve C can be calculated as the true spectrum of $FeNCS^{2+}$ complex, which exhibits a peak at 450 nm. The spectra A and C coincide well with those of Wada *et al.*[9,12] and Csiszar *et al.*,[13] respectively. The spectra were not influenced by the change in acid concentration.

The formation constant of $FeNCS^{2+}$, $K_1=[FeNCS^{2+}]/[Fe^{3+}][SCN^-]$, was determined by means of Job's continuous variation method.[12] Job's curves at $C_a=1.00\times10^{-3}$ and $C_b=0.70\times10^{-3}$ M are depicted in Fig. 2, C_a and C_b being the sum of the total concentrations of iron(III) and thiocyanate ion, $[Fe^{3+}]_0$ and $[SCN^-]_0$. The maximum points appear just at the center of the symmetrical curves indicating that the complex formed at these concentrations is of the composition $Fe^{3+}:SCN^-=1:1$. The observations were carried out at 440, 450, and 460 nm. K_1 and the

molar extinction coefficient ε_1 of $FeNCS^{2+}$ are calculated by the following equation.[12]

$$A = \varepsilon_0[Fe^{3+}] + \varepsilon_1[FeNCS^{2+}] - \varepsilon_0[Fe^{3+}]_0$$
$$= (\varepsilon_1-\varepsilon_0)[FeNCS^{2+}] \quad (1)$$

$$[FeNCS^{2+}] = \frac{x_a(1-x_a)C_a^2-x_b(1-x_b)C_b^2}{C_a-C_b} \quad (2)$$

$$[Fe^{3+}] = x_aC_a - [FeNCS^{2+}] \quad (3)$$

$$[SCN^-] = (1-x_a)C_a - [FeNCS^{2+}] \quad (4)$$

$$\varepsilon_1 = \frac{A}{[FeNCS^{2+}]} + \varepsilon_0 \quad (5)$$

The values of $\varepsilon_0[Fe^{3+}]+\varepsilon_1[FeNCS^{2+}]$ in Eq. (1) correspond to the observed absorbances of the sample at individual wavelengths. By means of Eqs. (2), (3), and (4), the following value was obtained.

$$K_1 = (8.4\pm0.9) \times 10^2\ M^{-1} \text{ at } 25°C \quad (6)$$

Another K_1 value obtained by means of stopped flow method by other authors is $1.18\times10^3\ M^{-1}$ at $\mu=0.024$ M and 25°C, which is a little larger than ours.[14,15]

At higher concentrations, dithiocyanato complex seems to be formed gradually, because the linearity between $\bar{\varepsilon}$ and $(\bar{\varepsilon}-\varepsilon_0)/[SCN^-]$ is no longer established.[12,16] However, the linear relationship between $\bar{\varepsilon}$ and $\Delta\bar{\varepsilon}(1+K_1[SCN^-])/K_1[SCN^-]^2$ becomes noticeable, according to the equation

$$\bar{\varepsilon} = \varepsilon_2 - \frac{1}{K_2}\frac{\Delta\bar{\varepsilon}(1+K_1[SCN^-])}{K_1[SCN^-]^2} \quad (7)$$

where $\bar{\varepsilon}$ is the apparent molar extinction coefficient of iron(III), $\Delta\bar{\varepsilon}$ the deviation of the observed $\bar{\varepsilon}$ from hypothetical $\bar{\varepsilon}$ which would have been obtained if no $Fe(NCS)_2^+$ formation occurred, and K_2 is defined to be the stepwise formation constant $K_2=[Fe(NCS)_2^+]/[FeNCS^{2+}][SCN^-]$. Figure 3 shows the straight line according to Eq. (7), from whose intercept and slope ε_2 and K_2 are obtained at 25°C as follows:

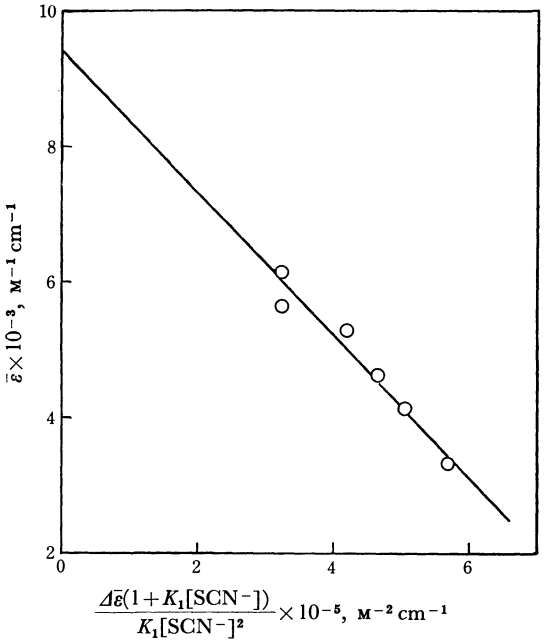

Fig. 3. Linear relation of $\bar{\varepsilon}$ against $\Delta\bar{\varepsilon}(1+K_1[SCN^-])/K_1[SCN^-]^2$ at $[HClO_4]=0.02$ M, $\mu=0.10$ M, 25°C and 450 nm.
$[Fe^{3+}]_0=1.89\times10^{-4}$ M
$[SCN^-]_0=(3.14-11.73)\times10^{-3}$ M

$$\varepsilon_2 = (9.4\pm0.5) \times 10^3\ M^{-1}\,cm^{-1} \text{ at } 450\ nm \quad (8)$$

$$K_2 = (0.97\pm0.10) \times 10^2\ M^{-1} \text{ at } 25°C \quad (9)$$

The dependence of K_1 and K_2 upon the dielectric constant of the solvents is listed in Table 1, in which the solvents are arranged in the sequence of their dielectric constants. It is seen that the lower the dielectric constant, the larger the stability of the complex, as expected theoretically. The linear relationship of $\log K_1$ *vs.* the reciprocal of the dielectric constant is roughly established.

By similar trials to determine the formation constant

Table 1. Dependence of K_1 and K_2 upon the dielectric constant of solvents

14) C. H. Langford and F. M. Chung, *J. Amer. Chem. Soc.*, **90**, 4485 (1968).

15) According to Keiko Ohnishi in our laboratory, the value of K_1 determined by conductivity method is $6\times10^4\ M^{-1}$, which is much larger than that by spectrophotometry. The discrepancy indicates that iron(III) ion has a widely spread ionic atmosphere around itself with its high electric charges in low dielectric medium. The value determined by the spectrophotometry only measures the complex which coordinates with thiocyanate ion in the first coordination sphere of the central ion.

of the Fe^{2+}-SCN^--DMSO system, no formation of complex species was recognized, in spite of the fact that the formation of $FeNCS^+$ has been found with the equilibrium constant $7.0\pm0.5\ M^{-1}$ by a flow technique in water.[11]

Rate Constants of Electron Transfer Reaction. According to McKay, isotopic exchange reactions including such types as the present electron transfer generally obey the rate equation[21-23]

$$\ln\left(1-\frac{x}{x_\infty}\right) = -\frac{a+b}{ab}Rt \qquad (10)$$

in which x and x_∞ represent radioactivity at time t and infinite time t_∞, respectively, and a and b the analytical total concentrations of iron(II) and iron(III), respectively, employed in the reaction system. R is the reaction rate. A typical linear relation of $\log(x_\infty-x)$ *vs.* time is drawn in Fig. 4. If the half life of the reaction is denoted by $t_{1/2}$, and if the reaction is regarded as that of first order with respect to both iron(II) and iron(III) concentrations, the apparent second order rate constant k_{app} is given by

$$k_{app} = \frac{0.693}{(a+b)t_{1/2}} \qquad (11)$$

If the reaction is of first order with respect to the individual concentrations of both iron(II) and iron(III), a rate equation $R=k_{app}ab$ is doubtlessly established, since the arbitrary variation in both concentrations gave a good constant k_{app} as long as other conditions of the reaction were kept unchanged, although it was practically impossible to assure the separate concentration dependence of both iron(II) and iron(III) because of experimental difficulty.

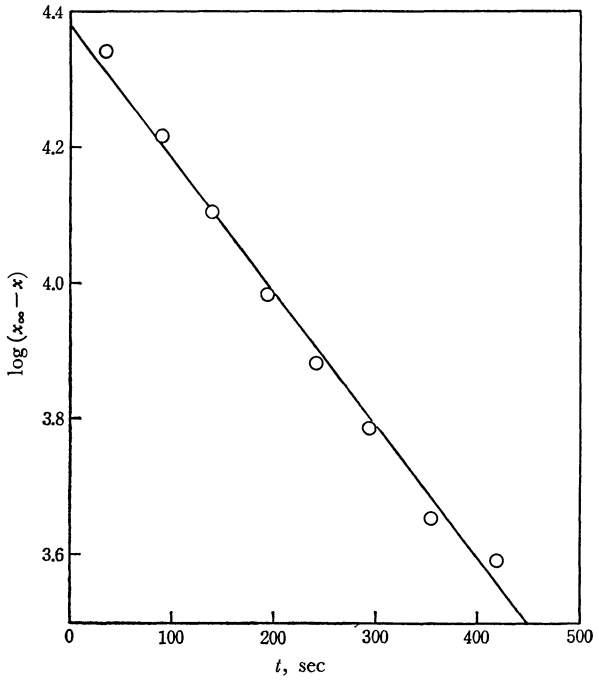

Fig. 4. Typical rate measurement of the reaction at 25°C.
$[Fe(II)]_0=3.69\times10^{-5}$ M
$[Fe(III)]_0=2.61\times10^{-5}$ M
$[SCN^-]_0=2.32\times10^{-4}$ M
$[HClO_4]=1\times10^{-2}$ M
$\mu=0.2$ M

Calculation of the values of k_{app} was performed by the method of least squares. The probable error was usually less than 5%.

Dependence of k_{app} on Acid Concentrations. Table 2 shows the dependence of k_{app} on the variation of acid concentrations in the range 6.9×10^{-5}—1.01×10^{-1}M. This indicates a slight but regular decrease of k_{app} with the increase of acid concentration. Acid concentration dependence of k_{app} appears to be much less than in the case of chloride ion-catalyzed electron transfer reaction in DMSO.[24] It might be said that k_{app} is nearly independent of the acid concentration except at very high acid concentration.

Table 2. Dependence of k_{app} upon acid concentration
$[SCN^-]_0=3.07\times10^{-4}$ M, $\mu=0.2$ M, 25°C

$[HClO_4]$ M	$[Fe(II)]_0\times10^5$ M	$[Fe(III)]_0\times10^5$ M	k_{app} $M^{-1}sec^{-1}$
6.9×10^{-5}	5.27	2.77	84.9
1.4×10^{-4}	9.67	3.36	79.6
3.4×10^{-4}	6.63	3.85	79.5
1.03×10^{-3}	7.28	2.06	79.2
5.15×10^{-3}	10.32	1.68	78.8
1.00×10^{-2}	3.86	1.46	77.3
1.01×10^{-1}	7.77	1.14	58.5

Dependence of k_{app} on SCN^- Ion Concentration. The reaction is markedly catalyzed by thiocyanate ion; its effects on k_{app} are summarized in Table 3. k_{app} is accelerated by the presence of SCN^- ion, similar as to the case of Cl^- ion.[9] Thus, the following three reaction paths can be considered to represent the principal mechanisms.

$$Fe^{2+} + {}^*Fe^{3+} \rightarrow Fe^{3+} + {}^*Fe^{2+} \qquad k_0 \quad (12)$$

$$Fe^{2+} + {}^*FeNCS^{2+} \rightarrow FeNCS^{2+} + {}^*Fe^{2+} \qquad k_1 \quad (13)$$

$$Fe^{2+} + {}^*Fe(NCS)_2{}^+ \rightarrow Fe(NCS)_2{}^+ + {}^*Fe^{2+} \qquad k_2 \quad (14)$$

The symbols Fe^{2+}, Fe^{3+}, $FeNCS^{2+}$, and $Fe(NCS)_2{}^+$ in the equations stand for the individual solvated species $Fe(DMSO)_6{}^{2+}$, $Fe(DMSO)_6{}^{3+}$, $Fe(DMSO)_5(NCS)^{2+}$, and $Fe(DMSO)_4(NCS)_2{}^+$, respectively, and the rate constants for the reactions (12), (13), and (14) are represented by k_0, k_1, and k_2, respectively. The first five values of k_{app} in Table 3 indicate that $k_0=34.4\ M^{-1}sec^{-1}$ as the mean value.

Since the observed rate is the sum of the values through the three paths, and the concentrations of the complexes involved in the reaction are decided by their formation constants, k_{app} is written as follows:

$$k_{app} = \frac{k_0+k_1K_1[SCN^-]+k_2K_1K_2[SCN^-]^2}{1+K_1[SCN^-]+K_1K_2[SCN^-]^2} \qquad (15)$$

When the denominator in Eq. (15) is substituted into D for simplicity, Eq. (15) can be rearranged to

express a linear relationship between Y and $[SCN^-]$:

$$Y=\frac{k_{app}D-k_0}{[SCN^-]}=k_1K_1+k_2K_1K_2[SCN^-] \quad (16)$$

The plot of Y against $[SCN^-]$ is shown in Fig. 5. The intercept and the slope of the straight line give k_1 and k_2 respectively, by the least squares calculation, using the given values of K_1 and K_2:

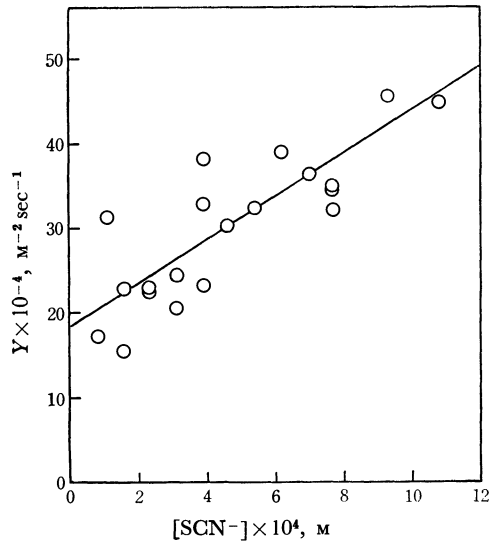

Fig. 5. Linear relation of Y against $[SCN^-]$ at $[HClO_4]=0.01$ M, $\mu=0.2$ M, 25°C.

$$k_1=(2.24\pm0.35)\times10^3\ M^{-1}sec^{-1} \quad (17)$$

$$k_2=(2.96\pm0.64)\times10^3\ M^{-1}sec^{-1} \quad (18)$$

Temperature Dependence of k_{app} and Activation Parameters. At constant acid and thiocyanate ion concentrations, the reaction rate was measured at different temperatures; 20, 25, 30, and 35°C. The results are given in Table 4. The plots of $\log k_0$ and $\log k_1$ against $1/T$ correspond to the activation parameters in the following:

$$\Delta H_0^{\neq}=9.7\pm0.7\ kcal/mol \quad (19)$$

$$\Delta H_1^{\neq}=8.9\pm1.0\ kcal/mol \quad (20)$$

$$\Delta S_0^{\neq}=-19\pm2\ cal/deg\cdot mol \quad (21)$$

$$\Delta S_1^{\neq}=-17\pm3\ cal/deg\cdot mol \quad (22)$$

The values of $\Delta H_0^{\neq}$ and $\Delta S_0^{\neq}$ agree with those by Menashi *et al.*[8]; $\Delta H_0^{\neq}=9.6$ kcal/mol and $\Delta S_0^{\neq}=$

General Discussion. The various elementary rate constants at room temperature and the activation enthalpies and entropies of the electron transfer reactions between iron(II) and iron(III) uncatalyzed and catalyzed by Cl^- and SCN^- ions in water and DMSO are collected and listed in Table 5. Generally speaking, k_0, k_1, and k_2 in DMSO are much larger than the corresponding ones in water, k_1 catalyzed by SCN^- ion is about twice as large as k_1 catalyzed by Cl^- ion in both solvents. So is also k_2 catalyzed by SCN^- ion compared to k_2 catalyzed by Cl^- ion in DMSO, while k_2 catalyzed by SCN^- ion is much smaller than k_2 catalyzed by Cl^- ion in water.

The exchange rates of DMSO molecules between the molecules coordinated to Co(II) or Ni(II) and the ones in the bulk in DMSO[25] and in mixed solvents of DMSO and nitromethane[26] are known by the NMR method. If the exchange rates in the case of iron ions do not differ very much from those of Co(II) and Ni(II), since the solvated species of these metal ions are considered to be high spin complexes, the exchange rate constant of DMSO may be greater than the rate constants of the electron transfer reaction k_0 and k_1 in DMSO listed in Table 5. Langford and Chung[14] determined the rate constant of the anation reaction $FeS_6^{3+}+SCN^-\rightarrow FeS_5(NCS)^{2+}+S$ in which S stands for DMSO by the stopped-flow method to be 670 ± 10 $M^{-1}sec^{-1}$, which is also greater than k_0 and k_1 in DMSO in Table 5. Considering this with the fact that DMSO has no hydrogen atoms which would play an important role in the hydrogen atom transfer mechanism, it is very probable that the inner-sphere mechanism is the path actually occurring in the electron transfer reaction in DMSO. Thus, the effects of the bridging ligands appear clearly in DMSO, although it is not the case in water, where the role of the anions is indirect and latent when the reaction proceeds through the hydrogen atom transfer mechanism. Recently, however, Cl^- and SCN^- ions were found to act as bridging anions in the inner-sphere mechanism even in water,[11] as stated before. As a bridging ligand, SCN^- ion appears to be better than Cl^- ion in both water and DMSO. A detailed discussion on the observed values of the activation parameters is not possible as yet.

Appendix: Incomplete Separation of Radioactive Precipitate. In the rate measurements, we frequently experienced a small fraction of the radioactive iron(III) to penetrate through filter paper into the filtrate liquid containing iron(II), when iron(III) was coprecipitated with aluminum hydroxide by ammonia. Thus, the extent of the electron transfer reaction at time t looked apparently larger than the true rate, because the radioactivity of the filtrate was larger than that purely due to the iron(II) species only. According to preliminary tests, however, the penetration factor of iron(III) through the precipitate layer leaking into the filtrate, α, was independent of the concentrations of iron(II) and iron(III) under the present experimental conditions, as long as the concentrations of aluminum ion and ammonia were kept constant. Consequently, the α can be easily fixed to be constant throughout at least one kinetic run.

When radioactivity at time t of iron(II), iron(III), and total iron is represented by x, y, and c respectively, then $x+y$ is equal to c, where c is time-independent. Since the radioactivity of iron(III) which has leaked into iron(II) is $(c-x)\alpha$, the apparent radioactivity of iron(II) at time t, x', is given by

$$x' = x + (c-x)\alpha \tag{23}$$

In the same way, the apparent radioactivity of iron(II) at time t_∞, x'_∞, is given by

$$x'_\infty = x_\infty + (c-x_\infty)\alpha \tag{24}$$

In the actual plotting of Eq. (10), $1-(x'/x'_\infty)$ is used instead of $1-(x/x_\infty)$. Then, the following ratio β is defined by use of Eqs. (23) and (24).

$$\beta = \frac{1-(x'/x'_\infty)}{1-(x/x_\infty)} = \frac{(1-\alpha)x_\infty}{(1-\alpha)x_\infty+c\alpha} \tag{25}$$

The value of β at any different time is shown to be constant for a kinetic run, because β is independent of x, x', and x'_∞, being smaller than unity ($\beta=1$ only when $\alpha=0$). Thus, the linearity of $\log(x'_\infty-x')$ and $\log(x_\infty-x)$ *vs.* time is given by

$$\log (x'_\infty - x') = \log x'_\infty + \log \beta - \frac{(a+b)R}{2.303\,ab}t \quad (26)$$

$$\log (x_\infty - x) = \log x_\infty - \frac{(a+b)R}{2.303\,ab}t \quad (27)$$

The slope of the straight line does not change even if x' and x'_∞ are used instead of x and x_∞ respectively, whereas the intercept of the straight line is lowered by $(\log x'_\infty + \log \beta) - \log x_\infty$, since $x'_\infty \beta / x_\infty$ is equal to $1-\alpha$. As a result of the lowering of the straight line, the reaction seemingly proceeds somewhat faster than the true reaction. Theoretically, x should be zero at time zero, but it frequently happens that x shows an appreciable value when time is extrapolated to zero. This does not affect the rate constant, as long as the leaking of iron(III) occurs by a definite factor α.

Infrared Spectra of Pentacyanonitrosylmanganese (^{14}NO and ^{15}NO) Complexes

Eiichi Miki, Soto-o Kubo,* Kunihiko Mizumachi, Tatsujiro Ishimori, and Hisateru Okuno

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received September 14, 1970)

The ^{15}NO-complexes for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, $K_3[Mn(CN)_5(NO)]$ and $Ag_2[Mn(CN)_5(NO)]$ were prepared. By measuring and calculating the effect of the nitrogen isotope ^{15}N on the infrared spectra, the Mn–N–O arrangement was found in all the complexes, and the absorption bands due to the skeletal vibrations between the manganese and the NO group were clearly assigned.

X-Ray crystal structures have been determined for a number of transition-metal nitrosyl compounds. However, the X-ray method does not seem to be useful for distinguishing nitrogen from oxygen in the NO group.

Recently, for the nitrosylruthenium(III), nitrosylchromium(II) and nitrosylcobalt(II) complexes, the effect of the nitrogen isotope ^{15}N on the infrared spectra was measured, and the isotopic shifts were compared with those calculated by the simple three-body model of the metal and the NO group.[1,2] This method was found to be useful for determining the coordinating atom of the NO group to the metal atom, and for assigning the skeletal vibrations between the metal and the NO group.

In this paper are described infrared studies on $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, $K_3[Mn(CN)_5(NO)]$, $Ag_2[Mn(CN)_5(NO)]$ and their ^{15}NO-complexes.

Experimental

$K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ with normal nitrogen isotopes was prepared by the method of Blanchard and Magnusson[3] who used NO gas, and was purified by the method of Cotton *et al.*[4] $K_3[Mn(CN)_5(NO)]$ and $Ag_2[Mn(CN)_5(NO)]$ were also prepared according to the same method. $K_3[Mn(CN)_5(NO)]\cdot 2D_2O$ was prepared by treating the unhydrated salt with D_2O in a vacuum line.

The ^{15}NO-complexes were prepared on about 1/10 the ordinary scale. $K_3[Mn(CN)_5(^{15}NO)]$ was prepared in a vacuum line; with the aid of liquid nitrogen, 3 mmol of ^{15}NO gas derived from $K^{15}NO_3$ (^{15}N atom% = 99) was trapped in a reaction vessel containing an outgassed pale-greenish slurry which was prepared by mixing 2 mmol of $Mn(C_2H_3O_2)_2\cdot 4H_2O$/(2.5 m*l* H_2O), 3 mmol of KOH/(2.5 m*l* H_2O), and 10 mmol of KCN/(2.5 m*l* H_2O) in succession. The reaction vessel was shaken under running water until the frozen solution was molten. The pale-greenish slurry was shaken for 5—6 hr at room temperature to give a clear violet solution containing $[Mn(CN)_5(^{15}NO)]^{3-}$. The yield of the purified $K_3[Mn(CN)_5(MO)]\cdot 2H_2O$ was about 50% based on $Mn(C_2H_3O_2)_2\cdot 4H_2O$. Preparation of the ^{15}NO-complexes on such a semi-micro scale was thought to give the correct products because the ^{14}NO-complexes prepared on the semi-micro scale gave the same infrared spectra as those prepared on an ordinary scale, and their elementary analyses showed the correct values.

Found: K, 31.9; Mn, 15.1; C, 16.5; N, 23.3; H_2O, 9.79%. Calcd for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$: K, 31.84; Mn, 14.9; C, 16.30; N, 22.82; H_2O, 9.78%. Found: C, 18.5; N, 25.2%. Calcd for $K_3[Mn(CN)_5(NO)]$: C, 18.07; N, 25.29%. Found: Ag, 49.4; Mn, 12.4; C, 14.1; N, 18.7%. Calcd for $Ag_2[Mn(CN)_5(NO)]$: Ag, 50.07; Mn, 12.75; C, 13.94; N, 19.51%.

Infrared spectra were measured over 200—4000 cm^{-1} in Nujol mull, hexachlorobutadiene mull, and a potassium bromide disk. The spectra were recorded on JASCO DS-402G (700—4000 cm^{-1}), JASCO model IR-F, and Hitachi EPI-L type (200—700 cm^{-1}) infrared spectrophotometers. The wave numbers of the observed absorption bands were calibrated with 1,2,4-trichlorobenzene, polystyrene film and water vapour. Reproducibility was about ± 1 cm^{-1} in the region 200—3000 cm^{-1}, and ± 10 cm^{-1} in the region 3000—4000 cm^{-1}.

Results

Assignments of Infrared Spectra. Assignments of the N–O stretching and the skeletal vibrations between the manganese and the NO group were made on the

basis of the ^{15}N-isotopic shifts. The observed frequencies and their assignments for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, $K_3[Mn(CN)_5(NO)]$ and $Ag_2[Mn(CN)_5(NO)]$ are shown in Table 1. The two very strong absorption bands in the region 1700—1740 cm^{-1} of $K_3[Mn(CN)_5(^{14}NO)]\cdot 2H_2O$ and its unhydrate correspond to the N–O stretching vibrations since these bands shift upon ^{15}N-substitution. The wave number of the stronger peak was used to calculate the isotopic shifts. For the hydrate, the absorption bands at 663 and 653 cm^{-1} shifted and split to 660, 651 and 646 cm^{-1} upon ^{15}N-substitution as shown in Fig. 1. These bands can be assigned to the skeletal vibrations between the manganese and the NO group because the wave numbers for the deuterate hydrate were the same as those for the normal hydrate. For $K_3[Mn(CN)_5(NO)]$, on the other hand, the single absorption band at 659 cm^{-1} split into two peaks at 661 and 648 cm^{-1} upon ^{15}NO-substitution as shown in Fig. 1. For $Ag_2[Mn(CN)_5(NO)]$, a strong band of the ^{14}NO-complex at 1888 cm^{-1} was assigned to the N–O strethcing vibration; this band shifted to 1850 cm^{-1} upon ^{15}NO-substitution. A broad absorption at 628 cm^{-1} shifted to 620 cm^{-1} upon ^{15}NO-substitution, but did not split. This band seems to be due to the skeletal vibrations between the manganese and the NO group.

A number of absorption bands observed in a region lower than 620 cm^{-1} could be assigned to the skeletal vibrations between the manganese and the CN group.[5] For $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, such bands were observed on the background of a very broad absorption band centered at about 450 cm^{-1}. This broad band seems to be due to the libration of the crystal water because the absorption shifted to about 330 cm^{-1} upon deuterium substitution.

Calculation of Isotopic Shifts. An X-ray study of $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ has shown an approximately linear arrangement of the manganese and the

$\Delta\nu_{calcd} = \nu_{^{14}NO\text{-complex(calcd)}} - \nu_{^{15}NO\text{-complex(obsd)}}$

Assignment 1: Of the two wave numbers in the region 630—670 cm^{-1}, the higher wave number is assigned to the stretching vibration between the manganese and the NO group and the lower one to the bending vibration.

Assignment 2: The reverse of Assignment 1.

a: The N–O stretching vibration.

b: The stretching vibration between the manganese and the NO group.

c: The bending vibration between the manganese and the NO group.

*: This observed isotopic shift($\Delta\nu_{obsd}$) is explained by Ref. 8.

**: These observed isotopic shifts are very rough values since the two skeletal vibrations appear to be adjacent to each other.

NO group.[6] The isotopic shifts were calculated for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, its unhydrate[7] and $Ag_2[Mn(CN)_5(NO)]$[7] by the use of the two linear three-body models, Mn–N–O and Mn–O–N as described previously.[1,2] A probable assignment of the skeletal vibrations and determination of the arrangement were based on a comparison of the calculated isotopic shifts with the observed ones. Table 2 shows the observed and the calculated isotopic shifts for $K_3[Mn(CN)_5(NO)]$ and $Ag_2[Mn(CN)_5(NO)]$.

Arrangement and Assignment. The calculated isotopic shifts in the case of the Mn–N–O arrangement with Assignment 1 for the unhydrate (see Table 2) are in agreement with the observed ones. The Mn–N stretching and the Mn–N–O bending vibrations seem to overlap accidentally at 659 cm^{-1}. They shifted and split into the 661 cm^{-1} (the Mn–N stretching vibration) and 648 cm^{-1} (the Mn–N–O bending vibration) bands upon ^{15}NO-substitution.[8] Both the hydrate and $Ag_2[Mn(CN)_5(NO)]$ were found to show the Mn–N–O arrangement from the observed isotopic shifts for the N–O stretching vibrations upon ^{15}NO-substitution.

For $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$, three absorption bands were observed in the region 640—670 cm^{-1} on the ^{15}NO-complex, and two on the ^{14}NO-complex. They are caused by the skeletal vibrations of the Mn–NO group. The doubly degenerate Mn–N–O bending vibrations of the free complex ion can be assumed to split into two absorption bands in the crystalline state. For the isotopic shifts of the absorption bands, the following assignments may be most probable. Two absorption bands due to the Mn–N stretching and one of the Mn–N–O bending vibrations overlap at 663 cm^{-1} for the ^{14}NO-complex. They shift and split into two bands at 660 cm^{-1} (the Mn–^{15}N stretching vibration) and 651 cm^{-1} (the Mn–^{15}N–O bending vibration), while another Mn–^{14}N–O bending vibration (653 cm^{-1}) shifts to 646 cm^{-1} upon ^{15}NO-substitution (Fig. 1).

Discussion

The Mn–N–O arrangement was found in the pentacyanonitrosylmanganese complexes as conventionally described for metal nitrosyl complexes. In $K_2[RuX_5(NO)]$ (X=Cl and Br), the overtone band of the Ru–N–O linear bending vibration is observed in the frequency region near twice the value of the fundamental frequency of the Ru–N–O bending vibration.[9] $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ and its unhydrate show bands at 1325 and 1313 cm^{-1}; these frequencies are nearly

6) A. Tullberg and N. Vannerberg, *Acta Chem. Scand.*, **21**, 1462 (1967).

7) For $K_3[Mn(CN)_5(NO)]$ and $Ag_2[Mn(CN)_5(NO)]$, the linear three-body model was assumed although a crystal X-ray study was not carried out.

8) The absorption intensity of the Mn–N stretching vibration would be very weak as compared with that of the Mn–N–O bending vibration. If the two absorptions are adjacent to each other, the wave number of the overlapping bands will be approximately equal to that of the Mn–N–O bending vibration and roughly to that of the stretching vibration. The Mn–^{14}N stretching vibration can be estimated to appear at about 665 cm^{-1} by calculation of the isotopic shift as shown in Table 2.

9) J. Hiraishi, Ph. D. Thesis, The University of Tokyo (1956).

the same as twice the 663 and 659 cm^{-1} bands ($663\times 2=1326$ and $659\times 2=1318$). From this observation, the 663 and 659 cm^{-1} bands can be assigned to the Mn–N–O linear bending vibrations. This is in agreement with the assignment by the comparison of the observed isotopic shifts with the calculated ones. For $Ag_2[Mn(CN)_5(NO)]$, the overtone band of the Mn–N–O bending vibration was not observed.

One Mn–N stretching and two Mn–N–O bending vibrations were observed in $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$. This can be explained as follows. The $[Mn(CN)_5(NO)]^{3-}$ ion belongs to the point-group symmetry C_{4v} and the reduced representation can be shown as $8A_1+A_2+4B_1+2B_2+9E$. The A_1 and the E species are infrared active, and the N–O and the Mn–N stretching vibrations belong to the A_1 species and the Mn–N–O bending vibration to the E species. $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ crystallizes in the space group No. 9 Cc,[6] where E species is expected to split into infrared active A' and A'' species, but not A_1 species. Thus, one Mn–N stretching and two Mn–N–O bending vibrations are expected to be observed in crystalline state.

The wave numbers of the N–O stretching vibrations increase in the order of $K_3[Mn(CN)_5(NO)]$, $K_3[Mn(CN)_5(NO)]\cdot 2D_2O$ and $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ (see Table 1). The changes suggest that hydrogen bonds are formed between the NO group and the crystal waters as revealed by X-ray study of $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$.[6] The changes were observed in the N–O stretching vibrations but hardly at all in C–N stretching vibrations.

The wave numbers of the N–O and the C–N stretching vibrations for $Ag_2[Mn(CN)_5(NO)]$ are higher than those for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ and its unhydrate, while the reverse is observed for the skeletal vibrations between the manganese and the NO group. This can be explained from the difference of oxidation states of the manganese atom; the oxidation state of the manganese atom for the K-salts and the Ag-salt are II and III, respectively.

The assignment of the skeletal vibrations between the manganese and the NO group for the examined complexes is tentative, and no distinction between the skeletal vibrations was made.[10] However, a probable assignment of the skeletal vibrations for $K_3[Mn(CN)_5(NO)]\cdot 2H_2O$ and its unhydrate is thought to have been established.

The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

Formation of Hypophosphate in the Radiolysis of Phosphite Solution

Niro MATSUURA, Masahito YOSHIMURA, Masao TAKIZAWA,* and Yukio SAKAKI*

Department of Pure and Applied Sciences, The University of Tokyo, College of General Education, Komaba, Meguro-ku Tokyo

**Tokyo Institute of Photographic Technology, Atsugi, Kanagawa*

(Received September 14, 1970)

The formation of hypophosphate and phosphate in the radiolysis of a phosphite solution was established by the anion-exchange chromatographic technique. The quantitative determination of their yields was made by colorimetry of the phosphate and hypophosphate with the Mo(V)+Mo(VI) reagent, which develops molybdenum-blue colors in two steps at different temperatures. The G values in an aerated condition are 0.01 molecules/100 eV in acid and 0.1 molecule/100 eV in neutral pH with respect to the hypophosphate formation, independent of the phosphite concentration. In a deaerated system much higher values are obtained, amounting to around 0.5 molecules/100 eV at a phosphite concentration of 10^{-3} M. The G values of hypophosphate plus phosphate are around 3.0; this is in agreement with the half-value of the primary radical yields, $1/2\cdot(g_{red}+g_{OH})$, reported in the data derived from the radiation-chemical studies in the aqueous system. The hypothesis that the hypophosphate (IV) ion radical is a transient species in the oxidation of phosphite to phosphate is supported by the results obtained in this work.

The neutron activation of phosphate in an aqueous solution produces ^{32}P-labelled hypophosphate simultaneously with other oxyphosphorus compounds of different oxidation numbers.[1] However, we failed in an attempt to prepare hypophosphate from phosphite by oxidation in an aqueous medium, despite its high stability and inertness.[2] The synthesis of labelled hypophosphate could not be ascribed absolutely to the recoil process of ^{32}P hot atoms, because the transformation of a primary product of labelled phosphite into hypophosphate under ambient radiations in nuclear reactor might be involved. Cottin and Haissinsky[3] proposed a reaction mechanism for the radiolysis of phosphite to phosphate in the aqueous phase by assuming that the hypophosphate-ion radical is a transient intermediate. Hypophosphate-ion radicals have been detected by ESR study in a gamma-irradiated orthophosphate in the form of $\cdot H_2PO_3$.[4] The

defect formed by gamma-irradiation in glassy P_2O_5 or glassy alkaline phosphate has been ascribed to this radical,[5] but with no chemical evidence. Haissinsky's report stated that the hypophosphate-ion radicals produced during the radiolysis of phosphite were oxidized further by certain additives, such as O_2, H_2O_2, and N_2O, and that there was little chance to form hypophosphate by a recombination of $\cdot H_2PO_3$.[6] A new technique of the colorimetry of hypophosphate developed by Ohashi *et al.*[7] is now available for determining the yields of hypophosphate in the radiolysis of phosphite by the application of the Mo(V)+Mo(VI) reagent.[8]

Experimental

Materials and Reagents. Sodium phosphite salt, $Na_2HPO_3 \cdot 5H_2O$, was purchased from Wako Pure Chemicals Co., Ltd., and was used without purification. Sodium hypophosphate salt was prepared from elemental phosphorus by hypochlorite oxidation according to the procedure described in the literature.[9] Triply-distilled water was used for preparing the samples to be irradiated.

Irradiation. The sample solutions, in Pyrex tubes, were irradiated with ^{60}Co gamma-ray source (3.8×10^{18} eV/g·hr at 10 cm from the center); the experiments were done in the Institute for Solid State Physics, The University of Tokyo. Irradiations were performed at room temperature, and the absorbed gamma-dose was calibrated by means of a Fricke dosimeter under the same conditions as were used for the irradiation of the samples by assuming $G(+Fe^{3+})=15.5$.

Chemical Analysis. For the detection of hypophosphate the development of the molybdenum-blue color by Mo(V)+Mo(VI) reagent[8] was effected in three different stages. First, a sample solution kept for 30 min at 25°C after the addition of the reagent develops a full color as a result of the hypophosphate. Second, heating on a boiling water bath for some ten minutes results in an increase in the blue color by an amount corresponding to the orthophosphate concentration. Finally, the color due to phosphite is developed on a separate sample solution by the use of the same reagent, with acid sulfite added. The last treatment provides the total content of the oxyphosphorus acid present in the irradiated solution. A batch test tried on synthetic samples showed a slight deviation in the observed values from the expected values as a result of background absorption by the successive treatment of the color development. On the basis of the batch-test data, a correction was made on the measured absorbancies, but it amounts to less than 10%, depending on the amounts of phosphate and hypophosphate present. A phosphite solution, when heated at near the boiling point of water, degrades into phosphate and hydrogen or phosphine.[10] If phosphite is concentrated too much in a sample solution, the "autoredox" decomposition of phosphite also affects the results of the absorbancy by augmenting the phosphate content during the heat treatment for the color development in the second stage. However, the background absorbancy caused by the thermal degradation of phosphite can be disregarded if the phosphite concentration is less than 10^{-3} M. According to our observations, the rate of phosphate formation was proportional to the square of the phosphite concentration, but independent of the concentration of dissolved oxygen. A sharp increase in phosphate was observed at a phosphite concentration higher than about 10^{-3} M. For this reason, the measurements of the radiation-induced yields of phosphate from phosphite were carried out at the concentrations lower than 10^{-3} M.

The ion-exchange chromatographic separation of hypophosphate from phosphate and phosphite was effected by the gradient elution technique, running 0.1 to 0.3 M KCl solutions through a 20-cm Dowex 1×8 anion-exchange resin column. Each 5-ml fraction was subjected to colorimetry by the molybdenum-blue method.

Results and Discussion

Evidence for the formation of hypophosphate in an irradiated solution of phosphite was given by the chromatographic technique combined with the colorimetry of phosphorus by the molybdenum-blue method. Gradient elution with 0.1 M to 0.3 M potassium chloride solutions, buffered with borate at pH 8 develops the phosphoxy-acids of different oxidation states in the order of: hypophosphite, phosphate, phosphite, and hypophosphate. The elution peak at 190 ml in the chromatographic pattern shown in Fig. 1 can be assigned to the peak due to hypophosphate.[11] The yield of hypophosphate in the radiolysis of the phosphite solution was computed from the area of the chromoatogram peak, whose value was in good agreement with the value found by the differential colorimetry of hypophosphate.

A systematic survey of the yields of hypophosphate in the radiolysis of phosphite was made by the differential-colorimetric method both in 0.5 N sulfuric acid and in a neutral solvent under aerated or deaerated conditions. The yields are plotted against the absorbed gamma-dose for a given concentration

of phosphite in Fig. 2. These plots provide a straight line falling on the abscissa at a point corresponding to the gamma-dose of around 2×10^{17} eV/m*l* for the radiolysis in both acid and neutral media, irrespective of the presence of oxygen. In an acid medium under aerated conditions, there is practically no formation of hypophosphate, as may be seen in Fig. 2.

The radiation-chemical yields in *G* value were determined at a gamma-dose of 6.4×10^{17} eV/m*l* as a function of the phosphite concentration. The results are represented in Fig. 3. The *G* value of hypophosphate formation in an aerated neutral solution attains a value of 0.1 ions per 100 eV, independent of phosphite concentration. In a deaerated solution, on the other hand, the *G* values increase with an increase in the concentration of phosphite. The hypophosphate detected in the radiation-induced oxidation of phosphite to phosphate is strong evidence that the hypophosphate-ion radicals are in the monomer form, produced as transient intermediates and acting as precursors of hypophosphate. The fact that the yields of hypophosphate are greatly influenced by the concentration of phosphite is connected with the properties of the hypophosphate-ion radicals, which are relatively inert to the radical species of water radiolysis as compared with the reactivity of the phosphite. The reaction between the phosphite and hydrogen peroxide occurs only very slowly, while it proceeds at an appreciable rate under the influence of ultra-violet rays, which generate the OH radicals by the decomposition of hydrogen peroxide. The hypophosphate is described in the literature as being resistant to the attack of the common redox reagents. In our experiments, too, the yields of phosphate from hypophosphate in the radiolysis were observed to be relatively small and to be entirely suppressed in the presence of phosphite.

From these facts and observations, we assumed that the radiolysis of phosphite was initiated through process (1) by the abstraction of the hydrogen atom from

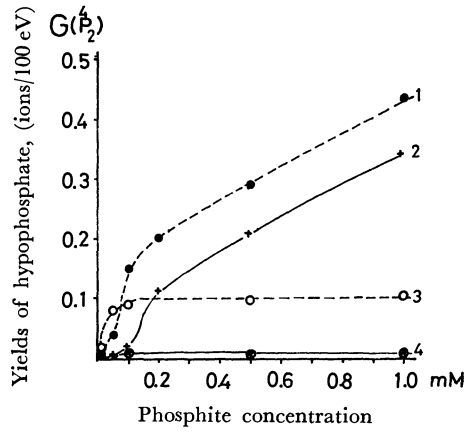

Fig. 3. *G* values of hypophosphate formation as fnuction of phosphite concentration.
1. in deaerated neutral solution, 2. deaerated acid solution, 3. aerated neutral solution, and 4. aerated acid solution

the P–H bond of phosphite ions:

$$H\text{-}\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}\text{-}OH + H \text{ (or OH)} = \cdot\underset{\underset{OH}{|}}{\overset{\overset{O}{\|}}{P}}\text{-}OH + H_2 \text{ (or } H_2O) \quad (1)$$

The hypophosphate radicals thus formed are oxidized further into phosphate by the OH radicals, but the rate of oxidation may be slowed down so long as phosphite is predominant as a powerful radical scavenger. When the hypophosphate-ion radicals are accumulated to a certain extent by the absorption of the critical gamma-dose, the recombination reaction through (2) competes with the oxidation by the OH radicals through (3):

$$2\cdot H_2PO_3 = H_4P_2O_6 \quad (2)$$

$$\cdot H_2PO_3 + OH = H_2PO_4^- + H^+ \quad (3)$$

Since, $G(H_2)=g_{H_2}+g_H$ has been known in the acid radiolysis of phosphite,[3] the reduction of the hypophosphate radical to phosphite by the reducing radicals to provide $G(H_2)=g_{H_2}+g_H/2$ is improbable. However, in the presence of oxygen, the H atoms acting as reducing agents are converted into the HO_2 radicals through (4) as the oxidizing agent, and the reducing radicals in turn take part in the oxidation of the hypophosphate radicals through (5):

$$H + O_2 = HO_2 \quad (4)$$

$$\cdot H_2PO_3 + HO_2 + H_2O = H_3PO_4 + H_2O_2 \quad (5)$$

Consequently, the low yields of hypophosphate in the radiolysis under aerated conditions can be explained by the contribution of the HO_2 radical to phosphate formation by reactions (4) and (5) in stead of to hypophosphate formation in the dimer form by (2).

The yields of phosphate in the radiolysis of phosphite were determined by differential colorimetry, along with the yields of hypophosphate. The *G* values of phosphate formation plus hypophosphate formation, thus determined, are shown in Fig. 4 as a function of the phosphate concentration. The results show that the *G* values tend to attain a certain limiting value at a concentration of phosphite higher than 10^{-4} M beyond this concentration all the radical products of water

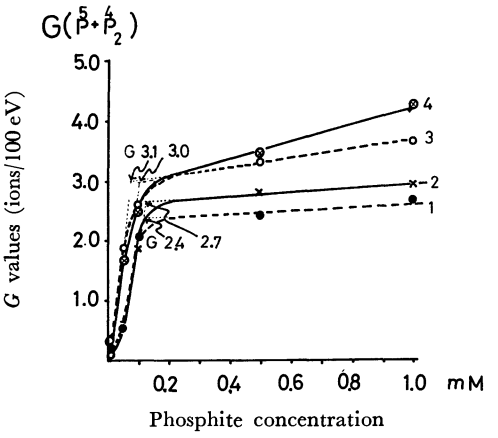

Fig. 4. G values of phosphate plus hypophosphate as function of phosphite concentration in
1. deaerated neutral solution, 2. deaerated acid solution, 3. aerated neutral solution, 4. aerated acid solution.

radiolysis that escape from recombination in the spur space are swept away by the phosphite. The steep rises in the curves, followed by plateaus, make it possible to find the lowest concentration of phosphite necessary for fulfilling the above-cited conditions by the extension of the ascending and plateau parts of the curve, as is shown in Fig. 4. At these particular points, the G values are from 2.4 to 2.7 for the radiolysis in the deaerated system and from 3.0 to 3.1 for the radiolysis in the aerated system.

Since the conversion of phosphite to phosphate is a two-equivalent oxidation, these G values must be a half of the sum of the primary radical yields with respect to the OH and the reducing species. Accordingly, the G values of phosphate plus hypophosphate shown in Fig. 4 can be interpreted in terms of the primary radical yields, denoted by g_{OH} and g_H as below by (6). According to (6), the observed value of G agrees well with the theoretically-derived value,[12] 3.35 at pH 0.2 or 3.5 at pH 6.0:

$$G(\overset{5}{P} + \overset{4}{P_2}) = 1/2 \cdot (g_H + g_{OH}) \qquad (6)$$

In (6) g_H implies the primary yields of the reducing radicals, the H atoms as well as the solvated electrons.

In our experiment, the G values steadily increase beyond 10^{-4} M of phosphite, and at 10^{-3} M the observed G value is 4.3 in the aerated-acid medium. However, an extraordinary G value by the chain mechanism has not yet been observed. The slow increase, followed by a rapid rise in $G(\overset{4}{P_2}+\overset{5}{P})$, can be ascribed to the fact that radical products remaining alive in the spurs come to be partially scavenged by phosphite. The contribution of hydrogen peroxide from the molecular product of radiolysis to the increasing $G(\overset{4}{P_2}+\overset{5}{P})$ can not be excluded, particularly in the aerated system, even though the rate of the reaction of hydrogen peroxide with phosphite is very slow where there is no influence of radiation. Since there is no formation of hypophosphate below a critical gamma-dose of about 2×10^{17} eV/ml, denoted by D_{crit}, the hypophosphate ion radicals must attain a stationary concentration amounting to $2G\cdot(\overset{4}{P_2}+\overset{5}{P})\cdot D_{crit}$. The stationary concentration of the hypophosphate ion radicals under consideration is around 2×10^{-5} M, if the $G(\overset{4}{P_2}+\overset{5}{P})$ value is taken to be 3.0 on the average. The latter concentration is about ten times smaller than the phosphite concentration, giving plateau G values, 1×10^{-4} M. By comparing the phosphite concentration of 10^{-4} M for reaction (1) with the hypophosphate ion radical concentration of 2×10^{-5} M for reaction (2), a majority of the radical OH can be said to react with phosphite through (1) unless the second-order rate constant of (1) is much smaller than that of (3). Our results show that the phosphate formation (3), which is at least ten times larger than that of reaction (1).

In connection with the protective action of phosphite, the effect of hypophosphite was studied in order better to understand the critical dose, D_{crit}, in this system. If hypophosphite solution is irradiated with gamma-rays, no phosphate is formed and the increase of phosphite continues until a greater part of the hypophosphite is consumed. Thus, the oxidation of phosphite to phosphate is entirely protected against the attack of the radical products of water radiolysis, as may be seen in Fig. 5. The critical gamma-dose for

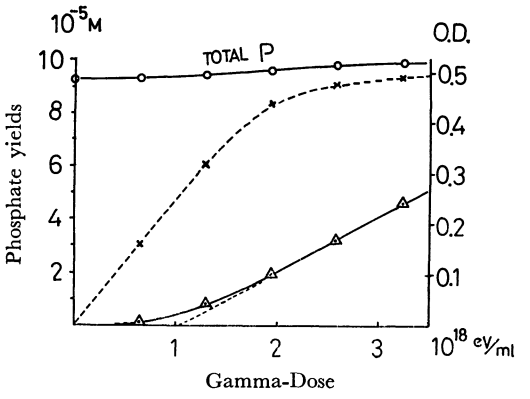

Fig. 5. Yields of phosphate ($\overset{5}{P}$) in the radiolysis of 10^{-4} M hypophosphite (full line curve with △).
Total phosphorus content, including hypophosphite, phosphite, hypophosphate, and phosphate, for checking the amount lost by thermal degradation during the heat treatment of color development (upper full line with ○).
For the sake of comparison the yields of phosphate in the radiolysis of the same concentration of phosphite solution are plotted by the break line with ×.

the complete protection of phosphate formation was 1.0×10^{18} eV/ml. At this critical value, the hypophosphite concentration is lowered significantly to such an extent that the rate of oxidation of phosphite to phosphate becomes compatible with the rate of the conversion of hypophosphite to phosphite.

Photon-Activation Analysis for Zirconium with Molybdenum Used as the Internal-Reference Element[1)]

Tong-Chuin PUNG,* Toyoaki KATO, and Yoshinaga OKA**
Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai
(Received September 16, 1970)

A method for the determination of zirconium has been studied by activation analysis with bremsstrahlung photons, with molybdenum used as the internal-reference element. This method is based on the γ-ray spectrometric measurement of the ^{89}Zr activity produced by the ^{90}Zr(γ,n) reaction and on the comparison of this activity with the ^{88}Zr activity formed by the (γ,α) reaction on molybdenum. The reaction products and their rates of production in zirconium and in molybdenum have also been examined as functions of bremsstrahlung maximum energies up to 60 MeV, and the best conditions for the determination of zirconium are proposed. When the maximum energy was set at 20 MeV, no interfering reactions occurred; under the present experimental conditions, a zirconium content down to about 18 μg can be determined accurately. The reliability and the versatility of this method are demonstrated.

A minute amount of zirconium can be determined by photon-activation analysis using ^{89}Zr activity induced in an irradiated sample. This technique has been applied to the determination of zirconium in hafnium samples, using the non-destructive internal-reference method.[2,3)]

In a previous report,[4)] a method for the determination of niobium by photon-activation analysis has been proposed, with molybdenum used as the internal-reference element. The activity of the ^{92m}Nb produced by the (γ,n) reaction was utilized for the determination, while ^{95m}Nb or ^{96}Nb activities coming from molybdenum by the (γ,p) processes were used as references. On the basis of similar principles, methods for the determination of arsenic,[5)] rubidium,[6)] and cesium[7)] have also been established. Besides the (γ,n) and the (γ,p) reactions, the (γ,α) reactions can be induced by activation with photons in the giant resonance-energy region; the yields of (γ,α) reactions in several medium-weight nuclei for 20 MeV bremsstrahlung were given previously.[8)]

Thus, an element can be determined by comparing the activity of its (γ,n) reaction product with the activity induced by the (γ,α) reaction on the reference element having an atomic number higher by two.

The present work concerns a method for the determination of zirconium using molybdenum as the internal-reference element. In order to determine the best conditions for this purpose, some work has also been carried out on the yields of photonuclear reactions over the energy range of bremsstrahlung photons up to 60 MeV. When a maximum energy was set at 20 MeV, no interfering reactions occurred, and traces of zirconium down to about 18 μg could be determined accurately.

Experimental

Materials and Irradiation. The zirconium oxide was of an analytical-reagent grade and was from the Johnson Mathey Corp. The molybdenum was a metallic powder of 99.9% purity, from Wako Pure Chemical Industries, Ltd. Synthetic mixtures of these two samples, with known zirconium-to-molybdenum weight ratios ranging from 2.46×10^{-3} to 2.49×10^{-5}, were prepared in order to examine the sensitivity and the accuracy of the method. Each sample, weighing from 0.1 to 2 g, was placed either in a silica or Pyrex tube with an internal diameter of 8 mm. The tube was then placed in a water-cooled target holder immediately behind the bremsstrahlung generator, a 3-mm-thick platinum plate, and was irradiated. The irradiation periods varied between 1 and 3 hr.

Two kinds of linear-electron accelerators of Tohoku University were the bremsstrahlung sources. One of them provided a 20 MeV-electron beam. The other machine, which was capable of accelerating electrons with much higher energies, was used as the 30-to-60 MeV bremsstrahlung source. The experimental method, involving bremsstrahlung-flux monitoring, and the details of the irradiation were essentially the same as have been described in detail in a previous report.[9)]

Separation of Zirconium. The separation of zirconium activities from an irradiated sample was performed, after the addition of a zirconium carrier (10 mg), by means of the anion-exchange method, with a mixture of hydrofluoric and hydrochloric acid as the eluent.

The method was essentially the same as has been described in a previous report.[4)] The zirconium activities were eluted from a Dowex 1×8 column[10)] with 80 m*l* of a 0.01 N hydrofluoric acid - 9 N hydrochloric acid mixture. To this fraction, 5 m*l* of a saturated aqueous solution of boric acid were added. The zirconium hydroxide was precipitated from this solution by the addition of aqueous ammonia, filtered, washed, and then ignited to give zirconium oxide. This was wrapped with a thin sheet of aluminum for γ-ray counting. The chemical yield was determined, if needed.

Measurement of Radioactivity. The γ-ray measurements were made with a Ge(Li) detector, with a sensitive volume of 36 cm^3, coupled to a TMC 1024-channel pulse-height analyzer. The counting system had a resolution of 4 keV for the 661.6 keV γ-line of ^{137}Cs. The sample was measured at a fixed position, 1 cm from the sensitive surface of the detector.

A 3″ dia. × 3″ NaI(Tl) crystal was also used as the detector. This was coupled to an 800-channel pulse-height analyzer made by the Tokyo Shibaura Electric Co., Ltd. The sample was located at a distance of 1 cm from the crystal surface.

For the study of various photonuclear reaction products, in which a much greater resolving power was required, the Ge(Li) detector was used exclusively. For analytical purposes, the NaI(Tl) detector was used.

Results and Discussion

Photonuclear Reaction. The nuclear data of present importance are given in Table 1. For a zirconium sample irradiated with 20 MeV bremsstrahlung, ^{89}Zr and ^{95}Zr produced by the (γ,n) reactions and ^{91m}Y produced by the (γ,p) reaction were measured at a cooling time of 45 min. At 30 MeV, ^{88}Zr was produced by the $(\gamma,2n)$ reaction and ^{90m}Y and ^{93}Y were produced by the (γ,p) reactions, beside the above products. With this energy, ^{88}Y formed by the (γ,pn) and (γ,d) reactions on ^{90}Zr was also recognized after the relatively short-lived products had decayed away. In addition, the ^{90}Zr$(\gamma, 3n)^{87}$Zr reaction occurred for an energy beyond 45 MeV. These zirconium and yttrium activities are summarized in terms of their γ-ray photopeak intensities, and are plotted against bremsstrahlung maximum energy, in Fig. 1. All the activity data are expressed in counts per minute per milligram of zirconium at the end of an 1-hr irradiation by bremsstrahlung with the given maximum energies, after being normalized to a standard dose rate required to produce 1.0 μCi ^{196}Au by the 1-hr irradiation of 1 mg of gold. It is clear that the

0.910 MeV γ-ray of ^{89}Zr gives the highest photopeak activity for all the bremsstrahlung maximum energies. The annihilation radiation (0.511 MeV) can also be used for the sensitive determination of zirconium.

When molybdenum was irradiated with 20 MeV bremsstrahlung and the zirconium activity was separated, only the 0.394 MeV γ-ray was observed; it was attributed to ^{88}Zr produced by the ^{92}Mo(γ,α)^{88}Zr reaction. With 30 MeV bremsstrahlung, γ-rays due to the ^{89}Zr produced by the ^{94}Mo(γ,αn) reaction have also been measured. In addition, ^{87}Zr and ^{95}Zr were produced by the (γ,αn) reactions on molybdenum at energies beyond 45 MeV. Since the ^{89}Zr activity was used in the determination of zirconium, the irradiation conditions leading to the production of ^{89}Zr from molybdenum had to be avoided. Below 20 MeV, only the ^{94}Mo(γ,αn)^{89}Zr reaction ($-Q=14.06$ MeV) can produce ^{89}Zr. The experimental results showed that no appreciable amount of ^{89}Zr was produced from molybdenum with 20 MeV bremsstrahlung.

The Determination of Zirconium. The annihilation radiation or the 0.910 MeV γ-ray photopeak can be utilized for the determination of zirconium, while the ^{88}Zr activity arising from molybdenum can be used as a reference. The accuracy of the method was assessed by processing synthetic zirconium-molybdenum mixtures. They were irradiated with 20 MeV bremsstrahlung for 3 hr at a dose rate of 8×10^{4} R/min.[11] After the irradiation, the zirconium activities were separated chemically as has been described above. Figure 2 shows a typical γ-ray spectrum of the zirconium fraction. The photopeak area of the 0.511 MeV or 0.910 MeV peak of ^{89}Zr was measured and compared with that of the 0.394 MeV peak of ^{88}Zr. The results are given in Table 2. In each case, a good proportionality was obtained between R_W and R_{A_0}, where R_W is the weight ratio of zirconium to molybdenum and where R_{A_0} is the ratio of the photopeak activities corrected at the end of a 3-hr irradiation. The zirconium content can be determined down to 45 μg by this relationship, with a relative error of within 4% under the present experimental conditions.

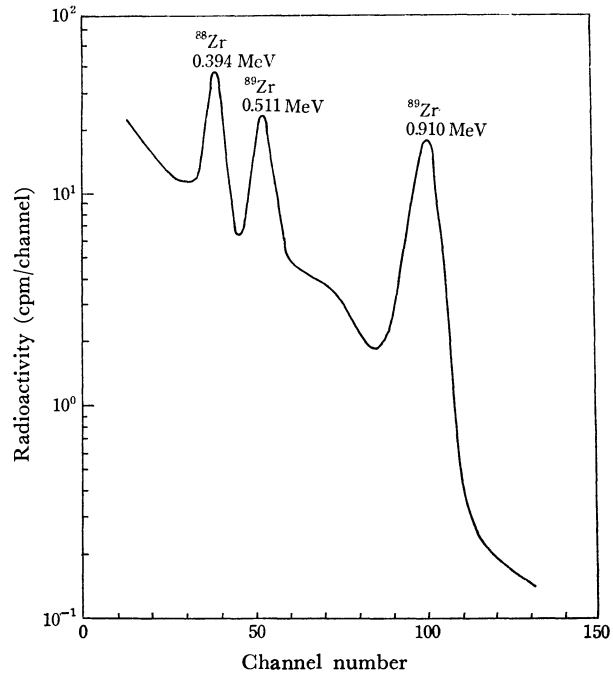

Fig. 2. γ-Ray spectrum of radiozirconium separated from a mixed sample (Zr 45.2 μg + Mo 1.815 g), 23.3 hr after irradiation with 20 MeV bremsstrahlung for 3 hr with a NaI(Tl) detector.

When a photopeak activity of 10 cpm is selected as the limit of determination, about 18 μg of zirconium in 2 g of molybdenum can be determined. With an accelerator giving a higher bremsstrahlung dose rate, the sensitivity is improved. In the energy region of 20 MeV bremsstrahlung, no interfering photonuclear reactions can occur from the coexisting elements. In the present case, the neutron reactions which arise from photoneutrons cause no serious problems.

This method can be used generally for the determination of zirconium when we add a proper amount of molybdenum, 2 g in most cases, to the sample as the reference element. When this method is combined with that reported previously for the determination of niobium,[4] zirconium and niobium may be determined simultaneously with molybdenum used as the reference.

In conclusion, the present authors believe that the method presented here is promising for the accurate

11) The dose-rate determination has been done by means of a method reported earlier.[12]

determination of zirconium in samples of various origins, provided that those samples do not contain a large amount of molybdenum.

The authors express their appreciation to members of the linac staff at the Institute of Nuclear Science, Tohoku University, for their very fine services.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1034—1039 (1971)

Studies of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes. I. The Preparation and Some Properties of Ethylenediamine-*N,N'*-diacetatocobalt(III) Complexes, with Chloride, Water, Ammonia, Ethylenediamine, 1,10-Phenanthroline, and 2,2'-Dipyridyl as the Additional Ligands

Kashiro KURODA and Kiyokatsu WATANABE

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama, Ehime

(Received September 29, 1970)

A series of cobalt(III) complexes containing the tetradentate ethylenediamine-*N,N'*-diacetate anion (EDDA) and chloride, water, ammonia, ethylenediamine, 1,10-phenanthroline, and 2,2'-dipyridyl as the ligands occupying the residual coordination positions have been prepared, and some of their physical and chemical properties have been examined. Two isomers have been isolated in the cases of the phenanthroline and dipyridyl complexes; they have been inferred to be the *α-cis*(pink) and the *β-cis*(red) isomers* on the basis of their electronic absorption spectra. A new convenient route for the preparation of the series has been presented, a route which passes through the dichloro, chloroaquo, and diaquo complexes.

Although a number of cobalt(III) complexes which contain the tetradentate ethylenediamine-*N,N'*-diacetate anion (EDDA) have been reported in the literature,[1-6] the number is still small in comparison with those of such other series as the triethylenetetraminecobalt(III) and nitrilotriacetatocobalt(III) series. The main reason for the rather few instances of isolation is undoubtedly the large solubilities or the difficulty in the crystallization of the members of the series. The addition of an organic solvent such as ethanol to a concentrated reaction mixture, a method which is often used in the complex preparations, almost always gives oily materials or highly hygroscopic precipitates in this series. For example, the carbonato-(ethylenediamine-*N,N'*-diacetato)cobalt(III) ion reacts with various anions in the acidic solution, but the addition of ethanol to the reaction mixture gives no satisfactory materials. In order to obtain good crystals, we attempted the crystallization or precipitation of a complex from an aqueous solution, keeping the other components in the solution as few in number as possible. Thus, several new complexes as well as the known species have been isolated in the nonhygroscopic state. A new convenient route of preparation will be reported in this communication.

Theoretically, a di(monodentate)-EDDA-Co(III) complex may exist in three different stereoisomers, and a bidentate-EDDA-Co(III) complex in two, as is shown in Fig. 1. Legg and Cooke isolated *α-cis*-[Co(EDDA)(en)]NO_3 and *β-cis*-[Co(EDDA)(en)]-ClO_4.[2] From the very low yield of the *β-cis* isomer and the failure to isolate *β-cis*-[Co(EDDA)$(NH_3)_2$]X, it has been considered that EDDA very much prefers the *α-cis* coordination mode.[2-5] Recently, Coleman, Legg, and Steele obtained the *α-cis* and *β-cis* isomers of oxalato-EDDA-Co(III) and malonato-EDDA-Co-

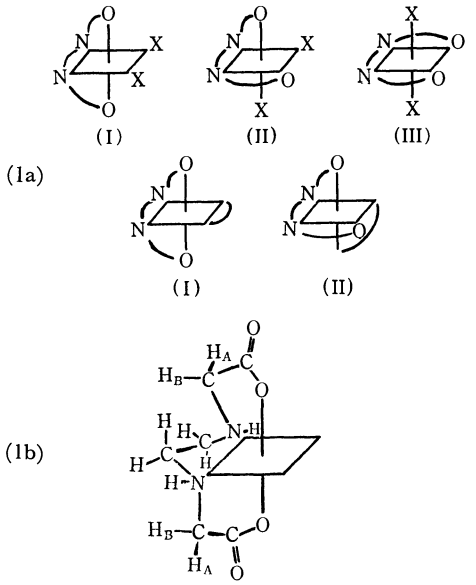

Fig. 1. Coordination modes of EDDA-Co(III) complexes.

* In this article, the nomenclature proposed by A. M. Sargeson and G. H. Searle (*Inorg. Chem.*, **4**, 45 (1965)) has been adopted in order to distinguish the isomers. The *trans* and *cis* isomer named in several articles are *α-cis* and *β-cis* isomer here, respectively.

(III) complexes.[6] In these cases, the yields of the two isomers were comparable. It has not yet been clearly established what factors determine the coordination mode of EDDA around the central cobalt ion. In our new preparative procedure, in which the chloroaquo or the diaquo complex was used as the starting material, both *α-cis* and *β-cis* isomers were obtained in the cases of the 1,10-phenanthroline and the 2,2'-dipyridyl complexes. It was possible to control the yield of the isomers by adjusting the reaction temperature.

Experimental

Materials. The ethylenediamine-*N,N'*-diacetic acid (Dotite Reagents), 1,10-phenanthroline, and 2,2'-dipyridyl (Nakarai Chemicals) and all the other reagent-grade chemicals were used without further purification.

Analysis. The cobalt was analysed by a direct EDTA titration, using murexide as an indicator, after the decomposition of a complex with hot concentrated sulfuric and nitric acid. The other elements were analysed at the Institute for Chemical Research in Kyoto University.

Apparatus and Measurements. The visible and ultraviolet absorption spectra were measured with a Hitachi ESP-3 Recording Spectrophotometer. The infrared spectra were recorded with a Hitachi EPI-G Spectrophotometer. The proton nuclear magnetic resonance spectra were recorded with a Japan Electron Optics JNM-4H-100 Spectrometer (100 MHz), using deuterium oxide as the solvent. The temperature of the probe was maintained at 22±1°C. The chemical shifts, referred to TMS as zero, were calculated from the observed shifts of a complex from the resonance of HDO (4.69 ppm downfield from the TMS resonance). The solubility measurements and the reactions with various anionic reagents were carried out by a procedure described elsewhere.[7]

*Preparations. (1) Hydrogen Dichloro(ethylenediamine-*N,N'*-diacetato)cobaltate(III), H[Co(EDDA)(Cl)$_2$]*: In 40 m*l* of water, ethylenediamine-*N,N'*-diacetic acid (1.76 g), sodium hydroxide (0.8 g), and cobalt(II) chloride hexahydrate (2.3 g) were added in this order. We then started to bubble air into the mixture, and 10 m*l* of hydrogen peroxide (30%) were added, drop by drop, through the air inlet. Air bubbling was continued for 5 hr, during which time the color of the solution changed from brown to dark red-violet and finally deep red-violet. Eighty milliliters of concentrated hydrochloric acid were added to the oxidation product, and then the mixture was concentrated on a steam bath, with continuous stirring, to about 60 m*l*. The color changed to a dark bluish green; at the same time a dark green precipitate appeared. After cooling, the precipitate was collected on a filter, and washed with concentrated hydrochloric acid, methanol, and ether. Yield, 2 g.

Found: Co, 19.35; C, 23.43; H, 3.65; N, 9.02%. Calcd for H[Co(EDDA)(Cl)$_2$]=$CoC_6H_{11}O_4N_2Cl_2$ (305.00): Co, 19.32; C, 23.63; H, 3.64; N, 9.18%.

An additional product was obtained by the further evaporation of the filtrate, but the deposit contained colorless crystals (NaCl). This product was useful for the preparation of the following chloroaquo complex.

*(2) Chloroaquo(ethylenediamine-*N,N'*-diacetato)cobalt(III) Monohydrate, [Co(EDDA)(Cl)(H$_2$O)]·H$_2$O*: One gram of hydrogen dichloro(ethylenediamine-*N,N'*-diacetato)cobaltate(III) was dissolved in a minimal amount of water (~30 m*l*); then the solution was kept at room temperature for one day. The blue-violet crystals which deposited were washed with cold water, ethanol, and ether. Yield, 0.5 g. The mother liquid was useful for the preparation of the following diaquo complex.

Found: Co, 19.27; C, 23.71; H, 4.59; N, 8.85%. Calcd for [Co(EDDA)(Cl)(H$_2$O)]·H$_2$O=$CoC_6H_{14}O_6N_2Cl$ (304.58): Co, 19.35; C, 23.66; H, 4.63; N, 9.20%.

*(3) α-cis-Diaquo(ethylenediamine-*N,N'*-diacetato)cobalt(III) Perchlorate, α-cis-[Co(EDDA)(H$_2$O)$_2$]ClO$_4$*: In 30 m*l* of water, 1 g of the above chloroaquo complex was suspended, and the mixture was heated at 60°C. After the starting complex had dissolved and the color of the solution had changed from blue-violet to red-violet, the solution was concentrated to 5 m*l*, and then 2 m*l* of 6 N $HClO_4$ was added. The mixture was placed in a refrigerator for 1—2 days. The red crystals which formed was washed with methanol and ether. Yield, 1 g. In order to deposit the complex more quickly or to recover the material from the filtrate in this procedure and from the filtrate in the chloroaquo complex preparation, the solution was evaporated in a large, flat dish with an aid of an air stream and gentle heating. When the solution contained a relatively large amount of chloride ions (in the case of the recovery), repeated evaporation was necessary to let chloride ions leave as hydrogen chloride; otherwise, the evaporation residue consisted mainly of the chloroaquo complex.

Found: Co, 15.73; C, 19.70; H, 3.82; N, 7.42%. Calcd for [Co(EDDA)(H$_2$O)$_2$]ClO$_4$=$CoC_6H_{14}O_{10}N_2Cl$ (368.57): Co, 15.99; C, 19.55; H, 3.83; N, 7.60%.

*(4) α-cis-Ethylenediamine-*N,N'*-diacetato(diammine)cobalt(III) Perchlorate Monohydrate, α-cis-[Co(EDDA)(NH$_3$)$_2$]ClO$_4$·H$_2$O*: Though the nitrate of this complex had previously been prepared by Legg and Cooke,[2] the following procedure was found to be simpler. The mixture of cobalt(II) chloride hexahydrate (2.3 g), ethylenediamine-*N,N'*-diacetic acid (1.8 g), active charcoal (0.5 g), and 10 m*l* of 6 N ammonia in 80 m*l* of water was oxidized by vigorous air bubbling for 4 hr. After the removal of the charcoal by filtration, 10 m*l* of 6 N $HClO_4$ were added to the red-purple filtrate. A large amount of crystals appeared after a while. The precipitate was recrystallized from 150 m*l* of warm (~50°C) water with the addition of a few milliliters of 6 N $HClO_4$ for complete precipitation. It was washed with ethanol and ether. Yield, 2.0 g.

Found: Co, 15.35; C, 18.50; H, 4.55; N, 14.42%. Calcd for [Co(EDDA)(NH$_3$)$_2$]ClO$_4$·H$_2$O=$CoC_6H_{18}O_9N_4Cl$ (384.62): Co, 15.32; C, 18.74; H, 4.72; N, 14.57%.

The same product was obtained from [Co(EDDA)(Cl)(H$_2$O)]·H$_2$O. A suspension which contained 0.5 g of the chloroaquo complex in 40 m*l* of water was heated until the complex dissolved completely. The complex aquated during the dissolution, and the color of the solution was red-violet. By the addition of 5 m*l* of 6 N ammonia, the color changed immediately to a more reddish tone. After the solution had been heated till the odor of ammonia vanished, 3 m*l* of 6 N $HClO_4$ were added. The precipitate thus obtained showed properties identical with those of the product prepared by the preceding procedure.

*(5) α-cis-Ethylenediamine-*N,N'*-diacetato(ethylenediamine)-cobalt(III) Perchlorate, α-cis-[Co(EDDA)(en)]ClO$_4$*: Although a procedure for the preparation for the nitrate of this complex had previously been described by Legg and Cooke,[2] the following more simple procedure was found to give a satisfactory yield. A mixture of cobalt(II) chloride hexahydrate (2.3 g), ethylenediamine-*N,N'*-diacetic acid (1.8 g),

7) K. Kuroda and P. S. Gentile, This Bulletin, **38**, 1362 (1965).

ethylenediamine (0.8 g), and active charcoal (0.5 g) in 80 ml of water was oxidized by vigorous air bubbling for 4 hr. After the removal of the charcoal by filtration, the red solution was concentrated to about 30 ml and then cooled. A large amount of a fibrous material thus appeared. (This material, which is probably the chloride of the desired complex, has a curious character; it gets entangled like fine threads in a liquid.) The material was recrystallized from warm water. When it was then mixed with concentrated perchloric acid, the crystalline form changed to powder. The perchlorate thus obtained was washed with ethanol and ether. Yield, 2.2 g.

Found: Co, 14.93; C, 24.52; H, 4.56; N, 14.24%. Calcd for $[Co(EDDA)(en)]ClO_4 = CoC_8H_{18}O_8N_4Cl$ (392.64): Co, 15.01; C, 24.47; H, 4.62; N, 14.27%.

The same product was obtained from the chloroaquo complex (2). In 40 ml of water, 0.5 g of the chloroaquo complex was aquated by gentle heating. An aqueous solution, which contained the equivalent amount of ethylenediamine (0.11 g), was then added. The color of the solution changed immediately from red-violet to reddish orange. After evaporation to about 10 ml, 3 ml of concentrated perchloric acid were added. The precipitate thus formed showed properties identical with those of the product prepared by the preceding procedure.

(6) α - cis - Ethylenediamine - N,N' - *diacetato (1,10 - phenanthroline) cobalt(III) Perchlorate, α-cis-[Co(EDDA)(phen)]ClO₄*: A mixture of the diaquo complex (0.3 g), 1,10-phenanthroline monohydrate (0.165 g), and active charcoal (0.1 g) in 50 ml of a methanol (70%)-water mixture was heated at 40°C for 1 hr with continuous stirring. After the removal of the charcoal by filtration, 2 ml of 6 N $HClO_4$ was added to the filtrate. The precipitate thus formed was collected on a filter and then extracted by warm water. The first 10 ml extract was disregarded. A few drops of 6 N $HClO_4$ were added to the last main extract (~80 ml). The pink precipitate thus formed was washed with ethanol and ether. Yield, 0.3 g.

Found: C, 42.38; H, 3.58; N, 10.85%. Calcd for $[Co(EDDA)(phen)]ClO_4 = CoC_{18}H_{18}O_8N_4Cl$ (512.75): C, 42.16; H, 3.54; N, 10.93%.

(7) β - cis - Ethylenediamine - N,N' - *diacetato (1,10 - phenanthroline) cobalt(III) Perchlorate, β-cis-[Co(EDDA)(phen)]ClO₄*: A suspension of 0.3 g of the chloroaquo complex in 20 ml of water was gently heated until the complex dissolved completely. The resulting solution was mixed with 0.1 g of active charcoal and a solution which contained 0.217 g of 1,10-phenanthroline in 30 ml of methanol, and then the mixture was concentrated to ~10 ml with continuous stirring on a steam bath. The reaction temperature was about 90°C. After the removal of the charcoal by filtration, 2 ml of 6 N $HClO_4$ were added to the filtrate. The viscous phase which was thus formed became solid after a day. This solid, after crushing, was collected on a filter and then extracted by warm water. The first extract (10 ml) was disregarded. To the main extract (~70 ml), a few milliliters of 6 N $HClO_4$ were added. The red precipitate thus formed was recrystallized once again in the same way. It was washed with methanol and ether. Yield, 0.15 g.

Found: C, 41.71; H, 3.70; N, 10.55%. Calcd for $[Co(EDDA)(phen)]ClO_4 = CoC_{18}H_{18}O_8N_4Cl$ (512.75): C, 42.16; H, 3.54; N, 10.93%.

(8) α - cis - Ethylenediamine - N,N' - *diacetato (2,2' - dipyridyl) cobalt(III) Perchlorate Monohydrate, α-cis-[Co(EDDA)(dipy)]ClO₄·H₂O*:

(9) β - cis - Ethylenediamine - N,N' - *diacetato (2,2' - dipyridyl) cobalt(III) Perchlorate Monohydrate, β-cis-[Co(EDDA)(dipy)]ClO₄·H₂O*:

These two isomers were separated from one reaction product. It is also possible to prepare each isomer separately by procedures similar to those for the phenanthroline complexes described above.

A mixture of 0.3 g of the diaquo complex (3), 0.127 g of 2,2'-dipyridyl, and 0.1 g of active charcoal in 50 ml of methanol (70%)-water mixture was heated at 55°C for 1 hr with continuous stirring. After the removal of the charcoal, the filtrate was condensed to 20 ml. A pink precipitate began to appear by cooling; it grew to a considerable amount by the addition of a few drops of 6 N $HClO_4$. This precipitate was recrystallized twice from warm water. The filtrate which was separated from the above precipitate was concentrated to 10 ml, and then 1 ml of 6 N $HClO_4$ was added. The red precipitate thus formed was recrystallized twice from warm water. Both products were washed with ethanol and ether. Yield: the pink *α-cis* isomer, 0.15 g; the red *β-cis* isomer, 0.13 g.

Found: C, 37.77; H, 3.45; N, 11.05% for the pink isomer; C, 37.47; H, 3.82; N, 10.99% for the red isomer. Calcd for $[Co(EDDA)(dipy)]ClO_4 \cdot H_2O = CoC_{16}H_{20}O_9N_4Cl$ (506.74): C, 37.92; H, 3.98; N, 11.06%.

Results and Discussion

Preparation Procedures. The preparative procedures used in this study are shown schematically

in Table 1. In this new preparative route for the series, the dichloro complex was synthesized first. All of the other species were derived from this complex, although the ethylenediamine and the diammine complexes were synthesized from cobalt(II) chloride and the ligands, too. The preparative procedure for the dichloro complex followed those of *trans*-[Co$(Cl)_2(en)_2$]Cl and the analogous dichloro complexes. It is satisfactorily simple and gives a good yield.

The solubility of [Co(EDDA)(Cl)(H_2O)], the first aquation product of the dichloro complex, is exceptionally small among the various Co(III)-EDDA complexes. It spontaneously comes out from the concentrated solution of the dichloro complex. It aquates in warm water, resulting in the diaquo complex without any decomposition. The diaquo complex reacts with various anions and neutral ligands almost instantaneously. Therefore, the chloroaquo complex is the most suitable starting substance for the syntheses of the series. This has been illustrated in the present study and will be discussed further in subsequent communications.

In the preparation of the phenanthroline and the dipyridyl complexes, the reaction temperature strongly affected the yield of the *α-cis* and the *β-cis* isomers. The *α-cis* isomer occurred at relatively low temperatures (~40°C), whereas the *β-cis* isomer was formed at higher temperatures (>55°C). Because the starting diaquo complex is the *α-cis* isomer and the *α-cis* configuration is probably more stable than the *β-cis* configuration, it is reasonable to consider that the occurrence of the *β-cis* isomer needs the heat of the rearrangement of the ligands and, hence, a higher temperature.

Reactions with Anionic Reagents. The solubility and the reactions with various anionic reagents were examined on several of the cationic complexes prepared. The results are summarized in Table 2. The color change in the diaquo complex with CN^-, NO_2^-, NCS^-, *etc.* are undoubtedly due to the substitution of the coordinated water by the anions. The isolation of these acido-complexes will be reported in subsequent communications.

It has been reported that trichloroacetic acid makes precipitates with *trans*-[CoN_4O_2]-type complexes, but not with their *cis*-isomers in general.[8] The diammine and the ethylenediamine complexes in this study, which have the *α-cis* configuration (the *trans* configuration with respect to O), as will be discussed below, make precipitates with trichloroacetate, as is indicated in Table 2; that is to say, the two complexes also have the common property observed previously in the other *trans*-[CoN_4O_2]-type complexes.

(4) β-*cis*-[Co(EDDA)(dipy)]ClO_4

of the complexes studied. Two samples of the diammine complex as well as of the ethylenediamine complex, which were obtained by the two different procedures, showed completely identical spectra; those spectra also agreed with those obtained by Legg and Cooke[2] within the limits of experimental error. The absorption curves have the characteristic feature of *trans*-isomers, namely, a large split in the first band, and are similar to those of *trans*-[Co$(CH_3CO_2)_2(NH_3)_4]^+$ and *trans*-[Co$(CH_3CO_2)_2(en)_2]^+$ previously studied.[8] The spectra show clearly that the complexes have the α-*cis* configuration.

The absorption maxima and their intensities of the dichloro, chloroaquo, and diaquo complexes are on the ordinary line of the spectrochemical and hyperchromic series:

$$\bar{\nu}_{Cl_2} < \bar{\nu}_{ClH_2O} < \bar{\nu}_{(H_2O)_2}$$

$$\varepsilon_{Cl_2} > \varepsilon_{ClH_2O} > \varepsilon_{(H_2O)_2}$$

The spectrum of the dichloro complex is worth examining in relation to its structure. Although the shape of the first band is nearly symmetrical, a small deformation (expansion) in the higher-wave-number region ($\sim 19\times10^3$ cm^{-1}) of the band is observable, as may be seen in Fig. 3. If the complex be the *trans*-isomer (III in Fig. 1), a large split in the first band would be expected as the spectrum of *trans*-[Co$(Cl)_2(en)_2]^+$, because of the *trans*-coordination of the two chlorine atoms. Therefore, the possibility of the III mode may be eliminated. If the complex be the β-*cis* isomer (II), two atoms of the same kinds (Cl–Cl, N–N, O–O) are at the *cis*-positions. In this configuration, a very intense absorption would be expected, since the ligand field around the central atom is highly unsymmetrical. The α-*cis* configuration (I), though the evidence from the spectrum alone is not conclusive, is the most reasonable assignment for the dichloro complex, and the small deformation mentioned above may be attributed to the *trans(O)*-component of the coordination mode.

Since ethylenediamine, 1,10-phenanthroline, and 2,2′-dipyridyl are near to each other in the spectrochemical series, the spectra of the α-*cis* isomer of the phenanthroline and the dipyridyl complexes are expected to resemble that of α-*cis*-[Co(EDDA)(en)]$^+$, at least in the *d-d* transition region. As may be seen in Figs. 2 and 4, one of the two isomers of the phenanthroline and dipyridyl complexes shows an analogous absorption curve between 15×10^3 and 25×10^3 cm^{-1} to that of the ethylenediamine complex, although the Ib absorption is less pronounced. Therefore, the pink isomers have undoubtedly the α-*cis* configuration. It has been observed that the first band of a *cis*-[CoN_4O_2]-type complex has a slight deformation in the lower-wave-number region of the band and has a higher absorption intensity than the corresponding *trans*-isomer.[9] The red isomers of both the phenanthroline and the dipyridyl complexes showed these characteristics. The facts indicate that the red isomers have the β-*cis* configuration. In the ultraviolet region of

9) K. Kuroda and P. S. Gentile, *J. Inorg. Nucl. Chem.*, **27**, 155 (1965).

the spectra of these complexes, there are several maxima and shoulders, as may be seen in Fig. 4. These absorptions are sure to be originated from the conjugate π-bond systems of the bidentate ligands. The complete similarity of the curves between the two geometrical isomers means that the ligand specific bands are little influenced by the structure as a whole and that, furthermore, the two substances are certainly a pair of different configurational isomers.

Infrared Spectra. The infrared spectra were supplementally used in this study for the estimation of the structure of the complexes prepared. The anhydrous dichloro complex showed only one strong absorption (3165 cm^{-1}) in the NH, OH stretching region, whereas three peaks (3625, 3495, 3170 cm^{-1}) were observed in the chloroaquo complex (monohydrate) and two peaks (3470, 3300 cm^{-1}) in the diaquo complex (anhydrous). Two absorptions, that at 3170 cm^{-1} of the chloroaquo and that at 3300 cm^{-1} of the diaquo complex, may be assigned to the NH-stretching mode. It may be considered that the other two peaks of the former come from the lattice and the coordinated water, and that one peak of the latter originates from the equivalent H_2O ligands of the *α-cis* configuration.

In the complexes which contain ligands with a carboxyl group, another noteworthy region in the infrared spectra is around 1650 cm^{-1}, the CO-stretching region. Each of the complexes studied showed a broad strong absorption in this region, which is considered to be due to the CO-stretching overlapped by the NH_2 and OH_2 deformation modes. The lack of absorption between 1700--1800 cm^{-1} indicates that the two carboxyl groups of EDDA certainly coordinate to the central cobalt and are not present as the free-acid type.[10]

Proton Nuclear Magnetic Resonance Spectra. Van Saun and Douglas measured the PMR spectra of the M[Co(EDDA)(AA)] they had prepared, where AA= ox, mal; they observed only one AB quartet pattern due to the glycinate ring protons of EDDA.[4] Because CO_3, of the equivalency of the two glycinate rings in the *α-cis* configuration, they concluded that their complexes were *α-cis* isomers. Recently, Coleman, Legg, and Steele prepared the *β-cis* isomers of $[Co(EDDA)(ox)]^-$ and $[Co(EDDA)(mal)]^-$ and analysed the PMR spectra of the isomers as well as the *α-cis* isomers.[6] As expected from the configuration of the *β-cis* isomers, the spectra were much more complicated than those of the *α-cis* isomers.

The PMR spectrum of $[Co(EDDA)(H_2O)_2]ClO_4$ is shown in Fig. 5. It can be seen that one AB quartet pattern due to the glycinate protons and a symmetrical

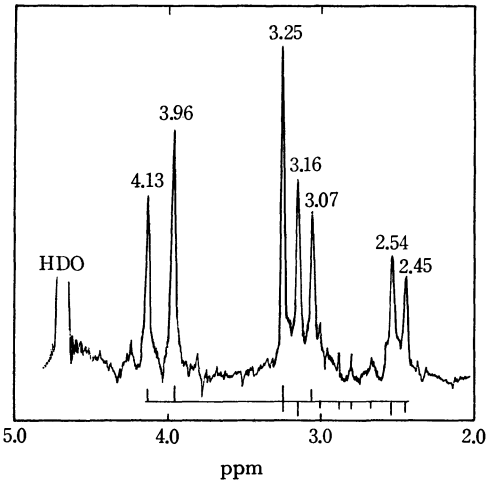

Fig. 5. PMR spectrum of D_2O solution of $[Co(EDDA)(H_2O)_2]ClO_4$.

A_2B_2 pattern due to the ethylene backbone protons are present, although not all the resonances of the latter protons theoretically expected (12 resonances) can be clearly observed. The chemical shifts of the glycinate protons (H_A and H_B in Fig. 1b) are 4.04 and 3.17 respectively, and the coupling constant, J_{AB}, is 18 Hz. These values are in agreement with those which have been obtained previously with the analogous complexes.[2-6] These results indicate that the diaquo complex is the *α-cis* isomer.

The spectra of the other complexes are a little more difficult to measure or to analyse because of the low solubility (chloroaquo complex), the rapid aquation (dichloro complex), or the presence of many kinds of protons in a complex ion (phenanthroline and dipyridyl complexes). The research is still in progress.

Conclusion

Seven new complexes, $H[Co(EDDA)(Cl)_2]$, $[Co(EDDA)(Cl)(H_2O)]\cdot H_2O$, *α-cis*-$[Co(EDDA)(H_2O)_2]ClO_4$, *α-cis*- and *β-cis*-$[Co(EDDA)(phen)]ClO_4$, *α-cis*- and *β-cis*-$[Co(EDDA)(dipy)]ClO_4\cdot H_2O$, as well as two known complexes, *α-cis*-$[Co(EDDA)(NH_3)_2]ClO_4\cdot H_2O$ and *α-cis*-$[Co(EDDA)(en)]ClO_4$, have been prepared by new, simple preparation procedures. The *α-cis* and *β-cis* isomers of the phenanthroline and the dipyridyl complexes have been identified by means of their electronic absorption spectra. The *α-cis* configuration of the diaquo complex has been confirmed by a study of the PMR spectrum. The dichloro and the chloroaquo complexes are supposed to be *α-cis* isomers from the electronic absorption spectra, although this is not completely certain.

The Indirect Determination of Microamounts of Mercury(II) by Means of Dithizone Extraction and AC Polarography

Tomihito KAMBARA and Minoru HARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 12, 1970)

It was found that dithizone in an aqueous alkaline solution shows sharp AC polarographic peaks; the indirect determination of mercury by means of these peaks was investigated. After the extraction of mercury(II) dithizonate into benzene, the excess dithizone was eliminated. Then the mercuric ion was stripped into the aqueous phase containing the iodide ion. The isolated dithizone in the benzene layer was back-extracted into the alkaline supporting electrolyte solution and the polarogram was recorded. By the present method, up to 30 μg of mercury can be determined.

Dithizone(H_2Dz) is a very sensitive reagent which has been used for the colorimetric determination of many metals. Separation by means of solvent extraction is very easy, useful, and selective. In polarographic determinations of copper, zinc,[1] lead,[2] and cadmium,[3] the metals are extracted as dithizonates into an organic layer, the solvent is evaporated, and the residue is redissolved in water, or the dithizonates are back-extracted from the organic phase into a suitable aqueous solution. Recently Yamashita[4] has reported the interesting polarographic behavior of dithizone and metal dithizonates in a ternary solvent mixture consisting of chloroform, water, and methylcellosolve.

The present authors have now found that dithizone in an aqueous alkaline solution gives sharp peaks in AC polarography, and have investigated the application of these dithizone peaks to the microdetermination of mercury. In the present method, the microamount of mercury is extracted into benzene, and then the excess dithizone in organic layer is back-extracted into an aqueous ammonia solution. Then, dithizone is stripped from the mercury dithizonate by shaking it with an aqueous potassium iodide solution. The dithizone remains in benzene, but the mercury goes into the aqueous phase as an iodo-complex. The electrolysis solution was prepared by shaking the supporting electrolyte solution, consisting of sodium sulfate and sodium hydroxide, with the remaining organic layer, containing the isolated dithizone. The mercury is determined indirectly from the height of the dithizone peak. The fundamental conditions for this method are discussed below.

Experimental

Reagents. 30 mg of dithizone (Wako Chemicals Co., guaranteed reagent) were dissolved in benzene and purified as usual; then the volume was made up to 200 m*l* with benzene. This stock solution was diluted, and the concentration of the dithizone was estimated by the absorbance and the molar absorptivity at 620 mμ.[5]

The standard stock solution of mercury(II) was prepared by dissolving 0.1354 g of mercuric chloride in 100 m*l* of 1 N sulfuric acid and was then diluted when used.

The stripping solution was prepared by dissolving 10 g of potassium hydrogen phthalate and 25 g of potassium iodide in 500 m*l* of distilled water, a few crystals of sodium thiosulfate being added to reduce any trace of the iodine liberated. The solution was then further purified by shaking it with a dithizone-benzene solution in order to remove any heavy metal.

The supporting electrolyte solution was prepared by mixing 250 m*l* of 0.4 M sodium sulfate and an appropriate volume of 1 N sodium hydroxide, and by then making the volume up to 500 m*l* with distilled water.

The other chemicals used were all guaranteed reagents.

Apparatus. AC polarographic measurements were performed by using a Yanagimoto polarograph, type PA-102. The dropping mercury electrode with the following characteristics was used: $m=0.526$ mg/sec, $t=5.57$ sec at $h=65.0$ cm, at an open circuit in the deaerated supporting electrolyte solution.

The absorbances and absorption spectra were measured with a Shimadzu spectrophotometer, type QV-5, by the aid of a 1-cm glass cell. The pH of the solutions was measured with a Hitachi-Horiba glass electrode pH meter, type F-5.

Established Procedure. Take the sample solution up to 50 m*l* containing mercury up to 30 μg that is made about 0.5 N in sulfuric acid. If necessary, add masking reagents. Add 10 m*l* of 1×10^{-4} M dithizone-benzene solution and shake for 1 min. Transfer the organic layer to another separating funnel. Add 10 m*l* of 0.15 N ammonium hydroxide, shake for 15 sec, and discard the aqueous solution. Repeat this operation once again. The excess dithizone is thus removed. Add 10 m*l* of the above-cited stripping solution into a separating funnel, in which the benzene layer containing only mercury dithizonate should remain, and shake for 1 min. Then mercury(II) is transfered into the aqueous solution. Allow the mixture to stand for a while, transfer 5 m*l* of the benzene layer containing the isolated dithizone to another separating funnel containing 5 m*l* of the supporting electrolyte solution (pH=12.5), and shake for 10 sec. Transfer the aqueous solution into a polarographic cell. Record an AC polarogram at 25±0.1°C, after deaeration by passing nitrogen gas through for 5 min.

Results and Discussion

AC Polarogram of Dithizone. Figure 1 shows the AC polarogram of dithizone in a 0.2 M sodium sulfate alkaline solution. Two prominent peaks are observed in the AC polarogram, but the corresponding DC

(1) peak I. (2) peak II.

steps are very ill-defined. Without deaeration, the heights of the two peaks tend to decrease; peak I, appearing at the more negative potential, decreases especially rapidly.

The effect of the pH of the supporting electrolyte solution on the heights of the two peaks is shown in Fig. 2. The height of the peak I increases linearly with the increasing pH, but that of peak II remains constant in the pH region between 12.4 and 12.9.

Figure 3 shows the temperature dependance of the AC peaks. Although the height of peak I increases with the temperature, that of peak II shows an almost constant value. Under the above conditions, the peak I is always higher than peak II. This indicates that the determination of dithizonate using peak I is more sensitive; however, the height of peak I is remarkably

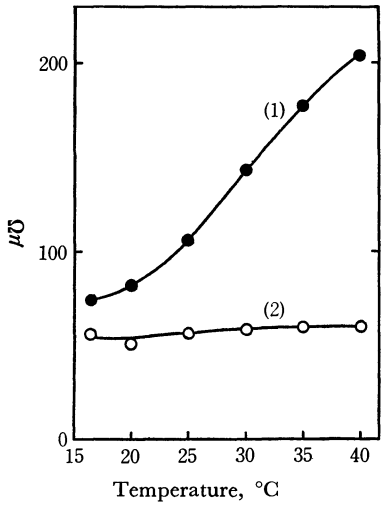

Fig. 3. Effect of temperature on the AC peak heights of dithizonate ion.

pH=12.47 at 19°C.
(1) peak I. (2) peak II.

influenced not only by the pH but also by the temperature. Hence, a little deviation in pH and temperature would cause a significant analytical error. In order to avoid these errors, the present authors employed peak II for the determination of dithizone. The temperature was fixed at 25±0.1°C, and the pH was adjusted to about 12.5. Under the above conditions, the AC peak height shows a linear relationship up to a dithizone concentration of 3×10^{-5} M. In the concentration range higher than the above value, the polarogram becomes ill-defined.

Extraction of Mercury and Elimination of Excess Dithizone. It was first confirmed that 20 μg of mercury(II) in 10 m*l* of 0.5 N in sulfuric acid can be extracted quantitatively by shaking it for only 30 sec with a 4.4×10^{-5} M dithizone-benzene solution.

Now, the method of eliminating the excess dithizone from organic solution will be investigated. When the organic solution is shaken with 10 m*l* of 0.15 N ammonium hydroxide, the free dithizone in the organic solution is back-extracted. In order to eliminate the free dithizone completely, this operation is done once again. 10 m*l* of a 1×10^{-4} M dithizone-benzene solution was found to show no absorbance at 620 mμ after these operations. Milton and Hoskins[6] investigated the mono-color determination method of mercury(II) dithizonate, in which the excess dithizone is removed by shaking with dilute ammonia. According to them, shaking with 0.75 N ammonium hydroxide converts the primary dithizonate, $Hg(HDz)_2$, into the secondary dithizonate, HgDz. When 0.75 N ammonium hydroxide is used in the present study, the longer the shaking time, the greater the decrease in the absorbance at the wavelength of the maximum absorption of mercury (II) dithizonate, $Hg(HDz)_2$. However, the evidence for the formation of the secondary complex has not been found, the shape of the absorption spectrum showing no change. When 0.15 N ammonium hydro-

6) R. F. Milton and J. L. Hoskins, *Analyst*, **72**, 6 (1947).

xide is used, neither a change in the absorption spectrum nor a decrease in the absorbance was recognized. It was found that 10 m*l* of a 1×10^{-4} M dithizone-benzene solution can extract 20 μg of mercury quantitatively from 60 m*l* of an aqueous solution.

Stripping of Mercury. In order to isolate the dithizone from the mercury dithizonate, the reversion method proposed by Irving *et al.*[7] was used. That is, the mercuric ion was back-extracted into the acidified iodide solution, presumably as triiodo-mercurate(II).

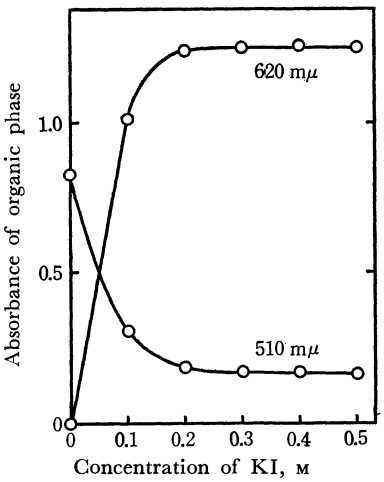

Fig. 4. Effect of the concentration of potassium iodide on the back-extraction of mercury.
$Hg(HDz)_2$ in org. soln.: 1.61×10^{-5} M
pH=3.67 (0.1 M phthalate buffer)
Shaking time: 2 min
$V_{org.} = V_{aq.} = 10$ m*l*

Figure 4 shows the effect of the iodide concentration on the stripping of mercury. 10 m*l* of the organic layer is shaken for 2 min with an equal volume of an iodide solution. The maximum absorbance of dithizone in benzene at 620 mμ shows a constant value when the concentration of potassium iodide is higher than 0.3 M. Also, at 510 mμ, at which dithizone has its minimum absorptivity but mercuric dithizonate shows a high extinction, shaking with a potassium iodide solution higher than 0.3 M results in a constant absorbance. The absorption spectra of these organic layers being the same as that of dithizone in a benzene solution, the existence of the mercury dithizonate in the organic layer may be disregarded.

Thus, it is confirmed that the 0.3 M potassium iodide solution can back-extract mercury quantitatively from an equal volume of a benzene solution of mercury dithizonate. The shaking time of 30 sec is found to be sufficient for the back-extraction under the above conditions. Further, it is found that the ratio of the concentration of the isolated dithizone to that of the mercury taken is two. Hence, the extraction and back-extraction of mercury can be carried out quantitatively. Furthermore, the mercury dithizonate, $Hg(HDz)_2$, is not converted into the secondary complex, HgDz.

Aqueous Solution of Dithizone. The step in which the isolated dithizone is transferred into the supporting electrolyte solution is investigated. A 0.2 M sodium sulfate solution, the pH of which is adjusted with a sodium hydroxide solution, is used as the supporting electrolyte solution. When the pH of the supporting electrolyte solution is higher than 11.5, the dithizone in the benzene layer is back-extracted into the aqueous solution as the dithizonate ion. Irving *et al.*[8] reported the decomposition of dithizone in an aqueous alkaline solution. They stated that dithizone in 1.5 N ammonium hydroxide decomposes at a rate of 20—30%/hr, but in 0.15 N ammonium hydroxide the velocity becomes very slow.

In the present experiment, the dithizonate ion is stable for one hour, at least in 0.2 M sodium sulfate solution, the pH of which is adjusted to 12.52 with sodium hydroxide.

Thus, in this procedure the decomposition of the dithizonate ion can be neglected. It should be further mentioned that the electrolysis solution should be completely free from the iodide ion. Because the iodide ion shows a broad peak as the result of an anodic process, the peak of dithizone is very much disturbed. When a 5-m*l* portion of the isolated dithizone solution is pippeted out to another separating funnel, contamination by the iodide ion is avoided.

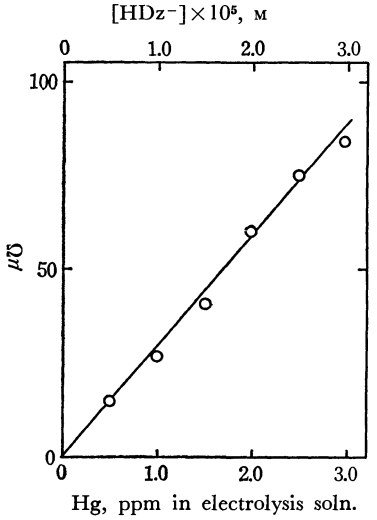

Fig. 5. Calibration curve.

Calibration Curve. The calibration curve obtained according to the above procedure is shown in Fig. 5. Up to 30 μg of mercury the peak height is proportional to the amount of mercury taken. When the determination of 20 μg of mercury was repeated seven times, the relative standard deviation was 4.2%.

For comparison, the same amount of mercury was determined by dithizone spectrophotometric methods. The relative standard deviation of six measurements was 4.6% in the mixed color method and 3.1% in the mono-color method. In the method of the measuring the absorbance of the free dithizone in benzene which is liberated from the mercury(II) dithizonate by stripping mercury(II) with the iodide ion, the relative standard deviation was 2.1%.

$F(2, 6, 0.025)=7.26 > F_0=2.22$
$F(6, 2, 0.025)=39.3 > F_0=18.03$
$t(8, 0.025)=2.306 > t_0$
(1) Add 200 mg of NaCl, discard the aqueous layer, shake with 10 m*l* of 1% NaCl in 0.5 N H_2SO_4.
(2) Add 200 mg of EDTA-2Na salt.

Effect of Diverse Ions. The mercury(II) sample solution is 0.5 N in sulfuric acid, so it is supposed that gold(III), palladium(II), platinum(II), silver(I), and copper(II) are extracted together and that they interfere with the determination of mercury. It is known, however, that these ions are masked with the chloride ion and EDTA.[9] In this work the interferences by silver and copper have been investigated.

The extraction of 20 μg of mercury was investigated; the results are shown in Table 1. When 2.2 mg of silver(I) coexists in 20 m*l* of the sample solution, it is not masked completely by adding 200 mg of sodium chloride. However, as may be seen in Table 1, the silver(I) ion does not interfere if the benzene extract is shaken once again with 10 m*l* of a 1% sodium chloride solution in 0.5 N sulfuric acid; further, 1.3 mg of copper(II) is masked completely with EDTA. According to the familiar *t*-test, no significant difference is found between the means of the peak heights at the 95% significant level.

The Effect of Solvents on the Adduct Formation of Uranyl Thenoyltrifluoroacetonate with Tributyl Phosphate

Kenichi Akiba and Nobuo Suzuki*

Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Sendai

(Received October 28, 1970)

Addition compound formation between uranyl bis-thenoyltrifluoroacetonate (UO_2A_2) and tributyl phosphate(S) was studied by a partition method, using uranium-237 as the tracer. The formula of the adduct complex was shown to be $UO_2A_2 \cdot S$. The solvent effect on the adduct formation constant was taken into account in connection with the activity; the activity coefficients of each species in various solutions were calculated from the molar volume and the solubility parameter. The formation constants based on the molar fraction, K_x, in a number of solvents were pre-estimated, employing $\log K_x = 7.08$ in carbon tetrachloride as a reference. They are in agreement with the observed values. The formation constant in terms of activity was found to be constant $\log K_S^\circ = 5.77 \pm 0.30$. A correlation between the formation constants of the two adducts, $UO_2A_2 \cdot S$ and $ZnA_2 \cdot S$, was demonstrated.

An addition of one or more basic molecules to a formally neutral chelate with unsaturated coordination sites has been found in many organic solutions. Most of the synergistic effects in extraction are ascribed to the formation of addition compounds, though various explanations of these effects have been postulated.[1] The adduct formations of uranyl complexes with neutral ligands have received much attention; several authors have investigated the effects of β-diketones (*e.g.*, TTA) and/or organophosphorous esters (*e.g.*, TBP).[2-4] However, there have been only a few systematic studies of the solvent properties governing the equilibrium constants in synergistic extraction processes.

In previous papers, the solvent effect on distribution coefficients was elucidated in typical extraction systems.[5-7] Further, the adduct formation constants of the zinc-TTA chelate with TBP in a variety of organic solvents were correlated with the activity coefficients of the substances involved in the reaction.[7]

The present study has been undertaken in order to clarify the regularities in the formation of an adduct complex between a coordinatively unsatulated chelate, uranyl bis-thenoyltrifluoroacetonate, and tributyl phosphate. The formation constants are pre-estimated from the calculated activity coefficients and are compared with those observed. The relation between the formation constants of uranyl -and zinc-TTA adducts with TBP is also investigated.

Experimental

Materials. A radioisotope of uranium-237 was produced by irradiating natural uranium with a 60 MeV bremsstrahlung from a linear electron accelerator in the Laboratory of Nuclear Sciences, Tohoku University. The irradiated sample was then treated as before.[5]

Thenoyltrifluoroacetone (TTA) was purified by sublimation under reduced pressure, while tributyl phosphate (TBP) was purified as before.[7]

The organic solvents used were purified in the usual manner.

Procedure. An aqueous $(H,Na)ClO_4$ solution (ionic strength=0.10) including ^{237}U was shaken for 20 hr with an equal volume of a desired organic solution containing TTA and TBP. The phases were separated by centrifugation, and aliquots of both phases were taken for the measurement of the γ-radioactivity. All the experiments were performed in a room thermostated at 25±1°C.

Results and Discussion

The adduct formation of the neutral chelate in the organic solution is expressed by:

$$UO_2A_2 + m\,S \rightleftarrows UO_2A_2 \cdot m\,S \qquad (1)$$

$$K_S = \frac{[UO_2A_2 \cdot m\,S]}{[UO_2A_2][S]^m} \qquad (2)$$

where UO_2A_2 represents the uranyl-TTA chelate; S, tributyl phosphate, and K_S, the molar formation constant of the adduct.

In the extraction of the uranyl complex with a TTA solution containing TBP from an aqueous medium, the distribution ratio of uranium ($D_{M,S}$) is given by:

$$D_{M,S} = \frac{P_M\beta_2[A^-]_{aq}^2\{1+\sum K_S[S]^m\}}{1+\sum\beta_n[A^-]_{aq}^n} \qquad (3)$$

where $P_M=[UO_2A_2]_{org}/[UO_2A_2]_{aq}$ and $\beta_n=[UO_2A_n^{(2-n)+}]/[UO^{2+}][A^-]_{aq}^n$. At a fixed aqueous concentration of the TTA anion, the next equation is given:

$$\frac{D_{M,S}}{D_M} = 1 + \sum K_S[S]^m \qquad (4)$$

where D_M is the distribution ratio in the absence of TBP. When only one adduct is predominant, Eq. (4) may be simplified to:

$$K_S = \frac{D_{M,S}}{D_M}\frac{1}{[S]^m} \qquad (5)$$

The formation constant can be obtained by a curve fitting method[8] according to Eq. (4) or by Eq. (5).

Distribution of Uranyl Complexes. The distribution ratios in the presence of TBP are independent of the uranyl concentration in the experimental range of 10^{-7} to 10^{-4} M, as Fig. 1 shows, even for paraffinic solvents such as *n*-hexane where the influence of the uranyl concentration has been found in the absence of TBP, as has been described previously.[5] It seems likely that the addition of organophilic TBP very greatly increases the solubility of the uranyl complex in these solvents and eliminates the change in the activity coefficients with an increase in the concentration.

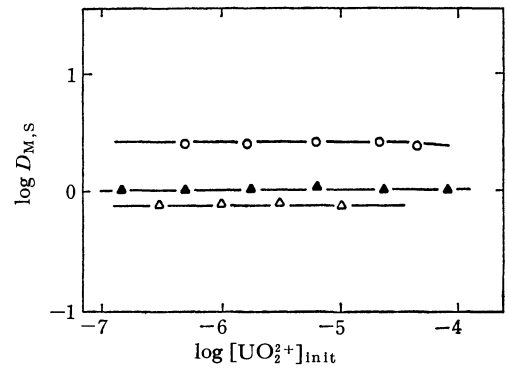

Fig. 1. Distribution ratios of uranyl complexes as a function of uranyl concentration.
[HA]=10^{-2} M; [S]=3.66×10^{-3} M; ○, *n*-hexane (pH=1.76); ▲, carbon tetrachloride (pH=1.76); △, benzene pH=1.80)

The uranyl concentration was kept at 10^{-5} M in subsequent experiments.

The plots of log $D_{M,S}$ against pA at a fixed concentration of TBP gave a series of straight lines, with a slope of −2, which run parallel with the broken line for benzene at no TBP, as Fig. 2 shows; the addition

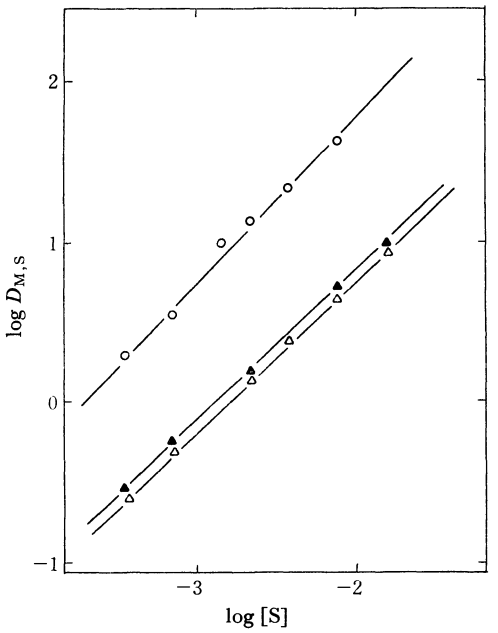

Fig. 3. Distribution ratios of uranyl complexes as a function of TBP concentration.
[HA]=10^{-2} M; ○, *n*-hexane (pH=2.24); ▲, carbon tetrachloride (pH=1.96); △, benzene (pH=2.03)

of TBP much enhances the distribution ratios, but the uranyl complexes still retain the two molecules of TTA which are bonded with each uranyl ion. It seems that the formally neutral chelate transfers to the organic phase from the aqueous phase and associates with TBP to form a coordinatively saturated adduct, or that, preferably, the water molecules in the complex are replaced by hydrophobic-donor molecules of TBP.

The variation in $\log D_{M,S}$ with $\log [S]$ were represented by a family of straight lines with a slope of 1, as Fig. 3 shows; this indicates that only one molecule of TBP is associated with the chelate and that there is no higher adduct, $UO_2A_2 \cdot mS$ ($m>1$), under the experimental conditions here adopted. The extraction of the uranyl complex with TBP alone, free from any chelating agent, is negligibly small at these low concentrations of TBP and acid. Accordingly, only one adduct, $UO_2A_2 \cdot S$, is taken up in this study.

Estimation of Adduct Formation Constants. An equilibrium constant will be strongly influenced by the nature of the medium, though the stoichiometry of the adduct remains unaltered. For a comparison of reactions in different media, the formation constant should be considered in connection with the activity, because the activity coefficient of the solute is very sensitive to the properties of the medium and the concentration is not always directly proportional to the activity. In a previous paper, an approach to the problem of the role of solvents in the adduct formation of the zinc-TTA chelate with TBP was made from this point of view; the regularity of equilibrium constants in various organic solutions was fairly well established.[7] Such a treatment seems to be valid for the uranyl adduct in this work.

The formation constant expressed in activities is:

$$K_S^\circ = \frac{a_{M \cdot S}}{a_M \cdot a_S} \tag{6}$$

where a is the activity, and where the two subscripts, M and M·S, denote the molecules of the chelate and its adduct respectively. When the activity of a pure supercooled-liquid is chosen as the standard state, K_S° can be considered to be constant, regardless of the solvents; the effect of the solvent may be connected with the change in the activity coefficient with the solvent properties. In using the expression based on the molar fraction for thermodynamic convenience, K_S° is represented by:

$$K_S^\circ = \frac{x_{M \cdot S}}{x_M \cdot x_S} \cdot \frac{\gamma_{M \cdot S}}{\gamma_M \cdot \gamma_S} \tag{7}$$

where x is the molar fraction, and γ, the activity coefficient. Eq. (7) is then rewritten as follows:

$$\log K_x = \log K_S^\circ - \log F_\gamma \tag{8}$$

where $K_x = x_{M \cdot S}/x_M \cdot x_S$ and $F_\gamma = \gamma_{M \cdot S}/\gamma_M \cdot \gamma_S$. Therefore, when the quantity related to the activity coefficients is given in the desired solvents, the constant, K_S°, can be derived from the K_x value obtained experimentally in a certain solvent; the K_x values in others can be pre-estimated from the values of K_S° and F_γ.

The activities of TBP have been measured in many solutions,[9,10] but those of the uranyl chelate and the adduct have never been given. It is not always easy to measure the activity, but the activity may be practically evaluated by the aid of the following equation for a regular solution consisting of two components, A and B:[11]

$$RT \ln a_A = RT\left[\ln \varphi_A + \varphi_B\left(1 - \frac{V_A}{V_B}\right)\right] + V_A \varphi_B^2 (\delta_A - \delta_B)^2 \tag{9}$$

where φ is the volume fraction; V, the molar volume, and δ, the solubility parameter. Taking into account the dilute solution of the solute A in the solvent B, the activity coefficient based on molar fraction can be written as:

$$RT \ln \gamma_A = RT\left[\ln \frac{V_A}{V_B} + \left(1 - \frac{V_A}{V_B}\right)\right] + V_A (\delta_A - \delta_B)^2 \tag{10}$$

Accordingly, the activity coefficient can be calculated from the physicochemical properties of a pure liquid, *i.e.*, the molar volumes and the solubility parameters of the solute and of the solvent.

As to the chelate, it is reasonable to postulate that $\delta_M \fallingdotseq \delta_{HA} = 9.9$ (HA denotes the TTA molecule) and $V_M \fallingdotseq 2V_{HA} = 320$ m*l* as has been described previously.[5] We have no sufficient data to evaluate the V and δ of the uranyl adduct. The solubility parameter of $UO_2A_2 \cdot S$ is probably close to that of $ZnA_2 \cdot S$, because the molecular forms of the adducts appear to be similar to each other. The $\gamma_{M \cdot S}$ values were calculated on the assumption that $\delta_{UO_2A_2 \cdot S} \fallingdotseq \delta_{ZnA_2 \cdot S} = 9.4$ and that $V_{M \cdot S} = V_M + V_S = 593$ m*l*.[7] The γ_S values were ob-

a) Observed value employed as reference.

tained from the data on TBP.[9,10]

The constant, $\log K_S^\circ = 5.85$, was given from the calculated F_γ value and $\log K_x = 7.08$ in carbon tetrachloride, which was used as a reference solvent. The adduct formation constants pre-estimated according to Eq. (8) are listed in the sixth column of Table 1. No estimate in methylene chloride or isopropylbenzene is given because of the lack of data on TBP.

The relation between the formation constants for uranyl and zinc adducts with TBP is considered, as the formation constants of $ZnA_2 \cdot S$ have been obtained in various organic solutions.[7] The formation constant for $ZnA_2 \cdot S$ is also expressed as:

$$K^\circ_{S(Zn)} = \frac{x_{ZnA_2 \cdot S}}{x_{ZnA_2} \cdot x_S} \cdot \frac{\gamma_{ZnA_2 \cdot S}}{\gamma_{ZnA_2} \cdot \gamma_S} = K_{x(Zn)} \cdot F_{\gamma(Zn)} \qquad (11)$$

The activity coefficients of different solutes having the same values of the solubility parameter and of the molar volume should be equal to one another in a given solvent, according to Eq. (10), so long as the specific interaction between the solute and solvent molecules is small enough to be neglected. As the above assumptions for the δ and V of uranyl chelate seem to hold also for the zinc chelate, the activity coefficients of these chelate are taken as equal to each other. Similarly, the γ values for uranyl and zinc adducts may be identical in the same media. These findings lead to the conclusion that $F_{\gamma(U)} \fallingdotseq F_{\gamma(Zn)}$ in a given solvent. Each K_S° value for uranyl and zinc adducts is constant; therefore, the following relation can be given by eliminating the terms of the activity coefficients:

$$\frac{K_{x(U)}}{K_{x(Zn)}} = \frac{K^\circ_{S(U)}}{K^\circ_{S(Zn)}} = h \qquad (12)$$

or $\log K_{x(U)} = \log K_{x(Zn)} + \log h$

The formation constants of the uranyl adduct can also be estimated from those of the zinc adduct. The constant, $\log h = 1.63$, was obtained from the observed values for two adducts in carbon tetrachloride. The estimates from Eq. (12) are shown in the seventh column of Table 1.

Regularities in Adduct Formation. The observed adduct formation constants are summarized in Table 1. The molar formation constants ($K_S/K_x = V_B/1000$) are also tabulated. The observed values are in rough accord with the estimates; they are especially consistent with the pre-estimations from Eq. (12). The K_S values in two solvents have been reported. The present datum in cyclohexane agrees with $\log K_S = 6.77$,[12] but that in benzene is larger than the $\log K_S = 5.28$ and 4.74 in the literature.[1]

Figure 4 shows the relation between the adduct

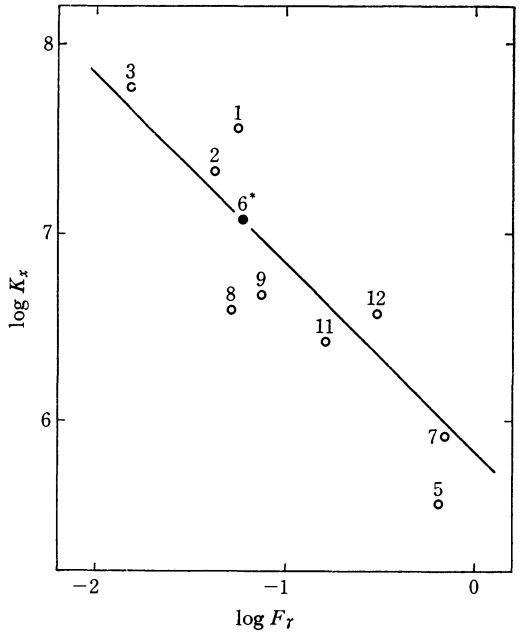

Fig. 4. Relation between the adduct formation constants and the activity coefficients.
The numbers in Figs. 4 and 5 correspond to those in Table 1.

formation constants and the activity coefficients. The straight line with a slope of −1 passing through a experimental point in carbon tetrachloride is the estimate. The points observed are close to the line, although negative deviations are found in benzene and chloroform and a positive one in *n*-hexane. This tendency is similar to the case of the zinc adduct.[7] The negative deviation in chloroform appears to be due to the formation of a hydrogen bond between TBP and solvent molecules.[13] The values of log K_S° were found to be 5.77±0.30 by the method of least-squares. Thus, the solvent effect on the equilibrium constant was explained in connection with the activity coefficients evaluated from the properties of pure substances.

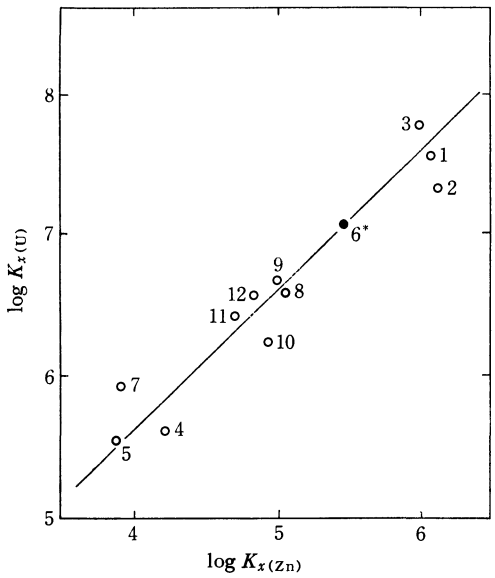

Fig. 5. Relation between the formation constants of $UO_2A_2 \cdot S$ and $ZnA_2 \cdot S$.
The $K_{x(Zn)}$ values were given from Ref. 7.

The formation constants of the uranyl adduct are plotted against those of the zinc adduct in Fig. 5. The values thus established are in accord with the estimated line, with a slope of 1, passing through the point in carbon tetrachloride. There are small deviations even in the solvents such as chloroform where some deviations are found in evaluating from the activity coefficients. This shows that the influence of the solvent on the formation of the uranyl adduct is essentially the same as that in the case of the zinc adduct, as was expected. In the estimation by Eq. (12), since there is no need to calculate the γ values, the estimates seems to be free from errors due to the evaluation of such fundamental values as V or δ. This method may be practically useful for the reactions involving components with unknown V or δ values, when we have evidence that these values of the desired substance are equal to those of the reference. For example, the formation constants for the same type of adducts may be estimated in a similar manner. However, it should be remembered that this simple method is based on the similarity of complexes and is not always valid for different types of adducts. In general, the change in the activity coefficients should be taken into account for each species in solution.

The authors are grateful to Professor T. Kanno for his interest in this study, and to the members of the Laboratory of Nuclear Sciences, Tohoku University, for the irradiation of uranium. Thanks are also due to Miss H. Asano for her assistance in the experimental work.

Synthesis and Properties of Two α-Phenylazostilbenes. A New Method for the Elimination of Water and *p*-Toluensulphonate Ion from Substituted Phenylhydrazones[1]

Luciano CAGLIOTI and Angelo G. GIUMANINI*

Istituto di Chimica Organica e Industriale, Universita' di Bologna, 40136 *Bologna, Italy*

(Received October 2, 1970)

The synthesis of a linear azoalkene, α-phenylazostilbene (**1**), not conjugated to strong electron withdrawing groups is reported. α-(*p*-Methoxyphenylazo)stilbene (**3**) was prepared by a direct method. The mass spectra of **1** and **3** showed a rearrangement yielding positive ions of benzonitrile and benzaldehyde anils (**7**).

We wish to report a facile one step preparation of α-phenylazostilbene (**1**) which appears to be the first[2] azoalkene isolated in which the carbon-carbon double bond is not part of a ring[3] or conjugated to a strongly electron withdrawing group.[4] When benzoin phenylhydrazone (α- or β-form, **2**) was stirred with an equimolecular amount of *p*-tosyl chloride in pyridine at 40°C during 10—20 hr, a 45—73% yield of **1** could be obtained as a red stable crystalline solid, mp 90.5—91°C, IR (KBr) bands at 6.94, 10.96, 13.09, 13.22, 13.29, 14.25, and 14.66 μ, PMR ($CDCl_3$) peaks at 7.16 and 7.34 (m, 14 H) and 7.78 ppm (m, 2 H, δ values). The mass spectrometrically determined MW was 284 (calcd 284) with structurally important ions at *m/e* values of 207 (−Ph), 193 (−PhN), 180 (−H, $-C_6H_5CN$), 179 (base peak, $-PhN_2$), 105 ($-Ph_2C_2H$), 103 ($PhCN^+$), 93 (PhN^+), and 77 (Ph^+). The structure of **1** was proved chemically by transforming it into benzoin osazone (mp 234—235°C, no depression with authentic sample) upon reflux with phenylhydrazine in glacial acetic acid. The UV spectrum of **1** resembles very closely that of *trans*-azobenzene[5] with maxima (in *n*-C_6H_{14})[6] at 233.0 ($\varepsilon=1.38\times10^4$), 325.0 ($3.54\times10^4$), 344.5 ($3.68\times10^4$), and 444.0 nm ($6.20\times10^2$). **1** dissolved in 97% sulphuric acid to give a colourless solution (UV max at 247.0 ($\varepsilon=1.135\times10^4$), 275.0 ($1.042\times10^4$) and 348.0 nm ($1.201\times10^4$)) which turned violet in *ca.* 10 min (*vis* max at 538.0 nm ($\varepsilon=6.97\times10^2$)). The stable colouration can be ascribed to the formation of a carbonium ion.[7] **1** could be exactly titrated with *n*-butyllithium, one equivalent of this reagent being used up for the disappearance of the red colour from an hexane solution of **1**.

The mechanism of formation of **1** appears to involve the *O*-tosyl derivative of **2** for which pyridine performs a 1,4 ionic elimination of *p*-toluensulphonic acid. Pure pyridine (14 hr at 45°C) produced no **1**.

It is of interest that a derivative of **1**, namely α-(*p*-methoxyphenylazo)stilbene (**3**), was obtained by simply bringing *p*-methoxy-phenylhydrazine in contact with benzoin at 105°C during 14 hr without solvent. The new compound, obtained in 30% yield, was an orange, stable crystalline solid, mp 106—107°C (109—111°C for an analytical sample), whose analysis, MW (M^+ at 314), infrared, PMR and mass spectra are in agreement with the proposed formula.

The present synthesis affords an easy access to these new compounds which cannot be prepared by the diazo coupling method,[8,9] and represent new examples

5) H. H. Jaffe, S.-J. Yeh, and R. W. Gardner, *J. Mol. Spectrosc.*, **2**, 120 (1958).

6) The whole spectrum undergoes a red shift of small entity in methanol except for the longest wavelength band. The individual shifts amount to 2.9, 2.9, and 1.4 kcal/mol in the order of increasing wavelength. This can be interpreted in terms of small alteration of charge distribution in the corresponding excited states. Even the longest wavelength maximum, a n-π^* transition is completely unaffected by solvent change, thus indicating that a large charge reorganization should take place. A similar phenomenon was observed for azobenzene: H. H. Jaffe and M. Orchin, "Theory and Application of Ultraviolet Spectroscopy," John Wiley and Sons, New York (1965), p. 286.

of 1,4 sulphonic acid and water[10] elimination in the azoalkene preparation from hydrazonic substrates.

If our interpretation of the low resolution mass spectra of **1** and **3** concerning ions at 180 and 211, respectively, is correct, an interesting rearrangement with intermediate four member ring charged species **4** and **6** took place, as evidenced by the detection of the corresponding fragments **5**, **6**, and **7** (Scheme 1). Structure **5** is very likely to be correct. However, formula **6** most probably only reflects the composition of the actual ion.

Experimental

UV spectra were recorded with a Unicam sp. 800, IR spectra with a Beckman IR 5 (KBr pellet technique), PMR spectra[11] with a Varian DP60 and low resolution mass spectra[11] with a Perkin Elmer 270. Values of *m/e* for the 10 highest peaks are reported with relative abundance in brackets. "Half" masses (hm) due to double charged ions and metastable ions (mi) are reported when considered of interest.

α-Benzoin Phenylhydrazone. This compound was prepared according to Smith and Ranson.[12] The solvent was evaporated in a vacuum and the thick residue washed thoroughly with hot hexane. A fractional crystallization from benzene gave the lower melting isomer (*β*-form, mp 95—96°C): hexane was added to the mother liquor, from which the α-isomer was obtained, mp 159—161°C. Yield: 45% (α and *β*). One recrystallization from hexane - ether gave slightly yellow compound, mp 161°C (lit,[12] 158—159°C). PMR (d_6-acetone): 5.88 (1H, s, CH), 6.31 (1H, s, OH), 6.83 (1H, s, NH), 7.1, 7.2, 7.8 ($3H_{ar}$, $10H_{ar}$, $2H_{ar}$, m). UV (hexane) max:[13] 214.0 ($\varepsilon = 1.71 \times 10^4$), 235.0 ($1.53 \times 10^4$), 297.5 ($0.79 \times 10^4$), and 342 nm ($1.97 \times 10^4$).

β-Benzoin Phenylhydrazone. This compound was prepared in 57% yield by bringing equimolecular amounts of benzoin and phenylhydrazine[14] in contact at 120°C for 30 min, extracting the resulting thick oil many times with hexane and recrystallizing from hot ethanol, mp 101—102°C (lit[12,14] 106°C). PMR (d_6-acetone): 4.98 (1H, d, $J = 4.5$ Hz, CH), 5.59 (1H, d, $J = 4.5$ Hz, OH), 7.25 (15H, m, arom. protons), and 8.15 (1H, s, NH). UV (hexane) max:[13] 216.0 ($\varepsilon = 1.71 \times 10^4$), 253.0 ($1.39 \times 10^4$), 258.0 ($1.54 \times 10^4$), 264.5 ($1.50 \times 10^4$), 272.3 ($1.48 \times 10^4$), and 305.3 nm ($1.11 \times 10^4$).

The actual structure of the two benzoin phenylhydrazones was discussed by a number of workers.[13,15,16]

α-Phenylazostilbene (**1**). 1) A solution of 15.09 g *p*-tosyl chloride and 23.94 g of a mixture of α- and *β*-isomers of benzoin phenylhydrazone in 150 m*l* dry pyridine was refluxed for 7 hr. An intensely red colouration appeared immediately and a white precipitate formed. The cool mixture was washed with brine, dried over sodium sulphate and the solvent evaporated to give a red oil. Since direct crystallization from common solvents failed to yield a solid product, absorption chromatography (silica gel, hexane - benzene 1 : 1 vol) was employed to give 3 well separated fractions: the first eluted was a trace of a rose oil not further analyzed, the second was a red oil (55% yield), which was recrystallized to the desired compound (mp 89—90°C) from methanol, the third unreacted α-benzoin phenylhydrazone (mp 155—158°C).

2) *From Benzoin Phenylhydrazone*: A solution of the α-benzoin phenylhydrazone (3.83 g) and tosyl chloride (3.38 g) in 23 m*l* pyridine was stirred at 40°C for 33 hr. The red colour appeared very soon after mixing the reactants. The reaction mixture was heated with 50 m*l* water and extracted with hexane. The organic layer, dried over sodium sulphate, was freed from solvent, to yield a viscous red oil. Chromatography on a 4×30 cm silica gel column, using benzene as an eluent, gave, after a 200 m*l* forerun, compound **1** (3.60 g, 72.5%, 250 m*l*) as a thick red oil, homogeneous by tlc analysis (R_f 0.75, on silica gel with cyclohexane - ethylacetate 85/15 vol).[17] Two recrystallizations from alcohol gave red-orange crystals, mp 90.5—91°C (lit,[1] 90°C).

3) *From β-Benzoin Phenylhydrazone*: Using the same procedure as described above for the reaction of the α-form, we obtained the same product **1** 45%, mp 90°C (lit,[1] 90°C), mixed mp with that obtained from the α-form showed no depression.

Found: C, 84.21; H, 5.55; N, 10.04%. Calcd for $C_{20}H_{16}N_2$: C, 84.47; H, 5.67; N, 9.85%. PMR ($CDCl_3$):[18] 7.16 and 7.34 (14H, partially overlapped multiplets), 7.78 (2H, m). IR (KBr):[19] 6.26 w, 6.81 w, 6.94 m, 7.02 s, 7.03 m, 7.10 m, 7.41 w, 7.43 w, 7.80 w, 8.66 w, 9.31 w, 9.45 m, 9.49 m, 9.85 m, 9.93 w, 10.95, and 10.98 (doublet, m), 11.32 w, 11.45 m, 12.93 w, 13.09 vs, 13.22 s, 13.29 s, 13.34 vs, 13.59 w, 14.17 vs, 14.25 vs, 14.50 vs, 14.66 vs, 14.69 vs, 16.04 s, 16.47 m, 17.15 s, 19.32 w, 19.38 w, 20.06 s, and 20.19*μ* s. UV maxima are indicated in the descriptive part. Mass spectrum:[20] 179 (100, $-PhN_2$), 284 (82, parent peak), 178 (73, $PhCCPh^+$), 283 (31, −H), 77 (30, Ph^+), 180 (26, −H, −PhCN), 285 (18, +H), 177 (12), 181 (10, −PhCN), 105 (10, PhN_2^+), 193 (10, −PhN) and 207 (10, −Ph); hm: 142.5 ($M+1^{2+}$), 142 (M^{2+}) and 141.5 ($M-1^{2+}$).

Reactions of **1**. *A) Reaction with* n-*Butyllithium*: The red colour of a hexane solution of **1** changed to pale yellow and a white precipitate appeared upon dropwise addition of one equivalent of *n*-butyllithium (hexane solution). The reactions were instantaneous. No attempt was made to separate and identify the product(s).

B) Reaction with Phenylhydrazine: A mixture of **1** (251 mg) and phenylhydrazine (381 mg) in glacial acetic acid (4 m*l*) was refluxed for 7 hr, the solvent was then evaporated under reduced pressure, the solid yellow residue taken up with chloroform and washed with aqueous bicarbonate, the organic solution was dried over sodium sulphate and evaporated to yield the crude benzoin osazone, mp 325—328°C.

10) H. Simon and W. Moldendauer found that 2-cyclohexanolone phenylhydrazone exchanged the OH substituent with a MeO group in methanol in *acidic* conditions. They *proposed* the intermediary of 1-phenylazocyclohexene, *Chem. Ber.*, **101**, 2124 (1968).

11) We are indebted to Mrs. A. B. Giumanini for recording the spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1050—1054 (1971)

The Solvent Effect on the Reaction of 1,1,4,4-Tetraphenyl-2-halobuta-2,3-dien-1-ol with Mercuric Halide

Fumio Toda, Nobuhiro Ooi, and Katsuhiko Akagi

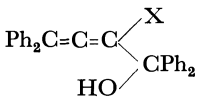
Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received August 3, 1970)

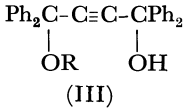
The reaction of the title compound (I) with mercuric halide in an aprotic and in a protic solvent afforded the fulvene derivative (VII) and the dihydrofuran derivative (VIII or IX) respectively. Both the cross-reactions (bromo-analog of I (Ia)+$HgCl_2$, chloro-analog of I (Ib)+$HgBr_2$) in an aprotic solvent afforded the chloro-fulvene derivative (VIIb). However, when the above reactions were carried out in a protic solvent, the product was the dihydrofuran derivative (IX), in which the halogen combining with carbon is chlorine and that combining with mercury is bromine. On the basis of the results of those cross-reactions, the reaction mechanism will be discussed. Acetonitrile showed distinctive behavior. In acetonitrile, the bromine of Ia was easily exchanged with the chlorine of sodium chloride at room temperature, and Ib was obtained quantitatively.

In a previous paper,[1] we have reported the reaction of the bromo-analog of the title compound (Ia) with mercuric acetate to afford various reaction products, depending on the nucleophilicity of the solvent used. When the reaction was carried out in acetic acid, the acetoxymercuration product II was obtained as the sole product. The reaction in alcohol, however, afforded the corresponding alkoxy acetylene alcohol (III), derived by the retropropargyl rearrangement,[2] and the mercurated dihydrofuran derivative (IV), derived by mercuration, followed by intramolecular cyclization, in various ratios depending on the bulkiness of the alkyl of the alcohol used. In the solvent with which it is not necessary to take account of its nucleophilicity, such as acetone, the reaction of Ia with mercuric acetate afforded the naphthalenone derivatives (V and VI), probably *via* an allenic epoxide intermediate.

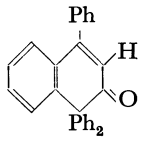
In order to clarify the role of a protic solvent on the reaction of I with mercuric salt, we have studied the halomercuration of I in various protic and aprotic solvents. We have found that the variation in the



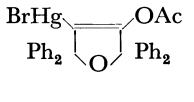
(I) a: X=Br; b: X=Cl



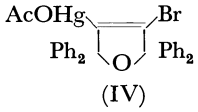
(III)



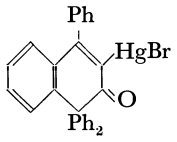
(V)



(II)



(IV)



(VI)

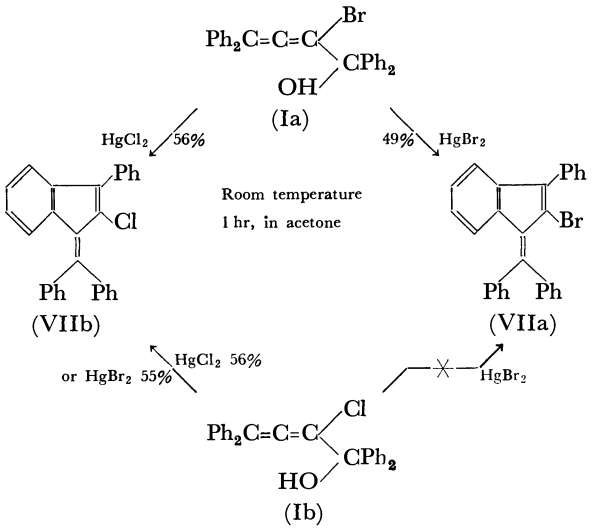
main reaction product depends on whether the solvent used is protic or aprotic.

Results. The treatment of an acetone solution of I with an equimolar amount of mercuric halide (HgX_2) for 1 hr at room temperature afforded mainly the fulvene derivative (VII) in the yields shown in Scheme 1 in addition to a small amount of the dihydrofuran derivative (VIII or IX). The structures of the main products were determined by a comparison of their mp's and infrared spectral data with those of

1) F. Toda and K. Akagi, *Tetrahedron*, **25**, 3795 (1969).
2) F. Toda, M. Higashi, and K. Akagi, This Bulletin, **42**, 829 (1969).

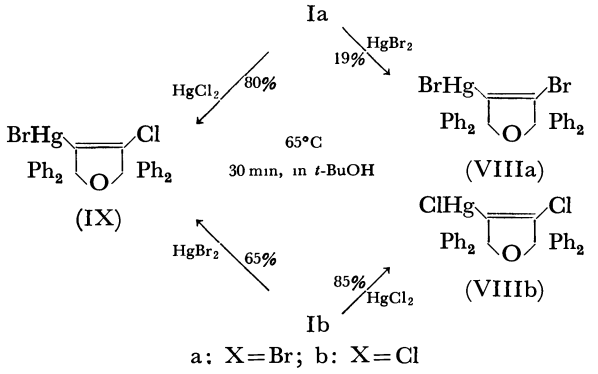
the corresponding authentic samples, VIIa[3] and VIIb.[4] Since both the cross reactions, Ia+$HgCl_2$ and Ib+$HgBr_2$ yielded the same product, VIIb, and since the VII product did not exchange the halogen upon treatment with HgX_2 under the same conditions as those employed for the halomercuration reaction, the reaction must proceed through a process in which halogen-exchange is possible. The above observation is important in order to clarify the reaction mechanism. It will be discussed in the following section.

The same treatment of I with HgX_2 in *t*-butanol as that employed for the reaction in acetone afforded VIII or IX in the yields shown in Scheme 2. The reaction of Ia+$HgBr_2$ and Ib+$HgCl_2$ afforded di-dibromo (VIIIa) and dichloro-derivatives (VIIIb) respectively. The two cross reactions, Ia+$HgCl_2$ and Ib+$HgBr_2$, however, yielded the same product, bromochloro derivative (IX), in which the halogen combining with carbon is chlorine and that combining with mercury is bromine. The results show again that the reaction proceeds *via* an intermediate in which halogen-exchange occurs. The reaction mechanism will be described in detail in the Discussion section.



Scheme 1

The structures of VIII and IX were determined by the methods shown in Scheme 3. The infrared spectral data of VIIIa thus obtained were identical with those of an authentic sample[1] prepared by shaking an acetone solution of IV with aqueous potassium bromide. The treatment of VIIIa with sodium borohydride in alcohol at room temperature afforded a demercurated product,



a: X=Br; b: X=Cl

Scheme 2

Xa, quantitatively. The spectral data of Xa were identical with those of an authentic sample prepared according to a previously-reported method[3], the acid-catalyzed cyclization of Ia. The sodium borohydride reduction of VIIIb and IX gave the same product, Xb, and its spectral data were identical with those of an authentic sample prepared by the acid-catalyzed cyclization of Ib.

As was described above, the type of the main product of the reaction of I with HgX_2 depends on the solvent used. In order to test the generality of the solvent effect on the reaction, several aprotic and protic solvents were employed for the reaction. The yields of the products of the reaction of Ia and $HgCl_2$ are summarized in Table 1, together with the reaction conditions. Because of the difference in the solubility of the reactants and in the reaction rate, the reaction condition differs slightly from each other. However, the product ratio was slightly affected by the reaction temperature and the time.

In all the aprotic solvents, the major product was VIIb. In some cases, however, IX was isolated as a minor product in addition to VIIb. Reversely, the major product of the reaction in a protic solvent, such as *t*-amyl, *t*-butyl and cyclohexyl alcohol, was IX. The anomalous behavior of acetic acid, phenol, and acetonitrile was also observed.

Discussion. On the basis of the finding that the reaction of Ia with $HgCl_2$ in aprotic and protic solvests afforded mainly the fulvene derivative (VIIb) and dihydrofuran derivative (IX) respectively (Table 1), and of the results of the cross reactions (Schema 1,2), the reaction mechanism which is shown in Scheme 4 was postulated. In Scheme 4, ketone is representative of the aprotic solvent.

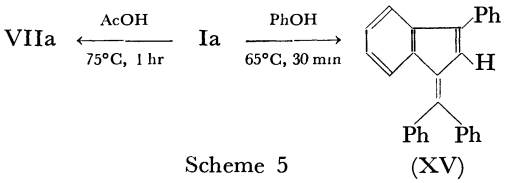
a) Room temperature, b) Reflux.

the chloromercuration on Ia, an aprotic solvent serves as an electron-donor species and coordinates with the hydrogen of the hydroxyl group. The hydrogen bonding increases the electron density around the oxygen of the hydroxyl, and facilitates the coordination between mercury and the hydroxyl oxygen. Dechloromercuration, followed by the dehydroxylation of XI, affords the cation (XII). It is reasonable to consider that Br^- is more facile at leaving a moiety than Cl^- and that XI affords the chlorine-substituted cation (XII). The intramolecular cyclization of the cation (XIII) derived by the migration of the double bond of allene in XII affords VIIb.

In a protic solvent, however, the mercury-oxygen coordination in the chloromercurated intermediate (XIV) is inhibited because of the decreased electron density around the hydroxyl oxygen resulting from hydrogen bonding between the protic solvent and the hydroxyl oxygen. Therefore, the coordination between mercury and bromine is preferable. Intramolecular coordination between mercury and bromine has been postulated.[1,5] Of two halogens on the carbon of XIV, the elimination of Br^- occurs predominantly. Therefore, the reaction can be interpreted by a combination of the following two main processes: the Br^- attacks the mercury, and then the Cl^- leaves the mercury. The migration of the double bond and the intramolecular cyclization yields IX.

Of the five protic solvents cited in Table1, acetic acid and phenol differed widely from the others in the mode of reaction. In those solvents, the main reaction product was VIIb, not IX. A strong acid, such as acetic acid or phenol, would promote the dehydroxylation of the intermediate XI and finally afford VIIb *via* XII. The observation that the heating of Ia in acetic acid for 1 hr at 75°C afforded VIIa in a 68% yield, supports the above assumption. The conversion of I into VII by treatment with sulfuric acid has been reported.[2] Nevertheless, since the reaction of Ia with $HgCl_2$ in acetic acid afforded the halogen-exchanged product VIIb, but not VIIa, the process must also contain a halomercurated intermediate such as XI. The same interpretation is applicable to the reaction in phenol, which affords mainly a halogen-exchanged product VIIb and a small amount of halogen-free fulvene (XV). The process giving XV must proceed by a direct reaction of Ia and phenol, since the treatment of Ia with phenol at 65°C for 30 min afforded XV in an 90% yield (Scheme 5), even though its mechanism is not clear.



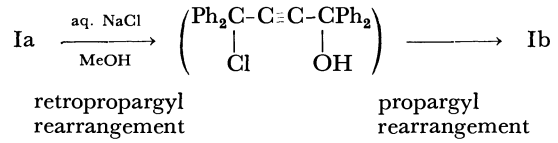
Scheme 5 (XV)

It is reasonable to assume that the halogen-exchange process on the reaction of I and HgX_2 is a part of the reaction, as has been discussed above, since neither of the reaction products, VII and VIII, exchanged its halogens with those of HgX_2 under the same conditions as were employed for the halomercuration. Nevertheless, the possibility that the exchange occurs before the reaction starts cannot be ruled out. If the halomercuration process of I to afford XI or XIV is reversible, halogen-exchange will occur before the reaction starts. This possibility can, however, be disregarded on the basis of the following observation. The reaction of Ia with five molar amounts of $HgCl_2$ in *t*-butyl alcohol afforded IX, but not any detectable VIIIb. If the halogen-exchange process precedes the reaction to afford the dihydrofuran derivative, the reaction product might be VIIIb or, at least, might be contaminated with VIIIb.

The reaction of Ia and $HgCl_2$ in acetonitrile is distin-

4) E. D. Bergmann, E. Fischer, and J. H. Jaffe, *J. Amer. Chem. Soc.*, **75**, 3230 (1953).

5) E. F. Kiefer and W. Gericke, *ibid.*, **90**, 5131 (1968).



Scheme 6

guishable from those in other aprotic solvents. The reaction at room temperature in acetonitrile afforded VIIIb (6%) instead of IX, in addition to VIIb (77%). Since shaking an acetonitrile solution of IX with $HgCl_2$ did not yield VIIIb, and since IX was recovered quantitatively, the complete halogen-exchange leading to VIIIb should occur before the completion of reaction. It can reasonably be assumed that the chloro-analog of Ia (Ib) initially formed by a halogen exchange between Ia and $HgCl_2$ reacts with $HgCl_2$ to afford VIIIb. This assumption was certified by shaking an acetonitrile solution of Ia with sodium chloride at room temperature for 30 min; this afforded Ib quantitatively. The halogen-exchange probably proceeds by the sequence of retropropargyl-propargyl rearrangements shown in Scheme 6. The exchange, however, was not observed in other aprotic solvents tested, such as acteone and tetrahydrofuran. The treatment of Ib with aqueous potassium bromide in acetonitrile, however, did not afford Ia.

Experimental

All the melting points were uncorrected. The infrared spectra were recorded in Nujol mull on a spectrophotometer, IR-E, of the Japan Spectroscopic Co. The molecular weights were determined by means of a molecular-weight apparatus of Hitachi-Perkin Elmer, model 115, in benzene.

1,1,4,4-Tetraphenyl-2-halobuta-2,3-dien-1-ol (I). The bromo-analog (Ia) was prepared according to a previously-reported method.[3] The chloro-analog (Ib) was prepared by a modified version of that method used for the preparation of Ia. Into an ice-cooled solution of 1,1,4,4-tetra-phenyl-but-2-yne-1,4-diol (5 g, 13 mmol) in acetic acid (30 m*l*) - benzene (12 m*l*), concentrated hydrochloric acid (5 m*l*) dissolved in acetic acid (20 m*l*) was stirred drop by drop, over a period of 10 min. After the stirring had then been continued for a further 30 min, ice water (100 m*l*) was added to the reaction mixture. The crude product which separated was extracted with ether. The ether solution was washed with water, aqueous sodium bicarbonate, and water successively, and dried over sodium sulfate. The crude crystals obtained by the evaporation of the solvent were recrystallized from benzene - petroleum ether to afford Ib as colorless prisms (2.7 g) (51%); mp 100—101°C. IR 3400 (OH) and 1945 cm^{-1} (C=C=C).

Found: C, 82.16; H, 5.38%. Calcd for $C_{28}H_{21}OCl$: C, 82.25; H, 5.14%.

Acid-catalyzed Intramolecular Cyclization of Ib. A solution of Ib (0.1 g) in acetone (3 m*l*) containing two drops of concentrated hydrochloric acid was heated under reflux for 10 min. The crude crystals obtained by the evaporation of the solvent were washed with water and recrystallized from methyl alcohol to give Xb as colorless needles (0.03 g) (30%); mp 169—169.5°C. IR 1630 (C=C) and 1020 cm^{-1} (C–O).

Found: C, 81.98; H, 5.07%. Calcd for $C_{28}H_{21}OCl$: C, 82.25; H, 5.14%.

General Procedure of the Reaction of I and HgX_2. A mixture of I (1 mmol), HgX_2 (1 mmol), and solvent (5 m*l*) was treated under the reaction conditions summarized in Table 1 and in Scheme 1 and 2. When the reaction was carried out in a solvent with a boiling point lower than 100°C, such as all the aprotic solvent used except di-*t*-butyl ketone and cyclohexanone, the reaction product was isolated by the evaporation of the solvent. On the other hand, when the reaction was carried out in a solvent which boils at temperature higher than 100°C, the reaction product was isolated by adding petroleum ether to the reaction mixture.

The crude product thus obtained was purified by recrystallization or was fractionated into components by fractional recrystallization.

Some examples of each case are shown in the following columns.

Reaction of Ia and $HgCl_2$ in Acetone. A solution of Ia (0.46 g, 1 mmol) and $HgCl_2$ (0.28 g, 1 mmol) in dry acetone stirred at room temperature for 1 hr. The crude product obtained by the evaporation of the acetone was extracted with petroleum ether (20 m*l*). The evaporation of the solvent afforded VIIb as red prisms (0.22 g) (56%); mp 158°C (lit,[4] mp 159—160°C). The spectral data of VIIb were identical with those reported in the literature.[4] The residue remaining after the extraction with petroleum ether was extracted with cyclohexane (20 m*l*). The removal of the solvent of the cyclohexane solution afforded IX as colorless plates (0.08 g) (12%); mp 194—195°C. IR 1610 (C=C) and 1015 cm^{-1} (C–O).

Found: C, 48.67; H, 2.92%; mol wt (benzene), 696. Calcd for $C_{28}H_{20}OHgBrCl$: C, 48.84; H, 2.91%; mol wt 688.

The reaction of IX by sodium borohydride in ethyl alcohol yielded Xb in an almost quantitative yield.

By the same procedure, Ib was treated with $HgBr_2$ in acetone to afford VIIb (55%) and IX (9%).

Under the same conditions, Ia reacted with $HgBr_2$ to give VIIa (49%) as red prisms; mp 160°C (lit,[3] mp 160—161°C).

Under the same conditions, Ib reacted with $HgCl_2$ and yielded VIIb (56%) and VIIIb (4%) as colorless plates; mp 253—260°C. IR 1615 (C=C) and 1020 cm^{-1} (C–O).

Found: C, 52.85; H, 3.23%; mol wt (benzene), 669. Calcd for $C_{28}H_{20}OHgCl_2$: C, 52.26; H, 3.11%; mol wt, 644.

The sodium borohydride reduction of VIIIb afforded Xb quantitatively.

Reaction of Ia and $HgCl_2$ in t-Butyl Alcohol. A mixture of Ia (0.46 g, 1 mmol), $HgCl_2$ (0.28 g, 1 mmol), and *t*-butyl alcohol (5 m*l*) was stirred at 65°C for 30 min. The crystals which separated out upon the addition of petroleum ether (20 m*l*) to the reaction mixture were collected by filtration and were recrystallized from cyclohexane to afford IX (0.48 g) (70%). The petroleum ether solution remaining after the removal of IX was concentrated to dryness. The fractional recrystallization of the residue from petroleum ether afforded VIIb (0.06 g) (15%) and some additional IX (0.07 g) (10%).

By the same procedure as was employed for the above reaction, Ia was treated with $HgBr_2$ in *t*-butyl alcohol to afford VIIIa (19%) and (2%). The structure of VIIIa was determined by a comparison of its infrared spectrum (1620 (C=C) and 1015 cm^{-1} (C–O)) with that of an authentic sample prepared according to the previously-reported method,[1] as is shown in Scheme 3. The sodium borohydride reduction of VIIIa gave Xa quantitatively.

The reactions of Ib+$HgCl_2$ and Ib+$HgBr_2$ in *t*-butyl alcohol afforded VIIIb (85%), and VIIIb (65%) and VIIb (15%), respectively.

Reaction of Ia and $HgCl_2$ in Phenol. A mixture of Ia (0.46 g, 1 mmol), $HgCl_2$ (0.28 g, 1 mmol), and phenol (5 m*l*) was stirred at 65°C for 30 min. After cooling, water was added to the reaction mixture, the product which was crystallized out was fractionated by fractional recrystallization from *n*-hexane to afford VIIb (0.24 g, 61%) and XV (0.05 g, 11%) as yellow prisms; mp 204°C (lit,[3,6] mp 204—205°C). The infrared spectral data of XV were identical with those of an authentic sample prepared according to the literature.[3]

Reaction of Ia and Phenol. A solution of Ia (0.23 g, 0.5 mmol) in phenol (2.5 m*l*) was heated at 65°C for 30 min. After cooling, the reaction mixture was diluted with water to give XV (0.16 g) (90%).

Reaction of Ia with Acetic Acid. A solution of Ia (0.23 g, 0.5 mmol) in acetic acid (2.5 m*l*) was heated at 75°C for 1 hr. The evaporation of the solvent gave VIIa, after recrystallization from acetone (0.15 g) (68%).

Reaction of Ia with Five Molar Amounts of $HgCl_2$ in t-Butyl Alcohol. A mixture of Ia (0.46 g, 1 mmol), $HgCl_2$ (1.35 g, 5 mmol) and *t*-butyl alcohol (5 m*l*) was heated at 65°C under stirring for 30 min. The residue remaining after evaporation of the solvent under reduced pressure was extracted with cyclohexane (20 m*l*). The evaporation of the solvent of the cyclohexane solution afforded IX (0.688 g) (100%). The bromochloro compound (IX) thus obtained was proven, by a careful infrared spectral study, not to be contaminated with any detectable amount of dichloro-analog (VIIIb).

Reaction of Ia with Aqueous Sodium Chloride in Acetonitrile. A solution of Ia (0.23 g, 0.5 mmol) in acetonitrile (2.5 m*l*) was shaken with saturated aqueous sodium chloride (2.5 m*l*) at room temperature for 30 min. An acetonitrile layer was then separated and concentrated to dryness to afford Ib (0.19 g) (97%).

Reaction of Ia with Aqueous Sodium Chloride in Acetone (or Tetrahydrofuran). The same treatment of Ia as above with aqueous sodium chloride in acetone (or tetrahydrofuran) gave the recovered Ia in a quantitative yield in both cases.

The authors wish to express their thanks to Mr. Shoichi Kato for the elemental analyses, and to Miss Toshiko Matsumoto for her measurement of the molecular weights.

Electronic Spectra of Phenanthrene Derivatives. Effect of Substitution

Shuzo AKIYAMA, Masazumi NAKAGAWA, and Kichisuke NISHIMOTO*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

**Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka*

(Received August 5, 1970)

During the course of studies on the spectral regularities of linear conjugated systems bearing aromatic terminal groups (*cf. Tetrahedron Lett.*, **1964**, 719; *ibid.*, **1968**, 1121; This Bulletin, **39**, 2320 (1966); *ibid.*, **40**, 340 (1967)), we found that the free electron model (FEM) cannot explain the effect of substitution on the electronic spectrum of phenanthrene. In order to get further information the electronic spectra of forty-eight phenanthrene derivatives each bearing a substituent at 2-, 3-, or 9-positions have been examined, and it was found that the electronic spectra of these derivatives also cannot be explained on the basis of FEM. SCF-MO-CI calculation has been carried out on phenanthrylpoly-ynes and hydroxyphenanthrenes revealing that the discrepancy between the observation and the expectation from FEM in the behavior of L_a and L_b of phenanthrene derivative is attributable to a complex configuration interaction.

It is well-known that the free electron model (FEM) proposed by Platt[1] gave a satisfactory explanation for the electronic spectra of polycyclic aromatic compounds. In the case of linear polyacenes, it was concluded on the basis of FEM treatment that the polarizations along the short axis (y-axis) were responsible for the B_a and L_a bands, and the transitions associated with L_b and B_b bands were considered to be polarized in the direction of the long axis (x-axis) (Fig. 1).

Empirical assignment of polarization on the basis of the substituent effect,[2] the result of the measurement of polarized spectrum of crystal[3] and the conclusion of MO calculation were found to be consistent with the FEM assignment.

For the electronic spectrum of phenanthrene, the first member of phene series, Platt assigned[1] long

axis polarized transitions to L_a and B_b species, and short axis polarized transitions to L_b and C_b species. However, the strong transition, called B_b by Platt[1] was relabeled B_a by Ham and Ruedenberg.[4]

Since SCFMO calculation[5] was consistent with that of Ham and Ruedenberg, the state assignment indicated in Fig. 2 was employed in this paper. Little experimental verification of the assignment has been done, probably owing to the lack of spectral data on phenanthrene derivatives.

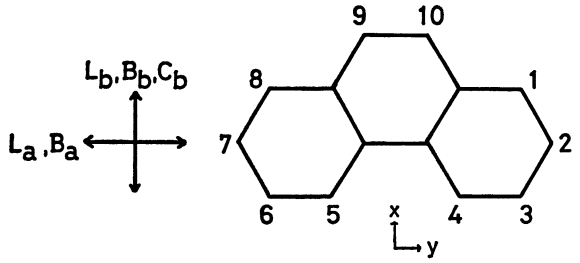

Fig. 2. Polarization diagram of phenanthrene.

During the course of studies on the regularities of the electronic spectra of diarylpoly-ynes,[6] we noticed that the behavior of L_a and L_b bands in the spectra of substituted phenanthrenes could not be explained simply on the basis of FEM. It was desirable to get further spectral data on monosubstituted phenanthrene derivatives to solve the interesting problem. Several monosubstituted derivatives bearing a substituent at 2-, 3-, or 9-positions have been prepared.[7] It was anticipated that the substituent may exert a distinctly different effect on the electronic spectrum at these three positions. The electronic spectra of the 37 phenanthrene derivatives we prepared, together with those of the reported ones (11 compounds), were examined with respect to the nature and position of the substituent, and were compared with the expected effect from FEM consideration. The 48 compounds are given in Fig. 11.

Electronic Spectra[8]

The absorption bands of phenanthrene have been assigned to be L_b, L_a, B_a, and C_b in the sequence of diminishing wavelength.[4,5] From the standpoint of FEM, it was anticipated that a substitution at 2-position of phenanthrene may exert a more marked effect on the B_a and L_a bands than does a substitution at the 3- or 9-position, and C_b and L_b bands should be affected more strongly by a substitution at 3- or 9-position than that at 2-position.

A brief summary of the substituent effect observed in some of the substituted phenanthrenes is given in the following.

Methyl and Hydroxymethylphenanthrenes [R-CH_3 *and* R-CH_2OH] *(R=phenanthryl).* An essestial difference between the electronic spectra of phenanthrene and of methylphenanthrenes could not be observed.[9] As illustrated in Fig. 3, similar spectra have been obtained in hydroxymethylphenanthrenes. The difference of position of substitution gave no appreciable change in the electronic spectra, indicating the lack of electronic interaction between these substituents and the nucleus.

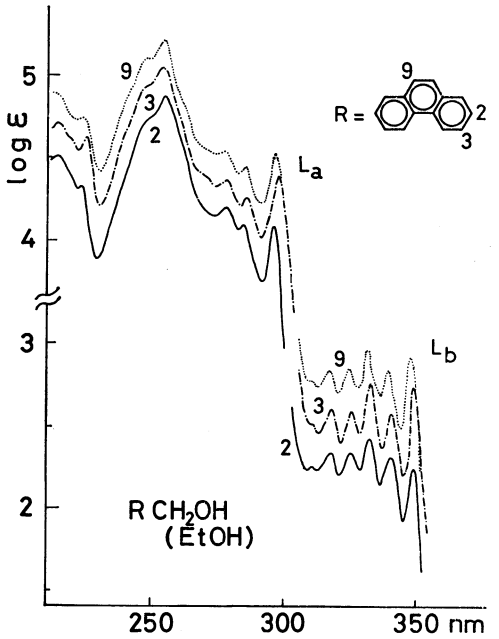

Fig. 3. The absorption curves of hydroxymethylphenanthrenes. The curves, with the exception of 2-substituted compound at the bottom, have been displaced upward on the ordinate axis by 0.1 log ε unit increments from the curve immediately below.

Acetylphenanthrenes [$RCOCH_3$] *and Formylphenanthrenes* [RCHO]. The absorption curves of the methylketones and the aldehydes are given in Figs. 4 and 5. The spectra of 2-isomers show close resemblance to that of phenanthrene itself, while the 3- and 9-isomers exhibit similar absorption curves which differ from that of the 2-isomer. The large red-shift of B_a band of 2-isomers as compared with 3- and 9-isomers is in line with the expectation from FEM. In the case of 3- and 9-isomers, the C_b bands seem to submerge under the B_a bands resulting in broad absorption bands around 250 nm. The large red shift of C_b band of 3- or 9-isomer is also in line with FEM anticipation. On the other hand, contrary to expectation from FEM consideration, the largest blue-shift of L_a band of the

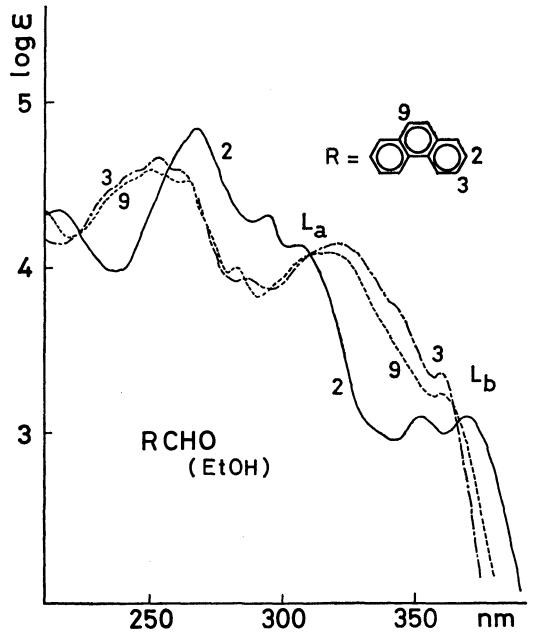

Fig. 5. The absorption curves of formylphenanthrenes.

2-isomer was observed, and the L_b band showed the largest red-shift in the case of 2-isomer.

Ethynylphenanthrenes [R–C≡CH]. The electronic spectrum of 2-ethynylphenanthrenes was found to be closely related with that of phenanthrene (Fig. 6). 3- and 9-Isomers exhibited C_b bands (230—240 nm) at longer wavelength than 2-isomer (200 nm), and the B_a band of 2-isomer showed a bathochromic shift accompanied with appreciable hyperchromism as compared with B_a bands of 3- and 9-isomers. The spectral change caused by the change of position of substitution is consistent with FEM anticipation. However, though the L_a bands of 3- and 9-isomers showed an appreciable red-shift as compared with that of phenanthrens, no shift of the L_a band was observed in 2-isomer. With regard to the L_b band, the 2-isomer

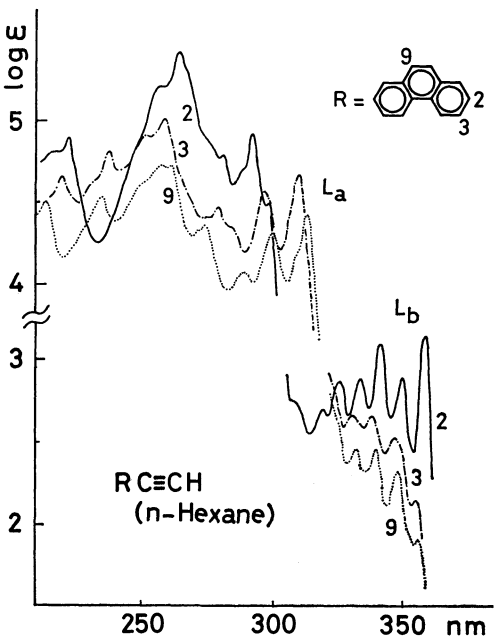

Fig. 6. The absorption curves of ethynylphenanthrenes. The curves, with the exception of 9-substituted compound at the bottom, have been displaced upward on the ordinate axis by 0.2 log ε unit increments from the curve immediately below.

absorbed at the longest wavelength. Thus behavior of L_a and L_b bands are inconsistent with FEM argument.

Diphenanthrylpoly-ynes [R(C≡C)$_n$R]. As illustrated in Fig. 7, 2,2′-diphenanthrylacetylene (n=1) exhibited a characteristic absorption curve owing to the marked red-shift of the B_a band. The broad band observed at around 250 nm in the spectra of the 3- and 9-isomers seem to be the composite of B_a and submerged C_b bands. The increasing red-shift of L_a band in the sequence of 2-, 3-, and 9-isomers is in contrast with the expectation from FEM. The trend observed in the spectra of diphenanthrylacetylenes was also observed in the spectra of di- (n=2), tri- (n=3) and pentaacetylenes (n=5) (Figs. 8, 9, and 10). The regular bathochromic shift of L_a band in line with the increasing number of n is impressive (*cf.*, Fig. 11).

From the results, it is evident that the behavior of C_b and B_a bands is in line with FEM anticipation. However, the spectral shifts of L_a and L_b bands were found to be inconsistent. The effect of substitution

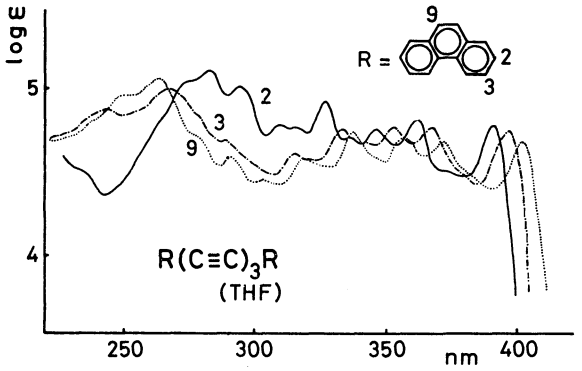

Fig. 9. The absorption curves of diphenanthryltriynes.

on the shifts of L_a and L_b bands is summarized in Fig. 11. When a bulky group such as $NHCOCH_3$, $COCH_3$, or CHO is introduced to the 9-position of phenanthrene nucleus, it should interfere sterically with the hydrogen atom at the 8-position. This seems to be responsible for the observed small red-shift and the hypochromism of the L_a band of phenanthrene bearing a large group at 9-position. The increasing red-shift of L_a band in phenanthryl mono-, di-, and tri-acetylenes [$\mathbf{R(C{\equiv}C)_nH}$, $n=1,2$, and 3] in the sequence of 2-<3-<9-isomers seems to support the above argument, as the linear substituents should suffer minor steric interference from the hydrogen at 8-position.

The Results of Semi-Empirical SCF-MO-Cl Calculation

The apparent contradiction between the observed spectral behavior of substituted phenanthrenes and the expected spectral change from the FEM of substituted phenanthrenes prompted us to elucidate this problem theoretically. In previous papers,[10] it was concluded theoretically that a linear polyacene having a substituent at α-position, such as α-naphthol, should exhibit an electronic spectrum having practically the same band characteristics as those of the parent hydrocarbon. On the other hand, in the electronic spectrum of a β-substituted linear polyacene, such as β-naphthol, a considerable mixing of the L_a and L_b species should occur modifying the band characteristics of the parent hydrocarbon. In the case of β-naphthol, the longest-wavelength absorption band should be the L_b band containing about 30% of L_a component.

Phenanthrene can be regarded as benznaphthalene. Consequently, the 9-position in phenanthrene is either an α- or a β-position of the naphthalene nucleus. Thus a more complicated spectral change by introduction of a substituent in the nucleus of phene-series is expected as compared with that of acene-series.

We have calculated the electronic structures of phenanthrene, 2-, 3-, and 9-phenanthrylpoly-ynes, and 2-, 3-, and 9-hydroxyphenanthrenes by a semi-empirical SCF-MO-CI method based on π-electron approximation and variable β approximation.[3] Two-centre electron repulsion integrals were calculated by the method proposed previously by one of us (K. N.).[11] As shown by Hinze and Jaffé,[12] the valence state ionization potential (I) and the electron affinity (A) associated with carbon atom are almost independent of hybridization. The same values of I and A were used for all carbon atoms in this paper. The parameters are summarized in Table 1. In the vari-

able β approximation, a conventional geometry is assumed in which all the bond lengths are set at 1.40 Å.[13] The transition energies have been computed after including approximately the same amount of configuration interaction as involved for phenanthrene.[13] Singly excited configurations up to 3.0 eV from the lowest excited configuration are included in the calculation. The calculated transition energies and intensities are summarized together with experimental data in Table 2. A satisfactory agreement between the calculated results and experimental data was obtained affording theoretical basis to the observed bathochromic shift of L_a band in the 2-, 3-, and 9-substituted phenanthrenes (2-<3-<9-) and that of L_b band (9-<3-<2-).

It is interesting to note that the B_a and B_b species of phenanthrene are approximately degenerated (*i.e.*, $\Delta E(B_a)=4.91$ eV, $\Delta E(B_b)=5.00$ eV). However, B_a should be very intense ($f(B_a)=1.260$; $f(B_b)=0.425$). According to the present calculation, the absorption band at around 250 nm region of phenanthrene is associated with the long-axis (y-axis) polarized transition. The result is in line with the assignment by Ham and Ruedenberg.[4]

For phenanthrene, there are as usual two non-mixing pairs of states. As the calculation indicates, the b states arising from the paired excitation $\psi_7\rightarrow\psi_9$ and $\psi_6\rightarrow\psi_8$ are associated with the short-axis polarized transitions, and the a states which arise from $\psi_7\rightarrow\psi_8$ and $\psi_6\rightarrow\psi_9$ are related with the long-axis polarized transitions. In the case of phenanthrene derivatives, because of the complete loss of molecular symmetry, all the singly excited configurations usually interact with each other. However, by means of the criteria we obtained,[10] we can assign the state levels as shown in Table 3.

The following conclusions can be deduced from Table 3.

1) The nature of the excited states of phenanthrene derivatives is considerably dependent on the type of substituent.

2) The effect of substituent on the mixing of configurations at the lower excited states is found to be the largest at 2-position and rather small at 3- and 9-positions.

3) The L_a species of phenanthrene is considerably shifted by the substitution at 3- and 9-positions. Since it was indicated that a rather large interaction between L_a and L_b species should be produced by the substitution at 2-position, very much shifts of the L_a species in 2-substituted derivatives are expected. In fact as indicated in Fig. 11, a small change of L_a band of

phenanthrene by substitution at the 2-position was observed [*e.g.*, phenanthrene: 292 nm (in *n*-hexane); 2-ethynylphenanthrene: 291 nm (in *n*-hexane); 2-hydroxyphenanthrene: 292 nm (in ethyl alcohol)].

This suggests that 3- and 9-positions should resemble the α-position in linear polyacenes, while the 2-position would be similar to the β-position in polyacenes.

The intensities of L_b species of phenanthrylpoly-ynes are calculated to be zero. However, if we use different valence state ionization potentials for different hybridization, we will have non-zero, but very small intensities.

The calculation reveals that the discrepancy between the observation and the expectation from FEM

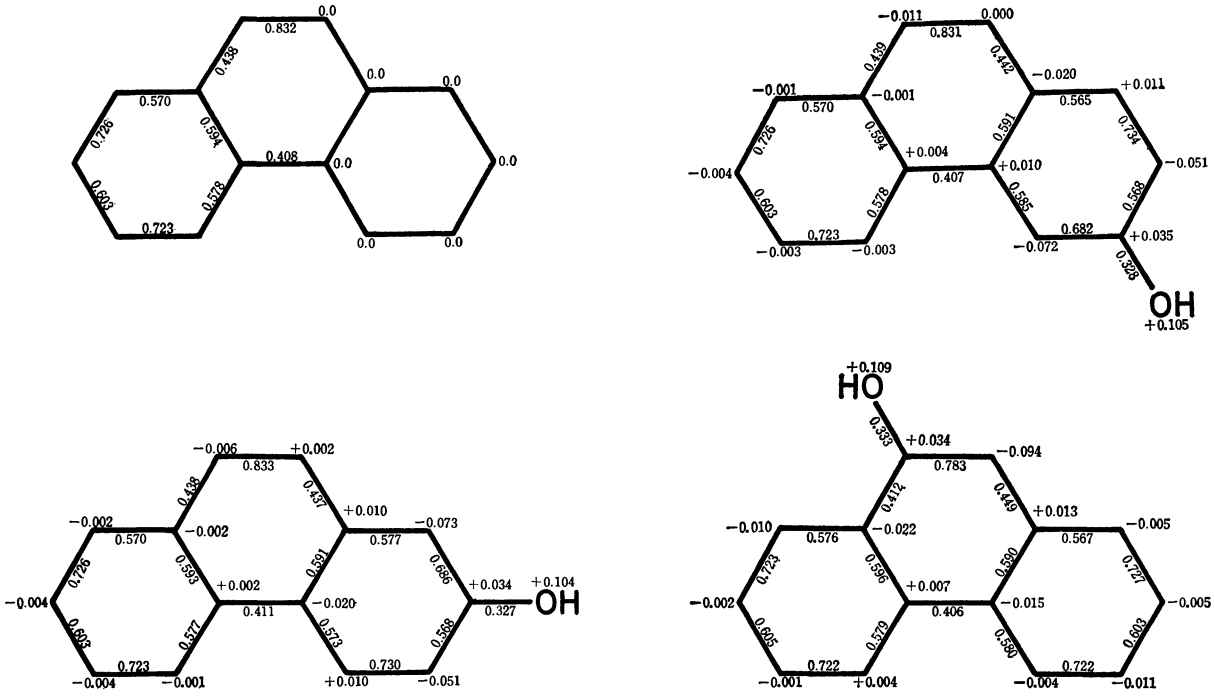

Fig. 12. Molecular diagrams of phenanthrene and its hydroxy derivatives in the ground states.

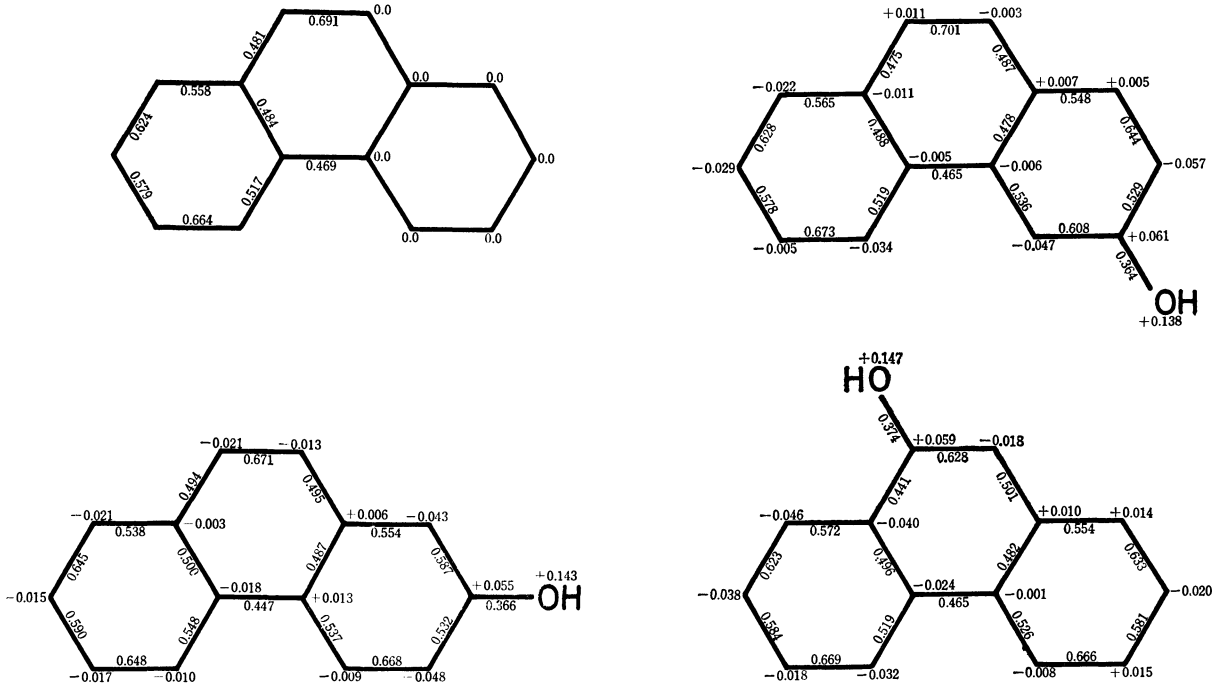

Fig. 13. Molecular diagrams of phenanthrene and its hydroxy derivatives in the lowest exited singlet states.

on the behavior of L_a and L_b species of phenanthrene derivatives should be attributed to a complex configuration interaction. It should be noted that the FEM treatment should be carefully applied to phene-series, especially in the case of qualitative argument of substituent effect on the electronic spectra of phene-series.

Appendix

Appendix 1. Changes of the molecular properties of hydroxyphenanthrenes by excitation.

The molecular diagrams of phenanthrene and its hydroxy derivatives are given in Figs. 12 and 13. The molecular properties, expected by the present SCF-MO calculation are summarized as follows:

Molecular Geometry: As indicated by the molecular diagram (Fig. 12), the molecule will expand and take a round shape in the excited state. The marked change of the bond order at 9—10 position is noteworthy.

Reactivity: In the ground state, the nucleus bearing hydroxy group will be most reactive. However, in the excited state, the 1-, 3-, 8-, and 9-positions in 2-hydroxy derivative, the 2-, 4-, 5- and 7-positions in 3-hydroxy isomer and 5-, 7-, and 8-positions in 9-hydroxy derivative are expected to be reactive.

pK_a: The molecular diagrams indicate that the acidity (pK_a) of the hydroxy derivatives will be as follows:

Ground state: $2 \approx 3 > 9$

Excited state: $3 > 2 > 9$

The change of charge density in hydroxy derivatives on excitation is found to be fairly large. On the other hand, no change of charge density is found in the phenanthryl-poly-ynes on excitation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1062—1067 (1971)

Sterically Controlled Syntheses of Optically Active Organic Compounds. XIII. Catalytic Hydrogenation of Symmetric Substrates in the Presence of Asymmetric Molecules[1]

Takao YOSHIDA and Kaoru HARADA

Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida 33134, U.S.A.

(Received August 10, 1971)

Several organic acids which contain C=O, C=N, and C=C double bonds are catalytically hydrogenated in the presence of various optically active organic bases by the use of several solvent systems. Effects of bases and solvents on the optical activities of the products are examined.

Many asymmetric hydrogenation reactions have been reported;[2-7] however, only few reports on the asymmetric hydrogenation using symmetric substrate and catalyst in the presence of asymmetric molecules have appeared in the literature. Lipkin and Stewart[8] reported the catalytic hydrogenation of β-methylcinnamate and β-(α-naphthyl)-cinnamate with hydrocinchonine, in which a small degree of asymmetric hydrogenation was demonstrated. Nakamura[9] reported asymmetric hydrogenation of acetophenone oxime in the presence of *l*-menthoxyacetic acid.

In this paper, catalytic hydrogenations of various symmetric organic acids which contain C=O, C=N, and C=C double bonds were carried out by using several solvent systems in the presence of asymmetric organic bases. The substrates used were: benzoylformic acid, α-acetamidoacrylic acid, α-acetamidocinnamic acid, β-phenylpyruvic acid, and α-oximino-propionic acid. Optically active organic bases used were: *l*-sparteine, *l*-ephedrine, (S)-(−)- and (R)-(+)-α-methylbenzylamine, (R)-(+)-α-ethylbenzylamine, and (S)-(−)- and (R)-(+)-α-(1-naphthyl)ethylamine. The

solvents used were: water, methanol, ethanol, isopropanol, *t*-butanol, and dioxane. Results are summarized in Tables 1, 2, and 3 and in Figs. 1, 2, and 3.

In Fig. 1, optical purities of mandelic acid (reaction A), alanine (reaction B), phenylalanine (reaction C), and β-phenyllactic acid (reaction D) prepared in the presence of *l*-sparteine by the use of various solvents are presented. The discontinuity of optical purity curves in reactions A, B, and C by the use of various solvents is observed between methanol and ethanol, and in reaction D, discontinuity is found between ethanol and isopropanol.

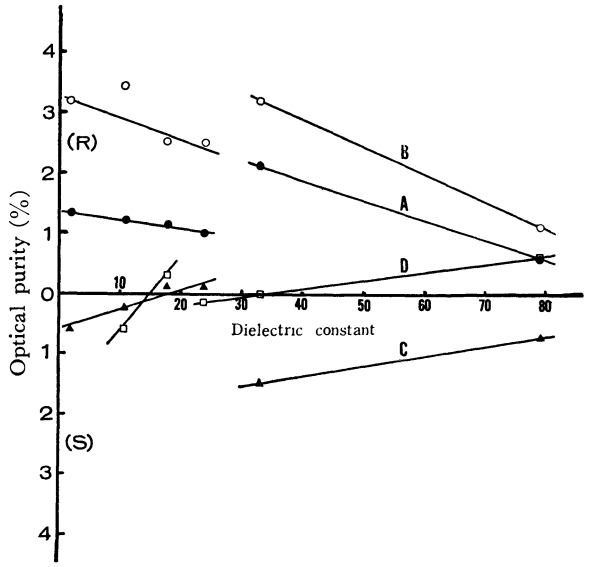

Fig. 1. Catalytic hydrogenation in the presence of *l*-sparteine.
A Benzoylformic acid+*l*-sparteine
B α-Acetamidoacrylic acid+*l*-sparteine
C α-Acetamidocinnamic acid+*l*-sparteine
D Phenylpyruvic acid+*l*-sparteine

In Fig. 2, the optical purity of mandelic acid (reaction E), alanine from α-acetamidoacrylic acid (reaction F), alanine from α-oximino-propionic acid (reaction G), and β-phenyllactic acid (reaction H) are shown. In reaction G, optical purity of alanine from α-oximino propionic acid is rather high and the value reaches 10% by the use of isopropanol. Optical activity of β-phenyllactic acid reaches 7.5% by the use of methanol. The discontinuity of optical purity curves of the products is found in all reactions E, F, G, and H. Inversion of configuration of the products is observed in reactions E, F, and G.

In Fig. 3, alanine formation from α-acetamidoacrylic acid by the use of various optically active bases is presented. In reactions I and J, S-(−)-α-methylbenzylamine and (R)-(+)-α-methylbenzylamine are used respectively for the synthesis of alanine. The optical purity curve of reactions I and J are similar in magnitude but are opposite in sign. The antipodal results are also obtained in the formation of alanine by the use of (R)-(+)-α-(l-naphthyl)ethylamine (reaction L) and (S)-(−)-α-(l-naphthyl)ethylamine (reaction M). The magnitude of optical activity and also sign of configuration of the resulting alanine change, depending on the solvent used. The discontinuity

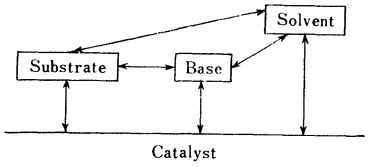
a) (S)-(+)-Mandelic acid: $[\alpha]_D$=+156.2° (H_2O)
DNP-(S)-(+)-Alanine: $[\alpha]_D$=+143.9° (1 N NaOH)
(R)-(+)-β-Phenyllactic acid: $[\alpha]_D$=+22.2° (H_2O)
DNP-(S)-(−)-Phenylalanine: $[\alpha]_D$=−93.7° (1 N NaOH).
b) Optical purity is defined as ($[\alpha]_D$ obs/$[\alpha]_D$ lit)×100.

of optical purity curves is observed in reactions I, J, and K.

An explanation of these results would be very difficult because of the complexity of the reaction system. A substrate (acid) and a base would interact with each other, and these two kinds of molecules would also be absorbed on the catalyst surface. The solvent molecule in the reaction system would also interact with the substrate, the base, and the catalyst.



In reaction (A), optical purity of mandelic acid prepared from benzoylformic acid tends to increase to the R-configuration depending on the decrease of dielectric constant of the solvent used. On the other hand, in reaction (D), optical purity of β-phenyllactic acid from phenylpyruvic acid tends to increase to the S-configuration, depending on the decrease of polarity of the solvent used. In reaction (B), the configuration of alanine from α-acetamidoacrylic acid is R and the optical purity increases to the R-configuration depending on the use of less polar solvents. However, in reaction (C), configuration of phenylalanine from α-acetamidocinnamic acid which is a similar homologue of α-acetamidoacrylic acid, is S and the direction of increase of optical purity curve is antipodal to the reaction (B). These results suggest that the phenyl residue of acetamidocinnamic acid could be an important factor to determine the conformation of the substrate on the catalyst surface.

In reaction (A) and (B), by the use of *l*-sparteine, configurations of mandelic acid and alanine are both found to be R and optical activity curves change similarly to the R-configuration, depending on the decrease of polarity of the solvent. However, in reactions (E) and (F) by the use of *l*-ephedrine, configurations of mandelic acid and alanine from the same substrate are antipodal to each other. These results suggest that the replacement of optically active base could

a) (S)-(+)-Mandelic acid: $[\alpha]_D$=+156.2° (H_2O)
DNP-(S)-(+)-Alanine: $[\alpha]_D$=+143.9° (1 N NaOH)
(R)-(+)-β-Phenyllactic acid: $[\alpha]_D$ +22.2° (H_2O).
b) Optical purity is defined as ($[\alpha]_D$ obs/$[\alpha]_D$ lit)×100.
c) Yields are calculated from DNP-alanine.

result in the change of the conformation of the substrate molecule on the catalyst surface. The discrepancies between reactions (A) and (B) and reactions (E) and (F) might be accounted for by the fact that *l*-sparteine has a rigid structure and *l*-ephedrine has a relatively flexible structure. The optical purity of mandelic acid (reaction E) is rather low, however, while the optical purity of β-phenyllactic acid (reaction H), which is a similar homologue of mandelic acid, is rather high (~8%).

In reactions (J) and (K), alanine was prepared by the use of (R)-(+)-α-methylbenzylamine and (R)-(+)-α-ethylbenzylamine. The optical purity curves of (J) and (K) are almost the same as shown in Fig. 3. This implies that the difference between methyl and ethyl residue in the optically active amines does not affect the optical purity of the resulting alanine.

In order to avoid fractionation of the partially optically active amino acids during the isolation and purification procedures, a part of the amino acids were converted to DNP-derivatives. The DNP-amino acids were purified by using Celite column chromatography[10] without fractionation of the optical isomers.[11] Optical activities of mandelic acid and β-phenyllactic acid were measured before recrystallization to avoid fractionation of these optical isomers.

Experimental

All hydrogenations were carried out by the use of Parr 3910 shaker type hydrogenation apparatus at room temperature (23—25°C) with initial pressure of 40 psi.

All optical rotation measurements were carried out by the use of JASCO-ORD-UV-5 spectropolarimeter. The length of the cell used for the measurement of optical activity were 1 cm and 10 cm. All solutions for the measurement of optical activity were filtered through 0.2 μ Millipore filter or whatman No. 50 hardened filter paper. Optical rotatory

a) DNP-S(+)-Alanine: $[\alpha]_D$ = +143.9° (1 N NaOH).
b) Optical purity is defined as ($[\alpha]_D$ obs/$[\alpha]_D$ lit)×100.

dispersion curves of some of the samples were recorded in order to determine that the rotatory power of the samples was due to the optically active specific compounds which formed by the asymmetric hydrogenation.

Elemental analyses were carried out by Micro-Tech Laboratories, Inc., Skokie, Illinois. Melting points were measured by the use of Mel-Temp apparatus. Melting points measured were uncorrected.

Dielectric constants of the solvents used were as follows:

H_2O	78.5
MeOH	32.6
EtOH	24.3
i-PrOH	18.3
t-BuOH	10.9
Dioxane	2.2

Optically active amines used were: *l*-(−)-sparteine, $[\alpha]_D^{25}$ −4.59° (benzene); *l*-(−)-ephedrine, $[\alpha]_D^{25}$ −5.13° (ethanol); S-(−)-α-methylbenzylamine, $[\alpha]_D^{25}$ −42.4° (benzene); R-(+)-α-methylbenzylamine, $[\alpha]_D^{25}$ +40.0° (benzene); R-(+)-α-ethylbenzylamine, $[\alpha]_D^{25}$ +21.7° (benzene); R-(+)-α-(1-naphthyl)ethylamine, $[\alpha]_D^{25}$ +77.8° (benzene); S-(−)-α-(1-naphthyl)ethylamine, $[\alpha]_D^{25}$ −80.0° (benzene).

Hydrogenation of Benzoylformic Acid with l-*Sparteine.* A mixture of benzoylformic acid (450 mg, 0.003 mol) and *l*-sparteine (700 mg, 0.003 mol) in 15 m*l* of water was subjected to hydrogenation at room temperature with 500 mg of 5% palladium on charcoal. After the hydrogenation was over, the catalyst was removed by filtration and the filtrate was concentrated under reduced pressure. The residual oil was dissolved in 6 N hydrochloric acid and the mixture was extracted with ether several times. The combined ethereal extract was washed once with water and dried with anhydrous sodium sulfate. After evaporation of ether, mandelic acid was crystallized. Yield, 400 mg (88%), mp 116.5—117°C, $[\alpha]_D^{32}$ −0.96° (*c* 2.21, H_2O), optical purity 0.6%. A part of this sample was recrystallized from benzene, mp 120—121°C.

Found: C, 62.92; H, 5.25%. Calcd for $C_8H_8O_3$: C, 63.15; H, 5.30%.

Similar experiments by using other solvents are listed in Table 1 (A).

Hydrogenation of Benzoylformic Acid with l-*Ephedrine.* The hydrogenation procedures are the same as described above. The results are summarized in Table 2 (E).

Hydrogenation of α-Acetamidoacrylic Acid with l-*Sparteine.* A mixture of α-acetamidoacrylic acid (390 mg, 0.003 mol) and *l*-sparteine (700 mg, 0.003 mol) in 30 m*l* of water was hydrogenated with 5% palladium on charcoal (500 mg). After hydrogenation was over, the catalyst was removed by filtration. The filtrate was concentrated *in vacuo*. The residual oil was hydrolyzed with 6 N hydrochloric acid (20 m*l*) under reflux for 5 hr. The hydrolyzate was evaporated to dryness under reduced pressure. The residue was dissolved in 10% aqueous sodium carbonate solution and the solution was extracted with ether repeatedly to remove sparteine. The aqueous solution was acidified and was evaporated to dryness *in vacuo*. The residual amino acid hydrochloride was extracted with absolute ethanol. The ethanol solution was evaporated under reduced pressure. Free alanine was obtained by using a Dowex-50 ion exchange column. Yield, 200 mg (75%), DNP-alanine, $[\alpha]^{25}$ −1.56° (*c* 0.34, 1 N NaOH), optical purity, 1.1%, mp 178—179°C.

Found: C, 42.50; H, 3.53; N, 16.9%. Calcd for $C_9H_9O_6N_3$: C, 42.36; H, 3.55; N, 16.47%.

Similar experiments by the use of other solvents are summarized in Table 1 (B).

Hydrogenation of α-Acetamidoacrylic Acid with l-*Ephedrine.* The hydrogenation procedures are similar to those described above. The results are summarized in Table 2 (F).

Hydrogenation of α-Acetamidoacrylic Acid with S-(−)-α-Methylbenzylamine. The procedures are similar to those described above. The results are summarized in Table 3 (I, J, K, L, M).

Hydrogenation of α-Acetamidocinnamic Acid with l-*Sparteine.* The procedures are similar to those described above. From α-acetamidocinnamic acid (615 mg, 0.003 mole) and *l*-sparteine (700 mg, 0.003 mole), 420 mg of phenylalanine was obtained (85%), DNP-phenylalanine, $[\alpha]^{25}$ −0.61° (*c* 2.45, 1 N NaOH), optical purity 0.65%, mp 216.5—217.5°C.

Found: C, 54.11; H, 3.84; N, 12.57%. Calcd for $C_{15}H_{13}O_6N_3$: C, 54.38; H, 3.96; N, 12.68%.

Other results obtained by the use of other solvents are listed in Table 1 (C).

Hydrogenation of Phenylpyruvic Acid with l-*Epherine.* Phenylpyruvic acid (820 mg, 0.005 mole) and *l*-ephedrine (825 mg, 0.005 mole) were dissolved in 30 m*l* of water. The mixture was hydrogenated and β-phenyllactic acid was isolated as above. Yield, 700 mg (85%), mp 94—95°C, $[\alpha]_D^{25}$ +0.48° (*c* 2.07, H_2O), optical purity 2.2%. A part of the sample was recrystallized from benzene, mp 96—97°C.

Found: C, 62.92; H, 5.25%. Calcd for $C_9H_{10}O_3$: C, 63.15; H, 5.30%.

Other results obtained by using other solvents are summarized in Table 2 (H).

Sterically Controlled Syntheses of Optically Active Organic Compounds. XIV. Syntheses of Dipeptides from *N*-(α-Ketoacyl)-α-amino Acid Esters[1]

Kaoru HARADA and Kazuo MATSUMOTO

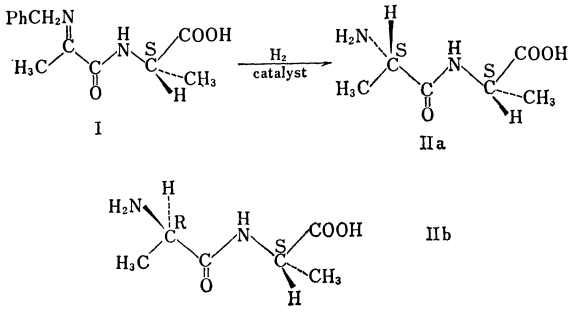
Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida 33134, U.S.A.

(Received August 10, 1970)

Optically active α-amino acids were synthesized from azomethines of *N*-α-ketoacyl-amino acid esters by catalytic hydrogenation. When optically active (S)-alanine was used, (R)-amino acyl-(S)-alanine ester was obtained. When alkyl groups of optically active (S)-amino acids in the *N*-α-ketoacyl-amino acid esters were larger than ethyl group, the configurations of newly formed amino acids were found to be (S). From these results possible steric courses of the asymmetric syntheses are discussed.

Several nonenzymatic asymmetric syntheses of α-amino acids from α-keto acids have been reported.[2–14] Hiskey and Northrop[4] published a description of a stereospecific synthesis of dipeptide from benzylamine Schiff bases of *N*-pyruvoyl-(S)-alanine. They discussed the question of whether (S)-alanyl-(S)-analine would result (Scheme I), if the catalytic hydrogenation of the Schiff base were to follow the "Prelog Rule".[15] However, the ratio of resulting dipeptide, (R)-ala-(S)-ala: (S)-ala-(S)-ala, was found to be 2: 1. The results indicate that the catalytic hydrogenation does not follow the Prelog rule.

In order to clarify the stereochemical course of the sterically controlled synthesis, several reactions were carried out.[8] Oximes of (S)- and (R)-*N*-phenylglyoxyl-oyl-α-methylbenzylamine and *N*-(S)- and (R)-ethyl-



Scheme 1

benzoylformamide were hydrogenated and the hydrogenated products were hydrolyzed. When optically active (S)- or (R)-α-methylbenzylamine was used, the configuration of the resulting phenylglycine was (R) and (S), respectively,[8] which agreed with the results obtained by Hiskey and Northrop.[4] However, when (S)- or (R)-α-ethylbenzylamine was used, the resulting phenylglycine was (S) or (R) respectively, which agreed with the configurations expected by the formal application of the Prelog rule. The clear inversion of the configuration of the products depending on the α-methyl- and α-ethylbenzylamines could not be explained by an electronic effect. These results suggest that the reaction would be controlled by steric factors. In order to solve the problem, it has been proposed that the substrate might form a five-membered chelate ring structure with the catalyst (Scheme 2).[8] When (S)-α-methylbenzylamine was used as an optically active moiety of benzoylformamide, the conformation was proposed as structure III (conformation A). However, when (S)-α-ethylbenzylamine was used, the conformation of the substrate could be structure IV (conformation B). Since the ethyl group is bulkier than the methyl group, the ethyl group could reach the catalyst surface if the substrate were to take on con-

15) V. Prelog, *Helv. Chim. Acta*, **36**, 308 (1953). The Prelog rule was originally proposed for homogeneous reactions. Therefore, the Prelog rule might not be applicable for catalytic hydrogenation of the Schiff base of α-keto acid amides. It is important to consider that the configurational agreement of the final product does not always mean that the conformation of the substrate follows the Prelog rule, because several possible conformations of the substrate would result in the specific configuration predicted by the Prelog rule.

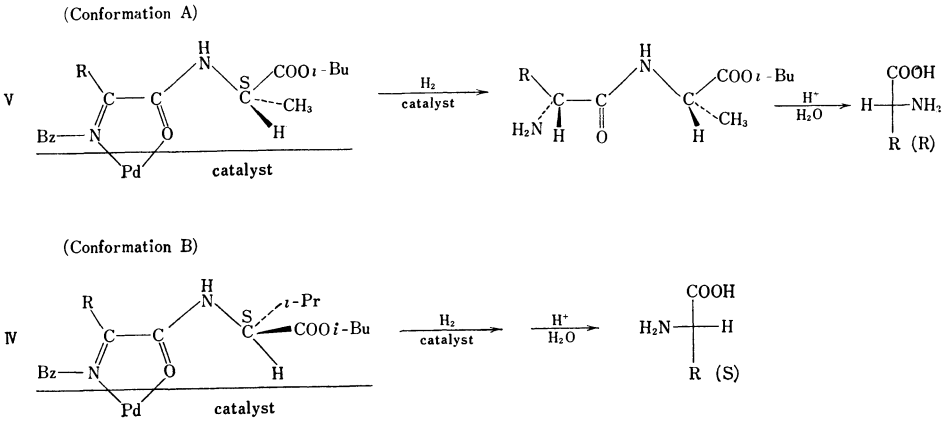
b) The ratio of diastereomeric dipeptides was measured by amino acid analyzer after saponification. From these results optical purities were calculated.
c) The optical activity of alanine was calculated from the results of $[\alpha]_D$ of free amino acid mixture and the composition of amino acids.
d) Optical purity defined as ($[\alpha]_D$ observed/$[\alpha]_D$ literature)×100, DNP-(S)-alanine, $[\alpha]_D$=+143.9° (1 N NaOH).



Scheme 3

formation A. Therefore, the most probable conformation is structure IV (conformation B) when the R-group of the amine is larger than the ethyl group. Then the cyclic intermediate complex could be adsorbed on the less bulky side of the molecule and the hydrogenation reaction would take place (Scheme II)[8] (two step mechanism).

In order to confirm further the proposed steric course of the asymmetric synthesis, a series of dipeptide syntheses were carried out in the study reported here. When benzylamine Schiff base of *N*-pyruvoyl-(S)-alanine isobutyl ester was used as a starting material, the configuration of the newly formed alanine was (R), (R)-ala-(S)-ala : (S)-ala-(S)-ala=82 : 18. When isobutyl (S)-α-aminobutyrate was used as an asymmetric center, (S)-alanine was obtained, (R)-ala-(S)-NH_2-Bu : (S)-ala-(S)-NH_2-Bu=29 : 71. In this series of reactions, also the inversion of configuration of the resulting amino acid was observed when asymmetric moieties containing methyl or ethyl residues were used. Results are summarized in Table 1. These results agreed with those obtained in the phenylcine synthesis.[8] The possible steric course of the reactions is shown in Scheme 3.

When the alkyl group of the asymmetric moiety is methyl (alanine isobutyl ester), structure A could be the preferred conformation. When the alkyl group is larger than the ethyl group (isobutyl α-aminobutyrate), structure B could be the major conformation in the sterically controlled syntheses of dipeptides. Intermediates A and B were then absorbed on the catalyst at the less bulky side and the hydrogenation reaction could take place. Optical purities of the newly formed alanine using valine and leucine isobutyl ester

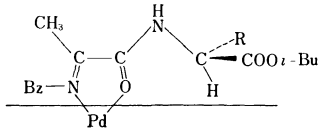
a) Yields are calculated from α-ketobutyric acid.
b) Optical purity defined as ($[\alpha]_D$ observed/$[\alpha]_D$ literature)×100. DNP(S)-α-amino-*n*-butyric acid, $[\alpha]$=+98.8° (1 N NaOH)

are larger than those of alanine obtained by the use of valine or leucine methyl ester. This finding may also support the fact that structure B could be the major conformation in these reactions.

If structure B is the preferred conformation when the R group is larger than the ethyl group, one could state an order of effective bulkiness of the R group in this reaction by the use of the optical purity of newly formed alanine. When R is phenyl, the optical purity of newly formed alanine is zero, so that the effective bulkiness of the phenyl group and of the –COO–*i*-Bu group are the same. In the same way, the bulkiness of the benzyl group and of the $-CH_2COO$–*i*-Bu group are almost the same. However, these are smaller than those of the phenyl or –COO–*i*-Bu groups. The order of effective bulkiness of the R group could be arranged as shown below.



(Conformation B)

$$-COO\text{-}i\text{-}Bu \sim Ph > -CH_2Ph \sim -CH_2COO\text{-}i\text{-}Bu > i\text{-}Pr > i\text{-}Bu > Et$$

The order of bulkiness does not agree with the order of residue weight. In the order of effective bulkiness, the phenyl group is larger than the benzyl group and also the isopropyl group is larger than the isobutyl group. This relationship can be explained on the basis that the phenyl group and isopropyl group are rigid and branched and that these groups also cannot be bent. On the other hand, benzyl and isobutyl groups are flexible; these are not branched at the α-carbon to which these groups are attached. Therefore, the effective bulkiness of rigid and branched phenyl and isopropyl groups does not follow the order of residual weight.

Table II describes α-aminobutyryl peptides. The reaction products have all S–S and R–R structures. The R groups used were phenyl, benzyl, and $-CH_2$–COO–*i*-Bu. Therefore, structure B could be the major conformation in these reactions.

In summary, (a) a chelation hypothesis in the sterically controlled synthesis of dipeptide is proposed; (b) an order of effective bulkiness of side chains is assigned by the use of optical purity of the newly formed amino acids; (c) the dimension of the space between substrate and catalyst surface is inferred by the use of chemical data; (d) the possibility is advanced that one can determine the configurations of structurally unknown primary amines by the use of these results, when the proposed stereochemical course is further established.

Experimental

Amino Acid Esters. Amino acid methyl ester hydrochlorides were prepared by the thionyl chloride method.[16] Amino acid isobutyl ester *p*-toluenesulfonates (amino acid ester PTS) were prepared by the use of the azeotropic method in benzene with a Dean and Stark separation tube.[17] Yields were between 70 to 80%, (Table 3).

N-α-*Ketoacyl-α-amino Acid Esters.* Experimental procedures in the syntheses of dipeptide esters are similar to those described earlier.[8] α-Keto acid (0.03 mol) and α-amino acid ester (hydrochloride or *p*-toluenesulfonate), (0.03 mol) were dissolved in anhydrous tetrahydrofurane (150 m*l*) or freshly purified chloroform (100 m*l*). The solution was cooled to about −15°C. To this, 2.75 m*l* (0.03 mol) of phosphorus oxychloride was added dropwise in a period of 10 min. The mixture was kept at −10°C for 1 hr and at 0°C for 30 min. Then the mixture was again cooled to −15°C. To this solution 7.5 m*l* (0.09 mol) of pyridine was added dropwise in a period of 30 min at −15——10°C. After the addition, the solution was kept at −10——5°C for 1 hr, then the solution was brought to room temperature. Solvent was removed under reduced pressure. The residual syrup was dissolved in ethyl acetate and the solution was washed with 1 N hydrochloric acid, 5% sodium hydrogen carbonate, and then with water. The solution was dried with anhydrous sodium sulfate. Ethyl acetate was evaporated under reduced pressure. The attempt to crystallyze the residual yellow syrup was unsuccessful. The syrup was

used for further experiment.

Alanyl and α-Aminobutyryldipeptide Isobutyl Esters. *N*-α-Ketoacyl-α-amino acid ester and an equimolar amount of benzylamine were dissolved in benzene. The solution was gently refluxed for 20 minutes with a Dean-Stark separator. The benzene was removed under reduced pressure. The residual syrup was dissolved in absolute methanol. Hydrogenation and hydrogenolysis were carried out with 10% palladium on charcoal at room temperature, by the use of a Parr 3910 shaker type hydrogenation apparatus. After the reaction was over, the catalyst was removed and the methanol was evaporated under reduced pressure. The residue was dissolved in ethyl acetate and the solution was extracted with 1 N hydrochloric acid. To the aqueous solution, sodium hydrogencarbonate was added to bring the pH to 8. The solution was extracted with ethyl acetate. The solution was dried with anhydrous sodium sulfate and the solvent was evaporated under reduced pressure. The residual product (dipeptide ester) was used for further experiments (for saponification or for hydrolysis).

Optical Purity of Newly Formed Amino Acid Residues. Dipeptide esters were refluxed with 6 N hydrochloric acid for 8 hr. The hydrolyzate was evaported to dryness *in vacuo*. The residue was dissolved in a small amount of water and the solution was applied to a Dowex 50×2 column (hydrogen form, 100—200 mesh, 20×1.8 cm). After washing with water, amino acid mixture was eluted with 1 N aqueous ammonia. After evaporation of water and ammonia under reduced pressure, a mixture of free amino acids was obtained. The amino acid mixture was treated with 2,4-dinitrofluorobenzene in a conventional manner.[18] The resulting DNP-amino acids were separated by the use of a Celite column treated with pH 7.0 citrate buffer[19] without fractionation of optical isomer.[8,12]

In the synthesis of alanylphenylalanine in Table 1, DNP-(S)-alanine was isolated and analyzed.

Found: C, 42.42; H, 3.66; N, 16.64%. Calcd for $C_9H_9O_6N_3$; C, 42.36; H, 3.55: N, 16.47%.

In the synthesis of alanylaspartic acid in Table 1, free (S)-alanine was isolated by the use of Dowex 50×2 column.

Found: C, 40.68; H, 8.01; N, 15.58%. Calcd for $C_3H_7O_2N$: C, 40.44; H, 7.92; N, 15.72%.

Optical activities of separated DNP-amino acids were measured in 1 N sodium hydroxide by the used of a Rudolph model 80 polarimeter with PEC-101 photometer. In the case of alanyl-α-aminobutyric acid synthesis, the optical purity of alanine was determined by the measurement of specific rotation and composition of free amino acid mixture which was obtained by acid hydrolysis. The amino acid compositions were determined by the used of a Phoenix model K-5000 automatic amino acid analyzer.

The Catalytic Dehydrogenation of Alcohols with Reduced Copper under Ultraviolet Light[1]

Shigeaki NAKAMURA and Kazuaki KAWAMOTO[2]
Department of Chemistry, Takamatsu Technical College, Takamatsu
(Received August 15, 1970)

In order to investigate whether or not the dehydrogenation activity of the reduced copper is affected by ultraviolet light, the reaction of such alcohols as ethanol, 1-propanol, 2-propanol, and 1-butanol was carried out with reduced copper and ultraviolet light at 250°C. It was found that the conversion of alcohols and the yield of aldehydes were larger with the reduced copper under ultraviolet light than without the light, and that aldol condensation for the ethanol reaction was recognizable when the reduced copper catalyst was used without ultraviolet light.

Many papers have reported on the decomposition of alcohols with copper catalysts.[3-6] The main products of the formation of a complex[4,7] between the alcohols and the copper catalysts were found to be aldehydes, ketones, and esters. On the other hand, the photochemical reaction of alcohols has been carried out recently.[8,9]

It has been reported that the radical formation of alcohol under ultraviolet light produced mainly RR'-$\dot{C}$OH,[9] from which aldehyde, pinacol, and so on were obtained. Although the photo-oxidation of such reactants as alcohol, water, and carbon monoxide has been studied with ZnO[10] sensitized by ultraviolet light, the reaction of gaseous alcohol in the presence of a reduced copper catalyst and ultraviolet light has not been carried out. Accordingly, the present work was carried out in order to study the difference between the catalytic reaction of alcohols with the reduced copper alone and that with the reduced copper under ultraviolet light. It was found that the yield of aldehydes and the conversions of ethanol, 1-propanol, and 1-butanol increased considerably with the catalytic reaction under ultraviolet light, with the exception of 2-propanol, and that 1-butanol might be formed from ethanol through an aldol condensation mechanism with the catalyst without ultraviolet light.

Experimental

Preparation of Catalyst. Copper nitrate, the starting material, was prepared from electrolytic copper and nitric acid.

A mixture of 20 g of electrolytic copper in an aqueous solution of nitric acid (90 g of 60% HNO_3 and 90 m*l* of distilled water) was heated gradually on a sand bath.

After the electrolytic copper has been completely dissolved, the solution was diluted with the same amount of distilled water and filtered through a glass filter. The diluted solution was evaporated below 60°C to give crystals of cupric nitrate hexahydrate. The blue crystals were dried under reduced pressure for several hours. A solution of 30 g of cupric nitrate hexahydrate, prepared by the method described above in 900 m*l* of distilled water, was kept at 22°C. A sodium hydroxide solution prepared from 15 g of sodium hydroxide and 300 m*l* of distilled water was brought to the same temperature and added rapidly to a stirred copper nitrate solution.

After the mixture had been stirred at this temperature for 30 min, the precipitate was washed well with distilled water by decantation, collected on a glass filter, dried in an electric oven at 105°C for 20 hr, powdered in an agate mortar, and finally stored in a stoppered bottle. The precipitates were reduced in the following ways. When hydrogen (or carbon monoxide) was passed through at the rate of 750—900 m*l* per hour over 10 g of the precipitate, the reduction temperature was always below 180°C in the case of hydrogen and below 140°C in the case of carbon monoxide, and the reduction time was 4—5 hr.

Apparatus and Procedure. The apparatus employed was similar to that used in the previous investigation,[6] with the exception that a low-pressure mercury lamp (UL1—8 DQ 80 W made by Ushio Electric Co., Ltd.) was inserted into the center of the reaction tube (Fig. 1). A definite amount (10 g) of the precipitate was spread in a Pyrex reaction tube (reaction part: 35 mm in inside diameter and 550 mm long), which was then set in an electrically-heated furnace of the horizontal type.

The furnace was heated to the reduction temperature and kept at this temperature for the period of the reduction.

The resulting catalyst was then heated to the reaction temperature (250°C) under ordinary pressure. The alcohols (ethanol, 1-propanol, 2-propanol, and 1-butanol) purified by the ordinary method were passed through the tube at a constant flow rate of 7.2 to 9.3 g per hour (carrier gas, nitrogen).

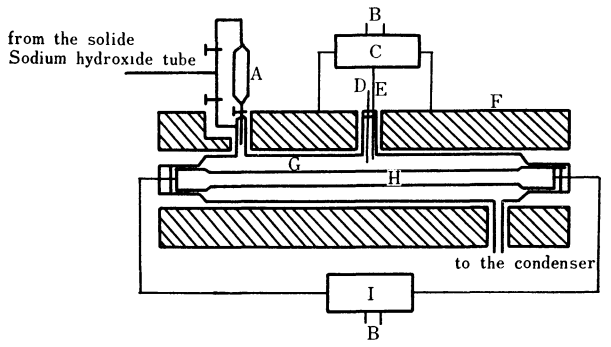

Fig. 1. Apparatus.
A: Funnel, B: Electric source, C: Temp. regulator, D: Thermometer, E: Thermocouple, F: Electric furnace, G: Reaction tube, H: Mercury lamp, I: Voltage stabilizer.

The reaction products coming out of the reaction tube were removed by being passed through a condenser filled with ice water, supplemented by two traps which were cooled with dry ice and acetone. The volume of gas evolved was determined by allowing it to displace the water from a graduated 2-*l* cylinder.

All the values given in the present research are averages of two to three measurements under constant reaction conditions, as Tables 1—4 show.

Analysis of the Products. The reaction products were identified by comparing them with authentic samples obtained by gas chromatography. In addition, the liquid products were dried over anhydrous sodium sulfate and then fractionally distilled, and the constituents of the cut were identified by their boiling points, densities, refractive indices, and the formation of the corresponding derivatives. All the derivatives for the identification of the reaction products were made by the Shriner, Fuson, and Curtin method.[11]

The reaction products were analyzed quantitatively by gas chromatography, using a Shimadzu Type GC-2C apparatus. A 5-m column of the filler (polyethylene glycol-6000, tricresyl phosphate, silicone DC-550 and diethylene glycol succinate in the case of the liquid products, and activated charcoal, molecular sieve-13X, hexamethylphosphoramide, tricresyl phosphate, acetonylacetone and dimethylsulfolane in the case of the gaseous products) was used at an operating temperature of 100°C and a flow rate of 22.0 ml/min of helium. For the determination of the water, a 3-m column packed with Shimalite F impregnated with polyethylene glycol-1000 was used at 100°C, with a hydrogen carrier and at 11.5 ml/min.

Results and Discussion

Tables 1—5 show the results of the present experiments.

Comparison of the Copper Catalyst under Ultraviolet Light with the Non-irradiated Copper Catalyst. In the case of the gaseous reaction of ethanol, as is shown in Table 1, the conversion in the presence of the copper catalyst under ultraviolet light was much larger than that without the light.

The conversion of ethanol under only ultraviolet light was smaller than all those obtained in the presence of the copper catalyst.

As is shown in Tables 1—3, the conversion of 1-propanol and 1-butanol had an inclination similar to that of ethanol, but it was found that the conversions of the primary alcohols decreased slightly in proportion to the molecular weights of the primary alcohols. As is shown in Table 4, the conversion of 2-propanol in the presence of the catalyst and the light was almost the same as that obtained with the catalyst without the light. In the case of the catalytic reaction of 2-propanol, it is considered that the 2-propanol reaction differs from those of other primary alcohols by having the reactive α-hydrogen atom.

The total amounts of the main products of the alcohols, such as the aldehydes, the esters and the ketones, accounted for over 95% of the conversions of the present alcohols for both the catalytic reaction under ultraviolet light and the reaction without the light. The aldol condensation was observed with the catalytic reaction of ethanol in the absence of the light, but it did not occur quite as in the cases of the other alcohols.

The formation of diols by the use of ultraviolet light

was observed in the cases of ethanol, 1-propanol, and 2-propanol, but not in the case of 1-butanol. The gaseous products are shown in Table 5. When the reaction of alcohol in the presence of the catalyst and ultraviolet light was compared with that in the presence of the non-irradiated catalyst, more gaseous products were found to be formed under the former reaction conditions.

Comparison between the Reduced Copper Catalysts. As is shown in Table 1, the formation of ethanal from ethanol by dehydrogenation was more increased by the use of the hydrogen-reduced copper catalyst than by the use of the carbon monoxide-reduced copper catalyst and was further promoted by ultraviolet light. The same tendency was observed in the formation of propanal and butanal from 1-propanol and 1-butanol respectively, as is shown in Tables 2 and 3. As is shown in Table 4, the formation of propanone from 2-propanol by dehydrogenation was remarkably accelerated by ultraviolet light. The conversion of 2-propanol into propanone with the carbon monoxide-reduced catalyst under ultraviolet light was above 90% in all the products (included the unreacted alcohol). The aldehydes and the ketone mentioned above were obtained in any small amounts under ultraviolet light without the catalyst. Esters were obtained in larger quantities by the use of a reduced copper catalyst treated with carbon monoxide than with one reduced with hydrogen, and the production was further promoted by ultraviolet light. From the results mentioned above, it was found that the formation of the esters occurred preferentially with the carbon monoxide-reduced catalyst, and that the copper catalyst treated with hydrogen as the reducing agent was suitable for the formation of the aldehyde. The above facts suggest that the different structures of the catalyst surface are formed by the different reducing agents used. As Table 1 shows, the yield of propanone, which seems to have been formed by the secondary reaction process of ethanol, was nearly proportional to that of ethanal from ethanol. A similar tendency was also observed in the formation of 3-pentanone from 1-propanol, but little 4-heptanone was formed from 1-butanol.

Non-reduced Copper Catalyst. As is shown by Experiment No. 6 in Tables 1—3, the yield of aldehydes, such as ethanal from ethanol, propanal from 1-propanol, and butanal from 1-butanol, was the largest, and much more water was formed than under other experimental conditions. The hydrogen formed by dehydrogenation and the non-reduced copper catalyst might react to form water on the surface of the catalyst.

Formation Mechanism of the Main Products from Ethanol in the Presence of the Catalyst. From the facts mentioned above, the reaction mechanism of ethanol is considered to be as follows.

The main products, such as ethanal and ethyl acetate, appear to be formed by the following schemes:[5,12,13]

$$C_2H_5OH \rightarrow CH_3CHO + H_2$$

$$C_2H_5OH + CH_3CHO \rightarrow$$

$$CH_3CH(OH)OC_2H_5 \xrightarrow{-H_2} CH_3COOC_2H_5$$

The formation of propanone from ethanol with a catalyst can probably be presented by Kagan's process,[14] with the result that ethylene and carbon dioxide are formed:

$$2CH_3COOC_2H_5 \rightarrow$$

$$CH_3COCH_3 + C_2H_5OH + C_2H_4 + CO_2$$

Judging from such gaseous products as methane and hydrogen, methanol, which was little produced in a catalytic reaction, seems to be formed by hydrogenolysis:[13]

$$C_2H_5OH \xrightarrow{H_2} CH_3OH + CH_4$$

The ethylene in gas products is considered to be provided by dehydration,[13] also. Morgan and Kagan proposed the following mechanism for the formation of alcohol by aldol condensation and hydrogenation as follows:[15]

$$2CH_3CHO \rightarrow CH_3CH(OH)CH_2CHO \xrightarrow[H_2]{-H_2O}$$

$$CH_3CH_2CH_2CHO \xrightarrow{H_2} CH_3CH_2CH_2CH_2OH$$

Accordingly, 1-butanol seems to be formed by the aldol condensation of ethanal, which is itself the product of the primary catalytic reaction process of ethanol. Aldol condensation was not observed under ultraviolet light. On the other hand, one of the present authors has previously reported that the main reaction mechanism of 2-propanol with the copper catalyst is represented by the steps shown below.[6]

$$(CH_3)_2CHOH \rightarrow (CH_3)_2CO + H_2$$

$$(CH_3)_2CHOH + (CH_3)_2CO \rightarrow$$

$$(CH_3)_2CHCH_2COCH_3 + H_2O$$

$$(CH_3)_2CHOH + CH_3COCH_2CH(CH_3)_2 \rightarrow$$

$$(CH_3)_2CHCH_2COCH_2CH(CH_3)_2 + H_2O$$

2-Methyl-2-pentanol may be formed from 4-methyl-2-pentanone by hydrogenation.

Photochemical Reaction Mechanism of Ethanol. As is shown in Table 6, the photochemical reaction of ethanol seems to proceed without a catalyst, judging from the products obtained in the present work and from the results previously reported.[8,9]

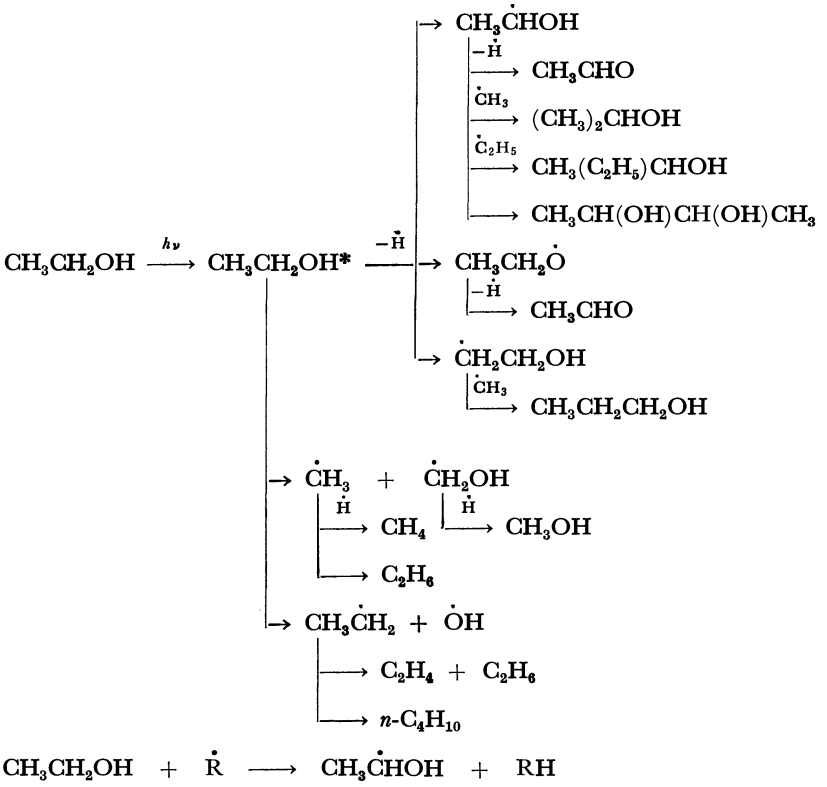
TABLE 6. PHOTOCHEMICAL REACTION SCHEME
(Reactant: Ethanol)



Reaction Process of Alcohol with the Catalyst under Ultraviolet Light. The reaction of the alcohols with the catalyst under ultraviolet light promoted the formation of aldehydes and esters, and their conversions, except in the case of 2-propanol, were much accelerated by ultraviolet light. By the use of the non-reduced copper catalyst under the light, the formation of aldehyde from alcohol was especially remarkable.

However, the conversion of alcohol under ultraviolet light without the copper catalyst was small. Accordingly, it is considered that the scarcely no decomposition of alcohol occurs under ultraviolet light without the catalyst, and that the main products were almost all formed by the catalytic reaction of alcohol. The facts mentioned above may be represented by the two following reaction processes.

The first is:

$$S \xrightarrow{h\nu} S^*$$

$$R + S^* \rightarrow R\cdots\cdots S^* \rightarrow \text{Products} + S$$

where:

S, catalyst; R, alcohol; h, Plank's constant, and ν, the frequency of ultraviolet light.

As is shown in Table 1, no aldol condensation was observed under ultraviolet light, but it occurred slightly with the non-irradiated catalyst. The above facts suggest that the surface of the catalyst was altered slightly by the irradiation of ultraviolet light. One of the present authors has previously reported that the formation of higher ketones from 2-propanol with the reduced copper catalyst seems to be attributable to the effect either of a trace of water or of a lower oxide of copper in the catalyst.[6] Also, from the fact that the copper catalyst reduced in the present work was reddish purple, it seems to include such oxides of copper as Cu_2O,[16] which shows photoconductivity, though no strong and sharp absorption of copper and copper compounds has been observed in the range of ultraviolet light.[17] Accordingly, we consider that the copper catalyst gives rise to electrons and positive holes which may enhance the activity of the catalyst when irradiated under ultraviolet light. The above process has been reported for the ZnO - O_2 system by Kwan.[18]

17) Miner (1903), Tool (1910), Mecke and Ley (1924), and French and Lowry (1924). In "International Critical Tables of Numerical Data, Physics, Chemistry and Technology," Vol. V, ed. by J. W. Clarence, McGraw Hill Book Co., New York and London (1933), pp. 249, 330.

18) T. Kwan, "Photochemistry and Its Application," ed. by M. Koizumi *et al.*, Kagaku Dojin Tokyo, Tokyo (1965), pp. 101—119.

The reaction schemes described in the above report are as follows:

$$M \xrightarrow{h\nu} M^* \xrightarrow{O_2} MO_2^*(MO_2) \xrightarrow{B} M + BO_2 \quad (1)$$

$$M \xrightarrow{h\nu} M^* \xrightarrow{B} MB^*(MB) \xrightarrow{O_2} M + BO_2 \quad (2)$$

where M is a photocatalyst and B is the reactant oxidized. In the present work, oxygen was not present in the reaction system.

Accordingly, it is considered that the photo-response may occur in the adsorption of alcohol on the surface of the present catalyst, as is shown in Scheme (2).

The second is:

$$R + S \rightarrow R\cdots\cdots S \xrightarrow{h\nu} (R\cdots\cdots S)^* \rightarrow \text{Products} + S$$

Although alcohols like ethanol show the absorption in the extreme range of ultraviolet light,[19] the wavelength of its absorption seems to be shifted[20] when it is adsorbed on the surface of the catalyst. Accordingly, an intermediate state like an activated complex seems to be excited by ultraviolet light, and its decomposition seems to be promoted. When the reaction with the copper catalyst under ultraviolet light was compared with that in the presence of the non-irradiated copper catalyst, the species of the main products, such as ethanal, ethyl acetate, and propanone, were, in the case of ethanol, almost the same in both the experiments, and the yields of the main products increased in all the main products upon irradiation of ultraviolet light. Moreover, the total amounts of the main products accounted for over 95% of the conversions of the primary alcohol for both the catalytic reaction under the light and the reaction without the light. From the above facts, it can be considered that the direction of the catalytic reaction with the catalyst and the light may be almost the same as that of the catalytic reaction without the light, and that the reaction velocity may be accelerated by the irradiation. In the case of the first process, the species of the main products with the catalyst under ultraviolet light may differ somewhat from those obtained with the catalyst alone, so the state of the non-irradiated catalyst might be altered considerably by ultraviolet light. Accordingly, the second reaction process may occur rather than the first process. The tendency of the catalytic reactions of 1-propanol and 1-butanol was similar to that of ethanol. In the case of 2-propanol, the dehydrogenation may be more rapid than that of the primary alcohols,[7] so 2-propanol may have a reactive α-hydrogen atom, though the second process is considered to be valid for the catalytic reaction under the light. Accordingly, the yield of propanone by the catalytic dehydrogenation may be especially large and may be further promoted by ultraviolet light.

The authors wish to thank Dr. Yoshio Masuyama, President of Takamatsu Technical College, for his encouragement throughout this work.

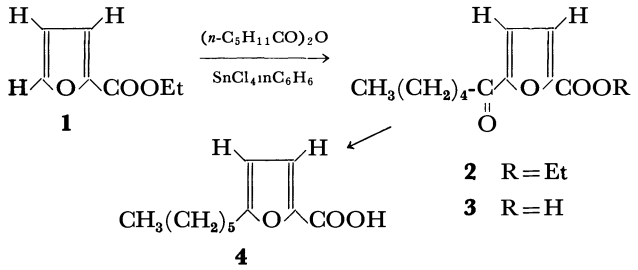
Anodic Reaction of 5-Alkyl-2-furoic Acids in Protic Solvents

Sigeru Torii, Hideo Tanaka, Hitosi Ogo, and Siro Yamasita
Department of Industrial Chemistry, Okayama University, Okayama
(Received August 26, 1970)

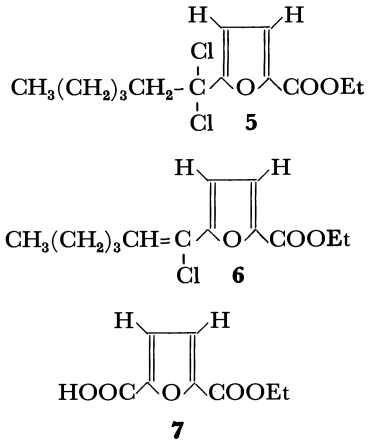
Anodic oxidation of 5-alkyl-2-furoic acids (**4** and **10**) in protic solvents has been studied. The major products were 1-butenolides (**12**, **13**, **16**, and **17**) and γ-keto esters (**11** and **15**) and their acids (**14** and **18**). Methyl 5-*n*-hexyl-2,5-dimethoxy-2,5-dihydro-2-furoate **19** was converted into γ-keto ester **11** and its acid **14** by hydrolysis with alkali and into 1-butenolide **12** by electrolysis of the alkaline solution. A possible mechanism of the anodic oxidation of 5-alkyl-2-furoic acids has been discussed.

Anodic oxidation of a number of furan derivatives in protic media in the presence of appropriate electrolytes gives mainly 2,5-disubstituted 2,5-dihydrofurans.[1] However, similar experiments on 2-furoic acids have not been described, except for one by Hellström.[2] We are especially interested in 2-furoic acids both for their synthetic utility[3,4] and for anodic oxidation that is expected on both the furan ring and carboxyl group. We report that the anodic oxidation of 5-*n*-hexyl and 5-



1 4

(1,1-dimethylbutyl)-2-furoic acids (**4** and **10**) in protic media can lead to γ-hexyl-γ-keto acid derivatives and also to γ-alkyl-1-butenolides, which can be rationalized as arising from 2,5-substituted intermediates (b).



5-Alkyl-2-furoic acids have been synthesized by Gilman and Calloway[5] from the condensation of alkyl 2-furoates with alkyl halides using aluminum chloride. *n*-Alkyl chains are found to be isomerized to give secondary and tertiary derivatives.[5] An attempt to prepare 5-*n*-alkyl-2-furoic acids by the reaction of 2-furoates with acid anhydrides has been reported.[6]

The reaction of ethyl 2-furoate **1** with *n*-hexanoic anhydride in the presence of stannic chloride was reinvestigated and found to give a 4—10% yield of oily materials which seem to be a mixture containing **5** and **6**, in addition to the expected crystalline ester (**2**, 15—20%). A constituent of the crude oil was isolated by preparative vpc after treatment with pyridine, and assigned to be **6** on the basis of spectral data and elemental analysis.

In the initial stage of this reaction, a large amount of *gem*-dichloride **5** is believed to be produced, but the high reactivity and instability of the dichloride function has precluded its isolation and characterization. As a matter of fact, halide **6** was converted into 5-carbethoxy-2-furoic acid[7] liberating hydrogen chloride while the oil stood at room temperature for several hours. Preferential formation of the mixture of chlorides (**5** and **6**) over **2** occurred when the reaction of **1** with *n*-hexanoyl chloride in carbon tetrachloride was carried out using ferric chloride as a catalyst.[8] Conversion of **2** into **4** *via* **3** was realized by the Huang-Minlon reduction.[9]

We studied in detail the structure of the products in the alkylation of **1** with *n*-hexyl bromide. By fractional distillation, two components of bp 140—142.5°C/20 mmHg could be isolated in the ratio 3:1 and the analytical specimens (**8** and **9**) were obtained by preparative vpc. The structure of **8**, a fraction boiling at 142°C/20 mmHg, was assigned from spectral data and elemental analysis. By comparing the NMR spectrum of **8** with that of **9**, a conspicuous difference was found at τ 8.00—9.50. In this region the NMR spectrum of **9** exhibited a triplet at 9.26 (6H), a singlet at 8.78 (3H), a triplet at

8.65 (3H), and a multiplet at 8.34 (4H). Except for the region 1250—1150 cm^{-1} the infrared spectra of **8** and **9** are similar with respect to all major peaks. Hydrolysis of **8** in the usual manner gave **10** in good yield.[5]

Electrolysis of furoic acids (**4** and **10**) was carried out in various protic media, using two platinum foil electrodes. Details of the experimental conditions along with the results are shown in Tables 1 and 2. In runs 1 and 5, mixtures of γ-keto esters (**11** and **15**), 1-butenolides (**12** and **16**) and γ-keto acids (**14** and **18**) were obtained. In experiments 2 and 4, an increase in the proportion of acetic acid in the electrolyte solution facilitated the formation of γ-acetoxy-1-butenolides (**13** and **17**). In procedures 3 and 6, formation of both γ-keto acids (**14** and **18**) and their methyl esters (**11** and **15**) increased considerably. Analytical samples of these compounds were obtained by preparative vpc.

The structures of **11** and **14** were confirmed by comparison of their NMR and infrared spectra with those of authentic specimens.[4,10] The proposed structure for **15** was supported by its infrared spectrum, showing γ-keto ester carbonyls at 1745 and 1709 cm^{-1}, and

10) Authentic methyl 4-oxo-decanoate was prepared from the corresponding acid by methylation with diazomethane.

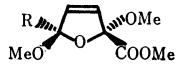
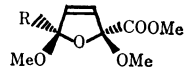
by its NMR spectrum which shows geminal methyls at τ 8.86 as a singlet, and also by its elemental analysis. The γ-keto acid **18** was converted into **15** by the action of diazomethane. The structures of γ-methoxybutenolides (**12** and **16**) were deduced from their spectral properties and elemental analyses. The infrared spectra of both **12** and **16** had equal absorption bands at 3100, 1830, 1778, and 1613 cm^{-1}. NMR spectra of **12** and **16** exhibited a three-proton signal at τ 6.88 and 6.83, respectively, in place of the peak at τ 7.92 due to methyl protons of the acetoxy group of **13** and **17**. The NMR spectrum of **17** showed two doublets at τ 2.56 and 3.71 (J=6Hz) ascribable to olefinic protons. The NMR spectrum of **13** closely resembled that of **17**. Further evidence confirming the structural similarity of **13** and **17** was found in the absorption bands at 1786 and 1760 cm^{-1} due to lactone and acetoxy carbonyls, respectively.

The electrochemical behavior of 5-alkyl-2-furoic acids (a) is of particular interest in clarifying competitive anodic oxidation between the furan ring and carboxyl group. A tentative mechanism for the formation of γ-keto derivatives (c) and 1-butenolides (e) is shown in Scheme 1. As seen in route 1, anodic oxidation of furoic acids (a) would occur *via* two electron oxidation of the furan ring similar to the mechanism previously proposed, which involves cation radical or dication intermediates.[1] On the other hand, plausible intermediates (g) that may be derived from two electron oxidation of the carboxyl group of (a) *via* cation precursor (f) as shown in route 2 might be subjected to hydrolysis to give (c). Some evidence is required of the presence of the obtainable intermediates (g) in the initial products from the anodic oxidation of (a), but no appreciable amount of (g) was detected on vpc. Thus, it seems that an initial oxidation mechanism of the furan ring (route 1) for the anodic oxidation of (a) accounts for the results.

In order to obtain evidence for the proposed mechanism, anodic oxidation of (b) under our conditions was attempted. Anodic oxidation of methyl 5-*n*-hexyl-2-furoate in methanol in the presence of a catalytic amount of sulfuric acid afforded *trans* and *cis* isomers of 2,5-dimethoxy derivatives (**19**a and **19**b). Isolation of both **19**a and **19**b could be carried out by preparative vpc.

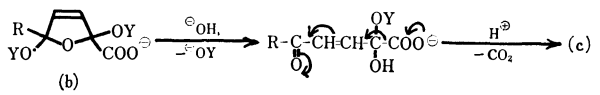


19a, *trans*



19b, *cis*

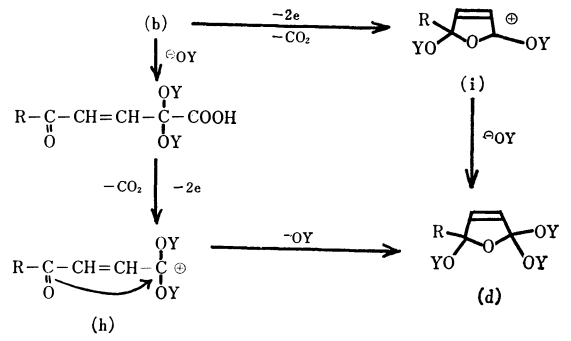
Hydrolysis of **19** in aqueous methanol-potassium hydroxide gave an alkaline solution from which only γ-keto ester **11** and γ-keto acid **14** were obtained after acidification with dilute sulfuric acid. Evolution of carbon dioxide took place when the pH of the alkaline solution fell below 7. This suggests that 2, 5-dimethoxy derivative (b) is a precursor of **11** and **14** (path A). On the other



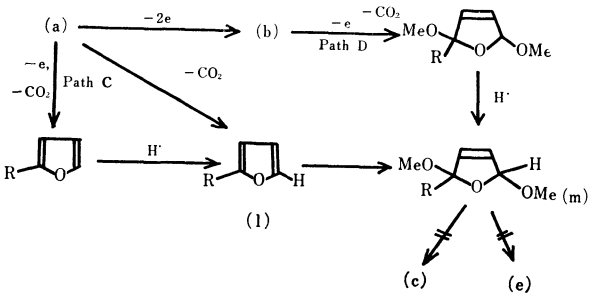
Y=H, Me Path A

hand, electrolysis of the alkaline solution gave 10—15% yield of 1-butenolide **12** together with **11** and **14**. The result reveals the probability of 2,5-dimethoxy derivative (b) as an intermediate which can lead to **12** (path B). Further two electron oxidation of the carboxyl group of (b) might give an unstable compound (d) *via* cation intermediates (h and/or i) as shown in Scheme 2.

Alkaline hydrolysis, followed by treatment with mineral acid, of 2,5-dimethoxy-2-*n*-hexyl-2,5-dihydrofuran (m) resulting from anodic dimethoxylation of 2-*n*-hexylfuran (l), which may be derived from one electron oxidation of (a) and (b) as shown in path C and D in



Scheme 2



Scheme 3

Scheme III, provided no evidence for the presence of (c) and (e).

Experimental[11]

Reaction of Ethyl 2-Furoate (1) with n-*Hexanoic Anhydride.* Condensation of **1** (14.0 g) with *n*-hexanoic anhydride (21.4 g) in benzene (50 ml) in the presence of stannic chloride (52 g) was carried out. A mixed oil was obtained (7.1 g) according to the procedure reported by Kawabe *et al.*[6] Upon standing for several hours, white crystals **2** were precipitated and purified by preparative vpc to give analytical sample of **2**, mp 57—58°C: IR (neat) 3150 (=C–H), 3100 (=C–H), 1730 (ester C=O), 1675 (C=O), 1570 (C=C), 1503, 1295, 1260, 1220, 1165, 1015, 960, 770 cm^{-1}; NMR ($CDCl_3$) τ 2.80 (s, 2H, =C–H), 5.60 (q, 2H, J=5.6 Hz, O–CH_2–C), 7.10 (t, 2H, –CH_2CO), 8.25 (m, 8H, –$(CH_2)_4$–), 8.60 (t, 3H, J=5.6 Hz, O–C–CH_3), 9.10 (t, 3H, C–CH_3).

Found: C, 65.78; H, 7.82%. Calcd for $C_{13}H_{18}O_4$: C, 65.53; H, 7.61%.

Ketonic component **2** was separated from the oily filtrate by extraction with Girard reagent P.[12] A total 4.5 g of **2** was obtained. The residual yellow oil, after being treated with a few drops of pyridine, was purified by distillation to give 2.2 g of **6**, bp 125—128°C/2 mmHg. The analytical specimen was obtained by preparative vpc; IR (neat) 3150 (=C–H), 3100 (=C–H), 1725 (ester C=O), 1640 (C=C), 1580 (C=C), 1510, 1300, 1258, 1211, 1140, 1014, 800, 755 cm^{-1}; NMR ($CDCl_3$) τ 2.86 (d, 1H, J=2.7 Hz, =C–H), 3.36 (t, 1H, J=5.6 Hz, CCl=C–H), 3.40 (d, 1H, J=2.7 Hz, =C–H), 5.60 (q, 2H, J=5.6 Hz, O–CH_2–C), 7.58 (m, 2H, =C–CH_2), 8.00—8.70 (m, 4H, –$(CH_2)_2$–), 8.60 (t, 3H, J=5.6 Hz, O–C–CH_3), 9.07 (t, 3H, C–CH_3).

Found: C, 60.44; H, 6.74%. Calcd for $C_{13}H_{17}ClO_3$: C, 60.82; H, 6.68%.

The chlorovinyl derivative **6** was decomposed on standing for several days to give crystals **7**, mp 147.5—148°C (lit,[7] mp 149°C); IR (Nujol mull) 3700—2100 (COOH), 1733 and 1685 (ester and carboxyl C=O) cm^{-1}.

The solid **7** was esterified with diazoethane[13] to give diethyl 2,5-difuroate whose infrared spectrum was superimposable in every detail with that of the authentic specimen.[14]

Preparation of Ethyl 5-Hexyl-2-furoates (8 and 9). Condensation of ethyl 2-furoate (23 g) with *n*-hexyl bromide (28 g) in carbon disulfide (100 m*l*) in the presence of aluminum chloride (43 g) was carried out at room temperature according to the procedure by Gilman and Calloway.[5] After being treated in the usual manner, distillation of the product gave a fraction (20 g) boiling at 110—130°C/10 mmHg. Upon fractional redistillation of the fraction using a spinning band-type distillation apparatus, two major fractions were obtained in the ratio 3:1, one was assigned to **8** (rich fraction) boiling at 142°C/20 mmHg and the other (**9**) boiling at 143°C/20 mmHg.[15] Analytical specimens (**8** and **9**) were provided by preparative vpc (Rt: 18.0 and 19.2 min, respectively). Ethyl 5-(1,1-dimethylbutyl)-2-furoate **8**, IR (neat) 3100 (=C–H), 1725 (conjugated ester C=O), 1590 (C=O), 1520 (C=C), 1300, 1135, 1016, 800, 760 cm^{-1}; NMR ($CDCl_3$) τ 2.95 (d, 1H, J=2.7 Hz, =C–H), 3.89 (d, 1H, J=2.7 Hz, =C–H), 5.67 (q, 2H, J=5.6 Hz, O–CH_2–C), 8.16—8.60 (m, 4H, –$(CH_2)_2$–), 8.64 (t, 3H, J=5.6 Hz, O–C–CH_3), 8.70 (s, 6H, *gem*-CH_3), 9.14 (t, 3H, C–CH_3).

Found: C, 69.88; H, 8.69%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

Ethyl 5-(1-methyl-1-ethylpropyl)-2-furoate **9**, IR (neat) 3100, 1725, 1590, 1520, 1300, 1135, 1018, 760 cm^{-1}; NMR ($CDCl_3$) τ 2.93 (d, 1H, J=2.7 Hz, =C–H), 3.87 (d, 1H, J=2.7 Hz, =C–H), 5.67 (q, 2H, J=5.6 Hz, O–CH_2–C), 8.32 (m, 4H, *gem*-CH_2–C), 8.65 (t, 3H, J=5.6 Hz, O–C–CH_3), 8.78 (s, 3H, C–CH_3), 9.26 (t, 6H, J=6.2 *gem*-C–CH_3).

Found: C, 69.59; H, 9.31%. Calcd for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

Hydrolysis of Ethyl 5-(1,1-Dimethylbutyl)-2-furoate (8). A mixture of **8** (5 g), potassium hydroxide (1.8 g), and ethanol (7 m*l*) with a few drops of water was heated at 80°C for 30 min with stirring, then poured into 100 m*l* of ice water and acidified with dilute sulfuric acid to give **10** (3.1 g), mp 60.5°C (crude); IR (Nujol mull) 1689 (carboxylic acid C=O), 1600 (C=C), 1528, 1310, 1160, 1019 cm^{-1}. By treating **10** with diazomethane, methyl 5-(1,1-dimethylbutyl)-2-furoate was obtained, bp 91—92°C/4 mmHg. Purification of the methyl ester of **10** was performed by preparative vpc: IR (neat) 3150, 1735, 1593, 1520, 1308, 1142, 1022, 990, 926, 795, 760 cm^{-1}.

Found: C, 68.43; H, 8.72%. Calcd for $C_{12}H_{18}O_3$: C, 68.55; H, 8.63%.

Electrolysis Apparatus. The electrolysis cell was a

11) All melting and boiling points are uncorrected. Preparative gas chromatography was operated by a partially modified Yanagimoto GCG-550T type apparatus fitted with 10% coated SE-30 packed column, 3 m long, carrier gas H_2 20 m*l*/min at 130—175°C. Infrared spectra were determined with a Hitachi EPI-S2 spectrophotometer. NMR spectra were obtained on a Japan Electron Optics Laboratory spectrometer (JNM-C-60) in deuteriochloroform with TMS as an internal reference. Microanalyses were carried out by Miss M. Harada of our laboratory.

12) A. Girard and G. Sandulesco, *Helv. Chim. Acta*, **19**, 1095 (1936).

14) R. Andrisano, *Ann. Chim.* (Rome), **40**, 30 (1950); *Chem. Abstr.*, **45**, 7563 (1951).

15) The constitution of both fractions was estimated as follows: the former fraction contained 97% of **8** and the latter 50% of **9**, elucidated by vpc using poly-neopentyl glycol succinate 10% coated Diasolid L. M. column.

water-jacketed beaker, 3.2 cm long in diameter and 10 cm high, fitted with a gas lead pipe, a thermometer, and a magnetic stirrer. The electrodes were two platinum foils (1.5×2.0 cm^2) about 1 mm apart from each other. Current was controlled by manually adjusting the applied voltage as required. The direction of current was changed every 30 sec by means of a commutator.

*Electrolysis of 5-n-Hexyl-2-furoic Acid (**4**) in Acetic Acid-Methanol-Water.* A solution of **4** (1.5 g), potassium hydroxide (0.65 g) in acetic acid (20 ml)-methanol (15 m*l*)-water (10 m*l*) was electrolyzed at 29—34°C for 26 hr under a current of 0.8—1.2 A at 16—17 V (Experiment 1, Table 1). 10 m*l* of acetic acid was added every 4 hr. The reaction mixture was poured into 200 m*l* of ice water and extracted with ether. The ethereal solution was washed with aqueous sodium bicarbonate followed by aqueous sodium chloride and dried over Na_2SO_4. Evaporation of the solvent gave 1.2 g of neutral product, whose vpc analysis showed presence of two main constituents (Rt min, peak area%): **11** (14.2, 28) and **12** (15.4, 46), along with minor constituents (total peak area 26%) as shown in Table 2. Analytical specimens (**11** and **12**) were obtained by preparative vpc. IR spectrum and retention time of **11** on vpc were identical with those of authentic sample.[4] The physical data of **12** together with microanalytical results are as follows: IR (neat) 3100 (=C–H), 1830 (shoulder), 1779 (lactone C=O), 1613, 1463, 1171, 912, 822 cm^{-1}; NMR ($CDCl_3$) 2.90 (d, 1H, J=5.6 Hz, =C–H), 3.79 (d, 1H, J=5.6 Hz, =C–H), 6.88 (s, 3H, O–CH_3), 7.90—8.30 (m, 2H, C–CH_2–C–C=C–C=O), 8.73 (broad, 8H, –$(CH_2)_4$–) and 9.14 (t, 3H, C–CH_3).

Found: C, 66.52; H, 9.32%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

The alkaline solution was acidified with dilute sulfuric acid and extracted with ether. The ethereal solution was washed with aqueous sodium chloride, dried over Na_2SO_4 and concentrated *in vacuo*. The remaining oil was treated with diazomethane to give 0.3 g of methyl ester whose vpc showed a sharp peak at Rt 14 min (peak area 60%) along with many minor peaks. The major constituent after purified by preparative vpc was identical with that of authentic sample **11**.

In a similar manner, electrolysis of 5-(1,1-dimethylbutyl)-2-furoic acid **10** in acetic acid-methanol-water media, as seen in Experiment 4, gave 2.0 g of neutral and 0.5 g of acidic portions. Vpc analysis of the neutral portion showed presence of three main compounds (Rt min, peak area%): **15** (11.7, 5), **16** (13.6, 18) and **17** (28.6, 30) along with many minor constituents. From the acidic portion, 0.5 g of methyl ester was obtained after being treated with diazomethane. Vpc analylysis showed a sharp peak (Rt 11.7 min, peak area 61%) and minor peaks (total 10 peaks). IR spectrum of the main component, after being purified by preparative vpc, was identical with that of **15**. Compound **15**: IR (neat) 1745 (ester C=O), 1709 (ketone C=O), 1471, 1440, 1369, 1213, 1170, 1090, 840 cm^{-1}; NMR ($CDCl_3$) τ 6.32 (s, 3H, O–CH_3), 7.30 (m, 4H, CO–$(CH_2)_2$–CO), 8.11—8.90 (broad, 4H, –$(CH_2)_2$–), 8.86 (s, 6H, *gem*-CH_3), 9.10 (t, 3H, C–CH_3).

Found: C, 66.01; H, 10.04%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Compound **16**: IR (neat) 3100 (=C–H), 1830 (shoulder), 1778 (lactone C=O), 1613, 1134, 1108, 914, 826 cm^{-1}; NMR ($CDCl_3$) τ 2.80 (d, J=6.0 Hz, 1H, =C–H), 3.70 (d, J=6.0 Hz, 1H, =C–H), 6.83 (s, 3H, O–CH_3), 8.65 (m, 4H, –CH_2–), 9.03 (s, 9H, $3CH_3$).

Found: C, 66.70; H, 9.46%. Calcd for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

Compound **17**: IR (neat) 3100 (=C–H), 1786, 1760 (acetoxy, lactone C=O), 1619, 1394, 1372, 1333, 1223, 1124, 1097, 1055, 1015, 992, 913, 840, 820, 736 cm^{-1}; NMR ($CDCl_3$) τ 2.56 (d, 1H, J=6.0 Hz, =C–H), 3.71 (d, 1H, J=6.0 Hz, =C–H), 7.92 (s, 3H, O–CO–CH_3), 8.65 (m, 4H, –$(CH_2)_2$–), 8.98—9.03 (s, 9H, $3CH_3$).

Found: C, 63.50; H, 8.47%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Electrolysis of 5-n-Hexyl-2-furoic acid (**4**) in Acetic Acid.* A solution of **4** (1.0 g) and potassium acetate (0.6 g) in acetic acid (35 m*l*) was electrolyzed at 28—35°C for 8 hr under a current of 0.2—0.3 A at 50 V (Experiment 2, Table 1). After the usual working-up, 0.8 g of neutral oily material was obtained. Vpc analysis showed presence of a major constituent **13** (Rt: 29.0 min, peak area 71%) along with minor constituents (total 12 peaks). Analytical specimen **13** provided by preparative vpc has following physical constants: IR (neat) 3100 (=C–H), 1781, 1750 (acetate and lactone C=O), 1383, 1220, 816 cm^{-1}; NMR ($CDCl_3$) τ 2.42 (d, 1H, J=5.6 Hz, =C–H), 3.79 (d, 1H, J=5.6 Hz, =C–H), 7.91 (s, 3H, O–CO–CH_3), 8.68 (broad, 10H, 5–CH_2–), 9.11 (t, 3H, C–CH_3).

Found: C, 63.86; H, 8.17%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*Electrolysis of 5-n-Hexyl-2-furoic Acid (**4**) in Aqueous Methanol.* A solution of **4** (0.9 g) and potassium hydroxide (0.3 g) in 66% aqueous methanol (30 m*l*) was electrolyzed at 25—26°C for 2 hr under a current of 1 A at 15 V (Experiment 3, Table 1). After the usual working-up, 0.7 g of neutral and 0.5 g of crystalline acidic portions were obtained. Analytical data of the neutral portion are shown in Table 2. An acid, mp 64—65°C (*n*-hexane) (lit,[4] mp 60—60.5°C), treated with diazomethane, gave the corresponding methyl ester whose IR spectrum and retention time on vpc coincided with those of authentic sample **11**. Similarly, electrolysis of 5-(1,1-dimethylbutyl)-2-furoic acid **10** in acetic acid-methanol-water media and in aqueous methanol were carried out (Experiments 5 and 6). These results are also shown in Table 2.

*Methyl 5-n-Hexyl-2,5-dimethoxy-2,5-dihydro-2-furoates (**19**a and **19**b).* A solution of methyl 5-*n*-hexyl-2-furoate (1.1 g) in 25 m*l* of methanol containing two drops of concentrated sulfuric acid was electrolyzed with platinum electrodes at 20°C for 6 hr under a current density of 0.06 A/cm^2 at 15.5—16 V. The reaction mixture was concentrated *in vacuo* and extracted with ether. The ethereal solution was washed with aqueous sodium chloride and then concentrated *in vacuo*. Distillation of the residue gave 1.3 g of oil, bp 115—120°C/2.5 mmHg, consisting of two products (Rt 11.5 and 12.8 min in a ratio of 1:0.7). Isolation of two stereoisomers of methyl 5-*n*-hexyl-2,5-dimethoxy-2,5-dihydro-2-furoates was carried out by preparative vpc; **19**b (*cis* isomer) Rt: 11.5 min, **19**a (*trans* isomer) Rt: 12.8 min. *trans* Isomer **19**a, IR (neat) 3100 (=C–H), 1755 (ester C=O), 1635 (C=C), 1465, 1442, 1260, 1064, 1035, 857, 794 cm^{-1}; NMR ($CDCl_3$) τ 3.91 (s, 2H, =C–H), 6.17 (s, 3H, –CO–O–CH_3), 6.61 (s, 3H, O–CH_3), 6.80 (s, 3H, O–CH_3), 8.20 (m, 2H, C–CH_2–C–C=C–C=O), 8.68 (m, 8H, 4–CH_2–), 9.10 (t, 3H, C–CH_3).

Found: C, 61.65; H, 9.00%. Calcd for $C_{14}H_{24}O_5$: C, 61.75; H, 8.88%.

cis-Isomer **19**b: IR (neat) 3100 (=C–H), 1755 (ester C=O), 1635 (C=C), 1465, 1442, 1340, 1270, 1160—1000, 940, 859, 794 cm^{-1}; NMR ($CDCl_3$) τ 3.91 (s, 2H, =C–H), 6.17 (s, 3H, CO–O–CH_3), 6.55 (s, 3H, O–CH_3), 6.70 (s, 3H, O–CH_3), 8.15 (m, 2H, C–CH_2–C–C=C–C=O), 8.68 (broad, 8H,

4-CH_2-), 9.10 (t, 3H, C-CH_3).

Found: C, 61.65; H, 8.96%. Calcd for $C_{14}H_{24}O_5$: C, 61.75; H, 8.88%.

Hydrolysis of Methyl 5-n-Hexyl-2,5-dimethoxy-2,5-dihydro-2-furoate. A solution of 0.5 g of **19**, potassium hydroxide (0.1 g) and two drops of water in methanol (2.2 m*l*) was stirred at room temperature for 24 hr. The mixture was poured into 25 m*l* of ice water, neutralized with acetic acid to pH 7.0—7.5 and extracted with ether. The extracts, after being concentrated in *vacuo*, gave a trace of oil whose vpc chart showed no peak corresponding to **19**. The aqueous solution was acidified to pH 4—5 with dilute sulfuric acid. Carbon dioxide was evolved. The organic layer was taken up in ether, washed with aqueous sodium bicarbonate and aqueous sodium chloride and concentrated in *vacuo*. The residue (0.25 g) contained a constituent corresponding to the γ-keto ester **11** (peak area 85% on vpc). IR spectrum of the analytical specimen coincided well with that of authentic sample mentioned in the preceeding paragraph. The alkaline solution was acidified with dilute sulfuric acid, taken up in ether, washed with aqueous sodium chloride and concentrated in *vacuo*, giving 1.5 g of oily material. On treatment with diazomethane the corresponding methyl ester **11** was obtained.

Electrolysis of the alkaline solution obtained by hydrolysis of **19** was carried out as follows: to a methanol solution prepared from 0.5 g of **19**, 1.0 g of potassium hydroxide and 2.2 m*l* of methanol with a few drop of water, 12.8 m*l* of methanol and 5 m*l* of water were added (in total methanol 15 m*l*, water 5 m*l*). The solution was electrolyzed at 23—27°C for 0.5 hr under a current of 0.33 A at 14.4—15 V. The reaction solution was concentrated in *vacuo*, poured into 25 m*l* of ice water, neutralized with acetic acid to pH 7.0—7.5 and extracted with ether. Evaporation of the solvent gave 0.28 g of neutral portion whose vpc data are very similar to those of Experiment 3 in Table 2. The aqueous solution was acidified with dilute sulfuric acid and extracted with ether. After the usual working-up, the ethereal solution gave a crystal (0.05 g): mp 64.5—65°C from *n*-hexane (lit,[4] mp 60—60.5°C). The crystal was treated with diazomethane to give **13** whose retention time on vpc and IR spectrum are identical with those of the specimen mentioned in the paragraph above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1084—1089 (1971)

Syntheses and Reactions of Functional Polymers. LIV. Syntheses and Polymerizations of *O*-Substituted-*N*-hydroxymaleimides

Mitsuaki NARITA, Takero TERAMOTO, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 11, 1970)

The reverse Diels-Alder reaction of *N*-substituted maleimide adducts of furan is a useful method for the preparation of *N*-substituted maleimides which can not be obtained by the direct dehydration of maleamic acids owing to the formation of the corresponding isomaleimides. *O*-Benzyl, *O*-acetyl, *O*-benzoyl, *O*-benzenesulfonyl, and *O*-methyl-*N*-hydroxymaleimide adducts of furan decompose at 140—190°C to produce the corresponding maleimides. The homo- and co-polymerization with styrene of these maleimides were carried out and monomer reactivity ratios and *Q-e* values for these maleimides were determined. The copolymer obtained were converted to the copolymer of *N*-hydroxymaleimide and styrene.

We reported the preparation of polymers having the *N*-hydroxyimide structure in the chain and activation of carboxylic acid group by use of those polymers.[1,2] Syntheses of several *N*-substituted maleimides were investigated for the preparation of such polymers.[3] However, the dehydrocyclizations of *N*-substituted maleamic acids afforded only isomaleimides instead of maleimides. Several attepmpts to convert isomaleimides to maleimides were unsuccessful except for a special case.

In this paper, we report a new method to obtain *N*-substituted maleimides effectively *via* the Diels-Alder adducts. The homo- and co-polymerization with styrene of these maleimides were carried out and the polymers obtained were hydrolyzed to give the corresponding *N*-hydroxyimide structure.

Results and Discussion

Preparation of O-*Substituted*-N-*hydroxymaleimide Adducts of Furan.* Dehydration of *N*-substituted maleamic acids produces the corresponding maleimides or isoimides depending on the nature of the maleamic acids and the conditions for dehydration.[4,5] On the other hand, it is well known that dehydration of *N*-substituted saturated amic acids produce only the corresponding imides except for *N*-substituted camphoramic acids.[5] The reverse Diels-Alder reaction is known to be a useful method for the preparation of maleimides. Maleic anhydride adducts of anthracene and cyclopolyenes give imides by treatment with amines since the dehydration of the *N*-substituted saturated amic acids produce only the corresponding imides. When these imides are pyrolized at 200—500°C, maleimides are

obtained.[6] Thus, the reverse Diels-Alder reaction is thought to be a very useful method for the preparation of *N*-substituted maleimides which can not be obtained by direct dehydration of maleamic acids owing to the formation of the corresponding isomaleimides.

The maleic anhydride adduct of furan, which is obtained easily in quantitative yield by the reaction of furan with maleic anhydride at room temperature, decomposes at lower temperature (*ca.* 125°C) than maleic anhydride adducts of anthracene and cyclopolyenes. We therefore prepared *N*-substituted maleimide adducts of furan by the reaction of the maleic anhydride adduct of furan with amines and decomposed them to synthesize *N*-substituted maleimides.

The maleic anhydride adduct of furan (3,6-endoxo-1,2,3,6-tetrahydrophthalic anhydride) reacted with *N*-benzyloxyamine produce *O*-benzyl-*N*-hydroxymaleimide adduct of furan (*O*-benzyl-*N*-hydroxy-3,6-endoxo-1,2,3,6-tetrahydrophthalimide) (I) in quantitative yield in benzene by heating. Similarly the *N*-hydroxymaleimide adduct of furan (II) was obtained by treatment of maleic anhydride adduct of furan with hydroxylamine in 64% yield in methanol as shown below.

V: R=$C_6H_5SO_2$ (X=Cl)
VI: R=CH_3 (X=I)

Scheme 2

The structures were confirmed by elemental analyses and infrared spectra. The results are summarized in Table 1 and Table 2. A characteristic feature of five membered ring imides is the presence of bands at *ca.* 1780 cm^{-1} (medium) and 1730 cm^{-1} (strong) in the infrared spectra. Infrared spectra of isoimides generally exhibit a strong absorption due to carbonyl group at 1780 cm^{-1} and a medium absorption due to imine linkage at 1670 cm^{-1}. All the compounds in Table 2 exhibit characteristic absorptions of imides.

We did not investigate the stereochemistry of the compounds. However it is well known that furan forms *exo* adducts exclusively with maleic anhydride[7] and maleimide.[8] From the results and the reaction condition, we presume that compounds (I—VI) are *exo* adducts.

Syntheses of O-*Substituted*-N-*hydroxymaleimides by Pyrolyses of Those Adducts of Furan.* We carried out the reverse Diels-Alder reaction of the *O*-substituted-*N*-hydroxymaleimide adducts of furan (preceding section). The compounds decompose at 140—190°C producing

Scheme 3

The *N*-hydroxyimide (II) was decomposed at 190°C, but no *N*-hydroxymaleimide was obtained since it is probably unstable thermally. Confirmation of the structures of compounds (VII—XI) was achieved from elemental analyses, infrared and NMR spectra. Results are summarized in Tables 3, 4, and 5. The NMR spectra of compounds (VII—XI) were measured in deuteriochloroform solutions using tetramethylsilane as an internal reference. We stated that the NMR spectra of isomaleimides show two doublets due to unsymmetrical nature of olefinic hydrogen and maleimides have only one singlet due to the symmetrical nature of olefinic hydrogen[3]. The NMR data in Table 4 show only one singlet due to the symmetrical nature of olefinic hydrogen in every case and indicate the compounds to be maleimides. We described further that isomaleimides generally have two sharp bands in the infrared at *ca.* 1780 cm^{-1} (strong) and 1670 cm^{-1} (medium) which are associated with the anhydride-like carbonyl and imine bonds present in the isomaleimide ring and that maleimides have a characteristically broad carbonyl band in the infrared with maxima near 1720 cm^{-1}.[3] The infrared data in Table 5 show two bands at *ca.* 1780 cm^{-1} (medium) and 1740 cm^{-1} (strong) which are characteristic of five membered ring imides and indicate the compounds to be maleimides.

Polymerization of O-*Substituted*-N-*hydroxymaleimides.* It is known that the radical homopolymerization of 1,2-disubstituted ethylenes proceeds only with great difficulty. The polymerization of maleic anhydride and maleimide was reported recently.[9]

Homopolymerization of the maleimides obtained above was carried out in dioxane with azobisisobutyronitrile (AIBN) at 70°C. The results are summarized in Table 6. The inherent viscosities observed were low, but the infrared absorption band at 810—830 cm^{-1} which can be associated with out-of-plane deformations of hydrogen of the -CH=CH- link disappeared completely in the products. The copolymerization of those maleimides (M_2) with styrene (M_1) were conducted in dioxane by use of AIBN as an initiator at low temperature (35°C) to suppress the rapid polymerization. Typical results (VIII-styrene) are shown in Table 7.

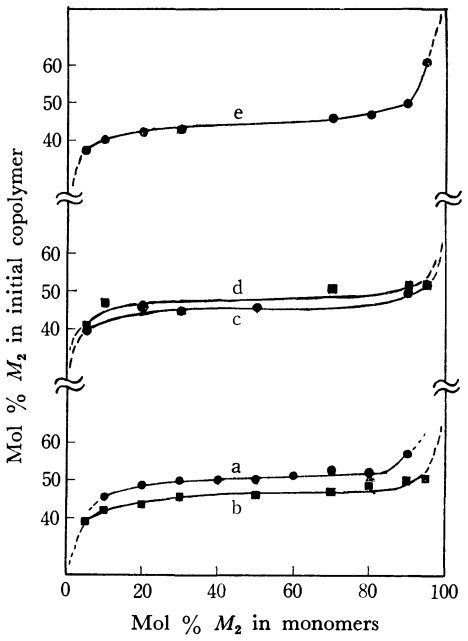

Fig. 1. Copolymerization diagram for *N*-substituted maleimides (M_2) and styrene (M_1).
a: VII, b: VIII, c: IX, d: X, e: XI

The polymerization curves were determined by inserting successive values of r_1 and r_2 in the following equation, until the best fit of the resulting curve with the experimental points was obtained.

$$\frac{m_1}{m_2} = \frac{M_1}{M_2} \cdot \frac{r_1 M_1 + M_2}{r_2 M_2 + M_1}$$

A marked tendency for alternation can be observed as shown in copolymerization diagram for *N*-substituted maleimides and styrene (Fig. I). The Q and e values for these maleimides were calculated by means of the equation of Alfrey-Price with the values of r_1 and r_2, and the results are shown in Table 8. The high Q value as well as a strong alternation tendency would be explained by the fomation of molecular complexes in the transition

Table 8. Monomer reactivity ratios and Q-e values of maleimides (M_2) [(M_1)=styrene]

M_2	r_1	r_2	Q_2	e_2
VII	0.02	0.03	5.65	1.93
VIII	0.02	0.01	4.85	2.12

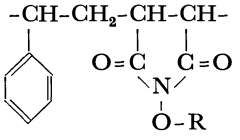
state between styrene and maleimides as in the case of styrene and maleic anhydride. The formation of charge transfer complex was examined by measurement of UV spectrum in the N-actoexymaleimide-styrene system. However, neither the change of λ_{max} (290 mμ) of *N*-acetoxymaleimide nor an appearance of new absorption band due to the C-T complex formation was observed by the addition of styrene.

Conversion of Copolymers into N-*Hydroxymaleimide-Styrene Copolymer.* Treatment of the *N*-benzyloxyimide polymer (VII′) with hydrogen bromide in acetic acid,[3] gave debenzylated *N*-hydroxymaleimide type copolymer (XIII). The structure of polymer was confirmed by the agreement of infrared absorption peaks with those of the polymer obtained previously.[2] The *N*-acetoxyimide polymer (VIII′) was hydrolyzed into the hydroxymaleimide type copolymer (XIII) when the polymer in dioxane containing 6N hydrochloric acid was refluxed for ten hours. Treatment of the copolymer (VIII′), (IX′), and (X′) with water - triethylamine in dioxane gave also hydrolyzed polymer (XIII). However, the polymers obtained were combined with triethylamine tightly. Polymer (XIII) showed imide carbonyl absorption band at 1710 cm^{-1} in the infrared spectrum, while in the case of the polymer (XIII′) it shifted to 1710 and 1680 cm^{-1}. In order to confirm the interaction of triethylamine with the *N*-hydroxyimide group, the model reaction was carried out. Thus *N*-hydroxysuccinimide and triethylamine gave a 2:1 molecular compound, whose infrared specturm also showed two peaks at 1710 and 1680 cm^{-1}.



VII′: R=CH_2-C_6H_5
VIII′: R=$COCH_3$
IX′: R=COC_6H_5
X′: R=SO_2-C_6H_5

Experimental

All melting and boiling points are uncorrected. Infrared spectra of the products were obtained as potassium bromide disks using a Hitachi Infrared Photometer Model EPI-S2. NMR spectra were obtained with a Japan Electron Optics C-100 spectrometer in deuteriochloroform solution with tetramethylsilane as an internal standard. Solvents used for reactions were purified by the usual method.

Preparation of N-*Benzyloxymaleimide Adduct of Furan (I).* Maleic anhydride adduct of furan (4.15 g) was dissolved in 100 m*l* of benzene and 3.08 g of *N*-benzyloxyamine was added. The mixture was refluxed for 3 hr and then concentrated to *ca.* 15 m*l* and cooled. The white crystals (6.33 g) were filtered off and washed with ethanol, yield 95%. They are recrystallized from ethanol, mp 115—116°C (dec. 150°C).

Preparation of N-*Hydroxymaleimide Adduct of Furan (II).* Maleic anhydride (300 g) was added to a solution of 210 g of furan in 400 m*l* of benzene and the mixture was kept overnight at room temperature with stirring. The mixture became a lump. The lump was added little by little by cooling with ice-cold water and stirring to a solution of 102 g of hydroxylamine in 1.5 *l* of methanol prepared by Lashua's procedure.[10] When heat evolution from the reaction mixture ceased, the mixture was kept for 7 hr at room temperature. Benzene and methanol were then distilled off and 700 m*l* of ethanol was added to the residue. The mixture was refluxed for 3 hr and cooled by ice-cold water. The white crystals were filtered off and washed with ethanol, yield 270 g, mp 187—188°C (dec.). After concentration of the mother liquor, an additional 78 g of the product was obtained to give a total yield of 64%.

Preparation of N-*Acetoxymaleimide Adduct of Furan (III).* *N*-Hydroxymaleimide adduct of furan (II) (7.0 g) was suspended in 20 m*l* of acetic anhydride and kept at 80—90°C for 3 hr when all the compounds dissolved in the solution gradually. After the reaction was over, it was cooled with ice-cold water and the product was filtered under suction and washed thoroughly with benzene, yield 5.0 g, mp 135—136°C (dec.). After concentration of the mother liquor, an additional 2.4 g of the product was obtained to give a total yield of 97%. It was recrystallized from benzene, mp 137—138°C (dec.).

Preparation of N-*Benzoyloxymaleimide Adduct of Furan (IV).* *N*-Hydroxymaleimide adduct of furan (II) (54.6 g) and 48 g of benzoyl chloride were dissolved in 200 m*l* of *N,N*-dimethylformamide. Pyridine (27 g) was added dropwise to this solution with stirring and by cooling with ice-cold water. The mixture was stirred for 7 hr at 0—20°C and then poured into 1 *l* of water. The precipitate was filtered off and washed with water. Recrystallization from benzene gave 68 g of the product, mp 134.5—136°C. After concentration of the mother liquor, an additional 4 g of the product was obtained to give a total yield of 84%.

Preparation of N-*Benzenesulfonyloxymaleimide Adduct of Furan (V).* *N*-Hydroxymaleimide adduct of furan (II) (36.4 g), 40 g of benzenesulfonyl chloride, and 18 g of pyridine were dissolved in 400 m*l* of benzene. The mixture was refluxed for 3 hr and then cooled. The crystals were filtered off and washed thoroughly with water. Recrystallization from acetone gave 29 g of the product, mp 171—173°C (dec.). After concentration of the mother liquor, an additional 17.5 g of the product was obtained to give a total yield of 73%.

Preparation of N-*Methoxymaleimide Adduct of Furan (VI).* *N*-Hydroxymaleimide adduct of furan (II) (18.2 g) and 56 g of methyl iodide were dissolved in 100 m*l* of *N,N*-dimethylformamide (free from water). Granulated barium oxide (45 g) was added to this solution and allowed to stand for 15 hr at room temperature. The precipitates of barium oxide and barium iodide were filtered off and the filtrate was concentrated under reduced pressure. The viscous residue was poured into 300 m*l* of water. The precipitate was filtered off and washed with water, yield 7.8 g, mp 138—140°C (dec.). It was recrystallized from ethanol, mp 139—140.5°C (dec.).

Synthesis of N-*Benzyloxymaleimide (VII).* The *N*-benzyloxyimide (I) (2.0 g) was heated in an oil bath at 170—180°C under a gentle stream of air. The solid slowly melted with vigorous furan evolution. After 1 hr, the yellowish liquid was cooled. Recrystallization from *n*-hexane gave 1.4 g (95% yield) of the product, mp 88—90°C. A second recrystallization from *n*-hexane gave light yellow crystals, mp 89.5—91°C (lit,[3] 89.5—91).

Synthesis of N-*Acetoxymaleimide (VIII).* The *N*-acetoxyimide (III) (36g) was pyrolized in an oil bath at 180—190°C under reduced pressure (25 mmHg). The solid slowly melted

10) S. C. Lashua, U. S. 3202689 (1965); *Chem. Abstr.*, **64**, 599d (1966).

with vigorus furan evolution and *N*-acetoxymaleimide was distilled at ~140°C (25 mmHg), yield 23.8 g (95 %), mp 68—71°C. Recrystallization of crude product from carbon tetrachloride furnished white crystals, mp 70.5—71.5°C.

Synthesis of N-*Benzoyloxymaleimide (IX).* The *N*-benzoyloxyimide (IV) (20 g) was dissolved in 70 m*l* of nitrobenzene and heated in an oil bath at 170—175°C for 1 hr under a gentle stream of air. Nitrobenzene was then distilled off under reduced pressure. The residue was recrystallized from carbon tetrachloride to give 14.3 g of the product, yield 95%, mp 85—88°C. A second recrystallization from *n*-hexane - carbon tetrachloride using charcoal gave white crystals, mp 87—89°C.

Synthesis of N-*Benzenesulfonyloxymaleimide (X).* The *N*-benzenesulfonyloxyimide (V) (13 g) was heated in an oil bath at 190—195°C under a gentle stream of air. The solid solwly melted with vigorous furan evolution. After 20—30 min, the liquid was cooled and combined with 50 m*l* of acetone and allowed to stand in a refrigerator overnight. Crystals (V) were filtered off and the filtrate was concentrated and the residue was recrystallized from carbon tetrachloride-chloroform to give 9 g of the product, yield 90%, mp 107—109°C. Further recrystallization from carbon tetrachloride-chloroform gave white crystals, mp 108—109.5°C.

Synthesis of N-*Methoxymaleimide (XI).* The *N*-methoxyimide (VI) (18 g) was pyrolyzed in an oil bath at 180—185°C under reduced pressure (27 mmHg). The solid slowly melted with vigorous furan evolution and *N*-methoxymaleimide was distilled at 128°C/27 mmHg, yield 80%, mp 102—108°C. Recrystallization from carbon tetrachloride - *n*-hexane using charcoal gave light yellow crystals, mp 108—110°C.

Homopolymerization of O-*Substituted*-N-*hydroxymaleimides.* Homopolymerization of maleimides (VII, VIII, IX, X, and XI) was performed in 5 m*l* of dioxane with 0.082 g of AIBN as an initiator at 70°C. The amounts of monomers used are described in Table 6. The polymerization tubes were sealed off in a vacuum. After 10 hr, the polymer solution was poured into ether and the polymer obtained was purified by dissolving twice in dioxane and precipitating in ether.

Copolymerization of O-*Substituted*-N-*hydroxymaleimides.* Copolymerization of maleimides (VII, VIII, IX, X, and XI) with styrene was perfomred in dioxane with AIBN as an initiator. The total amount of monomers was 1.0 mol/*l* and the amount of initiator was 0.025 mol/*l*. The polymerization tubes were sealed off in a vacuum and heated in a thermostated bath at 35°C, till a yield of approximately 10% of polymer was obtained. The polymer solution was then poured into ether, and the polymer was purified by reprecipitation from dioxane to ether. The polymer composition was determined by nitrogen analysis. The measurement of UV spectrum of *N*-acetoxymaleimide (VIII) was carried out for the ethylene chloride solution (2.5—10^{-3} mol/*l*) in the absence or presence of a large excess of styrene with a Hitachi Spectrophotometer EPS-3T.

Conversion of Copolymers into N-*Hydroxymaleimide-Styrene Copolymer.* Treatment of the *N*-benzyloxymaleimide type copolymer (VII′) with hydrogen bromide in acetic acid was performed as mentioned previously.[3] The *N*-acetoxyimide polymer (VIII′) (15.0 g) was dissolved in 250 m*l* of dioxane containing 50 m*l* of 6N hydrochloric acid and refluxed for 10 hr. The polymer solution was poured into 1 *l* of water and the polymer obtained (XIII) was purified by dissolving twice in dioxane and precipitating in ether. Yield 11.7 g.

The *N*-acetoxymaleimide polymer (VIII′) (0.3 g) was hydrolyzed in 10 m*l* of dimethylformamide containing 1 m*l* portions of water and triethylamine at room temperature for 7 hr. The polymer solution was poured into ether and 0.2 g of polymer (XIII′) was obtained. Hydrolysis of polymer IX′ and X′ was carried out in the same procedure.

Molecular Compound of N-*Hydroxysuccinimide with Triethylamine.* To a solution of *N*-hydroxysuccinimide (1.16 g) in 10 m*l* of tetrahydrofuran, was added 2.02 g of triethylamine. The precipitate appeared instantly, and the reaction mixture was kept at room temperature for 30 min. The precipitate was filtered and washed with tetrahydrofuran, yield 1.97 g, mp 112—113°C. From elemental analyses, the product was found to consist of 2 moles hydroxysuccinimide and 1 mole triethylamine.

Found: C, 50.99; H, 7.62; N, 12.70%. Calcd for $2C_4H_5NO_3C_6H_{15}N(C_{14}H_{25}N_2O_3)$: C, 50.74; H, 7.61; N, 12.68%.

The Stereochemistry of Nucleophilic Addition. I. The Reformatsky Reaction of 2-Methyl- and 2-Ethylcyclohexanones[1]

Takashi MATSUMOTO and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received September 24, 1970)

The Reformatsky reaction of 2-methyl- or 2-ethylcyclohexanone with ethyl bromoacetate gave a mixture of epimeric alcohols, which were then separated by column chromatography in an 80 : 20 ratio. The configurations of these major and minor products were identified as ethyl *trans*- and ethyl *cis*-2-methyl (or ethyl)-1-hydroxycyclohexylacetate respectively on the basis of their IR analyses, their chromatographic behavior, and correlation with the products of the Grignard reaction, the stereochemistry of which is well known. The NMR spectra of these epimeric alcohols are also discussed, and it is suggested that the chemical shifts of the methylene protons alpha to the ethoxycarbonyl group and of the proton of the hydroxyl group gives useful data for their stereochemical assignments. From these results, it is evident that the Reformatsky and the Grignard reactions proceed in a similar fashion; that is, the entering group predominantly approaches to the carbonyl group from the equatorial side. The stereoselectivity of the Reformatsky reaction is slightly less than that of the Grignard reaction.

The Reformatsky reaction[2] has been utilized for over eighty years as a convenient method for preparing β-hydroxy-carboxylic esters, which in turn can be converted to the corresponding unsaturated esters and acids. However, the stereochemistry of this reaction with cyclic ketones containing a substituent in the position alpha to the carbonyl group has been little studied.

Recently Epstein and Sonntag[3] reported that the condensation of 2-chlorocyclohexanone with methyl bromoacetate gives only one diastereomer, methyl *trans*-2-chloro-1-hydroxycyclohexylacetate. More recently, the Reformatsky reactions of monocyclic terpenes ((−)-menthone, (+)-isomenthone, and (−)-carvomenthone) with ethyl bromoacetate have also been reported by Perry and Maroni-Barnaud;[4] the stereochemistry of the major products in these reactions assigned the *trans*-configuration of the ester group to the alpha-substituted alkyl group.

During the course of other synthetic experiments in this laboratory, we also studied the stereochemistry of the Reformatsky reaction with 2-methyl- and 2-ethylcyclohexanones; the present paper will describe our results.

The condensation of 2-methylcyclohexanone (I) with ethyl bromoacetate is known to yield ethyl 2-methyl-1-hydroxycyclohexylacetate (II),[5] but the composition of the mixture of the isomers formed was not examined. In the present study, this reaction was reinvestigated in more detail; the results are summarized in Table 1, which lists the average values obtained from two or more determinations. It can be seen from Table 1 that a good yield (84%) of the β-hydroxy ester was obtained by the use of an excess of the bromoester and zinc in a benzene solution, while when tetrahydrofuran was used as the solvent in place of benzene, the yield was somewhat low (63%). The distilled product was successfully separated by means of column chromatography on sillica gel to give two epimeric oily esters (IIa and IIb) in an approximately 80: 20 ratio. Each of these esters(IIa and IIb) was converted to the corresponding crystalline acid (IIIa, mp 78—79°C and IIIb, mp 80—81°C) by alkaline hydrolysis. The reported melting point for 2-methyl-1-hydroxycyclohexylacetic acid is 67—68°C;[5] this substance is apparently a mixture of the epimers (IIIa and IIIb), thus accounting for the lower melting point. The acids (IIIa and IIIb) were further characterized as their *p*-bromophenacyl esters (IVa, mp 86—88°C and IVb, mp 91.5—92.5°C, respectively). The configurations of IIa and IIb are assigned on the basis of the following evidence. The reduction of IIa and IIb with $LiAlH_4$ in ether afforded, respectively, the corresponding diols (Va, mp 67—68°C and Vb, liquid). Subsequently, Va and Vb were subjected to tosylation with *p*-toluenesulfonyl chloride in pyridine, followed by the reduction of the resulting tosylates (VIa and VIb) with $LiAlH_4$ in tetrahydrofuran; this gave the epimeric 2-methyl-1-ethylcyclohexanols, VIIa and VIIb, respectively.

Since it is well known[6-8] that the Grignard reaction of 2-alkylcyclohexanones with simple alkylmagnesium halides yields *cis*-2-alkylcyclohexanol derivatives possessing an axial hydroxyl group as the major product, the preparation of the epimeric 2-methyl-1-ethylcyclohexanols by the Grignard reaction was attempted in order to make possible direct comparisons with the above alcohols (VIIa and VIIb). Although the Grignard reaction of I with ethylmagnesium iodide has already been reported by Cook and Laurence[9] the composition of the epimeric alcohols was not examined. Therefore, the separation of the epimers was carried out by means

1) Although the formulas depicted represent only one enantiomer, they are taken to indicate a racemate.

of column chromatography; two epimeric alcohols were thus successfully separated in a 90: 10 ratio. The major and minor alcohols of this reaction were shown to be identical with VIIa and VIIb respectively by comparisons of their IR and NMR spectra.

Similarly, 2-ethylcyclohexanone (VIII) was also condensed with ethyl bromoacetate to give an 83% yield of epimeric β-hydroxy-carboxylic esters, which were then separated into IXa (liquid) and IXb (mp 50.5—51.5°C) in an 80:20 ratio. The reduction of the major (IXa) and minor (IXb) esters with $LiAlH_4$ gave the corresponding diols (Xa, mp 93.5—94.5°C and Xb, mp 73—73.5°C), which were then further converted to the corresponding 1,2-diethylcyclohexanols (XIIa and XIIb) *via* tosylates (XIa and XIb). The Grignard reaction[10] of VIII with ethylmagnesium bromide gave epimeric alcohols in a 93:7 ratio; these major and minor alcohols were also shown to be identical with XIIa and XIIb respectively.

The IR spectra of IIa, IIb, IXa, and IXb are summarized in Table 2, in which the hydroxyl absorption bands have been assigned by comparing their spectra with those of the corresponding acetates (XIIIa, XIIIb, XIVa, and XIVb). The IR spectra of IIa and IXa showed bands at 988 cm^{-1} and at 986 cm^{-1} respectively; they suggest the presence of the axial hydroxyl groups, while in the cases of IIb and IXb their spectra (IIb: 1050 cm^{-1} and IXb: 1056 cm^{-1}) suggest the presence of the equatorial hydroxyl groups. These stereochemical assignments of the hydroxyl groups were further supported by the chromatographic behavior of mixtures of isomeric alcohols. Winstein and Holness[11] have stated that isomers with equatorial hydroxyl groups can be expected to be adsorbed more strongly on chromatography and, therefore, to be more difficult to elute than the isomers with the more hindered axial hydroxyls. In the present study, the isomers (IIa, VIIa, IXa and XIIa) assigned to the axial hydroxyl group were eluted first in each instance.

Table 2. The IR spectra of IIa, IIb, IXa and IXb in $CHCl_3$ (cm^{-1})

	IIa	IXa	IIb	IXb

the major products (IIa and IXa) are observed as well-defined AB-type quartets in $CDCl_3$, while completely-collapsed singlets result in pyridine-d_5. On the other hand, the methylene protons of the minor products (IIb and IXb) in $CDCl_3$ are observed as a singlet and as a slightly separated quartet, respectively, which is also collapsed to a singlet in pyridine-d_5. All of the acetates show well-defined quartets arising from methylene protons alpha to the ethoxycarbonyl group in $CDCl_3$. Tables 3 and 4 report the Δ values[12] for the methyl and methylene protons present in the ethyl cyclohexylacetate derivatives obtained in this study. It is evident from the data presented in these tables that definite relationships exist between the chemical-shift values induced in pyridine (Δ values) and the location and orientation of solute protons. The methyl protons of the ester group experience shielding effects of 0.12—0.15 ppm in pyridine relative to chloroform, while those of methylene protons of the ester group are small, 0.03—0.06 ppm. Since the differences in these values due to the ester group of epimeric alcohols are very small, these shifts induced in pyridine have no value for conformational analysis. However, in IIa and IXa the Δ values observed for methylene protons alpha to the ethoxycarbonyl group are large (Δ= −0.22 and −0.24 ppm respectively), while relatively small values are observed in IIb (Δ= −0.10 ppm) and IXb (Δ= −0.10 ppm). Therefore, these pyridine-induced shifts of the methylene protons of $-CH_2CO_2R$ group seem to be useful for the conformational analysis. Furthermore, the $\delta_A-\delta_B$ values[13] which are summarized in Table 7 are also useful for this purpose, for the compounds (IIa, IXa, XIIIa, and XIVa) possessing an equatorial $-CH_2CO_2R$ group have larger values than the compounds (IIb, IXb, XIIIb, and XIVb) possessing an axial $-CH_2CO_2R$ group. The chemical shift of the hydroxyl proton also depends on its conformation. As may be seen in the IIa (3.07 ppm) and IXa (*ca.* 2.9 ppm) compounds, the axial hydroxyl protons show signals in a higher magnetic field than do those of equatorial hydroxyl protons (IIb: 3.64 ppm and IXb: 3.65 ppm).

TABLE 7. THE $\delta_A-\delta_B$ VALUES OF METHYLENE PROTONS OF CH_2CO_2R GROUP IN $CDCl_3$

$-CH_2CO_2R$ (Hz)			
equatorial		axial	
IIa	23	IIb	0
IXa	26	IXb	6

XIVa	28	XIVb	14

From the above correlation between the Reformatsky and the Grignard reaction products, the results of the spectral analysis, and the chromatographic behavior, the configurations of the entering ester group relative to the alkyl group at the 2 position of the major products (IIa and IXa) in the Reformatsky reaction may be identified as *trans* configurations, while those of the minor products (IIb and IXb) are *cis*. Therefore, it is evident that the Reformatsky and the Grignard reaction with 2-alkylcyclohexanones proceed in a similar fashion; that is, the entering group predominantly approaches to the carbonyl group from the equatorial side, which derives to the axial hydroxyl compound.

The stereoselectivity of the Reformatsky reaction observed is slightly less than that of the Grignard reaction.

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. Their chemical shifts are presented in terms of δ values; s: singlet; bs: broad singlet; d: doublet; t: triplet; q: quartet. The column chromatography was performed on Merck silica gel (0.08 mm).

Ethyl 2-Methyl-1-hydroxycyclohexylacetate (II). A solution of ethyl bromoacetate (12.5 g: 0.075 mol) in dry benzene (12.0 m*l*) was added, drop by drop at 80°C and over a period of 25 min, to a thoroughly stirred mixture of 2-methylcyclohexanone (5.6 g: 0.050 mol), purified zinc powder[14] (4.9 g: 0.075 mol), and dry benzene (6.0 m*l*). When the exothermic reaction started, the heating bath was removed, if neccessary; the temperature was kept at 80—87°C during the addition. After the addition was complete, the mixture was refluxed for 30 min, cooled, decomposed with dilute hydrochloric

12) Δ ppm=δ in $CDCl_3$−δ in pyridine-d_5.

13) Calculated from the chemical shifts (AB-type quartets) of the methylene protons alpha to the ethoxycarbonyl group.

14) R. L. Shriner, "Organic Reactions," Vol. 1, Wiley, New York (1942), p. 16.

acid (5%: 60 ml), and then extracted with ether. The ether extract was successively washed with water, a sodium hydrogencarbonate solution, and water, and then dried over sodium sulfate. The solvent was evaporated and the residue was distilled to give II as an oil; bp 119—122°C/10 mmHg; yield 8.4 g (84%). The other runs of this condensation are summarized in Table 1.

Separation of II into IIa and IIb. A 4.2×30 cm column was prepared from silica gel (200 g) suspended in purified benzene. To this was added the above sample (II: 2.520 g), after which elution with benzene containing 3% ether was carried out. Fractions 1—8 (800 ml) were discarded. Fractions 9—19 (550 ml) were evaporated to give IIa (2.035 g) as an oil.

Found: C, 65.87; H, 10.11%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Fraction 20 (50 ml) gave nothing. Fractions 21—36 (800 ml) were evaporated to give IIb (0.458 g) as an oil.

Found: C, 66.21; H, 9.82%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Hydrolysis of IIa and IIb. *a*) A mixture of IIa (1.00 g), aqueous sodium hydroxide (10%: 4.0 ml), and methanol (10 ml) was refluxed for 1.5 hr. After a usual work-up, the crude product was recrystallized from petroleum benzin containing a small amount of ether to give *trans*-2-methyl-1-hydroxycyclohexylacetic acid (IIIa) as colorless crystals; mp 78—79°C; yield 780 mg. A mixed-melting-point determination with IIIb (mp 80—81°C) showed 68—71°C. NMR in $CDCl_3$: 0.94 (3H, bs, $-C\underline{H}_3$), 2.36 and 2.77 (2H, each d and J=15 Hz, $-C\underline{H}_2CO_2H$), 6.80 (2H, bs, $-O\underline{H}$ and $-CO_2\underline{H}$). NMR in pyridine-d_5: 1.14 (3H, d, J=5.0 Hz, $-C\underline{H}_3$), 2.78 and 2.91 (2H, each d and J=14 Hz, $-C\underline{H}_2CO_2H$).

Found: C, 62.73; H, 9.55%. Calcd for $C_9\underline{H}_{16}O_3$: C, 62.76; H, 9.36%.

The *p*-bromophenacyl ester (IVa) was prepared from IIIa by a usual method. The crude product was recrystallized from aqueous methanol to give colorless crystals, mp 86—88°C, which gave a positive Beilstein halogen test.

Found: C, 55.12; H, 5.79%. Calcd for $C_{17}H_{21}O_4Br$: C, 55.29; H, 5.73%.

b) A mixture of aqueous sodium hydroxide (10%: 2.0 ml) and IIb (500 mg) in methanol (5.0 ml) was treated as has been described for IIIa; *cis*-2-methyl-1-hydroxycyclohexylacetic acid (IIIb) was thus obtained as colorless crystals; mp 80—81°C; yield 300 mg. NMR in $CDCl_3$: 0.94 (3H, d, J=7.0 Hz, $-C\underline{H}_3$), 2.53 (2H, s, $-C\underline{H}_2CO_2H$), 7.08 (2H, bs, $-O\underline{H}$ and $-CO_2\underline{H}$). NMR in pyridine-d_5: 1.05 (3H, d, J=6.5 Hz, $-C\underline{H}_3$), 2.72 (2H, s, $-C\underline{H}_2CO_2H$).

Found: C, 62.68; H, 9.51%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The *p*-bromophenacyl ester (IVb), colorless crystals, mp 91.5—92.5°C, was prepared from IIIb by a usual method.

Found: C, 54.97; H, 5.84%. Calcd for $C_{17}H_{21}O_4Br$: C, 55.29; H, 5.73%.

Reduction of IIa and IIb with $LiAlH_4$. *a*) A solution of IIa (1.760 g) in dry ether (15 ml) was added, drop by drop and over a period of 50 min, to a suspension of $LiAlH_4$ (650 mg) in dry ether (15 ml) at room temperature, and then the mixture was gently refluxed for 2 hr. After a usual work-up, the crude product was recrystallized from petroleum benzin to give Va as colorless crystals; mp 67—68°C; yield 1.140 g (82%).

Found: C, 68.46; H, 11.63%. Calcd for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

b) The IIb ester (2.770 g) was reduced with $LiAlH_4$ (1.060 g) by a method similar to that used for Va. The diol, Vb, was thus obtained as an oil (2.060 g) which showed no carbonyl absorption band in its IR spectrum and which could be used for the next step without purification. For analysis it was purified by means of column chromatography on silica gel.

Found: C, 68.10; H, 11.68%. Calcd for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

cis- *and* trans-*2-Methyl-1-ethylcyclohexanols (VIIa and VIIb).* *a*) *From Va and Vb*: A mixture of Va (1.100 g) and *p*-toluenesulfonyl chloride (1.330 g) in dry pyridine (10 ml) was allowed to stand at room temperature for 30 hr and then poured into a mixture of ice and dilute hydrochloric acid (10%: 50 ml). The mixture was extracted with ether, and the extract was washed with water, dried over sodium sulfate, and then evaporated under a vacuum to give crude VIa as a yellow oil (1.284 g).

A solution of the above crude tosylate (VIa) in dry tetrahydrofuran (10 ml) was added, drop by drop and over a period of 10 min at room temperature, to a suspension of $LiAlH_4$ (500 mg) in dry tetrahydrofuran (10 ml); there after then the mixture was refluxed for 3 hr. After a usual work-up, the crude product was purified by means of chromatography on silica gel (70 g), after which elution with benzene containing 3% ether was carried out. Fractions 1—7 (350 ml) were discarded. Fractions 8—14 (175 ml) were evaporated to give VIIa (293 mg) as a colorless oil.

Found: C, 75.74; H, 12.71%. Calcd for $C_9H_{18}O$: C, 75.99; H, 12.76%.

When elution was continued with benzene containing 50% ether, the starting Va was recovered as colorless crystals (219 mg: mp 67—68°C).

By a method similar to that used for VIIa, the Vb diol (2.060 g) was tosylated with *p*-toluenesulfonyl chloride and then reduced with $LiAlH_4$ to give crude VIIb (1.359 g). When this was purified by means of chromatography on silica gel (150 g), pure VIIb (306 mg) was obtained as a colorless oil.

Found: C, 75.80; H, 12.68%. Calcd for $C_9H_{18}O$: C, 75.99; H, 12.76%.

The starting Vb (451 mg) was also recovered.

b) *From the Grignard Reaction*: 2-Methyl-1-ethylcyclohexanol (VII: bp 70—74°C/11 mmHg) was prepared in a 75% yield from I and ethylmagnesium iodide by the method of Cook and Laurence.[9] The product (2.078 g) was chromatographed on silica gel (200 g), after which elution with benzene containing 3% ether was carried out. The first (1.220 g) and second (0.115 g) fractions thus obtained were shown to be identical with the above VIIa and VIIb respectively by a spectral comparison.

Ethyl trans- *and* cis-*2-Ethyl-1-hydroxycyclohexylacetates (IXa and IXb).* A mixture of 2-ethylcyclohexanone (VIII: 5.00 g), purified zinc powder (3.90 g), and dry benzene (5.0 ml) was treated with a solution of ethyl bromoacetate (10.0 g) in dry benzene (10 ml) by a method similar to that used for II. The crude product was distilled under a vacuum to give a colorless oil (7.10 g: bp 137—141°C/14 mmHg) in an 83% yield.

The above ester (2.190 g) was chromatographed on silica gel (200 g), after which elution with benzene containing 3% ether was carried out. Fractions 1—18 (900 ml) were discarded. Fractions 19—25 (350 ml) were evaporated to give *trans*-2-ethyl-1-hydroxycyclohexylacetate (IXa: 1.687 g) as a colorless oil.

Found: C, 67.06; H, 10.43%. Calcd for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35%.

Fraction 26 (50 ml) was evaporated to give a colorless oil (0.105 g) which was shown to be a mixture (*ca.* 1:1) of IXa and IXb by IR and NMR analyses. Fractions 27—36 (500 ml) were evaporated to give *cis*-2-ethyl-1-hydroxycy-

clohexylacetate (IXb: 0.386 g) as colorless crystals; mp 50.5—51.5°C.

Found: C, 67.05; H, 10.42%. Calcd for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35%.

Reduction of IXa and IXb with $LiAlH_4$. *a*) The IXa ester (1.280 g) was reduced with $LiAlH_4$ (0.450 g) by a method similar to that used for Va. The product was recrystallized from petroleum benzin containing a small amount of ether to give Xa as colorless crystals; mp 93.5—94.5°C; yield, 0.850 g.

Found: C, 69.68; H, 11.83%. Calcd for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

b) The IXb ester (0.720 g) was also reduced with $LiAlH_4$ to give Xb as colorless crystals; mp 73—73.5°C; yield, 0.400 g.

Found: C, 69.66; H, 11.83%. Calcd for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

cis- *and* trans-*1,2-Diethylcyclohexanols (XIIa and XIIb).* *a*) *From Xa and Xb*: By a method similar to that used for VIIa, the Xa diol (350 mg) was tosylated and then reduced to give crude XIIa (280 mg), which was subsequently chromatographed on silica gel (30 g) to give pure XIIa (161 mg) as a colorless oil.

Found: C, 76.69; H, 12.93%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

XIIb was also obtained from Xb by a method similar to that used for XIIa.

Found: C, 76.82; H, 12.88%. Calcd for $C_{10}H_{20}O$: C, 76.86; H, 12.90%.

b) *From the Grignard Reaction*: 1,2-Diethylcyclohexanol was prepared by the method of Dice *et al.*[10] This (2.300 g) was chromatographed on silica gel (200 g), after which elution with benzene containing 3% ether was carried out. The first (1.753 g) and second (0.123 g) fractions obtained were shown to be identical with XIIa and XIIb respectively by a spectral comparison.

The Acetates (XIIIa, XIIIb, XIVa and XIVb). *a*) A mixture of IIa (930 mg), *p*-toluenesulfonic acid monohydrate (50 mg), isopropenyl acetate (2.0 m*l*), and dry toluene (10 m*l*) was refluxed for 3 hr; then the solvent was slowly distilled off over a period of 60 min to *ca.* 5 m*l*. To the cold solution solid sodium hydrogencarbonate (200 mg) was added, and, after stirring for 10 min, the mixture was filtered. The filtrate was evaporated under a vacuum, and the residue was purified by chromatography to give XIIIa as a colorless oil; yield, 1.105 g.

Found: C, 64.58; H, 9.26%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

b) The other acetates (XIIIb, XIVa, and XIVb) were also prepared in an almost quantitative yield by a method similar to that used for XIIIa.

XIIIb, Found: C, 64.27; H, 9.21%. Calcd for $C_{13}H_{22}O_4$: C, 64.44; H, 9.15%.

XIVa, Found: C, 65.61; H, 9.56%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

XIVb, Found: C, 65.53; H, 9.51%. Calcd for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1095—1101 (1971)

The Catalytic Dehydrogenation, Dehydroxylation, and Dehydroxymethylation of Benzyl Alcohol. II. The Effects of Sodium Compounds as Additives

Masayoshi ISHIGE,* Koji SAKAI, Masatoshi KAWAI, and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 29, 1970)

The reaction of benzyl alcohol has been examined over stabilized nickel (S-Ni) catalysts which have been modified by treating the catalyst surface with solutions of sodium compounds; this has been done in order to obtain some information about the relation between the behavior of the molecule adsorbed on the metal catalyst and the chemical nature of the catalyst surface. On the basis of the f_H, f_{CH_3}, and f_{CHO} values, which were defined as representing the catalytic activity for the formation of benzene, toluene, and benzaldehyde respectively, the variation in the activity for each modified S-Ni was evaluated. The general aspects may be summarized as follows: (1) The reaction is generally retarded with an increase in the amount of a sodium compound which is adsorbed on the catalyst during the modification process. (2) When the modification is of a lower grade, the effect of additives on the catalytic activity represented by f values is in the following order: $NaNO_3 < NaOH < Na_2S_2O_3 < NaI < NaBr < NaCl$. (3) A proper amount of NaCl on the catalyst promotes the reaction. The increase in S_H and S_{CH_3} values, which were defined as representing the selectivity factors for the formation of benzene and toluene toward that of benzaldehyde, is roughly associated with the increase in the corresponding f values.

As was reported in the previous paper,[1] the concurrent dehydrogenation, dehydroxylation, and dehydroxymethylation of benzyl alcohol was observed when it was heated at 150—170°C in the presence of various kinds of metal catalysts. The proportions of benzaldehyde, toluene, and benzene in the reaction product were found to be greatly affected by the chemical nature of the catalysts used, and it was assumed that the reaction proceeded through a metal benzyl complex, which was considered to be an adsorbed transition complex on the catalysts.

In order to obtain more detailed information regard-

0.2487	0.2620	1.047	10.7

ing the relationship between the behavior of the adsorbed molecule and the chemical nature of the catalysts, an extensive study of the catalytic reaction of benzyl alcohol was carried out in the presence of various kinds of modified nickel catalysts; these catalysts had been prepared by treating their surfaces with various inorganic sodium compounds.

Several observations have been reported on the variation in the catalytic activity and selectivity of the catalysts modified by a variety of additives on the surface of the catalyst: for example, there is the promoting or poisoning effect of a small amount of platinic chloride or amines in hydrogenation on Raney nickel,[2] and that of the pyridine and thiophene which were added to Raney nickel in the reductive dehydroxymethylation of alcohols.[3] There is also the interesting instance of an optically-active alcohol synthesized from methyl acetoacetate by hydrogenation in the presence of modified Raney nickel catalysts; the surfaces of these catalysts had been treated with optically-active carboxylic acids or amino acids.[4] These results suggest that a small amount of an additive on the catalyst surface interacts both with the catalyst metal and with the reactant, thereby bringing about not only a change in the conditions of the catalyst surface, but also a change in the behavior of the reactant molecule on the catalyst. Pines and his collaborators proposed that nickel[3,5] and alumina[6] catalysts possess inherent acid properties, and that the poisoning of active contact sites of the catalysts by sulfur-containing compounds causes an accentuation of the acid properties of the catalysts. However, it is necessary to examine other operative factors of the catalysis in addition to the dual-function mechanism of the reforming catalyst,[7] because the stereospecific property or the reaction selectivity in the catalysis has not yet been sufficiently elucidated.

Results

The Modification of a Stabilized Nickel Catalyst. It has been found that nickel catalysts, such as Raney nickel, Urushibara nickel A, and Stabilized nickel, are useful for the dehydrogenation of benzyl alcohol.[1] Stabilized nickel (abbreviated as S-Ni)[8] was employed in all the following experiments, because it is the most stable in the air and the most convenient of the three catalysts cited. Various kinds of modified S-Ni were prepared by treating S-Ni with sodium hydroxide or various sodium salts. S-Ni was kept soaking for 24 hr in an aqueous solution of the respective sodium compound. Then, the catalyst was separated from the solution and dried at below 80°C. Since the degree of the modification of the catalyst is dependent on the initial concentration of the solution,[9] modified nickels of the

same kind but of a different degree of modification were expected to be obtained when solutions of various concentrations were used in treating the catalyst.

The Nature of Stabilized Nickel Modified by Sodium Hydroxide. (*a*) *The Measurement of the Amount of NaOH Adsorbed on S-Ni*: The amount of sodium hydroxide on the catalyst surface adsorbed from solutions of various concentrations was measured by the following method. A definite amount of S-Ni was separately soaked in aqueous NaOH solutions of various concentrations and then allowed to stand at room temperature for 24 hr. Then, the diminution in the concentration of each solution was measured by titration with a standard solution of hydrochloric acid. The relation of the amounts of NaOH adsorbed per gram of nickel to the initial concentration of the NaOH solution is shown in Table 1 and Fig. 1. Figure 1 shows an approximately linear relationship between these quantities.

(*b*) *The Measurement of the Activity of the Modified S-Ni to Decompose H_2O_2*: Hydrogen peroxide is readily decomposed in first order in the presence of S-Ni.[10] Thus, it is expected that the degree of modification of the modified S-Ni may be represented in terms of the rate constant of the decomposition of H_2O_2. The rate constant of this reaction in the presence of each modified S-Ni cited in the preceding section is evaluated by means of the volumetric measurement of the oxygen generated at 20.03°C. The experimental results are shown in Table 1 and Fig. 2. By referring to the preceding experiment, it was found that the rate constant does not always increase with an increase in the amount of OH^- adsorbed on the surface of the catalyst. However, the intercept of a straight line through the three points in the middle range of the graph provides a value zero for the rate constant at the zero concentration. The slope of this line may represent the relation between the catalytic activity for the decomposition of H_2O_2 and the amount of OH^- on the surface of the catalyst. The deviation of the plots at both ends of the graph clearly suggests the complicated catalytic behavior of each modified catalyst.

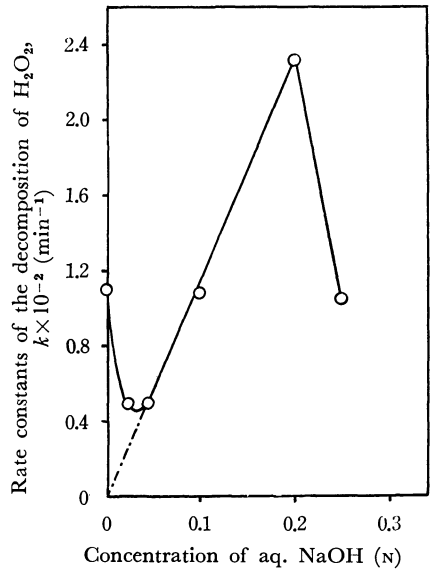

Fig. 2. Relation of the rate constant of the decomposition of H_2O_2 *vs.* concentration of aq. NaOH.

(*c*) *The Relative Catalytic Activities of Modified S-Ni for the Dehydrogenation of Benzyl Alcohol*: Benzyl alcohol was dehydrogenated to benzaldehyde by refluxing at 151—156°C for 24 hr in the presence of each catalyst. After 24 hrs' refluxing, the yield of benzaldehyde was estimated by gas chromatography. The yields of benzaldehyde are shown in Table 1 and Fig. 3. In the region of relatively little modification, the reaction was found to be retarded by an increase in the amount of OH^- on the catalyst. However, the yield of benzaldehyde remained almost constant in the presence of the highly-modified catalysts.

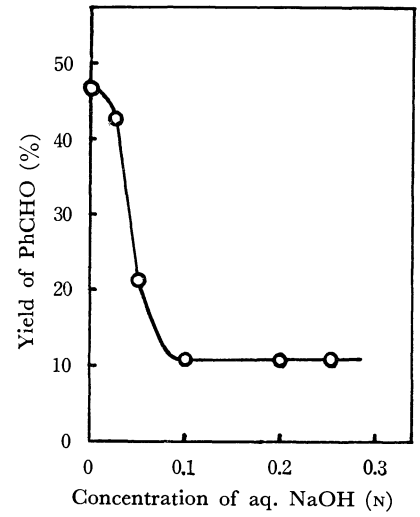

Fig. 3. Relation of relative ratio of the dehydrogenation of benzyl alcohol *vs.* concentration of aq. NaOH.

The Effects of Various Additives on the Catalytic Reaction of Benzyl Alcohol. Different modified nickel catalysts were prepared from S-Ni by treating it with various sodium salts, such as NaCl, NaBr, NaI, $Na_2S_2O_3$, and $NaNO_3$. The same procedure as was used in the preparation of the NaOH-modified S-Ni was employed; variation in the degree of modification was also attained by the use of different concentrations of the salt solution.

The catalytic reaction of benzyl alcohol in the presence of these modified S-Ni catalysts was examined from the point of view of the variation in the catalytic activity and the selectivity of these catalysts. In each of the following experiments, benzyl alcohol was heated in a sealed tube at 154.5—155.0°C in the presence of a modified S-Ni. After the mixture was kept on heat for 24 hr, the sealed tube was cooled to 0°C; the composition of the reaction mixture was then evaluated by gas chromatography. The results are summarized in Table 2. Since it was assumed that the reaction proceeds competitively through an adsorbed transition complex on the

10) It is well-known that the catalytic decomposition of H_2O_2 is often utilized to estimate the excess oxygen on the metal oxide surface, which is an important factor of the activity of the oxide catalysts: *Cf.*, S. E. Voltzi and S. E. Weller, *J. Amer. Chem. Soc.*, **76**, 1586 (1954); Y. Matsunaga, This Bulletin, **30**, 984 (1957); I. Mazin and T. Braun, *J. Phys. Chem.*, **24**, 532 (1963).

a) Rate constant of the conversion of benzyl alcohol.

catalyst,[1] the activity of each catalyst for the formation of benzene, toluene, and benzaldehyde was expressed in terms of the f_H, f_{CH_3}, and f_{CHO} factors respectively; these factors are proportional to the approximate values of the rate constants for the formation of each product in the early period of the reaction (within the period in which 30% of the alcohol reacted).[11] The f_H, f_{CH_3}, and f_{CHO} were defined as follows:

$$\left.\begin{aligned} f_H &= 100\ k_{alc}\ (\text{mol\% of PhH}) \\ f_{CH_3} &= 100\ k_{alc}\ (\text{mol\% of PhCH}_3) \\ f_{CHO} &= 100\ k_{alc}\ (\text{mol\% of PhCHO}) \end{aligned}\right\} \quad (1)$$

where k_{alc} is the first-order rate constant in the disappearance of the alcohol.

The selectivity factors for the formation of benzene and toluene toward that of benzaldehyde were represented by S_H and S_{CH_3}, which were defined as follows:

$$\left.\begin{aligned} S_H &= 100 \log (f_H/f_{CHO}) \\ &= 100 \log (\text{mol\% of PhH/mol\% of PhCHO}) \\ S_{CH_3} &= 100 \log (f_{CH_3}/f_{CHO}) \\ &= 100 \log (\text{mol\% of PhCH}_3\text{/mol\% of PhCHO}) \end{aligned}\right\} \quad (2)$$

The values of the f and S factors are shown in Table 2.[12] Figures 4 and 5 illustrate the relations of these values *vs.* the approximate degrees of the modification of the catalyst, which were represented by the initial concentrations of the solution used for modifying the catalyst, on the assumption that the degree of modification and the concentration of the sulution are proportional in the region of low concentration.

The results shown in Table 2 indicate that the catalytic activity and selectivity of the catalyst are affected by the nature of the adsorbate on the catalyst surface. The general aspect may be summarized as follows: (1) an increase in the amount of the adsorbate generally brings about a retardation of the reaction; (2) a proper amount of NaCl on the catalyst surface promotes the reaction; (3) variations in the kind and amount of the adsorbate have particular effects on the production of toluene, whereas they have a lesser effect on the formation of benzene; (4) the effect of additives on the catalyst activity, which is expressed by the values f_H, f_{CH_3}, and f_{CHO}, is generally in this order for the S-Ni

11) With the further progress of the reaction, the aspect of the reaction becomes complicated and the simple expression adopted here is no more valid.

12) A positive value of S_H and S_{CH_3} indicates that the formation of benzene or toluene is superior to that of benzaldehyde, whereas a negative value means the less formation of benzene or toluene than that of benzaldehyde.

modified to a lesser degree: $NaNO_3$ <NaOH< $Na_2S_2O_3$ <NaI<NaBr<NaCl; (5) the increase in f values is roughly associated with the increase in S values; (6) with regard to the selectivity change for the formation of

toluene when the amount of the adsorbate is increased, the sodium compounds as additives may be classified into two groups: one with decreasing S_{CH_3} values, and the other with increasing S_{CH_3} values. The compounds with larger f_{CH_3} values generally belong to the former group, whereas those with smaller f_{CH_3} values belong to the latter. On the other hand, the effects of various additives on the selectivity for the formation of benzene can not be estimated so clearly as for the formation of toluene. However, an appreciable change in the S_H value is observed with an increase in the amount of the adsorbate in the cases of additives with smaller f_H values.

Discussion

The increasing coverage of the catalyst surface by additive substances might necessarily lead to a decrease in the catalytic activity due to the hindrance of the approach of the benzyl alcohol molecule to the catalyst surface. The data in Table 2 are generally consistent with this consideration, but some of them deviate. Especially, the change in selectivity caused by the additives on the catalyst cannot be simply understood by the coverage, though selectivity does not undergo so great a change as activity as a result of the presence of the additives on the catalyst. It is, however, noteworthy that the observed S values are somewhat influenced by the kinds and the amounts of the additives, and that the

(b)

Fig. 6. The plots of $\log f$ *vs.* S for benzene and toluene. (The notations are the some as in Fig. 4.)

influence is related to the f value under the given conditions. This fact suggests the possibility that the change in the catalytic activity for the formation of each product might bring about a change in selectivity for the corresponding product. Therefore, the correlation between f and S values was examined. As is shown in Fig. 6, the plots of $\log f$ *versus* S in each graph were distributed near a straight line, which can be represented by the following equation:

for the formation of benzene,

$$\log f_H = 0.0137 S_H + 1.31$$

for the formation of toluene,

$$\log f_{CH_3} = 0.0147 S_{CH_3} + 1.23 \qquad (3)$$

However, no such a linerar relation was observed when the reaction proceeded either too fast or too slow.

It is assumed that the first step in the reaction is the dehydrogenation of benzyl alcohol to benzaldehyde through an adsorbed transition complex on the catalyst, and that the succeeding dehydroxylation and dehydroxymethylation utilize the hydrogen generated by the dehydrogenation. If each product of the reaction is competitively produced from the same transition intermediate at an early stage of the reaction, it is understandable that the selectivity is correlative with the activity of the catalyst. The deviation from the linear relation between $\log f$ and S by the faster reaction can be explained as follows: the faster approach to the pseudo-equilibrium between benzyl alcohol and benzaldehyde brings about a feedback of benzaldehyde to

benzyl alcohol, resulting in an increase in the apparent S_H and S_{CH_3} values.

A small amount of sodium chloride was found to promote the reaction. The increase in the activity of the catalyst as a result of the presence of halide ions is found to be in an order consistent with the basicity or inductive effect of halogens.[13] This fact suggests that halide anions on the catalyst surface induce electron transfer around them, thus accentuating the acid property of the catalyst surface.[3,5,14] However, the possibility cannot be excluded that, as has been observed in the catalysts modified by some potassium halides,[15] different amounts of the anion adsorbed from solutions of different halides of the same concentration affect the catalytic activity.[16] Nevertheless, the unique promotion by a proper amount of NaCl as additive indicates that the chloride ion might play an important role in the catalytic reaction.[17] It implies that the change in catalytic activity is mainly dependent on the intrinsic property of the halide ion, rather than being a mere coverage-change.

In the preceding paper, we proposed the intervention of a metal benzyl complex in the reaction. If this is the case, the anions on the catalyst surface might participate as ligands in the complex, thus exerting a certain influence on the activity of the catalyst.

Experimental

Material. Benzyl Alcohol: Benzyl alcohol was purified according to the procedure described previously.[1] The purity was found to be over 99% by gas chromatography.

Catalyst: A commercial stabilized nickel (S 10) (supplied by Nikko Shokai Co., Ltd.), containing 50% of kieselguhr, was used as the catalyst.

Preparation of Modified S-Ni. (i) Sodium hydroxide (10.3 g) was dissolved in distilled water, and then diluted to 1 *l* to make a 0.2487N NaOH solution. The concentration of the solution was determined by titration with a standard solution of oxalic acid. Several portions of the NaOH solution were taken out and separately diluted to prepare 0.1966, 0.09929, 0.04824, and 0.02352N solutions. Every 3.00-g portion of the S-Ni catalyst was soaked in a 30.0-m*l* portion of the NaOH solution, and then left to stand for 24 hr at room temperature. After the adsorption equilibrium had been attained, a 10.0-m*l* portion of the solution was taken out from the upper layer and titrated with 0.1084N hydrochloric acid. The amount of NaOH adsorbed was calculated from the difference in the concentrations.

(ii) Aqueous solutions of NaCl, NaBr, NaI, $Na_2S_2O_3 \cdot 5H_2O$, and $NaNO_3$ were prepared, the concentrations of the solution being regulated to 0.02, 0.04, 0.08, and 0.16N respectively. In an Erlenmeyer flask we then placed a 30-m*l* portion of a solution and a 3-g portion of S-Ni; the mixture was left to stand under a cork-stopper for 24 hr at room temperature. Then, the aqueous layer was removed by decantation, and the catalyst was dried for 12 hr at below 80°C. The catalysts modified by NaOH and $Na_2S_2O_3$ were dried in a desiccator for more than 24 hr at room temperature.

Decomposition of H_2O_2 by Modified S-Ni. Commercial H_2O_2 (30%) was diluted with water to about fifty times the initial volume. In a 30-m*l* flask joined to a gas burette we then placed 20 m*l* of the H_2O_2 solution; the temperature was regulated to maintain 20.03°C. Then, a 0.1210-g portion of modified S-Ni was quickly added; the oxygen generated was measured volumetrically after a proper interval.

Reaction of Benzyl Alcohol in the Presence of Modified S-Ni under Ordinary Pressure. Benzyl alcohol (6 m*l*) and modified S-Ni (1 g) were placed in a 30-m*l*, round-bottomed flask equipped with a reflux-condenser. The content was refluxed for 24 hr in an oil bath, which had been heated at 151—156°C in advance. After the reaction was over, the reaction mixture was analyzed by gas chromatography in order to estimate the amount of benzaldehyde produced.

Reaction of Benzyl Alcohol in the Presence of Modified S-Ni in a Sealed Tube. Benzyl alcohol (2.00 g) and a modified S-Ni catalyst (0.333 g) were heated at 155°C for 24 hr in a sealed tube. After the reaction was over, the tube was cooled with ice, and the composition of the reaction mixture was analyzed by gas chromatography.

The authors wish to express their hearty thanks to Dr. Ken-ichi Watanabe for his helpful encouragement.

Photochemical Reduction of Nitrobenzene and Its Reduction Intermediates. IX. The Photochemical Reduction of 4-Nitropyridine in a Hydrochloric Acid-Isopropyl Alcohol Solution[1]

Shizunobu HASHIMOTO, Koji KANO, and Kazuo UEDA
Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto

(Received October 3, 1970)

The photochemical reduction of 4-nitropyridine has been investigated in hydrochloric acid-isopropyl alcohol solutions. 4-Nitropyridine was not photoreduced in isopropyl alcohol, whereas when the photolysis was carried out in hydrochloric acid-isopropyl alcohol solutions, the photoreduction of 4-nitropyridine proceeded from its n,π^* triplet state to give 4-hydroxylaminopyridine in a quantitative yield. The quantum yields for the disappearance of 4-nitropyridine in hydrochloric acid-isopropyl alcohol solutions increased with the concentration of hydrochloric acid up to 3.6×10^{-2} mol l^{-1} ($\Phi=0.27$—0.94). These results suggest that the hydrogen abstraction of photoexcited 4-nitropyridine proceeds electrophilically because of the decrease in the electron density of the nitro group, in decrease resulting from the protonation of heterocyclic nitrogen and the n,π^* excitation of the nitro group.

It is well-known that aromatic nitro compounds are photoreduced in hydrogen-donative solvents to give the corresponding amino or hydroxylamino compounds.[2] Few investigation of the relationships between the electronic structures of photoexcited nitro compounds and their reactivities of hydrogen abstraction have, however, been done to date. Hurley and Testa[3] have reported that the reactivity of the hydrogen abstraction of the protonated nitrobenzene triplet is greater than that of the unprotonated nitrobenzene triplet. Janzen and Gerlock[4] reported the substituent effects on the photochemistry and nitroxide-radical formation of nitro aromatic compounds, as studied by electron-spin-resonance spin-trapping techniques. Meanwhile, we ourselves have reported that, when the photoreduction of *para*-substituted nitrobenzenes is done in isopropyl alcohol (IPA), there is a linear correlation between the log-values of the relative quantum yields of nitrobenzenes and the nitrobenzene and the Hammett constants (ρ: +); therefore, the hydrogen abstraction of photoexcited nitrobenzenes may proceed electrophilically.[1] On the other hand, 4-nitropyridine is not reduced photochemically in IPA, and it is photoreduced in hydrochloric acid (HCl) - IPA solutions to give 4-hydroxylaminopyridine in a quantitative yield.[5] These facts are very interesting and may prove useful in investigating the correlation between the reactivity of the photochemical reduction and the electronic structure of nitro aromatic compounds in the photoexcited states.

In this paper, we wish to report in detail our findings on the photoreduction of 4-nitropyridine and to discuss the photoreduction mechanism. Both the reporting and discussing were begun in a communication (Ref. 5).

Results

Photochemical Reduction of 4-Nitropyridine. Identification of the Reduction Products. Figure 1 shows the progressive spectral change during the course of the photolysis of a 2×10^{-3} mol l^{-1} solution of 4-nitropyridine in IPA on irradiation with an immersion-type 130-W high-pressure mercury lamp under a nitrogen atmosphere at room temperature. As Fig. 1 shows, no isosbestic points were observed on the spectra, and the reaction product (Product A) had an absorption at 250 mμ. "Product A" (mp>300°C, brown plate from ethanol) has not yet been identified; however, it is clearly not a reduction product of 4-nitropyridine, such as 4-hydroxylamino-, 4,4'-azoxy-, 4,4'-azo-, and/or 4-aminopyridine, as has been shown by a comparison of the UV spectra with those of authentic samples.

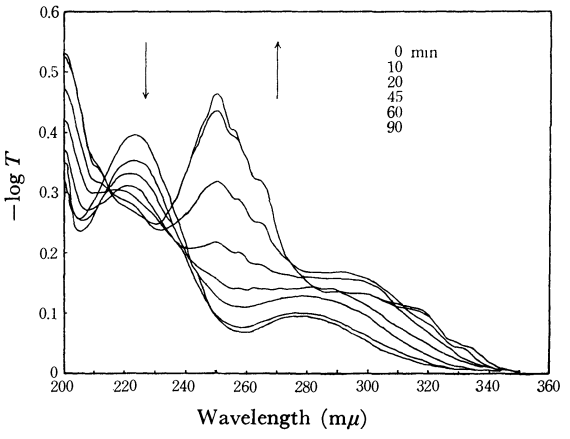

Fig. 1. The progressive spectral change of the photoreaction of 4-nitropyridine in IPA.

Meanwhile, the progressive spectral change during the reaction of a 2×10^{-3} mol l^{-1} solution of 4-nitropyridine in a 4 vol% concentrated HCl - IPA solution on irradiation with an immersion-type 130-W high pressure mercury lamp under a nitrogen atmosphere at room temperature is shown in Fig. 2. Two isosbestic points were observed at 214 and 244 mμ respectively. The absorption at 273 mμ (Product B) gradually in-

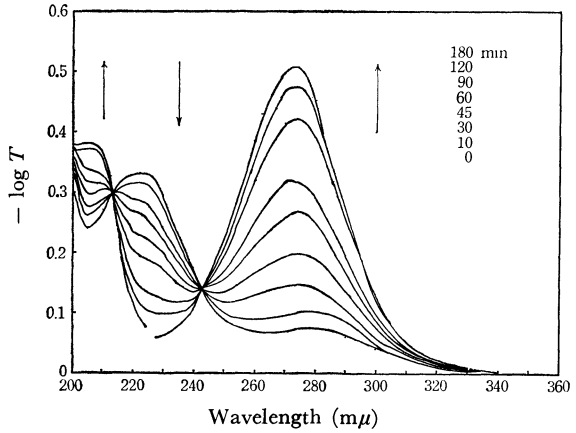

Fig. 2. The progressive spectral change of the photoreduction of 4-nitropyridine in HCl-IPA solution.

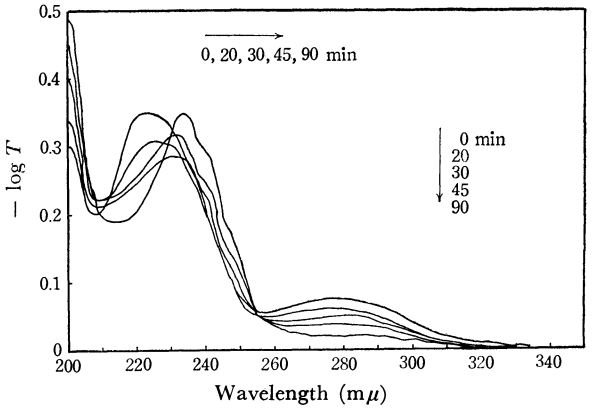

Fig. 3. The progressive spectral change of the photoreaction of 4-nitropyridine in HCl-IPA solution under an oxygen atmosphere.

creased in intensity with the progress of the photolysis. "Product B" was converted by alkali to afford 4,4'-azopyridine (yield 32%), and then converted to 4,4'-azoxypyridine (yield 24%) on treatment in a neutral solution. It has been established that 4-hydroxylaminopyridine 1-oxide converts to 4,4'-azopyridine 1,1'-dioxide on treatment in an alkaline solution, and converts to 4,4'-azoxypyridine 1,1'-dioxide on treatment in a neutral solution,[6] while phenylhydroxylamine converts to azoxybenzene.[7] These facts suggest that "Product B", which is a precursor of 4,4'-azopyridine and 4,4'-azoxypyridine, is 4-hydroxylaminopyridine.

Effect of Triplet Quenchers. The quenching effects for the photoreduction of 4-nitropyridine in HCl-IPA solutions were investigated by using 1,3-pentadiene and/or oxygen as triplet quenchers.

A 2×10^{-3} mol l^{-1} solution of 4-nitropyridine in a 4 vol% concentrated HCl-IPA solution containing 1,3-pentadiene (2.5×10^{-2} mol l^{-1}) was irradiated with an immersion-type 130-W high-pressure mercury lamp under a nitrogen atmosphere at room temperature. In the photoreduction of 4-nitropyridine in the absence of 1, 3-pentadiene, about 3.0 hr is required to complete the photolysis, but in the presence of 1,3-pentadiene, which is 1.5 times as large in quantity as 4-nitropyridine, about 4.5 hr is required. The photoreduction of 4-nitropyridine proceeded under irradiation by a near 316 mμ light, and we do not need consider the inner-filter effect by 1,3-pentadiene ($\lambda_{max}^{IPA}=223$ mμ) in this reaction. These facts suggest that the photoreduction of 4-nitropyridine is quenched by 1,3-pentadiene.

The quenching effect by oxygen was also studied. A 2×10^{-3} mol l^{-1} solution of 4-nitropyridine in a 4 vol% concentrated HCl - IPA solution was irradiated with an immersion-type 130-W high-pressure mercury lamp under an oxygen atmosphere at room temperature. The progressive spectral change during the photolysis is shown in Fig. 3. As Fig. 3 shows, the photochemical reaction of 4-nitropyridine under an oxygen atmosphere proceeded in a complicated way; finally, a product which had an absorption at 235 mμ was generated. The generation of 4-hydroxylaminopyridine was not observed on the UV spectrum. A reaction other than photoreduction might occur, and so it could not clarified whether or not the photoreduction of 4-nitropyridine was quenched by oxygen. Kaneko *et al.*[8] have reported that 4-nitropyridine 1-oxide is not reduced photochemically in ethanol under an oxygen atmosphere, and that 4-hydroxypyridine 1-oxide is thus prepared. The photolysis of 4-nitropyridine in oxygen-saturated solutions is now under investigation.

The Role of HCl. The Quantum Yield for the Disappearance of 4-Nitropyridine. HCl plays an important role in the photochemical reduction of 4-nitropyridine. The quantum yields for the disappearance of 4-nitropyridine (Φ) were measured in order to clarify the role of HCl.

Several 1×10^{-3} mol l^{-1} solutions of 4-nitropyridine in 80% IPA-water solutions containing varying amounts of HCl were irradiated by a 316-mμ light under a nitrogen atmosphere at room temperature. Here, 4-hydroxylaminopyridine was the only product. The correlation between the quantum yields and the concentration of HCl is shown in Fig. 4. The quantum yields of the 4-nitropyridine disappearance increased

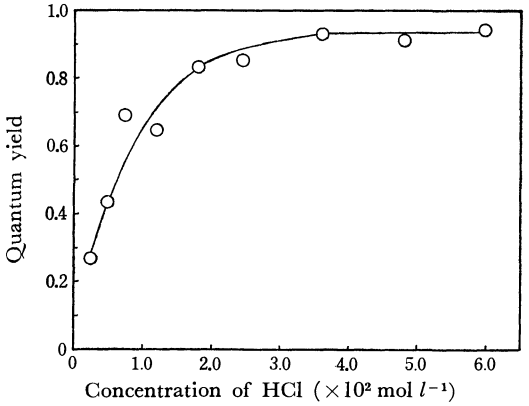

Fig. 4. The correlation of the quantum yields for the disappearance of 4-nitropyridine and the concentration of HCl.

with the concentration of HCl up to 3.6×10^{-2} mol l^{-1}, and while they were constant above this concentration ($\Phi_{av.}=0.93$). The quantum yields of the 4-nitropyridine disappearance ($\Phi=0.27-0.94$) were greater than that of nitrobenzene in IPA ($\Phi=0.0114$)[9] and/or IPA - HCl solutions ($\Phi=0.04-0.14$).[3]

Discussion

It has been studied by several workers how aromatic nitro compounds, such as nitrobenzene,[9-11] *para*-substituted nitrobenzenes,[1,12] 1-nitronaphthalene,[13,14] and 4-nitropyridine 1-oxide,[15,16] are photoreduced in hydrogen-donative solvents to give the corresponding amino or hydroxylamino compounds. On the other hand, 4-nitropyridine was not photoreduced in IPA, but was reduced photochemically in HCl-IPA solutions under a nitrogen atmosphere to afford 4-hydroxylaminopyridine in a quantitative yield.

The photoreduction of 4-nitropyridine was quenched by 1,3-pentadiene; this suggested that the hydrogen abstraction proceeded from the excited triplet state of 4-nitropyridine. However, it seems that the quenching effect by 1,3-pentadiene is not significant in the photoreduction of 4-nitropyridine. This finding is similar to the oxygen quenching of the nitrobenzene triplet.[9] The photochemical behavior of nitro compounds in hydrogen-donative solvents may be written as in the following sequence:

$$N + h\nu \xrightarrow{k_1} N^{*(1)} \quad (1)$$

$$N^{*(1)} \xrightarrow{k_2} N \quad (2)$$

$$N^{*(1)} \xrightarrow{k_3} N^{*(3)} \quad (3)$$

$$N^{*(3)} \xrightarrow{k_4} N \quad (4)$$

$$N^{*(3)} + Q \xrightarrow{k_5} N + Q \quad (5)$$

$$N^{*(3)} + AH \xrightarrow{k_6} NH + A \quad (6)$$

A steady-state approximation for solutions containing quenchers such as 1,3-pentadiene and/or oxygen leads to this expression for the disappearance of nitro compounds:

$$\Phi = \frac{\Phi_T}{\left[1+\frac{k_4+k_5(Q)}{k_6(AH)}\right]}$$

where Φ is the quantum yield for the disappearance of nitro compounds, Φ_T is the yield of the triplet, (AH) is the concentration of the hydrogen-donative solvents, and (Q) is the concentration of the quenchers. It can be explained, in accounting for the ineffective oxygen quenching of the nitrobenzene triplet, that k_4 is greater than $k_5(Q)$.[9] In the photoreduction of 4-nitropyridine, however, k_4 may be small, since the quantum yield for the disappearance of 4-nitropyridine was about 0.9 in the absence of 1,3-pentadiene when an IPA solution of 4-nitropyridine containing 4 vol% concentrated HCl was irradiated with the 316 mμ light.[17] Therefore, it is reasonable to expect that $k_6(AH)$ will be greater than $k_5(Q)$.

Meanwhile, 4-nitropyridine in IPA absorbed broadly near the 340—420 mμ light. Since this weak band overlapped with the intense π,π^* band, it was impossible to distinguish the n,π^* band. It has been established that the hydrogen abstraction of photoexcited benzophenones proceeds from their n,π^* triplet states and that the reactivity of hydrogen abstraction falls off in their π,π^* triplet states.[18] By the way, the quantum yields for the diappearance of 4-nitropyridine in HCl-IPA solutions were strikingly large ($\Phi=0.27$—0.94). These facts suggest that the photoreduction of 4-nitropyridine proceeds from its n,π^* triplet state.

In the photoreduction of 4-nitropyridine to 4-hydroxylaminopyridine, HCl had to exist in the reaction system. The UV spectra of 4-nitropyridine in acidic IPA solutions, suggest that the protonation of heterocyclic nitrogen proceeded, while the protonation of the nitro group in the ground state does not occur, in the range of the HCl concentration used in our experiments, since the absorption of the conjugated acid of 4-nitropyridine at 280 mμ in IPA increased in its intensity with an increase in the acidity and the isosbestic point was observed at 248 mμ. These results suggest that 4-nitropyridine hydrochloride is reduced photochemically. It seemed that, since 4-nitropyridine partly forms its hydrochloride in the range of the HCl concentration from 0.24×10^{-2} to 3.6×10^{-2} mol l^{-1}, the quantum yield for the disappearance of 4-nitropyridine increased with the concentration of HCl; above this concentration, the formation of hydrochloride was perfect, and so the quantum yields became constant.

The electron density on the nitro group of 4-nitropyridine may be lower than that of nitrobenzene because of the electron-withdrawing effect of heterocyclic nitrogen. When the lone pair of heterocyclic nitrogen is protonated, the electron-withdrawing effect will be enhanced; therefore, the electron density on the nitro group of protonated 4-nitropyridine may be lower than that of unprotonated 4-nitropyridine.

Meanwhile, the n-π^* transition of the nitro group may be pictured as follows:[19]

(I) (II) (III)

Ground state n,π^* Excited state

·: π electron; ∘: sp electron; y: p_y electron

The structure (I) and (III) imply that a nitro n,π^* excited state exhibits biradical properties. On the other hand, as is shown in the structure (II), n,π^* excitation removes an electron from the oxygen atom and promotes it to same π^* orbital, which is then shared by both atoms, formally leaving a 1/2 positive charge on oxygen. For these reasons, the n,π^* excited states of nitro compounds are similar to those of carbonyl compounds; therefore, it is reasonable to assume that the reactivity of the hydrogen abstraction of the n,π^* photoexcited nitro compounds is also similar to that of carbonyl compounds. Porter and Suppan[20] have reported that the reactivity of the hydrogen abstraction of benzophenones may be classified, in decreasing order, as n,π^*, π,π^*, and charge-transfer (CT) states; these properties can be interpreted in term of the electron distribution in the lowest triplet level.

As has been mentioned above, the formal positive charge at oxygen atoms on the nitro group of 4-nitropyridine, may increase in this order: the unprotonated 4-nitropyridine, protonated 4-nitropyridine, and the n,π^* excited state of protonated 4-nitropyridine. In view of the above facts, it seems reasonable to assume that the hydrogen abstraction of photoexcited 4-nitropyridine may be dominated by the electron density on the oxygen of the nitro group, and that it proceeds electrophilically similarly to that of photoexcited benzophenones. This deduction may be supported by the fact that there is a linear correlation between the log-values of the quantum yields for the disappearence of *para*-substituted nitrobenzenes and the Hammett constants (ρ: +) when the photoreduction of *para*-substituted nitrobenzenes is done in IPA.[1]

Experimental

Materials. The 4-nitropyridine was prepared according to the procedures described in the literature.[21] Reagent-grade IPA was distilled prior to use. 1,3-Pentadiene commercially obtained was further purified by distillation (bp 42—45°C).

Determination of Quantum Yields. The 316-mμ light was isolated from a high-pressure 130-W mercury lamp with a combination filter of Toshiba UV-D25, an aqueous nickel sulfate solution, and carbon tetrachloride. The light intensities were determined with a potassium ferrioxalate actinometer described by Hatchard and Parker.[22]

Analytical Procedures. The disappearance of 4-nitropyridine was determined by measuring the optical densities of photolyzed solutions. Polarographic analysis for following the 4-nitropyridine disappearance was also undertaken (pH=6.0, $E_{1/2}=-0.3$ V), but satisfying data could not obtained by this method. A Hitachi 124 spectrophotometer was used for the quantitative absorbance measurements and for following the progressive spectral change in the 4-nitropyridine photochemistry.

Preparation of 4,4'-Azoxypyridine and 4,4'-Azopyridine by the Photolysis of 4-Nitropyridine. A mixture of 0.62 g (5×10^{-3} mol) of 4-nitropyridine and 2.5 m*l* of concentrated HCl was exactly diluted to 1 *l* with IPA, and then irradiated with an immersion-type 130-W high-pressure mercury lamp for 10 hr under a nitrogen atmosphere at room temperature. After the irradiation, the photolyzed solution was evaporated to half of its volume *in vacuo*; the "reaction mixture" was thus obtained. The "reaction mixture" was neutralized with an aqueous sodium carbonate solution, and then evaporated to 100 m*l* of its volume. The brown residue thus obtained was heated to *ca.* 95°C for 2.5 hr and then extracted with chloroform. After the evaporation of the chloroform, the residue was recrystallized from water. The plate crystal thus obtained was identified as 4,4'-azoxypyridine; yield, 0.12 g (24%); mp 125—126.5°C. In mass spectroscopy, a molecular radical ion M^+ (*m/e* 200), was found corresponding to the molecular formula of $C_{10}H_8N_4O$.

Found: C, 60.10; H, 4.05; N, 28.12; O, 7.73%. Calcd for $C_{10}H_8N_4O$: C, 59.99; H, 4.03; N, 27.99; O, 7.99%.

The UV and IR spectra of 4,4'-azoxypyridine are shown in Figs. 5 and 6.

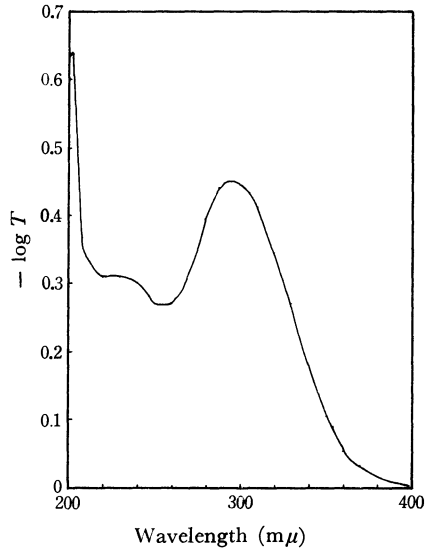

Fig. 5. UV-spectrum of 4,4'-azoxypyridine (4×10^{-5} mol l^{-1}).

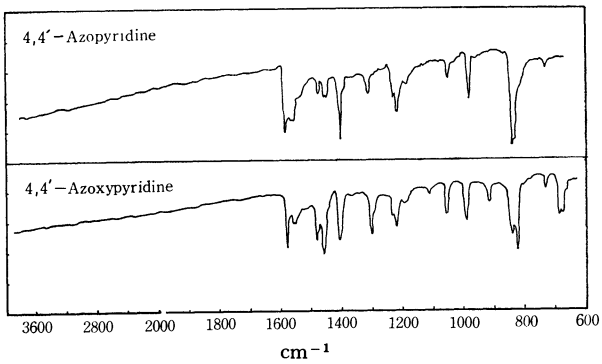

Fig. 6. IR-spectra of 4,4'-azoxypyridine and 4,4'-azopyridine (KBr).

20) G. Porter and P. Suppan, *Trans. Faraday Soc.*, **61**, 1664 (1965).

The "reaction mixture" was basified with 300 m*l* of a 33% aqueous sodium hydroxide solution, and then evaporated as far as possible. The redish-orange residue was dissolved in water and extracted with chloroform. After the evaporation of the chloroform, the residue was recrystallized from water. The redish-orange needles thus obtained were identified as 4,4′-azopyridine; yield, 0.15 g (32%); mp 109—110.5°C (lit,[6] mp 108—109°C). In mass spectroscopy, a molecular radical ion, M^+ (*m/e* 184), was found corresponding to the molecular formula of $C_{10}H_8N_4$.

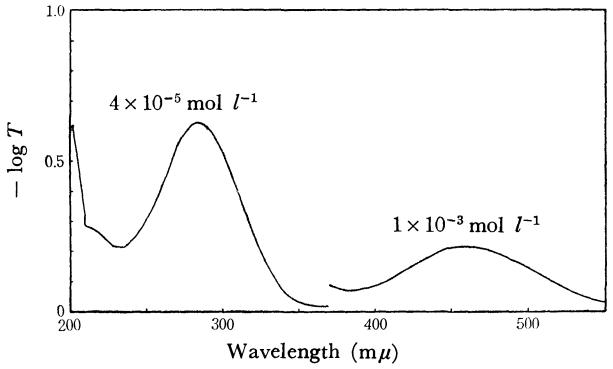

Fig. 7. UV-spectrum of 4,4′-azopyridine in IPA.

Found: C, 65.39; H, 4.22; N, 30.16%. Calcd for $C_{10}H_8N_4$: C, 65.20; H, 4.38; N, 30.42%.

The UV and IR spectra of 4,4′-azopyridine are shown in Figs. 7 and 6.

The authors wish to thank Mr. Ikuo Takada and Miss Tomi Inoue for their assistance in the experiments.

Alkoxysilanes. VII. The Preparation of Alkylalkoxysiloxanes

Ichiro KIJIMA, Keisuke OKUDA, and Yoshimoto ABE*

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received October 6, 1970)

Trimethylsiloxytri-*t*-butoxysilane (I), bis(trimethylsiloxy)di-*t*-butoxysilane (II), and bis(trimethylsiloxy)bis-(tri-*t*-butoxysiloxy)silane (III) were prepared by the reaction of trimethylchlorosilane with tri-*t*-butoxysilanol, di-*t*-butoxysilanediol, and bis(tri-*t*-butoxysiloxy)silanediol respectively. Bis(tri-*t*-butoxysiloxy)dimethylsilane (IV) was also obtained by the reaction of dimethyldichlorosilane with tri-*t*-butoxysilanol. The reaction of dimethyldichlorosilane with di-*t*-butoxysilanediol or bis(tri-*t*-butoxysiloxy)silanediol gave tetramethyltetra-*t*-butoxy (V) or tetramethyltetra(tri-*t*-butoxysiloxy)cyclooctasiloxane (VI). These compounds were identified by means of elemental analysis, molecular-weight determination, and a study of the IR and NMR spectra.

Alkylalkoxysiloxanes have been obtained by the hydrolysis of alkylalkoxychlorosilanes and alkylalkoxysilanes,[1,2] but the preparation of the alkylalkoxysiloxanes[3] by the reaction of alkoxysilanols with alkylchlorosilanes has not been described. In this paper, we wish to report an investigation of the preparation of alkylalkoxysiloxanes bearing methyl and *t*-butoxy groups as organic radicals.

Since we had already prepared several alkoxysilanols, tri-*t*-butoxysilanol,[4] di-*t*-butoxysilanediol,[5] and bis-(tri-*t*-butoxysiloxy)silanediol, we expected that the reaction of these silanols with alkylchlorosilanes would lead to the formation of mixed siloxanes. Furthermore, polyalkylalkoxysiloxanes may be obtained by the reactions of the silanediols with dichlorosilanes. It was found that the following reactions, (A) and (B), easily afforded the products (I), (II), (III), and (IV):

$$Me_3SiCl + (RO)_{4-n}Si(OH)_n + nC_5H_5N \rightarrow (RO)_{4-n}Si(OSiMe_3)_n + nC_5H_5NHCl \quad (A)$$

where R=Bu^t and n=1: (I), n=2: (II)
R=(Bu^{t}O)$_3$Si and n=2: (III)

$$Me_2SiCl_2 + 2(RO)_3SiOH + 2C_5H_5N \rightarrow [(RO)_3SiO]_2SiMe_2 + 2C_5H_5NHCl \quad (B)$$

where R=Bu^t (IV)

These products could be distilled as a colorless viscous liquid (IV) which solidified as soon as distilled. As Table 1 shows, the results of the elemental analysis and molecular-weight determination agreed with the calculated values for the compounds. The IR spectra of these comopunds are essentially identical and show absorption peaks at 1388 and 1360 (branching of the alkyl group), 1240 and 1255 (Si–Me$_3$, methyl group), 1052 (Si–O–Si), 841 (Si–Me$_3$), and 799 (Si–Me$_2$)cm^{-1}.[6] The NMR spectra of the compound (I) also show the proton signals at 8.73 (Bu^t) and 9.90 (Me) τ. The formation of these compounds indicates that the hydroxy groups in the silanols are easily replaced by the trimethylsiloxy group, although they are sterically hindered. It is generally known that it is difficult to replace the X group in the alkoxysilanes $(RO)_{4-n}SiX_n$

Table 2. Cyclic Alkylalkoxysiloxanes

Reactants (g) A	B	N	Products	Yield (%)	Mp °C	Mol wt Found (Calcd)	Found Anal % (Calcd) C	H	Si
21.0	34.0	25.4	(V)	66	109—110[a]	527 (529)	45.31 (45.51)	9.56 (9.15)	21.31 (21.24)
1.5	6.6	1.8	(VI)	35	132—133[b]	1294 (1290)	47.71 (48.41)	8.82 (9.32)	17.62 (17.42)

A: Dichlorosilane, B: Silanediol, a) Recrystallized from *n*-hexane, b) Recrystallized from ethanol

(n=halogen, amino group; R=t-alkyl group; n=1 or 2) by a bulky alkoxy group.[7-9] In the present case, however, the replacement is very easy. This difference seems to result from the difference in the bond length between the Si–O–C and Si–O–Si bonds.

Since it was found that the reaction of (A) and (B) easily afforded the alkylalkoxysiloxanes, we can expect that the reaction of dialkyldichlorosilanes with silanediols will produce polyalkylalkoxysiloxanes. With this view, the following reaction was carried out:

$$Me_2SiCl_2 + (RO)_2Si(OH)_2 + 2C_5H_5N \rightarrow \text{(cyclic tetrasiloxane)} + 2C_5H_5NHCl \quad \text{(C)}$$

where R=Bu^t: (V), R=(Bu^{t}O)$_3$Si: (VI)

The products obtained (V and VI) could be distilled or recrystallized. As is shown in Table 2, (V) solidified as soon as distilled (mp 109—110°C); (VI) could not be distilled because of the decomposition (240°C/1mmHg), but it was recrystallized from ethanol (mp 132—133°C). These products were soluble in common organic solvents. The analytical data and the results of the molecular-weight determination agreed with the calculated values for the cyclooctasiloxanes shown by Equation (C).

The formation of these compounds was also confirmed by the spectroscopic data; the IR spectra of these compounds show the absorption peaks at 1388 and 1360 (Bu^t), 1252 and 1240 (Si–Me), 1060 (Si–O–Si), and 799 (Si–Me$_2$) cm^{-1}. The NMR spectra of (V) show proton signals at 8.72 (Bu^t) and 9.87 (Me) τ. In this reaction, the formation of the cyclic alkylalkoxysiloxanes may be ascribed to the steric effect of the t-butoxy and tri-t-butoxy-siloxy groups.

Experimental

All the experiments were carried out under a dry atmosphere. The melting and boiling points are uncorrected.

Materials. Commercially-available trimethylchlorosilane and dimethyldichlorosilane were redistilled before use.[10] The aldoxysilanols used were prepared by a method already described.[4,5]

Preparation of Alkylaldoxysiloxanes. To a solution of silanol or silanediol and pyridine in toluene, dimethyldichlorosilane in the same solvent was added, drop by drop, about 0°C. After the mixture had been refluxed for 2 hr, pyridine hydrochloride was filtered off; then the solvent was removed, and the residue was recrystallized or distilled *in vacuo*, giving crystals or a liquid.

Instruments. The molecular weight was determined by the cryoscopic method in benzene. The IR spectra were measured in a liquid film or KBr disk by means of a Hitachi EPI-S2 spectrometer. The NMR spectra were measured with a Varian A-60 spectrometer in a carbon tetrachloride solution, with tetramethylsilane as the internal standard.

Peptide Synthesis by Oxidation-Reduction Condensation. I. Use of NPS-Peptides as Amino Component

Masaaki Ueki, Hiroshi Maruyama, and Teruaki Mukaiyama

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 12, 1970)

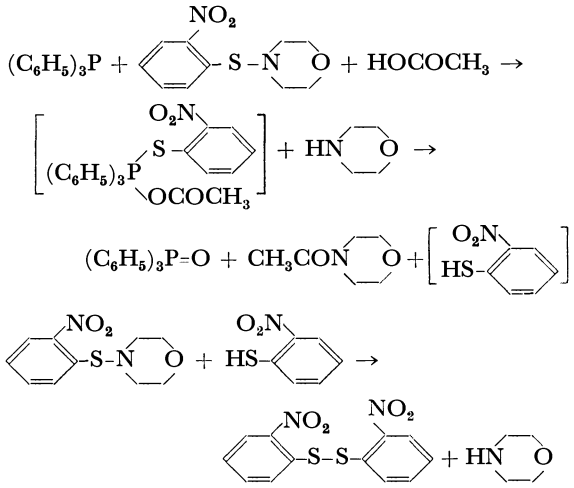
Sulfenamides were found to react readily with soft nucleophiles in the presence of active hydrogen compounds. A new method for the synthesis of carboxamide from metal carboxylate, sulfenamide and tertiary phosphine was developed. The effects of metal component were examined. Copper(II) salts gave the best result. In a similar way, peptides were synthesized by the reaction of copper(II) salts of acylamino acid, or free acylamino acid in the presence of cupric chloride and triethylamine, with NPS-amino acid derivatives and triphenylphosphine. When organo-mercuric compounds such as dianisylmercury were used in place of cupric chloride and triethylamine in the above reaction, almost complete retention of configuration was observed by the Young test.

In a previous communication,[1] a new amide (peptide) forming reaction by use of sulfenamide as an amino component was reported. The reaction is described more in detail in this paper.

Most sulfenic acid derivatives such as sulfenyl halide, sulfenate ester, disulfide, thiocyanate react very easily with phosphite triester. However, sulfenamide does not react with the ester because of the least polarizability of sulfur-nitrogen bond. On the other hand, sulfenamide is easily attacked by phosphite diester, which has a similar nucleophilicity as triester, to yield thiophosphate and amine.[2] The difference in reactivity between phosphite di- and tri-esters could be attributed to the presence or absence of active hydrogen. Mercaptan, which possesses a soft nucleophilic center and a proton in the molecule, also readily reacts with sulfenamide to give disulfide and amine. This reaction has been used for the removal of *o*-nitrophenylsulfenyl (NPS) protecting group introduced to α-amino function in peptide synthesis.[3] This shows that sulfenamides are activated by the protonation to yield active species, which are in turn easily attacked by soft nucleophile.

The reaction of sulfenamide and tertiary phosphine, a representative soft nucleophile, in the presence of active hydrogen compounds such as water and alcohol was tried first. When *p*-chlorobenzenesulfenanilide was allowed to react with triphenylphosphine in ether saturated with water, quantitative cleavage of sulfur-nitrogen bond was observed. On the other hand, no reaction occurred when the same reaction was tried in anhydrous methanol. However, quantitative cleavage of sulfur-nitrogen bond was observed by the addition of boron trifluoride etherate to the reaction system.

The same reaction of sulfenamide, phosphine and active hydrogen compound was tried by using carboxylic acid. After a short reaction period, acetomorpholide was obtained in a 63% yield from *o*-nitrobenzenesulfenic morpholide, triphenylphosphine and acetic acid. Formation of carboxamide is well explained by considering a subsequent acylation of the liberated amine with acyloxyphosphorane.



This reaction is not sufficient for the preparation of carboxamide because of the undesirable consumption of the starting sulfenamide by the subsequent reaction with mercaptan produced. This side reaction can be minimized by employing a mercaptan scavenger, which turns mercaptan into an inactive form. For example, when copper(II) hexanoate was allowed to react with *N*-*n*-butylbenzenesulfenamide and triphenylphosphine, a 95% yield of *N*-*n*-butylhexanamide was obtained, as shown in the following equation.

$$(R^1CO_2)_2Cu + 2R^2SNR^3R^4 + 2(C_6H_5)_3P \rightarrow 2R^1CONR^3R^4 + [(R^2S)_2Cu] + 2(C_6H_5)_3P{=}O$$

Since the copper(II) mercaptide produced does not react at all with sulfenamide in this reaction, yields of carboxamides are good as shown in Table 1. It is to be noted that mercury(II) and lead (II) salts of hexanoic acid also gave good results.

It is known that sulfenyl groups such as tritylsulfenyl and *o*-nitrophenylsulfenyl (NPS) can be used selectively as removable protecting groups in peptide synthesis. It can be expected that new peptide bond formation could be completed without removing the protecting group by the application of the above method to NPS-amino acid derivatives. *N*-Benzyl-*o*-nitrobenzenesulfenamide was chosen as a model compound and allowed to react with triphenylphosphine and benzoic acid. Contrary to expectation, the sulfenamide strongly resisted the

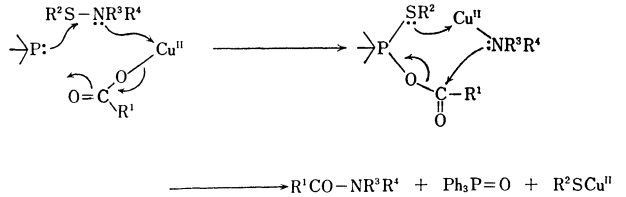
reaction. This might be due to the lower electron density on nitrogen atom of this sulfenamide by conjugation with nitro group through sulfur *d* orbital and aromatic ring. However, it was found that addition of equimolar excess of triphenylphosphine gave rise to reaction. After the reaction period of 3 hr, *N*-benzylbenzamide was obtained in 90% yield by separating by column chromatography on silica gel. During the reaction about 1.5 equivalents of triphenylphosphine were oxidized even when reaction was carried out under nitrogen atmosphere, and copper mercaptide was obtained as a complex with triphenylphosphine. The detailed mechanism of the oxidation of the excess phosphine is not made clear as yet.

The above mentioned reaction of the preparation of carboxamide was modified to start from free carboxylic acid and sulfenamide. When *N*-*n*-butylbenzenesulfenamide was treated with hexanoic acid and triphenylphosphine in the presence of mercury(II) chloride and triethylamine. *N*-*n*-butylhexanamide was obtained in 79% yield. Various inorganic metallic compounds were examined through the reactions by using *N*-benzyl-*o*-nitrobenzenesulfenamide (see Table 2). The effcts of the metallic compounds in these reactions are explained by means of the following mechanism.



In the first stage of the reaction, metallic compound activates sulfur-nitrogen bond by accommodating the lone pair electrons on nitrogen atom. Thus a hard metal such as zinc is more effective in this stage. In the second stage, a metal component is used for mercaptide forming reaction. Thus a soft metal such as mercury(II) is more effective. The presence of both zinc chloride and mercuric chloride in the reaction gave good results as expected.

The new method was applied to the peptide synthesis by using NPS-amino acid derivatives as amino component. First, synthesis of benzyloxycarbonyl (Z)-L-phenylalanylglycine ethyl ester, which is free from the problem of racemization, was tried. Copper(II) Z-L-phenylalaninate was prepared by treating sodium salt with aqueous copper(II) sulfate solution. To a stirred mixture of the copper salt in methylene chloride, NPS-Gly-OEt and 1 molar excess of triphenylphosphine were added. The copper salt dissolved soon and a clear reddish brown solution resulted. Z-L-Phe-Gly-OEt was obtained by ordinary treatment in 96% yield. Further, it was found that the reaction of free Z-L-Phe-OH with NPS-Gly-OEt and excess triphenylphosphine in the presence of copper(II) chloride and triethylamine also gave dipeptide in 90% yield.

Table 2. Reaction of benzoic acid, *N*-benzyl-*o*-nitrobenzenesulfenamide, and triphenylphosphine in the presence of metal chloride and triethylamine

Metal chloride	Conditions	Products: $C_6H_5CONHCH_2C_6H_5$ Yield (%)	Products: $(C_6H_5)_3P=O$ Yield (%)
$CuCl_2$	RT 1 day	88	150
$HgCl_2$	RT 1 day	no reaction	—
$ZnCl_2$	RT 3 hr	71	100
$CuCl_2+ZnCl_2$	RT 1 day	75	100
$HgCl_2+ZnCl_2$	RT 1 day	80	92

2 equiv of triphenylphosphine was used.

The test for racemization in these two types of reactions was carried out by employing the Young method.[4] When copper(II) benzoyl(Bz)-L-leucinate, NPS-Gly-OEt and triphenylphosphine were allowed to react in methylene chloride at room temperature, Bz-Leu-Gly-OEt was obtaind in 77% yield. Its specific rotation was −19.0° (*c* 3.1, EtOH), which indicated that the L-isomer content was 57%. When Bz-L-Leu-OH, NPS-Gly-OEt and triphenylphosphine were allowed to react in the presence of copper(II) chloride and triethylamine in methylene chloride at room temperature for 15 hr, completely racemized Bz-Leu-Gly-OEt was obtained in 72% yield. No improvement was observed even when they were allowed to react at −70°C for 5 hr.

It is most probable that the racemization occurs

4) M. W. Williams and G. T. Young, *J. Chem. Soc.*, **1963**, 881.

through as oxazolone derived from the postulated acyloxyphosphorane intermediate. Thus, it is expected that basic species such as triethylamine and copper amide involved in the reaction would accelerate the formation of oxazolone from the intermediate.

It is known that the addition of acidic substances is very effective for the prevention of racemization in DCC[5] and mixed anhydride methods.[6] The effects of the acidic additives in this method were examined (Table 3). As expected, it was found that racemization was considerably suppressed by acidic additives according to their acidity except for *N*-hydroxysuccinimide. From its pK_a value, *N*-hydroxysuccinimide was more effective than expected. Pivalic acid, which showed no effect in the DCC method,[6] also showed some prevention. It was found that the reaction could be carried out without use of excess triphenylphosphine. Thus it is clear that acidic substances are useful not only for the prevention of racemization, but also for the activation of sulfenamides.

Table 3. Reaction of copper(II) Bz-L-leucinate, NPS-Gly-OEt, and triphenylphosphine in the presence of acidic additives

Additive	pK_a	Bz-L-Leu-Gly-OEt	
		Yield (%)	L-Isomer content (%)
none	—	77	57
C_6H_5OH	9.89	75	0
	9.40	64	84
p-$O_2NC_6H_4OH$	7.15	90	11
$(CH_3)_3CCO_2H$	5.01	57	39
2,4-$(O_2N)_2C_6H_3OH$	3.96	81	77
2,4,6-$(O_2N)_3C_6H_2OH$	0.38	48	80

From these findings basic substances such as triethylamine can be expected to be purged by employing the metallic salts derived from the above mentioned acidic compounds,mercaptan scavenger, in place of copper(II) chloride and triethylamine. This makes the reaction medium acidic and racemization would consequently be prevented. Mercury was found to be the best metal, since in such conditions metallic compounds are necessary only for complete trapping of mercaptan produced and not for the activation of sulfenamides. Mercury(II) bis-2,4-dinitrophenolate was prepared and the reaction of Bz-L-Leu-OH, NPS-Gly-OEt and triphenylphosphine was tried in the presence of the mercuric salt. As expected, Bz-L-Leu-Gly-OEt was obtained in 88% yield and its L-isomer content was 74%. When aryl mercuric compounds such as dianisyl mercury and anisyl mercuric bromide were used as a mercaptan scavenger, almost complete retention of configuration was observed as shown in Table 4.

Table 4. Reactions of Bz-L-Leu-OH, NPS-Gly-OEt, triphenylphosphine, and organomercuric compounds

Organomercuric compounds	Bz-L-Leu-Gly-OEt		$(C_6H_5)_3P=O$ Yield (%)
	Yield (%)	L-Isomer (%)

$(p\text{-}CH_3OC_6H_4)_2Hg$	93	87	99
p-$CH_3OC_6H_4HgBr$	92	93	97

In conclution, highly optically pure peptides can be prepared by the new method starting from the NPS-peptides as amino component by a one step procedure. Mild reaction condition starting with free carboxyl component is a merit of this new method as compared with the other method using NPS-peptides as an amino component.[7]

Experimental

Reagents. Sulfenamides were prepared from the corresponding chloride and amines. NPS-Gly-OEt was prepared by the method in literature.[3] Bz-L-Leu-OH, commercial product of Takara Kosan Co., was used without further purification.

Copper(II) salts of acylamino acids were prepared by treating the sodium salts of acylamino acids with copper (II) sulfate in aqueous solution. The copper salts precipitated were extracted with ethyl acetate, and the extracts were dried and evaporated *in vacuo*. The crude copper salts were purified by reprecipitation from chloroform-petroleum ether (bp 30—50°C).

(Z-L-Phe-O)$_2$Cu Found: C, 61.13; H, 5.04; N, 4.33%. Calcd for $C_{34}H_{32}N_2O_8Cu$; C, 61.86; H, 4.89; N, 4.24%.

(Bz-L-Leu-O)$_2$Cu Found: C, 57.87; H, 6.27; N, 4.97%. Calcd for $C_{26}H_{32}N_2O_6Cu$; C, 58.65; H, 6.02; N, 5.27%.

Mercury (II) bis-2,4-dinitrophenolate was prepared by the following procedure. A solution of 2,4-dinitrophenol and mercuric acetate in 1/1(v/v) aqueous ethanol was refluxed. Precipitates were collected by filtration and washed with water and acetone and dried.

Found: C, 30.51; H, 1.76; N, 5.61%. Calcd for $C_{12}H_8N_2O_6Hg$; C, 30.25; H, 1.68; N, 5.88%. *p*-Anisylmercuric bromide[8] and bis-*p*-anisylmercury[9] were prepared according to literature.

Reactions of Metal Carboxylates, Sulfenamides, and Triphenylphosphine(I). (General Procedure) Sulfenamide (10 mmol) in anhydrous methylene chloride (10 m*l*) was added drop by drop to a vigorously stirred mixture of metal carboxylate (5 mmol) and I (10 mmol) in methylene chloride (20 m*l*). The mixture was stirred for several hours and kept standing overnight. The precipitated copper mercaptide was removed by filtration, and carboxamide was obtained from the filtrate by distillation or chromatography on silica gel. Physical properties are as follows: $CH_3CON(C_2H_5)_2$, bp 93—100°C/40 mmHg; $CH_3CONH(n\text{-}C_4H_9)$, bp 110—112°C/22 mmHg; $n\text{-}C_5H_{11}CONH(n\text{-}C_4H_9)$, bp 95—98°C/0.05 mmHg; $C_6H_5CONH(n\text{-}C_4H_9)$, mp 68—70°C; $p\text{-}CH_3C_6H_4CONH(n\text{-}C_4H_9)$, mp 55—57°C: [Found: C, 75.60; H, 8.83; N, 7.30%. Calcd for $C_{12}H_{17}NO$; C, 75.75; H, 8.96; N, 7.32%.

Reaction of Copper(II) Benzoate, N-*Benzyl-o-nitrobenzenesulfenamide, and I.* Reaction was carried out under the same conditions as described above except that I was used in one molar excess. The resulting solution was evaporated and reddish brown copper complex was precipitated from the residue by trituration with methanol. After filtration of the precipitate, the filtrate was condensed and chromatographed on silica gel. Copper complex and a small amount of disulfide were eluted by benzene. Elution with 1:1 mixture of benzene-methylene chloride gave *N*-benzylbenzamide (90%), mp 104—105°C. Further elution with 9:1 mixture of methylene chloride - methanol gave triphenylphosphine oxide (159%).

Reaction of Hexanoic, Acid, N-n-*Butylbenzenesulfenamide, and I in the Presence of Mercury(II) Chloride and Triethylamine(TEA).* Ten mmol of the sulfenamide in methylene chloride (10 m*l*) was added to a vigorously stirred mixture of hexanoic acid (10 mmol), I (10 mmol), mercuric chloride (5 mmol) and TEA (10 mmol) in methylene chloride (15 m*l*). After stirring for 3 hr at room temperature, mercury mercaptide precipitated was filtered off. The organic layer was dried and evaporated. From the residue, insoluble materials in petroleum ether (30—50°C) were removed by filtration. The filtrate was condensed and distilled to give *N-n*-butylhexanamide, (77%), bp 105—108°C/0.20 mmHg, which was purified by passing short column of silica gel.

Reactions of Benzoic Acid, N-*Benzyl-o-nitrobenzenesulfenamide, and I in the Presence of Metal Chlorides and TEA.* Reaction was carried out under similar conditions as mentioned above except that I was used in one molar excess when copper(II) chloride was employed. Isolation was carried out by chromatography on silica gel. The results are listed in Table 2.

Reaction of Copper(II) Z-L-phenylalaninate, NPS-Gly-OEt, and I. The copper salt (5 mmol), NPS-Gly-OEt (10 mmol), and I (20 mmol) were mixed in methylene chloride at room temperature. The resulting solution was stirred for 3 hr and kept standing overnight. After evaporation of the solvent, copper mercaptide-phosphine complex was precipitated by the addition of methanol and filtered off. The filtrate was condensed to about 5 m*l*, and 15 m*l* of ether and 25 m*l* of petroleum ether (30—50°C) were added to give Z-L-phe-Gly-OEt, 2.60 g (68%), mp 96—100°C. Additional 1.10 g (29%) of the peptide, mp 96—112°C, was obtained by chromatography on silica gel. The sample for analysis was recrystallized from ethyl acetate - petroleum ether, mp 109—111°C, $[\alpha]_D^{20}$ −17.0° (*c* 2, EtOH), lit,[10] mp 110—113°C, $[\alpha]_D^{20}$ −16.6° (*c* 2, EtOH).

Found: C, 65.59; H, 6.34; N, 7.02%. Calcd for $C_{21}H_{24}N_2O_5$; C, 65.61; H, 6.29; N, 7.29%.

Reaction of Z-L-Phe-OH, NPS-Gly-OEt, and I in the Presence of Copper(II) Chloride and TEA. NPS-Gly-OEt (10 mmol) in methylene chloride was added at room temperature to the stirred mixture of Z-L-Phe-OH (10 mmol), I (20 mmol), copper(II) chloride (5 mmol) and TEA (10mmol) in methylene chloride. The mixture was stirred for 1 day, washed with water and dried. The products were separated by chromatography on silica gel to give copper mercaptide-phosphine complex 3.12 g; Z-L-Phe-Gly-OEt 3.58 g, mp 109—112°C, $[\alpha]_D^{20}$ −17.3° (*c* 2, EtOH) and triphenylphosphine oxide, 4.28 g (154%).

Test for Racemization in This Type of Reaction by the Young Method.[4] *A) Reaction of Copper(II) Bz-L-leucinate, NPS-Gly-OEt, and I:* The reaction was carried out in the same manner as in the synthesis of Z-L-Phe-Gly-OEt. Hydrogen sulfide gas was introduced for 1 hr to the resulting solution. Cupric sulfide precipitated was filtered off and the filtrate was washed with 1N HCl, 5% $NaHCO_3$ solution and water, and dried. The products were then separated by preparative thin layer chromatography to give Bz-Leu-Gly-OEt 2.47 g (77%), mp 148—149°C. The crude material was subjected to measurement of optical purity without any purification to avoid fractionation, $[\alpha]_D^{20}$ −19.0° (*c* 3.1, EtOH), L-isomer content 56%.

B) Reaction of Bz-L-Leu-OH, NPS-Gly-OEt, and I in the Presence of Copper(II) Chloride and TEA: The reaction was carried out in the same manner as in the synthesis of Z-L-Phe-Gly-OEt starting from free carboxyl component. Hydrogen sulfide gas was introduced for 1 hr to the resulting solution. On filtering off the precipitated copper mercaptide, the filtrate was condensed and chromatographed on silica gel to give bis-*o*-nitrophenyl disulfide (quantitative), Bz-Leu-Gly-OEt 2.30 g (72%), mp 143—145°C, $[\alpha]_D^{20}$ 0°(*c* 3.1, EtOH) and triphenylphosphine oxide 3.34 g (120%).

Reaction of Copper(II) Bz-L-Leucinate, NPS-Gly-OEt, and I in the Presence of Acidic Additives. Copper(II) Bz-L-leucinate (5 mmol), NPS-Gly-OEt (10 mmol), I (10 mmol), and acidic substances listed in Table 3 (10 mmol) were mixed in methylene chloride at room temperature. The mixture was stirred for several hours and kept standing overnight. On filtering off copper mercaptide the filtrate was washed with 1N HCl, 5% $NaHCO_3$ solution and water and dried. On evaporation of the solvent, chromatographic separation gave crude Bz-Leu-Gly-OEt, which was subjected to the measurement of optical purity. The results are listed in Table 3.

Reactions of Bz-L-Leu-OH, NPS-Gly-OEt, I, and Organomercuric Compounds. The reaction was carried out by mixing equimolar amounts of Bz-L-Leu-OH, NPS-Gly-OEt, I, and bis(*p*-anisyl)mercury, mercury bis(2,4-dinitrophenolate) or *p*-anisylmercuric bromide in methylene chloride at room temperature. Work-up was done as above and results are listed in Table 4.

Decomposition of *cis*- and *trans*-α-Phenylcinnamoyl Peroxide and *t*-Butyl *cis*- and *trans*-α-Phenylperoxycinnamate. Stereochemistry of 1,2-Diphenylvinyl Radical[1]

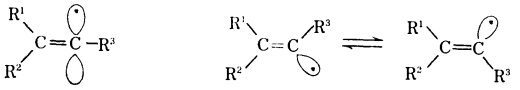
Naoto WADA, Katsumi TOKUMARU, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received October 23, 1970)

Decomposition of *trans*- and *cis*-α-phenylcinnamoyl peroxide and *t*-butyl *trans*- and *cis*-α-phenylperoxycinnamate were carried out in solution and the products were determined. *t*-Butyl *trans*- and *cis*-α-phenylperoxycinnamate, on decomposition in carbon tetrachloride, gave mixtures of *cis*- and *trans*-α-chlorostilbene in the same *cis* to *trans* ratio at 110°C, but in different ratios at 80°C, the higher ratio being obtained from *t*-butyl *trans*-α-phenylperoxycinnamate. In the decomposition of *trans*- and *cis*-α-phenylcinnamoyl peroxide in various solvents at 60°C, the α-halostilbenes formed in carbon tetrachloride and bromotrichloromethane and the stilbenes produced in cumene, chloroform and triethylsilane were shown to be richer in the isomer of the same configuration as the peroxide decomposed. The stereochemical course of the reaction of the 1,2-diphenylvinyl radical generated from these peroxy-esters and peroxides is discussed.

The stereochemistry of vinyl radicals has recently been investigated by several groups of workers.[2-8] Unsubstituted vinyl[2,3] and 1-methylvinyl radicals[2] have been shown by electron spin resonance measurements to exist not in an *sp*-hybridized linear form but in two sp^2-hybridized bent forms which are interconvertible. However, from the viewpoint of organic reaction mechanisms, the stereochemical behaviour of various vinyl radicals can not be regarded as completely clarified.[4-8]

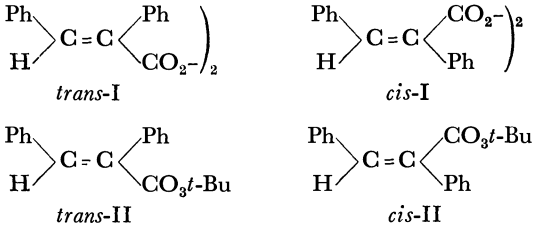


Linear form Bent forms

In a previous paper,[6] we showed that styryl radicals exist in two bent forms from the finding that *trans*- or *cis*-cinnamoyl peroxide, on decomposition in carbon tetrachloride at 77°C, gave mixtures of *trans*- and *cis*-β-chlorostyrene in the same ratio, whereas in bromotrichloromethane at 77°C, *trans*- and *cis*-β-bromostyrene were produced in different ratios. Singer and Kong have also presented evidence that 1-bromo-2-phenylvinyl radicals have *cis*- and *trans*-forms.[4d] Sargent and Browne have shown that *cis*- or *trans*-3-chloro-3-hexene, on treatment with sodium naphthalenide in tetrahydrofuran or dimethoxyethane, gave mixtures of *trans*- and *cis*-3-hexene in different *cis* to *trans* ratios which suggest that the 1-ethyl-1-butenyl radicals intermediately formed are in two bent forms.[7]

It seemed of interest to investigate the stereochemistry of the 1,2-diphenylvinyl radical. It is possible that it might exist in linear form, since this form could be stabilized by a possible conjugation between the unpaired electron in a *p*-orbital on the *sp*-hybridized α-carbon atom and the π-electron system on the adjacent α-phenyl group. Singer and Kong considered these radicals, which they generated by decomposition of *t*-butyl *trans*- and *cis*-α-phenylperoxycinnamate in solution at 110°C, to exist in two bent forms in equilibrium[4b] by analogy with the structure of simpler vinylic radicals.[2,3] Kopchik and Kampmeier have recently concluded that the 1,2-diphenylvinyl radical is *sp*-hybridized at the radical centre, from the analysis of experimental data and of molecular orbital calculations with the 1-vinylvinyl radical as a model.[5d]

In the present investigation, *trans*- and *cis*-α-phenylcinnamoyl peroxide (I) and *t*-butyl *trans*- and *cis*-α-phenylperoxycinnamate (II) were allowed to decompose in solution in order to generate 1,2-diphenylvinyl radicals and the products were examined.



trans-I *cis*-I

trans-II *cis*-II

Results and Discussion

Preparation and Properties of α-Phenylcinnamoyl Peroxides. *trans*-α-phenylcinnamoyl peroxide was prepared by treatment of *trans*-α-phenylcinnamoyl chloride with sodium peroxide. It showed characteristic absorption

bands of diacyl peroxides at 1750 and 1772 cm^{-1} (Nujol). The isomeric *cis*-peroxide was prepared according to Greene and Kazan's procedure[9] from *cis*-α-phenylcinnamic acid and hydrogen peroxide with *N*, *N'*-dicyclohexylcarbodiimide as a condensing agent. Preparation both from *cis*-α-phenylcinnamoyl chloride and sodium peroxide by the conventional procedure[10] and from *cis*-α-phenylcinnamoylimidazole and hydrogen peroxide[11] was unsuccessful. The *cis*-α-phenylcinnamoyl peroxide obtained was a pale yellowish oil at room temperature, and displayed characteristic bands of diacyl peroxides at 1779 and 1795 cm^{-1} (Nujol).

Both peroxides, particularly the *cis*-peroxide, were found unstable in neat state or in solution even at room temperature. The instability of α-phenylcinnamoyl peroxides is attributable to facile conversion into their carboxy-inversion products from the following observations. When the *trans*-peroxide was allowed to stand as Nujol mull at room temperature, its infrared absorption bands due to a diacyl peroxide group at 1750 and 1772 cm^{-1} gradually decreased in intensity and finally disappeared, while new absorption bands at 1810 and 1740 cm^{-1} characteristic of alkyl alkanoyl carbonates[12] appeared and increased in intensity (see Fig. 1); in fact the product from this change was shown to be 1,2-diphenylvinyl *cis*-1,2-diphenylethylenecarbonyl carbonate.[13]

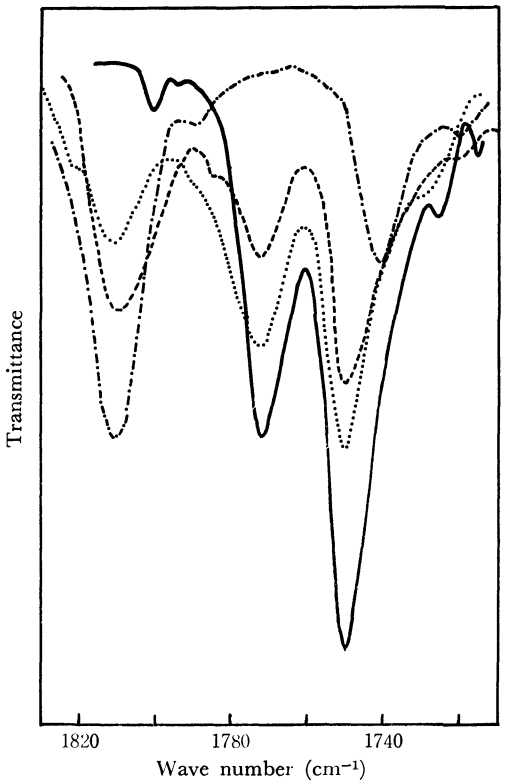

Fig. 1. IR spectra at various times of *trans*-α-phenylcinnamoyl peroxide (Nujol mull) at 24.5°C.
—— immediately after the preparation of the mull; ····· after 55 hr; ---- after 79 hr; —·—· after 258 hr.

The unsuccessful attempt to prepare *cis*-α-phenylcinnamoyl peroxide by treatment of *cis*-α-phenylcinnamoyl chloride with sodium peroxide gave an oily material, which solidified at −78°C, contained no peroxidic oxygen and displayed infrared absorption bands at 1740 and 1803 cm^{-1} characteristic of an alkyl alkanoyl carbonate.[12] On being dissolved in dichloromethane at room temperature, it decomposed spontaneously giving *cis*-α-phenylcinnamic anhydride, while with alkali it afforded *cis*-α-phenylcinnamic acid and diphenylacetylene. This suggests that the reaction of *cis*-α-phenylcinnamoyl chloride with sodium peroxide once gave *cis*-α-phenylcinnamoyl peroxide, which, under the experimental conditions, readily rearranged into the carboxy-inversion product, 1,2-diphenylvinyl *trans*-1, 2-diphenylethylenecarbonyl carbonate, and that this carbonate subsequently decomposed, as is generally known to be the case with acyl alkyl carbonates,[12b] to give *cis*-α-phenylcinnamic anhydride and 1,2-diphenylvinyl carbonate, the latter probably giving rise to diphenylacetylene.

Products from Thermal Decomposition. *trans*- and *cis*-α-Phenylcinnamoyl peroxide were allowed to decompose in carbon tetrachloride at 60, 80, and 110°C, and in bromotrichloromethane, chloroform, cumene, and triethylsilane at 60°C, and *t*-butyl *trans*- and *cis*-α-phenylperoxycinnamate were also subjected to decomposition in carbon tetrachloride at 80 and 110°C. The products from these decompositions are listed in Tables 1, 2, and 3.

Operation of a homolytic mechanism in the decomposition of the peroxides and the peroxy-esters is demonstrated by the formation of bicumyl in cumene and of hexachloroethane in carbon tetrachloride, bromotrichloromethane, and chloroform, both arising from dimerization of the radical derived from solvents, and also by the production of α-halostilbenes in carbon tetrachloride and bromotrichloromethane resulting from abstraction of a halogen atom by the 1,2-diphenylvinyl radical; this is further supported by the finding that the presence of 2,2-diphenyl-1-picrylhydrazyl completely suppressed the formation of α-chlorostilbene in the decomposition of the *trans*-peroxide in carbon tetrachloride. The sole production of the α-phenylcinnamic acid of the same geometrical configuration as the starting peroxide or the peroxy-ester shows that neigher the starting materials nor the intermediate α-phenylcinnamoyloxy radicals isomerize to their isomeric forms under the reaction conditions employed. Separate experiments also confirmed that no isomerization of stilbenes or α-halostil-

TABLE 3. ISOMER RATIO OF α-CHLOROSTILBENE FROM DECOMPOSITION OF *t*-BUTYL *trans*- AND *cis*-α-PHENYLPEROXYCINNAMATE IN CARBON TETRACHLORIDE[a]

Temp. °C	100	110	80	80
Peroxy-ester	*trans*-II	*cis*-II	*trans*-II	*cis*-II
(*cis*-PhCH=CPhCl)/(*trans*-PhCH=CPhCl)	73 : 27[b]	76 : 24[b]	84 : 16[c]	77 : 23[c]

a) Initial concentrations of peroxy-ester were between 0.06 and 0.1 M. Decompositions were carried out in sealed tubes. The yields of α-chlorostilbenes were between 30 and 40%.
b) Mean of triplicate runs.
c) Mean of duplicate runs.

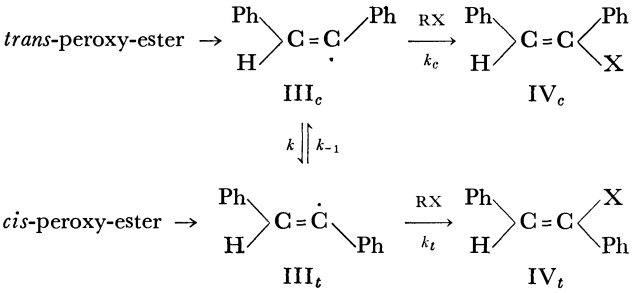
benes took place under the reaction conditions used or in the work-up process. These observations enable us to discuss the stereochemical behaviour of intermediate 1,2-diphenylvinyl radicals by examining the isomer ratio of α-halostilbenes formed in carbon tetrachloride or bromotrichloromethane.

The *trans*- and *cis*-peroxide were found to give more complex mixtures of products than the peroxy-esters. Moreover, the *cis*-peroxide, compared with the *trans*-peroxide, afforded much lower yields of those products which could arise from the reaction of 1,2-diphenylvinyl radicals with solvents. *cis*- and *trans*-Stilbene were produced from the peroxides, not only in solvents carrying a transferable hydrogen atom such as chloroform, cumene, and triethylsilane, but also, though in smaller yields, in solvents containing no hydrogen atom such as carbon tetrachloride and bromotrichloromethane, indicating that the stilbene was not exclusively formed by abstraction of a hydrogen atom by 1,2-diphenylvinyl radicals from solvents. Diphenylacetylene and deoxybenzoin were also shown to arise from both *cis*- and *trans*-peroxides in various solvents. *dl*-1,2-Dibenzoyl-1,2-diphenylethane resulted from the *cis*-peroxide. Some of these compounds might have been formed as cage reaction products or the products from the decomposition of 1,2-diphenylvinyl 1,2-diphenylethylenecarbonyl carbonate.

Decomposition of *cis*- and *trans*-peroxy-ester in carbon tetrachloride, on the other hand, gave neither stilbene nor 1,2-dibenzoyl-1,2-diphenylethane, although diphenylacetylene was formed in lower yield than in the case with the peroxides, showing that the peroxy-esters decompose with less complexity than the peroxides.

Isomer Ratios of Olefins Resulting from Decomposition. Decomposition of *t*-butyl *cis*- or *trans*-α-phenylperoxycinnamate in carbon tetrachloride at 110°C gave α-chlorostilbenes in an approximately equal ratio of the *cis*- to *trans*-isomer, *viz.*, 73:27 from the *trans*- and 76:24 from the cis-peroxy-ester. Decreasing the reaction temperature to 80°C, however, resulted in different *cis* to *trans* ratios of the chloro-olefins: 84:16 from the *trans*- and 77:23 from the *cis*-peroxy-ester. These findings clearly exclude the possibility that the 1,2-diphenylvinyl radical is directly produced in linear form by homolysis of the peroxy-esters, because the linear radical would lead to the same *cis* to *trans* ratio of α-chlorostilbenes, irrespective of the configuration of the peroxy-ester decomposed. Thus, the results are readily explained by assuming that the 1,2-diphenylvinyl radical exists in two bent forms corresponding to *cis* and *trans* configurations in line with the prevalent view on the structure of various vinylic radicals,[2-8,18] and the reaction steps are formulated in the following scheme (RX=CCl_4).

Both forms of the 1,2-diphenylvinyl radical, at 110°C, rapidly isomerize to each other to attain equilibrium before abstraction of a chlorine atom from carbon tetrachloride, so that the same *cis* to *trans* ratio of the the products is obtained irrespective of the configuration of the starting material. Singer and Kong concluded



Scheme 1.

such a rapid equilibration for this radical on the basis of the finding that the ratio of *cis*- to *trans*-stilbene resulting from decomposition of both *t*-butyl *cis*- and *trans*-α-phenylperoxycinnamate in cumene, cyclohexane or toluene at 110°C were not dependent on the configuration of the peroxy-esters.[4b] However, it is evident that at 80°C, the equilibration of these radicals is sufficiently slow in rate for the abstraction from carbon tetrachloride to compete with it; the *trans* peroxy-ester, therefore, gave a higher *cis* to *trans* ratio of α-chlorostilbenes (84:16) than the *cis* peroxy-ester (77:23), the configuration of the starting peroxy-ester being partly reflected in the isomer ratio.

Decomposition of *cis*-α-phenylcinnamoyl peroxide in carbon tetrachloride gave mixtures of *cis*- and *trans*-α-chlorostilbene in *cis* to *trans* ratios of 43:57 at 60°C and of 75:25 at 80°C, while the *trans*-peroxide gave *cis* to *trans* ratios of 97:3 at 60°C, 99:1 at 80°C, and 89:11 at 110°C; it is apparent that with decreasing temperature these peroxides tend to yield α-chlorostilbene predominantly of the same configuration as the starting peroxide. The same tendency was also observed in the decomposition at 60°C in some other solvents (Table 2), indicating that, at 60°C, the interconversion between *cis*- and *trans*-1,2-diphenylvinyl radicals is not so rapid as to complete the equilibration before abstraction.

In a previous paper,[6] decomposition of *trans*- or *cis*-cinnamoyl peroxide at 77°C was shown to afford mixtures of *trans*- and *cis*-β-chlorostyrene in the same *cis* to *trans* ratio in carbon tetrachloride, but mixtures of *trans*- and *cis*-β-bromostyrene in different *cis* to *trans* ratios in bromotrichloromethane, the *cis*-peroxide giving a higher *cis* to *trans* ratio. These findings led to the conclusion that the isomerization between *cis*- and *trans*-styryl radicals takes place rapidly enough to be complete before the abstraction of a chlorine atom from carbon tetrachloride, but its rate is comparable with that of the abstraction of a bromine atom from bromotrichloromethane. However, in contrast with this, the isomerization between isomeric 1,2-diphenylvinyl radicals at 60°C or 80°C is not so rapid as to complete equilibration before reaction with various solvents. This difference between the styryl and 1,2-diphenylvinyl radical is attributed to the presence, in the latter, of an α-phenyl group, which is heavier than the α-hydrogen in the former, the phenyl group moving less rapidly than the hydrogen in the isomerization step. This result is in line with the observation by Singer and Kong that 1-bromo-2-phenylvinyl radicals do not equilibrate at 110°C, owing to the presence of a heavier α-bromine atom,[4d] and with the fact that, according to the electron spin

18) O. Simamura, "Topics in Stereochemistry," Vol. 4, ed. by N. L. Allinger and E. L. Eliel, Wiley-Interscience, New York (1969), p. 21.

resonance spectroscopy, at −172°C, 1-methylvinyl radicals do not isomerize,[2] whereas unsubstituted vinyl radicals isomerize.[2,3]

Notwithstanding the above arguments, the possibility is not ruled out that a linear form of 1,2-diphenylvinyl radical corresponding to a state of energy minimum exists between those two bent forms in which the radicals are initially produced and which also correspond to energy minima. If the linear form exists as well, the *cis* to *trans* product ratio should be the same irrespective of the configuration of the starting material or reflect its difference according to whether the equilibration among the three forms of the radical is rapid or slow.

The Difference in Reactivity between cis- *and* trans-*1,2-Diphenylvinyl Radicals; the Steric Effect.* By reference to Scheme 1 ($RX=CCl_4$) the product isomer ratio and the four reaction rate constants are correlated, so that a quantitative measure of the difference in reactivity between *cis*- and *trans*-1,2-diphenylvinyl radicals may be obtained on the assumption that a linear form of this radical is not involved. The ratio of *cis*- to *trans*-α-chlorostilbene formed from *trans*-peroxy-ester, $(IV_c/IV_t)_{yield}$, which may be denoted by C, is expressed by the use of the steady state approximation as follows:

$$C = (IV_c/IV_t)_{yield} = k_c/k_t \cdot \{k_{-1} + k_t[CCl_4]\}/k \quad (1)$$

Similarly, the ratio of *trans*- to *cis*-olefin, arising from *cis*-peroxy-ester, $(IV_t/IV_c)_{yield}$, which may be denoted by T, isgiven as follows:

$$T = (IV_t/IV_c)_{yield} = k_t/k_c \cdot \{k + k_c[CCl_4]\}/k_{-1} \quad (2)$$

Elimination of the concentration of carbon tetrachloride $[CCl_4]$ from Eqs. (1) and (2) leads to

$$(T + 1)/(C + 1) = k_t/k_c \cdot k/k_{-1} \quad (3)$$

When the isomeric vinyl radicals III_c and III_t equilibrate, we have $k/k_{-1}=[III_t]/[III_c]=K_{eq}$ where K_{eq} denotes the equilibrium constant of interconversion between these radicals. In the absence of any evidence available for assessment of the equilibrium constant K_{eq}, this value may be assumed to be approximated by the equilibrium constant of isomerisation between *trans*- and *cis*-stilbene, since it does not seem unreasonable that the steric effect caused by an odd electron is not significantly different from that caused by a hydrogen atom. The value for K_{eq} or k/k_{-1} is therefore estimated at 100 and 180 at 110°C and 80°C, respectively, on the basis of the data reported for stilbenes.[19]

Substitution of the observed values of C and T and of the estimated values of k/k_{-1} in equation 3 gives $k_t/k_c = 1.2\times10^{-3}$ at 80°C and 3.5×10^{-3} at 110°C. Thus, the *cis* radical III_c abstracts a chlorine atom from carbon tetrachloride several hundred times faster than the *trans* radical III_t; evidently, this difference is attributable to a crowded situation around the radical centre of the *trans* radical, which places steric hindrance to an incoming molecule of carbon tetrachloride.

The above ratios of the rate constants at 80°C and 110°C correspond to the difference in activation free energy of 4.7 and 5.1 kcal/mol, respectively, since $\Delta G_t^{\ddagger} - \Delta G_c^{\ddagger} = -2.3RT\cdot\log(k_t/k_c)$. These values are larger than what one would expect on the ground of the presence of a phenyl group at the β-position, since the *cis*-styryl radical reacts with carbon tetrachloride at 77°C with an activation free energy higher by 1.0 kcal/mol than the *trans*-styryl radical, the cause of this being evidently steric retardation exerted by the *cis*-phenyl group.[8,16] The higher value of $\Delta G_t^{\ddagger} - \Delta G_c^{\ddagger}$ for the 1,2-diphenylvinyl radical is explained by the fact that the disposition of the α-phenyl group is different between III_c and III_t. In III_t the α-phenyl lies in the plane of the double bond, so that its ortho-hydrogen exerts steric hindrance toward an approaching carbon tetrachloride molecule in addition to that exerted by the β-phenyl group, whereas, in III_c, the α-phenyl is twisted away from the plane of the C=C double bond because of the β-phenyl group on the same side of it,[20] so that the hindrance due to the ortho-hydrogen is absent.

Experimental

Preparation of trans-α-*Phenylcinnamoyl Peroxide. trans*-α-Phenylcinnamic acid, prepared by the usual procedure,[21] was treated with six molar equivalents of thionyl chloride in dry benzene at room temperature for 52 hr and the resulting *trans*-α-phenylcinnamoyl chloride was recrystallized from petroleum ether (boiling below 40°C), mp 42.5—44°C (lit,[22] mp 47—48°C). This chloride (3.2 g, 0.0132 mol) was added with stirring to a mixture of sodium peroxide (2.4 g, 0.031 mol), ice (15 g), water (15 m*l*), and petroleum ether (40 m*l*) cooled in an ice bath. Stirring was continued for 5 hr, and the precipitate was filtered off by suction, washed repeatedly with cold water, and dried between sheets of filter paper in a vacuum for 2 hr at 8°C to afford 2.0 g (68%) of the required peroxide (purity, 94.0% as determined by iodometric titration). It decomposed at 52—55°C with gas evolution. IR($\nu_{C=O}$): 1750 and 1772 cm^{-1} (Nujol). NMR: τ 2.1 (singlet, 1H) and 2.8 (multiplet, 10H); *trans*-α-phenylcinnamic acid shows peaks at τ 2.1 (singlet, 1H) and 2.7 (multiplet, 10H).

Preparation of cis-α-*Phenylcinnamoyl Peroxide.* This peroxide was prepared according to Greene and Kazan's procedure.[9] To a cold stirred solution of *N,N'*-dicyclohexylcarbodiimide (2.0 g, 0.01 mol) and anhydrous solution (10 m*l*) of hydrogen peroxide in ether (5M) was added dropwise a solution of *cis*-α-phenylcinnamic acid[23] (2.2 g, 0.01 mol) in dichloromethane (25 m*l*). The mixture was stirred at 0°C for 3 hr and then filtered by suction through a sintered glass funnel, and the *N,N'*-dicyclohexylurea collected in the funnel was slurried three times with 20 m*l* portions of cold dichloromethane and the washings were added to the main filtrate. This filtrate was added with 60 m*l* of cold ether and was

19) The equilibrium ratio of *trans*- to *cis*-stilbene of 96 : 4 at 200°C (T. W. J. Taylor and A. R. Murray, *J. Chem. Soc.*, **1938**, 2078). corresponds to the difference in free energy of $\Delta G=3.03$ kcal/mol. This value and the difference in heat of hydrogenation between *cis*- and *trans*-stilbene, 5.7 kcal/mol (R. B. Williams, *J. Amer. Chem. Soc.*, **64**, 1395 (1942).), which corresponds to ΔH, give the difference in entropy of 5.7 e.u. These values enable ΔG, and, accordingly, equilibrium constants at given temperatures to be estimated.

washed in succession with three 25 m*l* portions of cold saturated ammonium sulphate solution, two 25 m*l* portions of cold 10% sodium carbonate solution, and two 25 m*l* portions of cold aqueous saturated sodium chloride solution. The organic layer was dried over anhydrous sodium sulphate and the solvent was completely removed under reduced pressure at 0°C in a rotary film evaporator. The remaining *cis*-α-phenylcinnamoyl peroxide (0.35 g, yield 17%) was pale yellowish oil at room temperature and solidified at −35°C (purity, about 30% as determined by iodometry). It was extremely unstable at room temperature and decomposed with gas evolution, and attempted recrystallization from several solvents was unsuccessful. IR($\nu_{C=O}$): 1779 and 1795 cm^{-1} (Nujol).

Preparation of t-*Butyl* trans-α-*phenylperoxycinnamate.* This compound was prepared according to the procedure of Milas and Surgenor.[24] To a cold stirred mixture of *t*-butyl hydroperoxide (4.5 g, 0.05 mol) and potassium hydroxide (2.8 g, 0.05 mol) in 60 m*l* of water was added dropwise a solution of *trans*-α-phenylcinnamoyl chloride (8.0 g, 0.034 mol) in 60 m*l* of ether in 10 min, and the mixture was stirred for a further 22 hr at room temperature. The reaction mixture was then washed with three 150 m*l* portions of 5% aqueous sodium carbonate and dried over anhydrous sodium sulphate. After removing ether, the remaining white material was recrystallized from ether–petroleum ether to give 5.0 g (50% yield) of the required peroxy-ester, mp 107—108°C (purity, 99% as determined by iodometric titration. Found: C, 76.89; H, 6.80%; Calcd for $C_{19}H_{20}O_3$: C, 77.03; H, 6.76%). Its spectroscopic data (IR and NMR) were in accord with those reported by Singer and Kong.[4b]

Preparation of t-*Butyl* cis-α-*phenylperoxycinnamate.* *cis*-α-phenylcinnamic acid (5.0 g, 0.022 mol) was treated with thionyl chloride (20.0 g, 0.17 mol) in dry benzene at room temperature for 49 hr in the dark. Volatile matter was removed from the resulting mixture in a rotary film evaporator, and the remaining yellowish matter was repeatedly recrystallized from petroleum ether to give *cis*-α-phenylcinnamoyl chloride, mp 66.0—68.0°C (Found: C, 73.74; H, 4.62%; Calcd for $C_{15}H_{11}OCl$: C, 74.08; H, 4.53%). IR($\nu_{C=O}$): 1740 cm^{-1} (Nujol). NMR: τ 2.60 (multiplet, 10H) and 3.16 (singlet, 1H). The required peroxy-ester was prepared from this chloride in a similar way to the preparation of the *trans* isomeride. The *cis*-peroxy-ester, mp 78—80°C (purity, 99%), obtained in 60% yield, showed satisfactory spectroscopic data[4b] (IR and NMR) and elementary analysis (Found: C, 77.05; H, 6.95%; Calcd for $C_{19}H_{20}O_3$: C, 77.03; H, 6.76%).

Authentic Materials and Solvents. The authentic samples, used for comparison with reaction products, of *cis*- and *trans*-α-chlorostilbene, *cis*- and *trans*-α-bromostilbene, *cis*- and *trans*-stilbene, deoxybenzoin, diphenylacetylene, and bicumyl *etc.* were prepared in the usual way. Carbon tetrachloride (Wako, special grade) was used without further purification. Commercial chloroform was shaken with concentrated sulphuric acid, washed with 5% aqueous sodium carbonate and water, dried over calcium chloride and distilled. Cumene was shaken with concentrated sulphuric acid, washed with water and 5% aqueous sodium carbonate, dried over calcium chloride, and distilled over sodium wire. Bromotrichloromethane (Eastman Kodak) was distilled in the dark immediately before use. Triethylsilane was prepared from trichlorosilane and ethylmagnesium bromide.[25]

Decomposition of trans-α-*Phenylcinnamoyl Peroxide at Room Temperature.* The infrared spectrum of this peroxide was examined in five times amount of Nujol at 24.5°C at intervals with a Hitachi EPI-G2 infrared spectrophotometer. The spectrum in the carbonyl region changed during 258 hr as shown in Fig. 1. Another specimen of the same peroxide was set aside at 24.5°C for 258 hr without apparent change, but it displayed the same infrared spectrum as the above sample in Nujol after 258 hr, and was further shown, by iodometric titration, to contain only 2.8% of the active oxygen initially present in the peroxide. This material (0.87 g) was dissolved in 20 m*l* of ether and extracted with three 200 m*l* portions of 5% aqueous sodium carbonate to afford 0.224 g of *trans*-α-phenylcinnamic acid on acidification of the extract. Removal of ether from the organic layer gave 0.665 g of a yellowish solid, and it was recrystallized twice from chloroform–petroleum ether to give 1,2-diphenylvinyl *cis*-1,2-diphenylethylenecarbonyl carbonate, mp 127—135°C (Found: C, 80.88; H, 4.71%; Calcd for $C_{30}H_{22}O_4$: C, 80.72; H, 4.93%); IR($\nu_{C=O}$): 1810 and 1740 cm^{-1} (Nujol).

Decomposition of cis-α-*phenylcinnamoyl Peroxide at Room Temperature.* To a cold solution of *cis*-α-phenylcinnamoyl chloride (2.0 g, 8.2 mmol) in 30 m*l* of tetrahydrofuran were added dropwise 1.0 g (8.7 mmol) of 30% aqueous hydrogen peroxide and 2 m*l* of aqueous sodium hydroxide (0.33 g, 8.3 mmol), and the mixture was stirred at 0°C for 26 hr. Cold dichloromethane (50 m*l*) was added. It was then washed with three 100 m*l* portions of cold water and three 100 m*l* portions of 5% sodium hydrogen carbonate, and dried over anhydrous sodium sulphate. The solvent was removed at 0°C in a rotary film evaporator, the remaining yellowish oil was dissolved in a small amount of dichloromethane, methanol was added to the solution at 10°C and this was cooled to −78°C to deposit a white solid. The mixture was centrifuged at −78°C and the supernatant liquid removed with a pipette; the remaining solid was washed with cold methanol and dried *in vacuo* at −78°C to give 1.5 g of a white solid. This was found to contain only a trace of active oxygen by iodometric titration, and showed absorption bands at 1803 and 1740 cm^{-1} (in carbon tetrachloride) characteristic of the alkyl alkanecarbonyl carbonate. When a portion of this substance was added to dichloromethane at room temperature in an attempt at recrystallization, gas evolved vigorously indicating its decomposition; work-up of the mixture gave *cis*-α-phenylcinnamic anhydride, characterized by mp and mixed mp 149.5—150°C, and comparison of its spectrum with an authentic specimen. Hydrolysis of the above substance by heating with potassium hydroxide (5 g) for an hour in a mixture of 40 m*l* of ethanol and 20 m*l* of water afforded *cis*-α-phenylcinnamic acid and trace of diphenylacetylene.

General Procedure for Thermal Decomposition. In a round-bottomed three-necked flask fitted with a gas inlet, a stopper, and a reflux condenser, to which were connected a trap cooled with dry ice–ethanol, a magnesium perchlorate tube and an Ascarite tube, in the order mentioned, was placed a measured amount of a solvent (60—100 molar excess of the peroxide to be added). This was heated under reflux in a slow stream of nitrogen for an hour and cooled down to room temperature; then a weighed amount of the peroxide was added. The resulting solution was allowed to stand under nitrogen in a thermostat kept at a specified temperature until the peroxide had been completely decomposed (6—10 hr). In the decomposition of *cis*-α-phenylcinnamoyl peroxide which is unstable, reaction solutions were prepared by dissolving in a measured amount of a solvent the *cis*-peroxide immediately after it was obtained by removal of the solvent from the reaction mixture for

24) N. A. Milas and D. M. Surgenor, *J. Amer. Chem. Soc.*, **68**, 642 (1946).

25) H. Ishii, "Yukikagobutsu Goseiho," Vol. IV, Gihodo, Tokyo (1966), p. 107.

the preparation of this peroxide, and the concentration of the peroxide in the solution was determined by iodometry.

In decompositions conducted at higher temperatures, a solution of the peroxide or peroxy-ester (0.3—0.5 g) in 20 m*l* of a solvent was placed in a small pyrex ampoule which was connected to a vacuum line, degassed by three cycles of the usual procedure consisting of solidification by chilling, evacuation and thawing, and sealed at 3×10^{-3} mmHg. The ampoule was kept in a thermostat until the peroxide had been completely decomposed.

Product Analysis. A reaction mixture, transferred to a separating funnel with ether, was shaken with three 100 m*l* portions of 5% aqueous sodium carbonate to isolate and determine α-phenylcinnamic acid. The organic layer was dried over anhydrous sodium sulphate and ether was distilled off. The residue was subjected to vpc (Perkin-Elmer 154-D with a column of silicone oil) for determination of products; products in some runs were isolated by either column or gas chromatography and identified by comparison with authentic specimens.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1118—1121 (1971)

Oligomerization of Isoprene by Vanadium Catalysts

Yasuzo UCHIDA, Ken-ichi FURUHATA, and Hisayasu ISHIWATARI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 5, 1970)

Oligomerization of isoprene by the catalyst system consisting of $VO(OEt)_3$ and organoaluminum compounds was studied. Isoprene was oligomerized to a mixture of dimers, trimers and higher oligomers by $VO(OEt)_3$–Et_2AlCl catalyst system. 2,6-Dimethyl-1,*trans*-3,6-octatriene was the main dimer of isoprene in this reaction. The addition of tetrahydrofuran, dioxane, triphenylphosphine, bis-diphenylphosphinoethane, triethylamine or tetramethylethylenediamine to this catalyst system raised the reaction rate and the selectivity for the dimer at lower donor/$VO(OEt)_3$ molar ratios but suppressed the reaction at higher molar ratios. By $VO(OEt)_3$–Et_3Al catalyst system, isoprene was converted to a liquid polymer and by $VO(OEt)_3$–$EtAlCl_2$ catalyst system, it was cyclopolymerized to an insoluble polymer. Structures of two new oligomers of isoprene were also reported.

The oligomerization of isoprene to linear oligomers of head-to-tail structures is of great interest for the synthesis of raw materials of terpenic compounds. A linear dimer of isoprene, 2,6-dimethyl-1,3,6-octatriene which is formed by the head-to-tail addition of isoprene, was formed by titanium,[1] chromium,[2] or nickel[3] based catalysts but by these catalysts cyclic dimers were also formed. Palladium based catalyst[4] gave selectively 2,7-dimethyl-1,3,7-octatriene from isoprene but this compound has a tail-to-tail structure.

We reported previously the oligomerization of isoprene by zirconium[5] and hafnium[6] based catalysts. By these catalysts, 2,6-dimethyl-1,*trans*-3,6-octatriene was formed without six- or eight-membered cyclic dimers, and in the case of zirconium based catalysts, the addition of electron donors such as triphenylphosphine to the catalyst system raised the selectivity for this dimer to over than 90%.

In this paper we report the oligomerization of isoprene by the catalyst system consisting of ethyl orthovanadate and organoaluminum compounds.

Experimental

Reagents. Isoprene, benzene, tetrahydrofuran, 1,4-dioxane, triethylamine, *N,N,N′,N′*-tetramethylethylenediamine and tetrahydrothiophene were dried and distilled under a nitrogen stream.

Organoaluminum compounds were purified by distillation and were diluted in benzene.

Ethyl orthovanadate synthesized by the reported method[7] was diluted in benzene and stored in a refrigerator.

1,2-Bisdiphenylphosphinoethane was synthesized by the reported method.[8]

Commercial triphenylphosphine was used without further purification.

Reaction Procedure. In a typical reaction, to a 20 m*l* glass ampule filled with nitrogen, 3.75 g of benzene, 50 mmol of isoprene, 0.5 mmol of ethyl orthovanadate (14.3 wt% benzene solution) and 6.0 mmol of diethylaluminum chloride (14.8 wt% benzene solution) were charged in this order with syringes under a nitrogen stream. The total amount of benzene was controlled to be 8.3—8.5 g. The ampule was then sealed and kept at 70°C for 1 hr.

Analysis. The gas chromatography was used for calculating the conversion percent of isoprene and quantitative analysis of products. A 2 m stainless steel column,

8) W. Hewertson and H. R. Watson, *J. Chem. Soc.*, **1962**, 1490.

4 mm in diameter, packed with polydiethylene glycol succinate on Shimalite was used. Operation conditions: column temperature, 120°C and 180°C for dimers and trimers, respectively; flash evaporator, 300°C; carrier gas(helium) speed, 30 ml/min. Benzene was used as an internal standard.

Infrared spectra were taken using a Hitachi infrared spectrophotometer EPI-S2.

Nuclear magnetic resonance spectra were taken using a JMN-4H-100(Japan Electron Optics Laboratory Co.).

Results and Discussion

Oligomerization of Isoprene by $VO(OEt)_3$—Et_2AlCl Catalyst System. Isoprene was oligomerized to a mixture of dimers, trimers and higher oligomers by this catalyst system. Two dimers were found on gas chromatography and the structure of the main dimer was determined to be 2,6-dimethyl-1,*trans*-3,6-octatriene by comparing the infrared spectrum with that of the pure sample obtained by the zirconium catalyst.[5] The yield of another dimer was less than 14% of that of 2,6-dimethyl-1,*trans*-3,6-octatriene. As shown from the gas chromatographic data, the mixture of trimers was consisted of more than six isomers in which four were predominantly formed.

The Effect of the Al/V Molar Ratio: The effect of the molar ratio of diethylaluminum chloride to ethyl orthovanadate is shown in Fig. 1. Reactions were carried

out at 70°C for 1hr. At the molar ratio 4, the reaction solution was very viscous and no low oligomers were formed. A yellow, wax-like polymer of isoprene obtained at this ratio contained 67% of *cis*-1,4-, 25% of *trans*-1,4-, 6% of 3,4- and 2% of 1,2-structures.[9]

The maximum yield of 2,6-dimethyl-1,*trans*-3,6-octatriene was accomplished when the molar ratio of diethylaluminum chloride to ethyl orthovanadate was 12. The yield and the selectivity for this dimer at this ratio were 23.3% and 33.4%, respectively. The infrared spectrum of the mixture of higher oligomers obtained at this ratio showed absorptions due to methyl and methylene groups (2960, 2920, 2850, 1450, and 1380 cm^{-1}), a three-substituted double bond (1670 and 840 cm^{-1}), a terminal methylene group (1650 and 890 cm^{-1}) and a *trans* two-substituted double bond (980 cm^{-1}, weak). At higher molar ratios, the conversion of isoprene and the yield of dimers slightly decreased.

The Effect of Electron Donors: The effect of electron donors on the oligomerization by this catalyst system was studied using monodentate and potentially bidentate compounds (Figs. 2—5). The reactions were carried out at 70°C for 1 hr keeping the molar ratio of diethylaluminum chloride to ethyl orthovanadate constant at 12.0. The addition of tetrahydrofuran, 1,4-dioxane, triethylamine, *N,N,N',N'*-tetramethylethylenediamine,

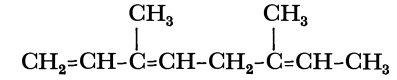
triphenylphosphine or 1,2-bis-diphenylphosphinoethane raised the reaction rate at lower donor/$VO(OEt)_3$ molar ratios. The selectivity for 2,6-dimethyl-1,*trans*-3,6-octatriene was also raised to 50—60%. The reactions were suppressed at higher molar ratios. Tetrahydrothiophene suppressed the reaction at every molar ratio.

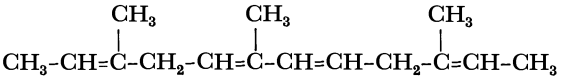
Reaction of Isoprene by $VO(OEt)_3$—Et_3Al or $VO(OEt)_3$—$EtAlCl_2$ Catalyst System. By the catalyst system consisting of ethyl orthovanadate and triethylaluminum, isoprene was consumed nearly completely and was converted into a liquid polymer in the reaction at 40—100°C for 1 hr. Only small amount of the dimer (less than 1.3%) was formed at 40—70°C. The infrared spectrum of the brown liquid polymer obtained in the reaction at 70°C for 1 hr and at the molar ratio of triethylaluminum to ethyl orthovanadate 5—10 showed absorptions due to methyl and methylene groups (2950, 2925, 2850, 1455, and 1380 cm^{-1}), a terminal methylene group (1790, 1650, and 890 cm^{-1}), three-substituted and *trans* double bonds (1670, 970, 840, and 810 cm^{-1}) and a vinyl group (910 cm^{-1}, sh). It contained about 55% of 1,4-, 40% of 3,4- and 5% of 1,2-structures.[9]

The catalyst system consisting of ethyl orthovanadate and ethylaluminum dichloride caused the vigorous polymerization of isoprene at room temperature. The infrared spectrum of the insoluble polymer obtained showed only methyl and methylene absorption (2925, 2850, 1455, and 1380 cm^{-1}) and did not show any absorption due to carbon-carbon double bonds. This spectrum was idential with that of the polymer formed by the cationic cyclopolymerization of isoprene by ethylaluminum dichloride.[10]

Structures of New Oligomers of Isoprene. The minor dimer formed by the catalyst consisting of ethyl orthovanadate and diethylaluminum chloride had the same gas chromatographic retention times as the dimer obtained in a small amount by zirconium[5] and hafnium[6] based catalysts. The mixture of dimers obtained by the zirconium catalyst was fractionated by distillation and the sample of the minor dimer (92% purity, containing 8% of 2,6-dimethyl-1,*trans*-3,6-octatriene) was analyzed with the use of infrared and nuclear magnetic resonance spectra. The infrared spectrum showed absorptions due to methyl and methylene groups (2965, 2925, 2850, 1440, and 1380 cm^{-1}), a conjugated double bond (1610 cm^{-1}), a vinyl group (1795, 1645, 990, and 895 cm^{-1}), a three-substituted double bond (1670 and 810 cm^{-1}) and a weak absorption at 960 cm^{-1} due to 2,6-dimethyl-1,*trans*-3,6-octatriene. The nuclear magnetic resonance spectrum showed the presence of three methyl groups (τ=8.41, doublet; 8.38, singlet; 8.24, singlet), one methylene group between two double bonds (τ=7.17, doublet), one vinyl group (τ=5.17—4.87, three absorptions; 3.68, double doublet) and two olefinic protons (τ=4.90—4.55, complex absorptions). Thus the structure of this compound is considered to be 3,6-dimethyl-1,3,6-octatriene.



Relative retention times (retention time of benzene =1) of four main trimers obtained by the catalyst system consisting of ethyl orthovanadate and diethylaluminum chloride were 4.1, 4.6, 6.8, and 9.9 (operation conditions of gas chromatography, see experimental part). Two isomers (relative retention time, 6.8 and 9.9) were gas chromatographically identical with those obtained by the zirconium based catalyst and one isomer (relative retention time, 9.9) was assumed to be 3,6,10-trimethyl-2,5,*trans*-7,10-dodecatetraene.[5]



trans

The mixture of trimers obtained by the zirconium catalyst was fractionally distilled and the isomer with the relative retention time 6.8 was obtained in a pure

10) I. Koessler, M. Stolka, and K. Mach, *J. Polym. Sci. Pt C*, **No. 4**, 977 (1963).

state. The infrared spectrum of this isomer showed absorption due to methyl and methylene groups (2970, 2925, 2850, 1455, 1445, and 1380 cm^{-1}), a conjugated double bond (1610 cm^{-1}), a *trans* double bond (1670 and 970 cm^{-1}), a terminal methylene group (1780, 1650, and 885 cm^{-1}) and three-substituted double bonds (1670, 840, and 810cm^{-1}). Its nuclear magnetic resonance spectrum showed the presence of four methyl groups(τ= 8.45, doublet; 8.34, singlet, two methyl groups; 8.20, singlet), two adjacent methylene groups between doubl bonds (τ=7.98—7.90), one methylene group between double bonds (τ=7.20, doublet), one terminal methyl group (τ=5.16, singlet), two olefinic protons (τ=4.92 —4.70, complex absorptions) and one *trans* two-substituted double bond (τ=4.48, double triplet; 3.88, doublet). Thus the structure of this isomer is considered to be 2,6,10-trimethyl-1,*trans*-3,6,10-dodecatetraene or 2,7,10-trimethyl-1,*trans*-3,7,10-dodecatetraene.

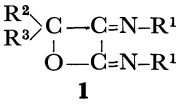
The Thermal Rearrangement and Degradation of 2,3-Bis(alkylimino)oxetane

Takeo SAEGUSA, Naotake TAKA-ISHI, and Yoshihiko ITO
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 20, 1970)

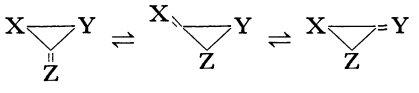
The thermal rearrangement of 2,3-bis(alkylimino)oxetane (**1**) was investigated. At 200°C, 2,3-bis(secondary alkylimino)oxetane was converted into 3-imidazolin-5-one (**8**). 2,3-Bis(tertiary alkylimino)oxetane was stable at 200°C, but it was rearranged at 300°C to a cyclobutanone derivative (**18**). A mechanism involving the β-lactam intermediate (**12**) (**17**) formed by the Chapman rearrangement of **1** was proposed.

This paper will describe the thermal rearrangement and the accompanying decomposition of 2,3-bis(alkylimino)oxetane (**1**).



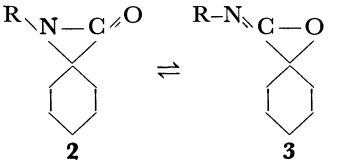
1

The rearrangement of **1** constitutes a significant extension of the molecular rearrangement of methylenecyclopropane derivatives with hetero atoms in their framework (Eq. (1)), which has recently attracted considerable attention.[1,2]



(1)

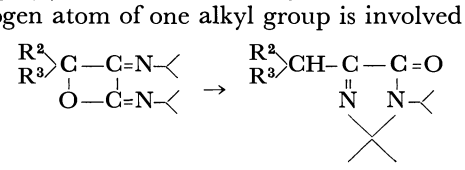
Among several examples, the tautomeric interconversion of three-membered α-lactam (**2**) and imino-oxirane (**3**) reported by Sheehan and Lengyel[2] (Eq. (2)) is taken to be especially closely related to the present study.



2 **3** (2)

Further, the imino-oxirane–lactam rearrangement has been assumed in the following scheme of the $BF_3 \cdot OEt_2$-catalyzed reactions of isocyanides[3] with carbonyl compounds[4] to produce 2,3-diimino-oxetane (**1**).[3-7] The formation of a by-product, **7**, in the acid-catalyzed reaction of isocyanide with carbonyl compounds has been explained by a process involving the molecular rearrangement of **4** to **5** (Scheme 1).

The course of the thermal rearrangement of **1** is dependent upon the nature of alkyl groups (R^1) attached to the imino nitrogen atoms. When R^1 is a secondary alkyl, the rearrangement occurs at 200°C and takes the course of Eq. (3), in which the migration of the secondary hydrogen atom of one alkyl group is involved:



(3)

When R^1 is a tertiary alkyl in **1**, rearrangement requires a higher temperature of 300°C and involves the migration of the hydrogen of the alkyl group of R^2 or R^3 (Eq. (4)):

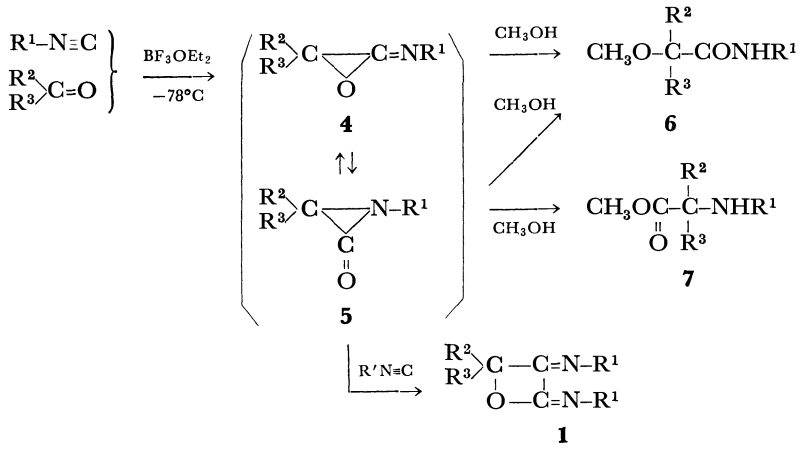
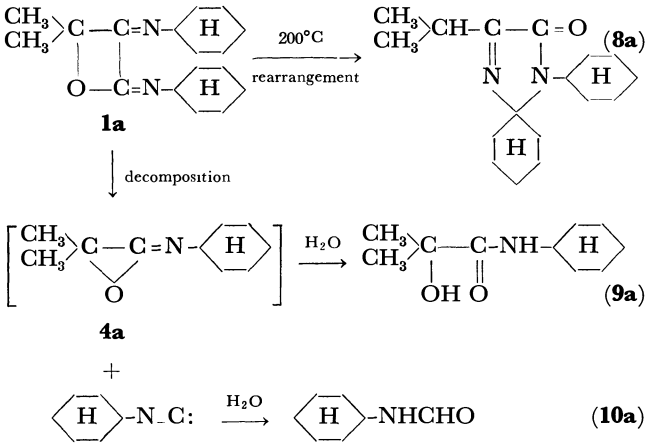


Scheme 1

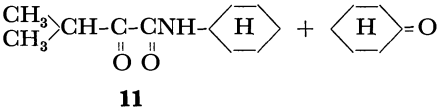
Results and Discussion

When **1a** (R^1=  , R^2=R^3=Me) was heated at 200°C, the rearranged compond **8a** was obtained in a yield of 43%, along with small amounts of 2-hydroxy-2-methyl-*N*-cyclohexylpropionamide (**9a**) and *N*-cyclohexylformamide (**10a**) (Scheme 2). The structure of **8a** was established on the basis of spectral analyses in addition to elemental analysis. The presence of the isopropyl group in **8a** was clearly demonstrated by the NMR spectrum. The absence of NH and OH groups was indicated by the IR spectrum. Other observations of the IR and NMR spectra as well as the results of the elemental analysis fit the structure **8a** (see Experimental Section).



Scheme 2

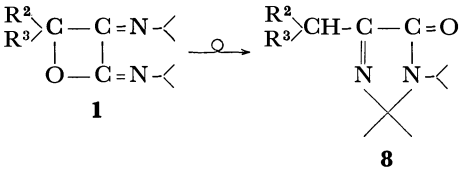
Additional support for the structure **8a** was given by acid hydrolysis, which produced an α-keto acid amide (**11**) and cyclohexanone:



11

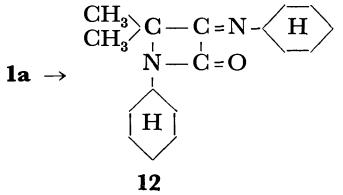
Some other homologues, **1b** (R^1=  , R^2=Me, R^3=Et) and **1c** (R^1=*i*-Pr, R^2=Me, R^3=Et), were also converted to the corresponding 3-imidazolin-5-one. The results are shown in Table 1. The employment of a solvent such as benzyl benzoate and diphenylmethane did not increase the yield of the rearranged product.

TABLE 1. REARRANGEMENT OF 2,3-BIS(SECONDARY ALKYLIMINO)OXETANE



Compound	-<	R^2	R^3	Solvent	Yield of **8** (%)
1a	- 	CH_3	CH_3	—	43
1b	- 	CH_3	C_2H_5	—	62
1c	$-CH(CH_3)_2$	CH_3	C_2H_5	—	49
1c	$-CH(CH_3)_2$	CH_3	C_2H_5	$C_6H_5CH_2OCOC_6H_5$	38
1c	$-CH(CH_3)_2$	CH_3	C_2H_5	$(C_6H_5)_2CH_2$	37

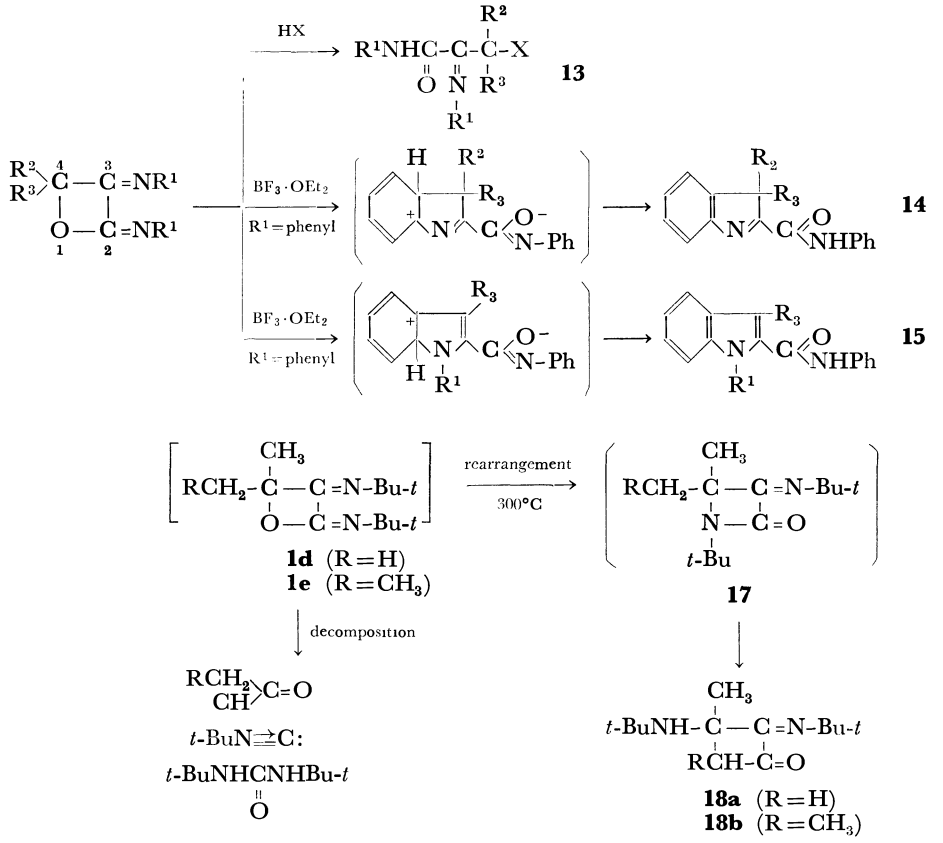
As to the reaction mechanism, the normal Chapman reaction may be thought of an as antecedent process which may produce a precursor intermediate (**12**).



12

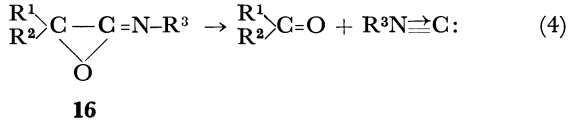
However, several attempts to isolate **12** were all unsuccessful. The structure of the product shows unequivocally the cleavage of the O–4C bond. The position of the bond-cleavage of the thermal rearrangement is the same as that of the cationic reaction of 2,3-bis-iminooxetane. The cationic ring-opening of **1** by acid, producing **13**, has been previously reported by Kabbe[8] and by us.[4] When the R^1 or R^2 of **1** is an aromatic ring, the BF_3-catalyzed bond-cleavage takes place at the O–4C bond

8) H. J. Kabbe, *Chem. Ber.*, **102**, 1410 (1969).



to produce indol derivatives, **14** and **15**.[9,10]

The formation of by-products of **9a** and **10a** may be explained by assuming the decomposition of **1a** into cyclohexyl isocyanide and an unstable imino-oxirane **4a**. The hydrolytic cleavage of **4a** affords **9a**, and the hydrolysis of cyclohexyl isocyanide gives rise to **10a**. The decomposition of **1a** depicted in Scheme 2 resembles the decomposition of imino-oxirane (**16**) to isocyanide and a carbonyl compound, as has been reported by Kagen and Lillien.[11] (Eq. (4)):



(4)

16

The bis(tert-alkylimino)homologue of **1** has no hydrogen at the α-carbon atom of nitrogen, and its thermal rearrangement takes a different route. At 200°C, **1d** (R^1=*t*-Bu, R^2=R^3=Me) is stable and does not rearrange. The rearrangement of **1d**, however, occurs at 300°C to produce **18a**. The concurrent decomposition of **1d** takes place to give *t*-butyl isocyanide, acetone, and di-*t*-butylurea.

The structure **18a** was established by a study of the spectral data and by elemental analysis. The presence of a secondary amino group was indicated in both the IR and the NMR spectra. In the NMR spectrum, the appearance of two new peaks at τ 6.50 (NH) and τ 6.28 (-CH_2)-was taken to support the structure **18a**. Similarly, **1e** (R^1=*t*-Bu, R^2=Me, R^3=Et) was converted into **18b**. The acetylation of **18b** with acetyl chloride gave the *N*-acetyl derivative. This result also supports the structure of **18b**.

As to the mechanism of the rearrangement of **1d** and **1e**, the structure of the product **18** may be taken to suggest a scheme *via* an intermediate of β-lactam (**17**) which is formed by the Chapman rearrangement of **1**. The cleavage of the bond between the amide nitrogen and the carbonyl carbon atom in **17** leads to the formation of **18**. The rearrangement **1d** and **1e** may be compared with the thermal reactions of the related compounds. Sheehan has reported[12,13] the rearrangement of triphenyl-substituted α-lactam (**19**) which proceeded the analogous bond cleavage. Singer and Barlett[14] have shown the photo- and thermal-decomposition of an iminooxetan (**20**) into the corresponding isocyanate (**21**) and olefin (**22**).

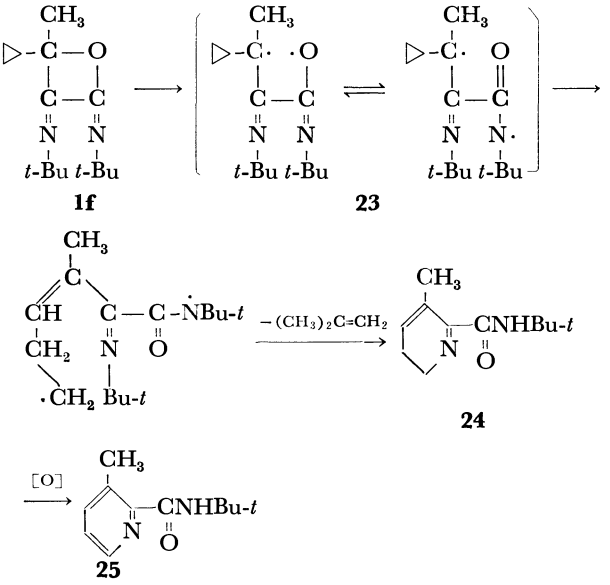
a) Distilled with partial degradation. b) Lit, bp 76°C/10 mmHg.[6]

A bis(alkylimino)oxetane with a cyclopropane ring at 4-C (**1f**, R^1=*t*-Bu, R^2=Me, R^3=cyclopropyl) rearranged *via* different way, one involving the cleavage of the cyclopropane ring. The product was a picolinamide (**25**).



In the above scheme, the first step is the cleavage of the carbon oxygen bond at the same position as that of Scheme 2. The ring-opening of the cyclopropane ring of **23** followed by the cyclization of the resulting radical, with the elimination of isobutene, will produce a dihydropicolinamide derivative (**24**), whose dehydrogenation then gives rise to **25**.

Experimental

Materials. 2,3-Bis(cyclohexylimino)-4,4-dimethyloxetane[4] (**1a**) and 2,3-bis(*t*-butylimino)-4,4-dimethyloxetane[6] (**1d**) have been previously reported. The other iminooxetanes were prepared by a procedure described previously.[4] The properties of the iminooxetanes are shown in Table 2.

Thermal Rearrangement of 2,3-Bis(cyclohexylinino)-4,4-dimethyloxetane (**1a**). At 200°C, 1.1 g (4 mmol) of **1a** was heated for 7 hr and then subjected to distillation. From the distillate, bp 150—153°C/8 mmHg, 1-cyclohexyl-4-isopropyl-2,2-pentamethylene-3-imidazolin-5-one(**8a**) was obtained in a yield of 43%.

Found: C, 73.07; H, 10.51; N, 9.76%. Calcd for $C_{17}H_{28}N_2O$: C, 73.87; H, 10.21; N, 10.13%. IR spectrum (neat): 1680 ($\nu_{C=O}$) and 1625 ($\nu_{C=N}$) cm^{-1}; NMR spectrum ($CDCl_3$): τ 8.78 (doublet, 6H, $(\underline{CH_3})_2CH$–), 7.8—9.0 (complex, 20H, $-CH_2-$ of cyclohexyl ring), 7.2—7.8 (broad multiplet, 1H, –CH– of the cyclohexyl ring), 7.05 (multiplet, 1H, $(CH_3)_2\underline{CH}$–). The by-products, *N*-cyclohexylformamide (**10a**) and 2-hydroxy-2-methyl-*N*-cyclohexylpropionamide (**9a**), were isolated by preparative glpc in yields of 4% and 8% respectively. **9a** was identified by a comparison of the glpc retention time and IR spectrum with those of an authentic sample prepared according to the method of Hagedorn.[15]

Hydrolysis of 1-Cyclohexyl-4-isopropyl-2,2-pentamethylene-3-imidazolin-5-one (8a). A solution of 1.4 g (5 mmol) of **8a** in 20 ml of ethanol saturated with hydrochloric acid was refluxed for 1 day. After the ethanol has then been evaported, the reaction mixture was treated with aqueous sodium hydrogencarbonate and extracted with methylene chloride. The methylene chloride extract was washed with water and then subjected to glpc analysis. Cyclohexanone and *N*-cyclohexyl-3-methyl-2-oxobutyramide (**11**) were obtained in yields of 70% and 78% respectively.

Found: C, 66.30; H, 9.76; N, 6.82%. Calcd for $C_{11}H_{19}NO_2$: C, 66.97; H, 9.71; N, 7.10%. IR spectrum (neat): 1725 ($\nu_{C=O}$) and 1665 ($\nu_{N-C=O}$) cm^{-1}, NMR spectrum ($CDCl_3$):

IR spectrum (neat): 1685 ($\nu_{C=O}$) and 1630 ($\nu_{C=N}$) cm^{-1}; NMR spectrum ($CDCl_3$); τ 9.10 (triplet, 3H, $\underline{CH_3}CH_2$–), 8.78 (doublet, 3H, $\underline{CH_3}CH$), 7.5—9.0 (complex, 21H, cyclohexane ring protons), 7.25 (multiplet, 1H, $CH_3\underline{CH}$); Mass spectrum: *m/e* 290 (M^+).

*4-*sec*-Butyl-1-isopropyl-2,2-dimethyl-3-imidazolin-5-one (8c).* **8c** was obtained in a yield of 49% by the thermal rearrangement of 2,3-bis(isopropylimino)-4-ethyl-4-methyloxetane (**1c**), bp 89—90°C/18 mmHg.

Found: C, 68.25; H, 10.82; N, 13.07%. Calcd for $C_{12}H_{22}N_2O$: C, 68.53; H, 10.54; N, 13.32%. IR spectrum (neat): 1680 ($\nu_{C=O}$) and 1625 ($\nu_{C=N}$) cm^{-1}; NMR spectrum ($CDCl_3$): τ 9.08 (triplet, 3H, $\underline{CH_3}CH_2$), 8.77 (doublet, 3H, $\underline{CH_3}CHCH_2CH_3$), 8.55 (singlet, 6H, N–C$(CH_3)_2$–N), 8.53 (doublet, 6H, $(\underline{CH_3})_2CH$), 8.35 (multiplet, 2H, $CH_3\underline{CH_2}$–CH), 7.22 (multiplet, 1H, $CH_3\underline{CH}CH_2CH_3$), 6.25 (multiplet, 1H, $(CH_3)_2\underline{CH}$).

*Thermal Rearrangement of 2,3-Bis(*t*-butylimino)-4,4-dimethyloxetane (1d).* At 300—350°C, 2 g (9 mmol) of **1d** was heated for 1 hr and then distilled. The volatile material trapped by a dry ice-methanol bath, was shown to be a mixture of acetone and *t*-butyl isocyanide by a study of the glpc and NMR spectra. From the distillation condensate, bp 118°C/12 mmHg, 3-*t*-butylamino-2-*t*-butylimino-3-methylcyclobutanone (**18a**) was obtained by means of preparative glpc in a yield of 30%.

Found: C, 68.94; H, 10.55; N, 12.66%. Calcd for $C_{13}H_{24}N_2O$: C, 69.60; H, 10.78; N, 12.49%. IR spectrum (neat): 3350 (ν_{NH}) and 1665 ($\nu_{C=O}$ and $\nu_{C=N}$) cm^{-1}; NMR spectrum ($CDCl_3$): τ 8.77 (singlet, 9H, *t*-Bu), 8.55 (singlet, 9H, *t*-Bu), 8.00 (singlet, 3H, CH_3), 6.50 (singlet, 1H, NH), 6.28 (singlet, 2H, CH_2), Mass spectrum: *m/e* 224 (M^+). From the residue, 1,3-di-*t*-butylurea was obtained in a yield of 11%; it was identified by a comparison of IR and NMR spectra with those of the authentic sample.

3-t-Butylamino-2-t-butylimino-3,4-dimethylcyclobutanone (18b). **18b** was obtained in a yield of 64% by the thermal rearrangement of 2,3-bis(*t*-butylimino)-4-ethyl-4-methyloxetane (**1e**), bp 135°C/12 mmHg.

Found: C, 69.97; H, 11.39; N, 11.60%. Calcd for $C_{14}H_{26}N_2O$: C, 70.54; H, 10.99; N, 11.75%. IR spectrum (neat): 3350 (ν_{NH}) and 1665 ($\nu_{C=O}$ and $\nu_{C=N}$) cm^{-1}. NMR spectrum ($CDCl_3$): τ 8.78 (singlet, 9H, *t*-Bu), 8.65 (doublet, 3H, $\underline{CH_3}CH$), 8.50 (singlet, 9H, *t*-Bu), 8.05 (singlet, 3H, CH_3), 6.85 (singlet, 1H, NH), 6.10 (quartet, 1H, $CH_3\underline{CH}$). Mass spectrum: *m/e* 238 (M^+).

Acetylation of 3-t-Butylamino-2-t-butylimino-3,4-dimethylcyclobutanone (18b). Into a solution of 0.5 g of **18b** (2 mmol) and 0.5 m*l* of triethylamine in 10 m*l* of ether, we stirred, drop by drop, 1 m*l* of acetyl chloride at room temperature. After standing for 20 hr, the reaction mixture was treated with aqueous sodium hydrogencarbonate. The ether layer was then subjected to glpc analysis to yield the *N*-acetylated compound quantitatively.

Found: C, 68.30; H, 10.00; N, 9.71%. Calcd for $C_{16}H_{28}N_2O_2$: C, 68.53; H, 10.07; N, 9.99%. IR spectrum (neat): 1660 cm^{-1}; NMR stectrum ($CDCl_3$): τ 8.58 (doublet, 3H, $\underline{CH_3}CH$), 8.57 (singlet, 9H, *t*-Bu), 8.49 (singlet, 9H, *t*-Bu), 8.21 (singlet, 3H, CH_3), 8.08 (singlet, 3H, CH_3), 5.95 (multiplet, 1H, $CH_3\underline{CH}$). Mass spectrum: *m/e* 280 (M^+).

N-t-*Butyl-3-methylpicolinic Amide (25).* At 200°C, 1 g (4 mmol) of 2,3-bis(*t*-butylimino)-4-cyclopropyl-4-methyloxetane (**1f**) was heated for 1 hr and then subjected to glpc analysis. **25** was thus obtained in a yield of 23%.

Found: C, 68.92; H, 8.64; N, 14.69%. Calcd for $C_{11}H_{16}N_2O$: C,68.72; H, 8.39; N, 14.57%. IR spectrum (neat): 3350 (ν_{NH}), 1670 ($\nu_{C=O}$), and 1510 (ν_{NH}) cm^{-1}. NMR spectrum (CCl_4): τ 8.52 (singlet, 9H, *t*-Bu), 7.30 (singlet, 3H, CH_3), 2.80 (multiplet, 1H, $\underline{H}C{=}C{-}CH_3$), 2.50 (multiplet, 1H, $\underline{H}C{=}CH{-}N$), 2.50 (broad singlet, 1H, NH), 1.70 (multiplet, 1H, CH=N). Mass spectrum: *m/e* 192 (M^+).

Radical Cations of Halogenated Tetrahydroxybenzene Diethylene Ethers

Teruzo ASAHARA, Manabu SENŌ, and Takuma TESHIROGI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 30, 1970)

It was observed that two newly-prepared substances, 3,6-dichloro- and 3,6-dibromo-1,2,4,5-tetrahydroxybenzene diethylene ether, underwent one-electron oxidation to afford the corresponding radical cations in concentrated sulfuric acid. Their electronic spectra and ESR spectra were recorded in a sulfuric acid and nitromethane - $AlCl_3$ medium. The chloro - compound gives an ESR spectrum with a hyperfine structure, while the bromo-compound shows a spectrum without hyperfine splitting. Some different behavior was observed in several model compounds with similar structures.

Some aspect of the behavior of methoxybenzenes in concentrated sulfuric acid have been investigated, and the formation of the corresponding radical cations has been confirmed by means of a study of the ESR[1] and electronic absorption spectra.[2] We reported in a preceding paper[3] the syntheses of 3,6-dichloro- and 3,6-dibromo-1,2,4,5-tetrahydroxybenzene diethylene ether

1) A. Zweig, W. G. Hodgson, and W. H. Jura, *J. Amer. Chem. Soc.*, **86**, 4124 (1964).

2) K. Kimura and H. Yamada, This Bulletin, **42**, 3032 (1969).

3) T. Asahara, M. Senō, S. Shiraishi, and T. Teshirogi, *Kogyo Kagaku Zasshi*, **74**, 231 (1971).

(I and II) through the reaction of 2,5-dichloro- and 2,5-dibromo-3,6-dihydroxy-*p*-benzoquinone respectively with ethylene glycol. During the course of investigation of these properties, we observed the red coloration and ESR spectra of the compounds I and II in a sulfuric acid medium.

For comparison, some model compounds–2,5-dichloro- and 2,5-dibromohydroquinone dimethyl ether (III and IV), tetrachloro- and tetrabromohydroquinone dimethyl ether (V and VI), and 3,6-dichloro- and 3,6-dibromo-1,2,4,5-tetramethoxybenzene (VII and VIII)– were synthesized, and their ESR and electronic spectra were examined in sulfuric acid. The results will be presented in this paper.

Experimental

Syntheses. Compounds I and II synthesized according to the description in a previous paper.[3] Compound III was prepared from hydroquinone dimethyl ether and chlorine gas according to the method of Habermann,[4] mp 125°C (lit, 126°C), while V was prepared by treating III with chlorine gas, mp 165°C (lit, 164°C). Compound IV was prepared from the reaction of hydroquinone dimethyl ether with bromine, mp 141°C (lit, 142°C), and VI was prepared by the reaction of tetrabromohydroquinone with a potassium hydroxide solution of dimethyl sulfate, mp 193°C (lit, 194°C). Although the syntheses of compounds VII and VIII were described by Marini-Bettolo's report,[5] where chloranil or bromanil was methoxylated reductively in a zinc-methanol system, another procedure was adopted here; that is, 2,5-dichloro- or 2,5-dibromo-3,6-dimethoxy-*p*-benzoquinone was reduced with sodium dithionite and then reacted with dimethyl sulfate in an aqueous potassium solution. The products were recrystallized from ethanol-water; mp 114°C (VII) and 107°C (VIII). The electronic spectra were recorded on a Hitachi EPS-3T spectrophotometer, while the ESR spectra were measured by means of a JEX-3X ESR spectrometer. The sulfuric acid used for the solvent was of a special grade (98%) and nitromethane - aulminium chloride was prepared according to the description in the literature.[6]

Results and Discussion

The electronic spectra of I and II in concentrated sulfuric acid are shown in Fig. 1. The absorptions in the visible region (500 and 540 mμ) may be supposed to result from the radical cations which are formed through the one-electron oxidation of the original compounds. These absorptions correspond to the peaks at 440 and 460 mμ respectively of hydroquinone dimethyl ether, which was analysed by Kimura.[2]

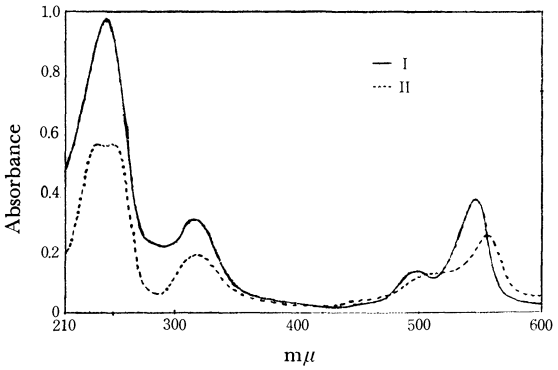

Fig. 1. Electronic spectra of I and II in sulfuric acid. (concn. 4×10^{-5} mol/*l*)

The ESR spectra of I and II in sulfuric acid are shown in Figs. 2 and 3. The spectrum of I has an hfs with nine

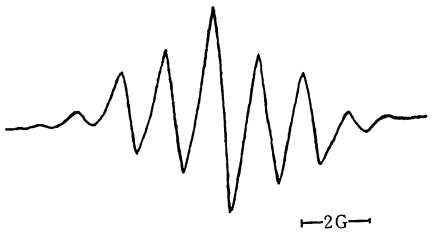

Fig. 2. ESR spectrum of I in concentrated sulfuric acid. (concn. 2×10^{-4} mol/*l*).

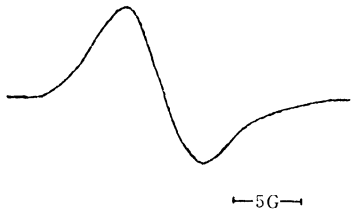

Fig. 3. ESR spectrum of II in concentrated sulfuric acid. (concn. 2×10^{-4} mol/*l*)

peaks. This is ascribed to the splitting by eight equivalent hydrogen atoms of I and has the expected intensity ratio of 1 : 8 : 28 : 56 : 70 : 56 : 28 : 8 : 1. The coupling constant, a^H is 1.33 gauss; this may be compared with the value, 2.21 gauss, for 1,2,4,5-tetramethoxybenzene.[1] The spectrum of II shows no hfs. Shine *et al.*[7] observed that 2,7-dichlothianthrene shows a three-line spectrum, but 2,7-dibromothianthrene shows a single broad-line spectrum.

Similar ESR spectra were observed in the nitromethane - aluminium chloride medium.[6] The hfs splitting of the spectrum of I is poorer under similar conditions in this medium than in sulfuric acid. The spectrum of II is a single broad line in this medium. The lack of any splitting into hfs in the spectra of II is probably the result of the spin-orbit coupling, as has been suggested by Shine *et al.*[7] An anisotropy is observed in these spectra; it is probably the result of the high viscosity of the medium and the spin-orbit interaction. The electronic spectra of I and II in this medium are nearly the same as those in sulfuric acid, (I, λ_{max} 498, 538 mμ; II λ_{max} 508, 546 mμ).

As has been stated above, the spectra of the radical cations of the chloro derivative are different from those of the bromo derivative. In order to obtain further information on this question, the spectra of several model compounds were examined. The model compounds synthesized for this purpose were as follows:

4) J. Habermann, *Chem. Ber.*, **11**, 1034 (1878).
5) C. B. Marini-Bettolo and F. S. Trucco, *Gazz. Chim. Ital.*, **73**, 300 (1943).
6) W. F. Forbes and P. D. Sullivan, *J. Amer. Chem. Soc.*, **88**, 2862 (1966).

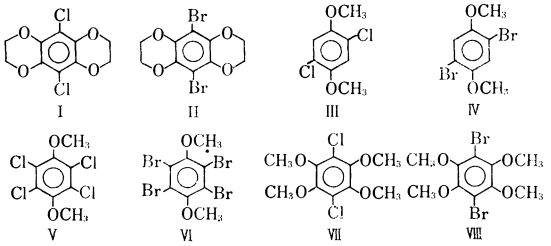
Table 1. Electronic spectra in sulfuric acid

Compound	I		II		III		IV		VII		VIII	
λ_{max} (mμ)	502	542	512	552	457	490	485	518	454	481	438	464
log ε	3.62	3.99	3.57	3.83	3.48	3.68	3.45	3.63	2.04	2.18	1.90	2.32

Table 2. ESR spectra

Compound	No. of lines (in concentrated sulfuric	Hyperfine splitting	Over-all splitting acid)	g-Values	No. of lines (in nitromethane - aluminium	Hyperfine splitting	Over-all splitting chloride)
I	9	1.33	12.0	2.0025	5[a]	—	18.5
II	1	—	16.5	2.0036	1	—	20.0
VII	5	1.74	12.0	2.0023	9	1.97	19.0
VIII	11[a]	—	20.5	2.0034	11	2.25	19.5

a) Poorly resolved.



The tetrahalogeno compounds (V and VI) are insoluble in sulfuric acid, probably because of the electron-withdrawing property of halogens. The other compounds are soluble in sulfuric acid to form red solutions. The absorption peaks in the visible region, which are supposed to be due to radical cations, are characterized as is shown in Table 1. While the red solutions of VII and VIII show ESR spectra, no signals of ESR were observed for the red solutions of III and IV. The chloro compound VII has an ESR spectrum with only five peaks. The bromo compound VIII also shows an hfs; this hfs is very complicated, probably because of the restricted rotation of the four methoxy groups. When nitromethane - aluminium chloride was used instead of sulfuric acid as an oxidation medium, the hfs was also observed for the compounds VII and VIII. The results of the ESR spectra are summarized in Table 2. It should be noted that nitromethane - aluminium chloride is a stronger oxidation medium than sulfuric acid and that the radical cations of the bromo compounds have a more labile unpaired electron than the radical cations of chloro compounds. Moreover, a comparison of the signal intensities revealed that the chloro compounds have a higher radical concentration than the corresponding bromo compounds. The g-values are smaller for the chloro compounds than for the bromo compounds, as is to be expected from the values of the spin-orbit coupling constant.

The authors wish to thank Dr. Kōzi Ōhigashi, Basic Research Laboratories, Toray Co., for many useful suggestions regarding the ESR spectra.

Stereoselectivity of Phenylcarbenoid of Zinc in Cycloaddition with Olefin

Jun NISHIMURA, Junji FURUKAWA,* Nariyoshi KAWABATA,** and Hiroaki KOYAMA
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received December 2, 1970)

The stereoselectivity of phenylcarbenoid of zinc generated from diethylzinc and benzal iodide was investigated in the cycloaddition reaction with olefin. The carbenoid showed larger *syn*-selectivity than phenylcarbenoid of lithium. Electron-donating substituent attached to the phenyl group of the phenylcarbenoid enhanced the *syn*-selectivity of the carbenoid. The *syn*-selectivity of the phenylcarbenoid was larger in ether than in *n*-pentane, contrary to the case of phenylcarbenoid of lithium.

The authors have reported briefly the formation of phenylcyclopropane by the reaction of diethylzinc and benzal iodide in the presence of olefin.[1] The generation of an phenylcarbenoid of zinc was assumed in the reaction.

* To whom inquiries should be directed.
** Present address: Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Kyoto.

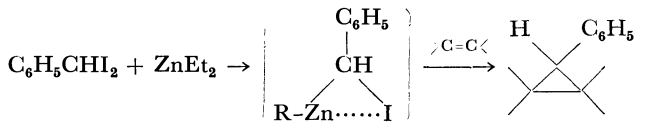
The present paper describes details of the stereochemistry of this reaction.



(1)

The reaction of diethylzinc and the substituted benzal iodide with 2-methylbut-2-ene and cyclohexene in moderate reaction conditions gave arylcyclopropanes in 18—69% yield. Results are given in Table 1.

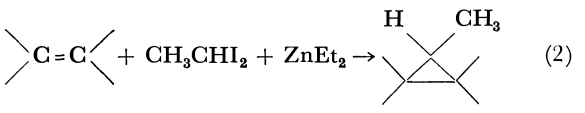
TABLE 1. FORMATION OF ARYLCYCLOPROPANES

X-  -CHI_2	2-Methylbut-2-ene[a]		Cyclohexene[c]	
	syn/*anti*	Yield (%)[b]	*syn*/*anti*	Yield (%)[b]
p-CH_3	5.3	30	—	—
H	4.2	42	17.1	69[d]
p-Cl	2.0	18	—	—

a) Reactions were carried out at room temperature.
b) Based on the iodide.
c) Ref. 1.
d) Determined by vapor phase chromatography.

As was mentioned before,[1] this phenylcarbenoid of zinc shows the *syn*-selectivity.

In the reaction of diethylzinc and ethylidene iodide with olefin, methylcyclopropanes were formed with the result that *syn* isomer generally predominated over *anti* isomer.[2]



(2)

The electrostatic interaction between methyl group of the methylcarbenoid and substituents of olefin was proposed to explain the *syn*-selectivity of reaction (2).[2]

In the reactions with cyclohexene, the phenylcarbenoid in reaction (1) showed higher *syn*-selective behavior (*syn*/*anti*=17.1)[1] than the methylcarbenoid in reaction (2) (*syn*/*anti*=1.5).[2] As can be seen in Table 1, the electron-donating substituent attached to the phenyl group of benzal iodide enhanced the *syn*-selectivity of reaction (1). The electrostatic interactions between substituents in carbenoid and olefin may be significant factors which determine the isomer ratio in reaction (1).

The stereoselectivity of phenylcarbenoid in reaction (1) is compared with those of other phenylcarbene and carbenoids (Table 2).

The *syn*-selectivity of phenylcarbenoid in reaction (1) is higher than that of phenylcarbenoid of lithium,[3] but is much the same order of magnitude as that of other phenylcarbenoid of zinc.[4]

Diethylene glycol dimethyl ether	9.6	low
Tetrahydrofuran	9.6	low

a) Reactions were carried out at 25°C.
b) Determined by vapor phase chromatography and based on the iodide.

The phenylcarbenoid shows much higher *syn*-selective behavior in ethers than in hydrocarbons. The *syn*/*anti*

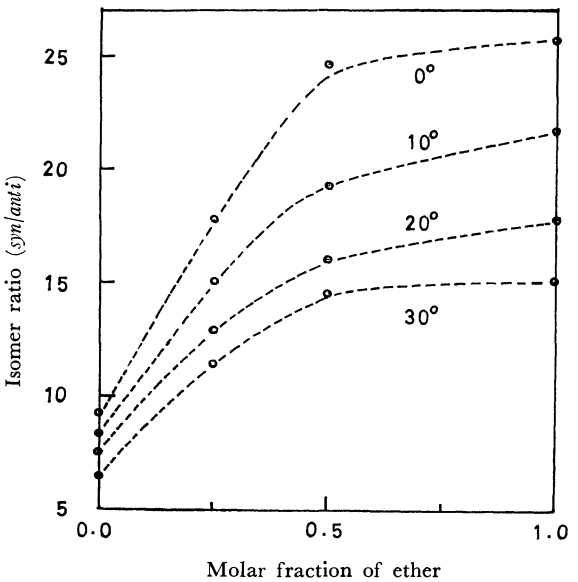

Fig. 1. Dependence of *syn*/*anti* isomer ratio on ether content in reaction (1) with cyclohexene in ether-pentane mixture.

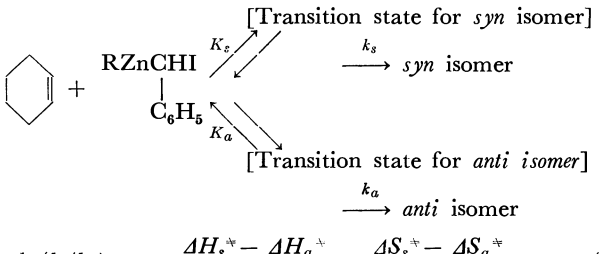
Table 4. Temperature dependence of *syn*/*anti* isomer ratio in reaction (1) with cyclohexene in ether-pentane mixture

No.	Molar fraction of ether	Isomer ratio (*syn*/*anti*) 0°C	10°C	20°C	30°C	$\Delta H_s^{\ddagger} - \Delta H_a^{\ddagger}$ (kcal/mol)	$\Delta S_s^{\ddagger} - \Delta S_a^{\ddagger}$ (e. u.)
1	1.00	25.6	21.7	17.9	15.1	−2.91	−4.18
2	0.50	24.6	19.3	16.1	14.6	−2.88	−4.23
3	0.25	17.7	15.0	12.9	11.4	−2.41	−3.14
4	0.00	9.2	8.3	7.5	7.3	−1.31	−0.42

isomer ratio in reaction (1) with cyclohexene was examined in the mixed solvent of ether and *n*-pentane. The *syn*/*anti* isomer ratio increased with the molar fraction of ether in the mixed solvent as is shown in Fig. 1. These facts show the special solvent effect of aliphatic ethers upon the stereoselectivity of reaction (1), which might include the coordination of ether to zinc atom of the carbenoid. In the case of the reaction of *n*-butyllithium and *p*-methylbenzal bromide with *cis*-but-2-ene in the mixed solvent of ether and *n*-pentane,[3] the *syn*/*anti* isomer ratio of 1-*p*-tolyl-*cis*-2,3-dimethylcyclopropane decreased with the increasing molar fraction of ether contrary to the case of reaction (1). Metal atom of carbenoid may play an important role in this solvent effect.

Temperature dependence of the *syn*/*anti* isomer ratio in reaction (1) with cyclohexene in the ether - pentane mixture is given in Table 4.

According to the theory of absolute reaction rate,[5] $\ln(k_s/k_a)$ is given by Eq. (3) if transmission coefficients κ_s is equal to κ_a:



$$\ln(k_s/k_a) \cong -\frac{\Delta H_s^{\ddagger} - \Delta H_a^{\ddagger}}{RT} + \frac{\Delta S_s^{\ddagger} - \Delta S_a^{\ddagger}}{R} \qquad (3)$$

where k_s and k_a are the rate constants for the formation of *syn* and *anti* isomer, respectively. If the reaction is kinetically controlled, k_s/k_a can be calculated from the *syn*/*anti* isomer ratio with Eq. (4).

$$[syn \text{ isomer}]/[anti \text{ isomer}] = k_s/k_a \qquad (4)$$

The isomerization between *syn*- and *anti*-7-phenylnorcaranes is not very significant under the conditions of reaction (1) and subsequent experimental procedures,[6] and consequently this reaction can be assumed to be kinetically controlled. The differences in activation enthalpy and entropy between *syn* and *anti* isomer formation in reaction (1) were calculated and given in Table 4.

The activation enthalpy and the activation entropy for the *syn* isomer formation are smaller than those for the *anti* isomer formation. This result means that the transition state for *syn* isomer formation is energetically more stable than that for *anti* isomer formation, but entropically the situation is reverse.

The difference in activation energy between *syn* and *anti* isomer formation is larger in ether than in *n*-pentane. The phenomenon might be attributed to the specific solvation of ether to zinc atom of the carbenoid. Further experiments are required to discuss this point.

Experimental

Elemental analyses were performed at the Elemental Analyses Center of Kyoto University. NMR spectra were obtained with a Varian associates A-60 NMR Spectrometer or a Japan Electron Optics Lab. Model C60H Spectrometer in carbon tetrachloride using tetramethylsilane as the internal standard. Vapor phase chromatographic analyses were made on a Shimadzu GC-2C gas chromatograph. Melting points were corrected, but boiling points were not.

Materials. *t*-Butyl methyl ether was prepared according to the procedure of Norris and Rigby.[7] Tosylhydrazones of arylaldehydes[3] and ring substituted benzal iodides[8] were prepared by conventional methods: $C_6H_5CHI_2$, mp 44—46°C; p-$CH_3C_6H_4CHI_2$, mp 36—38°C (lit,[8] 35—37°C); p-$ClC_6H_4CHI_2$, mp 55—57°C.

Solvents were purified by the usual methods.[9] Other reagents were purified as described in the previous paper.[10]

Aryl-2,2,3-trimethylcyclopropanes. The reaction procedure was the same as have been described in a previous paper.[2] The reaction was carried out at room temperature. Stereochemical structures of products were determined by NMR chemical shift of methyl protons as shown in Table 5.[3] Physical properties and analytical data of the compounds were given in Table 6.

Temperature and Solvent Dependence of endo/exo *Isomer Ratio in Reaction (1) with Cyclohexene.* Cyclohexene (0.10 mol, 10.2 m*l*), benzal iodide (0.01 mol, 3.44 g) and solvent (20 m*l*) were placed in a 50 m*l* three necked flask equipped with a magnetic stirrer, a reflux condenser, a dropping funnel, and a gas-inlet with three-way cock under an atmosphere of nitrogen. The mixture was heated or chilled to prescribed temperature, and diethylzinc (0.02 mol, 2 m*l*) was added slowly from dropping funnel. After stirred for 5 hr, tetralin (0.005 mol) was added as internal standard for vapor phase chromatographic analysis. The reaction mixture was treated with aqueous ammonium chloride and analysed by vapor phase chromatography.

a) Ref. 3.

The reaction of diethylzinc, methylene iodide, and cyclohexene was carried out under a similar reaction condition for 5 hr at room temperature in the presence of an isomer mixture (*syn*/*anti*=19.4) of 7-phenylnorcarane. The reaction mixture was treated in a similar manner as mentioned above. Vapor phase chromatographic analysis of the reaction mixture indicated that the *syn*/*anti* isomer ratio of the recovered 7-phenylnorcarane was 18.4. Thus, the isomerization between *syn*- and *anti*-7-phenylnorcarane during reaction (1) and subsequent experimental procedures is not so significant.

The Pyrolysis of Halocyclopropanes at High Temperatures

Teruzo ASAHARA, Katsumichi ONO,* and Kazuki TANAKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 14, 1970)

The pyrolysis reactions of dihalocyclopropanes and monohalocyclopropanes were carried out at 200—400°C. Bromo-substituted cyclopropanes were readily decomposed in this temperature range. In all cases, the pyrolysis products were ring-opened olefinic hydrocarbons. As for the monohalocyclopropanes, the reactions proceed in a stereospecific manner. The possible mechanism was discussed in terms of the requirements of the electrocyclic ring opening.

The slow solvolysis rates of cyclopropyl compounds have attracted much attention from organic chemists. The low reactivity of these compounds toward nucleophilic substitution has been attributed to the steric strain of the ring, which makes the intermediate cyclopropyl cation unstable.[1] Generally, the solvolysis, products are exclusively ring-opened allyl derivatives.

Examples of this type of transformation, the so-called cyclopropyl-allyl transformation, have been reported by many authors; the reaction presented in our next report, in which ring-opened products were obtained by the Friedel-Crafts reaction of halocyclopropanes, may also be included in this category.

The transformation requires the rotation of substituted groups on the cyclopropane ring. As a result, several steric courses may be considered with regard to the direction of rotation. According to the proposal of Woodward and Hoffmann,[2] the steric course of this process is determined by the symmetry of the highest occupied orbital of the ground state. They predicted

b) The weight % of pyrolysis product to total pyrolysate.

that the direction of the ring opening of the cyclopropyl cation must be disrotatory. Some experimental evidence has been given by the solvolysis reactions of substituted cyclopropyl tosylates.[3,4]

In the present investigation, the pyrolysis reaction of halocyclopropanes was studied. Some differences with regard to the stereospecificity may be expected between the pyrolysis and cationic ring-opening reactions of cyclopropanes. Since the pyrolysis rates of halocylopropanes are quite fast at 200—400°C, this reaction is suitable for the investigation of the reactivity of chemically-inactive halocyclopropanes. The steric course of the pyrolysis reaction will be discussed on the basis of analyses of the pyrolysis products.

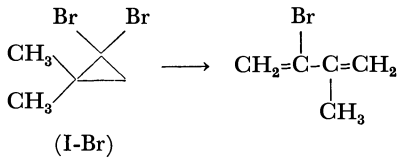
Results and Discussion

It is expected that dihalocyclopropanes are less reactive than the corresponding monohalocyclopropanes as a result of the introduction of electron-withdrawing halogen atoms. However, the thermal decompositions of some dichlorocyclopropanes have been reported recently,[5,6] and it has been recognized that, at temperatures higher than 400°C, even these chemically stable cyclopropanes can be decomposed.

In this work, the pyrolysis reactions of *gem*-dibromocyclopropanes were mainly investigated. The results for *gem*-dihalocyclopropanes are summarized in Table 1. The pyrolysis products which could not be isolated were identified by the use of a mass spectrometer directly connected to a gas chromatograph.

1,1-Dichloro-2,2-dimethylcyclopropane (I-Cl) was pyrolyzed at 390°C to give 2-chloro-3-methylbutadiene. This reaction has already been reported by Robinson.[5] Similarly, 1,1-dibromo-2,2-dimethylcyclopropane (I-Br) gave 2-bromo-3-methylbutadiene as a sole product at lower temperatures.

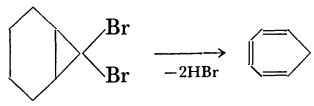
The formation of the butadiene derivative may be attributed to the above-described cyclopropyl-allyl



(I-Br) (1)

transformation, followed by the migration of the bromine atom, just as in the case of dichlorocyclopropanes. It must be noted that the ring opening is accompanied by the elimination of hydrogen bromide. As is well known, halogenated hydrocarbons easily decompose to olefins in the above temperature range, with the elimination of hydrogen halide. Therefore, dehydrohalogenation would seem to occur simultaneously with ring opening under the conditions studied in this work. This consideration is supported by the absence of ring-opened dibromides in the pyrolysis products.

The pyrolysis of 7,7-dibromonorcarane (III) gave cycloheptatriene as has been reported[6] for the high-temperature pyrolysis of 7,7-dichloronorcarane (II). However, the yield was relatively poor because of the carbonization of the starting material.



(III) (2)

II did not decompose in the temperature range studied in this work. 1,1-Dibromo-2-phenylcyclopropane (IV) gave complex products at 350°C which could not be identified.

The pyrolysis of monohalocyclopropanes was carried out under the same conditions as were used for dihalocyclopropanes. As it was very difficult to separate completely *cis*- and *trans*-isomers of monohalocyclopropanes by distillation, mixtures of the two isomers were pyrolyzed.

Bromocyclopropane (V) was prepared by the bromination of cyclopropane carboxylic acid.[7] The other monohalocyclopropanes were prepared by the reduction of the corresponding dihalocyclopropanes with tri-*n*-butyltin hydride. The ratio of the *cis* isomer to the *trans*

Table 2. Pyrolysis of monohalocyclopropanes

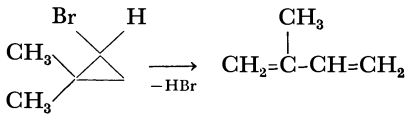
Cyclopropane	Pyrolysis temperature (°C)	Total pyrolysate (%)	Pyrolysis product	Yield (%)	Recovered cyclopropane (%)
V	303	61	$CH_2=CH-CH_2Br$	72	1
VI	300	34	$CH_2=C(CH_3)-CH=CH_2$	98	0
	210	49		90	0
VII	355	43		61	6
	300	53		56	5
	253	41		40	8
VIII	300	37	$CH(C_2H_5)=CH-CH=CH_2$	75	0
	250	34		66	0

one was determined by using a gas chromatograph and NMR as has been described by Seyferth.[8]

The pyrolysis of V gave allyl bromide as the main product. This bromide was identified by a comparison of its gas chromatograph with that of an authentic sample. The elimination of hydrogen bromide did not occur in this case.

(3)

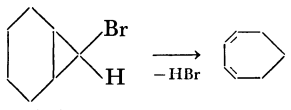
1-Bromo-2,2-dimethylcyclopropane (VI) was pyrolyzed almost completely at 300°C. None of the stereoisomers exist for this cyclopropane. Carbonization was not observed, and the single product was identified as isoprene. Isoprene is probably formed by the dehydrohalogenation after the rearrangement of VI to 2-bromo-2-methylbutene-1. However, the rearranged bromide was not found in the pyrolysis product.



(4)

(VI)

A mixture of *exo*- and *endo*-7-bromonorcarane (VII) gave a hydrocarbon with a parent mass of 94. However, a considerable amount of the starting material was recovered. The hydrocarbon in the pyrolysate was separated by distillation and was identified as 1,3-cycloheptadiene by NMR and elemental analysis. On the other hand, the recovered starting material was



(5)

(VII)

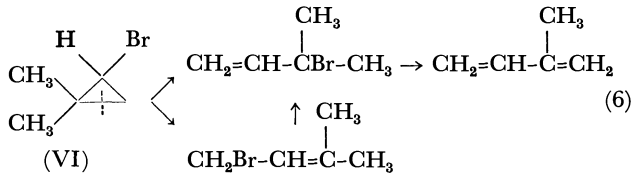
found by gas-chromatographic analysis to be an almost pure *exo* isomer of VII. It is evident that the *endo* isomer was completely decomposed to 1,3-cycloheptadiene, while the *exo*-isomer was quite stable in the temperature range studied in this work.

A mixture of *cis*- and *trans*-1-bromo-2-propylcyclopropane (VIII) was pyrolyzed to give two major products with a parent mass of 82. The product formed in the higher yield may be *trans*-1,3-hexadiene, as the results of the NMR analysis indicate. The other product is probably *cis*-1,3-hexadiene, but no unambiguous assignment for the two isomers formed in this reactions was possible because of the presence of other components.

Monohalocyclopropanes with a phenyl group, *i.e.*, 1-bromo-2-phenylcyclopropane and 1-bromo-2-methyl-2-phenylcyclopropane, were also investigated. However, the products were complex and could not be identified.

The pyrolysis conditions for monohalocyclopropanes are summarized in Table 2.

In view of the pyrolysis product of V, it is rather surprising that the only product of the pyrolysis of VI was isoprene, which may be formed by the dehydrobromination of 3-bromo-3-methylbutene-1. Another possible bromide, 1-bromo-3-methylbutene-2, probably rearranges to 3-bromo-3-methylbutene-1 to form the same product.



(6)

The lack of the reactivity of *exo*-norcaranyl compounds toward solvolysis reaction was attributed to its incapability of forming an intermediate allylic carbonium ion by the outward rotation of groups trans to the leaving group, as is shown in Fig. 1.[3]

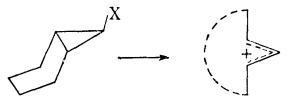


Fig. 1

Analogous considerations can possibly explain the great difference in the pyrolysis rates of *exo*- and *endo*-7-bromonorcarane. As is shown in Fig. 2, if the electrons of the C_2–C_3 bond move to the back face of the C_1–Br bond, as has been described by DePuy[3], the bromine atom would migrate to the C_2 or C_3 position along the lower side of the plane formed by the three-membered ring. On the other hand, if the electrons of the C_2–C_3 bond move to the same side of the bromine atom with respect to the cyclopropane ring, the bromine atom must go across the plane of cyclopropane to migrate to the C_2 or C_3 position.

8) D. Seyferth, H. Yamazaki, and D. L. Alleston, *J. Org. Chem.*, **28**, 703 (1963).

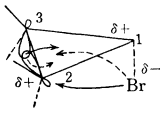

Fig. 2

In conclusion, in the pyrolytic rearrangement of halocyclopropanes, the direction of the rotation of the groups on the cyclopropane ring also obeys the rule proposed by DePuy,[3] *i.e.*, the groups *trans* to the halogen atom rotate outward, while the groups *cis* to the halogen atom rotate inward. As for the *exo* isomer VII, the groups *trans* to the bromine atom are ristricted by the cyclohexane ring. Therefore, the outward rotation of these groups is impossible.

Experimental

gem-Dihalocyclopropanes. Dihalocarbenes generated from haloform and potassium *t*-butoxide were added to the corresponding olefins, and finally purified by distillation.[9] The dihalocyclopropanes investigated in this work were 1,1-dichloro-2,2-dimethylcyclopropane (I-Cl) (bp 120—121°C), 1,1-dibromo-2,2-dimethylcyclopropane (I-Br) (bp 62—64°C/21 mmHg), 7,7-dichloronorcarane (II) (bp 78—79°C/15 mmHg), 7,7-dibromonorcarane (III) (bp 104°C/3 mmHg), and 1,1-dibromo-2-phenylcyclopropane (VI) (bp 110—112°C/4 mmHg).

Monohalocyclopropanes. These cyclopropanes were prepared by the reduction of the corresponding *gem*-dihalocyclopropanes with tri-*n*-butyltin hydride.[8] The monohalocyclopropanes thus obtained were mixture of *cis* and *trans* isomers. The clear separation of these isomers by distillation could not be achieved. The ratios of the *cis* isomer to the *trans* one were determined by gas chromatography with the aid of the NMR spectra, as has been reporyed bt Seyferth.[8]

1-Bromo-2,2-dimethylcyclopropane (VI)
bp 50—52°C/130 mmHg, lit,[8] 107—108°C.

7-Bromonorcarane (VII)
bp 86—96°C/28 mmHg, lit,[8] 94—109°C/24—27 mmHg.
cis/*trans* : 2.8.

1-Bromo-2-propylcyclopropane (VIII)
bp 52—54°C/33 mmHg, *cis*/*trans* : 2.0.

1-Bromo-2-phenylcyclopropane
bp 93—102°C/3 mmHg, lit,[8] 48—50°C/0.15 mmHg.

1-Bromo-2-methyl-2-phenylcyclopropane
bp 80—83°C/4 mmHg.

The accurate determination of the *cis*-to-*trans* ratios for the last two cyclopropanes were not possible because of their decompositions in the column of the gas chromatograph.

Bromocyclopropane (V) was prepared by the bromination of cyclopropane carboxylic acid[7] (bp 67—68.5°C, lit, 69°C).

Pyrolysis Apparatus. The pyrolysis reactions were carried out in a vertical electric furnace equipped with a calcium oxide column. From the top of the furnace, halocyclopropanes were introduced, drop by drop, with nitrogen as the carrier gas. The hydrogen halide evolved in the couse of the reaction was absorbed by calcium oxide. The gaseous pyrolysis products were condensed in a dry ice - methanol bath. The trapped pyrolysates were dried and distilled or were directly analyzed by gas chromatography. The pyrolysis temperature was 200—400°C.

Identification of Pyrolysis Products. 2-Chloro-3-methylbutadiene had a bp of 89—95°C (lit,[5] 91—101°C).

Found: C, 58.37; H, 7.05; Cl, 34.57%. Calcd for C_5H_7Cl: C, 58.55; H, 6.88; Cl, 34.73%.

2-Bromo-3-methylbutadiene had a bp of 36—37°C/35 mmHg, (lit,[10] 35°C/40 mmHg).

Found: C, 40.23; H, 4.79; Br, 54.88%. Calcd for C_5H_7Br: C, 40.85; H, 4.80; Br, 54.35%.

Cycloheptatriene had a bp of 53.5—55°C/97 mmHg, (lit,[6] 61°C/125 mmHg).

Found: C, 90.91; H, 8.37%. Calcd for C_7H_8: C, 91.25; H, 8.75%.

NMR signals (in carbon tetrachloride): $\tau=3.5$, 3.7, 4.7 (olefinic protons), $\tau=7.83$ (methylene protons, triplet).

The allyl bromide was identified by comparing the retention time of its gas chromatograph with that of an authentic sample.

Found: C, 30.04; H, 4.07; Br, 65.79%. Calcd for C_3H_5Br: C, 29.78; H, 4.17; Br, 66.05%.

The isoprene was also identified by gas chromatography using an authentic sample.

Found: C, 88.35; H, 11.85%. Calcd for C_5H_8: C, 88.16; H, 11.84%; mol wt (parent mass), 68.

1,3-Cycloheptadiene had a bp of 119—121°C (lit,[11] 121.5°C).

Found: C, 89.24; H, 10.90%. Calcd for C_7H_{10}: C, 89.29; H, 10.71%; mol wt (parent mass), 94.

NMR signals (in carbon tetrachloride): $\tau=4.33$ (olefinic protons), $\tau=7.69$, 8.10 (methylene protons).

The pyrolysis product of VIII was distilled to give a fraction of 67.5—73°C. The gas chromatograph of this fraction showed two major components, both of which have a parent mass of 82. The NMR signals indicate that the product formed in a higher yield may be *trans*-1,3-hexadiene.

Found: C, 86.79; 13.06%. Calcd for C_6H_{10}: C, 87.73; H, 12.27%.

NMR signals: $\tau=8.7$ (methylene protons), $\tau=9.0$ (methyl protons, triplet). The signals for the olefinic protons were complex and could not be assigned.

The Anchoring Effect of the Fine, Powdery Copolymer of Glycidyl Methacrylate-Divinyl Benzene for Antioxidants in Polypropylene

Yukio MIZUTANI, Koshi KUSUMOTO, and Shigeo HISANO
Tokuyama Soda Co., Ltd., Tokuyama, Yamaguchi
(Received September 14, 1970)

The anchoring effect of the fine, powdery copolymer of glycidyl methacrylate-divinylbenzene, blended in polypropylene, for phenolic antioxidants was studied by the oxygen absorption method and by studying the infrared spectrum. As a result, the anchoring effect was recognized, and it was confirmed that the effect came from the reaction between the phenolic hydroxyl groups of antioxidants and the epoxy groups of the fine, powdery copolymer and that, furthermore, the anchoring effect was related to the molecular structure of the antioxidants. It is interesting to note that these results suggests that polymeric antioxidants practically overcome the defect of the migration or the volatility observed on low-molecular-weight antioxidants.

In a previous paper,[1] we reported that the fine, powdery copolymer of glycidyl methacrylate-divinylbenzene was useful as a mordant for the dyeing of polypropylene fiber, and showed the anchoring phenomena of the dye with the amino group in the substrate, a phenomena resulting from the reaction between the epoxy group of the fine, powdery copolymer and the amino group of the dye.

The reaction between the phenolic hydroxyl group and the epoxy group is well known.[2] These facts suggest that the fine, powdery copolymer might be effective in anchoring the phenolic antioxidant in polypropylene. This effect was studied by the oxygen-absorption method and by infrared spectroscopy.

Experimental

Materials. The polypropylene (PP) powder used contains no antioxidant. The properties were as follows: melt index (at 230°C, load; 2.16 kg/cm^2): 0.25 g/10 min, specific gravity (at 23°C): 0.912 g/cm^3, and grain size: under 30 mesh.

Fine, powdery copolymers (PFPC) of glycidyl methacrylate (GMA)-divinylbenzene (DVB) [PFPC-GD] and styrene (St)-DVB [PFPC-St] were prepared by the procedure described in the previous paper.[3] The synthetic conditions of PFPC and the epoxy values are shown in Table 1. The epoxy value was determined by the HCl-dioxane method.[4]

TABLE 1. SYNTHETIC CONDITIONS AND EPOXY GROUP CONTENT OF PFPC

TABLE 2. STRUCTURAL FORMULAS OF ANTIOXIDANTS

	Structural formula
DVMP	MTVP	VHMP	MDTP	TTBP	DLTDP	$S(CH_2CH_2COOC_{12}H_{25})_2$

The antioxidants used are shown in Table 2.

Preparation of Samples. PP powder and PFPC were mixed in a sufficient amount of methanol with a mixer. The polymer mixture thus obtained was filtered and dried in a vacuum at room temperature. Then, the polymer mixture was dipped into an acetone solution of the antioxidant, after which the acetone was evaporated at room temperature under reduced pressure. The mixture was extruded at 200—230°C with an extruder (Type MK-1, from the Modern Machinery Co., Ltd.) and then pelletized.

In order to obtain the specific surface area of the sample over the safe limit of the specific surface area for an oxygen-absorption reaction[5] and in order to eliminate the unreacted antioxidant, the pellets were dissolved in hot *p*-xylene under a nitrogen atomosphere, poured into methanol, filtered out, extracted with acetone for about 16 hr, and then dried in a vacuum at room temperature.

5) Y. Mizutani, H. Ihara, K. Yamamoto, and S. Matsuoka, *Kobunshi Kagaku*, **21**, 437 (1964).

The Measurement of Oxygen Absorption. The measurements were carried out with an apparatus previously described.[5] The reaction temperature was maintained by means of a vapor bath. As a vapor bath, monochlorobenzene, *p*-xylene, and a mixture of them with a trace of ethanol were used. The amount of oxygen absorbed was transformed into the value at 25°C and 760 mmHg.

The amount of oxygen absorbed gradually increased in the initial stage, and then it increased steadily. The oxygen absorption rate at the steady state (Kc, ml/min·g) was determined by the slope of the linear part of the oxygen absorption curve, and the induction period (P, min), by the extrapolation of the slope.[5]

The Measurement of the Infrared Spectrum. The spectrum was measured on a filmy sample with a Hitachi model EPI-G_2 spectrometer. For the accuracy of the experiment, an equimolar antioxidant (MTVP) to the epoxy-group of PFPC-GD was added, and the absorption intensity of the hydroxyl group of MTVP ($(\log I_0/I)/d$; where $\log I_0/I$ was the absorbance and d was the thickness of the film) was calculated. This value was used as a measure of the concentration of the antioxidant.

Results and Discussion

Anchoring Effect of PFPC-GD in the Practical Recipe. The compositions of the samples used are summarized in Table 3. DLTDP was used as a co-inhibitor.[6] P-1

Table 3. Compositions of samples in practical recipe

Sample	Added material,	wt %
P-1	MTVP	0.056
	DLTDP	0.110
P-2	PFPC-St	4.55
	MTVP	0.056
	DLTDP	0.110
P-3	PFPC-GD	4.55
	MTVP	0.056
	DLTDP	0.110

contains no polymeric, fine powder, and P-2 contains PFPC-St, which has no reactive group. These two samples were used as the reference samples. P-3 contains PFPC-GD, which has an epoxy group. Examples of the oxygen absorption curves of these three samples are shown in Fig. 1. It was observed that the induction period of the oxygen absorption curve of P-3 was longer than that of either reference sample, P-1 or P-2. The co-inhibitor (DLTDP) was not detected in these samples by studying the infrared spectrum. Therefore, the difference in the induction period shows that the antioxidant (MTVP) was anchored in PP resin and was not extracted with acetone. In P-2, the anchoring effect was not observed, because PFPC-St had no reactive group. These results suggest that the anchoring effect comes from the reaction between the epoxy groups of PFPC-GD and the phenolic hydroxyl groups of the antioxidant (MTVP).

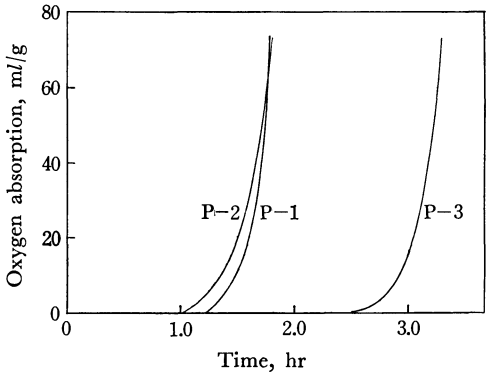

Fig. 1. Oxygen absorption curves in practical recipe at 133°C.

The reciprocal of the induction period ($1/P$) and oxygen absorption rate at the steady state (K_c) were obtained from the oxygen absorption curves at various

temperatures, as is shown in Table 4. The activation energy of the reaction in the induction region (E_t) and that in the steady state (E_s) were calculated from the Arrhenius plots shown in Fig. 2 and Fig. 3. The values of the activation energies were as follows: E_t=25—28 kcal/mol and E_s=40 kcal/mol. These values almost correspond with those reported in a previous paper[5] (E_i=22 kcal/mol, E_s=43 kal/mol).

Confirmation of the Reaction between PFPC-GD and MTVP by Studying the Infrared Spectrum in a Model Recipe. The polypropylene powder in a model recipe contains 4.6 wt% ofPFPC-GD and 3.2 wt% of MTVP.

The infrared spectra of the samples investigated are shown in Fig. 4. P-4-1 consisted of pellets obtained by

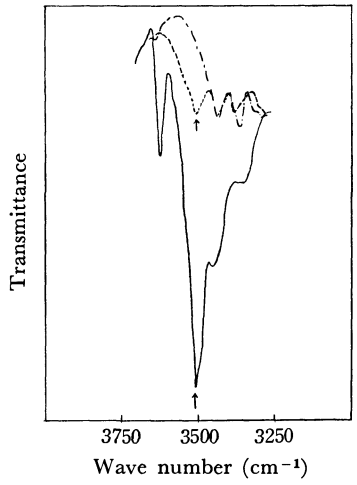

Fig. 4. Infrared spectra in model recipe.
——— Reference, —— P-4-1, ---- P-4-2, P-4-3, P-4-4

extruding the PP powder of the model recipe, P-4-2 consisted of the powder obtained by treating the pellets with hot *p*-xylene, and P-4-3, and P-4-4 consisted of the powder extracted with acetone. As the reference sample, pellets without any added MTVP were used. The infrared spectra of P-4-2, P-4-3, and P-4-4 were identical. The absorption band at 3510 cm^{-1} was assigned to the characteristic band of the phenolic hydroxyl groups of MTVP, and the absorption intensities of the band were calculated. The results are shown in Table 5. The constancy of the value under treatment

TABLE 5. THE CHANGE OF ABSORPTION INTENSITY IN THE MODEL RECIPE

Sample[a]	Time of aceton-extraction (hr)	$(\log I_0/I)/d$[d]

d) Based upon the value of reference sample, PP+PFPC-GD.

with hot *p*-xylene (P-4-2) and the extraction time with acetone shows that the antioxidant (MTVP) reacted with PFPC-GD and was anchored in PP resin.
The decrease in the absorption intensity upon treatment with hot *p*-xylene or upon extraction with acetone shows that the degree of the reaction of MTVP with PFPC-GD was low. For reference, the induction period of the oxygen-absorption reaction of P-4-3 at 128°C was over 10 hr.

Influence of the Molecular Structure of Antioxidants on the Anchoring Effect. If the reactivities of the phenolic hydroxyl groups are equal, it seems that quantity of antioxidants to be anchored will be greater as the numbers of the hydroxyl groups in a molecule increases. Also when the numbers of the hydroxyl groups are equal, it seems that the quantity will be mainly due to the reactivity of the hydroxyl group. In order to confirm the above suppositions, oxygen absorption curves on various antioxidants are compared in Fig. 5. The anti-

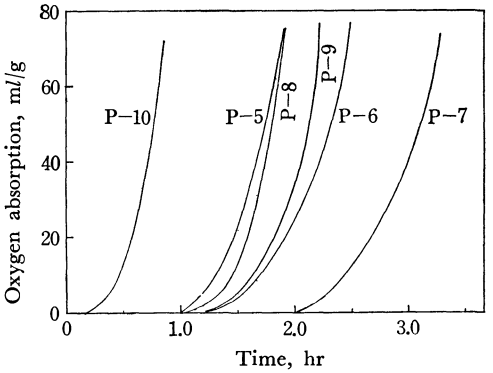

Fig. 5. Influence of the molecular structure of antioxidants on anchoring effect. (at 129°C)

oxidants used and the quantities added, which were so fixed that the quantities of the phenolic hydroxyl groups were equal, are shown in Table 6. Figure 5 shows that

TABLE 6. NUMBERS OF PHENOLIC HYDROXYL GROUPS AND QUANTITIES OF ANTIOXIDANTS ADDED

Sample[a]	Antioxidant	Number of -OH in a molecule	Antioxidant added mmol/g
P-5	DVMP	1	4.0×10^{-3}
P-6	MTVP	2	2.0×10^{-3}
P-7	VHMP	3	1.3×10^{-3}
P-8	MDTP	2	2.0×10^{-3}
P-9	TTBP	2	2.0×10^{-3}
P-10	—	—	—

a) PFPC-GD content: 4.6 wt%.

the induction period increases as the number of hydroxyl group increases. Also, the induction period increased in such an order as: P-8 (MDTP) <P-9 (TTBP) <P-6 (MTVP); this order may be mainly due to the decrease in the steric hindrance to the hydroxyl groups of antioxidants, as can be guesssed from the molecular structure. However, it has not yet been explained why the induction period of P-5 (DVMP)(shown in Fig. 5), the one phenolic hydroxyl group of which may be consumed in the reaction with the epoxy groups of PFPC-GD was longer than that of P-10.

The authors wish to thank Professor Y. Takegami of the Faculty of Engineering, Kyoto University, for his valuable advice.

Intramolecular Hydrogen Bonds. XVI.[1] Preferable Conformation of 1-Tetralols

Nobuo Mori, Mitsuo Yoshifuji, Yoshihiro Asabe, and Yojiro Tsuzuki
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo
(Received July 10, 1970)

It has recently been suggested[2,3] that, for the OH–π interaction in 1-tetralols, the *quasi-equatorial* conformation of the hydroxyl group is preferable to the *quasi-axial* one. This seems contradictory if the hydrogen-accepting site is the π-electrons on the 9-position as in benzyl alcohols,[4] because examination of the model shows that the *quasi-axial* conformation is sterically preferable for the interaction. In order to solve this problem, the steric and electronic effects of substituents on the infrared OH spectra of 1-tetralols have been investigated in their dilute carbon tetrachloride solutions.

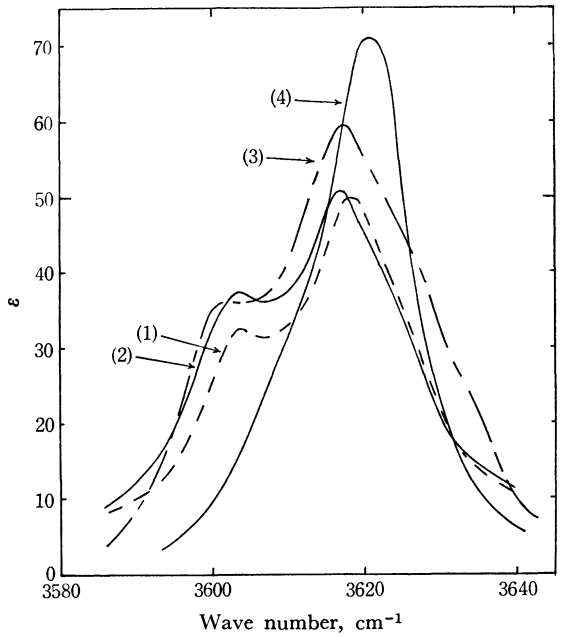

Fig. 1. OH Spectra of 1-tetralols: unsubst. (1), 7-methoxy (2), 7-nitro (3), and 5,8-dimethyl (4).

The OH spectra of 1-tetralols and 1-methyl-1-tetralols, which consist of two split bands, are in contrast with each other (Figs. 1 and 2). In the former the higher-frequency band is stronger, while in the latter the lower-frequency band is stronger, and the weaker bands of both spectra almost disappear by the 8-methyl substitution. The following can be considered as reasons for band splitting: (1) interaction between the OH group and the π-electrons,[4,5] (2) rotational isomerism of the OH group about the C–O bond,[4,5] and (3) conformational isomerism of the OH group to be caused by the ring conversion of the saturated-ring portion. The observed spectra should be contributed by different OH species. However, the pronounced spectral change by the 8-methyl substituent can be explained mainly by (3), *viz.*, by the conformational interconversion of the saturated-ring portion resulting from the steric interaction between the *quasi-equatorial* 1- and the 8-substituents, because the 8-substituent is not expected to have a similarly significant influence on (1) and (2). It thus appears that the steric repulsion between the *quasi-equatorial* 1- and the 8-substituents is sufficiently high to overcome the steric interaction between the *quasi-axial* 1-substituent and the *axial* 3-hydrogen atom.[6] Therefore, the hydroxyl groups in 1-tetralols are preferably in a *quasi-axial* conformation, while in 1-methyl-1-tetralols they are in a *quasi-equatorial* conformation, as can be expected from the oridnary order of steric size: H<OH<CH_3.

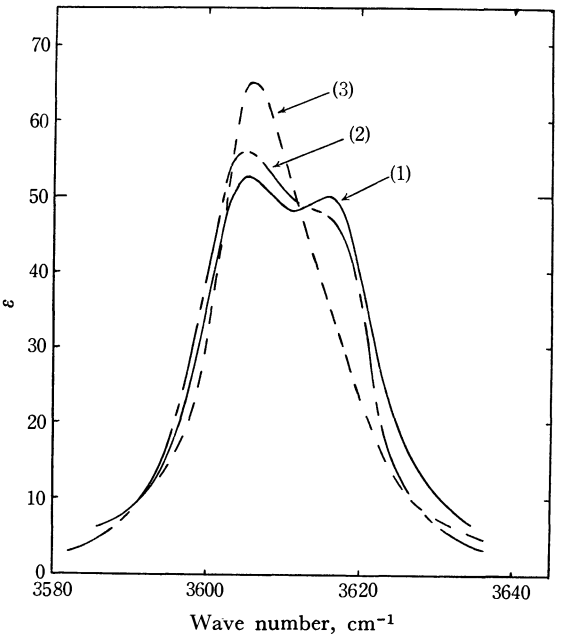

Fig. 2. OH Spectra of 1-tetralols: 1-methyl (1), 1-methyl-7-methoxy (2), and 1,5,8-trimethyl (3).

The higher- and the lower-frequency bands can thus be assigned to the *quasi-axial* and *-equatorial* OH groups,

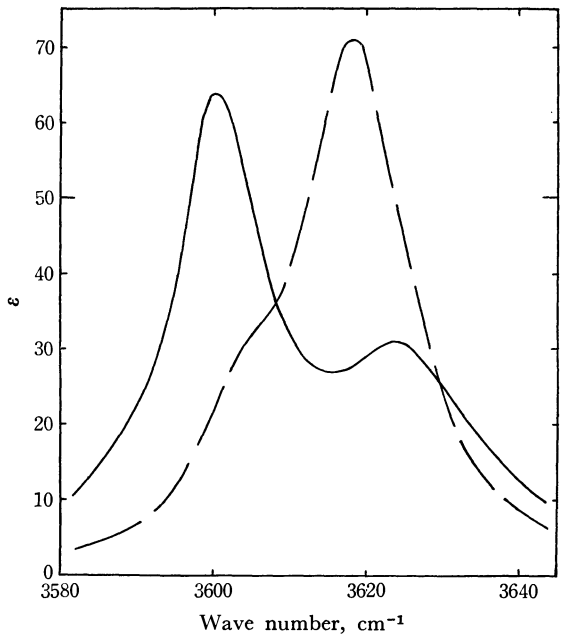

Fig. 3. OH Spectra of *cis*- and *trans*-3-phenyl-1-tetralols: *cis* (——), *trans* (— —).

respectively. They probably contain further absorption bands due to the other OH species, such as their conformational and/or rotational isomers, to some extent.

In the interaction with the π-electrons, the observed effect of a 7-substituent on the intensity ratio indicates that one or both of the *quasi-axial* and *-equatorial* OH groups participate. The *quasi-equatorial* one evidently interacts, since the frequency is lower than both of the free ν_{OH} values (3627 and 3620 cm^{-1}) and the interacted ν_{OH} values (3616 and 3607 cm^{-1}) of α-phenylethanol and -isopropanol.[4] Substantially all the OH species in the *quasi-equatorial* conformation seem to interact, since 1,5,8-trimethyl-1-tetralol shows, apart from a very intense band of the *quasi-equatorial* interacted OH group, only a very low unsymmetry due to other OH species on the higher-frequency side.

Whether the *quasi-axial* OH group interacts is not clear on account of the fact that the OH frequencies of 1-tetralols are very close to the interacted OH frequency of α-phenylethanol, while those of 1-methyl-1-tetralols are close to the free OH frequency of α-phenylisopropanol. However, there are several suggestions for the *quasi-axial* OH group to be free; if it is assumed that *trans*-3-phenyl-1-tetralol is fixed in such a conformation that the hydroxyl and the phenyl group are *quasi-axial* and *equatorial*, respectively, the strong band observed at 3618 cm^{-1} should be assigned to the free OH species, with the unsymmetry of the band being attributable to the rotational isomerism about the C–O axis or the interacted OH species. The same assignment should be given for the unsymmetric band of 5,8-dimethyl-1-tetralol whose OH group should preferably be *quasi-axial*. If interaction take place, the *quasi-axial* OH group would be prone to an electronic effect of substituents. However, even the 7-nitro substitution results in no appearance of a significant band on the higher-frequency side, suggesting that the *quasi-axial* OH group is practically free, and the observed intensity ratio of the two bands (*quasi-axial* to *quasi-equatorial*) increases with the 7-substituents in the order: $CH_3O<H<NO_2$, suggesting that the electronic effect is operative on the *quasi-equatorial* OH group and the interaction between this group and the π-electrons becomes weaker in that order, thereby some of the interacted OH species becoming free and then *quasi-axial*. For the electronic effect of substituents, a further study of 5- and 6-substituted 1-tetralols would be desirable.

In the case of isomeric 3-phenyl-1-tetralols[8] (Fig. 3), the *trans* isomer may exist predominantly in a conformation with the *quasi-axial* OH group, as mentioned above. The *cis* isomer exists in two conformations; one con-

a) ν_{OH} at the shoulder part (the assignment is uncertain).

b) Configuration was determined by NMR spectroscopy.[15]

8) In the presence of a shoulder, the spectrum of the *trans* isomer differs somewhat from that reported by Hanaya,[2] probably because of the different temperatures of measurement (25°C in Hanaya's work, 20°C in our work).

tains the OH group in the *quasi-axial* conformation and the other, in the *quasi-equatorial* one. Preference of the latter indicates that the steric interaction between the *quasi-axial* 1-hydroxyl and the *axial* 3-phenyl group is higher than that between the *quasi-equatorial* 1-hydroxyl group and the 8-hydrogen atom. Accordingly, our spectral data support the configurations proposed by Mitsui *et al.* on the basis of NMR spectroscopy.[15]

Experimental

Samples. All the tetralols, except for 1-methyl-7-methoxy-1-tetralol, were prepared and purified by the methods described in the literature. Isomeric 3-phenyl-1-tetralols were further purified through chromatography on silica gel using a mixture of hexane and benzene. Their melting and/or boiling points were equal, or very close, to those reported. The above 7-methoxy-compound was prepared in the usual manner[13] from 7-methoxy-1-tetralone. (Found: C, 75.16; H, 8.50%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%).

Infrared Measurement. This was carried out at *ca.* 20°C in the same manner as described previously.[1] The concentration used was 0.003 mol/*l* in carbon tetrachloride and the cells used had a path-length of 5.0 cm.

The spectral data are summarized in Table 1 together with the physical constants.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1139—1141 (1971)

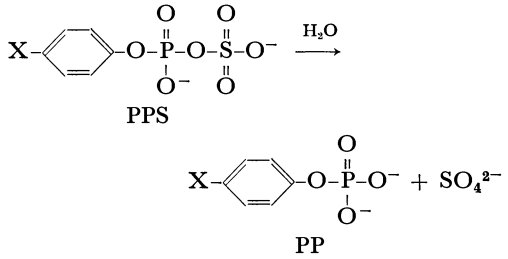
The Syntheses and Hydrolyses of *p*-Substituted Phenyl Phosphosulfates[1]

Waichiro TAGAKI, Toshio EIKI, and Itsuya TANAKA

Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma

(Received August 5, 1970)

Very recently, Benkovic and Hevey have reported a study on the mechanism of nonenzymatic hydrolysis of phenyl phosphosulfate.[2] Independently, we have also been investigating the mechanism of the hydrolysis of the same compound. Since little is known about the chemistry of phosphosulfate linkage and in view of its importance for biochemistry,[3] it seems to be significant to report our own results. In this paper, we will describe the syntheses and hydrolyses of *p*-substituted phenyl phosphosulfates (PPS, I).



PPS

PP

I. X=CH_3O, CH_3, H, Cl (diammonium salts)

Results and Discussion

Syntheses of PPS (I). Pyridine-SO_3 complex has been used for the preparation of PPS.[2] However much better yield of PPS (usually 60—70%) was obtained when the reaction was conducted using the diammonium salts of PP and dimethylformamide (DMF)-SO_3 complex in DMF.

Hydrolyses of PPS. The products were found to be exclusively phenyl phosphate (PP) and inorganic sulfate under both alkaline and acidic conditions.

1. The rate of alkaline hydrolysis was first order with respect to the hydroxide ion concentration in a range of [NaOH]=0.01—1.0 M. The substituent effect was larger than that for the acidic hydrolysis (Fig. 1). The value of entropy of activation (Table 1) was in the range expected for a bimolecular reaction.[4]

In an alkaline solution, the major ionic form of PPS is undoubtedly the dianion. This dianion would undergo a nucleophilic attack by hydroxide ion on either sulfur or phosphorus to give PP and inorganic sulfate in the rate determining step. An alternative mechanism is a rate determining unimolecular fission of S-O bond of

○: 0.01N NaOH, 98°C, $\rho=0.67$

PPS to give PP and sulfur trioxide. The above results seem to support the first bimolecular mechanism.

2. The rate of acidic hydrolysis was first order with respect to the hydronium ion concentration in a range of $-\log[H^+]=0-2$. The ρ value for the substitution effect was small (Fig. 1). Such small ρ values have also been observed in the hydrolyses of sulfates[5] and phosphates[6] of substituted phenols, and the values have been interpreted as to support A-1 type mechanisms. The value of entropy of activation (Table 1) was appreciably larger than that for the alkaline hydrolysis and is consistent with that expected for an A-1 type solvolysis. The solvent isotope effect (Table 1) was also in the range expected for an A-1 type mechanism.[7]

Experimental

DMF-SO_3 solution was prepared by distilling SO_3 into anhydrous DMF, and the concentration of SO_3 was estimated by an alkaline titration and by the yield of *p*-nitrophenyl sulfate (obtained by the reaction wih sodium *p*-nitrophenoxide). *DCl-D_2O solution* (5N) for the determination of the isotope effect was prepared by dissolving dry DCl gas in D_2O (99.8%, Showa Denko).

p-*Substituted Phenyl Phosphorodichloridates* were prepared by the reaction of phenols and $POCl_3$ at 110°C and the desired fractions were collected by distilling the reaction mixture under reduced pressure.[8]

p-*Substituted Phenyl Phosphates (PP)* were prepared by the hydrolyses of the above dichloridates in water at room temperature:[8] *p*-substituent, mp (°C); CH_3O, 90—100; CH_3, 113—114; H, 99—100; Cl, 123—124.

Diammonium salts of p-*Substituted Phenyl Phosphosulfates (PPS, 1).* The diammonium salt of unsubstituted PP (2.0g, 9.6 mmol) was dissolved in DMF solution (16*ml*) of DMF-SO_3 complex (14.4 mmol), and this reaction mixture was left at room temperature for one hour. The reaction mixture was then cooled down to about −50°C and neutralized with a saturated ethanol solution of ammonia to give somewhat pasty mass. This mixture was allowed to warm up to room temperature and ether was added to effect further precipitation. The solid was collected by filtration, and then dissolved in ethanol and filtered again to remove some insoluble solid. The filtrate was concentrated to give colorless needles. This was recrystallized twice from ethanol ether mixture to give pure diammonium salt of PPS, yield 1.7 g. A small amount of the starting PP was recovered from the mother liquor.

The other substituted PPS were prepared similarly. The R_f values of paper chromatography and elementary analyses of thus obtained diammonium salts of PPS are shown in Tables 2 and 3.

Table 2. The R_f values in paper chromatography[a]

	(26.42	4.75	8.81	9.74)
CH_3	27.50	5.03	8.25	10.09
	(27.82	5.00	9.25	10.25)
H	24.64	4.43	9.88	10.98
	(25.02	4.51	9.72	10.77)
Cl	23.33	4.45	9.02	
	(22.33	3.74	8.68)	

a) Determined by the method of Fleury and Leclere (P. Fleury and M. Leclere, *Bull. Soc. Chim. Biol.*, **25**, 201 (1943)).

The following UV absorption maxima were observed for the substituted PPS and PP in alkaline solutions. a) For PPS, *p*-substituent and λ_{max} in mμ (ε_{max}) were: CH_3O, 276 (1420); CH_3, 267 (720); H, 260 (440); Cl, 269 (530). b) For PP: CH_3O, 280(1830); CH_3, 274(1100); H, 267(740); Cl, 274(840).

Kinetics. a) Alkaline hydrolysis. An alkaline solution of PPS (1.0×10^{-3}M) was sealed in 10 ampoules and kept in a constant temperature bath. At suitable time intervals, an ampoule was withdrawn and chilled in an ice-water bath, and the optical density of the content was recorded at the absorption maximum of PP which increased smoothly as the reaction proceeded. From this optical density change, good first order rate costants (deviation, within ±3%) were calculated by using an equation, $k_{obs}=1/t \ln (OD_\infty-OD_0)/(OD_\infty-OD_t)$.

At high temperature (98°C) and with a high hydroxide ion concentration (>0.5 N NaOH), further hydrolysis was observed giving an absorption at 290 mμ due to the formation of phenoxide ion. However, the amount of phenol produced at the end

of reaction was estimated to be less than 1%, and therefore the correction of optical density for the phenol formation was neglected. Plots of log k_{obs} against log[OH^-] gave a straight line with a slope=1.0. Other data are shown in Table 1 and Fig. 1.

b) Acidic hydrolysis. Aqueous solutions of PPS and HCl were temperature equilibrated and mixed to make a reaction mixture containing PPS, 1.0×10^{-2}M, and the acid of desired concentration. A part of this reaction mixture was quenched at suitable time intervals by diluting with an alkaline solution (to 1.0×10^{-3}M of PPS) and the optical density change was recorded as described above. The formation of phenol was not detected. Plots of log k_{obs} against log[H^+] gave a straight line with a slope=1 as observed by Benkovic and Hevey.[2] Other data are shown in Table 1 and Fig. 1.

This research has been initiated at the laboratory directed by Professor Shigeru Oae at Osaka City University. The authors wish to thank Professor Oae and the members of his research group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1141—1143(1971)

The Photodecomposition of *N*-Bromosulfonamides

Takehisa OHASHI, Mitsuo OKAHARA, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received August 18, 1970)

In a previous paper,[1] the present authors reported a competitive hydrogen abstraction by the chlorine atom and the sulfonamide radical, and the predominant intramolecular hydrogen abstraction by the sulfonamide radical in an aqueous solution in the photodecomposition of *N*-alkyl-*N*-chloroalkanesulfonamides. It has also been reported[1,2] that *N*-*t*-butyl-*γ*-bromo-*n*-butanesulfonamide was formed in the photodecomposition of *N*-bromo-*N*-*t*-butyl-*n*-butanesulfonamide, unlike the result[1] obtained in the photodecomposition of *N*-*t*-butyl-*N*-chloro-*n*-butanesulfonamide. In this experiment, the photodecomposition of *N*-alkyl-*N*-bromo-*n*-alkanesulfonamides was investigated in order to study hydrogen abstraction by the sulfonamide radical.

N-Alkyl-*N*-bromo-*n*-alkanesulfonamides were prepared by the treatment of *N*-alkyl-*n*-alkanesulfonamides with freshly-prepared NaOBr in a buffer solution (Table 1). The results of the photodecomposition of *N*-bromosulfonamides are listed in Table 2. In the reaction of *N*-bromo-*N*-*t*-butyl-*n*-hexanesulfonamide in benzene, glpc and NMR analyses showed the formation of *N*-*t*-butyl-*γ*-bromo- (I) and *N*-*t*-butyl-*δ*-bromohexanesulfonamide (II), while the *ε*-bromo isomer was not formed. This suggests that the *γ*-and *δ*-bromo isomers were formed *via* intramolecular 1,5 and 1,6 hydrogen transfer by the sulfonamide radical, and that no intermolecular hydrogen abstraction by the sulfonamide radical or the bromine atom occurs; this is distinct from the result[1] observed in the reaction of *N*-*t*-butyl-*N*-chloro-*n*-hexanesulfonamide, in which the participation of the chlorine atom was observed. This must be due to the difference in reactivity between bromine and chlorine.

The isomer ratio (I/II=1.96—1.98) in this reaction was similar to that (*N*-*t*-butyl-*γ*-chlorohexanesulfonamide/*N*-*t*-butyl-*δ*-chlorohexanesulfonamide=1.93—1.94) observed in the reaction of *N*-*t*-butyl-*N*-chloro-*n*-hexanesulfonamide in an aqueous solution (AcOH/H_2O=2.1)[1]; a similar value (I/II=2.04) was obtained in the reaction of *N*-bromo-*N*-*t*-butyl-*n*-hexanesulfonamide in the AcOH–H_2O system. These facts support the hypothesis described in the previous paper[1] that the reactivity of the chlorine atom is retarded by solvation, that the predominant intramolecular hydrogen abstraction by the sulfonamide radical occurs in an aqueous solution, and that the reactivity in the hydrogen abstraction of the sulfonamide radical in the aqueous solution does not differ from that of the sulfonamide radical in benzene. The same result was obtained in the reaction of *N*-bromo-*N*-*t*-butyl-*n*-pentanesulfon-

I=RSO_2NHR', II=*N*-Alkyl-*γ*-bromo-*n*-alkanesulfonamide, III=*N*-Alkyl-*δ*-bromo-*n*-alkanesulfonamide

amide. The isomer ratio of the two rearranged products (*γ*-bromo isomer/*δ*-bromo isomer=1.19) was similar to that (*N*-*t*-butyl-*γ*-chloropentanesulfonamide/*N*-*t*-butyl-*δ*-chloropentanesulfonamide=1.14)[1)] obtained in the reaction of *N*-*t*-butyl-*N*-chloro-*n*-pentanesulfonamide in an aqueous solution. In the decomposition of *N*-bromosulfonamides in the aqueous solution, the low yield of conversion to the rearranged products is due to the unstability of *N*-bromosulfonamides in the aqueous solution and to the reduction to the original sulfonamides. Several sultam derivatives were obtained by the treatment of rearranged products with ethanolic NaOH (see Experimental Section).

Experimental

Apparatus. The glpc analyses were conducted by a Shimadzu GC-3A using Apieson L grease 10% or Silicone oil 550 10% on Diasolid L, 60—80 mesh, 1 m column. The Hg lamp was an Eikosha 150 W high-pressure Hg lamp.

Materials. The benzene, AcOH, and CCl_4 were purified by an ordinary method.

General Procedure of N-*Bromination.* *N*-Alkyl-*n*-alkanesulfonamide (0.05 mol) was suspended in a buffer solution (100m*l*, pH=6.6), and to the solution, a 50-m*l* portion of aqueous NaOBr (freshly prepared from Br_2 (24 g) and Na_2CO_3 (16 g)) was added; the solution was then stirred for 4 hr at room temperature. The insoluble oil separated as a lower layer was collected and dissolved in CCl_4 and dried over Na_2SO_4, and the solvent was evaporated. Yield, 75—80%.

Photodecomposition of N-*Bromosulfonamides.* *N*-Bromosulfonamides were irradiated at 28—30°C under N_2 until the active bromine was negligible.

Isolation and Analyses of Reaction Products. Analyses of the products in the reaction of *N*-bromo-*N*-*t*-butylbutanesulfonamide, the alkali treatment, and analyses of sultams were carried out as has been described in our previous papers.[1,3)]

N-t-*Butyl-γ-bromo*-n-*propanesulfonamide.* This substance was obtained by adding hexane to an ether solution of reaction products and was recrystallized from cold ether. Mp 76°C. IR: 3285, 2960, 1315, and 1135 cm^{-1}, NMR (in $CDCl_3$): τ; 5.45 (lH), 6.45(triplet, 2H), 6.80(triplet, 2H), 7.65(multiplet, 2H), 8.62(singlet, 9H).

Found: C, 32.80; H, 6.20; N, 5.25; Br, 30.8%. Calcd for $C_7H_{16}BrNO_2S$: C, 32.57; H, 6.25; N, 5.43; Br, 30.95%.

N-t-*Butylpropanesultam.* This was obtained by the ethanolic treatment of *N*-*t*-butyl-*γ*-bromopropanesulfonamide with ethanolic NaOH. Yield, 96%. Mp 56°C. IR: 2960, 1310, 1210, 1130, 1000, and 730 cm^{-1}. NMR (in $CDCl_3$): τ; 6.55—6.98 (multiplet, 4H), 7.55—7.90(multiplet, 2H), 8.63(singlet, 9H).

Found: C, 47.46; H, 8.51; N, 7.72%. Calcd for $C_7H_{15}NO_2S$: C, 47.43; H, 8.53; N, 7.90%.

N-t-*Butyl-δ-bromo*-n-*pentanesulfonamide.* This was obtained by cooling the hexane solution of the reaction mixture and was recrystallized from cold ether. Mp 55°C. IR: 3280, 2960, 1310, and 1130 cm^{-1}. NMR(in $CDCl_3$):τ; 5.60(1H), 5.95(multiplet, IH), 6.95(triplet, 2H), 8.05(multiplet, 4H), 8.25(doublet, 3H), 8.62(singlet, 9H).

Found: C, 37.44; H, 7.24; N, 4.85; Br, 27.7%. Calcd for $C_9H_{20}BrNO_2S$: C, 37.77; H, 7.04; N, 4.89; Br, 27.91%.

The alkali treatment of this product gave *N*-*t*-butylpent-3-enesulfonamide.[1)] Yield, 91%.

N-t-*Butyl-γ-bromo*-n-*pentanesulfonamide.* The presence of this isomer was confirmed by the formation of *N*-*t*-butyl-3-ethylpropanesultam[3)] by the alkali treatment of the reaction mixture obtained after the removal of the *δ*-bromo isomer.

N-t-*Butyl-δ-bromo*-n-*hexanesulfonamide (II).* On cooling the hexane solution of the products to −50°C, a white precipitate was obtained; this was shown to be a mixture of two isomers by glpc and elementary analyses. On the cooling of an ether solution of this mixture, II was isolated and recrystallized from ether and hexane. Mp 63°C. IR: 3280, 2960, 1320, and 1140 cm^{-1}. NMR(in CCl_4): τ; 4.85(1H), 6.05(multiplet, 1H), 7.00 (multiplet, 2H), 7.80—8.30 (multiplet, 6H), 8.62 (singlet, 9H), 8.93(triplet, 3H).

Found: C, 40.16; H, 7.43; N, 4.59; Br, 26.5%. Calcd for $C_{10}H_{22}BrNO_2S$: C, 40.00; H, 7.39; N, 4.67; Br, 26.61%.

4-Ethylbutanesultam[1)] was obtained by the alkali treatment of the *δ*-bromohexanesulfonamide produced by the treatment of II with HCl in a similar manner to that described in a previous paper.[1)] Yield, 87%.

N-t-*Butyl-γ-bromo*-n-*hexanesulfonamide (I).* When the hexane solution of the filtrate was cooled to −70°C after the

3) M. Okahara, T. Ohashi, and S. Komori, *J. Org. Chem.*, **33**, 3066 (1968).

the removal of the δ-bromo isomer, I was isolated as a white precipitate which melted at room temperature. n_D^{20} 1.4838. IR: 3280, 2960, 1320, and 1140 cm^{-1}. NMR (in CCl_4): τ; 4.75(1H), 5.95 (multiplet, 1H), 6.90(triplet, 2H), 7.60—8.35 (multiplet, 6H), 8.63 (singlet, 9H), 9.00 (triplet, 3H).

Found: C, 40.30; H, 7.54; N,4.26; Br, 26.4%. Calcd for $C_{10}H_{22}BrNO_2S$; C, 40.00; H, 7.39; N, 4.67; Br, 26.61%.

3-Propylpropanesultam[1] was obtained from I in the same manner as has been described above. Yield, 80%.

N-*Methyl-γ-bromo*-n-*butanesulfonamide.* The presence of this compound was confirmed by a study of the NMR of the reaction mixture. NMR (in $CDCl_3$): τ; 5.85(multiplet, CHBr), 8.25(doublet, CH_3CHBr).

Furthermore, the formation of *N*-methyl-3-mehtylpropanesultam was observed by glpc and NMR of the products obtained by the alkali treatment of the reaction mixture described above.

N-*Methyl-3-methylpropanesultam.* An authentic sample of this sultam was obtained by the alkali treatment of *N-methyl-γ*-chloro-*n*-butanesulfonamide.[1] Bp 78—80°C/0.2mmHg, n_D^{32} 1.4660. IR: 2960, 1310, 1140, 1050, 930, 845, and 755cm^{-1}. NMR(in $CDCl_3$): τ; 6.65—7.05(mutiplet, 3H), 7.40(singlet, 3H), 7.50-8.10(multiplet, 2H), 8.72(doublet, 3H).

Found: C, 39.96; H, 7.12; N, 9.40%. Calcd for $C_5H_{11}NO_2S$: C, 40.26; H, 7.43; N, 9.39%.

Synthetic Studies of the Flavone Derivatives. XX.[1] The Synthesis of Sorbifolin

Mitsuru NAKAYAMA, Kenji FUKUI, Tokunaru HORIE,*
Masao TSUKAYAMA,* and Mitsuo MASUMURA*

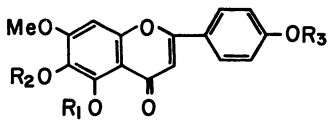
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima
** Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima*

(Received August 19, 1970)

Recently, sorbifolin[2] was isolated, along with sorbarin (scutellarein-7-monorhamnoside), from the fresh leaves of *Sorbaria stellipila* SCHNEID. Its structure was identified as 7-methoxy-5,6,4′-trihydroxyflavone (I) on the basis of chemical and spectral evidence.[2]

The present paper will describe the synthesis of I from 3,6-dihydroxy-2,4-dimethoxyacetophenone (II).[3] The monobenzyl ether (III)[4] of II was esterified with *p*-benzyloxybenzoyl chloride in the presence of anhydrous pyridine, and then the resulting ester was converted into 3-benzyloxy-2,4-dimethoxy-6-hydroxy-ω-(4-benzyloxybenzoyl)acetophenone (IV) by Baker-Venkataraman transformation. The cyclodehydration of IV with anhydrous sodium acetate in acetic acid afforded 6,4′-dibenzyloxy-5,7-dimethoxyflavone (V). The debenzylation of V by hydrogenolysis gave the 6,4′-dihydroxyflavone derivative (VI). Then, the partial demethylation of VI with anhydrous aluminum chloride in acetonitrile gave the desired flavone I, which was easily converted into the acetate (VII).

I and VII were shown to be identical with the natural pigment and its acetate respectively by a mixed-melting-point determination and by NMR, IR, and UV spectral comparisons.

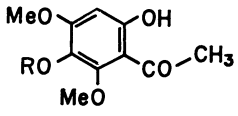


I $R_1 = R_2 = R_3 = H$

V $R_1 = Me,\ R_2 = R_3 = C_6H_5CH_2$

VI $R_1 = Me,\ R_2 = R_3 = H$

VII $R_1 = R_2 = R_3 = Ac$



II $R = H$

III $R = C_6H_5CH_2$

Experimental[5]

3-Benzyloxy-2,4-dimethoxy-6-hydroxy-ω-(4-benzyloxybenzoyl)-acetophenone (IV). A mixture of the crude III[4] (2 g) and *p*-benzyloxybenzoyl chloride (2.5 g) in anhydrous pyridine (10 ml) was heated at 120°C for 2 hr. The cooled reaction mixture was poured into dilute hydrochloric acid and then extracted with ether. The removal of the solvent gave a semi-solid (a crude ester).

A mixture of the above ester, freshly-powdered potassium hydroxide (2.0 g), and pyridine (15ml) was heated at 60°C for 4 hr with stirring. The reaction mixture was acidified with dilute hydrochloric acid, and then extracted with ether. The ether layer was washed with a sodium carbonate solution and water, and then evaporated. The resulting residue was treated with methanol-ether (1:1). The separated crystals were recrystallized from methanol-ethyl acetate to give IV as yellow prisms; mp 111—112.5°C; yield, 1.0 g (30% from III).

Found: C, 72.58; H, 5.52%. Calcd for $C_{31}H_{28}O_7$: C, 72.64; H, 5.51%.

6,4'-Dibenzyloxy-5,7-dimethoxyflavone (V). A mixture of IV (720 mg) and anhydrous sodium acetate (1.6 g) in acetic acid (8 ml) was heated at 140°C for 1 hr. The reaction mixture was then diluted with water and ether. The separated crystals were recrystallized from ethyl acetate to give V as colorless prisms; mp 154.5—155.5°C; yield, 600 mg (86%). UV: λ_{max}^{EtOH} mμ(log ε); 271(4.26), 330(4.50). NMR: ($CDCl_3$) 6.53(s, H-3), 6.72(s, H-8), 7.02(d, J=9.0 Hz, H-3', -5'), 7.80(d, J=9.0 Hz, H-2', -6').

Found: C, 75.07; H, 5.24%. Calcd for $C_{31}H_{26}O_6$: C, 75.29; H, 5.30%.

6,4'-Dihydroxy-5,7-dimethoxyflavone (VI). A mixture of V (890 mg) and Pd-C (10%; 90 mg) in ethyl acetate-methanol (2:1:150 ml) was shaken in an atmosphere of hydrogen for 5 hr. After the catalyst had been filtered off, the filtrate was evaporated. The residue was recrystallized from ethanol to give VI as colorless needles; mp 286—288°C; yield, 500 mg (88%). UV: λ_{max} mμ (log ε); (EtOH) 280(4.30), 334(4.50); (EtOH-AcONa) 285_{sh}(4.21),[6] 332 (4.32), 380(4.15). NMR: (DMSO) 6.56(s, H-3), 6.89(d, J=8.3 Hz, H-3', -5'), 7.08(s, H-8), 7.88(d, J=8.3 Hz, H-2', -6').

Found: C, 64.87; H, 4.24%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

Diacetate: mp 213—214°C (colorless prisms from ethyl acetate). UV: λ_{max}^{EtOH} mμ (log ε); 264(4.35), 312(4.41). NMR: ($CDCl_3$) 6.58(s, H-3), 6.80(s, H-8), 7.21(d, J=9.0 Hz, H-3', -5'), 7.88(d, J=9.0 Hz, H-2', -6').

Found: C, 63.03; H, 4.63%. Calcd for $C_{21}H_{18}O_8$: C, 63.31; H, 4.55%.

Sorbifolin (7-Methoxy-5,6,4'-trihydroxyflavone) (I). A mixture of VI (300 mg) and anhydrous aluminum chloride (2.0 g) in anhydrous acetonitrile (20 g) was heated at 65°C for 12 hr. The reaction mixture was then diluted with 1% hydrochloric acid (100 ml). After the solvent had been removed as much as possible under a vacuum, the separated solid was recrystallized from methanol to give I as yellow needles; mp 290—292°C; yield, 140 mg (49%). UV: λ_{max} mμ (log ε); (EtOH) 290(4.31), 343(4.41); (EtOH-$AlCl_3$) 306 (4.38), 366(4.47); (EtOH-AcONa) 380(4.25) (natural pigment:[7] (EtOH) 290(4.29), 343(4.39); (EtOH-$AlCl_3$) 306 (4.36), 366(4.44); (EtOH-AcONa) 380(4.17)). NMR: (DMSO) 3.89(s, OCH_3), 6.75(s, C-3 or -8), 6.80(s, H-8 or -3), 6.90(d, J=8.3 Hz, H-3', -5'), 7.93(d, J=8.3 Hz, H-2', -6'), 8.63(bs, OH-6), 10.3(bs, OH-4'), 12.65(s, OH-5).

Found: C, 64.06; H, 3.93%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

Triacetate (VII): mp 228—229°C (colorless needles from methanol). UV: λ_{max}^{EtOH} mμ (log ε); 261.5(4.28), 310(4.43).

Found: C, 61.70; H, 4.22%. Calcd for $C_{22}H_{18}O_9$: C, 61.97; H, 4.26%.

The authors are grateful to Dr. Munehisa Arisawa, Kokando Co., Ltd., for his gifts of the natural pigment and its acetate.

5) All the melting points are uncorrected. The NMR spectra were measured with a Hitachi R-20 spectrometer (60 MHz), using tetramethylsilane as the internal standard (δ, ppm); s, singlet; bs, broad singlet; d, doublet.

Inverse Gas Chromatographic Investigation of Fractionated Polycarbonates

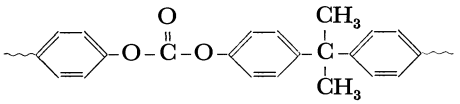
Yoshiyuki YAMAMOTO, Shin TSUGE, and Tsugio TAKEUCHI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

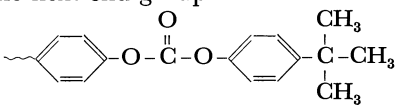
(Received August 24, 1970)

Inverse gas liquid chromatography (glc) has recently been used to measure the interactions between stationary test compounds and solute vapors. Davis, *et al.*[1] characterized asphalts by means of inverse glc. Lavoie and Guillet,[2] and Smidsrød and Guillet[3] also investigated second order transitions (*e.g.* glass transition, *Tg*) and polymer-solute interactions for polymeric materials using this method.

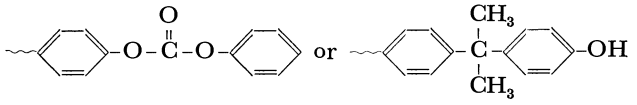
Poly[2,2-propanebis(4-phenyl carbonate)] (PC) is a most thermostable polymer and has the following repeating unit.



However, PC synthesized by the solvent method (SM-PC), in which *p-t*-butylphenol is used as terminater, provides the next end group.



On the other hand, PC synthesized by the melt method (MM-PC) is known to yield either end groups.[4]



In this work, fractionated PC with various molecular weight was investigated by means of inverse glc. Effect of the end groups, molecular weights, and *Tg* of PC on the retention behaviors are also discussed.

Results and Discussion

Molecular Weight of PC and Retention Behaviors. When polymers are used as a stationary phase in glc, it is expected that the smaller the molecular weights of the polymers, the stronger the interactions between their end groups and test solute. The interactions can also be affected by the nature of the end groups.

Figure 1 gives schematic chromatograms of benzene and diphenylmethane obtained by use of MM-PC with various molecular weights as the stationary phase in glc at 220°C. The retention time of diphenylmethane changes markedly as a function of the molecular weight of PC, while that of benzene is almost constant regardless of its molecular weight. The same tendency was observed for SM-PC.

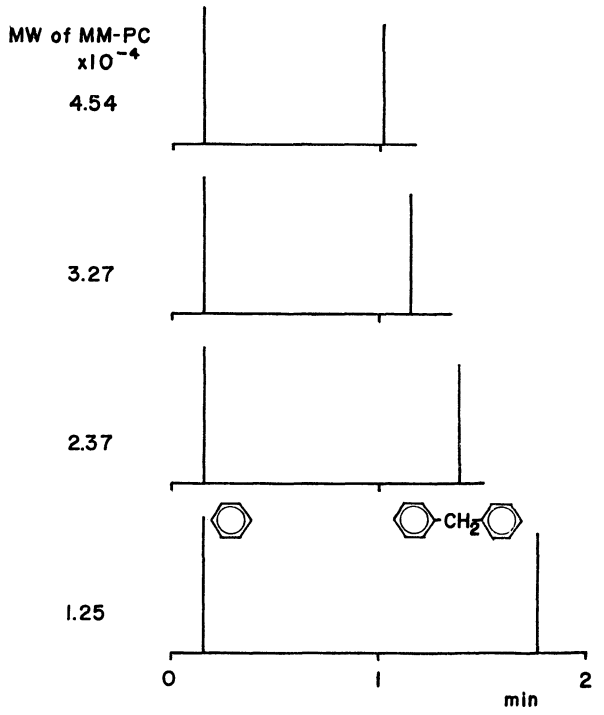


Fig. 1. Schematic chromatograms of benzene and diphenylmethane obtained by use of MM-PC with various molecular weights as the stationary phase in glc at 220°C.

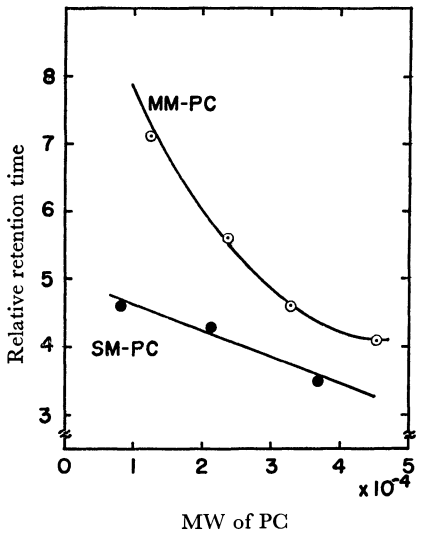

Fig. 2. The relationship between the relative retention time of diphenylmethane to benzene and the molecular weight of PC.

The results are shown in Fig. 2, where the relative retention time of diphenylmethane to benzene is plotted against the molecular weight of PC.

The relative retention time was adopted for compensa-

4) S. Tsuge, T. Okumoto, Y. Sugimura, and T. Takeuchi, *J. Chromatogr. Sci.*, **7**, 253 (1969).

tion of small changes in the experimental conditions such as flow rate of carrier gas and column temperature.

We see from Fig. 2 that the polarity of MM-PC column decreases nearly hyperbolically with the increase of molecular weight. This is mainly due to the end hydroxy groups of MM-PC. On the other hand, the retention data of SM-PC shows relatively small changes because of the terminal *t*-butyl groups, whose polarity is smaller than that of the hydroxy group.

These data suggest that rough estimation of the molecular weight of PC is possible by this method, provided that the synthetic method is known.

Retention Behavior near T_g. The chain mobility of polymer varies considerably before and after T_g, which is expected to cause remarkable change of its interaction with the solute.

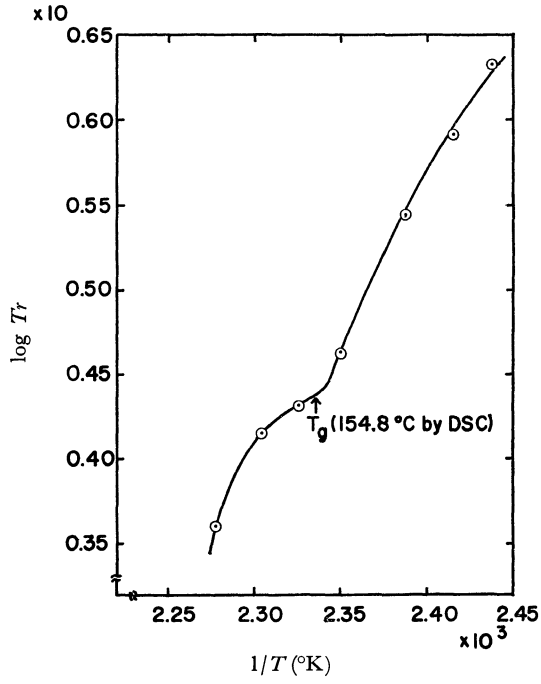

Fig. 3. The relationship between the reciprocal of the absolute column temperature and logarithms of the relative retention time (*Tr*) of *N,N*-dimethylformamide to cyclohexane near *Tg* for MM-PC.

Figure 3 shows the relationship between the reciprocal of the absolute column temperature and logarithms of the relative retention time of *N,N*-dimethylformamide to cyclohexane near T_g (154.8°C by DSC) for MM-PC. The relative retention time decreases with the rise of column temperature. However, a point of inflection exists near T_g. The same inclination was obtained for SM-PC. However, no appreciable differences were observed with variation of the molecular of PC.

Experimental

Materials. Fractionated PC-samples having molecular weights 10000—50000 were used. Raw PC was fractionated as reported previously[4] by successive precipitation method in methylene chloride-*n*-pentane system and the molecular weight of each fraction was measured by the viscosimetric method.

Preparation of Column Packing. PC weighting aboug 0.25 g was dissolved in 50 m*l* of methylene chloride. Then 0.75g of Celite 545 (80-100 mesh) was added to the solution. After the solvent was evaporated at 50°C in a vaccum with constant stirring, the coated support was packed in a column tube.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1147—1148(1971)

The Chemical Modification of Biopolymers. IV. The Introduction of Succinyl Groups into Bacterial α-Amylase

Shuichi SUZUKI, Yutaka HACHIMORI, Ryuichi MATOBA, and Kinya TAKASAKI
Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo
(Received October 1, 1970)

The introduction of functional groups into enzymes has been studied for its effect on enzymic properties. As has been shown previously, the mercaptosuccinylation of Taka-amylase A[1] (EC. 3.2.1.1) caused an increase in the enzymic activity, but the enzymic activity was not elevated, but was lowered, by succinylation.

However, the introduction of succinyl groups into bacterial α-amylase (*Bacillus subtilis*, EC. 3.2.1.1) raised the activity.

The preparation of succinyl α-amylase and their properties has been studied.

Experimental

Activity Measurements. The hydrolytic activity of the native and modified α-amylase was measured by studying the decrease in absorbance at 700 mμ due to iodine-amylose complex formation (the blue-value method),[2] and by studying the increase in the reducing groups (the Somogyi-Nelson method).[3,4] The digestion was conducted at 37°C for 30 min in a 0.07 M acetate buffer.

The protein concentration was estimated by spectrophotometry with the extinction coefficient, $E^{1\%}_{1cm}$ of 25.3 at 280mμ,[5] or by the method of Lowry.[6]

Preparation of Succinyl α-Amylase. Succinyl α-amylase was prepared as follows: One milliliter of a succinic anhydride solution in dioxane (2.2×10^{-6} mol to 2.2×10^{-4} mol) was added to 20 ml of the buffered protein solution (4.4×10^{-7} mol in a 0.2 M phosphate buffer, pH 8.0) at 2—4°C. After 30 min, 6 ml of a 0.4M hydroxylamine solution in a 0.2M phosphate buffer (pH 7.5) were added in order to stop the reaction. The reaction mixture was then dialyzed against distilled water for 24 hr at 5°C. The extent of succinylation was estimated by studying the decrease in the amino groups by the method of Matsushima *et al.*[7]

Results and Discussion

Determining the Extent of Succinylation of α-Amylase. Figure 1 shows the effect of the concentration of succinic anhydride on succinylation at 2°C. The extent of the succinylation of lysyl residues increased in accordance with the increase in the concentration of succinic anhydride. Fifteen succinyl groups per mole of enzyme was obtained when a 500-fold mole excess was used.

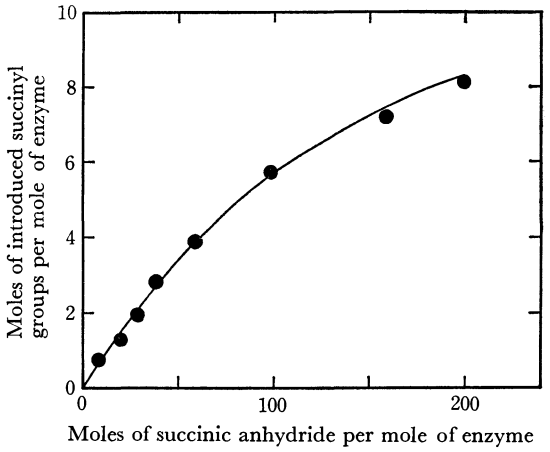

Fig. 1. The effect of concentration of succinic anhydride on degrees of succinylation of α-amylase.

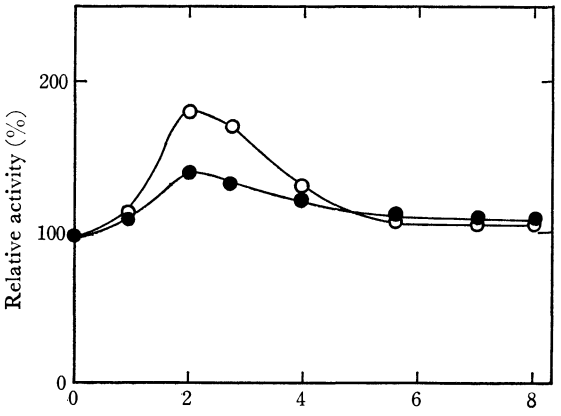

Fig. 2. The activities of the native and modified α-amylase on amylose measured at these pH optima in a 0.07 M acetate buffer and a 4.1×10^{-3}M amylose solution by the blue-value method (Curve A, open circle) and by the Somogyi-Nelson method (Curve B, closed circle).

Enzymic Activities of Succinyl α-Amylase. The enzymic activities of the modified enzymes are shown as curve A (the blue-value method) and curve B (the Somogyi-Nelson method) in Fig. 2. The enzymic activities were measured in a 4.1×10^{-3}M amylose solution and are expressed in percentages of the native enzymic activity. The enzymic reactions were carried out at the optimal pH values, which were shifted by the succinylation as is shown below. When two moles of succinyl groups were introduced per mole of enzyme, the activity on amylose, as measured by the blue-value method, increased to 180%, while that as measured by the Somogyi-Nelson method increased to 140%, of that of the native enzymic activity.

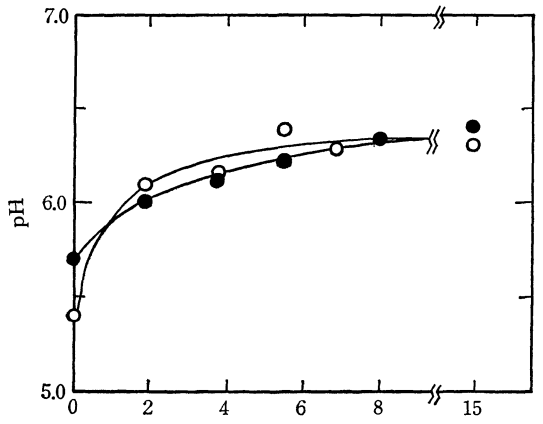

Fig. 3. The effect of the extent of succinylation of α-amylase on pH optima in a 0.07M acetate buffer and a 4.1×10^{-3}M amylose solution by the blue-value method (Curve A, open circle) and by the Somogyi-Nelson method (Curve B, closed circle).

pH Optima of Succinyl α-Amylase. The pH optima of the native and modified α-amylase are plotted against the numbers of the introduced succinyl groups by curve A (the blue-value method) and curve B (the Somogyi-Nelson method) in Fig. 3.

The pH optima were shifted higher with the progress of succinylation. The pH optima of the native enzymes were 5.4 and 5.7, as measured in a 4.1×10^{-3}M amylose solution by the blue-value method and by the Somogyi-Nelson method respectively, while the pH optima of the modified enzyme into which 15 succinyl groups per mole of enzyme has been introduced were 6.3 (the blue-value method) and 6.4 (the Somogyi-Nelson method).

Properties and Characteristics of Succinyl α-Amylase. The kinetic properties of the native and modified amylase with two succinyl groups per mole of enzyme were determined by the Lineweaver-Burk method.

The V_{max} values for the native and modified enzymes were 1.3×10^4 and 1.4×10^4 mol per min per mole of enzyme respectively.

However, succinylation decreased the K_m for amylose from 4.4×10^{-3}M^{-1} to 2.6×10^{-3}M^{-1}.

These results suggest that the increase in enzymic activity is due to the increase in affinity for amylose.

The reaction with succinic anhydride replaces the positively charged ammonium groups, NH_3^+, at a neutral pH with a $NHCOCH_2CH_2COO^-$ function. The changes that had been produced in the viscosity and sedimentation behavior of succinylated proteins would suggest a considerable expansion or unfolding of the molecular structure.

The $S^0_{20,w}$ values for the native and modified enzymes were found to be 4.4 and 5.0 respectively by ultracentrifugal analysis. That this is not primarily due to aggregation of the molecules is likely to be indicated by the fact that the change in the sedimentation constant is small and the ultracentrifugal patterns of the modified amylase showed a single well-defined peak. The native and the succinyl α-amylase show intrinsic viscosities of 0.024 *dl*/g and 0.021 *dl*/g respectively.

From these experiments, we have concluded that the effective volume occupied by the succinyl amylase molecule increased compared to that of untreated α-amylase, and that the increase in the affinity for amylose is likely to be due to the expansion of the molecular structure. As has been reported previously,[1] the succinylation of Taka-amylase A caused a decrease in the enzymic activity. The difference in the effects of succinylation on the two enzymic activities seem to be due to the extent of conformational change taking place by succinylation.

Electrochemical Evidence for the Mechanism of the Primary Stage of Photosynthesis[1)]

Akira FUJISHIMA and Kenichi HONDA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received October 13, 1970)

A phenomenon analogous to photosynthesis was observed by using an electrochemical system involving semiconductor electrodes, such as *n*-type titanium dioxide (rutile) single crystals. The results help greatly to establish the nature of the initial stage of photosynthesis, especially the oxygen evolution reaction, from the electrochemical point of view. One of the most important processes in the photosynthesis is a hole injection into a water molecule, though it is not clear whether the hole exists before injection in a localized level or in an excess hole band of chlorophylls. Since van Niel[2)] proposed that the photolysis of water was the basic reaction for converting light into chemical energy, Arnon and others[3)] have developed this idea, especially the relation between the excitation of chlorophylls and oxygen evolution. According to the results of Arnon's primary photochemical reaction, an absorbed light quantum excites a chlorophyll molecule and expels an

3) D. I. Arnon, *Nature*, **184**, 10 (1959).

electron. This electron naturally has a higher potential energy at the expense of the energy of the absorbed light quantum. The chlorophyll molecule, as it expels an electron, becomes ready to accept another from water with oxygen evolution and, in this way, returns to a normal state. However, the mechanism of the oxygen evolution reaction has not yet been sufficiently explained.

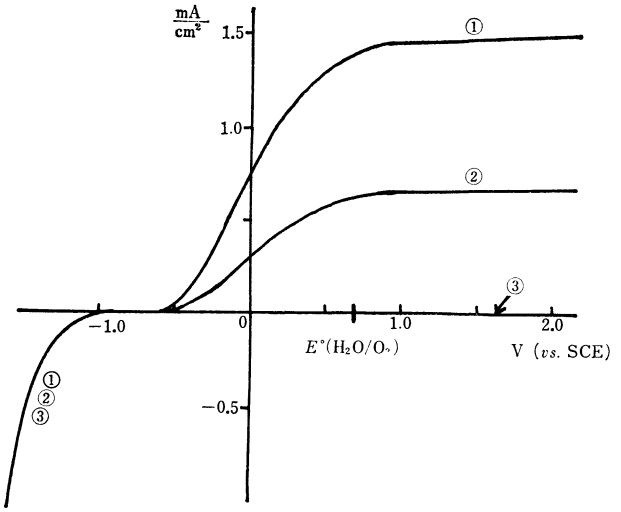

Fig. 1. Current-voltage curves of TiO_2 electrode with and without irradiation of light in the buffered solution of pH 4.7.
Curve ①: under irradiation (relative intensity of light, 100%).
Curve ②: under irradiation (relative intensity of light, 50%).
Curve ③: without irradiation.

Photosensitized Electrolytic Oxidation. The present authors[4] have previously studied the electrochemical behavior of semiconductor electrodes under the irradiation with light. In the present experiment, *n*-type titanium dioxide (TiO_2) single crystals were used after reduction treatment in order to increase the electric conductivity. The current voltage data were obtained potentiostatically. Figure 1 shows typical current-voltage curves with and without irradiation. Without irradiation, hydrogen evolution occurred in the cathodic polarization region, but the anodic current was extremely small. Under irradiation, the cathodic branch of the current-voltage curve was not influenced, but a large anodic current flowed at a potential more positive than −0.5 V (*vs.* SCE) in a neutral electrolyte solution. The magnitude of the anodic current was proportional to the light intensity and depended on the wavelength of the light. A large anodic current flowed when the semiconductor electrode was irradiated with light with an energy higher than the band gap of TiO_2, 3.0 eV.

This anodic reaction may be related to the holes, the minority carriers, which are produced in the valence band of TiO_2 by light. When an anodic current flowed, gas evolution was observed at the TiO_2 electrode surface. It was observed by gas chromatography that the gas was oxygen. As TiO_2 is very stable, it seems unlikely that the TiO_2 electrode was decomposed under irradiation. Even after the anodic current had flowed for a long time with a strong light, the TiO_2 electrode surface was not at all changed and no titanium ions could be detected in the electrolyte solution. In a 0.1 N Na_2SO_4 electrolyte solution, the relation between the change in the pH and the amount of current at 0.0 V in the case of the TiO_2 electrode was the same as that when the Pt electrode was used at 1.0 V. Therefore, the anodic reaction may be attributed to the electrolytic oxidation of water to oxygen gas.

Though the reversible oxidation potential of water to oxygen is 0.7 V (*vs.* SCE) at pH 4.7, the anodic current flowed, in fact, at potentials more positive than −0.5 V under irradiation. This fact indicates that the oxidation potential of water shifts by about 1.2 V towards the more negative region at pH 4.7. From the results described above, a mechanistic model of the electrochemical reaction at the *n*-type TiO_2 electrode is proposed; it is illustrated in Fig. 2. We call the above-mentioned phenomenon "photosensitized electrolytic oxidation." The origin of the photosensitized electrolytic oxidation is, of course, the absorption of the energy of light by the semiconductor electrode.

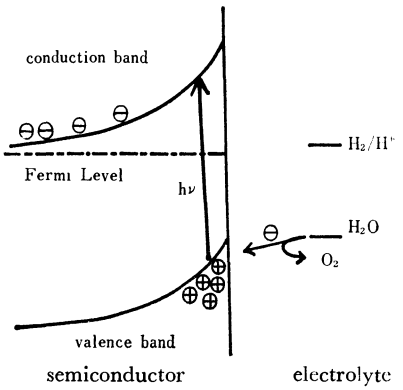

Fig. 2. A mechanistic model of photosensitized electrolytic oxidation.

If the electrolyte solution involved halogen ions, such as iodide or bromide ions, they are also oxidized in competition with the oxygen evolution reaction in relation to the concentration of halogen ions. Recently, we have investigated the photo-electrochemical reactions of *n*-type semiconductor electrodes of the zinc oxide single crystal and the cadmium sulfide single crystal;[5] under anodic polarization these crystals are dissolved because of the positive holes formed in the valence band by the irradiation with light. In the electrolyte solution involving halogen ions, the electrochemical oxidation of these anions occurs instead of the dissolution reaction on both ZnO and CdS electrodes. The oxidation potentials of halogen ions on TiO_2, ZnO, and CdS electrodes are more negative than the standard oxidation potential. Therefore, the photosensitized electrolytic oxidation of halogen ions seems to occur even with ZnO and CdS electrodes.

Photo-electrochemical Cell and Its Relation to the Primary

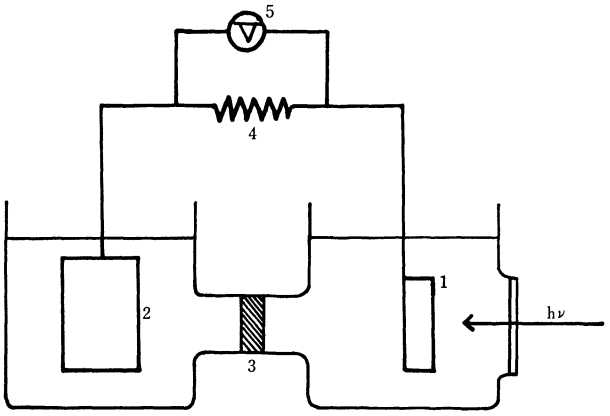

Fig. 3. An electrochemical cell with TiO_2 electrode under irradiation.
1: TiO_2 electrode, 2: Pt electrode, 3: sinter-glass diaphragm, 4: an outer load, 5: a voltmeter

Stage of Photosynthesis. The function of the TiO_2 semiconductor electrode in relation to the primary stage of photosynthesis can be better understood by constructing an electrochemical cell with a semiconductor electrode under irradiation, as is shown in Fig. 3. When the surface of the TiO_2 electrode was irradiated, the current which passed through the load was proportional to the light intensity. It was seen from the direction of the current that an oxidation reaction occurred at the TiO_2 electrode and a reduction, at the Pt electrode. The oxidation reaction was oxygen evolution resulting from water electrolysis. This fact indicates that the TiO_2 electrode absorbed the energy of light and caused the electrolysis of water to oxygen gas without any applied electric power and that, at the same time, a reduction occurred at the Pt counter electrode and electric energy was supplied to the outer load.

There has previously been presented a model[6] which regarded aggregated chlorophylls as a kind of semiconductor. This opinion has been supported in part by experimental results with regard to the photoconductivity[7] and the delayed light emission[8] of chloroplasts and other phenomenon. It may be considered that the reaction at the TiO_2 electrode and the Pt counter electrode, and the work done by electric energy to the outer load, approximately correspond to those which occur in chlorophylls, carbon assimilation, and photophosphorylation respectively. In a model of photosynthesis[9,10] where oxidation-reduction potentials were introduced with a view of placing great emphasis on the electron transfer in plants, the stages of the photoexcitation of chlorophylls and oxygen evolution are similar to the mechanism of photosensitized electrolysis at the TiO_2 electrode. This kind of work with an electrochemical system containing a semiconductor or insulator electrode will be of great help in studying the primary processes involved in photosynthesis.

The authors wish to thank Dr. M. Sukigara for his useful discussions.

Asymmetric Reduction of Some Dehydrophenylalanyl Peptides[1]

Mikizo NAKAYAMA, Gun'ichi MAEDA, Takeo KANEKO,* and Hakuji KATSURA*

Faculty of Education, Mie University, Tsu, Mie

**Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka*

(Received October 14, 1970)

Recently, Sheehan *et al.*[2] reported the stereoselective reduction of *N*-acetyldehydrovaline *S*-α-phenylethylamide by means of Raney-nickel catalyst. To clear stereochemical factors of this type of asymmetric reduction, authors carried out stereospecific reduction of a dehydropeptide, *N*-acetyldehydrophenylalanyl-D-valine and its esters. After saponification, D-phenylalanine was afforded, having specific rotation between +6.29°—+15.88° (optical purity 18—45%).

N-Acetyldehydrophenylalanyl-D-valine, prepared by the condensation reaction[3] of 4-benzal-2-methyl-5-oxazolone[4] and D-valine, was esterified in alcohols by treatment with a small amount of hydrochloric acid. The dehydropeptide and its esters were hydrogenated with palladium on charcoal, then hydrolyzed by refluxing with hydrochloric acid. From the reaction mixtures, D-valine and D-phenylalanine were separated in chemically pure states according to the method of Partridge.[5] Following table shows these results.

a) Specific rotations of optically pure L-phenylalanine and L-valine are −35.0° (H_2O) and +23.0° (6N HCl), respectively.

Experimental

N-Acetyldehydrophenylalanyl-D-valine (IIIa). To a solution of 11.7g (0.1mol) of D-valine ($[\alpha]_D$ −23.0°) in 200m*l* of 0.5N sodium hydroxide solution, was added 18.8 g (0.1mol) of 4-benzal-2-methyl-4-oxazolone[4] followed by about 190 m*l* of acetone until the mixture became clear. After standing overnight, the reaction mixture was acidified by adding 100m*l* of 1N hydrochloric acid. Crude crystals separated were recrystallized from 99% ethanol; pure crystals (yield, 19.5g (64%)) mp 218°C, $[\alpha]_D^{27}$ −24.0° (*c* 2.32, 99% ethanol), $[\alpha]_D^{25.5}$ −35.94° (*c* 2.96, pyridine). Found: C, 63.14; H, 6.62; N, 9.21%. Calcd for $C_{16}H_{20}O_4N_2$: C, 62.95; H, 6.69; N, 9.22%.

N-Acetyldehydrophenylalanyl-D-valine Esters (IIIb, c, and d). To a solution of 5.0g of above peptide (IIIa) in 100 m*l* of methanol was added 2m*l* of concentrated hydrochloric acid at 0°C. After standing for 2 days at room temperature, separated crystals were filtered off, and pure crystals were obtained by recrystallization from a mixture of water and methanol.

Methyl Ester (IIIb): mp 195°C (yield, 76%), $[\alpha]_D^{25}$ −24.13° (*c* 3.22, pyridine).
Found: C,64.16; H,7.01; N,8.63%. Calcd for $C_{17}H_{22}O_4N_2$: C, 64.13; H, 6.97; N, 8.80%.

Ethyl ester (IIIc) and *n*-propyl ester (IIId) were afforded by the analogous methods described above.

Ethyl Ester (IIIc): mp 154°C (yield, 82%), $[\alpha]_D^{25}$ −34.44° (*c* 3.20, pyridine).
Found: C, 65.19; H, 7.20; N, 8.43%. Calcd for $C_{18}H_{24}O_4N_2$: C, 65.04; H, 7.28; N, 8.43%.

n-Propyl Ester (IIId): mp 151°C (yield, 76%). $[\alpha]_D^{25}$ −38.73° (*c* 4.83, pyridine).
Found: C,65.34; H,7.52; N,8.27%. Calcd for $C_{19}H_{26}O_4N_2$:

C, 65.87; H, 7.57; N, 8.09%.

Asymmetric reduction and hydrolysis. A solution of 1.5g of the peptide or its esters in 100m*l* of ethanol was hydrogenated with 0.1g of 5% palladium on charcoal under atmospheric pressure at room temperature. After absorption of hydrogen was ended (about 45 min), catalyst was filtered off and the filtrate was evaporated to dryness under reduced pressure. The residue was hydrolyzed by refluxing with 15m*l* of concentrated hydrochloric acid for 50 min, and the hydrolysate was evaporated at below 40°C to dryness under reduced pressure. To the residue water was added and evaporated again as described above. These procedures were repeated until free hydrochloric acid was removed completely from the residue. The hydrolysate was treated with the activated charcoal prepared according to the method of Partridge.[5] From the aqueous layer D-valine was obtained, and from the charcoal D-phenylalaine was eluted. These amino acid fractions were neutralized by means of Amberite IR-4B resin. The optical rotation of D-valine was measured in solution of 6N hydrochloric acid.

As the solubility of optically active phenylalanine in water is larger than that of racemic isomer, to avoid fractional crystallization a part of a solution of phenylalanine obtained above was completely evaporated to dryness and weighed, then the residue was dissolved in a definite volume of water and optical rotation of this solution was measured. In each instance the identity and purity of the amino acids were confirmed by paper chromatography developed by 80% phenol. The phenylalanine (R_f=0.87) and valine (R_f=0.79) obtained above, showed single ninhydrin-positive spots which had the same R_f values as those of authentic samples, respectively.

Discussion

As dehydrophenylalanyl peptides may be regarded as derivatives of cinnamic acid, phenyl and carboxyl groups of the peptides should be oriented "trans" position to each other with regard to double bond, since the longest conjugated system is the most stable configuration. The peptides in this paper, would have three staggered conformations as shown by III, IV, and V. According to the assumptions by Prelog[6] and Sheehan,[2] hydrogen will be absorbed on the surface of catalyst and the substrate will approach the catalyst surface from the least sterically hindered side. From III, VI will be deduced, and from IV, VII will be expected. Stereostructure of VIII, the reduction product from V, is yet obscure, because of no significant difference between the bulkiness of "isopropyl" and "carboxylate" groups. After saponification, the products obtained from VI will be D-(R)-phenylalanine and D-(R)-valine, on the other hand L-(S)-phenylalanine and D-(R)-valine will be given from VII, but from VIII, D-valine and racemic or faintly optically active phenylalanine will be obtained. Because D-phenylalanine produced predominantly in these experiments, it is supposed that the conformer III is the most preferable one among the three probable conformers (III, IV, and V) of dehydrophenylalanyl peptides.

The Mass Spectra of 2-Oxo-3-aryl-1,2,3-oxathiazolidines

Fukiko YAMADA, Tomihiro NISHIYAMA, Yasuyoshi FUJIMOTO, and Motokazu KINUGASA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received October 24, 1970)

Various oxathiazolidines are easily prepared by the reactions of *N*-sulfinylanilines with alkene oxides.[1,2] We have prepared 2-oxo-3-phenyl-1,2,3-oxathiazolidine (I) and 2-oxo-3-*p*-tolyl-1,2,3-oxathiazolidine (II) by a reported method[2] and have examined their mass spectra. In this report, we wish to describe the fragmentation schemes of the compounds I and II; the correlation between the fragmentation pathways and the related organic reaction mechanisms will also be discussed.

The mass spectral data of I and II are shown in Table 1. The compounds gave distinct molecular ions, as would be predicted from the presence of the aromatic nucleus; the fragment ions were formed by loss of SO_2 from the molecular ions. The base peaks occur from the loss of the SO_2 group, followed by the loss of the methyl radical. The most prominent fragment ions of the masses at 104 and 118 lose HCN to give hydrocarbon ions with masses of 77 II and 91 respectively. There are three steps of cleavage in the oxathiazolidine ring, the eliminations of SO_2 (1), the methyl radical (2), and HCN (3). The path of the fragmentation of the ring in the compounds I and II is indicated

TABLE 1. MASS SPECTRAL DATA OF COMPOUNDS I AND II[a] (75 eV)

No.	I			II		
	m/e	Ion composition[b]	Rel. Int. (%)	*m/e*	Ion composition	Rel. Int. (%)

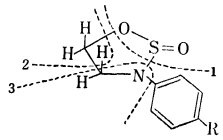
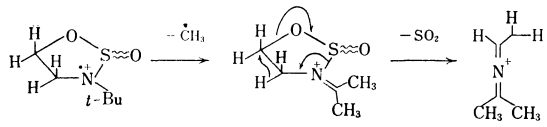
by the dotted lines in the diagram below.



I, R=H II, R=CH_3

These phenomena can be explained in part by the observation that the bond connecting the SO group and the nitrogen atom in the oxathiazolidine ring of I and II has a high probability of fission.

It is interesting to compare this spectrum with the spectra of the other oxathiazolidines reported by Deyrup and Moyer.[3,4] In contrast to the present behavior, the major peak in the fragmentation of 2-oxo-3-*t*-butyl-1,2,3-oxathiazolidine occurs from the loss of the methyl radical, followed by the loss of SO_2, as follows:



2-Oxo-3-aryl-1,2,3-oxathiazolidines, I and II, can be converted to the corresponding *N,N'*-diarylpiperazines by thermal decomposition and can easily be hydrolyzed to the *N*-(2-hydroxyethyl)anilines by water.[2] In the case of the above reactions, we suggest that, after the loss of the SO_2 group, the remaining atoms in the oxathiazolidine ring are rearranged to become an intermediate which has the same composition as the ion 2, as is shown in Table 1. Thus, the intermediate reacts with another one to give *N,N'*-diarylpiperazines or with water to give *N*-(2-hydroxyethyl)anilines. The ions, although few in number, are detected in both the spectra. This is best explained by the formation of the piperazine molecule and of *N*-(2-hydroxyethyl)-aniline.

Moyer[4] attempted the pyrolysis of some 2-oxo-3-*t*-butyl-1,2,3-oxathiazolidines; however, the reaction products have not been determined. Attempts to hydrolyze the above oxathiazolidines under homogeneous basic aqueous conditions failed. These compounds can only be hydrolyzed to the corresponding amino alcohols by dilute acid.

These differences can be explained by the mass spectral data that, in the first step of the fission, the two compounds, I and II, both produce ions corresponding to the loss of the SO_2 group from the molecules, whereas no corresponding ions from the 2-oxo-3-*t*-butyl-1,2,3-oxathiazolidines are observed.

Experimental

The mass spectra were obtained with a Japan Electron Optics Co., Ltd., JMS-O1SG Mattauch-Herzog double-focusing mass spectrometer. In the photographic-plate measurements, about 50μg of a sample was introduced with a marker (PFK), under normal operating conditions (accelerating voltage, 6.4kV). Accurate masses were determined by using a JMC-1A comparator, while the elemental compositions were evaluated by using Lederberg's Table.[5]

The Mercury Content of Several Acid Hot Springs in Japan

Naoichi OHTA and Minoru TERAI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received October 24, 1970)

The geochemical data of mercury are still insufficiently especially for materials related to volcanic activity.[1] As to hot spring waters, two investigations have been reported hitherto. Stock and Cucuel[2] found 0.0001—0.0005g/ton mercury in spring water. Iwasaki *et al.*[3] reported on the chemical composition of Tamagawa Hot Spring, Akita Prefecture, in which the amount of mercury was estimated to be 0.01ppm. In this paper, the present authors will report the results of a quantitative estimation of mercury in several acid hot springs in Japan.

Sampling and Analytical Method

The samples shown in Table 1 were collected from 10 hot springs distributed around the Shirane volcano, Gunma Prefecture, on July 17th, 1970. The pH values and the temperatures were measured at the orifice of the springs. The determination of mercury was carried out in the laboratory according to the method of a previous work.[4] Mercuric sulfide should be

precipitated as quickly as possible after the sample has been collected in order to prevent any loss of mercury. Cadmium nitrate solution containing 2.5 mg of cadmium was added to 500 m*l* of sample water as a carrier. The acidity of the solution was adjusted to 0.1N. After the solution had then been saturated with hydrogen sulfide, 0.5 m*l* of 5% aluminum nitrate solution was added and the mixture was mixed well. After not less than 24 hr, the sulfide precipitate was filtered and treated with 3 m*l* of aqua regia. The solution was aerated for several minutes, and then 2 m*l* of 20% hydroxylamine hydrochloride solution were added. The pH of the solution was adjusted to 4.5 with ammonium hydroxide; the final volume should be approximately 50 m*l*. The cupric ion was eliminated from this solution by adding 5 m*l* of 0.1 mol/*l* trifluoroacetylacetone-chloroform solution and shaking it for 10 minutes. The aqueous solution was separated and adjusted to 0.25N in sulfuric acid. Five milliliters of 0.001% dithizone-chloroform solution were added to the solution, and the mixture was shaken for one minute. The chloroform phase was separated, and the absorbance was measured at 490 mμ with a Shimadzu-Bausch & Lomb Spectronic 20 spectrophotometer.

Results and Discussion

The mercury contents of the acid hot springs are shown in Table 1, together with the pH values and the temperatures. The average mercury contents of hot springs of the Kusatu and Manza districts are shown in Table 2, along with the previously-reported values of various natural waters.

The mercury content of spring water seems to differ much according to the locality and the type of each hot spring. The values of Kusatu and Yukama are high and close to the data reported by Iwasaki *et al.*[3] On the other hand, the values of Manza are low and resemble the data of Stock and Cucuel.[2]

Table 2. Mercury content of natural waters

Sample	Location	Hg ($\mu g/l$)	Reference
Hot spring	Kusatu	19(av. of 4 samples)	This work
	Manza	<0.1(av. of 5 samples)	This work
	Tamagawa	10	Iwasaki *et al.*[3]
		0.1 —0.5	Stock and Cucuel[2]
Mineral water		15	Krainov[5]
Sea water	Ramapo Deep, Japan Trench	0.08—0.15	Hamaguchi *et al.*[6]
	Minamata Bay	1.6 —3.6	Hosohara *et al.*[7]
	Sagami Bay	2.7	Ohta *et al.*[4]
River water	Tokyo-to	2.8	Ohta *et al.*[4]

Kusatu and Manza hot springs are located at the east and the west foot of the Shirane volcano, respectively. It was suggested by Noguchi *et al.*[8] that the Kusatu and Manza hot springs belong to different types of springs. Both Kusatu and Manza are of the strong-acid type, but the contents of many chemical constituents, such as alkali metals, magnesium, calcium, iron, arsenic, vanadium, chloride and sulfate, differ considerably; for example, chloride is more abundant in Kusatu (231—622 mg/*l*) than in Manza (139—197 mg/*l*).[8,9] However, the difference in mercury contents between Kusatu and Manza is excessively large compared to that of other constituents. This fact is of great interest and suggests a relationship between the mercury content and the mechanism by which the spring water wells out.

The authors wish to thank Mr. T. Araki, Tokyo Metropolitan University, for his useful comments.

Addition Reactions of Heterocumulenes to the Sb-N Bond

Jugo KOKETSU, Masaki OKAMURA, and Yoshio ISHII

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received October 15, 1970)

Even though much information on the reactions of Group Va metal amides with various unsaturated compounds is available, it has largely been limited to those of phosphorus and arsenic amide.[1-3] In this communication, some of our results on the reactions of organoantimony(III) amide with alkyl or aryl isocyanate or isothiocyanate are presented.

The reactions of *N,N*-dimethylaminodimethylstibine with equimolar alkyl or aryl isocyanate or isothiocyanate in ethyl ether took place exothermally at room temperature to give the simple insertion products as shown below.

$$Me_2SbNMe_2 + RNCX \longrightarrow Me_2Sb(R)NC(X)NMe_2$$

R=Me, Et, Bu^t, Ph; X=O or S

These addition products are very hygroscopic liquids and decomposed into white solids when exposed to air. The yield, physical properties, and the relevant spectral data are shown in experimental section and Tables 1 and 2.

The spectral data suggest that the 1:1 addition products are formed across the Sb–N bond.

Hydrolysis of all the addition products was performed with dilute hydrochloric acid, and the hydrolysis product were identified as trisubstituted urea and thiourea derivatives by their spectral data and by their failure to depress the melting points on admixture with authentic samples.

Experimental

Preparation of N,N-*Dimethylaminodimethylstibine.* To a solution of lithium amide, prepared from dimethylamine and *n*-buthyllithium in petroleum ether, an equimolar amount of dimethylchlorostibine, prepared according to the method of Davies,[4] was added slowly with ice cooling. The reaction mixture was heated for 1hr under reflux. Separation of lithium chloride by decantation and removal of the solvent gave crude *N,N*-dimethylaminodimethylstibine, which was purified by column distillation. Bp 62—65°C/75mmHg, yield 46%.

Proton NMR Spectrum of *N*-Phenethyl-*o*-anisidine[1)]

Teruzo Asahara, Manabu Senō, Sadayoshi Tanaka, and Masatoshi Akiyama
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 2, 1970)

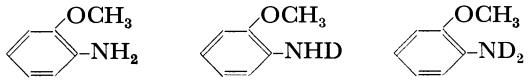
It was reported that anionic telomerizations where anisidines and phenetidines were allowed to react as a telogen with styrene as a taxogen in the presence of alkali metals gave phenethylamines.[1)] Each of the telomers showed two methylene triplets in the NMR spectrum, the assignment of which was not elucidated.

This paper reports on the preparation of mixed telomers composed of *N*-phenethyl-*o*-anisidine and *N*-phenethyl-*β*-*d*-*o*-anisidine and the assignment of NMR spectrum of *N*-phenethyl-*o*-anisidine done by analyzing the NMR spectra of the mixed telomers.

Results and Discussion

Exchange Reaction between O-*Anisidine and Deuterium Oxide*

The exchange reaction between *o*-anisidine and deuterium oxide in the presence of a small amount of potassium deuteroxide gave mixed amines, *i.e. o*-



1 **2** **3**

anisidine **1**, *o*-anisidine-*N*-*d* **2**, and *o*-anisidine-*N*-d_2 **3**. Since the above is an equilibrium reaction, the partly deuterated *o*-anisidine may be composed of **1**, **2**, and **3**. The extent of deuteration of the amino group calculated from the integral curve of NMR spectrum was 55%. On treating *o*-anisidine with deuterium oxide, the intensity of –NH– stretching vibration of the amine at 3350—3450 cm^{-1} decreased and –ND– stretching vibration appeared at 2400—2600 cm^{-1}. This is consistent with the fact that the amino group of *o*-anisidine was partly deuterated.

Anionic Telomerization of Mixed o-*Anisidine with Styrene.*

In the first place the mixed *o*-anisidine was allowed to react with an alloy of sodium and potassium to form organometallic compounds **5** and **6**, which acted as an initiator (I). In the next place telomerization was carried out by dropping styrene into the amine-alloy system (II,III). Finally, the reaction product was washed with water and dried, and thereafter purified by vacuum distillation (IV) : bp 156°C/2mmHg, n_D^{25} 1.5747, mol wt by VPO 229. Found: C, 79.02 ; H, 7.73; N, 6.40 %. Calcd for $[C_{15}H_{16}NO]_{0.48}$ $[C_{15}H_{15}DNO]_{0.52}$: C, 79.08; H and D, 7.79; N, 6.15 %.

These reactions are summarized as follows.

Thus, a mixture of *N*-phenethyl-*o*-anisidine **13** and *N*-phenethyl-*β*-*d*-*o*-anisidine **14** was prepared by the telomerization of styrene with the mixed amines.

Proton NMR Spectrum of Mixed Telomers **13** *and* **14**.

Figures 1 and 2 show the proton NMR spectrum of *N*-phenethyl-*o*-anisidine and that of the mixed telomers derived from the partly deuterated *o*-anisidine, respectively. In Fig. 1 two triplets with equal intensities appear at 2.79 ppm and 3.27 ppm, while in Fig. 2 the area of the triplet at 2.79 ppm decreases and the shape of the signal at 3.27 ppm is modified.

It may be derived from the reaction scheme and the consideration on the spectra that a triplet signal at 2.79 ppm should originate from the methylene group neighboring to the phenyl group and the other triplet at 3.27 ppm should be assigned to the methylene group attached to the nitrogen atom. The extent of deuteration of the obtained telomers, calculated from the integral curve in Fig. 2, reached 52 % of the mixed telomers.

The proton NMR spectra of *N*-phenethyl-*m*-anisidine, *N*-phenethyl-*p*-anisidine, *N*-phenethyl-*o*-phenetidine, *N*-phenethyl-*m*-phenetidine, and *N*-phenethyl-*p*-phenetidine previously reported[1)] can be interpreted in the same manner.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1158—1160(1971)

On the Mechanism of Bromination of Olefins with Cupric Bromide

Takashi KOYANO

Central Research Laboratory, Toa Nenryo Kogyo Co., Oi-machi, Iruma-gun, Saitama

(Received November 2, 1970)

Although it is generally accepted that cupric chloride does not liberate chlorine molecule in chlorination of organic substances,[1] the active species has not been established in bromination of organic compounds with cupric bromide. The bromination of acetone to bromoacetone in methanol at 0°C has been explained as the reaction of cupric bromide molecule,[2] while in the nuclear bromination of alkylbenzenes at 110—120°C a possibility of participation of bromine molecule has been suggested.[3] Rate of the bromination of allyl alcohol to form 2,3-dibromopropanol in refluxing methanol has been reported to be second order in cupric bromide and independent of olefin.[4] This rate equation was

$$\text{rate} = k[CuBr_2]^2 \qquad (1)$$

explained by assuming the dissociation of cupric bromide to molecular bromine, which was claimed to be the actual brominating agent in the reaction. Consumption of bromine[4] or removal of cuprous bromide by complex formation with olefin[5] has been believed to be a driving force for the dissociation of cupric bromide.

$$2CuBr_2 \underset{k_b}{\overset{k_a}{\rightleftharpoons}} 2CuBr + Br_2 \qquad (2)$$

In order to obtain further experimental results to discuss the reaction mechanism, the bromination of 1-hexene has been kinetically investigated in methanol.

The products were the dibromide (I) and the methoxybromide (II) with a small amount of by-products ($<1\%$). To avoid complication by the effect of resulting cuprous bromide, the rates are expressed by initial rates and shown in Table 1.

Plots of log[$CuBr_2$] and log[hexene] *vs.* log v showed straight lines, and rate orders were calculated from these lines. The rates were expressed by following equations, where v_1 and v_2 are the rates of formations of I and II, respectively.

$$v_1 = k_1[\text{hexene}][CuBr_2]^{1.8-2.0} \qquad (3)$$

$$v_2 = k_2[\text{hexene}][CuBr_2] \qquad (4)$$

Since the rate order in [$CuBr_2$] is smaller for II, I can not be a precursor of II, that is, II was not formed by methanolysis of I.

2) S. Kawaguchi and Y. Kojima, *Shokubai*, **8**, 239 (1966).

3) P. Kovacic and K. E. Davis, *J. Amer. Chem. Soc.*, **86**, 427 (1964).

4) C. E. Castro, E. J. Gaughan, and D. C. Owsley, *J. Org. Chem.*, **30**, 587 (1965).

5) W. C. Baird, Jr., and J. H. Surridge, *ibid.*, **35**, 2090 (1970).

Table 1. Rate of reaction

Method	Temp. (°C)	hexene (mol/l)	$CuBr_2$ (mol/l)	$v_1 \times 10^6$ (mol/l·sec)	$v_2 \times 10^6$ (mol/l·sec)	n_1	n_2	m_1	m_2
A	40	0.184	0.197	3.96	2.99	2.0	1.1		
		0.182	0.288	8.56	4.73				
		0.192	0.374	14.3	5.82				
B	50	0.088	0.291	4.23	3.47	1.8	1.0	1.1	1.0
		0.175	0.290	9.38	6.75				
		0.350	0.287	18.3	12.5				
		0.350	0.453	41.3	19.3				

$v_1 = k_1[\text{hexene}]^{m1}[CuBr_2]^{n1}$ $v_2 = k_2[\text{hexene}]^{m2}[CuBr_2]^{n2}$

If the equilibrium of Eq. 2 had been attained rapidly, Eq. (5) must have been realized.

$$k_a[CuBr_2]^2 = k_b[CuBr]^2[Br_2] = 4k_b[Br_2]^3 \quad (5)$$

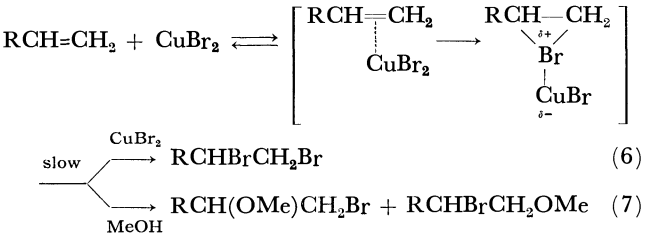
Then, concentration of bromine should be approximately proportional to the 2/3 power of cupric bromide added. The present data are hardly interpreted as the bromination with bromine.

If the reaction proceeds by bromination with bromine, an allylic bromination may be expected.[6] However, the bromination of cyclohexene with cupric bromide in refluxing carbon tetrachloride afforded 1,2-dibromocyclohexane but no 3-bromocyclohexene.

A possible explanation is that the olefin initially forms a complex with cupric bromide, followed by competitive attack of this complex by solvent methanol and another cupric bromide molecule or bromide ion. The latter step should be rate-determining.

We have also studied the bromination of isomeric 2-butenes in refluxing methanol. The resulted dibromides were composed exclusively of those expected from "*trans*" addition of bromine, in contrast to the case with cupric chloride, where a mixture of diastereomeric dichlorides was obtained.[7] Similarly, the products from cyclohexene have been reported to be only *trans*-dibromide and *trans*-methoxybromide,[5] while cupric chloride yielded the corresponding *cis*-compounds at the same time.[7] Therefore, the intermediate complex must resemble a bridged bromonium ion type species.

In summary, the reaction may be represented by the following scheme.



$$\xrightarrow[\text{slow}]{CuBr_2} RCHBrCH_2Br \quad (6)$$

$$\xrightarrow[MeOH]{} RCH(OMe)CH_2Br + RCHBrCH_2OMe \quad (7)$$

Experimental

Materials. All the reagents were the commercially available purest reagents, purified appropriately when necessary. I and II, 1,2-dibromocyclohexane, and diastereomeric 2,3-dibromobutanes were synthesized by addition of bromine to 1-hexene in methanol,[8] cyclohexene in CCl_4,[9] and *trans*- and *cis*-2-butenes in CH_2Cl_2,[10] respectively. 3-Bromocyclohexene was prepared by allylic bromination of cyclohexene with NBS in CCl_4 in the presence of benzoyl peroxide[11] (bp 65—66.5°C/20 mmHg).

Analysis. Cupric ion was determined by iodometry.[12] Cuprous ion was titrated with the standard ceric solution using ferroin as the indicator.[13] Glpc was performed on a Shimadzu GC-4AF gas chromatograph (dioctyl sebacate on Chromosorb W, 135°C, H_2 flame detector).

Kinetic Measurements. *Method A*: A solution of cupric bromide in methanol was placed in a Schlenk tube under N_2 and prewarmed in a constant temperature bath (±0.05°C). A measured amount of 1-hexene was added in the solution and the reaction was started. From time to time 10m*l* of the reaction solution was removed and was poured into 20ml of 0.05 M ferric ammonium sulfate solution (in 3N H_2SO_4) immediately after taking a small amount of sample for glpc, and the cuprous ion was titrated.

Method B: A sealed tube technique was employed; in each 15m*l* glass sealed tube 10m*l* of the reaction mixture was placed under N_2. At intervals the tube was taken out from the bath (± 0.05°C), cooled in ice-water, and kept in a freezer (−20°C). After the last tube was removed, the reaction solutions were analyzed as quickly as possible.

The amount of consumed cupric bromide was divided between the dibromide and the methoxybromide in the ratio of the glpc analysis. Then, amounts of the products were calculated on assumption that one mole of either product was formed by consumption of two moles of the cupric salt. The methoxy-bromide was composed of approximately 18% of 1-methoxy-2-bromohexane and 82% of 1-bromo-2-methoxyhexane (by Hitachi 063 gas chromatograph with Apiezon L capillary column at 90°C).

Reaction of Cyclohexene. A mixture of cyclohexene (3.3g, 0.04 mol) and cupric bromide (8.9g, 0.04mol) in CCl_4 (40 m*l*) was refluxed for 1hr under N_2. The resulted grey powder was dissolved in aqueous methanol after drying under reduced pressure, and cupric ion was titrated. The conversion was *ca.* 98%. The main reaction product was 1,2-dibromocyclohexane with some by-products (*ca.* 5%), and 3-bromocyclohexene was

not detected by glpc.

Reaction of 2-Butenes. A solution of cupric bromide in methanol (0.50 mol/*l*) was refluxed for 4 hr under 2-butene atmosphere (1 atm). The results were (the starting 2-butene, conversion, and ratio of the dibromide (III) to the methoxybromide (IV)): *trans*, 14.1%, 0.87; *cis*, 25.3%, 1.07. The dibromides formed were exclusively the "*trans*" addition products, *i.e.*, *meso* from *trans* and *dl* from *cis*.

The dibromides were sufficiently stable under the reaction conditions. When III (4 mmol) was heated in refluxing methanol (30 m*l*) with cupric bromide (15 mmol) for 4 hr under N_2, 1.1% of *erythro*-IV was formed from the *meso*-III and 0.2% of *threo*-IV from the *dl*-III.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1160(1971)

The Synthesis of 2,8-Diphenyl-4*H*,10*H*-benzodipyran-4,10-dione

Yoshimori OMOTE, Yasuomi TAKIZAWA, and Noboru SUGIYAMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo
(Received November 6, 1970)

Recently one of the present authors has reported a new flavone, "arthraxin" (I), with a 4*H*,10*H*-benzodipyran-4,10-dione skeleton.[1] Now the unequivocal synthesis of 2,8-diphenyl-4*H*,10*H*-benzodipyran-4,10-dione (II) has been performed in a way which will be described below.

The acetylation of 5,7-dihydroxyflavone (III) with acetic acid in the presence of boron trifluoride affords 8-acetyl-5,7-dihydroxyflavone (IV). The alternative structure V is rejected by means of a study of the NMR spectrum, as is shown in Table 1. From the calculation, based on the analysis in terms of the additive substituent shielding values,[2-4] each proton at H-6 or H-8 can be predicted to have the same value. The difference between the real value of the protons at H-6 and H-8 can be explained as being caused by the ring current of the structure IX. Heating an *o*-hydroxyacetophenone, IV, with benzoic anhydride and sodium benzoate gives the title compound, II. All the spectral data as well as the result of the elemental analysis support this structure.

III: $R_1=R_2=H$ VI: $R_1=R_2=CH_3$
IV: $R_1=COCH_3$, $R_2=H$ VII: $R_1=CH_3$, $R=H$
V: $R_1=H$, $R_2=COCH_3$ VIII: R_1COCH_3, $R_2=H$

Experimental

8-Acetyl-5,7-dihydroxyflavone (IV). Through a solution of 5,7-dihydroxyflavone (III) (0.4g) in acetic acid saturated with boron trifluoride, boron trifluoride gas was passed for 5 hr with stirring. The color of the reaction mixture turned from yellow to brown, and then yellow precipitates appeared. The precipitates were filtered and treated by heating under reflux in 200m*l* of water for 20 min to produce IV as yellow precipitates. This was purified by sillica-gel-column chromatography, using a benzene-ethyl acetate (2:1) mixture, to give pale yellow needles; mp 208 —209°C; UV, 235 (15700), 248 (15200), and 276 (16700) nm (ε); IR (KBr), 3450, 1655, 1605, and 1590 cm^{-1}; NMR ($CDCl_3$), δ 2.85 (s, 3H, $PhCOCH_3$), 6.35 (s, 1H, H-6), 6.70 (s, 1H, H-3), 7.5—8.0 (m, 5H, H-2', 3', 4', 5', 6'), 13.8 (s, IH), 14.3 (s, 1H).

Found: C, 69.04; H, 4.22%. Calcd for $C_{17}H_{12}O_5$: C,68.91; H, 4.08%.

2,8-Diphenyl-4H,10H-benzodipyran-4,10-dione (II). A mixture of 8-acetyl-5,7-dihydroxyflavone (0.5 g), benzoic anhydride (10 g), and sodium benzoate (1 g) was blended in a mortar and then heated in an oil bath at 180°C for 6 hr. The reaction mixture was dissolved in 30 m*l* of ethanol, and to this solution a solution of potassium hydroxide (3.2 g) in water (2 m*l*) was added; the mixture was then heated under reflux for 30 min to decompose a benzene of II. After the ethanol had been evaporated from the mixture, water was added and a stream of carbon dioxide was passed through to give yellow precipitates. The precipitates were filtered, washed with acetone, and then reprecipitated from a benzene-ethyl acetate (1:1) mixture to afford pale yellow powders; mp 275°C (decomp.); UV, 256 (41900) and 287 (40700) nm(ε); IR, 3450, 1655, 1640, and 1585 cm^{-1}; NMR δ 6.85 (s, 1H), 6.95 (s, 1H), 7.30—7.65 (m, 7H), 7.8—8.1 (m, 4H), 12.25 (s, 1H).

Found: C, 75.02; H, 3.79%. Calcd for $C_{24}H_{14}O_5$:C, 75.39; H, 3.69%.

Spontaneous Electron Transfer from Amines to Simple Quinones in an Aqueous Medium

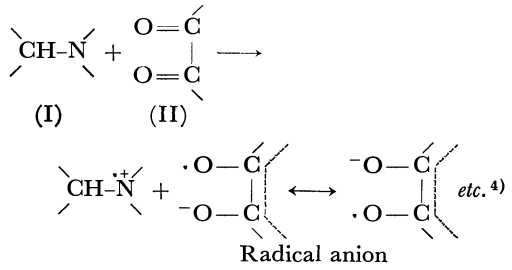
Kazuhiro MARUYAMA, Shigetoshi SUZUE, and Jiro OSUGI

Department of Chemistry, College of Liberal Arts and Science, and Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received November 6, 1970)

The formation of radical anions arising from thermal electron transfer between tetrahalogenated *p*-benzoquinone and *N*-tetramethyl-*p*-phenylenediamine has already been established.[1] Photochemically-activated electron transfer from amines to carbonyl compounds to result in the corresponding radical anions has also been recently reported by Davidson and Wilson.[2] The use of tetrahalogenated *p*- or *o*-benzoquinones as mild dehydrogenating reagents provides us with a useful method for preparing less stable quinones from the corresponding hydroquinones; the subject has been well documented by several authors.[3]

Recently we found that spontaneous electron transfer from amines to simple quinones without any electron-attracting substituents can occur in a deaerated aqueous medium. Stable radical anions of quinones, such as phenanthraquinone, acenaphthenequinone, and potassium phenanthraquinone-2-sulfonate, can be detected by ESR spectroscopy. The radical anions thus obtained are identified by comparison with that produced by the reduction of the corresponding quinone with alkali metal in tetrahydrofuran. Although phenanthraquinone and acenaphthenequinone are only slightly soluble in water, one can observe a strong ESR signal if the aqueous quinone solution saturated with a suitable amine is deaerated thoroughly. The ESR spectra of typical radical anions observed are shown in Fig. 1, together with that of the radical anion produced by the reduction of phenanthraquinone with calcium metal. The amines examined in these expreiments are ethylamine, diethylamine, and triethylamine. The mode of electron transfer may be formulated as follows:



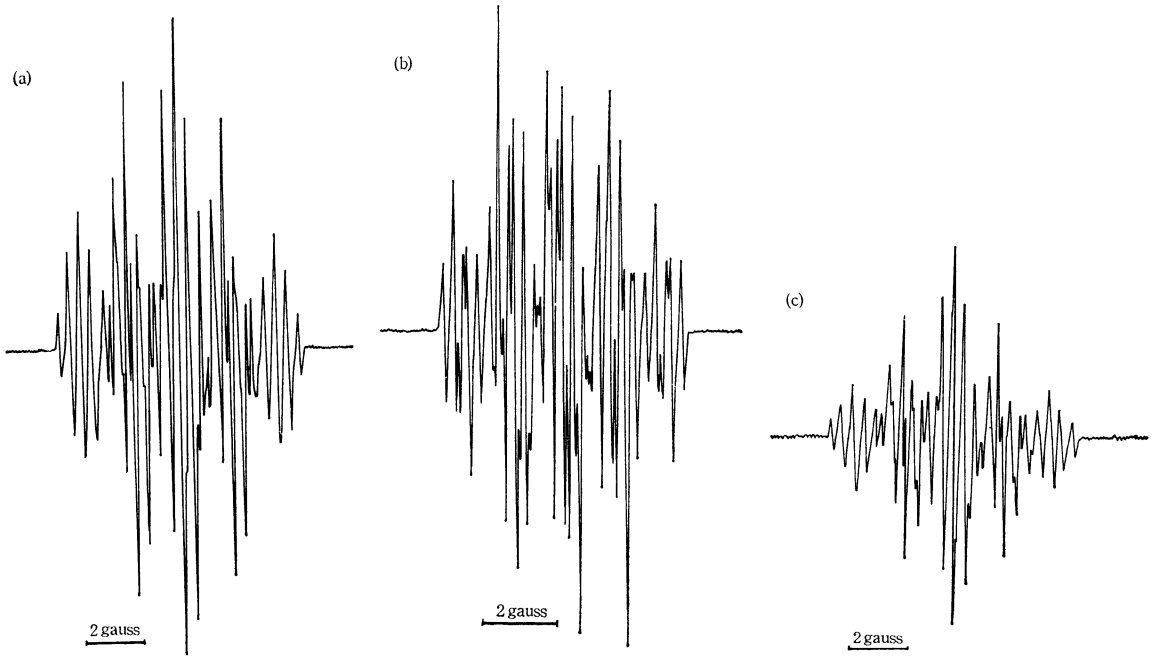


Fig. 1. (a) ESR spectrum of phenanthraquinone radical anion observed in the system phenanthraquinone-diethylamine-water (2H:1.73 gauss, 2H:1.69 gauss, 2H:0.41 gauss).
(b) ESR spectrum of potassium phenanthraquinone-2-sulfonate radical anion observed in the system potassium phenanthraquinone-2-sulfonate-diethylamine-water.
(c) ESR spectrum of radical anion produced by reduction of phenanthraquinone with metallic calcium-Hg in THF.

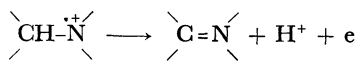
4) A detailed chemical analysis of the products derived from amines is now being performed.



(III)

The *g*-values of the radical anions are summarized in Table 1.

TABLE 1. *g*-VALUES OF RADICAL ANIONS

Quinone	Reducing Reagent	*g*-Value
phenanthraquinone	diethylamine	2.0049[a]
phenanthraquinone	Na	2.0050[b]
phenanthraquinone	K	2.0051[b]
acenaphthenequinone	triethylamine	2.0049[a]
potassium phenanthraquinone-2-sulfonate	diethylamine	2.0050[a]
potassium phenanthraquinone-2-sulfonate	triethylamine	2.0050[a]

a) in water b) in tetrahydrofuran

For a comparison of the effect of the presence or absence of a counter cation around a radical anion molecule, the *g*-values of phenanthraquinone potassium and sodium ketyls have been determined; they are also tabulated in Table 1. However, although the distribution of the unpaired electron in radical anions is much affected by the presence or absence of a counter cation,[5] no meaningful difference in *g*-value between a free radical anion and an ion-paired one is observed.

Procedure. Quinone, dissolved in pure water, and amine were each deaerated, mixed by means of the technique of a breakable seal in the dark, and left overnight. The characteristic color of the radical anion gradually appeared; thereupon the sample was submitted to ESR spectroscopy. An X-band ESR spectrophotometer with 100 Kc modulation manufactured by JEOL was used in this research.

Fluorescence and Phosphorescence Spectra of α-Naphthol in Relation to Hydrogen Bonding and Proton Transfer

Akio MATSUYAMA* and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received November 9, 1970)

Formation of a hydrogen bond between α-naphthol and a suitable proton-accepting substance may result in a change of the fluorescent state (or the lowest excited singlet state S_1) of α-naphthol from ^1L_b to ^1L_a state. It is possible that the proton may be transferred from the naphthol to the proton acceptor in the fluorescent state.[1] These problems were discussed in a previous paper by Suzuki and Baba using ether and triethylamine as proton acceptors.[2] The present note reports the results of further investigations on the same problems and also on the possibility of proton transfer in the phosphorescent state (or the lowest triplet state T_1). In this study we have employed dimethylformamide as a proton acceptor in addition to ether and triethylamine.

Figure 1 shows fluorescence and phosphorescence spectra of α-naphthol at 77°K in a mixture of isopentane and methylcyclohexane containing ether, dimethylformamide, or triethylamine.

From the behavior of the excitation-polarization spectra related to fluorescence, it has been demonstrated that the naphthol-ether system forms a simple hydrogen-bonded complex in S_1 state of ^1L_b type, while in the naphthol-triethylamine system the proton transfer takes place to yield an ion pair within the lifetime of the excited singlet state, and the fluorescence originates in the ion pair from its S_1 state which can be assigned to ^1L_a state[2].

It is seen from Fig. 1 that on changing the proton acceptor from ether to dimethylformamide the fluorescence spectrum is displaced to the red, as expected from the greater proton-accepting power of the amide as compared to ether.[3,4] In the case of dimethylformamide as acceptor, however, the fluorescence spectrum is located at a considerable distance from the spectrum of the ion pair of naphthol-triethylamine system. Thus the former is regarded as due to the α-naphthol molecule which forms a simple hydrogen bond with the amide. On the other hand, the spectrum of the naphthol-amide system is structureless, suggesting the S_1 state to be ^1L_a. The excitation-polarization spectrum related to the fluorescence of this system was measured and found to be very similar to the corresponding polarization spectrum obtained for the ion pair of naphthol-amine system.[2] We thus conclude that the fluorescent state of the hydrogen-bonded complex between the naphthol

4) When dimethylformamide was used as proton acceptor, a small amount of ether (0.2 mol/*l*) was added to get a better rigid glass. However, owing to the greater proton-accepting power of the amide, α-naphthol is considered to form the hydrogen bond only with the amide molecule.

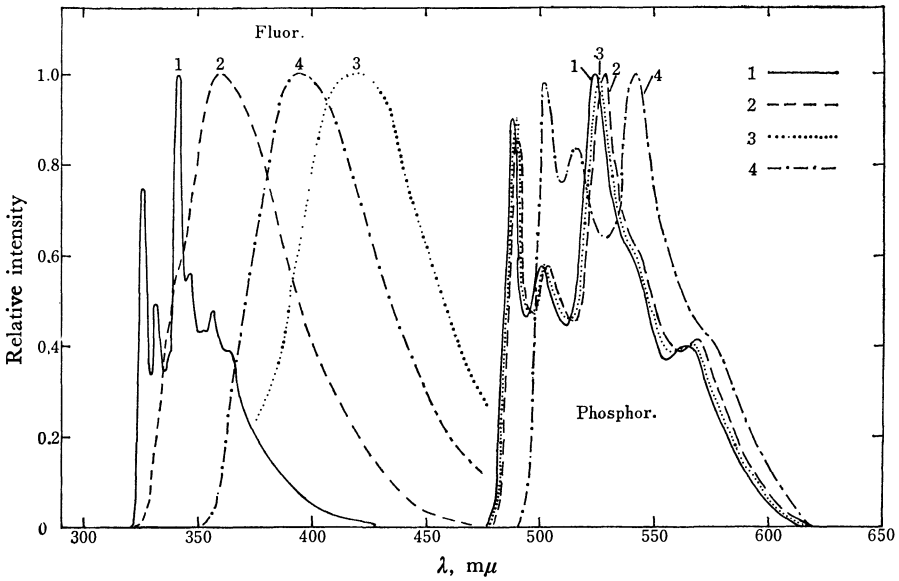

Fig. 1. Fluorescence and phosphorescence spectra of α-naphthol at 77°K: 1, 2, and 3, in isopentane-methylcyclohexane (volume ratio, 1:1) containing ether (1.0 mol/*l*), dimethylformamide (0.015 mol/*l*), and triethylamine (0.2 mol/*l*), respectively; 4, in ethanol-methanol (5:1) containing potassium hydroxide (5×10^{-3} mol/*l*).

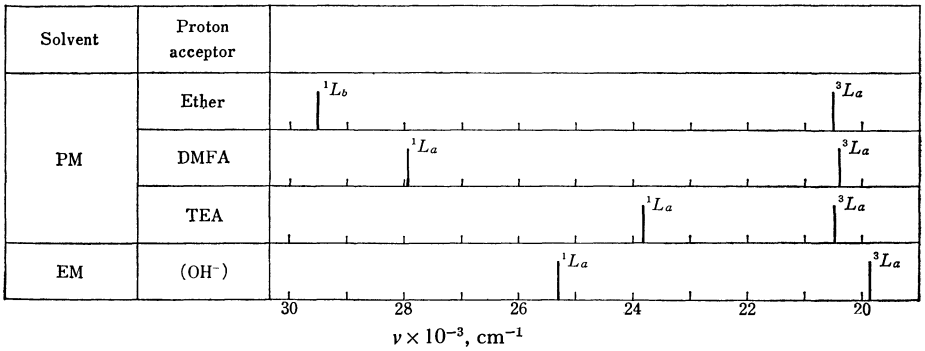

Fig. 2. Location of fluorescence maxima and phosphorescence 0–0 bands at 77°K for α-naphthol hydrogen-bonded with proton acceptors of different strengths and for α-naphtholate ion. PM, isopentane-methylcyclohexane (1 : 1); EM, ethanol-methanol (5 : 1); DMFA, dimethylformamide; TEA, triethylamine.

and dimethylformamide is of ^1L_a type.

In Fig. 1 are also shown the fluorescence and phosphorescence spectra of α-naphthol in an alkaline ethanol - methanol mixture in which the naphthol is converted to the naphtholate ion. Figure 2 shows the positions of the fluorescence and phosphorescence spectra of α-naphthol coupled with different proton acceptors, together with the positions of spectra of naphtholate ion. The emitting states are given in the Platt notation; the phosphorescent states are assigned to ^3L_a, as is generally accepted.[5] It should be noted that S_1 and T_1 states have the same electron configuration L_a in all cases except for the case of ether as proton acceptor.

The phosphorescence spectrum of α-naphthol - triethylamine system closely resembles the corresponding spectra of the naphthol - ether and naphthol - dimethylformamide systems both in position and in shape. The phosphorescence spectra of the naphthol associated with any of the proton-accepting substances are quite different from the spectrum of the α-naphtholate ion. Consequently, it is reasonable to attribute the former spectra to the respective hydrogen - bonded complexes in which no proton transfer occurs. Thus, phosphorescence is emitted solely from the simple hydrogen - bonded species even when triethylamine is used as the proton acceptor. Since in the naphthol - triethylamine system the ion pair is responsible for the fluorescence, proton transfer must occur in the reverse direction within the lifetime of T_1 state.

The results of the present investigations on the fluorescence and phosphorescence spectra of α-naphthol in relation to hydrogen bonding and proton transfer are consistent with the view that the acidity of a phenolic compound is in general much weaker in the triplet state than in the excited singlet state.[6]

Experimetal

α-Naphthol was recrystallized from ligroin and was sublimed *in vacuo*. Methylcyclohexane of spectroscopic quality was used without further purification. Isopentane was passed through a silica-gel column. Ethyl ether was distilled over metallic sodium. Dimethylformamide was shaken with potassium hydroxide and calcium oxide and was then distilled. Triethylamine was fractionally distilled over phosphorus pentoxide. Absorption and emission spectra and excitation-polarization spectra were measured at 77°K in the same way as described previously.[7]

Elementary Reactions of Metal Alkyl in Anionic Polymerization. VI. The Synthesis and Reactivity of Calciumzinc Tetra-*n*-butyl

Yusuke KAWAKAMI, Yoshiro YASUDA, and Teiji TSURUTA
Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received November 14, 1970)

According to the standard method proposed by Gilman,[1] calciumzinc tetraethyl ($CaZnEt_4$) is prepared in benzene by an interchange reaction between diethylzinc and metallic calcium. Diethyl ether cannot be used for the solvent, because it is too reactive, the calcium ate complex formed being decomposed by the ether.[2] Diethyl ether, on the other hand, has been found to be an appropriate solvent for the preparation of calciumzinc tetra-*n*-butyl ($CaZn(n\text{-}Bu)_4$).

Experimental

*Preparation and Analysis of Calciumzinc Tetra-*n*-butyl.* A mixture of 4.0g (0.10 atom) of calcium metal, 27 m*l* (0.155 mol) of $n\text{-}Bu_2Zn$, and 27 m*l* of diethyl ether was heated, under stirring, to 50—60°C (bath temperature), the temperature was maintained at that value for about 24hr. During the reaction a reddish suspension was produced. After 24hr, heating and stirring were stopped and the reaction mixture was allowed to stand at least one night. The supernatant layer was then taken out with a syringe and put into a 100-m*l* flask. Then the ether and the unreacted $n\text{-}Bu_2Zn$ were removed under reduced pressure. The yellow residue was washed with *n*-heptane several times and then freeze-dried from benzene. The residue was dissolved again into diethyl ether, and the calciumzinc tetra-*n*-butyl in the supernatant solution was analyzed by EDTA chelate titration, NMR, and vapor-phase chromatography(vpc). The tetrabutyl compound, unlike $CaZnEt_4$, cannot be prepared in benzene. The use of tetrahydrofuran as a solvent resulted in producing the ate compound in a lower yield. Dimethoxyethane and 1,4-dioxane could not be used as solvents because of their high reactivities toward the calcium compound.

*Analysis of Calciumzinc Tetra-*n*-butyl.* In EDTA chelate titration, the amount of zinc was determined by using xylenol orange (XO) as an indicator at pH 5.0—5.5 (CH_3COOH-CH_3COONa buffer solution).[3] The total amount of calcium plus zinc was determined by using Eriochrome Black T (EBT) as an indicator at pH 10.0 (NH_3-NH_4Cl buffer solution).[3] The results of the analyses are shown in Table 1. As is shown in Table 1, the ratio of calcium to zinc(1.05±0.02), as well as that of *n*-butyl to metal (4.1±0.1), is in accordance with the $CaZn(n\text{-}Bu)_4$ composition. A new triplet, observed in the vicinity of 9.8 τ in the NMR spectrum of Fig. 1, is assigned to the methylene signal of metal-CH_2- in the ate complex.

TABLE 1 EDTA AND VPC ANALYSES OF $CaZn(n\text{-}Bu)_4$

No	Ca/Zn	*n*-Butyl/Ca	*n*-Butyl/Zn
1	1.03	4.0	4.1
2	1.07	4.1	4.2

TABLE 2. REACTION OF $CaZn(n\text{-}Bu)_4$ WITH CCl_4

Initial $CaZn(n\text{-}Bu)_4$	Recovered *n*-butane from supernatant (A)		Titrated metal in supernatant (A)		*n*-Butyl/Zn
	before drying-up	after drying-up	Zn	Ca	
0.390 mmol	0.787 mmol	0.784 mmol	0.389 mmol	0.0	2.0

Reaction with Carbon Tetrachloride. Di-*n*-butylzinc scarcely reacts with carbon tetrachloride. On the other hand, as is shown in Table 2, calciumzinc tetra-*n*-butyl, when reacted with exess CCl_4 to form white precipitates in diethyl ether, leaves di-*n*-butylzinc in the supernatant diethyl ether solution, (A), no calcium being detected by the EDTA chelate titration of the supernatant. Since *n*-butane corresponding to a half of the *n*-butyl groups of the $CaZn(n\text{-}Bu)_4$ used was recovered after the hydrolysis of the supernatant (A), the zinc alkyl component in $CaZn(n\text{-}Bu)_4$ was considered to survive in the supernatant without any reactions with carbon tetrachloride. This consideration was further supported by the following results: (i) The amount of the *n*-butane recovered by hydrolyzing the supernatant (A) after the "drying-up" procedure[4] was just the same as that of the *n*-butane recovered from (A) before the "drying-up" procedure.

(ii) The supernatant (A) polymerized methyl vinyl ketone (MVK) to give a stereoregular polymer. The behavior of (A) was in harmony with that of a zinc alkyl solution.[6]

(iii) Copolymerization between MVK and styrene initiated with (A) was shown to possess an anionic character in a way similar to the copolymerization initiated with zinc alkyl.

(iv) α,β-Unsaturated esters, *e.g.*, methyl methacrylate (MMA), were not polymerized by the supernatant (A). If the supernatant had contained a trace of calcium species, the unsaturated esters would have been polymerized anionically.

Judging from the data described above, $CaZn(n\text{-}Bu)_4$ seems to have an ate complex structure consisting of $Ca(n\text{-}Bu)_2$ and $Zn(n\text{-}Bu)_2$. Recently, a detailed report about the nature of the $MZnEt_4$, (in which M=Ca, Ba, and Sr) was published.[7] Another report concerning the structure of the ate complexes of the alkaline earth metals will be published elsewhere.[2]

Reaction with α,β-Unsaturated Ketones. The only elementary reaction of calciumzinc tetra-*n*-butyl with the saturated ketone or aldehyde is the hydrogen abstraction reaction. The calcium ate compound can virtually cause no carbonyl addition reaction, even with such a reactive carbonyl group as those of C_2H_5CHO, $C_2H_5COC_2H_5$, and CH_3COCH_3, as is shown in Table 3. The addition reaction would result in a decrease in the *n*-butane recovered before the "drying-up" procedure. When an α,β-unsaturated ketone was treated with $CaZn(n\text{-}Bu)_4$, no carbonyl addition products were detected, the elementary reactions between $CaZn(n\text{-}Bu)_4$ and α,β-unsaturated ketones presumably being conjugate addition and hydrogen abstraction reactions in the same way as is the case with $n\text{-}Bu_2Zn$.[5] When a diethyl ether solution of $CaZn(n\text{-}Bu)_4$ was added to MVK in diethyl ether (molar ratio 1 : 100), a rapid polymerization of MVK was observed, thus forming polymer precipitates. The supernatant (B) was found to contain neither MVK monomer nor any calcium compounds, the only species detected in (B) by EDTA chelate titration being zinc compound. When MVK was newly added to the supernatant (B), the polymerization of MVK was observed to take place, giving a stereoregular polymer.[6] MMA was not polymerized by the supernatant(B). The chemical behavior of the supernatant layer, (B), toward the α,β-unsaturated ketone and ester seems to coincide with the known chemical behavior of zinc alkyl. These observations showed that the calcium-alkyl part of $CaZn(n\text{-}Bu)_4$ reacted with MVK very rapidly, forming polymer precipitates, and that $n\text{-}Bu_2Zn$ was liberated in the supernatant layer, (B). The liberated $n\text{-}Bu_2Zn$ was reacted with MVK competitively with the calcium-alkyl part, though the reactivity of the former was much lower than that of the latter.

TABLE 3. REACTION OF $CaZn(n\text{-}Bu)_4$ WITH CARBONYL COMPOUNDS[a]

Compound	Recovered *n*-butane from supernatant (B)

SHORT COMMUNICATIONS

On Electro-optic Effect in Lyotropic Liquid Crystals

Taro TACHIBANA and Mitsuko TANAKA
Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo
(Received November 13, 1970)

Some semitransparent lyotropic liquid crystals become turbid at once on application of an electrical potential and recover rapidly on removal of the potential. This phenomenon, found at first by Winsor[1] with the aqueous solutions of ionic surfactants of alkyl sulfate type, was attributed to the alignment of a randomly oriented liquid crystal by the electrical field. We have found a similar electro-optic effect in some lyotropic liquid crystals of ternary systems composed of ionic surfactant-amphiphile-water[2].

The systems examined were I, Na caprylate-caprylic acid (or decanol)-water, II, K caprylate-decanol-water, and III, cetyltrimethylammonium bromide-hexanol-water. The samples contained in a narrow-bore glass tube like a salt bridge between two electrodes were visually observed. A DC potential of about 100 V/cm was applied between two electrodes as a pulse of the order of 10 msec. Though a current of several milliamperes passed through the samples, the short time was sufficient for observing the turbidity preventing the sample from undue heating. The electro-optic effect was examined for all regions of the phase diagram.

According to Mandell and Ekwall,[3] there are structurally different liquid crystalline phases designated B, C, D, E, and F in the ternary systems I, II, and III. We found that the regions exhibiting the electro-optic effect were confined to phase B (*e.g.* 9.0% KC_8, 9.0% C_8-acid, and 82% H_2O) for system I, phases B (*e.g.* 8.6% KC_8, 9.3% decanol, and 82.1% H_2O) and C (*e.g.* 20.6% KC_8, 24.4% decanol, and 55.0% H_2O) for system II, and a part[4] of water-rich region of phase D (*e.g.* 7.6% CTAB, 5.0% hexanol, and 87.4% H_2O) for system III. Turbidity was produced only in phase B also when the alcohol in the systems was replaced by heptanol or octanol. This shows that the effect is specific for such types of liquid crystal. Phase B is smectic and has a lamellar structure comprising parallel layers of amphiphilic ions and molecules with interlayer water. Fontel *et al.*[5] considered from X-ray and other data that, in phase B, the stability of the double layers is possibly so low that they are easily divided into smaller fractions of varying size. Such a labile structure also might be associated with electro-optic effect.

Thin films of the samples in these phases were examined under a microscope between crossed Nichols. They showed weak birefringence with a woven texture. On application of a continuous potential (about 1.5 sec) of 50 V/cm to opposite edges of the film, it became turbid and the microscopic texture changed rapidly from woven to granular. At the same time the field of view as a whole darkened, showing a decrease of birefringence. This could be accounted for by assuming that the structure of liquid crystal is disrupted in part, probably by the shear induced in the liquid crystal by ionic migration, and that the fractions of liquid crystal thus produced disperse as large micelles in the medium and act as light-scattering centers.

Electro-optical turbidity effect has been also found in thin layers of some thermotropic liquid crystals of nematic class. Heilmeier *et al.*[6] attributed this effect to the orientation fluctuation produced by disruptive effects of ions in transit through the aligned nematic medium. In contrast to this case, the turbidity effect in lyotropic liquid crystals might be due to density fluctuation.

A New Oxygen-Insertion Reaction into Silicon-Silicon Bonds with Tertiary Amine Oxides

Hideki SAKURAI, Mitsuo KIRA, and Makoto KUMADA*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

**Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto*

(Received December 1, 1970)

We reported an oxidation reaction of organodisilanes with perbenzoic acid.[1] Spialter and Austin subsequently described oxidative cleavage of the silicon-silicon bonds with oxides of nitrogen[2] and ozone.[3] These reagents are regarded as electrophilic and kinetic investigations led to the suggestion of a mechanism similar to that of epoxidation.[1,3] We now wish to describe a new and mechanistically interesting insertion reaction of oxygen from tertiary amine oxides into silicon-silicon bonds. The reaction also constitutes a new reduction of amine oxides.[4]

Trimethylamine *N*-oxide reacts exothermally with phenoxypentamethyldisilane in dimethyformamide (DMF), yielding phenoxypentamethyldisiloxane in a moderate yield.[5] Oxidation of hexamethyldisilane to hexamethyldisiloxane with trimethylamine *N*-oxide required somewhat drastic conditions, the yield being 71% after heating at 90—100°C for 6 hr in DMF. Vinylpentamethyldisilane afforded vinylpentamethyldisiloxane in contrast to the reaction with perbenzoic acid.[1]

$$CH_2{=}CHSiMe_2SiMe_3 \xrightarrow{Me_3NO} CH_2{=}CHSiMe_2OSiMe_3$$

$$CH_2{=}CHSiMe_2SiMe_3 \xrightarrow{PhCO_3H} CH_2{-}CHSiMe_2OSiMe_3 \quad (\backslash O /)$$

Pyridine *N*-oxide reacts more slowly than does trimethylamine *N*-oxide. Treatment of phenoxypentamethyldisilane with pyridine *N*-oxide in DMF, dioxane or toluene afforded phenoxypentamethyldisiloxane in over 85% yield. Although hexamethyl disilane did not react with pyridine *N*-oxide, other organodisilanes such as phenyl, 1,2-diphenyl-, and 1,1-diphenyl-substituted permethylated disilanes gave the corresponding disiloxanes as single products together with pyridine in dioxane.

$$X\text{-}SiMe_2SiMe_3 + C_5H_5NO \longrightarrow X\text{-}SiMe_2OSiMe_3 + C_5H_5N$$

These results suggest a nucleophilic attack of *N*-oxides on the silicon-silicon bond as a primary step, which was supported by kinetic studies.

Table 1. Second Order rate constants for oxidation reaction of phenoxypentamethyldisilanes with pyridine *N*-oxide in toluene at 135.0°C[a]

Substituent	$10^5\ k$,[b] $l\ mol^{-1}\ sec^{-1}$
p-CH_3O	6.43±0.27
m-CH_3	6.32±0.16
H	9.74±0.50
p-Cl	21.9 ±0.7
m-CF_3	38.7 ±2.4
p-CH_3CO	37.5 ±0.8

a) Initial concentrations of silanes and pyrdine *N*-oxide were 0.02—0.21 mol l^{-1} and 0.03—0.3 mol l^{-1}, respectively.

b) Average of two to four runs.

The extent of reaction of substituted phenoxypentamethyldisilane with pyridine *N*-oxide in toluene at 135.0°C was followed by the disappearance of disilanes (glpc), the second-order rate law being found to hold accurately. The results are listed in the Table.

A tolerably good Hammett plot was obtained between log (k/k_H) and σ (r=0.971). A positive reaction constant ρ = +1.18 indicates nucleophilic attack of *N*-oxides at silicon to be involved in the rate-determining step.

The mechanism and rate parameters of the reaction appeared interesting in connection with the peracid oxidation of disilanes.[1]

3) L. Spialter and J. D. Austin, *Inorg. Chem.*, **5**, 1975 (1966).

4) K. Naumann, G. Zon and K. Mislow, *J. Amer. Chem. Soc.*, **91**, 2788, 7012 (1969), reported the use of hexachlorodisilane as a reducing agent for phosphine oxides, amine oxides, and sulfoxides. They suggested the intermediacy of hexachlorodisiloxane formed by a mechanism involving a free trichlorosilyl anion. In the present study, however, it has been disclosed that organodisilanes are generally capable of reducing amine oxides.

5) Yields of disiloxane depend on the degree of dehydration of $Me_3NO{\cdot}2H_2O$. Main by-products were phenol and $(Me_3SiMe_2Si)_2O$ through hydrolysis.

Elektronenübertragungsfähigkeit des durch die Elektroreduktion entstandenen Dimeres der 1,3-disubstituierten Pyridine

Shozo KATO, Jun'ichi NAKAYA,* und Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

**Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Sakai, Osaka*

(Eingegangen am 7. Januar, 1971)

Es scheint selbstverständlich, daß der Dihydropyridinring im allgemeinen als eine Art Elektronendonator geeignet ist, weil das 1,4,4-Trimethyl-1,4-dihydropyridin mit dem Maleinsäureanhydrid einen *CT*-Komplexe bilden kann.[1] Andererseits erwähnt Wallenfels,[2] daß das Tetracyanoäthylenradikal auf die Reaktion zwischen Dihydropyridin und TCNE momentan zurückgeführt werden kann. Auch berichteten er und Gellrich,[3] daß bei der metallischen Reduktion von *N*-alkylierten Nicotinamiden das Dimere hergestellt wird und daß es beim Vergleich der UV-Spektren[3] order NMR-Spektren[4] in 6-Stellung des Pyridinrings verknüpft ist.

Bisher haben wir einige einelektronische Reduktionsprodukte von aza-heteroaromatischen Verbindungen einheitlich beobachtet; bei der im allgemeinen als Energie für die Reduktion das beschränkte Potential auf Grund der polarographischen ersten Welle verwendet wurde. Wenn durch eine derartige Elektroreduktion das Dimere der 1,3-disubstituierten Pyridine entsteht, für das wir uns als Modellverbindung der NADH interessieren, wird man auch die Möglichkeit einer Elektronenübertragungsfähigkeit statt einer Dihydroverbindung erwarten können. Bei der elektrolytischen Reduktion kennzeichnet es sich durch den radikalischen Angriff, infolgedessen ist die Struktur des einelektronischen Reduktionsproduktes nicht das Dimere des 1,4-Dihydrotyps, wie es bei der Reduktion mit Natriumdithionit der Fall ist, sondern 1,6-Dihydrotyp.[5]

Hier wollten wir die Elektronenübertragungsfähigkeit des von *N*-Benzyl-3-carbamoylpyridinium Chlorid (Ia) hergestellten Dimeres (Ib)[5] mit *N*-Benzyl-3-carbamoyl-1,4-dihydropyridin (Ic) vergleichen. In der Pufferlösung (pH 10) zeigt Ib seine polarographische Oxydationswelle an −0,30 V (*vs.* SCE), aber nach dem Verlauf ergibt sich eine andere Reduktionswelle an −0,97 V, die der Reduktion von Ia zukommt.[5] Es ist bemerkenswert, daß Ic keine Oxydationswelle im Gebiet von anliegender Spannung zeigen kann. Unter Hinweis darauf, ist das Verhalten des von *N*-Benzyl-3-carboxylpyridinium Chlorid (IIa) hergestellten Dimeres (IIb), das die allernegativste Oxydationswelle (−0,59 V) innerhalb des Dimeres von derartigem *N*-Alkyl-3-substituierten Pyridin ergeben konnte,[5] in Kürze zugefügt worden; über die ordnungsgemäß berichtet werden soll.

In der elektrolytischen Zelle, in der man gleichzeitig das UV-Spektrum messen kann,[6] werden 2, 13 mg ($5\cdot10^{-6}$ mol) Ib mit 1,72 g Tetrabutylammonium Perchlorat in 50 m*l* DMF aufgelöst. Sobald man 2,46 mg ($1\cdot10^{-5}$ mol) Chloranil Zufügt, färbt sich die Lösung tiefgelb. Nachdem ungefähr 10 min unter der stickstoff'schen Atmosphäre gerührt wurde, mißt man Polarogramme und Spektren. Auf dem Polarogramm erscheint die neue Oxydationswelle (0,0V) des Chloranilanionradikals statt Ib quantitativ. Die Erscheinung des Radikals wird auch nach der Entstehung eines stark absorbierten ESR-Spektrums festgestellt. Durch den Vergleich der Extinktion der langwelligen Bande (450 mμ) des UV-Spektrums, die dem Chloranilanionradikal zukommt, kann man erkennen, daß im Fall von Ic diese nur 27%-ige Elektronenübertragungsfähigkeit gegen Ib besitzt. Ib reagiert außerdem mit TCNQ in DMF quantitativ und ergibt das grün gefärbte Tetracyanochinodimethananionradikal, das auf Grund der Absorption des ESR-Spektrums ermittelt wurde. Und das von *N,N'*-Diphenyl-*p*-phenylendiamin elektrolytisch entstandene Kationradikal,[7] das sich blau in Acetonitril gefärbt hat, entfärbt sich sofort durch Zusatz von Ib.

Wenn man *p*-Phenanthrolin-di-methiodid in der Lösung von IIb (pH 10) zufügt, entsteht sogleich das einelektronische Reduktionsprodukt, ein tiefrotes Radikal, das wegen seiner kationischen Abstoßung sehr stabil ist. Dieses Radikal selbst ist durch das polarographische Verhalten[6] bestätigt worden.

Photoaddition Reactions of Pyromellitic Acid Tetramethylester to Olefins

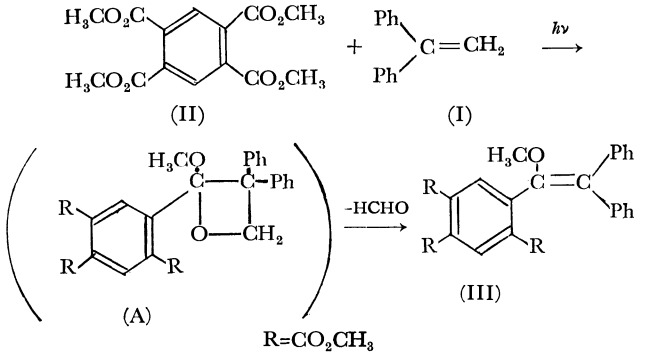
Yutaka KATSUHARA, Yasuo SHIGEMITSU, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received January 28, 1971)

In our previous paper, we reported the photoadditions of some aromatic carboxylate esters with one or two electron-withdrawing groups to 1,1-diphenylethylene (I).[1] As part of our series of studies of the photochemistry of aromatic carboxylate esters, we will now report on the photoreactions of pyromellitic acid tetramethylester (II) with olefins.

A mixture of 0.03 mol of II and 0.09 mol of I in acetonitrile was irradiated through a Pyrex filter with a 500-W high-pressure mercury lamp for 120 hr under a nitrogen atmosphere to give pale yellow needles (mp 108—109°C) in a 95% yield based on the reacted ester. This photoproduct was identified as the olefin (III) by a study of its IR, NMR, and mass spectra and by elemental analysis. Obviously, III would be derived from an intermediary oxetane (A) by deformylation due to the steric hindrance of the adjacent *o*-methoxycarbonyl group.

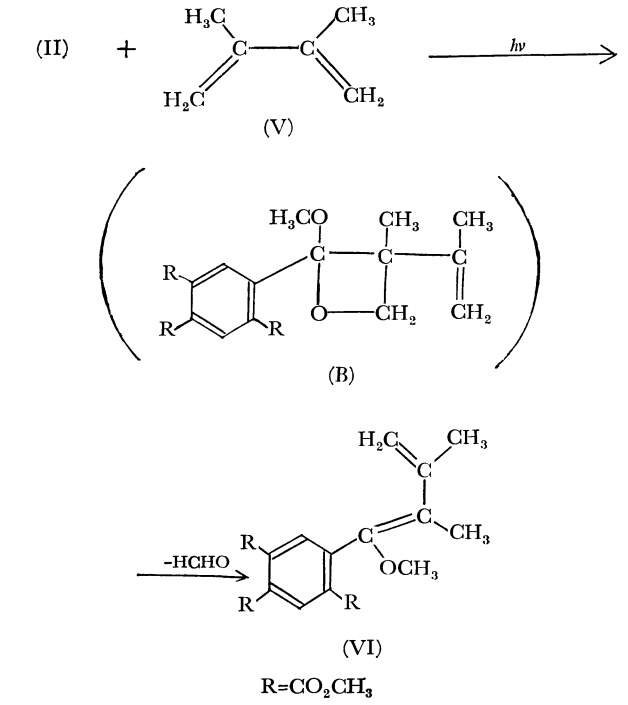


(II) (I) (A) (III)

R=CO_2CH_3

Recently Koltzenburg *et al.* reported that benzene reacted photochemically with butadienes at the 1,4-position of the aromatic ring to give cycloadducts.[2] On the other hand, we have observed a photocycloaddition of the aromatic ring of trimesic acid triesters to cyclooctene (IV).[3] In order to examine the possibility of photocycloaddition at the aromatic ring of II, the following photoreactions of II with some olefins were done.

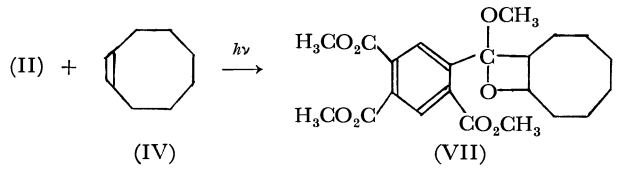
First, a solution of 0.02 mol of II and 0.10 mol of 2,3-dimethylbutadiene (V) was irradiated for 20 hr under the conditions described above. The diene product (VI), consisting of S-*cis*- and S-*trans*-forms, was obtained in a 13% yield, together with large amounts of butadiene polymers, but no photocycloaddition reaction at the aromatic ring took place at all. It was also reasonable to consider that VI was formed *via* an unstable oxetane (B).



(II) (V) (B) (VI)

R=CO_2CH_3

Second, a solution of 0.03 mol of II and 0.09 mol of IV was irradiated in a similar manner, an unstable oxetane (VII) was thus obtained in a 16% yield as the sole detectable product.



(IV) (VII)

From the facts that only one isomeric oxetane was formed in each photocycloaddition of II to olefins, and that acetone was produced by the photoreduction of II in 2-propanol, the reactive species of these reactions were assumed to be n-π^* in nature. Studies of the reactive species of polysubstituted aromatic carboxylate esters are currently in progress.

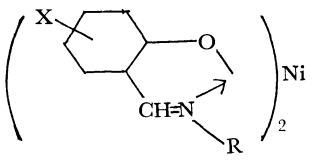
A New Tetrahedral Nickel(II) Complex—Bis(*N*-4-methoxyphenyl-3-methoxysalicylideneiminato)nickel(II)

Akira TAKEUCHI and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received February 6, 1971)

It was concluded[1,2] that bis(*N*-aryl-substituted salicylideneiminato)nickel(II) complexes (abbreviated as Ni(X-SAL·R)$_2$, Formula I) in non-donor solvents existed as an equilibrium mixture composed of various species such as planar, tetrahedral and associated forms, the equilibrium depending upon the nature of X and R as well as upon concentration and temperature. Both a planar and an associated species could be isolated as crystals, but no tetrahedral species has so far been obtained for these complexes. The present communication describes the first isolation of a tetrahedral species, which has been achieved with bis(*N*-4-methoxyphenyl-3-methoxysalicylideneiminato)nickel-(II).



Formula I

The crude product of Ni(3-CH_3OSAL·4-CH_3O–Ph)$_2$ was obtained, Ph being phenyl group, by a reaction of bis(3-methoxysalicylaldehydato)-nickel(II) (0.01 mol) with 4-methoxyphenyl amine (0.02 mol) in ethanol or chloroform. A solution of the crude product in chloroform or benzene was slowly evaporated at about 50°C, until red-brown crystals separated out. The red-brown crystals were filtered off, while the solution was kept warm. Mp 239—240°C. Found: C, 62.66; H, 4.92; N, 4.78%. Calcd for Ni($C_{15}H_{14}NO_3$)$_2$: C, 63.07; H, 4.94; N, 4.90%.

Planar coordination is ruled out for this compound, since it is paramagnetic with a magnetic moment of 3.30 B.M. at room temperature. The solid spectrum of this complex displays main features typical of the tetrahedral nickel(II) complex,[3] having *d-d* bands at about 5.7, 8.0, and 14.0 kK. It is concluded that the red-brown form of Ni(3-CH_3O–SAL·4-CH_3O–Ph)$_2$ has a tetrahedral configuration. Inspection of electronic spectra also reveals that Ni(3-CH_3O–SAL·4-CH_3O–Ph)$_2$ in chloroform exists predominantly as a tetrahedral species.

It is presumed that the steric hindrance arising from the methoxy-group at the 3-position does not absolutely exclude the planar configuration for Ni(3-CH_3O–SAL·4-CH_3O–Ph)$_2$, since Ni(3-CH_3O–SAL·2,6-$(CH_3)_2$Ph)$_2$, in which steric hindrance is much higher, was concluded to have a planar configuration in solid state and in non-donor solvent.[4] For occurrence of the tetrahedral species in crystalline state, the steric condition is not considered to be the only responsible factor. Another important factor might be the suitable field strength produced by the ligand 3-CH_3O–SAL·4-CH_3O–Ph, which seems to be low enough to disfavour the planar configuration for the complex.

Besides the red-brown crystals, olive-green crystals with composition of Ni(3-CH_3O–SAL·4-CH_3O–Ph)$_2$·H_2O have also been isolated by recrystallization of the crude product from 95% ethanol.

Phase Transition in Hexammine Nickel Halides

Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received February 15, 1971)

Palma-Vittorelli *et al.*[1] found a sudden broadening of the ESR absorption line of Ni^{2+} in $[Ni(NH_3)_6]X_2$ crystals (X; halogens) at low temperature. It was pointed out that this anomalous behavior is not of magnetic origin but is concerned with the motional state of ammonia. Aiello *et al.*[2] showed that over a narrow range temperature a sharp line was superposed on a broader one in the ESR spectrum of the chloride, indicating coexistence of the two phases. These works and an entropy anomaly in the analogous iodide briefly mentioned by van Kempen *et al.*[3] stimulated us to investigate the thermodynamic property of the substances. We report here a preliminary result of a heat capacity measurement on $[Ni(NH_3)_6]Cl_2$ and $[Ni(NH_3)_6]Br_2$. The specimens were crystals 0.5—1 mm in size prepared by the standard method and dried in a desiccator over calcium oxide for a year. The heat capacity measurement was performed between 12 and 300 K with an adiabatic calorimeter of nearly the same construction as that of the previous one.[4,5] the accuracy of the measurement was estimated to be better than 1% at 30 K and 0.3% at 200 K. In total 132 heat capacity data were collected for the chloride and 125 data for the bromide, some of which are shown in Fig. 1. The anomalous increase of heat capacity was found to occur with peaks at 83.17 K and 34.99 K for the chloride and the bromide, respectively. These temperatures are to be compared with 82.5 K and 35 K at which the line width transitions were observed in the ESR spectra.[1] Time required for attaining thermal equilibrium in the calorimeter was usually 5—10 min, but in the transition region of the chloride more than 45 min was required, while for the bromide roughly 20 min was sufficient even at the peak of the anomaly. In contrast to the sharp peak of the bromide the peak of the chloride is rather broad. A preliminary estimate of the entropy of transition was made by interpolating the normal heat capacity smoothly to the transition region. It was found to be 35.1 $JK^{-1}mol^{-1}$ for the chloride and 17.4 $JK^{-1}mol^{-1}$ for the bromide, with a somewhat larger ambiguity for the latter due to larger arbitrariness in the interpolation.

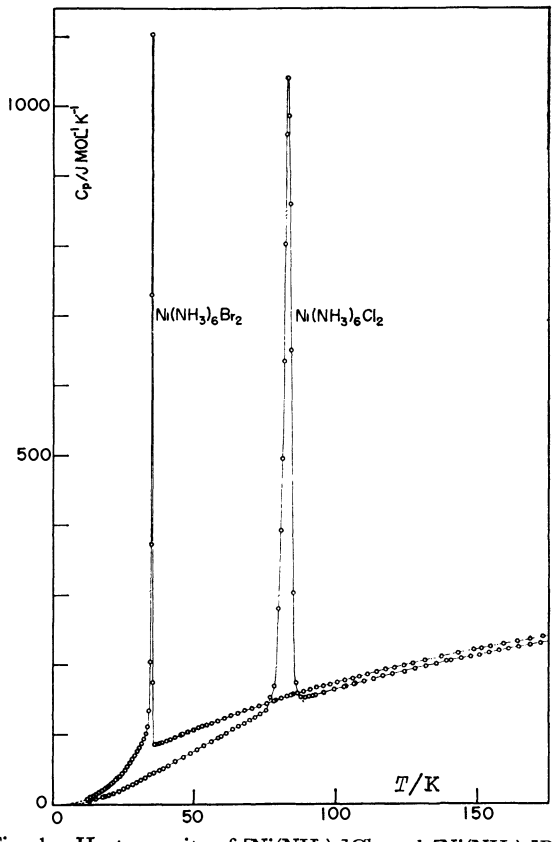

Fig. 1. Heat capacity of $[Ni(NH_3)_6]Cl_2$ and $[Ni(NH_3)_6]Br_2$.

Recently, Klaaijsen *et al.*[6] found heat capacity anomalies in several hexammine metal iodides. They inferred from the estimated entropy change that the transitions in the series of the iodides might have the same physical background. As Bates and Stevens[7] pointed out on an electrostatic model, it is possible that there are eight equivalent configurations which the single complex cation can take in the isolated state. If one of them is favorable at low temperature, the transition entropy would amount to Rln8, which is close to the estimated value for the bromide.

Binuclear Copper(II) Complexes Derived From 3-Formyl-5-methylsalicylaldehyde and Glycine

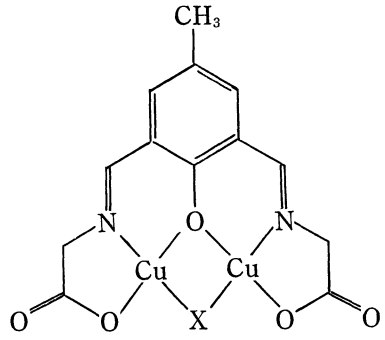
Hisashi Okawa and Sigeo Kida

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received February 17, 1971)

Although many binuclear copper(II) complexes have been synthesized, there are few in which two copper (II) ions are bridged with two different groups.[1,2] We report here the syntheses of three new binuclear copper (II) complexes formed by the reaction of copper(II) ion with 3-formyl-5-methylsalicylaldehyde and glycine. These complexes possess the same surrounding organic moiety except for the second bridging group, which is chloride, bromide, or hydroxide anion (Fig. 1), and seem useful in investigating the role of the bridging group in exchange interaction.

The Cl-bridged complex (green needles) was prepared as follows. To a hot ethanolic solution of copper(II) chloride dihydrate and aldehyde was added an aqueous solution of a stoichiometric amount of glycine. The resulting clear solution was heated on a water-bath for ten min to give green needles. The same procedure was employed in the synthesis of the corresponding Br-bridged complex (green needles) by using anhydrous copper(II) bromide instead of copper(II) chloride dihydrate. The OH-bridged complex was obtained as blue prisms, when copper(II) acetate monohydrate or copper(II) sulfate pentahydrate was used as a metal source. Analytical data of the complexes given in Table 1 agree with the formulas shown in Fig. 1.



X=Cl, Br, OH

Fig. 1.

Table 1. Analytical data of complexes

Complex	Found(%)			Calcd(%)		
	C	H	N	C	H	N
X=Cl	35.42	2.67	6.11	35.67	2.53	6.40
Br	32.65	2.41	5.51	32.38	2.30	5.81
OH	35.88	3.25	6.33	35.70	3.23	6.41[a]

a) Calculated for monohydrate.

Infrared spectra of the complexes exhibit no $\nu_{C=O}$ mode of a formyl group and show a strong broad band due to the C=O (carboxylate), C=N, and C=C vibration in the region 1645—1600 cm^{-1}. The reflectance spectra of the Cl-, Br-, and OH-bridged complexes show one broad *d–d* band at 695, 695, and 650 mμ respectively. The Cl- and Br-bridged complexes seem to take a binuclear structure in water as well as in pyridine, judging from the close resemblance of the spectra in solutions to those in solid states. Magnetic moments of the Cl- and Br-bridged complexes measured at room temperature were 1.72 and 1.76 B.M. respectively, which are close to the value 1.73 B.M. calculated from the spin-only formula. The magnetic moment of the OH-bridged complex was 1.09 B.M., suggesting a fairly strong antiferromagnetic interaction between the copper (II) ions.

The Photo-doping of Metals into Solids for New-type Imaging Systems

Isamu SHIMIZU, Hiraku SAKUMA, Hiroshi KOKADO, and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 23, 1971)

New imaging systems are presented by using photosensitive thin films of chalcogenides-metal or metal halogenides-metal systems. Photosensitive thin films of PbI_2-Ag have been used for recording the hologram by Tubbs,[1] and the photoreaction was described as follows:

$$PbI_2 \xrightarrow{h\nu} (PbI_2)^*$$
$$(PbI_2)^* + 2Ag \longrightarrow Pb + 2AgI \quad (1)$$

Kostyshin *et al.*[2] mentioned, without giving any details, that Ag could be reacted with As_2S_3 by light.

The photosensitive double layers were prepared by the successive vacuum (10^{-5} Torr) evaporation of viterous chalcogenides (ex., As_2S_3, $As_2Se_3As_2Te_3$, *etc.*) and metal (Ag, Cu, Cd, *etc.*) on glass supports. When the (As_2S_3-Ag) sample was irradiated with light at room temperature, a metal (Ag) was diffused into the chalcogenide layer (As_2S_3). The photoinduced reaction may be presented as follows:

$$As_2S_3 + Ag \xrightarrow{h\nu} As_2S_3(Ag) \quad (2)$$

The name "photo-doping" is given to the reaction. The light absorption in the visible region due to the Ag layer was diminished by the irradiation. On the other hand, the absorption edge of the Ag-doped As_2S_3 layer (As_2S_3 (Ag)) was shifted to a longer wavelength. The absorption spectra of As_2S_3 and As_2S_3 (Ag) are shown in Fig. 1. The reaction (2) occurred upon irradiation with light from a He–Ne laser (6328Å). As the light absorption was not admitted at 6328Å on the As_2S_3 layer, the photoreaction seemed to be induced by the excitation of Ag with light as follows:

$$Ag \xrightarrow{h\nu} Ag^*$$
$$Ag^* + As_2S_3 \longrightarrow As_2S_3(Ag) \quad (3)$$

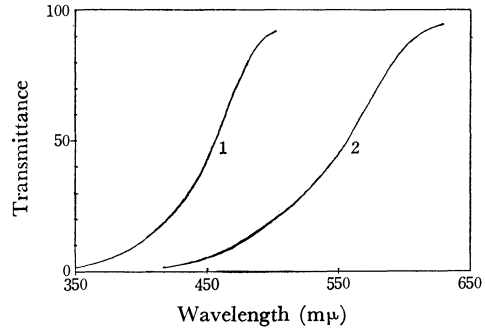

Fig. 1. Absorption spectra of As_2S_3 and As_2S_3(Ag).
1. As_2S_3
2. As_2S_3(Ag)
} thickness 1250 Å

After the image-wise exposure, the fixed image was obtained by dissolving out the unchanged Ag layer by using a mixture of sulfuric acid and potassium dichromate. As As_2S_3 was easily soluble in an alkali solution, while As_2S_3 (Ag) was not, an As_2S_3 (Ag) image which well resists etching with acids, including that of a HF solution, was obtained by dissolving the As_2S_3 part.

The photo-doping efficiency greatly depended on the host materials. A layer of Ag more than 0.1 μ thick was doped in the $As_2Se_3As_2Te_3$ layer (1 μ thick) within a few seconds by irradiation with a 250W-Hg lamp. The "photo-doping" process has a number of advantages, such as a high resolution, a wide range of sensitivity in the visible region, and a higher sensitivity than photopolymers; it is thus of considerable interest in the recording of images and photomicrofabrication.

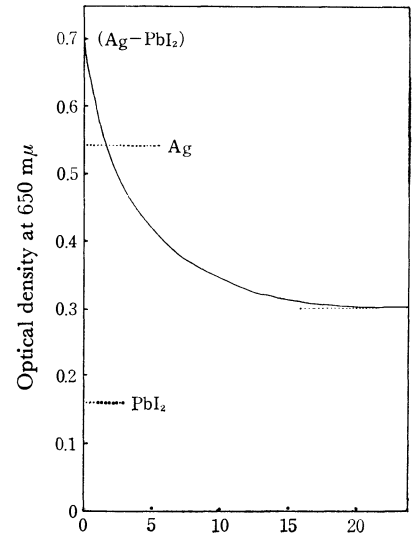

Fig. 2. Density change of PbI_2-Ag system under illumination of a Hg lamp.
thickness of PbI_2: 0.2 μ
light intensity (high pressure Hg lamp): 3.5×10^{-2} W/cm^2

Concerning the PbI_2-Ag system, the Ag layer was diffused into the PbI_2 layer by irradiation with light, and it educed Pb upon continuous irradiation. The relation between the irradiation time and the density change in the PbI_2-Ag system is shown in Fig. 2. The photoinduced reaction of PbI_2-Ag may be represented as follows:

$$(PbI_2)^* + 2Ag \longrightarrow PbI_2(2Ag)$$
$$PbI_2(2Ag) \longrightarrow Pb + 2AgI \quad (4)$$

The first step of this reaction is similar to the photo-doping of the As_2S_3-Ag system. The difference in electrical resistivity between PbI_2 and PbI_2 (Ag) was enough to make electrophotographic images. The electrical properties were also drastically changed by the photo-doping of metals in viterous semiconductive chalcogenides; this is of interest for the making of electronic devices.

The Vibrational Structure of the Charge-Transfer Band in Solution

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received March 3, 1971)

Several authors have reported the existence of a vibrational structure in the absorption spectra of charge-transfer (CT) complexes in the solid state, while the solution spectra of the complexes are generally likely to be continuous.[1,2] No one has yet observed the fine structure in the solution spectra, though we have no definite evidence for its absence.[3]

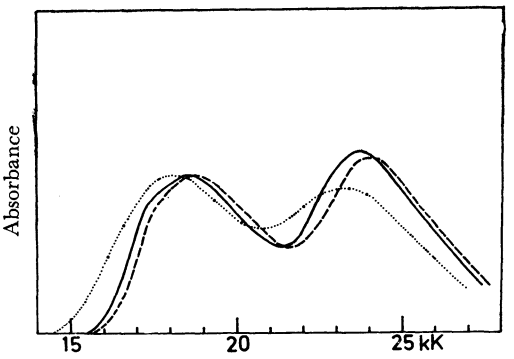

Fig. 1. Absorption spectra of the naphthalene-TCNE complex in cyclohexane (——), in *n*-hexane (------), and in methylene chloride (·····).

Recently, we undertook a further investigation of the solution spectra of the CT complexes; partial success has been achieved in detecting some structure in the solution spectra of the naphthalene-tetracyanoethylene (TCNE) complex. Figure 1 shows typical CT absorption spectra of the naphthalene-TCNE complex in solution. This complex is known to have two CT absorption bands which correspond to the transitions from the highest and the second-highest filled orbital of naphthalene to the lowest vacant orbital of TCNE.[4]

We first found some anomaly on the low-energy side of the first CT band in *n*-hexane. The absorption maximum is preceded by a distinct shoulder; the locations are at 18800 and 17500 cm^{-1} respectively. The separation between them is approximately 1300 cm^{-1}, the uncertainty of this figure being ± 100 cm^{-1}. The spectrum of the cyclohexane solution has a close resembrance to that of the *n*-hexane solution. A similar situation is also found among other saturated hydrocarbon solutions of this complex. The spacings are approximately equal in these solvents. These are listed in Table 1.

Table 1. Absorption maxima and shoulders of the first CT band of the naphthalene-TCNE complex in various solvents (cm^{-1})

Solvent	Maximum	Shoulder	Difference
n-Hexane	18800	17500	1300
n-Heptane	18800	17400	1400
Cyclohexane	18500	17200	1300
Methylcyclohexane	18600	17300	1300

On the other hand, the majority of the solvents do not cause such a distinct structure in the CT spectra. As is exemplified in Fig. 1, the spectrum in methylene chloride appears very continuous and structureless, as usual. Various solvents, classified as benzenes, haloalkanes, ethers, and alcohols, do not induce such a structure. Hence, the appearance of the shoulder is confined to the saturated hydrocarbon solutions.

What is the origin of such a structure? The possibility of a third CT band in this region can be precluded as was recently proved by photoelectron spectroscopy and by theoretical calculations.[4,5] It seems that this structure is not due to another rotational isomer, either, in view of the fact that the second CT band is not accompanied by such a shoulder before the peak. The structure is characteristic of only the first CT band. Accordingly, we concluded that the fine structure originates from the vibronic interaction of the charge-transfer transition with the vibrational mode belonging to either the donor or the acceptor molecule. This presumption seems acceptable, though doubts may be voiced. It is not necessary to take the vibration of the donor against the acceptor into consideration, since the frequency of this mode is expected to be 100—200 cm^{-1}.[3]

Another support for this came from the fact that there exists a similar vibrational structure in the photoelectron spectrum of the molecular naphthalene.[5] When naphthalene is photo-ionized by the 584-Å radiation, a distinct 1410 cm^{-1} progression appears in the spectrum of the photoelectrons from the uppermost filled orbital. It is missing in that from the second highest filled orbital. This parallelism is quite consistent, since the ionization process of naphthalene is also involved in the charge-transfer transition of the naphthalene-TCNE complex.

As has been mentioned above, we could detect the fine structure of the CT bands in solution very rarely. However, its finding at all effectively aids the analysis of the electronic structure of the CT complex in solution. We will go on to examine the absorption spectra of other CT complexes in solution.

The Effect of Pressure on the Rate of the Acid-catalyzed Hydration of Propylene

Haruo TAKAYA, Naoyuki TODO, Tadasuke HOSOYA, and Toshio MINEGISHI
The Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo
(Received March 14, 1970)

In order to confirm whether a water molecule (or molecules) is held in a protonated activated complex by electrostatic interaction or by a partial valence bond, the pressure dependency of the activation volume, ΔV^{*}, for the hydration of propylene was measured at 180°C. The pressure effect on the rate of the hydration of propylene was studied in such dilute sulfuric acid solutions of a 0.0000108 mole fraction (0.00060N under S.T.P.) that the dielectric constant, D, and the density of pure water could be replaced for those of the reacting solution. The absolute value of the ΔV^{*} decreases steeply from 19 ml/mol at 300 kg/cm² to 4 ml/mol at 5000 kg/cm². The activation energies and entropies, obtained from the temperature dependency of the reaction rate, are 22.7 kcal/mol and −16.6 e.u./mol respectively at 1000 kg/cm² and 21.9 kcal/mol and −17.0 e.u./mol respectively at 3000 kg/cm². The ΔV^{*} is approximately proportional to the $-\partial D/D^{2}\partial p$ value, (D: dielectric constant of medium; p: pressure), which follows from the Krichevski equation; hence, it was concluded that the contraction of water around an activated complex by electrostatic interaction contributes to the ΔV^{*} and that a water molecule (or molecules) is held in the activated complex by electrostatic interaction. The case of a water molecule being held by a partial valence bond was discussed in terms of the molar volumes of the reactants.

Investigations of the transition state of the acid-catalyzed hydration of olefins have been made by several workers.[1-3] It has been reported that the rate-determining step, for simple olefins, is either the formation of a carbonium ion, which is rapidly captured by water,[1] or a proton transfer from a hydrated proton to an olefin.[4] In any case, the transition state contains perhaps one or more molecules of water. In order to determine the rate-determining step, it is valuable to investigate the behavior of water molecules in the transition state.

Baliga and Whalley[5] studied the pressure effects on the rates of the hydration of ethylene, propylene, and isobutene; they obtained activation volumes of −15.5 ml/mol at 180°C, −9.6 ml/mol at 100°C, and −11.5 ml/mol at 35°C. They concluded that, at the transition states for these reactions, the partial covalent bond is formed between a protonated olefin and a water molecule. The proposed state, however, is based on the assumption that there is only a small difference between the contraction of water around an activated complex and the electrostriction of the proton in the formation of the transition state.

On the other hand, Taft[1] found that the logarithm of the rate of the hydration of isobutene is proportional to the acidity function, $-H_0$, and concluded that the transition state is a "free" carbonium ion. By "free" carbonium ion he meant an ion hydrated only by ion-dipole interaction, without any strong covalent interactions between the ion and a water molecule. This mechanism was, however, proposed on the basis of the Zucker-Hammett hypothesis, and this hypothesis has been shown not always to be applicable to the reactions thus far examined.[6-9] Moreover, this mechanism presents another contradiction: the ratio of the rate constant in D_2O to that in H_2O was actually close to unity, although the values of the ratio for most A-1 reactions are between two and three.

In order to confirm whether a water molecule (or water molecules) is held in the protonated activated complex by electrostatic interaction or by a partial valence bond, the present investigation into the pressure dependency of the activation volume, ΔV^{*}, for the hydration of propylene was undertaken at 180°C. At 180°C the dielectric constant of water, which affects the electrostatic interaction, increases considerably with the pressure, but the decrease in the molar volume of water is small,—*i.e.*, the decrease in the radius of a water molecule is small. If the electrostatic bonds between the protonated activated complex and water result in a larger contraction of water around an activated complex than that around the hydrated proton,—if, *i.e.*, the principal term contributing to ΔV^{*} is a change in the contraction of water between an activated complex and a hydrated proton, —the absolute value of ΔV^{*} will decrease considerable with the pressure as a result of the increase in the dielectric constant with the pressure. On the other hand, if the formation of a partial valence bond between a protonated propylene and a water molecule contributes to the activation volume, ΔV^{*}, the decrease in the absolute value of ΔV^{*} with the pressure will be small since the decrease in the molar volume of water with pressure is small.

Experimental

Materials. The water used in this experiment was purified by passing it through two kinds of ion exhange-resin; it was subsequently distilled twice to remove fine particles of the exchange-resins, which have a superior catalytic activity

for the hydration of olefin. The propylene (extra-pure grade), obtained commercially, and the sulfuric acid (guaranteed reagent) were used without further purification.

Apparatus and Procedure. The equipment used is shown in Fig. 1, while the details of the pressure technique were described in an earlier paper.[10] The reacting solution in the reactor (2), which is contained in a high-pressure vessel (1), can be repeatedly replaced at chosen reaction temperatures under a pressure of 300 kg/cm². The reacting solutions were prepared by dissolving propylene into aqueous acid in a pressure vessel (5) at 0°C under high pressures (up to 8 atm); they were then injected into the reactor (2), kept at chosen reaction temperatures under the pressure of 300 kg/cm² by using a high-pressure injector (6). The reactor (2) was constructed so as to keep the solution in contact only with Teflon. The mole fraction of the propylene dissolved as the reactant was varied from 0.006 to 0.0010

Analysis. The progress of the hydration of propylene was followed by analyzing the product extracted at fixed intervals. The gaseous propylene in the products was measured by a gas burette, while the amount of propylene dissolved in the products was determined by gas chromatography. The column used for this measurement was 2 m in length, and 4 mm in dia., and it was packed with 25% P.E.G. 1500 on celite 545 (60-80 mesh).

Results

The reaction was the first order in propylene,[5] and the rate constant, k_1, was calculated by the usual equation (1):

$$\ln x = -k_1 t + \text{constant} \quad (1)$$

where x is the ratio of the mole fraction of the unreacted propylene at the reaction time, t, to the initial mole fraction. For the reactions in the dilute sulfuric acid solution of a mole fraction 0.0000108 (0.00060N under

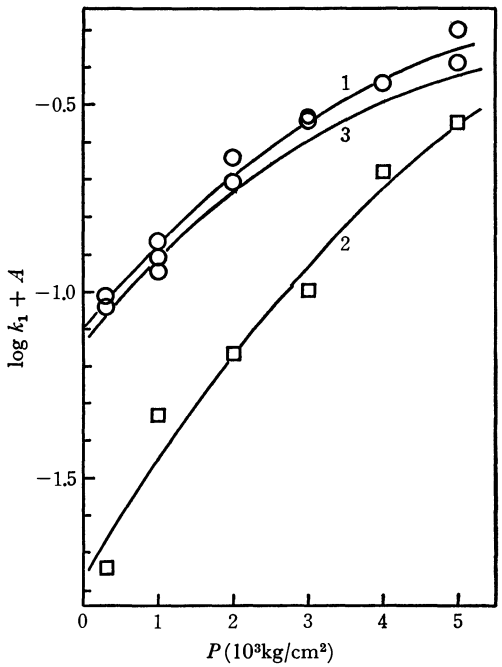

Fig. 2. Effect of pressure on the rate of hydration of propylene at 180°C. The curves 1, 2, and 3 correspond to Eqs. (2), (3), and (4) resperctively.
Curve 1: in aqueous sulfuric acid, $A=0$.
Curve 2: in aqueous solution without acid catalysis, $A=0.6$.
Curve 3: log K_{1c}, A=0.

S.T.P.) at 180°C, the correlation of log k_1 with the pressure, p, was as is shown in Fig. 2, where the log k_1 increases from −1.0 at 300 kg/cm² to −0.3 at 5000 kg/cm² and is represented by Eq. (2):

$$\log k_1 = -1.109 + 0.245 \times 10^{-3}p - 0.0182 \times 10^{-6}p^2 \quad (2)$$

In the present work, considerably diluted acid was used as the catalyst since the dielectric constant and the density of a diluted acid solution could be replaced with

10) T. Hosoya, T. Minegishi, H. Takaya, N. Todo, and M. Yoneoka, *Tokyo Kogyo Shikensho Hokoku*, **64**, 499 (1969).

those of pure water. Therefore, it was necessary to measure the rate for the solution consisting of pure water and propylene. As is shown in Fig 2, it was observed that the reaction without any acid catalysts proceeds, though the rate, k_{1w}, was much lower than that for the solution with an acid catalyst. The log k_{1w} was represented by Eq. (3):

$$\log k_{1w} = -2.371 + 0.347 \times 10^{-3}p - 0.0203 \times 10^{-6}p^2 \quad (3)$$

Accordingly, the correct rate constant, k_{1c}, with an acid catalyst was calculated by subtracting those of k_{1w} from k_1. In Fig. 2 the log k_{1c} is also plotted against p, its dependence on p can be represented by Eq. (4):

$$\log k_{1c} = -1.144 + 0.247 \times 10^{-3}p - 0.0203 \times 10^{-6}p^2 \quad (4)$$

In Fig. 3 the relation between the activation volume, ΔV^*, as defined by Eq. (5), and the reacting pressure is shown.

$$\Delta V^* = -2.303RT\frac{\partial \log k_1}{\partial p} \quad (5)$$

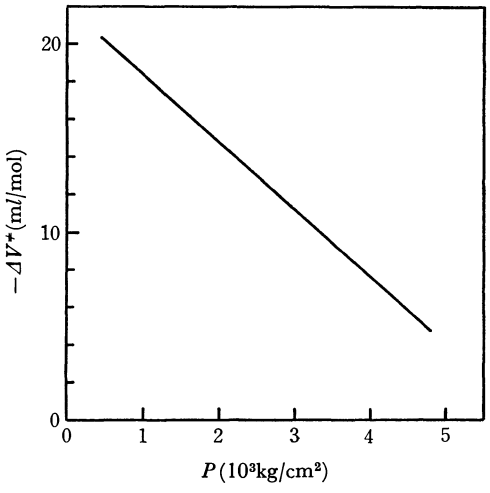

Fig. 3. Effect of pressure on volume of activation for the acid-catalyzed hydration of propylene in water at 180°C.
$-\Delta V^* = 21.9 - 3.6 \times 10^{-3}p$ (ml/mol)

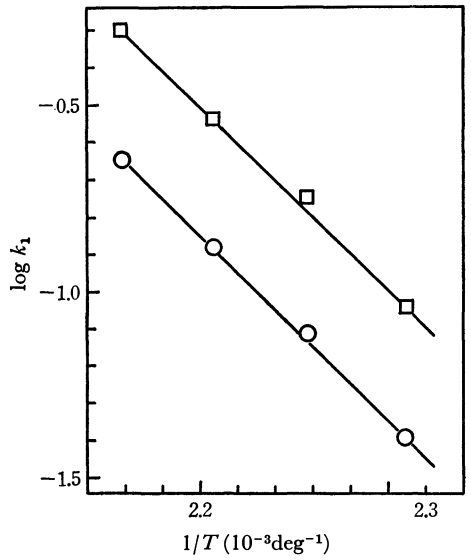

Fig. 4. Effect of temperature on the rate of the acid-catalyzed hydration of propylene. ○: at 1000 kg/cm^2. □: at 3000 kg/cm^2.

This figure indicates that the absolute values of the activation volume, the pressure dependency of which is represented by Eq. (6), decrease steeply with the pressure as the same manner as in the case of the hydration of ethylene observed by Baliga at 180°C.[5] However, the absolute value obtained at 180°C under 300 kg/cm^2, 19 ml/mol, is twice as large as the value, 9.6 ml/mol, obtained by Baliga[5] for propylene at 100°C under about 1 kg/cm^2.

$$-\Delta V^* = 21.9 - 3.6 \times 10^{-3}p \text{ (ml/mol)} \quad (6)$$

The temperature dependency of the reaction is shown by Arrhenius plots in Fig. 4. The activation energies and entropies are 22.7 kcal/mol and −16.6 e.u./mol respectively at 1000 kg/cm^2 and are 21.9 kcal/mol and −17.0 e.u./mol respectively at 3000 kg/cm^2, where the entropies are calculated in the same manner as in Baliga's report.[5]

Discussion

As was shown in the preceding paper[9] the mechanism of the acid-catalyzed hydration of propylene can be represented by Eq. (7) and Eq. (8):

$$C_3H_6 + H^+ \cdot h_2H_2O + (h_1 - h_2)H_2O \overset{K_1}{\rightleftharpoons} [C_3H_6 \cdot H^+ \cdot h_1H_2O]^* \quad (7)$$

$$[C_3H_6 \cdot H^+ \cdot h_1H_2O]^* \rightarrow C_3H_7OH + H^+ \cdot h_2H_2O + (h_1 - h_2 - 1)H_2O \quad (8)$$

where h_1 and h_2 are the hydration numbers of the activated complex and the proton respectively; the hydration number of propylene has been considered to be zero. The activation volume for the reaction represented by Eq. (7) can be defined by Eq. (9)[11]:

$$\Delta V^* = \bar{V}_{act.} - \bar{V}_{prop.} - \bar{V}_{h.p.} - (h_1 - h_2)\bar{V}_w \quad (9)$$

$$= \Delta V_{act.} - \Delta V_{H^+} \quad (10)$$

where $\bar{V}_{act}$, $\bar{V}_{prop.}$, $\bar{V}_{h.p.}$, and $\bar{V}_w$ are the partial molar volumes of the activated complex, propylene, the hydrated proton, and water respectively, and where $\Delta V_{act.}$ and ΔV_{H^+} are defined by Eq. (11) and Eq. (12) respectively:

$$\Delta V_{act.} = \bar{V}_{act.} - \bar{V}_{prop.} - h_1\bar{V}_w \quad (11)$$

$$\Delta V_{H^+} = \bar{V}_{h.p.} - h_2\bar{V}_w \quad (12)$$

Here, the volume change, ΔV_{H^+}, is the electrostriction of the proton. In connection with $\Delta V_{act.}$, it is convenient to split it into two terms: $\Delta_1 V_{act.}$, which is the change in the volume of the reacting molecules when they form the transition state, and $\Delta_2 V_{act.}$, which is the accompanying change in the volume of the surrounding liquid water, arising principally from the change in the contraction of water around an ion by means of electrostatic interaction. Equation (10) can, then, be rewritten as Eq. (13):

$$\Delta V^* = \Delta_1 V_{act.} + \Delta_2 V_{act.} - \Delta V_{H^+} \quad (13)$$

According to Baliga and Whalley, the principal term contributing to the ΔV^* is $\Delta_1 V_{act.}$, and the contribution

11) S. D. Hamann, "High Pressure Physics and Chemistry," Vol. 2, ed. by R. S. Bradley, Academic Press, London and New York (1963), p. 165.

of the ($\Delta_2V_{act.}$ $-\Delta V_{H^+}$) term to the ΔV^* may be very small. Their consideration, however, is based on the assumption that the size of the activated complex is larger than that of H_3O^+, though it is known that the formula of the hydrated proton is not H_3O^+, but $H^+ \cdot h_2H_2O$, where h_2 is, *e.g.*, about 4 at 25°C. It seems, therefore, more likely that the size of the ionic activated complex is smaller than that of the hydrated proton. It is probable, then, that $\Delta_2V_{act.}$ is smaller than ΔV_{H^+} and that $\Delta_1V_{act.}$ is negligibly small; the principal term contributing to the ΔV^* is ($\Delta_2V_{act.}$ $-\Delta V_{H^+}$).

Let us now discuss which of the two cases is related to the observed large decrease in the absolute value of the activation volume with the pressure: the case 1, where the term contributing to ΔV^* is ($\Delta_2V_{act.}$ $-\Delta V_{H^+}$); and the case 2, where the term contributing to ΔV^* is $\Delta_1V_{act.}$

Case 1. In order to discuss the contraction of water around an ion, the method of the calculation of the contraction must first be considered. The contraction is expressed by Krichevski equation, which follows from Born's model:

$$\Delta V_{el.} = -\frac{z^2e^2\partial D}{2rD^2\partial p} \qquad (14)^{11}$$

where $\Delta V_{el.}$ denotes the contraction of a medium of the dielectric constant, D, around a sphere of the radius, r, carrying a charge of ze, e being the electronic charge, and z, an intergal number, and where p is the pressure. Hamann[11] derived the equation of the contraction by considering the pressure dependency of r. In order to calculate the correct value of the contraction, the arrangements of the water molecules at the nearest neighbor of an ion must be taken into account.[12] The arrangement effect is especially important in the case of a small ion.[12] However, there have been reported none of the experimental data necessary to evaluate the arrangements of the water molecules and the pressure dependency of r at high temperatures and pressures. Therefore, in this paper it is assumed, neglecting these effects, that $\Delta V_{el.}$ is proportional to the $-\partial D/D^2\partial p$ value. This assumption is partly supported by the fact that the radius of a protonated activated complex is large and by the following facts. The variation of the radius of *n*-heptane, even at 300°C, is only about 10 per cent with the increase in pressure from 1000 kg/cm² to 5000 kg/cm², since their molar volumes under pressures of 1000 kg/cm² and 5000 kg/cm² are 164 m*l* and 129 m*l* respectively.[13] Those molar volumes are not greatly different from that under S.T.P. (145 m*l*). Therefore, it may be deduced that the variation in the radius of propylene is also small, since the molar volume of propylene, 79 m*l*, at 180°C under a pressure of 1000 kg/cm² is not greatly different from that in the liquid state, 60 m*l*.

If the principal terms contributing to ΔV^* are the ($\Delta_2V_{act.}$ $-\Delta V_{H^+}$) terms, ΔV^* should be proportional to the $-\partial D/D^2\partial p$ value, because $\Delta_2V_{act.}$ and ΔV_{H^+} are both proportional to the $-\partial D/D^2\partial p$ value. Figure 5 shows that the observed activation volumes, in which the values observed by Baliga at 100°C have been included, are approximately proportional to the $-\partial D/D^2\partial p$ value. Here, the values, $-\partial D/D^2\partial p$, for pure water were calculated by the Quist equation,[14] and the density of water, which is necessary to evaluate the dielectric constant, was obtained from Sharp's report.[15] From this figure it may be reasonable to conclude that the main contribution to the ΔV^* consists of the ($\Delta_2V_{act.}$ $-\Delta V_{H^+}$) terms; that is, water molecules (or a water molecule) are held in an activated complex by electrostatic interaction.

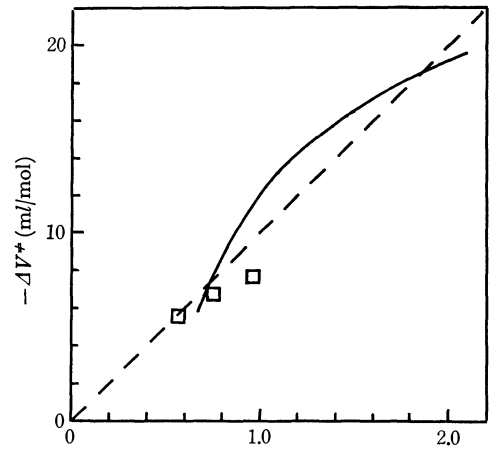

Fig. 5. $-\Delta V^*$ *versus* $-\partial D/D^2\,\partial p$.
—: present results.
□: Baliga, at 100°C. Ref. 5.

Case 2. By the following procedure it can be shown that the Case 2 is unlikely. If the principal term contributing to ΔV^* is $\Delta_1V_{act.}$, the observed ΔV^* should be caused by contraction, δl, from the length of a van der Waals bond between a propylene and a water molecule into that of a partial valence bond between a protonated propylene and a water molecule. Therefore, the activation volume, ΔV^*, can be approximately represented by Eq. (15):

$$\Delta V^* = -S\delta l \qquad (15)$$

where S is a cross-sectional area for a water molecule. The observed $-\Delta V^*$ value, 18 m*l*/mol, at a pressure of 1000 kg/cm² is nearly equal to a molar volume of water under the same conditions, 19.1 m*l*/mol.[15] This means, from Eq. (15), that a water molecule is completely embraced in a protonated propylene upon the formation of the activated complex. From the above conception of the activation process, the $-\Delta V^*$ value at a pressure of 5000 kg/cm² should be a molar volume of water, 17 m*l*/mol.[15] However, the observed $-\Delta V^*$ value at a pressure of 5000 kg/cm² is only 4 m*l*/mol. The large discrepancy shows that the case 2 is unlikely.

The Nature of a Bond between a Water Molecule and a Protonated Propylene in the Activated Complex for the Acid-catalyzed Hydration of Propylene

Haruo TAKAYA, Naoyuki TODO, Tadasuke HOSOYA, and Toshio MINEGISHI
The Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo
(Received March 14, 1970)

The nature of a bond between a water molecule and a protonated propylene in the activated complex for the acid-catalyzed hydration of propylene was discussed. The number of water molecules contained in the activated complex, 1.3, was obtained by applying the acidity function, T_0, to the dependency of the log k_1 on the acid concentration for the hydration of various olefins. The general relationship between the electrostriction and the hydration number of various uni-valent cations was also discussed, and these ions were divided into two separate groups. In the first group, the hydration was caused by electrostatic interaction, while in the second group, the hydration was caused mainly by covalent bond formation. Since the representative point of the hydration of propylene was located near the first group, it was concluded that a molecule of water is held in the activated complex by electrostatic interaction. On the basis of these considerations, the present authors propose a hypothesis which is useful in characterizing the nature of a bond between a water molecule and a protonated substrate in an activated state: (a) If the log k_1 for a reaction increases linearly with $-H_0$, a water molecule (or molecules) is held in an activated complex by electrostatic interaction. (b) If the log k_1 for a reaction increases linearly with the log m_a, a water molecule is held in an activated complex by the formation of a covalent bond. k_1: the first order rate constant; H_0: Hammett's acidity function; m_a: acid concentration.

In an earlier paper[1], the following mechanisms of acid-catalyzed reactions in moderately concentrated acid solutions have been proposed:

$$S\cdot h_5H_2O + H^+\cdot h_2H_2O + (h_1-h_2-h_5)H_2O \overset{K_1}{\rightleftharpoons} [SH^+\cdot h_1H_2O]^* \quad (1)$$

$$[SH^+\cdot h_1H_2O]^* \rightarrow \text{Product} \quad (2)$$

where S is a substrate and where h_1, h_2, and h_5 are the hydration numbers of the activated complex, the proton, and the substrate respectively. The number of water molecules contained in an activated complex, h_1, can be calculated from the dependency of the log k_1 on the acid concentrations:

$$\log k_1 = C - T_0 \quad (3)$$

where k_1 and C are a rate constant and a constant respectively, and where T_0 is a new acidity function which varies with the hydration number, h_1, and with the acid concentrations. The respective acidity functions T_0, for various acid solutions are given by Eqs. (4)–(6): in hydrochloric acid solutions:

$$T_0 = 2.4(3.9-h_1+h_5)\log a_w - \log m_a \quad (4)$$

in nitric acid solutions:

$$T_0 = 2.3(3.9-h_1+h_5)\log a_w - \log m_a \quad (5)$$

in perchloric acid solutions:

$$T_0 = 2.3(3.9-h_1+h_5)\log a_w - \log m_a \quad (6)$$

where a_w is the activity of water and where m_a is the molality of acid. Usually, the hydration number of a substrate, h_5, is zero because, as was shown in the derivation process of T_0, the hydration number even of a water molecule, which has a larger affinity for water than hydrocarbons, is zero. These equations are derived in much the same manner as in the Glueckauf's calculation of the hydration numbers of ions in aqueous solutions,[2] therefore, the hydration number of an activated complex, h_1, as calculated by these equations, can be treated equally as the hydration numbers of various kinds of alkali metal ions as calculated by his method.

The present authors previously studied the pressure effect on the rate of the acid-catalyzed hydration of propylene and reported that the absolute values of the observed activation volume are approximately proportional to the value, $-\partial D/D^2\partial P$, derived from the Drude and Nernst equation; here D is a dielectric constant of water and p is a pressure.[3] From this result, it was concluded that the activation volume is caused by the contraction of water around a protonated propylene by electrostatic interaction; that is water molecules (or a water molecule) may be held in the activated complex by electrostatic interaction.

In this paper the above conclusion will be discussed in terms of the relationship between the hydration number and the electrostriction of various uni-valent cations.

Calculation and Discussion

Hydration Number of a Hammett Base. In order to examine the process of calculating the hydration number of an activated complex, h_1, first, the hydration numbers of a protonated Hammett base in various acid solutions were calculated.

The acidity function, T_0, for the protonation of a Hammett base is equal to the acidity function, H_0,[4] as defined by Eq. (7), because the value of m_{AH^+}/m_A in Eq.(7) is equivalent to the first-order rate constant, k_1, in Eq.(3) and both the H_0 and T_0 functions are defined as being equal to $-\log m_a$ in a dilute acid solution[1]:

2) E. Glueckauf, *Trans. Faraday Soc.*, **51**, 1235 (1955).

3) H. Takaya, N. Todo, T. Hosoya, and T. Minegishi, This Bulletin, **44**, 1175 (1971).

4) M. A. Paul and F. A. Long, *Chem. Rev.*, **57**, 1 (1957).

$$\log \frac{m_{AH^+}}{m_A} = C - H_0 \quad (7)$$

where A is a Hammett base and where AH^+ is a protonated Hammett base. By the substitution of the values in Table 1 into Eq.(5) and Eq.(6), the hydration number of a protonated Hammett base, h_1, can be calculated. The results obtained are 0.8 and 0.4 in nitric acid and in perchloric acid respectively, as is shown in the last column of Table 1. As for the value in hydrochloric acid, it was shown in an earlier paper that h_1 is 0.7.[1] It seems to be possible to decide that the hydration numbers do not vary with the kind of acid. The small disagreement among these values, which is caused probably by omitting a part of the salting-out effects in the course of the calculation of the T_0, may be interpreted on the assumption that the salting-out effects for a protonated Hammett base are almost completely canceled by those for the Hammett base. The fact that there was not so large a disagreement among the hydration numbers of a Hammett base in various acids suggests that the same procedure can be used in calculating the hydration numbers for other protonated activated complexes.

TABLE 1. HYDRATION NUMBER OF A HAMMETT BASE IN VARIOUS ACID SOLUTIONS

	Molality	$\log m_a$	H_0 or T_0	$\log a_w$	h_1
in HNO_3	3.0	0.477	−0.94	−0.065	0.8
in $HClO_4$	3.0	0.477	−1.07	−0.074	0.4

Numbers of Water Molecules Contained in the Activated Complexes for Hydration of Olefins. The dependency of $\log k_1$ on the acid concentrations for the hydration of propylene has not been observed. Therefore, the hydration numbers were calculated by using the results observed by Taft for the hydration of various olefins,[5] and the average value of these was used as the number of water molecules contained in the activated complex for the hydration of propylene. The $\log k_1$, which was represented by $\log k_c$ in Taft's paper, is represented by:

$$\log k_1 = -\rho' H_0 + C \quad (8)$$

where ρ' is a parameter to be determined by experiments. By comparing Eq.(8) with Eq.(3), it can be seen that $\rho' H_0$ must be T_0. In Table 2 the observed values of $-\rho' H_0$ (or $-T_0$) and also the hydration numbers of the various protonated olefins calculated by Eq.(5) are tabulated. From Table 2 it can be seen that the average hydration number is 1.3.

TABLE 2. THE OBSERVED $-\rho' H_0$ (or $-T_0$) AND THE HYDRATION NUMBERS CALCULATED BY Eq. (5)

Substrate	HNO_3 Molarity	$-\rho' H_0$ or $-T_0$	Hydration number
Trimethylethylene	2.995[a]	0.88	1.7
Methylenecyclobutane	2.995[a]	1.00	1.0
Triptene	2.995[a]	0.89	1.6
Isobutene	2.525[b]	0.81	1.0

a) $\log m_a = 0.52$ and $\log a_w = -0.071$.
b) $\log m_a = 0.44$ and $\log a_w = -0.056$.

Relationship between the Conventional Electrostriction, $\Delta_c V_{el.}$, and the Hydration Number, h_1, of Uni-valent Cations. The relationship between the conventional electrostriction, $\Delta_c V_{el.}$, of various uni-valent alkali metal cations[6] and hydration number is shown in Fig. 1, where the value of $\Delta_c V_{el.}$ is represented by setting the $\Delta_c V_{el.}$ of H^+ as zero. The conventional electrostriction of a cation, $\Delta_c V_{el.}$, is correlated with its electrostriction, $\Delta V_{el.}$, as is shown by Eq. (9)[7]:

$$\Delta_c V_{el.} = \Delta V_{el.} - \Delta V_{el.H^+} \quad (9)$$

where $\Delta V_{el.H^+}$ is the electrostriction of the proton. From this figure, it can clearly be seen that the alkali metal ions are divided into the following separate two groups. In the first group, which consists of Rb^+, K^+ and Na^+, the values of $\Delta V_{el.}$ can be represented by the value, $-Bz^2/r_s$,[8] derived from the Drude and Nernst equation. Here, r_s is the radius of an ion, which has a charge of z, and B is a constant. Since the Drude and Nernst equation was derived by using the theory of the electrostriction of a homogeneous dielectric around a charged sphere, it seems to suggest that the hydration of the ions in the first group is caused by electrostatic interaction. On the other hand, the $\Delta V_{el.}$ of the second group, which consists of H^+ and Li^+, can not be given by the $-Bz^2/r_s$ value; moreover, the electrostriction of H^+ is small because of the large radius of the hydrated proton, the formula of which is accepted as $H^+ \cdot (H_2O)_4$.[2,8]

It may be generalized from the discussion above described that if the representative point for a reaction is located near the first group, the water molecules are held in an activated complex by electrostatic interaction and the number of water molecules may be 0, 1, or 2. On the other hand, if the representative point for a reaction is located near the second group, that is, if its hydration number is 3 and the activation volume is nearly zero, the structure of the activated complex may be similar to that of a hydrated proton, $H^+ (H_2O)_4$.

Consideration of an Activation Volume, ΔV^*. It can be shown by the following treatment that the change in volume for the reaction of Eq. (1), ΔV^*, as defined by Eq. (11), is equivalent to the electrostriction in Fig. 1, $\Delta_c V_{el.}$:

$$\Delta V^* = \bar{V}_{act.} - \bar{V}_S - \bar{V}_{h.p.} - (h_1 - h_2)\bar{V}_w \quad (11)$$

where $\bar{V}_{act.}$, $\bar{V}_S$, $\bar{V}_{h.p.}$, and $\bar{V}_w$ are partial molar volumes of the activated complex, the substrate, the hydrated proton, and water respectively. Equation (11) can be re-written as Eq. (12) and Eq. (13):

$$\Delta V^* = (\bar{V}_{act.} - \bar{V}_S - h_1\bar{V}_w) - (\bar{V}_{h.p.} - h_2\bar{V}_w) \quad (12)$$

$$= \Delta V_{act.} - \Delta V_{H^+} \quad (13)$$

where $\Delta V_{act.}$ and ΔV_{H^+} are defined by Eq. (14) and Eq. (15) respectively:

$$\Delta V_{act.} = \bar{V}_{act.} - \bar{V}_S - h_1\bar{V}_w \quad (14)$$

6) R. M. Noyes, *ibid.*, **86**, 971 (1964).

7) The electrostriction of an ion is defined by Eq. (10) where the partial molar volume, $\bar{V}_0$, can be determined by experiments, however, the intrinsic ionic volume, V, can not be done by experiments but only deduced theoretically.

$$\Delta V_{el} = \bar{V}_0 - V, \quad (10)$$

8) P. Mukerjee, *J. Phys. Chem.*, **65**, 740 (1961).

$$\Delta V_{H^+} = \bar{V}_{h.p.} - h_2\bar{V}_w \quad (15)$$

Generally, the electrostriction of a proton, $\Delta V_{el.H^+}$, is determined on the basis of the assumption that the intrinsic molar volume of H^+, V in Eq. (10),[7] is zero. However, if a proton is hydrated in water, the above assumption means that the intrinsic molar volume of $H^+ \cdot h_2H_2O$ is equal to the volume of h_2H_2O, *i.e.*, h_2V_w. Therefore,

$$\Delta V_{H^+} = \Delta V_{el.H^+} \quad (16)$$

On the other hand, the electrostriction of an activated state, $\Delta V_{el.act.}$, is given by Eq. (17):

$$\Delta V_{el.act.} = \bar{V}_{act.} - V_{SH\cdot h_1H_2O} \quad (17)$$

where $V_{SH.h_1H_2O}$ is the intrinsic molar volume of an activated complex, and where $SH \cdot h_1H_2O$ is a imaginary and non-cationic activated complex, one which is formed by the imaginary subtraction of an univalent charge from an activated complex, $[SH^+ \cdot h_1H_2O]^*$. On the basis of the same assumption as was used in the case of H^+, the value of $V_{SH.h_1H_2O}$ can be determined by Eq. (18):

$$V_{SH\cdot h_1H_2O} = \bar{V}_S + h_1\bar{V}_w \quad (18)$$

In this case, the substrate, S, corresponds to a water molecule in a hydrated proton, $H^+(H_2O)_4$. Therefore, from Eqs. (14), (17), and (18), we can obtain Eq. (19):

$$\Delta V_{act.} = \Delta V_{el.act.} \quad (19)$$

From Eqs. (13), (16), and (19), we can obtain Eq. (20):

$$\Delta V^* = \Delta V_{el.act.} - \Delta V_{el.H^+} \quad (20)$$

It is evident from a comparison of Eq. (20) and Eq. (9) that the ΔV^* is equivalent to $\Delta_c V_{el.}$.

Application of the Relationship to Reactions. First, the relationship shown in Fig. 1 was applied to the classification of protonation of ammonia and enolization of acetone.

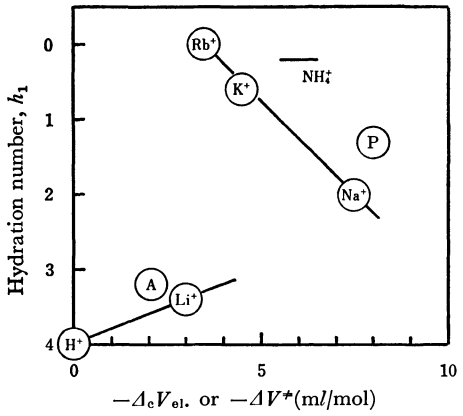

Fig. 1. Hydration number*1 *versus* conventional electrostriction, $\Delta_c V_{el}$, or activation volume, ΔV^*, of uni-valent cations at 25°C.
Ⓟ: hydration of propylene ($\Delta V = -8$ml/mol Ref. 3, $h_1 = 1.3$)
Ⓐ: enolization of acetone ($\Delta V^* = -2.1$ ml/mol Ref. 11, $h_1 = 3.2$ Ref. 12)
*1 The hydration number is obtained by calculating the entropy change; thus, the water molecules in hydration should be tightly bond with the ion.

The former reaction is represented by Eq. (21):[9]

$$H_3^+O + NH_3 \rightleftharpoons H_2O + NH_4^+ \quad (21)$$

For this reaction, $-\Delta V_{el.}$ is 5.5—6.5 ml/mol[9] and the hydration number, h_1, is 0.2.[2] Since its position is located near the first group, the hydration may be caused by electrostatic interaction. The nature of the electrostriction of the ammonium ion is the same as those of alkali metal cations, since the hydration number of the ammonium ion can be correlated with Pauling's ionic radius in the same manner as in the case of the alkali metal cation.[2] In Fig. 1 the absolute value of the electrostriction of the ammonium ion deviates from that of the first group by 2 ml/mol. This may arise partly from the values of the electrostrictions of alkali metal cations used, since the $\Delta V_{el.}$ is not a completely experimental value.[7]

For the latter reaction there is general agreement that the slow step is the removal of a proton from the α-carbon of the protonated ketone by water acting as a base.[10] For this reaction, the ΔV^* is −2.1 ml/mol,[11] and the h_1 is 3.2,[12] and the representative point is located near the second group; the probable structure of the activated complex is, then, similar to that of a hydrated proton, as is shown in Fig. 2. In this model the bond between the proton and the oxygen in the water molecule must be strong and covalent, since two hydrogen atoms of the water molecule must be cationic enough to attract two more water molecules.

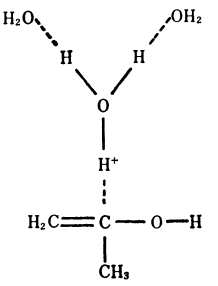

Fig. 2. Probable structure of the activated complex for enolization of acetone.

Consideration of the Activated Complex for the Hydration of Propylene. Since ΔV^* is −8 ml/mol[13] and h_1 is 1.3, the representative point of the hydration of propylene is located near the first group, as is shown in Fig. 1. As a consequence, it is a reasonable interpretation that the hydration of the activated complex is caused by electrostatic interaction and that the structure of the activated complex can not be similar to that of a hydrated proton.

Bunton[14] proposed two models for the activated state

11) E. Whalley, *Can. J. Chem.*, **42**, 1835 (1964).
12) The values of w^* from Bunnett's report for the reaction are 1.42 and 1.66 in hydrochloric acid. Hence 3.2 is obtained as h_1 by using Eq. (4). J. F. Bunnett, *J. Amer. Chem. Soc.*, **83**, 4956 (1961).
13) At 25°C the ΔV^* is about −8 ml/mol from the Fig. 5 in an earlier paper,[3] since the value $-\partial D/D^2\partial p$ under S. T. P. is 0.8×10^{-6} cm²/kg.
14) C. A. Bunton and V. J. Shiner, Jr., *J. Amer. Chem. Soc.*, **83**, 3207 (1961).

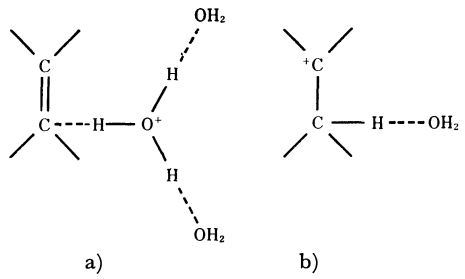

Fig. 3. Two models for the activated state of hydration of olefin proposed by Bunton (Ref. 14).
a) The activated state is similar to initial state. In his paper a hydrated proton is represented by H_3O^+, however, in this paper it is done by $H(H_2O)_4^+$.
b) The activated state is akin to the carbonium ion.

of the hydration of various olefins; by the use of these models the observed isotope effect can be rationally explained: a) the activated state is similar to the initial state, and b) the activated state is akin to the carbonium ion, *i.e.*, the proton is bound to the reaction center (Fig. 3). In view of the hydration number, it is necessary to exclude the a) structure, since its hydration number, 3, is different from the value, 1.3, obtained in the present investigation. On the other hand, the b) model is in good agreement with the results of this study.

According to our results, the "free" carbonium ion model proposed by Taft[15] is plausible for the activated complex, and one molecule of water may be bound to the "free" carbonium ion by electrostatic interaction.

If the observed value of the activation volume[3], -8 m*l*/mol, is caused by the partially covalent bond formation between a protonated olefin and a water molecule, as was proposed by Baliga,[16] its bond must be strong and nearly equal to the covalent bond, since the value of 8 m*l*/mol corresponds to nearly half of the molar volume of water. The covalent bond may be formed by the transfer of an electron from the oxygen in a water molecule to the protonated olefin. Hence, the two hydrogen atoms of the water molecule become cationic and attract two more water molecules. This means that the number of the water molecules contained in the activated complex must be 3; this is inconsistent with the observed hydration number of 1.3.

New Hypothesis as to the Nature of a Bond between a Water Molecule and a Protonated Substrate in an Activated Complex. Zucker and Hammett have proposed a hypothesis which seemed useful in distinguishing the A-1 mechanism from the A-2 mechanism according to whether log k_1 increases linearly with log c_{H^+} or with $-H_0$, where c_{H^+} is the concentration of the acid.[17] This hypothesis has, however, been sharply criticized by several authors[12,18] and has not been generally accepted.

The present authors hereby propose a hypothesis which is useful in characterizing the nature of a bond between a water molecule and a protonated substrate in an activated state: (a) If the log k_1 for a reaction increases linearly with $-H_0$, a water molecule (or water molecules) is held in an activated complex by electrostatic interaction.

(b) If the log k_1 for a reaction increases linearly with log m_a, a water molecule is held in an activated complex by a covalent bond.

Strictly speaking, the water molecule held in an activated complex by a weakly and partially covalent bond can not be distinguished from that contained by electrostatic interaction. However, this does not seem significant, because, in the present state, a discussion of such a fine difference between the two cases seems meaningless.

A Theoretical Study of the Possible Interaction between Sulfonium Salts and Molecular Oxygen

Katsutoshi OHKUBO* and Tokio YAMABE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 17, 1970)

The interaction between sulfonium salts and molecular oxygen was studied by the ASMO SCF method. Firstly, the results of the ASMO SCF calculation of trimethylsulfonium chloride suggested that the bond between the sulfonium cation and the anion was constituted mainly of the bonding $(d\text{-}p)\pi$-type overlaps (made by $3d_{yz}$- (or $3d_{xz}$-) of S and $3p_y$ (or $3p_x$) of Cl) and of the antibonding $(d\text{-}p)\sigma$-type overlaps (made by $3d_{z^2}$ (or $3p_z$) of S and $3p_z$ (or $3d_{z^2}$) of Cl). Secondly, the sulfonium salt interacts with molecular oxygen mainly through a $(d\text{-}p)$ σ-type overlap between the $3d_{yz}$-(or $3d_{xz}$-)orbital of the former and the $(1\pi_g)_z$-orbital of the latter. Thirdly, a maximum overlap formed between $3d$-sulfur orbitals and $1\pi_g$-orbitals of O_2 is established at the O_2-rotation angle of $\pi/4$ to the direction of the d-orbital expansion. Finally, the change in the energy state of O_2 caused by the sulfonium-salt interaction was discussed.

Some theoretical investigations into the interaction of oxygen with various organic or inorganic compounds have been made: a donor-acceptor interaction with organic solvents by Hoijtink[1] and by others[2,3] (experimentally by Evans,[4-8] Tsubomura *et al.*,[2,9] and many other authors[10-15]) with pottasium chloride by Känzig,[16] and with iodides;[17] moreover, Khan and Kearns[18] calculated the energy of the interaction of molecular oxygen with organic molecules. These studies are characterized by discussions based on the donor-acceptor interaction.

From our own previous work[19] on the catalytic nature of sulfonium salt based on the interaction with molecular oxygen, it was suggested that the "partially-occupied" d-orbitals on the central sulfur of the sulfonium ion might interact with $1\pi_g$-orbitals of the oxygen molecule and that the interaction might be possible through the orbital symmetries between the d_{yz} (or d_{xz})-sulfur orbitals and the $(1\pi_g)_z$-orbital of the oxygen molecule (a strong $(d\text{-}p)\sigma$ type) and between d_{xy} and $(1\pi_g)_x$ (a weak $(d\text{-}p)\pi$ type). Moreover, from the ultraviolet spectroscopic study[20] of the interaction between the sulfonium salts and molecular oxygen, it was found that the characteristic band near 200 mμ should not be assigned to the charge-transfer bands, but to the transition from the nonbonding $3p_z$ lone pair-orbital on the central sulfur to the $3d$-sulfur orbitals. Moreover, it was found that the molecular oxygen interacting with the sulfonium salt shifted the band to the longer wavelength in the energy region of *ca.* 0.05—0.25 eV.

It is of interest to investigate further the interaction of sulfonium salts with molecular oxygen from a theoretical point of view. The present theoretical study intends to clarify the following: a) the nature of the bond[19] between the sulfonium cation and the counter anion; b) the configuration of the mode of interaction between the sulfonium and molecular oxygen, and c) the chemical property of the oxygen molecule "activated" through the interaction with the sulfonium salts. A zero-differerential-overlap approximated ASMO SCF method including the d-orbitals of sulfur was employed for the investigations of these three features.

Method of Calculation

For the sake of mathematical convenience, a zero-differential-overlap approximated ASMO SCF method was used for the calculations of trimethylsulfonium chloride, by itself and also in interaction with oxygen.

For the calculations, the values of the orbital exponents of H, C, O, S, and Cl were supplied from the data of Clementi;[21] the ionization potentials and electron affinities of the above atoms were chosen from the values calculated by Jaffé,[22] while the values of the effective nuclear charge and the ionization potential of $3d$-sulfur orbitals were taken from Levison and Perkins.[23] These values are listed in Table 1. For one-center exchange repulsion integrals, the values of the Frank-

	2*p*	2.2266	18.53	3.40

For the assumed configuration of the sulfonium salt, a D_3 propeller-like configuration is most plausible, as was discussed in our previous report.[19] The bond distances and angles were set up as follows: S–C=1.82 Å, C–H=1.10 Å, S–Cl=2.5—4.5 Å and ∠HCH=109°28′, ∠CSC=120°, ∠CSCl=90°. The geometry used for the ASMO SCF calculation is illustrated in Fig. 1.

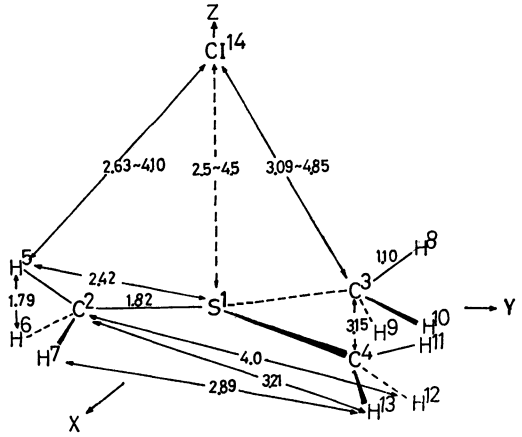

Fig. 1. Geometry used for the calculation.

Results and Discussion

Contributions of d-*Sulfur Orbitals to the Electronic State of Sulfonium Salt. Atom Population and Bond Population, Total Energy and Dipole Moment.* In order to estimate the contribution of *d*-sulfur orbitals to the S–Cl bond, an ASMO SCF calculation of trimethylsulfonium chloride was carried out both with and without inclusion of the *d*-sulfur orbitals with respect to the S–Cl distance of 2.5—4.5Å. The atom population, total energy, and dipole moment are shown in Fig. 2. As is shown in Fig. 2, in the case including *d*-sulfur orbitals, the contribution of *d*-orbitals may be reflected by the results of the smaller atom population of Cl and the significant amounts of the charge density at the *d*-orbitals of sulfur. Moreover, the charge of the C-atoms of methyl substituents becomes larger through *d*-π conjugation.[27] The *d*-π conjugation between the sulfonium cation and the counter chloride anion is directly related to the covalent nature of the S–Cl bond, as has been discussed previously.[19] On the other hand, the minimum total energy at the S–Cl distance of 3.5Å in the assumed configurations of the sulfonium chloride suggests the ionic molecular structure of the salt, considering the van der Waals radii of S (1.85 Å) and Cl (1.80Å).

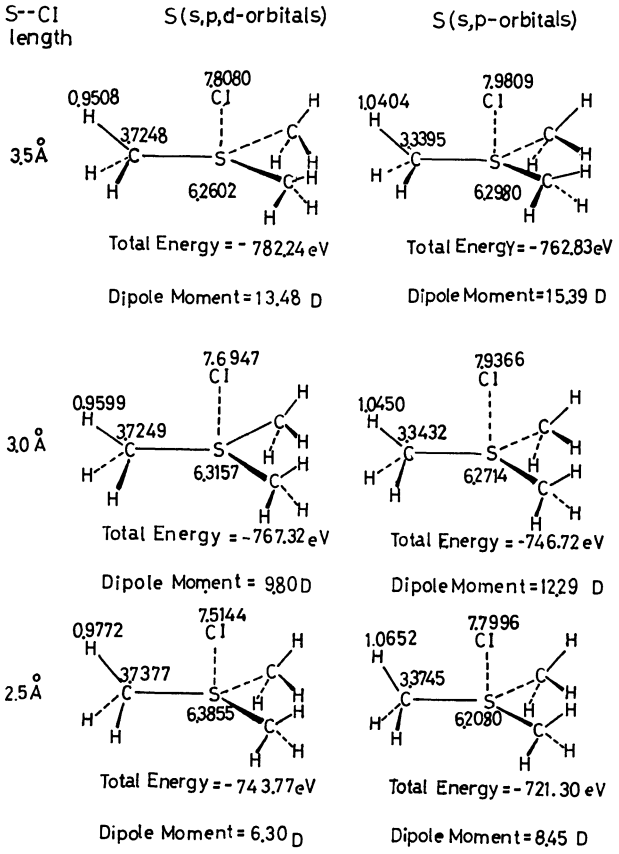

Fig. 2. The atomic population of $(CH_3)_3SCl$.

The Property of the Bond between the Sulfonium Cation and the Anion. It is well known that the orbital overlapping between atoms gives some idea of the aspects of the bond nature.

The bond property of S–Cl was, then, investigated from the viewpoint of the orbital overlappings in the coulomb and van der Waals distances of S–Cl (2.0 and 3.65 Å respectively). In this case, the contribution of the *s*-orbitals of both atoms to the bond formation can be neglected. The modes of the orbital overlappings of various orbitals are shown in Fig. 3. The overlap

26) K. Ohno, *Theor. Chim. Acta*, **2**, 219 (1964).

27) In the case of triphenylsulfonium tetrafluoroborate, the *d*-π conjugation between the *d*-sulfur orbitals of the central sulfur atom and the π-orbitals of phenyl substituents was reflected by the red shift of the ^1L_b transition of the sulfonium in the order of 0.27 eV, as compared with the ^1L_b transition of triphenylcarbonium tetrafluoroborate, as established ultraviolet spectroscopic study (K. Ohkubo and T. Yamabe, *Bull. Japan Petr. Inst.*, **12**, 130 (1970)).

between the *d*-orbitals of sulfur and those of chlorine does not participate dominantly in the bond formation, even though a suitable maximum overlap appears in the 2.5—4.5 Å region of S-Cl, because of the vacancy of the *d*-orbitals on both atoms. The bond formation can, then, be considered to be mainly dependent on the $(d\text{-}p)\sigma$ and $(d\text{-}p)\pi$ overlaps, because the contribution of the $p\sigma$ and $p\pi$ overlaps is not so dominant in the separation beyond the distance of 3 Å. Therefore, the atomic orbital populations of both atoms and the bond orders between the atoms exhibit the bond natures characteristic of the $(d\text{-}p)\pi$ bonding orbital between the d_{xz} (or d_{yz}) of sulfur and the p_x (or p_y) of chloride and the $(d\text{-}p)\sigma$ antibonding orbital between d_{z^2} (or p_z) of S and p_z (or d_{z^2}) of Cl (see Table 2).

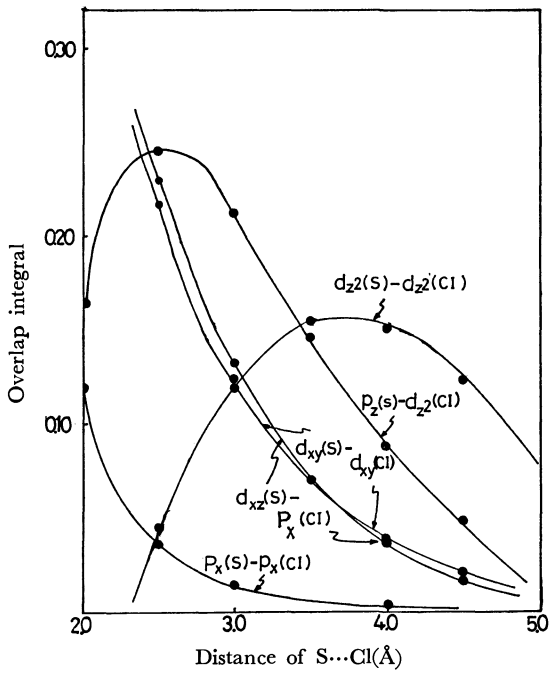

Fig. 3. Orbital overlaps between the orbitals of the central sulfur and those of the chloride.

From Table 2, the decrease in the distance of S-Cl promotes the charge transfer, as is shown in the following schemes:

Electron migration through the π-bonding orbital:

$$p_x^{(Cl)}\,(\text{or } p_y^{(Cl)}) \xrightarrow{\text{through } d_{xz}^{(S)}-p_x^{(Cl)} \text{ or } d_{yz}^{(S)}-p_y^{(Cl)}} d_{xz}^{(S)}\,(\text{or } d_{yz}^{(S)})$$

The electrons of $p_x^{(Cl)}$ which migrate to d_{xz} (or d_{yz}) push out the electrons of $p_x^{(S)}$ (or $p_y^{(S)}$) to $p_x^{(Cl)}$ (or $p_y^{(Cl)}$):

$$p_x^{(S)}\,(\text{or } p_y^{(S)}) \xrightarrow{\text{through } p_x^{(S)}-p_x^{(Cl)}} p_x^{(Cl)}\,(\text{or } p_y^{(Cl)})$$

Electron migration through the σ-antibonding orbital:

$$p_z^{(Cl)} \xrightarrow{\text{through } d_{z^2}^{(S)}-p_z^{(Cl)}} d_{z^2}^{(S)}$$

The electron of $p_z^{(Cl)}$ which has migrated to $d_{z^2}^{(S)}$ repulses the electrons of $p_z^{(S)}$, thus promoting the migration of the electrons of $p_z^{(S)}$ to $p_z^{(Cl)}$ or $d_{z^2}^{(S)}$.

$$p_z^{(S)} \xrightarrow{\text{through } p_z^{(S)}-p_z^{(Cl)}} \begin{cases} p_z^{(Cl)} \\ d_{z^2}^{(S)} \end{cases}$$

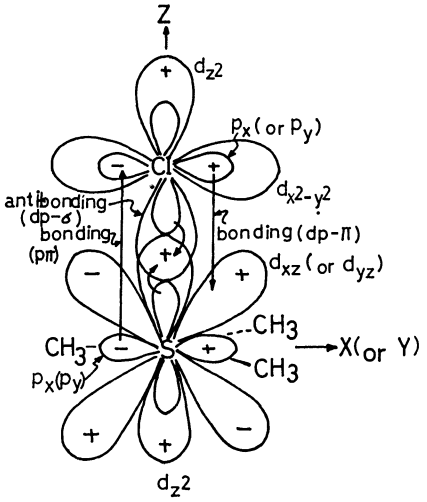

Fig. 4. The directions of electron migrations between sulfonium cation and chloride anion in the case of the decrease of S···Cl bond length.

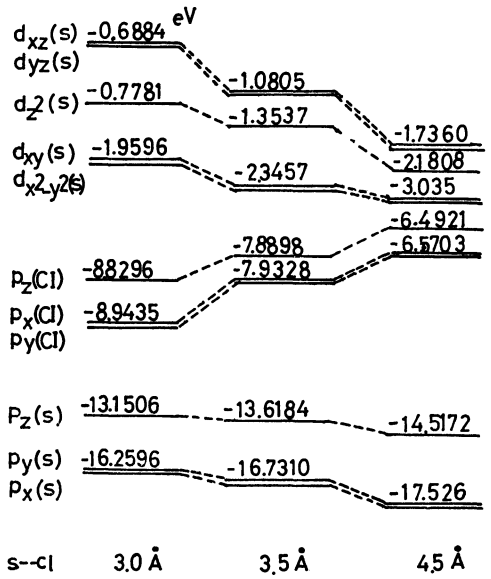

Fig. 5. An energy diagram of $(CH_3)_3SCl$.

These circumstances are illustrated in Fig. 4.
In this case, the changes in the net charges of carbon and hydrogen were very small as compared with those of sulfur and chlorine. The change in the energy levels of the *p*- and *d*-orbitals of the central sulfur and the chlorine atom with the variation in the S-Cl bond length is shown in Fig. 5.
From Fig. 5, it may be seen that, at the larger separation between S and Cl (4.5 Å), the $p_z^{(Cl)}$ is the highest occupied orbital and the $d_{x^2-y^2}^{(S)}$ is the lowest unoccupied one, while at the smaller separation (3.0 Å), the former is lowered remarkably because of the outdrawing of the charge and, as a result, the latter comes to have a partially-occupied nature, with an elevation of the energy level.

Interaction between the Sulfonium Salt and Molecular Oxygen. For the interaction between the sulfonium salt and molecular oxygen, two probable configurations can be considered as the model for the mode of interaction: One is the parallel form, and the other is the triangular one, as is shown in Fig. 6. Among the orbital overlaps between the *d*-orbitals of the central sulfur atom and the $1\pi_g$-orbitals of the oxygen molecule, a $(d\text{-}p)\pi$-type overlap or d_{yz}-$(1\pi_g)_x$ and a $(d\text{-}\pi)$ π-type overlap of d_{xy}-$(1\pi_g)_y$ for the parallel form, and $(d\text{-}p)\sigma$-type overlaps of d_{xy}-$(1\pi_g)_x$ and d_{yz}-$(1\pi_g)_y$ for the triangular form, are possible.

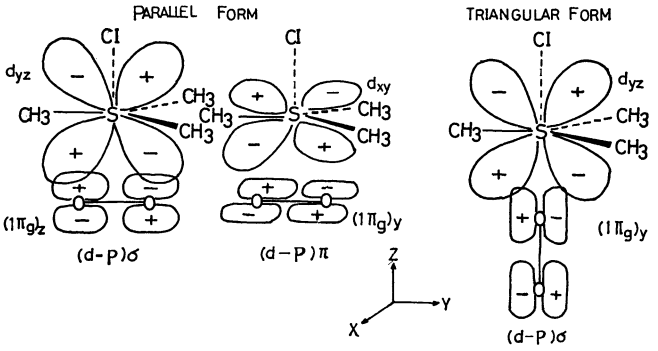

Fig. 6. Interactions between *d*-orbitals of trimenthylsulfonium chloride and $1\pi_g$-orbitals of molecular oxygen.

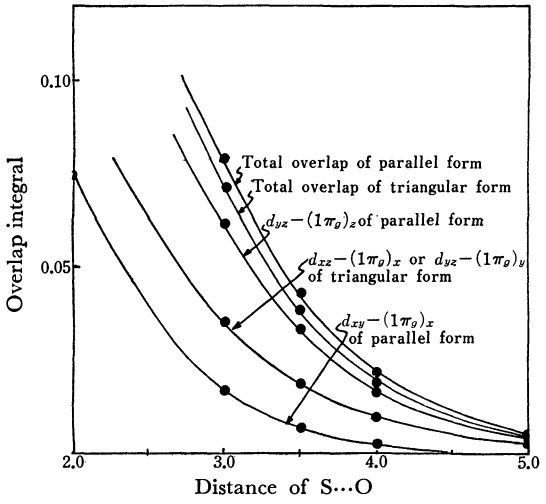

Fig. 7. Orbital overlap between *d*-orbitals of central sulfur of sulfonium and $1\pi_g$-orbitals of molecular oxygen.

The individual values of their overlap integrals were calculated. The geometry used for the mode of interaction between trimethylsulfonium chloride and the oxygen molecule is indicated in Fig. 6. As is indicated in Fig. 7, the total overlap of the parallel form is larger than that of the triangular one, and the $(d\text{-}p)\sigma$-type overlap is apparently larger than the $(d\text{-}p)\sigma$-type one; this is in agreement with the previous discussion.[19]

The Dependence of Orbital Overlaps on the Rotation around the Bond Axis between Two Oxygen Atoms.
The ASMO SCF calulation was further adopted for the parallel form, in which the oxygen molecule rotates in a way parallel to the sp^2-hybrid ligand plane, as is shown briefly in Fig. 8.

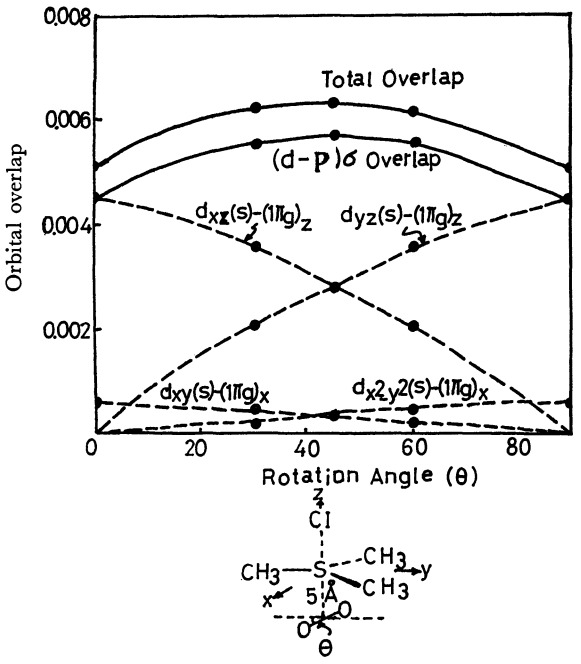

Fig. 8. Orbital overlap in case of O_2 rotation.

The dependence of the orbital overlap integrals on the rotation of the molecular axis of the oxygen molecule is indicated in Fig. 8.
Fig. 8 shows that the most preferable overlap is brought about at the rotation angle of 45° to the direction of *d*-orbital expantion. In this situation, the orbital symmetry is favorable for the formation of a methane-like bonding overlap. These circumstances are illustrated in Fig. 9. Here, it is necessary to consider the chemical nature of the oxygen molecule activated through the interaction with the sulfonium salt. When the *d*-orbitals of the central atom interact with the $1\pi_g$-orbitals of the oxygen molecule, the partially-occupied *d*-sulfur orbitals[19] (d_{yz} or d_{xz}) to which the electron flows from the counter anion may transfer the charge to the $(1\pi_g)_z$-orbital of O_2, and the $(1\pi_u)_z$-orbital electron may back-donate to the d_{z^2}-sulfur orbital. Such electron migrations promote the increase in the bond length of the oxygen molecule by the electron repulsion, and the odd-electron-charge density may localize in each oxygen atom so as to increase the radical nature of O_2. In this situation, the half-occupied, doubly-degenerated $1\pi_g$-orbitals come to be free from the de-

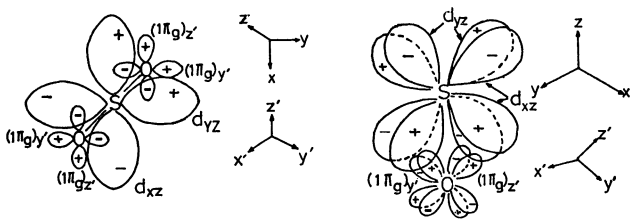

Fig. 9. An optimized interaction between sulfur *d*-orbitals and 1π-orbitals of oxygen molecule.

generated state, considering the Jahn-Teller effect.[28,29] It should be stressed here that the electron affinity and the ionization potential of the oxygen molecule are 0.15 eV[30,31] and 12.075 eV[32,33] respectively. Considering that the energy levels of the $3d$-sulfur orbitals, in particular those of d_{xz} and d_{yz}, are -0.688, -1.736 eV at the S-Cl distances between 3.0 and 3.4 Å (see Fig. 5), the energy level of -0.15 eV of the oxygen molecule might play an important role in the interaction with the $3d$-sulfur orbitals because of possibility of perturbation between them. Further work about the electronic state of the oxygen molecule calculated by means of non-empirical calculation may clarify this point.

32) K. Watanabe, *J. Chem. Phys.*, **26**, 542 (1957).
33) Other data are 12.2 ± 0.3 eV (G. L. Weissler, J. A. R. Samson, M. Ogawa, and G. R. Cook, *J. Opt. Soc. Amer.*, **49**, 338 (1959)) and 12.21 ± 0.04 eV (D. C. Frost and C. A. McDowell, in "Advance in Mass Spectrometry," edited by J. D. Waldron, Pergamon Press, London (1959), p. 413).

The most suggestive results obtained from this study may be summarized as follows:

a) The bond between the sulfonium cation and the anion of the sulfonium salts is constituted mainly by the bonding $(d\text{-}\pi)\pi$-type overlaps made by the $3d_{yz}$- (or $3d_{xz}$-) sulfur orbital and the $3p_y$- (or $3p_x$-) chloride orbital and by the antibonding $(d\text{-}\pi)\sigma$-type overlaps made by the $3d_{z_2}$- (or $3p_z$-) sulfur orbital and the $3p_z$- (or $3d_{z_2}$-) chloride orbital.

b) As to the interaction between the *d*-orbitals of sulfonium salt and the $1\pi_g$-orbitals of the oxygen molecule, orbital symmetries allow two modes of interaction (the parallel form and the triangular one). The former is stronger than the latter. In the parallel form of the interaction, a $(d\text{-}p)\sigma$-type overlap is predominant over a $(d\text{-}p)\pi$-type overlap, as has been suggested previously.[19]

c) The maximum overlap of the $(d\text{-}p)\sigma$ type formed between the sulfonium salt and molecular oxygen is possible when the oxygen molecule rotates at the angle of $\pi/4$ around its bond axis parallel to the sp^2-hybrid ligand plane of the sulfonium cation.

d) The electron inflowing from the $3d$-orbitals of the sulfonium to the $1\pi_g$-orbitals of O_2 localizes the electron charge of the orbitals, which may be connected with the increase in the radical nature of O_2.

The calculations have been carried out on the FACOM 230.60 computer at the Computer Center of Kyoto University.

The authors wish to express their cordial thanks to Professor Kenichi Fukui, who made a number of valuable suggestions and commented on major portions of this study.

A Theoretical Study of the Catalytic Activity of Group I Metal Salts in the Homogeneous Liquid-Phase Oxidation

Katsutoshi OHKUBO, Hidetoshi SHIMADA, Yasuhiro SHIOTANI, and Masahide OKADA
Faculty of Engineering, Kumamoto University, Kurokami-machi, Kumamoto
(Received October 1, 1970)

A theoretical consideration of the catalytic activity of group I metal salts, especially of lithium ones, for the homogeneous liquid-phase oxidation of hydrocarbons was developed by extended Hückel molecular orbital calculations, with particular reference to the interaction between the salts and molecular oxygen. We made several findings. First, a marked activity of lithium salt-catalysts was reflected by a remarkable "electron-partial occupation" of the lithium cation in their salts. Second, a strong interaction of the lithium catalyst with O_2 occurred at the angle of 15° to the direction of the $1\pi_g$-orbital expansions of O_2. Third, the lithium catalyst participated strongly in the activation of O_2 at the distance of 2 Å—3 Å, increasing the electron-population of one oxygen atom located farther from the lithium cation. Finally, the contribution of the "activated" oxygen molecule to the initiation of the oxidation of hydrocarbons was discussed.

In the field of liquid-phase catalytic oxidations, it is usually accepted that oxidation catalysts such as transition metal compounds[1] exhibit catalytic effects on the acceleration of the reaction rate through the so-called "*Haber-Weiss*"mechanism.[2] On the other hand, the different proposals of some other authors[3-5] have been based on the concept that oxidation catalysts might interact with molecular oxygen to form "*activated*" oxygen. This concept is surely plausible considering that the main product (hydroperoxide) accumulated is little decomposed by the catalyst in low-temperature oxidation in spite of the appreciable amounts of oxygen consumed to hydrocarbons. However, the above concept has not been confirmed precisely on the basis of experimental work.

It is hard to deny that hydroperoxides formed in such small amounts (below 2%[6] of the total conversion, as determined from the amount of O_2 absorbed) during the induction period initiate the oxidation reaction as radical initiators through their thermal or catalytic decompositions. In this case, radicals produced secondarily from such a hydroperoxide take part in the decomposition of the hydroperoxide formed successively.

From our previous works concerning the catalytic behavior of such salt-type catalysts as onium compounds[7-9] and metal salts[10] in the homogeneous liquid-phase oxidation, the phenomena of the increasing rates at the initial stage of the reaction could be well explained by the assumption of an interaction between the catalysts and molecular oxygen; furthermore, this assumption was supported more precisely by a spectroscopic study[11] of the above interaction. Recently, the donor-acceptor interaction[12-14] between organic compounds (donor) and molecular oxygen (acceptor) has been studied in detail in connection with the "*contact charge-transfer complex*";[15-17] a theoretical calculation of this complex can be found in Ref. 18. Moreover, a possible interaction of KCl with O_2 has been confirmed by Känzig and Cohen[19] by a study of the ESR spectra, which indicated the presence of the O_2^- anion. It was found in our recent study[10] that alkali metal salts, in particular lithium salts, promote the oxidation reaction remarkably without an incubation period: this suggests the interaction of the salts with molecular oxygen at the initial, short stage of the reaction.

The aim of this study is to clarify the following points: a) the electronic states of metal salts, especially of lithium salts, and their correlations to the catalytic activity of the salt-type catalysts, b) the mode of the intraction of the catalysts with molecular oxygen, and c) the chemical property of the oxygen molecule "*activated*" through the interaction with the above salt-type catalysts. The extended Hückel method proposed by Hoffman[20] was employed to investigate these items.

Methods of Calculation

The calculations by the extended Hückel method were performed at first on group I metal chlorides and

several lithium salts: LiCl, NaCl, KCl, RbCl, LiBr, LiI, LiF, Li_2SO_4, Li_2CO_3, LiO_2CH, $LiO_2CC_2H_5$, $LiNO_3$, $(LiO_2C)_2$, Li_3PO_4, and so on. Secondly, the calculations were carried out for the interaction between LiCl and O_2 with the variation in the bond angles of OOLi at 0°, 10°, 15°, 30°, 60°, and 90° at a fixed distance (O_2–LiCl=3.0 Å). Thirdly, the calculations were performed on the interactions between LiCl and O_2 at the distances (O_2–LiCl) of 1.0—5.0 Å at a fixed angle ($\angle$OOLi=15°). For the calculations, the values of the orbital exponents for H, Li, Na, Rb, Be, C, N, O, P, S, and Cl were taken from the data of Clementi[21], while the valence-state ionization potentials used for the diagonal *H*-matrix elements (H_{ii}) were supplied by Hinze[22,23] and Pople[24]. These parameters are listed in Table 1. For the off-diagonal matrix elements (H_{ij}), the Wolfsberg-Helmholtz approximation[25] was employed:

$$H_{ij} = K(H_{ii}+H_{jj})S_{ij}/2$$

where the value of K is taken to be 1.75[26] and where S_{ij} is the overlap integral between AO's.

In regard to the bond lengths and angles of the metal salts, they are indicated in the proper tables and figures in this paper. For the H_{ij} of the O atom, there exist three different sets of values for cheking the charge of the atom: H_{ii}(eV)=−36.02 (O 2*s*) and −18.53 (O 2*p*) (Method I), −32.38 (O 2*s*) and −15.85 (O 2*p*) (Method II), and −35.30 (O 2*s*) and −13.61 (O 2*p*) (Method III). Finally, the contour maps of the interaction between the partially-occupied *s*-Li^+ orbital and $1\pi_g$-orbitals of O_2 were portrayed using the effective nuclear charges of the two atoms as derived from Slater's rule.[27]

Results and Discussion

The Correlation between the Catalytic Activity of the Metal Salt and the Atom Population of its Metal Ion. Before discussing the correlation between the catalytic activity of metal salt and the atomic population of its metal cation ($M(M^+)$), it is necessary to emphasize that the catalytic activity of metal salt is not directly dependent upon the counter anion of the salt, but upon its metal cation, and that it is affected mediately by the difference in the structures of the anions. Moreover, the counter anion of the effective salt-type catalyst is not required to have a radical as metal halide.[28] Among the group I metal salts tested, lithium salts exhibited a striking catalytic activity for the acceleration of the reaction rate, without the decomposition of the hydroperoxide formed at the initial stage of the oxidation. It was considered that such a remarkable activity of lithium salts was related to the small 2*s*-lithium orbital "partially occupied" by an electron-inflowing from the counter anion. The lowest vacant *s*-orbital (speaking strictly, a partially occupied one) of Li^+ would thus play an important role in the catalytic activity. This consideration may be true in the case of the $M(M^+)$ of Li^+. The relation between $M(M^+)$ and the catalytic activity (defined by the maximum rate of reaction (R_{max})) is shown in Table 2. Table 2 indicates the marked partial electron-occupation on the vacant orbital of Li^+ in a large separation[29] at a van der Waals distance of Li–Cl (3.31 Å), even though all the $M(M^+)$ values except $M(Li^+)$ is almost zero. This feature of the partial electron-occupation on the vacant orbital of the cation may be related to the weak covalent nature of lithium salts, in view of the appreciable value of the overlap population (indicated by M(M–Cl)) as compared with the negligible populations of other group I metal salts. Such a weak covalency of lithium salts can be understood in terms of the very appreciable solubilities of lithium salts to organic solvents, such as alcohol and ether.

The Bond Nature of Lithium Salts. In order to investigate the nature of the bond of lithium salts, the extended Hückel molecular orbital calculation for Li_3PO_4 was carried out with the bond lengths of Li–O varying from an ionic distance (2.91 Å) to the covalent one (2.30 Å). The changes in the atomic population and the total energy with those of the distance are illustrated in Fig. 1, where the geometry used for the calculation is also portrayed. As is shown in Fig.1, the total energy of Li_3PO_4 indicates, interestingly, that the ionic structure of this phosphate is very stable. In this case, however, the total energy excludes the energies of core repulsions and electron-electron interactions. Considering the circumstances of the hydrocarbons around the metal salt-catalysts in the reaction system, it seems preferable to use the ionic structures of the catalysts. The present calculations will hereafter

28) In fact, phosphate, formate, *etc.* of lithium salts are more effective than halides in tetralin oxidation.[10]
29) The bond distance of Li–Cl has been reported to be *ca.* 2.2029 Å (L. Pauling, "The Nature of the Chemical Bond," Cornell Univ. Press, Ithaca, N. Y. (1960), p. 532).

a) This maximum rate was determined by the moles of O_2 absorbed corresponding to those of hydroperoxide formed in the oxidation of cumene saturated with the metal chlorides at 70°C.
b) Atomic population of the metal cation.
c) Overlap bond population between the metal cation and the anion.
d) They were taken for the purpose of comparison.
e) The L.V. orbital of $BeCl_2$ is 2p-one in the case of sp-hybrid-valence state, while that of Be^{2+} is a vacant 2s-orbital. The former may be preferable because of the feeble ionic character of $BeCl_2$.
f) This level corresponds to the vacant p-Be orbital.

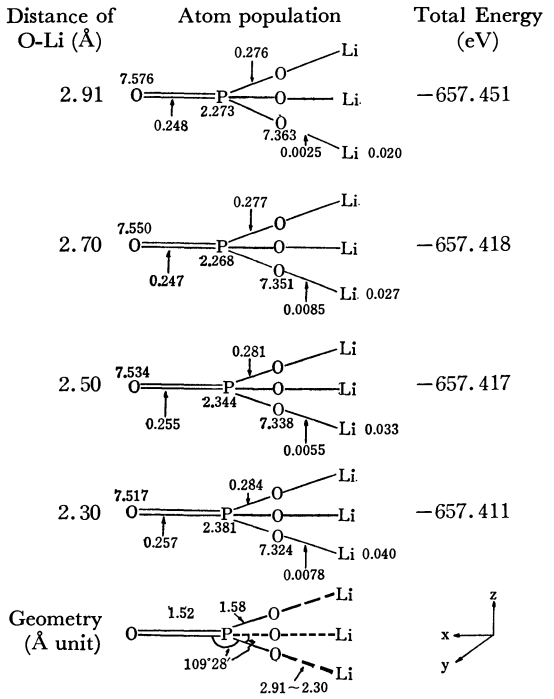

Fig. 1. Electronic states of Li_3PO_4 in some possible structures.

be performed on the ionic structures of the salts.

The Correlation between the Catalytic Activity of Several Lithium Salts and the Atomic Population of the Lithium Cation (M(Li$^+$)) in Them. The counter anions of salt-type catalysts appreciably affect the catalytic activity, as has been discussed previously.[7-10] It is of interest to investigate the relation between the activity (defined by R_{max}[30]) and M(Li$^+$). In this case, M(Li$^+$) would be related directly to the covalency of the bond between the lithium cation and the counter anion, as is indicated by the total overlap population of Li^+–X^-, (M(Li^+–X^-)). R_{max}, M(Li$^+$), and M(Li^+–X^-) are listed in Table 3. An interesting correlation between R_{max} and M(Li$^+$) could be found with some irregularities caused by a gap between the structures calculated and those in the reaction system. This correlation suggests that electrons on the "partially occupied" orbitals of lithium cation participate directly in the activity and that the counter anion contributes not a little toward the changing of the electron-occupation on the cation by an electron-inflow through the somewhat "covalent" bond.

Interaction between the Lithium-salt Catalysts and Molecular Oxygen. The catalytic activity of lithium salts as effective catalysts for the oxidation may be attributed to the contribution of the partially-occupied 2s-lithium orbital, in view of the above discussion. It is plausible here to discuss the interaction between the orbital mentioned above and the half occupied,doubly-degenerated 1π_g-orbitals of $^3\Sigma^-$ molecular oxygen, because the catalysts are unlikely to promote the reaction by the decomposition of the hydroperoxide formed, especially during the initial stage of the reaction.[10] There exist three different representative configurations of the interaction (angular-, linear-, and triangular one), as Fig. 2 indicates. Our previous report[10] demonstrated that the "angular interaction" is plausible in view of the orbital symmetry. From Fig. 2 in which the total orbital overlaps between the orbitals of Li^+ and 1π_g-orbitals of O_2 are recorded, the demonstration mentioned above may be seen to be in good agreement with the present results of calculations, because the overlaps of the angular interaction is larger than those of the others. However, the strength of the interaction should vary with the direction of the orbitals of the Li^+ to 1π_g-orbitals of O_2; it is also affected by the total orbital overlaps between the lithium cation and the 1π_g-orbitals (S(Li^+–O_2(1π_g))). The variation in S(Li^+–O_2(1π_g)) with the angles of the interaction is shown in Table 4. Moreover, the participation of the catalyst in the electronic state of molecular oxygen accompanies the energy splitting of the 1π_g-orbitals from the degenerated state, reflecting the Jahn-Teller

30) This was determined by means of the quantity of O_2 consumed to tetralin at 120°C during the formation of equimolar quantities of its hydroperoxide to those of O_2.

effect.[31,32] This situation may be understood in terms of the energy difference between the removed $1\pi_g$-orbitals (indicated by the notation of "$\Delta E(1\pi_g)$" in Table 4). The value of $\Delta E(1\pi_g)$ suggests that the larger it becomes, the more O_2 comes to have an active radical nature.

From the data of the extended Hückel calculations by both methods (Methods I and II), shown in Table 4, $S(Li^+-O_2(1\pi_g))$ and $\Delta E(1\pi_g)$ shown clearly that the strongest interaction occurrs at the angle of 15° to the direction of $1\pi_g$-orbital expansion. This fact may be closely related to the bond angles of ROOH ($\angle$ROO $=105°$[33]), H_2O ($\angle$HOH$=104°27'$[34,35]), CH_3OH ($\angle$COH$=104°40'$[36]), *etc.* The change in the angles of the interaction, however, has little influence upon the

state of the antibonding $sp\sigma$-type orbitals of the O–O bond, as is shown by the bond-order density (P(O–O)) in Table 4.

The investigation of the interaction of the lithium catalyst with molecular oxygen was, then, developed further by calculating the angular interaction with the variation in the distances of O_2-LiCl from 5 Å to 1 Å at a fixed angle of 15°. The data obtained from the calculations are summarized in Table 5. As is shown in Table 5, a monotonous increase in the total overlap, S (Li^+–O_2 ($1\pi_g$)), with a shortening of the distance between the catalyst and O_2 brings about a larger separation in the orbital energies ($\Delta E(1\pi_g)$). However, in the case of the distance of 1 Å, hardly no interaction might occur because of the core repulsions of the two molecules; this is reflected by the relatively small value of $S(Li^+–O_2(1\pi_g))$. On the other hand, when the lithium catalyst interacts with O_2 at 4 Å—5 Å, the catalyst has little effect upon the activation of O_2, as is suggested by the fact that the values of $S(Li^+–O_2(1\pi_g))$ are so much smaller than those at 3 Å and 4 Å. The contour map for the interaction (at 5 Å) between the $1\pi_g$-orbitals of O_2 and the partially-occupied s-lithium orbital of the catalyst indicates little influence of the catalyst upon the orbitals of O_2, as is shown in Fig. 3. In this situation of the

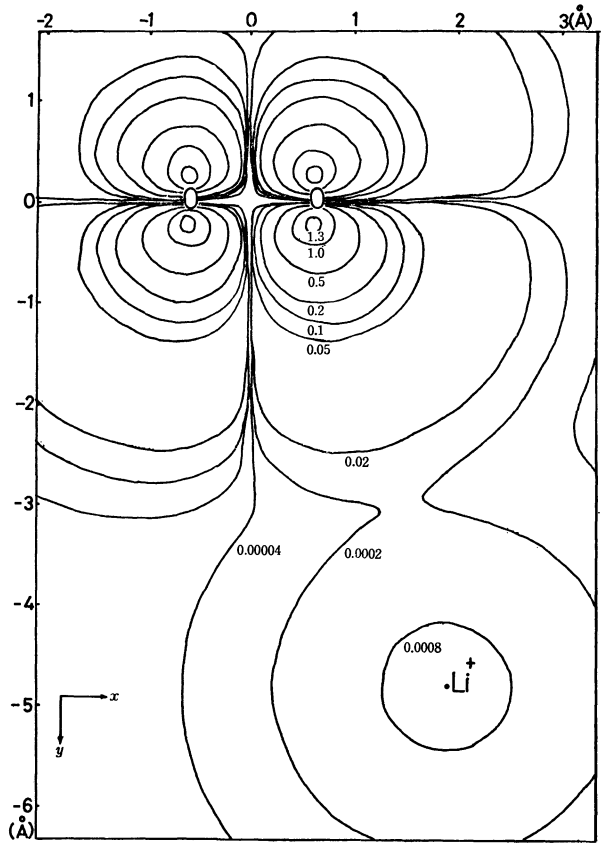

Fig. 3. Contour map for the angular interaction between the 1π-O_2 orbitals and the partially occupied s-Li orbital at 5Å. The values of the contour in this map and the following ones are those of the wave functions.

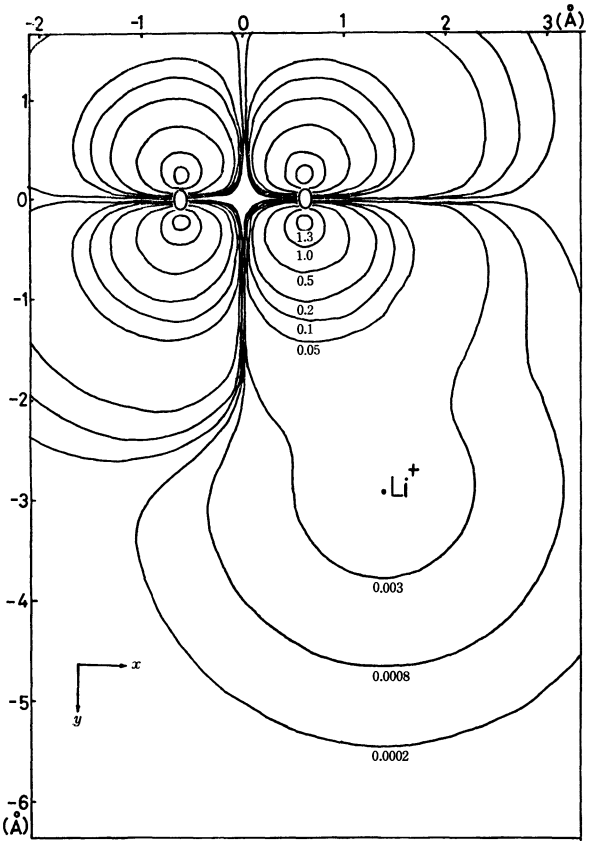

Fig. 4. Contour map for the angular interaction between the $1\pi_g$-O_2 orbitals and the s-Li orbitals at 3Å.

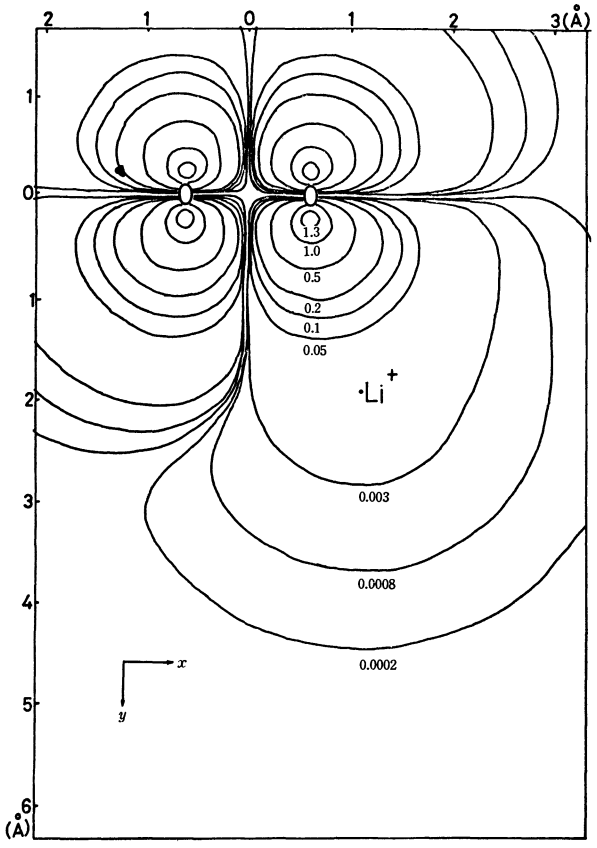

Fig. 5. Contour map for the angular interaction between the $1\pi_g$-O_2 orbitals and the s-Li orbital at 2Å.

small $S(Li^+–O_2(1\,\pi_g))$ value, electrons may be transferred mainly from the $1\,\pi_u$-orbitals of O_2 to the lithium cation to some extent, considering the increase in the atomic population of Li^+ ($M(Li^+)$) with the decrease in the distance between O_2 and the catalyst, while the total population of Cl^- stays constant. Then a favorable interaction would occur at distances from 2 Å to 3 Å, considering the $2p$-orbital expansions of O_2 and the small $2s$-orbital of Li^+. These circumstances are comprehensible in terms of the maps in Figs. 4 and 5. In this case, it is expected that electrons migrate from the partially-occupied $2s$-Li^+ orbital to the $1\,\pi_g$-orbitals of O_2, with a back-donation from the the $1\,\pi_u$-orbitals of the latter to the former. This is suggested by the decreasing $M(Li^+)$.[37]

Speaking about the population of the two oxygen atoms in O_2, the one atom remote from the catalyst, O_f, accepts more electrons than the other (O_n). Further, the $sp\sigma$-type O–O bond may lengthen its interatomic distance, since its bond-order density, P(O–O), is not only negative but also appreciably smaller than that of normal $^3\sum_g^-$ O_2 (see Table 5). Under the circumstances of hydrocarbons (RH), the position of O_f will be the more active side in O_2 for the reaction with RH: the electrons of O_f may transfer to the lowest laying, antibonding σ^*-orbital of RH through the $1\,\pi_g$-orbitals, thus increasing the antibonding character of the bond and causing the scission of the bond. When a hydrogen is abstracted from RH by O_2 through the cleavage of the R-H linkage, electrons migrating from O_2 to RH will be back-donated to the catalyst through the same $1\,\pi_g$-orbitals. Further work on the precise calculation including RH will clarify this assumption.

Finally, the results obtained from the present study may be summarized as follows:

a) Among group I metal salts, as calculated by the extened Hükel method, lithium salts were found to bear a remarkable electron-occupancy in their $2s$-orbitals; in this connection, lithium salts have a somewhat covalent bond.

b) The catalytic activity of group I metal salts can be well explained on the basis of their close relation to the atomic population of the metal cation, and the high activity of the lithium catalyst is reflected by the remarkable population of Li^+.

c) The lithium catalyst interacts most strongly with molecular oxygen at the angle of 15° to the direction of the $1\,\pi_g$-orbital expansions of O_2: this was understood on the basis of the suitable orbital overlap between the "partially-occupied" orbitals of Li^+ and the $1\pi_g$-orbitals of O_2.

d) Such an effect of the lithium-salt catalyst was exhibited best at the distance of 3 Å—2 Å from O_2. The electrons of Li^+ may inflow to the $1\,\pi_g$ of O_2 with the back-donation of $1\,\pi_u$ of the latter and an increase in the electron population of the farther oxygen atom (O_f) for the catalyst. This phenomenon furthered the orbital-removement of $1\,\pi_g$ from the degenerated state.

e) As for the hydrogen abstraction of "activated" O_2 from hydrocarbons, the orbitals of O_f take part in the abstraction more effectively than those of O_n.

The calculations were carried out on the FACOM 230.60 computer at the computation center of University of Kyushu.

37) The atomic population of Cl also stayed constant.

Analysis of Skeletal Deformation Vibration Spectra in Relation to the Molecular Structure

Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 19, 1970)

Deformation vibrations associated with displacements of skeletal heavy atoms are mainly discussed. It is shown that skeletal deformation vibrations are sensitive to the change of an azimuthal angle θ and that the frequencies of the vibrations are specific for the structure of rotational isomers. The θ-dependency of skeletal deformation vibrations corresponds exactly to that of elements of a kinetic energy matrix $\bar{G}$. The results emphasize the simplicity and the usefulness of the approximate normal coordinate treatment in which only skeletal heavy atoms are taken into account.

The concept of group frequencies has played an important role in the interpretation of vibration spectra, and it has contributed greatly to the progress of vibration spectroscopy. On analysing the spectra of large molecules, however, it is difficult to find those appropriate frequencies in the so-called finger print region because of the complexity of the coupling between the group frequencies and the overlapping of vibration bands. Sometimes the normal coordinate treatment affords a useful solution of the problem. However, many of the molecules which arouse great interest of chemists are composed of many atoms and the normal coordinate treatment for such molecules is often time consuming. Moreover, it is not always easy to obtain a reasonable set of force constants that can explain very complicated spectra.

A series of studies on molecular structures for various aliphatic compound showed that it is very hard to make a complete analysis of the vibration spectra of the molecules which have internal rotation axes because of their complexity. In order to overcome the difficulties we tried to find the absorption bands which are sensitive to the change of geometry of rotational isomers and are easily found in the spectra free from the overlapping of other absorption bands. The skeletal deformation vibrations are just the absorption bands satisfying the above requirements and will become still more useful with the remarkable progress in far-infrared spectrometers and laser-Raman instruments. Details of the spectral data used in the present report will be found in the references.[1-3]

Basic Concept

Intrinsic Frequency. The vibrations discussed herewith are deformation vibrations associated with displacements of skeletal heavy atoms of a given molecule. The basic concept of the vibrations will be drawn from the vibration frequencies of the CH_3CH_2X type molecules, because a molecule of this type has only one skeletal deformation vibration.

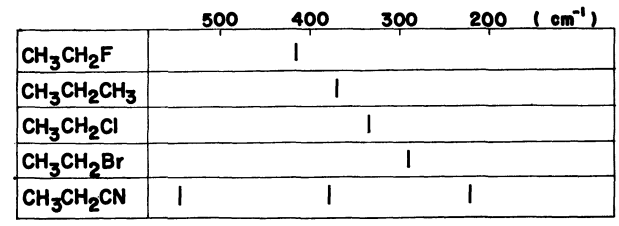

Fig. 1. Observed frequencies for CH_3CH_2X type molecules.

Figure 1 shows the observed frequencies of CH_3CH_2X type molecules. It is clear that the frequency of the deformation vibration decreases with the increase of the mass of atom X. This implies that deformation vibration frequency is determined mainly by the diagonal element of a kinetic energy matrix $\bar{G}$ corresponding to a coordinate $\Delta\alpha_{CCX}$, where $\Delta\alpha_{CCX}$ represents the change of the angle C–C–X. The calculated diagonal elements of $\bar{G}$ matrices for the CH_3CH_2X type molecules are compared with the observed deformation vibration frequencies in Table 1, where g_{CCX} denotes the diagonal element of $\bar{G}$ matrix corresponding to the coordinate $\Delta\alpha_{CCX}$ in $amu^{-1}\cdot A^{-2}$, ν the deformation vibration frequency in cm^{-1}, and A or f_{CCX} is defined by the relations

Table 1. Relation between frequencies and diagonal elements of $\bar{G}$ and $\bar{F}$ matrices of CH_3CH_2X type molecules

Molecule	ν (cm^{-1})	A (amu^{-1} A^{-1} md)	g_{CCX} ($amu^{-1}A^{-2}$)	f_{CCX} (md A)
CH_3CH_2F	415	0.103	0.168	0.61
$CH_3CH_2CH_3$	371	0.082	0.163	0.50
CH_3CH_2Cl	336	0.066	0.126	0.52
CH_3CH_2Br	290	0.053	0.115	0.46

$$A = \frac{4\pi^2 c^2}{N}\nu^2, \tag{1}$$

and

$$f_{CCX} = A/g_{CCX}. \tag{2}$$

In these equations f_{CCX} is expressed in md·A, A is in $amu^{-1}\cdot A^{-1}\cdot md$, while N and c represent the Avogadro number and the velocity of light, respectively. We see that a close relationship exists between g_{CCX} and A as expected. The observed frequencies of Fig. 1 are not assigned exactly to the CCX deformation modes, but they might be considered, to the first approximation,

1) T. Fujiyama, MA thesis submitted to the University of Tokyo (1963).

2) T. Fujiyama, Ph. D. thesis submitted to the University of Tokyo (1966).

3) Tables of Molecular Vibrational Frequencies, Part 1, U. S. Department of Commerce, N. B. S. (1967), and the references cited therein,

to be the *intrinsic frequencies* of the deformation vibrations expressed by the coordinate $\Delta\alpha_{CCX}$. The f_{CCX}'s are values calculated by Eq. (2), and not the real values of $\bar{F}$ matrices. However, the values can be used for the estimation of the intrinsic frequencies.

The frequencies of CH_3CH_2CN exhibit quite exceptional behaviour in the group, because the molecule has two extra vibrations occurring from the linear part of a cyanide group. The intrinsic frequency of a CCN bending vibration is expected to be near 370 cm^{-1}, because the degenerate CCN bending vibration of CH_3CN occurs at 370 cm^{-1}. The CCC deformation vibration and the parallel component of the CCN bending vibration have strong mutual interaction because of the closeness of their unperturbed frequencies, and separate into 544 cm^{-1} and 226 cm^{-1}, leaving the unperturbed perpendicular component of the CCN bending vibration at 378 cm^{-1}. We designate these three vibrations occurring at 544, 226, and 378 cm^{-1} as A, C, and B type vibrations of a cyanide group,

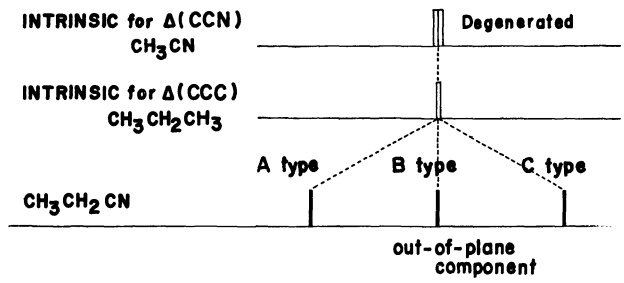

Fig. 2. Frequency diagram for CH_3CH_2CN.

respectively. Figure 2 shows the frequency diagram for CH_3CH_2CN. It seems better to classify CH_3CN into a CH_3CH_2X group rather than CH_3CH_2CN as far as skeletal deformation vibrations are concerned. Then the intrinsic frequency for a cyanide group may be chosen near 370 cm^{-1} referring to the spectra of CH_3CN. However, much clearer pictures would be obtained if one chooses the frequencies of CH_3CH_2CN as the intrinsic frequencies of cyanide compounds. The choice of an intrinsic frequency may be changed inaccordance with the characteristics of a given molecule so as to make the results of spectral analysis clearer and simpler.

Coupling between Intrinsic Frequencies. As intrinsic frequencies can be obtained from the observed frequencies of CH_3CH_2X type molecules, the next step is to estimate the feature and the degree of interaction between them.

$CH_3CH_2CH_2X$ Type Molecules: This type of molecule is expected to have two skeletal deformation vibrations corresponding to the coordinates, $\Delta\alpha_{CCC}$ and $\Delta\alpha_{CCX}$ whose intrinsic frequencies are known from the observed frequencies for $CH_3CH_2CH_3$ and CH_3CH_2X, respectively. The $\bar{G}$ and $\bar{F}$ matrices of this type of molecules are

$$G = \begin{array}{c} \begin{matrix} \text{other} \\ \text{coordinates} \end{matrix} \quad \begin{matrix} \Delta\alpha_{CCC} & \Delta\alpha_{CCX} \end{matrix} \\ \begin{pmatrix} & \\ \hline & \begin{matrix} g_1 & c \\ c & g_2 \end{matrix} \end{pmatrix} \end{array}, \tag{3}$$

$$F = \begin{array}{c} \begin{matrix} \text{other} \\ \text{coordinates} \end{matrix} \quad \begin{matrix} \Delta\alpha_{CCC} & \Delta\alpha_{CCX} \end{matrix} \\ \begin{pmatrix} & \\ \hline & \begin{matrix} f_1 & \\ & f_2 \end{matrix} \end{pmatrix} \end{array}, \tag{4}$$

where the matrix elements g_1 and f_1 are associated with the coordinate $\Delta\alpha_{CCC}$, g_2 and f_2 are associated with the coordinate $\Delta\alpha_{CCX}$, and c is the cross term of the coordinates $\Delta\alpha_{CCC}$ and $\Delta\alpha_{CCX}$. Of these five elements, only c depends on the angle θ through the relation:

$$c = \text{Constant} \times \cos\theta, \tag{5}$$

where θ is the azimuthal angle of the skeleton C–C–X.

Consider, to a first approximation, the two dimensional parts of the matrices $\bar{G}$ and $\bar{F}$, which are indicated in Eqs. (3) and (4). The frequencies of the two deformation vibrations are then expressed as

$$\nu_{\pm} = [(g_1f_1+g_2f_2) \pm \sqrt{(g_1f_1-g_2f_2)^2+4c^2f_1f_2}]/2. \tag{6}$$

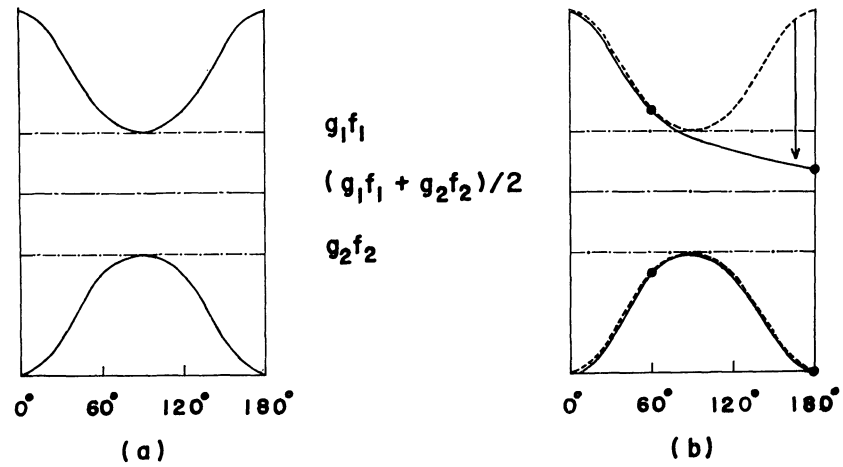

Fig. 3. θ-dependency of skeletal deformation vibration.
(a) Effect of deformation-deformation interaction.
(b) Effect of stretching-deformation interaction.

Equation (5) shows that the element c is zero when θ is 90° and has the largest value when θ is 0° or 180°. Thus, we can understand from Eq. (6) that frequency separation of these two vibrations, $\nu_+ - \nu_-$, is the largest for $\theta=0°$ or for $\theta=180°$ and the smallest for $\theta=90°$. Figure 3(a) shows the θ-dependency for the skeletal deformation frequencies. If c is zero, ν is either g_1f_1 of g_2f_2, which is the intrincis frequency associated, respectively, with $\Delta\alpha_{CCC}$ or $\Delta\alpha_{CCX}$.

The effects of the other vibrations such as a stretching vibration of C-X bond are considerable in this case. In addition to deformation-deformation interaction, we have to consider the effect of stretching-deformation interaction. It is known that the effect of the latter interaction if remarkable when azimuthal angle θ takes a value larger than 90°.[5] Usually the frequency of C–X stretching vibration is higher than those of deformation vibrations. Therefore the effect is remarkable only for ν^+ of Eq. (6). Thus, the θ-dependency of the skeletal deformation frequencies of $CH_3CH_2CH_2X$ type molecules leads to that shown in Fig. 3 (b).

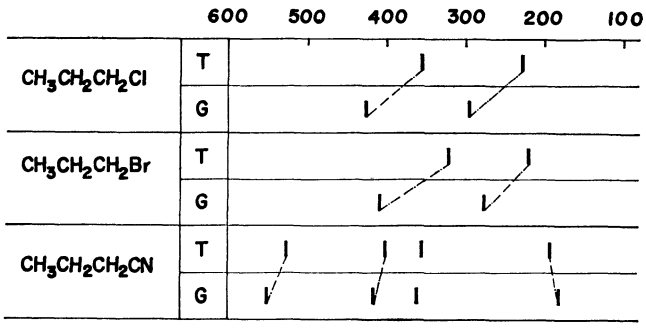

Fig. 4. Observed frequencies for $CH_3CH_2CH_2X$ type molecules.

The observed skeletal deformation frequencies of the $CH_3CH_2CH_2X$ type molecules are summarized in Fig.4. Recall that *trans* (hereafter T) and *gauche* (hereafter G) forms of these molecules correspond to the values of azimuthal angles of 180° and 60°, respectively. Then the correspondence of Fig. 3(b) and Fig. 4 is most striking.

For $CH_3CH_2CH_2CN$, it is convenient to consider the coupling between the intrinsic frequencies taken from CH_3CH_2CN and the additional intrinsic frequency taken from $CH_3CH_2CH_3$. In this case, it is sufficient to consider the interaction between the A and the C type vibrations of cyanide group and the intrinsic vibration for $\Delta\alpha_{CCC}$; the type B vibration of cyanide group is perpendicular to the plane of the skeleton. The interaction of the A and the C type vibrations with the additional $\Delta\alpha_{CCC}$ vibration is also very small, because these frequencies are well separated from each other. One remarkable change thus expected is a slight lowering of the frequency of the type A deformation for the T form due to the stretching-deformation interaction. Figure 5 shows the frequency diagram for $CH_3CH_2CH_2CN$.

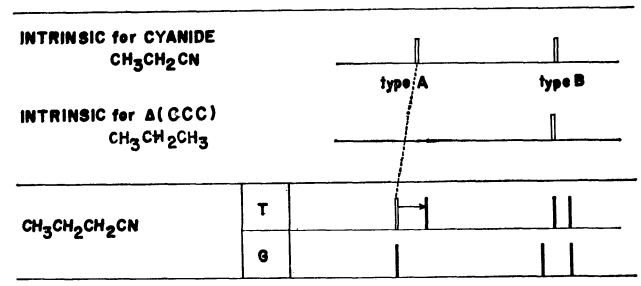

Fig. 5. Frequency diagram for $CH_3CH_2CH_2CN$.

It is interesting to note that the stretching-deformation interaction pushes the C–X stretching vibration of T form up to higher frequency side. This situation explains the well-known empirical rule which correlates molecular conformation and the C–Cl stretching frequencies.[4]

XCH_2CH_2X Type Molecules: The deformation vibrations of these molecules are analyzed satisfactorily by taking into account the two vibrations corresponding to the coordinates $\Delta\alpha_{CCX}$'s. Therefore, a similar approach used in the last section may be applied for this case. The only difference comes from the fact that the two intrinsic frequencies are identical, *i.e.*, $g_1f_1=g_2f_2$. Thus, the extent of coupling becomes most sensitive for

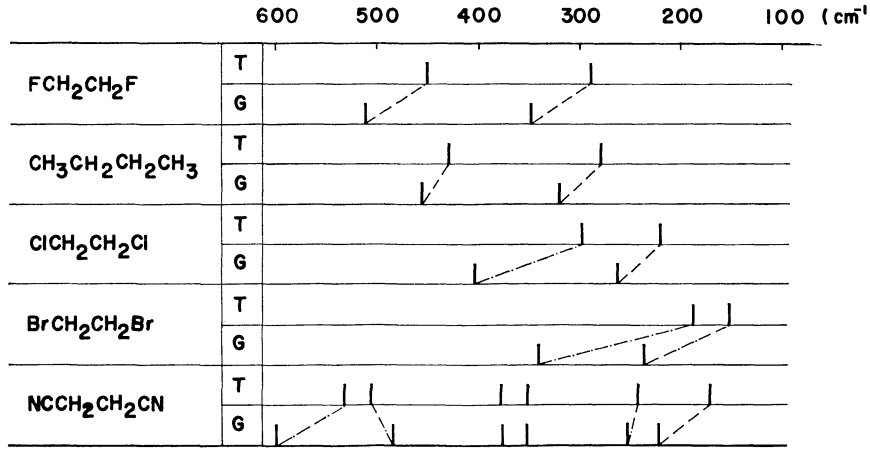

Fig. 6. Observed frequencies for XCH_2CH_2X type molecules.

4) T. Shimanouchi, S. Tsuchiya, and S. Mizushima, *J. Chem, Phys.*, **30**, 1365 (1959).

5) Here, the term stretching is used symbolically. The frequency of the stretching vibration under consideration is the lowest of all the other vibrations which interact with skeletal deformation vibrations indirectly. For a complete description of the deformation-stretching interaction, see I. Nakagawa, *Nippon Kagaku Zasshi*, **76**, 813 (1955), and the related reports cited therein.

the change of the element c of Eq. (6). Figure 6 shows the observed frequencies for XCH_2CH_2X type molecules and the close similarity of Fig. 4 and Fig. 6 is quite obvious.

For succinonitrile, the vibration frequencies of type A and type C exhibit similar patterns, respectively, in the 600—500 cm^{-1} and the 250—150 cm^{-1} regions. The B type vibrations locate in the region of 350—380 cm^{-1} and change their frequencies little for all θ.

Application to More Complicated Molecules

$XCH_2CH_2CH_2X$ Type molecules. This type of molecule has three skeletal deformation vibrations associated with the coordinates $\Delta\alpha^1_{CCX}$, $\Delta\alpha_{CCC}$, and $\Delta\alpha^2_{CCX}$. The submatrix of $\bar{G}$ corresponding to the three deformation coordinates is given as:

$$\bar{G} = \begin{array}{c} \begin{matrix} \Delta\alpha_{CCC} & \Delta\alpha^1_{CCX} & \Delta\alpha^2_{CCX} \end{matrix} \\ \begin{pmatrix} A & & \\ C_1 & B & \\ C_2 & D & B \end{pmatrix} \end{array}, \qquad (7)$$

where A and B are independent of θ, C_1, C_2, and D are related with θ by the relations:

$$C_1 = \text{Constant} \times \cos\theta_1, \qquad (8)$$

$$C_2 = \text{Constant} \times \cos\theta_2, \qquad (9)$$

and $$D = \text{Constant}\,(\sin\theta_1 \sin\theta_2 - (1/3)\cos\theta_1 \cos\theta_2). \qquad (10)$$

In these equations, θ_1 and θ_2 are two azimuthal angles made by the skeleton of $XCH_2CH_2CH_2X$ and the coefficients are calculated by assuming all the valence angles are tetrahedral. For this case we may well consider the coupling of the skeletal deformation vibrations in two steps, of which the first is the interaction between $\Delta\alpha^1_{CCX}$ and $\Delta\alpha^2_{CCX}$. The second is that between $\Delta\alpha_{CCC}$ and the two resultant vibrations from the first step. The matrix element D plays a dominant role in the first stage, while C_1 and C_2 do in the second process. If we use the matrix expression, the first process corresponds to stransforming the three deformation coordinates by an unitary matrix $\bar{U}$, where

$$\bar{U} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1/\sqrt{2} & 1/\sqrt{2} \\ 0 & 1/\sqrt{2} & -1/\sqrt{2} \end{pmatrix} \qquad (11)$$

After the trasformation, the matrix **G** of Eq. (7) becomes

$$\bar{G}_s = \bar{U}\bar{G}\tilde{\bar{U}} = \begin{array}{c} \begin{matrix} S_1 & S_2 & S_3 \end{matrix} \\ \begin{pmatrix} A & & \\ (C_1+C_2)/\sqrt{2} & B+D & \\ (C_1-C_2)/\sqrt{2} & 2 & B-D \end{pmatrix} \end{array} \qquad (12)$$

and the relation between the two sets of coordinates is

$$\begin{pmatrix} S_1 \\ S_2 \\ S_3 \end{pmatrix} = \bar{U} \times \begin{pmatrix} \Delta\alpha_{CCC} \\ \Delta\alpha^1_{CCX} \\ \Delta\alpha^2_{CCX} \end{pmatrix} \qquad (13)$$

Consider the three rotational isomers, TT, TG, and GG of the $XCH_2CH_2CH_2X$ type molecules, then the magnitude of D is calculated for these three rotational isomers from Eq. (10) as:

$$D(\text{TT}) : D(\text{TG}) : D(\text{GG}) = 2 : 1 : 4.$$

Thus the frequency separation due to the first step coupling is expected to be that of Fig. 7.

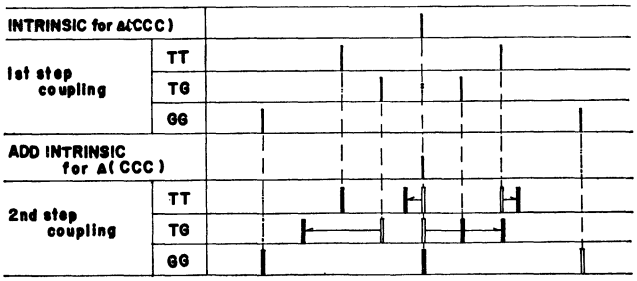

Fig. 7. Frequency diagram for $XCH_2CH_2CH_2X$ type molecules.

The second step is explained by the magnitude and the θ-dependency of C_1 or C_2. The magnitudes of (C_1+C_2) and (C_1-C_2) give the measures of coupling between S_1 and S_2, or between S_1 and S_2, respectively. Referring to the calculated C_1 and C_2 values and to the intrinsic frequency of S_1 obtained from $CH_3CH_2CH_3$, we can expect the frequencies of $CH_3CH_2CH_2CH_2CH_3$, the results of which are shown in Fig. 7. In fact, the observed frequencies given in Fig. 8 for pentane follow the expected pattern reasonably.

As for $NCCH_2CH_2CH_2CN$, the first step coupling is essential, because the intrinsic frequencies for cyanide groups are far apart from that of the intrinsic frequency for $\Delta\alpha_{CCC}$. Both the A type and the C type frequencies of cyanide groups exhibit the patterns quite close to that expected from the first step interaction. They are found, respectively, in the region of 600—400 cm^{-1} and of 200—100 cm^{-1}. The frequencies observed in the region of 400—300 cm^{-1} correspond to the $\Delta\alpha_{CCC}$ and type B vibrations of cyanide groups.

From the analogy of the cyanide compounds, it is convenient to designate the frequencies separated into the higher and the lower frequency regions by the first step coupling as A type and C type deformation vibrations, respectively, and to designate the additional

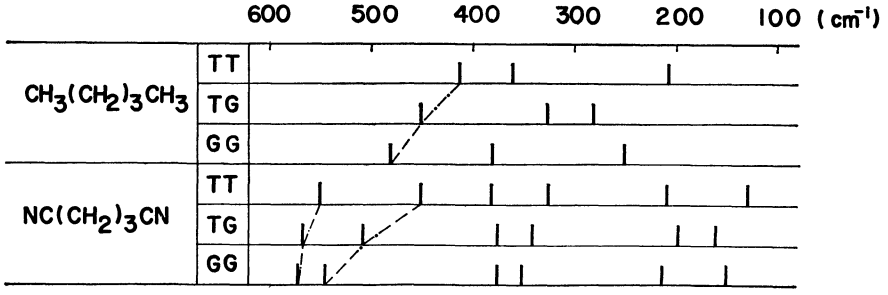

Fig. 8. Observed frequencies for $XCH_2CH_2CH_2X$ type molecules.

intrinsic frequencies for the second step coupling as B type deformation vibration. Generally, the deformation vibrations of type A occur in the region around 600—400 cm^{-1} and are appropriate vibration to study molecular conformation. The frequencies of the A type vibrations are moderately sensitive to the change of azimuthal angles and their relative locations originated from different rotational isomers are fairly analogous with different molecules. On the other hand, the B and the C type vibrations are not always useful for the purpose. Although the C type vibrations are also sensitive to the molecular geometry, the coupling effects with torsional vibrations spoil the structural specificity of the spectral pattern. The frequencies of B type vibrations are almost the same as those of intrinsic freuqencies and, therefore, insensitive to molecular structures. The spectral analysis of CH_3-$CH_2CH_2CH_2Cl$ is the most striking example demonstrating this conclusion.

$CH_3CH_2CH_2CH_2Cl$: This molecule has five possible rotational isomers, TT, GT, TG, GG, and GG'. A similar approach used in the last section is applicable to this case.

The matrix element D of Eq. (7) changes its magnitude in accordance with the conformation of the molecule. The magnitude of D is calculated for the five possible rotational isomers from Eq. (10) as:

$$D(\mathrm{TT}):D(\mathrm{GT}):D(\mathrm{TG}):D(\mathrm{GG}):D(\mathrm{GG}') = 2:1:1:4:5$$

Thus, the general pattern of the frequency separations due to the first step coupling is expected to be that of

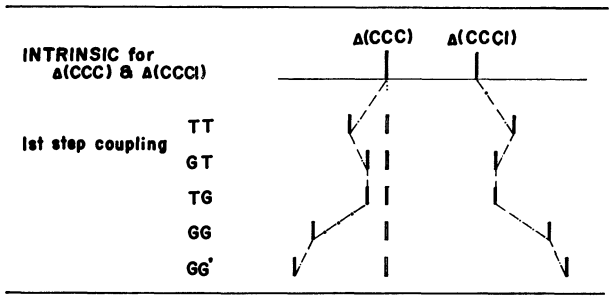

Fig. 9. Frequency diagram for $CH_3CH_2CH_2CH_2Cl$.

Fig. 9. If we neglect the second step interaction, it is clear that the A type vibrations occur in the region around 500—400 cm^{-1}. With reference to the A type vibrations of $CH_3CH_2CH_2CH_2CH_3$ of Fig. 8, the highest and the lowest frequencies of the A type vibrations of $CH_3CH_2CH_2Cl$ are expected, respectively, to be 500 cm^{-1} and 370 cm^{-1}, since the intrisic frequency for $\Delta\alpha_{CCCl}$ is lower than that of $\Delta\alpha_{CCC}$. The frequency diagram of Fig. 7 indicates that the A type vibrations of GT and TG forms are shifted to the higher frequency side by the second step coupling effect. Thus, the A type vibrations of this molecule are expected to occur in the frequency order:

$$\nu(\mathrm{GG}') > \nu(\mathrm{GG}) > \nu(\mathrm{TG}) \gtrsim \nu(\mathrm{GT}) > \nu(\mathrm{TT}).$$

Figure 10 shows the observed infrared spectra of liquid $CH_3CH_2CH_2CH_2Cl$ in the region of 700—200 cm^{-1}. Actually, four bands are seen in the A region of the spectra, namely 472, 456, 435, and 380 cm^{-1}. This

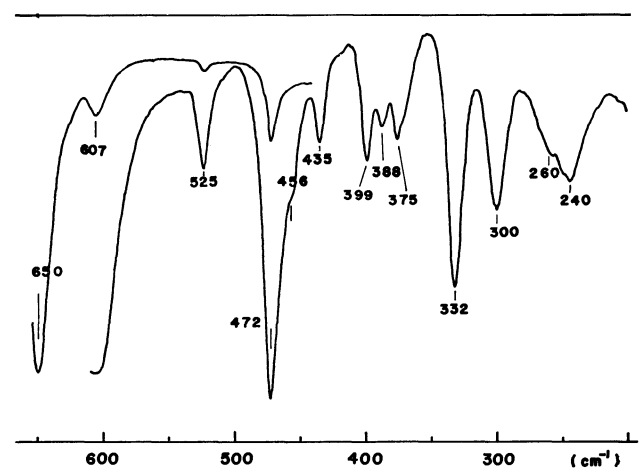

Fig. 10. Infrared spectra of liquid $CH_3CH_2CH_2CH_2Cl$ in the region of 700—200 cm^{-1}.

indicates the existence of at least four rotational isomers in liquid $CH_3CH_2CH_2CH_2Cl$. A more detailed analysis of the spectra including the B and the C type vibrations will be reported elsewhere.

Molecules Having Side Chains. We have discussed so far the normal chain molecules. The skeletal deformation vibrations of molecules having side chains are also interesting. The intrinsic frequencies of these molecules are reasonably obtained from the vibration spectra of $(CH_3)_2CHX$ type molecules.

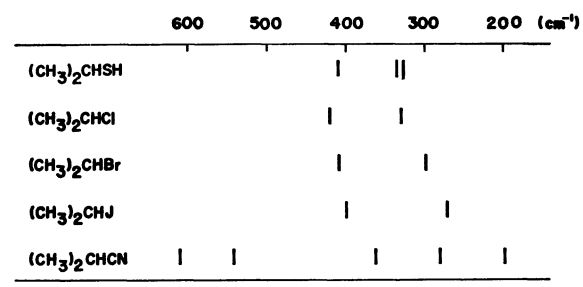

Fig. 11. Observed frequencies for $(CH_3)_2CHX$ type molecules.

$(CH_3)_2$ CHX type molecules: The observed frequencies for the molecules of this type are summarized in Fig. 11. These molecules have three skeletal deformation vibrations, of which two are of the species A' and the other is of the species A''. The A'' vibration which is called an out-of-plane bending vibration is expected to show strong frequency dependency on the mass of X atom. The A' vibrations are assigned either to CH_3–C–CH_3 bending or to inplane C–X bending vibration. It is seen from Fig. 11 that the former exhibit almost the same frequency regardless of the X atom. The slight difference in frequency may be attributed to the effect of the intraction with the C–X stretching vibration.

For $(CH_3)_2CHCN$ also, the intrinsic frequencies can be found as is the case for CH_3CH_2CN. Define the internal coordinates, $\Delta\alpha_1$, $\Delta\alpha_2$, $\Delta\alpha_3$, $\Delta\beta_s$, and $\Delta\beta_p$, which are associated with the skeletal displacements of $(CH_3)_2CHCN$ molecule, then the symmetry coordinates which define the approximate vibrational modes of the molecule are:

$$S_1 = (2\Delta\alpha_1 - \Delta\alpha_2 - \Delta\alpha_3)/\sqrt{6}$$
$$\sqrt{2}S_2 = (\Delta\alpha_1 + \Delta\alpha_2 + \Delta\alpha_3)/\sqrt{3} - \Delta\beta_p,$$
$$\sqrt{2}S_3 = (\Delta\alpha_1 + \Delta\alpha_2 + \Delta\alpha_3)/\sqrt{3} + \Delta\beta_p, \quad (14)$$
$$\sqrt{2}S_4 = (\Delta\alpha_2 - \Delta\alpha_3)/\sqrt{2} - \Delta\beta_s,$$
and $$\sqrt{2}S_5 = (\Delta\alpha_2 - \Delta\alpha_3)/\sqrt{2} + \Delta\beta_s,$$

where $\Delta\alpha_1$ corresponds to the change of an angle CH_3–C–CH_3, $\Delta\alpha_2$ and $\Delta\alpha_3$ to those of CH_3–C–CN, and $\Delta\beta_s$ and $\Delta\beta_p$ to the parallel and the perpendicular bending of C–C≡N part, respectively. The coordinates, S_1, S_2, and S_3, belong to A' species, while S_4 and S_5 to A'' species. The S_2 and the S_4 vibrations are called A type intrinsic vibrations of a cyanide group and occur in the region of 600—550 cm^{-1}. The S_3 and the S_5 vibrations are called C type vibrations of a cyanide group and occur in the region of 300—100 cm^{-1}. The CH_3–C–CH_3 deformation vibration occurring at 360 cm^{-1} corresponds to the coordinate S_1 and is called B type vibration. The frequency of the B type vibration is close to the intrinsic frequency of $\Delta\alpha_{CCC}$ for normal chain molecules. These five frequencies of $(CH_3)_2$-CHCN molecule can be chosen as the intrinsic frequencies of the cyanide group attached to a secondary carbon atom, the details of which are seen in the lower part of Fig. 13.

$CH_3CH(CN)CH_2CH_3$: 2-cyanobutane is chosen as an appropriate example of application to secondary substituted molecules with an internal rotation axis. In addition to the five intrinsic frequencies obtained from $(CH_3)_2CHCN$, it is enough to consider one skeletal deformation vibration corresponding to the coordinate $\Delta\alpha_{CCC}$, whose intrinsic frequency is supposed to be near 370 cm^{-1}. The first step coupling takes place between the two vibrations, $\Delta\alpha_{CCC}$ at 370 cm^{-1} and the B type vibration of $(CH_3)_2CHCN$ at 360 cm^{-1}. As already discussed, this type of coupling has the most serious effect on frequencies when the molecule takes T form. The second step coupling corresponds to the interaction of the A type vibrations of cyanide part with the resultant vibrations from the first step interaction. The effect of the interaction is strong when the molecule takes G form both for the out-of-plane and the in-plane vibrations of the type A. When the molecule takes T conformation, the frequency shift due to the coupling is expected to be very small, so that the vibration of the A type would not be affected much. Thus, we can expect the frequency diagram of this molecule as shown in Fig. 12.

Figure 13 shows the observed inrfared spectra of liquid 2-cyanobutane in the region of 700—100 cm^{-1} together with the skeletal deformation frequencies of $(CH_3)_2CHCN$ at the bottom. From the spectra the existence of at least two rotational isomers is concluded because there appear thirteen bands in the region of 600—100 cm^{-1} when only six skeletal deformation vibrations are expected for each rotational isomer. It is seen in the figure that there exist four bands with strong intensities in the 600—500 cm^{-1} region where the A type vibrations of cyanide group are expected to occur. The bands at 577 cm^{-1} and 528 cm^{-1} increase their relative intensities in the low temperature spectra, while those at 602 cm^{-1} and at 555 cm^{-1} follow the reverse tendency. This implies that those frequencies correspond, in pairs, to the stable rotational isomers T and G. From the frequency diagram of Fig. 12, we may conclude that the pair at 577 and 528 cm^{-1} is assigned to that of T form, while the pair at 602 and 555 cm^{-1} is assigned to that of G form. It is also understood that the T form is a more stable rotational isomer. It should be noticed that two bands are found at 666 and 492 cm^{-1} in the spectra of Fig. 13. These may also be of the A type and may be assigned to the rotational isomer G which is assumed to be most unstable form. In fact, the bands disappear in the low temperature spectra.

Discussion

It was shown in the former sections that the molecular conformations of same complicated molecules could be determined by the analyses of skeletal deformation vibrations. The process of the analysis may be summarized as follows.

(a) Find the intrinsic frequencies from the simpler molecules which have the similar chemical structures or substituents as those of molecules in question. The molecules suitable for this purpose are of the type CH_3CH_2X, $(CH_3)_2CHX$, and $(CH_3)_3CX$. The choice of the intrinsic frequencies should be made so as to make the analyses simpler.

(b) Consider the coupling between the intrinsic frequencies. The frequency shift due to the coupling can be estimated from the off-diagonal elements of

$\bar{G}$ matrix associated with the two coordinates of the intrinsic frequencies in question.

(c) We may consider the couplings in several steps. The resultant frequencies from one interaction step will play a role as the intrinsic frequencies in the next process.

(d) When the matrix elements of $\bar{G}$ depend on the azimuthal angle θ, the frequencies involved are naturally θ-dependent. When the diagonal elements of the deformation coordinates involved have θ-dependency, it is not very hard to determine the structure of the molecule by comparing the observed frequencies with the expected values for skeletal deformation frequencies. Therefore, when off-diagonal elements of $\bar{G}$ matrix are θ-dependent, it is desirable to make transformation which brings the θ-dependency into the diagonal parts.

(e) Sometimes it is necessary to take into account the effect of the stretching vibrations, the frequencies of which are located close to those of the skeletal deformation vibrations. The effect is important when the substituents X are composed heavy atoms, because the stretching vibration frequencies come close to those of the skeletal deformations. The effects are often θ-dependent.

(f) Throughout the analyses, a $\bar{F}$ matrix is tacitly assumed to be diagonal. The validity of the assumption can hardly be guaranteed theoretically, but the good correspondence between the expected and the observed spectral patterns indicates the practical usefulness of the method.

The above discussions lead to the very important conclusion about the normal coordinate treatment of complicated molecules. It is good enough to take into account the skeleton of a given molecule in the calculation, if the determination of the molecular structures of rotational isomers is the main object of the calculation. In that case the force constants used for the calculations are purely empirical parameters appropriate to explain the vibration frequencies produced by the displacements of heavy atoms. Mostly it is possible to choose the suitable set of force constants to explain spectra of skeletal deformation region. The simplicity and usefulness of such treatment may easily be understood by considering the size of the secular determinant to be solved. In the case of *n*-butylchloride, for example, the determinant is 36 in its order if all the atoms were considered, while mine order matrix is necessary if we neglect the light atoms.

It must be emphasized here, however, that the estimated frequencies from the above processes are of course not exact. It is always necessary to compare the expected frequencies with the observed as a group or as a pattern. Vital to this type of work is the isolation of the bands originating from one rotational isomer from those of the others. This can be done by examining the effects of temperature and of solvents on the spectra as well as by observing the spectra in various phases.

This work was performed under the guidance of Professor Takehiko Shimanouchi in the University of Tokyo. The author is grateful to Professor T. Shimanouchi for helpful discussion. Electronic Structures of the Oxocarbon Anions. III. Application of the Extended Hückel and Variable Electronegativity Extended Hückel Methods[1]

Kazuyoshi SAKAMOTO[2] and Yasumasa J. I'HAYA

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo

(Received August 20, 1970)

The extended Hückel (EH) method with different basis functions and the variable electronegativity extended Hückel (VEEH) method are applied first to the calculation of the electronic structure of CO and then to that of three oxocarbon anions, $(C_4O_4)^{2-}$, $(C_5O_5)^{2-}$, and $(C_6O_6)^{2-}$. MO energies of CO calculated by both methods are closer to those computed by a non-empirical SCF method and also to observed values, compared with those obtained by the CNDO/1 method. It is also found for CO and the three anions that in the EH method the charge distributions are not dependent on the basis functions chosen and are much more localized on the oxygen atoms than in the VEEH method. The latter method yields a π-electron distribution which is close to that predicted by the variable electronegativity π-electron SCF method. The EH and VEEH methods predict reasonable values for the lower excitation energies of these oxocarbon anions; specifically the calculated $\sigma \rightarrow \pi^*$ excitation energy of $(C_4O_4)^{2-}$ agrees well with an observed value.

In previous papers,[3,4] the lower π-electronic states of three oxocarbon anions, $(C_4O_4)^{2-}$, $(C_5O_5)^{2-}$, and $(C_6O_6)^{2-}$, have been investigated by a Pariser-Parr-Pople type self-consistent field (PPP-SCF) method with configuration interaction including up to doubly excited configurations. The calculated lowest $\pi \rightarrow \pi^*$ transition energies for these anions were shown to be in good agreement with observed values. However, we have so far not referred to their σ-electronic structures, in other words we have assumed the sp^2 hybridized σ-skeletons for all anions. Recently, we observed a new absorption band of $(C_4O_4)^{2-}$ at 325 mμ with $\varepsilon =$ 174[5] and confirmed that this band is most probably due to an $n \rightarrow \pi^*$ transition.[6] Partly for explaining this theoretically and partly for elucidating the σ-structures of the anions, we feel the need of an all valence electron treatment not only for $(C_4O_4)^{2-}$ but for the series of oxocarbon anions.

For this purpose, we first take up the extended Hückel (EH) method.[7,8] As is well known, the method has many advantages but has some drawbacks also. Some disadvantages are: (1) in heteroatom-containing molecules, the resultant charge distribution becomes unrealistic, *i.e.* excess amounts of charge tend to concentrate on more electronegative centers; (2) the results for molecule ions are not good. To improve this, we first try to choose an appropriate basis set which is different from Slater orbitals ordinarily used. In so far as we know, such sort of attempts has not been made elsewhere.

Alternatively, several authors[9-12] have tried iterative methods in which matrix elements H_{pp} are assumed to be linear functions of a net atomic charge q_N or of both q_N and a total gross population in each AO (AO population).

Such iterative methods, however, do not always lead to satisfactory conclusions. For example, Carroll *et al.*[10] compared the usual EH calculation with the iterative one for small inorganic molecules and gave no definite answer to a question of which procedure was preferred. Duke[12] indicated, in the calculation of relatively small molecules, that a similar iterative method does not always lead to improvements in the wave functions but some better tendency is found for molecule ions.

In this paper, a somewhat different procedure is proposed for solving an iterative EH equation with the intention of improving the above-mentioned weak points of the usual EH treatment. In the method, tentatively called a variable electronegativity extended Hückel (VEEH) method, the valence state ionization potentials (VSIP) are taken to be quadratic functions of the effective nuclear charge Z_p, just like the case of the π-electron SCF treatment (VESCF for example). We first apply the method to a pilot molecule, CO, in order to see whether the calculated charge distribution is reasonable, then to the series of oxocarbon anions. Overall comparison of the EH method with different basis sets and the VEEH method will be made in regard to the electronic structures of the oxocarbon anion series together with that of carbon monoxide.

Method of Calculation

In the EH calculations, the following three basis sets are used for the sake of comparison: (a) Slater-type orbitals (STO) in which the orbital exponent ζ is determined by Slater's rule, (b) the free-atom-ζ single-ζ STO's,[13,14] (c) the free-atom-ζ double-ζ STO's.[13,15] Within the framework of the EH method, the diagonal matrix elements H_{pp} are chosen to be the negative of the VSIP, *i.e.* $H_{pp}=-I_p$. The values of I_p's are taken from Pritchard's paper[16] and are assumed to be constant throughout the whole calculation. The off diagonal matrix elements H_{pq} are assumed to take the form

$$H_{pq} = (K/2)(H_{pp}+H_{qq})S_{pq}, \quad K = 1.75 \qquad (1)$$

The reason for this is as follows. The alternative formula assumes $K=2-|S_{pq}|$, *i.e.*

$$H_{pq} = [(2-|S_{pq}|)/2](H_{pp}+H_{qq})S_{pq} \qquad (2)$$

and both Eqs. (1) and (2) have been used successfully.[8,9] To check which formula is more favorable, both equations are applied to preliminary calculations of the oxocarbon anions. In Tables 1 and 2 are illustrated the results for $(C_4O_4)^{2-}$ obtained when the free-atom-ζ single-ζ basis set is used. As these tables show, the electronic distributions and excitation energies are not very much dependent on the assumption of which formula is used. Similar results are obtained for other oxocarbon anions. Therefore, Eq. (1) is chosen hereafter in this paper only for its simpler form.

In the VEEH method, the values of the matrix elements are modified by new Z_p's at each stage of the iteration process. The values of Z_p for $2s$ and $2p$ valence orbitals of carbon and oxygen are determined by

$$Z_p = N_x - 1.35 - 0.35M_x \qquad (3)$$

where N_x stands for the atomic number of atom x contributing pth orbital, and M_x is the atomic population of atom x determined by Mulliken's population analysis.[17] A new M_x is estimated from the previous one, M_x*, by the following equation[18]

$$M_{x\,\text{input}} = M^*_{x\,\text{input}} - \lambda(M^*_{x\,\text{input}} - M^*_{x\,\text{output}}) \qquad (4)$$

with a constant λ, the steepest decent parameter, which value is taken to be 0.1 in this paper. Being assumed the quadratic dependence on Z_p, the VSIP's for $2s$ and $2p$ orbitals of carbon and oxygen are obtained as shown in Table 3. These quadratic formulae are determined from atomic spectroscopic data[16,19-23] for the corresponding iso-electronic series by least squares method, as usual. The whole iteration process is continued until the total gross atomic population (atomic population) remains constant within the limits of 0.01. Such convergence was obtained by fifteen iterations, on the average. The computations used a double precision (18 places) routine.[24]

a) See the text.
b), c) See footnotes c and d of Table 4.

CNDO/1[25] and a non-empirical LCAO-SCF[26] are included. The occupied MO energies calculated by the EH and the VEEH methods are rather close to those computed by the non-empirical SCF method, and also to observed values,[27] compared with those of the CNDO/1 calculation.

The AO population and the atomic population of CO calculated by various methods are compared in Table 5. The charge tends to delocalize in going from basis (a) to basis (c) in the EH method. When the VEEH approximation is applied the charge distribution gets closer to that calculated by the non-empirical SCF method. The dipole moments of CO, including the atomic polarization term,[25] are calculated to be 2.86, 2.58, and 1.59 Debyes, respectively, for three basis sets (a), (b), and (c) in the EH method, all in the sense of C^+O^- polarity. On the other hand, the VEEH method yields a dipole moment 0.22 Debye, the polarity being C^-O^+. This explains well the observed sign and magnitude of the dipole moment of CO.[28] From the above, the following points are noteworthy. (1) The MO energies and charge distributions produced by the VEEH approach are pretty close to those obtained by a non-empirical SCF calculation, and the calculated dipole moment is in accord with the observed value. (2) In the EH method, the charge distributions and orbital energies are hardly influenced by suitable choices of basis functions.

In Table 6 are shown the calculated orbital energies and their symmetries of three oxocarbon anions, $(C_4O_4)^{2-}$, $(C_5O_5)^{2-}$, and $(C_6O_6)^{2-}$. Only the results obtained by the EH method with basis (a) are listed, since the data for those calculated with bases (b) and (c) and also by the VEEH method are not very much different from the entries in Table 6. In particular, in the EH calculation the energies of the occupied MO's

Table 6. Orbital energies calculated from EH method with STO basis set (eV)[a]

are not affected so much by the starting basis functions, just as in the case of CO. In both EH and VEEH calculations, it is found that each highest occupied MO of the anions is made up of a linear combination of $2p_x$ and $2p_y$ AO's centered on all the carbon and oxygen atoms and does not contain a $2s$ character.[29] Therefore these highest occupied MO's are characterized to be not a so-called lone-pair orbital but a σ-type orbital. Furthermore, it is found that the charge flows from oxygen to carbon in the EH method, while in the VEEH method the situation is reverse and the degree of delocalization increases. On the other hand, the second highest occupied and the lowest and the second lowest vacant MO's are all clearly specified to be of pure π-characters.[30]

TABLE 7. LOWER EXCITATION ENERGY FOR OXOCARBON ANIONS (eV)

a) See the text.
b) Ref. 5.

The lower excitation energies for the anions, being assumed to be orbital energy differences, are given in Table 7. The $\sigma\rightarrow\pi^*$ excitation energy of $(C_4O_4)^{2-}$, 3.41 eV, which corresponds to an electron excitation from the highest occupied (σ-type) to the lowest vacant (π-type) orbital, is in good accord with our observed value, 3.81 eV.[5] The overall agreement with the experimental $\pi\rightarrow\pi^*$ excitation energies is fairly good in the EH treatment; specifically the method with the use of basis (c) is the best.

As for the VEEH treatment, the calculated $\pi\rightarrow\pi^*$ and $\sigma\rightarrow\pi^*$ excitation energies of $(C_4O_4)^{2-}$ are qualitatively consistent with the experimental conclusion that the $\pi\rightarrow\pi^*$ excitation energy is larger than the $\sigma\rightarrow\pi^*$ one. However, the $\pi\rightarrow\pi^*$ excitation energies predicted by the VEEH method for other anions are too low to be compared with the corresponding observed values. This can not be understood at present, but will be improved by the inclusion of electronic repulsion.[31]

TABLE 8. AO POPULATION FOR OXOCARBON ANIONS

Molecule	Atom	AO	EH basis (a)	EH basis (b)	EH basis (c)[a]	VEEH	PPP–VESCF[b]

a) See the text.
b) Under the approximation of Pariser-Parr equation for two-center electronic repulsion integral and of including all the terms for resonance integral.
c) Ref. 3.

The results of the AO population analysis are given in Table 8. The overall charge distribution obtained by the EH method is not very much dependent on starting basis functions as before. Comparing the VEEH method with the EH method, the former yields more delocalized picture for electrons than the latter does. Furthermore, the former computes the π-type AO populations (indicated as $2p_\pi$ in Table 8) very close to the π-electron densities calculated by a Pariser-Parr type π-electron approximation (see the last column

TABLE 9. ATOMIC BOND POPULATION FOR OXOCARBON ANIONS AND CARBON MONOXIDE

Molecule	Bond	EH basis (a)	EH basis (b)	EH basis (c)[a]	VEEH
$(C_4O_4)^{2-}$	C–C	0.93	0.95	0.96	0.87
	C–O	0.64	0.65	0.65	0.94
$(C_5O_5)^{2-}$	C–C	0.94	0.96	0.98	0.90
	C–O	0.65	0.67	0.68	0.95
$(C_6O_6)^{2-}$	C–C	0.91	0.93	0.94	0.90
	C–O	0.66	0.68	0.70	0.96
CO	C–O	1.11	1.15	1.24	1.44

a) See the text.

29) The highest occupied MO of $(C_5O_5)^{2-}$ contains a small amount of $2s$ component.

30) That is, σ-MO's levels are embedded between π-MO's levels. Indeed, such a behavior is noted for many aromatic substances, for example benzene.[8]

31) A study on the electronic structures of the same anion series by means of a semi-empirical VESCF method including all valence electrons has just been completed and will be submitted for publication in the future.

of Table 8). The effective σ-type AO populations, that is, ratios of the $2s$ and $2p_\sigma$ AO populations, do not change from anion to anion and from method to method, and are approximately $2s^{1.0}\ 2p_\sigma^{1.5}$ for the carbon atom and $2s^{1.0}\ 2p_\sigma^{2.0}$ for the oxygen atom.

In Table 9 are presented the results of the atomic bond population analysis for the three anions and CO. It is found that the atomic bond population for CO is always larger than those for the C–O bonds of the anions, irrespective of the method of calculation. This is consistent with the observed fact that the bond length in CO (1.128 Å) is shorter than any C–O bond length in the three anions (1.259—1.262 Å).

The values of VSIP's produced at the final stage of iteration in the VEEH method are considerably different from the constant values used in the EH method. For example, with regard to the carbon atom of $(C_4O_4)^{2-}$, the quantity obtained from the VEEH method is greater than that used in the EH method, by 1.7 eV for $2s$ AO's and by 1.5 eV for $2p$ AO's. As for the oxygen atom, the former is less than the latter, the differences being 6.5 and 4.0 eV for $2s$ and $2p$ AO's, respectively. A similar conclusion is also obtained in other two anions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 1205—1212(1971)

The Emission Spectra of Pyrazine and Deuterated Pyrazines in the Vapor and in Rigid Matrices at 90°K

Hajime Ishii, Motohiko Koyanagi, and Yoshiya Kanda
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka
(Received August 31, 1970)

Emission spectra of pyrazine and its deuterated derivatives have been observed in the vapor and the vibronic structure has been analyzed in detail. The vibronic structures of the phosphorescence spectra of these compounds have been explained all in terms of totally symmetrical vibrations, while the first main bands of the fluorescence spectra were anomalous as well as their progression bands in respect to the band position and intensity distribution. For comparison, the fluorescence spectra have also been studied in rigid matrices at 90°K.

The fluorescence and phosphorescence spectra of pyrazine-d_0 and -d_4 in the vapor were first observed by Logan and Ross.[1] The 0—0 bands of the phosphorescence spectra of these compounds coincided with those of the lowest T←S absorption spectra, and the shorter-wavelength region emissions were identified with the fluorescence spectra. The observation of the fluorescence spectrum of pyrazine gave a great sensation together with a similar report on 1,2- and 1,3- diazines[2] since it had been generally accepted that the fluorescence should be, if any, too weak to be observed for such a compound with a $^1(n,\pi^*)$ level as the lowest excited singlet state. The fluorescence spectrum has also been studies in rigid solution,[1] in fluid solutions,[3] and in the crystal at 77°K.[4] However, no vibrational analyses of those spectra have yet been made in detail. On the other hand, photoisomerization efficiency from pyrazine to pyrimidine has been discussed in the vapor[5] and in solutions.[6]

The fluorescence and phosphorescence spectra of pyrazine and deuterated pyrazines have been studied here in the vapor. For comparison the fluorescence spectra of pyrazines were also observed in rigid solutions at 90°K. The vibronic structures will be discussed. It is interesting that the phosphorescence spectra from photochemically produced pyrimidines have been observed when the pyrazines in solutions have been excited with the 2537 Å line of the Hg-lamp in agreement with the result by Lahmani *et al.*[6] in which the photochemical products were detected by gas chromatography.

Experimental

A quartz cell for study of emissions in the vapor is essentially the same as that reported by Base and Sponer.[7] A super high pressure Hg-lamp was used as a light source. Two filter systems were employed. One was a combination consisting of a path of 5 cm saturated *aq.* solution of $NiSO_4$ with a little amount of $CoSO_4$ added and that of 1 cm *aq.* solution of mono sodium phthalate of sufficient concentration to cut off the exciting light shorter in wavelength than 3000 Å for observation of the emissions in the vapor and the other consisted of the former of the above filter combination and a path of 1 cm D_3P[8] *aq.* solution for the emissions in solutions. The former combination is suitable for taking out mainly 3130 Å of the Hg-lamp and so is the latter for 2537 Å. The vapor pressure was estimated from the temperature near the outside of the bottom of a side tube where a sample was placed,

according to the equations cited in Ref. 1. The temperature of the sample vapor was assumed equal to the inside temperature of the main oven in which the main part of the fluorescence cell was mounted. With an increase in temperature of the vapor the phosphorescence decreased considerably in intensity while the fluorescence remained unchanged in intensity. Pyrazine obtained from Tokyo Kasei Co., Ltd. was first converted into its salt form with sulfuric acid, recrystallized from alcohol, delivered from the salt form, and sublimed several times in vacuum. Pyrazine-d_4 and -2,3-d_2 were synthesized in the same way as that previously given,[9,10] and sublimed several times in vacuum. Spectra were photographed with a Shimadzu quartz spectrograph type QM-60. Slitwidths employed were 50 μ and 100 μ for measurement of the emissions in the vapor and solutions, respectively. The spectral position was determined within an accuracy of 3 cm^{-1} for the phosphorescence in the vapor, and 5 cm^{-1} and 20 cm^{-1} for the fluorescence in the vapor and in solution, respectively.

Results and Discussion

The Phosphorescence Spectra in the Vapor State. The phosphorescence spectra of pyrazine-d_0, -2, 3-d_2 and -d_4 were observed in the vapor. The microphotometer tracings and the spectral data are given in Figs. 1—3 and Tables 1—3, respectively. As has been pointed out by Logan and Ross,[1] the origin bands of the phosphorescence spectra of pyrazine-d_0 and -d_4 coincided exactly within experimental errors with those of the previously reported T←S absorption spectra.[11] The 0—0 band of pyrazine-2,3-d_2 was located at 26895cm^{-1} and the promotion energy in substitution of an H with a D was found to be 37 cm^{-1} in the vapor, very close to a value of 35 cm^{-1} in the crystal.[9] The overall spectral pattern is rather simple in all three cases as can be seen in Figs. 1—3. Active vibrations observed in the phosphorescence

spectra are the modes of ν_{6a}, ν_{9a}, and ν_1 and their combinations.[12] However, there are many bands that lie with considerable intensity between 27100 and 25900 cm^{-1} and it is impossible to analyze them in terms of the normal mode frequencies in the ground state only. They are schematically reproduced in Fig. 4, and referred hereafter to the band (1), (2),···(7). The assignments are wholly based on the band positions since no other information is available. For instance a study of temperature dependence of the vapor spectra proved of no help, since it was practically impossible to compare the band intensities under different temperatures. With an increase in temperature, the continuous emission from the vapor overlapping on the phosphorescence spectrum increased in intensity, while the

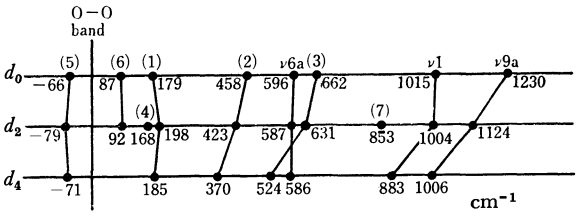

Fig. 4. Schematic representation of first main bands of the phosphorescence spectra of pyrazines in the vapor.

phosphorescence spectrum decreased in intensity. This made a precise measurement of the band intensity impossible.

The band (1) may be ascribed to the 1–1 transition of the ν_{16b}, since hot bands −474 (d_0), −419 (d_2), and −424 cm^{-1} (d_4) could be assigned to the overtones of this vibrational mode in the excited state, and fundamental frequencies of this mode are 416, 409, and 399 cm^{-1} in the ground state, respectively. This situation is analogous to the first S←S (π^*–n) absorption spectrum of pyrazine-d_0.[13] Similarly, the band (2) may arise from the 1–1 transition due to the mode ν_5 if we take 461, 442, and 351 cm^{-1} as ν_5 frequencies in the triplet state which are smaller in frequency by about 50% than those in the ground state, but still greater as compared with the value in the lowest singlet (n,π^*) state.[14] Here, the ν_5 mode frequency of pyrazine-2,3-d_2 in the ground state has been taken to be 865 cm^{-1}. Whether this is valid will be discussed later in connection with the band (7). On the basis of the numerical relationships found in the pyrazine-2,3-d_2 spectrum, the band (3) was assigned to an overtone frequency of a non-totally symmetrical mode in the ground state. These are; 631↔316×2 (ground state), −295↔−148 ×2 (excited state), 168 (band (4))↔316−148 (1–1 transition). Thus the frequencies 331 (d_0), 316 (d_2), and 262 cm^{-1} (d_4) were obtained as fundamentals of a non-totally symmetrical mode in the ground state of the respective compounds in the parentheses, which could be assigned to the ν_{16a} vibrational mode. The experimental value of the frequency has not yet been established but a value of 340 cm^{-1} (d_0) has tentatively been given, which has been taken from the Raman data in the liquid phase[15] and has been supported by the normal mode calculation based on the valency force constants transferred from benzene.[16] The band (5) has its counterpart in the T←S absorption spectrum, but has not been assigned.[17] The band (6) is the 1–1 transition of the ν_{9a} according to a list of designation in Ref. 11. The band (7) has a frequency difference of 853 cm^{-1} from the 0–0 band and this is too large to be interpreted as 1–1 transition. This band is also too strong in intensity to be accounted for as 2–2 transition, *e.g.*, overtone of the 423 cm^{-1} band. From its magnitude

a) $\Delta\nu=\nu_{abs}^{0-0}-\nu$ ($\nu_{abs}^{0-0}=31030$ cm^{-1}).

b) Bands (1′)···(4′) could be assigned as are shown in parentheses, and those are possible in contrast to the pyrazine-d_0 spectrum since the numerical agreement is fair and the vibrational modes are the same as those observed in the fluorescence in solution. Bands (1) and (2) are assigned as are shown in parentheses on the assumption that a false origin lies at 31988 cm^{-1}.

in frequency two assignments may be possible; $\nu_5(a_2$ in $C_{2v})$ and $\nu_{15}(a_1$ in $C_{2v})$. In order to clarify this point, the hot bands of the lowest S←S absorption spectrum of pyrazine-2,3-d_2 in the vapor was investigated and two bands were found at 854 and 865 cm^{-1} from the 0—0 band located at 30952 cm^{-1}, the latter being much stronger in intensity. The fact that ν_5 appears strongly in the absorption spectra of pyrazine-d_0 and -d_4 in the vapor[14] suggests that 865 cm^{-1} may be of the mode ν_5 and 853 cm^{-1} the mode ν_{15}, in good agreement with Ref. 18.[19] Therefore, it has been concluded that all the progressions observed in the phosphorescence spectra of pyrazines in the vapor with sufficient intensity are of totally symmetrical, *i.e.*, a_g (or a_1) mode, overtone vibration, or arise from v–v transitions.

The Fluorescence Spectra in the Vapor State. The fluorescence spectra of pyrazine-d_0 and -d_4 have been studied in the vapor. The microphotometer tracings and the spectral data are given in Figs. 5 and 6 and Tables 4 and 5, respectively, although no unambiguous interpretation of these spectra has yet completely been made. It seems strange to say that the emission spectrum of pyrazine between 31500 and 28000 cm^{-1} is not explainable. But this is not a result conflicting with Ref. 1, in which the identification of the fluorescence spectra was based on the rough coincidence in the Franck-Condon contour between the emissions and the hot bands of the lowest S←S absorption spectra in the vapor. The details will be discussed in the following: At first, let us consider a difference between the tracing curves given by Logan and Ross and those of the present work (Figs. 5 and 6). The most remarkable one lies on a band denoted as −22 cm^{-1} in pyrazine-d_0 spectrum in Fig 5 (−22 cm^{-1} means its distance from the origin band of the first S←S (π^*-n) absorption spectrum). This is one of the strongest bands in our fluorescence spectrum but missing from that by Logan

18) E. F. Zalewski, Ph. D. Thesis, University of Chicago, 1968.

19) However, ν_5 mode has been observed with moderately strong intensity in the phosphorescence spectra of pyrazine-d_0, -d_2, and -d_4 at the isotopically mixed crystal experiments. M. Koyanagi, T. Shigeoka, and Y. Kanda, This Bulletin, to be submitted.

and Ross. The observation was repeatedly made at various temperatures and pressures with and without foreign gas (air). A careful comparison of the curve by Logan and Ross with our various tracing curves showed that the $-22\ cm^{-1}$ band was possibly reabsorbed by the origin band and the hot bands lying close to it in the curve by Logan and Ross since the curve in a region between -500 to $+1000\ cm^{-1}$ coincided well with one of the tracing curves with a strong continuous background of the exciting light source and an intense absorption or reabsorption appearing on it.

No bands that correspond to the hot bands in the absorption were observed in the fluorescence spectrum of gaseous pyrazine-d_0, but several bands in that of gaseous pyrazine-d_4. These phenomena shoud not be attributed to reabsorption or difference in absorbance due to low population of "hot molecules" in the ground state. On the other hand, there are many bands that can be analyzed in terms of four normal mode frequencies of pyrazines, such as the modes of ν_1, ν_5, ν_{6a}, and ν_{9a}, if several origins are tentatively assumed as given in Tables 4 and 5. One of the most probable interpretations of the fluorescence spectra in the vapor may be based on the so-called resonance spectra. An attempt along this line shows that several strong bands become explainable with pseudo-origins. Another may be to assume many abnormally populated emitting levels higher than the zero vibrational level in the excited state. This is probable but too speculative.

Fluorescence in Solution at Low Temperature. The fluorescence spectra of pyrazine-d_0 and -d_4 in methyl cyclohexane and pyrazine-d_0 in benzene have been measured at 90°K. The fluorescence spectrum of pyrazine in methyl cyclohexane consists of somewhat broad bands but becomes rich in structure in benzene solution. The 0—0 band diminishes its intensity with an increase of the concentration. N_{6a} and ν_5 are active vibrations in pyrazine-d_0 in methyl cyclohexane, but whether its 600 cm^{-1} long progressions are overtones of ν_{6a} or combinations of ν_{6a} and ν_{9a} was not certain bacause of its broad linewidth. In a benzene solution they are clearly of the latter type. The spectrum in a benzene solution was rather complicated because there are several sub-systems besides its main progressions.

a) s: strong.
b) ( ): phosphorescence bands of pyrimidine-d_4.

A separation of about 60 cm^{-1} associated with this spectrum may be due to a lattice vibration.[20] In pyrazine-d_4, ν_{6a}, ν_5, ν_{9a}, and ν_1 are active. This last mode was not found in pyrazine-d_0. The observation of the $0-\nu_5$ band in the fluorescence spectra at low temperature in both -d_0 and -d_4 favors the interpretation given by Innes *et al.* that all strong vibronic bands of the 3200 Å absorption system of pyrazine must be assigned to a single electronic transition of mixed character in polarization.[14] An alternative assignment had been given to this band by Ito *et al.* as belonging to an electronically forbidden transition into an another $^1(n, \pi^*)$ state.[13] However, in the case of ordering of energy levels, the fluorescence will occur solely from the lower one at low temperature, especially if the higher transition is of forbidden character and the lower one is of allowed one. Thus it has been concluded that the fluorescence spectrum in solution is explainable by one electronic transition and is a normal one.

The phosphorescence spectra from photochemically produced pyrimidines were also observed, whose 0—0 bands were located at 28220 (d_0) and 28330 cm^{-1} (d_4) and separated by about 1500 cm^{-1} to the shorter wavelengths from that of the pyrazine phosphorescence. This additional emission did not appear when the 3130 Å system of the Hg-lamp was used as an exciting light in agreement with the results by Lahmani *et al.*[5] The mechanism of the photoisomerization of pyrazine has been discussed by several investigators,[6,5,21] and a diazavenzvalene has been proposed as a reaction intermediate. A thermally promoted rearrangement has also been reported.[21] It may be of another interest to examine whether the reversed photoreaction, *i.e.*, pyrimidine into pyrazine, may occur or not.

From the analyses of the vibronic structure of the emission spectra of pyrazine and its deuterated compounds in the vapor, it has been found that the phosphorescence spectrum is straightforward but the fluorescence spectrum is anomalous, and several fundamentals of the vibrations including ν_{16a} mode have been found. They are summarized in Table 8. It has also been found that the fluorescence spectrum of pyrazine in solution at liquid air temperature is of single electronic transition and the photochemical reaction of pyrazine occurs even at such temperature.

Table 8. Fundamental frequencies of pyrazines observed in the phosphorescence spectra in the vapor

vib. mode	elec.[a] state	fundamental frequencies (cm^{-1}) -d^0	-2,3-d^2	-d^4
ν_{16b}	T	237	210	214

Spectroscopic Determination of Quenching Cross-Sections of Excited Mercury Atoms (6^3P_1, 6^3P_0) in Molecular Collisions

Hiroyuki HORIGUCHI and Soji TSUCHIYA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Meguro-ku, Tokyo

(Received September 4, 1970)

The concentrations of $Hg(6^3P_1)$ and (6^3P_0) atoms, $[Hg_1^*]$ and $[Hg_0^*]$, were determined from the absorptions of 4358 and 4047 Å lines in the Ar-diluted mercury vapor in the presence of several quenching molecules, under the radiation of 2537 Å emission. An apparent absorption intensity was not proportional to $[Hg_1^*]$ or $[Hg_0^*]$, and was sensitive to the ratio of the spectral half-width of the light source to that of the absorption line. Therefore, a method to correct an absorption intensity was proposed. The relation of $[Hg_1^*]$ to [Q], a concentration of quenching molecules, is explained well by the Stern-Volmer equation. The value of $[Hg_0^*]$ increases with [Q] until it reaches a maximum at a certain value of [Q], and a further increase of [Q] results in a decrease of $[Hg_0^*]$. These findings are explained well by the following mechanism: (1) $Hg+h\nu \rightarrow Hg_1^*$, (2) $Hg_1^* \rightarrow Hg+h\nu$, (3) $Hg_1^*+Q \rightarrow Hg+Q$, (4) $Hg_1^*+Q \rightarrow Hg_0^*+Q$, (5) $Hg_0^*+Q \rightarrow Hg+Q$, (6) $Hg_0^* \rightarrow Hg$ (by collisions with a wall). The respective values of cross-sections (σ^2) of N_2, CO, and NO for process (3) are ≤ 0.03, 0.60, and 20 Å^2, and those for process (4) are 0.36, 2.1 and 5 Å^2, and those for process (5) are $\leq 3.6\times10^{-4}$, 0.15 and 8.0 Å^2.

The collisional cross-section for quenching an excited mercury atom $Hg(6^3P_1)$ has been obtained by the intensity measurement of the fluorescence from $Hg(6^3P_1)$[1,2] or by observing directly a lifetime of 6^3P_1 state[3]. However, the cross-section thus determined is the sum for the two quenching processes, *i.e.*, from 6^3P_1 to the ground state 6^1S_0 and to the metastable state 6^3P_0. Scheer and Fine[4] found that collisional cross-sections of CO and N_2 for quenching 6^3P_1 to 6^3P_0 were nearly the same, and concluded that CO was a more efficient quencher than N_2 for the process 6^3P_1 to 6^1S_0. Later, Callear and Williams[5] observed the time history of the absorption due to the existence of $Hg(6^3P_0)$ after the flash excitation of mercury atoms, and concluded that all of the cross-sections of various molecules for the process 6^3P_0 to 6^1S_0 were very small compared with the 6^3P_1 quenching cross-sections. Furthermore, they could not find any systematic relation between a cross-section for quenching 6^3P_1 to 6^3P_0 and an energy discrepancy which could not be converted to the vibration of a quenching molecule. Kimbell and Le Roy[6] previously determined the stationary concentration of $Hg(6^3P_0)$ in the system of N_2 gas with mercury vapor illuminated by the mercury resonance line assuming the Lambert-Beer rule. However, their assumption should be uncertain.

In this paper, we propose an accurate method to determine the concentrations of $Hg(6^3P_1)$ and (6^3P_0) from the absorptions of 4358 Å (7^3S_1—6^3P_1) and 4047 Å (7^3S_1—6^3P_0) spectral lines. Based on this method, the cross-sections of N_2, CO, and NO for the quenching processes, $^3P_1 \rightarrow {}^1S_0$, $^3P_1 \rightarrow {}^3P_0$, and $^3P_0 \rightarrow {}^1S_0$ are determined.

Experimental

An outline of the apparatus in this experiment was similar to that used by Karl, Kruus, and Polanyi.[7] The reaction cell was a Vycol glass tube, 4 cm in diameter and 100 cm long, and was surrounded by four low pressure mercury lamps (Toshiba Electric Co., germicidal lamp) that were made from quartz tubes, 2.5 cm in diameter and 89.3 cm long. Each of these exciting lamps was operated by the direct current and had a power of 7.5 watt at 2537 Å radiation, and the emission intensities of other spectral lines were less than 1/30 of that of 2537 Å line. The intensity of 2537 Å radiation from the exciting lamps was monitored by a photoelectric tube (Toshiba Electric Co., PV-43), that was sensitive only to the 2537 Å line. Another low pressure mercury lamp (Ushio Co., ULO-6DQ), d.c. operated, was used as a light source for the measurement of absorption. Apparent concentrations of $Hg(6^3P_1)$ or (6^3P_0) atoms were determined in terms of the optical density, $\log I_0/I$, at 4358 Å for 6^3P_1 atoms and 4047 Å for 6^3P_0 atoms. The light beam, 5 mm in diameter, from the ULO-6DQ lamp was modulated at 25 Hz by a chopper before entering the cell and was passed longitudinally through the cell. The intensity of the beam was measured by a grating monochrometer (Japan Spectroscopic Co., CT-1), and the out-put from the photomultiplier was filtered by a 25 Hz tuned amplifier. The spectral slit-width of the monochromator was usually about 2 cm^{-1}, so that the observed intensity was an integrated one of 4358 or 4047 Å spectral line profile.

Sample gases used were all commercial ones, and their nominal purities were 99.99% for Ar. 99.999% for N_2, 99.5% for CO, and 98.5% for NO. Argon and nitric oxide were purified by successive distillation at liquid nitrogen temperature, and other gases passed through a U-shaped glass tube packed with active charcoal. In order to minimize the pressure dependence of the absorption intensity, quenching gases were diluted in argon, and the total pressure in the reaction cell was kept constant, where argon could be assumed to be a very poor quencher. A quenching gas diluted in argon, from which mercury vapor was removed by passing through a spiral tube cooled to an appropriate temperature, −194.5°C or −119°C, was fed into the reaction cell *via* a mercury saturator at a constant temperature.

Results and Analyses

Absorption Intensity and Concentration of Excited Mercury Atom. The absorptions of 4047 and 4358 Å lines were seen, when a gaseous mixture of Ar, N_2, and Hg was irradiated by the exciting lamp. In this case, the Lambert-Beer rule cannot be applied, since it is well known in atomic absorption spectroscopy that the properties of the spectral line itself, *i.e.* (1) the hyperfine structure of the lines, (2) the ratio of the absorption and emission line widths, (3) the resonance line broadening, must be considered. To investigate this point in experiment, it was examined how the absorption intensity of 4047 Å line was dependent on the intensity of 2537 Å radiation from the exciting lamp. Two examples of the results are shown by curves A and B in Fig. 1. The optical density is not in a linear relation to the intensity of exciting radiation, though the concentration of $Hg(6^3P_0)$ in the cell should be proportional to the intensity of 2537 Å line.

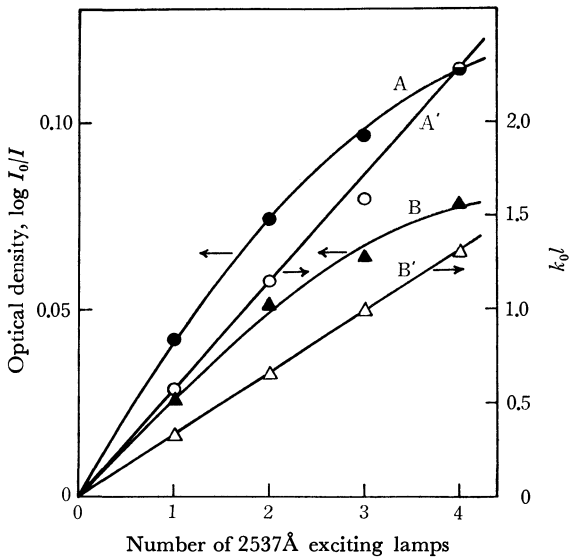

Fig. 1. Relative intensity of 2537Å radiation *vs.* the optical density at 4047Å, and relative intensity *vs.* calculated values of $[Hg_0^*]$ in k_0l unit.
A(●), A'(○): $p(N_2)=0.03$ Torr, $p(Ar)=4.97$ Torr; B(▲), B'(△): $p(N_2)=0.03$ Torr, $p(Ar)=0.97$ Torr.

To analyze this result, the profiles of the 4047 Å line from the light source and the absorption line of $Hg(6^3P_0)$ are assumed to be of Doppler broadened type. This assumption is only approximately applicable, because the spectral line profile from the discharge lamp must be dependent on many factors, *e.g.*, Doppler, collision, Stark effects, *hfs*, *etc.*, and the absorption line has a combined form of Doppler and collision broadened profiles with *hfs*. However, the purpose of the present experiment is not to clarify the spectral line profile, but to find the physical quantity proportional to the concentration of the excited mercury atoms from the optical density. Therefore, we tried to correct the curves of the absorption intensities in Fig. 1 to be linear to the intensity of 2537 Å line under the above assumption. The spectral intensity, E_ν, at a wave number ν from the light source is represented by[1]

$$E_\nu = \text{const} \times \exp[-(\omega/\alpha)^2], \quad (1)$$

where

$$\omega = 2(\nu-\nu_0)(\ln 2)^{1/2}/\Delta\nu_D,$$

$\Delta\nu_D$, the Doppler breadth of the absorption line, and ν_0 is the wave number at the line center or peak of the profile, and α is the ratio of the emission line breadth to absorption line breadth. Equating the absorption coefficient, k_ν, to $k_0\exp(-\omega^2)$ in Doppler broadening, the absorbancy A is

$$A = \int_{-\infty}^{+\infty}[\exp-(\omega/\alpha)^2]\{1-\exp[-k_0l(\exp-\omega^2)]\}d\omega \Big/ \int_{-\infty}^{+\infty}\exp-(\omega/\alpha)^2 d\omega, \quad (2)$$

where l is the length of the reaction cell, and k_0 is the absorption coefficient at the peak, that can be related to the oscillator strength f as

$$k_0 = 2(\ln 2/\pi)^{1/2}(\pi e^2 fN/mc\Delta\nu_D), \quad (3)$$

where e and m are electron's charge and mass, respectively, c, the light velocity, and N, the concentration of absorbing atoms per unit volume. Using the theoretical value of f,[8] k_0 for Hg (6^3P_1) and (6^3P_0) are 6.21×10^{-12} N and 5.90×10^{-12} N cm^{-1}, respectively. The absorbancy can be developed as[1]

$$A = \sum_n(-1)^n(k_0l)^n/n!(1+n\alpha^2)^{1/2}, \quad (4)$$

and this value is calculated by the HITAC 5010 computer with various values of α and k_0l, where l is 100 cm in this study. Some of the calculated results from Eq. (4) are shown graphically in Fig. 2, where the optical density, derived from the calculated value of $A(=(I_0-I)/I_0)$, is used. It is seen from this figure that the optical density is strongly dependent on the value

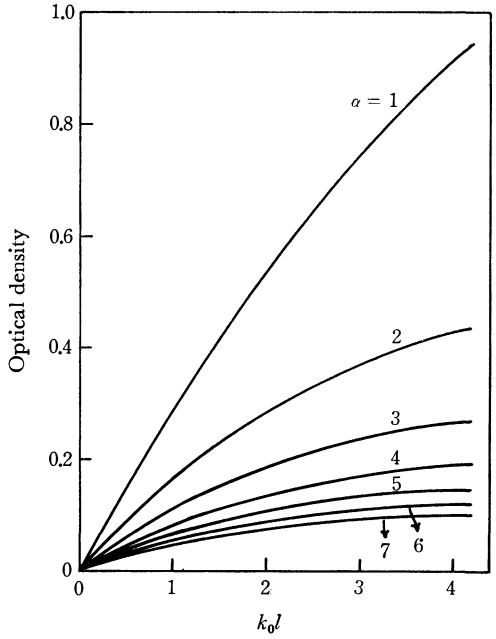

Fig. 2. Relation of the calculated optical density to k_0l with various values of α.

8) N. P. Penkin, *J. Quant. Spectrosc. Radiat. Transfer*, **4**, 74 (1964).

of α, that is, when the half-width of the spectral line from the light source is larger than that of the absorption line, the absorption intensity becomes small though the concentration of absorbing atoms is constant.

The experimental curves in Fig. 1 should be represented by one of the theoretical curves in Fig. 2. When the scale of the abscissae in Figs. 1 and 2 is converted to the logarithmic one, one can seek a theoretical curve that agrees with the experimental one in the range of 0.04—0.06 of the optical density. The values of α thus obtained are 5.2 for 1 Torr of the total pressure, and 5.0 for 5 and 10 Torr. A small dependence of α on the total pressure is due to the fact that the half-width of the collision-broadened line is about 1/10 that of the Doppler broadened one at 10 Torr if the optical collision cross-section of Ar or N_2 is 100 Å^2. By the use of the theoretical curves in Fig. 2 and the obtained value of α, a value of $k_0 l$, in other words, a concentration of $Hg(6^3P_0)$ can be determined from an absorption intensity. The curves A′ and B′ in Fig. 1 are thus obtained, and show that the concentration of $Hg(6^3P_0)$ is proportional to the intensity of 2537 Å radiation from the exciting lamp. It is also seen from Fig. 1 that the absorption intensity for 5 Torr of the total pressure is larger than that for 1 Torr even if the partial pressure of N_2 is the same. This is due to the fact that the deactivation of $Hg(6^3P_0)$ is governed by the collision with the wall of the reaction vessel. The collisional frequency with the wall is much dependent on the total pressure (see later).

In conclusion, the simple application of the Lambert-Beer rule is inappropriate in the present experimental condition, and the total pressure must be kept constant to avoid the collision broadening effect and the influence of wall collisions. In the following experiment, it is assumed that argon and quenching molecules have the same optical collision cross-section, and that the 4358 Å line profile from the light source has the same line-width as the 4047 Å line. The latter assumption may be open to question, but an apparent optical density is nearly proportional to the concentration of $Hg(6^3P_1)$, which is very small compared with that of $Hg(6^3P_0)$.

Quenching Mechanism and Rates. The following processes are considered as a quenching mechanism in the present system,

$$\text{(i)}\quad Hg(6^1S_0) + h\nu \xrightarrow{k_1} Hg(6^3P_1),$$

$$\text{(ii)}\quad Hg(6^3P_1) \xrightarrow{k_2} Hg(6^1S_0) + h\nu,$$

$$\text{(iii)}\quad Hg(6^3P_1) + Q \xrightarrow{k_3} Hg(6^1S_0) + Q,$$

$$\text{(iv)}\quad Hg(6^3P_1) + Q \xrightarrow{k_4} Hg(6^3P_0) + Q,$$

$$\text{(v)}\quad Hg(6^3P_0) + Q \xrightarrow{k_5} Hg(6^1S_0) + Q,$$

$$\text{(vi)}\quad Hg(6^3P_0) \xrightarrow{k_6} Hg(6^1S_0),$$

where Q represents a quenching molecule, and the concentration of $Hg(6^3P_1)$ will be denoted by $[Hg_1^*]$, and that of $Hg(6^3P_0)$ by $[Hg_0^*]$, and that of $Hg(6^1S_0)$ by [Hg]. McAlduff and Le Roy[9] have proposed further processes including the collision between an excited mercury atom and a ground state atom;

$$\text{(vii)}\quad Hg(6^3P_1) + Hg(6^1S_0) \longrightarrow Hg_2^*,$$

$$\text{(viii)}\quad Hg_2^* \longrightarrow Hg(6^3P_0) + Hg(6^1S_0),$$

$$\text{(ix)}\quad Hg_2^* + Q \longrightarrow Hg_2 + Q.$$

If these processes take place besides the reactions (i)—(vi), the concentration of $Hg(6^3P_0)$ produced in the system of Ar, N_2, and Hg mixture, must not have a simple linear relation to the pressure of mercury vapor. This is not the case in the present experiment, since $[Hg_0^*]$ has been found proportional to a pressure of mercury vapor in the range of 2×10^{-5}—1.9×10^{-4} Torr. Here, the pressure of mercury vapor was ordinarily 1.9×10^{-4} Torr, that is the saturated one at 0°C, and the effective collision frequency of an excited mercury atom with ground state atoms is very small compared with that of quenching by N_2 molecules, even if the collision cross-section of an excited mercury atom with a ground state atom is supposed about 100 Å^2.

From the reactions (i)—(vi), the stationary concentration of $Hg(6^3P_1)$ is expressed by

$$[Hg_1^*] = k_1 I[Hg]/\{k_2+(k_3+k_4)[Q]\}, \qquad (5)$$

where I is an intensity of 2537 Å radiation. If $[Hg_1^*]$ without quenching molecules is denoted by $[Hg_1^*]_0$, Eq. (5) reduces to the Stern-Volmer relation,

$$[Hg_1^*]_0/[Hg_1^*] = 1 + [(k_3+k_4)/k_2][Q]. \qquad (5')$$

The concentration of $Hg(6^3P_0)$ can be formulated as

$$[Hg_0^*] = k_2k_4[Hg_1^*]_0[Q]/\{(k_3+k_4)k_5[Q]^2 + [k_2k_5+(k_3+k_4)k_6][Q]+k_2k_6\}. \qquad (6)$$

The value of $[Hg_0^*]$ increases with increasing [Q] untill [Q] reaches $[Q]_{max}$,

$$[Q]_{max} = [k_2k_6/(k_3+k_4)k_5]^{1/2}. \qquad (7)$$

With this value of [Q], $[Hg_0^*]$ has a maximum value. Further increase of [Q] results in a decrease of $[Hg_0^*]$, and finally $[Hg_0^*]$ reduces to zero with very large amount of quenching molecules. Eq. (6) can be rewritten as

$$[Hg_0^*] = (k_4/k_6)[Hg_1^*]_0[Q]/\{([Q]/[Q]_{max})^2 + [(k_5/k_6)+(k_3+k_4)/k_2][Q]+1\}. \qquad (6')$$

The observed relation of $[Hg_1^*]$ or $[Hg_0^*]$ against [Q] is explained well by the above equations, and $(k_3+k_4)/k_2$, k_4/k_6, and k_5/k_6 can be determined.

The experimental values of $[Hg_1^*]_0/[Hg_1^*]$ are plotted in Fig. 3 against the partial pressure of N_2, CO, or NO as a quencher. The linear slope of the curve in Fig. 3 gives a value of $(k_3+k_4)/k_2$. As is mentioned, the line broadening effect by the existence of argon atoms causes an increase of $[Hg_1^*]$, because the absorption of 2537 Å radiation becomes more effective. Here, $[Hg_1^*]_0$ is 4.8×10^7 atoms cc^{-1} with 5 Torr of argon pressure, and 3.5×10^7 with 1 Torr.

Figure 4(a) shows that $[Hg_0^*]/[Hg_1^*]_0$ increases monotonously with increasing pressure of N_2, and that $[Hg_0^*]/[Hg_1^*]_0$ at 5 Torr of the total pressure is larger than that at 1 Torr. The former fact means that the value of $[Q]_{max}$ is far from the present experimental

9) J. E. McAlduff and D. J. Le Roy, *Can. J. Chem.*, **43**, 2279 (1965).

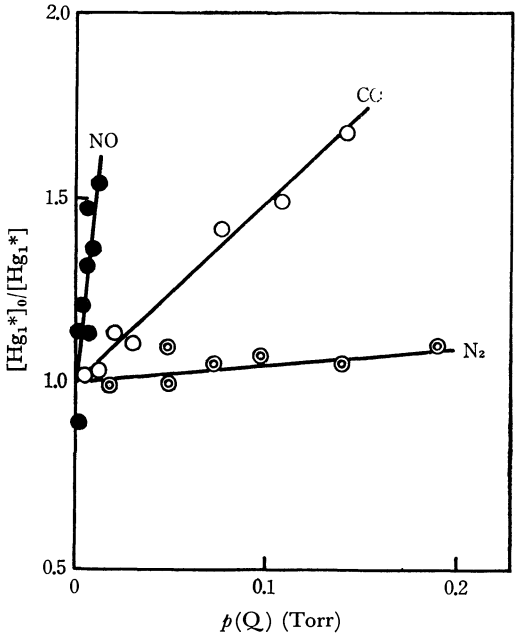

Fig. 3. Plots of $[Hg_1^*]_0/[Hg_1^*]$ *vs.* partial pressure of quencher. Total pressure in the cell is 5 Torr, and a partial pressure of Hg vapor is 1.9×10^{-4} Torr. N_2: ◎, CO: ○, NO: ●

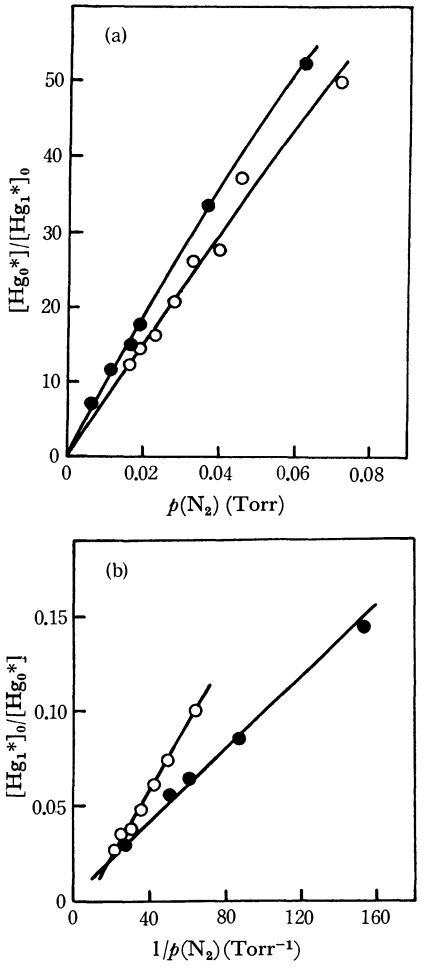

Fig. 4. (a) Plots of $[Hg_0^*]/[Hg_1^*]_0$ *vs.* partial pressure of N_2. Total pressure in the cell is 5 Torr (●) and 1 Torr (○), and a partial pressure of Hg vapor is 1.9×10^{-4} Torr.
(b) Plots of $[Hg_1^*]_0/[Hg_0^*]$ *vs.* $1/p(N_2)$.

range, *i.e.*, k_5 is very small. The later experimental finding is to be explained by the fact that a value of k_6 becomes larger as a total pressure decreases. This shows that the deactivation of $Hg(6^3P_0)$ is not due to a radiative process, but to collisions with the wall of the cell. Very long radiative lifetime of $Hg(6^3P_0)$, *i.e.*, 5.6 sec,[10] supports this explanation. Under the condition, $[Q]\ll[Q]_{max}$, Eq. (6′) can be approximated to,

$$[Hg_1^*]_0/[Hg_0^*] = (k_6/k_4)(1/[Q]) + (k_5/k_4) + [(k_3+k_4)k_6/k_2k_4]. \quad (8)$$

The values of $[Hg_1^*]_0/[Hg_0^*]$ are plotted *vs.* $1/[Q]$ in Fig. 4(b), using the data in Fig. 4(a), and a value of k_6/k_4 is obtained from a slope of a straight line in Fig. 4(b).

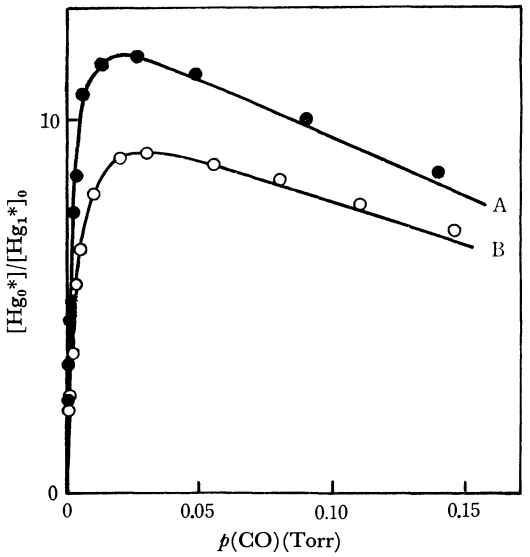

Fig. 5. Plots of $[Hg_0^*]/[Hg_1^*]_0$ *vs.* partial pressure of CO. Total pressure in the cell is 5 Torr (●) and 1 Torr (○), and a partial pressure of Hg vapor is 1.9×10^{-4}Torr. The curves, A and B, show the calculated values of $[Hg_0^*]/[Hg_1^*]_0$ from Eq. (6′) with the following values, $(k_3+k_4)/k_2=1.50\times10^{-16}$ cc·molecules^{-1}, $k_4/k_6=2.25\times10^{-13}$ (the curve A), $=8.47\times10^{-14}$ (the curve B) cc·molecules^{-1} and $k_5/k_6=1.61\times10^{-14}$ (A), $=7.14\times10^{-15}$ (B) cc·molecules^{-1}.

The experimental relation between $[Hg_0^*]/[Hg_1^*]_0$ and [CO] is shown in Fig. 5, and is explained well by Eq. (6). The larger value of $[Hg_0^*]/[Hg_1^*]_0$ at 5 Torr of the total pressure than that at 1 Torr arises from the longer lifetime of Hg (6^3P_0) at 5 Torr than at 1 Torr, and this also causes an decrease in a value of $[Q]_{max}$ at higher pressure. In the pressure range of CO that is very small compared with $[Q]_{max}$, the same procedure as the case of N_2 can be applied for the determination of k_4/k_6. By the use of this value of k_4/k_6, $[Q]_{max}$ can be found by fitting the experimental values of $[Hg_0^*]/[Hg_1^*]_0$ with the curve calculated by Eq. (6′). Then, a value of k_5/k_6 can be obtained by substituting the value of $k_2/(k_3+k_4)$ into Eq. (7). In the case of quenching by NO, the experimental curve of $[Hg_0^*]/[Hg_1^*]_0$ *vs.* partial pressure of NO could not be observed accurately owing to a very small

10) R. H. Garstang, *J. Opt. Soc. Amer.*, **52**, 845 (1962).

concentration of $Hg(6^3P_0)$, that is caused by an efficient quenching of the 6^3P_1 state to 6^1S_0 or 6^3P_0 to 6^1S_0. This also explains the fact that Callear and Williams[5] have not been able to detect the $Hg(6^3P_0)$ atoms by the flash excitation of Hg in NO or other polyatomic gases. The observed value of $[Hg_0^*]/[Hg_1^*]_0$ was 0.11 when a partial pressure of NO was 3.65×10^{-4} Torr at 10 Torr of the total pressure. By the direct measurement (see next) of the lifetime of $Hg(6\,^3P_0)$ in the same experimental condition, k_5 and k_6 were found to be 1.24×10^{-10} cc molecules^{-1} sec^{-1} and 1.0×10^2 sec^{-1}, respectively. Substituting these rate constants into Eqs. (7) and (6'), 3.7×10^{-4} Torr of $[Q]_{max}$ and 5.3 Å^2 of k_4 are obtained.

Table 1. Observed values of quenching rates (cc·molecules^{-1}) of Hg (6^3P_1) and Hg (6^3P_0)

Quencher	$(k_3+k_4)/k_2$	k_4/k_6	k_5/k_6
N_2	2.2×10^{-17}	3.2×10^{-14}	$\leq1\times10^{-17}$
CO	1.5×10^{-16}	2.2×10^{-13}	1.6×10^{-14}
NO	1.4×10^{-15}	5.5×10^{-13}	8.3×10^{-13}

These data are obtained at a total pressure of 5 Torr and a partial pressure of Hg of 1.9×10^{-4} Torr.

The observed values of $(k_3+k_4)/k_2$, k_4/k_6, and k_5/k_6 are summarized in Table 1. The lifetimes of $Hg(6^3P_1)$ and $Hg(6^3P_0)$, *i.e.*, k_2 and k_6, cannot be determined in the present experiment. The value of k_2 should be $1/\tau$, where τ is a radiative lifetime of $Hg(6^3P_1)$, 1.0×10^{-7} sec. However, the peak absorption coefficient, k_0 for 2537 Å line is 4.0 cm^{-1} in the present experimental condition, and the imprisonment effect of the radiation must be considered. Here, the effective radiative lifetime τ' given by Milne[11] is adopted. In his calculation, τ' for the case of infinite slab is,

$$\tau'/\tau = 1 + (k_0 l/\lambda)^2, \qquad (10)$$

where $\lambda\tan\lambda = k_0 l$. Kibble, Copley, and Krause[12] ascertained that the observed radiative lifetime of Na (3^2P) was in good agreement with the value calculated by Eq. (10). In our case, τ' is 3.52×10^{-6} sec, from which we can calculate the total quenching cross-section of $Hg(6^3P_1)$ as shown in Table 2.

To determine the rate of deactivation of $Hg(6^3P_0)$, the time history of the absorption of 4047 Å after the excitation radiation was suddenly turned off, was observed in the system of $Ar+N_2+Hg$ mixture, where N_2 molecules could be assumed as very inefficient quenchers of $Hg(6^3P_0)$ atoms. The result shows that a lifetime of $Hg(6^3P_0)$ is 2.8 msec at 1 Torr of the total pressure, 6.7 msec at 5 Torr, and 10 msec at 10 Torr, and is independent of a pressure of Hg atoms. This shows that the deactivation of $Hg(6^3P_0)$ is mainly caused by collisions with the wall of the reaction vessel as already pointed out. The details of this experiment will be reported in near future. Thus, the cross-sections for the processes, $6^3P_1\rightarrow6^3P_0$ and $6^3P_0\rightarrow6\,^1S_0$, can be calculated, and are shown in Table 2. The uncertainty in a value of k_2 produces a somewhat unaccuracy in an absolute value of the total quenching cross-section for $6^3P_1\rightarrow6^3P_0$, 6^1S_0. Hence, the calculated cross-section for the process $6^3P_1\rightarrow6^1S_0$ as the difference of $\sigma^2(6^3P_1\rightarrow6^1S_0, 6^3P_0)$ and $\sigma^2(6^3P_1\rightarrow6^3P_0)$ is most unreliable in the present results. However the present finding that the cross-section of N_2 for $6^3P_1\rightarrow6^1S_0$, 6^3P_0 is very close to that for $6^3P_1\rightarrow6^3P_0$, is consistent with the experimental result of Samson.[13] This is also supported by the later experiment of Matland,[3] who has found that the temperature dependence of the quenching cross-section of $Hg(6^3P_1)$ is nearly explained by $\exp(-\Delta E/kT)$, where ΔE is 0.07 eV. This value of the ΔE is necessary for a N_2 molecule as a kinetic energy if the energy difference between the 6^3P_1 and 6^3P_0 states is transferred to the vibration of N_2 molecule. Therefore, the result of Matland shows that the quenching of $Hg(6^3P_1)$ is mainly to the 6^3P_0 state and scarcely to the 6^1S_0 state. Thus, the estimated value of k_2 is not very different from the true one, and the cross-sections for the process 6^3P_1—6^1S_0 in Table 2 are reliable at least in an order of magnitude except that of N_2, whose cross-section for this process might be hidden in errors of the observed ones for the processes $6^3P_1\rightarrow6^3P_0$ and $6^3P_1\rightarrow6^1S_0$, 6^3P_0.

Discussion

The quenching cross-section of 6^3P_0 to 6^1S_0 obtained by us show a marked difference from those by Callear and Williams.[5] In their flash experiment, the half-width of flash duration reaches 51 μsec, and the production of $Hg(6^3P_0)$ from $Hg(6^3P_1)$ may not be neglected about 100—150 μsec after a flash excitation. Hence, there might be a possibility to underestimate a value of k_5. For the quenching process $6^3P_1 \rightarrow 6^3P_0$, Scheer and Fine[4] obtained $k_4(\text{for CO})/k_4(\text{for } N_2)$ to be about 1, while its value was 5.8 in our result. However, absorption of 2537 Å radiation might become smaller as the total pressure in the cell decreased, owing to the pressure dependency of α, as we already discussed. In their experimental condition, the pressure of CO in the cell was lower than that of N_2 by one order of magnitude, and this might cause that the absorption of 2537 Å line for the case of CO in the cell is smaller than that for the case of N_2, and that the apparent value of $k_4(\text{for CO})/k_4(\text{for } N_2)$ become large compared with the true value.

Callear and Oldman[14] assumed that collisional transitions between spin-orbit splitting levels of various atoms are due to the electronic-to-vibrational energy transfer, and found the systematic relations of cross-sections to energy discrepancies between spin-orbit splittings and vibrational quanta of colliding molecules. In the present case, the ratio of cross-sections for $6^3P_1 \rightarrow 6^3P_0$ is,

$$\sigma^2(N_2):\sigma^2(CO):\sigma^2(NO) = 1:5.8:14.$$

Dickens, Linnett, and Sovers[15] calculated this ratio, assuming that the repulsive potential of exponential type, $\exp(-\alpha \mathbf{r})$, where $\mathbf{r}$ means the distance between an atom and a molecule, made a perturbation to the nuclear motion of molecule and the electronic one in $Hg(6^3P_1)$ atom at an instance of collision. Their calculated ratio is 1: 9.8: 250 in the case of $\alpha = 5$ Å^{-1}. Therefore, the quenching process $6^3P_1 \rightarrow 6^3P_0$ of N_2 or CO may be explained by a small perturbation due to the repulsive potential between Hg atom and N_2 or CO molecule, but the mechanism for $Hg(6^3P_1)$—NO collision is far from this explanation. Since NO molecule has an unpaired electron, its collisional process with $Hg(6^3P_1)$ atom must be a strongly non-adiabatic one. This is perhaps a reason why the quenching cross-section of NO for 6^3P_1—6^1S_0 is much larger than that of N_2 or CO.

Conclusion

Conclusions derived in this work are following. (1) The concentration of $Hg(6^3P_1)$ and $Hg(6^3P_0)$ atoms can be determined from the absorption intensity of 4358 and 4047 Å lines emitted from a mercury discharge lamp. Here, the Lambert-Beer rule is not applicable since the spectral half-width of the 4358 or 4047 Å line is five times of the absorption line, *i.e.*, a Doppler half-width at 300°K. (2) The energy transfer mechanism in the system of Ar+Quencher+Hg illuminated with the 2537 Å radiation is: (i) $Hg + h\nu \rightarrow Hg_1^*$, (ii) $Hg_1^* \rightarrow Hg + h\nu$, (iii) $Hg_1^* + Q \rightarrow Hg + Q$, (iv) $Hg_1^* + Q \rightarrow Hg_0^* + Q$, (v) $Hg_0^* + Q \rightarrow Hg + Q$, (vi) $Hg_0^* \rightarrow Hg$ (by collisions with a wall). The cross-sections for the processes, $6^3P_1 \rightarrow 6^1S_0$, $6^3P_1 \rightarrow 6^3P_0$, and $6^3P_0 \rightarrow 6^1S_0$ can be determined as shown in Table 2. (3) Most of the quenching process of $Hg(6^3P_1)$ by a collision with N_2 or CO is $6^3P_1 \rightarrow 6^3P_0$, while the process is mainly $6^3P_1 \rightarrow 6^1S_0$ in a quenching collision with NO. (4) The cross-section for quenching 6^3P_1 to 6^1S_0 is larger by several-fold than that for quenching 6^3P_0 to 6^1S_0. The latter value is not very small except for N_2. (5) A systematic relation of cross-sections for $6^3P_1 \rightarrow 6^3P_0$ to vibrational frequencies can not be found.

Note added in proof: It has been reported by Callear and McGurk (*Chem. Phys. Letters.*, **6**, 417 (1970)) with a new flash device that $\sigma^2(^3P_0 \rightarrow {}^1S_0)$ of NO, CO_2, and H_2 are 16.2, 0.033, and 0.95 Å^2 and that these values are much greater than previous estimates by Callear and Williams[5] with the standard flash technique.

Liquid-phase Adsorption from Binary Solutions on Silica Gel. Separation Factors and Orientation of Adsorbed Components on the Surface

Tsutomu KAGIYA, Yūzō SUMIDA, and Toshihiro TACHI
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received September 7, 1970)

The preferential adsorption equilibria of various binary solutions of cyclohexane-aromatic compounds and cyclohexane-cyclic ethers on chromatographic silica gel have been studied at 30°C. On the basis of the assumption that the adsorption is of the Langmuir-type, the separation factors (α) and the numbers of moles in the adsorbed-phase per unit mass of silica gel (n^σ/m) have been calculated. The values of log α correlate well not only with the electron-donating properties of the preferentially-adsorbed components, but also with the powers of the gas-phase adsorption on silica gel and of the liquid-liquid interaction with liquid trimethylsilanol. Moreover, on the basis of the information on n^σ/m, the orientation angles of the adsorbed components on the surface have been evaluated. The adsorption of the aromatic hydrocarbons was nearly flat to the surface, and that of the cyclic ethers, perpendicular.

Theoretical and experimental studies of the gas-phase adsorption on the solid surface have been actively made since the latter half of the 1910's.[1] The chemical structures of the surface have also been made clearer by means of analytical instruments.[2] The liquid-phase adsorption on the solid surface has been mainly studied from the standpoint of the industrial purifications of the organic solvents, the lubricating oils, and so on.[3-6] Little attention has, however, been paid to quantitative discussions of the power of adsorption from solutions on the solid surface and of the orientation of the adsorbed components on the surface, although they have been some qualitative studies.[7-9]

In this investigation, the adsorption equilibria of various binary solutions of cyclohexane-aromatic compounds and cyclohexane-cyclic ethers on chromatographic silica gel have been studied at 30°C. The objectives of the present work are: (1) to discuss the separation factors in connection with the electronic properties of the adsorbed components, (2) to compare the liquid-phase adsorption on silica gel (solid-liquid interaction) with the gas-phase adsorption on silica gel (solid-gas hydrogen bond) and with the liquid-phase coordination to trimethylsilanol (liquid-liquid hydrogen bond), and (3) to evaluate the orientation angles of the components adsorbed on the surface.

Experimental

Materials. Spectro-grade cyclohexane, benzene, toluene, *p*-xylene, chlorobenzene, anisole, dioxolane, 1,4-dioxane, and tetrahydrofuran were used as the adsorbates. These adsorbates were dried with silica gel and were then used without further purification. The adsorbent was silica gel (100−200 mesh) for thin-layer chromatography. The silica gel (dried at 160°C) had the following characteristics; B.E.T.(N_2) area = 383 m^2/g, and pH of aqueous suspension = 7.0.

Adsorption Equilibria. Portions of about 4 g of accurately-weighed silica gel, dried at 160°C, were placed in glass ampoules and degassed for about 6 hr. The ampoules were then filled with about 10 m*l* of a binary solution of the cyclohexane-second solvent of a known composition. The sealed ampoules were placed in a constant-temperature bath controlled at 30 ± 0.2°C and then allowed to equilibrate while being stirred frequently. The analysis of the equilibrium mixture was made with a Shimadzu gas chromatograph, GC-4AIT.

Results and Discussion

In order to discuss quantitatively the adsorption equilibrium of the mixture of the cyclohexane (S_1)-second solvent (S_2) on the silica gel, we must first determine the form of the adsorption isotherm. The selective adsorbed capacity (a_2) of the preferentially-adsorbed component, which is S_2 in each binary solution, can be approximately calculated by the following equation:[8]

$$a_2 = \frac{V_{M2} \cdot n^0}{m} \frac{x_2^0 - x_2^l}{1 - x_2^l} \quad (1)$$

where V_{M2} is the molar volume of S_2 (ml/mol); m, the weight of silica gel (g); n^0, the total number of moles of the original mixture (mol), and x_2^0 and x_2^l, the mole fractions of S_2 in the original liquid and the non-adsorbed liquid at equilibrium respectively. It can be said that Eq. (1) holds over a wide concentration range ($0 < x_2^l < 1$) when the adsorption power of S_2 is so large in comparison with that of S_1 that the surface

S_2: ⊙, Chlorobenzene; ○, Benzene; ●, Toluene; ◑ *p*-Xylene; ◐, Anisole; ⊖, Dioxolane; ◓, 1,4-Dioxane; ◒, Tetrahydrofuran.

can be almost entirely covered by S_2, even in a low concentration range of S_2. The above condition was assumed to be satisfied for the present binary solutions.

The adsorption isotherms of a_2 *versus* x_2^l are shown in Fig. 1. In the high concentration range of S_2, it is so difficult to evaluate accurately the very small difference between the x_2^0 and the x_2^l that the experimental error in the a_2 becomes larger. However, there are good linear relationships between x_2^l/a_2 and x_2^l, as is shown in Fig. 2. From these results, we assumed that the adsorption from the mixtures used in this experiment was of the Langmuir-type.[10]

On the other hand, according to Everett,[11] the behavior of a perfect solution in contact with a Langmuir-type adsorbing surface can be discussed on the basis of the following equation:

$$\frac{x_1^l \cdot x_2^l}{n^0 \cdot \Delta x_2^l/m} = \frac{m}{n^\sigma}\left(x_2^l + \frac{1}{\alpha - 1}\right) \qquad (2)$$

where n^σ is the number of moles in the adsorbed-phase; Δx_2^l, the change in the mole fraction of S_2 due to the adsorption, and α, the separation factor for the equilibrium reaction:

$$(S_1)^\sigma + (S_2)^l \rightleftarrows (S_1)^l + (S_2)^\sigma \qquad (3)$$

The above equation (2) rests on the assumptions that; (i) the adsorption is of the Langmuir-type; (ii) α remains constant over the entire concentration range; (iii) the ratio of the activity coefficients ($\gamma_1^l\gamma_2^\sigma/\gamma_1^\sigma\gamma_2^l$) can be approximated to unity, and (iv) the adsorbed components have similar molecular sizes in the adsorbed-phase or the S_2 covers the surface entirely, even in the low concentration range of S_2. Regarding assumption (ii), Yagi *et al.* have reported that the values of α in the *n*-heptane-aromatic hydrocarbon systems are constant over a wide concentration range ($0.2 < x_2^l < 1.0$).[6] Assumption (iii) cannot be checked at present because of the difficulties in measuring the activity coefficients

Table 1. Separation factors and numbers of moles of adsorbed components in cyclohexane - preferentially adsorbed component mixtures

Preferentially adsorbed components	α	$n^{\sigma}/m \times 10^4$ (mol/g)
Chlorobenzene	14.0_6	15.3_8
Benzene	16.0_3	18.4_8
Toluene	18.5_5	14.8_0
p-Xylene	19.3_8	15.0_4
Anisole	49.2_4	18.9_9
Dioxolane	37.8_0	40.3_2
1,4-Dioxane	63.2_2	27.6_6
Tetrahydrofuran	80.0_2	23.4_5

of the components in the adsorbed-phase.[11-13]

Figure 3 shows the analytical data for various binary solutions plotted according to Eq. (2). The good linear relationships may indicate that the above assumptions are almost satisfied over the concentration range used in this experiment, in spite of the difference in the chemical structures of S_2. The separation factor (α) and the number of moles in the adsorbed-phase per unit mass of adsorbent (n^{σ}/m) are listed in Table 1.[14] It should be noted in Table 1 that the α and n^{σ}/m values of dioxolane, 1,4-dioxane, and tetrahydrofuran are sufficiently large in comparison with those of the aromatic hydrocarbons. This suggests difference in the adsorption behavior, *i.e.*, the adsorption power and the orientation of adsorption.

The Separation Factors and the Electron-donating Properties of Solvents. It may be considered that the values of log α, indicating the power of the nucleophilic adsorption of S_2 on the silica-gel surface covered with cyclohexane (S_1), are related to the electron-donating properties of S_2. The log α of the aromatic hydrocarbons and derivatives are plotted against the ionization potentials (I_p) and the Hammett's substituent constants (σ_p) in Fig. 4.[15] The log α increased linearly as the ionization potentials became smaller and as the electron-relieving properties of the substituents became larger. This suggests that the adsorption of the aromatic hydrocarbons is mainly caused by the π-electrons of the benzene nuclei.[19] The deviation of chlorobenzene from the log α-I_p line may imply that the first ionization of chlorobenzene was not caused by the benzene ring. On the other hand,

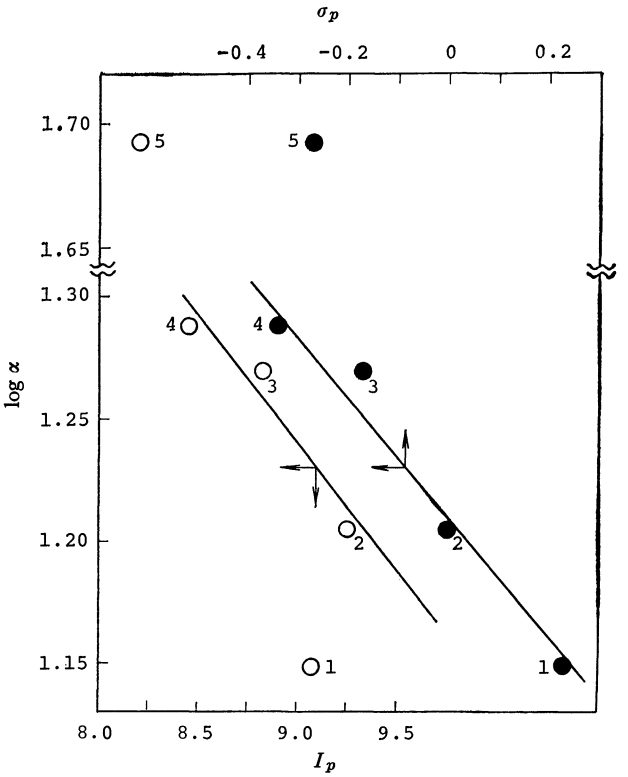

Fig. 4. Relation between log α and ionization potentials (I_p) or Hammett's substituent constants (σ_p) for substituted benzene derivatives.
1, Chlorobenzene; 2, Benzene; 3, Toluene; 4, *p*-Xylene; 5, Anisole.

the declination of anisole from both lines can be inferred to indicate the existence of strong adsorption by the oxygen atom rather than weak adsorption by the benzene nuclei.

The Separation Factors and the Hydrogen-bonding Interaction with the Surface Silanol or Liquid Trimethylsilanol. In order to make clear the liquid-phase adsorption phenomenon, we discussed the separation factors, *i.e.*, the liquid-phase adsorption powers, in connection with the strengths of the solid-gas and liquid-liquid hydrogen-bonding interactions. The strength of the solid-gas hydrogen bond can be evaluated by the IR technique as the difference ($\Delta\nu^S_{OH}$) in the adsorption frequencies of the free O-H band and the bonded O-H band caused by the monolyaer adsorption of gas on silica gel:[20,21]

$$\Delta\nu^S_{OH} = \nu^S_{OH}(\text{free}) - \nu^S_{OH}(\text{bonded})$$

That of the liquid-liquid hydrogen bond can be similarly estimated by means of the frequency shift ($\Delta\nu^L_{OH}$) of liquid trimethylsilanol caused by the solvent, which has a chemical structure (SiO-H bond) analogous to the silanol group on the silica-gel surface:[22]

TABLE 2. EFFECTIVE MOLECULAR OCCUPANCIES AND ORIENTATION ANGLES OF PREFERENTIALLY ADSORBED COMPONENTS ON SILICA GEL

Preferentially adsorbed components	A_2 (Å²/molecule)	d_2[a] (Å)	h_2[a] (Å)	θ (degree)	A_2[b] (Å²/molecule)	S[b] (m²/g)
Chlorobenzene	41.3_4	5.45_9	7.34_2	3	30.9_1	$286._4$
Benzene	34.4_1	5.45_9	6.30_3	0	27.9_2	$310._8$
Toluene	42.9_6	5.45_9	7.53_8	5	31.4_6	$280._5$
p-Xylene	42.2_8	5.45_9	8.74_5	11	34.7_3	$314._7$
Anisole	33.4_8	5.45_9	7.71_5	17	31.9_5	$365._5$
Dioxolane	15.7_7	5.37_8	5.11_5	77	23.8_0	$578._1$
1,4-Dioxane	22.9_9	5.38_3	6.21_6	90	27.1_5	$452._4$
Tetrahydrofuran	27.1_1	5.65_0	5.37_1	86	26.0_0	$367._2$

a) Values calculated from Eq. (6).
b) Values calculated from the assumption of the spherical molecules for the preferentially adsorbed components.

$$\Delta\nu^L_{OH} = \nu^L_{OH}(\text{bonded by benzene}) - \nu^L_{OH}(\text{bonded})$$

where benzene is conveniently employed as a reference solvent. As is shown in Fig. 5, good correlations between logα and $\Delta\nu^S_{OH}$ or $\Delta\nu^L_{OH}$ were obtained; that is, the values of logα increased linearly with the increase in the $\Delta\nu^S_{OH}$ or the $\Delta\nu^L_{OH}$. From the relationships, we may conclude that the liquid-phase adsorption on silica gel is mainly governed by the proton-accepting properties of solvents. A comparison of $\Delta\nu^S_{OH}$ and $\Delta\nu^L_{OH}$ shows a large proton-donating property of surface silanol.[22]

The Orientation Angles of the Components Adsorbed on the Surface. According to Schay and Nagy,[12b,23] if the effective molecular occupancies (A) of the two components in the adsorbed-phase are known, the total surface area per unit mass of solid (S) is given by the following equation:

$$S = N\left(\frac{n_1^\sigma}{m}A_1 + \frac{n_2^\sigma}{m}A_2\right) \quad (4)$$

where n_1^σ and n_2^σ are, respectively, the number of moles of S_1 and S_2, and where N is the Avogadro number. When the α of S_2 is so large that the surface is preferentially covered with S_2, or when $A_1=A_2$, Eq. (4) can be approximated with Eq. (5):

$$S = \frac{n^\sigma}{m}A_2N \quad (5)$$

The above conditions can be considered to be satisfied for the binary mixtures in this paper. By assuming that the specific surface area is equal to the B.E.T. (N_2) area, the effective molecular occupancies were calculated from Eq. (5); they are summarized in the second column of Table 2. The values of A in the sixth column of Table 2 are calculated from $A=(V_M/N)^{2/3}$.[12b,24] This calculation rests on the assumption that the adsorbed molecules are cube-shaped and have the same packing on the surface as the molecules of the adsorbed liquid have in the neat solution. The specific surface area, listed in the last column of Table 2, was calculated with the n^σ/m values and the A_2 values obtained with the latter method. It appears that the S values calculated by the above method yield lower values for the aromatic compounds and higher values for the cyclic ethers in comparison with the B.E.T. (N_2) area of 383 m²/g for the adsorbent.[12] This disagreement in the areas provides negative support for the assumption of the spherical molecules in the adsorbed phase and suggests the orientation of the adsorbed components on the surface.

We then tried to estimate the orientation of the adsorption by the use of the effective molecular occupancy. If the preferentially-adsorbed molecules with six- or five-membered rings are cylindrical (diameter=d(Å) and height=h(Å)), then we can approximately obtain the following equation:

$$\pi\left(\frac{d}{2}\right)^2 h\cdot N = V_M \quad (6)$$

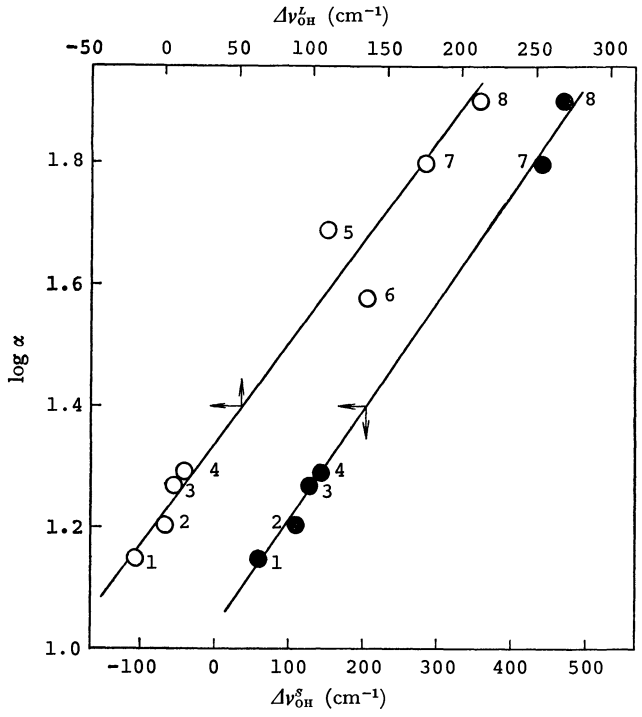

Fig. 5. Relationship between log α and O–H frequency shifts ($\Delta\nu^S_{OH}$) of silica gel surface silanol by gas-phase adsorption or O–H frequency shifts ($\Delta\nu^L_{OH}$) of trimethylsilanol by solvents.
1, Chlorobenzene; 2, Benzene; 3, Toluene; 4, *p*-Xylene; 5, Anisole; 6, Dioxolane; 7,1,4-Dioxane; 8, Tetrahydrofuran.

23) a) G. Schay, L. Gy. Nagy, and T. Szekrenyesy, *Periodica Polytechnica*, **6**, 91 (1962); b) L. Gy. Nagy, *ibid.*, **7**, 75 (1963).

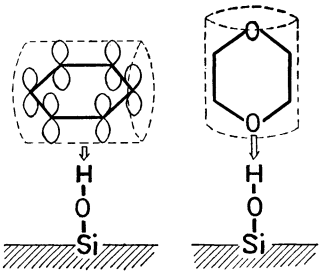
24) F. Paneth and W. Vorwerk, *Z. Phys. Chem.*, **101**, 445 (1922).

Between the diameter and the height, these relations may hold; $d=h\cdot\cos 30°$ for benzene and 1,4-dioxane, and $h=d\cdot\cos 18°$ for tetrahydrofuran and dioxolane. By substituting the above relations into Eq. (6), the diameters and the heights of S_2 molecules were calculated. The diameters of the other aromatic derivatives were taken to be that of benzene.

When the preferentially-adsorbed component adsorbs with an orientation angle (θ) on the surface, it should be given by the following equation:

$$A_2 = \pi\left(\frac{d}{2}\right)^2 \sin\theta + hd\cdot\cos\theta \qquad (7)$$

The values of θ obtained are also listed in the fifth column of Table 2. It is obvious from Table 2 that the adsorptions of all the aromatic compounds except anisole are nearly flat to the surface and that those of the cyclic ethers are nearly perpendicular (Fig. 6-a,b). The orientation angle ($\theta=77°$) for dioxolane may be understood as the simultaneous adsorption by two oxygen atoms in a dioxolane molecule, although it cannot be exactly illustrated. If the adsorption of anisole is caused only by the interaction force between the oxygen atom in an anisole molecule and the surface, the orientation angle should be nearly equal to 30°. On the contrary, for the adsorption due to the benzene nuclei, it should be nearly zero. Therefore, it can be considered that the orientation angle ($\theta=17°$) obtained for anisole suggests the existence of the two kinds of



(a) Benzene (b) 1,4-Dioxane

Fig. 6. Adsorption models of benzene and 1,4-dioxane on silica gel.

interactions, that of the strong adsorption by the oxygen atom and that of the weak adsorption by the benzene nuclei.[25] This consideration also agrees with the discussion of the large deviation of anisole from both straight lines of log α *versus* I_p and σ_p. This conclusion corresponds well to the spectroscopic data that the two unassociated O-H vibrational bands of trimethylsilanol appear in the anisole solution; the one showing the large shift and intensity is assigned to the O-H band due to the hydrogen bond formed by the lone-pair-electrons of ether oxygen, and the other, showing the small shift and intensity, to that formed by the benzene nuclei.[22a]

Ultrasonic and Thermodynamic Study on Solute-Solvent Interaction. Binary Mixtures of *t*-Butyl Chloride, *t*-Butyl Bromide and 1,1,1-Trichloroethane with Carbon Tetrachloride, Benzene and *p*-Xylene

Osamu KIYOHARA and Kiyoshi ARAKAWA
Research Institute of Applied Electricity, Hokkaido University, Sapporo
(Received September 7, 1970)

Sound velocity and density of binary mixtures of *t*-butyl chloride (*t*BC), *t*-butyl bromide (*t*BB), and 1,1,1-trichloroethane (TCE) with carbon tetrachloride (CT), benzene (B), and *p*-xylene (*p*X) were measured at temperatures, 25 and 35°C. The excess molar volume and excess compressibility of these systems were calculated. The temperature dependency of excess volume was negative for aromatic solutions and positive for CT solutions. The temperature coefficients of excess compressibility were negative for all systems. The relation between thermodynamic properties and intermolecular interactions in these systems were discussed. Two systems, B-TCE and CT-TCE, were found to be nearly ideal. The solute-solvent interactions in CT-*t*BC and *t*BC-TCE systems were found to be more attractive than in other systems.

Adiabatic compressibility of binary mixtures has been studied by a number of investigators using ultrasonic methods.[1-8] Though considerable data are found in literature, there are not many systematic studies on the dependency of compressibility upon the interaction between unlike molecules. It has been pointed out by several workers that the excess thermodynamic functions are sensitively dependent not only on the difference in intermolecular forces, but also on the difference in size of molecules.[9,10] It is obvious that the study of excess compressibility and excess molar volume gives important information on intermolecular forces determining the properties of mixtures.

The purpose of the present study is to investigate the solute-solvent interaction from ultrasonic velocity and density data, using the statistical theory of solutions.[9]

In this study, *t*-butyl chloride, *t*-butyl bromide, and 1,1,1-trichloroethane were used as solutes which are polar and nearly spherical in molecular shape, and carbon tetrachloride, benzene and *p*-xylene as solvents. Carbon tetrachloride was chosen as a typical solvent which is spherical in molecular shape.

Measurements of sound velocity and density were carried out at 25 and 35°C for nine binary mixtures.

Experimental

Samples of carbon tetrachloride (CT),[11] benzene (B), *p*-xylene (*p*X), *t*-butyl chloride (*t*BC), *t*-butyl bromide (*t*BB), and 1,1,1-trichloroethane (TCE) are guaranteed reagents obtained from Wako Pure Chemical Industry Co. Ltd., and used after purification.[12] Boiling points agreed with the values in literature. The purity of samples was examined by the measurements of density at 25°C.

Sample	Observed values of density at 25°C	Literature values[13]
Carbon tetrachloride	1.58446	1.58434
Benzene	0.87361	0.87362
p-Xylene	0.85663	0.85669
t-Butyl chloride	0.8356_1	0.8354[a]
t-Butyl bromide	1.2131_1	1.2132_1[a]
1,1,1-Trichloroethane	1.3293_3	1.3293_5[a]

a) Interpolated values

The sound velocity was measured at 3 Mc. The interferometer used is described in a previous paper.[7] The results are accurate within 0.3 m/sec. Density measurements were made using a pycnometer of the usual type. Its accuracy is within 0.01%. *t*-Butyl bromide is fairly unstable at ordinary temperatures and should be treated carefully. Thus, the accuracy of the sound velocity and density in the systems including *t*-butyl bromide is within 0.5 m/sec and 0.03%, respectively.

Results

The density d and sound velocity v were measured over the whole concentration range at 25 and 35°C for nine systems: CT-*t*BC, CT-*t*BB, CT-TCE, B-*t*BC, B-*t*BB, B-TCE, *p*X-*t*BC, *p*X-TCE, and *t*BC-TCE.

Excess Molar Volume on Mixing. Excess molar volume V^E was calculated from the density data, and its dependency of mole fraction is shown in Figs. 1(a)-(i) for each system. The abscissa x represents the mole fraction of solutes. The accuracy of V^E is about ± 0.02 cc/mole, except for that of *t*-butyl bromide solutions, which is ± 0.05 cc/mole.

All the systems except CT-TCE, B-*t*BB, B-TCE, and *p*X-TCE give negative values of V^E. The V^E *vs.* mole fraction curves in B-*t*BB and B-TCE systems are of nearly inverse S type, and that for CT-TCE system positive. The temperature dependency of V^E is negative for B-*t*BC, B-TCE, *p*X-*t*BC, and *p*X-TCE, and positive for CT-*t*BC and *t*BC-TCE systems. However, the temperature coefficients are very small, and those for CT-*t*BB, CT-TCE, and B-*t*BB are zero within experimental error.

Mathot and Desmyter[14] measured the V^E of CT-*t*BC and CT-TCE systems and obtained −0.26 cc/mol and 0.25 cc/mole for equimolar mixtures at 0°C, respectively. The values we obtained are −0.36 and 0.04 cc/mol for CT-*t*BC and CT-TCE at 25°C, respectively. There is a discrepancy between these values, which is larger in CT-TCE system.

The values of V^E can be represented by

$$V^E = x(1-x)\sum_{t=0}^{2} A_t \cdot (1-2x)^t \qquad (1)$$

Sound Velocity. The values of sound velocity in pure components are given in column 3 of Table 2, together with literature values in the last column. The sound velocity of all these systems deviates negatively from linear addivity in mole fraction, and the deviation decreases with the rise of temperature. The sound velocity *vs.* concentration curves for CT-TCE, B-TCE, *p*X-TCE, and *t*BC-TCE systems at 25°C are shown in Fig. 2.

Adiabatic Compressibility. The values of adiabatic compressibility calculated from the values of v and d by means of the equation

$$\kappa_s = 1/(v^2 d) \tag{2}$$

are given in column 4 of Table 2 for pure liquids.

The excess compressibility $(V\kappa_s)^E$ is defined by means of the equation

$$(V\kappa_s)^E = V\kappa_s - (V_{AA}\kappa_{s,AA}x_A + V_{BB}\kappa_{s,BB}x_B) \tag{3}$$

where V, V_{AA} and V_{BB} are the molar volume of solution and pure liquids for species A and B, respectively, and $\kappa_{s,AA}$ and $\kappa_{s,BB}$ are the adiabatic compressibility of pure liquids A and B, respectively. The values of $(V\kappa_s)^E$ are shown in Figs. 3(a)—(i) for each system. $(V\kappa_s)^E$ becomes linear in mole fraction if a system behaves like an ideal solution.[7]

○ 25°C, △ 35°C

The $(V\kappa_s)^E$ values of all systems except CT-TCE have negative values and their dependency on temperature is negative for all systems except *p*X-TCE system, where it is zero within experimental error. The κ_s^E *vs.* mole fraction curves fit into the following equation.

$$\kappa_s^E = x(1-x)\sum_{i=0}^{2} B_i \cdot (1-2x)^i \qquad (4)$$

Coefficients B_i are given in Table 1(b). The accuracy of κ_s^E is within 0.05%, and that for *t*-butyl bromide solutions within 0.1%.

Discussion

The curves of excess volume with respect to mole fraction differ from those of excess compressibility.

○ 25°C, △ 35°C

The latter are more symmetrical except for CT-TCE system. In particular, asymmetry of V^E is marked in aromatic systems.

It is seen that the temperature dependency of V^E has negative coefficients for aromatic solutions and positive ones for CT solutions, although the temperature coefficients are very small for all systems. The general trend in temperature dependency of κ_s^E and $(V\kappa_s)^E$ seems to be negative.

The interaction between unlike molecules in these systems seems to be ascribed to dispersion forces and dipole-induced dipole interactions, considering the chemical nature of the species in these systems. Recently, Fort, Jr., and Lindstrom[15] reported that there is no complex formation.

Molecular size V^* for pure liquids was obtained from the values of molar volume V and thermal expansion coefficient α, by the equation[9].

$$V^* = V \times \left[(1+\alpha T) \Big/ \left(1+\frac{4}{3}\alpha T\right) \right]^3. \tag{5}$$

The values of these parameters are listed in Table 3, together with dipole moments of solute.

We showed that the V^E was expressed as the sum of two terms[9]: the one V^E_{size} associated with the size difference of molecules and the other $V^E_{int.}$ associated with the interaction forces between molecules. Thus, for a mixture composed of species A and B, we have

$$V^E = V^E_{size} + V^E_{int.} \tag{6}$$

and

$$V^E_{size} = [(V^*_A - V^*_{AA})x_A + (V^*_B - V^*_{BB})x_B] \times [1-(9RT/\pi)(V^0/W_m)]^{-1} \tag{7}$$

where $W_m = N^2 \times (\gamma\varepsilon_A{}^* r_A{}^{*3} x_A + \gamma\varepsilon_B{}^* r_B{}^{*3} x_B)$, $V^* = N\beta r^{*3}$, $V^\circ = V_{AA}x_A + V_{BB}x_B$, and pure components are denoted by AA and BB. γ, β, r^*, and ε^* have the same meaning as in the previous paper.[9] r^* and ε^* are related to those of pure liquids by means of the equations

$$r^*_A = r^*_{AA}x_A + r^*_{AB}x_B, \quad r^*_B = r^*_{AB}x_A + r^*_{BB}x_B,$$
$$r^*_{AB} = (r^*_{AA} + r^*_{BB})/2 \tag{8}$$

and

$$\varepsilon^*_A = \varepsilon^*_{AA}x_A + \varepsilon^*_{AB}x_B, \quad \varepsilon^*_B = \varepsilon^*_{AB}x_A + \varepsilon^*_{BB}x_B \tag{9}$$

The relation of molar volume and interaction energy

e) A. L. McClellan, "Tables of Experimental Dipole Moments," W. H. Freeman Co., San Francisco and London (1963).

for a mixture is given by

$$W_m = (9RT/2\pi) \times [V^2/(V-V^*)] \quad (10)$$

where $V^* = V_A^* x_A + V_B^* x_B$ and V is molar volume of solution, and that for a pure liquid A by

$$N^2 \gamma \varepsilon_{AA}^* r_{AA}^{*3} = (3RT/2\pi) \times [V_{AA}^{4/3}(V_{AA}^{1/3} - V_{AA}^{*1/3})] \quad (11)$$

The value of θ, which is associated with intermolecular interaction energy ε_{AB}^*, is defined as follows.

$$\theta = [\varepsilon_{AB}^* - (\varepsilon_{AA}^* + \varepsilon_{BB}^*)/2]/\varepsilon_{AA}^* \quad (12)$$

The values ε_{AB}^* for equimolar mixtures are calculated from the observed values of V^E and the molecular parameters in Table 3, using Eqs. (6)—(11). The values of θ are determined from ε_{AB}^* and are given in Table 4. $\theta_{disp.}$, obtained using Bertholet's relation $\varepsilon_{AB}^* = (\varepsilon_{AA}^* \cdot \varepsilon_{BB}^*)^{1/2}$, and the values of V_{size}^E and $V_{int.}^E$ obtained for equimolar mixtures are also listed.

We see that the values of θ are negative and smaller than those of $\theta_{disp.}$, except for the systems CT-*t*BC and *t*BC-TCE which has positive values of θ. All the systems except these two have positive values of $V_{int.}^E$.

It is seen that the values of θ decrease in the order CT, B, and *p*X as solvents for a common solute and those of $V_{int.}^E$ increase in this order. The results are consistent with the idea that the attractive interaction between solute and solvent becomes stronger in the order *p*X, B, and CT as solvents.[9]

Carbon tetrachlordie, *t*-butyl chloride, trichloroethane, and *t*-butyl bromide are similar chemically. They are regarded as derivatives of CH_4: in the first three compounds H atoms of CH_4 are replaced by Cl and CH_3 groups and in the last by Br and CH_3 groups. The molecular shape of these four compounds are nearly spherical. Carbon tetrachloride is non-polar and the other three have the dipole moment about 2D as given in Table 3.

In CT-TCE system, the observed values of V^E and $(V\kappa_s)^E$ are one order smaller than those in other systems, and the magnitude of θ is negative and small. Similar situations are found in B-TCE systems. Thus, it is concluded that these two systems are nearly ideal. Turner *et al.*[16] reached the same conclusion from the measurements of dielectric relaxation times, boiling point diagram and heat of mixing of B-TCE system. From the fact that CT-B system is nearly ideal,[9] it can be said that all binary mixtures consisting of CT, B, and TCE are regarded as ideal solutions.

As seen in Table 4, the observed values of V^E and $(V\kappa_s)^E$ in the systems including *t*BC are negative and comparatively larger in their absolute magnitude, compared with those in the systems including TCE. Moreover, the values of θ in CT-*t*BC and TCE-*t*BC systems are positive, which is in sharp contrast to the situation in CT-TCE and B-TCE systems. This means that the solute-solvent interactions in CT-*t*BC and *t*BC-TCE systems are more attractive than those in other systems.

The molecules of *t*BC and TCE have structures in which methyl groups and chlorine atoms are exchanged and have nearly the same dipole moments.

Table 4. Thermodynamic quantities of equimolar mixtures (25 °C)

System	$V^E_{obs.}$	V^E_{size} (cc/mol)	$V^E_{int.}$	$(V\kappa_s)^E \times 10^4$ (cc/bar·mol)	θ (10^{-3})	$\theta_{disp.}$

16) E. M. Turner, D. W. Anderson, L. A. Reich, and W. E. Vaughan, *J. Phys. Chem.*, **74**, 1275 (1970).

The molecular size V^* of CT, *t*BC, and TCE do not differ much. This is shown in Table 3. It might be concluded that the nature of more attractive interactions in CT-*t*BC and TCE-*t*BC systems is due to the interactions between methyl groups and chlorine atoms. This suggests that the interaction between these molecules can not be described by means of the central force field which is a function of the separation between molecular centers.[10] This might be assumed to be an interaction through molecular surfaces.[17]

17) P. J. Flory, *J. Amer Chem. Soc.*, **87**, 1833 (1965); A. Abe and P. J. Flory, *ibid.*, **87**, 1838 (1965).

The values of dipole moments of 1,2-dichloroethane (DCE) in pure liquid (2.1 D) and in benzene solution (1.7 D) are nearly equal in the order of magnitude to those of *t*BC and TCE, respectively. However, B-DCE system has positive values of V^E, $(V\kappa_s)^E$ and θ, which are in marked contrast to the negative values in B-*t*BC and B-TCE.[7] A more refined treatment of a ternary mixture, which includes the conversion between gauche and trans forms in DCE, is desirable for B-DCE system.

In the systems including B and *p*X as solvents, the values of θ in *p*X solutions are more negative than those in B solutions. It indicates that the solutes studied are more attractive to B than to *p*X.

ESR Study of Adsorbed Monomer and Dimer Cation Radicals of Benzene and Its Methyl Derivatives

Siro NAGAI, Shun-ichi OHNISHI, and Isamu NITTA

Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, Neyagawa City, Osaka

(Received September 14, 1970)

Benzene, toluene, *o*-, *m*-, *p*-xylene, and mesitylene adsorbed on silica gel were γ-irradiated at -196°C. ESR spectra observed at -196°C for these systems at low contents of the methylbenzenes were assigned to the respective monomer cations. Dimer cations of benzene, toluene, and *p*-xylene were produced on γ-irradiation at -196°C of the adsorbed systems at higher contents and also by the reaction of monomer cations and neutral molecules at higher temperature than -160°C.

Edlund *et al.*[1] reported that the monomer and dimer cations of benzene were produced in γ-irradiated benzene-silica gel system and these authers[2] studied the formation of these cations, as well as neutral radicals, as functions of adsorption amount and irradiation dosage. Tanei[3] also observed these cations adsorbed on silica gel by ultraviolet irradiation. In the present paper, we describe results of our study on γ-irradiated methylbenzenes adsorbed on silica gel. From the analysis of the ESR spectra, we determined the structure of the radicals produced on the gel and followed reactions of the radicals on raising the temperature.

Experimental

Silica gel (Mallinckrodt Chemical Works, 100 mesh) was heated *in vacuo* at 500—550°C for 10 hr before use. The BET surface area determined by N_2 adsorption was 500 m^2/g. Chemicals were obtained from commercial sources; spectro-grade benzene from Merck and toluene, *o*-, *m*-, *p*-xylene, and mesitylene from Nakarai Chemical Co., Ltd. (reagent grade). These reagents were used without further purification. Adsorbed samples were prepared by adding methylbenzene gas of known volume to silica gel in a vacuum line at room temperature, and a part of them (*ca.* 300 mg) was transferred *in vacuo* to spectrosil tube for ESR measurement. Amount of adsorption was determined with a Hg manometer, and was limited in the present study to the low coverage region, from 1.0×10^{-5} mol/g to the amount of monolayer. The amount of monolayer (coverage) was estimated from the area occupied by an adsorbed methylbenzene molecule[4] and the BET surface area. The obtained value was approximately 2×10^{-3} mol/g for benzene and its methyl derivatives.

γ-Irradiation was carried out at -196°C with a 2,000 Ci Co-60 source to a dose of 5.0×10^5R. ESR spectra were recorded using a Varian V-4500 spectrometer and variable temperature accessorries at various temperatures from -196°C to room temperature. The ESR signal from the γ-irradiated silica gel did not contribute significantly to the observed spectra for the methylbenzene-silica gel system.

Results and Discussion

ESR Spectra of Irradiated Adsorbed Aromatic Compounds. ESR spectrum of the adsorbed benzene was dependent on the amount of adsorption as reported by Edlund *et al.*[2] The adsorbed methylbenzenes also showed quite similar dependence. When the adsorbed amount was about 1/100 of the monolayer coverage, the ESR spectra shown in Figs. 1 to 5 were observed. For benzene, the observed spectrum (Fig. 1a) was the same as that reported by Edlund *et al.*[2]; the seven lines with

asymmetric individual lines, the splitting value being $a_H=4.4$ gauss. Toluene gives the 5-line spectrum of $a_H=14.0$ gauss with additional splitting of 3 gauss (Fig. 2a). The spectrum of *p*-xylene consists of seven lines ($a_H=14.5$ gauss) with additional 3 gauss splitting (Fig. 3a). The splitting values for *m*-xylene, *o*-xylene, and mesitylene are 11.0 gauss, 11.0 gauss with additional splitting of 6 gauss, and 8.0 gauss, respectively.

When the amount of adsorption was increased, but still smaller than the monolayer coverage, the spectra for benzene, toluene, and *p*-xylene changed into those having splitting values a'_H equal to one half of a_H. No half-field resonances were observed for benzene. Benzene gives the 13-line spectrum with $a'_H=2.2$ gauss (Fig. 1b), in agreement with the result by Edlund *et al.*[1] The spectra for toluene and *p*-xylene have the splitting values $a'_H=7.0$ gauss, and 7.5 gauss, respectively. For *m*-xylene, *o*-xylene, and mesitylene, on the other hand, no such spectra with $a'_H=a_H/2$ were observed. Instead, the spectra became broadened, as shown in in Fig. 4 for *m*-xylene.

On increasing the adsorption amount further, close to and larger than the monolayer coverage, all the samples gave broad spectra which can be assigned to the cyclohexadienyl type radicals. These types of spectra were observed as trace background also for the lower coverage samples.

Assignment of the Spectra. ESR spectra observed

for the adsorbed compounds with the lowest coverages can be assigned to the respective monomer cations. Theoretical hyperfine splitting values are calculated by the simple Hückel MO method. The splitting values of the methyl protons, taking $Q_H^{CCH_3}=44$ gauss obtained for the cation of durene,[5] are 14.7 gauss for the cations of toluene and *p*-xylene, 11.0 gauss for *o*- and *m*-xylene, and 7.3 gauss for mesitylene. These theoretical values agree well with the observed values. The additional splittings are due to the ring protons and the observed equal splittings for toluene and *p*-xylene are reasonable, in view of the same spin density (1/12) at the 2,3,5,6-ring carbon atoms of the two methylbenzenes.

Difference in the spectra for *o*-xylene and *m*-xylene cannot be explained by the simple Hückel theory. With the perturbation calculation,[6] however, this difference could be explained; the 4,5-protons in *o*-xylene would have smaller splitting values than the 4,6-protons in *m*-xylene.

ESR spectra of toluene and *p*-xylene at the intermediate coverages can be asigned to the respective dimer cations, in view of the half splitting values a_H'.

Formation of Dimer Cations

ESR spectra of the adsorbed benzene, toluene, and *p*-xylene became those of the dimer cations, through intermediate composite spectra, as the adsorption amounts were increased.

This change of monomer to dimer was studied for benzene as a function of absorption amount and temperature. At −196°C, the formation of dimer cation began at the benzene content as low as 2×10^{-5} mol/g and the dimer increased at the expense of monomer, as the adsorption amount became larger (Fig.6).

The monomer spectrum was stable at −196°C for several weeks. At about −160°C, the seven-line

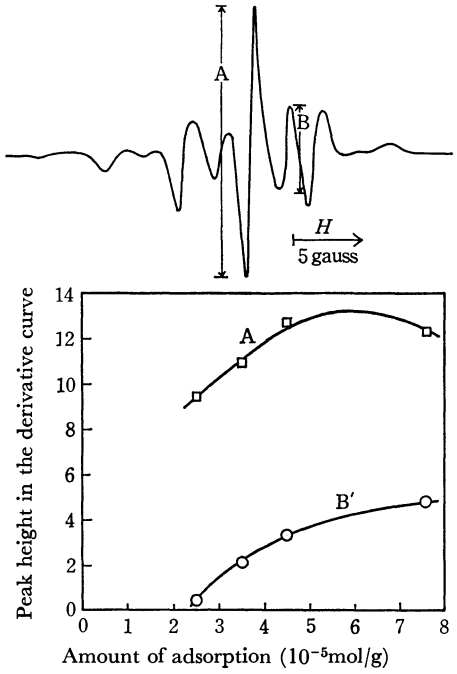

Fig. 6. Formation of the dimer cation as a function of the benzene content. The peak height B', which is the peak height B multiplied by the binomial ratio 924/792, was plotted against the content. The peak A is a superposition of the peaks of the spectra of the monomer and the dimer cations.

spectrum began to change and the 13-line spectrum appeared. The latter spectrum became predominant at −140°C and at still higher temperatures it began to decay, the individual lines of the spectrum becoming sharp. Formation of the dimer at higher temperatures was studied with benzene by following spectral change at a constant temperature −155°C (Fig. 7). The result suggests that the dimer cations are produced from the monomer cations. The temperature for this conversion depends on the heat-treatment of silica gel. On a silica gel heat-treated at 850°C, the conversion occurs even at −196°C, while it hardly occurs at about −140°C with a silica gel heated at 200°C.

At −196°C, the adsorbed benzene as well as the monomer cation radicals produced by irradiation does

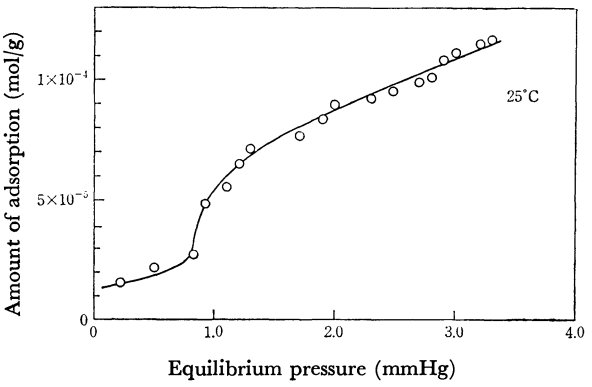

Fig. 8. Adsorption isotherm of benzene on silica gel at 25°C.

not have sufficient mobility to come close to form the dimer cation radicals. When the adsorption amount exceeds 2×10^{-5} mol/g, there seems to occur a certain change in the mode of adsorption as evidenced from the adsorption isotherm (Fig. 8). Adsorptions as benzene dimer might occur and these species would give the dimer cation on irradiation. The slower rates of motions of the monomer and dimer cations at −196°C can be noted from the asymmetry of the individual lines of the 7-line spectrum and the line-widths variation of the 13-line spectrum depending on the total nuclear quantum numbers.

At higher temperatures, the adsorbed monomer cations and molecules become mobile to come close to form the dimer cations. Such mobilization can be seen from the spectral changes and the decay. Different behavior for the monomer-to-dimer conversion with silica gels subjected to different heat-treatments suggests alterations in mobility of adsorbed benzene on silica gel heat-treated at various temperatures.

The same mechanism would also hold for the dimer formation of toluene and *p*-xylene. At higher temperatures, the spectra of dimer cations were observed.

For the cases of *o*-xylene, *m*-oxylene and mesitylene, such clear evidence for the dimer formation was not obtained from ESR spectra. At higher temperatures, however, the adsorbed molecules become also mobile in view of decay of the signals. The spectra also change to the broad spectra, which might be responsible for the dimer cation radials.

The Crystal Structure of *cis*-Ammonium Disulfitotetrammine-cobaltate(III) Trihydrate, $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$[1]

Teruo NOMURA and Masayoshi NAKAHARA
Department of Chemistry, Rikkyo University, Ikebukuro, Tokyo

(Received September 22, 1970)

The structure of $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$ has been determined by the heavy-atom method and refined to $R=0.12$ by a least-squares analysis based on 874 three-dimensional visual data. The compound crystallizes in the orthorhombic space group $P2_12_12_1$, with unit cell dimensions of $a=10.995$, $b=17.563$, $c=6.834$ Å, and $Z=4$. The two sulfito groups in the complex anion are coordinated to the central cobalt atom in *cis* positions through their sulfur atoms, with Co-S distances of 2.23 Å (mean). The *cis*-configuration of brown sodium salt, with an absorption spectrum similar to that of the trihydrate of ammonium salt, has also been established.

There are two stereoisomers conceivable for the disulfitotetramminecobaltate(III) complex anion: the *cis* and *trans* forms. In fact, in the case of the ammonium salt of this complex, the two isomers have been known as the dark brown trihydrate and the reddish brown tetrahydrate respectively. The absorption spectrum of the dark brown ammonium salt in an aqueous solution has a chage-transfer band at 265 mμ and a sulfito-specific band at 297 mμ in the ultraviolet region, whereas that of the reddish brown ammonium salt has only a sulfito-specific band at 274 mμ. In the sodium salts, the spectra are nearly identical with those of the corresponding ammonium salts; that is, the brown salt corresponds to the dark brown ammonium salt, and the golden-yellow salt, to the reddish brown ammonium salt. These spectra were first measured by Shimura[2] and are followed in the present work (Fig.1).

The assignment of the configurations of these salts has not yet been established; Hofmann and Jenny,[3] who first prepared the two isomers of sodium salts, designated a brown, less soluble dihydrate as the *cis* form and another golden-yellow, more soluble tetrahydrate as the *trans* form. They also concluded that the dark brown and reddish brown ammonium isomers correspond to the brown or golden-yellow sodium salts, respectively. Schwarz and Tede[4] showed, from their studies of the photochemical decomposition of the ammonium salts, that the dark brown, more decomposable salt is the *cis*-isomer and the reddish brown, less

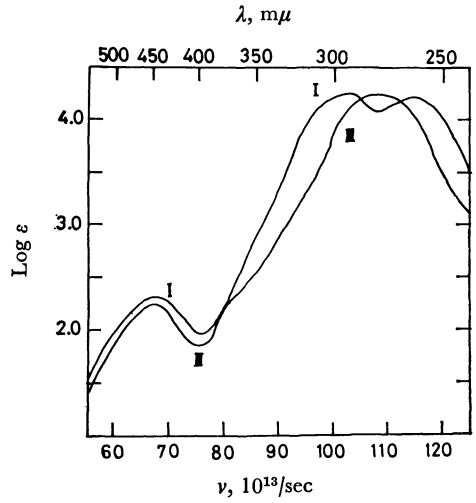

Fig. 1. Absorption spectra of the dark brown isomer (I) and of the reddish brwon isomer (II) of ammonium salt in a 3% aqueous solution of ammonia.

decomposable salt is the *trans*-isomer. Klement[5] and Bailar and Peppard[6] also concluded that the sulfito groups of the dark brown trihydrate must be located in the *cis* positions, in view of the fact that only two ammonia molecules are replaced by an ethylenediamine molecule. On the other hand, in view of the position of the charge-transfer band, Shimura[2] suggested that the dark brown salt has a *trans* configuration with respect to the sulfito groups and assumed, from the first absorption band at 465 mμ, that the sulfito groups in the complex anion were more symmetrical or more stable than a free SO_3 radical, that is, that they were bonded through the sulfur atom to the central atom.

In the present work, the dark brown trihydrate, $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$, has been subjected to a three-dimensional X-ray analysis in order to establish the structure of the complex anion and in order to elucidate in detail the way of the coordination of the sulfito groups to the metal.

Experimental

Ammonium disulfitotetramminecobaltate(III) trihydrate was prepared by the method of Bailar and Peppard.[6] This compound crystallizes in dark brown pillars elongated along the *c* axis, the shortest crystallographic axis. The specimens used for the collection of the intensity data were reformed into cylinders with diameters of 0.024 cm and of 0.026 cm, the axes of which were parallel to the *c* and *a* axes respectively. Using Fe*K*α radiation, Weissenberg photographs with spot-integrating procedure were taken from the zero to fourth levels and from the zero to seventh levels about the *c* and *a* axes respectively. The intensities were measured visually by use of standard calibrated scales and were converted to structure amplitude values in the usual way. Corrections were also applied for absorption, the crystal being assumed to be perfectly cylindrical.[7] A total of 874 independent intensity data were collected.[8]

The crystal data are as follows: $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$, F.W.=359.3, orthorhombic, space group $P2_12_12_1$ (D_2^4, No. 19); a=10.995(6), b=17.563(15), c=6.834(5) Å, U=1322 Å^3; D_m=1.81 g·cm^{-3}. Z=4, D_x=1.80 g·cm^{-3}; linear absorption coefficient for Fe*K*α radiation, μ=94.5 cm^{-1}.

Determination of the Structure

The location of the cobalt atom could be readily determined from Patterson projections, $P(u, v)$ and $P(v, w)$ (Fig. 2).

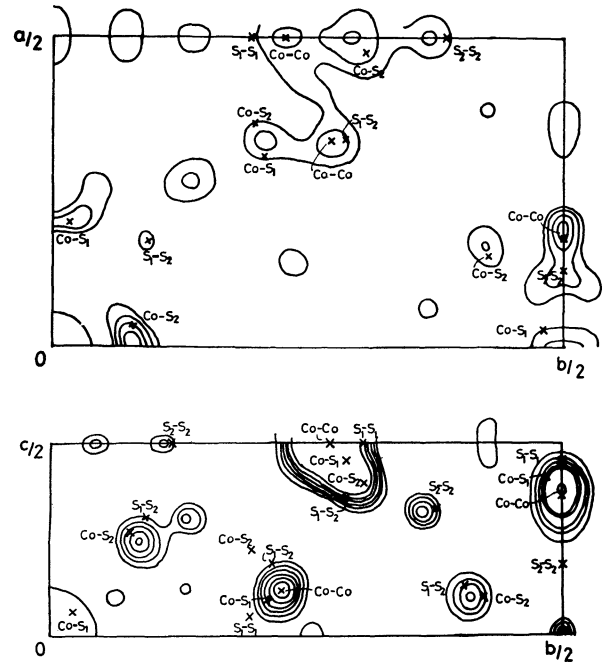

Fig. 2. Patterson projections, $P(u,v)$ and $P(v,w)$, where the vectors between heavy atoms are shown by the crosses.

However, the positions of the two sulfur atoms of the sulfito groups could not be definitely fixed from Patterson maps until a three-dimensional Fourier synthesis has been calculated by the use of phases based on the cobalt atom. The coordinates of these heavy atoms were refined by the block-diagonal, least-squares method.[9] The discrepancy factor, $R=\sum(|F_o|-|F_c|)/\sum|F_o|$, decreased to 0.30. A three-dimensional Fourier synthesis with phases determined by the heavy atoms allowed the four nitrogen atoms to be located around the cobalt atom. Successive refinements were carried out and the positions of all the remaining lighter atoms except those of the hydrogen atoms were revealed, though the nitrogen atom of the ammonium ion and the oxygen atoms of the water molecules were not sufficiently distingushed from each other. These syntheses also indicated that

7) International Tables for X-Ray Crystallography, Vol. II, Kynoch Press, Birmingham (1959).

8) A FFLP program written by Dr. F. Iwasaki and Dr. H. Iwasaki was used for the Lorentz and polarization corrections of the intensity data.

9) The Fourier synthesis and least-squares program used was HBLS-4 (in the "Universal Crystallographic Computation Program System" edited by Dr. T. Sakurai and published by the Crystallographic Society of Japan), written by Dr. T. Ashida. The weights at the final least-squares refinement were assumed to be as follows: $w=(3.52/F_0)^2$ if $F_0\geq 3.52$, and $w=1$ if $F_0\leq 3.52$.

anisotropic temperature factors should be used for all the atoms.

After several cycles of least-squares refinement with anisotropic thermal parameters, the discrepancy fractor became 0.12. A final difference Fourier synthesis gave no significant indications of the positions of the hydrogen atoms. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[10]

At a later stage of the refinement, extinction corrections were applied for some of the larger F_o values.

The final three-dimensional electron density map is shown in Fig. 3. The final parameters are given in Tables 1 and 2.

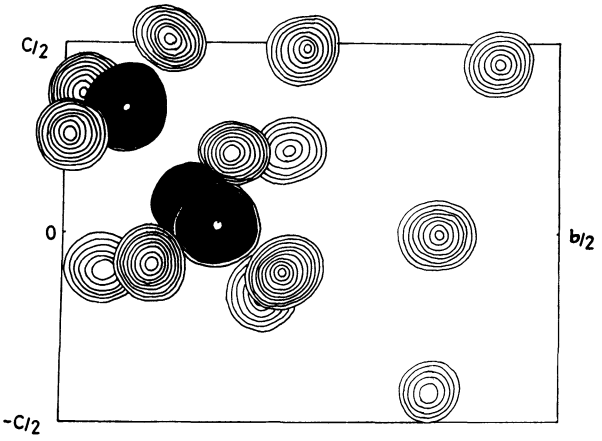

Fig. 3. The final three-dimensional electron density map composed of sections through the atomic centers parallel to (100). The contours are drawn at intervals of 1.0 e.Å^{-3} starting with 1.0 e.Å^{-3}.

The agreement between the observed and calculated structure amplitudes is reasonable.[11]

The standard deviations of the coordinates, estimated from the least-squares results, are 0.004 Å (mean) for the cobalt and sulfur atoms and 0.02 Å (mean) for the others.

Description of the Structure and Discussion

A projection of the contents of an asymmetric unit along the *a* axis is presented in Fig. 4. The bond lengths

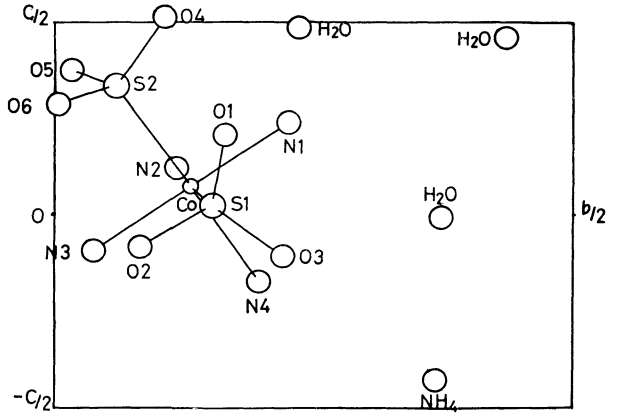

Fig. 4. The structure in an asymmetric unit, viewed along the *a* axis.

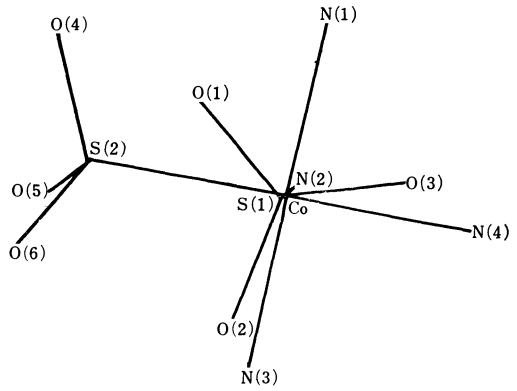

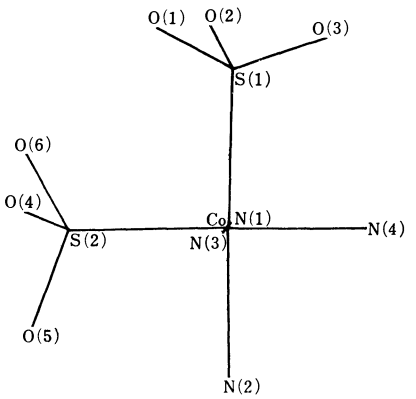

Fig. 5. Projections of the complex anion onto (a) the plane defined by the three oxygen atoms of O(1), O(2), and O(3) in a sulfito group and (b) the least-squares plane for Co, S(1), S(2), N(2), and N(4).

and angles with their e.s.d.'s are listed in Table 3, while the pertinent intermolecular contacts (*i.e.*, those less than 3.22 Å) are given in Table 5.

In the complex anion, the two sulfito groups are coordinated to the central cobalt atom in *cis* positions through their sulfur atoms, the Co-S distances of 2.22 Å and 2.25 Å. These bond lengths are somewhat shorter than the sum of the covalent radii (2.26 Å) obtained from the radius of 1.22 Å for Co(III) and that of 1.04 Å for tetrahedral sulfur, while they are a little longer than the Co-S distance of 2.20 Å found in the crystal of $[Co(SO_3)(SCN)en_2]$,[12] whose crystal structure was first determined among the Co(III) complexes containing the sulfito group as a ligand. The sulfito groups are of a somewhat distorted trigonal-pyramidal struc-

12) S. Baggio and L.N. Becka, *Acta Crystallogr.*, **B25**, 946 (1969).

ture, three oxygen atoms and a lone pair of electrons being bound tetrahedrally around the central sulfur atom; they do not possess a strict three-fold symmetry. The O–S distances range from 1.47 to 1.56 Å, the values of the S–O–O angles being 106°—111°. In the crystals of $(NH_4)_2SO_3\cdot H_2O$[13] and $NiSO_3\cdot 6H_2O$[14] containing ionic sulfito groups, the mean values of the S–O distances and the O–S–O angles are 1.53 Å and 104° respectively, whereas, in the crystals of $[Co(SO_3)(SCN)en_2]$ and $[Pd(SO_3)(NH_3)_3]$[15] involving the coordinated sulfito groups, the corresponding values are 1.49 Å and 110° respectively.

The planes formed by O(1), O(2), and O(3), and O(4), O(5), and O(6), are approximately perpendicular to the Co–S(1) and Co–S(2) bonds respectively (*cf.*, Fig. 5(a)).

The intermolecular distances, Co–N(NH_3), are 1.98—2.01 Å and are quite normal, with the exception only of 2.07 Å of Co–N(4), which is slightly longer.

The nitrogen and sulfur atoms are displaced from the regular octahedral positions around the central cobalt atom. The displacement is irregular, though the geometry is partially kept almost regular as may be seen in, for example, the dimensions of two of the triangles formed by three nitrogens. Mainly as a result of the repulsions between the non-bonded oxygen atoms belonging to different sulfito groups, the S-Co-S angle is larger than 90° (Fig. 5(b)) and two sulfito groups are located so as to keep their oxygen atoms at distances longer than 3.17 Å from those in another (Fig. 6 and Table 3). This distortion of the complex anion from the regular octahederal configuration seems to make the complex more photochemically decomposable than another isomer.[4]

The crystal is essentially ionic. The layers of the complex anions and those of the ammonium ions are alternately piled up, approximately parallel with the (120) and (1$\bar{2}$0) planes. The interstices among the complex anions form channels, which are elongated

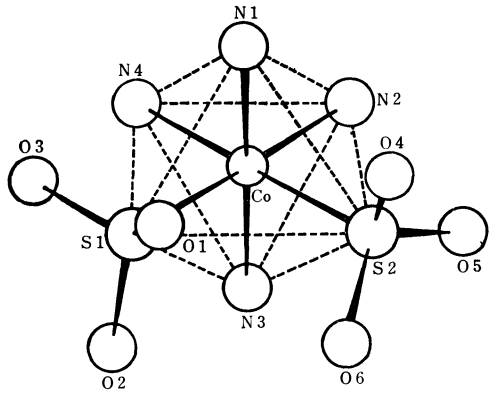

Fig. 6. A drawing of the complex anion, viewed along the direction perpendicular to the plane composed of three nitrogen atoms, N(2), N(3), and N(4). The displacement of sulfur and nitrogen atoms from their regular octahedral positions and the relative locations of oxygen atoms belonging to different SO_3 groups are also shown.

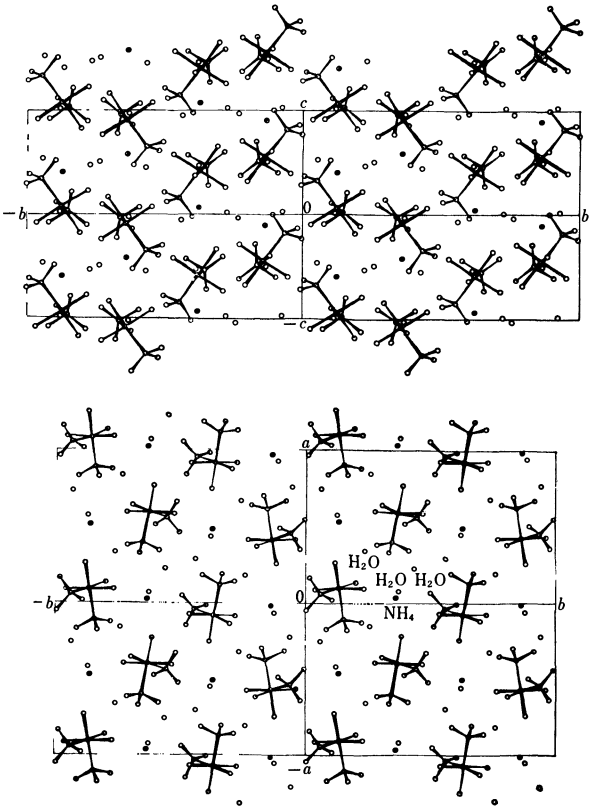

Fig. 7. Arrangement of the complex anions, ammonium ions, and water molecules in the crystal lattice.

along the *c* and *a* axes and which are packed with ammonium ions and water molecules (Fig. 7).

A complex anion is surrounded by six ammonium ions: four closest N···NH_4 and two O···NH_4 approaches can be found at distances ranging from 3.22 to 3.62 Å (Table 4).

TABLE 4. SIX CLOSER APPROACHES FROM AMMONIUM IONS TO NITROGEN AND OXYGEN ATOMS IN ANIONS

Reference atom at (x,y,z)				Distances
N(1)-N(5) at (	x,	y,	$1+z$)	3.50(3)Å
N(2)-N(5) at (	$1/2+x$,	$1/2-y$,	$-z$)	3.48(3)
N(3)-N(5) at (	$-x$,	$-1/2+y$,	$-1/2-z$)	3.22(3)
N(4)-N(5) at (	x,	y,	z)	3.62(3)
O(1)-N(5) at (	$-1/2+x$,	$1/2-y$,	$-z$)	3.61(3)
O(6)-N(5) at (	$-x$,	$-1/2+y$,	$-1/2-z$)	3.47(3)

The closest O···N contact occurs at a distance of 2.69 Å between NH_4 and H_2O (9[a]), the closest O···O distance being 2.69 Å between O(1) and H_2O (7[f]) and the closest N···N distance being 3.22 Å between N(3) and NH_4[d], while the van der Waals radii are 1.50 Å for nitrogen and 1.40 Å for oxygen. Intermolecular contacts less than 3.22 Å are presented in Table 5, while the short contacts in the structure are shown in Fig. 8. The complex anions are held together in the crystal by hydrogen bonds of the N–H···O and O–H···O types. These bonds involve each complex anion in a three-dimensional bonding network.

In the present structural study, the configuration of the dark brown ammonium trihydrate salt, NH_4-

N(5)-O(8)	2.87(3)	O(1)-O(8^e)	3.22(2)

$[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$, has been established as the *cis* form. It may also be concluded that the brown sodium salt with an absorption spectrum similar to that of the present substance is the *cis* isomer. The results thus obtained are consistent with those of several other studies.[3-6]

Both of the sulfito groups are pyramidal and are bonded to the cobalt through the sulfur atom.This is consistent with the prediction of Shimura.[2] The large value of the molar extinction coefficient in the charge-transfer band (log ε=4.20) can be reasonably explained by the coordination of the sulfito group through the sulfur.

During the preparation of the manuscript of this report, a short communication about the structure of this complex anion has been published by other workers.[16]

The Codimerizations of Styrene with Vinyl Compounds Catalyzed by Olefin-palladium(II) Chloride Complexes

Keiji KAWAMOTO, Atsushi TATANI, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received September 26, 1970)

The codimerization of styrene with vinyl compounds catalyzed by di-μ-chloro-dichlorobis(styrene)dipalladium(II), $(Pd(C_6H_5CH{=}CH_2)Cl_2)_2$, was investigated in a homogeneous system under mild conditions. The reaction of styrene and methyl acrylate carried out at 50°C for 6 hr yielded 220% codimers, 169% dimers of methyl acrylate, and 18% dimers of styrene, on the basis of the palladium(II) used. The codimerizations of styrene with vinyl acetate and with methyl vinyl ketone gave 50% codimer and 125% codimers respectively. When nitroethylene and *n*-butyl vinyl ether were used as the vinyl compound, no codimers were formed. The codimerization of styrene-d_3 with ethylene was also carried out. The reaction mechanism involving the five-coordinate hydridopalladiumolefin intermediate was proposed and discussed in the terms of the distribution of deuterium in the codimer of styrene-d_3 and ethylene, the functional group effects of vinyl compounds, and solvent effects on the codimerization.

Many investigations have recently been reported for the cooligomerizations of conjugated dienes with mono-olefins catalyzed by transition-metal compounds. Few reports have appeared, however, concerning the codimerizations of simple olefins with vinyl compounds and the dimerizations of vinyl compounds.[1)]

As has been reported in a preliminary communication,[2)] we have found that olefin-palladium chloride complexes are an effective catalyst for the codimerization of styrene with ethylene. Afterwards, Barlow and his co-workers reported the dimerizations and the codimerizations of olefins catalyzed by a benzonitrile palladium chloride complex and suggested that the palladium hydride is an intermediate.[3)] The investigations of the substituent effects of vinyl compounds and the structure of codimers on codimerization reactions give an important suggestion as to the reaction mechanism of the oligomerizations of olefins. In this paper, the codimerization of styrene with various vinyl compounds will be investigated. A reaction mechanism involving the five-coordinate hydridopalladium-olefin intermediate will be proposed and discussed in the terms of the functional group effects of vinyl compounds and solvent effects on the codimerization.

Experimental

Codimerization of Styrene with Vinyl Compounds. A reaction vessel was charged with 10.7 mmol of a styrene-palladium complex, 0.7 mol of styrene, and 0.7 mol of a vinyl compound; then, the mixture was stirred at 50°C for 6 hr. This solution thereby turned reddish-brown. The resulting solution was diluted with petroleum ether after the unreacted reagents had been removed under reduced pressure at 50°C; then it was filtered to remove the catalyst and palladium metal. The filtrate was distilled under reduced pressure. The products were separated by distillation or preparative-glcg, and were identified by infrared spectroscopy (Jasco model IR-E), proton magnetic resonance spectroscopy (JNM-4H-100 and JNM-C60HL), mass spectrometry (Hitachi RMS-4 mass spectrometer), and elemental analysis.

Codimerization of Styrene-d_3 with Ethylene. Styrene-d_3 was prepared using the method described by Kirchner.[4)] Mixtures of acetophenone (25 g), 99.75% D_2O (30 m*l*), and 40% NaOD in D_2O (0.3 m*l*) were stirred at 85°C for 10 hr. The resulting solutions gave 98% acetophenone-d_3 (23 g) when the same procedure was repeated three times. The reduction of acetophenone-d_3 with $LiAlD_4$ (4 g) gave $C_6H_5CD(OH)CD_3$ (20.5 g). The alcohol was dehydrated using

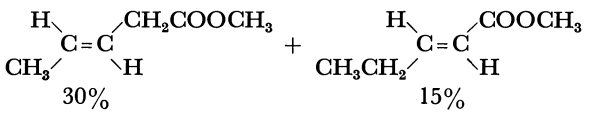
the method of Overberger *et al.*[5] to give styrene-d_3 (12.5 g). From the analysis of the integral curve of the NMR spectrum, assuming the phenyl protons to be 5H, the α and β protons of styrene were found to contain 0.02H and 0.04H respectively. A glass autoclave was charged with an ethylene-palladium complex (1.5 g) and styrene-d_3 (10 g). The autoclave was flushed with ethylene and pressured to 4 atm, and then the mixture was stirred at 50°C for 6 hr. From the NMR spectrum analysis of the codimer thus obtained, assuming the phenyl protons to be 5H, it was calculated that olefinic methynyl, saturated methylene, and methyl protons in *trans*-1-phenyl-1-butene contained 0.97H, 0.78H, and 0.98H respectively. The estimated error in the observed values of the protons was *ca.* 0.02H.

Results and Discussion

The codimerization reaction of styrene with ethylene reported in a preliminary communication[2] was applied to the system of ethylene and methyl acrylate with a functional group. Ethylene was bubbled into a methyl acrylate solution containing an ethylene-palladium chloride complex catalyst at 50°C for 6 hr. The following products were thus obtained:

$$CH_2{=}CH_2 + CH_2{=}CH{-}COOCH_3 \longrightarrow$$



(based on palladium(II))

Methyl acrylate also could be successfully codimerized with ethylene. However, the yield is rather low because ethylene dissolves slightly in methyl acrylate under atmospheric pressure; therefore, the codimerization reactions of styrene instead of ethylene with various vinyl compounds were investigated.

The codimerization reactions of styrene with vinyl compounds catalyzed by the styrene-palladium chloride complex were carried out at 50°C for 6 hr. The results are shown in Table 1. The codimerization reaction of styrene with methyl acrylate gave not only the codimers of styrene and methyl acrylate, but also the dimers of methyl acrylate. When the other polar vinyl compound were used, no dimers of polar vinyl compounds were formed. Though the codimerization rate of styrene with vinyl acetate is slow, the complex remains as a stable catalyst for at least 6 hr. As is shown in Table 1, it was found that the codimers obtained as the main products have a linear structure in which the β carbon of styrene is bonded to the β carbon of the vinyl compound, with a shifting of the hydrogen on the β carbon of styrene. The relation between the functional groups on vinyl compounds and the yields of the codimers is shown in Table 2. When methyl acrylate bearing a carbomethoxy group is used as the vinyl compound, the best yield of codimers is obtained; the yield decreases in the following sequence: $-CO_2CH_3 > -COCH_3 > -OCOCH_3$. When nitroethylene, which has a strongly electron-withdrawing group, and *n*-butyl vinyl ether, bearing a *n*-butoxy group which is an electron-donating group are used, no codimer has been formed. When nitroethylene is used as the vinyl compound, we obtained a stable yellow-brown precipitate which shows the presence of phenyl and nitro groups in its infrared spectrum. When *n*-butyl vinyl ether is used, a viscous solution containing a higher polymer of *n*-butyl vinyl ether whose infrared spectrum shows the presence of a C–O–C bond is instantaneously formed.

Table 2. Relation between functional groups of vinyl compounds (CH_2=CH–X) and yield of codimers

X	$-NO_2$	$-\overset{\overset{O}{\|}}{C}-CH_3$	$-\overset{\overset{O}{\|}}{C}-O-CH_3$	$-O-\overset{\overset{O}{\|}}{C}-CH_3$	$-OC_4H_9$
Yield[a], %	—	125	220	50	—

a) Yields are based on the catalyst used.

The dependence of the concentration of vinyl compounds on the rates of the codimerization reactions of styrene with methyl acrylate and with vinyl acetate is shown in Fig. 1. The rate of the codimerization of styrene with methyl acrylate is proportional to the concentration of methyl acrylate in a high concentration of styrene and is independent of the concentrations of the reactants in a high concentration of methyl acrylate, because the styrene-palladium chloride complex has been used as a catalyst and the rate of the codimerization was

Table 1. Reaction of styrene and vinyl compounds

Vinyl compound	Products[a]
CH_2=CH–CO_2CH_3	*trans*-$C_6H_5CH{=}CH(CH_2)_2CO_2CH_3$, 190%; *trans*-$C_6H_5CH_2CH{=}CHCH_2CO_2CH_3$, 10%. *trans*-$C_6H_5CH{=}CHCH(CH_3)CO_2CH_3$, 20%. *trans*-$CH_3O_2CCH{=}CH(CH_2)_2CO_2CH_3$, 153%; *trans*-$CH_3O_2CCH_2CH{=}CHCH_2CO_2CH_3$, 16%. Dimers of styrene[b], 18%.
CH_2=CH–$OCOCH_3$	*trans*-$C_6H_5CH{=}CH(CH_2)_2OCOCH_3$, 50%. Dimers of styrene,[b] 32%.
CH=CH–$COCH_3$	*trans*-$C_6H_5CH{=}CH(CH_2)_2COCH_3$, 18%; isomers of codimer,[c] 107%. Dimers of styrene,[b] 14%.

Styrene-palladium complex (Pd): 10.7 mmol, styrene: 0.7 mol, vinyl compound: 0.7 mol. 50 C, 6 hr.
a) Yields are based on the catalyst used.
b) Four isomers of dimer of styrene containing *trans*-1,3-diphenyl-1-butene.
c) Three isomers of codimer of styrene with methyl vinyl ketone which were identified by infrared spectrum.

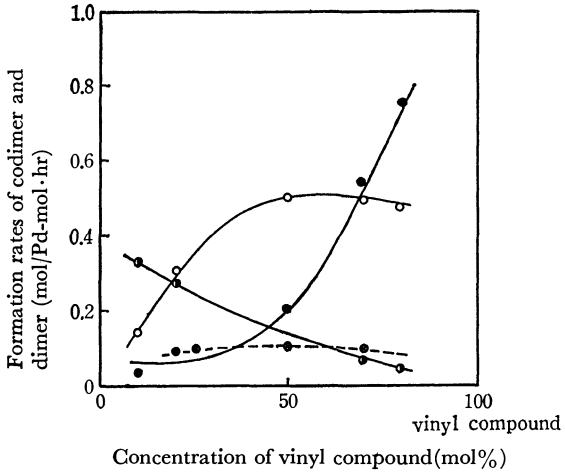

Fig. 1. The dependence of the concentration of vinyl compounds on the formation rates of codimerization and dimerization reactions.
○: Codimer of styrene with methyl acrylate, ●: dimer of methyl acrylate, ◑: dimer of styrene, ⊗: codimer of styrene with vinyl acetate. Styrene-palladium complex (Pd): 10.7 mmol, styrene+vinyl compound: 0.94 mol, nitromethane: 0.47 mol. 50°C.

measured at the point where codimers were formed in an equal amount of the catalyst used. The dimerization rates of styrene and methyl acrylate increase with increases in the styrene and methyl acrylate concentrations respectively, and the increase in the dimerization rate of methyl acrylate is larger than that in the dimerization rate of styrene. An induction period has been observed in the dimerization of methyl acrylate, but not in the dimerization of styrene; this may result from the use of the styrene-palladium complex as a catalyst. The rate of the codimerization of styrene with vinyl acetate is smaller than that of styrene with methyl acrylate and is not remarkable dependent upon the concentration of the reactants.

The solvent effect on the codimerization of styrene with methyl acrylate and on the dimerization of methyl acrylate is summarized in Table 3.[6] The formation ratio of the codimer to the dimer does not remarkably depend on the solvents except in the case of acetic acid. As was observed in the dimerization of ethylene and in the codimerization of styrene with ethylene in previous papers,[7,8] the reaction rate is enhanced in solvents containing the oxygen atom, such as phenol, nitromethane, and nitrobenzene. The reaction rate is larger in systems without a solvent than in acetic acid and benzene solvents. It appears that the reactant itself is a good solvent. Since the solvent effect was not observed in benzene on the dimerization of ethylene[7] or on the codimerization of styrene with ethylene,[8] benzene is deduced to play a role in diluting the catalytic solution. On the other hand, in contrast with the rate of the codimerization of styrene with methyl acrylate, the rate of the dimerization of methyl acrylate in acetic acid is lower than that in benzene. Since acetic acid is a good solvent in the dimerization of ethylene[7] and in the codimerization of styrene with ethylene[8], and since the dimer of styrene in acetic acid is formed in more than 3 mol equivalents of that in systems without a solvent, it may be suggested that acetic acid disturbs the coordination of methyl acrylate to the catalyst through some interactions between acetic acid and methyl acrylate.

Table 3. Solvent effects on the codimerization of styrene with methyl acrylate and on the dimerization of methyl acrylate

Solvent	Formation rate of codimer (mol/Pd-mol·hr)	Formation rate of dimer (mol/Pd-mol·hr)	Dielectric constant[6] ε(°C)
Phenol	0.530	0.311	6.15(20)
Nitromethane	0.495	0.192	22.7(10)
Nitrobenzene	0.431	—	34.8(25)
Dioxane	0.304	0.118	2.28(0)
Non solvent	0.218	0.103	—
Acetic acid	0.197	0.035	9.78(60)
Benzene	0.109	0.063	2.44(0)

Styrene-palladium complex (Pd): 10.7 mmol, styrene: 0.47 mol, methyl acrylate: 0.47mol, solvent: 0.47 mol. Reaction temperature: 50°C.

Furthermore, when the codimerization of styrene-d_3 with ethylene was carried out at 50°C for 6 hr, the results were as follows:

$$CH_2{=}CH_2 + C_6H_5CD{=}CD_2 \longrightarrow CH_{2.02}D_{0.98}{-}CH_{1.22}D_{0.78}{-}CH{=}CH{-}C_6H_5$$
$$H:D = 1.03:0.97$$

This experimental evidence on the distribution of deuterium can be interpreted according to the following scheme:[9]

$$CH_2{=}CH_2 + C_6H_5CD{=}CD_2 \longrightarrow CH_2{=}CH{-}CD_2{-}CHD{-}C_6H_5 \longrightarrow CH_2D{-}CH{=}CD{-}CHD{-}C_6H_5 \longrightarrow$$
$$CH_2D{-}CHD{-}CH{=}CD{-}C_6H_5 \text{ and } CH_2D{-}CH_2{-}CD{=}CD{-}C_6H_5$$

The codimerization reactions of styrene with vinyl compounds have the following characteristic features: (i) the use of methyl acrylate as a vinyl compound gives more codimers than that of the other vinyl compounds; (ii) the codimers produced as main products have a linear structure in which the β carbon of styrene is bonded to the β carbon of vinyl compound *via* a hydrogen shift of the β carbon of styrene; (iii) this reaction is enhanced in solvents containing the oxygen atom, particularly in weak dissociated solvents and in strongly polar solvents such as nitrobenzene, and (iv) the use of nitrobenzene or dioxane as solvent which can not be considered to be hydride sources makes it easy to give the codimer. The codimerization reaction includes the following two processes: (a) the coordina-

9) Harrod and his co-workers reported that the palladium complexes isomerize the olefins by a C_3—C_1 hydrogen shift in the isomerization of 1-heptene-3-d_3.[10]

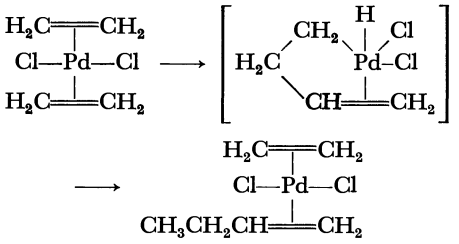
10) J. F. Harrod and A. J. Chalk, *J. Amer. Chem. Soc.*, **88**, 3491 (1966).

tion reaction includes the following two processes: (a) the coordination of the vinyl compound to the palladium ion, and (b) the hydrogen shift between the coordinated styrene and the vinyl compound. An electron-withdrawing property of the functional groups decreases in the following order on the basis of Hammett's σ value:[11]

$-NO_2 > -COCH_3 > -CO_2CH_3 > -OCOCH_3 >$ Phenyl $> n$-butoxy

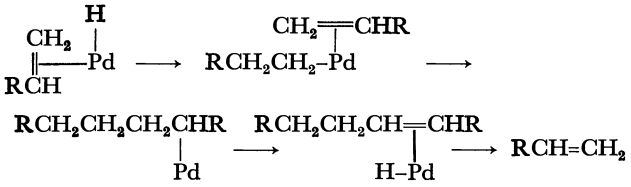
If the π-bond formation between olefins and the palladium (II) ion depends predominantly on the back-donation of filled d-electrons in the palladium ion, the π-bonding ability of the vinyl compound to the palladium ion will decrease with a decrease in the σ value. On the other hand, since hydrogen is easily bonded to most transition metals as a hydride, the ease with which the hydride is formed from the coordinated vinyl compound is the opposite of the order of the σ values. It may be assumed that the best yield of the codimer when methyl acrylate is used in the codimerization of styrene with vinyl cmpounds is derived from these two opposite components.

Recently, Ketley *et al.* have suggested the following mechanism for the palladium-catalyzed dimerization of ethylene;[12]

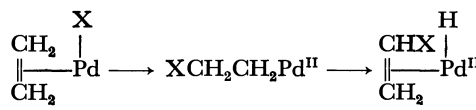


This mechanism can not, however, account for the main process of the dimerization reaction of ethylene, namely, the insertion reaction, because the carbon atom of the ethylene π-bonded to palladium has a partially positive charge, unlike free ethylene, and so the insertion reaction between π-bonded ethylenes can not be expected. It can also not account for the remarkable effect of the solvents described above.

Barlow *et al.* have reported a mechanism of the dimerization of olefins which involves the formation of the palladium hydride as a catalytic active species:[3]

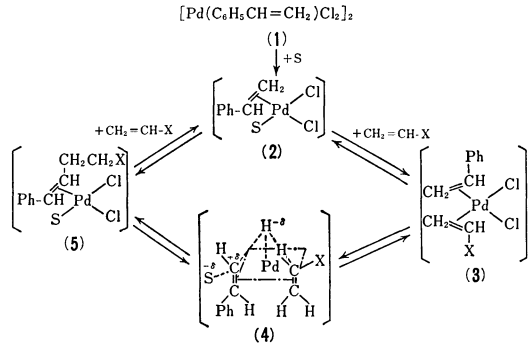


The hydrogen of the initially-formed Pd^{II}–H has been described as resulting from the solvents or the olefins as is shown in the following scheme:



However, this mechanism, assuming the Pd^{II}–H to be a catalytic active species, can not reasonably account for the following facts: (a) styrene and vinyl compounds readily codimerize in systems without a solvent or in such solvents as nitrobenzene and dioxane, which can not be considered to be hydride sources; (b) analysis of the reaction solutions by glcg show no trace of the corresponding halogenated compound, and (c) in the experiment of the codimerization of styrene-d_3 with ethylene, if ethylene and styrene-d_3 are codimerized by Pd^{II}–H and Pd^{II}–D without any exchange reaction of Pd^{II}–H and Pd^{II}–D in the isomerization, the expected products are CH_3–CH_2–CD=CD–C_6H_5 and mixtures of CH_3–CHD–CD=CH–C_6H_5 and CH_3–CHD–CD=CD–C_6H_5 or of CH_2D–CH_2–CD=CD–C_6H_5 and CH_3–CHD–CD=CD–C_6H_5. These results are different from this experimental evidence. On the other hand, the presence of the exchange reaction of Pd^{II}–H and Pd^{II}–D in every stage of the isomerization gives mixtures of numerous products in which deuterium is distributed in various ways. Therefore, the ratio of hydrogen to deuterium in the methyl group of the codimer can be expected to be higher than 2 in the Pd^{II}–H mechanism; the observed ratio was found to be approximately 2 in this experiment. We are inclined to believe that the codimerization proceeds through a reaction path which requires no external source of hydride.

On the basis of the above facts (i)—(iv) and the results of the codimerization reaction of styrene-d_3 with ethylene, we wish to propose the reaction mechanism, with a hydride shift between coordinated styrene and vinyl compound, shown in Scheme 1.[13]



Scheme 1

The styrene-palladium complex (1) initially dissociates into a complex (2) in the presence of a solvent. The coordination of the vinyl compound with the complex (2) results in another complex (3). In the stage of the insertion reaction from the complex (3) to the complex (5) *via* an intermediate (4), the palladium ion easily abstracts the β carbon of styrene as a hydride rather than the vinyllic hydrogen of the vinyl compound, with an electron-withdrawing group, thus reforming the five-coordinate hydridopalladium-olefin intermediate (4). This hydride is added to the α carbon of the vinyl compound with the electron-withdrawing

group to the four-coordinate palladium-alkyl complex and then, this alkyl group is inserted into the partially-positive β carbon of styrene, thus reforming the complex (5) through the coordination of the solvent to a vacant coordination site. The codimerization reaction may proceed by repeating these processes. A nucleophilic approach of the solvent can facilitate the abstraction of a hydride from styrene by the palladium ion and stabilize the partially-positive β carbon of styrene. These functions of the solvent were suggested by Volger in the oxidative dimerization of β-substituted α-olefins by palladium acetate.[14] Recently, Fackler *et al.* have reported ascertaining the presence of the five-coordinate complex by nuclear magnetic-resonance spectroscopy in reactions of xanthates and dithiocarbamates of palladium (II) and platinum (II) with methyldiphenylphosphine[15] while Tayim *et al.* have proposed a reaction mechanism involving the five-coordinate complex as an intermediate in the isomerization catalyzed by the platinum complexes.[16] In addition to the function of the solvent described above, the solvent may catalytically keep the coordination site active through its coordination in the stage of changing from the complex (3) to the complex (5) and may also accelerate the coordination of the vinyl compound through its dissociation in the stage of changing from the complex (2) to the complex (3). The same argument was previously made by the present authors in attempting to explain the dimerization of ethylene[7] and the codimerization of styrene with ethylene.[8]

Conformation of Adsorbed Polymeric Chain. III

Kinsi MOTOMURA, Kōjū SEKITA, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received October 9, 1970)

Average properties of a copolymeric chain in which a segments of the kind A and b segments of the kind B occur alternatively are calculated for an infinite chain length. For the simplest case of $a=b=1$, *i.e.* an alternating copolymeric chain $(-A-B-)_N$, the average number of adsorbed segments of A, $\bar{\nu}_A$, that of B, $\bar{\nu}_B$, and the mean square end-to-end distance $\overline{r^2}$ are computed numerically as functions of the adsorption energies ε_A and ε_B. The values of $\bar{\nu}_A$, $\bar{\nu}_B$, and $\overline{r^2}$ are proportional to N for larger values of η_A $(=\exp(\varepsilon_A/kT))$ than the critical value $(\eta_A)_c$ at fixed η_B, as found for the case of a homogeneous polymeric chain. It is seen that the behavior of the copolymeric chain near an interface is affected distinctively by the adsorption energies of the segments A and B, and the copolymeric chain is forced to adsorb even for a fairly low adsorption energy of the segment of one kind if the adsorption energy of the segment of the other kind is sufficiently large.

Statistical-mechanical theories of the adsorption of polymeric chains at interfaces have been presented by many investigators.[1-7] For the homogeneous polymeric chain which is a long sequence of segments of the same kind, it was shown that the conformation of the isolated polymeric chain near the interface changes discontinuously at a certain value of the adsorption energy which depends on a lattice model used. In the case of the polymeric chain consisting of $n+1$ segments on a simple cubic lattice we obtained results where the average number of adsorbed segments is given by

$$\begin{aligned}
\bar{\nu} &= n\{1-\eta[2(\eta-1)]^{-1} \\
&\quad + \eta[4(\eta-1)^2+(\eta-1)]^{-1/2}\}, && \eta>\eta_c \\
\bar{\nu} &= (5/2)(\pi n/6)^{1/2}, && \eta=\eta_c \\
\bar{\nu} &= 6/(6-5\eta), && \eta<\eta_c
\end{aligned} \tag{1}$$

and the mean-square end-to-end distance by

$$\begin{aligned}
\overline{r^2} &= 2l^2n(\eta-1)[4(\eta-1)^2+(\eta-1)]^{-1/2}, && \eta>\eta_c \\
\overline{r^2} &= (8/9)l^2n, && \eta=\eta_c \\
\overline{r^2} &= l^2n, && \eta<\eta_c
\end{aligned} \tag{2}$$

where η is related to the energy gain per segment associated with the adsorption $-\varepsilon$, by the equation

$$\eta = \exp(\varepsilon/kT), \tag{3}$$

η_c equals 6/5, and l is the distance between neighboring segments.[6,7] It is interesting to estimate the effect

of foreign segments introduced into the polymeric chain upon the above equations. This is useful to understand better the strange behavior of copolymers at interfaces.

We extended the theoretical treatment given in previous papers to a copolymeric chain consisting of segments of various kinds. For convenience, we consider a copolymeric chain in which the segments of kinds A and B, the same in size, occur in alternative succession of a segments of the kind A and b segments of B.

Theoretical

1. Probability of an Adsorbed Polymeric Chain. The behavior of polymer molecules near an interface is represented by a symmetrical random walker whose way is blocked by the interface when the self-excluded volume is neglected and the concentration is extremely dilute. We are concerned with a polymeric chain $(-A_a-B_b-)_N$ consisting of $(a+b)N$ segments lying in the positive z domain of a simple cubic lattice and adsorbing at the interface which is the xy plane through $z=0$. We also assume that the polymeric chain is always adsorbed by the end segments of the chain on the interface, because the dangling chain ends make a negligible contribution to the properties in an adsorbed state $(\eta>\eta_c)$.[4,7] A given conformation of the absorbed polymeric chain, of which one chain end is located at the origin and the other end at a point $(x,y,0)$, is characterized by a sequence of random walkers which touch the interface only at two ends and have probabilities $f_{k_j}(x_j,y_j)$. The probability of the adsorbed polymeric chain is then given by

$$p_{(a+b)N}(x,y,\eta_A,\eta_B) = \sum_m \sum_k \sum_{x,y} \eta_A\eta_B f_{k_m}(x_m,y_m) \prod_{j=1}^{m-1} \eta_j f_{k_j}(x_j,y_j), \tag{4}$$

where

$$\eta_A = \exp(\varepsilon_A/\boldsymbol{k}T), \quad \eta_B = \exp(\varepsilon_B/\boldsymbol{k}T), \tag{5}$$

and η_j takes η_A or η_B according to whether the j-th random walker terminates in the segments A or in B. A set of $\boldsymbol{k}$, $\boldsymbol{x}$, and $\boldsymbol{y}$ means a microscopic state satisfying the conditions

$$\sum_{j=1}^{m} k_j = (a+b)N - 1 \tag{6}$$

which come from the fact that the polymeric chain of $(a+b)N$ segments is replaced by the random walk of $(a+b)N-1$ steps,

$$\sum_{j=1}^{m} x_j = x, \quad \text{and} \quad \sum_{j=1}^{m} y_j = y, \tag{7}$$

and the sums are taken over all possible values. On introducing generating functions

$$\sum_{x,y} p_{(a+b)N}(x,y,\eta_A,\eta_B) \exp(ix\theta+iy\phi) = P_{(a+b)N}(\theta,\phi,\eta_A,\eta_B)$$

$$\sum_{N=1}^{\infty} P_{(a+b)N}(\theta,\phi,\eta_A,\eta_B) w^{(a+b)N-1} = P(\theta,\phi,\eta_A,\eta_B;w) \tag{8}$$

and

$$\sum_{x,y} f_{(a+b)n+k}(x,y) \exp(ix\theta+iy\phi) = F_{(a+b)n+k}(\theta,\phi)$$

$$\sum_{n=0}^{\infty} F_{(a+b)n+k}(\theta,\phi) w^{(a+b)n+k} = F_k(\theta,\phi;w), \tag{9}$$

Eq. (4) becomes

$$P(\theta,\phi,\eta_A,\eta_B;w) = \eta_A \boldsymbol{a}\left(\sum_{m=1}^{\infty} \mathbf{M}^m\right)\boldsymbol{\beta}^+ = \eta_A \boldsymbol{a}\mathbf{M}(\mathbf{I}-\mathbf{M})^{-1}\boldsymbol{\beta}^+, \tag{10}$$

where

$$\mathbf{M} = \begin{pmatrix} \eta_A F_{a+b} & \eta_A F_1 & \cdots \eta_A F_{a-1} & \eta_B F_a & \cdots \eta_B F_{a+b-1} \\ \eta_A F_{a+b-1} & \eta_A F_{a+b} \cdots & \eta_A F_{a-2} & \eta_B F_{a-1} \cdots & \eta_B F_{a+b-2} \\ \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \eta_A F_1 & \eta_A F_2 & \cdots \eta_A F_a & \eta_B F_{a+1} \cdots & \eta_B F_{a+b} \end{pmatrix}, \tag{11}$$

$$\boldsymbol{a} = (1\ 0\ \cdots\ 0), \text{ and } \boldsymbol{\beta} = (0\ \cdots\ 0\ 1).$$

Substituting Eq. (A9) in the Appendix into the above equation, we obtain

$$P(\theta,\phi,\eta_A,\eta_B;w) = \eta_A \Delta_1(1)/D(1), \tag{12}$$

where

$$D(1) = (-1)^{a+b} \begin{vmatrix} \eta_A F_{a+b}-1 & \eta_A F_1 & \cdots \eta_B F_{a+b-1} \\ \eta_A F_{a+b-1} & \eta_A F_{a+b}-1 \cdots & \eta_B F_{a+b-2} \\ \cdots\cdots & \cdots\cdots & \cdots\cdots \\ \eta_A F_1 & \eta_A F_2 & \cdots \eta_B F_{a+b}-1 \end{vmatrix} \tag{13}$$

and

$$\Delta_1(1) = \begin{vmatrix} \eta_A F_1 & \eta_A F_2 \cdots \eta_B F_{a+b-1} \\ \eta_A F_{a+b}-1 & \eta_A F_1 \cdots \eta_B F_{a+b-2} \\ \cdots\cdots & \cdots\cdots \\ \eta_A F_3 & \eta_A F_4 \cdots \eta_B F_1 \end{vmatrix} \tag{14}$$

It is now necessary to know $F_k(\theta,\phi;w)$ as a function of θ, ϕ, and w in order to have an explicit expression of $P(\theta,\phi,\eta_A,\eta_B;w)$.

2. Evaluation of $F_k(\theta,\phi;w)$. There exist relations between the probabilities $f_{(a+b)n+k}(x,y)$ and corresponding probabilities $u_{(a+b)n+k}(x,y)$ of an unrestricted random walk:

$$\begin{aligned} u_{(a+b)n+k}(x,y) &= \sum_{x',y'} f_1(x',y') u_{(a+b)n+k-1}(x-x',y-y') \\ &+ 2\sum_j \sum_{x',y'} f_{(a+b)j+1}(x',y') u_{(a+b)(n-j)+k-1}(x-x',y-y') \\ &+ \cdots\cdots \\ &+ 2\sum_j \sum_{x',y'} f_{(a+b)(j+1)}(x',y') u_{(a+b)(n-j-1)+k}(x-x',y-y'), \\ & k = 1, 2, \cdots, a+b. \end{aligned} \tag{15}$$

Defining generating functions

$$\sum_{x,y} u_{(a+b)n+k}(x,y) \exp(ix\theta+iy\phi) = U_{(a+b)n+k}(\theta,\phi)$$

$$\sum_{n=0}^{\infty} U_{(a+b)n+k}(\theta,\phi) w^{(a+b)n+k} = U_k(\theta,\phi;w)^{8)} \tag{16}$$

analogous to Eq. (9), Eq. (15) becomes

$$\begin{aligned} U_k(\theta,\phi;w) &= [2F_1(\theta,\phi;w) - wF_1(\theta,\phi)]U_{k-1}(\theta,\phi;w) \\ &+ 2F_2(\theta,\phi;w)U_{k-2}(\theta,\phi;w) + \cdots \\ &+ 2F_{a+b}(\theta,\phi;w)U_k(\theta,\phi;w), \\ & k = 1, 2, \cdots, a+b-1 \\ U_{a+b}(\theta,\phi;w) - U_0(\theta,\phi) &= [2F_1(\theta,\phi;w) \\ &- wF_1(\theta,\phi)]U_{a+b-1}(\theta,\phi;w) \\ &+ 2F_2(\theta,\phi;w)U_{a+b-2}(\theta,\phi;w) + \cdots \\ &+ 2F_{a+b}(\theta,\phi;w)U_{a+b}(\theta,\phi;w). \end{aligned} \tag{17}$$

Rearranging the above equations after introducing

8) For $k=a+b$ the equation is slightly modified by adding $U_0(\theta,\phi)$ to the left-hand side.

$$U_0(\theta, \phi) = 1 \text{ and } F_1(\theta, \phi) = c/3 \tag{18}$$

where

$$c = \cos\theta + \cos\phi, \tag{19}$$

we obtain

$$\begin{aligned}
&U_{k-1}(\theta, \phi; w)F_1(\theta, \phi; w) + U_{k-2}(\theta, \phi; w)F_2(\theta, \phi; w) + \cdots \\
&\quad + U_k(\theta, \phi; w)F_{a+b}(\theta, \phi; w) = (1/2)[U_k(\theta, \phi; w) \\
&\quad + (cw/3)U_{k-1}(\theta, \phi; w)], \quad k = 1, 2, \cdots, a+b-1 \\
&U_{a+b-1}(\theta, \phi; w)F_1(\theta, \phi; w) + U_{a+b-2}(\theta, \phi; w)F_2(\theta, \phi; w) + \cdots \\
&\quad + U_{a+b}(\theta, \phi; w)F_{a+b}(\theta, \phi; w) = (1/2)[U_{a+b}(\theta, \phi; w) \\
&\quad + (cw/3)U_{a+b-1}(\theta, \phi; w) - 1].
\end{aligned} \tag{20}$$

These equations allow us to evaluate $F_k(\theta, \phi, w)$. We have

$$\begin{aligned}
F_1(\theta, \phi; w) &= cw/6 + D_1/D \\
F_k(\theta, \phi; w) &= D_k/D, \quad k = 2, 3, \cdots, a+b-1 \\
F_{a+b}(\theta, \phi; w) &= 1/2 + D_{a+b}/D,
\end{aligned} \tag{21}$$

where

$$D = \begin{vmatrix} U_{a+b} & U_{a+b-1} \cdots U_1 \\ U_1 & U_{a+b} \cdots U_2 \\ \cdots\cdots & \cdots\cdots \\ U_{a+b-1} & U_{a+b-2} \cdots U_{a+b} \end{vmatrix} \tag{22}$$

and D_k is the determinant obtained on replacing the respective elements in the k-th column of D by

$$0, 0, \cdots, 0, -1/2.$$

$U_j(\theta, \phi; w)$ in the determinants are given by

$$\begin{aligned}
U_j(\theta, \phi; w) &= \frac{1}{2\pi}\int_{-\pi}^{\pi} d\phi \left[\frac{w}{3}(c+\cos\phi)\right]^j \Big/ \\
&\quad \left\{1 - \left[\frac{w}{3}(c+\cos\phi)\right]^{a+b}\right\} \\
&= [3/(a+b)]\sum_{l=0}^{a+b-1} \{1/\omega^{(a+b-j)l}[(3 - cw/\omega^l)^2 \\
&\quad - (w/\omega^l)^2]^{1/2}\}, \quad j = 1, 2, \cdots, a+b,
\end{aligned} \tag{23}$$

where

$$\omega = \exp[2\pi i/(a+b)]. \tag{24}$$

3. Expressions for Average Properties. We may write $P(\theta, \phi, \eta_A, \eta_B; w)$, which we will denote by $P(c, \eta_A, \eta_B; w)$ hereafter, as an explicit function of c, η_A, η_B, and w. It is now possible to calculate the average properties of the adsorbed polymeric chain. Taking into account Eqs. (4) and (8), the mean square end-to-end distance is given by

$$\overline{r^2} = l^2[c\{\partial P_{(a+b)N}(c, \eta_A, \eta_B)/\partial c\}/P_{(a+b)N}(c, \eta_A, \eta_B)]_{c=2}, \tag{25}$$

where $P_{(a+b)N}(c, \eta_A, \eta_B)$ is used instead of $P_{(a+b)N}(\theta, \phi, \eta_A, \eta_B)$. On the other hand, the average number of adsorbed segments of the kind A per polymeric chain is computed by

$$\bar{\nu}_A = \eta_A\{\partial P_{(a+b)N}(2, \eta_A, \eta_B)/\partial\eta_A\}/P_{(a+b)N}(2, \eta_A, \eta_B) \tag{26}$$

and that of B by

$$\bar{\nu}_B = \eta_B\{\partial P_{(a+b)N}(2, \eta_A, \eta_B)/\partial\eta_B\}/P_{(a+b)N}(2, \eta_A, \eta_B). \tag{27}$$

In order to carry out the calculation of Eqs. (25), (26), and (27), it is necessary to know $P_{(a+b)N}(c, \eta_A, \eta_B)$ and its derivatives with respect to c, η_A, and η_B. These functions are found by applying Cauchy's residue theorem to Eq. (8). We obtain

$$\begin{aligned}
P_{(a+b)N}(c, \eta_A, \eta_B) &= (1/2\pi i)\oint_{C_0} (1/w^{(a+b)N}) \\
&\quad \times P(c, \eta_A, \eta_B; w)dw,
\end{aligned} \tag{28}$$

$$\begin{aligned}
[\partial P_{(a+b)N}(c, \eta_A, \eta_B)/\partial c]_{c=2} &= (1/2\pi i)\oint_{C_0} (1/w^{(a+b)N}) \\
&\quad \times [\partial P(c, \eta_A, \eta_B; w)/\partial c]_{c=2}dw,
\end{aligned} \tag{29}$$

$$\begin{aligned}
\partial P_{(a+b)N}(2, \eta_A, \eta_B)/\partial\eta_A &= (1/2\pi i)\oint_{C_0} (1/w^{(a+b)N}) \\
&\quad \times \{\partial P(2, \eta_A, \eta_B; w)/\partial\eta_A\}dw,
\end{aligned} \tag{30}$$

and

$$\begin{aligned}
\partial P_{(a+b)N}(2, \eta_A, \eta_B)/\partial\eta_B &= (1/2\pi i)\oint_{C_0} (1/w^{(a+b)N}) \\
&\quad \times \{\partial P(2, \eta_A, \eta_B: w)/\partial\eta_B\}dw,
\end{aligned} \tag{31}$$

where the contour C_0 includes only the pole at $w=0$.

4. Average Properties of $(-A-B-)_N$. Taking up the simplest case $a=b=1$, *i.e.* an alternating copolymeric chain $(-A-B-)_N$, we will consider the effect of different adsorption energies of segments A and B on the conformation. Let us first derive the generating functions of unrestricted random walk $U_1(c; w)$ and $U_2(c; w)$ which are necessary for knowing $F_1(c; w)$ and $F_2(c; w)$. This is done by introducing $a=b=1$ and $\omega=-1$ resulting from Eq. (24) into Eq. (23); we have

$$\begin{aligned}
U_1(c; w) &= (3/2)\{[(3-cw)^2 - w^2]^{-1/2} - [(3+cw)^2 - w^2]^{-1/2}\} \\
U_2(c; w) &= (3/2)\{[(3-cw)^2 - w^2]^{-1/2} + [(3+cw)^2 - w^2]^{-1/2}\}.
\end{aligned} \tag{32}$$

Substituting these equations and Eq. (22) into Eq (21), we get

$$\begin{aligned}
F_1(c; w) &= cw/6 - (1/12)\{[(3-cw)^2 - w^2]^{1/2} \\
&\quad - [(3+cw)^2 - w^2]^{1/2}\} \\
F_2(c: w) &= 1/2 - (1/12)\{[(3-cw)^2 - w^2]^{1/2} \\
&\quad + [(3+cw)^2 - w^2]^{1/2}\}.
\end{aligned} \tag{33}$$

The generating function of the probability of adsorbed polymeric chain is connected with $F_1(c; w)$ and $F_2(c; w)$ with the aid of Eqs. (12), (13), and (14), and is expressed as the explicit function of c, η_A, η_B, and w:

$$P(c, \eta_A, \eta_B; w) = \eta_A\eta_B F_1(c; w)/D(c, \eta_A, \eta_B, w), \tag{34}$$

where

$$\begin{aligned}
D(c, \eta_A, \eta_B, w) &= 1 - (\eta_A + \eta_B)F_2(c; w) \\
&\quad + \eta_A\eta_B[F_2(c: w)^2 - F_1(c; w)^2] \\
&= \frac{(\eta_A+\eta_B)^2}{4\eta_A\eta_B}\left\{\left(1 - \frac{1}{6}\frac{2\eta_A\eta_B}{\eta_A+\eta_B}(3+cw\right.\right. \\
&\quad \left.\left. - [(3-cw)^2 - w^2]^{1/2}\right)\left(1 - \frac{1}{6}\frac{2\eta_A\eta_B}{\eta_A+\eta_B}\right.\right. \\
&\quad \left.\left. \times (3 - cw - [(3+cw)^2 - cw^2]^{1/2})\right) \right. \\
&\quad \left. - \left(\frac{\eta_A - \eta_B}{\eta_A + \eta_B}\right)^2\right\}.
\end{aligned} \tag{35}$$

On introducing Eq. (34) into Eq. (28), the generating function $P_{2N}(2, \eta_A, \eta_B)$ is given by

$$P_{2N}(2, \eta_A, \eta_B) = \frac{1}{2\pi i}\oint_{C_0} \frac{1}{w^{2N}} \frac{\eta_A\eta_B F_1(2; w)}{D(2, \eta_A, \eta_B, w)} dw. \tag{36}$$

It is seen from Eq. (35) that the equation $D(2, \eta_A, \eta_B, w)=0$ has two roots w_1 and w_2 which are related to each other by

$$w_1 = -w_2 \tag{37}$$

and coincide with branch-points $w=1$ and -1 respectively for a set of η_A and η_B satisfying

$$36 - 6(3-6^{1/2})(\eta_A+\eta_B) - 5(24^{1/2}-1)\eta_A\eta_B = 0. \tag{38}$$

We are interested in the behavior of the adsorbed polymeric chain only when the values of η_A and η_B are larger than the critical values given by Eq. (38), because the polymeric chain is in reality in the adsorbed state for the values of η_A and η_B. If the values of η_A and η_B are larger than the critical values and N is infinitely large, the principal contribution to the integral of Eq. (36) comes from residues of w_1 and w_2.[5,6] Thus we have

$$P_{2N}(2, \eta_A, \eta_B) = -\frac{1}{{w_1}^{2N}} \frac{\eta_A\eta_B F_1(2; w_1)}{\partial D(2, \eta_A, \eta_B, w_2)/\partial w} - \frac{1}{{w_2}^{2N}} \frac{\eta_A\eta_B F_1(2; w_2)}{\partial D(2, \eta_A, \eta_B, w_2)/\partial w}, \tag{39}$$

where $\partial D(2, \eta_A, \eta_B, w_1)/\partial w$ and $\partial D(2, \eta_A, \eta_B, w_2)/\partial w$ denote the values of $\partial D(2, \eta_A, \eta_B, w)/\partial w$ at $w=w_1$ and w_2, respectively. Combining

$$\partial D(2, \eta_A, \eta_B, w)/\partial w = -(\eta_A+\eta_B)\partial F_2(2; w)/\partial w + 2\eta_A\eta_B[F_2(2; w)\partial F_2(2; w)/\partial w - F_1(2; w)\partial F_1(2; w)/\partial w] \tag{40}$$

where

$$\partial F_1(2; w)/\partial w = 1/3 + (1/4)\{(2-w)[(3-2w)^2-w^2]^{-1/2} + (2+w)[(3+2w)^2-w^2]^{1/2}\}$$
$$\partial F_2(2; w)/\partial w = (1/4)\{(2-w)[(3-2w)^2-w^2]^{-1/2} - (2+w)[(3+2w)^2-w^2]^{-1/2}\} \tag{41}$$

with Eq. (37), we obtain

$$\partial D(2, \eta_A, \eta_B, w_1)/\partial w = -\partial D(2, \eta_A, \eta_B, w_2)/\partial w. \tag{42}$$

From this and

$$F_1(2; w_1) = -F_1(2; w_2), \tag{43}$$

Eq. (39) is reduced to

$$P_{2N}(2, \eta_A, \eta_B) = -\frac{2}{{w_1}^{2N}} \frac{\eta_A\eta_B F_1(2; w_1)}{\partial D(2, \eta_A, \eta_B, w_1)/\partial w} \tag{44}$$

On the other hand, the substitution of the derivative of $P(c, \eta_A, \eta_B; w)$ with respect to c into Eq. (29) gives

$$\left[\frac{\partial P_{2N}(c, \eta_A, \eta_B)}{\partial c}\right]_{c=2} = \frac{1}{2\pi i}\oint_{c, w^{2N}} \frac{dw}{} \left[\frac{\eta_A\eta_B\partial F_1(2; w)/\partial c}{D(2, \eta_A, \eta_B, w)} - \frac{\eta_A\eta_B F_1(2; w)\partial D(2, \eta_A, \eta_B, w)/\partial c}{D(2, \eta_A, \eta_B, w)^2}\right], \tag{45}$$

where

$$\partial D(2, \eta_A, \eta_B, w)/\partial c = -(\eta_A+\eta_B)\partial F_2(2; w)/\partial c + 2\eta_A\eta_B[F_2(2; w)\partial F_2(2; w)/\partial c - F_1(2; w)\partial F_1(2; w)/\partial c] \tag{46}$$

in which

$$\partial F_1(2; w)/\partial c = w/6 + (w/12)\{(3-2w)[(3-2w)^2-w^2]^{-1/2} + (3+2w)[(3+2w)^2-w^2]^{-1/2}\}$$
$$\partial F_2(2; w)/\partial c = (w/12)\{(3-2w)[(3-2w)^2-w^2]^{-1/2} - (3+2w)[(3+2w)^2-w^2]^{-1/2}\}. \tag{47}$$

Carrying out integration in a similar way and retaining the predominant term in the limit $N\gg1$, Eq. (45) becomes

$$\left[\frac{\partial P_{2N}(c, \eta_A, \eta_B)}{\partial c}\right]_{c=2} = -\frac{2N}{{w_1}^{2N+1}} \frac{\eta_A\eta_B F_1(2; w_1)\partial D(2, \eta_A, \eta_B, w_1)/\partial c}{[\partial D(2, \eta_A, \eta_B, w_1)/\partial w]^2}. \tag{48}$$

We may obtain expressions for $\partial P_{2N}(2, \eta_A, \eta_B)/\partial\eta_A$ and $\partial P_{2N}(2, \eta_A, \eta_B)/\partial\eta_B$ by using a method similar to that used to derive the above equation:

$$\frac{\partial P_{2N}(2, \eta_A, \eta_B)}{\partial\eta_A} = -\frac{2N}{{w_1}^{2N+1}} \frac{\eta_A\eta_B F_1(2; w_1)\partial D(2, \eta_A, \eta_B, w_1)/\partial\eta_A}{[\partial D(2, \eta_A, \eta_B, w_1)/\partial w]^2}$$
$$\frac{\partial P_{2N}(2, \eta_A, \eta_B)}{\partial\eta_B} = -\frac{2N}{{w_1}^{2N+1}} \frac{\eta_A\eta_B F_1(2; w_1)\partial D(2, \eta_A, \eta_B, w_1)/\partial\eta_B}{[\partial D(2, \eta_A, \eta_B, w_1)/\partial w]^2} \tag{49}$$

where

$$\partial D(2, \eta_A, \eta_B, w)/\partial\eta_A = -F_2(2; w) + \eta_B[F_2(2; w)^2-F_1(2; w)^2]$$
$$\partial D(2, \eta_A, \eta_B, w)/\partial\eta_B = -F_2(2; w) + \eta_A[F_2(2; w)^2-F_1(2; w)^2]. \tag{50}$$

The final equations for the average properties are derived by substituting Eqs. (44), (48), and (49) into Eqs. (25), (26), and (27):

$$\overline{r^2} = 2Nl^2\frac{2}{w_1}\frac{\partial D(2, \eta_A, \eta_B, w_1)/\partial c}{\partial D(2, \eta_A, \eta_B, w_1)/\partial w}, \tag{51}$$

$$\bar{\nu}_A = 2N\frac{\eta_A}{w_1}\frac{\partial D(2, \eta_A, \eta_B, w_1)/\partial\eta_A}{\partial D(2, \eta_A, \eta_B, w_1)/\partial w}, \tag{52}$$

and

$$\bar{\nu}_B = 2N\frac{\eta_B}{w_1}\frac{\partial D(2, \eta_A, \eta_B, w_1)/\partial\eta_B}{\partial D(2, \eta_A, \eta_B, w_1)/\partial w}. \tag{53}$$

We can now calculate the average values $\overline{r^2}$, $\bar{\nu}_A$, and $\bar{\nu}_B$ of the polymeric chain $(\text{–A–B–})_N$ at the interface as functions of η_A and η_B and compare them with previous results.

Discussion

Let us first consider how the average number of adsorbed segments of kind A in the alternating copolymeric chain $(\text{–A–B–})_N$ varies with η_A in the limit $N\gg1$ when η_B has a given value. This is determined by numerical calculation of Eq. (52) which is made by evaluating one root w_1 of the equation $D(2, \eta_A, \eta_B, w)=0$ at a given set of η_A and η_B and then substituting the root into Eq. (52) with Eqs. (40) and (50). The variation of $\bar{\nu}_A$ with η_A at few fixed values of η_B is illustrated in Fig. 1, where the ratio $\bar{\nu}_A/2N$ is plotted against ε_A measured in the unit kT. It is seen that the average number of adsorbed segments is proportional to the total number of segments of the copolymeric chain for values of η_A larger than the critical value $(\eta_A)_c$ derived from Eq. (38) at given η_B, as found for the case of a homogeneous polymeric chain consisting of identical segments. The critical value $(\eta_A)_c$ increases remarkably with the decrease in η_B. The increase of $\bar{\nu}_A$ with η_A is slower than the corresponding one of the homogeneous polymeric chain calculated by Eq. (1).

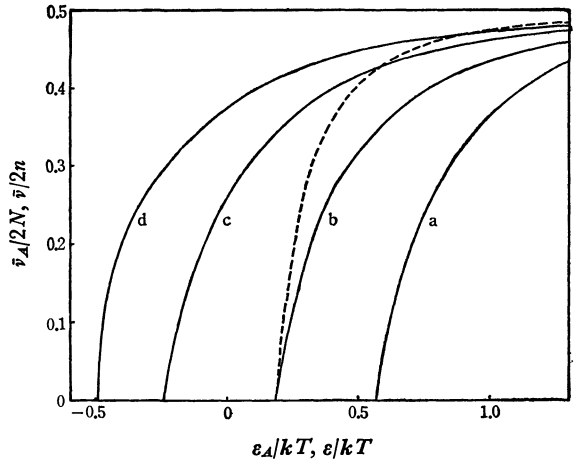

Fig. 1. The ratio $\bar{\nu}_A/2N$ of the copolymeric chain $(-A-B-)_N$ is plotted against ε_A/kT in the limit $N \gg 1$: (a) $\varepsilon_B/kT = -0.223$, (b) 0.182, (c) 0.588, (d) 0.916. The dotted line corresponds to the homogeneous polymeric chain calculated by Eq. (1).

It is probable that the adsorption of the segment A in the copolymeric chain is obstructed by the existence of the segment B having a low adsorption energy when $\eta_B > 6/5$ ($\varepsilon_B/kT < 0.182$). On the other hand, when $\eta_B > 6/5$, adsorption is preferred at the initial stage, becomes equal to that of the homogeneous polymeric chain at $\eta_A = \eta_B$, and then accepts a negative contribution at larger η_A.

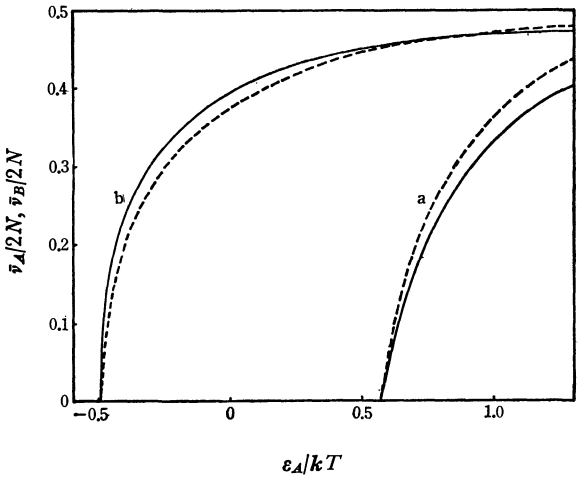

Fig. 2. Comparison of $\bar{\nu}_B/2N$ *versus* ε_A/kT (solid line) and $\bar{\nu}_A/2N$ *versus* ε_A/kT (dotted line) at (a) $\varepsilon_B/kT = -0.223$ and (b) 0.916.

It is also interesting to see the variation of the average number of adsorbed segments of kind B with η_A when η_B is given. The plot of $\bar{\nu}_B/2N$ against ε_A/kT is shown in Fig. 2 where the curves are calculated by Eq. (53) by a similar procedure. Adsorption of segment B occurs and increases gradually with η_A even when η_B has a value lower than 6/5 at which the homogeneous polymeric chain consisting of B segments does not exist in the adsorbed state. For $\eta_B > 6/5$, the value of $\bar{\nu}_B$ increases fairly steeply with η_A.

From the above results, we can know the effect of the adsorption energy of the segments on the total average number of adsorbed segments of the alternating

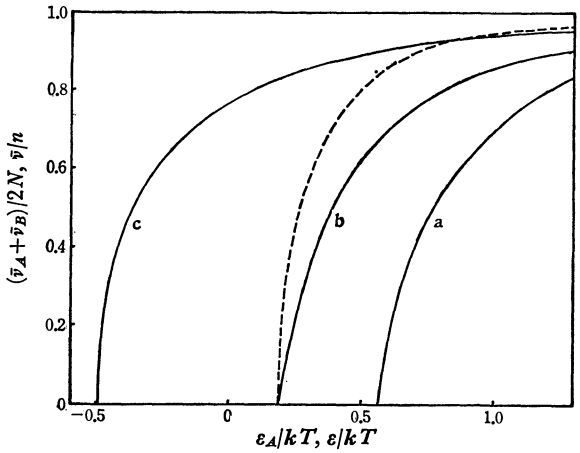

Fig. 3. The sum $(\bar{\nu}_A+\bar{\nu}_B)/2N$ is plotted against ε_A/kT: (a) $\varepsilon_B/kT = -0.223$, (b) 0.182, (c) 0.916. $\bar{\nu}/n$ of Eq. (1) is shown by the dotted line.

copolymeric chain. In Fig. 3, the sum of $\bar{\nu}_A/2N$ and $\bar{\nu}_B/2N$ given in Figs. 1 and 2 *versus* ε_A/kT curves at fixed values of η_B are illustrated together with the curve of a homogeneous polymeric chain calculated by Eq. (1). It is noticeable that the behavior of the copolymeric chain near an interface is affected distinctly by the adsorption energies of segments A and B, and the copolymeric chain is forced to adsorb even for a fairly low adsorption energy of the segment of one kind if the adsorption energy of the segment of the other kind is sufficiently large.

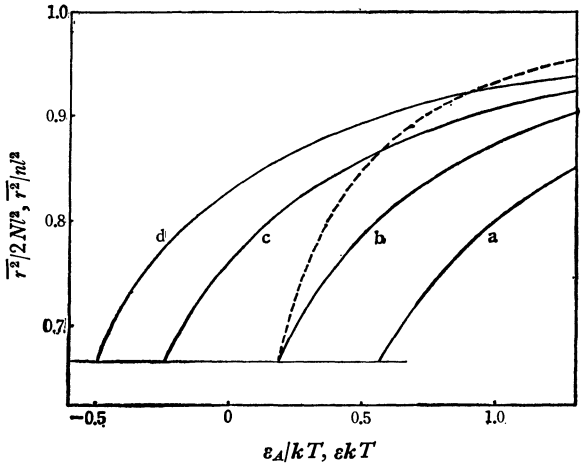

Fig. 4. The ratio $\overline{r^2}/2Nl^2$ of the copolymeric chain is plotted against ε_A/kT: (a) $\varepsilon_B/kT = -0.223$, (b) 0.182, (c) 0.588, (d) 0.916. The dotted line indicates $\overline{r^2}/nl^2$ given by Eq. (2).

Finally we evaluate the end-to-end distance of the copolymeric chain $(-A-B-)_N$ in the limit $N \gg 1$. The value of $\overline{r^2}$ calculated from Eq. (51) by a similar procedure is given as a function of ε_A/kT at the constant value of ε_B/kT in Fig. 4. The effect of adsorption energies on the end-to-end distance is remarkably large in comparison to those on the average number of adsorbed segments. This seems in part due to the fact that the symmetric random walk model which allows any step to retrace the previous one on a simple cubic lattice shortens specifically the end-to-end distance

of the alternating copolymeric chain at the small value of η_B.

Average properties of copolymeric chains of other kinds will be discussed elsewhere.

Appendix

The square matrix of order $a+b$, **M**, of Eq. (11) is related to a diagonal matrix by

$$\mathbf{M} = \mathbf{T}\Lambda\mathbf{T}^{-1}, \tag{A1}$$

where

$$\Lambda = \begin{pmatrix} \lambda_1 & 0 & \cdots & 0 \\ 0 & \lambda_2 & \cdots & 0 \\ \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & \lambda_{a+b} \end{pmatrix}, \tag{A2}$$

λ_i being the eigenvalues of **M**. The eigenvectors of **M** can be obtained by solving simultaneous equations:

$$\begin{aligned} &(\eta_A F_{a+b}-\lambda_j)t_{1,j} + \eta_A F_1 t_{2,j} + \cdots + \eta_B F_{a+b-1} t_{a+b,j} = 0 \\ &\eta_A F_{a+b-1} t_{1,j} + (\eta_A F_{a+b}-\lambda_j)t_{2,j} + \cdots + \eta_B F_{a+b-2} t_{a+b,j} = 0 \\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \\ &\eta_A F_1 t_{1,j} + \eta_A F_2 t_{2,j} + \cdots + (\eta_B F_{a+b}-\lambda_j)t_{a+b,j} = 0, \\ &\qquad j = 1, 2, \cdots, a+b. \end{aligned} \tag{A3}$$

For notational simplicity it may be taken that

$$t_{1,j} = 1, \quad j = 1, 2, \cdots, a+b. \tag{A4}$$

The other vector elements are obtained from the $a+b-1$ equations out of Eq. (A3); we have

$$t_{i,j} = \Delta_i(\lambda_j)/\Delta_1(\lambda_j), \quad i = 2, 3, \cdots, a+b. \quad \text{and} \quad j = 1, 2, \cdots, a+b, \tag{A5}$$

where

$$\Delta_1(\lambda_j) = \begin{vmatrix} \eta_A F_1 & \eta_A F_2 \cdots \eta_B F_{a+b-1} \\ \eta_A F_{a+b}-\lambda_j & \eta_A F_1 \cdots \eta_B F_{a+b-2} \\ \cdots\cdots & \cdots\cdots\cdots\cdots \\ \eta_A F_3 & \eta_A F_4 \cdots \eta_B F_1 \end{vmatrix} \tag{A6}$$

and $\Delta_i(\lambda_j)$ is the determinant obtained on replacing the respective elements in the $(i-1)$-th column of $\Delta_1(\lambda_j)$ by

$$-(\eta_A F_{a+b}-\lambda_j), \; -\eta_A F_{a+b-1}, \; \cdots, \; -\eta_A F_2.$$

The transformation matrix **T** consists of the eigenvectors obtained above:

$$\mathbf{T} = (t_{i,j}) \tag{A7}$$

$$\mathbf{T}^{-1} = (t_{i,j}^{-1}) \tag{A8}$$

where

$$t_{i,j}^{-1} = \text{cofactor}\,(t_{j,i})/|\mathbf{T}|.$$

By use of Eq. (A1) with Eqs. (A2), (A7), and (A8), it follows that

$$\begin{aligned} \boldsymbol{\alpha}\mathbf{M}(\mathbf{I}-\mathbf{M})^{-1}\boldsymbol{\beta}^+ &= \boldsymbol{\alpha}\mathbf{T}\Lambda(\mathbf{I}-\Lambda)^{-1}\mathbf{T}^{-1}\boldsymbol{\beta}^+ \\ &= \sum_{j=1}^{a+b} t_{1,j}\lambda_j(1-\lambda_j)^{-1}t_{j,a+b}^{-1} \\ &= \Delta_1(1)/D(1), \end{aligned} \tag{A9}$$

where

$$D(1) = (-1)^{a+b}|\mathbf{M}-\mathbf{I}| \tag{A10}$$

and $\Delta_1(1)$ is Eq. (A6) where λ_j is equated to unity.

Conformation of Adsorbed Polymeric Chain. IV

Kinsi MOTOMURA, Yoshikiyo MOROI, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received October 9, 1970)

In order to develop further the theoretical treatment of a polymeric chain adsorbed at an interface, a random walk model, in which each step has the same probability except that no step can retrace the preceding one on a simple cubic lattice, has been used. The average number of adsorbed segments $\bar{\nu}$, the average number of trains $\bar{m}$, and the mean square end-to-end distance $\overline{r^2}$ are calculated as functions of the adsorption energy of segment ε and the number of segments n when n is infinitely large. The average numbers of segments in a train and a loop, $\bar{k}'$ and $\bar{k}$, are also calculated. Through the increment in the value of critical adsorption energy ε_c, prohibition of immediate reversal for the random walk fairly influences the average properties of adsorbed polymeric chain. The decrease in $\bar{m}$ and the increase in $\bar{k}'$ with ε/kT at its large values are remarkable in comparison with those of the symmetric random walk, which may be accounted for by the diminution of the chance of making loops. It is shown that $\overline{r^2}$ is equivalent to the mean square two-dimensional end-to-end distance of a restricted random walk without immediate reversals on a simple cubic lattice at ε_c/kT and approaches that on a simple square lattice in the limit $\varepsilon/kT\rightarrow\infty$.

In the previous papers[1-3] the adsorption of polymeric chains at an interface was analyzed by making use of the symmetric random walk in which the probability of the next step at any stage is not influenced by that of the preceding one. McCrackin[4] and Bluestone and Cronan[5] have estimated numerically average

properties of the adsorbed polymeric chain having a relatively small number of segments by performing a Monte Carlo calculation to treat the effect of the self-exclusion. Rubin[6] has derived the expressions for the average number of adsorbed segments per polymeric chain and the mean distance of the end of a polymeric chain from the interface by means of a random walk model, when the number of segments of the polymeric chain is much larger than unity. In his model the direction of each step is assumed to be at right angles to the direction of the preceding step. A better knowledge about the behavior of a polymer molecule at an interface in an extreme dilution may be obtained by taking a correlation between steps of a random walker into consideration.

In this paper we wish to consider a restricted random walk in which each step has the same probability except that any step is forbidden to retrace its previous one on the simple cubic lattice and to know how the correlation between neighboring steps affects the conformation of the adsorbed polymeric chain.

Theoretical

1. Probability of an Adsorbed Polymeric Chain. As we are concerned only with the behavior of a polymeric chain in an adsorbed state, we assume that both the end segments of the polymeric chain are adsorbed on an interface; the adsorbed polymeric chain consists of an alternate sequence of trains and loops. Denoting the probabilities of loop and train by $f_{kj}(x_j, y_j)$ and $g_{k'j}(x'_j, y'_j)$, the probability of the adsorbed polymeric chain composed of $n+1$ segments is given by

$$p_n(x,y,t,\eta) = \sum_m \sum_{\mathbf{k}} \sum_{\mathbf{x},\mathbf{y}} \prod_{j=1}^{m} [t\eta^{k'_j+1} g_{k'_j}(x'_j, y'_j)] \prod_{j=1}^{m-1} f_{k_j}(x_j, y_j) \tag{1}$$

where

$$\eta = \exp(\varepsilon/kT). \tag{2}$$

Here $-\varepsilon$ is the energy gain per segment associated with the adsorption and t is the parameter to evaluate the number of trains. A set of $\mathbf{k}$, $\mathbf{x}$, and $\mathbf{y}$ means a microscopic state satisfying

$$n = \sum_j k_j + \sum_j k'_j, \quad x = \sum_j x_j + \sum_j x'_j,$$
$$\text{and} \quad y = \sum_j y_j + \sum_j y'_j$$

and the sums are taken over all possible values. On introducing generating functions

$$P_n(\theta,\phi,t,\eta) = \sum_{x,y} p_n(x,y,t,\eta) \exp(ix\theta + iy\phi)$$

$$P(\theta,\phi,t,\eta;w) = \sum_{n=1}^{\infty} P_n(\theta,\phi,t,\eta) w^n \tag{3}$$

and the corresponding ones for $f_k(x, y)$ and $g_k(x, y)$, we obtain

$$P(\theta,\phi,t,\eta;w) = t\eta G(\theta,\phi;\eta w)/[1 - t\eta G(\theta,\phi;\eta w) F(\theta,\phi;w)]. \tag{4}$$

It is now necessary to calculate $F(\theta, \phi; w)$ and $G(\theta, \phi; \eta w)$. Let us define the probability of the restricted random walk which arrives at a point $(x, y, 0)$ from the origin after n steps are $q_n(x, y)$ and that in which the direction of the final step is $-z$ as $q_n^{-z}(x, y)$. There exists a relation between $q_n(x, y)$, $q_n^{-z}(x, y)$, and $f_n(x, y)$:

$$q_n^{-z}(x,y) = \sum_{x',y'} \sum_{l=3}^{n} [q_{n-l}(x-x', y-y') - q_{n-l}^{-z}(x-x', y-y')] f_l(x', y'). \tag{5}$$

Introducing the generating functions analogous to Eq. (3), the above equation becomes

$$F(\theta,\phi;w) = [Q(\theta,\phi;w) - 1/6]/[Q(\theta,\phi;w) - Q^{-z}(\theta,\phi;w)] - 1. \tag{6}$$

With the help of the generating function of the random walk with no immediate reversals on the simple cubic lattice derived by Domb and Fisher[7]

$$Q(\theta,\phi,\psi;w) = [15 - (\cos\theta + \cos\phi + \cos\psi)w]/[15 - 6(\cos\theta + \cos\phi + \cos\psi)w + 3w^2], \tag{7}$$

$Q(\theta, \phi; w)$ is given by the expression

$$Q(\theta,\phi;w) = (1/2\pi)\int_{-\pi}^{\pi} Q(\theta,\phi,\psi;w)\,d\psi = (1/6)\{(25-w^2)[(5-2cw+w^2)^2 - 4w^2]^{-1/2} + 1\}, \tag{8}$$

where

$$c = \cos\theta + \cos\phi. \tag{9}$$

By a similar procedure, it follows that

$$Q(\theta,\phi;w) - Q^{-z}(\theta,\phi;w) = (5/12)\{5 + 2cw - w^2 + [(5-2cw+w^2)^2 - 4w^2]^{1/2}\}[(5-2cw+w^2)^2 - 4w^2]^{-1/2}. \tag{10}$$

Substituting Eqs. (8) and (10) into Eq. (6), we obtain

$$F(\theta,\phi;w) = (1/5)\{25 - 10cw + 3w^2 - 5[(5-2cw+w^2)^2 - 4w^2]^{1/2}\}/\{5 + 2cw - w^2 + [(5-2cw+w^2)^2 - 4w^2]^{1/2}\}. \tag{11}$$

On the other hand, $g_n(x, y)$ is the probability of a two-dimensional random walk in which the probability of each step is equal to 1/5 except that no step retraces the previous one on a simple square lattice and is correlated with the probability of the corresponding symmetric random walk $u_n(x, y)$:

$$u_{n+2}(x,y) = (1/9)u_n(x,y) + (1/12)\sum_{l=1}^{n} \sum_{x',y'} (5/6)^l g_l(x', y') \times u_{n-l}(x-x', y-y') + (5/6)^{n+2} g_{n+2}(x,y). \tag{12}$$

By applying the generating function

$$U(\theta,\phi;w) = \sum_{n=0}^{\infty} (6/5)^n U_n(\theta,\phi) w^n = \sum_{n=0}^{\infty} (6/5)^n w^n [\sum_{x,y} u_n(x,y) \exp(ix\theta + iy\phi)] = 5/(5-2cw) \tag{13}$$

and the generating function of $g_n(x, y)$ to Eq. (12), we can obtain an explicit expression for $G(\theta,\phi;w)$:

$$G(\theta,\phi;w) = 2(5c-2w)w/(25-10cw+3w^2). \tag{14}$$

Substituting Eqs. (11) and (14) into Eq. (4) and rearranging the resulting equation, we obtain the general solution for the adsorbed polymeric chain

6) R. J. Rubin, *J. Res. Nat. Bur. Stand.*, **B69**, 301 (1965).

7) C. Domb and M. D. Fisher, *Proc. Cambridge Phil. Soc.*, **54**, 48 (1958).

$$P(\theta, \phi, t, \eta; w) = N(c, t, \eta, w)/D(c, t, \eta, w) \quad (15)$$

where

$$N(c, t, \eta, w) = 10t\eta^2 w(5c-2\eta w)\{5+2cw-w^2 + [(5-2cw+w^2)^2-4w^2]^{1/2}\} \quad (16)$$

and

$$D(c, t, \eta, w) = 5(25-10c\eta w+3\eta^2 w^2)\{5+2cw-w^2 + [(5-2cw+w^2)^2-4w^2]^{1/2}\} - 2t\eta^2 w(5c-2\eta w) \times\{25-10cw+3w^2-5[(5-2cw+w^2)^2-4w^2]^{1/2}\}. \quad (17)$$

2. Evaluation of Average Properties. It is now possible to evaluate average properties of the adsorbed polymeric chain based on the model in which the random walk has no immediate reversals. The average number of adsorbed segments per polymeric chain $\bar{\nu}$ can be obtained by noting Eqs. (1) and (3):

$$\bar{\nu} = \eta[dP_n(2, 1, \eta)/d\eta]/P_n(2, 1, \eta) \quad (18)$$

where $P_n(c, t, \eta)$ is used instead of $P_n(\theta, \phi, t, \eta)$. In a similar manner we have for the average number of trains per polymeric chain the following equation:

$$\bar{m} = [\partial P_n(2, t, \eta)/\partial t]_{t=1}/P_n(2, 1, \eta). \quad (19)$$

It also follows that

$$\overline{r^2} = a^2[c\partial P_n(c, 1, \eta)/\partial c]_{c=2}/P_n(2, 1, \eta), \quad (20)$$

where $\overline{r^2}$ is the mean square end-to-end distance and a is the distance between neighboring segments.

Explicit expressions for $P_n(c, t, \eta)$ and its derivatives are immediately derived from Eq. (15). According to Cauchy's residue theorem, $P_n(2, 1, \eta)$ is found to be

$$P_n(2, 1, \eta) = (1/2\pi i)\oint_{C_0}(1/w^{n+1})P(2, 1, \eta; w)dw = (1/2\pi i)\oint_{C_0}(1/w^{n+1})[N(2, 1, \eta, w)/D(2, 1, \eta, w)]dw, \quad (21)$$

where C_0 includes only the pole at $w=0$. Denoting the smallest root of

$$0 = D(2, 1, \eta, w) = (5-\eta w)[5(5-3\eta w)\{5+4w-w^2+[(5-4w+w^2)^2 - 4w^2]^{1/2}\} - 4\eta^2 w\{25-20w+3w^2-5[(5-4w+w^2)^2 - 4w^2]^{1/2}\}] \quad (22)$$

by w_1, which coincides with the branch-point $w=1$ at the value $\eta=5/4$ which corresponds to the critical value of the adsorption energy, the integral of Eq. (21) may be approximated by the residue at $w=w_1$ when n is infinitely large. Thus we obtain

$$P_n(2, 1, \eta) = -\frac{1}{w_1^{n+1}}\frac{N(2, 1, \eta, w_1)}{\partial D(2, 1, \eta, w_1)/\partial w} \quad (23)$$

where

$$\partial D(2, 1, \eta, w_1)/\partial w = -(5-\eta w_1)[(5-4w_1+w_1^2)^2-4w_1^2]^{-1/2} \times\{[25(4\eta^2+3\eta-4)-10(16\eta^2-12\eta-5)w_1+9\eta(4\eta-5)w_1^2] \times[(5-4w_1+w_1^2)^2-4w_1^2]^{1/2}-5\eta(4\eta-3)[(5-4w_1+w_1^2)^2 - 4w_1^2]+10[5+\eta(4\eta-3)w_1](10-11w_1+6w_1^2-w_1^3)\}. \quad (24)$$

The derivative of $P_n(2, 1, \eta)$ with respect to η in the numerator of Eq. (18) is evaluated similarly. If terms which are not proportional to n are dropped, we have

$$\frac{dP_n(2, 1, \eta)}{d\eta} = \frac{1}{2\pi i}\oint_{C_0}\frac{1}{w^{n+1}}\frac{\partial P(2, 1, \eta; w)}{\partial \eta}dw = -\frac{n}{w_1^{n+2}}\frac{N(2, 1, \eta, w_1)dD(2, 1, \eta, w_1)/d\eta}{[\partial D(2, 1, \eta, w_1)/\partial w]^2} \quad (25)$$

where

$$dD(2, 1, \eta, w_1)/d\eta = -(5-\eta w_1)w_1\{25(8\eta+3)-20(8\eta-3)w_1 + 3(8\eta-5)w_1^2-5(8\eta-3)[(5-4w_1+w_1^2)^2-4w_1^2]^{1/2}\}. \quad (26)$$

The same procedure gives the expressions for $[\partial P_n(2, t, \eta)/\partial t]_{t=1}$ and $[\partial P_n(c, 1, \eta)/\partial c]_{c=2}$ in the limit $n \gg 1$. The results are

$$\left[\frac{\partial P_n(2, t, \eta)}{\partial t}\right]_{t=1} = -\frac{n}{w_1^{n+2}}\frac{N(2, 1, \eta, w_1)\partial D(2, 1, \eta, w_1)/\partial t}{[\partial D(2, 1, \eta, w_1)/\partial w]^2} \quad (27)$$

and

$$\left[\frac{\partial P_n(c, 1, \eta)}{\partial c}\right]_{c=2} = -\frac{n}{w_1^{n+2}}\frac{N(2, 1, \eta, w_1)\partial D(2, 1, \eta, w_1)/\partial c}{[\partial D(2, 1, \eta, w_1)/\partial w]^2} \quad (28)$$

where

$$\partial D(2, 1, \eta, w_1)/\partial t = -4\eta^2 w_1(5-\eta w_1)\{25-20w_1+3w_1^2 - 5[(5-4w_1+w_1^2)^2-4w_1^2]^{1/2}\} \quad (29)$$

and

$$\partial D(2, 1, \eta, w_1)/\partial c = -10w_1[(5-4w_1+w_1^2)^2-4w_1^2]^{-1/2} \times\{[25(\eta^2+\eta-1)-40\eta(\eta-1)w_1+\eta(4\eta^2-5)w_1^2] \times[(5-4w_1+w_1^2)^2-4w_1^2]^{1/2}-5\eta(\eta-1)[(5-4w_1+w_1^2)^2 - 4w_1^2]+[25+20\eta(\eta-1)w_1-\eta^2(4\eta-3)w_1^2] \times(5-4w_1+w_1^2)\}. \quad (30)$$

We can now calculate the average properties of the polymeric chain adsorbed on an interface in the limit $n \gg 1$. Combining Eqs. (23) and (25) with Eq. (18), the expression for the average number of adsorbed segments per polymeric chain is obtained:

$$\bar{\nu} = n\frac{\eta}{w_1}\frac{dD(2, 1, \eta, w_1)/d\eta}{\partial D(2, 1, \eta, w_1)/\partial w}. \quad (31)$$

For the average number of trains per polymeric chain and the mean square end-to-end distance, we obtain

$$\bar{m} = n\frac{1}{w_1}\frac{\partial D(2, 1, \eta, w_1)/\partial t}{\partial D(2, 1, \eta, w_1)/\partial w} \quad (32)$$

and

$$\overline{r^2} = a^2 n\frac{2}{w_1}\frac{\partial D(2, 1, \eta, w_1)/\partial c}{\partial D(2, 1, \eta, w_1)/\partial w}. \quad (33)$$

The derivatives on the right-hand side of the above formulas are already given explicitly in Eqs. (24), (26), (29), and (30).

Discussion

The average properties of the adsorbed polymeric chain based on the model in which no step of a random walk can retrace the previous one on the simple cubic lattice have been evaluated as functions of the adsorption energy and the chain length for infinite chain length. Computing w_1 satisfying Eq. (22) and substituting this value into Eq. (31) with Eqs. (24) and (26), we obtain

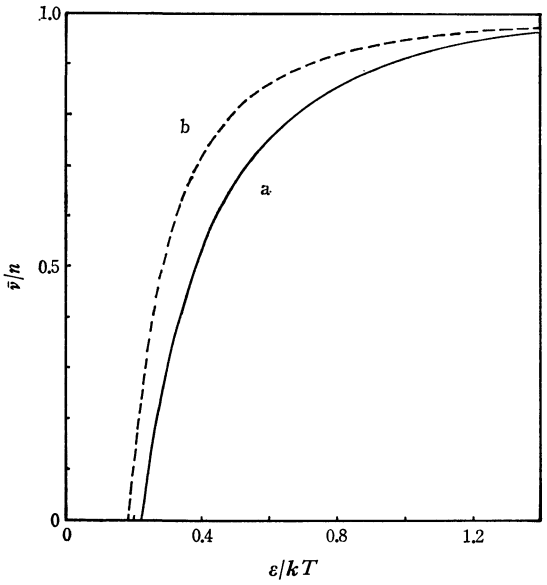

Fig. 1. The ratio of $\bar{\nu}$ to n is plotted against ε/kT in the limit $n \gg 1$: (a) restricted random walk without immediate reversal, (b) symmetric random walk.[1)]

the average number of adsorbed segments per polymeric chain. This is graphically shown in Fig. 1 where the ratio of $\bar{\nu}$ to n is plotted against the adsorption energy ε measured in unit kT. For comparison the ratio $\bar{\nu}/n$ for the symmetric random walk model discussed in Part I is also given in Fig. 1. We see that the prohibition of immediate reversals for the random walk fairly influences the amount of segments adsorbed on the interface. The resulting enhancement of critical adsorption energy and diminution of the average number of adsorbed segments can be explained by the difference between decreases in statistical weights of the two-dimensional and three-dimensional random walks, due to the restriction for the step to retrace the preceding step.

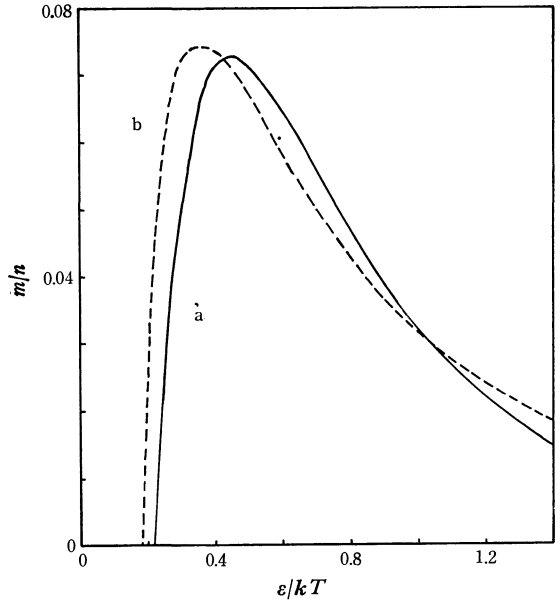

Fig. 2. The ratio $\bar{m}/n$ is plotted against ε/kT: (a) restricted random walk without immediate reversal, (b) symmetric random walk.[2)]

The average number of trains per polymeric chain $\bar{m}$ is calculated in the same way. The plot of ratio $\bar{m}/n$ against ε/kT is illustrated in Fig. 2 with the corresponding one of the symmetric random walk. Shapes of the curves, $\bar{m}/n$ *versus* ε/kT, seem to be alike as a whole, while the decrease of the value of $\bar{m}/n$ of the restricted random walk without immediate reversals at large values of η is rather steep. The smaller average number of trains (the smaller average number of loops) for large values of η may be accounted for by the diminution of the chance of making loops. The smallest number of segments in the loop for the restricted random walk without immediate reversals is $\bar{k}=2$ instead of $\bar{k}=1$ for the symmetric random walk, where $\bar{k}$ is the average number of segments in the loop and is given by

$$\bar{k} = (n-\bar{\nu})/(\bar{m}-1). \tag{34}$$

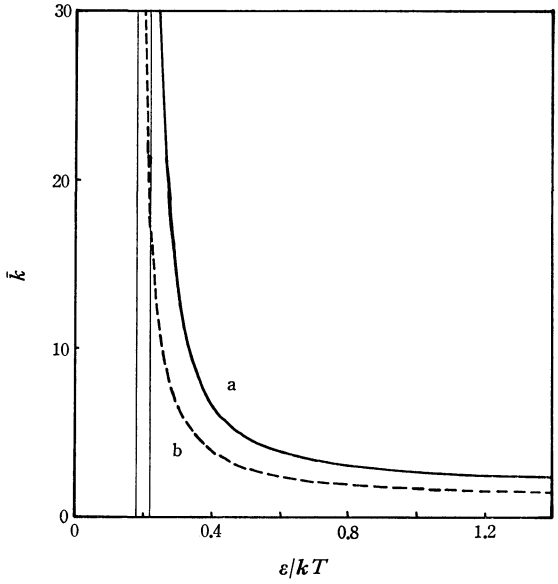

Fig. 3. $\bar{k}$ is plotted against ε/kT: (a) restricted random walk without immediate reversal (b) symmetric random walk.[2)]

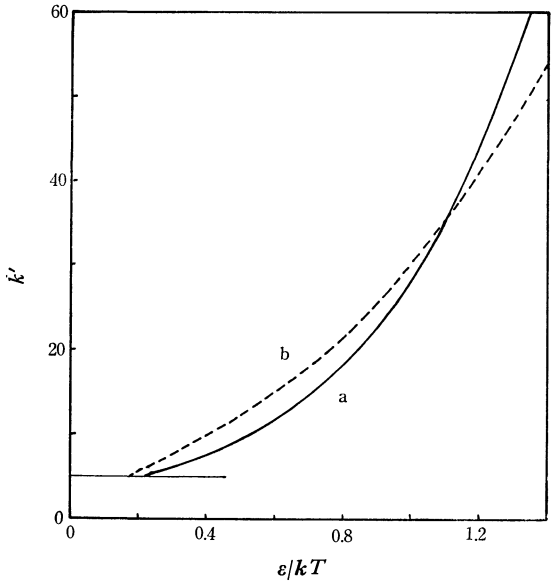

Fig. 4. $\bar{k}'$ is plotted against ε/kT: (a) restricted random walk without immediate reversal, (b) symmetric random walk.[2)]

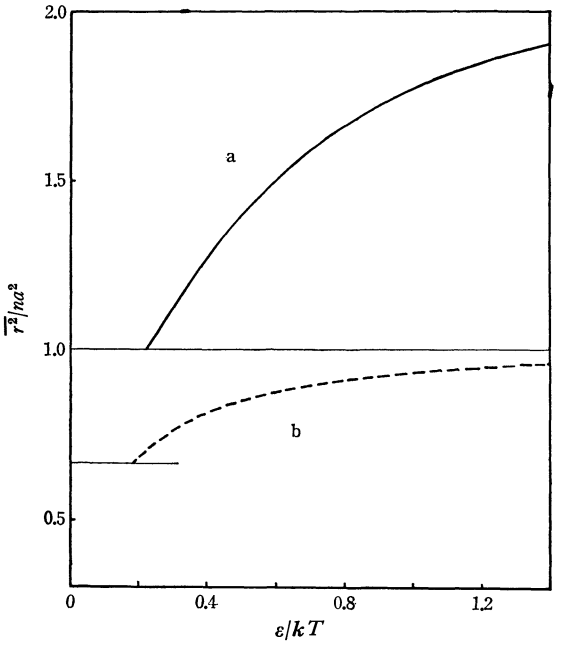

Fig. 5. The ratio $\overline{r^2}/na^2$ is plotted against ε/kT: (a) restricted random walk without immediate reversal, (b) symmetric random walk.[1]

The value of $\bar{k}$ computed is plotted against ε/kT in Fig. 3. We might expect that the average number of segments in the train $\bar{k}'$ increases rapidly with the adsorption energy. The value of $\bar{k}'$ is easily evaluated by the relation

$$\bar{k}' = \bar{\nu}/\bar{m}, \tag{35}$$

which is depicted against ε/kT in Fig. 4. Increase of $\bar{k}'$ *versus* ε/kT curve is remarkable compared with that obtained previously.[2]

Finally the mean square end-to-end distance in the limit $n \gg 1$ is calculated from Eq. (33) with Eqs. (24) and (30) by a similar procedure. The result is illustrated in Fig. 5 where the ratio $\overline{r^2}/na^2$ is plotted against ε/kT. It is clear that the polymeric chain of the restricted random walk without immediate reversals has a fairly extended conformation in comparison with that of the symmetric random walk in spite of the small value of the average number of adsorbed segments per polymeric chain. The value of $\overline{r^2}$ is na^2 at the critical adsorption energy and approaches $2na^2$ for infinite adsorption energy. According to Domb and Fisher,[7] the mean square end-to-end distance of the restricted random walk with no immediate reversals on lattices in the limit $n \gg 1$ is given by

$$(\overline{r^2})_{\mathrm{DF}} = na^2(1+\delta)/(1-\delta) \tag{36}$$

where

$$\delta = 1/(q-1), \tag{37}$$

q being the coordination number of lattice used. Equation (36) results in $(\overline{r^2})_{\mathrm{DF}} = (3/2)na^2$ for the random walk on a simple cubic lattice and $(\overline{r^2})_{\mathrm{DF}} = 2na^2$ on a simple square lattice. It is easily recognized that the mean square end-to-end distance of the adsorbed polymeric chain is equivalent to that of the restricted random walk without immediate reversals, of which both ends are located on xy plane through $z=0$ in the simple cubic lattice, at the critical adsorption energy and approaches that of the two-dimensional one on the simple square lattice for infinite adsorption energy.
