The absorption spectra of 7,7,8,8-tetracyanoquinodimethane (TCNQ) solubilized in surfactant solutions were found to be influenced by day light (hereafter referred to as light). The formation of the monomer band of TCNQ anion radical in the aqueous solution of DPCl (dodecylpyridinium chloride), DPBr (dodecylpyridinium bromide) and $C_{12}E_8$ (homogeneous octaethylene glycol dodecylether) were enhanced by light. On the other hand, the spectra of TCNQ solubilized in surfactant micelle in the dark suggested that TCNQ exists as dimer anion radical form $(TCNQ)_2^-$. Thus, in solubilized state of TCNQ in micelle there is an equilibrium between monomer $TCNQ^-$ and dimer $(TCNQ)_2^-$, which seems to be easily influenced by light and surfactant. Appearance of a monomer radical band was remarkable in DPCl, DPBr, and $C_{12}E_8$ but only the dimer band was found in SDS even in the light.

In a previous paper,[1] we reported that when TCNQ was solubilized into surfactant solutions above critical micelle concentration (CMC), a remarkable coloration took place in the surfactant solutions, and charge transfer complex bands were found in the spectra. The bands were considered to be due to the formation of the charge transfer complex between solubilized TCNQ and surfactant molecule, where the electron donor is surfactant and the acceptor is TCNQ. This suggests a new phenomenon concerning the solubilization of TCNQ with a different mechanism of the color change at CMC.

In this paper, the results of the study of the effect of light irradiation on spectra of TCNQ solubilized in surfactant solution are given.

Experimental

Preparation of Reagents. TCNQ was synthesized by the usual method.[2] Purification of TCNQ was carried out by recrystallization 5 times in acetonitrile. The crystals obtained had a rust-colored flaky form. Its purity was confirmed by elementary analysis:

Found: C, 70.2; H, 1.99; N, 27.7%. Calcd for $C_{12}H_4N_4$: C, 70.6; H, 1.97; N, 27.4%. Melting point of the TCNQ was 293.5—296°C.

Dodecylpyridinium chloride (DPCl) was prepared as follows. A mixture of chlorododecane and dry pyridine was refluxed for about 15 hr at 115°C.[3] The product was recrystallized three times from acetone, then dissolved in warm methanol, mixed with charcoal, and filtered. The filtrate obtained was extracted with petroleum ether for about 100 hr. The product was recrystallized five times from acetone.

Dodecylpyridinium bromide (DPBr) was prepared in the same manner as DPCl, taking bromododecane and dry pyridine.

Sodium dodecyl sulfate (SDS) was prepared by the reaction of dodecanol with chlorosulphonic acid in gracial acetic acid and by neutralization of the resulting acid with sodium carbonate.[4] The product was extracted with petroleum ether for about 200 hr and recrystallized five times from water-isopropanol mixture.

Homogeneous octaethylene grycol dodecyl ether ($C_{12}E_8$), supplied from Nikko Chemical Co. Ltd., was used as nonionic surfactant. Homogenity of polyethylene chain length was confirmed by means of IR spectra, elementary analysis, NMR, thin layer chromatography, and gas-liquid chromatograpy.

The water used was purified by passing tap water through a mixed-bed of ion-exchange resin. It was then distilled from alkaline potassium permanganate in the presence of sodium hydroxide in a pyrex still. The specific conductance of the water was 1 to 1.9×10^{-6} ohm^{-1} cm^{-1} at 25°C.

Solubilization Measurement. Solubilization of TCNQ was carried out as follows. A small amount of TCNQ was added to 15 m*l* of surfactant solutions of different concentrations, and the mixture was shaken in a thermostat at 25°C for about 72 hr. The small amount of TCNQ used was due to the fact that TCNQ is almost insoluble in water. The period of shaking (72 hr) was determined from the study of equilibrium time of solubilization. Shaking was carried out in the daylight and in the dark.

The absorption spectra of TCNQ solubilized in surfactant solutions were measured with a Hitachi Spectrophotometer (Model EPS-2).

Results

When TCNQ was solubilized in surfactant solutions above CMC, a remarkable coloration characteristic of the surfactant was observed. In solubilization equilibrium, the color of TCNQ solubilized was green in DPCl solution, blueish green in DPBr solution, pink in SDS solution and pink to greenish yellow in $C_{12}E_8$ solution. The spectra of TCNQ solubilized in these surfactant solutions change their shapes by the action of light. The absorption spectra of TCNQ solubilized in DPCl are shown in Figs. 1 and 2. Figure 1 shows the spectra measured in daylight. The spectra obtained below CMC had a slight absorption from 550 to 900 mμ, and its intensities were very broad. The forms of absorption spectra change with the increase of surfactant concentration, and new

TABLE 1. COMPARISON OF OPTICAL DENSITIES OF TCNQ SOLUBILIZED IN SURFACTANT SOLUTIONS AT DIFFERENT WAVELENGTH IN THE PRESENCE AND ABSENCE OF LIGHT AT 25°C

		Optical densities at different wavelength (mμ)			
		420	480	750	850
Concentration of DPCl solution is 30 mmol/*l* (above CMC)	Light condition	0.76	0.64	1.23	1.26
	Dark condition	0.63	0.94	0.20	0.35
Concentration of DPCl solution is 10 mmol/*l* (below CMC)	Light condition	0.22	0.12	0.34	0.22
	Dark condition	0.05	0.03	0.00	0.00

bands appeared at 420, 750, and 850 mμ (major) and 480 and 680 mμ (minor) above CMC.

Figure 2 shows the spectra obtained in the dark. In this case, a remarkable absorption cannot be found in the spectra below CMC, but new bands were observed at 420, 480, and 850 mμ (major) and 680 and 750 mμ (minor) above CMC. Comparison of optical densities of TCNQ solubilized in surfactant solutions at different wavelengths in the presence and absence of light is given in Table 1. As can be seen in Table 1, the ratio of the intensity at 420 mμ to that at 850 mμ in the presence of light was smaller than 1, but ratio was reversed in the absence of light.

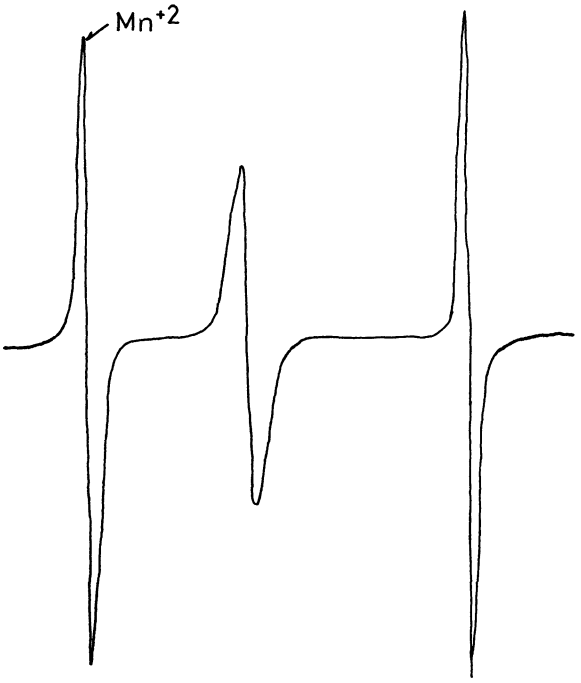

Fig. 3. Electron spin resonance spectra of TCNQ solubilized in 30 mmol/*l* DPCl solution in the presence of the light.

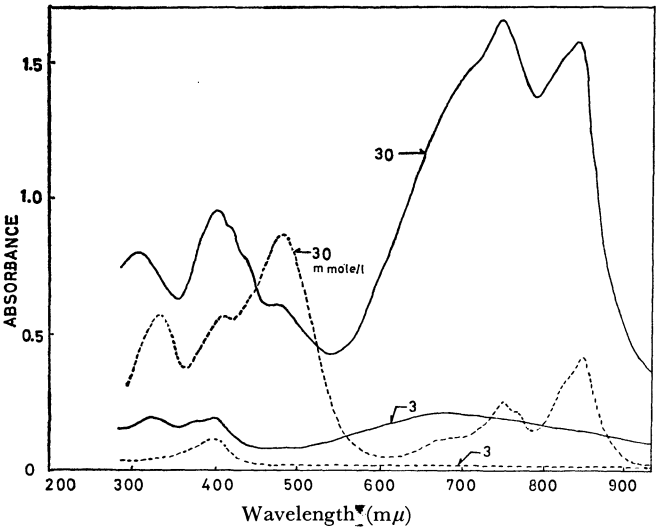

Fig. 4. Visible absorption spectra of TCNQ solubilized in DPBr solutions in the presence of the light and in the absence of the light. Figures show concentration of surfactant solutions.
The solid-line: in the presence of the light
The dashed portions: in the absence of the light

Figure 3 shows the ESR spectrum of TCNQ solubilized in DPCl solution above CMC. This is an evidence of the formation of charge transfer complex between TCNQ and surfactant.

Figure 4 shows the spectra of TCNQ solubilized in DPBr solution in the presence and absence of light. The results were almost the same as those obtained in DPCl solution.

The absorption spectra of TCNQ solubilized in anionic surfactant (SDS) are shown in Figs. 5 and 6. The shape of the absorption spectra of TCNQ solubilized in anionic surfactant solution was quite different. Figure 5 shows the spectra obtained in the presence of light, showing new bands at 400 and 600 mμ above, but no remarkable absorption below CMC. The spectra obtained in the dark are shown in Fig. 6, in which some change was found as compared with those obtained in the light, such as the increase at 400 mμ and decrease at 600 mμ with a slight shift of maximum absorption from 600 to 620 mμ.

Figure 7 shows the spectra of TCNQ solubilized in aqueous solution of homogeneous octaethyleneglycol dodecyl ether in the presence of light, giving the characteristic bands of charge transfer at 480, 750, and 850 mμ above CMC (the CMC value of $C_{12}E_8$ obtained by the surface tension method: 8.2×10^{-5} mol/l). Figure 8 shows the spectra measured in the dark. They are quite different from those in the light, with a decrease of intensities at 480, 750, and 850 mμ bands and the appearance of a new band at 400 mμ.

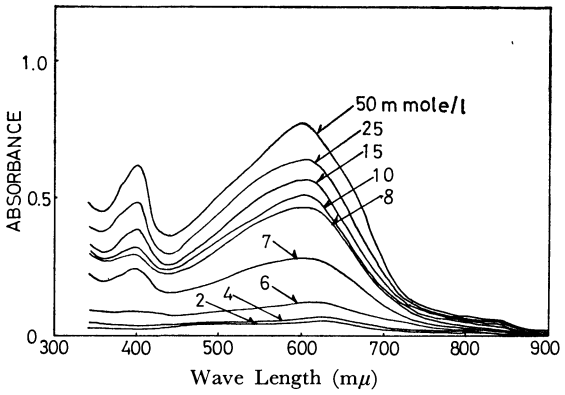

Fig. 5. Visible absorption spectra of TCNQ solubilized in SDS solutions (under light condition).

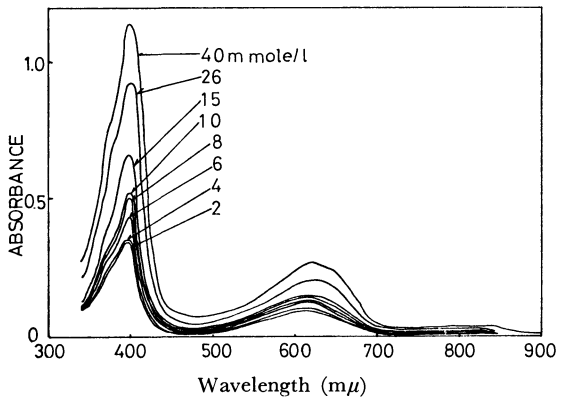

Fig. 6. Visible absorption spectra of TCNQ solubilized in SDS solutions (under dark condition).

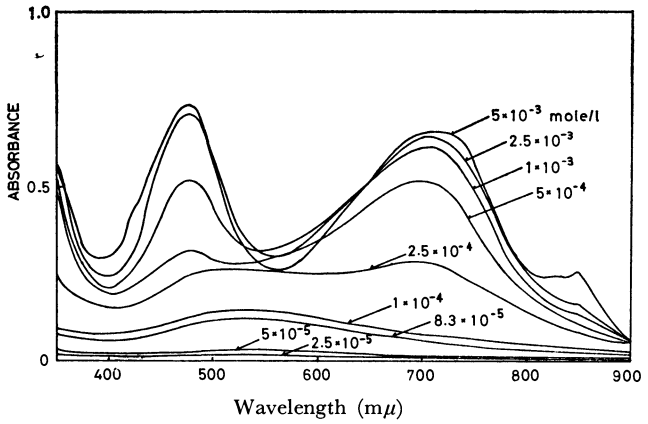

Fig. 7. Visible absorption spectra of TCNQ solubilized in octaethylene glycol dodecylether solutions in the presence of the light. Figures show concentration of surfactant solutions.

Discussion

Scheibe[5] reported in his study of light effect on the color of acridine orange that the dimer of acridine orange dissociates into monomer by irradiation of the light. Boyd[6] studied the visible spectrum of aqueous Li^+TCNQ^- solution and found the existence of equilibrium between the dimer and monomer of the TCNQ anion radical, and concluded that the bands of about 380 mμ and 643 mμ are characterized with the dimer of TCNQ and 420, 750, and 850 mμ bands were caused by the monomer anion radical.

Melby and *et al.*[7] reported that charge transfer complex of TCNQ has characteristic absorption at 420, 750 and 850 mμ in acetonitrile. They suggested that these TCNQ complexes are represented by the general formula $D^+(TCNQ^-)$ where D is an electron donor molecule generally containing a nitrogen atom and an oxygen atom. The coloration accompanied by the solubilization of TCNQ in cationic surfactant solution was characterized by major maxima at 420 and 850 mμ in the light. The absorption seems to be due to the formation of charge transfer complex and formation of TCNQ monomer anion radical ion.

On the other hand, the spectra of TCNQ solubilized in cationic surfactant in the dark show a decrease of

the absorbance at 420, 750, and 850 mμ, but a 400 mμ band due to the dimer anion radical solubilized in micelle.

In the study of the spectra of TCNQ solubilized in anionic surfactant SDS solution, a typical dimer band of $(TCNQ)_2^-$ was found in the light. This does not differ with light irradiation, except for some increase of the absorbance at 620 mμ with no shift in wave length of the absorbed bands. The cause of the production of the anion radical dimer of TCNQ will be the interaction between the counter ion Na^+ ion and solubilized TCNQ in surfactant micelle.

In the light, the spectra of TCNQ solubilized in nonionic surfactant were characterized by major bands at 480, 750, and 850 mμ of monomer band of TCNQ anion radical. In the dark, the spectra of monomer bands at 480, 750, and 850 mμ decreased and a new band appeared at 400 mμ.

Solubilization can be classified into sandwich and palisade types. Non-polar substances are solubilized in the sandwich type, and polar substances in the palisade type. As TCNQ is a non-polar substance, we might expect that the solubilization of TCNQ is of the sandwich type. However, from our results, the solubilization of TCNQ seems to be closer to the palisade type. If the charge transfer band of TCNQ was due to charge transfer between TCNQ and the nitrogen of cationic surfactant, or the oxygen atom of ethyleneoxide or hydroxyl group in nonionic surfactant, its appearance could be explained by assuming a palisade type of solubilization of TCNQ, even though TCNQ molecule is non-polar. However, there still remain questions as to why TCNQ, a non-polar substance, solubilizes in a palisade type solubilization, and also as to the theoretical mechanism for the formation of charge transfer complex between TCNQ and quaternary ammonium salts, such as cationic surfactant in the dark.

The Gas-Phase Radiolysis of Cycloheptatriene

Katsuyoshi NAKAMURA, Setsuo TAKAMUKU, and Hiroshi SAKURAI

The Radiation Laboratory, The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received February 12, 1971)

The γ radiolysis of cycloheptatriene (CHT) in the gas phase has been investigated as a function of the pressure (2—14 mmHg) and in the presence of various additives (NO, O_2, NH_3, N_2O, and C_3H_8). The G values obtained at 10.5 mmHg and at a total dose of 1.1×10^{19} eV are as follows: hydrogen, 0.50; methane, 0.16; acetylene, 1.52; cyclopentadiene, 0.29; benzene, 0.65; toluene, 1.68; dimers, 2.99. The yields of toluene and cyclopentadiene decrease with the pressure and are not appreciably affected by these additives; this suggests a contribution of the excited CHT molecules formed by direct excitation to their formation. The formation of dimers and benzene is affected by a radical scavenger (O_2, NO), indicating the importance of the radical processes. The reaction products obtained *via* a $C_7H_7^+$ ion, which is well known to be produced by the irradiation of CHT, have not been observed, while in the radiolysis of CHT in the presence of benzene and a radical scavenger, biphenylmethane has been produced, presumably by a reaction of the $C_7H_7^+$ ion with benzene. Therefore, it was assumed that the $C_7H_7^+$ ion produced from CHT does not contribute to the dimer formation, but may initiate the ionic polymerization.

Recently, much attention has been paid to ion-molecule reactions in the gas-phase radiolysis. Mass spectrometric studies provide useful information with regard to the ions produced in the gas-phase radiolysis. In the mass spectrometry of alkylbenzenes,[1] the most abundant ion has been observed to be a $C_7H_7^+$ ion (m/e=91), which has a completely symmetrical tropylium structure rather than that of benzyl, in common with these alkylbenzenes. In a previous paper,[2] it was observed that the $C_7H_7^+$ ion produced by the γ irradiation of toluene, ethylbenzene, and *m*-xylene vapors adds to the respective aromatic-ring, finally forming benzylated products, predominantly at a *meta* position to the resident alkyl group. Furthermore, the reaction mechanism has been discussed on the basis of electrophilic aromatic substitution in the gas-phase[3] and compared with the analogous isopropylation of benzene and toluene.[4]

In conjunction with these problems, we have recently investigated the γ radiolysis of cycloheptatriene (CHT) vapor, which is known, from mass spectrometric studies, to produce a $C_7H_7^+$ ion similar to those obtained from alkylbenzenes.[5] The present paper will describe the product formation and the reaction mechanism of this gas-phase radiolysis of CHT, though clear information about the structure and the reactivity of the $C_7H_7^+$ ion has not been obtained.

Experimental

Materials. CHT was prepared by the pyrolysis of 7,7-dichloronorcarane, which has been produced from cyclo-

hexene;[6] it was distilled through a spinning-band column and then purified by preparative-scale gas chromatography using a 3-m PEG-6000 column at 65°C and, further, a 3-m DNP column at 65°C. Gas-chromatographic analysis on a 4.5-m PEG-6000 column showed the presence of toluene (0.024 mol%) and an unknown impurity (<0.07%). The purified CHT was degassed, dried over phosphorus pentoxide and a sodium mirror in a high-vacuum line, and then stored in a glass tube with a mercury cut-off at a low temperature.

Nitric oxide, nitrous oxide, and propane obtained from Takachiho Trading Co., and ammonia generated from 28% ammonia water were dried over a sodium mirror in a high-vacuum line and then purified by low-temperature distillations. The oxygen (minimum purity: 99.9%) was used without further purification.

Sample Preparation. The irradiation cells were Pyrex cylinders with a break-seal, approximately 105 m*l* in volume. Prior to the sample introduction, the cells were baked and evacuated overnight at a pressure of 10^{-6} mmHg. The pressure of the sample was measured by means of a mercury manometer; the pressure range was 2—14 mmHg. In the experiment with an additive, the amount of the additive was measured by a gas buret and transferred into the cell through a break-seal.

Irradiation and Dosimetry. Irradiation was carried out at room temperature with a 5000 Ci ^{60}Co source. Dosimetry was based on $G(C_2H_4 \rightarrow H_2) = 1.28$,[7] assuming that the energy distribution was proportional to the electron density. The dose rate in the present experiments was 3.82×10^{15} eV/hr·μmol (CHT). The G values in the runs with an additive were calculated on the basis of the energy absorbed by CHT alone. The total dose range was $(1.1—2.7) \times 10^{19}$ eV.

Analysis. The hydrogen yield in the product gas volatile at −196°C was determined from the volume difference measured with a standard Toepler pump and gas buret arrangement, before and after passage through a palladium thimble heated at ca. 300°C. The C_2—C_4 hydrocarbons volatile at −120°C were transferred into a capillary with a Toepler pump and analyzed gas-chromatographically using a 3-m silica gel column at 100°C. All the non-volatile products at −120°C except for dimers were identified by gas-chromatographic comparison with authentic samples using several columns (PEG-6000, DNP, and APL). The dimers were identified by means of a gas chromatograph-mass spectrometer combination, but the structures were not investigated except that of bitropyl. The yields of the gaseous and liquid products were determined by a comparison of the peak areas with those for known amounts of propane and benzene respectively, which were submitted to gas chromatography before each analysis.

Results

The product yields in the irradiated CHT at 10.5 mmHg are shown in Table 1, together with those of the radiolysis of toluene vapor.[3] The observed gaseous products were hydrogen, methane, and acetylene. The yields of ethylene and ethane were negligibly small. Cyclopentadiene, benzene, toluene, and several kinds of dimers were also formed as liquid products, though a part of the cyclopentadiene was observed in the dimeric form because of the instability of the monomer at room temperature. Several dimers whose carbon

number might be fourteen were detected gas-chromatographically, though the structure have not determined except for that of bitropyl.[8] The G value of the total dimers is calculated on the assumption that the sensitivity of the detection of dimers is equal to that of bitropyl.

The effect of the total dose was small except in the case of cyclopentadiene at a CHT pressure of 10.5 mmHg over the dose range from 1.1×10^{19} to 2.7×10^{19} eV, as is shown in Table 1. The product yields at a dose of 1.87×10^{17} eV/μmol (CHT) as a function of the CHT pressure are shown in Fig. 1. Though the results for hydrogen and methane are not shown in the figure, $G(H_2)$ and $G(CH_4)$ were essentially unaffected by the CHT pressure.

The experimental results obtained in the presence of an additive, *i.e.*, oxygen, nitric oxide, nitrous oxide, ammonia, or propane, are shown in Fig. 2 and Table 2. Of particular interest is the remarkable increase in the G value of benzene upon the addition of nitric oxide and oxygen. When iodine was added to CHT, the formation of benzene was also observed without γ irradiation, while in the case of oxygen no such behavior was observed. Another significant feature in the additive experiment is the notable decrease in the yield of the dimer upon the addition of a radical scavenger (NO or O_2).

The γ radiolysis of binary mixtures of CHT and benzene was carried out in the presence of nitric oxide (10 mol%). Biphenylmethane and biphenyl were produced with G values of 0.069 and 0.094 respectively, as determined on the basis of the energy absorbed by CHT at a [CHT]/[benzene] molar ratio of 0.466.

Discussion

In the gas-phase radiolysis of CHT, the observed products were hydrogen, methane, acetylene, cyclopentadiene, benzene, toluene, and dimers; Table 1 lists those products together with the results on toluene.[3] The yields of the radiolytic products from CHT were, in general, large compared with those from toluene, especially those of acetylene, benzene, and dimers. Furthermore, cyclopentadiene was a new product which was not observed in the radiolysis of toluene. In the mass-spectrometric studies[1] of these isomeric compounds (CHT and toluene), it is well known that the $C_7H_7^+$ ions are the most abundant in these compounds. However, the present observations seem to show that the common intermediate does not always produce the same final products in both the reaction systems, as will be discussed later. In the liquid-phase radiolysis of CHT, relatively low G values of gaseous products have been reported by Arai *et al.*,[9] and the main reaction was a polymer formation, though the yields of the liquid products were not measured.

Formation of Toluene. As for the radiolytic products from CHT vapor, a fairly large amount of isomerization to toluene was observed, as has been reported in the photolysis[9,10] and pyrolysis[11] of CHT. The toluene formation is essentially unaffected by the addition of appreciable amounts of various scavengers, *i.e.*, oxygen and nitric oxide for radicals, nitrous oxide for electron, ammonia for positive-ions, and propane as a hydride-transfer agent to a positive ion, as is shown in Fig. 2 and Table 2. Thus, it is most reasonable to assume that radicals and positive-ions may be excluded as precursors of toluene in the radiolysis of CHT vapor. On the other hand, an electronically- or vibrationally-excited CHT molecule has been shown to easily isomerize to toluene in photolytic investigations in the gas phase.[9,10] From these results, a direct excitation process such as this seems most reasonable:

$$\text{CHT} \rightsquigarrow \text{CHT}^* \quad (1)$$

$$\text{CHT}^* \longrightarrow \text{Toluene} \quad (2)$$

$$\text{CHT}^* + \text{CHT} \longrightarrow 2\,\text{CHT} \quad (3)$$

The isomerization to toluene (reaction (2)) is presumed to compete with the collisional deactivation (reaction (3)). The steady-state treatment of reactions (1), (2) and (3) gives Eq. (I):

$$1/G(\text{Toluene}) = 1/G^0(\text{Toluene})\{1+k_3/k_2[\text{CHT}]\} \quad (\text{I})$$

where G^0 (Toluene) is the G value of toluene at zero

8) Bitropyl was prepared by the method of Doering and Knox. (mp 61.8°C) W. von E. Doering and L. H. Knox, *J. Amer. Chem. Soc.*, **79**, 352 (1957).

pressure. According to Eq. (I), a plot of $1/G$(Toluene) *vs.* the CHT pressure should give a straight line with a slope of $1/G^0 \cdot k_3/k_2$. Such a plot is shown in Fig. 3, from which the ratio of the rate constant of the deactivation and that of the isomerization, k_3/k_2, as determined by the method of least squares, is found to be 0.051 $mmHg^{-1}$.

In the mercury-sensitized photolysis of CHT vapor by Arai *et al.*,[9] and in the direct photolysis by Srinivasan,[10] a similar kinetic treatment has been carried out. An interesting point is that the value of k_3/k_2 is greater in the photolysis than in the radiolysis; furthermore, it is greater at 3130 Å than at 2600 Å, or in the mercury-sensitized photolysis at 2537 Å, in which the value was 0.11 $mmHg^{-1}$. This means that the higher the energy provided to the CHT molecule, the shorter the lifetime of the active intermediate leading to the toluene formation and quenched poorly by collision, though the nature of the excited state is not clear in the present study. The G value of toluene extraporated to zero pressure is 2.6 in Fig. 3, indicating the G value of the excited CHT which isomerizes to toluene if it is not quenched by collisions.

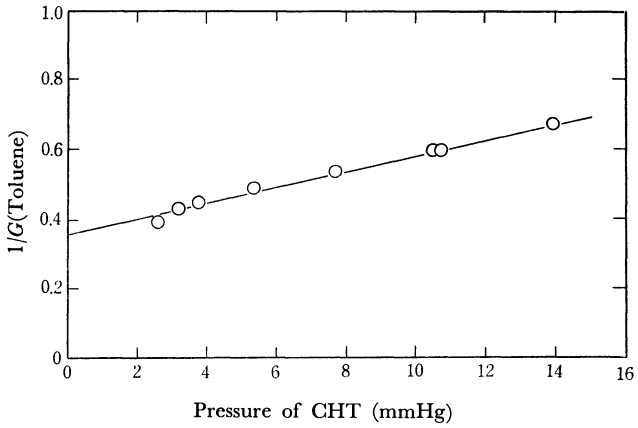

Fig. 3. Kinetic plots of $1/G$(Toluene) *vs.* pressure in the radiolysis of cycloheptatriene vapor.

Formation of Dimers. In the radiation chemistry of liquid hydrocarbon, a dimer which contains two hydrogen atoms less than the starting material has been observed as one of the typical products. For example, the bitropyl obtained from the radiolysis of liquid CHT has been observed to be formed *via* a symmetrical intermediate, the tropyl radical,[11] which has also been reported in the ESR study of the electron irradiated CHT at −196°C.[9] In the present study, bitropyl was not a predominant dimer, but many other dimers were produced to a similar extent, though their structures were not identified. The total dimer yields rapidly decreased upon the addition of oxygen and nitric oxide (Fig. 2 and Table 2), but the isomer distribution remained the same. It is generally assumed that the major effect of oxygen and nitric oxide on the product formation is due to the scavenging of free radicals, though it has been observed in some cases that nitric oxide acts as a charge-transfer agent,[12] since nitric oxide has an ionization potential (9.2 eV)[13] lower than those of many hydrocarbons. However, the decrease upon the addition of oxygen, which has a high ionization potential (12.1 eV),[13] strongly suggests a radical mechanism for the formation of dimers. On the other hand, CHT is also an efficient radical scavenger, so primarily-produced hydrogen atoms and hydrocarbon radicals may be almost all scavenged by CHT even in the absence of a radical scavenger:

$$\text{CHT} \rightsquigarrow \text{C}_7\text{H}_7\cdot + \text{H} \quad (4)$$

$$\text{H} + \text{CHT} \longrightarrow \text{C}_7\text{H}_9\cdot \quad (5)$$

$$\text{C}_7\text{H}_7\cdot + \text{CHT} \longrightarrow \text{C}_{14}\text{H}_{15}\cdot \quad (6)$$

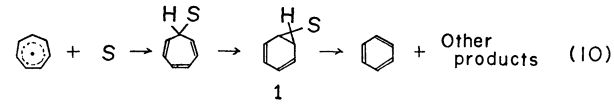
$$\text{C}_7\text{H}_9\cdot + \text{CHT} \longrightarrow \text{C}_{14}\text{H}_{17}\cdot \quad (7)$$

$$\text{R}\cdot + \text{R}\cdot \longrightarrow \text{R-R} \quad (8)$$

$$\longrightarrow \text{RH} + \text{R(-H)} \quad (9)$$

where R is a monomeric or dimeric radical. It may be explained that many kinds of dimers are formed *via* these processes. These observations are obviously different from those for the dimer formation in the gas-phase radiolysis of toluene, in which the effect of nitric oxide is very small and in which ionic processes were predominant.[2,3]

Formation of Benzene. Benzene is a new product which was not reported in the photolysis of CHT vapor.[9,10] The G value of benzene decreased with an increase in the CHT pressure, though the pressure dependence is different from that of toluene. No significant effect on the yield was observed upon the addition of ammonia, propane, or nitrous oxide. Furthermore, it is an interesting fact that the addition of nitric oxide or oxygen remarkably increases the yield of benzene. These additional benzene yields are too large to be explained as the result of sensitization by nitric oxide or oxygen. It is assumed that the active species produced by the irradiation of CHT come to form benzene by means of the added nitric oxide or oxygen. Moreover, ionic species must be excluded, since the ultimate G value of the additional benzene which is obtained by the extrapolation of $1/\Delta G(\text{C}_6\text{H}_6)$ to the infinite concentration of oxygen as shown below is very large ($G_\infty(\text{C}_6\text{H}_6)=8.0$) compared to the G_e of CHT. Since nitric oxide and oxygen are both well known to act as radical scavengers, it seems to be most reasonable to expect the following radical process for the formation of the additional benzene:



1

where S is a radical scavenger. The norcaradiene-type intermediate (1) was previously suggested in the formation of benzene.[14,15] When a radical scavenger

is absent in the system, tropyl radicals such as those produced by reaction (4) may undergo an addition reaction with CHT, as is shown in reaction (6), thus leading to the dimer formation. The fact that a radical scavenger competes with CHT for tropyl radicals is shown when we plot the yields of benzene and dimers against the concentration of a radical scavenger (Fig. 2). The yields of benzene were increased by an increase in the concentration, while the yields of the dimers were decreased. However, the correlation between these changes in the yields was not satisfactory. This cannot be explained well, but it may be partly caused by the different efficiencies in the dimer formation and the benzene formation from tropyl radicals. Since the reaction of tropyl radicals with CHT (reaction (6)) produces not only dimers but also high-molecular products, the efficiency of the dimer formation becomes relatively low.

A quantitative treatment of the formation of benzene in the presence of a radical scavenger is given by Eq. (II):

$$\frac{1}{\Delta G(C_6H_6)} = \frac{1}{G_1}\left(1 + \frac{k_6}{k_{10}} \cdot \frac{[CHT]}{[S]}\right) \qquad (II)$$

where $\Delta G(C_6H_6)$ is the difference in the G value of benzene, with and without a scavenger, and where G_1 is the G value of the C_7H_7 radical produced by reaction (4). In Fig. 4, $1/\Delta G(C_6H_6)$ is plotted against [CHT]/[S]. From the extrapolation of the straight line to the intercept, the ultimate yield of a tropyl radical (G_1) is observed to be 8.0. The mechanism of the formation of benzene from pure CHT is not clear, but such a free radical process seems to play a part. In this case, instead of oxygen or nitric oxide other small fragment radicals may act as radicals scavengers.

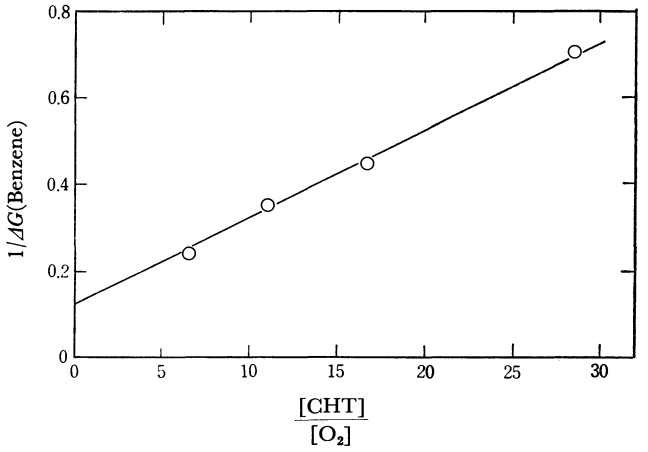

Fig. 4. Kinetic plots of $1/\Delta G$(Benzene) *vs.* [CHT]/[O_2] in the radiolysis of cycloheptatriene-O_2 mixtures.

Formation of Cyclopentadiene and Acetylene. In the mass spectrometry, a $C_5H_5^+$ ion, which could be a precursor of cyclopentadiene by a following hydride-transfer reaction, was reported to be produced by the secondary decomposition of a $C_7H_7^+$ ion:[1]

$$C_7H_7^+ \longrightarrow C_5H_5^+ + C_2H_2 \qquad (11)$$

However, under the radiolytic conditions, where the pressure is much higher compared than that of the mass-spectrometric conditions, a $C_7H_7^+$ ion is known to undergo a very fast ion-molecule reaction before its degradation to a $C_5H_5^+$ ion.[3] Moreover, the formation of cyclopentadiene is essentially unaffected by the addition of various scavengers (NO, O_2, N_2O, NH_3, or C_3H_8), much as in the case of toluene. These observations suggest a direct excitation process of the formation of cyclopentadiene and acetylene:

$$CHT \sim\!\!\wedge\!\!\wedge\!\!\rightarrow CHT^{**} \qquad (12)$$

$$CHT^{**} \longrightarrow \text{cyclopentadiene} + C_2H_2 \qquad (13)$$

$$CHT^{**} + CHT \longrightarrow 2\,CHT \qquad (14)$$

The effect of the CHT pressure on the yield of cyclopentadiene (Fig. 1) was consistent with the above mechanism. The nature of the excited CHT molecule that decomposes to cyclopentadiene and acetylene may be energetically higher than that of a precursor of toluene, since they are poorly quenched by collision and since the process (reaction (13)) was not observed in either the photolysis or the pyrolysis.

On the other hand, acetylene is not only formed by reaction (13) but also by some other processes, because the $G(C_2H_2)$ value is much larger than that of cyclopentadiene and the pressure dependence is different from that of cyclopentadiene. The effects of additives were also observed (Table 2), but the other processes have not yet been clarified.

The Fate of the Tropylium Ion. It was one of the principal purposes of this work to determine the fate of the $C_7H_7^+$ ion generated in the γ radiolysis of CHT vapor. Unfortunately, in the radiolysis of pure CHT vapor information about this has not been obtained from direct evidence, such as the identification of the reaction products *via* the $C_7H_7^+$ ion.

In the mass-spectrometric studies of simple alkylbenzenes,[1,5] it has been shown that the loss of an acetylene molecule (reaction (11)) is the only major decomposition process of the $C_7H_7^+$ ion at a low pressure. In the high-pressure mass spectrometry of toluene,[16,17] it has been reported that the $C_7H_7^+$ and $C_5H_5^+$ ions decay exponentially with the pressure, thus giving a new product ion, $C_{14}H_{15}^+$, However, the $C_{12}H_{13}^+$ product ion, which would be formed by a similar addition reaction of the $C_5H_5^+$ ion to toluene molecules, is absent among the ions in the spectra observed at high concentrations of toluene. It seems reasonable to assume that the addition reaction of the $C_7H_7^+$ ion to toluene and the reaction (11) are competitive and that, in the radiolysis in which the pressure is relatively high compared to that in the ionization chamber of the mass spectrometer, the $C_7H_7^+$ ion exclusively adds to toluene. Consistent with these observation, it has been shown that methyldiphenylmethanes, which are the main dimeric products in the gas-phase radiolysis of toluene, are formed by such an addition of the $C_7H_7^+$ ion to toluene, while the addition

17) A. Giardini-Guidoni and F. Zocchi, *Trans. Faraday Soc.*, **64**, 2342 (1968).

products of the $C_5H_5^+$ ion are not present.[2,3] Moreover, it has been confirmed that the $C_7H_7^+$ ion adds also to benzene, which is added in the γ radiolysis of toluene, and thus produces diphenylmethane.[18] These observations suggest that aromatic compounds, such as benzene and toluene, are excellent reagents for the carbonium ion in the gas phase and that they produce relatively stable ions which finally change to the corresponding substituted alkylbenzenes. This technique might be useful for the investigation of the formation and the reactivity of the $C_7H_7^+$ ion in the radiolysis of CHT vapor. The preliminary results showed the formation of the expected biphenylmethane in the radiolysis of CHT vapor in the presence of benzene and a radical scavenger, though the G value was small (0.069). The low yield of diphenylmethane was supposed to be caused by the competitive reactions of the $C_7H_7^+$ ion with benzene and with CHT.

In the present investigation, though the precise reaction mechanism of the $C_7H_7^+$ ion is not yet clear, it is most reasonable to assume an ionic polymerization of CHT initiated by the $C_7H_7^+$ ion, for the dimeric products disappear upon the addition of a radical scavenger and CHT is expected to be subject to ionic polymerization, much as in the case of cyclopentadiene.[19] The mechanistic details of the reaction of the $C_7H_7^+$ ion are currently under investigation in these binary mixtures, CHT-benzene, CHT-toluene, and CHT-h_8-toluene-d_8.

We wish to thank Mr. Tamotsu Yamamoto and Mr. Tomikazu Sawai of the Radiation Laboratory for their assistance in the γ irradiations.

Institute for Chemical Research, Kyoto University, Gokasho, Uji, Kyoto

* *Institute for Protein Research, Osaka University, Kitaku, Osaka*

(Received February 12, 1971)

Crystals of the 2 : 3 complex of zinc-phthalocyanine and normal hexylamine were studied. They are monoclinic, space group $P2_1/c$, with cell dimensions $a=12.40$, $b=15.76$, $c=20.05$, $\beta=93.2°$ and there are four phthalocyanine and six hexylamine molecules per cell. The phthalocyanine molecule is not planar and the central zinc ion is displaced from the plane by 0.48 Å toward the nitrogen atom of the amine. Zinc ion is of a square pyramidal five coordination. There are two bonding states for the amine in the complex crystal. One is weakly bonded and can be easily released from the lattice and the other is strongly bonded and coordinated directly to the zinc ion. None of the atomic parameters of these amines except those of the coordinating nitrogen were exactly determined.

Phthalocyanine and its metal derivatives have been regarded as important and being studied in many fields such as pigment industry, solid state physics of organic crystals, catalysis, colloid and coordination chemistry and X-ray crystallography. They assume a common molecular structure similar to porphin derivatives and are of interest also from a biological view point particularly when they form additive complexes with both aliphatic and aromatic amines with respect to Mn[2], Cr[3], Fe[4], and Zn[5] derivatives.

In the course of electron microscopy and X-ray diffraction study on the polymorphic transformation of powdery zinc phthalocyanine which usually takes place in various organic dispersion media, Kobayashi, Uyeda, and Suito[5] found that various additive complexes are produced as crystalline powders stoichiometrically taking up the molecules of amine in which the original powder was dispersed. By means of differential thermal analysis, the molecular ratio of amine molecules to the zinc phthalocyanine matrix was found to depend upon the species of amine itself, whereas the vibrational spectra of these compounds in both rock salt and far infrared regions strongly indicated[6] that the solvated amine molecules are, as strong n-donors, rigidly bound to the central zinc ion with the lone pair electrons of nitrogen atoms. In order to clarify the electronic configuration of the intermolecular bonding which has much to do with the physical properties of the complexes as the biological model or organic semiconductor, the three dimensional structure should be studied in more detail with respect

to the coordination number of the metal ion, the intermolecular bonding length, the mutual position of the phthalocyanine and solvated molecules. The crystal structure of pyridine complex of phthalocyanatomanganese was determined by Vogt *et al*[7]. to show that the pyridine molecules are perpendicularly conjugated with the nitrogen atoms to the central metal ions, a pair of which are further connected by an oxygen molecule to form a parallel double complex.

Although this result indirectly supported the idea about the molecular structure of the complexes of zinc-phthalocyanine as deduced from the vibrational spectra, no data about their crystal structures have been reported for those with aliphatic amines.

In view of this, three dimensional X-ray analysis has been undertaken with a well defined single crystal of *n*-hexylamine complex as the first example in a series of similar addition compounds of zinc phthalocyanine.

Experimental

Pure zinc phthalocyanine was prepared following the same procedure as described previously.[5] About 0.1 g of the powder zinc phthalocyanine was completely dissolved into 10 m*l* of specially prepared *n*-hexylamine. When the solvent was slowly evaporated at room temperature, purple hexahedral crystals were obtained in various sizes. After identifying the product as the expected complex with a rotation photograph, a crystal of about $0.2\times0.2\times0.5$ mm was chosen as a specimen for Weisenberg photographs with Ni-filtered Cu$K\alpha$ radiation. Intensity data were recarded on the Weisenberg photographs taken around the *a*-axis up to the ninth layer and around the *b*-axis up to the twelfth layer.

The number of independent reflections thus observed were about 3000 excluding the zero intensity reflections. Intensity data were derived from films prepared by the multiple-film equi-inclination technique. They were then converted to structure amplitudes after the usual Lorentz and polarization factors had been corrected. No correction for absorption was made.

The molecular ratio of *n*-hexylamine to zinc phthalocyanine was determined by thermal gravimetry,[5] and the density of the crystal was measured by the flotation method with an aqueous solution of potassium bromide.

Results

a) Crystal Data. The crystal of the *n*-hexylamine complex of zinc phthalocyanine belongs to the monoclinic system. The unit cell dimensions are

$$a = 12.40\,\text{Å} \pm 0.02$$
$$b = 15.76\,\text{Å} \pm 0.02$$
$$c = 20.05\,\text{Å} \pm 0.05$$
$$\beta = 93.2^\circ \pm 0.5$$
$$V = 3902.6\,\text{Å}^3$$

The systematic absences are recognized for reflections h0l and 0*k*0 with *l* and *k* odd, respectively, indicating that the space group is $p2_1/c$.

b) Number of n-*hexylamine Molecules in a Unit Cell.* The number of *n*-hexylamines relative to that of zinc phthalocyanine was determined by thermal gravimetry. When the complex is heated, decomposition takes place in two stages releasing *n*-hexylamine molecules stepwise at 140 and 180°C. At temperatures higher than 180°C, decomposition is completed leaving pure zinc phthalocyanine of the β polymorph. Thus, the total reaction can be described by the following equation, where *p* and *q* are the numbers of the component molecules in the complex and ZnPc and Am stand for zinc phthalocyanine and amine.

$$(\text{ZnPc})_p(\text{Amine})_q \rightarrow p\text{ZnPc} + q\text{Am}$$

The percentage weight loss W is related to *p* and *q* as follows.

$$W = \frac{q[\text{Am}]\times 100}{p[\text{ZnPc}] + q[\text{Am}]} = \frac{\text{Weight loss}\times 100}{\text{total weight of complex}}$$

where the brackets denote the molecular weights of components. The actual weight loss was determined to be 20.0%, which shows good agreement with the calculated value of 20.8% when $p : q$ is taken to be 2 : 3 (with $p : q = 1 : 1$, $W = 14.9\%$ and with $p : q = 1 : 2$, $W = 25.8\%$). Thus, the calculated density becomes 1.239 g/cm^3 if four phthalocyanine molecules are assumed to exist in the unit cell. Since the actual density was found to be 1.30 g/cm^3 by the floatation method, it seems reasonable to conclude that the unit cell has four zinc phthalocyanine and six *n*-hexylamine molecules.

c) Structure Determination. The coordinates of the zinc ion were derived from a three dimensional Patterson function as $x/a = 0.020$, $y/b = 0.028$, and $z/c = 0.182$. An electron density function was calculated with the phases due to the zinc ion. The Fourier maps showed all the non-hydrogen atoms of zinc phthalocyanine, and the nitrogen atom of a *n*-hexylamine 2.20 Å apart from the zinc ion lying almost in the center of the planar phthalocyanine molecule. The structure factors were calculated using these atomic positions shown in the maps and the atomic parameters were refined three times by successive cycles using the block-diagonal least-squares method. The discrepancy index R was 0.17 at this stage. Although the appearance of a nitrogen atom near the zinc ion indicated that only one *n*-hexylamine is coordinated to a phthalocyanine molecule, the positions of the carbon atoms of *n*-hexylamine could not be distinctly determined, since the electron density maps showed lower peaks at the positions of these atoms with only about one fifth of the peak heights of the carbon atoms in the phthalocyanine ring. With existence probabilities set as one half, the positions of the five carbon atoms of the *n*-hexylamine were added to those of the other well defined atoms. By use of this new set of positions, several cycles of structure factor calculations and least-squares refinements were performed to reach a discrepancy index of 0.15 in the final stage. No information concerning the other two amine molecules was obtained. The final atomic parameters and their thermal parameters are listed in Table 1, and the calculated and observed structure factors are compared in

A.). Figure 1 and 2 show the (100) and (001) projections of the structure. The zinc phthalocyanine molecules make a pair in the crystal and intermolecular distances between these paired molecules are also illustrated in Fig. 3.

Discussion

Bond distances and bond angles are given in Fig. 4-(a) and (b) only for a phthalocyanine molecule and the nitrogen atom of *n*-hexylamine bonded to it. The central zinc ion is coordinated to five nitrogen atoms, assuming a square pyramidal configuration as a whole. The four nitrogen atoms of pyrrole rings, N1 through N4, define a perfect plane with a shift of ±0.008 Å. The least-squares equation for this plane is

$$0.2671X - 0.7864Y - 0.5570Z = -1.8912$$

where X, Y, and Z are the coordinates (in Å) referring to the orthogonal axes a, b, and c, respectively. Shift of the zinc ion from this plane is significant, as is listed in Table 3 along with those of nine nitrogen atoms. It is obvious that the central zinc ion is displaced from the plane by nearly 0.5 Å presenting a pavilion roof shape, as shown in Fig. 5, which is an edge-on projection of the planar molecule viewed in a direction through two bridge nitrogen atoms, N6 and N8. Details of the coordinating feature around the zinc ion are given in Fig. 6. The Zn ion is displaced from the square nitrogen plane by 0.480 Å holding a bond length of 2.061 Å to the four pyrrole nitrogens on an average, and also that of 2.178 Å from the additive ligand nitrogen N9 toward which the Zn ion is shifted. The direction of the Zn–N9 bond is not perpendicular to the basal nitrogen plane, but slightly tilts towards the α carbon of *n*-hexylamine. Point C_t, the foot of a normal through Zn ion to the basal plane, is regarded as the center of the inner hole of phthalocyanine ring. The mean distance from C_t to the four pyrrole nitrogens is 2.005 Å on an average.

It seems worthwhile to compare the present data with those reported with regard to the five coordinated complexes of various metal derivatives of porphyrin which has the same central configuration as a phthalocyanine molecule. In Table 4, mean lengths and angles are listed for characteristic bonds which were reported concerning α-chlorohemin by Koenig[9] (1965), methoxyiron (III) mesoporphyrin-IX dimethyl ester (MeOFeMeso) by Hoard, Hamor, Hamor and Caughey[10] (1965), monochloroiron tetraphenylporphine (ClFe TPP) by Hoard, Cohen, and Glide[11] (1967) and monoaquozinc (II) tetraphenylporphine (H_2OZn TPP) by Glick, Cohen and Hoard[12] (1967). For comparison the list also includes the corresponding data for phthalocyanine formerly given by Robertson,[13] and its copper and platinum derivatives re-

cently determined by Brown.[14,15]

The characteristic bonds are associated with the atoms which are the metal ion (M), the ligand nitrogen coordinated to the metal (N_p), the additive ligand atom (L), the α and β carbon of pyrrole rings (C_α, C_β) and the methin carbon (C_m) or the bridge nitrogen (N_b) both of which connect two adjacent pyrrole rings. Although it is obvious that the corresponding values do not differ much from one another, the zinc phthalocyanine complex shows a closer resemblance to α-chlorohemin than the aquo zinc TPP, particularly in the dimensions of such bonds as M–N_p, C_t–N_p, C_t–M and N_p–C_α, all being associated with the configuration of coordinate systems of the common convex type. A characteristic feature of the porphine skeleton in which the bond N_p–C_α is always longer than the C–C bonds in benzene ring in the case of phthalocyanines also holds in the present complex. The inner hole radius, C_t–N_p, is longer than that of any other phthalocyanine though it is closer to the radii of Pt derivatives of both modifications. It is likely that the complex formation does not affect the bond lengths around the bridge nitrogens. The molecule of phthalocyanine and its metal derivatives is well known as a flat molecule. As an example, the shifts of carbon atoms in copper phthalocyanine crystal from the mean plane were reported by Brown[14] to be within ±0.05 Å. Every divalent metal ion situated in the center of a phthalocyanine molecule takes a square planar four coordinate structure, where the metal ion bonds with four nitrogens through dsp^2 hybrid orbitals. These square planar configurations are possible for Mn, Fe, Ni, Pd, and the four coordinate square planar configurations are very stable especially for Co, Ni, Cu, Pt ions. The fact that the phthalocyanine derivatives of nickel or copper do not make an additive complex with amines, and manganese derivative reacts with molecules of amine to form a six coordinate complex, suggests that the reactivity of metal phthalocyanine with the various amines depends mostly on the electronic configurations in 3*d* orbitals of metal ion. In other words, manganous and ferrous ion can form six coordinate octahedral configurations with d^2sp^3 hybrid orbitals. The phthalocyanine derivatives of these two metal ions, therefore, can easily form molecular complexes with other ligands such as pyridine, aniline or other amines.

In contrast, divalent zinc ion whose 3*d* electron orbitals are filled with its own ten electrons is apt to take tetrahedral configuration by use of sp^3 hybrid orbitals. The zinc ion uses outer sp^2d hybrid orbitals in order to stay in phthalocyanine ring because the zinc ion is required to assume a square planar coordination which is not a stable configuration for the ion. Thus, zinc phthalocyanine shows a tendency to form a five or six coordinate complex when *n*-donor molecule exists. In the complex with *n*-hexylamine, the zinc ion takes a square pyramidal five coordination as shown in Fig. 6. In this case sp^2d^2 hybridized orbitals were used for the coordination. It is interesting to note that the phthalocyanine molecule which is usually considered to have a rigid planner configuration can be easily distorted by complex formation in the crystal.

Another example of five coordinate zinc ion can be seen in the molecule of aquozinc tetraphenyl porphine, where zinc ion takes a square-pyramidal structure although copper or palladium derivatives show a square-planar structure without any water molecule coordinated to them. In this case, bond distances of Zn–N and Zn–O are 2.05±0.01 Å and 2.20±0.06 Å, respectively, and in the case of zinc phthalocyanine-*n*-hexylamine complex the bond lengths of Zn–N and Zn–N (amine) are 2.06±0.02 Å and 2.18±0.02 Å. These similarities indicate that the zinc ions in both complexes take the same electronic configuration by sp^2d^2 orbitals for coordinations which seems more stable than the square planar structure of sp^2d orbitals. The paired molecules viewed in a direction perpendicular to the molecular plane shows that the intermolecular overlapping area is very small. In general, the packing manner in the crystals of the planar molecules like phthalocyanines is said to be stable when the overlap of π-electron is made as large as possible. Judging from these facts the small overlap of the pair of planar molecules may suggest the change of distributions of π-electron density in phthalocyanine molecules due to the charge transfer from amine to phthalocyanine ring.

The number of *n*-hexylamine molecules which exist in a unit cell of the complex was determined by means of differential thermal analysis (DTA) and thermal gravimetric analysis (TGA). There are three endothermic reactions at about 140, 155, and 180°C.

The first reaction detected at 140°C by DTA is related to the partial decomposition of the complex. When the amines have been released by decomposition, they are usually discharged instantly into the air. The endothermic reaction at 155°C is related to the evaporation of these discharged hexylamines at boiling point. Though the boiling point of *n*-hexylamine is 130°C, it is detected as a peak temperature at 155°C by DTA when the rate of temperature rise is 10°C/min. The last peak was attributed to the decomposition and evaporation of the *n*-hexylamine tightly bonded to zinc phthalocyanine. It should be emphasized that there are two bonding states for *n*-hexylamine in the complex crystal. One is weakly bonded and can be easily released from the lattice at a temperature lower than the boiling point of *n*-hexylamine. The other is strongly bonded and stable up to about 180°C. It is evident from TGA that the total number of *n*-hexylamine in a unit cell is six where as that of zinc-phthalocyanine is four. The electron density map obtained by Fourier synthesis gave only four *n*-hexylamine molecules coordinated directly to the zinc ion in a unit cell. The other two amine molecules did not appear in the course of the Fourier synthesis. These molecules are considered to be located at random in a space of crystal lattices and discharged out of the lattice even at low temperature. The coordinated *n*-hexylamine molecules are considered to be more stable so as to be decomposed at about 180°C. None of the atomic parameters of these coordinated amines except the nitrogen were exactly determined and the electron densities of five carbon atoms of the amine were only about 1/3-1/5 of the density of the carbons in phthalocyanine ring at the final stage of refinement. No terminal methyl carbon of the *n*-hexylamine was detected. The indistinctness of the atomic parameters was due to a molecular rotation or a static disorder of the paraffine chain of the amine. A preliminary structural study on a series of similar additive complexes shows that the crystals of such molecular complexes of zinc phthalocyanine with normal amine, whose carbon numbers are three, four, and five have an isomorphous structure with the complex reported here. It is observed that thermal stability decreases with the decrease of the carbon number of amine. In the case of the complex with propylamine (C=3) the weakly bonded amine in the crystal lattice easily escapes from the lattice even at room temperature leaving 1 : 1 complex behind. It may be possible to determine the position of all the atoms of amine in the crystal by means of low temperature Weisenberg camera because the quenching of the movement of amine molecule can be expected.

Rare-Gas-Sensitized Radiolysis of Toluene

Yukio YAMAMOTO, Setsuo TAKAMUKU, and Hiroshi SAKURAI

The Radiation Laboratory, The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received February 22, 1971)

The Ar-, Kr-, and Xe-sensitized radiolyses of toluene was studied at room temperature in the gas phase. The discussion was concentrated on the formation of three isomers of methyldiphenylmethane (MDPM), which, it had been suggested in a previous paper on the direct radiolysis of toluene, were formed by the ion-molecule reaction of $C_7H_7^+$ ions. The sensitization effect on the MDPM formation was extremely large in the case of Ar, and decreased in the order of Ar, Kr, and Xe. These results were explained in terms of charge transfer from these rare gases to toluene, resulting in the formation of the $C_7H_7^+$ ions. The isomer distribution of MDPM's in the rare-gas-sensitized radiolysis was considered on the basis of the reaction mechanism proposed previously. The sensitization effect on the formation of other products was also discussed briefly.

In the gas-phase radiolysis, ionic species formed by irradiation play significant roles in the product formation; therefore, mass spectrometric studies have provided valuable information about the primary process of the gas-phase radiolysis. In the case of simple alkylbenzenes, such as toluene, ethylbenzene, and xylenes, the most abundant ion in the mass spectra is the $C_7H_7^+$ ion,[1,2] and its reactions in the gas-phase radiolysis of these alkylbenzenes have been expected to be important. It was suggested, in previous papers on the gas-phase radiolysis of toluene, ethylbenzene, and *m*-xylene, that the $C_7H_7^+$ ions react with parent alkylbenzene molecules to form the corresponding benzylated alkylbenzenes, which are the major products of these radiolyses.[3-5] Furthermore, the mechanism of such an electrophilic substitution reaction of aromatic nuclei caused by the $C_7H_7^+$ ions was discussed on the basis of the isomer distribution and the pressure dependence of the yields of the products, methyldiphenylmethanes (MDPM's), in the gas-phase radiolysis of toluene.[4] The present investigation of the rare-gas-sensitized radiolysis of toluene has been carried out in order to obtain additional information about the mechanism of the formation of MDPM's in the radiolysis of toluene. In the rare-gas-sensitized radiolysis, the product distribution is often characteristic of the kinds of rare gases, and the investigations of such experiments using various rare gases are of value in connection with the study of the primary process of the radiolysis.

Experimental

The toluene was the same as that used in a previous study.[4] The rare gases were obtained from Takachiho Shoji Co. and were used without further purification. The stated purities were 99.999%, 99.9%, and 99.9% for Ar, Kr, and Xe respectively. The experimental procedures were almost identical with those reported previously.[4] The irradiation cells were Pyrex cylinders approximately 120 m*l* in volume, and irradiations were carried out at room temperature with a 5000 Ci cobalt-60 source. The dose rate at the dose for toluene were 3.1×10^{15} eV/hr·μmol and 7.4×10^{16} eV/μmol respectively. The irradiated samples were analyzed with a gas chromatograph using a flame-ionization detector after the gas fraction volatile at -120°C (rare gas and the product gases) had been removed; all the liquid products except dimers were analyzed with a 3-m Apiezon L column at 100°C, while for dimers a 6-m mixed nitrate column[6] was used with temperature programming from 60 to 120°C. The experimental details were presented in a previous paper.[4]

Results

As has previously been reported,[4] the products detected in the gas-phase radiolysis of toluene were hydrogen, methane, ethane, acetylene, benzene, ethylbenzene, xylenes, bibenzyl, and MDPM's, though in this study the gaseous products were not analyzed. The effect of the added rare gases, Ar, Kr, and Xe, on the product yields was studied at an almost constant pressure of toluene, 10.1 ± 0.3 mmHg; the results are presented in Table 1. Approximately linear relationships exist between the product yields and the pressure of the added rare gas, although some scattering was observed. From these results, the sensitization G values, G_s, indicating the increases in the G values of the products on the basis of the energy absorbed by the rare gas, were calculated; they are presented in Table 2.[7] As is shown in this table, G_s (MDPM's) is extremely large in the Ar-sensitized radiolysis, and also has a considerable value in the case of Kr. In both cases, the sensitization effect is largest on the formation of MDPM's. On the other hand, in the Xe-sensitized radiolysis, the G_s (MDPM's) value is very small and most of the MDPM's may be formed by the direct absorption of energy by toluene.

The isomer distribution of the MDPM's was approximately independent of the pressure of rare gas within

2) Much attention has been paid to the structure and formation process of the $C_7H_7^+$ ions because of the isotope randomization observed in the mass spectra of labeled alkylbenzenes, and the $C_7H_7^+$ ions are believed to have a tropylium-ion structure (see Ref. 1).

		2-MDPM	3-MDPM	4-MDPM
—	—	12	76	12
Ar	50.0	12	74	14
Kr	52.8	8	85	7
Xe	52.5	13	75	11

the limits of experimental error; the percentages of the three isomers at a rare-gas pressure of about 50 mmHg are presented in Table 3, together with those obtained in the direct radiolysis of toluene. In all cases, a large portion of the MDPM's consists of 3-MDPM; it is formed by benzylation at the *meta* position of toluene. The dependence of the G_s values of the MDPM isomers on the toluene pressure was studied in the Ar- and Kr-sensitized radiolyses at constant rare gas pressures, 51.1 and 52.7 mmHg, of Ar and Kr respectively; the results are illustrated in Figs. 1 and 2. The pressure dependence of the G values of the MDPM isomers in the previous study of the radiolysis of pure toluene obtained is also shown with dotted lines in Fig. 2 for the sake of comparison. In both the Ar- and Kr-sensitized radiolyses, G_s(3-MDPM) decreased with an increase in the toluene pressure, while G_s(2-MDPM) and G_s(4-MDPM) were not appreciably affected by the toluene pressure. Such pressure dependencies of the G_s values of the MDPM isomers are similar to those of their G values in the direct radiolysis.

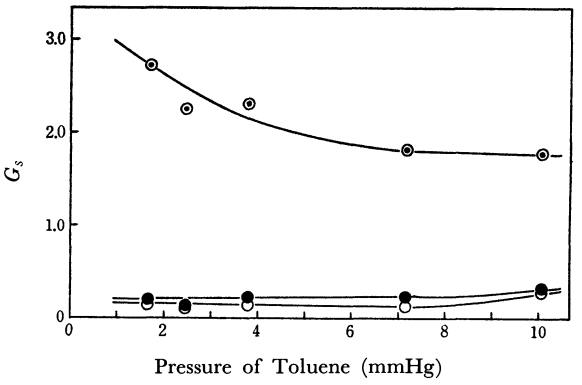

Fig. 1. The dependence of G_s(MDPM's) on toluene pressure in the Ar sensitized radiolysis at 51.1 mmHg of Ar pressure: ○, G_s(2-MDPM); ⊙, G_s(3-MDPM); ●, G_s(4-MDPM).

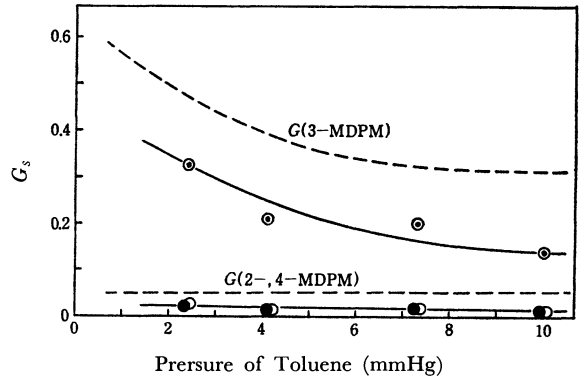

Fig. 2. The dependence of G_s(MDPM's) on toluene pressure in the Kr sensitized radiolysis at 52.7 mmHg of Kr pressure and that of G(MDPM's) in the radiolysis of pure toluene (dotted lines): ○, G_s(2-MDPM); ⊙, G_s(3-MDPM); ●, G_s(4-MDPM).

Discussion

The ionization potentials and the energy levels of the excited states of Ar, Kr, and Xe are shown in Table 4. Charge and excitation transfers from these states to toluene become the major modes of energy absorption by toluene molecules in the radiolysis of toluene in the presence of excess rare gas.

TABLE 4. IONIZATION POTENTIALS AND EXCITATION ENERGIES OF RARE GASES (in eV)[a)]

Rare gas	I.P.		Allowed state		Metastable state	
	$^2P_{3/2}$	$^2P_{1/2}$	$^3P_1$	$^1P_1$	$^3P_2$	$^3P_0$
Ar	15.75	15.93	11.62	11.82	11.56	11.72
Kr	14.00	14.66	10.03	10.64	9.91	10.56
Xe	12.13	13.43	8.43	9.57	8.31	9.44

The Sensitization on the Formation of MDPM's. In the previous paper on the gas-phase radiolysis of toluene, the following mechanism of the formation of MDPM's has been proposed on the basis of the pressure dependence of the yields of the three isomers.[4,8)]

$$C_6H_5CH_3 \rightsquigarrow C_6H_5CH_3^{+*} + e \quad (1)$$

$$C_6H_5CH_3^{+*} \longrightarrow C_7H_7^+ + H \quad (2)$$

$$C_7H_7^+ + C_6H_5CH_3 \longrightarrow \left(\text{C}_7\text{H}_8^+\text{-}\text{CH}_2\text{C}_6\text{H}_5\right)^* \quad (3)$$

I*

$$I^* + C_6H_5CH_3 \longrightarrow MDPM + C_7H_9^+ \text{ (minor)} \quad (4)$$

$$\longrightarrow I + C_6H_5CH_3 \text{ (major)} \quad (5)$$

$$I \longrightarrow \text{Im} \quad (6)$$

Im

$$Im + C_6H_5CH_3 \longrightarrow 3\text{-MDPM} + C_7H_9^+ \quad (7)$$

$$\longrightarrow \text{Adduct Ion} \quad (8)$$

where I* is an excited σ-complex producing three isomers of MDPM's, and where a less excited σ-complex, I, isomerizes to the most stable one, Im, which then produces 3-MDPM or a trimeric ion.

The G_s values of the MDPM's exhibit remarkable differences among the Ar-, Kr-, and Xe-sensitized radiolyses; they decreased in the order of Ar, Kr, and Xe, as is shown in Table 2. Such results can be explained as follows. The appearance potential of the $C_7H_7^+$ ion from toluene is 11.8 eV,[1)] and the possible mode of its formation by the rare-gas sensitization is considered to involve a charge-transfer process (see Table 4):[9)]

$$X \rightsquigarrow X^+ + e \quad (9)$$

$$X^+ + C_6H_5CH_3 \longrightarrow X + C_6H_5CH_3^{+*} \quad (10)$$

$$C_6H_5CH_3^{+*} \longrightarrow C_7H_7^+ + H \quad (11)$$

where X shows a rare gas such as Ar, Kr, and Xe. The excess energies available in the charge transfers from the $^2P_{3/2}(^2P_{1/2})$ states of Ar^+, Kr^+, and Xe^+ to toluene (Reaction (10)) are 6.93 (7.11), 5.18 (5.84) and 3.31 (4.61) eV respectively (the ionization potential of toluene is 8.82 eV[10)]), and end up as excess internal energies in the resulting toluene ion. Therefore, the probability of the fragmentation of the excited toluene ions to the $C_7H_7^+$ ions (Reaction (11)), *i.e.*, the sensitization effect on the formation of MDPM's, depends on the ionization potentials of rare gases and increases in the order of Xe, Kr, and Ar.

If the added rare gas contributed to the collisional stabilization of the excited σ-complex, I*, one might expect a more selective formation of 3-MDPM in these rare-gas-sensitized radiolyses than in the direct radiolysis of toluene. However, the isomer distribution of MDPM's was not affected by the addition of rare gas, except in the case of Kr (to be discussed below) (Table 3) and was approximately independent of the rare gas pressure, as has been discussed above. On this basis, it seemed reasonable to conclude that the collisional stabilization of I* with rare gas atoms can hardly compete with the reactions of I* with toluene molecules, Reactions (4) and (5). Two explanations may be offered for this observation. First, and less likely, it may be suggested that the collisional stabilization of I* with rare gas is less effective than that with toluene because the toluene molecule possesses a higher degree of freedom. A second, and perhaps more likely, explanation would be that Reaction (5) is not a simple collisional stabilization, but a certain rapid chemical reaction, involving addition and dissociation or the benzyl-cation transfer from I* to another toluene molecule[11)] analogous to the proton transfer (Reaction (4)).

As is shown in Figs. 1 and 2, the dependence of the G_s values of MDPM's on the toluene pressure in the Ar- and Kr-sensitized radiolyses is almost identical with the pressure dependence of the G values of MDPM's in the radiolysis of pure toluene. Such a result also indicates that the isomer distribution of MDPM's was altered only by the change in the toluene pressure and was not appreciably affected by the addition of the rare gas. Thus, the results obtained in this study suggest that the effect of the added rare gas on the formation of MDPM's is small, if present at all, except for the sensitization upon the primary formation of the $C_7H_7^+$ ions.

When the isomer distributions of MDPM's in the Ar- and Kr-sensitized radiolyses are compared, the percentage of 3-MDPM is found to be somewhat larger in the latter case than in the former case (Table 3).

8) An analogous mechanism was also proposed in the study of the reactions of $C_3H_7^+$ ions with aromatic hydrocarbons [S. Takamuku, K. Iseda, and H. Sakurai, *J. Amer. Chem. Soc.*, **93**, 2420 (1971).].

9) The excitation transfer from the $^1P_1$ state of Ar may also contribute to the sensitization upon the formation of the $C_7H_7^+$ ions.

10) S. C. Lind, "Radiation Chemistry of Gases," Reinhold, New York (1961), p. 270.

11) In such a reaction, I* might act as a less electrophilic reagent to another toluene molecule to form a less energetic complex, I, as has previously been proposed (see Ref. 8).

Such a discrepancy in the Ar- and Kr-sensitized radiolyses might be attributed to the difference in the internal energy of the $C_7H_7^+$ ions formed through the charge transfer from these rare gases to toluene; the internal energy of the $C_7H_7^+$ ions formed through the charge transfers from Kr is smaller than that from Ar because of the lower exothermicity of Reaction (10), and the addition of the less excited $C_7H_7^+$ ion to toluene results in the formation of a less excited complex, producing 3-MDPM with a higher probability. In the Xe-sensitized radiolysis, most of the MDPM's may be formed by direct energy absorption by toluene; the isomer distribution was similar to that in the direct radiolysis, as is shown in Table 3.

The Sensitization on the Formation of Other Products. As has been previously reported, in the gas-phase radiolysis of toluene the primary processes leading to the formation of benzene, ethylbenzene, xylenes, and bibenzyl are considered to be as follows:[4]

$$C_6H_5CH_3 \rightsquigarrow C_6H_5\cdot + CH_3\cdot \quad (12)$$

$$C_6H_5^+ + CH_3\cdot + e \quad (13)$$

$$\cdot C_6H_4CH_3 + H \quad (14)$$

$$C_6H_5CH_2\cdot + H \quad (15)$$

Thus, both the phenyl radicals and the phenyl cations have been considered to give rise to benzene, and the formation of ethylbenzene, xylenes, and bibenzyl has been attributed to combinations of the radicals, involving methyl, tolyl, and benzyl radicals. With regard to these products, the G_s values in the Ar-, Kr-, and Xe-sensitized radiolyses and the G values in the direct radiolysis do not differ significantly (Tables 1 and 2). However, from the results shown in Table 2 it may be considered that the sensitization effect on the formation of benzyl radicals, producing ethylbenzene and bibenzyl, increases in the order of Ar, Kr, and Xe; in the Xe-sensitized radiolysis, bibenzyl, the minor dimeric product in the direct radiolysis, was formed in a yield comparable to that of MDPM's at a higher pressure of Xe Table 1. As has previously been reported, in the mercury-photosensitized decomposition of toluene vapor at 2537 Å, the β C–H bond scission is a major primary process, as is the α C–C bond scission, and the only dimeric product detected is bibenzyl.[4] Thus, the distribution of the products formed by the Xe sensitization resembles that in the mercury-photosensitized decomposition rather than that in the direct radiolysis. Such a result may be attributed to the fact that the energy transferred from Xe to toluene in the sensitized radiolysis is smaller than those from Ar and Kr, and is also smaller than that directly absorbed by toluene.

We wish to thank Mr. Tamotsu Yamamoto and Mr. Tomikazu Sawai of the Radiation Laboratory for their assistance in the γ irradiations.

Heats of Immersion of Silica-alumina in Nonaqueous Solvents

Masaji MIURA, Toru IWAKI, Masayoshi KOMURO, Kusao TANAKA, and Kenji ITO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received March 1, 1971)

The heats of immersion of silica gel, alumina, and silica-aluminas in benzene, cyclohexane, and a solution of *n*-butylamine in benzene have been studied in connection with the acid properties of the surfaces. It was found that *n*-butylamine interacts more strongly with the surfaces of silica-aluminas than is the case in an aqueous system, which was previously investigated. Further, the interactions of benzene with the surfaces of silica-aluminas were discussed on the basis of the results of the adsorption isotherms of benzene on the surfaces.

Silica-alumina is one of the most important catalysts for various acid-catalyzed reactions.[1] These catalytic actions are considered to be connected with the acid sites on the surface of silica-alumina. In our previous study,[2] the surface properties of silica-aluminas with different contents of alumina were investigated by examining the relation between the property of the acid site and the heats of immersion in water and an aqueous solution of *n*-butylamine; it has been found that the molecule interacts preferentially with the strong acid sites and weakens the site strength. Therefore, it may be of interest to investigate the heats of immersion of silica-alumina in nonaqueous solvents. In this work, the heats of immersion of silica gel, alumina, and silica aluminas were measured in benzene, cyclohexane, and a solution of *n*-butylamine in benzene. Further, the interaction of benzene with the surfaces of the samples was discussed by examining the adsorption isotherms of benzene on the surfaces.

Experimental

Materials. Silica gel, alumina, and silica-aluminas with a content of 10% alumina, 10% SA, and that of 50% alumina, 50% SA, were prepared by the hydrolysis of ethyl ortho-silicate and/or aluminum isopropoxide by a procedure similar to that described in a previous paper.[2] The specific surface areas of the samples evacuated at 300°C for 3 hr were determined from the nitrogen adsorption by the BET

method. The results are given in Table 1. The surface area of silica-alumina exhibits a low value at a content of 10% alumina; this is analogous to the previous finding.[2]

Benzene and cyclohexane were purified by distillation, with several pieces of metallic sodium added to remove any moisture.

Heat-of-immersion Measurement. Prior to the measurements, the samples were evacuated at 300°C for 3 hr in a vacuum of 10^{-5} mmHg. The heats of immersion of these samples in benzene, cyclohexane, and a solution of *n*-butylamine in benzene were measured at 25°C by using a calorimeter[3] which was improved so as to be able to hold four ampoules at a time. Since trace quantities of water dissolved in these liquids have a significant effect on the heat value, the water was removed by an activated molecular sieve in the following way. After each of these liquids had been placed in the calorimeter, a large quantity of the molecular sieve was added to the liquids. Next, after a thermal equilibrium in the system had been established, an ampoule containing the molecular sieve was broken in order to dehydrate the liquid completely just before another ampoule containing a sample was broken for the measurement of the immersional heat.

Adsorption Measurement. The adsorption isotherms of benzene on the samples were volumetrically determined at 25°C by using an adsorption apparatus equipped with greaseless Teflon cocks. The equilibrium pressure of benzene vapor was measured by means of a mercury manometer.

Results

The heats of immersion of the samples in benzene and cyclohexane are shown in Fig. 1 as a function of the alumina content. The heat value in benzene ranged from 82 to 110 erg/cm², and that in cyclohexane, from 48 to 77 erg/cm². The heat values of silica gel in benzene and cyclohexane were similar to those reported by Whalen.[4] In Fig. 2, the heats of immersion of these four samples in a 1 M solution of *n*-butylamine in benzene are shown as a function of the alumina content. In the figure, the heats of immersion in water and the aqueous solution of *n*-butylamine are also presented for comparison.[2] The adsorption isotherms of benzene on the surfaces of silica,

silica-aluminas, and alumina are shown in Fig. 3. The dotted line in the figure shows a monolayer volume, V_m, estimated from the BET plots.

Discussion

When the silica-alumina is evacuated at a high temperature, such as 300°C, some hydroxyl groups bound with the aluminum atoms of the surface of silica-alumina are removed, resulting in the formation of strong acid sites which consist of Brönsted- and Lewis-acid sites,[5] whereas the remaining aluminol groups may act as weak acid sites. As for the silica, there is no strong acid site in spite of the presence of silanol groups on the surface. The alumina surface has aluminol groups and Lewis-acid sites. In our previous study,[2] the acidity of silica-alumina was obtained as a function of the alumina content, and it was found that the number of acid sites was at a maximum at an alumina content of 10—20%.

As can be seen in Figs. 1 and 2, the immersional-heat values of silica-alumina in benzene and cyclohexane did not vary much with the alumina content; this is unlike the case in water, where the heat value increased appreciably with the alumina content. The factors responsible for the generation of the heat in water have been considered to be the property of the surface hydroxyl groups as well as the number and strength of the acid sites.[2] The heat values of 10% SA in benzene and cyclohexane were larger than, respectively, the values estimated from the sum of the contributions of silica and alumina. This phenomenon may be interpreted on the basis of the contribution of the large number of acids sites on 10% SA to the generation of the heat in a nonpolar solvent.

The difference between the heat values in benzene and the solution of *n*-butylamine in benzene is remarkably larger than that between those in water and an aqueous solution of *n*-butylamine, as may be seen in Fig. 2. In the absence of water, as expected, *n*-butylamine interacts strongly with these samples; it seems probable that the remarkably large heat arises from the strong interaction of *n*-butylamine with the strong acid site, especially with the Lewis-acid site on the surface of alumina.

On the basis of the adsorption isotherms of benzene on the samples in Fig. 3, let us examine the interaction of benzene with the surface. The monolayer volumes, V_m, resemble one another though the adsorption isotherm on alumina is located higher than the others. The monolayer volume was converted to the benzene surface area, S_B, by assuming the cross-sectional area of benzene molecule to be 40.3 Å^2.[6] The ratio of the benzene area to the nitrogen area, S_B/S_{N_2}, for each sample is listed in Table 1. The benzene molecules adsorbed do not cover all the nitrogen area, suggesting that particular sites for benzene molecules are present on the surface. The number of sites where the benzene molecule can be adsorbed is about 2 per 100 Å^2. This number of sites does not correspond to the number of acid sites. Benzene molecules may be adsorbed not only on the acid sites, but also on other sites, such as those of silanol groups.

The interaction of the benzene molecule with the polar surface of a solid is considered to originate from: (a) the van der Waals interaction, (b) the Coulomb interaction between the surface and π-electrons of benzene, and (c) the dipole-induced dipole interaction. The last interaction (c) may be negligibly small compared with the other interactions.[7] On the other hand, the interaction of the cyclohexane molecule with the surface may arise from only the van der Waals interaction.

The immersional-heat values of the samples in benzene in Fig. 1 are larger by 30—37 erg/cm^2 than those in cyclohexane. The difference between the heat values in benzene and cyclohexane, ΔH, is given in Table 1. If the difference between the surface enthalpy of benzene, 67.6 erg/cm^2, and that of cyclohexane, 57 erg/cm^2, is disregarded, and if the cyclohexane surface area is equal to the S_B, the ΔH value may be the contribution of the interaction of π-electrons of benzene with the surface, as a rough estimate. The interaction energy, q, which is obtained by dividing the ΔH value by the monolayer volume, V_m, is presented in the last column of Table 1. As for silica, this value is in good agreement with that given by Kiselev and Poshkus.[8] They obtained, from the heat of adsorption, a value of 2—3 kcal/mol for the energy of interaction between the π-electron of benzene and hydroxyl groups on the surface of silica. Since the π-electron acts as an electron donor in this interaction, the relatively large energy for 10% SA may be ascribed to the contribution of the large number of acid sites.

Table 1. Surface area, number of site for benzene, and difference between heat of immersion in benzene and that in cyclohexane

Material	S_{N_2}(m^2/g)	S_B/S_{N_2}	Site/100Å^2	ΔH(erg/cm^2)	q(kcal/mol)

A Simple Relation among the Energy Differences between Conformers of XH_2C-CH_2Y, $C_6H_{11}X$, $C_6H_{11}Y$, and *trans*-1,2-$C_6H_{10}XY$

Etsuko FUJIMOTO, Kunio KOZIMA, and Yoshiko TAKEOKA*

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 4, 1971)

By measuring the infrared intensities, the energy differences between two conformers have been determined for bromocyclohexane, iodocyclohexane, *trans*-1-bromo-2-chlorocyclohexane, 1-bromo-2-chloroethane, ethylene bromohydrin, and ethylene iodohydrin in dilute solutions, and for cyclohexanol, *trans*-2-chlorocyclohexanol, ethylene chlorohydrin, and ethylene bromohydrin in vapors.

It was ascertained that the following relation holds for the energy differences:

$$E_t - E_g = (E_{aa} - E_{ee}) - (E_a - E_e) - (E_a' - E_e').$$

Here $E_t - E_g$ is the energy difference between the *trans* and the *gauche* isomer of XH_2C-CH_2Y, $E_{aa} - E_{ee}$ is that between the *aa*- and the *ee*-isomer of *trans*-1,2-$C_6H_{10}XY$, and $E_a - E_e$ and $E_a' - E_e'$ are those between the *a*- and the *e*-isomers of $C_6H_{11}X$ and $C_6H_{11}Y$ respectively, where X is a halogen and Y is a halogen or the O–H group.

The energy difference between the conformers may be considered to be the difference between the intramolecular potential energies, which are usually the sums of the potential energies for the various pairs of non-bonded atoms in each isomer. Furthermore, it is safe to assume, for similar molecules, that the potential energy between the same pair of non-bonded atoms does not differ from molecule to molecule, so long as the distance between non-bonded atoms remains almost the same. On the basis of these considerations, the following relation has been obtained:[1]

$$E_t - E_g = (E_{aa} - E_{ee}) - 2(E_a - E_e), \quad (1)$$

where E_t–E_g is the energy difference between the *trans* and the *gauche* isomer of 1,2-dihaloethane, XH_2C–CH_2X, E_{aa}–E_{ee} is that between the *aa*- and the *ee*-isomer of *trans*-1,2-dihalocyclohexane, $C_6H_{10}X_2$, and E_a–E_e is that between the *a*- and the *e*-isomer of halocyclohexane, $C_6H_{11}X$; this relation has been shown to be correct within the limit of experimental error when X is Cl.[1]

The relation can easily be extended to one for such compounds as XH_2C–CH_2Y, *trans*-1,2-$C_6H_{10}XY$, $C_6H_{11}X$, and $C_6H_{11}Y$, where X is a halogen and Y is a halogen or the O–H group. In an attempt to examine the extended relation, a study of the energy differences between two conformers has been carried out for bromocyclohexane, iodocyclohexane, *trans*-1-bromo-2-chlorocyclohexane, cyclohexanol, *trans*-2-chlorocyclohexanol, 1-bromo-2-chloroethane, ethylene chlorohydrin, ethylene bromohydrin, and ethylene iodohydrin by measuring the infrared intensities.

Experimental

Materials. The iodocyclohexane used in this research was prepared by adding cyclohexene to a solution of potassium iodide dissolved in 95% orthophosphoric acid.[2] The product was purified by fractional distillation; bp 48.5—49.0°C/4 mmHg.

The *trans*-1-bromo-2-chlorocyclohexane was prepared by adding a mixture of bromine and chlorine dissolved in chloroform to cyclohexene.[3] The product was purified by fractional distillation; bp 82.2—82.3°C/13 mmHg.

The ethylene iodohydrin was prepared by refluxing sodium iodide, absolute ethanol, and ethylene chlorohydrin.[4] The product was purified by fractional distillation; bp 47.6—47.8°C/3 mmHg.

The samples of bromocyclohexane, cyclohexanol, 1-bromo-2-chloroethane, ethylene chlorohydrin, and ethylene bromohydrin, which had been obtained from commercial sources, were purified by distillation.

The measurement of the infrared spectra and that of the integrated intensities of the infrared absorption bands were made by the method described in a previous paper.[5]

Results and Discussion

Existence of Conformers. By infrared studies of chlorocyclohexane[1] and bromocyclohexane,[6] it has been ascertained that two conformers, the *a*- and the *e*-isomer, exist in the liquid, while only the *e*-isomer exists in the solid.

Concerning iodocyclohexane, *trans*-1-bromo-2-chlorocyclohexane, and cyclohexanol, the infrared spectra were measured both in the liquid and in the solid. The results are shown in Tables 1-a, 1-b, and 1-c. Since several bands of the liquid-state spectra disappear on passing from the liquid to the solid, as can be seen from these tables, it is certain that the two conformers exist in the liquid, while only one of them remains in the solid.

Since the solid-state spectra of chloro-, bromo-, and iodocyclohexane show striking similarities, it is very probable that only the *e*-isomer exists in the solid of iodocyclohexane. Furthermore, additional evidence is obtained by the following consideration.

By comparing the liquid-state spectrum of iodo-

cyclohexane with those of the chloro- and the bromo-derivative, the 639- and the 655- cm^{-1} band of iodocyclohexane can safely be assigned to the C–I stretching vibration. For the bands assigned to the C-halogen stretching vibration of various halogen derivatives of cyclohexane, one of the present authors has previously pointed out the empirical rule[7] that the frequencies of the bands which are due to the halogen atoms attached to the *e*-positions of the ring are higher than those of the bands due to the same halogen atoms attached to the *a*-positions. According to this rule,

the 639- and the 655- cm^{-1} band can be assigned to the *a*- and the *e*-isomer respectively. Therefore, the same conclusion can be drawn here, since the higher-frequency band persists in the solid.

In order to determine the stable isomer of *trans*-1-bromo-2-chlorocyclohexane in the solid, the relative intensities of two pairs of bands, the 815- and 818-cm^{-1} bands, and the 976- and 999-cm^{-1} bands, were measured both in the acetone solution and in the carbon disulfide solution. As can be seen in Fig. 1, the intensities of the lower-frequency bands increase when the solvent changes from carbon disulfide to acetone. As it is well known[8] that the more polar isomer stabilizes in polar solvents except in the case of benzene, it follows that the lower-frequency bands which per-

8) S. Mizushima, "Structure of Molecules and Internal Rotation," Acad. Press, New York (1954), p. 43; I. Watanabe, S. Mizushima, and Y. Masiko, *Sci. Papers Inst. Phys. Chem. Res. Tokyo*, **40**, 425 (1943).

—— in the carbon disulfide solution
---- in the acetone solution
·—· in the solid

sist in the solid are to be assigned to the *ee*-isomer, because the *ee*-isomer is more polar than the *aa*-isomer.

Concerning cyclohexanol, it is very probable, in view of the results on halocyclohexanes, that only the *e*-isomer exists in the solid. This is supported by the following consideration. Winstein and Holness[9] have pointed out that *cis*-4-*t*-butylcyclohexanol exists as the *a*-isomer, and that *trans*-4-*t*-butylcyclohexanol exists as the *e*-isomer, with regard to the C–O bond, because of the steric hindrance of the *t*-butyl group, and that the 955-cm^{-1} band is assigned to the C–O stretching vibration of the *cis* isomer, and the 1062-cm^{-1} band, to that of the *trans* isomer. According to these findings, the 1067-cm^{-1} band of cyclohexanol which persists in the solid may be assigned to the C–O stretching vibration of the *e*-isomer. In the spectra of the liquid and of the solution for cyclohexanol, the 957-cm^{-1} band may be assigned to the C–O stretching band of the *a*-isomer. At first glance it is not clear whether or not this band disappears in the solid, because this band is masked by two strong and broad bands. However, by assuming that these two bands are represented by Lorentz's curves, it can be seen that the 957-cm^{-1} band disappears in the solid.

It has been shown[10] that ethylene chlorohydrin possesses two conformers, namely, the *trans* and the *gauche* isomer, both in the vapor and in the liquid, while only the *gauche* isomer exists in the solid. The infrared spectra of the bromo- and the iodo-derivative in the liquid were also measured. In the frequency region of C–halogen stretching vibrations, there are two bands, namely, the 573 and 676 cm^{-1} bands for the bromo-derivative, and the 518 and 622 cm^{-1} bands for the iodo-derivative. Of the two pairs of bands, the intensities of the lower-frequency bands increase with a decrease in the temperature. This fact shows that for the cases of the bromo- and the iodo-derivative also the two conformers exist in the liquid.

Energy Differences between Conformers. For bromo-

* The subscripts h and f refer to the hydrogen-bonded molecule and the non-bonded one, respectively.

cyclohexane, the values reported[11,12] do not agree with each other. Therefore, the relative integrated intensities of the 668- and the 658-cm^{-1} band of bromocyclohexane were measured as a function of temperature in the carbon disulfide in order to determine the energy difference. The results are shown in Table 2-a. From these data, the energy difference, E_a–E_e, is calculated to be 0.60 kcal/mol. The value thus obtained agrees with that of Jensen and Gale.[12]

For iodocyclohexane, the change in the relative integrated intensities of the 639- and the 655-cm^{-1} band with the temperature was measured. The results are shown in Table 2-b. From these data, the energy difference, E_a–E_e, is calculated to be 0.73 kcal/mol.

By comparing the values for bromo- and iodocyclohexane with the value of 0.33 kcal/mol for chlorocyclohexane,[1] it can be concluded that the stability of the *e*-isomer of halocyclohexane increases with an increase in the atomic radius of halogens.

For *trans*-1-bromo-2-chlorocyclohexane, the change in the relative integrated intensities of the 977- and the 1001-cm^{-1} band with the temperature was measured. The results are shown in Table 2-c. From these data, the energy difference, E_{ee}–E_{aa}, is calculated to be 0.12 kcal/mol.

Chiurdoglu *et al.*,[11] Masschelein,[13] and Neelakantan[14] have all estimated the energy difference of cyclohexanol in the liquid. Pickering and Price[15] have estimated it in the 0.3 mol/l carbon disulfide solution. However, these values cannot be taken to be the value of the energy difference, because the values are affected by the intermolecular hydrogen bond. The change in the relative integrated intensities of the 835-cm^{-1} band of the *a*-isomer and the 845-cm^{-1} band of the *e*-isomer with the temperature was measured in the vapor. The results are shown in Table 3-a. From these data, the energy difference of cyclohexanol is calculated to be 0.59 kcal/mol, the *e*-isomer being more stable.

Table 3. Temperature dependence of relative integrated intensities and energy difference between isomers in the vapor*

a) Cyclohexanol

Temp. (C)	Wave number	Isomer	C_1a_1/C_2a_2

74°	682	1 = t	0.52
	583	2 = g	

$E_t - E_g = 0.98$kcal/mol

* The integrated intensities were measured by the same method as described in the reference of (21).

The energy difference of *trans*-2-halocyclohexanols in dilute solutions has been reported in a previous paper.[5] In order to determine the energy difference of *trans*-2-chlorocyclohexanol in a vapor, the relative integrated intensities of the C–Cl stretching bands were measured at 60°C by using a 1-m cell and at 160°C by using a 10-cm cell. The results are shown in Table 3-b. From these data, the energy difference can be calculated to be 2.0 kcal/mol, the *ee*-isomer being more stable. The energy differences in the vapor for the bromo- and the iodo-derivative could not be measured because of the low vapor pressure.

In order to determine the energy difference of 1-bromo-2-chloroethane, the relative integrated intensities of the 1201-cm^{-1} band of the *trans* isomer and the 1259-cm^{-1} band of the *gauche* isomer were measured in

11) G. Chiurdoglu, M. L. Kleiner, W. Masschelein, and J. Reisse, *Bull. Soc. Chem. Belges*, **69**, 143 (1960).
12) F. R. Jensen and L. H. Gale, *J. Org. Chem.*, **25**, 2075 (1960).
13) W. Masschelein, *J. Mol. Spectrosc.*, **10**, 161 (1963).
14) P. Neelakantan, *Proc. Indian Acad. Sci.*, **A57** (**2**), 94 (1963).

a solution. The assignments used were those reported by Kuratani *et al.*[16] The results are shown in Table 2-d. From these data, the energy difference, E_g–E_t, can be calculated to be 0.95 kcal/mol.

The energy difference in the vapor for ethylene chlorohydrin is calculated to be 1.1 kcal/mol from the data shown in Table 3-c, the *gauche* isomer being more stable. This value is nearly equal to that obtained by Mizushima *et al.*[10] It may be safe to consider that the 573- and the 676-cm^{-1} band of ethylene bromohydrin and the 518- and the 622-cm^{-1} band of ethylene iodohydrin are due to the C–halogen stretching vibrations. Of the pairs of bands for both compounds, the lower-frequency bands can be assigned to the *gauche* isomer, and the others, to the *trans* isomers, as is the case for ethylene chlorohydrin. The temperature dependence of the relative integrated intensities of these bands was also measured. The results for ethylene bromohydrin are shown in Tables 3-d and 2-e for the vapor and the dilute solution respectively. From these data, the energy differences, E_t–E_g, can be calculated to be 0.98 and 0.59 kcal/mol in the vapor and in the dilute solution respectively. The results for ethylene iodohydrin are shown in Table 2-f. From these data, the energy difference, E_t–E_g, can be calculated to be 0.82 kcal/mol.

There are two O–H stretching bands in the 3μ region of the infrared spectra of ethylene halohydrins, even in dilute carbon disulfide solutions, as in the cases of *trans*-2-halocyclohexanols.[5] The lower-frequency bands can be assigned to the O–H stretching vibration for the hydrogen-bonded molecules, and the others, to that of the non-bonded molecules. The lower-frequency bands can be safely assigned to the *gauche* isomer, because, in view of its molecular geometry, only the *gauche* isomer is able to form an intramolecular hydrogen bond. Of these pairs of bands, the intensities of the lower-frequency bands increase with a decrease in the temperature. Concerning ethylene iodohydrin, in the spectra of which the frequency difference between these bands is relatively large, the relative intensity of these bands was measured by changing the temperature. The results are shown in Table 2-g. From these data, the difference between the energy of the hydrogen-bonded molecule, E_h, and that of the non-bonded one, E_f, can be calculated to be 0.88 kcal/mol, the hydrogen-bonded molecule being more stable. When taking into account the experimental error usually introduced in the intensity measurements, this value can be said to agree with the energy difference between the conformers obtained by measuring the C–I stretching bands. This shows that the *gauche* isomer exists exclusively in the form with the intramolecular hydrogen bond in the dilute solution.

Relation of Energy Differences between Conformers. On the basis of the information presented above, the following relation can be obtained for such compounds as XH_2C–CH_2Y, *trans*-1,2-$C_6H_{10}XY$, $C_6H_{11}X$, and $C_6H_{11}Y$:

$$E_t - E_g = (E_{aa} - E_{ee}) - (E_a - E_e) - (E_a' - E_e'), \quad (2)$$

where E_t–E_g is the energy difference between the *trans* and the *gauche* isomer of XH_2C–CH_2Y, E_{aa}–E_{ee} is that between the *aa*- and the *ee*-isomer of $C_6H_{10}XY$, and E_a–E_e and E_a'–E_e' are those between the *a*- and the *e*-isomers of $C_6H_{11}X$ and $C_6H_{11}Y$ respectively.

* The values reported in our previous article (5)
** The values reported in the reference of (1)

From Table 4-a it can be seen that Eq. (2) holds for the case in which X is Cl and Y is Br, since the agreement between the observed and the calculated value for the energy difference of ClH_2C–CH_2Br is satisfactory.

Potential functions for non-bonded hydrogen-hydrogen and for non-bonded carbon-hydrogen interaction energies have been given by Hendrickson.[17] According to these functions, the nuclear distances at the potential minima for hydrogen-hydrogen and carbon-hydrogen interactions are 2.5 and 2.8 Å respectively. Of these pairs of non-bonded atoms in these compounds, there are no pairs of shorter distances than those at the potential minima. Therefore, although the distances between the hydrogen

16) K. Kuratani, T. Miyazawa, and S. Mizushima, *J. Chem. Phys.*, **21**, 1411 (1953).

17) J. B. Hendrickson, *J. Amer. Chem. Soc.*, **83**, 4531 (1961).

atoms or between the hydrogen and the carbon atom may vary somewhat from molecule to molecule, it can be seen from the potential curves[17] that these changes do not affect the relation of Eq. (2) beyond the limit of experimental error. The pairs of non-bonded atoms which make an important contribution to the energy difference may be those of halogen-halogen, halogen-hydrogen, and halogen-carbon. However, these potential functions are not clearly known. From the fact that Eq. (2) holds for these compounds, it is, however, sure that, in the cases where the distances between the same pair of the non-bonded atoms are considered to be almost the same from the structural point of view, the potential energy between them is nearly the same from molecule to molecule at least for these compounds.

It seems that it would be interesting to consider the cases in which one of the substituents is an O–H group, and the other, a halogen. In these cases, one of the isomers forms an intramolecular hydrogen bond. The values of the frequency difference between the hydrogen-bonded O–H stretching band and the free one are shown in Table 5 for the *ee*-isomer of *trans*-2-halocyclohexanols and for the *gauche* isomer of ethylene halohydrins. From this table, it can be seen that the strength of the hydrogen bond of *trans*-2-chloro-, *trans*-2-bromo-, or *trans*-2-iodocyclohexanol is nearly equal to that of ethylene chloro-, ethylene bromo-, or ethylene iodohydrin respectively. Therefore, it seems probable that Eq. (2) holds for these cases. The results for the cases of the vapors of the chloro-derivatives are shown in Table 4-b. The agreement shown in this table is satisfactory. For the cases of the dilute solutions of the bromo- and the iodo-derivative the results are shown in Tables 4-d and 4-e respectively. In these tables, the value of the energy difference of cyclohexanol in the vapor is used, as the value in the dilute solution could not be measured because of the lack of an adequate solvent. Since, for this molecule, the dipole moment of the *e*-isomer is nearly equal to that of the *a*-isomer, the energy difference in the vapor seems not to be different from that in the dilute solution.[8] As Tables 4-d and 4-e show, the observed and the calculated values agree if account is taken of the experimental errors usually introduced in the intensity measurements. The energy difference of ethylene chlorohydrin in the dilute solution could not be measured because the bands of the usual non-polar solvents masked those of ethylene chlorohydrin. The value is, however, calculated by Eq. (2) to be 0.4 kcal/mol, as is shown in Table 4-c; this is lower by 0.7 kcal/mol than the value observed in the vapor. When taking into account the fact that the observed value of ethylene bromohydrin in the dilute solution is lower by 0.39 kcal/mol than that in the vapor, the estimated value of the chloro-derivative seems reasonable.

Table 5. Frequency difference between hydrogen-bonded O–H band and free one in the carbon disulfide solution (cm^{-1})

	trans-1,2-$C_6H_{10}XOH$	XH_2C-CH_2OH
X=Cl	25	28
X=Br	34	31
X=I	44	42

The dipole moment of the *trans* isomer of ethylene chlorohydrin, μ_t, is estimated to be 1.74 D by using the dipole moments of methanol[18] and methyl chloride[19] based upon the rule of the vector sum of bond moments. Since the dipole moment of the *gauche* isomer, μ_g, could not be estimated by using this rule because of the uncertainty of the moment due to the intramolecular hydrogen bond, it was calculated to be 1.79 D by the usual relation:

$$\mu^2 = (\mu_g^2+\mu_t^2\frac{1}{2}e^{-\Delta E/RT})/(1+\frac{1}{2}e^{-\Delta E/RT}),$$

where the value of ΔE used is the value of 1.1 kcal/mol obtained in the vapor and where μ is the dipole moment of 1.78 D observed in the vapor.[20] It can be seen from the results obtained above that the dipole moment of the *gauche* isomer is not very different from that of the *trans* isomer. Therefore, the finding that the *gauche* isomer is stabilized when the state changes from a dilute solution to a vapor violates the rule[8] that the more polar conformation is stabilized in a medium with a larger dielectric constant. The same violation can be seen in the cases of ethylene bromohydrin and *trans*-2-chlorocyclohexanol. However, this fact seems reasonable, because it is very probable the intramolecular hydrogen bond in the vapor is stronger than that in the dilute solution, as in the case with the intermolecular hydrogen bond between methanol and triethylamine.[21]

The Coadsorption of Nitric Oxide, Nitrogen, and Oxygen on Rhenium

Teijiro TAMURA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received March 8, 1971)

The coadsorption of nitric oxide, nitrogen, and oxygen on a polycrystalline rhenium filament was studied using flash desorption mass-spectroscopy. Substitutional desorption was not observed during the adsorption of nitric oxide, nitrogen, or oxygen on preadsorbed leayers. No oxygen or nitrogen adsorbs on rhenium saturated with nitric oxide. However, nitric oxide adsorbs on rhenium saturated with nitrogen or oxygen. The strength of the chemisorption bond between rhenium and adsorbed species becomes weaker in the order of: nitric oxide, oxygen, and nitrogen. When the same amount of nitric oxide molecules exist in various coadsorbed layers, the Tp of the nitrogen desorption spectrum from these layers is shifted to a lower temperature with an increase in the number of oxygen atoms in them, because the strength of the chemisorption bond of Re–N is weakened by the strongly-bonded Re–O. No desorption of the nitric oxide molecule from a coadsorbed layer of the "N_2+O_2" on rhenium was observed.

In the investigation of chemical reactions between metal and gas, studies of the chemisorption which precede these reactions will lead to a general understanding of the mechanism of chemical reactions. There has been much work done on the chemisorption of common gases, such as nitrogen,[1-6] oxygen,[7-11] hydrogen,[12,13] and carbon monoxide,[14-17] on metal surfaces.

The investigation of the chemisorption of nitric oxide, which possesses an odd number of electrons, is of interest. In a previous paper,[18] a study of the chemisorption of nitric oxide alone on rhenium has been reported.

In general, the temperature which gives the maximum rate of the desorption, Tp, and the peak height in the desorption spectrum from chemisorbed layers may be related to the desorption energy of the adsorbed species, so that different desorption spectra may be displayed by various adsorbed species with different surface coverages. Moreover, desorption spectra may be also changed by being affected by the coexistence of different adsorbed species. Thus, although the investigation of the coadsorption on metal surfaces is of interest, there have been only a few studies in this field.[8,19-22]

In the present investigation, the coadsorption of nitric oxide, nitrogen, and oxygen and the replacement of chemisorbed gases on a polycrystalline rhenium filament have been studied using flash desorption mass-spectroscopy.

Apparatus

The bakeable, ultra-high-vacuum apparatus used in this study was similar to that used in a previous work[18] except that it had two gas-supply system. It is shown in Fig. 1 schematically. The reaction systems, the volume of which was 0.8 l, contained a polycrystalline rhenium filament with a geometrical area of $A=0.6$ cm^2. The rhenium filament was analyzed spectroscopically. (Found: Si; 0.02%, Fe; 0.008%, Mg; 0.005%.) The ultimate pressure, read with a Bayard-Alpart gauge (B-A gauge), was 3×10^{-10} Torr in the system after a rigorous outgassing. The total pressure was measured by means of a Pirani gauge with a sensitivity of 7.2×10^{-8} Torr/μV for N_2 and NO, and 7.5×10^{-8} Torr/μV for O_2. An omegatron mass spectrometer was also used as a partial-pressure gauge; it had a sensitivity of 12 Torr^{-1} for N_2, 11.8 Torr^{-1} for NO, and 11 Torr^{-1} for O_2. The B-A gauge was used only in the ultimate-pressure measurement because the nitric oxide is dissociated by a hot filament of the gauge. The rhenium filament was heated to 2200°K using a transistor control circuit, as has been described previously.[18] The filament temperature was determined from a resistance-temperature relationship for rhenium;[23] above 1000°K, its temperature was measured with a micro optical pyro-

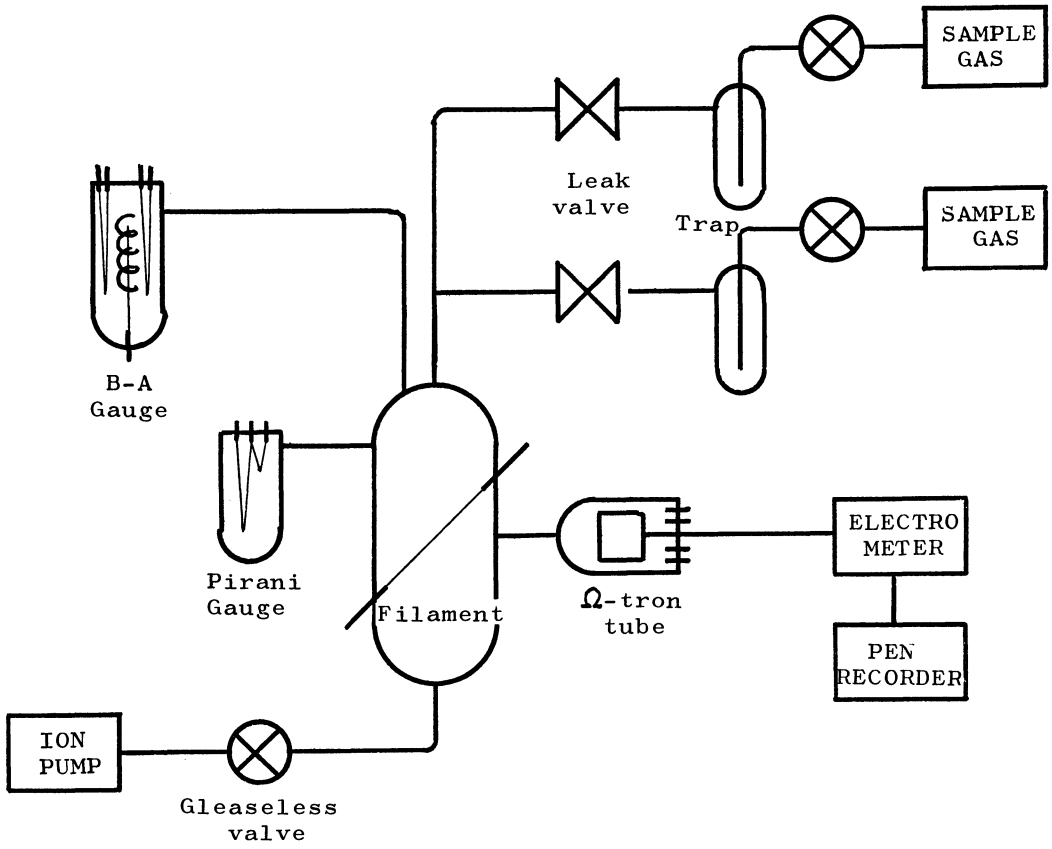

Fig. 1. Schematic drawing of Ultrahigh-vacuum apparatus for flash desorption mass spectroscopy.

meter.

The nitric oxide and nitrogen were prepared by the methods described in the previous paper. The oxygen was prepared by the thermal decomposition of high-purity potassium permanganate. The gas evolved was purified by liquid-nitrogen trap-to-trap distillation. No impurities up to mass 200 of any of the sample gases were detected by means of the omegatron mass spectrometer.

Procedure

Amount of Adsorption. The rhenium filament was purified by heating it at about 2000°K in oxygen of 1×10^{-6} Torr for several hours. The rhenium filament was then flashed to clean at 2200°K in a vacuum prior to the adsorption experiments, and then allowed to cool at room temperature. After nitric oxide had been passed through to obtain the saturation coverage, the system was evacuated; nitrogen or oxygen was then passed through to allow it to adsorb sufficiently. Such coadsorbed layers are expressed as "NO+N_2" or "NO+O_2". After the system had then been evacuated until the pressure dropped to 5×10^{-9} Torr, the rhenium filament was flashed at 2200°K in a closed system. The amount of molecules desorbed can be calculated from the pressure and the volume of the system. In the nitric-oxide adsorption, the number of molecules adsorbed is twice the number of molecules desorbed, because the desorbed gas is nitrogen.

Desorption Spectra. After the coadsorbed layer was formed, as has been described above, the slow flash desorption runs were initiated by using a transistor control circuit while the system was being evacuated. Ion currents of the omegatron mass spectrometer for each mass were recorded on the chart recorder.

Substitutional Desorption. For example, on the coadsorption of "NO+O_2", the ion current of the omegatron mass spectrometer corresponding to nitric oxide (preadsorbate) was measured during the adsorption of oxygen on rhenium saturated with nitric oxide. The substitutional desorption of nitric oxide could be detected from the change in this ion current

Results and Discussion

The amounts of nitrogen desorbed from various coadsorbed layers are shown in Table 1. The desorption spectra of nitrogen from the coadsorbed layers are shown in Fig. 2, while the temperatures of the desorption-peak maximum, Tp, are also shown in the second column of the table.

"*NO+N_2*". The substitutional desorption of nitric oxide was not observed during the adsorption of nitrogen on rhenium saturated with nitric oxide. Both the amount of nitrogen desorbed and the desorption spectrum of nitrogen from the "NO+N_2" layer were the same as those from a nitric oxide monolayer on rhenium. Therefore, nitrogen does not adsorb on the saturated nitric oxide layer on rhenium.

"*NO+O_2*". The substitutional desorption of nitric oxide was not observed in this case. Both the amount of nitrogen desorbed and the desorption spectrum of nitrogen from the "NO+O_2" layer were

TABLE 1. THE AMOUNT OF NITROGEN DESORBED AND THE Tp IN THE NITROGEN DESORPTION SPECTRUM FROM VARIOUS ADSORBED LAYERS ON RHENIUM

Layer	N_2 (desorbed) (molecules/cm^2)	Tp (°K)
NO	2.6×10^{14}	775
NO+N_2	2.6×10^{14}	775
NO+O_2	2.6×10^{14}	775
N_2+NO	3.4×10^{14}	775
O_2+NO	3.4×10^{13}	850
N_2	1.08×10^{14}	970
N_2+O_2	1.08×10^{14}	820
O_2+N_2	—	—

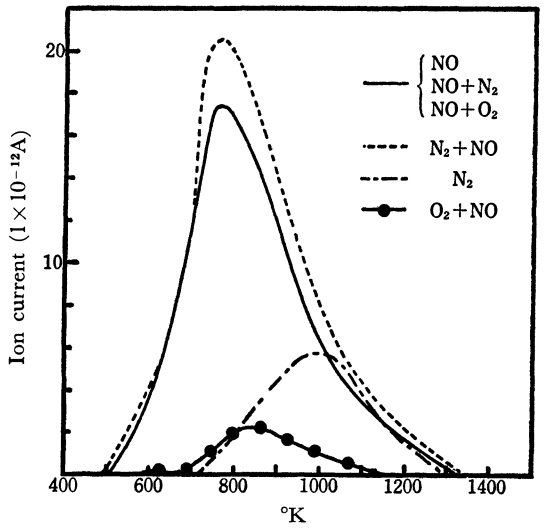

Fig. 2. Nitrogen desorption spectra from various coadsorbed layers on rhenium.

the same as those from a nitric oxide monolayer on rhenium. Although the oxygen desorption was observed at temperatures above 1500°K,[18] the majority of the oxygen evaporates as rhenium oxide at such a high temperature. Therefore, the detection of the amount of oxygen adsorbed is very difficult from the pressure burst in the flash-desorption experiment. Thus, it is impossible to know whether or not oxygen adsorbs on rhenium saturated with nitric oxide. If oxygen adsorbs on this surface, there may be some influence on the desorption spectrum of nitrogen. However, even the exposure of oxygen was changed in the coadsorption of "NO+O_2", the desorption spectrum of nitrogen from this layer being the same as that from a nitric oxide monolayer. From this fact, it may be considered that oxygen is not adsorbed on rhenium saturated with nitric oxide.

"*N_2+NO*". No substitutional desorption of nitrogen was detected during the adsorption of nitric oxide on the preadsorbed nitrogen layer. The Tp of the desorption spectrum of nitrogen from the "N_2+NO" layer was the same as that from a nitric-oxide monolayer, but the amount of nitrogen desorbed from this coadsorbed layer was 3.4×10^{14} molecules/cm^2, while the nitrogen desorbed from a nitric-oxide monolayer was 2.6×10^{14} molecules/cm^2. If the nitric-oxide molecule can be adsorbed on a site other than that occupied by preadsorbed nitrogen atoms, the nitric oxide of 3.04×10^{14} molecules/cm^2 will be adsorbed on rhenium saturated with nitrogen, as is shown in Fig. 3. (Nitrogen adsorbs dissociatively on rhenium.) From the amount of nitrogen desorbed, it is evident that an excess of 1.6×10^{14} molecules/cm^2 of nitrie oxide was adsorbed. The desorption spectra of nitric oxide from a nitric oxide monolayer and the "N_2+NO" layer on rhenium are shown in Fig. 4. The amount of desorbed nitric oxide as a molecule from the "N_2+NO" layer is more than that from a nitric-oxide monolayer. Furthermore, as is evident from Fig. 2, at an early stage the rate of nitrogen desorption from the "N_2+NO" layer in the nitrogen desorption spectrum is faster than that from a nitric-oxide monolayer. When nitric oxide was adsorbed on a preadsorbed nitrogen layer with a half coverage, "N_2(1/2)+NO", the amount of nitrogen desorbed from this layer was 3.0×10^{14} molecules/cm^2. By calculations similar to those in the case of "N_2(full)+NO", it can be concluded that an excess of 8×10^{13} molecules/cm^2 of nitric oxide is adsorbed. This is half the value of that from the "N_2(full)+NO" layer. The amount of the excess nitric oxide is proportional to the amount of preadsorbed nitrogen. From these facts, we can consider that some nitric oxide molecules were induced by the preadsorbed nitrogen atoms and were weakly held on it.

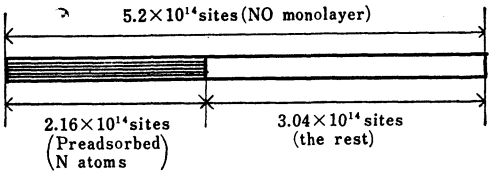

Fig. 3. The number of vacant and adsorbed sites in the nitrogen monolayer.

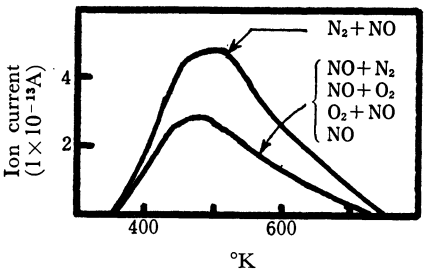

Fig. 4. Nitric oxide desorption spectra from various coadsorbed layers on rhenium.

"*O_2+NO*". No substitutional desorption of oxygen during the adsorption of nitric oxide was observed. Since the amount of nitrogen from the "O_2+NO" layer was 3.4×10^{13} molecules/cm^2, it shows that nitric oxide can adsorb on rhenium saturated with oxygen. The Tp of nitrogen desorption from this coadsorbed layer is 850°K.

This fact may suggest that the number of adsorptive sites for oxygen atoms is less than that for nitric oxide molecules. (Oxygen adsorbs dissociatively,[10] and nitric oxide adsorbs nondissociatively,[18] on rhenium.) If this is so, in the slow-flash desorption experiment of

nitric-oxide adsorption, the desorption of oxygen from the decomposition of nitric oxide must be observed in the temperature region of the nitrogen desorption. However, the desorption of neither molecular nor atomic oxygen was detected in this temperature region in these experiments.

If the oxygen atoms adsorbed are immobile, they will occupy two sites for oxygen adsorption, and some adsorptive sites will remain on the rhenium surface as vacant sites.[24] It is possible that nitric oxide adsorbs on these vacant sites. Oxygen adsorption was made on the rhenium surface while heating the rhenium filament to a high temperature at which adsorbed oxygen atoms were able to migrate over the surface;[25] the filament was afterward allowed to cool to room temperature. When this surface was exposed to nitric oxide, the amount of nitric oxide adsorbed on it was found to be about a half of that on the surface saturated with oxygen at room temperature. From the fact that, in the nitric-oxide adsorption, the desorption of neither molecular nor atomic oxygen is observed in the temperature region of nitrogen desorption, as has been mentioned above, nitric oxide can be said probably to adsorb on vacant sites formed with oxygen adsorption at room temperature, because the nitric oxide adsorbs nondissociatively.

On the other hand, although the desorption of nitric oxide molecules from the "O_2+NO" layer was observed by a slow-flash desorption experiment (Fig. 4), the nitric oxide desorption from a partial coverage of nitric oxide which desorbs the same amount of nitrogen as that from the "O_2+NO" layer was not observed. Moreover, the oxygen desorption from the "O_2+NO" layer was observed in the temperature region of the nitrogen desorption. We consider that some oxygen from the decomposition of nitric oxide in the "O_2+NO" layer was desorbed in this temperature region, for all the available sites for adsorption in first layer were occupied by oxygen atoms and nitric oxide molecules. It seems that a weakly-held adsorption of nitric oxide, such as could be seen in the coadsorption of the "N_2+NO", is also present in the "O_2+NO" layer. As has been mentioned above, it is considered that the nitric oxide adsorption in the "O_2+NO" layer has two types of binding states, that is, a gap-filling state and a weakly-bonded state on the immobile preadsorbed oxygen layer at room temperature. Although the Tp of nitrogen desorption from the "O_2+NO" layer was 850°K, the Tp of that from the partial coverage of nitric oxide which gave the same amount of nitrogen desorbed as that from the "O_2+NO" layer (the same amount of nitric oxide adsorbed) was 1000°K. There are more oxygen atoms in the "O_2+NO" layer than in the partial coverage of nitric oxide (the same amount of nitric oxide). This behavior may be interpreted as follows——the bonding strength of Re–N may be weakened by the oxygen adsorption, which binds strongly with rhenium in adjacent sites. We may thus consider that the nitrogen on the surface desorbs more easily and that the Tp of nitrogen desorption is shifted to a lower temperature (from 1000°K to 850°K).

"*N_2+O_2*". No substitutional desorption of nitrogen was also observed in this case, either. No desorption of nitric oxide molecule was observed from this layer during the slow-flash experiment. The amount of nitrogen desorbed from the "N_2+O_2" layer was the same as that from a nitrogen monolayer, but its Tp was 820°K and it was considerably shifted to a lower temperature. It is considered that the bonding strength of Re–N was also weakened as a result of the adsorption of oxygen atoms between the adsorbed nitrogen atoms, as has been described above. The Tp of nitrogen desorption from this coadsorbed layer is lower than that (870°K) from the partial coverage of nitric oxide giving the same amount of desorbed nitrogen. It is believed that the Tp might be shifted to a lower temperature, because there are more oxygen atoms in the "N_2+O_2" layer than in the partial coverage of nitric oxide (with the same amount of nitrogen atoms). Furthermore, the Tp of nitrogen desorption from the "N_2+O_2" layer is lower than that from the "O_2+NO" layer. It seems that the probability for the recombination of adsorbed nitrogen atoms is high, because the number of nitrogen atoms in the "N_2+O_2" layer is more than that in the "O_2+NO" layer.

"*O_2+N_2*". No desorption of either nitrogen or nitric oxide was observed by the slow-flash experiment. Therefore, nitrogen is not adsorbed on rhenium saturated with oxygen.

Conclusion

Since both the desorption spectra and the amounts of nitrogen desorbed from the "NO+N_2" and the "NO+O_2" layers were the same as those from the nitric oxide monolayer, it is considered that neither nitrogen nor oxygen is adsorbed on rhenium saturated with nitric oxide. Nitric oxide, however, adsorbs not only on vacant sites in the first layer, but on sites in the second layer on rhenium saturated with nitrogen or oxygen. Therefore, the bonding strength between rhenium and adsorbed species becomes weaker in the order of: nitric oxide, oxygen, and nitrogen.

When the more oxygen atoms exist in coadsorbed layers which include the same amount of nitrogen atoms, the Tp of the nitrogen desorption is shifted to a lower temperature.

No nitric oxide was detected in the desorption from a mixed nitrogen-oxygen layer. This indicates that nitric oxide was not produced in the adsorption and the desorption processes. Further, nitrogen does not adsorb on an oxygen-saturated rhenium surface, because the adsorption site for nitrogen is occupied by the oxygen atoms.

The author wishes to express his deep thanks to Professor Takuya Hamamura of this Institute, to Professor Kumasaburo Kodera and Dr. Masaru Onchi of Kyoto University for their kind discussions and encouragement, and to Dr. Minoru Ozasa of the Matsushita Electronics Corporation, who made the spectroscopic analysis of rhenium.

Magnetic Properties of Some Iminoxyl Polyradicals. II. TEMPOP Triradical and TEMPOS Tetraradical

Akira NAKAJIMA, Hiroaki OHYA-NISHIGUCHI, and Yasuo DEGUCHI*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

** College of Liberal Arts and Science, Kyoto University, Kyoto*

(Received March 11, 1971)

The EPR spectra of the TEMPOP triradical and the TEMPOS tetraradical in solution showed seven and nine absorption lines respectively, which were interpreted as the hyperfine interaction between unpaired electron and ^{14}N nuclei in the case of $|J_{in}| \gg A$. The paramagnetic susceptibilities of TEMPOP and TEMPOS were measured. In the case of TEMPOP, no typical short-range ordering effect was found, but the $1/\chi_M - T$ curve deviated from the Curie-Weiss law at very low temperatures. In the case of TEMPOS, the $1/\chi_M - T$ curve was divided into four regions. In the first and third regions, the $1/\chi_M - T$ curves both obey the Curie-Weiss law. The second region is the intermediate region between the first and third regions. In the last region, $1/\chi_M - T$ shows a slight deviation from the Curie-Weiss law of the third region. In order to explain this behavior, some spin-cluster models with three and four spins were applied.

Recently, the magnetic properties of many organic stable free radicals have been investigated very actively.[1-5] It has been reported that many of these organic radicals exhibit some effects of the coupling of magnetic spins—for example, spin cluster or low-dimensional spin array—caused by an exchange interaction between unpaired electrons.

Among these, the iminoxyl radicals are the most interesting group, since they are very stable and many derivatives can be synthesized.[6,7]

Karimov and Rozantsev reported the EPR studies of some solid stable iminoxyl radicals and interpreted them in terms of the effect of the exchange interaction between unpaired electrons belonging to different radicals.[4b] Yamauchi *et al.*[5b] and Karimov[4c,4d] independently measured the paramagnetic susceptibility of 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (TANOL radical, Fig. 1a), characterized as a one-dimensional Heisenberg linear chain.

On the other hand, the present authors had an interest in the polyradicals of the iminoxyl group as spin

clusters. In a previous work, we reported the paramagnetic susceptibility of bis(2,2,6,6-tetramethylpiperidine-4)azine-1,1′-dioxyl (TEMPAD biradical, Fig. 1b) and explained it as a pairing caused by an intra-molecular exchange interaction,[5a] but recent study has made it clear that the inter-molecular interaction is only the origin of the short-range ordering in the TEMPAD biradical.[8]

In this paper, we shall report the magnetic properties of two polyradicals, tris(2,2,6,6-tetramethylpiperidine-1-oxyl-4)phosphate (the TEMPOP triradical, Fig. 2a) and the tetrakis(2,2,6,6-tetramethylpiperidine-1-oxyl-4)silicate (the TEMPOS tetraradical, Fig. 2b), and will discuss them on the basis of some spin-cluster models.

Experimental

The TEMPOP triradical was prepared from the TANOL radical obtained by the oxidation of the corresponding amine by hydrogen peroxide, following the method of Neiman *et al.*[9] The TEMPOS tetraradical was also prepared from the same monoradical by the method of Rozantsev and Gulobev.[10] After purification by chromatography and recrystallization, the pure TEMPOP and TEMPOS (mps 143.5±0.5 and 160±1°C respectively) were obtained.

The electron paramagnetic resonance absorptions were measured using two 100 kHz modulated X-band spectrometers, JEOLCO's JES-3BX and JES-P-10.

The static magnetic susceptibility was measured with about 50—100 mg powder samples over the temperature range of 1.8—273°K and at a magnetic field strength of about 8—9 kOe, using a torsion balance described elsewhere.[11] All the data were corrected for the diamagnetic contribution calculated by the Pascal method (-3.57×10^{-4} emu/mol for the TEMPOP triradical and -4.82×10^{-4} emu/mol for the TEMPOS tetraradical).

Results and Discussion

TEMPOP Triradical. The EPR spectrum of the TEMPOP triradical in a tetrahydrofuran (THF) solution shows seven lines, all caused by the hyperfine interaction between three unpaired electrons and three ^{14}N nuclei, the splitting of which is 5.18 gauss and the g-value of which is 2.0060 (Fig. 3).[12] The spin Hamiltonian of this system is:

$$\mathcal{H} = -g\beta\mathrm{H}\cdot(\boldsymbol{S}_1+\boldsymbol{S}_2+\boldsymbol{S}_3) + A\sum_{i=1}^{3}\boldsymbol{I}_i\cdot\boldsymbol{S}_i + J_{\mathrm{in}}\sum_{\langle i,j\rangle}\boldsymbol{S}_i\cdot\boldsymbol{S}_i, \quad (1)$$

where A is the hyperfine interaction parameter and where J_{in} is the intra-molecular exchange interaction. When $|J_{\mathrm{in}}|\gg A$, the theoretical spectrum shows seven lines with an intensity ratio of 1 : 3 : 6 : 7 : 6 : 3 : 1. The experimental spectrum does not correspond accurately to this extreme case. We must pay attention to the fact that the line-widths of the inner three lines are fairly broad even in a very dilute solution. One may be able to explain them in terms of the dipole-dipole interaction between three unpaired electrons and/or some effects caused by the exchange interaction, which is not very large compared with the hyperfine interaction.[13] Taking account of this explanation, one can conclude that $A\lesssim|J|\ll kT$.

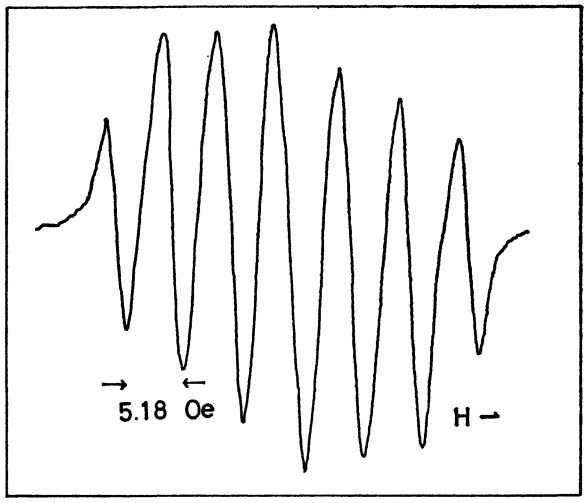

Fig. 3. The EPR spectrum of TEMPOP triradical in THF solution.

The inverse paramagnetic susceptibility of the powder TEMPOP triradical *versus* the temperature is shown in Fig. 4. The curve obeys the Curie-Weiss law except in the very low temperature region. The Curie constant, the effective Bohr magneton, and the Weiss constant, corresponding to a molecule with three unpaired electrons, are listed in Table 1. The devi-

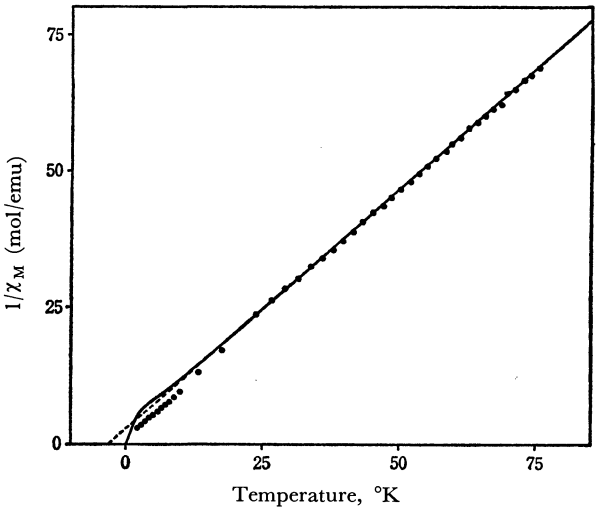

Fig. 4. The inverse paramagnetic susceptibility of powdered TEMPOP triradical *versus* temperature (truncated for clarity showing susceptibity between 1.8 and 77°K). The solid curve is that of the spin cluster with three spins of Eq. (3) as $J=-2.7$°K.

TABLE 1. SOME MAGNETIC CONSTANTS OF TEMPOP TRIRADICAL AT THE HIGH TEMPERATURE RANGE COMPARED WITH THE CALCULATED VALUES OF THREE SPINS WITH $S=1/2$ AND $g=2.00$

Constant	Experimental	Calculation
C	1.14	1.141
μ_{eff}	3.01	3.000
θ	-3.5°K	—

C: the Curie constant
μ_{eff}: the effective Bohr magneton
θ: the Weiss constant

ation from the Curie-Weiss law in the very low temperature region probably suggests a short range ordering effect caused by the exchange interaction between spins belonging to different molecules.

The spin-cluster Hamiltonian with three spins, involving the exchange and Zeeman terms, is given by:

$$\mathscr{H} = -2(J_{12}\boldsymbol{S}_1\cdot\boldsymbol{S}_2+J_{23}\boldsymbol{S}_2\cdot\boldsymbol{S}_3+J_{31}\boldsymbol{S}_3\cdot\boldsymbol{S}_1) - g\beta\mathrm{H}\cdot(\boldsymbol{S}_1+\boldsymbol{S}_2+\boldsymbol{S}_3) \quad (2)$$

with the following eigen values:

a. Quartet State:

$$E_q = -(J_{12}+J_{23}+J_{31})/2 - g\beta\mathrm{H}m \qquad (m = 3/2,\ 1/2,\ -1/2,\ -3/2)$$

b. Doublet State:

$$E_{d\pm} = (J_{12}+J_{23}+J_{31}) - g\beta\mathrm{H}m \pm [2\{(J_{12}-J_{23})^2 + (J_{23}-J_{31})^2 + (J_{31}-J_{12})^2\}]^{1/2} \qquad (m = 1/2,\ -1/2)$$

The paramagnetic susceptibility is given from the Van Vleck formula,[24] and when $J_{12}=J_{23}=J_{31}=J$ (negative), the theoretical susceptibility is given by:

$$|J|\chi_M/N(g\beta)^2 = (x/4)(5+e^{3x})/(1+e^{3x}) \qquad (x = |J|/kT). \quad (3)$$

This curve is shown in Fig. 4 as $J=-2.7$°K.

As for the TEMPOP triradical one can conclude from Fig. 4 that the exchange interaction appearing in the static susceptibility is fairly weak compared with kT, and no typical short-range ordering effect can be found.

TEMPOS Tetraradical. The EPR spectrum of the TEMPOS tetraradical in the THF solution shows nine lines, all of them caused by the hyperfine interaction between four unpaired electrons and four ^{14}N nuclei, the splitting of which is 3.94 gauss and the g-value of which is 2.0058 (Fig. 5).[12] The spin Hamiltonian of this system is:

$$\mathscr{H} = -g\beta\mathrm{H}\cdot\sum_{i=1}^{4}\boldsymbol{S}_i + \mathrm{A}\sum_{i=1}^{4}\boldsymbol{I}_i\cdot\boldsymbol{S}_i + J_{\mathrm{in}}\sum_{\langle i,j\rangle}\boldsymbol{S}_i\cdot\boldsymbol{S}_j \quad (4)$$

When $|J_{\mathrm{in}}|\gg A$, $g\beta$H, the theoretical spectrum shows nine lines with the intensity ratio of 1 : 4 : 10 : 14 : 19 : 14 : 10 : 4 : 1; the experimental results just agree.

The inverse paramagnetic susceptibility of the powder TEMPOS tetraradical *versus* the temperature is shown in Fig. 6. It is appropriate to divide the curve into four regions (Region I: above 25°K, II: from 15 to 25°K, III: from 5 to 15°K, and IV: below 5°K). In the I and III regions, the $1/\chi_M$–T curve obeys the Curie-Weiss law. The magnetic constants of these two regions are listed in Table 2. The II region is the intermediate region between I and III. The temperature dependence of the χ_M in these three regions suggests the formation of a spin

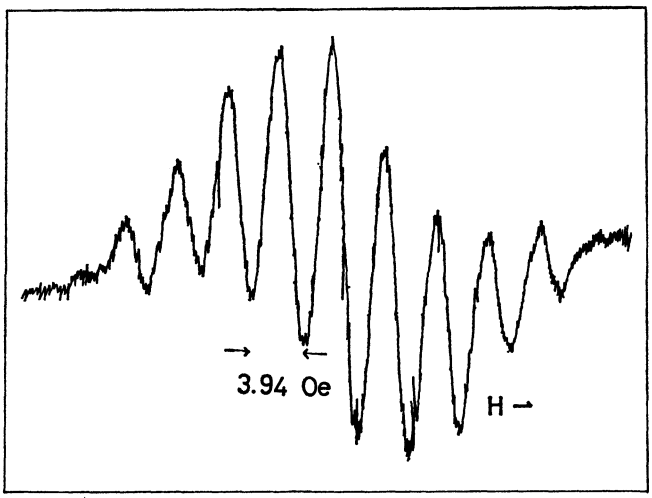

Fig. 5. The EPR spectrum of TEMPOS tetraradical in THF solution.

TABLE 2. SOME MAGNETIC CONSTANTS OF TEMPOS TETRARADICAL

	C	μ_{eff}	θ
Experimental			
Region I	1.55	3.52	-3.5°K
Region III	0.98	2.80	-16°K
Calculation			
$S_{total}=1$	1.01	2.83	—
Four spins with $S=1/2$	1.51	3.46	—

14) K. Kambe, *J. Phys. Soc. Japan*, **5**, 48 (1949); J. H. Van Vleck, "The Theory of Electric and Magnetic Susceptibilities," Oxford (1932).

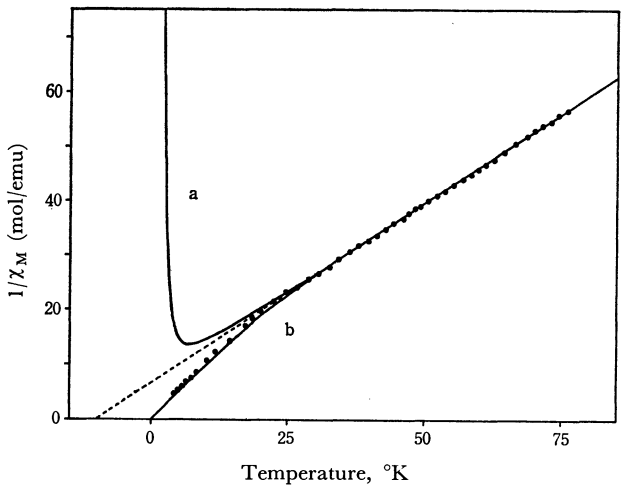

Fig. 7. Inverse paramagnetic susceptibility of TEMPOS tetraradical which was corrected for the inter-cluster interaction by multiplying $T/(T+3.5)$ with $1/\chi_M$. The solid curves are the theoretical $1/\chi_M - T$ of the spin cluster models with for spins: a) Tetrahedral model ($J=-5.55$°K), b) Trigonal model ($J=-15.9$°K).

cluster caused by the exchange interaction. In the IV region, the $1/\chi_M$–T shows a slight deviation from the Curie-Weiss law of the III region, with $\theta=-3.5$°K; this suggests the existence of an inter-cluster interaction, but in this paper, treating the exchange interaction in a cluster, we will not discuss the inter-cluster interaction further.

Now let us come back to our discussions of the I, II, and III regions. For the analysis of the results, two essential experimental parameters are taken into account. One is the μ_{eff} of the III region, which will give the total spin of the ground state; the other is the ratio of the Curie constants between the I and III regions ($\rho=C_I/C_{III}$), which indicates the relation of the spin states between the high- and low-temperature regions. In our case, $\mu_{eff}=2.80$—which corresponds to the total spin, S=1—and $\rho=1.58$.

As the TEMPOS tetraradical has four spins in a molecule, some spin-cluster models with four spins are applicable.[15] The spin Hamiltonian of the cluster models is:

$$\mathscr{H} = -2\{J_{12}\boldsymbol{S}_1\cdot\boldsymbol{S}_2 + J_{13}\boldsymbol{S}_1\boldsymbol{S}_3 + J_{14}\boldsymbol{S}_1\cdot\boldsymbol{S}_4 + J_{23}\boldsymbol{S}_2\cdot\boldsymbol{S}_3 + J_{24}\boldsymbol{S}_2\cdot\boldsymbol{S}_4 + J_{34}\boldsymbol{S}_3\cdot\boldsymbol{S}_4\} \quad (5)$$
$$(\text{all } \boldsymbol{S}_i = 1/2)$$

15) Of course we cannot say definitely that the exchange interaction occurs exclusively in a molecule, and the probability of the inter-molecular interaction will not be ommitted. Here we must understand that the above-mentioned models will be only practical ones.[8]

Table 3. Some spin cluster models with four spins

Model	$\lvert J\rvert\chi_M/N(g\beta)^2$	ρ	J
Tetrahedral	$\frac{2\times(5+e^{4x})}{5+9e^{4x}+2e^{6x}}$	—	−5.55°K
Rhombus	$\frac{2\times(5+e^{2x}+2e^{4x})}{5+3e^{2x}+7e^{4x}+e^{6x}}$	—	—
Trigonal	$\frac{2\times(5+e^{x}+2e^{4x})}{7+3e^{x}+6e^{4x}}$	1.50	−15.9°K

$S=1/2$ for all spins and $x=\lvert J\rvert/kT$. ρ is the ratio of the Curie constants between high and low temperature ranges. J was determined from the experimental Weiss constant, $\theta=-10$°K.

and the paramagnetic susceptibilities of each model, which is derived from the Van Vleck formula,[14] are listed in Table 3. The theoretical $1/\chi_M$–T curves of two typical models (tetrahedral and trigonal) are shown in Fig. 7 in comparison with the experimental result corrected for the inter-cluster interaction by multiplying $T(T+3.5)$ by $1/\chi_M$; the latter trigonal model ($\mu_{eff}=2.83$, $\rho=1.50$) agrees exactly with the experimental result, as $J=-15.9$°K. In our further discussions, we must proceed to a structural study of these polyradicals.

Summary

The paramagnetic susceptibilities of the TEMPOP triradical and the TEMPOS tetraradical have been measured; we have found some deviations from the Curie-Weiss law caused by an exchange interaction between electron spins. Though we could not make clear whether or not the exchange interaction occurs in a molecules, we adopted some spin-cluster models with three and four spins as one step to interpreting the experimental phenomena.

In TEMPOP triradical, we could find no suitable model, for this radical did not indicate any typical ordering phenomenon at any measuring temperature used so far. On the other hand, in the TEMPOS tetraradical, we found a short-range ordering effect and applied the spin-cluster models with four spins. The trigonal model best fit the experimental results.

The authors are very much obliged to Professor H. Takaki for his continuing guidance and encouragement through this work. The authors are also deeply indepted to Professor M. Mekata, Mr. J. Yamauchi and their collaborators for their helpful advice and discussions.

Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. XIV[1] Determination of Iodide Ions with Tris(1,10-phenanthroline)iron(II)

Yuroku YAMAMOTO, Tsunehiko TARUMOTO, and Masahiro TSUBOUCHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 2, 1970)

Iodide was extracted from the aqueous phase into nitrobenzene in a wide pH range of 3—9 by use of tris(1,10-phenanthroline)iron(II) chelate cations and then determined spectrophotometrically at 516 mμ. Beer's law was effective up to 8.0×10^{-5} M of iodide in the aqueous phase. Standard deviation of the determination was 1.1% at 15°C. The color intensity of the extracted species in nitrobenzene was constant for at least 3 hr. The distribution ratio was 1.02 at 15°C and 0.83 at 26°C. No serious interferences by foreign anions were observed except for perchlorate, chlorate, and thiocyanate. Cations did not essentially interfere with the determination.

Iodide can be determined colorimetrically through its catalytic action, by starch-iodide reaction or as a triiodo ion.[2] However, these procedures are tedious and delicate, and the reactions involved are not very well defined.

We have previously presented, as a short communication, a new method for the spectrophotometric determination of iodide which was based on the solvent extraction with tris(1,10-phenanthroline)iron(II) chelate cations.[3] At that time, acetate buffer solution was used, which showed a relatively high reagent blank in the pH range of 4 to 5. It was later found that the absorbance of the reagent blank is negligible when phosphate buffer solution is used instead. Here, an improved method is presented together with more detailed results.

Iodide ions are well extracted into nitrobenzene over a wide pH range of 3 to 9. Determination is carried out spectrophotometrically at 516 mμ. Beer's law is effective up to 8.0×10^{-5} M of iodide in the aqueous phase. A large amount of phosphate, sulfate, nitrate, or chloride does not interfere.

Experimental

Apparatus. Spectrophotometric measurements were made with a Hitachi 139 spectrophotometer with 10 mm glass cells. Shaking was done with an Iwaki Model KM shaker. pH measurements were done with a Hitachi-Horiba H-5 pH meter. Gamma ray counting of ^{131}I was done with an Aloka Model PSM 801 γ-ray spectrometer equipped with a NaI(Tl)crystal. An incubator, Taiyo Model M-1 with 200 times/min of shaking frequency was used as a temperature controlled shaker.

Reagent. Tris(1,10-phenanthroline)iron(II) sulfate solution. A solution of 4.0×10^{-3} M was prepared with ferrous ammonium sulfate and 1,10-phenanthroline.

Standard Iodide Solution: A standard iodide solution of 1.0×10^{-1} M was prepared with potassium iodide. Standardization was made by titration with silver nitrate solution.

Radioactive Iodide Solution: A radioactive iodide solution was prepared with NaI-^{131}I from Japan Radioisotope Association.

Buffer Solution: Phosphate buffer solution of 1.0 M was prepared with potassium dihydrogen phosphate and sodium monohydrogen phosphate. pH was adjusted to the desired values with sulfuric acid or sodium hydroxide.

Solvent: Nitrobenzene, purified by vacuum distillation at 20—30 mmHg, was used. It was equilibrated with distilled water before extraction. Other solvents were of analytical grade and were used without further purification.

Procedure. Calibration Curve: Take 5 ml of iodide solution of the concentration ranging from 8×10^{-5} to 4×10^{-4} M in a 100-ml separatory funnel. Add 5 ml of the tris(1,10-phenanthroline)iron(II) sulfate solution (4×10^{-3} M) and 5 ml of the phosphate buffer solution to adjust the pH of the mixture to 5.5. Dilute it to 25 ml with distilled water. Add 10 ml of nitrobenzene previously equilibrated with distilled water and shake the funnel for 2 min. About 30 min after the extraction, remove the organic layer and dehydrate it with 1 g of anhydrous sodium sulfate, allowing it to stand another 10 min. Measure its absorbance at 516 mμ with the reagent blank or nitrobenzene as a reference.

Distribution Ratio: a) By means of spectrophotometry. To 15 ml of aqueous solution of tris(1,10-phenanthroline)iron(II) iodide prepared from the synthesized salt (1×10^{-4} M) at pH 5.5 with phosphate buffer, add 15 ml of nitrobenzene and extract for 10 min at a constant temperature. After extraction, measure the absorbance of the aqueous and the organic phase at 510 mμ and 516 mμ, respectively. Use water or nitrobenzene as a reference.

b) By means of radioactivity measurement. To the same aqueous solution, add a trace amount of radioactive iodide solution. Proceed the extraction as above. After the extraction, measure the radioactivity of both phases.

Results and Discussion

Absorption Spectra. The absorption spectra of an extract and a reagent blank are shown in Fig. 1. The absorption maximum of the extract was identical with that of tris(1,10-phenanthroline)iron(II) iodide salt dissolved in nitrobenzene. The extracted species was confirmed to be $Fe(phen)_3\cdot I_2$ also by the continuous variation method, where phen represents 1,10-phenanthroline.

pH. This species shows a constant absorbance when extracted from aqueous phase with a wide pH range of 3 to 9 as shown in Fig. 2, indicating that the degree of extraction is maximum in this pH range. When acetate buffer solution was used instead of phos-

Temperature: 15—16°C

phate, the reagent blank showed a relatively high absorbance over a pH range of 4 to 6.[3,4] pH was adjusted to 5.5 throughout this experiment.

Concentration of Tris(1,10-phenanthroline)iron(II) sulfate. A constant amount of iodide (4.0×10^{-5} M) was extracted with varying amounts of the chelate. The result is shown in Fig. 3, from which it is seen that the maximum and constant extraction is attained at a mole ratio, the chelate : iodide=4 : 1. In this experiment the ratio was kept at about 10 : 1.

Shaking Time. Shaking time of the extraction was varied from 0.5 to 30 min. No difference was observed and therefore the shaking time was fixed to 2 min for convenience.

4) Y. Yamamoto, K. Kotsuji, S. Kinuwaki, and H. Sawamura, *Nippon Kagaku Zasshi*, **85**, 869 (1964).

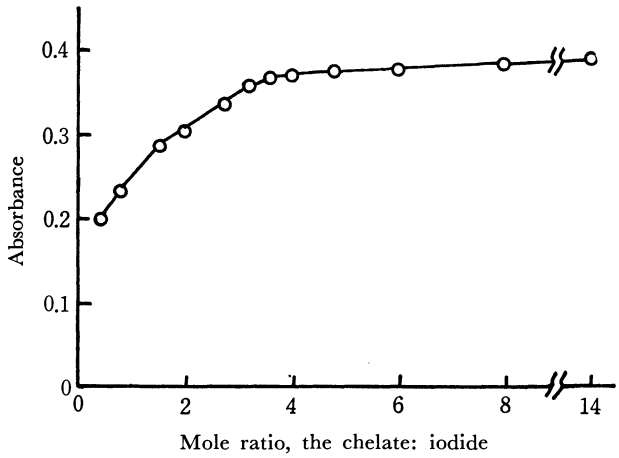

Fig. 3. Effect of the chelate concentration.
[iodide] = 4.0×10^{-5} M
Reference: Reagent blank
Temperature: 15—16°C

Stability of Color. Color intensity of the nitrobenzene phase was constant for 3 hr. A slight fading was observed after several hours (after 5 hr, 0.8%).

Frequency of Extraction. As shown in Table 1, the second and the third extracts still have appreciable absorbances. However, only the first extract was used in this experiment.

Table 1. Effect of frequency of extraction
(Iodide: 4×10^{-5} M, Reference: Nitrobenzene, Temp. 15—16°C.)

Number of extraction	Absorbance
1st	0.405
2nd	0.198
3rd	0.105
4th	0.053
5th	0.034
6th	0.024

Calibration Curve. The plot of absorbance of the nitrobenzene phase *versus* concentration of iodide in the aqueous phase gave a straight line up to 8.0×10^{-5} M. (*cf.* Fig. 4).

Precision. Six samples of iodide solution of 4.0×10^{-5} M were subjected to extraction. These samples gave a mean absorbance value of 0.380 against the reagent blank with a standard deviation of 0.004 or 1.1% at 15°C.

Distribution Ratio and Temperature Effect. Distribution ratio D by spectrophotometry will be expressed as:

$$D = \frac{[Fe(phen)_3I_2]_o + [Fe(phen)_3I^+]_o + [Fe(phen)_3^{2+}]_o}{[Fe(phen)_3I_2]_w + [Fe(phen)_3I^+]_w + [Fe(phen)_3^{2+}]_w}$$

because the synthesized salt of the formula, $Fe(phen)_3I_2$, is dissolved in the aqueous phase and therefore tris(1,10-phenanthroline)iron(II) cations exist in an equivalent amount to ioide. Results were as follows: at 15°C, 1.02 and at 26°C, 0.83, *i.e.*, the lower the temperature, the more effective is the extraction. This fact is also seen in Fig. 4 where calibration curves at various temperatures are shown. The distribution

TABLE 2. CHOICE OF ORGANIC SOLVENT
(Iodide: 4×10^{-5} M. Wavelength: 516 mμ.
Reference: pure solvent. Temp. 15—16°)

Solvent	Dielectric constant	Absorbance
Nitrobenzene	34.8	0.405
m-Nitrotoluene	23.8	0.134
o-Nitrotoluene	27.4	0.155
Benzene	2.3	~0
Benzonitrile	25.2	0.170
Toluene	2.4	~0
Chlorobenzene	5.6	~0
Chloroform	4.8	~0
Carbon tetrachloride	2.2	~0
Carbon disulfide	2.6	~0
Methyl-iso-butyl ketone	13.1	~0
2-Pentanone	15.4	~0
1,2-Dichloroethane	10.4	0.012
Isoamylalcohol	14.7	~0
Ethyl propionate	5.7	~0

ratio from radioactivity measurement with ^{131}I as a tracer agreed well with that from spectrophotometry. This means that *D* for iodide can be correctly estimated by measuring *D* for the chelate cations.

Choice of an Organic Solvent. Various organic solvents were tested. Of these, nitrobenzene was the most effective as shown in Table 2. Roughly saying, solvents with relatively high dielectric constants are able to extract the chelate ion pair.

Interference. Anions: Table 3 shows the effect of diverse anions on the recovery of iodide. Perchlorate, chlorate, and thiocyanate are easily extracted and therefore interfere with the determination even when they exist in an extremely low concentration. Bromide, cyanide, and bromate do not interfere with the determination if they are present in a concentration equal to or less than that of iodide, while as chloride can coexist several hundred times as much. Nitrate shows some effect while a large amount of sulfate and phosphate (used as buffer) shows none.

TABLE 3. EFFECT OF FOREIGN ANIONS
(Iodide taken: 4.0×10^{-5} M. Temp. 15—16°C)

Anion	Added as	Concentration (M)	Recovery of iodide (%)
Sulfate	Na_2SO_4	4×10^{-2}	100
Sulfate	Na_2SO_4	4×10^{-4}	100
Nitrate	$NaNO_3$	4×10^{-4}	105
Nitrate	$NaNO_3$	4×10^{-5}	100
Perchlorate	$KClO_4$	4×10^{-6}	110
Perchlorate	$KClO_4$	4×10^{-7}	100
Chloride	NaCl	4×10^{-2}	122
Chloride	NaCl	4×10^{-3}	103
Bromide	NaBr	4×10^{-3}	161
Bromide	NaBr	4×10^{-4}	100
Thiocyanate	KSCN	4×10^{-6}	108
Thiocyanate	KSCN	4×10^{-7}	100
Cyanide	KCN	4×10^{-3}	127
Cyanide	KCN	4×10^{-4}	100

Chlorate	$NaClO_3$	4×10^{-6}	100
Bromate	$KBrO_3$	4×10^{-3}	123
Bromate	$KBrO_3$	4×10^{-4}	100
Silicate	Na_2SiO_3	4×10^{-3}	100

TABLE 4. EFFECT OF FOREIGN CATIONS
(Iodide taken: 4.0×10^{-5} M, Temp. 15—16°C)

Cation	Added as	Concentration (M)	Recovery of iodide (%)
Magnesium	$MgSO_4$	4×10^{-3}	97.5
Calcium	$CaSO_4$	4×10^{-3}	97.0
Strontium	$SrCl_2$	4×10^{-3}	52.7
		4×10^{-3}	107[a]
Barium	$BaCl_2$	4×10^{-3}	106
Manganese(II)	$MnSO_4$	4×10^{-3}	100
Iron(III)	$Fe_2(SO_4)_3$	4×10^{-3}	80.4
		4×10^{-3}	93.5[a]
Cobalt(II)	$CoSO_4$	4×10^{-3}	97.5
Nickel	$NiSO_4$	4×10^{-3}	100
Copper(II)	$CuSO_4$	4×10^{-3}	97.5
		4×10^{-3}	100[a]
Zinc	$ZnSO_4$	4×10^{-3}	96.0
Cadmium	$CdSO_4$	4×10^{-3}	95.5
Mercury(II)	$HgSO_4$	4×10^{-5}	0
Aluminum	$KAl(SO_4)_2$	4×10^{-3}	97.5

a) 8×10^{-3} M EDTA added.

Cations: Table 4 shows the effect of diverse cations on the recovery of iodide. Almost any metals tested do not interfere. Mercury(II) that reacts with iodide interfere seriously. The interference of strontium seems inexplicable. Ferric ions form hydroxide at this pH. However, these interferences are easily eliminated by use of excess EDTA except for mercury(II).

Studies of 8-Mercaptoquinoline as Chelating Agents. I. Sodium Salt of 8-Mercaptoquinoline

Yoshiyuki MIDO and Eiichi SEKIDO
Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe
(Received December 4, 1970)

The infrared spectra of the sodium salt of 8-mercaptoquinoline and its related compounds have been measured in the region between 4000 and 400 cm^{-1}. Some substituent-sensitive bands have been investigated in order to find a clue to further infrared studies of its metal chelates. The thermal stabilities of the sodium salt have been examined by thermal gravimetric analysis and by differential thermal analysis. It has been shown that the sodium salt can be dried at temperatures between 100° and 200°C without any thermal change, and that, at *ca.* 210°C in air, the abrupt increase in weight of the sodium salt may be due to the absorption of oxygen. The effect of hydration on the sodium salt is discussed on the basis of results with regard to X-ray diffraction patterns, infrared spectra, and weights. The sodium salt is proposed to crystallize with two moles of water and to combine inequivalently with two waters of crystallization.

8-Hydroxyquinoline(oxine=HQ) is a convenient analytical reagent which reacts with various metal ions to form its metal chelates; the characteristics of the reagent and its metal chelates have been studied extensively.[1)]

Recently special attention has been paid to the 8-mercaptoquinoline(thiooxine=MQ) in which hydroxyl group of HQ is replaced by the thiol group and to the 8-selenoquinoline(selenooxine=SeQ) replaced by the selenol group.[2,3)] It may be of particular interest to compare the relationships between their dissociation constants and the stability constants of their metal chelates. Studies of MQ have been reported in the fields of analytical applications,[4–8)] absorption spectra,[4,9–11)] stability constants of metal complexes,[4,11)] and substituted compounds.[4,12–14)]

The central problem of this paper is to investigate the infrared spectra of the sodium salt of MQ for the purpose of finding a clue to further infrared studies of its metal chelates. Our interest lies particularly in the effect of the water of crystallization upon the infrared spectra because of its acceleration effect on the oxidation of the salt.

Experimental

Reagents. MQ, its disulfide, and its sodium salt were prepared and purified by the methods described in the literature.[8,11,15)] Hydrochloride of MQ was obtained from the Dojindo Pharmaceutical Co., Ltd. All the reagents were confirmed by a study of the absorption spectra.

Apparatus for Measurements. Thermal gravimetric analysis (TGA), differential thermal analysis (DTA), and studies by both X-ray diffractions and infrared spectra were carried out with a Chyo Thermobalance, a Rigaku-Denki Differential Thermal Analyser, a Rigaku-Denki Geigerflex D-3F X-Ray Analyser (Cu$K\alpha$ radiation) and a Hitachi EPI-2G Infrared Grating Spectrophotometer respectively. The weights of the salt were measured with a Mettler H-6 dig. Balance.

Results and Discussion

Infrared Spectra of MQ. The infrared spectra of MQ and its derivatives were obtained as Nujol and H.C.B. mulls. The infrared frequencies are summarized in Table 1. The spectra of MQ are essentially similar to those of HQ. In general, it has been suggested that a few bands in the 1600—1500 cm^{-1} region in quinoline derivatives are due to C=C and C=N vibrations.[16)] Furthermore, the bands in the 1200—1000 cm^{-1} region and those around 800 cm^{-1} are attributable to ring vibrations and C–H deformations influenced by chelation with a metal or by hydration respectively.[16)]

For the anhydride of MQ, which exists in a deep blue liquid, the effect of the substitution on the quinoline ring causes strong new bands at 2510, 990, and 654 cm^{-1}. The band at 2510 cm^{-1} is easily assigned to ν(SH), and the investigation of this vibration in a chloroform solution shows neither any possibility of hydrogen bonding nor any existence of the zwitter ionic from. The 990 cm^{-1} and the 654 cm^{-1} band rank as the highest and the second highest respectively of the substituent-sensitive bands affected

by the mass of the substituent atom directly bonded to the ring (HQ; 1093[17] and 781 cm^{-1},[18], SeQ; 959 and 640 cm^{-1},[19]). Although a band near 9 μ assigned to the C–O vibration of metal oxinates[17] is clearly metal-sensitive, the 990 cm^{-1} and the 654 cm^{-1} bands also exhibit a similar character, as will be described in the succeeding paper.[20]

For the disulfide of MQ, the bands appear at 974 and 655 cm^{-1}. This is very important in the case of chelation between MQ and a metal because the oxidation of MQ can be checked by the presence of these bands.

The above facts suggest that these two bands with strong intensities usually have a considerable contribution by C–S bonding, though the lower band is more effective. Our consideration is supported also by the infrared studies of halogenobenzene[21] and benzenesulphonyl compounds.[22] Moreover, studies of this lower band of various metal chelates may be directly related to the analytical applications.[20]

For the sodium salt of MQ, a very strong and broad band around 3300 cm^{-1} assigned to bonded ν(OH) appears. On the other hand, with an increase in the degree of dryness, the sodium salt of MQ changes from light yellow to bright yellow (*dry salt*), and the physical state of the salt changes from rigid to bulky.

The thermal analysis and the X-ray diffraction measurement of the salt were carried out in order to confirm whether or not these phenomena resulted from the hydration on the salt.

Thermal Analysis of the Sodium Salt of MQ. Both TGA and DTA curves obtained in air and in nitrogen gas are shown in Fig. 1, where the scale of DTA is arbitrary. The dotted line and the solid line correspond to the curve of the sodium salt of MQ dried at room temperature (called *salt* hereinafter) and to that of the salt completely dried in a vacuum and at 150°C (called *dry salt*) respectively.

The weight loss of *salt* in the 100—200°C region is about 16% of the initial weight corresponding to *salt*

with two moles of water of crystallization. At *ca.* 210°C, an abrupt increase in weight (about 7.5%) takes place in both *salt* and *dry salt*, and both salts turn brownish. There is a constant part of the weight in the 210—250°C region, and a weight loss due to decomposition occurs at higher temperatures.

The DTA curve of *dry salt* in nitrogen gas shows no thermal change[23,24] until 258°C, where thermal decomposition sets in.

The abrupt increase in weight in TGA may be attributable to the absorption of oxygen, as in suggested by the following facts: (1) The DTA curve of *dry salt* in nitrogen gas (the dot-dash line in Fig. 1) or in carbon dioxide did not show an abrupt increase. (2) The infrared spectra of the sample dried at 210°C in air exhibited a new strong band near 1100 cm^{-1} referrable to some rearrangement of atoms, though those of the sample dried at the same temperature in a vacuum did not show such a band. From the fact that the compounds containing sulfur tend to be oxidized in the process of thermal reaction, it may be concluded that the strong band is connected with a S–O vibration. (3) The DTA curve of *dry salt* in nitrogen gas showed no thermal change around 210°C.

X-Ray Diffraction Measurements. The X-ray diffraction patterns for *salt* and *dry salt* are shown in Fig. 2. These patterns indicate that the crystal structure of *dry salt* is different from that of *salt.* The X-ray pattern for a salt, containing *ca.* 10% of water,[25] seems to be made up of the superposition of the patterns of both *salt* and *dry salt.* The X-ray pattern for the other salt, containing more than 16% of water,[25] is obscure and weak.

Effect of Hydration on the Infrared Spectra. It should be noted that the sodium salt of MQ is strongly hygroscopic and that this property is closely connected with the oxidation of the salt. An increase in weight due to the absorbing water on *dry salt* was examined as a function of time at 25°C and at a relative humidity of 35% (Fig. 3). The result obtained from the increase in weight was in agreement with one of the results from TGA—the finding that the salt crystallizes with two moles of water.

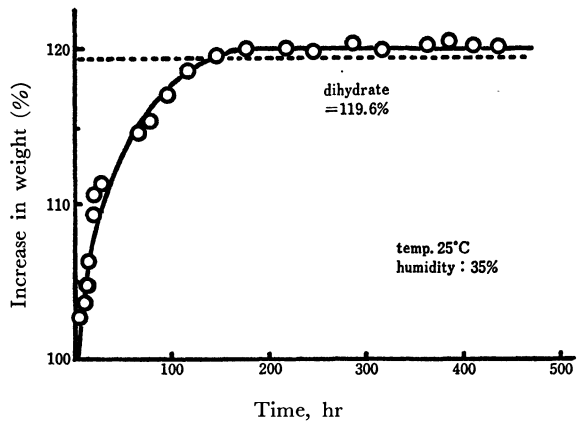

Fig. 3. Increase in weight due to the absorbing water on *dry salt* of MQ.

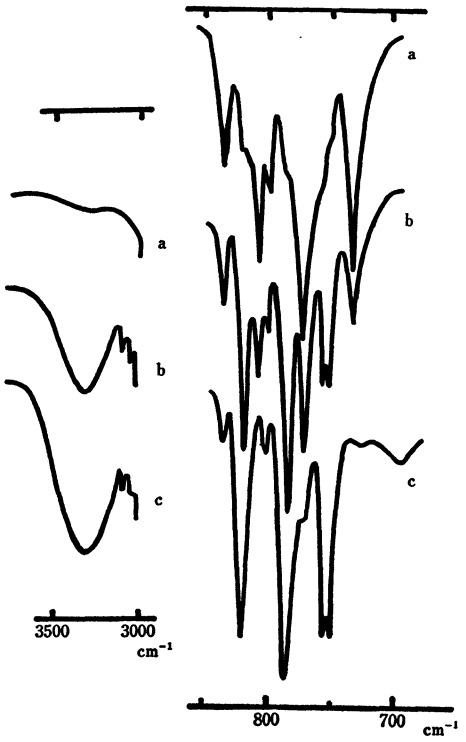

Fig. 4. O–H Stretching and C–H out-of-plane vibrations.
a) start, b) one day, c) one week

At the same time, the changes in the infrared spectra for the sodium salt of MQ were observed under the conditions specified above. The band at about 3300 cm^{-1} and the bands in the 850—700 cm^{-1} region exhibit remarkable changes in intensity and in frequency as is shown in Fig. 4. As the intensity of the 3300 cm^{-1} band(ν OH) becomes stronger and, simultaneously, those of these bands at 808, 772, and 730 cm^{-1} of *dry salt* diminish, two bands, at 817 and 785 cm^{-1}, and a doublet, at 753 and 749 cm^{-1}, appear and

25) This quantity of water determined by the weight loss of a salt.

gradually become stronger in their intensities.[26] This doublet is not observed in *dry salt*. Moreover, in *salt* there are two broader bands, at 690 and 530 cm^{-1}, which probably correspond to the librational modes of the water of crystallization (Table 1).[27] On the substitution of heavy water on *salt*, the 3300 cm^{-1} band shifted and split into two bands, at 2450 and 2370 cm^{-1}, the 690 cm^{-1} band was replaced by a band at 505 cm^{-1}, and the 530 cm^{-1} band was expected to shift to the region below 400 cm^{-1}. These results may provide strong evidence for the existence of an inequivalent bonding between two waters of crystallization and sodium salt, but it does not sufficiently account for the absence of a water molecule cyclically bound through a hydrogen bonding as proposed by Bankovsky.[9]

26) In the preliminary study for sodium salt of HQ and SeQ the same inclinations were also observed.

Studies of 8-Mercaptoquinoline as Chelate Agents. II. Infrared Absorption Spectra of its Divalent Metal Chelates

Yoshiyuki MIDO and Eiichi SEKIDO

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe

(Received December 4, 1970)

The infrared spectra of divalent metal thiooxinates have been measured in the region between 4000 and 400 cm^{-1}, and the relationships between these spectral bands and the characteristics of the metal-ligand bonding and the structures of the thiooxinates have been discussed. The plots of the frequencies of the metal-sensitive bands around 990 and 670 cm^{-1} against the atomic weight of the metal make it possible to classify these metal thiooxinates into two groups, one of which includes Cu-, Co-, Ni-, and Mn-thiooxinate, and the other, Cd-, Zn-, and Pb-thiooxinate. The deviation of the point for Zn-thiooxinate from the line belonging to thiooxinates with such metal atoms as have no available *d*-orbitals has been compared with the case of oxinates. Moreover, from the appearance of the 450 cm^{-1} band in the latter group, the structure of these thiooxinates may be tetrahedral. As for the frequencies of the two metal-sensitive bands mentioned above, those of Pd- and Pt-thiooxinate are the highest and that of Ag(I)-thiooxinate, examined for the sake of comparison, is the lowest. The possibility of the analytical application of the metal-sensitive band around 670 cm^{-1} has been discussed.

In the previous paper[1] describing infrared studies of 8-mercaptoquinoline, it was suggested that some substituent-sensitive bands are affected by the mass of the substituent atom directly bonded to the ring, and that these bands may be regarded as metal-sensitive bands (the 9μ band of metal oxinates,[2] for example, can be used for an analysis using infrared spectrometry).

Although several references concerning infrared studies of metal oxinates have been reported,[2-6] studies of the infrared spectra of the metal chelates of thiooxine with sulfur and nitrogen atoms as ligands have been limited in number.

From the investigations of the acid dissociation phenomena of oxine (HQ), thiooxine (MQ), and selenooxine (SeQ), HQ would be expected to yield a significantly more stable 1 : 1 metal chelate than MQ and SeQ, but this is not true. This has been interpreted as resulting from the greater covalent characteristic of the metal-ligand bond for thiooxinate and selenooxinate than in that for oxinate and from the possibility of π-bonding between the metal and ligand atoms for thiooxinate[7] or selenooxinate.[8]

In order to elucidate the relationships among some infrared bands, the character of the metal chelate-bonding, and the structure of thiooxinates, the infrared spectra of divalent metal chelates of MQ were studied.

Experimental

Reagents. The sodium salt of MQ was prepared by the method described in the previous paper.[1] The other reagents of an analytical grade were used without further purification.

Metal Thiooxinates. Divalent metal chelates of MQ were prepared under nitrogen gas and were purified by a technique developed from Dalziel-Kealey's method.[9] The

All of the metal thiooxinates were dryed at 120°C for several hours.

results of the elementary analysis of these metal chelates are summarized in Table 1. The results for Mn- and Co-thiooxinate are slightly different from those expected for each proposed formula.

Infrared Spectra. The infrared spectra were measured in the region between 4000 and 400 cm^{-1} with a Hitachi EPI-2G Infrared Grating Spectrophotometer. The spectrometer was calibrated with standard polystyrene film and water vapor. In the measurement, both the potassium bromide disc- and Nujol mulls-method were usually used, and both gave the same infrared spectra. To obtain a high resolution, the spectra in the special region where significant bands exist were repeatedly recorded at a slow speed and using a five-fold-scale expansion. The recorded spectra should be accurate to within ± 1 cm^{-1}.

Results and Discussion

The absorption frequencies of some divalent metal thiooxinates are summarized in Table 2. The spectra of the metal thiooxinates are all essentially similar to each other and to those of anhydride(liquid),[10] the disulfide and sodium salt of MQ which have been reported previously.[1]

Metal-Sensitive Bands and Structures of Metal Thiooxinates. Metal thiooxinates show a relatively strong absorption band in *the 1011—986 cm^{-1} region* and another strong band in *the 693—662 cm^{-1} region*, as shown in Table 2 and in Fig. 1. These bands have been assigned to substituent-sensitive bands.[1]

Although these thiooxinates show a few weak bands on the lower-frequency side of the metal-sensitive bands, it may be concluded, on the basis of an examination of the corresponding bands in each region of the disulfide of MQ (973 and 655 cm^{-1}), that all these thiooxinates are regular chelates except Mn-thiooxinate. For Mn-thiooxinate, as is shown in Fig. 1-(b), each metal-sensitive band appears as two bands, at 994 and 974 cm^{-1} (for *the 990 cm^{-1} band*) and at 674 and 655 cm^{-1} (for *the 670 cm^{-1} band*)

(b) ——: Mn-thiooxinate, ·····: Disulfide of MQ

Fig. 1. Infrared spectra of some metal thiooxinates.

respectively, and each latter band can be superimposed upon the corresponding bands of the disulfide of MQ. This suggests that these bands at 994 and 674 cm^{-1} may also be attributable to the metal-sensitive bands of a regular Mn-thiooxinate in a probable mixture with the disulfide of MQ and/or another chelate.

10) The absence of ν_{SH}(2515 cm^{-1}) in this spectrum may show the formation of metal chelate.

a) Bands in the region between 4000 and 1700 cm^{-1}, where only a kind of fundamental bands ν(C–H) appear 2980 cm^{-1}, were not exhibited in this Table.
b) Abbreviation; w, weak; m, medium; s, strong; v, very strong.
c) *Cf.* Bands of its disulfide, 973(s), 833(w), 760(s), 755(sh), 655(s), 634(w), 626(w) see Fig. 1-(b).
d) A point of Zn* shown in Fig. 2. exhibits the average frequency of bands at 994 and 985 cm^{-1} for Zn-thiooxinate.

Because the results of the elementary analysis of Co-thiooxinate were also slightly different from the expected value for the proposed formula, the infrared spectrum of Co-thiooxinate was compared with that of Co(III)-thiooxinate prepared from the salt of Co (III). The comparison suggests that the Co-thiooxinate formed by a conventional method may be thiooxinate of the divalent cobalt and that the strong bands at 996 and 683 cm^{-1} may be assigned to the metal-sensitive bands for a regular divalent chelate. A more detailed discussion of Co-thiooxinate will be presented in the future.

Charles *et al.*[2] have examined the infrared spectra of a series of divalent metal oxinates. They described how, when the frequencies of the 9 μ peak associated with a C–O vibration are plotted against the mass of the corresponding metal, the points for the transition metal chelates nearly fall on a straight line (the frequencies increase remarkably as the mass of the metal increases), while the points for the remaining metal chelates fall near on another (the frequencies decrease slowly). They have suggested that this may indicate either the involvement of 3*d*-orbitals in the metal-ligand bonding for the transition metal oxinates or, alternatively, a difference in crystal structure for the two classes of chelates.

In this work, the plot of frequency of *the 990 cm^{-1} band* for thiooxinates is similar to that of the 9 μ band

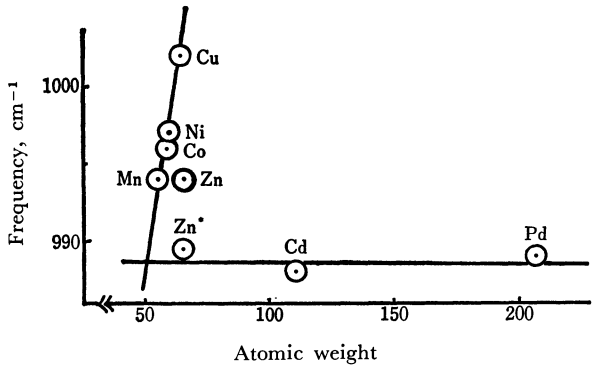

Fig. 2. Relationships between frequency of *the 990 cm^{-1} band* and atomic weight of central metal for divalent metal thiooxinate.
* A point of Zn* exhibits the average frequency of bands at 994 and 985 cm^{-1} for Zn-thiooxinate.

in oxinates, as is shown in Fig. 2. The character of this band may be not so simple as the diatomic vibration of oxinates, since the spectral shift is too little considering the large change in atomic weight upon the substitution of sulfur for oxygen as the coordinating atom. A similar plot of *the 670 cm^{-1} band* for thiooxinates is shown in Fig. 3. The similarity between these plots of *the 990 and 670 cm^{-1} bands* and the Charles plot supports their suggestion. Compared with the case of oxinates, the point for Zn-thiooxinate deviates considerably upwards from the lines belonging to thiooxinates with such metal atoms as have no available *d*-orbitals; the deviation from the line for the *670 cm^{-1} band* is larger than that for *the 990 cm^{-1} band.*

If the frequencies of *990 cm^{-1} bands* are arranged according to wave number, the order is as follows:

Cu->Ni->Co->Zn-=Mn->Pb->Cd-thiooxinate

This order is almost the same as that of the 9 μ band for metal oxinates[2] and also that of the 1250 cm^{-1} band for metal 2-(*o*-hydroxyphenyl)-benzoles,[11] which chelates through oxygen and nitrogen stoms. In the order of the frequencies for *the 670 cm^{-1} band* of thiooxinates, only the Zn-thiooxinate is located between Cu- and Ni-thiooxinate:

Cu->Zn->Ni->Co->Mn->Cd->Pb-thiooxinate

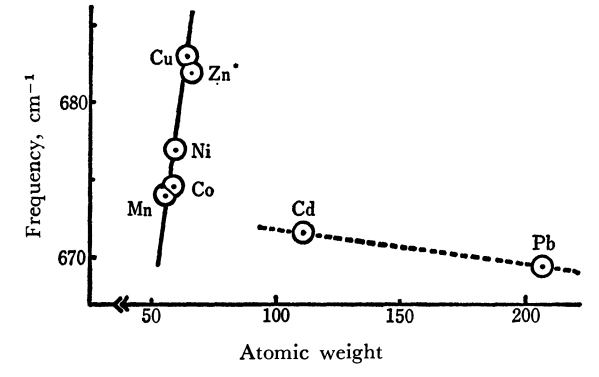

Fig. 3. Relationships between frequency of *the 670 cm^{-1} band* and atomic weight of central metal for divalent metal thiooxinate.

11) T. R. Harkins, J. L. Walter, O. E. Harris, and H. Freiser, *J. Amer. Chem. Soc.*, **78**, 260 (1956).

In metal selenooxinates, the bands around 975 and 660 cm^{-1} are metal-sensitive;[12] also the frequencies of both the bands are arranged in the same order as with *the 670 cm^{-1} band* for metal thiooxinates.

These facts may suggest that Zn-thiooxinate has a greater covalent character in metal-ligand bonding than does Zn-oxinate, and that the chemical affinity between the sulfur atom and the zinc ion is stronger than that between the oxygen atom and the cation.

A Peak near 450 cm^{-1} and the Structures of Metal Thiooxinates. A peak near 450 cm^{-1} appears in Zn-, Cd-, and Pb-thiooxinate, weakenning in relative strength in this order. In the transition-metal thiooxinates, this peak appears only slightly or not at all. Since the transition metal ions have *d*-orbitals available for dsp^2 bonding, it is reasonable to assume that they form square-planar complexes with MQ$_4$.

The method of group theory shows that the species of normal modes resulting from the D_{2h}-symmetry of the *trans* square-planar type include A_g, B_g, A_u, and B_u, of which the A_u and B_u species are active in the infrared. The 450 cm^{-1} band may be derived from one of the vibrations corresponding to A_g and B_g species from this type.

Therefore, it may be suggested that the degree of deviation from the square-planar structure is indicated by the effect on the strength of the 450 cm^{-1} band, and that Zn-thiooxinate, which has the largest strength, has a structure nearer to tetrahedral.

This consideration from the selection rule is conclusively supported by the X-ray diffraction studies confirming that Pb-thiooxinate is a distorted tetragonal pyramid[13] and suggesting that Zn-thiooxinate may be a tetrahedron.[14]

C–H Out-of-plane Bending Vibrations. All of the metal thiooxinates exhibit three strong bands assignable to C–H out-of-plane bending vibrations over the range between 820 and 740 cm^{-1}. Although the lowest band is most sensitive to metal, the relationship between its frequency and the atomic weight of the metal is not consistent. The lowest band for Zn- or Pb-thiooxinate splits into two bands; this may be additional evidence in favor of the structural consideration to be expected from the selection rule.

Pt-, Pd-, and Ag(I)-Thiooxinate. In general, the metal-ligand bonding in platinium or palladium chelates is strong covalent, and these chelates are both square planar.[15] The order of the frequencies of the metal-sensitive bands of both the thiooxinates precedes the order presented previously:

Pt->Pd->Cu-thiooxinate……

Also, the metal-sensitive bands of Ag(I)-thiooxinate, examined in order to compare them with divalent metal thiooxinate, appear at 986 and 662 cm^{-1}, and the frequencies of these bands are lower than those of

12) This will be discussed in a separate paper.

divalent-metal thiooxinates.

Possibility of Analytical Applications. Although there is considerable similarity among the infrared spectra of metal thiooxinates, each spectrum exhibits a few characteristic bands, as has been mentioned above. Of these bands, *the 670 cm^{-1} band* has more analytical advantages: (1) There is enough apparent difference in the frequency to permit its use in the detection of two metal cations by means of a certain combination of metal cations. (2) There are no near bands affecting this band. (3) The relative intensity of this band is strong.

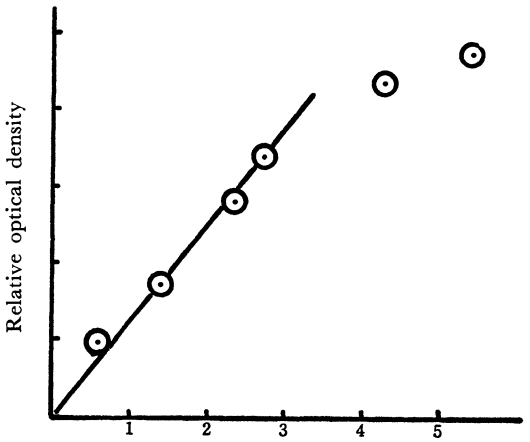
Pd-thiooxinate was selected as a reference on the basis of the following reasons; (1) the frequency of this band of Pd-thiooxinate is higher than that of any other metal thiooxinate, and (2) this chelate precipitates as a regular chelate over a wide range of pH.[16]

At the optimum pH for the formation of the other metal chelate, sodium salt of MQ reacts with a solution containing the palladium ion and the other metal ion to precipitate a mixture of the two metal chelates. In all these binary systems except the Pd–Pt system, the absorption bands of this mixture can be resolved into two components without any mutual interference; one is of Pd-thiooxinate, while the other is of the other metal thiooxinate.

The infrared spectra of both the Co–Ag and Cu–Ag systems indicated two distinguishable bands. The smallest difference in the frequency between two such bands observed in this binary systems was the 13 cm^{-1} obtained in the Co–Ag system. Therefore, if there is such a degree of difference at least, the metal cations can be identified by infrared study.

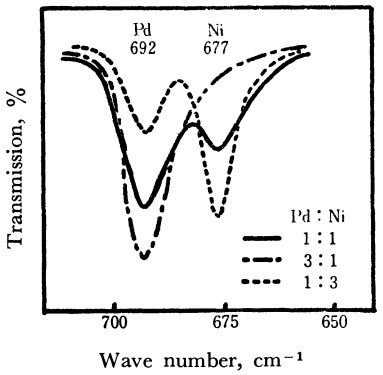
To obtain possible quantitative aspects, a typical calibration curve was drawn for Pd-thiooxinate employing the potassium bromide disc method.[5] As is shown in Fig. 4, Beer's law is followed in the 0.6—2.7 mg range of Pd-thiooxinate (0.15—1.11 mg of palladium) for the 300 mg disc.

As an example of a binary system, the Pd–Ni system is presented in Fig. 5. The nickel ion was undetectable in the precipitate from a mixture in which the gram-ionic ratio of the palladium ion to the nickel ion was 5 : 1, but when the ratio was reversed the palladium ion was detectable. This fact may explain why the molar extinction coefficient for this band of Pd-thiooxinate is larger than that of Ni-thiooxinate.



Concn. of Pd-thiooxinate in 300 mg KBr disc, (mg)

Fig. 4. Calibration curve.



Wave number, cm^{-1}

Fig. 5. Infrared spectra of *the 670 cm^{-1} bands* in Pd-Ni system.

Analytical applications of infrared study to metal chelates may be expected to be very useful in the identification of metal thiooxinates, but the other advantage, in quantitative aspects, remains obscure. Some probable disadvantages may be the troublesome for potassium bromide disc preparation and the need for compensation between the relative opitical density and the weight of the dics.

The authors wish to express their thanks to Mr. I. Fujiwara for his assistance in synthesising and to the Ministry of Education for a grant-in-aid.

The Infrared Spectra and Normal Coordinate Treatments of L_3Sn-$Mn(CO)_5$ (L=Cl, Br, CH_3, and C_6H_5)

Satoru ONAKA[1)]

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received January 7, 1971)

The infrared absorption spectra (2200—60 cm^{-1}) have been measured for four analogous compounds, Cl_3Sn–$Mn(CO)_5$, Br_3Sn–$Mn(CO)_5$, $(CH_3)_3Sn$–$Mn(CO)_5$, and Ph_3Sn–$Mn(CO)_5$. Normal coordinate analysis has been made for three molecules-Cl_3Sn–$Mn(CO)_5$, Br_3Sn–$Mn(CO)_5$, and $(CH_3)_3Sn$–$Mn(CO)_5$- on the basis of a modified Urey-Bradley force-field. The calculated frequencies attain close agreement with validly-assigned frequencies. The force constant, K(Sn–Mn), for each molecule varies with the substituent on the tin atom, and increases in the order of: K(Sn–Mn) of Cl_3Sn–$Mn(CO)_5$ > K(Sn–Mn) of Br_3Sn–$Mn(CO)_5$ > K(Sn–Mn) of $(CH_3)_3Sn$–$Mn(CO)_5$. The vibrational eigenvectors reveal that the Sn–Mn stretching vibrational modes are considerably coupled with other vibrational modes, especially with CMnC deformation and axial MnC stretching modes.

Recently, the nature of M–Co bonds (M=Si, Ge, and Sn) has been studied by means of NQR[2,3)] and the ^{119}Sn-Mössbauer effect,[4–6)] and it has been suggested that the stability of these compounds can be associated or correlated with M–Co π bonding.

The present author has also reported that the σ and π characteristics of the Sn–Mn bondings of a series of $R_{3-x}X_xSn$–$Mn(CO)_5$ compounds are extensively affected by the quantity of halogen on the tin atom; he reached this conclusion on the basis of ^{55}Mn- and ^{1}H-NMR and ^{119}Sn-Mössbauer-effect studies.[7,8)]

Although it is well recognized that the vibrational analysis is very profitable in determining the strengths of the bonds of interest as a total effect of σ and π interactions between atoms, especially in determining the strengths of the metal-metal bonds, such analysis has been successfully achieved in only a few cases[9–11)] because of the many difficulties which must be overcome. However, the diatomic or pseudo-diatomic models have been employed to obtain information about the strengths of the metal-metal bonds.[12,13)] According to Watters *et al.*,[10)] however, diatomic or pseudo-diatomic models may not be accurate for Cl_3-Si–$Co(CO)_4$ and Cl_3Ge–$Co(CO)_4$ because of the large extent of vibrational coupling with other modes.

The present author has now aimed to clarify the nature of the Sn–Mn bond further by making vibrational analyses of the series of L_3Sn–$Mn(CO)_5$ (L=Cl, Br and CH_3) compounds as a part of the study of the Sn–Mn bond. The present paper reports the infrared spectra of four molecules, Cl_3Sn–$Mn(CO)_5$, Br_3Sn–$Mn(CO)_5$, $(CH_3)_3Sn$–$Mn(CO)_5$, and Ph_3Sn–$Mn(CO)_5$, spectral assignments, their normal coordinate analyses, and the characterizations of the Sn–Mn bonds.

Experimental

The samples were prepared by the methods described in the literature.[14,15)] The purity of samples was determined by elemental analyses, by melting- or decomposing-point measurements, and by studying the infrared spectra (CO stretching region); the present values are in good agreement with previously published values.[15–17)]

The infrared spectra in the CO stretching region were measured with a Hitachi EPI-G2 spectrometer in a hexane solution with a KBr liquid cell. The Nujol mull samples were also examined with Hitachi EPI-G2, EPI-L spectrometers and a FIS-1 double-beam vacuum spectrophotometer in the region from 2200 to 60 cm^{-1}. The results are summarized in Table 1 and in Fig. 1.

Normal Coordinate Treatment

Spectral Assignment. The vibrational assignment for each molecule has been made by comparing the spectra of the four compounds with one another and by taking into consideration the calculated frequencies. The reported assignments of analogous compounds were also taken into account.[12,15–22)]

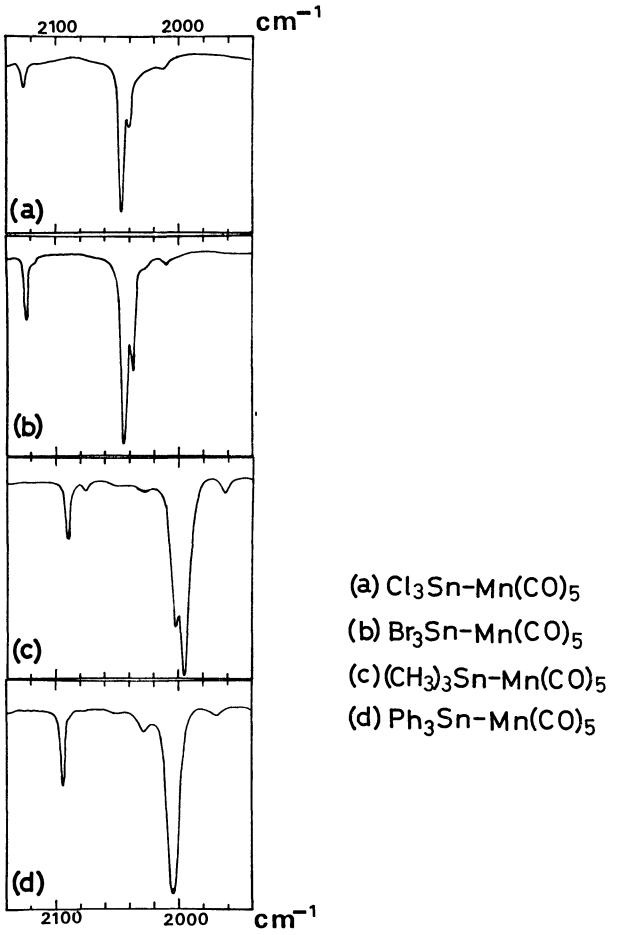

Fig. 1(a). Infrared spectra of L_3Sn-$Mn(CO)_5$.

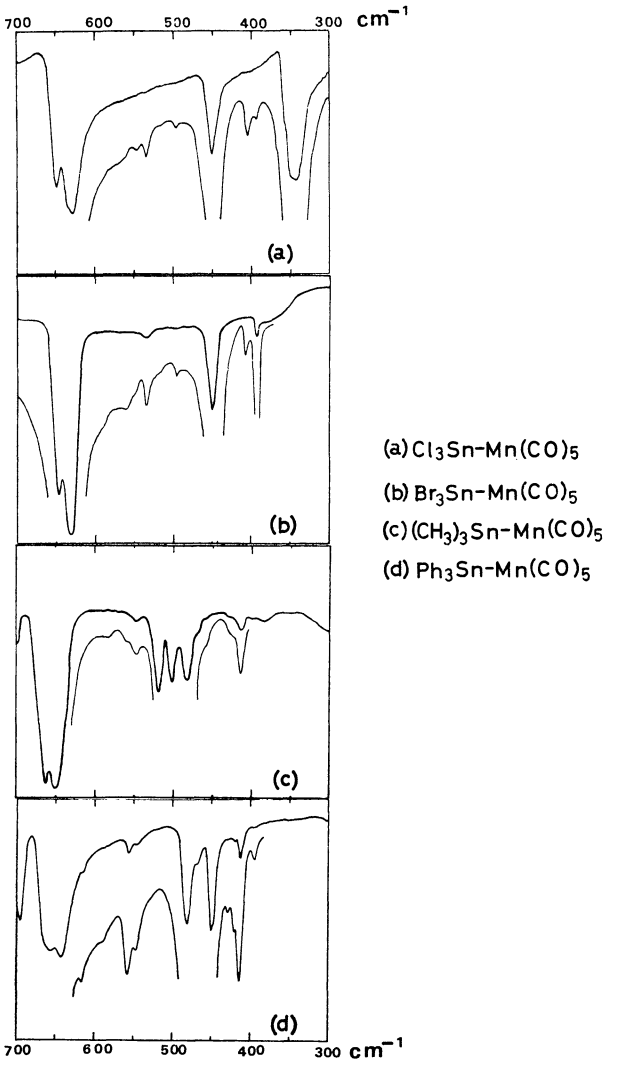

Fig. 1(b). Infrared spectra of L_3Sn-$Mn(CO)_5$.

The structure of $(CH_3)_3Sn$-$Mn(CO)_5$ is shown in Fig.2; it was determined by X-ray analysis.[23] In this molecule, the local symmetry around the tin atom is C_{3v}, and that of the manganese atom is C_4v.[24] In the vibrational analysis, this molecule can be regarded as a symmetry-top molecule, and the normal vibrations may be classified into 15 A_1, 2 A_2, and 11 E vibrations. It was assumed that the structure of X_3Sn-$Mn(CO)_5$ was the same as that of $(CH_3)_3Sn$-$Mn(CO)_5$. The close resemblance of their vibrational spectra supports this assumption.

The outline of the vibrational assignments is shown below.

The 2200—1900 cm^{-1} Region (CO Stretching Region): According to many reports on L-$Mn(CO)_5$-type compounds,[13,25-33] the highest-frequency absorption with a medium-to-weak intensity is assigned to the A_1 vibration; the most intense absorption is assigned to the E vibration due to the equatorial CO stretching mode, and the absorption with a medium-to-strong intensity to the A_1 vibration due to the axial CO stretching mode.

The 700—500 cm^{-1} Region: The highest-frequency absorption with a strong intensity is assigned to the A_1 vibration due to the equatorial MnCO bending mode, and the most intense absorption in this region is tentatively assigned to the E vibration due to the axial MnCO bending mode. The strong absorptions at 518 and 502 cm^{-1} for $(CH_3)_3Sn$-$Mn(CO)_5$ are assigned to the Sn-CH_3 stretching vibrations.[20]

The 500—350 cm^{-1} Region: The highest-frequency absorption with the strongest intensity in this region is assigned to the E vibration, and the weak absorptions around 400 cm^{-1} are assigned to the A_1 vibrations of the MnC stretching modes. The strong absorption at 450 cm^{-1} for Ph_3Sn-$Mn(CO)_5$ arises from the vibration of a mono-substituted benzene ring.[19]

The 350—200 cm^{-1} Region: The assignments of

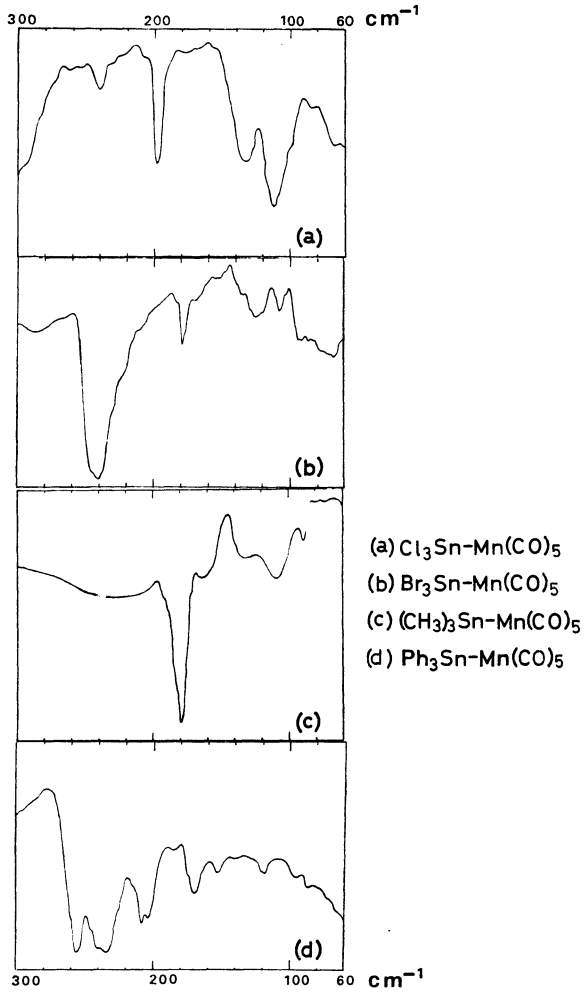

Fig. 1(c). Far-infrared spectra of L_3Sn-$Mn(CO)_5$.

the Sn–L stretching vibrations for each molecule are made on the basis of the assignments reported for SnX_4,[21] $Sn(CH_3)_3X$,[20] $SnPh_4$, and $SnPh_3X$.[19] The very strong and broad band at 345 cm^{-1} for Cl_3Sn–$Mn(CO)_5$ is assigned to the SnCl stretching vibration, and the similar band at 240 cm^{-1} for Br_3Sn–$Mn(CO)_5$, to the SnBr stretching vibrations.

The 200—170 cm^{-1} Region: The bands with strong to medium intensities observed at 197, 178, 179, and 170 cm^{-1} for Cl_3Sn–$Mn(CO)_5$, Br_3Sn–$Mn(CO)_5$, $(CH_3)_3Sn$–$Mn(CO)_5$, and Ph_3Sn–$Mn(CO)_5$ respectively are assigned to the Sn–Mn stretching vibrations.

The 170—60 cm^{-1} Region: For Cl_3Sn–$Mn(CO)_5$, the strong bands at 130 and 112 cm^{-1} are observed. These bands may be assigned to the deformation-vibrations of the $SnCl_3$ group. The bands observed at 125 and 108 cm^{-1} for Br_3Sn–$Mn(CO)_5$ may be assigned to the skeletal CMnC bending modes of the *E* species. The manganese carbonyl, $Mn_2(CO)_{10}$, also has two strong absorptions, at 120 and 110 cm^{-1}, which are due to the CMnC bending modes. The strong bands at 90—70 cm^{-1} for this molecule may be assigned to the $SnBr_3$ deformation-vibrations.[21] The bands at 160 and 130 cm^{-1} with medium intensities for $(CH_3)_3Sn$–$Mn(CO)_5$ may be assigned to the CSnC deformation-vibrations. The absorption

at 110 cm^{-1} for the $(CH_3)_3Sn$–$Mn(CO)_5$ molecule may be assigned to the CMnC skeletal bending mode of the *E* species.

All the vibrational assignments are listed in Table 1.

The Procedure of Calculation. Frequency calculations were made for Cl_3Sn–$Mn(CO)_5$, Br_3Sn–$Mn(CO)_5$, and $(CH_3)_2Sn$–$Mn(CO)_5$ molecules on the basis of Wilson's GF matrix method,[34] in which CH_3 group was treated as one unit. The symmetry coordinates are constructed based on the C_{3v} symmetry group and C_{4v} for $Mn(CO)_5$ group respectively, which are listed

34) E. B. Wilson, *J. Chem. Phys.*, **9**, 76 (1941).

in Table 2. The internal coordinates used are shown in Fig. 3. A normal coordinate analysis is made by solving a secular equation of 39th order. The values of the bond lengths, r(Sn–Mn), r(Mn–C), and r(C–O), listed in Table 3 are taken from the average values of $(CH_3)_3Sn$–$Mn(CO)_5$ and Ph_3Sn–$Mn(CO)_5$.[23,24] The bond lengths, r(Sn–Cl) and r(Sn–Br), are taken from the $(CH_3)SnCl_3$, and $(CH_3)SnBr_3$ values,[35] which were determined by electron-diffraction measurements. The L–Sn–L and L–Sn–Mn angles are assumed to be tetrahedral angles, and the C–Mn–C and Sn–Mn–C angles are assumed to be 90° on the basis of the crystal data.[23,24]

The modified Urey-Bradley force field is used for the calculation,[36] and twenty-four force constants are used for each molecule. The values of them are given in Table 4. The K, H, F, Y, and P symbols represent the stretching, deformation, repulsion, torsion and stretch-stretch interaction force constants respectively. The suffixes, a, e, i, o, t, and c, are explained in Table 4. The initial values of K_a(CO), K_e(CO), P_t(CO, CO), and P_c(CO, CO) of the Mn-$(CO)_5$ moiety are obtained by the Cotton-Kraihanzel method.[26] The other force constants for the Mn-$(CO)_5$ part are taken from the values for $Mo(CO)_6$

calculated by Jones.[37] The initial set of force constants of the SnL_3 groups are aken from the SnL_3X and the SnL_4 molecules.[20,21] The initial values of K(SnMn) are estimated on the basis of the diatomic models from the IR frequencies. The values of the repulsion force constants, F(Mn···L) and F(C···Sn), are estimated from the Lennard-Jones potentials for inert gasses.[38-40] The initial value of H(MnSnL) is estimated considering the H(CMnC) and H(LSnL) values. The value of Y(Mn–Sn) is arbitrarily assumed to be 0.005 md·Å, taking into account the values of the ethane derivatives.[41]

The numerical calculation was carried out by using a HITAC 5020*E* of the Computation Center of the University of Tokyo and programs set up in the laboratory of Professor T. Shimanouchi.[42] First, the force constants of Br_3Sn–$Mn(CO)_5$ were determined. The values of the force constants were adjusted to get the best fit of the calculated frequencies with the observed ones, with reference made to the Jacobian matrix elements. Then, the frequencies of the other two molecules were calculated using the same values of the force constants as those of Br_3Sn–$Mn(CO)_5$, except those which had to be changed essentially.

Results

The final set of all the force constants are listed in Table 4. The frequencies calculated by means of these force constants are in good agreement with the observed values, as is shown in Table 1.

The eigenvectors here obtained show that the vibrational modes associated with the Sn–Mn stretching vibration are extensively coupled with the other vibrational modes, especially with the CMnC deformation and axial MnC stretching modes. The vibrational coupling in the ν(Sn–Mn) with other vibrations for Br_3Sn–$Mn(CO)_5$ is different from those of the other two molecules, and the SnBr stretching vibration is appreciably mixed. The purities of the vibrational modes assigned to the Sn–Mn stretching vibrations are evaluated from the potential energy distribution to the Sn–Mn stretching coordinate (PED), shown in Table 5.

Discussion

For metal carbonyl compounds, it is well known that two types of electron donations act between the metal, M, and the ligand, CO, namely σ-electron donation from CO to M and π-electron back-donation from M to CO, and that the variation in the π-interaction between L and M in $LM(CO)_n$-type metal carbonyl compounds strongly affects the force constants, K(CO) and K(MC), in the following manner. The ligand, L, and the CO can both undergo π-bonding with the metal d orbitals. This π-interaction involves the back-donation of metal d orbitals to the vacant antibonding CO orbitals. If the ligand, L, can also accept metal d_π electrons into suitable π-type orbitals, it will compete with the CO for d electrons of the transition metal. The π-acceptor capability of L will also influence the force constants, K(CO) and K(MC). The grater the π-bonding to L, the less the electron density which will enter the antibonding orbitals of the CO, and the greater the CO stretching force constant, and the smaller the MC stretching force constant.[43-45]

The values of the force constants listed in Table 4 show that the strength of the Sn–Mn bond is strongly affected by the electronegativity of the L on the L_3Sn group; moreover, the smaller the values of K(MnC), the larger the values of K(CO) and K(SnMn) become. These facts suggest that not only the σ-electron donation but also the π-electron back-donation act on the Sn–Mn bond, and that the strength of the π-bond nature between Sn and Mn also varies with the substituent on the Sn atom. Therefore, it can be deduced that the π-bond strengths of the Sn–Mn bond increase in the order: $(CH_3)_3Sn–Mn(CO)_5 < Br_3Sn–Mn(CO)_5 < Cl_3Sn–Mn(CO)_5$, according to the above considerations and the force constants listed in Table 4. The difference in the π-bond strength between chloro- and bromo-complexes is, however, considered not to be large, because the K(MnC) and K(CO) force constants, which are a measure of the π-interaction between Sn and Mn, of the two compounds closely resemble each other. The values of the K-(SnMn) force constants, which are a direct measure of the total bond strength, $(\sigma+\pi)$, between Sn and Mn, are in the same order, but the difference in the K(SnMn) values of the two halogen complexes is much more enhanced.[46] One possible origin of this enhancement is due to the assumption of the same Sn–Mn bond length for these two compounds.

The author wishes to express his deep gratitude to Professor Takehiko Shimanouchi for his kind permission to use the programs set up in his laboratory for the calculations of the normal coordinate treatment analyses. Thanks are also due to Professor Yukiyoshi Sasaki for his encouraging advice and discussions.

Studies on Cobaloxime Compounds. V. Oxidation of Formaldehyde with Cobaloximes and Aquocobalamin

Yorikatsu HOHOKABE and Noboru YAMAZAKI

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 20, 1971)

Catalytic activities of cobaloximes in the oxidation of formaldehyde were compared with each other and with the activity of aquocobalamin (vitamin B_{12a}). All the cobaloximes showed much less activities than B_{12a}. Chlorocobaloximes had the highest activities. Reaction order was found to be -0.18 with respect to the concentration of hydrogen ion, 0.71 to that of formaldehyde, and 0.49 to that of chloroaquocobaloxime. In anaerobic conditions, the reduced-state B_{12r} considered to be an intermediate in the air-oxidation reaction of aldehyde was detected spectrochemically, but not the reduced-state of cobaloxime. A much slower reaction of aldehyde with cobaloximes as compared with cobalamin was attributed to the higher reduction potentials of the former.

Concerning the vitamin B_{12}-dependent enzymatic system which converts diols to the corresponding aldehydes, further oxidation reaction of the aldehydes might occur with the aid of the B_{12} component. The vitamin B_{12}-formaldehyde complex was reported to be a one-carbon unit precursor in the biosynthesis of methionine.[1] The catalytic activity of aquocobalamin in the air-oxidation of some aldehydes was reported by Komai *et al.*[2]

In the present work, oxidation reaction of aldehydes was examined with cobalamin and cobaloximes in order to compare their chemical reactivity; the resemblance of cobaloxime compounds to cobalamin compounds in chemical behavior has been described elsewhere.[3,4]

Experimental

Materials. All the cobaloximes were prepared as reported previously.[5] Aquocobalamin was kindly supplied by Eisai Co. Commercial G. R. grade formalin (containing about 37% formaldehyde) was diluted with distilled water to suitable concentration. Acetaldehyde, propionaldehyde and benzaldehyde were commercial E. P. grade reagents. All other reagents were G. R. grade obtained commercially.

Procedures. *pH Measurement*: A pH Meter, Toa Electronics Ltd., model HM-5A, was used for pH determination.

pH Change during the Course of the Oxidation Reaction of Aldehyde: The reactions were carried out as follows. To a mixture of 6.0 m*l* of 5×10^{-4} M aqueous solution of a complex and 5.0 m*l* of 1.0 M formaldehyde was added first 35 m*l* of distilled water, followed by adjustment of pH of the solution to 7.00 with 5 mM NaOH, and by final addition of distilled water, whereby total volume was brought up to 50.0 m*l*. Thus, the final concentrations of formaldehyde and the complex were 0.10 M and 6.0×10^{-5} M, respectively. The reactions were conducted at 40°C with shaking in aerobic conditions. At appropriate intervals, the pH of the solution was measured and 2.0 m*l*-aliquot was taken for analysis of the remaining aldehyde. Aldehyde content was determined by titration: 4 m of 1 N NaOH and 5.0 m*l* of 0.1 N iodine solution were added to the aliquot. After 20 min, 2.0 m*l* of 3 N H_2SO_4 and a small amount of starch solution were added. Excess iodine was titrated with 0.1 N $Na_2S_2O_3$, from which the amount of the remaining aldehyde in the aliquot was calculated.

Dependence of the Rate upon the Concentrations of Hydrogen Ion, Formaldehyde, and Cobaloxime: The reactions were conducted in 0.5 M potassium phosphate buffer and the residual aldehyde content was determined. The dependence was examined in the pH range 5.8—7.8; the concentration of formaldehyde (2.35×10^{-2} M—2.03×10^{-1} M), and that of chloroaquocobaloxime (1.04×10^{-3} M—4.01×10^{-3} M).

Paper Chromatography: Formic acid formed in the reaction mixture was extracted with ether, and the ether layer was shaken with 1% NH_4OH aqueous solution. Ammonium formate solution thus obtained was used for paper chromatographic analysis in a mixed solvent of 95% ethanol and concd. NH_4OH (100 : 1, by vol.). Formate was detected by a blue spot at R_f 0.30 ($\pm$0.04) by spraying a bromophenol blue solution, whereas the authentic sample gave a spot at R_f 0.28 ($\pm$0.05).

Reduction of Cobaloxime by $NaBH_4$: Into 20 m*l* of 3.0×10^{-4} M solution of chloroaquocobaloxime was passed nitrogen gas and evacuated by a vacuum pump. After the N_2 passage-evacuation procedure was repeated five times, a small amount of solid $NaBH_4$ (*ca.* 1 mg) was added to the solution with stirring under a nitrogen atmosphere. Rapid color change in the solution from light yellowish brown to yellow took place, and the absorption maximum appeared at 463 mμ which is a characteristic band of cobaloxime(II), *i.e.*, $Co^{II}(DH)_2(H_2O)$ (DH: dimethylglyoximato monoanion). From the spectra for several concentrations of the cobaloxime, its molar extinction coefficient was determined to be $3.76\ (\pm0.17)\times10^3$.

Reduction of Cobaloxime and B_{12a} by Aldehydes: When formaldehyde was used instead of $NaBH_4$ at the final concentration 0.050 M, no reduction of chloroaquocobaloxime was observed even after 160 hr. However, this is ambiguous, since the hyperchromic shift of chloroaquocobaloxime occurs in aqueous solution. Therefore the reduction was examined for hydroxoaquocobaloxime (1.0×10^{-4} M) as well as aquocobalamin (3.0×10^{-5} M) with a large excess (hundreds times of the complex) of formaldehyde, acetaldehyde or benzaldehyde in 0.1 M potassium phosphate buffer (pH 7.1) at 40°C. Even after 120 hr no reduction was observed in the case of cobaloxime. On the contrary, B_{12a} was reduced by formaldehyde, acetaldehyde or benzaldehyde in 20 hr. This was demonstrated spectrochemically by the appearance of

the absorption maximum at 475 mμ in accord with the value reported in literature.[2]

Results and Discussion

It is expected that pH of the solution will decrease if oxidation of aldehyde takes place in the presence of a catalyst in aerobic conditions. The catalytic activities of several cobaloximes and aquocobalamin (B_{12a}) were examined in the oxidation of formaldehyde in the presence of air. Typical pH change during the course of the reaction is shown in Fig. 1. We see that

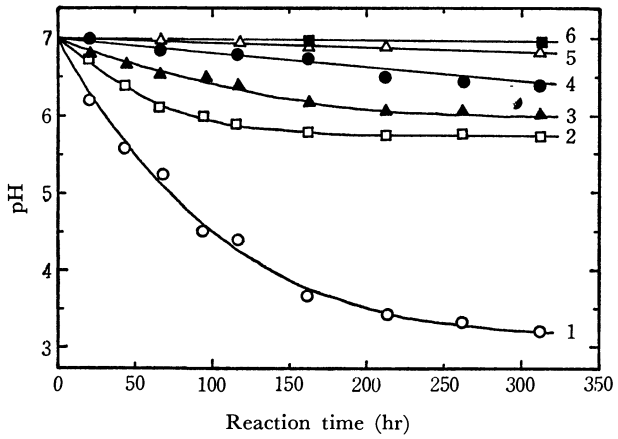

Fig. 1. pH change during the course of the oxidation reaction of formaldehyde.
[HCHO]=0.10 M, [Co]=6.0×10^{-5} M, at 40°C
1, B_{12a}; 2, $CoCl(DH)_2(H_2O)$; 3, $CoCl(DH)_2$(pyridine); 4, $CH_3Co(DH)_2(H_2O)$; 5, $Co(CN)(DH)_2(H_2O)$; 6, blank

B_{12a} acted as a much better catalyst than cobaloximes. After 300 hr the initial concentration of formaldehyde 0.10 M decreased to 0.082 M in the presence of B_{12a} with a concentration 6.0×10^{-5} M, which shows that the reaction proceeded catalytically. Of the cobaloximes, chlorocobaloximes exhibited the highest activity. The catalytic activity decreased in the order $B_{12a} \gg CoCl(DH)_2(H_2O) > CoCl(DH)_2$(pyridine) $> CoCl(DH)_2$(Copoly-AM-VPy) $> CH_3Co(DH)_2(H_2O) > Co(OH)(DH)_2(H_2O) \simeq Co(OH)(DH)_2$(Copoly-AM-VPy) $\simeq CH_3Co(DH)_2$(pyridine) $> Co(CN)(DH)_2(H_2O)$ as determined from the decrease of the pH of the reaction mixture, where DH denotes dimethylglyoximato monoanion and Copoly—AM-VPy a low molecular weight copolymer of acrylamide and 4-vinylpyridine.[6] The reason for the higher activity of chlorocobaloximes than hydroxo derivatives cannot be presented. Their higher activity than methyl or cyano derivatives might be due to weaker Co–Cl bond than Co–C bonds. Cyanocobalamin was reported to have no catalytic activity in the oxidation of aldehyde.[2] The oxidation of propionaldehyde was observed to take place much more slowly than that of formaldehyde in the presence of these catalysts.

Dependence of the reaction rates upon the concentrations of formaldehyde (2.35×10^{-2}—2.03×10^{-1} M), chloroaquocobaloxime (1.04×10^{-3}—4.01×10^{-3} M) and the acidity (pH 5.82—7.78) was examined.

6) N. Yamazaki and Y. Hohokabe, *Chem. Commun.*, **1968**, 829.

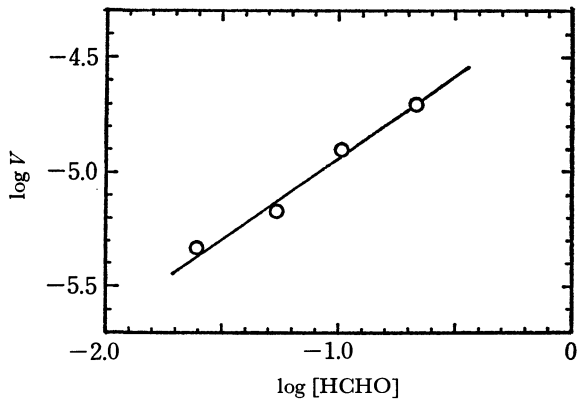

Fig. 2. Dependence of rate upon the concentration of formaldehyde.
[$CoCl(DH)_2(H_2O)$]=3.0×10^{-3} M, pH 7.0, at 40°C

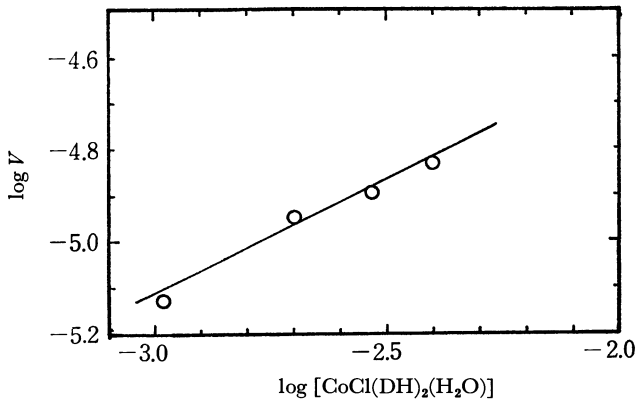

Fig. 3. Dependence of rate upon the concentration of chloroaquocobaloxime.
[HCHO]=0.10 M, pH 7.0, at 40°C

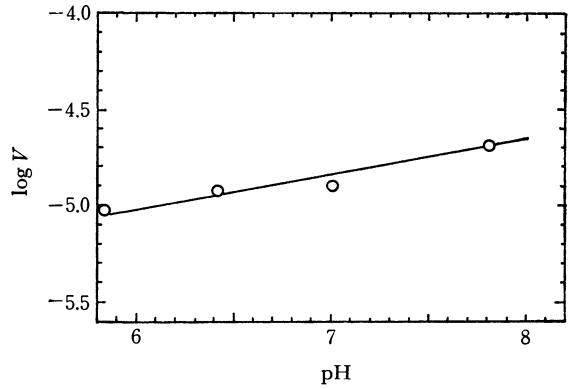

Fig. 4. Dependence of rate upon the pH.
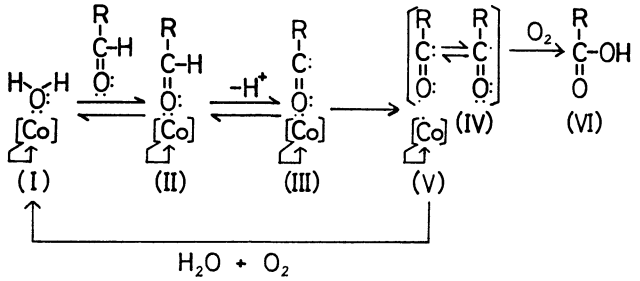
[HCHO]=0.10 M, [$CoCl(DH)_2(H_2O)$]=3.0×10^{-3} M, at 40°C

The results are shown in Figs. 2, 3, and 4. The reaction rate increased with concentrations of aldehyde or cobaloxime, and slightly with pH. The reaction order was found to be −0.18 with respect to [H^+]; 0.71 to the concentration of aldehyde and 0.49 to that of cobaloxime.

The oxidation reaction of formaldehyde in the presence of chloroaquocobaloxime proceeded too slowly; only twice the number of moles of the aldehyde, as compared to the cobaloxime added, was oxidized after about 400 hr. Thus cobaloximes

had a quite low catalytic activity, though B_{12a} acted as a better catalyst as mentioned above. The formation of formic acid was confirmed by paper chromatagraphy. Authentic formic acid gave a spot at R_f 0.28 (±0.05) in 95% ethanol - *concd.* NH_4OH (100 : 1, by vol.), whereas the sample gave a spot at R_f 0.30 (±0.04).

A mechanism for the oxidation of aldehyde was proposed as follows.[2]



1) Aldehyde coordinates to the Co atom in exchange for H_2O of B_{12a}. 2) Proton leaves from the aldehyde-cobalamin complex. 3) The unstable intermediate thus formed splits to give an acyl radical and vitamin B_{12r}. 4) Under aerobic conditions, the acyl radical is attacked by oxygen molecule and converted to carboxylic acid. 5) B_{12r} is reoxidized to aquocobalamin (B_{12a}).

A similar mechanism could be applied to the reaction with cobaloximes. Much lower catalytic activity of cobaloximes as compared with aquocobalamin might be due to higher reduction potentials of the former. Thus, the difficulty of reduction of cobaloxime by aldehydes was demonstrated spectrophotometrically: Since chloroaquocobaloxime shows a hyperchromic shift in the visible region due to the aquation reaction, it is difficult to detect the formation of the reduced-state of cobaloxime spectro-chemically. Hence, the reaction of aldehydes with hydroxoaquocobaloxime was examined in an aerobic conditions, as well as with aquocobalamin. In the case of B_{12a}, with formaldehyde, acetaldehyde or benzaldehyde, the absorption maximum attributable to B_{12r} was observed at 475 mμ in 20 hr, which disappeared in contact with oxygen giving rise to the restoration of the spectrum of the original solution. On the other hand, in the case of cobaloxime, the absorption maximum at 463 mμ attributable to cobaloxime (II) could not be observed even after 120 hr under the same conditions.

Thus, it is concluded that the reduction of cobaloximes with aldehydes, if any, takes place much more slowly, than that of B_{12a}, and the low catalytic activity of the former can be attributed to their higher reduction potentials. This is supported by the observation that cobalamins are reduced at less negative potentials than the corresponding cobaloximes in the polarographic reduction,[7] and the reduction of cobaloximes by thiols is much slower than that of cobalamins.[8]

Studies on Cobaloxime Compounds. VI. Decomposition of Formic Acid with Cobaloximes and Cobalamins

Yorikatsu HOHOKABE and Noboru YAMAZAKI

Departmnt of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 20, 1971)

Catalytic activities of cobaloximes in the decomposition reaction of formic acid were compared with each other and with those of cobalamins. In the cobalamin series, the activity decreased in the order aquocobalamin (vitamin B_{12a})>methylcobalamin>cyanocobalamin (vitamin B_{12}). In the cobaloxime series, the activity decreased in the order $Co(OH)(DH)_2(H_2O)>CoCl(DH)_2(H_2O)>Co(CN)(DH)_2(H_2O)>CH_3Co(DH)_2(H_2O)$. Cobalamins had much greater activities than the corresponding cobaloximes. The reaction proceeded with uptake of oxygen. No hydrogen gas was evolved in the reaction. The reaction rate slightly decreased with the increase of pH between 6.0 and 7.0. The reaction rate changes with 0.39 power of formic acid concentration less than 1×10^{-3} M (comparable to that of cobaloxime), and becomes independent of the concentration greater than 1×10^{-3} M. It changed with 0.89 power of the concentration of hydroxoaquocobaloxime. Aquocobalamin was reduced to B_{12r} in the presence of formic acid but not hydroxoaquocobaloxime in anaerobic conditions. The catalytic activities of cobaloximes lower than the corresponding cobalamins were attributed to the higher reduction potentials of the former.

So far, comparison between cobalamin and cobaloxime has been made in the reaction with CO,[1,2] O_2,[3] aldehyde,[4] electron transfer reaction,[5] photodecomposition reaction,[6,7] and other chemical and biochemical reactions.[8,9] Catalytic decomposition of formic acid by cobalamins was briefly described by Utsumi *et al.*[10]

In the present work, catalytic decomposition of formic acid by several cobaloximes and cobalamins was examined in order to compare their catalytic activities, and the results are given herewith.

Experimental

Materials. Preparation of the cobaloximes was described previously.[11] Cobalamins were kindly supplied by Eisai Co. All other reagents were commercial products of G. R. grade.

Procedures. *Decomposition Reaction*: The reactions were followed by means of the conventional Warburg manometric method.[12] A typical reaction mixture with a total volume of 4.0 m*l* contained 6×10^{-3} M of formic acid and 6×10^{-4} M of cobalamin or cobaloxime in 0.5 M phosphate buffer (pH 6.00). Two manometers were used for following a run, one with a chamber containing 0.2 m*l* of 20% KOH with a small filter paper to absorb CO_2 gas evolved in the reaction, and another without the alkali chamber. The pressure change resulting from the uptake of oxygen was followed with the former, and the total pressure change due to the difference between the uptake of oxygen and the evolution of CO_2 with the latter. Each reading was corrected by that of a thermobarometer. The reaction was carried out at 40°C with shaking at a rate of 100 rpm.

Reduction of Cobalamin or Cobaloxime with Formic Acid in Anaerobic Conditions: Reduction was examined for hydroxoaquocobaloxime (1.0×10^{-4} M) as well as aquocobalamin (3.0×10^{-5} M) in the presence of 5×10^{-3} M formic acid in 0.1 M phosphate buffer (pH 7.1) at 40°C under a nitrogen atmosphere, in the same way as reported previously.[4] B_{12a} was reduced in 20 hr which was demonstrated spectrochemically by the appearance of an absorption maximum at 475 mμ. No reduction was observed in the case of hydroxoaquocobaloxime even after 200 hr.

Gas Chromatography: The gases in the reaction mixture were examined by means of gas chromatography for hydrogen gas, which might be formed by non-oxidative decomposition of formic acid. For detection a Shimadzu Gas Chromatograph, model GC-4APT was used with nitrogen gas as carrier at the flow rate of 40 m*l*/min. Moelcular Sieves-13X (60—80 mesh) preheated at 500°C for 2 hr and cooled was packed in a steel column (3 mm×3 m). The detector temperature was 30°C, and the column temperature 20°C. Authentic hydrogen gas gave a retention time 89.4 sec. The gas phase of the reaction mixture with B_{12a} or chloroaquocobaloxime was thus examined and no hydrogen gas was detected.

Results and Discussion

Decomposition of formic acid with cobalamins or cabaloximes proceeded quantitatively with consumption of oxygen. The CO_2/O_2 ratios were 1.6—1.0. Initial rates for the decomposition of formic acid with some cobalamins and cobaloximes are summarized in Table 1. Aquocobalamin was found to be the most powerful catalyst among the cobalamins or cobaloximes examined. Methylcobalamin was the second. Cyanocobalamin showed the lowest activity among cobalamins, in good agreement with the results by Utsumi *et al.*[10] In the cobaloxime series, the catalytic activity decreased in the order hydroxo->chloro->cyano->methyl-aquocobaloxime.

Dependence of rate on the concentration of formic acid, hydroxoaquocobaloxime and pH was investigated. At a concentration comparable to that

a) [HCOOH]=6.0×10^{-3} M, [Co]=6.0×10^{-4} M, in 0.5 M phosphate buffer (pH 6.00), at 40°C. (total volume: 4.0 m*l*). The estimated relative errors are not more than 5%.
b) DH denotes dimethylglyoximato monoanion.

of cobaloxime, the rate increased with the substrate concentration, the reaction order being about 0.4. However, at a higher concentration, the rate curves become flat as shown in Fig.1. The rate increased with the concentration of cobaloxime, the reaction order being 0.89 as shown in Fig 2. A slight decrease in rate with the increasing of pH was unexpected (Fig. 3), since the coordination of formate anion to the complex was considered to be easier than that of the protonated form of formic acid. No reason can be given at present.

Change of activity with the variation of the axial ligand in cobalamins and cobaloximes suggests that the formate coordinate to the cobalt atom in the sixth position as in acetate anion,[13] though the formation

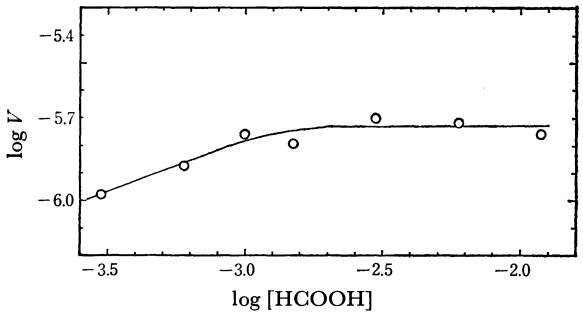

Fig. 1. Dependence of rate upon the concentration of formic acid.
[Co(OH)(DH)$_2$(H$_2$O)]=6.0×10^{-4} M, in 0.5 M phosphate buffer (pH 6.00), at 40°C

constant of acetate anion is very small. Thus two electrons are considered to be transferred from the formate anion coordinated to Co^{3+} in the complex to Co atom, producing CO_2 and H–Co^{1+}. The Co^{1+} species formed is quite unstable under these conditions and reoxidized to Co^{3+}. Otherwise, $HCO_2\cdot$ and Co^{2+} would be formed *via* one-electron transfer process, and oxidized by oxygen to CO_2+HO· and Co^{3+}, respectively. However, no detailed mechanism can be presented at present. The over-all decomposition reaction of formic acid in the presence of the cobalt catalyst in aerobic conditions may be written as

$$HCOOH + \tfrac{1}{2}\cdot O_2 + Co^{3+} \rightarrow CO_2 + H_2O + Co^{3+}.$$

Thus the CO_2/O_2 ratio should be 2.0 theoretically; the observed values were higher than unity, supporting the equation. Oxygen might be consumed by side reaction such as ligand oxidation of the complexes.[10] Much lower catalytic activities of cobaloximes as compared with cobalamins might be attributed to their higher reduction potentials, as in the oxidation of aldehyde.[4] An extremely slow reduction of cobaloximes by thiols in contrast to cobalamin has recently been demonstrated.[5] Reduction of B_{12a} with formic acid to B_{12a} was demonstrated spectrochemically by the appearance of the absorption maximum at 475 mμ in anaerobic conditions (pH 7.1). In contrast, reduction of hydroxoaquocobaloxime was not observed under similar conditions. Although B_{12s} might be expected to be formed in the reaction of B_{12a} and formic acid on the basis of the above mechanism, it was considered unstable under the conditions (pH 7.1) and converted to H·+ B_{12r} under a nitrogen atomosphere,[14] its presence being demonstrated in the visible spectrum. The hydrogen radical would attack the oxygen molecule in aerobic conditions and hence no hydrogen gas would be evolved, in agreement with the results we obtained.

The Separation and Concentration of Acetylacetonato Chelates Using a Benzene Column

Kazuo MARUYAMA and Micho MASHIMA
Faculty of Engineering, Niigata University, Nagaoka
(Received February 4, 1971)

This paper is concerned with the application of the zone-melting technique to metal-chelate compounds. An organic solvent which is liquid at room temperature such as benzene, and several acetylacetonato and thenoyltrifluoroacetonato chelates as solutes were prepared. The effective distribution-coefficient k dependence on the molecular weight was revealed by the normal freezing technique. In the deployment process, the acetylacetonato chelates of Fe and Th were chosen as solutes because their k values were different. The experiment was carried out at 2 cm/hr, the rate of zone travel. When a 30-cm column was used, the "removal percentages" of Fe from Th were 41 and 85% for 3 and 5 zone passes respectively. However there was a 22% loss of Th in the latter case. Furthermore, a remarkable concentration was found, and it was shown that the concentration effect may be useful for micro-analysis. At this stage, a relatively large bubble of benzene was observed at the liquid and solid interface; therefore we can call this "three-phase zone-melting."

The zone-melting technique[1] has recently been adopted for various fields,[2-4] but there have been few reports an its application to metal-chelate compounds.[5-7] In our previous experiment,[8] as a first step of this application, aluminum was succesfully separated from iron with an organic solid solvent after these metals had been converted to complex compounds.

In this paper, as an enlargement of the application, an organic solvent which is liquid at room temperature, such as benzene,[9] was used. Several metal acetylacetonato and thenoyltrifluoroacetonato chelates were prepared as solutes. The effective distribution-coefficient (k) of the chelates was determined and discussed in connection with the variation in the center metal. Then, a deployment chromatogram was obtained by the combination of acetylacetonato chelates of iron and thorium. A remarkable concentration was found when a molten zone traveled downward along the charge of the benzene solution of the chelate; thus, this method seems to be useful for micro-analysis.

Experimental

Materials. The acetylacetone. 2-thenoyltrifluoroacetone, metal salts, and organic solvents such as benzene were all reagent-grade. The metal acetylacetonato chelates, $Fe(AcAc)_3$,[10] $Cr(AcAc)_3$,[11] $Co(AcAc)_3$,[12] $Al(AcAc)_3$,[13] $Th(AcAc)_4$,[14] $Zr(AcAc)_4$,[15] and $Be(AcAc)_2$,[16] and the 2-thenoyltrifluoroacetonato chelates, $Fe(TTA)_3$,[17] $Al(TTA)_3$,[18] and $Co(TTA)_2$,[19] were prepared by the standard procedure and were purified by recrystallization with a suitable solvent.

Apparatus and Procedure. As is shown in Fig. 1A, the zone apparatus used in this experiment consisted of five ring heaters composed of electrified nicrom wire, and a refrigerator to keep the benzene solution in the glass tube solid during the zone-melting. The refrigerator was made of a six-part aluminium box with a circulation of −20°C ethyleneglycohol. The rate of the molten zone could be varied at will, but 2- and 6-cm/hr rates were mainly adopted. The zone width was 0.8—1 cm. All the glass tubes were 5 mm in inner diameter and about 20 cm in length.

A tube for the deployment process was first charged with pure benzene and then frozen to 3 cm by dipping it in −20°C

ethyleneglycohol. The supercooling at the bottom can be defended against by this charging. The tube was then charged with a solution of a metal chelate in benzene on the frozen benzene layer and frozen to 1.5 cm. The remaining 10.5 cm was filled with pure benzene, which was also frozen, as is shown in Fig. 1B. Zone melting was started at the bottom of the tube. The tube for the normal freezing and concentration process was charged with a benzene solution of the chelate; only the tube for the latter purpose was frozen to 15 cm. In the concentration process, the zone was started from the top of the charge and a bubble of benzene was formed by increasing the heater temperature. The effective distribution - coefficient was measured by the normal freezing technique.[27-29]

Analysis. After the zone-melting procedure, the solidified charge was removed from the glass tube and cut into sections, and the metal concentrations in the various fractions were determined photometrically after the separation of the solvent. The analytical methods are summarized in Table 1.

Results and Discussion

The effective distribution - coefficient (k) may be important in the actual zone-melting procedure,[27-29] and so it is necessary to study the factors governing the k value. Seven metal acetylacetonate chelates were, therefore, subjected to normal freezing at the rate of 6 cm/hr, and the concentration of chelate along the charge was determined as the metal concentration. The initial concentration was 1.5%. These k values of seven metal acetylacetonato chelates were examined in relation to various characteristics of these chelates.

As a result of this examination, these k values, when plotted against the molecular weight as in Fig. 2, were found to reveal a molecular weight dependence and to show the greatest fractionation in the case of $Be(AcAc)_2$. Ideally, the size of the solute molecule is one of the most important factors in determining the k value.

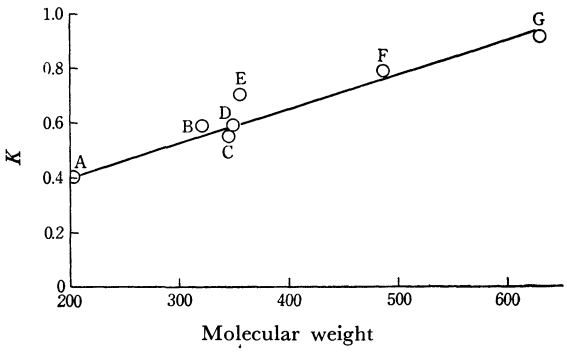

Fig. 2. Dependence of distribution-coefficient, k on molecular weight.
A) $Be(AcAc)_2$, B) $Al(AcAc)_3$, C) $Cr(AcAc)_3$, D) $Fe(AcAc)_3$, E) $Co(AcAc)_3$, F) $Zr(AcAc)_4$, G) $Th(AcAc)_4$.

From the point of view of mutual separation, a large difference in molecular weight may be desired. Therefore, $Fe(AcAc)_3$ (0.58) and $Th(AcAc)_4$ (0.90) were chosen as the solutes in the deployment process. In order to eliminate Fe from Th, the Fe must be greatly moved; therefore the effects of speed and zone passes on the movement of the Fe chelate were examined. The concentration effects of Fe were increased with a decrease in the zone speed and with an increase in the number of passes. For comparison, the k value of $Fe(AcAc)_3$ was 0.91 in benzoic acid, 0.95 in naphthalene, 0.96 in stearic acid, and 1.10 in ectyl alcohol.

Chromatograms after 3 and 5 zone passes using a 15-cm column at 2 cm/hr are shown in Fig. 3, using a mixture of Fe and Th chelates. Both Fe and Th weighed about 13 μg. The sample column was divided into five equal sections. The metal concentration was plotted *versus* a fractions of the charge. Judging from the k value, only $Fe(AcAc)_3$ was concentrated at the top of the charge; thus, a great difference in their distribution was observed. If the top section is removed, 39 and 55% of the total Fe may be eliminated from Th by 3 and 5 zone passes respectively.

Figure 4 shows the results in a 30-cm column. The zone speed, metal weight, and number of zone passes

are the same as in the above experiment. The distribution of the solute in the 30-cm column was similar to that in the 15-cm column. In this case, if the top section is removed, 41% of the Fe may be eliminated by 3 zone passes, while and if the top two sections are removed, 85% of the total Fe may be eliminated by 5 zone passes, with a 22% loss of Th.

When the zone moved toward the bottom along with the uniform charge, a remarkable concentration was observed, as is shown in Fig. 5. With only 3 passes, the solute was fairly well concentrated at the bottom of the column. In this case, 56% of the Fe, 72% of the Co, and 41% of the Th of each metal were concentrated in the 3-cm region at the bottom. At this stage, there was a relatively large bubble of benzene between the liquid and solid phases; therefore, we can call this "three-phase zone-melting." This phenomenon may be attributed to the great difference in the vapor pressure of the chelate and solvent at this temperature.

The same experiments were also done quantitatively with thenoyltrifluoroacetonato chelates of Co, Al, and Fe. The distribution after 3 passes at 2 cm/hr is shown in Fig. 6. The relative concentration is there plotted *versus* the fraction solidified. The results reveal that the concentration effect was great in this order: Fe>Al>Co; this corresponds to the decrease in the vaper pressure at this temperature.[13]

Conclusion

As an application of the zone-melting technique for chelate-solvent systems, several metal acetylacetonato chelates in benzene were zone-melted. The molecular-weight dependence of the k value was revealed by the normal freezing technique. In the deployment process, the application was proved to be a promising method for the elimination of Fe from Th after they had been converted into metal chelates; the percentages of the removal of Fe were 39 and 55% for 3 and 5 zone passes respectively. When a 30-cm column was used, the percentages were 41 and 85% for 3 and 5 zone passes respectively. In the latter case, there was a 22% loss of Th.

A remarkable concentration was also found, and it was shown that this effect may be useful for microanalysis; 56% of the Fe, 72% of the Co, and 41% of the Th were concentrated in the 3-cm region of the bottom, with only 3 zone passes.

Furthermore, the possibility of the separation of one metal from another will increase when the concentration process is combined with the deployment process.

Syntheses of a New Series of Transition Metal Chelates of Diphenylphosphinothioylthiourea Anion

Iwao OJIMA, Takaharu ONISHI, Toschitake IWAMOTO, Naoki INAMOTO, and Kenzi TAMARU

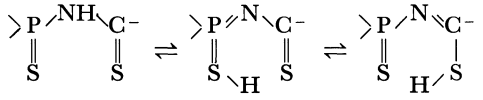
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 16, 1971)

New thiourea derivatives, 3-diphenylphosphinothioyl-1-phenylthiourea (PTTU-A), 3-diphenylphosphinothioyl-1,1-diethylthiourea (PTTU-B), and 3-diphenylphosphinothioyl-1,1-dimethylthiourea (PTTU-C) were found to behave as bidentate ligands with transition metal ions such as Ni(II), Pd(II), Co(II), and Cu(II) to give a series of novel metal chelates. The structures of these complexes are discussed on the basis of magnetic susceptibilities, infrared spectra, electronic spectra, powder X-ray diffraction patterns and elemental analyses. Tentative assignments of two metal-sulfur stretching vibrations in the far infrared spectra were made for Ni-PTTU and Pd-PTTU, which have square-planar configurations. However, the structures of the Cu-PTTU complexes could not be determined by these methods because of the instability of the complexes. They were confirmed by electronic and ESR spectroscopies.

In recent years, chelate complexes with sulfur-donor ligands have been extensively studied as an interesting topic in the field of coordination chemistry and many reports have been published on the properties and reactivities of such complexes as the metal chelates of dithiocarbamates, dithioacetylacetonates, and dithiolates.[1] However, no chelate complexes which have a P=S→M structure have been synthesized so far except for metal dialkyldithiophosphinates.[2]

Thus, it is of considerable interest to synthesize chelate compounds possessing an enolizable P=S bond in the ligand. A part of this work has been described previously[3]



These new chelate rings are important as a unit of polynuclear complexes, and are interesting in connection with the model complexes of enzymatic system such as ferredoxin which is a metal complex with ligands containing sulfur as donor atoms.

The new thiourea derivatives, diphenylphosphinothioylthioureas, PTTU-A, PTTU-B, and PTTU-C, can act as sulfur-donor chelating reagents because their structures include both enolizable P=S and C=S bonds. In view of this the reactions of PTTU with transition metal halides such as nickel(II) chloride hexahydrate, palladium(II) chloride, cobalt(II) chloride hexahydrate, and copper(II) chloride dihydrate, were investigated.

Experimental

Syntheses of Ligands. Diphenylphosphinothioylthioureas were prepared by the reaction of diphenylphosphinothioyl isothiocyanate with amines. A typical procedure is described for the preparation of 3-diphenylphosphinothioyl-1,1-diethylthiourea (PTTU-B). A solution of diethylamine (0.51 g, 7.0 mmol) in 50 m*l* of ether was added to a solution of diphenylphosphinothioyl isothiocyanate (2.0 g, 7.3 mmol) in 50 m*l* of ether with stirring at room temperature. An exothermic reaction took place and white crystals of 3-diphenylphosphionothioyl-1,1-diethylthiourea (PTTU-B) were precipitated in quantitative yield. Mp 125—127°C, IR (KBr disk): 3120(ν NH), 1555(δ NH), and 1475(Amide II) cm^{-1}. Found: C, 58.75; H, 6.01; N, 7.83; S, 18.50%. Calcd: C, 58.60; H, 6.07; N, 8.04; S, 18.40%. 3-Diphenylphosphinothioyl-1-phenylthiourea (PTTU-A): White prisms, mp 143—145°C, IR(KBr disk): 3290, 3220, 3160, 3125(ν NH), 1620, and 1570(δ NH) cm^{-1}. Found: C, 61.85; H, 4.62; N, 7.38; S, 16.90%. Calcd: C, 61.94; H, 4.65; N, 7.60; S, 17.40%. Dimethylammonium salts of 3-diphenylphosphinothioyl-1,1-dimethylthiourea (PTTU-C): When a 40% aqueous solution of dimethylamine (1.30 g, 11.5 mmol) and diphenylphosphinothioyl isothiocyanate (1.35 g, 4.9 mmol) were mixed, an exothermic reaction took place. By a treatment similar to that described above, white crystals of a dimethylammonium salt of 3-diphenylphosphinothioyl-1,1-dimethylthiourea (PTTU-C) were obtained in almost quantitative yield. Mp 118—120°C (lit,[4] 119—121°C), IR (Nujol): 3290, 3240 (ν NH) and 1530 (δ NH) cm^{-1}.

Syntheses of Copmlexes.. A typical procedure is described for the preparation of bis[3-diphenylphosphinothioyl-1,1-diethylthioureato]nickel (Ni-PTTU-B): A solution of PTTU-B (1.4 g, 4.0 mmol) in 10 m*l* of dichloromethane was allowed to react with nickel(II) chloride hexahydrate (0.95 g, 2.0 mmol) in 40 m*l* of ethanol at room temperature with stirring for an hour. Dark green needles of Ni-PTTU-B precipitated, which were recrystallized from dichloromethane-ethanol. Ni-PTTU-B was accordingly obtained in a nearly quantitative yield. The Ni(II) and Pd(II) complexes of PTTU-A(Ni-PTTU-A and Pd-PTTU-A), Pd(II) and Co(II) complexes of PTTU-B (Pd-PTTU-B and Co-PTTU-B) and the Ni(II), Pd(II), and Co(II) complexes of PTTU-C (Ni-PTTU-C, Pd-PTTU-C and Co-PTTU-C) were prepared in a similar way.

Ni-PTTU-A: Dark green needles, mp 193°C (dec.). Found: C, 57.9; H, 4.4; N, 6.6; S. 16.0; Ni, 7.3%. Calcd: C, 57.7; H, 4.1; N, 7.1; S, 16.2; Ni; 7.4%.

Pd-PTTU-A: Orange-yellow prisms, mp 215°C (dec.). Found: C, 53.3; H, 3.6; N, 6.0; S, 14.5%. Calcd: C, 54.3; H, 3.8; N, 6.7; S, 15.2%.

Pd-PTTU-A: Reddish-brown prisms, mp 254°C (dec.).

Pd-PTTU-C: Orange-yellow prisms, mp 209—211°C (dec.). Found: C, 46.6; H, 3.8; N, 8.0; S, 16.8%. Calcd: C, 48.4; H, 4.3; N, 7.5; S, 17.2%.

Co-PTTU-C: Bright bluish-green needles, mp 194—195°C (dec.). Found: C, 49.8; H, 4.4; N, 7.8; S, 17.9%. Calcd: C, 51.6; H, 4.6; N, 8.0; S, 18.4%.

Measurements. The infrared spectra of these complexes in the region 4000—700 cm^{-1} were measured using KBr disks with a 402 *G* spectrophotometer (Japan Spectroscopic Co., Ltd). The far infrared spectra in the region 700—200 cm^{-1} were obtained with a Hitachi EPI-L spectrophotometer. Samples were mixed with paraffin or fused polyethylene or mulled in Nujol. Electronic spectra were recorded on a Hitachi EPS-S spectrophotometer. An ESR spectrometer JEOL Model JES-118 X band was used. Molecular weights were ebullioscopically determined with a Hitachi-Perkin-Elmer Model 115.

Results and Discussion

Syntheses of the Complexes and Their Magnetic Properties. First, PTTU-A was allowed to react with nickel(II) chloride hexahydrate in dichloromethane - ethanol solution under reflux for an hour to give dark green needles of Ni-PTTU-A in 60—70% yield. In the same manner, the reaction of PTTU-A with palladium(II) chloride was performed and reddish-brown prisms were obtained (Pb-PTTU'-A). The bis-phosphinothioylthioureato-metal structure of Ni-PTTU-A was confirmed on the basis of elemental analysis, UV spectrum, and magnetic susceptibility. However, for Pd-PTTU-A, elemental analysis and infrared spectra showed that the ligands have decomposed during the syntheses. In order to prevent thermal decomposition of the product, PTTU-A was allowed to react with palladium(II) chloride in dichlorometahne - ethanol at room temperature for 3 hr with stirring. Yellowish-orange prisms of Pd-PTTU-A were obtained in 90% yield. When Pd-PTTU-A was heated in dichloromethane ethanol under reflux for one hour, the reddish-brown prisms were obtained and on the basis of the melting point, infrared spectra, elemental analysis, and powder X-ray diffraction patterns were found to be identical with the Pd-PTTU'-A prepared as above.

The powder X-ray diffraction patterns of these complexes are shown in Fig. 1. By comparison of these spectra, it was found that Pd-PTTU'-A has a simpler structure than that of Ni-PTTU-A and Pd-PTTU-A. This suggests that in the Pd-PTTU'-A the six membered chelate rings remain intact, but the aniline group is lost. The structure of Pd-PTTU'-A, therefore, was suggested to be the one shown in Scheme 1.

An attempt to obtain crystalline Co-PTTU-A was unsuccessful, but its formation in solution was observed

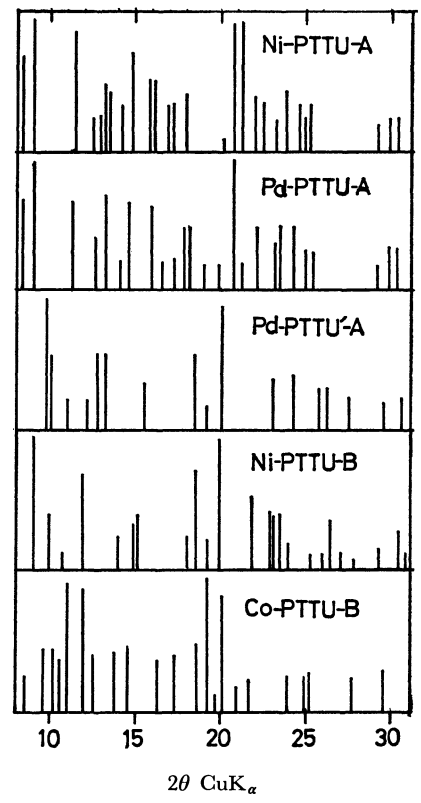

Fig. 1. The powder X-ray diffraction patterns of M-PTTU.

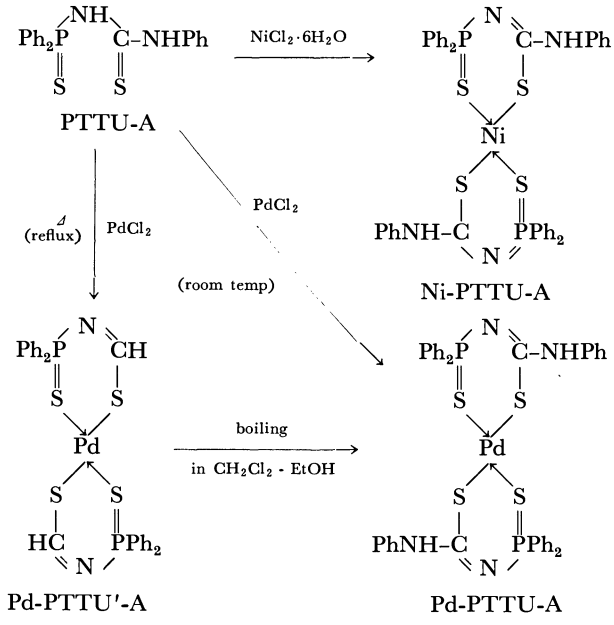

Scheme 1

by UV spectrum, as shown in Fig. 2. It is suggested that the central cobalt(II) (d^7) has a tetrahedral configuration.

Similarly, the nickel(II), palladium(II), and cobalt(II) complexes of PTTU-B and PTTU-C were obtained by the reaction of the corresponding PTTU with transition metal halides in dichloromethane-ethanol at room temperature with stirring for 1—2 hr as shown in Scheme 2. In contrast with Co-PTTU-A, Co-

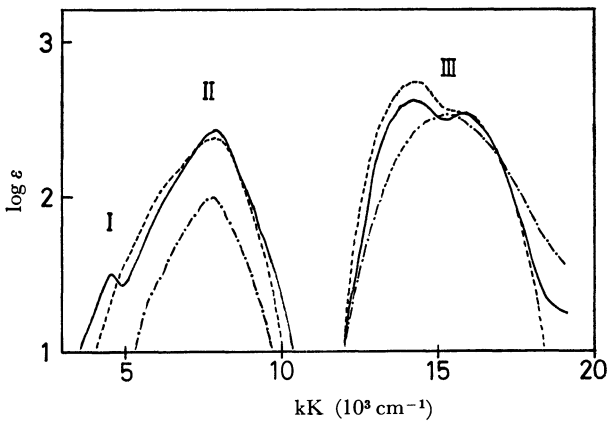

Fig. 2. The electronic spectra of Co-PTTU.

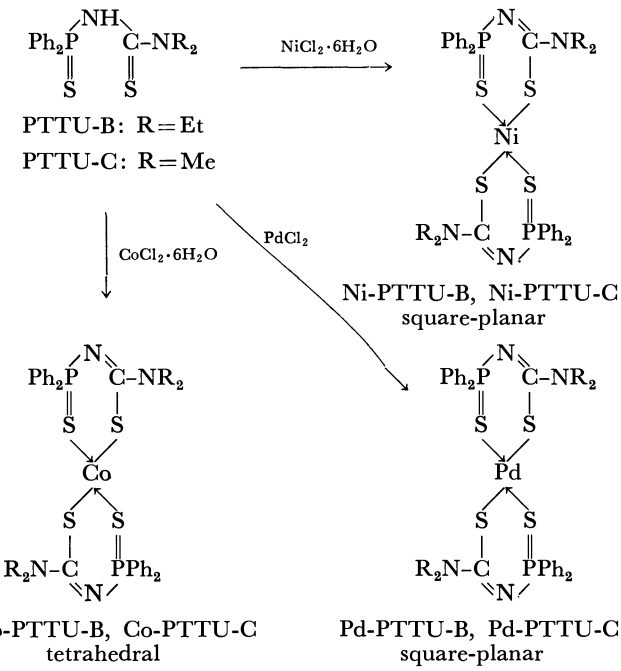

Scheme 2

PTTU-B and Co-PTTU-C were obtained as crystalline substances and a tetrahedral configuration was suggested on the basis of the magnetic susceptibility and electronic spectrum.

All these complexes have the same metal : ligand ratio (1 : 2). They are soluble in organic solvents such as benzene, chloroform, dichloromethane etc., but their solubilities in benzene were not high enough to determine their molecular weights except in the case of Co-PTTU. The molecular weights of Co-PTTU-B and Co-PTTU-C were ebullioscopically determined in benzene to be 751 and 678 (the calculated values for the monomers are 753 and 698), respectively. Except Co-PTTU, they are all diamagnetic at room temperature, which suggests that the complexes of Ni(II) and Pd(II) have square-planar configurations. Their crystal structures seem to be isomorphous according to the powder X-ray diffraction patterns as shown in Fig. 1. The effective magnetic moment of Co-PTTU-B, μ_{eff}=4.50 B.M. ($\chi_g=11.9\times10^{-6}$ cgsemu) at 297°K, and that of Co-PTTU-C, μ_{eff}=5.00 B.M. ($\chi_g=16.3\times10^{-6}$ cgsemu) at 297°K, correspond to the high spin state (S=2/3) of d^7 Co-(II) in a tetrahedral configuration. The powder X-ray diffraction pattern of Co-PTTU-B was quite different from those of Ni-and Pd-PTTU-B as shown in Fig. 1.

Electronic Spectra of Complexes. The electronic spectra of Ni-PTTU-A, Ni-PTTU-B and Ni-PTTU-C displayed an absorption band in the region of 17 kK and suggested a square-planar configuration of the central nickel(II) ions (d^8). The tetrahedral configurations for Co-PTTU-B and Co-PTTU-C. were suggested on the basis of the effective magnetic moment as described above. Moreover, the absorption bands appearing in the region 3-20 kK in the electronic spectra of Co-PTTU-A, Co-PTTU-B, and Co-PTTU-C can be assigned to Td symmetry. The absorption band III in the visible region and band II at 7.87 kK can be assigned to the transition from $^4A_2$ to $^4T_1$ (P) and from $^4A_2$ to $^4T_1$ (F), respectively. The values of $|Dq/B|$ and E/B were obtained by the use of the Tanabe-Sugano diagram according to the assignment mentioned above. Values of B and $10\,D_q$ were calculated to be 684 and 4790 cm^{-1}, respectively. It might be appropriate to assign the samll peak I, appearing in the spectrum of Co-PTTU-B at 4.65 kK, to the transition from $^4A_2$ to $^4T_2$ (the energy of this transition corresponds to $10\,Dq$). The value of Racah's electron repulsion parameter B corresponds to 60% of the free ions, thus reflecting the covalency of the cobalt-sulfur bonds. The value of Dq corresponds to 50% of that derived in the case of $[Co(H_2O)_6]^{2+}$ with O_h symmetry. This shows the adequacy of these assignments although the value of Dq(Td)/Dq(Oh) was slightly larger than 4/9. The values of B and Dq thus obtained are in reasonable agreement with those reported for several tetrahedral cobalt(II) complexes.[5] It is of interest that the cobalt(II) ion in Co-PTTU-A, Co-PTTU-B, and Co-PTTU-C has a tetrahedral configuration in contrast to the bis-dithioacetylacetonato-cobalt(II), which has a square-planar configuration.[6]

Infrared Spectra. The infrared spectra of the complexes were measured in the region 4000—200 cm^{-1}. In the far infrared spectra of the chelates with a square-planar structure, two metal-sulfur stretching vibrations were expected to appear in the region 500—200 cm^{-1},

Table 1. Characteristic bands in the infrared spectra of Ni-PTTU and Pd-PTTU (cm^{-1})

	νP=S	νM-S(ν_I)	νM-S(ν_{II})
Ni-PTTU-A	584	417	358
Pd-PTTU-A	582	412	336
Pd-PTTU-A	586	401	334
Ni-PTTU-B	580	391	340
Pd-PTTU-B	579	380	329
Ni-PTTU-C	579	404	344
Pd-PTTU-C	576	394	334

6) R. Beckett and B. F. Hoskins, *Chem. Commun.*, **1967**, 909.

as previously reported.[7] The bands appearing in the region 420—320 cm^{-1} that are most sensitive to the metal ion are tentatively assigned in Table 1 to these vibrations because of the covalent nature of metal-sulfur bond and the mass effect. The assignment of P=S stretching bands is also given in Table 1.

The strong bands appearing in the region 650—590 cm^{-1} in the spectra of the ligands can be assined to P=S stretching vibrations (PTTU-A: 635, 607 cm^{-1}, PTTU-B: 594 cm^{-1}, PTTU-C: 650, 632 cm^{-1}). When the chelate rings were formed, these bands shifted to lower frequencies by 20—70 cm^{-1}, and appeared in the region 585—575 cm^{-1}. The bands assigned to the NH stretching vibrations of Ni-PTTU-A and Pd-PTTU-A appeared at 3260 and 3250 cm^{-1}, respectively. The medium-to-strong bands observed in the region 1200—1350 cm^{-1} may be due to the thiourea structure of the ligands, and considerable changes were observed, as shown in Fig. 3, when the complexes were formed. In the case of Pd-PTTU'-A in particular, large changes were observed in these bands (Fig. 3) together with the absence of a NH stretching band between 3500 and 3000 cm^{-1}. This suggests that the aniline group has been lost.

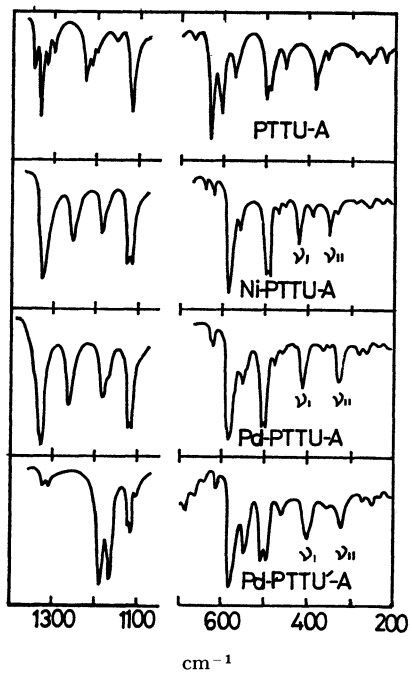

Fig. 3. The infrared and far infrared spectra of M-PTTU-A.

Synthesis of Cu-PTTU-B and Its ESR Spectra. When PTTU (2 eqiv.) and copper (II) chloride dihydrate (1 eqiv.) were reacted, a spontaneous reduction occurred and white grey prisms were precipitated. The structure was not clear, but the infrared spectrum suggests that the PTTU ligand remains although decomposition occurred in the other site. The copper contained in this complex was found on the basis of the magnetic susceptibility (diamagnetic) to be univalent.

7) I. Ojima, T. Onishi, T. Iwamoto, N. Inamoto, and K. Tamaru, *Inorg. Nucl. Chem. Lett.*, **6**, 65 (1970), and references therein.

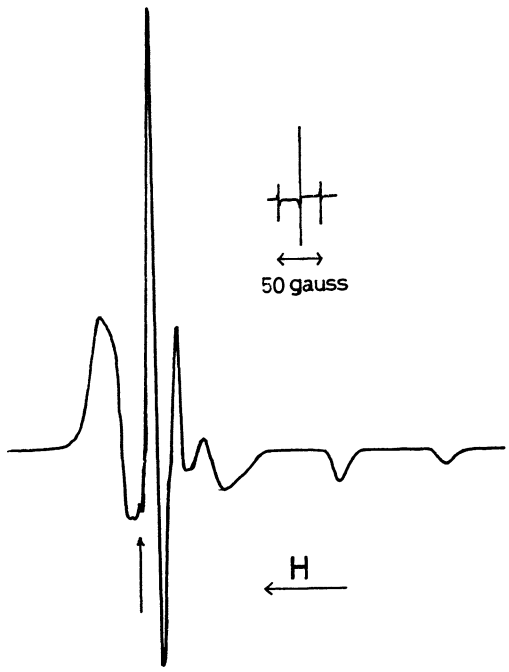

Fig. 4. ESR spectrum of Cu-PTTU-B in CH_2Cl_2-EtOH solution frozen at 77°K. The arrow indicates the resonance field for DPPH ($g=2.00354$).

Fig. 5. ESR spectrum of Cu-PTTU in CH_2Cl_2-EtOH solution at 15°C. The arrow indicates the resonance field for DPPH ($g=2.00354$).

The decomposition of Cu-PTTU-A and Cu-PTTU-C was so rapid that the initial formation of divalent complex could not be detected. In the case of PTTU-B, however, the formation of Cu-PTTU-B was observed in the presence of excess ligands (*ca.* 10 eqiv.) in CH_2Cl_2-EtOH solution by use of ESR spectroscopy, both at room temperature and in glassy state at 77°K. A broad absorption band was observed at 560 nm in the electronic spectrum. The observed ESR spectra of Cu-PTTU-B are shown in Figs. 4 and 5. The sample was prepared just before a measurement in a quartz tube by mixing PTTU-B in dichloromethane (10^{-1} mol/*l*) and copper (II) chloride dihydrate in ethanol

(10^{-2} mol/l). The deep violet color due to the formation of Cu-PTTU-B gradually disappeared at room temperature, but decomposition was completely suppressed at 77°K. The values of $g_{//}$, $g_{\perp}$, $|A_{//}|$ and $|A_{\perp}|$ obtained from the spectrum are 2.111, 2.026, 135×10^{-4} cm^{-1}, and 30×10^{-4} cm^{-1}, respectively. Similarly, the values of g_0 and $|A_0|$ are 2.060 and 60.1×10^{-4} cm^{-1}, respectively. Furthermore, the bonding parameter α^2 [8] was calculated to be 0.53 by the method proposed by Kivelson.[9] These values correspond precisely with those of CuS_4 type complexes, on the basis of the classification performed by Taminaga and Fujiwara,

Table 2. ESR parameters of copper(II) complexes

Ligand	Type	g_0[a]	$g_{//}$	$g_{\perp}$	$\lvert A_0\rvert$[a] ($\times10^4$ cm^{-1})	$\lvert A_{//}\rvert$ ($\times10^4$ cm^{-1})	$\lvert A_{\perp}\rvert$ ($\times10^4$ cm^{-1})
glycine	CuO_2N_2	2.129	2.252	2.068	69	196	5

Table 3. Bonding parameters, α^2, of copper(II) complexes

Type	Ligand	α^2	Type	Ligand	α^2
CuO_4	oxal.	0.84	CuN_2S_2	8-mercapt.	0.54
CuO_2N_2	L-alanine	0.84	CuS_4	dieth. dith.	0.55
CuN_4	dipyr.	0.80	CuS_4	PTTU-B	0.53

Abbreviation; oxal.: oxalic acid, dipyr.: 2,2′-dipyridyl, 8-mercapt.: 8-mercaptoquinoline, dieth.dith.: diethyldithiocarbamic acid, PTTU-B: 3-diphenylphosphinothioyl-1,1-diethylthiourea.

as shown in Tables 2 and 3.[10] An average of $g_{//}$ and $g_{\perp}$, 2.053 is in good agreement with g_0, 2.060, and an average of $|A_{//}|$ and $|A_{\perp}|$, 6.5×10^{-3} cm^{-1}, agrees with A_0, 6.0×10^{-3} cm^{-1}. These facts suggest that the species detected by ESR at room temperature is identical with the species existing at 77°K, and that the formation of a copper(II) complex by decomposition of the ligand did not occur.

The authors would like to thank Dr. I. Ikemoto and Mr. K. Ishii for the measurements of X-ray diffraction patterns and magnetic susceptibilities, and Prof. I. Nakagawa, Dr. T. Watanabe and Mr. T. Takeda for their helpful discussions. The authors are also indebted to Mr. S. Mohara of Sagami Chemical Research Center for the molecular weight determination.

Pd(II) Complexes with 2,2′-Diaminobiphenyl

Satoru ONAKA[1]

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received February 18, 1971)

The new palladium(II) complexes with 2,2′-diaminobiphenyl (DABP) have been synthesized under various conditions. The hexa-coordinated palladium complex, $[Pd(DABP)_2Cl_2]$, has been prepared under a high pressure. The square planar diamagnetic complexes, $[Pd(DABP)_2]X_2$ (X=Cl, Br), have been synthesized under atmospheric pressure. As to the $[Pd(DABP)_2]Cl_2$ complexes, two isomers, the yellow complex and the yellow-green complex, are obtained according to the temperature at which the complexes are synthesized. Both the complexes, the yellow and the yellow-green complexes, are similar with respect to the powder X-ray diffraction pattern and the IR spectra in the region from 4000 cm^{-1} to 200 cm^{-1}, but are somewhat different with respect to the stability to air, the thermal stability, and the solubility in chloroform.

Stereochemical and preparative studies of the 2,2′-diaminobiphenyl (DABP)-metal complexes have been reported.[2,3] The compounds subjected to these studies were prepared under an atmospheric pressure. The present author has reported that the Ni(II), Co (II), and Cu(II) complexes with 2,2′-diaminobiphenyl synthesized under a high pressure differ from those complexes prepared under the atmospheric pressure with respect to the spectroscopic behavior and melting or decomposing points.[4] The present paper aims to throw light upon the effect that the preparative conditions may have on the coordination of the ligand to the central metal atom or the other properties in the case of Pd(II)-DABP complexes.

Experimental

Materials. 2,2′-diaminobiphenyl (DABP) was prepared as has been previously reported.[4] Commercially-available $PdCl_2$ and $PdBr_2$ were used.

Syntheses of Compounds. *$[Pd(DABP)_2]Cl_2$ (I) and (II):*

$C_{24}H_{24}N_4Br_2Pd$	(45.42)	(3.81)	(8.83)	

a) Melting or decomposing point is uncorrected.

0.004 mol (0.74 g) of DABP was dissolved into 50 m*l* of ethanol. This solution was slowly dropped into a solution which contained 0.0014 mol (0.25 g) of $PdCl_2$ in 100 m*l* of ethanol below 50°C. The mixture was stirred for 2 hr under the same condition. The resulting yellow precipitates (I) were collected on a glass filter (4 *G*), washed with absolute ethanol, and then dried *in vacuo* for 24 hr at 80°C. (If the temperature is raised to 130°C in drying the precipitates, the compound turns grey-brown). Yield: 80%, based on $PdCl_2$. On the other hand, if the ethanol solution of DABP is dropped into the ethanol solution of $PdCl_2$ at a refluxing temperature, yellow-green precipitates (II) are obtained. (Yield: 80%, based on $PdCl_2$) The yellow-green product (II) is also obtainable by treating the yellow product (I) with an ethanol solution of DABP at a refluxing temperature for a few hours. This compound (II) is thermally more stable than the compound (I). The decomposing points for these compounds are shown in Table 1. Both the compounds are hygroscopic and turn grey-brown when left in air for a few hours. The yellow product is more stable than the yellow-green product in air. The solubility of the yellow-green product to chloroform is higher than that of the yellow product. The solubility of these compounds to methanol and water suggests the monomeric structure.[2,3]

$[Pd(DABP)_2]Br_2$ (III): Only a yellow product was obtained under the atmospheric pressure in the temperature region from 80°C to room temperature with the manner described above. Yield: 42%, based on $PdBr_2$.

$[Pd(DABP)_2Cl_2]$ (IV): In a steel autoclave, 0.01 mol (1.8 g) of palladium chloride, 0.02 mol (3.7 g) of DABP, 20 m*l* of ethanol, and 3 m*l* of concentrated hydrochloric acid were placed, and nitrogen gas was introduced at a pressure of 80 atm. Then the autoclave was heated at 120°C and shaken for 2 hr. A mixture of the yellow and grey powders was thus obtained. The yellow powder that was carefully separated from the grey powder was subjected to infrared measurement.

The results of the elemental analyses are shown in Table 1.

Magnetic Susceptibility.[5] The finely-powdered samples were measured with a Gouy balance at room temperature. The complexes prepared under the atmospheric pressure are diamagnetic.

Powder X-Ray Diffractometry. The powder X-ray diffraction data were obtained as has been previously described.[4] The results are shown in Table 2.

Table 2. The powder X-ray diffraction data

$[Pd(DABP)_2]Cl_2$ (I) (yellow product) 2θ, °	I/I_0	$[Pd(DABP)_2]Cl_2$ (II) (yellow-green product) 2θ, °	I/I_0

Relative intensities were calculated by comparing the height of the peaks. rad: $CuK\alpha_1$.
Less intensity lines are excluded.

Diffuse Reflection Spectra.[6] The reflection spectra in the ultraviolet and visible regions were measured with a Shimazu MP-S-50L apparatus equipped with a standard reflectance attachment. The reflectance rates were calculated by means of the Kubelka-Munk equation.[7]

Infrared Spectra. The infrared spectra were recorded with a Hitachi EPI-G2 spectrometer and a Hitachi EPI-L spectrometer for the samples in the Nujol mulls from 4000 cm^{-1} to 200 cm^{-1}. The results are shown in Fig. 1, in Fig. 3, and in Table 3.

Discussion

The magnetic measurements show that the complexes (I), (II), and (III) synthesized under atmospheric pressure are square planar. The coordination of the amino group to the palladium metal can be clearly explained on the basis of the infrared data. The absorption bands due to the amino group of the ligand amine are considerably shifted toward lower frequencies in its complexes. The far-infrared spectra of the compounds (I), (II), and (III) form additional evidence of the coordination of the amino group. It is expected that the participation of the halogen atoms in the coordination may cause remarkable shifts of the bands in the far-infrared region, depending on the halogen atoms.[8] As is shown in Fig. 1, the far-infrared spectrum of the compound (III) is almost the

same as that of compound (I) or (II), and bands which are assignable to a Pd–N stretching vibration with a reasonable intensity are observed at 410 cm^{-1} for compounds (I) and (II) and at 412 cm^{-1} for compound (III).[4,8,9] Therefore, the amine, DABP, acts as a bidentate ligand in these compounds.

Measurements of the powder X-ray diffraction analyses and the diffuse reflectance spectra of compounds (I) and (II) are made in order to clarify further the difference between the compounds (I) and (II). Compounds (I) and (II) give almost the same diffraction pattern, as is shown in Table 2. No serious differences are observed in the diffuse reflectance spectra of the compounds (I) and (II), as is shown in Fig. 2. Therefore, we may exclude the possibility that either the compound (I) or the compound (II) is a structural isomer, such as Vauquelin-type compounds or halogen-bridged compounds, as is shown below by (a),[10] or a diamine-bridged polynuclear complex, as is shown below by (b). Moreover, the

possibility that this isomerism is caused by the crystal dichroism[11] may be ruled out because of the size of the crystals: the fine precipitates (I) and (II) pass through a 3G-glass filter. It is well known that optically-active isomers are possible if the 2,2'-diaminobiphenyl is coordinated to a metal ion,[2-4] because the coordination with a metal ion prevents the rotation of the phenyl rings. As the compounds (I) and (II), however, show no optical activity, they may be racemic mixtures or of the meso form. A possible origin of this isomerism of these two compounds may be a conformational difference arising from the diamine which does not affect the optical activity.

The yellow compound (IV) synthesized under a high pressure gives a infrared spectrum which strikingly resembles that of $[Ni(DABP)_2(OAc)_2]$, as is shown in Fig. 3. Analytically-pure samples of the compound (IV) have not yet been obtained, though the infrared spectrum of Fig. 3 is clear evidence of the formation of a hexa-coordinated complex $[Pd(DABP)_2Cl_2]$.

It can be concluded that the preparative conditions have an important effect on the coordination of ligands to a metal atom, on the chemical behavior, and on the color of the compounds in the case of Pd-DABP complexes.

The author wishes to express his deep gratitude to Professor Yukiyoshi Sasaki for his encouraging advice and discussions.

Fourier Analysis of Alternating Current Polarography: Amplitude and Phase of Fundamental and Second Harmonic AC Polarographic Waves

Hiroyuki KOJIMA and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo

(Received February 19, 1971)

The Fourier analysis of the instantaneous AC polarographic current was performed with a computer *on-lined* to a potentiostat. From the Fourier spectra, the amplitudes and phase angles of both the fundamental and the second harmonic AC polarographic waves were obtained. In the Cd(II) system, the current amplitude DC potential curves and phase angle-DC potential curves for the fundamental and the second harmonic AC polarographic waves were compared with the theoretical curves. The method is applicable to the accurate analysis of electrode reaction kinetics.

Alternating current (AC) polarography has been found to be useful in studying electrode reaction kinetics, and various instrumental and theoretical approaches have been attempted. The phase angle of the fundamental harmonic AC wave and the intensity of higher order harmonic AC waves were measured and analyzed theoretically by Smith and his coworkers,[1-7] who employed a potentiostat with a phase-sensitive detector and tuned amplifiers.

In the present work, it is shown that Fourier analysis of instantaneous AC polarographic waves gives the phase angle and amplitude of fundamental and second harmonic AC polarographic waves. In general, AC polarographic waves can be expressed in the following form.

$$I = I_1 \sin(\omega t + \varphi_1) + I_2 \sin(2\omega t + \varphi_2) + \cdots \quad (1)$$

where ω is the angular frequency of an applied AC potential, I is the total alternating current, I_1 (I_2) and φ_1 (φ_2) are the amplitude and phase angle of the fundamental (second) harmonic AC polarographic wave, respectively. The Fourier transforms of Eq. (1) are

$$I_k \cos\varphi_k = \frac{2}{T}\int_0^T I \sin k\omega t \, dt \quad (2)$$

$$I_k \sin\varphi_k = \frac{2}{T}\int_0^T I \cos k\omega t \, dt \quad (3)$$

$$k = 1, 2, \cdots,$$

where T is the period of original data. Equations (2) and (3) show that both the amplitude and phase angle of the fundamental and the second harmonic AC polarographic waves can be obtained by the Fourier transformation.

In this paper, an instrumentation for the Fourier transformation is presented and the feasibility of this method for the measurement of faradaic currents is discussed.

Experimental

Outline of the Procedure. Figure 1 shows a block-diagram of the apparatus, which is a modified version of a digital polarograph used to analyze fluctuations of *i-t* curves.[8] It is composed of a potentiostat, a computer,[9] a synchroscope[10] and their supporting equipments. A sinuisoidal alternating potential with small amplitude is superposed on the direct current potential which is applied to the electrode. Using the dropping mercury electrode, the polarographic current on which the AC wave is superposed is sampled during the single drop life, and is stored in the computer which is *on-lined* to the potentiostat. The Fourier transformation is performed after the DC component of the polarographic current is eliminated by shifting the zero level. Calculated Fourier spectra are recorded on a chart paper in bar-graph style.

Potentiostat. The potentiostat is constructed mainly from solid-state operational amplifiers. A three-electrode cell is used with the voltage follower circuit. The drop-synchronizer is functioned by the control of the computer. The alternating current potential which is superposed on the direct potential is 15 mV and its frequency is adjusted to 34.5 Hz.

Computer. The analog to digital converter samples the polarographic current in 8-bit digital data every 240 μ sec. At the start, the mercury drop is knocked off with a pulse provided by the computer. The computer waits 3.5 sec for the growth of the mercury drop and begins to sample the polarographic current. It samples 121 points during a period of the applied AC potential and continues to sample until 16 sets of digital data in total are obtained.

Synchroscope. The synchroscope controls the gate of the computer, *i.e.*, it sends a triggering pulse to the computer so that the computer can start sampling at the time when the phase angle of the applied AC potential becomes zero. At the end of the period of the applied AC potential, the computer stops sampling, waits for the next triggering pulse from the synchroscope and again begins to sample the polarographic current. Sampling by the computer is performed during every period of the applied AC potential with the aid of the control of the synchroscope. The AC voltage which is sent to the synchroscope as the triggering source has to be large enough to achieve stability of triggering level.

1.0 mol/l Na_2SO_4 was used. Before the measurements, the triggering level of the synchroscope is adjusted by inserting a standard resister (1.00 kΩ) in place of the cell. The standard resister is also employed in order to calibrate the frequency of the oscillator and the intensities of the Fourier spectra. Charging currents are measured with the use of a reference solution which does not contain a depolarizer. The cell resistance is measured to be 102 Ω at potentials where the faradaic current is negligible. All these measurements are carried out by the phase-selective detection involving the Fourier transformation. The flow rate of mercury is 1.44 mg/sec at mercury column height of 60 cm. The drop time is 5.8 sec at 0 V *vs.* SCE. All polarographic measurements are made at 22.5±0.5°C.

Results and Discussion

Fourier spectra of the Cd(II) System. Figure 2 shows Fourier spectra for the Cd(II) system at three potentials near the half-wave potential. The Fourier spectra are given at an interval of 2.15 Hz which is one sixteenth of the frequency of the applied AC potential. The 16th and the 32nd components correspond to the fundamental and the second harmonic AC polarographic waves, respectively. The sine part of the Fourier spectra corresponds to the component *in-phase* with the applied AC potential, whereas the cosine part represents the component which advances in phase by 90° relative to the AC potential.

Smith and Reinmuth[11] showed theoretically that in reversible electrode processes the phase angle of the fundamental harmonic AC polarographic wave is 45° at any DC potential, but the phase angle of the second harmonic AC wave[12] is 135° (−45°) at potentials more anodic (cathodic) than the half-wave potential. However, the Fourier spectra given in Fig. 2 are quite different in shape from this theoretical prediction. This result may be interpreted in terms of non-faradaic effects due to the double layer capacitance and the ohmic resistance of the system. The cosine part of the fundamental harmonic AC waves is larger in magnitude than the sine part (Figs. 2-a and 2-c). At −0.550 V or −0.651 V, the faradaic current is small, and the charging current becomes dominant. At −0.601 V which is approximately equal to the half-wave potential, the sine part of the fundamental harmonic AC wave is dominant (Fig. 2-b). In the vicinity of the half-wave potential, the faradaic current is large enough to result in a considerable amount of IR-drop.

The second harmonic-AC wave is inverted in phase angle across the half-wave potential, where the second harmonic AC wave disappears. The intensity of the second harmonic AC waves given in Fig. 2 is much

System: 1.0 mM $CdCl_2$ in 1.0 M Na_2SO_4.
AC potential: 34.5 Hz, 30 mV peak-to-peak sine wave.
Measurement: instantaneous AC polarographic current during 3.5—5.0 sec of drop life.
Spectrum: each Fourier component is given at an interval of 2.15 Hz and the intensity is arbitrarily scaled.

11) D. E. Smith and W. H. Reinmuth, *Anal. Chem.*, **33**, 482 (1961).

12) The phase angle of the second harmonic AC wave is taken so that the sign of the amplitude can be positive.

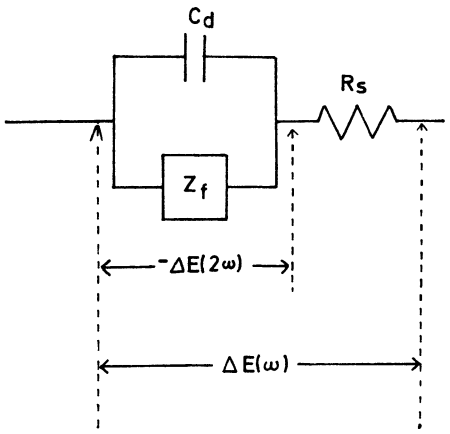

Fig. 3. Equivalent circuit to the cell.
$\Delta E(\omega)$ is the applied AC potential.
$\Delta E(2\omega)$ is the potential produced by the second harmonic alternating current.

smaller than what is predicted from the theory developed by Smith.[11] This discrepancy may be interpreted in terms of the IR-drop of the system as follows. The circuit which is equivalent to the cell is shown in Fig. 3, where Z_f, C_d, and R_s denote the faradaic impedance, the double layer capacitance and the cell resistance respectively. When an AC potential whose angular frequency is ω is applied to the electrade, and an additional AC potential with 2ω is also produced onto Z_f and C_d. This is because the second harmonic alternating current passes through R_s. The additional AC potential which is represented by $-\Delta E(2\omega)$ in Fig. 3 produces a fundamental harmonic AC wave with 2ω, which is opposite in phase to the second harmonic AC wave produced by the applied AC potential with ω. This leads to an appreciable decrease in the intensity of the second harmonic AC wave.[13]

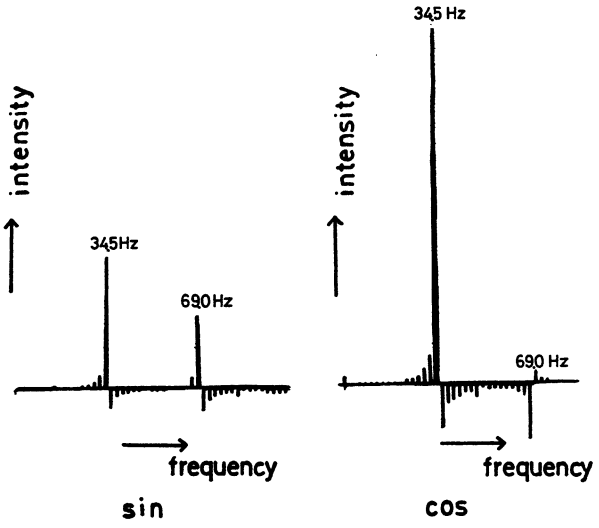

Fig. 4. Fourier spectrum of Cd(II) at −0.550 V.
The polarographic current is sampled consecutively during 16 periods of the applied AC potential without the aid of triggering pulses.

13) The double layer capacitance C_d also reduces the second harmonic AC wave a little.

In addition to the fundamental and the second harmonic AC waves mentioned above, a number of small peaks are observed in Fig. 2. Possible origins for these small peaks are the growth of the dropping mercury electrode and instability of the oscillater.

It can be shown that the growth of the mercury drop results in the additional small peaks, which become smaller in intensity as the frequencies of the small peaks are separated from those of the main components. It can also be shown that the drop growth makes only a minor contribution to the intensity of the main components. Details of the calculation are given in Appendix II.

Instability of the oscillator can effectively be compensated by the aid of a triggering pulse supplied by the synchroscope, which controls the start of sampling for every period of the applied AC potential. Sharp spectra such as shown in Fig. 2 can only be obtained under this control. Figure 4 shows an example obtained in the absence of the control of the synchroscope. We see that the intensity, and therefore the number of small peaks, is increased remarkably. Such spectra cannot be used to analyze faradaic components quantitatively.

Comparisons with the Calculated Curves. The current amplitude-DC potential curves are illustrated in Figs. 5 and 7 for the fundamental and the second harmonic AC polarographic waves, respectively.[14] The phase angle-DC potential curves are plotted in Figs. 6 and 8. In Figs. 5—8, solid lines show the

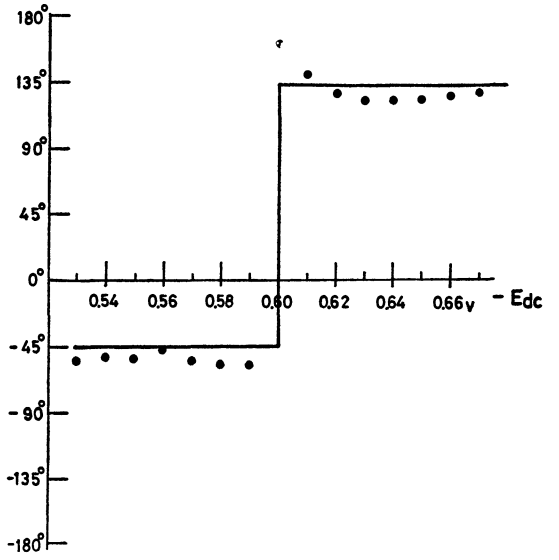

Fig. 8. Phase angle-DC potential curve for the second harmonic AC polarographic wave of the Cd(II) system.

theoretical curves obtained as in the following; the theoretical curves of the fundamental and the second harmonic-AC polarographic waves with the reversible process have been given by McCord and Smith[4] as

$$I(\omega t) = \frac{n^2F^2AC_0^*(\omega D_0)^{1/2}\Delta E}{4RT\cosh^2(j/2)}\sin(\omega t+\pi/4) \quad (4)$$

$$I(2\omega t) = \frac{n^3F^3AC_0^*(2\omega D_0)^{1/2}\Delta E^2\sinh(j/2)}{(4RT)^2\cosh^3(j/2)} \times \sin(2\omega t-\pi/4) \quad (5)$$

$$j = \frac{nF}{RT}(E_{dc}-E_{1/2}^r) \quad (6)$$

where $I(\omega t)$ and $I(2\omega t)$ represent the fundamental and the second harmonic AC waves, respectively. Other notations are defined in Appendix I. In calculating $I(\omega t)$ and $I(2\omega t)$, the value of $nFAC_0^*D_0^{1/2}$ was obtained using Eq. (7) along with the intensity of the diffusion-controlled DC polarographic wave,[15]

$$I_d(t) = \sqrt{\frac{7}{3}}nFAC_0^*D_0^{1/2}\frac{1}{\sqrt{\pi t}}. \quad (7)$$

As Figs. 5—7 show the experimental plots are in good agreement with the calculated curves. In Fig. 8 a considerable deviation is noticed in the case of the phase angle of the second harmonic AC wave. This is because Eq. (5) for the second harmonic AC wave is valid only for the ideally reversible process. The Cd(II) system which is not ideally reversible has a *quasi-reversibility* in the fundamental harmonic AC process. McCord and Smith have taken the effect of the *quasi-reversibility* into account, and given more precise equations.[4] The results given in Fig. 8 can satisfactorily be reproduced using these equations. As discussed by McCord and Smith, the phase angle of the second harmonic AC wave is influenced by the *quasi-reversibility* of the electrode reaction more sensitively than that of the fundamental harmonic AC wave.

General Characteristics of the Fourier Analysis. Figure 9 illustrates the charging current and its Fourier spectrum for a 1.0 mol/l Na_2SO_4 solution at −0.601 V. It should be noted that the charging current in-

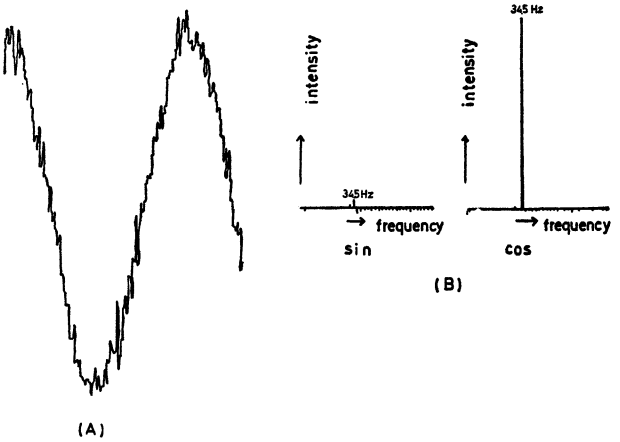

Fig. 9. Charging current and its Fourier spectrum of 1.0 M Na_2SO_4 solution at −0.601 V.

15) P. Delahay, "New Instrumental Methods in Electrochemistry," Interscience, New York (1954), p. 63.

volving much noise reproduces the Fourier spectrum satisfactorily. This is closely related to the process of numerical integration in the Fourier analysis; a possible contribution from noise is cancelled if the number of sampling points is large enough compared to the inverse of an average frequency of the noise. In this respect the results in Figs. 5—9 are not quite satisfactory. A computer with larger memory capacity and an analog to digital converter with higher resolution and speed would consolidate the advantage of the present method of Fourier analysis. *Accumulation* of signals would also serve for an improvement of the results.

In the analysis of electrode reactions, the second harmonic AC polarographic wave is more useful than the fundamental harmonic AC wave. In the first place, the former is not affected by the non-faradaic effects; the IR-drop of the system can be compensated properly by the application of the *positive feed back technique* in the potentiostat.[16-18] In contrast, when using the fundamental harmonic AC wave, it is difficult to eliminate accurately the effects of the double layer capacitance. Secondly, the line shape of the second harmonic AC wave responds more sensitively to the electrode reaction kinetics. As suggested by McCord and Smith,[4] the current amplitude-DC potential curve and the phase angle-DC potential curve are useful in analyzing the reaction scheme at the electrode.

In spite of these advantages, the second harmonic AC wave has seldom been used. This is because it is difficult to measure the second harmonic AC wave accurately for lack of sensitivity. The phase angle of the second harmonic AC wave in particular seems to have never been measured. In view of the above discussion, the method of the Fourier Transformation given here seems promising for an accurate analysis of the second harmonic AC wave.

The authors are indebted to Drs. Yoji Arata and Takeo Yamamoto for their valuable advice. They are also grateful to Mr. Teruhiko Kugo of Yanagimoto Manufacturing Co. for his helpful suggestions on measurements.

Appendix

I. *Notations*

A = electrode area
C_0^* = initial concentration of oxidized form
E_{dc} = DC component of applied potential
ΔE = amplitude of applied alternating current potential
$E_{1/2}^r$ = reversible polarographic half-wave potential
F = Faraday's constant
R = gas constant
T = absolute temperature
n = number of electrons transferred in heterogeneous charge transfer step
$I_d(t)$ = instantaneous DC faradaic limiting current
$I\omega(t)$ = fundamental harmonic faradaic alternating current
$I(2\omega t)$ = second harmonic faradaic alternating current
ω = applied angular frequency
s = rate of increase in amplitude of polarographic alternating current
t = time

II. *Effect of the Drop Growth upon Fourier Spectra.* Equation (1) should be modified in order to take into account the effect of the drop growth. It is a good approximation that the amplitude of the AC polarographic current changes almost linearly. Using the rate s of the increase in the amplitude the AC polarographic wave can be represented by the equation

$$I = \sum_{k=1}^{\infty} (1+st) I_k \sin(k\omega t + \varphi_k), \tag{A1}$$

where k denotes the order of each harmonic AC component. Eq. (A1) is expanded into the Fourier series in the range $0 \leqq t \leqq T$,

$$\begin{aligned} I = \sum_{k=1}^{\infty} I_k \Bigg\{ & \cos\varphi_k \left(1 - \frac{s}{2\omega k}\right) \sin k\,\omega t \\ & + \sin\varphi_k \left(1 - \frac{s}{2\omega k}\right) \cos k\,\omega t \\ & + \frac{sT\cos\varphi_k}{2\pi} \sum_{\substack{n=0 \\ n \neq km}}^{\infty} \frac{-2km}{k^2m^2 - n^2} \cos n\frac{\omega}{m} t \\ & + \frac{sT\sin\varphi_k}{2\pi} \sum_{\substack{n=1 \\ n \neq km}}^{\infty} \frac{2n}{k^2m^2 - n^2} \sin n\frac{\omega}{m} t \Bigg\}, \end{aligned} \tag{A2}$$

where m represents $\omega T/(2\pi)$, *i.e.*, the number of periods of the fundamental harmonic AC components in T. Equation (A2) shows that the intensity of each main component of the Fourier spectra is reduced by $s/(2\omega k)$. Under the present experimental conditions, *viz.*, $\omega = 216.7$ and $s < 2$, the value of $s/(2\omega k)$ is less than 0.005 for each order harmonic AC component. Equation (A2) can also describe the behavior of small peaks beside each main component.

The Acylation of *bz*-Hydroxy- and *bz*-Methoxy-2,3-dimethylbenzofurans and the Synthesis of Furobenzopyranone Derivatives[1]

Yoshiyuki KAWASE, Seiji YAMAGUCHI, Nobuo OKI, and Fumiko OKUMURA

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received July 6, 1970)

The action of acetic acid, phenylacetic acid, or β-phenylpropionic acid and polyphosphoric acid on 5-, 7-, and 6-hydroxy-2,3-dimethylbenzofurans afforded 6-acyl-5-hydroxy-, 6-acyl-7-hydroxy-, and 5-acyl-6-hydroxybenzofurans, some of which were also obtained by the Friedel-Crafts acylation of the corresponding methoxybenzofurans. The hydroxyketones thus obtained were converted to dimethylfuro derivatives of 4-hydroxycoumarins and isoflavones, and 3-benzyl-4-hydroxyfurocoumarins were also prepared by the thermal condensation of the hydroxybenzofurans and diethyl benzylmalonate.

The formylation and acetylation of *bz*-methoxy-2,3-dimethylbenzofurans have been reported by Royer *et al.*,[2] while the acetylation and phenylacetylation of 4- and 6-methoxy- and -hydroxybenzofurans have been reported by one of the present authors.[3] The acyl compounds obtained have been converted to dimethylfuro derivatives of coumarins, chromones, flavones, and isoflavones.[2-4]

In connection with this, the acetylation, phenylacetylation, and β-phenylpropionylation of 5-, 7-, and 6-hydroxy- (**3**, **9**, **15**) and -methoxy-2,3-dimethylbenzofurans (**2**, **8**, and **14**) were carried out in the present experiments; also, dimethylfuro derivatives of 4-hydroxycoumarins (**17**, **18**, and **19**) and of isoflavones (**20**, **21**, **22**, and **23**) were prepared from the acyl compounds in order to test the pharmacological activities.

The starting compounds, *bz*-methoxy-2,3-dimethylbenzofurans (**2**, **8**, and **14**), were prepared in good yields in the present experiments by the cyclodehydration of aryloxybutanones (**1**, **7**, and **12**) with polyphosphoric acid. The reagent seemed to be excellent in the case of 3-(*m*-methoxyphenoxy)-2-butanone[5] (**12**), as the 6-methoxybenzofuran (**14**) was obtained in the pure state.[6] For the preparation of the 6- or 4-hydroxybenzofuran, the cyclization of 3-(*m*-acetoxyphenoxy)-2-butanone (**13**) by sulfuric acid was attempted in order to obtain the 6-hydroxybenzofuran (**15**) in a low yield.

The action of acetic acid, phenylacetic acid, or β-phenylpropionic acid on the 5- and 7-hydroxy-2,3-dimethylbenzofurans[7] (**3** and **9**) in the presence of polyphosphoric acid afforded the corresponding 6-acyl compounds (**5a**, **5b**, **5c**, **11a**, **11b**, and **11c**), while the analogous β-phenylpropionylation of the 6-hydroxybenzofuran[8] (**15**) afforded the 5-(β-phenylpropionyl) compound (**16**) (Charts 1—3).

The 6-acyl-5-hydroxy compounds (**5a** and **5b**) were also obtained by the Friedel-Crafts acylation of the methoxybenzofuran (**2**) in carbon disulfide at the reflux temperature, while the β-phenylpropionylation under those conditions afforded the 6-acyl-5-methoxybenzofuran (**4c**), which was then dimethylated to **5c** by heating it with aluminum chloride in nitrobenzene (Chart 1). Royer *et al.*[2] have obtained the 6-acetyl-5-methoxybenzofuran (**4a**) by the Friedel-Crafts acetylation of the 5-methoxybenzofuran (**2**) at room temperature and then changed it to the hydroxyketone (**5a**) by demethylation. The Friedel-Crafts β-phenylpropionylation of the 7-methoxybenzofuran (**8**) afforded mainly the 4-acyl-7-methoxybenzofuran (**10c**), accompanied by a small amount of the 6-acyl-7-hydroxy compound (**11c**) (Chart 2) analogously

1) The major part of this work was presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

2) R. Royer, E. Bisagni, A.-M. Laval-Jeantet, and J.-P. Marquet, *Bull. Soc. Chem. Fr.*, **1965**, 2607.

3) Y. Kawase, M. Nanbu, and F. Miyoshi, This Bulletin, **41**, 2676 (1968).

4) Y. Kawase, M. Nanbu, F. Miyoshi, and H. Kawamura, *ibid.*, **41**, 2683 (1968).

5) Preliminary report: Y. Kawase, *Chem. Ind.* (London), **1970**, 687.

6) The reported cyclization by sulfuric acid or other reagents afforded a mixture of the 6- and 4-methoxybenzofurans (Ref. 7 and 8); their ratio was determined to be 97 : 3 in the case of sulfuric acid by estimating the areas of the peaks corresponding to each of the 3-methyl protons in the NMR spectrum (Ref. 5).

7) R. Royer, E. Bisagni, C. Hudry, A. Cheutin, and M.-L. Desvoye, *Bull. Soc. Chim. Fr.*, **1963**, 1003.

8) E. Bisagni and R. Royer, *ibid.*, **1962**, 925.

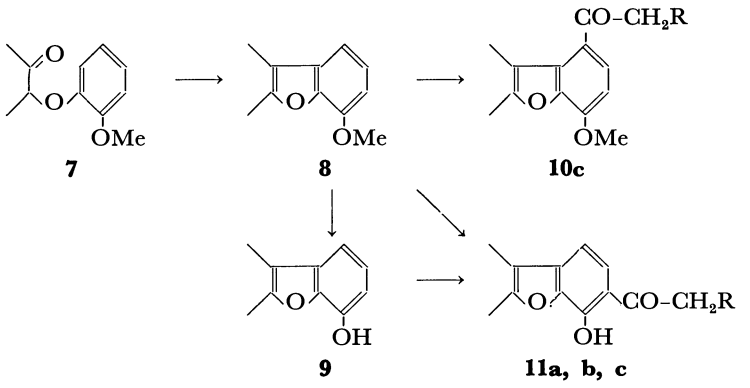

Chart 2

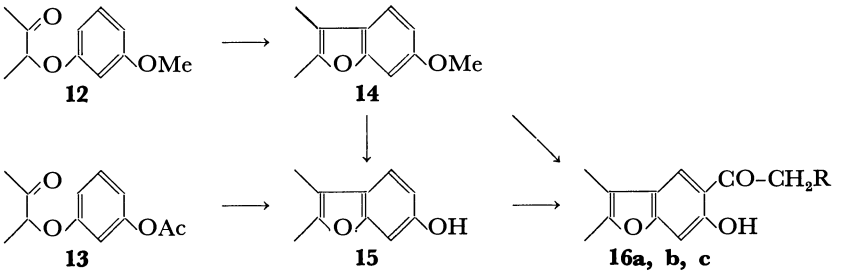

Chart 3

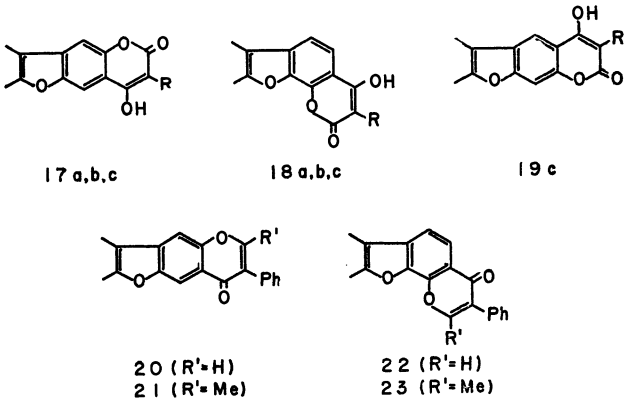

Chart 4

to what has been reported in the case of the acetylation.[2] The analogous β- phenylpropionylation of the 6-methoxybenzofuran (**14**) aforded also the 5-acyl-6-hydroxybenzofuran (**16c**), similarly as has been reported in the cases of the acetylation and phenylacetylation.[3] The Friedel-Crafts acetylation of **2** with a double amount of the reagents afforded the diacetyl compound (**6**), analogously to the cases of 5-methylbenzofuran[9] and 7-methoxybenzofuran.[2]

The positions of the acyl groups in the acylation product were determined by NMR spectroscopy; the methoxyketone (**4c**) and hydroxyketones (**5a**, **5b**, **5c**, and **16c**) have two singlets corresponding to two aromatic para protons, while the methoxyketone (**10c**) and hydroxyketones (**11a**, **11b**, and **11c**) have two doublets of J=8 Hz corresponding to two aromatic ortho protons (Table 3).

The hydroxyketones (**5a**, **5b**, **5c**, **11a**, **11b**, **11c**, and **16c**) thus obtained were converted to dimethylfuro derivatives of 4-hydroxycoumarins (**17a**, **17b**, **17c**, **18a**, **18b**, **18c**, and **19c**) by the action of diethyl carbonate and sodium,[4] and to dimethylfuro derivatives of isoflavones (**20**, **21**, **22**, and **23**) by the action of ethyl orthoformate and piperidine in pyridine or acetic anhydride and sodium acetate.[3] The furocoumarins (**17c**, **18c**, and **19c**) were also prepared by the thermal condensation of the hydroxybenzofurans (**3**, **9**, and **15**) with diethyl benzylmalonate, analogously as has been reported in the cases of 3-phenylfurocoumarins[10] (**17b**, **18b**, and **19b**) (Chart 4).

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were measured as KBr disks on a Hitachi EPI-S spectrophotometer, the UV spectra were measured on a Hitachi 139 spectrophotometer, the NMR spectra were measured on a JEOL JNM-C-60H (60 MHz) spectrometer, and the mass spectra were measured on a JEOL JMS-OlS spectrometer. The detailed data are summarized in Tables 1—4.

The Preparation of Methoxybenzofurans. A mixture of 3-(*p*-methoxyphenoxy)-2-butanone[7] (**1**) (3 g) and polyphosphoric acid (n=2.5, 60 g) was heated at 100°C for 1 hr, after which the cooled mixture was poured into ice water. The mixture was extracted with ether, and the residual product from the ethereal solution was distilled to give methoxybenzofuran (**2**), bp 143—147°C/21 mmHg (lit,[7] bp 133—134°C/11 mmHg); 1.5 g (55%). Similarly, **8** and

The fraction b was crystallized to give **16c**, and the fraction a was purified by chromatography on silica gel, with cyclohexane and then benzene as the solvent, to give the recovery **14** (total 39%) and indanone (total 68%). l) Lit. mp 187°C (Ref. 10). m) Lit. mp 287°C (Ref. 10).

14 were also prepared by this procedure.

The Preparation of Hydroxybenzofurans. Hydroxybenzofurans (**3**, **9**, and **15**) were prepared by the demethylation of the methoxybenzofurans (**2**, **8**, and **14**) by following the methods of Refs. 7 and 8. Compound **15** was also prepared by the cyclization of **13** as follows:

*The Preparation of 3-(m-Acetoxyphenoxy)-2-butanone (**13**).* A mixture of *m*-acetoxyphenol (28 g), 3-chloro-2-butanone (20.5 g), acetone (150 ml), and anhydrous potassiun carbonate (70 g) was refluxed for 8 hr; the mixture was treated with water and then extracted with ether. The residual product from the ethereal solution was distilled to give **13**, bp 145—150°C/7 mmHg; 29.6 g (72.5%).

*The Cyclization of **13**.* Concentrated sulfuric acid (20 ml) was stirred into **13** (13.5 g) with cooling below 15°C, after which the mixture was kept at 15°C for 1 hr. The resulting mixture was poured into ice water and extracted with ether. The residual product from the ethereal solution was crystallized from cyclohexane to give **15**, mp 105—107°C (lit,[7] mp 107.5—108°C); 1.7 g (17%).

a) δ-Values in CCl_4 (about 5% solution), with TMS as the internal standard. b) d: Doublet. c) 2,3-Dimethyl-4-methoxybenzofuran. d) In $CDCl_3$.

The Acylation of the Hydroxybenzofuran with Carboxlyic Acid and Polyphosphoric Acid (PPA). A mixture of **3**[7] (2.4 g), acetic acid (1 g), and PPA (n=1.5, 45 g) was heated at 100°C for 1 hr. The cooled mixture was poured into ice water and then extracted with chloroform. The residual product from the chloroform solution was crystallized from ethanol to give **5a**, mp 140—141°C (lit,[2] mp 141°C); 1.3 g (39%). Similarly, the acetyl, phenylacetyl, and β-phenylpropionyl compounds (**11a**, **5b**, **11b**, **5c**, **11c**, and **16c**) were also prepared by this procedure.

The Friedel-Crafts Acylation of the Methoxybenzofurans. Powdered aluminum chloride (9.7 g) was added, with stirring and cooling, to a solution of **2**[7] (5 g) and acetyl chloride (2.5 g) in carbon disulfide (50 m*l*); the mixture was stirred

a) s: Shoulder. b) 2,3-Dimethyl-4-methoxybenzofuran. c) 2,3-Dimethyl-4-hydroxybenzofuran. d) 2,3-Dimethyl-4-hydroxy-5-benzofuranyl methyl ketone. e) 2,3-Dimethyl-4-hydroxy-5-benzofuranyl benzyl ketone.

at room temperature for 2 hr and then at the reflux temperature for 1 hr. The cooled mixture was poured into ice water containing hydrochloric acid and extracted with chloroform. The chloroform solution was washed with an aqueous sodium hydroxide solution, and the residual product from the chloroform solution was crystallized from ethanol to give **5a**, mp 140—141°C, identical with the sample described above. Yield, 4.7 g (81%). Similarly, **5b** was obtained by the action of phenylacetyl chloride, while the methoxyketone (**4c**) was obtained in the case of β-phenylpropionyl chloride. The β-phenylpropionylation of **8** afforded a small amount of **11c** and a fairly large amount of the methoxyketone (**10c**), while that of **14** afforded a small amount of **16c** and fairly large amounts of the recovered **14** and indanone. The diacetylation of **2** afforded the hydroxydiketone (**6**).

*The Demethylation of the Methoxyketone (**4c**).* A mixture of **4c** (1.4 g), nitrobenzene (40 ml), and powdered aluminum chloride (0.9 g) was heated at 100°C for 1 hr. The cooled mixture was poured into dilute hydrochloric acid, and the nitrobenzene was removed by steam distillation. The residual precipitates obtained were crystallized from ethanol to give **5c**, mp 139—140.5°C, identical with the sample described above. Yield, 0.46 g (34%).

The Preparation of Furocoumarins. *a) From the Hydroxyketones*: Small pieces of sodium (1.1 g) was added to a mixture of **5a** (1.1 g) and diethyl carbonate (40 ml), after which the mixture was heated at 110—120°C for 30 min. The cooled mixture was treated with a small amount of methanol and with water, and was then extracted with ether. The aqueous layer was acidified, and the crystalline precipitates thus formed were recrystallized from ethanol to give 6*H*-8-hydroxy-2,3-dimethylfuro[2,3-*g*][1]benzopyran-6-one (**17a**), mp 308°C (dec.); 0.8 g (67.5%). Similarly, 7-phenyl and 7-benzyl derivatives (**17b** and **17c**) of **17a**, 8*H*-6-hydroxy-2,3-dimethylfuro[3,2-*h*][1]benzopyran-8-one (**18a**) and its derivatives (**18b** and **18c**), and 7*H*-6-benzyl-5-hydroxy-2,3-dimethylfuro[3,2-*g*][1]benzopyran-7-one (**19c**) were also prepared by this procedure.

b) From the Hydroxybenzofurans: A mixture of **3** (0.5 g) and diethyl benzylmalonate (2.5 g) was refluxed for 8 hr. The cooled mixture was washed with ether, and the residual solid was crystallized from ethanol to give **17c**, mp 285—286°C, identical with the sample described above. Yield, 0.54 g (55%). Similarly, **18c** and **19c** were also prepared by this procedure.

The Preparation of Furoisoflavones. *a) By the Action of Ethyl Orthoformate*: A mixture of the hydroxyketone **5b** (0.4 g), ethyl orthoformate (4 g), piperidine (1 drop), and pyridine (16 ml) was refluxed for 8 hr, after which the cooled mixture was poured into dilute hydrochloric acid to form crystalline precipitates, which were then recrystallized from ethanol to give 8*H*-2,3-dimethyl-7-phenylfuro[2,3-*g*][1]benzopyran-8-one (**20**), mp 233—234°C; 0.4 g (97%). Similarly, 6*H*-2,3-dimethyl-7-phenylfuro[3,2-*h*][1]benzopyran-6-one (**22**) was also prepared by this procedure.

b) By the Action of Ac_2O-AcONa: A mixture of **5b** (0.5 g), anhydrous sodium acetate (2 g), and acetic anhydride (10 ml) was refluxed for 12 hr, the cooled mixture was then poured into water to form crystalline precipitates, which were recrystallized from ethanol to give the 6-methylderivative (**21**) of **20**, mp 150.5—151.5°C; 0.15 g (28%). Similarly, the 8-methyl derivative (**23**) of **22** was also prepared by this procedure.

The authors are grateful to the members of the Laboratory of Analysis, Faculty of Pharmacology of Toyama University, for the microanalyses and the NMR spectroscopy.

Some Displacement Reactions of Neopentyl Type Bromide Derived from Thujopsene[1]

Masaaki Ito, Kazuo Abe, Hitoshi Takeshita,* and Mitsuyoshi Yatagai*

(Received December 26, 1970)

The reaction of thujopsene with gaseous hydrogen bromide at low temperature affords a 48% yield of neopentyl type bromide. The reactivity of the homoallyl bromide was inspected. First, the neopentyl type bromide was derived to a diethyl widdryl malonate in order to demonstrate the reaction which indicates the involvement of homoallylcyclopropylcarbinyl ion system. The malonate was converted to a carboxylic acid and then to isomeric lactone. To demonstrate the reaction which suggests the retention of carbon frame work in the reaction, the reaction of the neopentyl bromide was extended to Grignard reaction. The Grignard reagent reacted with cyclohexanone gave a tertiary alcohol, whereas a dimeric hydrocarbon was also obtained through the Wurtz type condensation. The tertiary alcohol was converted to a dehydrated hydrocarbon and then a glycol.

It is known that reactions of thujopsene I with several acids cause skeletal rearrangements to give a variety of types of compounds according to conditions. Treatment of I with oxalic acid in alcoholic solution gave widdrol II, widdryl ether III,[2] β-chamigrene IV, cuparene V, and hydrocarbons,[3] while, the reaction of I or II with mineral acid afforded the epimeric pair of the neopentyl type chlorides VI and VII by hydrochloric acid[4] and alcohols VIII and IX by sulfuric acid.[3] We thought it worthwhile to extend this reaction with hydrobromic acid to obtain more reactive bromo derivatives which could be employed in some displacement reactions. I was reacted with gaseous hydrogen bromide at low temperature giving a neopentyl type bromide, but no isomeric pair of this type. Evidence for this will be described.

Treatment of thujopsene obtained from Thujopsis dolabrata Sieb. et Zucc. with anhydrous hydrogen bromide yielded the bromide X in 48% after purification by fractional distillation. Among other products, "the hydrocarbon II" XI[3] was obtained as a second major product. The IR spectrum of X showed C–Br stretching frequency at 670 cm^{-1}. Gas-liquid chromatography revealed I to be a single compound, and the data of elemental analysis gives the molecular formula $C_{15}H_{25}Br$. NMR spectrum of X showed very similar features to that of VI, *i.e.*, four methyl singlets at 1.02 (3 Me) and 1.15 ppm, a vinyl hydrogen at 5.08 (singlet), and signal ascribed to a methylene hydrogens at 3.18 ppm (2H singlet) suggesting the structure shown.

The reactivity of the homoallyl bromide system of X was inspected. First, we examined the displacement with diethyl sodiomalonate, typical carbanion. Product XII isolated was not a diethyl malonate derivative expected from simple substitution, but skeletal rearrangement accompanying its formation. The gas-liquid chromatogram of XII showed it to be a single compound and saponification equivalent of XII showed it to be a diester $C_{15}H_{25}CH(COOC_2H_5)_2$. The NMR spectrum of XII showed, beside ethoxyl groups, (1.27 (6H) and 4.08 (4H)), 1.07 (3 Me, overlapping singlet), 1.00 (Me, singlet), 5.47 (1H, d, d, J=10.5, 6.0 Hz), and 3.20 (1H, s). Since the splitting pattern of the above olefinic proton signal accords with that of II,[5] XII must possess the widdryl skelton, and therefore its structure was deduced as diethyl widdryl malonate. Alkaline hydrolysis of XII gave a carboxylic acid XIII which, upon treatment with sulfuric acid in alcohol, afforded an isomeric lactone XIV in good yield. The carbonyl stretching frequency of XIV (1720 cm^{-1}), the lactonic ring, was free from a strain.

The rearrangement clearly indicates the involvement of homoallyl-cyclopropylcarbinyl ion system. Thus, the geometrical requirement for these interconversion leads to the α-orientation for the malonate moiety.

We extended the reaction of the neopentyl bromide X to Grignard reaction since the above mentioned homoallylcyclopropyl carbinyl ion should not be involved. The reaction with cyclohexanone was carried out in ether in the usual manner. The major product isolated by fractional distillation was found to be a tertiary alcohol XV. Its NMR spectrum revealed a sharp singlet at 5.30 ppm for an olefinic hydrogen, suggesting the retention of carbon frame work in the reaction. Four methyl signals at 0.99 (3H, s), 1.06 (3H, s), and 1.29 (6H, s) were in expected positions. When XV was passed through a silica gel column (Wako Gel Q-50), dehydrated hydrocarbon XVI was formed in nearly quantitative yield. Gas-liquid chromatogram of XVI proved it to be a single compound, whose NMR spectrum showed two singlets at 5.08 and 5.30 ppm. The singlet nature of the second olefinic hydrogen can not make the structure of XVI be regarded as XVIa, since various types of olefinic

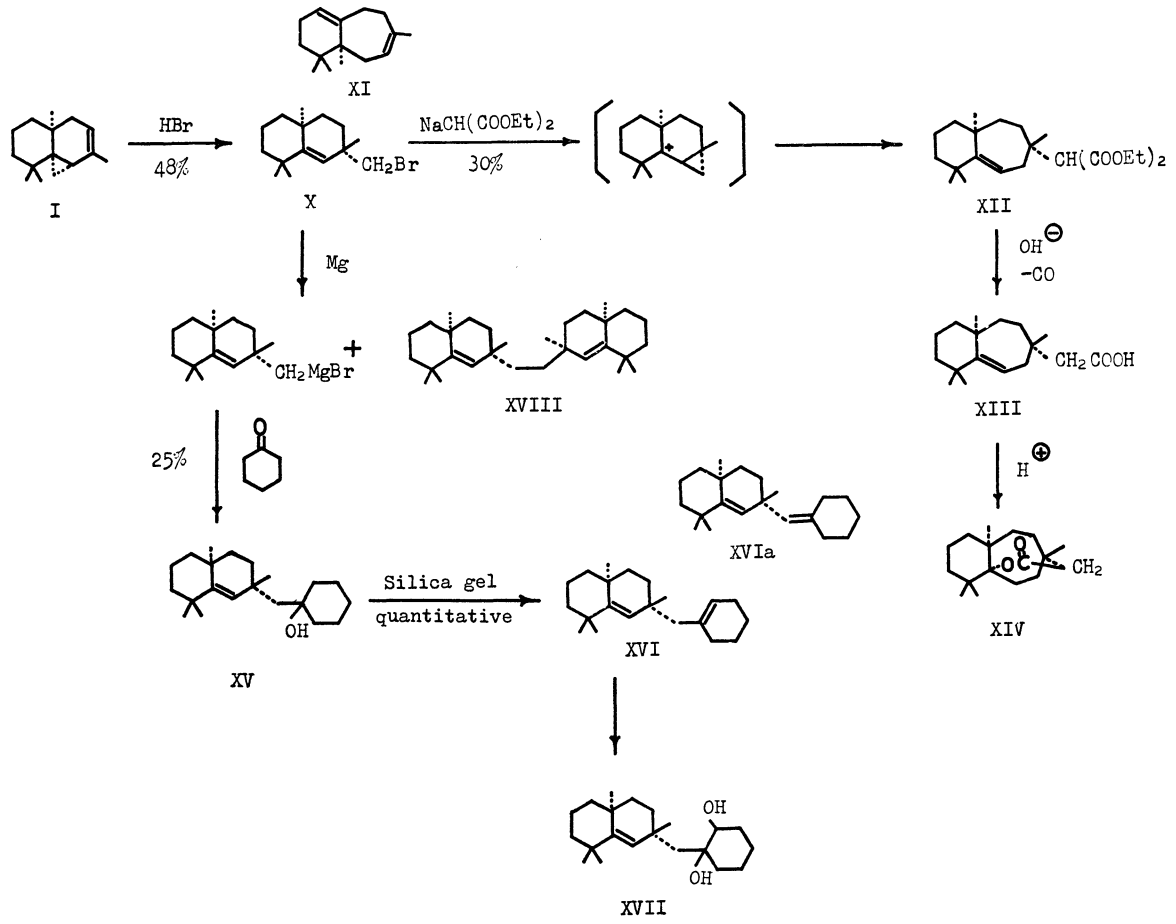


Scheme 1

hydrogen of cyclohexene often appeared without clear splittings. We carried out oxidation with osmium tetraoxide to afford the glycol XVII which clearly revealed a signal at 3.87 ppm due to a presence of a carbinyl proton with adjacent methylene group. Thus, the structure of XVI is as depicted.

The remaining crystalline mass on distillation of XV was recrystallized and gave a dimeric hydrocarbon XVIII in 14% yield. Its structure was deduced from elemental analysis, osmometric molecular weight determination, and mainly from the NMR spectrum which has a sharp singlet at 5.00 (2H), 0.91 (6H), 1.05 (6H), 1.09 (6H), and 1.13 (6H) ppm respectively, indicating a symmetric structure. We tried to obtain the same hydrocarbon on simple hydrolysis of the Grignard reagent and found the formation of XVIII in a fairly high yield through the Wurtz type condensation.

Experimental

All infrared absorption spectra were measured with a Shimadzu Model IR-27G grating spectrophotometer and the NMR spectra on a varian A-60A analytical spectrometer using tetramethylsilane as an internal standard. Gas-liquid chromatographic data were measured on a Shimadzu GC-1C gaschromatograph, using helium as a carrier gas. All melting points were obtained on a Büchi micro melting point apparatus and are uncorrected. Analyses performed on a Micro-Analyser, Shimadzu.

Thujopsene. This was isolated from Cedar H oil by repeated rectification: bp 119—120°C/10 mmHg, d_{20}^{20} 0.9362, n_D^{20} 1.5033, $[\alpha]_D^{20}$ −93.68.

Neopentyl-type Bromide of Thujopsene. Into freezing thujopsene in a round bottomed 200 m*l* flask was passed dry hydrogen bromide generated by dropping bromine into a mixture of red phosphorus and water and drying with calcium bromide, until absorption reached the calculated volume. The bromides were obtained in 48% yield at reaction temperature −20°C and in 40% at 0°C. The product was then dissolved in ether, washed with water, dried over calcium bromide and distilled, a fraction 149—151°C/10 mmHg, d_{20}^{20} 1.1592, $[\alpha]_D^{27}$ +83 (2% CCl_4) being collected. The gas-liquid chromatogram of the fraction exhibited two peaks, partly overlapping, due to compound X (*ca.* 70%, first eluted) and compound XI (*ca.* 30%, second eluted) which was identical with the authentic sample. The IR spectrum of X showed C–Br absorption at 15 μ.

Found: C, 63.82; H, 8.90%. Calcd for $C_{15}H_{25}Br$: C, 63.16; H, 8.83%.

No attempt was made to separate these two compounds on a preparative scale. The crude product was used directly in the following reactions.

Preparation of the Diethyl Malonate Derivative starting from the Neopentyl-type Bromide of Thujopsene. To an alcoholic solution of sodium ethylate containing 1.7 g metallic sodium (0.075 mol) and 40 m*l* absolute alcohol in an ice bath was added dropwise 12 g (0.075 mol) of diethyl malonate in a

100 ml flask equipped with a magnetic stirrer, and then 21.4 g (0.075 mol) of bromide X dropwise. The mixture was stirred for 0.5 hr after the addition was completed and then refluxed for 22 hr. The solvent was removed on a steam bath. The reaction mixture was poured into water and extracted with ether. The ether solution was dried and the solvent removed on the steam bath with a rotary evaporator. Analytically pure material XII bp 218—219°C/10 mmHg, d_{20}^{20} 1.0363, n_D^{20} 1.4891. $[\alpha]_D^{18}$ +87.4 (CCl_4), was obtained by further distillation. The yield was 30% theoretically. IR (carbon tetrachloride): $\nu_{C=O}$ 1752 cm^{-1} (S), 1726 cm^{-1} (S), λ_{max}^{MeOH} 215 mμ.

Found: C, 72.45; H, 9.83%. Calcd for $C_{22}H_{36}O_4$: C, 72.49; H, 9.95%.

Preparation of the Lactone XIV: Starting from the Diethyl Malonate XII. 814 mg (2.24 mmol) of XII was hydrolyzed in alcohol with 751 mg (13.4 mmol) of potassium hydroxide for 2 hr. After the usual work-up 762 mg of the dicarboxylic acid was obtained and then decarboxylated 2 hr at 150°C under a pressure of 20 mmHg. The resulting residue (160 mg) was dissolved in chloroform (7 ml) and the solution was added to a mixture of concentrated sulfuric acid (2 ml) and chloroform (2 ml) at −5°C. The mixture was swirled in an ice bath for 5 min and then poured on ice. The product was extracted with dichloroethane; the extract was washed with potassium bicarbonate solution and dried and the solvent was removed. Preparative tlc of the reaction mixture gave 16.5 mg of pure lactone XIV. The IR spectrum showed C=O absorption at 1720 cm^{-1}.

Grignard Reaction of Bromide X with Cyclohexanone. The Grignard reagent was prepared from 27.4 g (0.075 mol) of bromide X, 2.0 g (0.083 mol) of magnesium, and 10 ml of absolute ether in the usual way. It was cooled and 7.4 g (0.075 mol) of cyclohexanone in absolute ether was added dropwise with stirring for over 1 hr, cooled, and poured into a mixture of ice and an aqueous ammonium chloride solution. The ether layer was separated, and the aqueous layer was washed twice with ether. The combined ether extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated to leave crude oil which upon distillation at 202—203°C/10 mmHg gave 5.7 g (25%) of XV as a colorless liquid. The thin-layer chromatogram (silica gel, *n*-heptane : ethylmethyl ketone=80 : 20) showed a spot at R_f 0.89. The gas-liquid chromatogram showed a single peak. The molecular weight was determined to be 298.5 (Calcd for 304.5). IR (carbon tetrachloride): ν_{OH} 3550 cm^{-1} (S).

Found: C, 82.48; H, 11.78%. Calcd for $C_{21}H_{36}O$: C, 82.83; H, 11.12%.

The distillation residue of the reaction mixture gave a crystalline compound XVIII after recrystallization from ethyl acetate. Analytically pure material melted at 88—89°C, $[\alpha]_D^{20}$ +69.4 (CCl_4), molecular weight: Found 408.4 (Calcd 410.7). IR (carbon tetrachloride: ν_{C-H} 2840, 2850, 2910, 2950, 3025 cm^{-1}.

Found: C, 88.02; H, 12.13%. Calcd for $C_{30}H_{50}$: C, 87.73; H, 12.27%.

The Grignard reagent prepared from 2.0 g (0.01 mol) of bromide X in the manner mentioned above was, hydrolyzed directly with a mixture of ice and an aqueous ammonium chloride solution. Crude crystalline XVIII weighed 2.4 g.

The melting point, mixed melting point and IR spectrum were identical with those of the by-product of the Grignard reaction mentioned above.

Dehydration of Tertiary Alcohol XV to Hydrocarbon XVI on a Silica-gel Column. Chromatagraphy of XV over a column of silica-gel (Wako-gel Q-50) using petroleum ether gave 2 g of XVI, n_D^{20} 1.5159, $[\alpha]_D^{20}$ +101.1 (CCl_4). The gas-liquid chromatogram showed a single peak. The molecular weight was determined to be 283 (calcd 286). IR (carbon tetrachloride): ν_{C-H} 2815, 2915, 3150 cm^{-1}. NMR (CCl_4), 5.09 (1H, singlet olefinic proton), 5.30 (1H, singlet olefinic proton) ppm.

Found: C, 87.64; H, 11.90%. Calcd for $C_{21}H_{34}$: C, 88.04; H, 11.96%.

Osmium Tetraoxide Oxidation of Hydrocarbon XVI. Five hundred milligrams of XVI was oxidized in chloroform and pyridine with 550 mg of osmium tetraoxide overnight. The reaction mixture was washed with water and the reagent was removed by passage of hydrogen sulfide into the solution and filtration. Pale yellow oil obtained by evaporation of the solvent was fractionated through the silica gel column to yield 50 mg of XVII. Colorless liquid.

Found: C, 78.55; H, 11.41%. Calcd for $C_{21}H_{31}O_2$: C, 78.69; H, 11.32%.

The authors wish to express their gratitude to Professor S. Ito for stimulating discussions, and to Takasago Perfumery Co., Ltd., for the donation of Cedar H.

Tetraaminoethylenes. I. The Preparation and Some Reactions of Tetrapiperidino- and Tetramorpholinoethylene[1]

Otohiko TSUGE, Kiyoshi YANAGI*, and Masako HORIE
Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received January 11, 1971)

The preparation of new tetraaminoethylenes was attempted by the reaction of chlorotrifluoroethylene (CTFE) with several amines. It has been found that CTFE reacted with piperidine and morpholine to give tetrapiperidino- (TPE) and tetramorpholinoethylene (TME) in moderate yields respectively, although no tetraaminoethylenes were formed in the reactions with diethylamine, pyrrolidine, aniline, *N*-alkylaniline, and diphenylamine. Also, it has been made clear that the compounds whose structures were previously assigned to the tetraaminoethylenes, obtained from 1,1-dimethoxytrimethylamine or ethyl orthoformate and secondary amines are the corresponding triaminomethanes. It has been found that TPE and TME reacted with halogens, halogen-, nitrocompounds, and aromatic carboxylic acids to form mainly the corresponding oxamidinium salts.

Tetraaminoethylenes, such as tetrakis(dimethylamino)ethylene (TDAE) and bi(1,3-diphenylimidazolidin-2-ylidene), are characterized both by their odor and by the versatility of their chemical reactivity.[2-6] Such current interest in unusually reactive tetraaminoethylenes prompted us to investigate the preparation of new tetraaminoethylenes and their chemistry.

In this paper, we wish to report the preparation of tetrapiperidino- (TPE) and tetramorpholinoethylene (TME), which are new tetraaminoethylenes, and their unusual reactions with halogens, halogen-, nitrocompounds, and aromatic carboxylic acids.

Results and Discussion

The Preparation of TPE and TME. An attempt was made to prepare new tetraaminoethylenes by the reactions of chlorotrifluoroethylene (CTFE) with aliphatic and aromatic amines according to Pruett's procedure.[7]

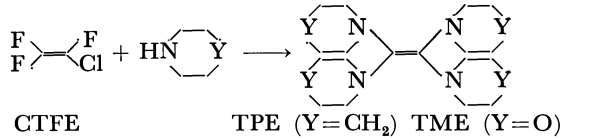
The reaction of CTFE with diethylamine gave only the compound assumed to be 1,2-bis(diethylamino)-1-chloro-2-fluoroethylene, while pyrroridine and aniline reacted with CTFE to give unidentified compounds, all in low yields. Also, no reactions of CTFE with *N*-alkylanilines and diphenylamine took place.

Although the preparation of new tetraaminoethylenes caused such difficulties, it has been found that similar reactions of CTFE with piperidine and morpholine afforded the expected tetraaminoethylenes, TPE (mp 151—152°C) and TME (mp 186—190°C), in moderate yields, accompanied by small amounts of the corresponding *N*-(diaminoacetyl)amines, whose structures were assumed on the basis of the elemental analyses and study of the IR spectra.

The structures of TPE and TME were confirmed by spectral studies as well as by elemental analyses; the molecular formulae of TPE and TME agreed with $C_{22}H_{40}N_4$ (M^+ *m/e* 360) and $C_{18}H_{32}O_4N_4$ (M^+ *m/e* 368) respectively.

After the completion of this work, we learned that two routes for the preparation of tetraaminoethylenes have been reported. Winberg *et al.*[8] described that tetraaminoethylenes, including TPE and TME, were obtained by the reactions of 1,1-dimethoxytrimethylamine with aliphatic secondary amines, and that TPE and TME melted at 59—61 and 170—171°C respectively. On the other hand, it has been reported by Hagedorn and Lichtel[9] that ethyl orthoformate reacted with *N*-alkylanilines to give the corresponding tetrakis(*N*-alkylanilino)ethylenes, which could not be obtained by Pruett's method, as has been mentioned above. However, it is surprising that the molecular weight (calculated value, 504.7) of tetrakis(*N*-ethylanilino)ethylene, mp 180—182°C (decomp.), was observed to be 312 or 336 by the vapor-pressure-osmometric determination.

In order to see whether or not the reported compounds are real tetraaminoethylenes, the reaction of 1,1-dimethoxytrimethylamine or ethyl orthoformate with amines was investigated. The reactions of 1,1-dimethoxytrimethylamine with piperidine and morpholine did not give any TPE and TME, but compounds which decomposed rapidly in air were obtained in low yields; these compounds were as-



CTFE TPE (Y=CH_2) TME (Y=O)

sumed, on the basis of the results of the elemental analyses, to be tripiperidino-, mp 52—56°C, and trimorpholinomethane, mp 142—147°C, respectively. Contrary to expectation, *N*-methyl- and *N*-ethylaniline reacted with ethyl orthoformate to afford tris(*N*-methylanilino)-, mp 268—269°C (decomp.), and tris(*N*-ethylanilino)methane, mp 181—185°C (decomp.), respectively. The structures of these compounds were established by the spectral studies as well as by the elemental analyses. Also, the reaction of ethyl orthoformate with morpholine or of 1,1-dimethoxytrimethylamine with *N*-ethylaniline gave the corresponding triaminomethanes.

It may be concluded from the above facts that TPE and TME obtained in this work are valid, and that the reported compounds were previously erroneously assigned to the tetraaminoethylenes.

The Reactions of TPE and TME with Halogens. Wiberg and Buchler[3] found that TDAE was oxidized easily with halogens, especially with bromine and iodine, to give the corresponding octamethyl-oxamidinium dihalides, $TDAEX_2$, and that several periodides, $TDAEI_n$ (n=4, 5, and 7), were also formed in the oxidation with iodine.

When chlorine gas was slowly passed through a benzene solution of TPE and TME at 0°C, the dichlorides $TPECl_2$, mp 240—241°C (decomp.) and $TMECl_2$, mp 265—266°C (decomp.), were obtained in good yields. Similarly, TPE and TME reacted with equimolar amounts of bromine and iodine to give the corresponding dihalides, $TPEBr_2$, mp 247°C (decomp.), $TPEI_2$, mp 282—284°C (decomp.), $TMEBr_2$, mp 300°C (decomp.), and $TMEI_2$, mp *ca.* 190°C (decomp.), respectively, accompanied by trace amounts of the hexahalides, $TPEBr_6$ and $TPEI_6$, in the reaction of TPE:

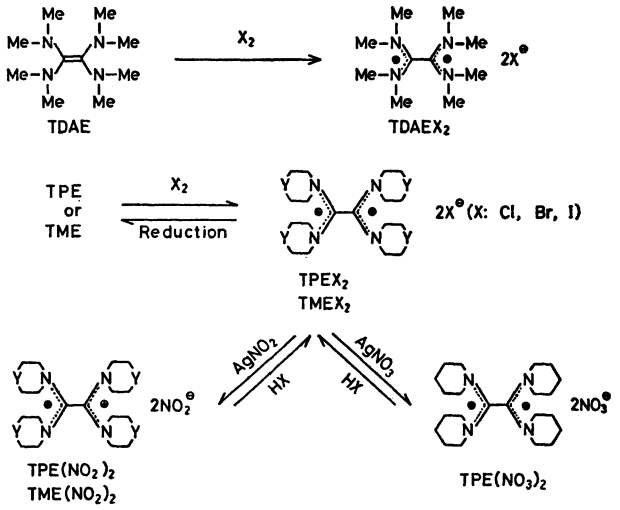
Table 1. Reactions of TPE and TME with halogens

TPE or TME	X_2	Reaction conditions: Solvent	Temp. (°C)	Time (min)	Products yields (%): $TPEX_2$ or $TMEX_2$	$TPEX_6$
TPE	Cl_2	benzene	0	15	100	
TME	Cl_2	benzene	0	15	80	
TPE	Br_2	*n*-hexane	0	10	70	+[a]
TME	Br_2	*n*-hexane	0	10	70	
TPE	I_2	benzene	0	10	88	+[a]
TME	I_2	benzene	0	10	24	

a) A plus sign, +, indicates a trace amount.

The above hexahalides were easily formed by the further reaction of $TPEBr_2$ or $TPEI_2$ with bromine or iodine, but the dihalides, $TPECl_2$, $TMECl_2$, $TMEBr_2$, and $TMEI_2$, did not give any perhalides under similar conditions.

The structures of dihalides were confirmed, by a study of the IR spectra as well as by the chemical transformations, to be the corresponding oxamidinium dihalides. The IR spectra of all the dihalides exhibited remarkably strong absorption bands which can be ascribed to the $[\rangle N{=}C{=}N\langle]^{\oplus}$ at 1620 and 1640 cm^{-1}. Also, the ion peak which corresponded to the molecular ion of TPE or TME appeared as the ion peak of the highest mass number in the respective mass spectra of dihalides.



The dihalides in aqueous solutions were reduced with zinc dust to the original TPE or TME, although TME could not be isolated because of its instability in relation to water. Furthermore, when the dihalides were treated with silver nitrite or nitrate, the corresponding dinitrites $TPE(NO_2)_2$ and $TME(NO_2)_2$ or dinitrate $TPE(NO_3)_2$, whose IR spectra were similar to those of the corresponding dihalides, were obtained quantitatively.

Also, the dinitrites and dinitrate were easily transformed to the corresponding dihalides in the treatment with hydrogen halides. Incidentally, the hexahalides, $TPEX_6$, were reduced with zinc dust to give TPE.

The above observations indicate that the dihalides, dinitrites, and dinitrate are the corresponding oxamidinium salts. The results of the reactions of TPE or TME with halogens are shown in Table 1.

The Reactions of TPE and TME with Halogen-Compounds. It has been reported that TDAE reacted with cuprous chloride or carbon tetrachloride to give the dichloride, $TDAECl_2$, with the deposition of copper metal or decomposition of carbon tetrachloride.[3]

The reactions of TPE or TME with various organic halogen-compounds were also investigated. In all cases, the corresponding dihalides were obtained; the results are summarized in Table 2.

In particular, it is noteworthy that the compounds originated from the starting halogen-compounds were isolated in the reactions with benzal chloride, benzotrichloride, benzenesulfonyl chloride, phenacyl bromide, and 2,2-dichloroacenaphthenone: stilbene and 1,1,2,2-tetrachloro-1,2-diphenylethane (tolan tetrachloride), tolan tetrachloride, diphenyldisulfone, biphenacyl, and diacenaphthylidenedione were isolated respectively.

As is shown in Table 2, the yield of $TPECl_2$ in the reaction of TPE with benzyl chloride in the pres-

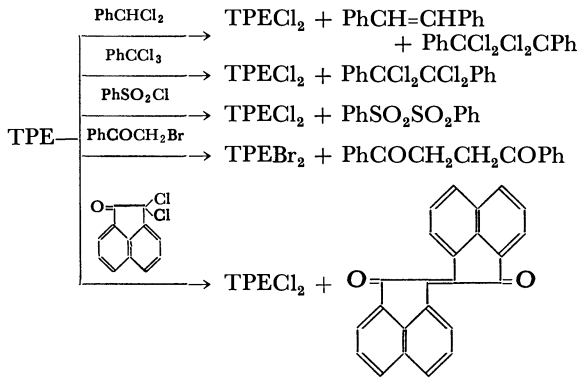
TME	$PhCCl_3$	benzene	60	15	51		
TPE	PhCOCl	benzene	40—50	120	86		
TME	PhCOCl	benzene	40	120	82		
TPE	$PhSO_2Cl$	benzene	room temp.	120	90	$PhSO_2SO_2Ph$	20
TME	$PhSO_2Cl$	benzene	room temp.	120	90	$PhSO_2SO_2Ph$	20
TPE	$PhCOCH_2Br$	benzene	60	30	70	$(PhCOCH_2)_2$	44
TPE	DCA[e]	benzene	room temp.	10	50	Diacenaphthylidenedione	27

a) A plus sign, +, indicates a trace amount.
b) The halogen-compound was used as the solvent respectively.
c) In the presence of benzoyl peroxide.
d) In the presence of *p*-benzoquione.
e) DCA: 2,2-Dichloroacenaphthenone.

ence of benzoyl peroxide is higher than in either the absence or presence of *p*-benzoquinone.



On the basis of the above facts, it seemed reasonable to assume that these reactions proceed through a free radical process.

The Reactions of TPE or TME with Nitro-Compounds. Previous investigations of the reactions of tetraaminoethylenes with nitro-compounds have not been extended beyond the reactions of TDAE with nitrobenzenes[10] and of bi(1,3-diphenylimidazolidin-2-ylidene) with nitromethane.[11]

The reactions of TPE or TME with several nitro-compounds were investigated.

It has been found that TPE and TME reacted with phenylnitromethane to give the respective dinitrites, $TPE(NO_2)_2$ and $TME(NO_2)_2$, which were identical with those obtained from the dihalides and silver nitrite. Surprisingly, TPE reacted with tetranitromethane to give a 1 : 2 addition product of TPE and tetranitromethane, accompanied by a small amount of the dinitrate, $TPE(NO_3)_2$. The nitrate was identified by a comparison of its IR spectrum with that obtained by the reaction of $TPEX_2$ with silver nitrate.

In the same way as in the case of TDAE,[10] TPE or TME formed charge-transfer complexes with nitrobenzene (NB), *m*-dinitro- (DNB), and 1,3,5-trinitrobenzene (TNB). Although purple-colored complexes with NB and DNB were not obtained as crystals, these complexes were established, by a spectroscopic estimation of the intensities of the absorption peaks at 514 mμ for TPE-NB, 450 mμ for TME-NB, 580 mμ for TPE-DNB, and 476.8 mμ for TME-DNB complex, to be TPE(NB), TME(NB), $TPE(DNB)_2$, and $TME(DNB)_2$ complexes respectively.

On the other hand, TPE reacted with TNB to form the charge-transfer complex $TPE(TNB)_2$, mp 122—124°C (decomp.), as a purple solid; it gradually decomposed in air.

10) N. Wiberg and J. W. Buchler, *Chem. Ber.*, **97**, 618 (1964).
11) H. -W. Wanzlick and E. Schikora, *ibid.*, **94**, 2389 (1961).

$$\text{TPE or TME} \xrightarrow{PhCH_2NO_2} \text{TPE}(NO_2)_2 \text{ or } \text{TME}(NO_2)_2$$

$$\text{TPE} \xrightarrow{C(NO_2)_4} \text{TPE}(NO_3)_2 + \text{TPE}[C(NO_2)_4]_2$$

$$\text{TPE or TME} \xrightarrow{NB} \text{TPE(NB) or TME(NB)}$$

$$\text{TPE or TME} \xrightarrow{DNB} \text{TPE}(DNB)_2 \text{ or } \text{TME(DNB)}$$

$$\text{TPE} \xrightarrow{TNB} \text{TPE}(TNB)_2$$

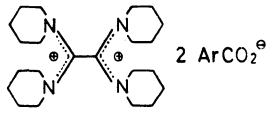
$$\text{TPE or TME} \xrightarrow{CH_3NO_2} \text{Y}\!\!<\!\!\text{N-CH=CH-NO}_2 \quad (\text{Y}=\text{CH}_2 \text{ or O})$$

Wanzlick and Schikora[11] found that bi(1,3-diphenylimidazolidin-2-ylidene) reacted with nitromethane to give 1,3-diphenyl-2-nitromethylimidazolidine upon the cleavage of the >C=C< bond in the ethylene.

When a benzene solution of TME or TPE was heated with nitromethane under an atmosphere of nitrogen, 1-nitro-2-piperidinoethylene, mp 94—95°C, or 2-morpholino-1-nitroethylene, mp 139—140°C, was obtained respectively.[12] The structures of the enamines were established by spectral studies as well as by elemental analyses.

The Reaction of TPE with Aromatic Carboxylic Acids. Little attention has been paid to the reactions of tetraaminoethylenes with carboxylic acids.

When a benzene solution of TPE was allowed to react with benzoic acid at room temperature, a compound, mp 104—105°C, was obtained as colorless needles. In the treatment with hydrobromic acid, the compound was easily transformed to $TPEBr_2$. The compounds was confirmed, by a study of its IR spectrum as well as by the elemental analysis, to the oxamidinium dibenzoate, $TPE(PhCO_2)_2$.



$TPE(ArCO_2)_2$ (Ar=Ph, p-MeC_6H_4, p-ClC_6H_4)

Similar reactions of TPE with *p*-methyl- and *p*-chlorobenzoic acid gave the corresponding oxamidinium salts, $TPE(p\text{-}MeC_6H_4CO_2)_2$, mp 101—103°C, and $TPE(p\text{-}ClC_6H_4CO_2)_2$, mp 109—111°C.

Experimental

All the melting and boiling points are uncorrected. The IR spectra were measured in KBr disks unless otherwise described, while the NMR spectra were determined at 60 MHz with a Hitachi R-20 spectrometer, using TMS as the internal reference. The mass spectra were obtained on a Hitachi RMS-4 spectrometer, using a direct inlet and an ionization energy of 70 eV.

The Reactions of CTFE with Amines. *i) With Piperidine*: In a 200 m*l*-autoclave cooled in a dry ice-methanol bath, 15 g (0.1 mol) of CTFE, which has been prepared from trichlorotrifluoroethane by the reported method,[13] and 110 g (1.92 mol) of piperidine were placed as rapidly as possible. The reaction mixture was stirred at room temperature for 3 hr and then at 80°C for 8 hr; during this time, the mixture gradually solidified and became difficult to stir. After the reaction mixture had been cooled, it was extracted with 500 m*l* of petroleum ether (bp 30—45°C), leaving a mixture of insoluble piperidinium chloride and fluoride. The extract was concentrated *in vacuo* under an atmosphere of nitrogen to yield 30 g (64%) of TPE; this, on recrystallization from ethyl acetate, afforded colorless needles, mp 151—152°C.

Found: C, 73.54; H, 11.30; N, 15.53%. Calcd for $C_{22}H_{40}N_4$: C, 73.38; H, 11.18; N, 15.55%. NMR spectrum in benzene: δ 0.86 (24H, multiplet) and 2.33 ppm (16H, multiplet). UV spectrum in *n*-hexane λ_{max} mμ (ε): 231.6 (15000), 258.4 (9900). Mass spectrum: *m/e* 360 (M^+), 275 ($M^+ -$ ), 193 ($275^+ -$ ), 110 ($193^+ -$ ), 84 ().

Also, a trace amount of *N*-(dipiperidinoacetyl)piperidine, mp 93—94°C, was isolated from the mother liquor of recrystallization.

Found: C, 69.41; H, 10.76; N, 14.23%. Calcd for $C_{17}H_{31}ON_3$: C, 69.56; H, 10.65; N, 14.31%. IR spectrum (Nujol): 1635 cm^{-1} ($\nu_{C=O}$).

ii) With Morpholine: In the same manner as in the reaction with piperidine, a mixture of 15 g (0.1 mol) of CTFE and 110 g (1.26 mol) of morpholine was heated at 70°C for 6 hr. After the reaction mixture had then been extracted with 1 *l* of ethyl acetate, the extract was concentrated *in vacuo* under an atmosphere of nitrogen to give 22 g (47%) of crude TME. Recrystallization from ethyl acetate gave colorless prisms, mp 186—190°C.

Found: C, 58.60; H, 8.92; N, 15.19%. Calcd for $C_{18}H_{32}O_4N_4$: C, 58.67; H, 8.76; N, 15.21%. NMR spectrum in benzene: δ 2.72 (16H, multiplet) and 3.54 ppm (16H, multiplet). UV spectrum in *n*-hexane λ_{max} mμ (ε): 222.5 (15000), 275.5 (9900). Mass spectrum: *m/e* 368 (M^+).

From the mother liquor of recrystallization, *N*-(dimorpholinoacetyl)molpholine, mp 125—126°C, was obtained in a trace amount.

Found: C, 56.03; H, 8.63; N, 13.99%. Calcd for $C_{14}H_{25}O_4N_3$: C, 56.17; H, 8.42; N, 14.04%. IR spectrum: 1640 cm^{-1} ($\nu_{C=O}$).

iii) With Diethylamine: A similar reaction of 15 g (0.1 mol) of CTFE with 100 g (1.37 mol) of diethylamine at 80°C for 10 hr gave 28 g of diethylammonium halide and 25 g (89%) of a colorless liquid bp 46°C/0.5 mmHg, which was assumed to be 1,2-bis(diethylamino)-1-chloro-2-fluoroethylene.

Found: C, 53.93; H, 9.33; N, 12.23%. Calcd for $C_{10}H_{20}N_2FCl$: C, 53.92; H, 9.05; N, 12.58%.

A similar reaction of CTFE with pyrrolidine or aniline gave only a small amount of an unidentified compound as yellow crystals, mp 68.5—69.5°C (Found: C, 67.84; H, 6.69; N, 15.58%), or as red prisms, mp 209—210°C (Found: C, 80.97; H, 5.20; N, 13.61%), respectively. Also, no reactions of CTFE with *N*-alkylaniline and diphenylamine took place under similar conditions.

The Reaction of 1,1-Dimethoxytrimethylamine with Morpholine. After a mixture of 10 g of 1,1-dimethoxytrimethylamine[14]

12) We found that various compounds having an active methyl or methylene group reacted with TPE and TME in the same manner as in the case of nitromethane, affording the corresponding enamines. The results will be reported in the near future.

13) H. S. Booth, P. E. Burchfield, E. M. Bixby, and J. B. McKelvey, *J. Amer. Chem. Soc.*, **55**, 2231 (1933).

14) H. Eilingsfeld, M. Seefelder, and H. Weidinger, *Chem. Ber.*, **96**, 2671 (1963).

and 10 g of morpholine had been vigorously refluxed for 5 hr, the unreacted materials were distilled out *in vacuo* to leave colorless crystals. Recrystallization from ethyl acetate gave 3.1 g (10%) of trimorpholinomethane, mp 142—147°C, as colorless needles which easily decomposed in air.

Found: C, 57.24; H, 9.29; N, 15.10%. Calcd for $C_{13}H_{25}O_3N_3$: C, 57.61; H, 9.30; N, 15.51%.

A similar reaction of 1,1-dimethoxytrimethylamine with piperidine gave colorless crystals, mp 52—56°C, bp 147°C/3 mmHg. This compound was assumed to be tripiperidinomethane, but no elemental analysis could be carried out because of its instability.

The Reactions of Ethyl Orthoformate with N-*Alkylanilines. i) With* N-*Methylaniline*: A mixture of 7.4 g (0.05 mol) of ethyl orthoformate and 5.3 g (0.05 mol) of *N*-methylaniline was stirred with one drop of concentrated sulfuric acid at room temperature for 2 hr: during this time a suspended reaction mixture changed into a clear solution. The removal of the unreacted materials by distillation *in vacuo* gave 3 g of colorless crystals. The crystals were washed with methanol and then recrystallized from dimethylformamide to afford tris(*N*-methylanilino)methane, mp 268—269°C (decomp.), as colorless prisms.

Found: C, 79.86; H, 7.76; N, 12.74%. Calcd for $C_{22}H_{25}N_2$: C, 79.70; H, 7.60; N, 12.68%.

ii) With N-*Ethylaniline*: A mixture of 44.5 g (0.3 mol) of ethyl orthoformate and 36.4g (0.3 mol) of *N*-ethylaniline was gently refluxed for 20 hr. The reaction mixture was then concentrated *in vacuo*, leaving 0.6 g of colorless crystals. The crystals were washed with diethyl ether and then recrystallized from acetone to give tris(*N*-ethylanilino)methane, mp 181—185°C (decomp.), as colorless prisms.

Found: C, 80.76; H, 8.67; N, 11.19%. Calcd for $C_{25}H_{31}N_3$: C, 80.38; H, 8.37; N, 11.25%. NMR spectrum in deuterochloroform: δ 6.76 (15H, phenyl protons), 5.76 (1H, singlet, methine proton), 3.39 (6H, methylene protons) and 1.09 ppm (9H, methyl protons). UV spectrum in chloroform λ_{max} mμ (ε): 249.5 (28100), 295.5 (5140).

The Reactions of TPE and TME with Halogens. The reaction of TPE with bromine will be described as a representative reaction. When an equimolar amount of bromine was added to a solution of 0.5 g of TPE in 10 m*l* of *n*-hexane, an orange solid precipitated immediately. After 10 m*l* of *n*-hexane had then been added to the reaction mixture, filtration gave an orange solid. Several fractional recrystallizations from acetonitrile gave 0.54 g (70%) of $TPEBr_2 \cdot 2H_2O$, mp 247°C (decomp.), as pale yellow prisms and 0.2 g of $TPEBr_6$, mp 223°C (decomp.), as orange prisms.

The reaction conditions of TPE and TME with halogens, the yields, the physical properties, and the results of elemental analyses of the corresponding oxamidinium halides are shown in Tables 1 and 3.

The Reactions of TPE and TME with Halogen-Compounds. The reaction of TPE with benzal chloride is shown as a representative reaction. A solution of 3 g of TPE and 5.4 g of benzal chloride in 20 m*l* of benzene was refluxed for 1 hr. After the reaction mixture had been cooled, it was filtered to give 3 g (83%) of $TPECl_2 \cdot 2H_2O$. The filtrate was concentrated *in vacuo* to leave yellow crystals which, on recrystallization from a benzene-methanol mixture gave 0.5 g (19%) of 1,1,2,2-tetrachloro-1,2-diphenylethane, mp 163—164°C (lit,[15] mp 163°C), as yellow needles.

Found: C, 52.68; H, 3.13%. Calcd for $C_{14}H_{10}Cl_4$: C, 52.53; H, 3.15%.

Furthermore, a small amount of stilbene was isolated by the gas chromatography of the filtrate after the separation of tetrachlorodiphenylethane.

The reaction conditions of TPE and TME with other halogen-compounds and the yields of the products are summarized in Table 2.

In the reactions with benzenesulfonyl chloride, phenacyl bromide, and 2,2-dichloroacenaphthenone,[16] diphenylsulfone, biphenacyl, and diacenaphthylidenedione were obtained respectively besides the corresponding oxamidinium dihalide.

Diphenyldisulfone, mp 194—195°C (lit,[17] mp 193—194°C).

Found: C, 50.86; H, 3.53%. Calcd for $C_{12}H_{10}O_4S_2$:

Table 3. Physical properties and elemental analyses of oxamidinium halides

Compound	Appearance (Recryst. solvent)	Mp(°C)	λ_{max}^{EtOH} mμ(ε)	Analysis (%), Found (Calcd)

C, 51.06; H, 3.57%.

Biphenacyl was identified as 2,4-dinitrophenylhydrazone, mp 239—240°C (decomp.). Found: C, 56.32; H, 3.68; N, 18.79%. Calcd for $C_{28}H_{22}O_8N_8$: C, 56.18; H, 3.70; N, 18.72%.

Diacenaphthylidenedione, mp 294°C, was identified by comparison with an authentic sample prepared from acenaphthenone and acenaphthenequinone.

The Reaction of TPE with Phenylnitromethane. A solution of 1.5 g of TPE and 5 g of phenylnitromethane in 20 m*l* of xylene was stirred at 90°C for 15 min; during this time crystals precipitated gradually. After the solution had then been cooled, filtration gave 1.0 g (51%) of colorless crystals which, on recrystallization from acetonitrile afforded a dinitrile, $TPE(NO_2)_2 \cdot 2H_2O$, mp 188°C (decomp.), as pale pink prisms.

Found: C, 54.00; H, 9.19; N, 17.00%. Calcd for $C_{22}H_{40}O_4N_6 \cdot 2H_2O$: C, 54.07; H, 9.08; N, 17.20%. IR spectrum: 1620, 1640 cm^{-1}. UV spectrum in water λ_{max} mμ (ε): 216 (28000), 291.5 (13400).

This compound was also obtained by the reaction of dihalides, $TPEX_2$, with silver nitrite.

A similar reaction of TME with phenylnitromethane in benzene at 80°C gave a 30% yield of crude dinitrite, $TME(NO_2)_2$, which, on recrystallization from methanol, gave yellow prisms, mp 246—248°C (decomp.).

Found: C, 43.35; H, 7.05; N, 16.97%. Calcd for $C_{18}H_{38}O_8N_6 \cdot 2H_2O$: C, 43.54; H, 7.31; N, 16.93%. IR spectrum: 1620, 1640 cm^{-1}. UV spectrum in water λ_{max} mμ (ε): 210 (31600), 296 (14600).

This compound was also obtained by the reaction of dihalides, $TMEX_2$, with silver nitrite.

The Reaction of TPE with Tetranitromethane. When a solution of 0.7 g of TPE and 0.5 m*l* of tetranitromethane in 15 m*l* of diethyl ether was stirred at 0°C for 30 min, yellow crystals precipitated gradually. Filtration gave 1.1 g of yellow crystals which, on fractional recrystallization from acetone, afforded 0.9 g of a 1 : 2 adduct, $TPE[C(NO_2)_4]_2$, mp 112°C (decomp.), as yellow needles and a small amount of a dinitrate, $TPE(NO_3)_2$, mp 222—223°C (decomp.) as colorless crystals.

Found: C, 43.82; H, 6.10; N, 21.12%. Calcd for $C_{24}H_{40}O_{12}N_{10}$: C, 43.63; H, 6.10; N, 21.10%.

The dinitrate was easily obtained from the dihalides, $TPEX_2$, with silver nitrate.

Found: C, 50.93; H, 8.61; N, 15.85%. Calcd for $C_{22}H_{40}O_6N_6 \cdot 2H_2O$: C, 50.75; H, 8.52; N, 16.14%. IR spectrum: 1620, 1640 cm^{-1}.

The Reaction of TPE with 1,3,5-*Trinitrobenzene.* To a benzene solution of 0.5 g of TPE was added, drop by drop, a benzene solution of two equimolar amounts of 1,3,5-trinitrobenzene at room temperature, forming purple crystals. Filtration gave purple crystals, mp 122—124°C (decomp.), which easily decomposed in air. The compound was analyzed without further purification.

Found: C, 51.52; H, 6.43; N, 17.07%. Calcd for $C_{34}H_{46}O_{12}N_{10}$: C, 51.90; H, 5.90; N, 17.80%.

The Reaction of TPE with Nitromethane. After a solution of 0.8 g of TPE and 4 m*l* of nitromethane in 6 m*l* of benzene had been refluxed under an atmosphere of nitrogen for 1.5 hr, the reaction mixture was concentrated *in vacuo*. The residue was washed with petroleum ether (bp 30—45°C) to leave 0.4 g (58%) of orange crystals which, on recrystallization from carbon tetrachloride, gave 1-nitro-2-piperidinoethylene, mp 94—95°C (lit,[18] mp 95°C), as pale yellow scales.

Found: C, 53.60; H, 7.73; N, 18.07%. Calcd for $C_7H_{12}O_2N_2$: C, 53.82; H, 7.74; N, 17.94%. IR spectrum: 1635 cm^{-1} ($\nu_{C=C}$). NMR spectrum in deuterochloroform: δ 1.71 (6H, methylene protons), 3.40 (4H, methylene protons), 6.86 and 8.17 ppm (each 1H, doublet, olefinic proton). UV spectrum in ethanol λ_{max} mμ (ε): 216.9 (7250), 240 (3780), 357 (33400). Mass spectrum: *m/e* 156 (M^+).

From the washings, 0.2 g of TPE was recovered.

A similar reaction of TME with nitromethane gave a 46% yield of 2-morpholino-1-nitroethylene, mp 138—140°C (lit,[18] mp 140—141°C), as yellow prisms (from ethyl acetate).

Found: C, 45.46; H, 6.32; N, 17.78%. Calcd for $C_6H_{10}O_3N_2$: C, 45.56; H, 6.37; N, 17.71%. IR spectrum: 1630 cm^{-1} ($\nu_{C=C}$). UV spectrum in ethanol λ_{max} mμ (ε): 213 (8250), 238 (3630), 353.5 (23000). Mass spectrum: *m/e* 158 (M^+).

The Reaction of TPE with Benzoic Acid. A mixture of 0.7 g of TPE and two equimolar amounts of benzoic acid in 10 m*l* of benzene was stirred at room temperature for 4 hr. Filtration gave 0.65 g (70%) of a colorless solid which, on recrystallization from methanol - ethyl acetate, afforded the dibenzoate, $TPE(PhCO_2)_2 \cdot 2H_2O$, mp 104—105°C, as colorless needles.

Found: C, 67.43; H, 8.76; N, 8.58%. Calcd for $C_{36}H_{50}O_4N_4 \cdot 2H_2O$: C, 67.68; H, 8.52; N, 8.77%. IR spectrum: 1635, 1610, 1550 cm^{-1}.

Similar reactions of TPE with *p*-methyl- and *p*-chlorobenzoic acid gave the corresponding oxamidinium salts. $TPE(p\text{-}MeC_6H_4CO_2)_2 \cdot 2H_2O$: mp 101—103°C, colorless needles (from methanol - ethyl acetate). Yield, 52%.

Found: C, 68.13; H, 8.95; N, 8.53%. Calcd for $C_{38}H_{54}O_4N_4 \cdot 2H_2O$: C, 68.44; H, 8.77; N, 8.40%. IR spectrum: 1637, 1610, 1545 cm^{-1}.

$TPE(p\text{-}ClC_6H_4CO_2)_2 \cdot 2H_2O$: mp 109—111°C, colorless needles (from methanol - ethyl acetate). Yield, 75%.

Found: C, 60.82; H, 7.75; N, 7.77%. Calcd for $C_{36}H_{48}O_4N_4Cl_2 \cdot 2H_2O$: C, 61.09; H, 7.40; N, 7.91%. IR spectrum: 1640, 1610, 1595, 1540 cm^{-1}.

(Received January 11, 1971)

An unequivocal determination of the absolute configuration of 5,5′- and 6,6′-disubstituted bis-1,1′-spiroindane and the behavior of the CD spectra of some 5,5′-disubstituted ones are described.

In the preceding paper,[1] the absolute configuration of (−)-6,6′-disubstituted-3,3,3′,3′-tetramethyl-bis-1,1′-spiroindanes was deduced to be (S)-configuration on the basis of the enantiomeric aspect of the CD spectra between (−)-6,6′-dihydroxy-3,3,3′,3′-tetramethyl-bis-1,1′-spiroindane, (−)-I and (+)-6,6′-dihydroxy-3,3,-5,3′,3′,5′-hexamethyl-bis-1,1′-spiroindane, (+)-II. The latter was determined to have (R)-configuration by an X-ray study of its 7,7′-dibromo derivative, (−)-III.[2] Also, the assignment of the absolute configuration was supported by the analysis of their CD spectra associated with the *p*-band transition by means of a coupled oscillator theory. However, there remains some ambiguity in the assignment of the absolute configuration, since a discrepancy is observed in the sign of the CD spectra of (−)-I and (+)-II associated with the *p*-band; also, the experimental CD spectrum in the α-band region is found to be inconsistent with the theoretical spectrum. Thus, it appeared to be important to establish the chemical correlation between the absolute configuration of (−)-I and that of (+)-II. Furthermore, as was pointed out in the previous paper, (+)-5,5′-dihydroxy-bis-1,1′-spiroindane, (+)-IX was considered to have (R)-configuration from the positively-signed Cotton effect associated with the α-band; this was done on the basis of an empirical observation that the sign of the CD spectra in the longest wavelength region was determined by the configuration of the spiro atom in bis-1,1′-spiroindanes. However, the empirical rule obtained previously could not be applied to (−)-III. Therefore, it is worthwhile to examine whether or not this rule can be applied to 5,5′-disubstituted derivatives.

In the present paper, an unequivocal determination of the absolute configuration of 5,5′- and 6,6′-disubstitutes bis-1,1′-spiroindane and the behavior of the CD spectra of some 5,5′-disubstituted ones will be described.

Chemical Correlation. 6,6′-Disubstituted bis-1,1′-spiroindane was easily prepared by the acid-catalysed cyclization of acetone with mono-substituted benzenes, such as phenols or toluene.[1,3] However, this method can not be applied to the preparation of 5,5′-disubstituted derivatives because of the orientation of the cyclization. As another route of preparing 5,5′-dimethoxy-bis-1,1′-spiroindane, we have adopted the cyclization of bis(3-methoxybenzyl)acetone with phosphorus oxychloride. However, the correlation of the absolute configurations of 6,6′-disubstituted derivatives with those of 5,5′-disubstituted derivatives has not yet been achieved by a chemical method.

The absolute configuration of (+)-6,6′-dihydroxy-3,3,5,3′,3′,5′-hexamethyl-bis-1,1′-spiroindane, (+)-II has already been established to be (R). Therefore, if the hydroxy group in (R)-(+)-II can be replaced by hydrogen, we can obtain the (R)-5,5′-dimethyl derivative VI. The conversion of the methyl groups of VI to other substituents or the replacement by hydrogen atoms will establish the configurational correlation among the 5,5′-, the 6,6′-disubstituted and the non-substituted spirobisindanes.

As is illustrated in the following scheme, the conversion has been realized. The treatment of the methanesulfonate of (R)-(+)-II with sodium in liquid ammonia afforded the desired deoxygenated product, the 5,5′-dimethyl derivative (R)-(+)-VI. (R)-(−)-3,3,3′,3′-Tetramethyl-bis-1,1′-spiroindane-5,5′-dicarboxylic acid (R)-(−)-VII was obtained by the chromium trioxide oxidation of (R)-(+)-VI. (R)-(−)-VII afforded (R)-(+)-5,5′-diamino-3,3,3′,3′-tetramethyl-bis-1,1′-spiroindane, (R)-(+)-VIII by the Schmidt reaction, as well as the nonsubstituted derivative (R)-(−)-V by the decarboxydation, according to the procedure[1] used for the 6,6′-dicarbohydroxy derivative (+)-IV.

As V obtained from (R)-(−)-VII had the same specific rotation at D-line and showed the same CD spectrum as that derived from (+)-IV, it is established, by the chemical correlation, that (S)-configuration must be assigned to (−)-6,6′-disubstituted bis-1,1′-spiroindanes; this assignment is in agreement with an inference based on the comparison of the CD spectra between (−)-I and (R)-(+)-II.

UV and CD Spectra. The UV and the CD spectra of these 5,5′-disubstituted derivatives are shown in Table 1 and in Figs. 1—4. The accessible UV and CD spectra of these compounds consist of three bands, which are termed α, *p*, and β from the longer wavelength, according to the classification by Clar. The analysis based upon the exciton theory was carried out for both the α- and the *p*-band systems of (R)-(+)-VI, (R)-(−)-VII, and (R)-(+)-VIII, the results are summarized in Table 2.

In dimeric systems with a C_2 symmetry axis, there are two coupling modes for each electronic transition

s: shoulder. !: lowest recorded values, not an extremum. a) As the result of re-examination, this weak CD band was found in (+)-(V) reported previously.

of the constituent monomer, one with *A*, and the other with *B* symmetry. The two coupling modes give rise to two CD bands with opposite signs, but the same in magnitude. Experimentally, the Cotton effects in the *p*-bands of these compounds are negative and then positive from the longer wavelength, and are almost identical in the magnitude of rotational strength, but in the α-band all the derivatives show mainly a single Cotton effect, as was observed in 6,6′-disubstituted derivatives.

In this method, we could obtain good results in the *p*-band region of the 6,6′-disubstituted derivatives, in

Table 2. Rotational strengths and frequency intervals of *R*-configuration

The values R and $\tilde{\nu}_A-\tilde{\nu}_B$ were calculated by the following equations:

$$R_A=-R_B=\pi\tilde{\nu}d\rho^2\cos v\cdot\cos t$$

$$\tilde{\nu}_A-\tilde{\nu}_B=2\rho^2(\cos^2 v-\cos^2 t+2\cos^2 r)/hcd^3$$

where d: the distance between the center of the two benzene rings; ρ: the transition dipole moment in the isolated chromophore; $\tilde{\nu}$: the wave number of the transition. The following value of the spectroscopic moment were used: COOH(−28), *t*-Butyl (2) and Methyl (7). The alkyl bridge which made up the spiro skeleton is regarded as a substituent except for (R)-(+)-VIII and the value of the *t*-Butyl was used. The angles r, t and v and d were calculated on the same geometry cited in the previous paper.[1]

Compd	Band	Found			Calculated				
		$\tilde{\nu}$ ($\times 10^2$ cm^{-1})	D (10^{-36} cgs)	R (10^{-40} cgs)	cos r	cos t	cos v	R (10^{-4} cgs)	$R\nu_A-\nu_B$ (cm^{-1})
(R)-(+)-VI	α A	363	2.34	+4.79	0.061	−0.811	0.582	−28.6	−39.1
	α B							+28.6	
	p B	444	1.40	−2.84	−0.890	0.233	−0.392	+ 4.01	+67.0
	p A			+4.54				− 4.01	
(R)-(−)-VII	α A	355	4.54	−1.90	−0.290	0.840	−0.458	−43.5	−80.1
	α B							+43.5	
	p B	403	24.3	−17.1	−0.842[a]	0.0[a]	0.540[a]	0.0	+1470.
	p A			+14.0				0.0	
(R)-(+)-VIII	α A	347	6.38	+9.07	−0.236	0.838	−0.491	−65.0	− 120.
	α B							+65.0	
	p B	412	22.9	−9.81	−0.859	0.056	0.508	−19.2	+2130.
	p A			+2.93				+19.2	

a) The values cos r, cos t and cos v amount to −0.866, 0.019 and 0.500, respectively, by the calculation on the envelope conformation described previously.[1] Employing them, the calculated sign of CD is consistent with that observed.

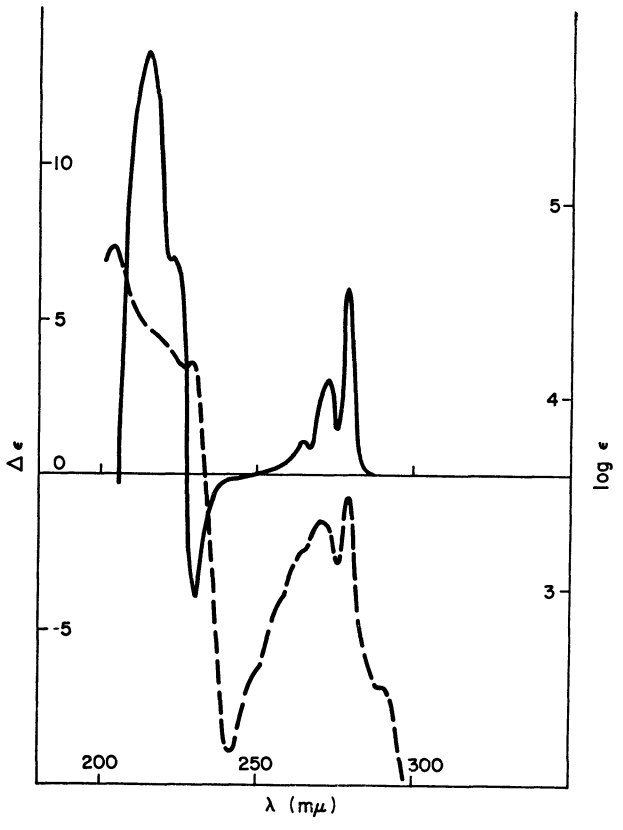

Fig. 1. CD (——) and UV (----) spectra of (R)-(+)-(VI) in isooctane.

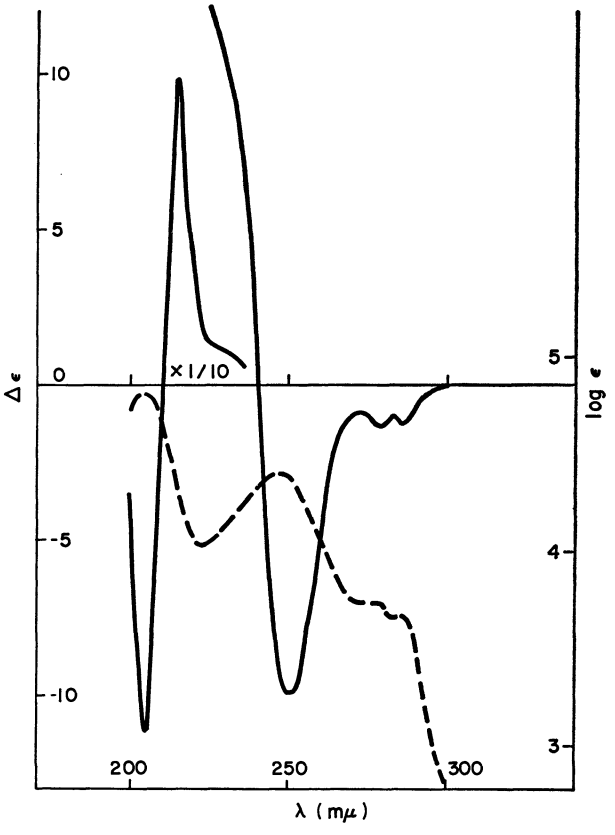

Fig. 2. CD (——) and UV (----) spectra of (R)-(−)-(VII) in methanol.

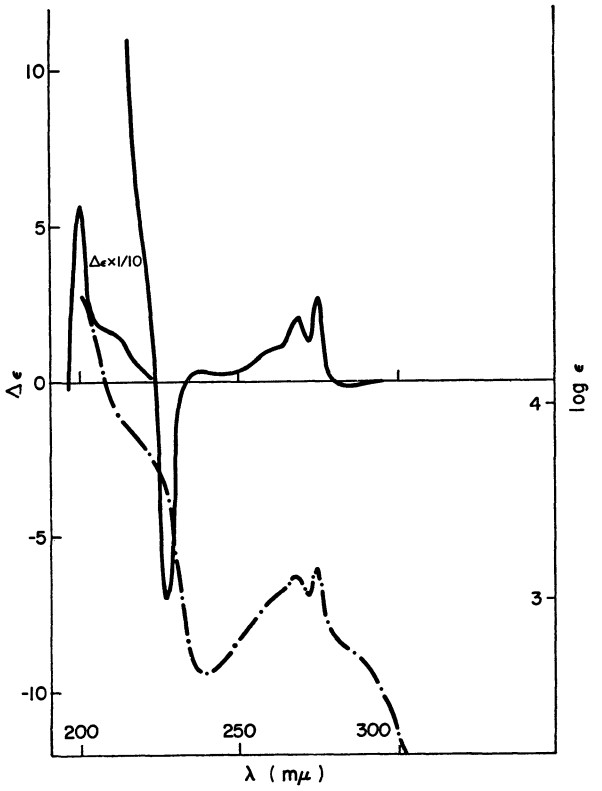

Fig. 4. CD (——) and UV (—·—·) spectra of (R)-(+)-(VIII)·HCl.

which substituents on benzene rings had a large value in the spectroscopic moment, as listed by Platt (Table 2). It can be said that the same results are observed in this series from the value in (R)-(+)-VIII, but the value of the cosine of the tangential angles, *t*, between the long-axis excitation dipole and the local Cartesian axis is small. Especially in (R)-(—)-VII, the excitation dipoles of the *p*-band of two chromophores are situated almost entirely on one plane. Therefore, the calculated value depends on the selection of the geometry of the molecule, the value of the spectroscopic moment for the alkyl bridge, and other factors. In such cases, extreme care must be taken in applying the coupled oscillator theory to the determination of the absolute configuration.

As is observed in 6,6′-disubstituted derivatives,[1] the values calculated by the coupled oscillator theory are not in accordance with those observed in the α-band region. The empirical rule obtained with 6,6′-disubstituted derivatives, that the spatial arrangement of the two benzene rings determines the sign of the CD in the longest-wavelength region, can be applied to (R)-(+)-VI and (R)-(+)-VIII, although the pattern of (R)-(—)-VII and (R)-(+)-VIII·HCl in the α-band does not agree with the above rule. The negative Cotton effect at the longest wavelength of (R)-(+)-VIII·HCl may not be correlated with the transition responsible for that of (R)-(+)-VIII. Therefore, the sign which corresponds to the same transition is positive in (R)-(+)-VIII·HCl (Figs. 1 and 4). The reason for the departure from the empirical rule of (R)-(—)-VII cannot, at present, be understood.

The CD of previously-prepared (+)-5,5′-dihydroxy-bis-1,1′-spiroindane, (+)-IX is similar to that of (R)-(+)-VIII in the pattern associated with the α- and *p*-bands. Since a hydroxy group has a large, positively-signed value in the spectroscopic moment, like an amino group, we can expect a similar CD pattern between VIII and IX with the same absolute configuration. Thus, we assign (R)-configuration to (+)-IX; this assignment is in agreement with that predicted previously.

Experimental

Melting points are uncorrected. Circular dichroism spectra were measured using a JASCO Model ORD/UV-6 apparatus. Optical rotations were measured on a Perkin-Elmer polarimeter Model 141 using a 1-dm quartz cell. Infrared spectra were taken with a JASCO Model 402G doublemonochromatic spectrophotometer. NMR spectra were measured in a solution of deuterio chloroform with a Varian A-60 spectrometer, using tetramethylsilane as the internal standard. Ultraviolet spectra were measured with a Hitachi Model EPS-3T spectrometer.

(R)-(+)-6,6′-Dihydroxy-3,3,5,5,3′,3′,5′-hexamethyl-bis-1,1′-spiroindanedimethanesulfonate. A solution of (R)-(+)-6,6′-dihydroxy-3,3,5,5,3′,3′,5′-hexamethyl-bis-1,1′-spiroindane ((R)-(+)-II, 2.2 g, $[\alpha]_D$ +18.9° (*c* 0.456, dioxane)),[1] and freshly-distilled methanesulfonyl chloride (2.2 m*l*) in pyridine (30 m*l*) was heated under reflux for one hour in a nitrogen atmosphere. A volatile material was then removed by distillation under reduced pressure. The residue was dissolved in ethyl acetate, after which the solution was washed with

water and dried over anhydrous sodium sulfate. After the evaporation of the ethylacetate under reduced pressure, the residue was crystallized from benzene-*n*-hexane to give prisms (2.14 g). mp 183—184°C, $[\alpha]_D$ +66.2° (*c* 0.998, chloroform). IR $\nu_{max}^{CHCl_3}$ 1368 cm^{-1}.

Found: C, 61.49; H, 6.56; S, 13.22%. Calcd for $C_{25}H_{32}O_6S_2$: C, 60.95; H, 6.55; S, 13.02%.

(R)-(+)-3,3,5,3',3',5'-Hexamethyl-bis-1,1'-spiroindane (R)-(+)-VI. A solution of the above obtained (+)-dimesyate (2.0 g) in dry tetrahydrofuran (10 m*l*) was added to liquid ammonia (150 m*l*). A small piece of sodium metal was then added under reflux with vigorous stirring. The end point of the reaction was shown by a persistent blue color of the reaction mixture. After stirring for 15 more min, ammonium chloride (0.5 g) was added and the ammonia was evaporated. Water (50 m*l*) was then added to the residue. The aqueous layer was extracted with ether and the combined organic layer was washed with water and dried on anhydrous sodium sulfate. The solvent was distilled under reduced pressure, and the residue was crystallized from methanolic water. Recrystallization from methanol gave prisms (811 mg, 65.6%). mp 76—78°C, $[\alpha]_D$ +1.8° (*c* 2.285, chloroform). NMR τ: 8.68 (6H, singlet), 8.63 (6H, singlet), 7.73 (4H, singlet), 7.67 (6H, singlet), 3.31 (2H, doublet, J=7.8 Hz), 2.9—3.2 (4H, multiplet).

Found: C, 90.56; H, 9.21%. Calcd for $C_{23}H_{28}$: C, 90.73; H, 9.27%.

(R)-(−)-3,3,3',3'-Bis-1,1'-spiroindane-5,5'-dicarboxylic Acid (R)-(−)-VII. Chromium trioxide (1.2 g) was added, in one portion, to a solution of (+)-VI (300 mg) in acetic acid (15 m*l*), water (9 m*l*), and concentrated sulfuric acid (1.5 m*l*). The mixture was heated under reflux for 7.5 hr and then poured into ice water (50 m*l*). After this mixture had been allowed to stand overnight, crystals were collected, washed with water, and then extracted with aqueous sodium hydroxide. The alkaline solution was acidified with dilute hydrochloric acid, and the resultant gel set aside overnight. The precipitated solid was dried and recrystallized from acetone-water (142 mg, 31.5%). mp>300°C, $[\alpha]_D$ −53.2° (*c* 0.468 dioxane). IR ν_{max}^{Nujol} 1690 cm^{-1}.

Found: C, 75.78; H, 6.64%. Calcd for $C_{23}H_{24}O_4$: C, 75.80; H, 6.68%.

(R)-(−)-3,3,3',3'-Tetramethyl-bis-1,1'-spiroindane (R)-(−)-V. A mixtur of (R)-(−)-VII (105 mg) and copper chromite (119 mg) in quinoline (3 m*l*, freshly distilled from copper chromite) was heated under reflux for 90 min. To the cooled reaction mixture, ether (20 m*l*) was added, after which an undissolved solid was removed by filtration. The solution was washed with 50% hydrochloric acid, aqueous sodium bicarbonate, and then water, and dried on anhydrous sodium sulfate. The ether was evaporated, and the residue was crystallized and recrystallized from ethanol to give colorless needles (42 mg, 52.7%). mp 124—125°C, $[\alpha]_D$ −30.4° (*c* 0.471, dioxane). The IR spectrum of this compound was identical with that of an authentic sample.[1)]

(R)-(+)-5,5'-Diamino-bis-1,1'-spiroindane (R)-(+)-VIII. Into a solution of (R)-(−)-VII (147 mg) in concentrated sulfuric acid (6.5 m*l*), sodium azide (215 mg) was added in small portions over a 50-min period at 40—45°C with stirring, Foaming occurred and stirring was continued at 50—55°C for 2 hr. The reaction mixture was allowed to stand overnight and then poured into ice water (50 m*l*). After this mixture had been made alkaline with 40% aqueous sodium hydroxide (35 m*l*) under cooling, yellow powders were collected, washed with water, and dried *in vacuo*. The crude powders were dissolved in benzene, and an amorphous solid was removed by filtration. After it had been concentrated to *ca.* 2 m*l* under reduced pressure, the solution was allowed to stand overnight; then the product was collected and dried *in vacuo* to give needles (64 mg). mp 208—210°C, $[\alpha]_D$ +8.3° (*c* 0.350, MeOH). IR ν_{max}^{Nujol} 3440, 3355 cm^{-1}.

Found: C, 82.55; H, 8.49; N, 9.41%. Calcd for $C_{21}H_{26}N_2$: C, 82.31; H, 8.55; N, 9.14%.

The Reaction of Nitriles with Phosgene. V[1]. Cyclization Reactions of *N*-(α-Chlorobenzylidene)carbamoyl Chloride

Shozo YANAGIDA, Masaaki YOKOE, Masataka OHOKA, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita

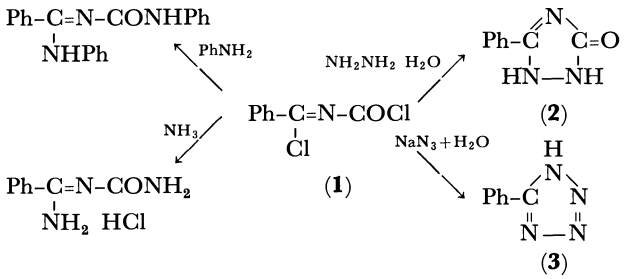
(Received January 20, 1971)

N-(α-Chlorobenzylidene)carbamoyl chloride (**1**) reacts with hydrazine hydrate to give 3-phenyl-1,2,4-triazolone (**2**), with sodium azide in the presence of water to give 5-phenyltetrazole (**3**), and with aliphatic nitriles in the presence of hydrogen chloride to give 6-chloro-2-phenyl-5-substituted-4(3*H*)-pyrimidones (**5**) and 4,6-dichloro-2-phenyl-5-substituted pyrimidines (**6**). However, the reaction of **1** with trichloroacetonitrile or pivalonitrile in the presence of hydrogen chloride did not give the expected triazines.

N-(α-Chlorobenzylidene)carbamoyl chloride (**1**) was prepared first by the reaction of benzoyl isocyanate with phosphorous pentachloride.[2] However, in the course of our work on the reaction of nitriles with phosgene, the carbamoyl chloride (**1**) has been found to be easily obtainable by the reaction of benzonitrile with phosgene in the presence of hydrogen chloride.[3] The carbamoyl chloride (**1**) has two reactive chlorine atoms in the molecule and thus can be expected to be useful as a precursor for the synthesis of nitrogen heterocycles. The Netherland patent claims that the carbamoyl chloride (**1**) reacts with amidines to give 2-hydroxy-6-phenyl-4-substituted-*s*-triazines.[4] In this paper we will report some cyclization reactions of the carbamoyl chloride (**1**) with some nucleophiles.

The reaction of the carbamoyl chloride (**1**) with excess aniline or ammonia gave *N*-phenyl-*N'*-anilinoformyl benzamidine and *N*-carbamoyl benzamidine hydrochloride respectively. On the other hand, the treatment of the carbamoyl chloride (**1**) with hydrazine hydrate gave the compound formulated as $C_8H_7N_3O$, which was confirmed to be 3-phenyl-1,2,4-triazolone (**2**) on the basis of the IR, NMR, and mass spectra.

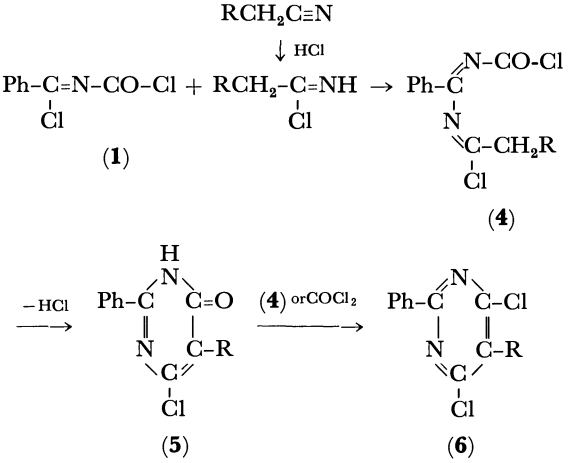
When the carbamoyl chloride (**1**) was allowed to react with sodium azide in aqueous acetone, 5-phenyltetrazole (**3**) was obtained, with the evolution of carbon dioxide. However, the reaction did not occur under anhydrous conditions, such as those in anhydrous THF.



Scheme 1

Recently several reactions concerning the electrophilic attack on the α-methylene of the C=N group have been reported.[5-7] In our previous papers,[7,8] we reported the preparation of 6-chloro-2,5-disubstituted-4(3*H*)-pyrimidones (**7**) by the reaction of aliphatic nitriles with phosgene in the presence of hydrogen chloride, in which *N*-(chloroformyl)-*N'*-(α-chloroalkylidene)alkylamidine was proposed as an intermediate. We assumed that the presence of hydrogen chloride promotes the polarization of the C=N bond in the intermediate, thus making the α-methylene more nucleophilic.

In view of these speculations, the carbamoyl chloride (**1**) can be expected to react with aliphatic nitriles in the presence of hydrogen chloride to afford 6-chloro-2-phenyl-5-substituted-4(3*H*)-pyrimidones (**5**) through *N*-(chloroformyl)-*N'*-(α-chloroalkylidene)-benzamidine (**4**), as is snown in Scheme 2. As expected, we have found the cyclization reaction of the carbamoyl chloride (**1**) with aliphatic nitriles in the presence of hydrogen chloride.



Scheme 2

When the carbamoyl chloride (**1**) was allowed to react with acetonitrile in the presence of hydrogen chloride (molar ratio 1 : 2 : 2) in a sealed glass tube at 60°C and the products were subjected to chromatographic separation, 6-chloro-2-phenyl-4(3*H*)-pyrimi-

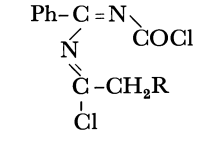
a) At room temperature.

done (**5a**), 4,6-dichloro-2-phenylpyrimidine (**6a**), 6-chloro-2-methyl-4(3*H*)-pyrimidone (**7a**), benzonitrile, and a tarry product were isolated. They were confirmed on the basis of the IR, NMR, and mass spectra, and by elemental analysis. It is known that the carbamoyl chloride (**1**) decomposes to benzonitrile and phosgene by heating.[3] Thus, the formation of **7a** is apparently due to the reaction of acetonitrile with the phosgene thus formed and hydrogen chloride.

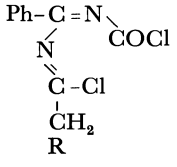
The reaction of **1** with aliphatic nitriles was extended to propionitrile, butyronitrile, valeronitrile, and capronitrile, giving the corresponding pyrimidine derivatives, **5b-e**, **6b-e**, and **7b-e**. (Table 1)

The treatment of **1** with 3-chloropropionitrile under comparable conditions, however, resulted in the isolation of a polymeric product which was similar in both appearance and quality to that obtained by the reaction of 3-chloropropionitrile with phosgene in the presence of hydrogen chloride.[7]

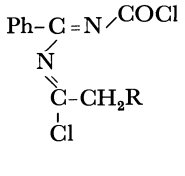
In order to avoid the side reactions and to increase the yield of **5**, the reaction was carried out at 30—35°C and finally the reaction temperature was raised to 60—65°C, as is shown in Runs 4, 5, 6, and 8 in Table 1. The formation of **7** was indeed diminished, as expected, but the dichloropyrimidines (**6**) were still forme din considerable amounts. In all the experiments the total yields of **5** and **6** were independent of the chain length of nitriles, but did not exceed 30%. It is assumed that the low yields are partly due to the configurations of the intermediate *N*-chloroformyl-*N'*-(α-chloroalkylidene)benzamidine (**4**) and/or the protonated one (**4'**). The intermediates **4** and/or **4'**, may have the following four configurations:



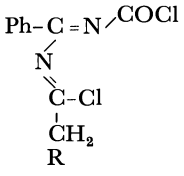
A



B



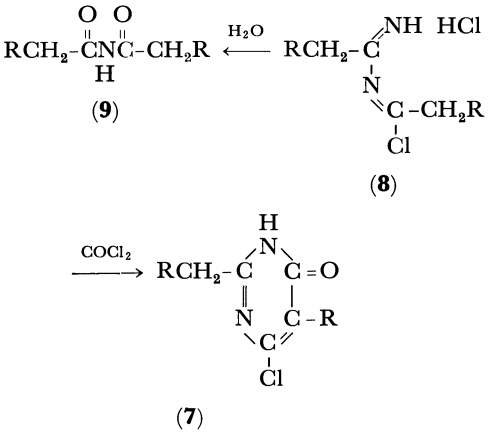
C



D

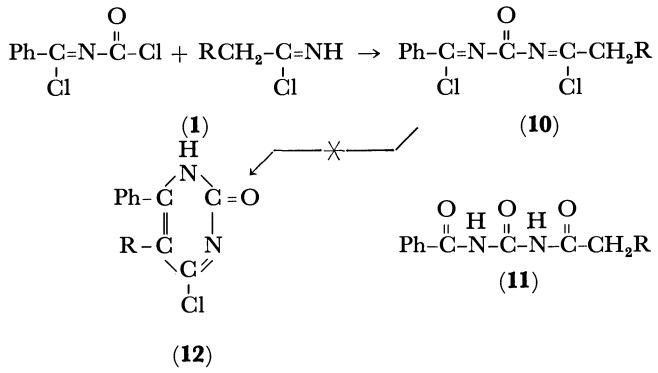
The protonation of **A**, **B**, **C**, and **D** would occur on a nitrogen bearing chloroalkylidene group.[7] It seems that **A** and protonated **A** are favorable configurations for the cyclization giving the **5** pyrimidones. However, judging from the facts that **6** did not produce under mild reaction conditions as is shown in Run 7 and that the pyrimidone **7** was formed only in traces in Runs 4, 6, and 8, non-cyclized intermediates which may exist in the **B**, **C**, and **D** and protanated **B**, **C**, and **D** forms may have a chlorinating ability and thus chlorinate **5** to give **6**, especially when the reaction temperature is raised. The chlorination by phosgene can not be neglected, either.

The treatment of the tarry residue obtained after column chromatographic separation with water gave a considerable amount of diacylamine (**9**) and a small amount of *N*,*N'*-diacylurea (**11**). The formation of **9** indicates the presence of *N*-(α-chloroalkylidene)-alkylamidine hydrochloride (**8**). As has been reported previously,[7] the pyrimidones **7** are formed by the reaction of **8** with phosgene. The isolation of **8** is now under investigation (Scheme 3).



Scheme 3

The isolation of **11** suggests the formation of *N*-(α-chlorobenzylidene)-*N'*-(α-chloroalkylidene)urea (**10**), which appears to be formed by the attack of the carbonyl carbon of **1** on the nitrogen atom of the imidoyl chloride (Scheme 4). The pyrimidone **12**, which may be formed by the intramolecular cyclization of **10**, was not isolated.



Scheme 4

In our preceding paper[3] we reported that the carbamoyl chloride (**1**) reacts with *p*-tolunitrile or benzonitrile in the presence of hydrogen chloride to give 2-chloro-4-phenyl-6-(*p*-tolyl)-*s*-triazine and 2-chloro-4,6-diphenyl-*s*-triazine respectively. Accordingly, it can be expected that **1** will react with aliphatic nitriles which have no α-hydrogen to give the corresponding triazines. However, the reaction of **1** with trichloroacetonitrile or pivalonitrile in the presence of hydrogen chloride gave only a small amount of 2-chloro-4,6-diphenyl-*s*-triazine, and the expected triazines were not obtained.

Experimental

All the melting points were determined on a Yanagimoto micromelting point apparatus and were corrected. The IR spectra were measured on a JASCO IR-E apparatus, the NMR spectra on a JEOL J.M. M-G-60 apparatus, and the mass spectra on a Hitachi RMU-6E apparatus.

N-(α-chlorobenzylidene)carbamoyl chloride was prepared from benzonitrile, phosgene, and hydrogen chloride according to our method.[3] The fraction with a bp of 85—90°C/1 mmHg was used.

Reaction of Aniline with ***1***. A solution of carbamoyl chloride **1** (1.0 g, 5 mmol) in 10 ml of benzene was added, drop by drop, to a solution of aniline (1.9 g, 20 mmol) in 15 *ml* of benzene under cooling in an ice-water bath. The precipitate thus formed was filtered and washed with cold water. After drying, they were recrystallized from aqueous acetone. The yield was almost quantitative (1.6 g, 100%), but the melting point was broad even after several recrystallizations. It began to melt around 159°C and melted completely below 172°C (lit,[9] 179—180°C) It was identified as *N*-phenyl-*N'*-anilinoformylbenzamidine on the basis of the following analytical results: IR(mull), 3200, 3070, 1695 and 1647 cm^{-1}; NMR(DMSO)(τ), 0.32(s, 1H), 0.55(s, 1H), 2.2—3.2(m, 15H); Mass(M^+) 315. Found: C, 76.30; H, 5.37; N, 13.42%. Calcd for $C_{20}H_{17}N_3O$, C, 76.17; H, 5.43; N, 13.33%,

Reaction of Ammonia with ***1***. The carbamoyl chloride **1** (1.8 g, 9.1 mmol) was stirred into an ethanol solution of ammonia under cooling. The precipitate thus formed was filtered, washed, dried, and recrystallized from a mixed solvent of methanol and isopropanol The yield was 49%. The melting point was also broad even after several recrystallizations. It began to melt around 167°C and melted completely below 185°C.(Lit,[10] 192—194°C). However, it was analyzed and identified as *N*-carbamoylbenzamidine hydrochloride on the basis of the following data: IR(mull), 3280, 3210, 1743 and 1671 cm^{-1}; Mass(M^+−HCl), 163. Found: C, 47.83; H, 5.05; N, 21.05; Cl, 18.09%. Cald for $C_8H_{10}N_3OCl$: C, 48.13; H, 5.05; N, 21.05; Cl, 18.09%.

Reaction of ***1*** *with Hydrazine Hydrate.* An acetone solution of hydrazine hydrate(0.25 g, 5 mmol) was mixed with the carbamoyl chloride **1** (0.5 g, 2.4 mmol) under cooling in an ice-water bath. The precipitate thus formed was treated as usual and recrystallized from acetone (58% yield). It was identified as 3-phenyl-1,2,4-triazolone (**2**) on the basis of the following data; mp 316.0—318.0°C (lit,[11] 321—322°C). Mass(M^+) 161, IR(KBr) *ca.* 3000, 1740 cm^{-1}, NMR (DMSO) (τ) *ca.* 2.25(m, 3H, *o*-H), −1.60(s, 1H, NH), −1.95(s, 1H, NH). Found: C, 59.50; H, 4.49; N, 26.29%. Calcd for $C_8H_7N_3O$: C, 59.62; H, 4.37; N, 26.07%.

Reaction of ***1*** *with Sodium Azide.* To a solution of sodium azide (0.16 g) in 1 m*l* of water we added a solution of the carbamoyl chloride **1** (0.5 g, 2.5 mmol) in 0.75 m*l* of acetone. The mixture was shaken in a water bath at 30°C. The precipitate thus formed was filtered, washed with acetone, and dried *in vacuo*. It was recrystallized from aqueous ethanol and identified as 5-phenyltetrazole (**3**) on the basis of the following analytical results: mp 217.0—219°C(dec)(lit,[12] 215°C(dec)). Mass(M^+) 146, IR(KBr) *ca.* 3000, 1560 cm^{-1}. Found: C, 58.00; H, 3.91; N, 38.53%. Calcd for $C_7H_6N_4$: C, 57.53; H, 4.14; N, 38.33%. Yield, 53%.

Reaction of ***1*** *with Aliphatic Nitriles in the Presence of Hydrogen Chlorides. General Procedure.* In a 20-m*l* glass tube we placed the carbamoyl chloride **1** (9.9 mmol), aliphatic nitrile (20 mmol), and chlorobenzene (2 g). Dry hydrogen chloride (16—17 mmol) was bubbled into the mixture under cooling. The tube was then stoppered, cooled in a dry ice-acetone mixture, sealed carefully, and allowed to stand at 30—35°C or heated to 60—65°C, as is shown in Table 1. After the end of the reaction, the reaction tube was chilled in dry ice-acetone mixture, and opened. The reaction mixture was concentrated under reduced pressure. In some cases, the removal of the hydrogen chloride gave the precipitate of the pyrimidone **5**. After the filtration of the precipitate, the mixture was concentrated as has been mentioned above. The resulting residue was chromatographed on silica gel. The dichloropyrimidines **6** were eluted with petroleum ether, the pyrimidones **5** with chloroform, and the pyrimidones **7** with a mixture of chloroform and ethanol. The pyrimidones **5** were purified by recrystallization from ethanol. The dichloropyrimidines **6** were purified by sublimation or recrystallization from aqueous ethanol. The analytical data are summarized in Tables 2 and 3.

The pyrimidones **7** were identified by comparison with authentic samples.

*Isolation of Diacylamines (****9****) and N-Benzoyl-N'-acylureas (****11****).* Oily products eluted with a mixture of chloroform and ethanol on the above-mentioned column chromatography were treated with aqueous acetone. The reaction mixture was then allowed to stand overnight. The resulting precipitates were filtered and sublimated under reduced pressure. Diacylamines **9** sublimed at 90°C under reduced pressure and *N*-benzoyl-*N'*-acylureas **11** at 140°C under the same conditions.

Photochemical Rearrangement of *N*-Substituted Benzylanilines[1]

Yoshiro OGATA and Katsuhiko TAKAGI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received January 26, 1971)

Photochemical migration of an alkyl group from nitrogen to ortho and para positions in *N*-substituted benzylanilines (I) has been studied. Quenching study suggests that the rearrangement proceeds *via* a triplet state. The rate of disappearance of *N*-(*p*-tolyl)-α-phenethylamine (III) in photolysis was found to be 3×10^7—3×10^8 sec^{-1}. Substituted benzylanilines (I) were synthesized to estimate their quantum yields of photorearrangement. A plot of the σ value for a substituent in the migrating benzyl group *vs.* logarithm of relative rate gives a positive ρ value with various quantum yields for intersystem crossing (0.1—1); the ρ value indicates that electron-withdrawing substituents in the benzyl group accelerate the rearrangement. A reaction scheme is presented.

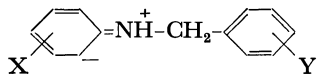
In a previous paper,[2] it was reported that irradiation of *N*-alkylanilines with UV light gave rearranged products, *ortho*- and *para*-alkylanilines (5.5—42.5%), together with aniline (1.6—12.8%) and coupling product of alkyl radicals (0—3%). Intramolecularity of migration of the alkyl group from *N* to ortho and para positions is probable because (i) no cross-bred product was detectable, and (ii) appreciable optical activity was retained in both ortho- and para-rearranged products derived from optically active *N*-α-phenethylaniline.

Photochemical aromatic rearrangements involving the migration of a side-chain group to the ring carbon are known with some aromatic esters,[3] amides,[4] carbonates,[5] ethers,[6] and amines.[2] So far the mechanism of rearrangement has been studied in only a few cases. As an example, it has been suggested in the photo-Fries reaction (X : O, Y : COAr) by either a molecular pathway involving ion-separated intermediate,[7-9] or a radical-pair process in which acyl-O homolysis is followed by an attack of the resulting acyl radical on the ring of phenoxy radical in a solvent cage.[10]

$$C_6H_5\text{-}X\text{-}Y \xrightarrow{h\nu} \begin{matrix}[C_6H_5\text{-}X^- \ {}^+Y] \\ [C_6H_5\text{-}X\cdot \ \cdot Y]\end{matrix} \rightarrow o\text{- and } p\text{-}Y\text{-}C_6H_4\text{-}XH$$

The former molecular mechanism involving ion-separated species seems to be supported by (i) the substituent effect[8,10] with a positive ρ value for migrating benzoyl groups and a negative ρ value for aryloxy groups, (ii) acceleration by polar solvents,[9] and (iii) the quantum yield for *p*-tolyl acetate which is unaffected by a 100-fold change in solvent viscosity, in contrast with 20-fold enhancement of *p*-cresol formation.

N-Alkylanilines generally absorb 243—248 nm light to be excited to charge-separated species (IV),[2] hence electron-withdrawing groups in the migrating alkyl groups and electron-releasing groups on the anilino



(IV)

group of *N*-alkylanilines may accelerate the rearrangement, if the reaction proceeds *via* a zwitterionic transition state (IV).

Since the mechanistic details of the photorearrangement of *N*-alkylanilines is unknown, we wish to report this mechanism, especially on the basis of substituent effect.

Results

Irradiation of *N*-phenylbenzylamine gave *ortho*- and *para*-benzylanilines (28.9 and 13.6%, respectively) together with aniline (5.8%) and bibenzyl (3.0%).

For elucidation of the reaction pathway, the para-position of the anilino group was shielded by a methyl group to yield ortho-rearranged product alone. A series of *N*-(*p*-tolyl)benzylamines with a substituent on the benzyl group (Ia—If) and phenylbenzylamines with a para substituent on the phenyl group (Ig—Ih) were prepared (Table 3).

The amines (Ia—If) were irradiated with ultraviolet light on a preparative scale as a solution of isopropanol–*t*-butanol (1 : 1 in vol.) (IPA–*t*-BuOH). The reaction products were separated by column chromatography, and identified and estimated by means of UV, IR, TLC and GLC techniques. The yields are summarized in Table 1. An attempt to crystallize the rearranged products failed.

In the case of the nitro compound (If), the rearranged product could not be obtained because of its slow rate of photorearrangement.

Measurement of Quantum Yields. Quantum yields for the disappearance of substrates were measured by the following method under UV light of 2537

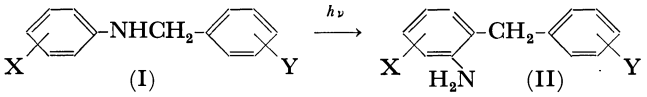
Table 1. Photochemical rearrangement of substituted *N*-benzylanilines[a]



Photolysate	X	Y	Conv. (%)	Yield (%)[b]	Irrad. time (hr)
IIa	*p*-Me	*p*-Me	34.7	24.9	51
IIc	*p*-Me	H	56	24	40
IId	*p*-Me	*p*-Cl	76	12	31
IIe	*p*-Me	*p*-CN	56	31	51

a) In a IPA–*t*-BuOH (*ca.* 0.1 M). The mixtures were condensed by evaporation and chromatographed on a 300×20 mm column of SiO_2. Isomers were confirmed by IR ($-NH_2$), UV, TLC, and GLPC.
b) Based on the consumed substrates.

Å with a low pressure mercury lamp (Halos POL 30). Light intensities were measured with a potassium ferrioxalate solution. Disappearance of secondary amines was potentiometrically determined by Siggia's method.[11]

The reaction was interrupted when the conversion was less than *ca.* 20% to minimize the absorption of the UV light by photoproducts. The quantum yields of the *p*-toluidine formation were determined by GLC. The results are summarized in Table 2.

Table 2. Quantum yields for the disappearance of substituted *N*-benzylanilines and formation of *p*-toluidine

Substituted *N*-benzylaniline	X	Y	Quantum yield (ϕ)	
			Disappearance of starting material	Toluidine formation[b]
Ia	*p*-Me	*p*-Me	0.16±0.01	0.06±0.01
Ib	*p*-Me	*m*-Me	0.15±0.01	0.05±0.01
Ic	*p*-Me	H	0.20±0.02	0.08±0.03
Id	*p*-Me	*p*-Cl	0.23±0.03	—
Ie	*p*-Me	*p*-CN	0.27±0.03	trace
If	*p*-Me	*p*-NO_2	0.13±0.02	—
Ig	*p*-MeO	H	0.22±0.01	—[a]
Ih	*p*-Cl	H	—[a]	—[a]

a) Not determined.
b) Decomposition product.

In the case of amines with an electron-withdrawing group, especially in Ih with para-chloro group in the anilino group, a decrease of amine basicity made potentiometric determination of quantum yield difficult. Table 2 lists average quantum yields calculated from at least three observed values. The difference between these quantum yields is regarded as significant beyond experimental error. The potentiometry was checked to give reliable data of less than 10% error in comparison with GLC technique.

Reaction Multiplicity. In a preliminary experiment, a heavy atom effect was observed, *i.e.*, the photorearrangement of *N*-(*p*-methylbenzyl)aniline was accelerated in *n*-propyl chloride compared with that in *n*-hexane. The result seems to indicate the intermediacy of a triplet state.[12] The reaction multiplicity was further confirmed by quenching experiments. Solutions of 0.02—0.03 M *N*-(*p*-tolyl)-α-phenethylamine in IPA-*t*-BuOH containing a quencher, naphthalene, were irradiated on a merry-go-round apparatus with 2537 Å light. A plot of reciprocal of quantum yield *vs.* quencher concentration lies on a good straight line. The disappearance of substrate and the formation of the rearranged product were measured by GLC.

In quenching by naphthalene, self absorption by the quencher may affect the intensity of incident light. As an example, the ratio of the light quanta absorbed by naphthalene to those by Ia was calculated to be more than 20% in the presence of two equivalent amounts of naphthalene. A singlet state as well as a triplet state may be quenched. Quenching by piperylene was also examined. The Sterm-Volmer plots obtained with piperylene is shown in Fig. 1, in which a fairly good linearity is observed. Piperylene was confirmed to be transparent at least at a wavelength longer than 250 nm, although it exhibits an absorption maximum at 232 nm in methanol. In the measurement of fluorescence intensities of Ia with various amounts of piperylene, neither fluorescence intensity nor the maximum at 370 nm varies with the change of 0—4.5 equivalents amount of piperylene, which implies that piperylene does not quench the singlet of Ia at all, since the Stern-Volmer plot of Fig. 1 is obtained within a range of 3 equivalents amount of piperylene.

The results suggest that the rearrangement occurs *via* a triplet state. The energy transfer from the excited substrate to the quencher would be allowed, since the triplet energies of 61 kcal/mol (naphthalene) and 59 kcal/mol (piperylene) are probably lower than that of substrate, which is expected to be *ca.* 70 kcal/mol from those of aniline (77 kcal/mol), diphenylamine (72 kcal/mol) and triphenylamine (70 kcal/mol).

Measurement of the Rate of Photolysis of III. Aqueous monochloroacetic acid is easily hydrolyzed to give glycolic acid and chloride ion by irradiation of 2537 Å light. The quantum yield for the hydrolysis of the acid (0.5 M) has been determined to be 0.351 at 28°C.[13] The solution was employed as a chemical actinometer, as it is convenient to measure the light intensities of 2537 Å in diffused light. The amount of 0.02 M *N*-(*p*-tolyl)-α-phenethylamine(III) in IPA–*t*-BuOH containing an appropriate amount of piperylene was irradiated by 2537 Å light at 28°C with a merry-go-round apparatus.

The conversion of substrate was determined by GLC using acenaphthene as an internal standard. The quantum yield for the disappearance of substrate was calculated to be 0.10 in the absence of a quencher. The Stern-Volmer plots (*cf.* Eq. (2)) obtained from reciprocals of the quantum yields ($1/\phi$) against the piperylene concentration ([Q]) gave a straight line, with a slope of 90 as shown in Fig. 1.

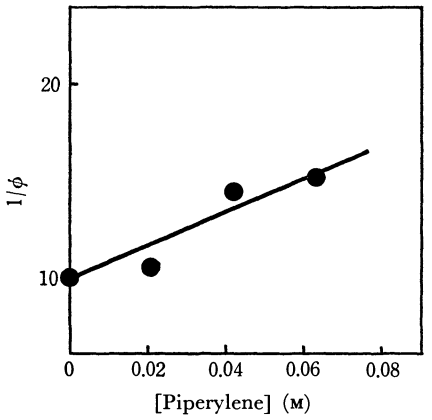

Fig. 1. Stern-Volmer plot of the disappearance of 0.02 M *N*-(*p*-toly)-α-phenethylamine (III).

The quenching rate was estimated by the following Debye equation.

$$k_q = 8RT/3000\eta \quad (1)$$

The rate constant k_q was 2.4×10^9 M$^{-1}\cdot$sec^{-1}, since the viscosity of IPA–*t*-BuOH, was found to be 0.0196 poise at 28°C. In the following Stern-Volmer equation, where k_d and k_r are rate constants for deactivation and reaction, respectively, [Q], the concentration of a quencher, and $f(=\phi_{isc})$, the quantum yield for intersystem crossing from excited singlet state to excited triplet state (Eq. (5)),

$$1/\phi = \{(k_d+k_r)/f\cdot k_r\} + \{k_q\cdot[Q]/f\cdot k_r\}, \quad (2)$$

the slope of the plot of $1/\phi$ *vs.* [Q] gave

$$k_q/f\cdot k_r = 90 \quad (3)$$

Assuming that the quenching rate is equal to the diffusion-controlled rate, we have $f\cdot k_r=2.7\times10^7$ sec^{-1}. The rate constant for the rearrangement was calculated to be 2.7×10^7—2.7×10^8 sec^{-1} because of $0.1<f<1$.

Discussion

The photochemical primary and secondary processes of the reaction can be expressed by means of Eqs. (4)—(10).

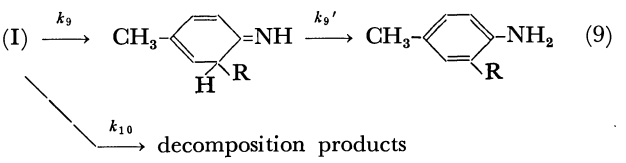
$$p\text{-}CH_3\text{-}C_6H_4\text{-}NHR \xrightarrow{h\nu} A^1 \quad (4)$$
$$(A^0)$$

$$A^1 \xrightarrow{k_{st}} A^3 \quad (5)$$

$$A^3 \xrightarrow{k_d} A^0 \quad (6)$$

$$A^3 \xrightarrow{k_r} [p\text{-}CH_3C_6H_4\text{-}NH\cdots\cdots R] \quad (7)$$
$$(I)$$

$$A^3 + Q \xrightarrow{k_q} A^0 + Q^3 \quad (8)$$



(9)

(10)

These equations give the quantum yield (ϕ) for the disappearance of substrate as

$$\phi = f\cdot k_r/(k_d + k_r + k_q[Q]) \quad (11)$$

From this equation, we obtain the following equation, since no quencher is added to the mixture, *i.e.*, [Q]=0.

$$\frac{1/\phi_H - 1/f_H}{1/\phi_X - 1/f_X} = \frac{f_X\cdot k_{rX}\cdot k_{dH}}{f_H\cdot k_{rH}\cdot k_{dX}} \quad (12)$$

Here, subscript X and H denote *N*-(*p*-tolyl)benzylamine substituted and unsubstituted in the benzyl ring, respectively; subscripts k_r and k_d denote the rate constants for Eqs. (6) and (7), respectively.

In general, the observed quantum yields for substituted *N*-(*p*-tolyl)benzylamines (I) decrease with the increase of electron-donative ability of the substituent, *e.g.*, from 0.27 in Ie (*p*-CN) to 0.16 in Ia (*p*-Me). The approximate linearity of the plot of log ϕ *vs.* Hammett σ was observed, in which a trend of an increase of the quantum yield with the increase of σ is obvious.

Since little information concerning f values is available at present, the following approximation was deduced to see a correlation between the σ value and the relative rate constant k_{rX}/k_{rH}, *i.e.* the approximate independence of f and k_d on substituents.

Firstly, as suggested by Lamola and Hammond,[14a] quantum yield f for intersystem crossing would depend little on substituent X, *i.e.*, $f_H\sim f_X\sim f$. They suggested that the same factors influence the rates of radiationless transitions ($S^1\rightarrow S^0$) and intersystem crossing ($S^1\rightarrow T^1$) in studying the substituent effect of substituted naphthalene on their quantum yields for f values. This means that a substituent hardly affects the efficiency of intersystem crossing.

Secondly, it can be assumed that the deactivation process (corresponding to k_{dX}) from a π–π^* excited state (as well as n–π^*) is hardly affected by substituent X. The approximate constancy of k_{dX}, but not k_{rX}, is often reported.[14b–f] Zimmerman[14c,d] estimated that the decay rate constant k_d remains nearly constant in the photorearrangement of 4,4'-diarylcyclohexanone, while k_r varies over *ca.* 100-fold. Mallory[14e] and Jungmann[14f] reported the substituent effect on the photocyclization of stilbenes to the corresponding phenanthrenes *via* a π–π^* excited state, in which a nice Hammett correlation with the correlation factor of 0.9996 between k_{rX}/k_{rH} and σ is observed assuming the decay

rate constant k_{dX} remains constant. The results seem to support the assumption that k_{dX} is approximately constant.

The substituents on the migrating benzyl group are expected to have less effect on the decay process of the excited energy on the aniline ring moiety of the substrate, if the excitation energy related to the 2537 Å light absorption at the latter moiety is localized on the aniline ring.[15]

From the above approximation, we have tentatively assumed that k_{dX} and f_X are independent of X for Ia—If studied. Hence, $(f_X/f_H)(k_{dH}/k_{dX})$ may be approximately constant, and Eq. (12) can be simplified to

$$\frac{1/\phi_H - 1/f}{1/\phi_X - 1/f} = \alpha\frac{k_{rX}}{k_{rH}} \tag{13}$$

where $\alpha = f_X \cdot k_{dH}/(f_H \cdot k_{dX})$. The Hammett equation is then applicable as in Eq. 14 which is shown in Fig. 2 based on the data on Table 2.

$$\log\left(\frac{1/\phi_H - 1/f}{1/\phi_X - 1/f}\right) = \sigma\rho + \text{const.} \tag{14}$$

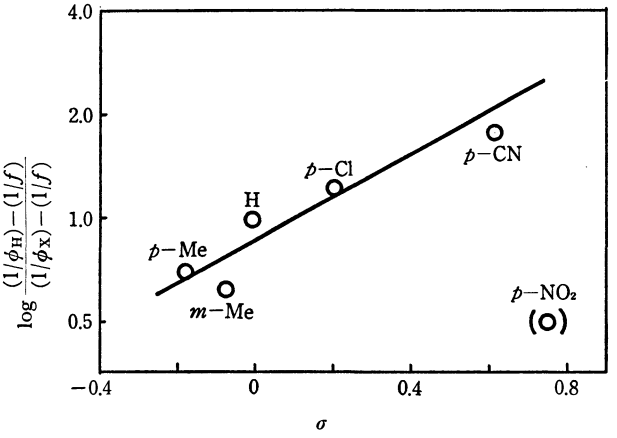

Fig. 2. Relationship between $\log\frac{(1/\phi_H)-(1/f)}{(1/\phi_X)-(1/f)}$ and σ with quantum yields for intersystem crossing (f) of 0.5.

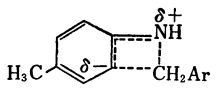
The nitro compound was excluded, since its unusual behavior would be due to the deactivation of excited compound by the reduction of the nitro group to nitroso[16] and/or amino groups.[17]

The σ values used for the plot were quoted from Jaffe's review.[18] A positive ρ value was obtained from Fig. 2 with values of f 0.1—1. A plot of Eq. (14) gave a better correlation than that of log ϕ *vs.* σ value. This also supports the above approximation that k_{dX} is less affected by substituent. A linear Hammett plot has been presented in the photo-Fries reaction,[8,10] which seems to suggest the validity of the Hammett equation for some photoreactions.

The electron density on the anilino nitrogen atom is delocalized into the ring in an excited state of *N*-alkylaniline (*cf.* IV). In the case of ionic mechanism, the requirement for the rearrangement is the electron defficiency at benzyl carbon and the electron richness at ortho position of the anilino ring, thus a positive ρ value for the migrating group can be expected. This ionic scheme, however, cannot explain the by-product, bialkyl. It is natural that the rearrangement almost certainly proceeds *via* a radical process, although the possibility of an ionic rearrangement cannot completely be discarded.

Our previous view that the optical activity is retained in the photorearrangement of optically active *N*-α-phenethylaniline excludes the possibility of the intermediacy of free benzyl radical which should be nearly planar in the migrating transition state. Thus either a bridged intermediate (V), or a radical-pair resulting from the scission of nitrogen-benzyl bond, which can very rapidly recombine in a solvent cage,[10] is conceivable in the transition state.



(V)

The positive ρ value can be explained by either reaction scheme. In the bridged scheme, the activated complex V should have more complete benzyl-ortho carbon bond and less complete benzyl-amino nitrogen bond, hence an electron-withdrawing group in the benzyl group can accelerate the rearrangement, because the rate seems to be determined by the electrophilic attack of the benzyl group but not by the benzyl-nitrogen bond fission.

In another mechanism of the homolytic scission in a solvent cage, the positive ρ value can be explained as follows. The rate-determining step for the homolytic rearrangement may be the coupling of benzyl radical with the anilino radical to give products, since the C–N fission step should be rapid in view of the analogous photo-rearrangement of *p*-substituted acetanilides which have high relative ratios ($\phi_B/\phi_F \sim 3$) of quantum yields for coupling of $CH_3CO\cdot$ and Ph-NH· to give starting materials (ϕ_B) compared to those of the forward reactions (ϕ_F).[4b] The observed ρ value suggests a higher contribution of substituent effect on the electrophilic nature of benzyl radical for an attack on the benzene ring. Although the substituent effect of benzyl radical attack is unavailable, reaction rates for phenylation of toluene by substituted phenyl radicals have been reported to vary with substituents in the order: *p*-NO_2>*p*-Cl>H>*p*-Me.[19] This means that the phenylation of toluene has a positive ρ value. Also the effect of substituent in the aryloxy ring in photo-Fries reaction is known to have a positive ρ value.[8,10]

On the other hand, the effect of substituent in anilino group on the present rearrangement is obscure on account of the small number of substituents and the difficulty in analysis. Further, the problem is complicated by the fact that a substituent para to the amino group is also meta to the attacking site. Observed

quantum yields are 0.20 (*p*-Me) and 0.22 (*p*-MeO), which are comparable to those observed with the substituents in benzyl groups.

Experimental

All mp and bp are uncorrected. IR spectra were measured by the method of liquid film using a Perkin-Elmer grating infrared spectrophotometer Model 337. UV spectra were measured with a Shimadzu UV spectrophotometer Model SV-50 A or a Hitachi spectrophotometer Model 124. GLC analysis was carried out by means of a Yanagimoto gas chromatograph with FID, Model GCG-550 F, employing a 1.7 m×2.5 mm column packed with PEG 20 M (2.5wt%) on Chamelite CS of 80—100 mesh using N_2 as a carrier gas at 160—250°C. Fluorescence spectra were measured at room temperature with a Hitachi fluorescence spectrophotometer, Model MPF-2A.

Preparation of Substituted Benzylanilines (I). Benzylanilines were prepared by the reaction of *p*-substituted anilines with substituted benzyl chlorides (or bromides) in an aqueous benzene solution containing $NaHCO_3$.[2] The products were purified by vacuum distillation, except for *p*-cyano (Ie) and *p*-nitro compounds (If) which solidified on distillation of starting materials and was purified by recrystallization from petroleum ether. The starting materials are listed in Table 3. All these amines were chromatographed for complete removal of unreacted toluidine before use.

Preparation of N-(p-Tolyl)-α-phenethylamine (III). *N*-(*p*-Tolyl)-α-phenethylamine(III) was prepared by the reaction of *p*-toluidine with α-chloroethylbenzene, mp 68.5—69°C (from petroleum ether), bp 130—133°C/2.5 mmHg, λ_{max}^{MeOH} (nm) (log ε), 248(4.10) and 302(3.27).

Isolation of Rearranged Products. On irradiation of *N*-substituted benzyl(*p*-tolyl)amines in a preparative scale, rearranged products were isolated.

All experiments were carried out in a cylindrical quartz vessel (20×150 mm) under N_2. A Halos high 300 W Hg lamp with a water cooling quartz jacket was used as a light source. Isolated products were identified and estimated by IR, UV, TLC, and GLC.

(2'-Amino-4'-methylphenyl)-4-methylphenylmethane (IIa). A solution of Ia (0.7 g) in *i*-PrOH-*t*-BuOH (30 ml) was irradiated in a quartz vessel for 51 hr. The condensed reaction mixture was chromatographed on a 15×300 mm column, slurry packed in benzene with 80—100 mesh silica gel, using benzene (600 g) and benzene- 3% acetone (100 g) as eluents. Fractions 4—9 was Ia (451 mg), fractions 21—41 was IIa (pale yellow oil, 63.4 mg, 24.9%), λ_{max}^{MeOH} (nm), 238, 292; ν_{max} (cm^{-1}), 3430, 3350, and fraction 85 was *p*-toluidine (62 mg).

(2'-Amino-4'-methylphenyl)phenylmethane (IIc). A solution of Ic (0.7 g) in *i*-PrOH-*t*-BuOH (30 ml) was irradiated for 40 hr. Column chromatography gave recovered starting material (Ic, 350 mg) and a rearranged solid product (IIc, 107 mg, 24%), λ_{max}^{MeOH} (nm), 237, 292; ν_{max} (cm^{-1}), 3430, 3350 (primary amine).

(2'-Amino-4'-methylphenyl)-4-chlorophenylmethane (IId). A solution of Id (0.7 g) in *i*-PrOH-*t*-BuOH (30 ml) was irradiated for 31 hr. In a similar manner, recovered Id (168 mg) and a rearranged liquid product (IId, 64 mg, 12%) were isolated, λ_{max}^{MeOH} (nm), 240 (sh), 294; ν_{max} (cm^{-1}), 3420, 3350 (primary amine), 1090 (C–Cl).

(2'-Amino-4'-methylphenyl)4-cyanophenylmethane (IIe). A solution of Ie (1.795 g) in ethanol (120 ml) in a quartz vessel (35×170 mm) was irradiated for 51 hr at room temperature. Rearranged product IIe (246 mg, 31%) was separated from the reaction mixture by column chromatography, λ_{max}^{MeOH} (nm), 235, 295; ν_{max} (cm^{-1}), 3430, 3350 (primary amine), 2200 (C–N). Rearranged products, except IIc, could not be crystallized even by keeping in an ice-box.

2-Phenethyl-4-methylaniline (IV). A solution of III (0.82 g) in methanol (30 ml) was irradiated in a quartz vessel for 25 hr. The condensed reaction mixture was similarly treated to yield the rearranged product (IV, 155 mg, 22%), ν_{max} (cm^{-1}), 3430 and 3350 (primary amine).

Measurement of Quantum Yield. Quantum yields were determined by method A or B. Method A affords the quantum yield for photolysis of *N*-benzylainlines, and method B

Table 3. Physical properties of substituted *N*-benzylanilines[a]

was used for quenching studies to measure the rate of photolysis of *N*-(*p*-tolyl)-α-phenethylamine (III).

Method A. A spiral type low pressure Hg lamp (Halos POL 30) was employed as a light source of 2537 Å. The light intensity incident on the sample was measured by a potassium ferrioxalate solution as a chemical actinometer. The long-size quartz cell (50×24 mm) for UV spectrophotometer was used as a reaction vessel with flat faces perpendicular to light beams.

About 23 m*l* of a *ca.* 0.04 M amine solution in *i*-PrOH-*t*-BuOH was photolyzed until 20% conversion was attained.

After irradiation, the reaction mixture was diluted to 25.0 m*l* with isopropanol. The amount of photolyzed amine was determined by Siggia's method.[11]

An aliquot (10 m*l*) of the above product solution, after dilution with ethylene glycol (10 m*l*), was potentiometrically titrated with 0.1 N HCl in ethylene glycol-isopropanol.

Neutralization point was determined by plotting the apparent pH against volume of the acid solution to give the total amount of secondary plus primary amines.

Another aliquot (10 m*l*) of the solution was added with ethylene glycol (10 m*l*), and titrated similarly with acid to estimate the amount of the secondary amine after 30 min. mixing excess salicylaldehyde (*ca.* 0.3 m*l*). The amount of photolyzed amine was calculated as a difference (total amine)−(secondary amine), within ±10% experimental error. For example, an *i*-PrOH-*t*-BuOH solution of Ia (1.00×10^{-3} mol) was irradiated by 2537 Å for 10 hr, and then diluted to 25.0 m*l*. An aliquot (10 m*l*) of the diluted solution was potentiometrically analyzed for unreacted secondary amine to be 0.65×10^{-3} mol and the other aliquot (5 m*l*) for the unreacted amine to be 0.59×10^{-3} mol by the method of GLC analysis. Both analytical methods exhibit relative experimental errors below 10%.

Method B. A cylindrical low pressure Hg lamp (Halos HIL 30) was employed as a 2537 Å light source. Irradiation was carried out under diffused light on a turn table which rotates around the light source. Five cylindrical quartz vessels (200×8 mm) were used for the reaction. The incident light intensities were measured on the basis of the known quantum yield (0.351 at 28°C) for photochemical hydrolysis of 0.5 M aqueous monochloroacetic acid by 2537 Å irradiation.[13] The chloride ion produced from the acid was measured by means of back-titration of excess silver nitrate by standard ammonium thiocyanate. An aqueous solution of the acid was photolyzed for 3 hr to yield *ca.* 1.0×10^{-4} mol of chloride ion.

For the quenching studies, a solution of 0.02—0.03 M *N*-(*p*-tolyl)-α-phenethylamine in *i*-PrOH-*t*-BuOH (10 m*l*) containing an appropriate amount of the quencher (0—0.15 M in naphthalene, 0—0.06 M in piperylene) was used.

The authors wish to thank Dr. Y. Izawa for his advice and Sumitomo Chem. Ind. Co. for their gift of materials. Thanks are also due to Dr. K. Aoki for his aid in the fluorescence spectrophotometric analysis.

A Facile Desulfurization Reaction with a Combination of Two Kinds of Metals in Acidic Media. The Synthesis of Hypoxanthine

Nobuhiro NAKAMIZO*, Kazuo SHIOZAKI, Seiichi HIRAI, and Shiro KUDO

Sakai Factory, Kyowa Hakko Kogyo Co., Ltd., Sakai, Osaka

(Received February 15, 1971)

A facile desulfurization procedure has been presented for the method that synthesizes hypoxanthine in one step by heating 4,5-diamino-6-hydroxy-2-mercaptopyrimidine with a desulfurizing agent in formic acid. When Raney nickel prepared in the usual way was used as the desulfurizing agent, it was necessary for the ratio of nickel atoms to sulfur atoms (the Ni/S ratio) to be more than 2.6 : 1. On the contrary, when the Raney alloy *per se* was used, the amount of nickel could be diminished to a catalytic amount (Ni/S 0.2—0.3). The higher the content of aluminum in the alloy, the smaller the Ni/S ratio required for the desulfurization. In contrast with usual desulfurization reactions carried out in neutral media, most of the sulfur was released from the reaction mixture as hydrogen sulfide. Although aluminum or iron powder by itself had little desulfurizing activity, its addition to the Raney alloy was useful in diminishing the Ni/S ratio. Furthermore, combinations of nickel or cobalt salts and aluminum or iron powder were as effective as the Raney alloy as desulfurizing catalysts. In the case of a combination of nickel formate and aluminum powder, a large portion of the nickel ion was proved to be reduced to metallic nickel. The desulfurization reaction also proceeded smoothly in an aqueous solution of hydrochloric or sulfuric acid. On the basis of these facts, a mechanism was proposed with which the active nickel catalyst is regenerated by such auxiliary metals as aluminum or iron.

Since the study[1] by Bougault *et al.* in 1939, desulfurization reactions of sulfur-containing organic compounds by means of Raney nickel have been extensively used both for synthesis and for structure determination.[2-4] In general, the desulfurization reactions are conducted by heating a mixture of sulfur-containing substrates with "excess" Raney nickel (the ratio of Ni : substrate by weight being from about 1 : 1 to 10 : 1) in such a solvent as ethanol. The hydrogen required for the formation of a new C–H bond usually comes, not from external hydrogen, but from that retained by the catalyst during its preparation. Most of the original sulfur is converted to nickel sulfide during desulfurization.[5]

From such characteristics of the reaction, it can be said that it is undesirable for reductive desulfurization to use an amount of Raney nickel less than that required for the formation of nickel sulfide. In practice, much more of the catalyst than the theoretical amount must be used in order to obtain a good yield. From an industrial standpoint, however, not only Raney nickel is expensive, but also its preparation on a large scale is very troublesome. Consequently, in spite of the usefulness of this procedure in laboratory work, its industrial application has been highly limited.

In the synthesis of hypoxanthine (VI) from 4,5-diamino-6-hydroxy-2-mercaptopyrimidine (I) (Scheme 1), the present authors found that, when the desulfurization is carried out with the Raney nickel *alloy* itself or with a combination of a nickel salt and aluminum (or iron) powder in an acidic medium, it is possible to decrease the amount of nickel required to a great extent.

origin. The Raney nickel alloy was purchased from the Nikki Kagaku Co., Ltd.

4,5-Diamino-6-hydroxy-2-mercaptopyrimidine (I) was prepared by the procedure of Albert *et al.*[10] with some modifications. Into a suspension of 192 g of 4-amino-6-hydroxy-2-mercapto-5-nitrosopyrimidine[6] in 950 m*l* of water, 576 g of sodium dithionite was added with stirring. Within 3 min, the color of the reaction mixture disappeared, the temperature rose from 28°C to 50°C, and the pH dropped from 7 to 5.5. After cooling to 0°C, the product was separated by filtration, washed with water, and dried *in vacuo*. Yield, 99%. (Found: C, 30.69; H, 4.01; N, 35.27; S, 20.41%)

Desulfurization Procedure. In a 3-*l* three-necked flask fitted with a mechanical stirrer, a reflux condenser, and a thermometer, 50.0 g (0.316 mol) of I and 1900 g of formic acid of the concentration desired were placed. After an appropriate amount of the desulfurizing catalyst had then been added, the mixture was refluxed with stirring for eight hours. The gas evolved from the reaction mixture was passed into a 2.5 N solution (1 *l*) of sodium hydroxide in order to collect the hytrogen sulfide, and was finally led to a gas meter. Aliquots of the hydrogen sulfide solution were withdrawn at suitable intervals and analyzed by iodometry. After 8 hr, the waste catalyst was filtered off and washed with formic acid of a concentration equal to that used in the reaction. (Although an evolution of heat from the waste catalyst was sometimes observed during the filtration, there was no danger of ignition.) The filtrate and the washings were then combined and evaporated to dryness under a pressure of 100 mmHg on a water bath. To the residue was added 300 m*l* of water. The crude crystals of hypoxanthine thus obtained were thoroughly triturated, filtered, and washed with 100 m*l* of water.

Analytical Procedure. *Total sulfur* was analyzed by the method of Bethge.[15] *Sulfide-type sulfur* in the waste catalyst was transformed to hydrogen sulfide with hydrochloric acid and determined iodometrically. *Nickel or aluminum* was determined in the form of perchlorate by chelatometric titration. A mixture of an aliquot of the sample dissolved in perchloric acid and 50 m*l* of F/100 EDTA was heated to boiling, and then titrated with F/100 $Pb(NO_3)_2$ at pH 5, using xylenol orange as an indicator, in order to determine the total amounts of Ni and Al.

After this titration, 10 m*l* of a 5% NH_4F solution was added and the mixture was again boiled in order to decompose the Al-EDTA chelate. The EDTA liberated by this treatment was titrated with F/100 $Pb(NO_3)_2$ in order to estimate the amount of Al. From the difference between these two values, the amount of Ni was determined. For samples which contain so little amount Ni or Al that the chelatometric titration could not be used, spectrophotometric analysis[16,17] was applied. If pyrimidines and/or purines were present in the sample, they were decomposed with a nitric acid-perchloric acid mixture before analysing the metals. The amount of metallic nickel in the waste catalyst was determined by subtracting the sum of the amounts of the water-soluble and the sulfide-type nickel from that of the total nickel. Similarly, the amount of metallic aluminum was estimated from the difference between the amount of the water-soluble aluminum and the total aluminum.

Results and Discussion

The Raney-nickel desulfurization reaction is very useful for syntheses of organic compounds, in particular, that of heterocyclic compounds.[2,3] For example, hypoxanthine can be synthesized from 4,5-diamino-6-hydroxy-2-mercaptopyrimidine (I) *via* Raney-nickel desulfurization,[8-12] formylation,[14] and cyclization,[11,12] as is indicated in Scheme 1.

In the procedure to synthesize hypoxanthine in one step by heating the pyrimidine (I) with Raney nickel in 90% formic acid[18], when the ratio of nickel atoms to sulfur atoms (Ni/S ratio) was 6.6 : 1, crude hypoxanthine was obtained in an 87% yield (Table 1). The sulfur content of the product was 0.23%, indicating that the desulfurization was almost complete. The crude product gave pure hypoxanthine in an 83% yield after recrystallization. However, at a Ni/S ratio of less than 2.6 : 1, the reaction was incomplete and gave a deep yellow product which was difficult to purify. Thus, it was confirmed that, so long as Raney nickel is used as a desulfurizing agent, the use of an "excess" of nickel is essential.

Table 1. Desulfurization reactions of I with Raney Ni and Raney alloy in 90% formic acid

Desulfurizing agents	Ni/S	Crude VI yield, %	Sulfur[a] in crude VI %
Raney Ni	6.6	87	0.23
	2.6	79	2.37
	1.8	77	2.73
Ni-Al alloy	2.6	88	0.00
	1.8	78	0.01
	1.3	82	0.00
	1.2	83	0.10
	1.0	76	0.25
	0.8	74	0.08

a) S% for 2-mercapto-6-hydroxypyrimidine: 19.06%.

It is known that the results of the reductive desulfurization depend on the quantity of hydrogen available as well as on that of nickel, as Eqs. (1) and (2) show:

$$\mathrm{R\text{-}S\text{-}R' \xrightarrow{Ni} R\cdot + \cdot R' \begin{cases} \xrightarrow{\text{excess H}} \mathrm{RH + R'H} & (1) \\ \xrightarrow{\text{deficient H}} \mathrm{RR + RR' + R'R'} & (2) \end{cases}}$$

When a so-called "degassed" catalyst is used, dimeric products are mainly produced.[2,3] For the purpose of the hydrogenolytic desulfurization, as in the present work, the more hydrogen there is, the better will be the result. Papa *et al.*[19] found that nickel-aluminum alloy (Raney alloy) and aqueous alkali bring about a rupture of the carbon-sulfur linkage. In this case, the quantity of hydrogen available may be much more than that in the desulfurization with Raney nickel.

18) C.-E. Liau, K. Yamashita, and M. Matsui, *Agr. Biol. Chem.* (Tokyo), **26**, 624 (1962).

19) D. Papa, E. Schwenk, and H. F. Ginsberg, *J. Org. Chem.*, **14**, 723 (1949).

These facts and considerations prompted us to use Raney alloy *per se* in aqueous formic acid. Table 1 shows that, under conditions similar to those used with Raney nickel, the treatment with Raney alloy containing 50% Al by weight leads to an almost complete desulfurization, even when the Ni/S ratio is 0.8 : 1. In contrast with the usual desulfurization, which is carried out in a neutral medium, a large portion of the sulfur eliminated from the substrate during the reaction is transformed into hydrogen sulfide and is released from the reaction mixture. Only a small portion of the sulfur remains in the system as nickel sulfide. When the Ni/S ratio was 0.8 : 1, more than 90% of the sulfur in the starting material was recovered as hydrogen sulfide and nickel sulfide. It should be noted that the gram atoms of sulfur removed amount to more than the nickel used. Furthermore, the value of the Ni/S ratio can be greatly diminished by using a Raney alloy which contains more than 50% aluminum. The results are shown in Table 2. The higher the content of aluminum in the alloy, the smaller the Ni/S ratio required for the desulfurization. By using an alloy which is 70% aluminum, the desulfurization yield reached 90%, even when the Ni/S ratio was 0.2 : 1.

Table 2. Desulfurization reactions of I with Raney alloy in 80% formic acid

Ni-Al alloy	Ni/S	Yield of VI		Sulfur in crystal %	Desulfurization yield, %[a)]
		Crystal	Mother liquor		
Al 58%	0.50	77	9	0.08	94
	0.40	82	8	0.27	94
	0.30	66	10	0.47	91
	0.20	38	17	4.69	72
Al 70%	0.30	79	6	—	92
	0.25	77	5	—	91
	0.20	82	3	—	90

a) $\frac{H_2S(mol)\ evolved + S(atom)\ in\ NiS}{S(atom)\ in\ starting\ material} \times 100$

Figure 1 shows the dependence of the hydrogen sulfide evolution rate on the aluminum contents of the alloys used. If the Ni/S ratio is constant, the higher the content of aluminum, the more rapid the rate of the evolution of hydrogen sulfide.[20)]

Figure 2 shows the effect of the Ni/S ratio on the evolution rate of hydrogen sulfide in the reactions with the alloy containing 70% aluminum in 80% formic acid. The effect of the Ni/S ratio on the hypoxanthine formation rate is indicated in Fig. 3. It can be seen by a comparison of Fig. 3 with Fig. 2 that the rate of the formation of hypoxanthine is independent of the Ni/S ratio, unlike the rate of the evolution of hydrogen sulfide, and that the former is smaller than the latter. These facts suggest that if the requirements for the desulfurization are satisfied, the desulfurization rate can not be rate-determining. The rate-determining step is assumed to be the cyclization step of V to VI for the following reasons: 1) it is well known that the formylation reactions of I to II[6,7)] and of IV to V[14)] are very rapid in hot formic acid; 2) the cyclization reaction

○ Ni/S=0.30; △ Ni/S=0.25; □ Ni/S=0.20

20) It should be remembered that the rate of the evolution of hydrogen sulfide may not necessarily represent the rate of the C–S bond cleavage, because the former rate depends on the rate with which hydrogen carries hydrogen sulfide out of the reaction vessel. As expected, the rate of the evolution of hydrogen becomes more rapid as the quantity of aluminum increases.

of II to III is said to be more difficult than that of V to VI[21]; 3) the ultraviolet absorption spectrum of a spot (R_f 0.61, solvent system 5 N acetic acid : 1-butanol=1 : 2) which appeared on the paper-chromatogram of the reaction mixture was identical with that of V, and 4) V was recovered in a 5% yield from the mother liquor of hypoxanthine after 8 hours of reaction.

Figure 4 demonstrates the effect of the addition of aluminum or iron powder on the desulfurization reaction in which Raney alloy (Ni/S ratio=0.2 : 1) was used. These metallic powders clearly revealed an accelerating effect, though they were not so effective as aluminum in the Raney alloy. Thus, it was established that hydrogenolytic desulfurization in aqueous formic acid does not always require a stoichiometric amount or an "excess" of nickel, provided that a sufficient amount of metallic aluminum or iron is present.

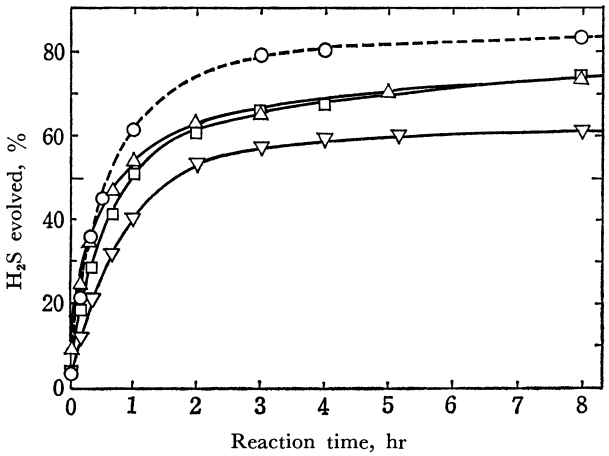

Fig. 4. Effect of addition of Al or Fe powder (Al content of alloy: 58%, in 80% HCOOH).

○ 0.30	—	1.04
△ 0.20	Fe	1.04
□ 0.20	Al	1.04
▽ 0.20	—	0.70

As will be described later (see Table 3), metallic aluminum or iron by itself has little desulfurizing activity. Therefore, we propose the following mechanism for the desulfurization reaction with the Raney nickel alloy in acidic media (Eqs. (3) to (9)):

$$\text{-Ni-Al-} + H^+ \rightarrow \text{active Ni} + Al^+ + H \quad (3)$$

$$\text{-Ni-Ni-} + RSH \rightarrow \text{-Ni-R} + \text{-Ni-SH} \quad (4)$$

$$\text{-Ni-R} + H \rightarrow \text{-Ni-} + RH \quad (5)$$

$$\text{-Ni-SH} \rightarrow \text{Ni sulfide} + H \quad (6)$$

$$\text{-Ni-SH} + H^+ \rightarrow Ni^+ + H_2S \quad (7)$$

$$Ni^+ + Al \rightarrow Ni + Al^+ \quad (8)$$

$$\text{-Ni-SH} + H^+ \rightarrow Ni + H_2S + Al^+ \quad (9)$$
(-Al)

To simplify, let us consider the transfer of only one electron.

As is shown in Eq. (3), the Raney nickel alloy reacts with the acid to provide an active catalyst and hydrogen.

The substrate is adsorbed on the nickel surface to give an organic radical (Eq. (4)), which subsequently changes into the final product by combining with a hydrogen atom (Eq. (5)). On the other hand, the sulfur atom bonded to the nickel atom, depending upon the acidity of the medium, yields nickel sulfide (Eq. (6)) or gives a nickel ion and hydrogen sulfide (Eq. (7)). The nickel ion produced in the latter process is again reduced into metallic nickel by metals (these will hereafter be called "auxiliary metals") having a larger tendency of ionization, such as aluminum or iron.

Therefore, the auxiliary metals seem to play two roles, that of a hydrogen-atom supplier for the substrate (Eq. (3)) and that of a reducing agent for ionized nickel (Eq. (8)). Such a regenerating mechanism of metallic nickel with catalytic activity can be operative only when two requirements are satisfied—that metals having a larger tendency of ionization than nickel are present and that the reaction medium is acidic enough to liberate hydrogen sulfide from nickel sulfide. In the case of the Raney alloy, electron transfer from aluminum to nickel may occur within the crystal lattice of the alloy as at the local cells in the corrosion of metals (Eq. (9)). In brief, nickel is considered to be protected by the auxiliary metals against inactivation due to ionization.

If the regenerating mechanism of nickel described above is correct, it will not always be necessary to use nickel in the metallic state, that is, it will be possible to use, for the same purpose, many combinations of appropriate nickel *salts* and metals with oxidation-reduction potentials more negative than that of nickel. This expectation was realized, as is shown in Fig. 5

and Table 3. The combination of nickel formate and iron powder caused about 80% of the theoretical yield of hydrogen sulfide to evolve. A similar result was also obtained when the combination of nickel formate and aluminum powder was used. Furthermore, even when a cobaltous chloride-iron powder system was used, a smooth desulfurization reaction was observed.[22]

Table 4 shows the fate of nickel and aluminum after the desulfurization reactions. It is clearly shown in the last column that a considerable portion of the nickel ions in the nickel formate was reduced to metallic nickel. When the desulfurization reaction was incomplete, as when the Ni/S ratio was 0.2 : 1 (see Table 2), little or no metallic nickel and aluminum remained after the reaction.

All of the desulfurization reactions described above were carried out in aqueous formic acid. Hence, there is a possibility that the formic acid might play a specific role in the reductive desulfurization. This is not the case, however. The desulfurization reaction was also successfully performed in some mineral acids, as is shown in Fig. 6. (In these cases, the product was not, of course, hypoxanthine, but 4,5-diamino-6-hydroxypyrimidine.) In particular, 1 N sulfuric acid was a good medium. Hydrochloric acid was inferior to sulfuric acid as a reaction medium. This disadvantage seems to be accounted for by the fact that hydrochloric acid allows a large portion of hydrogen to evolve before the reaction temperature required for desulfurization is reached. Therefore, the kinds and concentrations of acids must be selected so that the reaction of the auxiliary metals with acids does not proceed too violently below the temperature required for the desulfurization.

For the same reason, it is necessary to select the auxiliary metals, which should have a more negative oxidation-reduction potential than nickel (or cobalt), from such metals that the rate of the evolution of hy-

22) Since the presence of the auxiliary metals in the course of the desulfurization reaction is essential for the present purpose, the direct addition of the nickel or cobalt salt and the auxiliary metal to the reaction mixture is of greater advantage than the use of an Urushibara catalyst[23] prepared in the usual way.
23) Y. Urushibara, S. Nishimura, and H. Uehara, This Bulletin, **29**, 446 (1956).

drogen at a given acidity is not so fast as the rate of desulfurization. Zinc powder was, for example, unsuitable as an auxiliary metal, because it reacts with 80% formic acid so rapidly that the evolution of the theoretical amount of hydrogen was completed in the course of raising the temperature (below 60°C) (see Table 3).

Table 3 also reveals that the metallic salts other than nickel and cobalt salts, that is, cupric sulfate, lead diacetate, and cadmium diacetate, have little or no desulfurizing activity. Aluminum or zinc powder by itself shows little activity. As for iron powder, the desulfurization reaction was observed, but to a lesser extent.

Of great interest is the fact that the metals effective for the desulfurization in the present conditions are confined to the Group VIII metals in the periodic table. The question of why the Group VIII metals can dissociate the carbon-sulfur bond in the adsorbed compound into radicals is an important problem to be solved in the future.

In conclusion, the present procedure can be expected to provide a convenient technique for the desulfurization of acid-stable compounds not only in industry, but also in the laboratory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2197—2202 (1971)

Synthesis of Poly Substituted *cis*-Hydrindanes[1)]

Kagetoshi YAMAMOTO, Takashi SOHDA,* Ichiro KAWASAKI, and Takeo KANEKO**

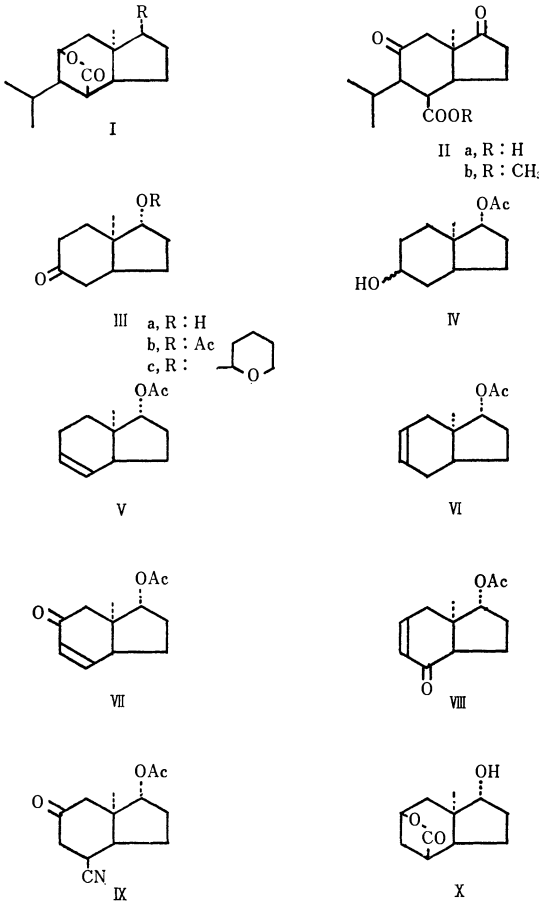
Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 17, 1971)

cis-4-Carboxy-5-isopropyl-8-methylhydrindane-1,6-dione was synthesized from *cis*-1-hydroxy-8-methylhydrindanone-5 as a useful intermediate for the synthesis of picrotoxin and dendrobine.

cis-4-Carboxy-6-hydroxy-5-isopropyl-8-methylhydrindane lactone-4,6 (I) is a moiety of picrotoxinin, picrotin, tutin, coriamytrin, dendrobine and related alkaloids which are known as peculiar sesquiterpene and sesquiterpene alkaloid.[2)] *cis*-4-Carboxy-5-isopropyl-8-methylhydrindane-1,6-dione (II) may be regarded as a possible intermediate on the way to the synthesis of these compounds. We have studied the procedure to derive compound II from *cis*-1-hydroxy-8-methylhydrindanone-5 (III), which was prepared according to Boyce's method.[3)]

Formation of γ-lactone on six membered ring of *cis*-hydrindane was first studied. Sodium borohydride reduction of acetate IIIb gave an alcohol in good yield. Dehydration of alcohol IV gave a mixture of olefins V and VI, which could not be separated from each other by means of gas chromatography or TLC. Allylic oxidation of the mixture of olefins with *t*-butyl chromate afforded a mixture of α,β-unsaturated ketones VII (75%) and VIII (25%). Pure compound VII was isolated by chromatography on silica gel. Hydrocyanation of compound VII gave a cyanoketone and a pure epimeric isomer was separated (mp 105—107°C) by chromatography on silica gel. Their stereochemistry was determined by the fact that reduction with sodium borohydride and subsequent hydrolysis gave a γ-lactone (IR: 1760 cm^{-1}). An attempt to introduce an isopropyl group at C_5-position of compound VII was unsuccessful, but we were able to ascertain the procedure of the formation of lactone. We therefore dealt with 5-isopropyl-8-



1) A part of this work was presented at the 22nd annual meeting the Chemical Society of Japan, Tokyo, April 3, 1969 and at the 14th symposium on the chemistry of natural products of the Chemical Society of Japan, Fukuoka, October 29, 1970.

* Present address: Chemical Research Laboratories, Takeda Chemical Ind., Ltd., Juso, Higashiyodogawa, Osaka.

** Present address: Research Laboratory of Shiseido Co. Ltd., Nippa-cho, Kohoku-ku, Yokohama.

2) L. A. Poter, *Chem. Rev.*, **67**, 441 (1967).

methylhydrindane derivatives in an analogous way.

To introduce the isopropyl group at C_5-position, compound III was treated with dihydropyran and a few drops of concentrated hydrochloric acid to give a pyranyl ether IIIc in good yield. Compound IIIc was treated repeatedly with isopropyllithium in petroleum ether to afford compound XIa in 52% yield. Dialcohol XIb, obtained from compound XIa by treatment with 2 N hydrochloric acid in tetrahydrofuran, was oxidized with chromium trioxide in a mixture of acetone and acetic acid to give a keto alcohol XII.

A Δ^4-olefinic compound will be obtained predominantly by dehydration of compound XII because a Δ^4-olefinic compound is more stable than a Δ^5-olefinic compound in *cis*-8-methylhydrindane system.[4]

A mixture of keto olefins was obtained from compound XII by heating at 200°C with potassium hydrogensulfate. VPC analysis of dehydration products showed three peaks with the ratio 7 : 3 : 1 (retention time: 2.7, 3.8, and 5.5 min, respectively). The main product was isolated by column chromatography using silica gel treated with silver nitrate.[5,6] The remaining isomers were separated by preparative gas chromatography. The structure of the main product XIII was confirmed by NMR spectra which showed olefinic proton at 5.32 ppm (d, 1H, J=2.5 Hz). The structures of the two other keto olefins were elucidated also by NMR spectra. Isomer XIV showed olefinic proton at 5.30 ppm (m, 1H), while isomer XV had no absorption of olefinic proton but olefinic methyl groups at 1.65 ppm (s, 6H).

Three other methods were investigated in order to increase the yield of XIII. Dehydration of XII by treatment with phosphorus oxychloride in pyridine gave XIII : XIV : XV=6 : 3 : 1. Dehydration by treatment with iodine-hydrochloric acid in benzene gave 6 : 3 : 1 and dehydration by heating on alumina which was treated with pyridine[7,8] gave 10 : 5 : 1. Evidently the most useful method was dehydration with potassium hydrogensulfate. Isomerization from XIV and XV to XIII did not occur under the conditions of sodium ethoxide or hydrochloric acid in ethanol.

For the preparation of compound XVII, allylic oxidation of compound XIII was studied. Direct oxidation of XIII with *t*-butyl chromate in benzene afforded an α,β-unsaturated ketone XIX in only 5% yield. On the other hand, reduction of XIII with lithium aluminum hydride in ether and successive acetylation gave compound XVIb in 90% yield. Oxidation of acetyl derivative XVIb with selenium oxide gave compound XVIIb in 19% yield and also gave a small amount of isomerized compound. Oxidation of XVIb with *t*-butyl chromate in benzene under reflux for 60 hr afforded a mixture, which was separated by silica gel chromatography to give compound XVIIb in 11% yield and recovered material XVIb in 50% yield. Therefore the latter route (XIII→XVIb→XVIIb) was useful for the preparation of the compound XVIIb.

Compound XVIIb was hydrolyzed with 2 N sodium hydroxide in methanol and then oxidized with Jones' reagent[9] to give compound XIX in good yield. Its structure was confirmed by the following synthetic route. Isomer XIV was treated with performic acid to afford diol XVIII in 30% yield. By subsequent oxidation with Jones' reagent and dehydration with iodine-hydrochloric acid in benzene under reflux, diol XVIII gave compound XIX in 60% yield. Hydrocyanation of diketo olefin XIX with potassium cyanide and ammonium chloride in dimethylformamide[10] afforded an isomeric mixture of cyanoketone, which showed three spot in TLC (R_f: 0.01, 0.41, and 0.38, ethyl acetate: benzene=3 : 10), in 85% yield. The main product (mp 117—118°C, R_f 0.38) separated by recrystallization, was recognized as an isomer XXi having an axial cyano group and an equatorial isopropyl group, since absorption of α-proton of cyano group appeared at 3.36 ppm (d-d) and their coupling constant was 3.5—1 Hz in NMR spectrum.[11] The conformation of the second isomer

(mp 115—116°C, R_f 0.61) obtained by silica gel chromatography of the mother liquor, was suggested to be an isomer XXii by NMR spectrum which showed absorption of α-proton of cyano group at 2.8 ppm and methyl protons of isopropyl group at a lower field than that of XXi. The third isomer XXiii which was expected to have equatorial cyano and isopropyl groups could not be isolated in a pure state. Hydrolysis of the isomeric mixture of cyanoketone XX with 6N sulfuric acid in acetic acid under reflux for 100 hr afforded an isomeric mixture of carboxylic acid IIa. Separation of the isomeric mixture as its methyl ester IIb by chromatography on silica gel resulted in the isolation of an isomer (mp 93—94°C), which was identical with the isomer derived from XXi by TLC and gas chromatography in the same way.

Treatment of the isomer of IIb with methanolic sodium methoxide yielded an equilibrium mixture of IIb and diastereomer having epimeric configuration of carbomethoxyl group.

Although the compound we aimed at was synthesized, it takes a long time to purify the intermediate and the method is troublesome. Studies of other methods to synthesize these compounds and the methods available for introduction of carbon chain at C_1-position are in progress.

Experimental

Preparation of 2-Methylcyclopentane-1,3-dione. 2-Methylcyclopentane-1,3-dione was prepared from diethyl oxalate *via* ester condensation according to Boyce's method.[12] Recently Grenda developed a convenient method for its preparation in a large amount from succinic anhydride and 2-buten-2-ol acetate.[13]

12) C. B. C. Boyce and J. S. Whitehurst, *J. Chem. Soc.*, **1959**, 2022.

13) V. J. Grenda, G. W. Lindberg, N. L. Wendler, and S. H. Pines, *J. Org. Chem.*, **32**, 1236 (1967).

cis-1-Hydroxy-8-methylhydrindanone-5 (IIIa). This was prepared by Boyce's method, mp 80—83°C.

cis-1-Acetoxy-8-methylhydrindanone-5 (IIIb). A mixture of IIIa (33.6 g), acetic anhydride (30.6 g), and pyridine (150 m*l*) was allowed to stand overnight, water was added and the separated organic layer was extracted with ether. The ethereal extract was washed and dried. The solvent was removed and the residual oil was distilled, bp 113—116°C/1 mmHg, 37 g (87%). IR: ν^{neat} 1740, 1710 cm^{-1}.

Found: C, 68.25; H, 8.64%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

cis-1-Acetoxy-8-methylhydrindan-5-ol (IV). To a solution of IIIb (36.8 g) in ethanol (100 m*l*) was added dropwise a solution of sodium borohydride (3 g) in ethanol (200 m*l*), and the reaction mixture was stirred for 10 hr at room temperature. Water and acetic acid were added to the reaction mixture which was then concentrated *in vacuo*. Water was added to the residue which was extracted with ether. The ethereal extract was washed and dried. The solvent was removed and the residual oil was distilled to give IV (32 g, 87%), bp 120—125°C/1 mmHg. IR: ν^{neat} 3400, 1740 cm^{-1}.

Found: C, 67.71; H, 9.47%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%.

cis-1-Acetoxy-8-methyl-6,7,8,9-tetrahydroindane (V and VI). To a solution of IV (21 g) in pyridine (100 m*l*) was added dropwise a mixture of phosphorus oxychloride (23 g) and pyridine (30 m*l*) under ice cooling. The reaction mixture was allowed to stand overnight at room temperature and then heated at 80°C for 4 hr. Ice was added to the cooled mixture and separated organic layer was extracted with ether. The ethereal extract was washed successively with 2N hydrochloric acid, sodium hydrogencarbonate solution and water and dried. The solvent was removed and the residual oil was distilled, bp 124°C/28 mmHg, 10.5 g (56%). IR: ν^{neat} 1740 cm^{-1}. NMR: $\delta(CCl_4)$ 5.62 (m, 2H), 2.0 ppm (s, 3H).

Found: C, 73.70; H, 9.27%. Calcd for $C_{18}H_{18}O_2$: C, 74.19; H, 9.34%.

This oil was a mixture of $\Delta^{4(5)}$- and $\Delta^{5(6)}$-olefin.

cis-1-Acetoxy-8-methyl-6,7,8,9-tetrahydroindanone-6 (VII). To a solution of a mixture of olefin (V and VI, 11.4 g) in benzene (100 m*l*) was added dropwise a solution of *t*-butyl chromate (prepared from 18.5 g of chromium trioxide) in acetic acid (4.5 g) and acetic anhydride (7.5 g) under reflux. After the reaction mixture was heated with stirring under reflux for 20 hr, water was added. Excess reagent was decomposed by addition of oxalic acid and separated organic layer was extracted with benzene. The benzene solution was washed with sodium hydrogencarbonate solution and water, and dried. On removing the solvent, the residual oil gave on distillation a mixture of VII and VIII, bp 124—128°C/3 mmHg, 4 g. The oil was chromatographed on silica gel and the fraction eluted with benzene gave pure VII. IR: ν^{neat} 1740, 1680 cm^{-1}. NMR: $\delta(CCl_4)$ 5.85 (d, 1H, J=10 Hz), 6.80 (d-d, 1H, J=10.5 Hz), 2.00 ppm (s, 3H).

Found: C, 69.47; H, 7.55%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.71%.

cis-1-Acetoxy-4-cyano-8-methylhydrindanone-6 (IX). To a solution of VII (1.27 g) in dimethylformamide (30 m*l*) and water (10 m*l*) was added a solution of potassium cyanide (0.54 g) and ammonium chloride (0.46 g) in water (15 m*l*). The reaction mixture was heated at 90°C for 20 hr and then the solvent was removed. To the residue was added water and it was extracted with chloroform. The chloroform solution was washed and dried. On evaporation of the solvent,

the residue was chromatographed on silica gel. The fraction eluted benzene-ether gave 350 mg of a crystalline substance, mp 105—107°C.

Found: C, 66.04; H, 7.19%. Calcd for $C_{13}H_{17}NO_3$: C, 66.36; H, 7.28%.

Reduction and Subsequent Hydrolysis of IX. Above cyanoketone IX (350 mg) was dissolved in ethanol and reduced with sodium borohydride in the usual way. The reaction mixture was evaporated *in vacuo*. Acetic acid and 6N sulfuric acid (3 : 1) were added to the residue and then it was heated under reflux for 30 hr. The hydrolyzate was extracted with ether and dried. On evaporation of the solvent, the residue showed IR absorption band at 1760 cm^{-1}.

cis-*8-Methyl-1-tetrahydropyranyloxyhydrindanone-5 (IIIc).* The ketol IIIa (17 g) was dissolved in 2,3-dihydropyran (50 m*l*) and then a few drops of concentrated hydrochloric acid were added. The reaction mixture was allowed to stand overnight at room temperature. Ether was added and the ether solution was washed with saturated sodium hydrogencarbonate solution and water, and dried. The solvent was removed and residual oil was distilled, 130—135°C/0.001 mmHg, 22 g (93%). IR; ν^{neat} 1720 cm^{-1} (cyclohexanone carbonyl).

Found: C, 71.15; H, 9.51%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

cis-*1-Tetrahydropyranyloxy-5-hydroxy-5-isopropyl-8-methylhydrindane (XIa).* To a solution of IIIc (25 g) in olefin free petroleum ether (50 m*l*), was added a solution of isopropyllithium (prepared from 2.1 g of lithium metal and 12 g of isopropyl chloride) in olefin free petroleum ether under nitrogen. After stirring for 3 hr under reflux, the reaction mixture was decomposed by the addition of 10% ammonium chloride solution (70 m*l*). The separated aqueous layer was extracted with ether. The combined organic layers were washed with saturated sodium chloride solution and dried. The solvent was removed and the remaining viscous yellow oil showed only 30% conversion to alcohol XIa in IR spectra. After three such treatments, the product was distilled, bp 140—145°C/0.001 mmHg, 15.4 g (total yield 52%). IR: ν^{neat} 3400 cm^{-1}. NMR: $\delta(CCl_4)$ 0.92 (d, 3H, J=7 Hz), 0.87 (d, 3H, J=7 Hz), 0.88 (s, 3H), 4.57 ppm (s, 1H).

Found: C, 72.36; H, 10.56%. Calcd for $C_{18}H_{32}O_3$: C, 72.93; H, 10.88%.

cis-*5-Hydroxy-5-isopropyl-8-methylhydrindanone-1 (XII).* To a solution of XIa (36.7 g) in tetrahydrofuran (120 m*l*), was added 2N hydrochloric acid (100 m*l*). After the solution was stirred for 5 hr at room temperature, 2N sodium hydroxide (100 m*l*) was added. The organic layer was separated and the aqueous layer was extracted with ether. The combined extracts were washed with water and dried. The solvent was removed and the residual oil was distilled to give a diol XIb (25 g), bp 135—138°C/0.001 mmHg. IR: ν^{neat} 3400 cm^{-1}. To a solution of XIb in acetone (50 m*l*) and acetic acid (100 m*l*), was added a solution of water (10 m*l*) and acetic acid (90 m*l*) containing chromium trioxide (13 g) under ice cooling. After stirring for 2 days at room temperature, ice (150 g) was added. The aqueous layer was extracted with ether. The ethereal extract was washed with saturated sodium hydrogencarbonate solution, and dried. The solvent was removed and the residual oil was distilled to give a ketol XII (20.5 g, 81%), bp 110—115°C/0.01 mmHg. IR: ν^{neat} 3450, 1740 cm^{-1} (cyclopentanone carbonyl). NMR: $\delta(CCl_4)$ 0.97 (s, 3H), 0.87 ppm (d, 6H, J=7 Hz).

Found: C, 74.24; H, 10.54%. Calcd for $C_{13}H_{22}O_2$: C, 74.11; H, 10.28%.

Dehydration of XII. i) XII (21 g) and potassium hydrogensulfate (2 g) were placed in a Claisen flask and then heated at 200°C for 30 min. After removal of the resulting water, the residue was subjected to distillation to give a mixture of olefins (16 g, 84%), bp 75—77°C/0.1 mmHg.

Found: C, 80.68; H, 10.40%. Calcd for $C_{13}H_{20}O$: C, 81.20; H, 10.48%.

The product showed no absorption of hydroxy group in IR spectra but three peaks by VPC analysis (P.E.G. 6000; their ratio was 7 : 3 : 1). The main product XIII (1.5 g) was isolated from the olefinic mixture (4.0 g) in a pure state by chromatography using silica gel pretreated with silver nitrate. IR: ν^{neat} 1740 cm^{-1}. NMR: $\delta(CCl_4)$ 0.96 (d, 6H, J=7 Hz), 0.94 (d, 3H), 5.32 ppm (d, 1H, J= 2.5 Hz). The second and the third isomer were obtained by preparative VPC (Carbowax-20M, at 170°C). $\Delta^{5(6)}$-Olefin XIV: NMR: δ (CCl_4) 0.94 (s, 3H), 1.02 (d, 6H, J=7 Hz), 5.30 ppm (m, 1H). Isopropylideneindanone XV: NMR: $\delta(CCl_4)$ 1.03 (s, 3H), 1.65 ppm (s, 6H).

ii) To a solution of XII (20 g) in pyridine (200 m*l*) was added phosphorus oxychloride (30.8 g) under ice cooling. The solution was warmed at 50°C for 3 hr. After cooling the solution was poured into ice-water (500 m*l*) and ex tracted with ether. The ethereal extract was washed with 5% hydrochloric acid, 10% sodium hydrogencarbonate solution and water, and dried. The solvent was removed and the residual oil was distilled to give a mixture of olefins (15 g, 84%). The ratio of XIII, XIV, and XV was 6 : 3 : 1 by VPC analysis.

iii) A mixture of XII (2.6 g) and alumina (8.0 g, Woelm grade I neutral, pretreated with 2% solution of pyridine) was evenly distributed on a glass "boat" consisting of a 20 cm glass tube. The glass boat was heated to 230°C by Corey's method under nitrogen. After 5 min, the product began to undergo distillation. The distillate was dissolved in ether and the ether solution was washed with water and dried. The solvent was removed and residual oil was distilled to give a mixture of XIII, XIV, and XV (2.1 g, 80%). Their ratio was 10 : 5 : 1 by VPC analysis.

cis-*1-Acetoxy-5-isopropyl-8-methyl-6,7,8,9-tetrahydroindane (XVIb).* A solution of XIII (13.5 g) in anhydrous ether (75 m*l*) was added to a stirred suspension of lithium aluminum hydride (1.4 g) in anhydrous ether (250 m*l*). The mixture was stirred for 4 hr at room temperature and then the required amount of ethyl acetate and water was added in order to decompose excess lithium aluminum hydride. The organic layer was separated and the aqueous layer was extracted with ether. The combined ethereal extracts were washed with water, and dried. The solvent was removed and the residual viscous oil was dissolved in pyridine (70 m*l*), and acetic anhydride (8 g) was then added under ice cooling with stirring. The reaction mixture was allowed to stand at room temperature overnight and then poured into ice-water. The organic material was extracted with ether and the ethereal extract was washed with water, and dried. The oil obtained by evaporating the solvent was distilled to give an acetate XVIb (14.8 g, 90%), bp 95—97°C/0.1 mmHg. IR: ν^{neat} 1745, 1380, 1240 cm^{-1}. NMR: $\delta(CCl_4)$ 0.97 (s, 3H), 1.0 (d, 6H, J=7 Hz), 2.0 (s, 3H), 4.8 (t, 1H), 5.37 ppm (d, 1H, J=2 Hz).

Found: C, 76.43; H, 10.22%. Calcd for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

cis-*1-Acetoxy-5-isopropyl-8-methyl-6,7,8,9-tetrahydroindanone-6 (XVIIb).* i) To a solution of XVIb (14.8 g) in anhydrous benzene (80 m*l*) was added a mixture of *t*-butyl chromate (prepared from 19 g of chromium trioxide, 13 g of acetic acid and 17.5 g of acetic anhydride) with stirring

at 70°C over 8 hr. After stirring for 40 hr at the same temperature, a solution of oxalic acid (20 g) in water (100 m*l*) was added to the cooled reaction mixture. The organic material was extracted with ether and the extract was washed successively with water, 5% sodium hydrogencarbonate solution and water. The residue obtained by evaporating the solvent was distilled to give 7.5 g of recovered starting material (bp 95°C/0.1 mmHg) and 6.1 g of XVIIb (bp 100—130°C/0.1 mmHg), which was purified by chromatography on silica gel (eluted by petroleum ether : ether= 9 : 1). XVIIb was obtained in a pure state, 1.6 g (11%). IR: ν^{neat} 1745, 1680, 1240 cm^{-1}. UV: λ_{max}^{EtOH} 240 mμ (ε 8600). NMR: $\delta(CCl_4)$ 0.98 (d, 6H, J=7 Hz), 1.08 (s, 3H), 1.82 (s, 3H), 4.75 (broad 1H), 6.24 ppm (d, 1H, J=3.5 Hz).

Found: C, 71.97; H, 8.86%. Calcd for $C_{15}H_{22}O_3$: C, 71.91; H, 8.76%.

ii) To a solution of XVIb (7.5 g) in benzene (60 m*l*) was quickly added selenium oxide (6 g), water (2.4 m*l*) and acetic acid (120 m*l*). The mixture was heated at 80°C for 1 hr. The reaction mixture was cooled to room temperature and added sodium acetate (24 g) and heated at 80°C for 5 min. After cooling, the deposited selenium was filtered off and the filtrate was poured into the saturated sodium chloride solution (240 m*l*). The aqueous layer was extracted with ether. The crude oil (8 g) obtained by evaporating the solvent was dissolved in a mixture of acetone (40 m*l*) and acetic acid (50 m*l*). To this solution was added a mixture of water (2 m*l*) and acetic acid (7 m*l*) containing chromium trioxide (2.5 g). After stirring for 12 hr at room temperature, the solution was poured into 100 g of ice and then extracted with ether. The ethereal extract was washed with saturated sodium hydrogencarbonate solution and water, and dried. The crude oil (5.5 g), obtained by removal of the solvent, gave an α,β-unsaturated ketone XVIIb (1.5 g, 19%) by purification of silica gel chromatography (eluted by petroleum ether : ether=10 : 1).

cis-*5-Isopropyl-8-methyl-6,7,8,9-tetrahydroindane-1,6-dione (XIX).* i) To a solution of XVIIb (1.4 g) in methanol (30 m*l*), was added 2N sodium hydroxide (30 m*l*). The solution was stirred for 4 hr at room temperature and then allowed to stand overnight. The solution was neutralized with acetic acid and evaporated. The residue was extracted with ether and the ethereal extract was washed with saturated sodium chloride solution, and dried. The residual oil obtained by evaporating the solvent was dissolved in acetone (30 m*l*). Jones' reagent (1.6 m*l*) was added to this solution with stirring under ice-cooling. After stirring for 20 min at room temperature, excess reagent was decomposed with methanol. The solvent was evaporated *in vacuo* and water was added to the residue which was extracted with ether. The ethereal extract was dried and evaporated. The residual oil was distilled to give a diketone XIX (1.2 g, 95%), bp 110°C/0.1 mmHg (bath temp.). IR: ν^{neat} 1740, 1680, 1630, 1410 cm^{-1}. NMR: $\delta(CCl_4)$ 0.98 (d, 3H, J=7 Hz), 1.02 (d, 3H, J=7 Hz), 1.10 (s, 3H), 6.47 ppm (d, 1H, J=3.5 Hz).

Found: C, 74.90; H, 8.70%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

ii) To a solution of XIII (5.3 g) in anhydrous benzene (30 m*l*) was added a solution of *t*-butyl chromate (prepared from 8 g of chromium trioxide, 5.3 g of acetic acid and 7 g of acetic anhydride) over 6 hr at 50—60°C with stirring. After stirring for an additional 30 hr at the same temperature, the solution was allowed to stand at room temperature overnight. A solution of oxalic acid (8 g) in water (50 m*l*) was added to the ice-cooled reaction mixture and the separated aqueous layer was extracted with ether. The combined extracts were washed with saturated sodium hydrogencarbonate solution and water, and dried. The residual oil obtained by removal of the solvent was purified by chromatography on silica gel (eluted by petroleum ether : ether=10 : 1) to yield a diketone XIX (250 mg, 4.5%).

iii) To a solution of XVIII (500 mg) in acetone (10 m*l*) was added 0.8 m*l* of Jones' reagent with stirring under ice-cooling. After stirring for 15 min at room temperature, excess reagent was decomposed with methanol (5 m*l*). Water was added and the solution was extracted with ether. The extract was washed with water and dried. The residual oil (450 mg) obtained by removal of the solvent was dissolved in benzene (10 m*l*) and to this solution was added iodine (10 mg) and a few drops of concentrated hydrochloric acid. The mixture was heated under reflux for 20 hr. After cooling, the organic layer was washed with saturated sodium thiosulfate solution and water, and dried. On distillation 300 mg of XIX (68%) was obtained.

cis-*5,6-Dihydroxy-5-isopropyl-8-methylhydrindanone-1 (XVIII).* To a mixture of formic acid (25 m*l*) and 30% hydrogen peroxide (3 m*l*) was added XIV (1.5 g) with stirring at 40°C. After stirring for an additional 4 hr at the same temperature, the reaction mixture was allowed to stand at room temperature overnight. After removal of excess formic acid, the remaining solution was added to a mixture of 10% sodium hydroxide solution (10 m*l*) and dioxane (40 m*l*) and then allowed to stand for one day at room temperature. The reaction mixture was concentrated *in vacuo* and the residue was extracted with ether. The ethereal extract was washed with water and dried. The crystals obtained by evaporating the solvent were recrystallized from ether to give XVIII (100 mg), mp 140—141°C. IR: ν^{nujol} 3450, 1735, 1415, 1380 cm^{-1}.

Found: C, 69.11; H, 9.75%. Calcd for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80%. Concentration of the mother liquors gave an oily diol (450 mg).

cis-*4-Cyano-5-isopropyl-8-methylhydrindane-1,6-dione (XX).* A solution of XIX (1.5 g) in dimethylformamide (45 m*l*) was treated with a solution of potassium cyanide (0.94 g) and ammonium chloride (0.59 g) in water (15 m*l*). After stirring at 100°C for 20 hr, the solution was concentrated under reduced pressure and extracted with chloroform. The extract was washed with water and dried. The residue obtained by evaporating the solvent was crystallized from ether to give XXi (0.50 g), mp 117—118°C. IR: ν^{nujol} 2240, 1745, 1720, 1410, 1380 cm^{-1}. NMR: $\delta(CDCl_3)$ 1.0 (d, 6H, J=7 Hz), 1.26 (s, 3H), 3.36 ppm (d-d, 1H, J=3.5—1 Hz).

Found: C, 72.10; H, 8.20; N, 5.97%. Calcd for $C_{14}H_{19}O_2N$: C, 72.07; H, 8.21; N, 6.00%. Concentration of the mother liquor yielded 1.05 g of oil, from which an isomer XXii (20 mg) was separated by silica gel chromatography (eluted by petroleum ether : ether=10 : 1), mp 115—116°C. IR: ν^{nujol} 2250, 1740, 1715, 1410, 1380 cm^{-1}. NMR: δ ($CDCl_3$) 1.08 (d, 6H, J=7 Hz), 1.25 (s, 3H), 2.8 ppm (m, 1H).

cis-*4-Carboxy-5-isopropyl-8-methylhydrindane-1,6-dione (IIa).* A solution of the isomer XXi (400 mg) in a mixture of acetic acid (7 m*l*) and 6N sulfuric acid (20 m*l*) was heated under reflux for 100 hr. After cooling, the reaction mixture was extracted with chloroform. The extract was washed with water and dried. The crystals obtained by evaporating the solvent were recrystallized from ethyl acetate to give an acid IIa (300 mg, 65%), mp 162—163°C. IR: ν^{nujol} 3500—2500, 1740, 1720, 1690, 1410, 1380, 1185 cm^{-1}. NMR: $\delta(CDCl_3)$ 0.93 (d, 6H, J=7 Hz), 1.15 (s, 3H), 8.95 ppm

(s, 1H).

Found: C, 66.62; H, 7.95%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%. Its methyl ester had mp 93—94°C.

cis-*4-Carbomethoxy-5-isopropyl-8-methylhydrindane-1,6-dione (IIb)*. A stereoisomeric mixture of XX (750 mg) was hydrolyzed and followed by esterification with ethereal diazomethane. The methyl ester was obtained by distillation, bp 150°C (bath temp.)/0.1 mmHg, 650 mg (80%). The main isomer was isolated by silica gel chromatography (eluted by petroleum ether : ether=200 : 25), 450 mg, which was recrystallized from ether, mp 93—94°C. IR: ν^{nujol} 1750, 1740, 1710, 1405, 1380, 1170 cm^{-1}. NMR: $\delta(CDCl_3)$ 0.95 (d, 3H, J=7 Hz), 1.04 (d, 3H, J=7 Hz), 1.13 (s, 3H), 3.79 ppm (s, 3H).

Found: C, 67.64; H, 8.33%. Calcd for $C_{15}H_{22}O_4$: C, 67.99; H, 8.33%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2202—2206 (1971)

The Photochemistry of Heterocyclic Compounds. IV. The Mechanism of the Photodecomposition of Alloxan Monohydrate. The Effects of Solvents

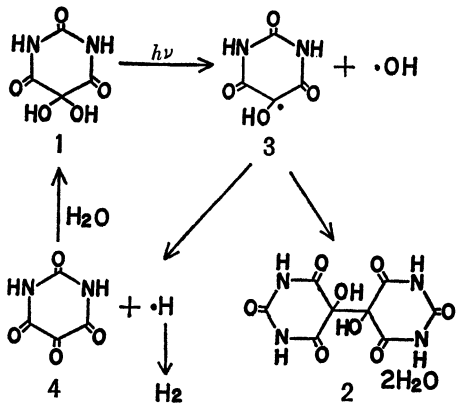
Shigeo WAKE, Takeshi MAWATARI, Yoshio OTSUJI, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received February 22, 1971)

The photolyses of alloxan monohydrate (**1**) were carried out in water, 2-propanol, and dioxane. Irradiation in water produced alloxantin dihydrate (**2**), glyoxal (**5**), oxaluric acid (**6**), parabanic acid (**7**), and oxalyl diureide (**8**). However, when the photolyses were conducted in 2-propanol and dioxane, **2** and **5** were isolated as the main products. A detailed examination of the changes in the product distributions in the three solvents led to the conclusion that **2** and **5** are produced through the pathways involving the radical fission of the C–OH and C–CO bonds in **1**. On the other hand, **6**, **7**, and **8** were supposed to be produced by the pathways involving the photochemical hydrolysis of **1** to alloxanic acid (**13**).

In the previous papers of this series, we have reported the results of the photolyses of alloxan monohydrate (**1**) and its derivatives in aqueous solutions.[1,2] The irradiation of an aqueous solution of **1** with ultraviolet light afforded hydrogen, hydroxyl radical, alloxantin dihydrate (**2**), and other decomposition products. The processes for the formation of the former three products have been accommodated mechanistically by invoking the water-decomposition pathways illustrated in Scheme 1.



Scheme 1

This photochemical reaction was, therefore, of considerable interest in view of the fact that **1** might serve as a useful catalyst of the photochemical decomposition of water. However, the efficiency of **1** as a catalyst was low because of the participation of decomposition pathways other than those indicated in Scheme 1.

The present study was undertaken in order to obtain more information about the mechanism of the photolysis of **1**. Specifically, the solvent effect on the pathways of the photolysis was examined in detail in the hope of elucidating the nature of the excited state(s) involved. The retults will be presented in this paper.

Results

Photolyses of Alloxan Monohydrate (1). When a dilute solution (3.1×10^{-2} M) of **1** in water was irradiated with a low-pressure mercury lamp under nitrogen at room temperature,[3] **2**, glyoxal (**5**), oxaluric acid (**6**), parabanic acid (**7**), and oxalyl diureide (**8**) were isolated from the reaction mixture.[4] The relative yields of these products were dependent upon the irradiation time. The yield of **2** decreased, and that

a) A 3.1×10^{-2} M solution of **1** was irradiated under N_2 atmosphere.
b) A 6.2×10^{-2} M solution of **1** was irradiated under N_2 atmosphere.
c) Based on total amount of the starting material.

of **5** increased, with an increase in the irradiation time. By 100 hr irradiation, only **7** (28%) and **8** (3.8%) were isolated. The results are summarized in Table 1.

The products were satisfactorily isolated by means of careful fractional crystallizations, as is presented in detail in the Experimental section. The unreacted starting material was separated from the reaction mixture as its semicarbazone (**9**). Glyoxal (**5**) was isolated as its 2,4-dinitrophenylhydrazone (**10**). It must be noticed here that **10** was obtained only when the reaction mixture was heated with an excess of a solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid on a boiling water bath for 3 hr or more. This result implies that **5** is produced by the acid hydrolysis of its precursor, which is presumably an acetal of **5** (**5** itself immediately forms **10** upon treatment with an acidic aqueous solution of 2,4-dinitrophenylhydrazine at room temperature).

The photolyses of **1** were also conducted in dioxane and 2-propanol under conditions similar to those employed for the photolyses in water. In these cases, **2** and **5** were isolated from the reaction mixture, the yields depending also on the irradiation time. The results are included in Table 1. The total yields of the isolated products for the photolyses of **1** in the organic solvents were better than those in water.

*Photolysis of **1** in the Presence of Urea.* We have recently found that, when the photolysis of an aqueous solution of **1** was carried out in the presence of urea, the evolution of H_2 completely ceased, although the evolution of CO and CO_2 was still observed. In order to shed light on the mechanism of this, an aqueous solution (6.2×10^{-2} M) of **1** in the presence of an equivalent of urea was irradiated for 7 hr. The subsequent fractional crystallization of the reaction mixture afforded **2** (0.2%), **8** (0.4%), uric acid glycol semihydrate (**11**, 9.1%), and some unidentified product (s) (**12**).

The compounds **11** and **12** thus obtained were also produced by the reaction of **1** with urea in the dark. A careful examination of this dark reaction revealed that the primary product was **11**, which was then gradually converted to **12**.

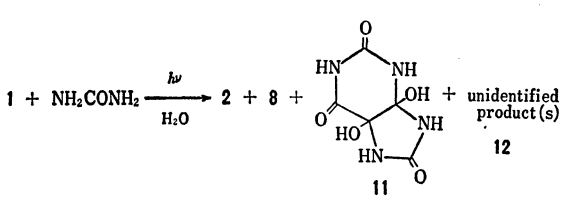
These results clearly suggest that a remarkable decrease in the photochemical reactivity of **1** in the presence of urea is due to the dark reaction between them, and that the **11** or **12** formed by this dark reaction would be photochemically unreactive.

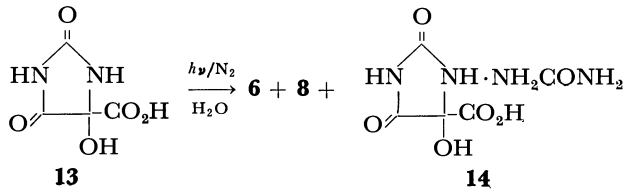
Photolyses of Related Compounds. Since alloxanic acid (**13**) and **7** were supposed to be among the intermediates of the photolysis of **1** in water, their photochemistry was examined briefly.

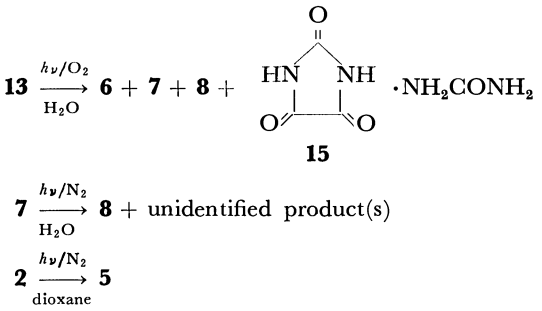
The irradiation of a solution (6.2×10^{-2} M) of **13** in water for 7 hr under nitrogen afforded **6**(3%), **8**(1.3%), and a 1 : 1 adduct(or salt) (**14**, 35%) between **13** and urea, the starting material being recovered in a 49% yield. On the other hand, the irradiation of an aqueous solution of **13** in the presence of air for 7 hr gave **6**(1.8%), **7**(26%), **8**(0.4%), and a 1 : 1 adduct (or salt) (**15**, 3.7%) between **7** and urea along with complex unidentified product(s).

The photolysis of a 6.4×10^{-2} M solution of **7** in water for 3 hr under nitrogen produced **8** (1.4%) and complex unidentified product(s), the starting material being recovered in a 35% yield.

Finally, a solution of **2** in dioxane was photolyzed for 3.5 hr under nitrogen to give **5** in a 40% yield.





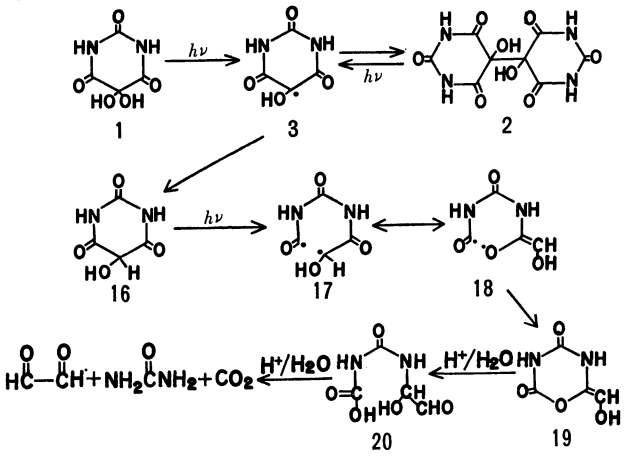


Discussion

A striking observation of this investigation concerns the effects of solvents on the product distributions in the photolyses of **1**. Experimental difficulties prevented us from making complete analyses of the products, specifically in the photolyses in hydroxylic solvents, and so no detailed discussion can be given at the present time; nevertheless, the following important conclusions can be drawn from the data in Table 1: (1) the products **2** and **5** are those derived from a radical intermediate, (2) the pathways leading to **2** and **5** are closely related to each other and **2** is converted to **5**, and (3) the products **6**, **7**, and **8** are those produced through the pathways involving ionic reactions of **1** or **2** with water.

Dioxane does not react to **1** in a manner characteristic of a nucleophilic reagent. Only the radical reactions are, therefore, expected to take place in this medium. Indeed, **6**, **7**, and **8** could not be isolated in detectable yields by the photolyses in dioxane. On the other hand, in water, which possesses a nucleophilic reactivity toward **1**, ionic products, **6**, **7**, and **8**, were formed, making the photochemical reaction a complex one.[5]

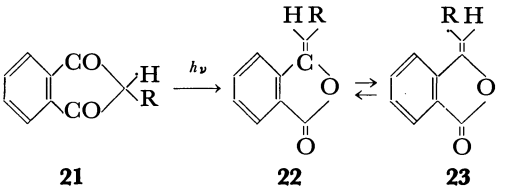
On the basis of these considerations as well as other experimental observations, we now propose a probable mechanism for the formation of **2** and **5** (Scheme 2).



Scheme 2

5) In the experiments in 2-propanol, no attempt was made to isolate of ionic products. However, the tendency for the yields of the products **2** and **5** to vary with the irradiation time in 2-propanol was parallel to that in water, supporting the view that the ionic products are being also formed in 2-propanol.

Evidence that the process **1**→**3** really takes place probably through the $n\rightarrow\pi^*$ state of **1** has been presented in a previous paper.[1] The combination of two of the radical **3** gives **2**. The irradiation of **2** also produces **3**, as may be inferred from the fact that the photolysis of **2** in dioxane gave **5** in a high yield. The disproportionation of **3** or the abstraction of hydrogen atom from solvent by **3** affords dialuric acid (**16**). The cleavage of the C—C bond α to the carbonyl in **16** would produce the lactone **19** *via* **17** and **18**. The process **16**→**19** can be induced by the photoexcitation of **16**. That this kind of reaction really occurs has been established in the photochemistry of cyclic β-diketones. For example, 2-substituted 1,3-indanedione (**21**, R=alkyl or aryl) isomerizes to the phthalide **22** or **23** through the $n\rightarrow\pi^*$ state of **21**[6] upon irradiation with ultraviolet light.

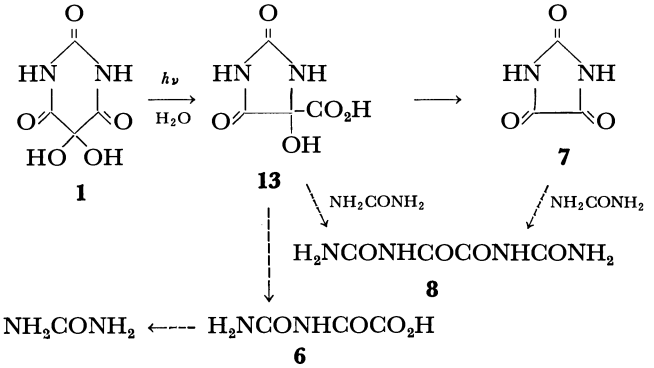


The acid hydrolysis of **19** affords **5**. The presence of the intermediate **19** in the reaction mixture, in which the aldehyde function of **5** is protected, accords with the experimental finding that heating with acid was neccessary to obtain **5**.

The solvent effects observed in this study are also consistent with the mechanism depicted in Scheme 2 if the reaction is initiated by the $n\rightarrow\pi^*$ excited states of **1**, **2**, and **16**. As is well established, the $n\rightarrow\pi^*$ excited state of a carbonyl group can be brought about in a higher probability in non-hydroxylic solvents such as dioxane than in hydroxylic solvents, such as water or 2-propanol. Indeed, our results (Table 1) indicate that **1** was photolyzed much more rapidly in dioxane than in water.

The mechanism of the formation of **6**, **7**, and **8** will now be only briefly discussed. A speculative mechanism which accommodates our results is shown in Scheme 3, although the real pathways must be much more complex.

The process **1**→**13** has been known to be achieved



Scheme 3

6) J. Rigaudy and P. Derible, *Bull. Soc. Chim. Fr.*, **1965**, 3047, 3055, 3061.

by the action of alkali on **1**[7] in the dark, but **1** was stable under the conditions of our photochemical reactions. Hence, this process must be of photochemically-accelerated. Our previous work has shown the possibility of this sort of ionic photochemical reaction. Barbital (**24**) has been found to be hydrolyzed to diethylacetylurea by the attack of the hydroxide ion on the carbonyl carbon at the 4-position upon the irradiation of its aqueous solutions through the singlet excited state.[8] The close similarity between the structure of **1** and that of **24** suggests that the similar ionic reaction, which should lead to **13**, might be accelerated by the irradiation. Although the oxidation of **13** has been known to give **7**,[9] this oxidation must be carried out by the hydroxyl radical, which is generated by the irradiation of **1**, in our photochemical reaction. This view is further supported by the fact that the irradiation of **13** in the presence of oxygen caused a remarkable increase in the yield of **7** as compared with that in photolysis under a nitrogen atmosphere. That the other isolated products could, in fact, be produced from **7** and **13** was shown by the photolyses of their aqueous solutions.

Experimental

The melting points are uncorrected. The UV spectra were determined on a Hitachi EPU-2U recording spectrophotometer. The IR spectra were determined on a Hitachi-EPI-S2 infrared spectrophotometer. The microanalyses were performed with a Yanagimoto MT-1 CHN Corder. Irradiation was carried out with a 15 W Taika low-pressure immersion mercury lamp at room temperature.

Materials. Alloxan monohydrate (**1**), alloxantin dihydrate (**2**), and parabanic acid (**7**) were prepared by the methods described in a previous paper.[1] Alloxanic acid (**13**) was prepared from Barium alloxanate[10] by the method of Biltz and Kobel[11] and was purified by means of column chromatography using Amberlite CG-120 Type 1 as the adsorbent and ether as the eluent; mp 153—157°C (decomp.). (Found: C, 30.24; H, 2.71; N, 17.30%. Calcd for $C_4H_4N_2O_5$: C, 30.01; H, 2.52; N, 17.50%).

Preparation of Authentic Samples. Oxaluric acid (**6**) and alloxan-5-semicarbazone dihydrate (**9**) were prepared by the methods described in the previous paper.[1] Oxalyl diureide (**8**) was prepared by the method of Biltz and Topp;[12] mp 250°C (decomp.). (Found: C, 27.56; H, 3.54; N, 32.22%. Calcd for $C_4H_6N_4O_4$: C, 27.59; H, 3.47; N, 32.18%). Uric acid glycol semihydrate (**11**) was prepared by the method of Biltz and Heyn;[13] mp 164—165°C (decomp.). The 1 : 1 adduct (or salt) (**14**) between alloxanic acid (**13**) and urea was prepared by adding a solution of 0.8 g (5 mmol) of **13** in 1 m*l* of water to a solution of 0.3 g (5 mmol) of urea in 0.5 m*l* of water. The mixture was then allowed to stand at room temperature for 12 hr. The crystals thus deposited were collected by filtration to give 0.68 g (62%) of **14**; mp 149—150°C (decomp.). An analytical sample was prepared by recrystallization from water; mp 150—153°C (decomp.). (Found: C, 27.34; H, 3.71; N, 25.35%. Calcd for $C_5H_8N_4O_6$: C, 27.28; H, 3.66; N, 25.45%). The 1 : 1 adduct (or salt) (**15**) between parabanic acid (**7**) and urea was prepared by adding a solution of 2.3 g (20 mmol) of **7** in 40 m*l* of water to a solution of 1.2 g (20 mmol) of urea in 2 m*l* of water. The mixture was allowed to stand at 0°C for 12 hr. The crystals thus deposited were collected by filtration and recrystallized from water to give 2 g (27.5%) of **15**; mp 204—206°C (decomp.). (Found: C, 27.73; H, 3.57; N, 32.37%. Calcd for $C_4H_6N_4O_4$: C, 27.59; H, 3.47; N, 32.18%).

Unless otherwise noted, the structures of the photoproducts were identified by a mixed-melting-point test and by a comparison of the IR spectra of the products with those of the corresponding authentic samples.

*Photoreaction of Alloxan Monohydrate (**1**) in Water.* A solution of 1.5 g (9.4 mmol) of **1** in 300 m*l* of water was placed in a cylindrical reaction vessel, and then N_2 was bubbled for 30 min. Irradiation was then carried out under N_2 at room temperature. After irradiation for an appropriate period of time, the solvent was evaporated to dryness under reduced pressure, and the residue was washed thoroughly with water. The residue was identical with **2** in every respect. The aqueous filtrate was again evaporated to dryness under reduced pressure, and then a 10 m*l* portion of water was added to the residue. An insoluble precipitate, which was separated by filtration, was proved to be **6**. To the filtrate we added a solution of 1 g of semicarbazide hydrochloride and 1.5 g of NaOAc in 10 m*l* of water. The filtration of this mixture gave alloxan-5-semicarbazone dihydrate (**9**); mp 231—232°C (decomp.). Finally, an acid solution of 2,4-dinitrophenylhydrazine was added to the above filtrate, after which the mixture was heated for 3 hr on a water bath and allowed to stand overnight. Filtration gave 2,4-dinitrophenylhydrazone of glyoxal (**10**); mp 309—310°C (decomp.).

When a solution of 3 g (18.7 mmol) of **1** in 300 m*l* of water was irradiated for 100 hr, crystals were deposited on the bottom of the reaction vessel. The crystals were separated by filtration to give 0.06 g (3.8%) of **8**; mp 249°C (decomp.).

*Photoreaction of Alloxan Monohydrate (**1**) in Organic Solvents.* A solution of 1.5 g (9.4 mmol) of **1** in 300 m*l* of an organic solvent was irradiated as has been described above. After irradiation, the solvent was evaporated to dryness under reduced pressure, and the residue was washed with 20 m*l* of water. The aqueous filtrate was evaporated to dryness under reduced pressure, and the residue was washed again with 20 m*l* of water. These evaporation and washing operations were repeated three or four times until no more water-insoluble precipitate was obtained. All of the water-insoluble precipitate was proved to be **2**. The aqueous filtrate obtained by the final washing operation was treated with semicarbazide hydrochloride and then with 2,4-dinitrophenylhydrazine in a manner similar to that described above to give **9** and **10** respectively.

*Photoreaction of Alloxan Monohydrate (**1**) in the Presence of Urea.* A mixture of 3.0 g (18.7 mmol) of **1** and 1.1 g (18.3 mmol) of urea in 300 m*l* of water was irradiated for 7 hr under N_2. A precipitate deposited on the bottom of the reaction vessel was collected by filtration; it was proved to be 7 mg (0.4%) of **8**; mp 249°C (decomp.). The filtrate was evaporated to dryness under reduced pressure and the residue was washed with 20 m*l* of water. An insoluble precipitate, which was separated by filtration, was 7 mg (0.2%)

of **2**; mp 202—203°C (decomp.). The filtrate was evaporated to dryness under reduced pressure. The residue was triturated with 200 m*l* of ethyl acetate and then filtered.[14] The filtrate was evaporated to dryness, and the residue was washed with 10 m*l* of ethyl acetate. The residue was 0.36 g (9.1%) of **11**; mp 170—172°C (decomp.).

*Photoreaction of Alloxanic Acid (**13**).* A solution of 3 g (18.8 mmol) of **13** in 300 m*l* of water was irradiated under N_2 for 7 hr. The filtration of the deposited crystals gave 0.02 g (1.3%) of **8**; mp 218—225°C (decomp.). The filtrate was evaporated to dryness under reduced pressure. The residue was triturated with 200 m*l* of ethyl acetate and then filtered. The evaporation of the filtrate gave 1.47 g (49%) of the starting material. The insoluble solid obtained upon trituration with ethyl acetate was triturated with 5 m*l* of water, after which the water-insoluble crystals were separated by filtration to give 0.075 g (3%) of **6**, mp 172—173°C (decomp.). The evaporation of the aqueous filtrate gave 0.71 g (35%) of the 1 : 1 adduct (or salt) (**14**), which melted at 150.5—151.5°C after recrystallization from water.

*Photoreaction of Alloxanic Acid (**13**) in the Presence of Air.* A solution of 3 g (18.7 mmol) of **13** in 300 m*l* of water was irradiated with bubbling air for 7 hr. The filtration of the deposited crystals gave 6 mg (0.4%) of **8**; mp 224—229°C (decomp.). The filtrate was evaporated to dryness under reduced pressure. The residue was triturated with 80 m*l* of ethyl acetate and then filtered. The evaporation of the filtrate gave 0.56 g (26%) of **7**, which melted at 235—238°C (decomp.) after recrystallization from water. The insoluble solid obtained upon trituration with ethyl acetate was triturated with 5 m*l* of water and the insoluble crystals were separated by filtration. The evaporation of the filtrate gave 1 g of a mixture of complex unidentified products. The recrystallization of the water-insoluble crystals from water gave 45 mg (1.8%) of **6**, mp 193—195°C (decomp.). The mother liquor from the recrystallization was evaporated to dryness, and the residue was recrystallized from water to give crystals (0.06 g) which were identified as the 1 : 1 adduct (or salt), **15**.

*Photoreaction of Parabanic Acid (**7**) in Water.* A solution of 2.2 g (19 mmol) of **7** in 300 m*l* of water was irradiated under N_2 for 3 hr. The filtration of the deposited crystals gave 0.03 g (1.4%) of **8**, mp 238°C (decomp.). The filtrate was evaporated to dryness under reduced pressure, and the residue was washed with 20 m*l* of acetone. The filtration of the insoluble precipitate gave about 0.8 g of a mixture of complex unidentified products. The evaporation of the filtrate gave 0.77 g (35%) of **7**.

*Photoreaction of Alloxantin Dihydrate (**2**).* A solution of 0.5 g of **2** in 300 m*l* of dioxane was irradiated, and then the reaction mixture was treated in a manner similar to that employed for **1** in dioxane.

14) The structure of the residue, 1.3 g, mp 159—160°C (decomp.), remains unidentified. However, this residue showed the same IR spectrum as that of the unknown by-product obtained by the treatment of **1** with urea in the dark.

Studies on Stable Free Radicals. V[1]

Reactivity of a Stable Free Radical, 2,2,6,6-Tetramethyl-4-oxopiperidine-1-oxyl

Takao YOSHIOKA, Susumu HIGASHIDA, Syoji MORIMURA, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received February 22, 1971)

A stable *N*-oxyl radical, 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I), afforded 1-hydroxy-2,2,6,6-tetramethyl-3-(2,2,6,6-tetramethyl-4-oxopiperidinoxy)-4-oxopiperidine (IX) by hydrogen-abstraction followed by the coupling reaction of the *N*-oxyl radical I with the *C* radical III derived from I. The product IX was characterized as the monoacetate (X), monobenzoate (XI), urethane (XII), semicarbazone (XIII), triol (XIV), triacetate (XV), and a new *N*-oxyl radical (XVI). It has been confirmed that i) the extremely stable *N*-oxyl radical abstracts the α-methylene-hydrogen of the ketone which affords a thermodynamically stable conjugated ketone, ii) radical I acts as a scavenger toward a *C*-radical intermediate and iii) the decomposition of radical I proceeds *via* the *C*-radical to give phorone (V).

Recently, the fact that 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I) and its analogs are extremely stable free radicals[2] has been established by the elegant studies of Rozantzev and his co-workers.[2a] In spite of the stabilization of radical I, it was found that these radicals still have the ability to act as a hydrogen abstracting agent,[3] an oxdizing agent,[3f,4] and a radical scavenger.[3d-g] In addition, we found that the *N*-oxyl I decomposed to give the corresponding hydroxylamine II and phorone (V) by heating, but did not decompose by the action of light.[3g]. The probable mechanism for the decomposition of radical I is shown in Chart 1. The free radical intermediate III, which

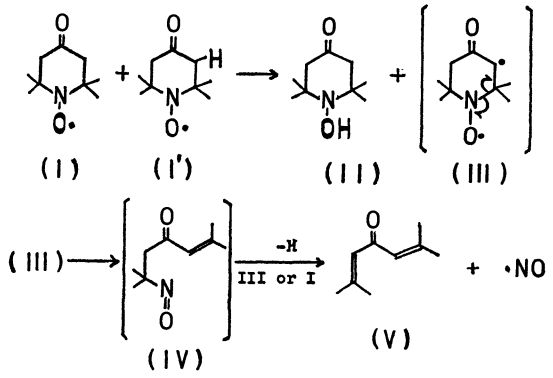

Chart 1

would be generated by the abstraction of an α-methylene ketone hydrogen by another radical I (=I'), was proposed.[3g] This mechanism was supported by the fact that the original radical I trapped intermediate III to give the coupling reaction product, 1-hydroxy-2,2,6,6-tetramethyl-3-(2,2,6,6-tetramethyl-4-oxopiperidinoxy)-4-oxopiperidine (IX) (Chart II).

Results and Discussion

When crystals of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I) were allowed to stand at room temperature for six months, the paramagnetic substance liquefied with subsequent formation of a grey precipitate (mp 139—140°C) which was shown to be diamagnetic by an ESR technique. Further, this product IX could be isolated as a by-product, when the *N*-oxyl I was prepared from the corresponding hindered amine[5] at temperatures 50—60°C. Elemental analysis, molecular weight determination and mass spectral data gave the formula $C_{18}H_{34}N_2O_4$ which corresponded to an O,O coupled dimer (VII) or an aldol condensation product (VIII). Structures VII and VIII were eliminated for the following reasons. In the IR spectrum, this product had a carbonyl band at 1720 cm^{-1} and a hydroxy band at 3360 cm^{-1}. In the NMR(τ)(100 Mc, in $CDCl_3$), it had a broad singlet at 5.25—5.60 (1H), a doublet at 5.74 (1H, J=1.5 Hz), a doublet at 7.12 (1H, J=12.0 Hz), a doublet of doublets at 7.61 (1H, J=12.0 Hz, 1.5 Hz), a broad apparent triplet due to an AA'BB' system (4H, J= *ca.* 15 Hz), and five singlets due to unequivalent methyl proton signals 8.65, 8.70, 8.72, 8.76 and 8.81 (24 H). From these spectral data, the structure of the product, $C_{18}H_{34}N_2O_4$, was assigned to be 1-hydroxy-2,2,6,6-tetramethyl-3-(2,2,6,6-tetramethyl-4-oxopiperidinoxy)-4-oxopiperidine (IX). The product IX was treated with acetic anhydride, benzoic anhydride, phenyl isocyanate, semicarbazide or sodium borohydride to give a monoacetate (X), a monobenzoate (XI), an urethane (XII), a disemicarbazone (XIII) or a triol (XIV),[6] respectively (Chart II). The derivatives X, XI and XII had no hydroxy band in the IR spectra. On exposure to air, triol XIV changed into 2,2,6,6-tetra-

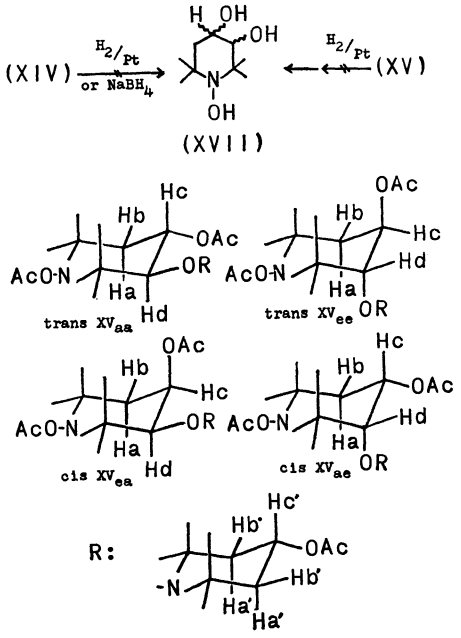
methyl-3-(2,2,6,6-tetramethyl-4-oxopiperidinoxy)-4-oxopiperidine-1-oxyl (XVI). When the new *N*-oxyl radical XVI was hydrogenated in the presence of the Adams catalyst in acetic anhydride solution, the corresponding triacetate (XV),[6] which was identical with triacetate derived from triol XIV, was obtained in good yield. These chemical reactivities corresponded to the properties of the assigned structure IX.

Thus we confirmed that i) the extremely stable *N*-oxyl radical I abstracted the α-methylene-hydrogen of the ketone which could give a thermodynamically stable conjugated ketone[3], ii) the radical I trapped a *C*-radical intermediate such as III, and iii) the decomposition of the radical I proceeded *via* the *C*-radical such as III to give phorone (V).

6) a) No antipode of triol XIV or triacetare XV was found. b) We were unable to establish the relative configuration of triol XIV and triacetate XV since the reductive cleavage of the C–N bond in XIV and XV to the corresponding 3,4-diol(triol XVII), which would be characterized as the acetonide, was unsuccessful using sodium borohydride or hydrogen in the presence of the Adams catalyst.



Further, the magnitude of the chemical shift and the coupling constant in the proton magnetic resonance was unreliable for configurational study because of the absence of the antipode of triol XIV and triacetate XV, and of the uncertainty in the conformation of the heterocyclic(piperidine) ring: the magnitude of the coupling constant (JHdHc=2.7 Hz) eliminated the *trans* XV_{aa}. However, the *trans* XV_{ee} and the *cis* XV_{ae} (or XV_{ea}) were undistinguishable by the coupling constant.

Experimental

All the melting points were uncorrected.

Unless otherwise stated, the IR spectra were determined by means of Nujol mull, and the molecular weight was determined by V. O. P. method. Mass spectra were obtained using a JEOL-JMS-OIS mass spectrometer.

1-Hydroxy-2,2,6,6-tetramethyl-3-(2,2,6,6-tetramethyl-4-oxopiperidinoxy)-4-oxopiperidine (IX). a) From the N-Oxyl I: When 1 kg of the crystals of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I)[3,5c] was allowed to stand for six months at room temperature, the crystals liquefied and then gave rise to *ca.* 100 g of a grey precipitate. The precipitate was filtered and washed with cold ether three times. The crude product was recrystallized from benzene to afford colorless prisms, mp 139—149°C (decomp.). The prisms were dried at 80°C for 3 hr under diminished pressure to give an analytically pure sample. Found: C, 63.43; H, 9.39; N, 8.33%; MW, 361.4 (in acetone). Calcd for $C_{18}H_{32}N_2O_4$: C, 63.50; H, 9.47; N, 8.23%; MW, 340.5. IR (cm^{-1}): ν_{O-H} 3360, $\nu_{C=O}$ 1720. NMR(τ)(in $CDCl_3$)(100 Mc): a broad singlet at 5.25—5.60 (1H), a doublet at 5.74 (1H, J=1.5 Hz), a doublet at 7.12 (1H, J=12.0 Hz), a doublet of doublets at 7.61 (1H, J=12.0 Hz, 1.5 Hz), a broad apparent triplet due to an AA'BB' system (4H, J=*ca.* 15 Hz) and five singlets due to unequivalent methyl proton signals at 8.65, 8.70, 8.72, 8.76 and 8.81 (24H).

b) From 2,2,6,6-Tetramethyl-4-oxopiperidine[5]: 2,2,6,6-Tetramethyl-4-oxopiperidine was oxidized with a 33% aqueous hydrogen peroxide solution at 50—60°C in the presence of EDTA and sodium tungstate. The reaction mixture was then saturated with potassium carbonate, and extracted with benzene. The benzene layer was washed with water saturated with sodium chloride and dried with potassium carbonate, and then the benzene solution was concentrated under

diminished pressure. The crude crystals, which separated from the reaction mixture, were filtered and washed with cold ether. The crude product was recrystallized from benzene to give an analytically pure sample, mp 139—140°C (decomp.), which was identical with the sample obtained by the above procedure *a*).

Monoacetate (X) of the Hydroxypiperidone IX. A solution of 0.5 g (1.47×10^{-3} mol) of IX in 1.5 m*l* of acetic anhydride was allowed to stand at room temperature for 18 hr. Evaporation of the solvent *in vacuo* gave an oily product. After the crude oil, dissolved with petroleum ether, was treated with active charcoal, pure crystals (0.4 g, 71.5%) were gradually obtained on concentration of the solution, and were recrystallized from petroleum ether three times to give an analytically pure sample, mp 89—90°C. Found: C, 62.90; H, 9.00; N, 7.33%; MW, 396.6 (in $CHCl_3$), 376 (in CCl_4). Calcd for $C_{20}H_{34}N_2O_5$: C, 62.83; H, 8.98; N, 7.35%; MW, 382.49. IR (cm^{-1}) (Grating): no ν_{O-H}; $\nu_{C=O}$ 1767,[7] 1745, 1722; (in CCl_4): 1785, 1745, 1725.

Monobenzoate (XI) of the Hydroxypiperidone IX. Into a mixture of 1.5 g (4.42×10^{-3} mol) of IX, 2.0 g (8.85×10^{-3} mol) of benzoic anhydride and 2.0 g (1.45×10^{-2} mol) of potassium carbonate in 4.0 m*l* of benzene was added slowly and dropwise 0.1 g of water with vigorous stirring at room temperature. Stirring was continued for 24 hr at room temperature after the evolution of carbon dioxide had ceased. The benzene layer was separated and washed with 5% aqueous solution of potassium carbonate and dried with potassium carbonate. The crude oil, obtained by evaporation of benzene *in vacuo*, solidified upon being scratched in a small amount of petroleum ether, (1.65 g, 84.5%). The crude crystals were dissolved in a small amount of benzene followed by addition of petroleum ether to give an analytically pure sample, mp 153.5-154.5°C. Found: C, 67.77; H, 8.15; N, 6.07%. Calcd for $C_{25}H_{36}N_2O_5$: C, 67.57; H, 8.16; N, 6.30%. IR (cm^{-1}): no ν_{O-H}; $\nu_{C=O}$ 1747, 1725.

Urethane (XII) of the Hydroxypiperidone IX. The ketone IX, 1.0 g (2.94×10^{-3} mol) exothermally dissolved at once in 0.6 g (5.04×10^{-3} mol) of pheny isocyanate, and the crude solid which separated was washed with petroleum ether, (1.3 g, 96.5%). An analytically pure sample was obtained by recrystallization from 95% ethanol, mp 147—148°C (decomp.). Found: C, 65.53; H, 8.18; N, 9.04%, MW, 488.5 (in acetone). Calcd for $C_{25}H_{37}N_3O_5$: C, 65.36; H, 8.13; N, 9.15%; MW, 459. IR(cm^{-1}): ν_{N-H} 3290; $\nu_{C=O}$ 1745, 1722.

Disemicarbazone (XIII) of the Hydroxypiperidone IX. Into a mixture of 0.34 g(1.00×10^{-3} mol) of IX and 0.3 g (3.66×10^{-3} mol) of sodium acetate in 4 m*l* of water was added gradually 0.3 g (2.70×10^{-3} mol) of semicarbazide hydrochloride with stirring for 3 hr at room temperature. The ketone IX dissolved and gave the crystals of the semicarbazone (0.35 g, 77.2%). An analytically pure sample was obtained by recrystallization from ethanol, mp 136°C (decomp.). Found: C, 52.79; H, 8.52; N, 24.39%. Calcd for $C_{20}H_{38}N_8O_4$: C, 52.84; H, 8.42; N, 24.65%. IR (cm^{-1}): ν_{O-H} 3460; ν_{N-H} 3350, 3270; $\nu_{C=O}$ 1678.

1,4-Dihydroxy-2,2,6,6-tetramethyl-3-(4-hydroxy-2,2,6,6-tetramethylpiperidinoxy)piperidine (=triol) (XIV). a) From the Hydroxypiperidone IX: Into a solution of 1.0 g (2.94×10^{-3} mol) of ketone IX in 20 m*l* of methanol was added ten 0.1 g portions (2.64×10^{-2} mol) of sodium borohydride under a nitrogen atmosphere for 5 hr at room temperature; then was added a solution of 0.5 g of ammonium chloride in 5 m*l* of water at 5°C. The solution was evaporated *in vacuo* to give a residue. The triol XIV was carefully extracted with absolute ethanol from the residue under nitrogen and obtained as an unstable crude product (0.75 g, 75%), which was recrystallized from methanol to give an analytically pure sample mp 168—171°C (decomp.).[6,8] Found: C, 63.07; H, 10.42; N, 8.27%. Calcd for $C_{18}H_{36}N_2O_4$: C, 62.77; H, 10.53; N, 8.13%. MS: M^+, *m/e* 343. IR (cm^{-1}): ν_{O-H} 3350; ν_{C-O} 1055.

b) From 2,2,6,6-tetramethyl-3-(2,2,6,6-tetramethyl-4-hydroxypiperidinoxy)-4-hydroxypiperidine-1-oxyl (=the diol-N-oxyl) (XVI): A solution of 0.1 g(2.94×10^{-4} mol) of the diol-*N*-oxyl XVI in 6 m*l* of methanol was shaken with hydrogen for 5 hr in the presence of the Adams catalyst until the yellow color disappeared. The catalyst was filtered off and the filtrate was evaporated under reduced pressure. After the residue was dissolved into a small amount of ether without exposure to air, the ethereal solution was diluted with petroleum ether. Gradually the unstable triol XIV crystallized, (84 mg, 84%), mp 167—171°C.[8]

1,4-Diacetoxy-2,2,6,6-tetramethyl-3-(4-acetoxy-2,2,6,6-tetramethylpiperidinoxy)piperidine (=triacetate) (XV). a) From the Diol-N-oxyl XVI: The diol-*N*-oxyl XVI, 2.0 g (5.82×10^{-3} mol), was dissolved in 60 m*l* of acetic anhydride and hydrogenated at room temperature for 5 hr in the presence of the Adams catalyst, until the yellow coloration of XVI disappeared. The catalyst was filtered off and 60 m*l* of pyridine was added into the filtrate. The reaction mixture was allowed to stand at room temperature for 24 hr. The solvent was then evaporated under reduced pressure. The crude oil obtained was dissolved in benzene, and the benzene layer was washed with a saturated aqueous solution of sodium bicarbonate. After the benzene was evaporated *in vacuo*, the residue solidified upon being scratched in a small amount of petroleum ether (2.2 g, 81.5%). The crude product obtained was recrystallized from petroleum benzine to afford an analytically pure sample, mp 173°C. Found: C, 61.50; H, 8.86; N, 5.96%. Calcd for $C_{24}H_{42}N_2O_7$: C, 61.25; H, 9.00; N, 5.95%. MS: M^+ *m/e* 470. IR (cm^{-1}): $\nu_{C=O}$ 1772, 1740. NMR(τ)(in C_5D_5N, 100 Mc)[6]: a doublet of doublets of doublets at 4.46 (1 Hc, J_{HcHb}=3.5 Hz, J_{HcHa}=3.0 Hz, and J_{HcHb}=2.7 Hz), a triplet of triplets at 4.90 (1 Hc′, $J_{Hc'Ha'}$=11.0 Hz, $J_{Hc'Hb'}$=5.0 Hz), a doublet at 5.93 (1 Hd, J_{HdHc}=2.7 Hz), doublets of doublets at 7.74 (1Hb, J_{HbHa}=15.5 Hz, J_{HbHc}=3.5 Hz) and at 8.19 (1 Ha, J_{HaHb}=15.5 Hz, J_{HaHc}=3.0 Hz), three singlets due to acetyl protons at 7.81 (3H), 7.97 (3H) and 8.01 (3H), and seven singlets due to methyl protons at 8.47 (3H), 8.52 (3H), 8.69 (3H), 8.77 (3H), 8.83 (6H), 8.87 (3H) and 8.92 (3H). Signals due to Ha′ and Hb′ overlapped with those due to the methyl protons and Ha at 8.5—8.1.

b) From the Triol XIV: A solution of 2.0 g (5.82×10^{-3} mol) of the triol XIV in 6 m*l* of acetic anhydride and 6 m*l* of pyridine was allowed to stand for 24 hr at room temperature. When the solvent was evaporated under reduced pressure, the crude product obtained was dissolved into benzene. The benzene layer was washed with a saturated aqueous solution of sodium bicarbonate. After the benzene was evaporated *in vacuo*, the residue solidified upon being scratched in a small amount of petroleum ether, (2.2 g, 81.8%), which was identical with the sample obtained by the above procedure *a*) (from XVI).

2,2,6,6-Tetramethyl-3-(2,2,6,6-tetramethyl-4-hydroxypiperidinoxy)-4-hydroxypiperidine-1-oxyl (=diol-N-oxyl) (XVI). a) From the Hydroxypiperidone IX: Into a solution of 0.6 g

7) O. Exner and B. Kanáč, *Collection Czech. Chem. Commun.*, **25**, 2530 (1960).

8) The crystals turned yellow on exposure to air.

(1.77×10^{-3} mol) of IX in 20 m*l* of methanol was added six 100 mg portions (1.58×10^{-2} mol) of sodium borohydride in the presence of oxygen (air) at room temperature. After additional stirring for 10 hr, a solution of 0.3 g of ammonium chloride in 5 m*l* of water was added into the mixture at 5°C. The solvents (methanol and water) were evaporated *in vacuo*. Extraction of *N*-oxyl XVI with absolute ethanol from the reaction mixture followed by evaporation *in vacuo* gave yellow paramagnetic crystals, (0.47 g, 78%), which was dissolved in a small amount of methanol and diluted with petroleum ether to give an analytically pure sample, mp 183—184°C (decomp.). Found: C, 63.07; H, 10.09; N, 8.21%; MW, 383.6 (in acetone). Calcd for $C_{18}H_{35}N_2O_4$: C, 62.91; H, 10.28; N, 8.17%; MW, 343. MS: M^+ *m/e* 343.258 (Calcd 343.259). IR (cm^{-1}): ν_{O-H} 3400; ν_{C-O} 1040.

b) From the triol XIV: When a solution of triol XIV in methanol was treated under an oxygen (air) atmosphere, the solution turned yellow. After the solution was allowed to stand at room temperature for two days, evaporation of methanol gave yellow crystals. The crude crystals were recrystallized from ether to give an analytically pure sample, mp 183—184°C (decomp.), which was identical with the sample obtained by the above procedure *a*) (from IX).

Thanks are due to Mr. H. Kuwano for 100 Mc-NMR, Mr. T. Kinoshita for mass spectrometry, Mr. H. Horiuchi and Mr. T. Kanai for their technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2210—2213 (1971)

The Synthesis of 1-Phenylazulene and 2-Phenylazulene from the Troponoid Compound

Tetsuo NOZOE, Kahei TAKASE* and Satoko FUKUDA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-2-chome, Sendai

(Received February 22, 1971)

1-Phenylazulene (I) and 2-phenylazulene (II) were synthesized from the troponoid compound. 3-Phenyl-(III) and 3-benzoyl-2*H*-cyclohepta[*b*]furan-2-ones (IV) were prepared by the reaction of 2-chlorotropone with ethyl phenylacetate and with ethyl benzoylacetate respectively. The reactions of III with malononitrile or ethyl cyanoacetate gave 1-phenylazulene derivatives, from which I was derived. On the other hand, the reactions of IV with ethyl cyanoacetate or diethyl malonate gave 2-phenylazulene derivatives, from which II was derived.

As has been described in previous papers,[1,2] it has been found that the reaction of 2*H*-cyclohepta[*b*]-furan-2-one derivatives with compound having a reactive methylene group, such as malononitrile, ethyl cyanoacetate, or diethyl malonate, gave azulene derivatives bearing the substituents at the 1-, 2-, and 3-positions. Moreover, the relationship between the kinds of substituents in the azulene derivatives formed and the structures of the starting 2*H*-cyclohepta[*b*]-furan-2-one derivatives or of the compounds with the reactive methylene group has also been revealed.[2] These findings suggest that this reaction can be used fruitfully in the synthesis of azulene derivatives bearing the desired substituents. As an application of this reaction, we have now studied the synthesis of 1-phenylazulene(I) and 2-phenylazulene(II) from the troponoid compound, though I has been synthesized by Plattner *et al.*[3] from bicyclo[5,3,0]decenone and by Hafner[4] through the condensation of the cyclopentadiene derivative and pyridinium salt, and II has also been synthesized by Plattner *et al.*[3] from phenylindane.

Considering the reaction mechanism[2] of the formation of azulene derivatives from 2*H*-cyclohepta-[*b*]furan-2-one derivatives, it is expected that 1-phenyl- and 2-phenylazulene derivatives should be formed from 3-phenyl- (III) and 3-benzoyl-2*H*-cyclohepta[*b*]furan-2-ones (IV) respectively by means of reactions analogous to those in the formations of the azulene-1-carboxylic esters (VIa) or 2-methylazulene derivatives (VIb) from 3-ethoxycarbonyl- (Va) or 3-acetyl-2*H*-cyclohepta[*b*]furan-2-ones (Vb)[2] respectively. Consequently, compounds III and IV

should be important intermediates in the synthesis of 1-phenylazulene(I) and 2-phenylazulene(II) from the troponoid compound. Moreover, compounds III and IV are expected to be prepared from 2-chlorotropone(VII)[5] in a way analogous to the preparation of Va and Vb.[6]

Results and Discussion

1-Phenylazulene. In order to prepare 3-phenyl-2*H*-cyclohepta[*b*]furan-2-one(III), the reaction of 2-chlorotropone(VII) with ethyl phenylacetate was examined. This reaction succeeded in the presence of sodium ethoxide, giving III in an 81% yield. The structure of III was revealed from the fact that its ultraviolet spectrum is similar to those of 2*H*-cyclohepta[*b*]furan-2-one derivatives,[6] while its infrared spectrum shows absorptions at 1736 and 1721 cm^{-1}, corresponding to those of the five-membered lactone.

Compound III easily reacted with malononitrile in the presence of sodium ethoxide to give an azulene derivative(VIIIa) in a good yield. The reaction of III with ethyl cyanoacetate also proceeded easily in the presence of sodium ethoxide to afford a mixture of a basic azulene derivative(VIIIb) and an acidic azulene derivative(IX). On the other hand, the reaction of III with diethyl malonate ended in the recovery of the original substance. The azulene derivatives obtained here, VIIIa, VIIIb, and IX, were assigned the structures of 2-amino-1-cyano-3-phenylazulene, ethyl 2-amino-3-phenylazulene-1-carboxylate and 1-cyano-2-hydroxy-3-phenylazulene respectively on the basis of a consideration of a reaction mechanism for their formation analogous to that for the formation of azulene derivatives from 2*H*-cyclohepta[*b*]furan-2-one derivatives,[2] as well as on the basis of the observations to be described below. The ultraviolet and visible absorption spectra revealed these compounds to be azulene derivatives. Their infrared spectra show the characteristic absorptions as shown in Table 1. Moreover, VIIIa gave a *N*-acetyl derivative, VIIIb gave a picrate, and IX gave a methyl ether with diazomethane.

Table 1. The infrared spectral data of the azulene derivatives

Compound	Absorptions, cm^{-1} (KBr)
VIIIa	3410, 3300, 3185 (NH_2); 2198 (CN)
IX	3135 (OH); 2222 (CN)
XI	3410, 3330, 3205 (NH_2); 2212 (CN); 1603 (CO)
XIIa	3330~2400, 1647, 931 (CO_2H); 2217 (CN)
Me ester of XIIa	2217 (CN), 1692 (CO)
XIIb	3165 (broad), 1647, 927 (CO_2H); 1698 (CO)
Me ester of XIIb	1678 (CO)

The treatment of VIIIa and of VIIIb with isoamyl nitrite in the presence of sulfuric acid in ethanol-dioxane gave deamination products, (Xa) and (Xb) respectively. Their infrared spectra show absorptions at 2208 and 1684 cm^{-1}, corresponding to those of the conjugated cyano and carbonyl groups respectively. The deamination of VIIIa was rather difficult; it produced a slightly soluble, black material, together with Xa. Upon heating in 100% phosphoric acid, both Xa and Xb gave the same blue hydrocarbon. Although its melting point, 61—62°C, was higher than that previously reported,[3] 54—55°C, its ultraviolet and visible absorption spectra and infrared spectrum were identical with those of 1-phenylazulene (I).[3] Moreover, the melting point of bistrinitrobenzolate was also identical with that of I.

2-Phenylazulene. 3-Benzoyl-2*H*-cyclohepta[*b*]furan-2-one (IV) was obtained in a 66% yield by the reaction of 2-chlorotropone (VII) with ethyl benzoylacetate in the presence of sodium ethoxide. The ultraviolet spectrum is similar to those of 2*H*-cyclohepta[*b*]-furan-2-one derivatives,[6] and the infrared spectrum shows an absorption at 1773 cm^{-1} corresponding to that of the five-membered lactone. These spectral data are consistent with the structure of IV.

Compound IV easily reacted with malononitrile in the presence of tert-butylamine to give a basic azulene derivative(XI). The reaction of IV with ethyl cyanoacetate and with diethyl malonate also proceeded easily in the presence of sodium ethoxide to give acidic azulene derivatives, XIIa and XIIb respectively. These azulene derivatives, XI, XIIa, and XIIb, were assigned the structures of 2-amino-1-benzoyl-3-cyanoazulene, 3-cyano-2-phenylazulene-1-carboxylic acid, and 3-ethoxycarbonyl-2-phenylazulene-1-carboxylic acid respectively on the basis of a consideration of the reaction mechanism for their formation analogous to that established for the formation of azulene derivatives from 2*H*-cyclohepta[*b*]furan-2-one derivatives,[2] as well as on the basis of the observations to be described below. The ultra-

6) S. Seto, *Sci. Repts. Tohoku Univ., Ser. I*, **37**, 367 (1953).

violet and visible absorption spectra revealed these compounds to be azulene derivatives. Their infrared spectra show the characteristic absorptions shown in Table 1. Moreover, compound XI gave a *N*-acetyl derivative upon treatment with acetic anhydride, and gave 2-amino-1-cyanoazulene,[2] identified as the *N*-acetyl derivative, and benzoic acid upon heating in concentrated hydrobromic acid. On the other hand, compounds XIIa and XIIb, which were assumed to be carboxylic acids on the basis of their infrared spectra, were soluble in a sodium hydrogen carbonate solution and gave the corresponding methyl esters on methylation with diazomethane.

The derivation of 2-phenylazulene(II) from XIIa was achieved by a two-step procedure. Thus, XIIa gave 1-cyano-2-phenylazulene (XIIIa) or 1-carbamoyl-2-phenylazulene(XIV) upon heating in 100% phosphoric acid or in concentrated sulfuric acid respectively. The infrared spectra of XIIIa and XIV show the absorptions at 2208 cm^{-1} and at 3367, 3155, and 1631 cm^{-1}, corresponding to the conjugated cyano and carbamoyl groups respectively. The further treatment of XIV with 100% phosphoric acid gave a blue hydrocarbon in a good yield; it was identified with 2-phenylazulene (II)[3] on the basis of a comparison of the ultraviolet and visible absorption spectra and on the basis of the infrared spectra. On the contrary, the treatment of XIIIa in concentrated sulfuric acid gave mainly XIV, together with a small amount of II.

On the other hand, compound XIIb gave II directly and in a good yield upon heating in 100% phosphoric acid. However,when heated in concentrated hydrobromic acid, XIIb gave ethyl 2-phenylazulene-1-carboxylate (XIIIb) by decarboxylation, together with II. Compound XIIIb easily gave II in a good yield when heated in 100% phosphoric acid.

As has been described above, 1-phenylazulene(I) and 2-phenylazulene(II) were easily synthesized from troponoid compounds in good yields. Moreover, this synthetic procedure is thought to be desirable since all the steps proceeded under rather mild conditions; consequently, there is no trouble in the thermal isomerization between I and II at high temperatures.[3]

Experimental

All the melting points are uncorrected. The ultraviolet and visible absorption spectra were measured on a Hitachi EPS-3 spectrophotometer, while the infrared spectra were recorded on a Shimadzu IR-27 infracord apparatus.

*3-Phenyl-2*H*-cyclohepta*[b]*furan-2-one (III).* Into a solution of 2-chlorotropone(VII) (2.80 g) and ethyl phenylacetate (6.60 g) in anhydrous ethanol (15 m*l*), a sodium ethoxide solution prepared from sodium (920 mg) and anhydrous ethanol (20 m*l*) was stirred under cooling with ice water. After having been stirred for an additional 2 hr, the mixture was allowed to stand for 2 days in a refrigerator and then poured into water (300 m*l*). The crystals thereby formed were collected by filtration. Yield, 3.59 g; mp 135—140°C. Recrystallization from ethanol gave III as reddish-orange needles; mp 146—147°C.

Found: C, 81.27; H, 4.60%. Calcd for $C_{15}H_{10}O_2$: C, 81.06; H, 4.54%. UV (MeOH): λ_{max} nm (log ε); 226 (4.48), 265 (4.40), 400 (4.28).

2-Amino-1-cyano-3-phenylazulene (VIIIa). To a solution of III (380 mg) and malononitrile (200 mg) in anhydrous ethanol (5 m*l*), 1 M sodium ethoxide solution (3 m*l*) was added; the mixture was stirred for 2 hr and then allowed to stand for 2 days at room temperature. Water was added to this mixture, and the crystals thereby formed were collected by filtration to give VIIIa (390 mg); mp 190—193°C. Recrystallization from dioxane afforded red micro-needles; mp 195—196°C.

Found: C, 83.17; H, 4.63; N, 11.20%. Calcd for $C_{17}H_{12}N_2$: C, 83.58; H, 4.95; N, 11.47%. UV (MeOH): λ_{max} nm (log ε); 247 (4.44), 316 (4.76), 380 (4.02).

N-*Acetyl Derivative*: Violet prisms (from dimethylformamide); mp 225—226°C.

Found: C, 79.66; H, 5.05; N, 9.50%. Calcd for $C_{19}H_{14}ON_2$: C, 79.70; H, 4.93; N, 9.78%. UV (MeOH): λ_{max} nm (log ε); 246 (4.40), 314 (4.75), 357 (3.82), 545 (2.79).

Ethyl 2-Amino-3-phenylazulene-1-carboxylate (VIIIb) and 1-*Cyano-2-hydroxy-3-phenylazulene (IX).* To a solution of III (380 mg) and ethyl cyanoacetate (480 mg) in anhydrous ethanol (6 m*l*), a 1 M sodium ethoxide solution (8 m*l*) was added; the mixture was stirred for 2 hr and then allowed to stand for 2 days at room temperature. The reaction mixture was then poured into water and shaken with chloroform. The chloroform layer was dried over anhydrous sodium sulfate, after which the solvent was evaporated. The oily residue was solidified by the addition of ethanol, giving VIIIb (260 mg); mp 121—122°C. Recrystallization from ethanol gave red prisms; mp 124—125°C.

Found: C, 78.14; H, 5.79; N, 4.49%. Calcd for $C_{19}H_{17}O_2N$: C, 78.33; H, 5.88; N, 4.81%. UV (MeOH): λ_{max} nm (log ε); 255 (4.43), 320 (4.58).

Picrate: Violet needles (from ethanol); mp 137—138°C.

Found: C, 58.08; H, 3.86; N, 10.41%. Calcd for $C_{25}H_{20}O_9N_4$: C, 57.69; H, 3.87; N, 10.77%.

The aqueous layer was acidified with 6 N hydrochloric acid, and the crystals thereby formed were collected by filtration to give IX (130 mg); mp 213—216°C. Recrystallization from dioxane gave reddish brown micro-needles; mp 232—233°C.

Found: C, 80.71; H, 4.82; N, 5.35%. Calcd for $C_{17}H_{11}ON\text{-}1/2H_2O$: C, 80.30; H, 4.76; N, 5.51%. UV (MeOH): λ_{max} nm (log ε): 247 (4.50), 314 (4.70), 449 (2.77).

Methyl Ether: Reddish violet needles (from ethanol); mp 136—137°C.

Found: C, 83.19; H, 5.26; N, 5.15%. Calcd for $C_{18}H_{13}ON$: C, 83.37; H, 5.05; N, 5.40%. UV (MeOH): λ_{max} nm (log ε); 245 (4.37), 308 (4.66). 358 (3.61), 400 sh (3.11), 503 (2.57).

1-Cyano-3-phenylazulene (Xa). To a solution of VIIIa (470 mg) in a mixture of ethanol (6 m*l*) and dioxane (6 m*l*) containing concentrated sulfuric acid (0.4 m*l*), isoamyl nitrite (0.3 m*l*) was added; the mixture was then stirred for 5 hr at room temperature. The reaction mixture was then poured into water, extracted with chloroform, and dried over anhydous sodium sulfate. After the evaporation of the solvent, the residue was dissolved in benzene and passed through a short column of alumina. The evaporation of the solvent from the effluent left blue crystals (200 mg), mp 117—122°C, which were recrystallized from ethanol to give Xa as blue needles; mp 127—128°C.

Found: C, 89.37; H, 4.69; N, 5.94%. Calcd for C_{17}-

$H_{11}N$: C, 89.05; H, 4.84; N, 6.11%. UV (MeOH): λ_{max} nm (log ε); 241 (4.52), 300 (4.55), 375 (3.87), 570 (3.31).

Ethyl 3-Phenylazulene-1-carboxylate (Xb). To a solution of VIIIb (725 mg) in a mixture of ethanol (10 ml) and dioxane (6 ml) containing concentrated sulfuric acid (0.5 ml), isoamyl nitrite (0.4 ml) was added; when the mixture was then treated in a manner similar to that described above, it gave violet crystals (390 mg), mp 74—76°C. Recrystallization from ethanol gave Xb as violet scales; mp 82—83°C

Found: C, 82.87; H, 5.76%. Calcd for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%. UV (MeOH): λ_{max} nm (log ε); 243 (4.56), 285 (4.66), 303 (4.68), 382 (4.08), 560 (2.65).

1-Phenylazulene (I). *a) From Xa*: A mixture of Xa (100 mg) and 100% phosphoric acid (1 ml) was heated at about 120°C for 40 min, and then poured into water and extracted with chloroform. After drying over anhydrous sodium sulfate, the solvent was evaporated, and the oily residue was dissolved in benzene and chromatographed through an alumina column. The first effluent gave blue crystals (40 mg); mp 53—55°C. Recrystallization from ethanol gave I as blue scales; mp 61—62°C. The melting point previously reported was 54—55°C.[3]

Found: C, 93.97; H, 6.25%. Calcd for $C_{16}H_{12}$: C, 94.08; H, 5.92%. UV (MeOH): λ_{max} nm (log ε); 238 (450), 294 (4.62), 353 (3.83), 369 (3.84), 435 (2.08), 466 (2.13).

From the second effluent of the chromatography, Xa (37 mg) was recovered.

b) From Xb: A mixture of Xb (200 mg) and 100% phosphoric acid (2 ml) was heated at about 100°C for 1 hr, and then treated in a manner similar to that described above. The effluent of the chromatography gave blue crystals (142 mg), mp 57—59°C, which were recrystallized from ethanol to give I as blue scales, mp 61—62°C.

3-Benzoyl-2H-cyclohepta[b]furan-2-one (IV). Into a solution of 2-chlorotropone (VII) (3.5 g) and ethyl benzoylacetate (7.2 g) in anhydrous ethanol (10 ml), a 1 M sodium ethoxide solution was stirred under cooling with ice water. After stirring for an additional 2 hr, the mixture was allowed to stand overnight in a refrigerator and then poured into water (200 ml). The crystals thereby formed were collected by filtration and washed with a small amount of acetic acid, thus giving crude IV (4.1 g), mp 137—145°C. Recrystallization from glacial acetic acid afforded yellow prisms; mp 157—158°C.

Found: C, 76.81; H, 4.29%. Calcd for $C_{16}H_{10}O_3$: C, 76.79; H, 4.03%. UV (MeOH): λ_{max} nm (log ε); 227 (4.34), 257 (4.43), 427 (4.40).

2-Amino-1-benzoyl-3-cyanoazulene (XI). To a suspension of IV (500 mg) and malononitrile (200 mg) in anhydrous ethanol (5 ml), *t*-butylamine (15 drops) was added; the mixture was stirred for 5 hr at room temperature and then allowed to stand overnight. Water (30 ml) was added to this mixture, and the crystals thereby formed were collected by filtration, giving XI (520 mg); mp 214°C. Recrystallization from pyridine afforded orange micro-scales; mp 214—215°C.

Found: C, 79.26; H, 4.55; N, 9.98%. Calcd for $C_{18}H_{12}ON_2$: C, 79.39; H, 4.44; N, 10.29%. UV (MeOH): λ_{max} nm (log ε); 227 (4.37), 249 (4.24), 292 (4.47), 338 (4.48), 470 (3.43).

N-*Acetyl Derivative*: Orange needles (from dimethylformamide); mp 209—210°C.

Found: C, 76.39; H, 4.41; N, 9.01%. Calcd for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%. UV (MeOH): λ_{max} nm (log ε); 225 (4.36), 305 (4.62), 370 (3.91), 480 (2.79).

3-Cyano-2-phenylazulene-1-carboxylic Acid (XIIa). To a suspension of IV (250 mg) and ethyl cyanoacetate (230 mg) in anhydrous ethanol (3 ml), a 1 M sodium ethoxide solution (3 ml) was added; the mixture was stirred for 5 hr and then allowed to stand for 2 days at room temperature. The reaction mixture was dissolved in water (30 ml) and shaken with chloroform. The aqueous layer was acidified with 6 N hydrochloric acid, and the crystals thereby formed were collected by filtration, giving XIIa (250 mg); mp 228°C. Recrystallization from dioxane afforded red needles; mp 232—233°C.

Found: C, 78.88; H, 4.00; N, 4.90%. Calcd for $C_{18}H_{11}O_2N$: C, 79.11; H, 4.06; N, 5.13%. UV (MeOH): λ_{max} nm (log ε); 228 (4.40); 267 (4.32), 320 (4.69), 345 (3.91), 517 (2.74).

Methyl Ester. This ester was obtained by treatment of XIIa with diazomethane. Red micro-needles (from benzene); mp 173—174°C.

Found: C, 79.69; H. 4.57; N, 5.03%. Calcd for $C_{19}H_{13}O_2N$: C, 79.43; H, 4.56; N, 4.88%. UV (MeOH): λ_{max} nm (log ε); 230 (4.39), 269 (4.32), 320 (4.66), 525 (2.73).

3-Ethoxycarbonyl-2-phenylazulene-1-carboxylic Acid (XIIb). To a suspension of IV (500 mg) and diethyl malonate (0.65 ml) in anhydrous ethanol (8 ml), a 1 M sodium ethoxide solution (8 ml) was added; the mixture was then treated in a manner similar to that described above. The crude crystals (360 mg), mp 182°C (decomp.), obtained by the acidification of the aqueous layer were recrystallized from dioxane to give XIIb as red micro-needles; mp 190°C (decomp.).

Found: C, 71.39; H, 4.84%. Calcd for $C_{20}H_{16}O_4 \cdot H_2O$: C, 70.99; H, 5.36%. UV (MeOH): λ_{max} nm (log ε); 233 (4.34), 268 (4.24), 310 (4.60), 520 (2.70), 560 (2.69).

Methyl Ester. This ester was obtained by the treatment of XIIb with diazomethane. Red prisms (from methanol); mp 160—161°C.

Found: C, 75.45; H, 5.51%. Calcd for $C_{21}H_{18}O_4$: C, 75.43; H, 5.43%. UV (MeOH): λ_{max} nm (log ε); 233 (4.42), 273 (4.34), 305 (4.54), 515 (2.63).

Treatment of XI with Hydrobromic Acid. A mixture o XI (100 mg) and concentrated hydrobromic acid (1 ml) was heated at about 100°C for 2 hr, then diluted with water, made alkaline with 6 N potassium hydroxide solution, and extracted with chloroform. After drying over anhydrous sodium sulfate, the solvent was evaporated from the organic layer, the residue was heated with acetic anhydride (1 ml) for 15 min, and the crystals thereby formed were collected and recrystallized from ethyl acetate, thus giving 2-acetamido-1-cyanoazulene[2] (30 mg) as red needles; mp 225—226°C.

The alkaline aqueous layer was acidified with 6 N hydrochloric acid and extracted with chloroform. The solvent was evaporated, and the residue was sublimed under reduced pressure, thus giving benzoic acid (20 mg) as colorless crystals; mp 120—121°C.

1-Cyano-2-phenylazulene (XIIIa). A mixture of XIIa (100 mg) and 100% phosphoric acid (1 ml) was heated at about 100°C for 30 min, then diluted with water and extracted with benzene. The benzene solution was passed through a short column of alumina and the evaporation of the solvent from the effluent gave XIIIa (80 mg) as violet crystals; mp 110—111°C. Recrystallization from ethanol afforded violet plates; mp 115—116°C.

Found: C, 89.35; H, 4.80; N, 5.98%. Calcd for $C_{17}H_{11}N$: C, 89.05; H, 4.84; N, 6.11%. UV (MeOH): λ_{max} nm (log ε); 273 (4.22), 311 (4.24), 319 (4.78), 364

(3.93), 565 (2.78).

1-Carbamoyl-2-phenylazulene (XIV). A mixture of XIIa (100 mg) and concentrated sulfuric acid (1 m*l*) was heated at about 100°C for 40 min, and then diluted with water and extracted with chloroform. The chloroform solution was passed through a short column of alumina; the subsequent evaporation of the solvent from the effluent gave XIV (54 mg) as violet crystals, mp 186°C. Recrystallization from chloroform afforded violet plates; mp 189—190°C.

Found: C, 82.33; H, 5.16; N, 5.30%. Calcd for $C_{17}H_{13}ON$: C, 82.57; H, 5.30; N, 5.66%. UV (MeOH): λ_{max} nm (log ε); 243 (4.29), 303 (4.72), 310 (4.75), 364 (3.86), 383 sh (3.82), 565 (2.61).

2-*Phenylazulene (II).* *a) Treatment of XIV with Phosphoric Acid*: A mixture of XIV (35 mg) and 100% phosphoric acid (1 m*l*) was heated at about 100°C for 30 min, and then diluted with water and extracted with benzene. The benzene solution was passed through a short column of alumina; the subsequent evaporation of the solvent from the effluent gave II (20 mg) as blue crystals; mp 229°C. Recrystallization from benzene afforded blue plates; mp 231—232°C. The melting point previously reported[3] was 230°C.

Found: C, 94.08; H, 6.02%. Calcd for $C_{16}H_{12}$: C, 94.08; H, 5.92%. UV (isooctane): λ_{max} nm (log ε); 242 (4.11), 296 (4.79), 307 (4.81), 355 (3.73), 372 (4.05), 392 (4.19), 590 (2.46).

b) Treatment of XIIb with Phosphoric Acid: A mixture of XIIb (100 mg) and 100% phosphoric acid was heated at about 100°C for 30 min, and then treated in a manner similar to that described about to give II (57 mg) as blue plates; mp 231—232°C.

Treatment of XIIIa with Sulfuric Acid. A mixture of XIIIa (60 mg) and concentrated sulfuric acid (1 m*l*) was heated at about 100°C for 40 min, and then diluted with water and extracted with chloroform. The solvent was evaporated, and the residue was chromatographed on an alumina column. The first effluent, when eluted with benzene, gave II (12 mg) as blue plates; mp 231—232°C. The second effluent, when eluted with chloroform, gave XIV (35 mg) as violet plates; mp 189—190°C.

Treatment of XIIb with Hydrobromic Acid. A mixture of XIIb (100 mg) and concentrated hydrobromic acid was heated at about 100°C for 30 min, then diluted with water and extracted with chloroform. The solvent was evaporated, and the residue was chromatographed on an alumina column. The first effluent, when eluted with a 1 : 2 mixture of benzene and cyclohexane, gave II (27 mg) as blue plates; mp 231—232°C. The second effluent, when eluted with benzene-chloroform, gave ethyl 2-phenylazulene-1-carboxylate (XIIIb) (40 mg) as reddish-violet needles; mp 85—86°C.

Found: C, 82.84; G, 6.08%. Calcd for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%. UV (MeOH): λ_{max} nm (log ε): 226 (4.27), 308 (4.67), 356 (3.80), 366 (3.81), 550 (2.62).

Treatment of XIIIb with Phosphoric Acid. A mixture of XIIIb (17 mg) and 100% phosphoric acid (0.4 m*l*) was heated at about 100°C for 30 min. Subsequent dilution with water gave II (12 mg) as blue crystals; mp 231—232°C.

The Synthesis of 7-Isopropyl-2,4-dimethylazulene (Se-Guaiazulene) from 4-Isopropyltropolone

Tetsuo NOZOE, Kahei TAKASE,* and Satoko FUKUDA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-2-chome, Sendai

(Received February 22, 1971)

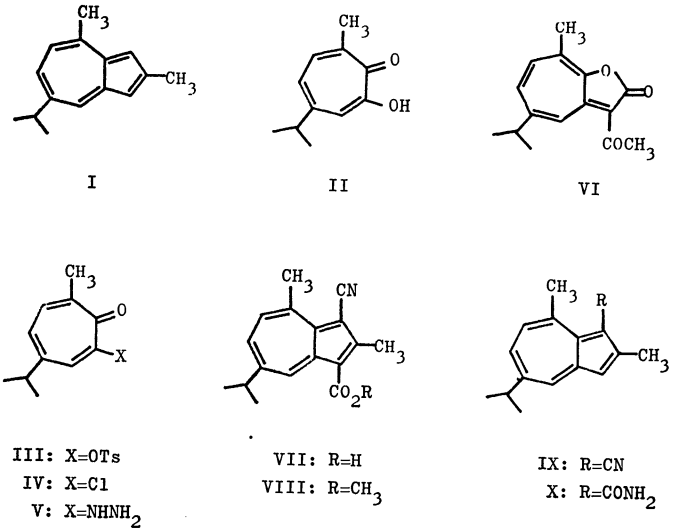
7-Isopropyl-2,4-dimethylazulene (Se-guaiazulene) (I) was synthesized from 4-isopropyl-7-methyltropolone (II), which had itself been derived from 4-isopropyltropolone. The tropolone, II, was then converted to 3-acetyl-5-isopropyl-8-methyl-2*H*-cyclohepta[*b*]furan-2-one (VI) *via* the *p*-tolylsulfonyloxytropone derivative derived from II. The application of the azulene synthesis to VI gave 3-cyano-7-isopropyl-2,4-dimethylazulene-1-carboxylic acid (VII), from which I was obtained by the removal of the carboxyl and cyano groups.

Since the discovery of the method for synthesizing azulenoid compounds from troponoid compounds,[1] a number of 2-amino- and 2-hydroxyazulene derivatives have been synthesized directly from troponoid compounds.[2] Moreover, as has been described in one of our previous papers,[3] it has been found that the reaction of 4-acetyl-2*H*-cyclohepta[*b*]furan-2-one (3-acetyl-1-oxaazulan-2-one) with ethyl cyanoacetate or diethyl malonate gave 2-methylazulene derivatives. This finding suggests that 2-alkylazulene derivatives can be easily synthesized from troponoid compounds *via* 3-acyl-2*H*-cyclohepta[*b*]furan-2-ones. As an example of the application of this method to the synthesis of azulenoid compounds from troponoid compounds, we have now studied the synthesis of 7-isopropyl-2,4-dimethylazulene (Se-guaiazulene) (I), obtained from the natural sesquiterpenoid precursors, from the troponoid compound, though this azulene had already been synthesized by Sǒrm *et al.*[4] from an indanone derivative.

Results and Discussion

6-Isopropyl-3-methyltropolone(II)[5] was used as the starting material for the synthesis of 7-isopropyl-2,4-dimethylazulene (**I**). This tropolone has the methyl and isopropyl substituents at the positions favorable for the synthesis of I, and was prepared from 4-isopropyltropolone in an 85% yield by means of morphorinomethylation and subsequent reductive demorphorination.[6]

It is known that the reaction of 2-chloro- or 2-(*p*-tolylsulfonyloxy)tropones and ethyl sodioacetoacetate gives 3-acetyl-2*H*-cyclohepta[*b*]furan-2-one derivatives.[7,8] Accordingly, the derivation of 2-(*p*-tolylsulfonyloxy)- or 2-chlorotropone derivatives from II was first examined. The treatment of II with *p*-toluenesulfonyl chloride gave a kind of *p*-tolylsulfonyloxy derivative(III).[6] Because of the highly mobile tautomerism in tropolones,[2] two isomeric *p*-tolylsulfonyloxy derivatives would be expected to be formed from unsymmetrical tropolone derivatives, but, in this case, only an isomer was obtained in a good yield. A similar result has been observed in the case of 3-methyltropolone, which gave only one of the isomers, 7-methyl-2-(*p*-tolylsulfonyloxy)tropone,[8] this is thought to be due to the steric hindrance of the methyl group. Consequently, the (*p*-tolylsulfonyloxy)-tropone derivative, III, obtained here was assumed to have the structure of 4-isopropyl-7-methyl-2-(*p*-tolylsulfonyloxy)tropone. The 2-chlorotropone derivative (IV) was derived from III as follows. The treatment of III with hydrazine gave a hydrazinotropone derivative (V), which could be converted to IV by oxidative decomposition with copper sulfate in concentrated hydrochloric acid.[9]



In order to obtain the 3-acetyl-2*H*-cyclohepta[*b*]-furan-2-one derivative(VI), the reaction of III or IV with ethyl acetoacetate was examined. This reaction took place upon the heating of a mixture of III or IV and ethyl sodioacetoacetate in benzene. When ethanol was used as the solvent in place of benzene, only a resinous substance was formed, even when

the mixture was cooled with ice water. The structure of VI was confirmed from the following evidence. Its ultraviolet absorption spectrum is similar to those of 2*H*-cyclohepta[*b*]furan-2-ones,[7] and its infrared spectrum shows absorptions at 1736 and 1639 cm^{-1}, corresponding to those of the five-membered lactone and the conjugated carbonyl group respectively. Moreover, it is known[8] that 2-(*p*-tolylsulfonyloxy)-tropones or 2-chlorotropones bearing the alkyl substituent at the 7-position gave such 2*H*-cyclohepta-[*b*]furan-2-one derivatives as are formed in a normal substitution reaction; that is, the carbanion attacked the 2-position of the tropone nucleus to give substitution products.

The derivation of the azulene derivative(VII) from VI took place when VI was treated with ethyl cyanoacetate in a way similar to that described in the formation of 2-methylazulene derivatives from 3-acetyl-2*H*-cyclohepta[*b*]furan-2-one.[3] The reaction of VI with diethyl malonate, however, ended in the recovery of the original substance. The structure of VII was established as 3-cyano-7-isopropyl-2,4-dimethylazulene-1-carboxylic acid on the basis of the consideration that the reaction mechanism was analogous to that of the formation of 2-methylazulene derivatives from 3-acetyl-2*H*-cyclohepta[*b*]furan-2-one,[3] as well as on the basis of the following evidence. This compound, VII, is an acidic substance and gave a methyl ester (VIII) upon methylation with diazomethane. The ultraviolet and visible absorption spectra of VIII are consistent with those of azulene derivatives. The infrared spectrum of VII shows absorptions at 3200—2500, at 1647 and 940, and at 2212 cm^{-1}, corresponding to those of the carboxyl and cyano groups respectively, and that of VIII shows absorptions at 1684 and 2217 cm^{-1}, corresponding to those of the conjugated ester and cyano groups respectively.

The decarboxylation of VII proceeded effectively when it was heated in phosphoric acid at about 100°C; this gave 3-cyano-7-isopropyl-2,4-dimethylazulene(IX). The infrared spectrum of IX shows the absorption at 2208 cm^{-1} corresponding to the cyano group. Upon further heating in concentrated sulfuric acid or 100% phosphoric acid at about 130°C for a long period of time, IX gave 7-isopropyl-2,4-dimethylazulene(I), which was identified with an authentic specimen[10] on the basis of a comparison of the ultraviolet and visible absorption spectra and the infrared spectra, and by an admixture of the trinitrobenzolates. On the other hand, when IX was heated in concentrated sulfuric acid at about 100°C, the cyano group could not be eliminated; rather, it was partially hydrolyzed to give a carbamoylazulene derivative (X), which also gave I upon heating in 100% phosphoric acid at about 130°C.

Since 4-isopropyltropolone has already been synthesized,[11] the results described above indicate the total synthesis of 7-isopropyl-2,4-dimethylazulene (Se-guaiazulene). The yield of I from 4-isopropyltropolone was 20%. In this case, there is no such trouble as in the thermal isomerization[4] between S-guaiazulene and Se-guaiazulene at high temperatures, since the reaction took place under rather mild reaction conditions.

10) Se-Guaiazulene prepared from guiene was supplied by Dr. Yoshiharu Matsubara of the Nippon Terpene Co., Ltd., for which we thank him.

Experimental

All the melting points are uncorrected. The ultraviolet and visible absorption spectra were measured on a Hitachi EPS-3 spectrophotometer, and the infrared spectra were recorded on a Shimadzu IR-27 infracord apparatus.

*4-Isopropyl-7-methyl-2-(*p*-tolylsulfonyloxy)tropone (III).* To a stirred solution of 6-isopropyl-3-methyltropolone(II) (4.07 g) in pyridine (8 m*l*), *p*-toluenesulfonyl chloride was added (6.5 g) under cooling with ice water. After it had been stirred for an additional 3 hr, the mixture was allowed to stand overnight in a refrigerator. Water was added to this mixture, and the crystals thereby formed were collected. Yield, 6.80 g; mp 76—78°C. Recrystallization from ethanol gave III (5.41 g) as colorless prisms; mp 85—86°C. The melting point previously reported was 86—87°C.[6]

2-Hydrazino-4-isopropyl-7-methyltropone (V). A mixture of III (1.65 g) and a 50% ethanolic hydrazine solution (10 m*l*) was refluxed for 3 hr. The solvent was evaporated, the residue was triturated with water, and the crystals thereby formed were collected by filtration. Recrystallization from ether gave V (450 mg) as yellow needles; mp 80—81°C.

Found: C, 68.57; H, 8.39; N, 14.40%. Calcd for $C_{11}H_{16}ON_2$: C, 68.72; H, 8.39; N, 14.57%.

2-Chloro-4-isopropyl-7-methyltropone (IV). To a solution of V (420 mg) in concentrated hydrochloric acid (10 m*l*) being heated at about 100°C, a 30% aqueous copper sulfate solution (10 m*l*) was added in one lot. After being heated for 5 min, the mixture was cooled to room temperature, diluted with water, and extracted with chloroform. The subsequent evaporation of the solvent left a brown, oily material which was then dissolved in benzene and passed through a short column of alumina. The evaporation of the solvent from the effluent gave IV (315 mg) as a pale yellow oil.

Found: C, 67.15; H, 6.62%. Calcd for $C_{11}H_{13}OCl$: C, 67.17; H, 6.66%.

*3-Acetyl-5-isopropyl-8-methyl-2*H*-cyclohepta*[b]*furan-2-one (VI).*
a) From III: Ethyl acetoacetate (4.20 g) was dissolved in a 1 M ethanolic sodium ethoxide solution (32 m*l*), and the solvent was evaporated to dryness, giving ethyl sodioacetoacetate. To this dry benzene (30 m*l*) and III (5.23 g) were added, and then the mixture was refluxed for 3 hr. The reaction mixture was shaken with water, and the organic layer was dried over anhydrous sodium sulfate. The evaporation of the solvent left a mixture of crystals and an oily material, from which VI (990 mg) was isolated, mp 141—143°C, by the addition of ether, followed by filtration. The ether-soluble part was chromatographed on an alumina column and eluted with ether to give further crops of VI (100 mg), mp 140—143°C. Recrystallization from ethanol afforded yellow needles; mp 144—145°C.

Found: C, 74.04; H, 6.63%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%. UV (MeOH): λ_{max} nm (log ε); 227 (4.42), 254 (4.12), 285 (4.41), 420 (4.40).

The aqueous layer was acidified with 6N hydrochloric acid and extracted with benzene. The benzene extract

was shaken with a 2 N sodium hydroxide solution (5 ml), to give the sodium salt of II (860 mg) as pale yellow scales.

b) From IV: To dried ethyl sodioacetoacetate prepared from ethyl acetoacetate (340 mg) and 1 M sodium ethoxide (2.6 ml), dry benzene (8 ml) and IV (350 mg) was added; the mixture was then treated as has been described above. The crude crystals (120 mg); mp 137—139°C, were recrystallized from ethanol to give VI as yellow needles (mp 144—145°C).

3-Cyano-7-isopropyl-2,4-dimethylazulene-1-carboxylic Acid (VII). To a solution of VI (450 mg) and ethyl cyanoacetate (450 mg) in anhydrous ethanol (5 ml), a 1 M sodium ethoxide solution (8 ml) was added; the mixture was stirred for 3 hr and then allowed to stand overnight at room temperature. The reaction mixture was dissolved in water and shaken with chloroform. The aqueous layer was acidified with 6 N hydrochloric acid, the product was extracted with chloroform, and the chloroform extract was shaken with a sodium hydrogen carbonate solution. The carbonate layer was acidified with 6 N hydrochloric acid to give VII (410 mg) as pale red crystals; mp 155°C (decomp.). Recrystallization from dioxane afforded pale red micro-needles; mp 157°C (decomp.).

Found: C, 76.71; H, 6.35; N, 5.38%. Calcd for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.41; N, 5.24%.

Methyl 3-Cyano-7-isopropyl-2,4-dimethylazulene-1-carboxylate (VIII). To a suspension of VII (130 mg) in ethyl acetate (5 ml), an ethereal solution of diazomethane (2 ml) was added; the mixture was then stirred for 5 hr under cooling with ice water. The solvent was evaporated, the residue was dissolved in benzene, and the benzene solution was passed through a short column of alumina. The evaporation of the solvent from the effluent left red crystals (130 mg), mp 102—106°C, which were subsequently recrystallized from methanol to give VIII as reddish-violet micro-needles; mp 108-109°C.

Found: C, 76.93; H, 6.66; N, 4.74%. Calcd for $C_{18}H_{19}O_2N$: C, 76.84; H, 6.81; N, 4.98%. UV (MeOH): λ_{max} nm ($\log \varepsilon$); 243 (4.51), 270 (4.05), 296 (4.40), 308 (4.52), 344 (3.86), 373 (3.64), 500 (2.77).

3-Cyano-7-isopropyl-2,4-dimethylazulene (IX). A mixture of VII (270 mg) and 100% phosphoric acid (2 ml) was heated at about 100°C for 15 min, then diluted with water and extracted with chloroform. The solvent was evaporated, the residue was dissolved in benzene, and the benzene solution was passed through a short column of alumina. The subsequent evaporation of the solvent from the effluent gave crude IX (207 mg), mp 62—63°C. Recrystallization from ethanol afforded reddish-violet needles; mp 65—66°C.

Found: C, 86.07; H, 7.94; N, 6.06%. Calcd for $C_{16}H_{17}N$: C, 86.05; H, 7.67; N, 6.27%. UV (MeOH): λ_{max} nm ($\log \varepsilon$); 223 (4.20), 241 (4.30), 295 (4.66), 301 (4.73), 313 (4.40), 354 (4.03), 371 (3.98), 530 (2.75).

3-Carbamoyl-7-isopropyl-2,4-dimethylazulene (X). A mixture of IX (65 mg) and concentrated sulfuric acid (1 ml) was heated at 100°C for an hour, then diluted with water and extracted with chloroform. The chloroform solution was chromatographed on an alumina column and eluted with the same solvent. The subsequent evaporation of the solvent from the effluent left pale violet crystals (60 mg); mp 184—185°C. Recrystallization from chloroform gave X as violet plates; mp 186—187°C.

Found: C, 79.49; H, 7.87; N, 5.74%. Calcd for $C_{16}H_{19}ON$: C, 79.63; H, 7.94; N, 5.80%. UV (MeOH): λ_{max} nm ($\log \varepsilon$); 244 (4.37), 291 (4.70), 335 (3.64), 348 (3.77), 555 (2.66). IR (KBr); 3425, 3289, 3165, 1642 cm^{-1}.

7-Isopropyl-2,4-dimethylazulene (I). *a) From IX*: A mixture of IX (100 mg) and 100% phosphoric acid (1 ml) was heated at 120—130°C for 6 hr, then diluted with water and extracted with benzene. The benzene solution was passed through a short column of alumina; the subsequent evaporation of the solvent from the effluent left a blue-violet oil (80 mg).

Found: C, 90.62; H, 9.17%. Calcd for $C_{15}H_{18}$: C, 90.85; H, 9.15%. UV (MeOH): λ_{max} nm ($\log \varepsilon$); 245 (4.43), 280 (4.76), 290 (4.82), 308 (4.00), 334 (3.51), 348 (3.77), 362 (2.96), 565 (2.58), 580 (2.53), 606 sh (2.52), 665 sh (2.12).

The infrared spectrum and the ultraviolet and visible absorption spectra of this oil are identical with those of 7-isopropyl-2,4-dimethylazulene (I).[9]

Trinitrobenzolate: Violet micro-needles (from ethanol); mp 154—154.5°C. The melting point previously reported[4] was 152°C.

Found: C, 61.37; H, 5.36; N, 10.02%. Calcd for $C_{21}H_{21}O_6N_3$: C, 61.31; H, 5.15; N, 10.21%.

Picrate: Reddish violet micro-needles (from ethanol); mp 116—117°C. The melting point previously reported[4] was 110°C.

Found: C, 59.32; H, 4.95; N, 9.69%. Calcd for $C_{21}H_{21}O_7O_3$: C, 59.01; H, 4.95; N, 9.83%.

A similar treatment of IX (100 mg) in 75% sulfuric acid also gave I (70 mg).

b) From X. A mixture of X (50 mg) and 100% phosphoric acid (1 ml) was heated at 130—140°C for 2 hr and then treated in a manner similar to that described in a) to give I (37 mg).

This research has been financially supported by grants of the Japanese Ministry of Education and of the Sankyo Co., Ltd. The sample of 4-isopropyltropolone for this study was supplied by the Takasago Perfumary Co., Ltd.

The Bromination of 2-Methoxytropone and Its Bromo Derivatives

Tetsuo NOZOE, Kahei TAKASE*, and Masafumi YASUNAMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-2-chome, Sendai

(Received February 25, 1971)

The reaction of 2-methoxytropone and its bromo derivatives with bromine was examined in various solvents. The treatment of 2-methoxytropone or 5-bromo-2-methoxytropone with bromine in methanol gave an addition product, 2,6-dibromo-7,7-dimethoxy- (II) or 2,4,6-tribromo-7,7-dimethoxy-2,4-cycloheptadien-1-one (XIV) respectively, together with the substitution products. On the contrary, the treatment of 2-methoxytropone with bromine in anhydrous ethanol, chloroform, or carbon tetrachloride gave a reddish complex compound. In aqueous ethanol or acetic acid, however, it gave 3,5,7-tribromotropolone. A possible reaction mechanism involving the nucleophilic attack of a methanol molecule on 2-methoxytropones at the 2-position is presented to account for the formation of the addition products.

It has been established that, on bromination with bromine, tropolone generally gives substitution products,[1-3] whereas tropone gives addition products which are only changed to substituted tropones upon heating in the presence of sodium acetate[4]; this fact is chemical evidence for the concept that the aromatic character of tropone is less than that of tropolone. On the other hand, in the case of 2-methoxytropone(I),[3,5,6] it is expected that its aromatic character is less than that of tropolone because of the localization of the double bonds, while its stability is larger than that of tropone because of the contribution of the mesomeric effect due to the methoxyl group; consequently, the behavior of I in regard to bromine is expected to be intermediate between that of tropolone and that of tropone. In order to find chemical evidence of this, the reaction of I and its bromo derivatives with bromine was examined.

Results and Discussion

The treatment of 2-methoxytropone(I) with bromine in methanol at 0—5°C gave an oily mixture, from which a dibromo compound(II), $C_9H_{10}O_3Br_2$, was subsequently isolated by crystallization. The chromatography of the mother liquor in an alumina column afforded a dibromo compound(III), $C_8H_6O_2Br_2$, together with 3,7-dibromo-2-methoxytropone (IV)[5] and 3,5,7-tribromo-2-methoxytropone(V).[5] The relative yields of these products varied in accordance with the molar ratio of bromine used, but II was always formed as the major product.

The infrared spectrum of II exhibits an absorption at 1692 cm^{-1} characteristic of the conjugated carbonyl group and absorptions at 1147, 1106, and 1070 cm^{-1} corresponding to the ether linkage. The NMR spectrum of II reveals two singlets, at 3.25 (3H) and 3.42 ppm (3H), corresponding to two methoxyl groups, and two doublets, at 4.75 (1H, J=7.5 Hz) and 7.25 (1H, J=9.0 Hz), and two double doublets, at 5.94 (1H, J=9.0, 12.0 Hz) and 6.37 ppm (1H, J=7.5, 12.0 Hz), corresponding to a partial structure, -ĊCHBr-CH=CH-CH=Ċ-. Moreover, II was easily changed to IV when its chloroform solution was passed through an alumina column. Judging from these facts, II must be assigned the structure of 2,6-dibromo-7,7-dimethoxy-2,4-cycloheptadien-1-one. The ultraviolet absorption spectrum is also consistent with this structure.

Compound II was stable under acidic treatment in spite of its ketal structure; that is, the treatment of II with concentrated hydrobromic acid resulted only in the recovery of the original compound, except for the formation of a small amount of IV. On the other hand, II was sensitive to alkaline treatment; that is, II was easily changed to IV by treatment with alumina, as has been described above. Moreover, the treatment of II with sodium methoxide easily gave methyl 2,6-dibromobenzoate(VI),[7] a rearrangement product, in a nearly quantitative yield, while treatment with sodium acetate in methanol gave IV and VI.

Compound III gave 3,5-dibromotropolone(VII)[1] upon hydrolysis with hydrobromic acid. Moreover, the treatment of III with hydrazine afforded hydrazinotropone(VIII), which in turn gave 2,4,7-tribromotropone(IX)[8] upon oxidative decomposition with copper sulfate in the presence of hydrobromic acid. From these facts, III was assigned the structure of 5,7-dibromo-2-methoxytropone. The ultraviolet absorption spectrum is also consistent with this structure.

When a solution of 2-methoxytropone(I) in anhydrous ethanol was treated with bromine, neither an addition product nor a substitution product was obtained; instead, a reddish compound (X) was formed. The same compound was also obtained on the treatment of I with bromine in chloroform or carbon tetrachloride. On the contrary, when I was treated with bromine in aqueous ethanol or acetic

acid, 3,5,7-tribromotropolone (XI)[1-3] was easily produced in a good yield. Compound X gave the addition compound, II, when dissolved in methanol, whereas it gave XI on treatment with water. On the other hand, the original compound, I, was reproduced when X was treated with water containing sodium hydrogen sulfite. These facts suggested that X must be a complex compound similar to that of tropone[4] or tropolone.[1,2]

Ia

The reaction of bromo derivatives of 2-methoxytropone with bromine was also examined. The treatment of 3-bromo-2-methoxytropone(XII)[9] with bromine in methanol at 0—5°C afforded the substitution products, IV or V, by the use of one or two molar equivalents of the reagent respectively, but no addition product was isolated. On the other hand, a similar treatment of 5-bromo-2-methoxytropone(XIII)[5] with bromine gave an addition product (XIV), $C_9H_9O_3Br_3$, together with small amounts of IV and V. The infrared spectrum of XIV shows absorptions at 1706 cm^{-1} and at 1115 and 1071 cm^{-1}, corresponding to the conjugated carbonyl and the ether linkage respectively. The NMR spectrum reveals two singlets, at 3.25 (3H) and 3.40 ppm (3H), due to the methoxyl groups, and two doublets, at 4.71 (1H, J=4 Hz) and 7.53 (1H, J=2 Hz), and a double doublet, at 6.80 ppm (1H, J=9, 2 Hz), corresponding to a partial structure, –C(–)–CHBr–CH=CBr–CH=C(–)–. Moreover, it was easily changed quantitatively to V on being passed through an alumina column. From these facts, it is reasonable to assign the structure of 2,4,6-tribromo-7,7-dimethoxy-2,4-cycloheptadien-1-one to XIV.

The treatment of 7-bromo-2-methoxytropone(XV)[9] with bromine in methanol at 0—5°C resulted in the recovery of the original compound, but that at room temperature over a long period afforded IV. The dibromo compound, IV, and the tribromo compound, V, did not show any change when treated similarly.

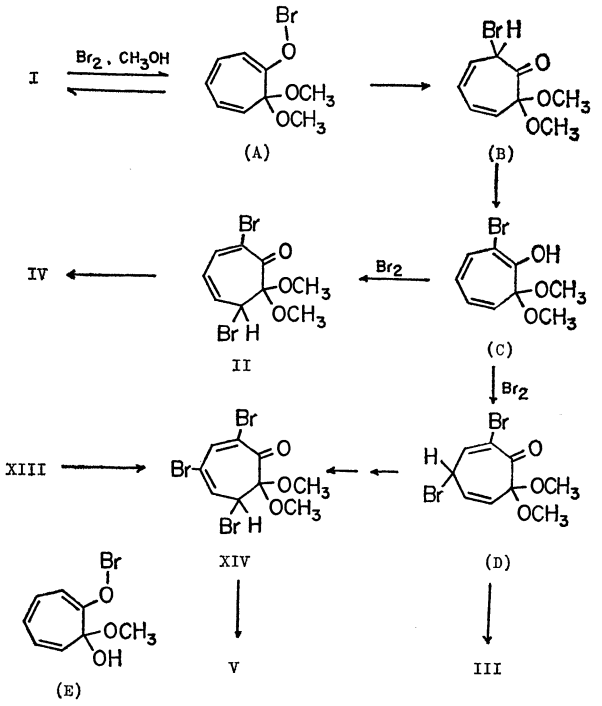

Chart 1. A possible mechanism for the reaction of 2-methoxytropone (I) with bromine in methanol.

From the findings described above, it is clear that the reaction of 2-methoxytropone(I) with bromine is markedly affected by the kind of the solvent used. It was also observed that the bromo substituents affected the reactivity of 2-methoxytropones toward bromine. Because of the rather large contribution of the polar structure(Ia),[5] the cationoid substitution can be expected to be difficult on I, for it is different from anisole. This is true when either anhydrous ethanol, chloroform, or carbon tetrachloride is used as the solvent, and I gave only a complex compound, X, as has been described previously. On the other hand, it was found that the treatment of I with bromine in methanol gave the addition compound, II, plus small amounts of the substitution products, IV and V. The formation of II is very interesting in the reaction mechanism. Although II has a structure corresponding to that consisting of the addition of a methanol molecule on IV, it is disproved that II is formed by the addition of methanol to IV, since IV did not show any change, at least under the present experimental conditions. Any possible mechanism for the formation of II would involve the nucleophilic attack of a methanol molecule on the 2-position of I, an attack which is facilitated by the coordination of the bromonium ion or its equivalent species on the carbonyl group, thus giving an intermediate (A), as is shown in Chart 1. The intermediate (A) changes immediately to a bromoketone-

9) T. Nozoe, Y. Kitahara, K. Yamane, and A. Yoshikoshi, *Proc. Japan Acad.*, **27**, 18 (1951).

type intermediate (B), which can then enolize to an enol-type intermediate (C). Although the two intermediates, (B) and (C), have structures consisting of the addition of a methanol molecule to 7-bromo-2-methoxytropone (XV), they are probably not produced through XV, since XV does not react with bromine under reaction conditions such as those under which I gave II. The reaction of bromine with the intermediate (C) affords the compound II. The substitution products, III, IV, and V, are assumed to be produced by the elimination of a methanol molecule from the corresponding addition compounds, (D), XIV and II respectively, which are formed through the intermediate (C). The addition compound XIV is also assumed to be formed from XIII through a similar reaction course.

In aqueous solvents, it is thought that a water molecule should attack the 2-position of I to give a hemiketal-type intermediate (E), which is similar to the intermediate (A). However, the intermediate (E) easily loses a methanol molecule, thus affording tropolone, which can then be easily brominated to give 3,5,7-tribromotropolone (XI).[1-3] On the other hand, in anhydrous ethanol it is presumed that an ethanol molecule can not attack the 2-position of I; consequently, probably no addition compound is formed. The reason for this has not yet been clear, but it seems to be due to the lesser nucleophilicity and/or to the greater sterical bulkiness of the ethanol molecule than that of the methanol molecule.

Experimental

All the melting points are uncorrected. The ultraviolet absorption spectra were taken on a Beckman DU spectrophotometer, and the infrared spectra, on a Shimadzu IR-27 infracord apparatus. The NMR spectra were determined with a Varian A-60 spectrometer on samples dissolved in deuteriochloroform and containing tetramethylsilane as an internal standard.

Bromination of 2-Methoxytropone(I) in Methanol. To a stirred solution of I (816 mg) in methanol (20 m*l*), a solution of bromine (1.0 g) in the same solvent (1 m*l*) was added under cooling at 0—5°C, after which the mixture was allowed to stand overnight in a refrigerator. The subsequent addition of water separated an oily material, which was then extracted with chloroform and dried over anhydrous sodium sulfate. The evaporation of the solvent left an oily residue (1.405 g), which was then crystallized by the addition of a small amount of methanol. The crystals (375 mg), mp 130—135°C, collected by filtration were recrystallized from benzene to give 2,6-dibromo-7,7-dimethoxy-2,4-cycloheptadien-1-one(II) as pale yellow prisms; mp 138—139°C.

Found: C, 33.32; H, 3.10%. Calcd for $C_9H_{10}O_3Br_2$: C, 33.47; H, 3.42%. UV (MeOH): λ_{max} nm (log ε); 330 (3.75).

All the filtrates were combined, and then the evaporation of the solvent left an oily material (870 mg) which was subsequently chromatographed on an alumina column. The fraction, when eluted with benzene, gave colorless crystals (130 mg). Recrystallization from methanol afforded 5,7-dibromo-2-methoxytropone(III) as colorless needles; mp 206—207°C.

Found: C, 32.72; H, 2.32%. Calcd for $C_8H_6O_2Br_2$: C, 32.01; H, 2.06%. UV (MeOH): λ_{max} nm (log ε); 275 (4.41), 320 (3.96), 335 (4.03), 373 (3.84).

Further elution with ether gave pale yellow crystals (85 mg). Recrystallization from ethyl acetate afforded 3,7-dibromo-2-methoxytropone(IV) as pale yellow needles, mp 134—135°C, which were identified with an authentic sample, mp 133—134°C,[5] by admixture and by a comparison of the infrared spectra.

A similar treatment of I (816 mg) with two or three molar equivalents of bromine gave II (839 mg), III (65 mg), IV (79 mg), and 3,5,7-tribromo-2-methoxytropone(V) (23 mg), mp 123—124°C,[5] and II (529 mg) and V (200 mg) respectively.

Treatment of II with Alumina. A solution of II (100 mg) in chloroform was passed through an alumina column. The subsequent evaporation of the solvent from the effluent gave IV (96 mg) as pale yellow needles; mp 134—135°C.

Treatment of II with Hydrobromic Acid. A solution of II (296 mg) in methanol (15 m*l*) containing concentrated hydrobromic acid (1 m*l*) was refluxed for 4 hr. The solution was concentrated to a small volume; the crystals thereby formed were then collected by filtration to give the original compound, II (265 mg), mp 138—139°C. The filtrate was diluted with water and extracted with chloroform. The subsequent evaporation of the solvent from the extract and the recrystallization of the residue from methanol gave IV (5 mg) as pale yellow needles; mp 134—135°C.

Treatment of II with Sodium Methoxide. A solution of II (592 mg) in methanol (20 m*l*) containing sodium methoxide (216 mg) was refluxed for 6 hr. The solvent was then evaporated, and the residue was dissolved in chloroform, washed with water, and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent left crystals (420 mg), mp 58—60°C, which were then recrystallized from petroleum ether to give methyl 2,6-dibromobenzoate(VI) as colorless needles; mp 63—64°C. This was identified with an authentic sample, mp 61—62°C[7] by admixture and by a comparison of the infrared spectra.

Treatment of II with Sodium Acetate. A mixture of II (1.48 g) and anhydrous sodium acetate (820 mg) in methanol (40 m*l*) was refluxed for 2.5 hr. The solution was then concentrated to a small volume, and to this was added water (30 m*l*). The precipitates thereby formed were collected by filtration and recrystallized from ethyl acetate to give IV (852 mg) as pale yellow needles; mp 134—135°C.

The subsequent evaporation of the solvent from the filtrate left an oily material (380 mg) which was then chromatographed on an alumina column and eluted with ether to give VI (354 mg) as colorless needles; mp 63—64°C.

3,5-Dibromotropolone (VII). A solution of III (60 mg) in methanol (30 m*l*) containing concentrated hydrobromic acid (4 m*l*) and water (4 m*l*) was refluxed for 3 hr. The subsequent evaporation of the solvent left crystals which were then recrystallized from methanol to afford VII (55 mg) as pale yellow needles; mp 152—153°C. VII was identified with an authentic sample, mp 152—153°C,[1] by admixture and by a comparison of the infrared spectra.

5,7-Dibromo-2-hydrazinotropone (VIII). To a suspension of III (294 mg) in ether (4 m*l*), 80% hydrazine hydrate (80 mg) was added under cooling at 0—5°C, after which the mixture was stirred for 9 hr. The orange crystals thereby formed were collected by filtration and recrystallized from ethyl acetate to give VIII (294 mg) as yellow needles; mp 155—156°C.

Found: C, 28.14; H, 2.56: N, 9.88%. Calcd for $C_7H_6ON_2Br_2$: C, 28.50; H, 2.05; N, 9.49%.

2,4,7-Tribromotropone (IX). Into a mixture of VIII

(260 mg) and concentrated hydrobromic acid (2 ml) being heated in a boiling water bath, a hot solution of 40% aqueous cupric sulfate solution was stirred; a vigorous evolution of nitrogen gas thus occurred. After the mixture had been heated for 5 min, it was allowed to cool to room temperature, diluted with water, and extracted with chloroform. After the chloroform solution had been dried over anhydrous sodium sulfate, the solvent was evaporated and the residue was dissolved in ether and passed through a short column of alumina. The subsequent evaporation of the solvent from the effluent, followed by the recrystallization of the residue from methanol, gave IX (60 mg) as pale yellow needles; mp 177—178°C. This was identified with an authentic sample, mp 177—178°C,[8] by admixture and by a comparison of the infrared spectra.

Reaction of I with Bromine in Anhydrous Ethanol. To a stirred solution of I (816 mg) in anhydrous ethanol (2 ml), a solution of bromine (1.0 g) in the same solvent (1 ml) was added under cooling at 0—5°C. A few minutes later, reddish orange precipitates were separated out. After being stirred for 5 min, the precipitates were collected by filtration to afford X (1.5 g) as a reddish powder.

Treatment of X with Methanol. A sample of X (500 mg) was dissolved in methanol (10 ml) and then allowed to stand overnight. The subsequent evaporation of the solvent left an oily material (384 mg) which was then crystallized by the addition of a few drops of methanol. The crystals (120 mg); mp 128—133°C, when collected by filtration, were recrystallized from ethyl acetate to give II (98 mg) as pale yellow prisms; mp 138—139°C.

All the filtrates were combined, the solvent was evaporated, and the oily residue (260 mg) was dissolved in ether and chromatographed on an alumina column. The fraction eluted with ether gave IV (83 mg) as pale yellow needles, mp 134—135°C, and V (56 mg) as yellow needles, mp 123-124°C.

Treatment of X with a Sodium Sulfite Solution. To a suspension of X (100 mg) in chloroform (2 ml), a 10% aqueous sodium hydrogen sulfite solution (9.5 ml) was added. After being stirred for 1 hr, the aqueous layer was separated and extracted with chloroform. All the chloroform layers were combined and dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent left an oily material (43 mg) which was identified with 2-methoxytropone, I, by a comparison of the infrared spectra.

Treatment of X with Water. A suspension of X (200 mg) in water (5 ml) was stirred for 5 hr; the reddish color gradually disappeared, and pale yellow precipitates were formed. The product was collected by filtration and recrystallized from methanol to give 3,5,7-tribromotropolone (XI) (82 mg) as yellow needles, mp 121—122°C, which were identified with an authentic sample[1] by admixture and by a comparison of the infrared spectra.

Bromination of I in Ethanol. To a stirred solution of I (816 mg) in ethanol (10 ml) containing a small amount of water, a solution of bromine (3.10 g) in ethanol (10 ml) was added under cooling at 0—5°C. When a half of the bromine solution had been added, reddish precipitates were separated out; they gradually dissolved upon stirring for 1 hr. After being allowed to stand overnight, the reaction mixture was diluted with water (100 ml) and extracted with chloroform and the chloroform layer was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent left crystals (2.327 g) which were recrystallized from ethanol to afford XI (1.628 g) as yellow needles; mp 121—122°C.

Bromination of I in Acetic Acid. To a solution of I (816 mg) in acetic acid (10 ml), a solution of bromine (2.12 g) in the same solvent (5 ml) was added under cooling at 0—5°C. After being allowed to stand overnight, the reaction mixture was treated in a manner similar to that described above; this gave XI (1.10 g) as yellow needles; mp 121—122°C.

Bromination of 3-Bromo-2-methoxytropone (XII). To a solution of XII (215 mg) in methanol (2 ml), a solution of bromine (160 mg) in the same solvent (1 ml) was added under cooling at 0—5°C, after which the mixture was allowed to stand overnight at room temperature. The reaction mixture was diluted with water, and the precipitates thereby formed were collected by filtration and recrystallized from methanol to give IV (250 mg) as pale yellow needles; mp 134—135°C.

A similar treatment of XII (215 mg) with bromine (320 mg) gave V (205 mg) as yellow needles; mp 123—124°C.

Bromination of 5-Bromo-2-methoxytropone (XIII). To a solution of XIII (215 mg) in methanol (15 ml), a solution of bromine (350 mg) in the same solvent (2 ml) was added under cooling at 0—5°C. After being allowed to stand overnight, the reaction mixture was diluted with water and extracted with chloroform, and the organic layer was dried over anhydrous sodium sulfate. The subsequent evaporation of the solvent left an yellow oil (481 mg), which was crystallized by the addition of a small amount of methanol. Recrystallization from methanol gave 2,4,6-tribromo-7,7-dimethoxy-2,4-cycloheptadien-1-one (XIV) as pale yellow prisms; mp 107—108°C.

Found: C, 26.98; H, 2.38%. Calcd for $C_9H_9O_3Br_3$: C, 26.69; H, 2.24%. UV (MeOH): λ_{max} nm (log ε); 333 (3.73).

A solution of XIV (100 mg) in chloroform was passed through an alumina column. The subsequent evaporation of the solvent from the effluent gave V (76 mg) as yellow needles; mp 123—124°C.

Reaction of 7-Bromo-2-methoxytropone (VII) with Bromine. a) To a stirred solution of VII (107 mg) in methanol (8 ml), a solution of bromine (80 mg) in the same solvent (2 ml) was added under cooling at 0—5°C, after which the mixture was allowed to stand overnight in a refrigerator. The reaction mixture was diluted with water (50 ml) and extracted with chloroform. The subsequent evaporation of the solvent gave the original compound, VII (92 mg).

b) To a stirred solution of VII (214 mg) in methanol (15 ml), a solution of bromine (240 mg) in the same solvent (5 ml) was added under cooling at 0—5°C, after which the mixture was allowed to stand for 7 days in a refrigerator and then for a few days at room temperature. Then, the reaction mixture was diluted with water; the precipitates thereby formed were collected by filtration to afford pale yellow crystals (89 mg), which later gave IV (56 mg); mp 134—135°C, by recrystallization from methanol.

Aminocyclitols. XXVI. A Synthesis of Aminocyclopentanetetrols

Tetsuo SUAMI, Yukio SAKOTA, Kinnichi TADANO, and Shigeru NISHIYAMA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received February 27, 1971)

Hydrogenation of 2,3-*O*-cyclohexylidene-5-nitro-1,2,3,4-cyclopentanetetrol, subsequently followed by hydrolysis and acetylation, afforded (1,4/2,3,5)- and DL-(1,2,3/4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol (**3** and **14**). Beginning with (1,4/2,3,5)-5-acetamido-1,4-di-*O*-acetyl-2,3-*O*-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**2**), two hitherto unknown (1,2,3,4,5)- and DL-(1/2,3,4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol (**10** and **12**) were prepared. The structures were established by proton magnetic resonance spectra.

Six DL-pairs and four meso compounds are theoretically possible in aminocyclopentanetetrols and nowadays three DL-pairs and two meso compounds are known.[1,2]

A presence of five membered carbocyclic compounds in antibiotics aristeromycin[3,4] and pactamycin[5,6] has stimulated the authors to explore a synthesis of new aminocyclopentanetetrols. In 1965, Angyal and Gero[7] prepared 2,3-*O*-cyclohexylidene-5-nitro-1,2,3,4-cyclopentanetetrol (**1**) by cyclization of *cis*-3,4-cyclohexylidenedioxy-2,5-dihydroxytetrahydrofuran with nitromethane. Very recently, it has been described that two aminocyclopentanetetrols were obtained as their pentaacetyl-derivatives by catalytic hydrogenation of **1**.[2]

In the present article, the authors wish to report a preparation of four aminocyclopentanetetrols in which a DL-pair and a meso compound are hitherto unknown ones.

Catalytic hydrogenation of **1** in ethanol with Raney nickel T-4,[8] followed by acetylation afforded (1,4/2,3,5)-5-acetamido-1,4-di-*O*-acetyl-2,3-*O*-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**2**)[2] in 40% yield. Hydrolysis of **2** in 80% aqueous acetic acid and subsequent acetylation of the hydrolyzate yielded (1,4/2,3,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol (**3**)[1,2] of mp 147.5°C in 89% yield.

From the hydrogenation mixture, it was successfully attempted to isolate another isomer by a following procedure. The mother liquor from which the compound **2** had been obtained was settled in a refrigerator to give DL-(1,2,3/4,5)-5-acetamido-1,4-di-*O*-acetyl-2,3-*O*-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**13**). Hydrolysis of **13** in 80% aqueous acetic acid, followed by acetylation, gave DL-(1,2,3/4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol (**14**).[1]

Beginning with the compound **2**, two unknown aminocyclopentanetetrols were prepared by the following reactions. When **2** was treated with ammonia in methanol, *O*-acetyl groups were selectively removed to give 5-acetamido-2,3-*O*-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**8**) of mp 160.5°C in 61% yield. Methanesulfonylation of **8** with a large excess amount of methanesulfonyl chloride in pyridine afforded 1,4-di-*O*-methane sulfonyl derivative (**9**) in 69% yield. A treatment in boiling water and subsequent acetylation converted **9** to (1,2,3,4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol (**10**) of mp 173°C in a yield of 62%. The compound **10** showed a remarkable depression of the melting point, when it was mixed with (1,4,5/2,3)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol of mp 176.5°C.[2]

A similar treatment of **8** with the smaller amount of methanesulfonyl chloride yielded a mixture of mono-*O*-methanesulfonyl derivative (**11**) and **9**. The mixture was heated in boiling water and subsequently acetylated to give a mixture of DL-(1/2,3,4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentan-

etetrol (**12**) of mp 116°C and the compound **10,** which were separated by a chromatographic fractionation.

The compound **3** (mp 147.5°C) was identical with the compound described by Hasegawa and Sable[1] and by Ahluwalia, Angyal, and Luttrell.[2] The proton magnetic resonance (PMR) spectrum of **3** revealed three sharp signals at δ 1.95, 2.05 and 2.08 (3 : 6 : 6 protons) which were attributed to an acetamido, two acetoxy (on C-2 and C-3) and two acetoxy groups (on C-1 and C-4) respectively.

The compound **13** showed three sharp signals in its PMR spectrum for an acetamido and two acetoxy groups at δ 1.96, 2.10 and 2.12 (3 : 3 : 3 protons), proving that the two acetoxy groups on C-1 and C-4 had different configurations for the acetamido group. And the compound **14** (mp 188.5°C) showed five sharp signals in its PMR spectrum at δ 1.99, 2.06, 2.07, 2.11 and 2.12 (3 : 3 : 3 : 3 : 3 protons) indicating that this compound was not symmetrical and identical with DL-(1,2,3/4,5)-5-acetamido-1,2,3,4-tetra-*O*-acetyl-1,2,3,4-cyclopentanetetrol described by Hasegawa and Sable.[1]

The compound **10** (mp 173°C) showed three sharp signals at δ 2.04, 2.06 and 2.13 (3 : 6 : 6 protons) in its spectrum, showing that **10** had a symmetrical molecular structure.

Among four theoretically possible meso compounds, two isomers of (1,2,3,4,5) and (1,2,3,4/5) have never been described and the compound **10** should be one of these two isomers.

The following reaction mechanism was proposed for the reaction from **9** to **10**. Removal of a methanesulfonyloxy group yields an oxazolinium ion with a participation of a neighboring *trans*-acetamido group and the cyclic carbonium ion is attacked by water to give *cis*-acetamido alcohol.[9,10] The same anchimeric reaction occurs again with another methanesulfonyloxy group to give the (1,2,3,4,5)-isomer.

The compound **12** (mp 116°C) exhibited five sharp signals in its spectrum at δ 1.96, 2.01, 2.04, 2.06 and 2.10 (3 : 3 : 3 : 3 : 3 protons) indicating that this compound was an unsymmetrical one. Therefore, it was reasonably established that **12** was DL-(1/2,3,4,5)-isomer. The above mentioned reaction mechanism is also proposed in this reaction.

Now seven isomers of aminocyclopentanetetrols have been described in their pentaacetyl derivatives and only three isomers remain unknown. An attempt to synthesize these isomers is still under way.

Experimental

A melting point was determined in a liquid bath and was uncorrected. PMR spectrum was recorded on a Varian A-60D spectrometer, unless otherwise noted, at a frequency of 60 MHz in deuteriochloroform with tetramethylsilane as an internal standard. The peak position was expressed in δ-value.

2,3-O-Cyclohexylidene-5-nitro-1,2,3,4-cyclopentanetetrol (***1***). A mixture of *cis*-3,4-cyclohexylidenedioxytetrahydrofuran-2,5-diol (10.4 g) and nitromethane (2.8 g) was treated with sodium methoxide by the method of Angyal and Gero[7] to give 8.1 g (65%) of **1** as an oily product. The product was used for a successive reaction without any purification.

(1,4/2,3,5)-5-Acetamido-1,4-di-O-acetyl-2,3-O-cyclohexylidene-1,2,3,4-cyclopentanetetrol (***2***). A 5.4 g portion of **1** was hydrogenated in ethanol (50 m*l*) with Raney nickel T-4

catalyst[8] at 3.4 kg/cm² of hydrogen stream for 20 hr. After the catalyst was removed by filtration, the ethanol solution was evaporated under reduced pressure to give 4.7 g of a residual oil. The residue was acetylated in a mixture of acetic anhydride (20 m*l*) and pyridine (20 m*l*). The mixture was evaporated *in vacuo* and the residue was crystallized in benzene to give 3.2 g (45%) of needles, mp 137—139°C. Recrystallization from benzene gave 2.9 g (40%) of crystals, mp 140.5—141.5°C. PMR: δ 1.93 (3 protons, NAc) and 2.08 (6 protons, OAc×2). (Found: C, 57.33; H, 6.93; N, 3.77%).

*(1,4/2,3,5)-5-Acetamido-1,2,3,4-tetra-O-acetyl-1,2,3,4-cyclopentanetetrol (**3**).* A 1.33 g portion of **2** was heated under reflux for 4 hr in 80% aqueous acetic acid (20 m*l*) and the mixture was evaporated *in vacuo*. The residue was acetylated with acetic anhydride in pyridine to give 1.10 g (89%) of the crude product. Recrystallization from ether afforded needle crystals of mp 146.5—147.5°C. PMR: δ 1.95 (3 protons, NAc), 2.05 (6 protons, OAc×2, on C-2 and C-3), 2.08 (6 protons, OAc×2, on C-1 and C-4), 4.33(H), 5.21 (4H) and 6.44 (NH, J=8 Hz). (Found: C, 50.31; H, 5.80; N, 3.81%). Lit. mp 147°C[1] and 138.5—140°C.[2]

*(1,4/2,3,5)-5-Acetamido-1,2,3,4-tetra-O-trideuterioacetyl-1,2,3,4-cyclopentanetetrol (**4**).* A 0.12 g protion of **5** was treated with 0.7 m*l* of acetic anhydride-d_6 in 2.5 m*l* of pyridine to give 0.18 g (78%) of the product, mp 144—145°C. PMR: δ 1.95 (3 protons, NAc), 4.34 (H), 5.24 (4H) and 6.28 (NH).

*(1,4/2,3,5)-5-Acetamido-1,4-di-O-acetyl-2,3-di-O-trideuterioacetyl-1,2,3,4-cyclopentanetetrol (**16**).* A 50 mg sample of **15** was treated with 0.5 m*l* of acetic anhydride-d_6 in pyridine (1.0 m*l*) to give 20 mg of the product, mp 145°C. PMR: δ 1.95 (3 protons, NAc), 2.08 (6 protons, OAc×2, on C-1 and C-4), 4.33 (H), 5.25 (4H) and 6.08 (NH).

*(1,4/2,3,5)-5-Acetamido-1,2,3,4-cyclopentanetetrol (**5**).* A 0.5 g portion of **3** was selectively de-*O*-acetylated in methanol (50 m*l*) saturated with ammonia. The solution was evaporated under reduced pressure and the residue was washed with ethyl acetate to give a crude product. Recrystallization from ethanol afforded 0.14 g (53%) of the product, mp 169.5—171°C.

Found: C, 44.02; H, 6.71; N, 7.12%. Calcd for $C_7H_{13}NO_5$: C, 43.97; H, 6.85; N, 7.33%.

*(1,4/2,3,5)-5-Acetamido-1,4-di-O-acetyl-2,3-O-isopropylidene-1,2,3,4-cyclopentanetetrol (**6**).* A mixture of **5** (87 mg), anhydrous acetone (50 m*l*) and methanol (5 m*l*) was agitated for 48 hr in the presence of Drielite and a half drop of conc sulfuric acid. The reaction mixture was neutralized to pH 7 with Amberlite IR-4B and then evaporated under reduced pressure to give a crystalline residue. The residue was acetylated to give a crude product. Recrystallization from ethanol afforded 89 mg (63%) of needles, mp 177—178°C. PMR: δ 1.29 (3 protons, CH_3), 1.51 (3 protons, CH_3), 1.91 (3 protons, NAc), 2.05 (6 protons, OAc×2), 4.55 (3H), 5.04 (2H) and 6.37 (NH, J=8 Hz).

Foudd: C, 53.61; H, 6.77; N, 4.36%. Calcd for $C_{14}H_{21}NO_7$: C, 53.32; H, 6.71; N, 4.44%.

*(1,4/2,3,5)-5-Amino-1,2,3,4-cyclopentanetetrol (**7**).* A 1.05 g portion of **3** was heated under reflux in 6 N hydrochloric acid for 2 hr. The solution was evaporated *in vacuo* to give 0.61 g of a residue, The residue was dissolved in water and treated with Amberlite IRA-400(OH^-). The aqueous solution was evaporated and the residue was crystallized in absolute ethanol (10 m*l*) to give 0.39 g (89%) of the product, mp 159—161°C. The product showed a positive ninhydrin test.

Found: C, 40.59; H, 7.25; N, 9.58%. Calcd for $C_5H_{11}NO_4$: C, 40.26; H, 7.43; N, 9.39%.

*(1,4/2,3,5)-5-Acetamido-2,3-O-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**8**).* A 3.55 g portion of **2** was dissolved in methanol (100 m*l*) previously saturated with ammonia and the solution was settled overnight at room temperature. Evaporation of the solution under reduced pressure yielded an oily residue, which was triturated in a mixture of ethyl acetate (9 m*l*) and ether (15 m*l*) to give 1.89 g (70%) of the crude product. Recrystallization from ethyl acetate afforded 1.65 g (61%) of the crystals, mp 159.5—160.5°C.

Found: C, 57.31; H, 7.80; N, 5.14%. Calcd for $C_{13}H_{21}NO_5$: C, 57.55; H, 7.81; N, 5.16%.

*(1,4/2,3,5)-5-Acetamido-2,3-O-cyclohexylidene-1,4-di-O-methanesulfonyl-1,2,3,4-cyclopentanetetrol (**9**).* To 1.00 g of **8** in dry pyridine (20 m*l*) was added 0.8 m*l* of methanesulfonyl chloride with a mechanical agitation under ice cooling. The mixture was settled overnight at room temperature and then it was poured into 50 m*l* of ice and water. The aqueous solution was stored in a refrigerator to give 0.95 g (62%) of crystals, mp 112—116°C. PMR: δ 1.64 (10 protons, cyclohexylidene group), 2.03 (3 protons, NAc), 3.14 (6 protons, OMs×2), 4.84 (5H) and 6.61 (NH, J=8 Hz).

Found: C, 41.70; H, 6.09; N, 3.26; S, 13.83%. Calcd for $C_{15}H_{15}NS_2O_9$: C, 42.14; H, 5.89; N, 3.28; S, 15.00%.

An alternative method was as followings. The aqueous solution was extracted with chloroform (50 m*l*×4) and the chloroform extracts were evaporated under reduced pressure and the residue was added to 30 m*l* of water to give 1.07 g (69%) of crystals, mp 111—114°C. Recrystallization from an organic solvent resulted in a partial decomposition of the product.

*(1,2,3,4,5)-5-Acetamido-1,2,3,4-tetra-O-acetyl-1,2,3,4-cyclopentanetetrol (**10**).* A mixture of **9** (200 mg) and water (20 m*l*) was heated under reflux for 40 min and then evaporated under reduced pressure. The residue was acetylated as usual and the product was recrystallized from ethanol to give 83 mg (62%) of needles, mp 172—173°C. Admixture of **10** with (1,4,5/2,3)-isomer which was prepared by the method of Ahluwalia *et al.*[2] showed a remarkable depression of the melting point.

PMR (100 MHz): δ 2.04 (3 protons, NAc), 2.06 (6 protons, OAc×2), 2.13 (6 protons, OAc×2), 4.85 (H), 5.37 (4H) and 5.86 (NH, J=9 Hz).

Found: C, 49.87; H, 6.08; N, 3.97%. Calcd for $C_{15}H_{21}NO_9$: C, 50.13; H, 5.89; N, 3.90%.

*DL-(1/2,3,4,5)-5-Acetamido-1,2,3,4-tetra-O-acetyl-1,2,3,4-cyclopentanetetrol (**12**).* To a solution of **8** (0.5 g) in pyridine (10 m*l*) was added methanesulfonyl chloride (0.4 m*l*) with an agitation under ice cooling. After 65 min the mixture was poured into ice cold water (15 m*l*) and the aqueous solution was extracted with chloroform (40 m*l*×3). The combined chloroform extracts were washed with 0.1 N hydrochloric acid and water. Evaporation of chloroform yielded an oily product. Tlc on silica gel with benzene-ethanol (5 : 1) showed **9** at R_f 0.7 and monomethanesulfonyl derivative (**11**) at R_f 0.6 as two major components.

The mixture of **9** and **11** was heated in water (40 m*l*) under reflux for 3 hr and evaporated under reduced pressure. The residue was hydrolyzed in 80% aqueous acetic acid and the hydrolyzate was acetylated to give an oily product. The crude product was chromatographed on a silica gel column (Wako gel C-200, 25 g, 400×18 mm) with benzene-ethanol (5 : 1) as an eluant and each fraction (2 m*l*) was tested by tlc. A substance with R_f 0.66 was found in the fractions from 9th to 17th, which were combined and evaporated to give 0.33 g of a residue. The residue was crystallized in ether and recrystallized from ether to give 89 mg (14%) of the compound **12** as fine needles, mp 116°C. PMR:

δ 1.96 (3 protons, NAc), 2.01, 2.04, 2.06, 2.10 (3 protons each, OAc), 4.52 (H), 5.33 (4H) and 6.16 (NH, J=8 Hz).

Found: C, 50.21; H, 5.84; N, 3.92%. Calcd for $C_{15}H_{21}NO_9$: C, 50.13; H, 5.89; N, 3.90%.

The fractions from 18th to 35th contained a product of R_f 0.52, which were combined and evaporated. The residue was recrystallized from ethanol to give 115 mg (17%) of the compound **10**, mp 172—173°C, which was identified by a comparison of IR spectrum and a mixed melting point determination with an authentic sample.

*DL-(1,2,3/4,5)-5-Acetamido-1,4-di-O-acetyl-2,3-O-cyclohexylidene-1,2,3,4-cyclopentanetetrol (**13**).* The crystalline nitro compound **1** (1.86 g, mp 102—108°C) which was prepared by the method of Ahluwalia *et al.*[2] was hydrogenated in ethanol with Raney nickel T-4[8] and subsequently acetylated as described in the preparation of **2**. After 0.70 g of **2** was obtained from the benzene solution, the mother liquor was settled in a refrigerator for three days to give 0.19 g of the crude product, mp 185—188°C. The product was recrystallized from benzene to give 0.13 g (5%) of **13**, mp 186—188°C. PMR: δ 1.50, 1.68 (10 protons, cyclohexylidene group), 1.96 (3 protons, NAc), 2.10 (3 protons, OAc) and 2.12 (3 protons, OAc).

Found: C, 57.99; H, 7.25; N, 3.85%. Calcd for $C_{17}H_{25}NO_3$: C, 57.45; H, 7.09; N, 3.94%.

*DL-(1,2,3/4,5)-5-Acetamido-1,2,3,4-tetra-O-acetyl-1,2,3,4-cyclopentanetetrol (**14**).* A 72 mg portion of **13** was hydrolyzed in 6 N hydrochloric acid (10 ml) for 1 hr under reflux. The solution was evaporated *in vacuo* and the residue was acetylated to give a crude product. Recrystallization from ether afforded 52 mg (72%) of **14** as needle crystals, mp 187—188°C. PMR (100 MHz): δ 1.99 (3 protons, NAc), 2.06, 2.07, 2.11, 2.12 (3 protons each, OAc), 4.85 (H), 5.40 (4H) and 6.12 (NH, J=8 Hz).

Found: C, 50.54; G, 5.51; N, 3.96%. Calcd for $C_{15}H_{21}NO_9$: C, 50.13; H, 5.89; N, 3.90%.

An alternative method was as followings. The benzene mother liquor from which **2** had been obtained in the preparation of **2** beginning with an oily nitro compound **1** was evaporated to give a dark residue (3.8 g). The residue was hydrolyzed in 80% aqueous acetic acid and the hydrolyzate was acetylated. The acetylated product was dissolved in chloroform and the solution was decolorized with activated alumina and evaporated. The residue was crystallized in chloroform-ether to give 0.21 g of needles. Recrystallization from chloroform-ether afforded 172 mg of crystals, mp 187—188.5°C. The product was identified to be **14** by a comparison of IR spectrum and a mixed melting point determination with an above mentioned product. The product showed a single spot in tlc with benzene-ethanol (5 : 1).

*(1,4/2,3,5)-5-Acetamido-1,4-di-O-acetyl-1,2,3,4-cyclopentanetetrol (**15**).* Hydrolysis of **2** (1.88 g) in boiling 80% aqueous acetic acid (40 ml) for 40 min afforded an oily product, which showed two major eomponents on tlc with benzene-ethanol (5 : 1) at R_f 0.3 and 0.5. The crude product was crystallized in ethanol giving 0.77 g of crystals, mp 161—164°C. Recrystallization from ethanol afforded 0.62 g (42%) of **15**, mp 167—168.5°C.

Found; C, 48.30; H, 6.34; N, 5.41%. Calcd for $C_{11}H_{17}NO_7$: C, 48.00; H, 6.22; N, 5.09%.

Electronic Spectra of Square-Planar Bis(tertiary phosphine)dialkynyl Complexes of Nickel(II), Palladium(II), and Platinum(II)

Haruo MASAI, Kenkichi SONOGASHIRA, and Nobue HAGIHARA
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received February 27, 1971)

Electronic spectra of *trans*-$[L_2M(C{\equiv}CR)_2]$, (L=tertiary phosphine or tertiary stibine, and M=Ni, Pd or Pt) have been studied in solution from 220 mμ to 360 mμ. Nickel and platinum complexes showed three intense absorption bands. The lowest energy band was particularly sensitive to substituents of alkynyl groups. This band was assigned empirically to the transition between the molecular orbitals involved in metal-alkynyl bonds. The possibility of π-interaction between the two alkynyl groups through central metal was discussed in relation to the influence of R.

We have been studying the properties of bis(tertiary phosphine)dialkynyl complexes, *trans*-$[L_2M(C{\equiv}CR)_2]$, where L is a tertiary phosphine or tertiary stibine, and M is nickel(II), palladium(II), and platinum (II). In a previous paper,[1] infrared spectra of the series of the complexes were discussed. From the influence of substituent R upon metal-carbon stretching frequencies, $d\pi$–$p\pi$ interaction (back-donation) was regarded as an important factor which reinforces the metal-alkynyl bond. The result threw light upon properties of the metal-carbon σ-bond which plays an important role in many reactions catalyzed by transition metal complexes.

For a discussion of the properties of this series of complexes, information on their electronic structure is necessary. However, only a few discussions on the electronic spectra of alkynyl complexes or of complexes having D_{2h} symmetry can be found.[2,3] Theoretical treatment of the spectra of these metals has been limited to the complexes in D_{4h} or T_d symmetry.

In this work, electronic spectra (220 mμ—360 mμ) of the series of alkynyl complexes in solution are reported and their general trends discussed in terms of π-interaction between metal and alkynyl groups.

Results and Discussion

General Features. Electronic spectra (UV) of *trans*-$[L_2M(C{\equiv}CR)_2]$, where M is Ni (II), Pd (II) or Pt (II), and L is a tertiary phosphine or stibine, were recorded in ether from 220 mμ to 360 mμ. Their absorption maxima (λ_{max}) and intensities (log ε) are listed in Table 1.

The intensities of absorption band are of the order of 4 in log ε scale. Thus, these bands are presumably due to the allowed transition within the molecule, *i.e.* intramolecular charge-transfer transition.[4] In our case, no band due to *d–d* transition was observed. It is probably obscured by intense charge-transfer bands.

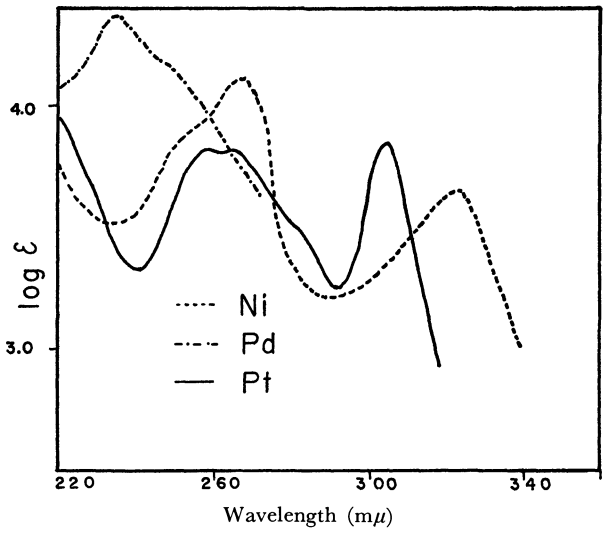

Fig. 1. Electronic spectra of *trans*-$[(Et_3P)_2M(C{\equiv}CH)_2]$ in ether.

The complexes show three intense absorption bands in this region expect for palladium complexes (Fig. 1 and Table 1), which exhibit unresolved bands at the shorter wavelength region than the others. Thus, we mainly discussed nickel and platinum complexes.

The characteristic feature of the palladium complexes has also been observed in UV spectra of teracyanide complexes of nickel(II), palladium(II) and platinum (II).[5,6]

Influence of Substituents of Alkynyl Groups. The change in substituents R's influences the wavelength of three absorption bands in different degrees (Fig. 2). The lowest energy band is most remarkably influenced as shown in Fig.2 and Table 1. Influence on the other bands was not clear, since in some cases they overlapped each other.

It is seen from Table 1 that the lowest energy band is subject to bathochromic effect of the substituents which increases in the following order.

$R=H<CH_3<CH_2F<CH_2{=}CH<HC{\equiv}C<Ph<CH_3C{\equiv}C$

Complicated absorption bands of butadiynyl derivatives (Fig. 3)may be assigned by a solvent effect. Plots of the position of the lowest energy band against ionization potentials (IP) of free alkynes[7] showed a linear correlation (Table 2 and Fig. 4).

The lowest band is evidently due to the charge-transfer transition involved in metal-carbon bonds as deduced from the remarkable influence of alkynyl groups. The relative one-electron energy diagram for these complexes (D_{2h} symmetry) is shown in Fig.

6, and the orbital transformation scheme in Table 3, derived from diagrams of tetracyanide complexes[5,6,8] and from our simple molecular orbital calculation.[9] The coordinate system is shown in Fig. 5.

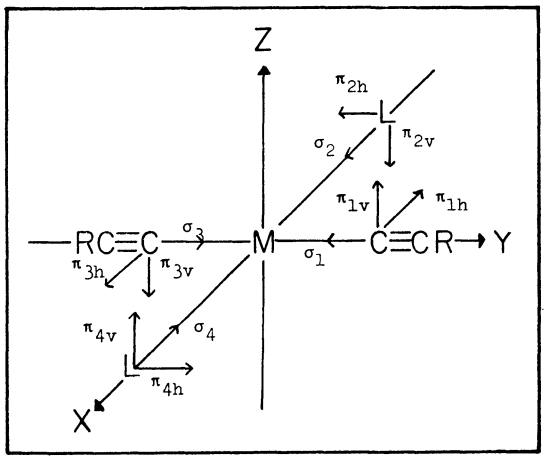

Fig. 5. Coordination system for the complex, *trans*-$[L_2M(C{\equiv}CR)_2]$.

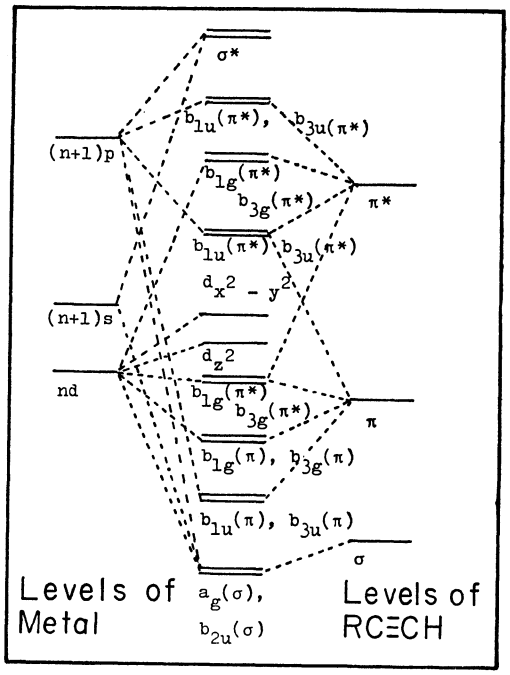

Fig. 6. Relative energy diagram of metal-carbon bond in *trans*-$[L_2M(C{\equiv}CR)_2]$.

The correlation shown in Fig. 4 suggests that the lowest band is presumably due to the transition from molecular orbitals consisting of bonding π-orbitals of alkynyl groups, *i.e.* $b_{1g}(\pi)$, or $b_{3g}(\pi)$, to $b_{3u}(\pi^*)$ or $b_{1u}(\pi^*)$ which contains the metal *p*-orbitals (Fig. 6 and Table 3).

The order of bathochromic shift of substituents is quite different from that of the square of metal-carbon stretching frequencies observed in the infrared spectra,[1] because the former concerns both ground and excited states and the latter only properties of the ground state.

The order of the bathochromic effect of R's is consistent with the increasing order of electronegativity

8) S. Kida, J. Fujita, K. Nakamoto, and R. Tsuchida, This Bulletin, **31**, 79 (1958).
9) N. Takeuchi, private communication.

of R's induced by the mesomeric effect, though some deviation was observed in nickel complexes.

As shown in Fig. 7, two alkynyl groups can mutually interact through metal d_{xy} and d_{yz} orbitals. Hence, a long conjugate system involving the metal *d*-orbitals is formed in the *trans* square-planar dialkynyl complexes, and b_{1g} (π) and b_{3g} (π) orbitals are used for the interaction. The bathochromic shift of the lowest band is regarded as evidence for existence of the conjugate system.

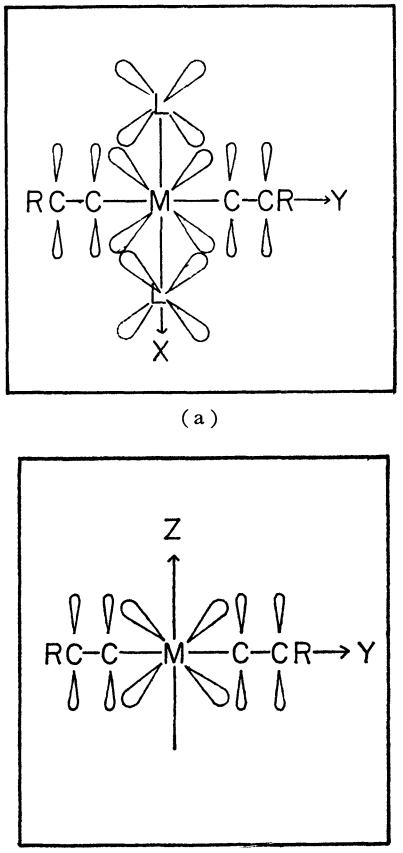

Fig. 7. Interaction between metal *d*-orbitals and alkynyl π-orbitals;
(a) *X*–*Y* plane (b) *Y*–*Z* plane

Influence of Solvents. Since the solution spectrum is inevitably influenced by solvents, we have studied the influence on the spectra of alkynyl complexes. There was no systematic influence on the intensities of absorption maxima. However, the lowest bands of the spectra showed a blue shift in alcohols (Fig. 8 and Table 4). No appreciable influence was observed in other solvents, such as *n*-hexane, cyclohexane, dichloromethane and acetonitrile, *i.e.* neither polar nor *n*-donor properties of solvents had influence upon the spectra.

The specific influence of alcohols is regarded as a consequence of some interaction between OH group and the alkynyl complexes. Formation of hydrogen bonding may be responsible for this effect. Here, proton acceptor orbitals are considered to be b_{3g} orbitals from the result of a study on electron donor-acceptor complexes.[10]

Butadiynyl derivatives, *trans*-[$(Et_3P)_2M(C{\equiv}CC{\equiv}CR)_2$], (M = Ni or Pt, R = H, CH_3 or Ph), gave very complicated spectra (Fig. 3). However, the lowest bands of these spectra displayed a similar behavior to those of the other alkynyl complexes in alcoholic solvents (Table 4 and Fig. 3). Thus, these bands may be regarded as the same as the lowest

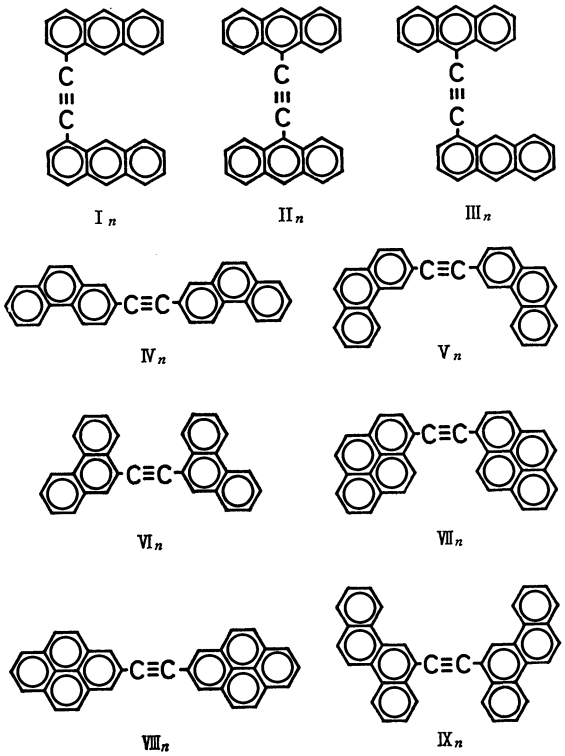
Linear Conjugated Systems Bearing Aromatic Terminal Groups. IV.[1] The Syntheses of Some Diarylacetylenes

Shuzo AKIYAMA, Kazuhiro NAKASUJI, and Masazumi NAKAGAWA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
(Received March 8, 1971)

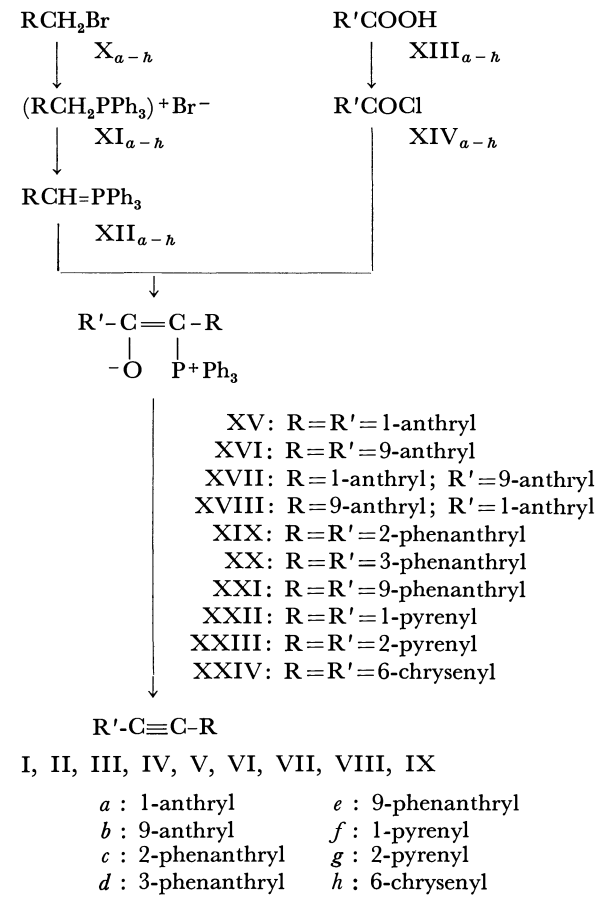
The syntheses of 1,1′-, 9,9′-, and 1,9′-dianthryl-, 2,2′-, 3,3′-, and 9,9′-diphenanthryl-, 1,1′-and 2,2′-dipyrenyl-, and 6,6′-dichrysenylacetylenes according to the pyrolytic reactions of the corresponding β-ketoalkylidenetriphenylphosphorane derivatives (intramolecular Wittig reaction) were described.

In relation to studies on the electronic spectral properties of diarylpoly-ynes,[2] we tried to prepare 1,1′-dianthryl- and 9,9′-dianthrylacetylenes (I and II). However, all attempts to prepare dianthrylacetylenes according to the usual methods were unsucessful. The well-known mercuric oxide oxidation of *bis*-hydrazone of α-diketone was not feasible for the present case, because the condensation of anthraldehydes by means of potassium cyanide and the dimerization of anthracene carboxylic acids or their acid chlorides on treatment with magnesium-magnesium iodide could not be carried out. In the case of phenanthrene series, it was found that the reaction of 9,9′-diphenanthril with hydrazine gave only monohydrazone.[3] Bromine addition to di-(1-anthryl)-and di-(9-anthryl)-ethylenes[4] could not be performed owing to the poor solubility of the ethylenes in common organic solvents.



Gough and Trippett[5], and Märkl[6] proposed a new method of formation of acetylenic bond by a pyrolytic decomposition of β-ketoalkylidenetriphenylphosphorane. This method has been applied successfully to the preparation of dianthrylacetylenes I, II, and III, diphenanthrylacetylenes IV, V, and, VI, dipyrenylacetylenes VII and VIII and 6,6′-dichrysenylacetylene IX.

As summarized in the following scheme, the bromomethyl compounds (X_{a-h}) derived from corresponding aldehydes were converted to the phosphoranes XII_{a-h} *via* triphenyl phosphonium bromides XI_{a-h}.



Scheme. Syntheses of the diarylacetylenes.

The reaction of the phosphoranes XII_{a-h} with a half mole of the acid chlorides XIV_{a-h} in xylene, toluene or benzene afforded betaines XV-XXIV. All betaines thus obtained exhibit characteristic intense absorption due to $\nu_{C=O}$ of ylid carbonyl groups in 1500 cm^{-1} region.[7]

Pyrolyses of the betaines except for XV were performed at 200—300°C in the absence of solvent under reduced pressure resulting in the corresponding acetylenes I, III—IX in high yields. On the other hand, XV was found to decompose very easily in boiling xylene to yield II. 9,9′-Dianthrylacetylene II and 1,9′-dianthrylacetylene(III) were obtained directly when a 2 : 1 molar mixture of XII_b and XIV_b, and that of XII_b and XIV_a in xylene were heated under refulx. The same treatment of a mixture of XII_a and XIV_b gave a mixture of the betaine (XVII) and the acetylene(III). However, the same treatment of a mixture of XII_a and XIV_b gave XV containing a small amount of I. These facts observed in anthracene series seem to indicate the following sequence of thermal stability of the betaines: XVI<<XVIII XVII<<XV. The sequence of the thermal stability of the betaines clearly indicates that the steric hindrance facilitates the decomposition of betaine into acetylenes. The fact that the less hindered betaines (XIX—XXIV) of other series were obtained in good yields without decomposition is consistent with this inference.

Diarylacetylenes (I—IX) thus obtained were found to be fairly stable and scarcely soluble in common organic solvents. The electronic spectra of the dianthrylacetylenes are illustrated in Fig. 1. The sequence of the bathochromic shift was found to be I→III→II with an increasing loss of vibrational structures. The spectrum of II exhibits only a shoulder at the position corresponding to the longest-wavelength peak. The electronic spectral properties of 1,1′- dianthryl-and 9,9′-dianthrylacetylenes (I and II) have been discussed in relation to the spectral regularities of the dianthrylpoly-ynes.[2]

The electronic spectra of the diphenathryl-, the dipyrenyl- and 6,6′-dichrysenylacetylenes will be discussed in a forthcoming paper.

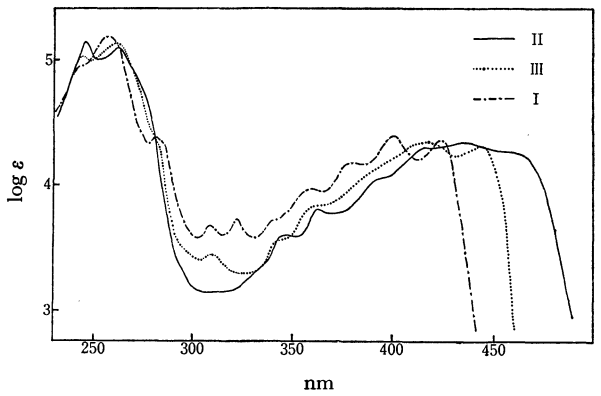

Fig.1 The electronic spectra of the dianthrylacetylenes (in tetrahydrofuran).

Experimental

All melting points are not corrected. The electronic spectra were obtained on a Hitachi EPS-3T spectrophotometer at room temperature. The IR spectra were measured with a Hitachi EPI-2 spectrophotometer by KBr-disk method.

1-Bromomethylanthracene (X_a). The bromide was prepared by the method reported previously.[8]

9-Bromomethylanthracene (X_b). Phosphorus tribromide (12.0 g, 0.044 mol) in chloroform (40 ml) was added over a period of 30 min to a mixture of 9-hydroxymethylanthracene (20.8 g, 0.1 mol), chloroform (350 ml) and pyridine (3.2 g, 0.044 mol) at −5°C. The mixture was allowed to gradually reach 20°C, after which it was stirred further for 1 hr. Cracked ice was added to the ice-cooled reaction mixture, and the organic layer separated was washed with water, sodium hydrogen carbonate solution and water, successively, and then dried. The yellow needles, mp 138—140°C, which were obtained in quantitative yield by the evaporation of the solvent *in vacuo* were recrystallized from petroleum benzine to give pure X_b as yellow needles, mp 139—140°C.

Found: C, 66.77; H, 4.19; Br, 29.54%. Calcd for $C_{15}H_{11}Br$: C, 66.44; H, 4.09; Br, 29.47%.

Anthrylmethyl-triphenylphosphonium Bromides (XI_a and XI_b). As the phosphonium bromides (XI_a and XI_b) were prepared according to a similar procedure, the preparation of XI_b will be described as an example. Triphenylphosphine (13.1 g, 0.05 mol) was added to a solution of X_b (11.1 g, 0.041 mol) in xylene (140 ml), and the mixture was refluxed for 17 hr. The crystals deposited were rinsed with a small amount of benzene, and then were recrystallized twice from water to give pure XI_b. Both of the salts were obtained in yields of over 90%. The physical properties and the analytical data are summarized in Table 1.

9,9′-Dianthrylacetylene (II). a) Pyrolysis of the Betaine (XVI_b) without Isolation. To a suspension of the phosphonium bromide (XI_b, 6.95 g, 0.013 mol) in xylene (70 ml), was added an ether solution of phenyllithium (1.18 N, 11.02 ml). The deep reddish-violet solution was stirred for 1 hr at 80°C, and then a hot solution of the acid chloride

Table 1. Physical properties and analytical data of XI_a and XI_b

	Mp (°C)	Crystal		Analytical data (%) C	H	Br
XI_a	275—280 (dec.)	pale yellow	Found:	73.91,	5.01,	14.62
XI_b	280 (dec.)	pale yellow	Found:	73.89,	4.91,	14.79
			Calcd for $C_{33}H_{26}BrP$:	74.30,	4.91,	14.98

7) *Cf.* A. J. Speciale and K. W. Ratts, *J. Amer. Chem. Soc.*, **85**, 2790 (1963).

8) S. Akiyama, S. Misumi, and M. Nakagawa, This Bulletin, **35**, 1826 (1962).

(XIV_b, 1.440 g, 6 mmol), prepared from 9-anthroic acid[9] and thionyl chloride in xylene (50 ml), was added. After the mixture had been stirred for 20 hr at 80°C, the mixture was refluxed for 2 hr. The hot solution was filtered to remove insoluble material which was digested with hot benzene three times (each 50 ml). The benzene extracts were combined with the filtrate, and the solvents were removed *in vacuo*. A small amount of benzene - petroleum benzine (1 : 1) was added to the residue, and the orange-yellow crystals deposited was collected by filtration (1.40 g, 62%). The crystals were re-dissolved in benzene, and the solution was percolated through a short column of alumina. The orange needles obtained by the concentration of the filtrate under reduced pressure were recrystallized from benzene to yield pure II, orange-red needles, which decomposed at *ca.* 310°C.

Found: C, 95.21; H, 4.77%; $M^+=378$. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%; Mol. wt. 378.

b) Pyrolysis of the Isolated Betaine (XVI_b). Using benzene as solvent, the same amounts of the reagents (XI_b, phenyllithium and XIV_b) used in the case of a) were treated in a similar manner. The mixture obtained was stirred for 20 hr at 15°C and then 4 hr at 35°C. The insoluble material was filtered, and repeatedly digested with benzene (total 500 ml) at 70°C. The extracts were combined with the filtrate. The yellow fine cubes, 2.150 g (55%) which was obtained by the evaporation of the solvent *in vacuo* were dissolved in hot benzene. The insoluble acetylene(II) was removed by filtration. Evaporation of the filtrate under reduced pressure gave betaine(XVI). The crude betaine was recrystallized twice from benzene to give pure XVI as yellow cubes. The yellow crystals turned to orange needles at 280°C, which decomposed at *ca.* 310°C (decomposition point of the acetylene, II).

Found: C, 88.51; H, 5.29%. Calcd for $C_{48}H_{33}OP$: C, 87.78; H, 5.07%. IR: 1496 (C=O) cm^{-1}.

Betaine (XVI, 0.131 g, 0.2 mmol) thus obtained was dissolved in xylene (20 ml), and the solution was refluxed for 3.5 hr to give a green fluorescent orange-yellow solution. Evaporation of the solvent afforded orange-red needles, 0.069 g (91%). Triphenylphosphine oxide (0.050 g, 89%) was obtained from the filtrate. The orange-red crystals were recrystallized from benzene to yield pure II.

1,1'-Dianthrylacetylene (I). Preparation of Betaine (XV). To a suspension of the phosphonium bromide (XI_a, 3.48 g, 6.5 mmol) in xylene (30 ml), was added at room temperature an ethereal solution of phenyllithium (0.87 N, 7.51 ml) under nitrogen atmosphere. After the mixture had been stirred for 1 hr at 80°C, a hot solution of the acid chloride of 1-anthroic acid[10] (XIV_a, 0.720 g, 3 mmol) in xylene (30 ml) was added, and stirred for 20 hr at 80°C. The insoluble material was filtered, and digested repeatedly with hot toluene (total 150 ml). The extracts were combined with filtrate, and the solvent was removed under reduced pressure. Benzene (3 ml) was added to the residue, and the yellow crystalline powder was collected by filtration, and washed with a small amount of benzene (0.570 g, 29%). The crystalline powder was recrystallized twice from toluene to give yellow cubes. The crystals fused at *ca.* 180—190°C under foaming. The melt solidified at 230°C to give needles, and re-melted at 267—270°C.

Found: C, 88.42; H, 5.38%. Calcd for $C_{48}H_{33}OP$: C, 87.78; H, 5.07%. IR: 1500 (C=O) cm^{-1}.

Pyrolysis of Betaine (XV). The betaine (XV, 0.100 g, 0.15 mmol) was heated under reduced pressure (18 mmHg) at 200°C for 30 min, Evolution of triphenylphosphine oxide was observed. The solid thus obtained was mixed with a a small amount of benzene, and was filtered to remove the oxide. The crude crystals thus obtained in an almost quantitative yield were dissolved in benzene, and the solution was passed through a short column of alumina. The crystals obtained by the evaporation of the filtrate were recrystallized twice from benzene to give pure I as bright yellow needles, mp 272—273°C.

The pyrolysis of betaine(XV) in boiling xylene was found to be very slow.

Found: C, 95.07; H, 4.80%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%. UV in tetrahydrofuran: λ_{max} (log ε) 245* (4.96), 257(5.19), 281(4.39), 309(3.68), 322.5(3.72), 340*(3.70), 359(3.97), 380(4.18), 400(4.39), and 425(4.36) nm. (asterisks denote shoulders).

1,9'-Dianthrylacetylene (III). Preparation of Betaine (XVII). To a solution of phosphorane (XII_a), prepared according to the method used for betaine(XV), was added a xylene solution of the acid chloride of 9-anthroic acid, and the mixture was refluxed for 2 hr to complete the reaction. The yellow cubes, 0.745 g (38%), collected by filtration were recrystallized twice from benzene to give pure XVII as yellow cubes. The crystals melted at 230—250°C and turned to orange needles at 260°C. The crystals re-melted at 286—288°C.

Found: C, 88.22; H, 5.42%. Calcd for $C_{48}H_{33}OP$: C, 87.78; H, 5.07%. IR: 1497 (C=O) $cm.^{-1}$

Concentration of the filtrate gave a mixture (0.05 g) of XVII and orange-yellow needles. The mixture was recrystallized twice from benzene. The crystals thus obtained were dissolved in the same solvent, and the solution was passed through a short column of alumina. Pure III was obtained from the filtrate as orange-yellow needles, mp 286—288°C.

Pyrolysis of Betaine (XVII). Betaine(XVII) was treated according to the procedure used for the pyrolysis of XV, and the product was dissolved in benzene (40 ml). The filtrate which was obtained by the percolation of the benzene solution through a thin layer of alumina (2 g) was concentrated to afford acetylene(III), 0.036 g, 97%, mp 282—285°C. The material was recrystallized twice from benzene to yield pure III, orange-yellow needles, mp 286—288°C.

Found: C, 95.11; H, 4.79%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%. UV in tetrahydrofuran: λ_{max} (log ε) 244(5.02), 261.5(5.14), 320(3.46), 344*(3.39), 362*(3.85), 419(4.36), and 444(4.32). (asterisks indicate shoulders).

Preparation of Betaine (XVIII). Betaine (XVIII) was obtained as tiny yellow cubes in a yield of 24% from XII_b and XIV_a according to the method used for XV. The crude betaine was recrystallized to afford pure XIII as tiny yellow cubes, which turned to orange at 230—240°C, and then solidified to give orange needles. The crystals re-melted at 286—288°C.

Found: C, 87.32; H, 5.00%. Calcd for $C_{48}H_{33}OP$: C, 87.78; H, 5.07%. IR: 1497 (C=O) $cm.^{-1}$

Pyrolysis of the Betaine(XVIII), a) Pyrolysis without Solvent. Pyrolysis of betaine(XVIII) was carried out according to the procedure used for XV. A benzene (40 ml) solution of the product was passed through a short column of alumina (3 g). The crude crystals, 0.055 g (95%), obtained by concentration of the filtrate were recrystallized twice from benzene to yield pure III as orange-yellow needles, mp 286—288°C.

Found: C, 95.01; H, 4.83%. Calcd for $C_{30}H_{18}$: C,

b) Pyrolysis in Xylene. A solution of betaine(XVIII, 0.153 g) in xylene (20 ml) was refluxed for 8 hr. The residue obtained by the evaporation of the solvent *in vacuo* was dissolved in benzene, and was passed through a short column of alumina (3 g). III was obtained from the filtrate as orange-yellow needles, 0.047 g (54%), mp 286—288°C.

Formation of Acetylene(III) without Isolation of Betaine (XVIII). A xylene solution of betaine(XVIII) prepared by the above method was refluxed for 3 hr to give orange-yellow crystals, 0.314 g (38%). This was recrystallized twice from benzene to afford pure III, mp 286—288°C.

Found: C, 94.80; H, 4.75%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%.

Bromomethylphenanthrenes (X_c, X_d, and X_e). According to a similar procedure used for the preparation of X_b, the hydroxymethylphenanthrenes were converted into bromomethyl derivatives. The melting points were found to be identical with reported values.[11]

Phenanthrylmethyl-triphenylphosphonium Bromides (XI_c, XI_d, and XI_e). Bromomethylphenanthrene (7.66 g, 0.028 mol) in toluene (70 ml) was mixed with triphenylphosphine (7.50 g, 0.029 mol), and the mixture was refluxed for 18 hr. The crystals deposited were washed with a small amount of benzene, and were recrystallized to give pure colorless salt. The results are summarized in Table 2.

Preparation of Betaines(XIX, XX, and XXI). Since the preparation of the betaines of phenanthrene series were performed under similar reaction conditions, that of 3-phenanthryl derivative(XX) will be described as an example. To a suspension of phosphonium bromide (XI_d, 4.700 g, 8.8 mmol) in toluene (55 ml), was added under nitrogen atmosphere a solution of phenyllithium in ether (0.64 N, 13.80 ml). After the orange-red mixture had been stirred for 30 min at 80°C, a hot solution of acid chloride (XIV_d, 0.960 g, 4 mmol) in toluene (30 ml) was added, and the mixture was stirred for 19 hr at 80°C. The insoluble material was filtered, and was digested with hot benzene (60 ml×2) and hot toluene (60 ml×2). The combined filtrate and extracts were concentrated under reduced pressure. The viscous oily residue was mixed with benzene - cyclohexane (1 : 1, 5 ml), and was warmed to give rise to crystallization. The pale yellow crystalline powder, 2.576 g (98%) was recrystallized from benzene to give pure XX. The physical properties and the analytical data are shown in Table 3.

Diphenanthrylacetylenes(IV, V, and VI). As the pyrolyses of betaines(XIX, XX and XXI) were carried out under the same conditions, the procedure employed for 3-phenanthryl derivative(XX) will be described as a typical example.

Betaine(XX, 0.329 g, 0.5 mmol) placed in an evacuated flask (18 mmHg) was gradually heated up to 250°C over a period of 15 min. Distillation of triphenylphosphine oxide was observed at 200°C. The cooled reaction mixture was digested with benzene (40 ml), and the resulting solution was passed through a short column of alumina (5 g). Concentration of the filtrate under reduced pressure afforded V

as almost colorless crystals in a quantitative yield. This was recrystallized to give pure V.

The physical properties and analytical data are summarized in Table 4.

Bromomethylpyrenes (X_f and X_g). To an ice-cooled suspension of 1-hydroxymethylpyrene (5.24 g, 0.023 mol) in chloroform (70 ml) containing pyridine (0.95 g, 0.012 mol), was added over a period of 20 min a solution of phosphorus tribromide (3.12 g, 0.012 mol) in chloroform (20 ml). The temperature was gradually raised to room temperature, and stirring was continued for 30 min. The reaction mixture was again chilled with an ice-bath, and cracked ice and chloroform (100 ml) were added. The organic layer was washed successively with water, aqueous sodium hydrogen carbonate and water, and then dried. Evaporation of the solvent under reduced pressure afforded pale yellow needles, mp 131—133°C, 6.45 g (96%). The crystals were recrystallized to give pure X_f. According to a similar procedure, X_g was obtained from 2-hydroxymethylpyrene.

The results are summarized in Table 5.

Pyrenylmethyl-triphenylphosphonium Bromides (XI_f and XI_g). A mixture of 1-bromomethylpyrene (X_f, 6.00 g, 0.020 mol), toluene (20 ml) and triphenylphosphine (6.55 g, 0.025 mol) was refluxed for 4 hr. The reaction mixture, upon cooling, gave phosphonium salt (XI_f) as colorless cubes in an almost quantitative yield. This was recrystallized twice from water to afforded pure XI_f. The 2-pyrenyl derivative (XI_g) was obtained under similar conditions from 2-bromomethylpyrene (X_g). The results are recorded in Table 6.

12) J. P. Greets and R. H. Martin, *Bull. Soc. Chim. Belges.*, **69**, 563 (1960).

was extracted under reflux repeatedly with toluene (total 200 ml) and then with benzene (total 300 ml). The extracts were combined with the filtrate, and the solvents were removed under reduced pressure. The crude crystals thus obtained were mixed with benzene - cyclohexane (1 : 1, 5 ml), and were filtered and washed with the same solvent. The crystals were recrystallized to give pure XXII. The 2-pyrenyl derivative(XXIII) was obtained according to the similar procedure.

The physical properties and analytical data are summarized in Table 7.

Dipyrenylacetylenes(VII and VIII). The thermal decomposition of betaines(XXII and XXIII) to give dipyrenylacetylenes (VII and VIII) was performed according to the procedure for the preparation of diphenanthrylacetylenes (IV, V and VI), and the results are summarized in Table 8.

6-Bromomethylchrysene (X_h). A solution of phosphorus tribromide (2.98 g, 0.011 mol) in tetrahydrofuran (10 ml) was added over a period of 20 min to an ice-cooled suspension of 6-hydroxymethylchrysene[13] (6.10 g, 0.024 mol) in tetrahydrofuran (140 ml) containing pyridine (0.8 g, 0.01 mol). After having been stirred for 1 hr at room temperature, the mixture was warmed to 30°C to give a homogeneous solution. Cracked ice was added to the ice-cooled solution, and the organic layer was separated. The organic layer was worked up in the usual manner to give colorless crystals in an almost quantitative yield. The crystals were recrystallized twice from dioxane to give pure X_h as colorless fine needles, mp 194—196°C.

Found: C, 70.92; H, 4.15; Br, 24.54%. Calcd for $C_{19}H_{13}Br$: C, 71.04; H, 4.08; Br, 24.88%. IR: 1500 (C=O) cm^{-1}.

6-Chrysenylmethyl-triphenylphosphonium Bromide(XI_h). The reaction of X_h with triphenylphosphine in toluene according to the usual conditions gave slightly crude XI_h. The crude material was recrystallized from methanol to give analytical specimen. The colorless plates thus obtained contained 1 mole of methanol of crystallization. The crystals cracked at *ca.* 200°C, and decomposed at 270—272°C.

Found: C, 74.09; H, 5.15; Br, 12.82%. Calcd for $C_{37}H_{28}BrP$–CH_3OH: C, 74.15; H, 5.24; Br, 12.98%.

Preparation of Betaine(XXIV). According to the procedure for the preparation of XXII and XXIII, the slightly crude XI_h was converted into betaine (XXIV) by the reaction with acid chloride(XIV_h).[14] The yellow cubes obtained in a yield of 89% was recrystallized twice from toluene to give pure material, yellow cubes, mp *ca.* 265°C (dec.).

Found: C, 88.70; H, 5.28%. Calcd for $C_{56}H_{37}OP$: C, 88.87; H, 4.93%.

6,6'-Dichrysenylacetylene(IX). The thermal decomposition of betaine(XXIV) under the conditions used in the preparation of diphenanthrylacetylenes(IV, V and VI) gave yellow crystals in an almost quantitative yield. The crystals were recrystallized from toluene to give pure IX as fine pale yellow needles. Acetylene(IX) was found to be highly stable, and neither fusion nor decomposition could be observed even at 330°C.

Found: C, 95.08; H, 4.63%. Calcd for $C_{38}H_{22}$: C, 95.37; H, 4.63%.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. V. Syntheses and Electronic Spectra of 2,2′-, 3,3′-, and 9,9′-Diphenanthrylpoly-ynes

Shuzo Akiyama and Masazumi Nakagawa

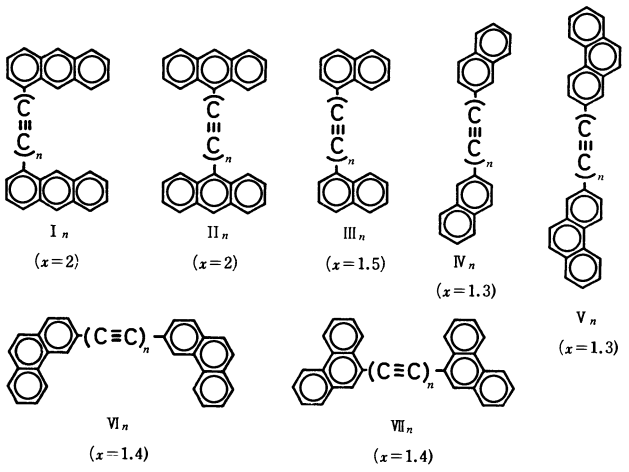
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 8, 1971)

2,2′-, 3,3′-, and 9,9′-Diphenanthrylpoly-ynes (V_n, VI_n, and VII_n, $n=1$—6) were synthesized and their electronic spectra were measured. It was found that the longest-wavelength absorption maxima (λ_{max}) in the spectra of each series of the diphenanthrylpoly-ynes (V_n, VI_n and VII_n) shift linearly with the xth power of the number of acetylenic bond (n), [$\lambda_{max} \propto n^x$], being $x=1.3$ for V_n and $x=1.4$ for VI_n and VII_n.

In previous papers of this series,[1-4] it was shown that the shifts of the absorption maxima (λ_{max}) of the long-wavelength bands of diarylpoly-ynes, such as 1,1′-dianthryl-(I_n), 9,9′-dianthryl-(II_n), 1,1′-dinaphthyl-(III_n) and 2,2′-dinaphthylpoly-ynes (IV_n) with the increase of the number of acetylenic bonds (n) can be expressed by the empirical formula:

$$\lambda_{max} = An^x + B$$



It is interesting that the values of x, given below the formulas, vary with the change of the nature of the terminal groups and the position of the linking of the polyacetylenic chain.

This paper deals with the syntheses and the electronic spectral characteristics of 2,2′-, 3,3′- and 9,9′-diphenanthrylpoly-ynes (V_n, VI_n, and VII_n, $n=1$—6).

Syntheses. Syntheses of diphenanthrylpoly-ynes (V_n, VI_n, and VII_n) were performed according to the analogous reaction sequence which had been employed in the syntheses of dianthryl-(I_n and II_n)[1,3] and dinaphthylpoly-ynes(III_n and IV_n).[4] Formyl and acetyl derivatives(VIII and IX) were used as starting materials. Preparation of diphenanthryl-acetylenes (V_1, VI_1, and VII_1) by means of an intramolecular Wittig reaction has been reported.[5]

Application of mild conditions to the conversion of the acetylenic hydroxy compounds to the corresponding chloro-derivatives was essential. Chloro-compounds(XI, XIV, XVI, XX, XXII, and XXVIII) were subjected to the following dehydrochlorination without isolation and purification owing to their intractable nature.

Elemental analyses of phenanthryldi-(XVII) and triacetylenes (XXIII) could not be performed due to their high instability. Diphenanthrylpoly-ynes (V_{1-5}, VI_{1-5}, and VII_{1-5}) were found to be fairly stable compounds. However, hexaacetylenes (V_6, VI_6 and VII_6) were unstable, and decomposed at room temperature in a few days. It was observed that the solubility of V_n, VI_n and VII_n in organic solvents remarkably decreased with the increase of the length of poly-yne chain. The color of crystals, melting points and IR absorption due to $\nu_{C\equiv C}$ are summarized in Table 1. The most intense peaks of the $\nu_{C\equiv C}$ bands of the diarylpoly-ynes (V_n, VI_n and VII_n) showed remarkable intensification and shift to lower wave number with the increase of the length of the poly-yne chain. The same trend has been observed in the IR spectra of the other series of diarylpoly-ynes.[1,3,4] The IR spectra of V_n are shown in Fig. 1 as a represen-

tative of the diphenanthrylpoly-ynes.

Electronic Spectra. The absorption curves and electronic spectral data of the three series of diphenanthrylpoly-ynes (V_n, VI_n and VII_n) are given in Figs. 2, 3, and 4, and Tables 2, 3, and 4.

Usually, the electronic spectra of the lower members of diarylpoly-ynes retain the characteristic of the spectra of the parent aromatic hydrocarbons corresponding to the respective terminal groups. However, in the case of the diphenanthryl derivatives (V_n, VI_n, and VII_n), the characteristic feature of the spectrum of phenanthrene can not be observed even in the spectra of diphenanthrylacetylenes (V_1, VI_1, and VII_1).

On the basis of free electron model (FEM),[6] the x-axis polarized transitions were assigned to ^1L_b and ^1C_b bands, and the y-axis polarized transitions were assigned to ^1L_a and ^1B_a bands for the electronic spectrum of phenanthrene (Fig. 5). The short-wavelength bands of diphenanthrylpoly-ynes (V_n, VI_n and VII_n) seem to be associated with the ^1C_b and the ^1B_a bands of phenanthrene.

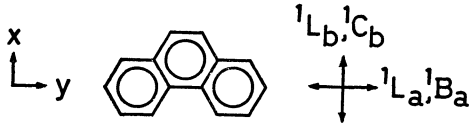

Fig. 5. Polarization diagram of phenanthrene.

The spectral feature of 3,3'-derivatives (VI_n) was found to be closely related to that of 9,9'-derivatives (VII_n). This indicates that the poly-yne chains extending in the same direction with regard to the molecular axis exert the same effect on the electronic spectra. On the other hand, 2,2'-derivatives (V_n) exhibit quite a different spectral feature as compared with 3,3'- and 9,9'-derivatives (VI_n and VII_n). The poly-yne chain attached to 2-position should exert a minor effect on the x-axis-polarized ^1C_b band, since the substituent at 2-position is parallel to the y-axis and can not contribute to the x-axis polarization. Consequently, the appearance of an absorption minimum at *ca.* 230—240 nm region in the spectrum of the lower member of 2,2'-derivative (V_n) might be ascribed to the separation of ^1C_b band and ^1B_a band due to the profound bathochromic shift of the y-axis-polarized ^1B_a band.

The long-wavelength bands of diphenanthrylpoly-ynes (V_n, VI_n, and VII_n) can be considered to arise from the interaction of poly-yne chromophore with ^1L_a band of the terminal group. ^1L_b band disappeared in the spectra of diphenanthrylpoly-ynes (V_n, VI_n, and VII_n) except for 2,2'-diphenanthrylacetylene(V_1), probably because of the large bathochromic shift of ^1L_a band. The remarkable enhancement of the vibrational fine structure and the regular bathochromic

a) Shoulders.

shifts in the longest-wavelength bands with the increase of n are also observed in the three series of diphenanthrylpoly-ynes. The same trend has been observed in other series of diarylpoly-ynes.[1-4] The sequence of the bathochromic displacement of the longest-wavelength bands was found to be $V_n < VI_n < VII_n$ in apparent contradiction to what we expected from FEM. The same apparent discrepancy was also observed in the spectra of ethynyl- (XXIV), butadiynyl- (XVIII) and hexatriynylphenanthrenes. The apparent contradictions have been explained in terms of a configuration interaction.[7] As shown in Table 5, the spacings between the longest-wavelength vibrational sub-bands (λ_I) and the next longest-wavelength sub-bands (λ_{II}) are found to be 1900—2000 cm^{-1} except those of diphenanthrylacetylenes (V_1, VI_1, and VII_1). The spacings, as in the other diarylpoly-ynes, correspond to the stretching vibrations of acetylenic linkage in their IR spectra (*cf.* Table 1.)

The plots of the sub-peaks, λ_I and λ_{II} of the 2,2′-series (V_n) *versus* $n^{1.3}$ gave excellent straight lines as is shown in Fig. 6. (The plot of λ_{II} of V_1 is omitted.) In the cases of 3,3′- and 9,9′-diphenanthrylpoly-ynes (VI_n and VII_n), good linear correlations between λ_I, λ_{II} and $n^{1.4}$ were obtained (Figs. 7 and 8). It is interesting that the value x is dependent on the posi-

7) S. Akiyama, M. Nakagawa, and K. Nishimoto, This Bulletin, **44**, 1054 (1971).

Table 5. Spacings between the longest-wavelength maxima (λ_I) and the next longest-wavelength maxima (λ_{II}) (cm^{-1})

n	V_n	VI_n	VII_n
1	(1710)	(1740)	(1780)
2	2090	2000	2020
3	2040	1980	2000
4	1990	2070	1980
5	1960	1980	1960
6	1930	1910	1940

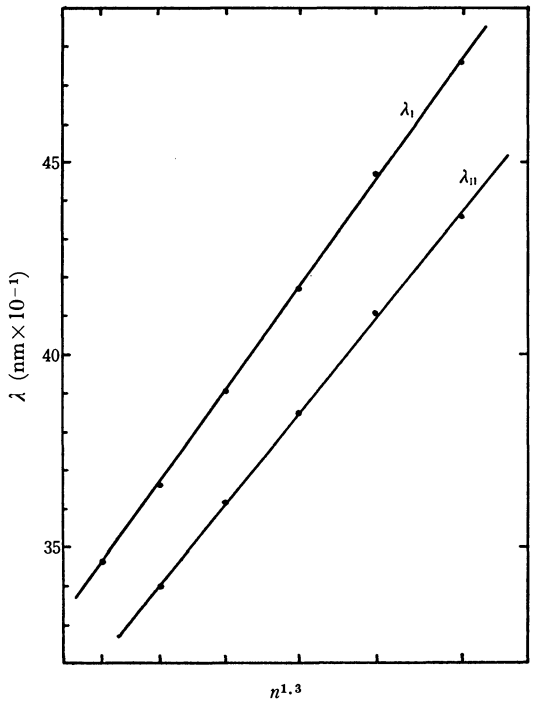

Fig. 6. Plot of λ_{max} *vs.* $n^{1.3}$ for 2,2′-diphenanthrylpoly-ynes (V_1—V_6).
λ_I: longest-wavelength maxima
λ_{II}: second-longest-wavelength maxima

tion of substitution as in the case of 1,1′- and 2,2′-dinaphthylpoly-ynes.[4]

The spectral reguralities are expressed by the following empirical formulas, and the agreement with the observed values is found to be excellent.

$$\lambda = An^x + B \text{ (in tetrahydrofuran)}$$

2,2′-series (V_n): $\lambda_I = 13.9\,n^{1.3} + 333$ nm
$\lambda_{II} = 12.3\,n^{1.3} + 310$

3,3′-series (VI_n): $\lambda_I = 10.8\,n^{1.4} + 347$
$\lambda_{II} = 9.4\,n^{1.4} + 324$

9,9′-series (VII_n): $\lambda_I = 10.5\,n^{1.4} + 352$
$\lambda_{II} = 9.0\,n^{1.4} + 329$

The spectral regularities in benzene and cyclohexane solution can be expressed by similar empirical formulas with about the same A and the same x as in the case of tetrahydrofuran solution, but with slightly modified B values.

The syntheses and electronic spectral properties of poly-ynes bearing other types of terminal groups will be reported in the near future.

Experimental

All the melting points are uncorrected. The electronic spectra were measured with a Hitachi EPS-3T spectrophotometer at room temperature employing a well-matched pair of 1-cm quartz cells. The IR spectra were obtained

on a Hitachi EPI-2 infrared spectrophotometer by KBr-disk method.

Acetylphenanthrenes (IX). 2- and 3-Acetylphenanthrenes. The acetylphenanthrenes were prepared according to the method of Mosettig and van de Kamp.[8]

9-Acetylphenanthrene. Diethyl ethoxymagnesiomalonate was prepared from magnesium (1.20 g, 0.05 g atom), diethyl malonate (8.0 g, 0.05 mol), anhydrous ethanol (5.05 g, 0.11 mol) and toluene (50 m*l*) and excess ethanol was removed. A solution of the acid chloride of 9-carboxyphenanthrene (6.03 g, 0.025 mol) in toluene (30 m*l*) was added to the toluene solution of ethoxymagnesiomalonate, and the mixture was heated for 2 hr at 80°C. 6 N Sulfuric acid was added to the ice-cooled reaction mixture. The organic layer was washed with water and a solution of sodium hydrogen carbonate, successively, and dried. The oily material obtained by the evaporation of the solvent under reduced pressure was mixed with acetic acid (40 m*l*) and 4 drops of concentrated sulfuric acid. The mixture was refluxed for 2.5 hr under evolution of carbon dioxide, then 4 N sulfuric acid (20 m*l*) was added to the reaction mixture. After having been refluxed for additional 3 hr, the reaction mixture was cooled. The solid deposited was collected and washed thoroughly with water and then dissolved in benzene (60 m*l*). The benzene solution was washed with sodium hydrogen carbonate solution and dried. The cubic crystals obtained by the evaporation of the solvent were re-dissolved in benzene and the solution was passed through a thin layer of alumina (6 g). The filtrate gave the acetyl compound, mp 73—74°C (lit. value, 74°C),[9] 5.14 g (94%). This material was recrystallized twice from ethanol to give an analytical specimen, mp 74°C, colorless needles.

Found: C, 87.43; H, 5.52%. Calcd for $C_{16}H_{12}O$: C, 87.24; H, 5.49%. IR: 1670 (C=O) cm^{-1}.

Formylphenanthrenes VIII. 2-Formylphenanthrene (2-VIII). 2-acetylphenanthrene was treated with alkaline sodium hypochlorite solution to give 2-carboxyphenanthrene. Lithium aluminum hydride reduction of the ester of the carboxyphenanthrene afforded 2-hydroxymethylphenanthrene. A solution of the hydroxymethyl compound (24.8 g, 0.12 mol) in pyridine (150 m*l*) was added to a chilled solution of chromium trioxide (36.0 g, 0.36 mol) in pyridine (500 m*l*).

The mixture was shaken in an ice-bath for 30 min, and then for 45 min at room temperature. The reaction mixture was poured into water (2.5 *l*) and was extracted with ether. The extract was washed successively with water, cold diluted hydrochloric acid, water, cold sodium hydroxide solution and water. The crude crystals (23.4 g, 97%) obtained on the evaporation of the solvent were converted into a sodium hydrogen sulfite adduct. Decomposition of the adduct gave 2-formylphenanthrene as colorless cubes, mp 55—58°C. The material was recrystallized twice from methanol-water to give pure specimen, mp 56—57°C. (lit. value, 59—59.5°C).[10]

Found: C, 87.48; H, 4.90%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR: 2820, 2730 (CHO), 1695 (C=O) cm^{-1}.

3-Formylphenanthrene (3-VIII). According to the procedure for the preparation of the 2-formyl compound, the 3-hydroxymethyl compound was oxidized to give 3-formylphenanthrene in yield of 86%, colorless needles, mp 77—79°C (lit. value, 79.5—80°C).[10] The material was recrystallized twice from methanol to yield pure aldehyde, colorless needles, mp 79—80°C.

Found: C, 87.38; H, 4.89%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR: 2835, 2740 (CHO), 1698 (C=O) cm^{-1}.

9-Formylphenanthrene (9-VIII). Dimethylformamide (4.4 g, 0.06 mol) was added dropwise to a stirred solution of 9-phenanthrylmagnesium bromide (prepared from 9-bromophenanthrene, 5.14 g, 0.02 mol and magnesium 0.504 g, 0.021 g atom)[11] in tetrahydrofuran under cooling in an ice-salt bath. After the addition had been completed, the cooling bath was removed and stirring was continued overnight. Diluted sulfuric acid was added to the reaction mixture, and then the mixture was extracted with benzene (50 m*l*). The extract was washed with a saturated solution of sodium chloride. A mixture of the extract and a saturated solution of sodium hydrogen sulfite was shaken overnight, and the deposited sulfite adduct was collected, washed with benzene, acetone, methanol, and water, successively. Treatment of the adduct with a saturated sodium hydrogen carbonate solution afforded 9-formylphenanthrene, mp 93—98°C, 2.46 g (62%). Recrystallization from benzene yielded pure 9-aldehyde, colorless fine needles, mp 100–102°C (lit. value. 100—101°C).[11]

Found: C, 87.28; H, 4.94%. Calcd for $C_{15}H_{10}O$: C, 87.35; H, 4.89%. IR: 2850, 2745 (CHO), 1690 (C=O) cm^{-1}.

1,4-Di(9-phenanthryl)-1,4-dihydroxy-2-butyne (X). To an ice-cooled solution of bis-Grignard derivative of acetylene (prepared from magnesium 1.75 g, 0.073 g atom and ethylbromide 9.70 g, 0.088 mol) in benzene-tetrahydrofuran (50 m*l*), was added a solution of 9-formylphenanthrene (6.18 g, 0.03 mol) in tetrahydrofuran (80 m*l*). After the mixture had been stirred at room temperature overnight, a saturated solution of ammonium chloride was added. The aqueous layer was removed, and was extracted with benzene. The organic layer was combined with the extract and dried (magnesium sulfate). It was concentrated under reduced pressure to yield colorless needles, mp 225—229°C, 5.41 g (83%), which was recrystallized from tetrahydrofuran-benzene, and then from tetrahydrofuran-toluene to afford pure butynediol, colorless needles, mp 230—235°C.

Found: C, 87.43; H, 4.97%. Calcd for $C_{32}H_{22}O_2$: C, 87.64; H, 5.06%. IR: 3430 (OH), 1070 (C–O) cm^{-1}.

Ethynylphenanthrenes (XXIV). 9-Ethynylphenanthrene (9-XXIV). A mixture of 9-acetylphenanthrene (2.20 g, 0.01 mol), phosphorus pentachloride (2.08 g, 0.01 mol) and benzene (25 m*l*) was refluxed for 1.5 hr. The viscous oily material obtained by the evaporation of the solvent *in vacuo* was kept in an evacuated desiccator containing potassium hydroxide for several hours. The crude chloride thus obtained was dissolved in tetrahydrofuran (10 m*l*), and the solution was added over a period of 10 min to a suspension of sodium amide (prepared from sodium 1.8 g, 0.08 g atom) in liquid ammonia (90 m*l*). After 1.5 hr, ammonia was allowed to evaporate, and ether (50 m*l*) and a saturated solution of ammonium chloride were added to the reaction mixture. The mixture was extracted with ether (200 m*l*). The residue obtained by evaporating the solvent was repeatedly digested with petroleum benzine (bp 60—80°C, 120 m*l*), and the benzine solution was passed through a short column of alumina (5 g). Concentration of the filtrate gave colorless cubes, mp 60—62°C, 1.71 g (85%). A solution of the crude crystals in petroleum ether (bp 40—60°C) was passed through a thin layer of alumina. The filtrate was concentrated to give pure material, color-

less needless, mp 62.5—63°C. The ethynyl compound gave pale yellow silver and yellow cuprous acetylides.

Found: C, 94.98; H, 4.95%. Calcd for $C_{16}H_{10}$: C, 95.02; H, 4.98%. IR: 3295 (≡CH) cm^{-1}. UV (in *n*-hexane): λ_{max} (nm)(log ε): 213 (4.51), 234 (4.53), 256.5 (4.72), 260 (4.73), 237.5 (4.36), 287.5 (4.08), 259 (4.31), 312 (4.42), 331.5 (2.47), 339.5 (2.48), 347 (2.33), 355.5 (1.93).

2-Ethynylphenanthrene (2-XXIV). According to the procedure used in the preparation of 9-ethynyl compound, 2-acetylphenanthrene gave 2-ethynyl compound as colorless cubes in a yield of 72%, mp 72—76°C. A petroleum ether solution of this material was passed through a short column of alumina. Pure 2-ethynyl compound was obtained from the filtrate as colorless tiny cubes, mp 77—78°C. The 2-ethynyl derivative gave white silver and yellow cuprous acetylides.

Found: C, 95.00: H, 5.03%. Calcd for $C_{16}H_{10}$: C, C, 95.02; H, 4.98%. IR: 3295 (≡CH) cm^{-1}.
UV (in *n*-hexene): λ_{max} (nm) (log ε) 256 (4.78), 264 (5.00), 280 (4.38), 291 (4.50), 297.5 (4.09), 309 (2.36), 320 (2.30), 326 (2.48), 334 (2.50), 341.5 (2.71), 350.5 (2.51), 358.5 (2.78).

3-Ethynylphenanthrene(3-XXIV). The 3-ethynyl compound was prepared according to the above-stated procedure. Pale yellow needles, mp 100—106°C (62%) obtained were recrystallized three times from petroleum benzine to give pure material, colorless needles, mp 110—111°C. The ethynyl compound gave yellow silver and bright yellow cuprous acetylides.

Found: C, 94.69; H, 4.90%. Calcd for $C_{16}H_{10}$: C, 95.02; H, 4.98%. IR: 3290 (≡CH), 2090 (C≡C) cm^{-1}. UV (in *n*-hexane): λ_{max} (nm) (log ε) 219.5 (4.47), 237 (4.61), 251 (4.71), 258.5 (4.81), 274 (4.21), 278.5 (4.27), 296 (4.37), 309 (4.46), 330.5 (2.50), 338 (2.49), 346.5 (2.36), 355 (1.98).

2,2′-Diphenanthryldiacetylene (V_2). A solution of 2-ethynylphenanthrene (0.940 g, 4.7×10^{-3} mol) and cupric acetate monohydrate (10.0 g) in pyridine (50 m*l*) and methanol (5 m*l*) was stirred at 50°C for 3 hr.[12] The reaction mixture was cooled, and the insoluble material was collected by filtration, and washed with water, thus affording V_2 as colorless fine needles, mp 241—245°C, 0.794 g (84%). A second crop of V_2, 0.083 g (9%) was obtained by concentrating the filtrate. The combined crystals were dissolved in toluene, and the solution was passed through a short column of alumina to yield pure V_2, colorless needles, mp 243—244°C.

Found: C, 95.31; H, 4.48%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

3,3′-Diphenanthryldiacetylene (VI_2). According to the procedure used in the preparation of V_2, 3-ethynylphenanthrene was converted into VI_2 as pale yellow needles in a yield of 86%. This material was recrystallized from toluene to give pure VI_2, pale yellow needles mp 280—282°C.

Found: C, 95.33; H, 4.53%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

9,9′-Diphenanthryldiacetylene(VII_2). a) Oxidative Coupling of 9-Ethynylphenanthrene(9-XXIV). 9-Ethynylphenanthrene was oxidatively coupled according to the above procedure to give VII_2, pale yellow cubes, mp 256—257°C (97%). The crystals were recrystallized to yield pure VII_2, mp 256—257°C.

Found: C, 95.30; H, 4.57%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

b) The Dehydrochlorination of 1,4-Bis-(9-phenanthryl)-1,4-dichloro-2-butyne(XI). A solution of thionyl chloride 0.43 g, 3.6 mmol) and pyridine (0.28 g, 3.6 mmol) in ether (5 m*l*) was added dropwise to a solution glycol (X, 0.562 g, 1.2 mmol) in tetrahydrofuran (15 m*l*) at −20°C over a period of 10 min. After being shaken for 1 hr at this temperature, the mixture was added to a stirred suspension of sodium amide (prepared from sodium 0.42 g, 18 mg atom) in liquid ammonia (60 m*l*). After 1 hr, ammonium chloride (2 g) was added to the mixture and the ammonia was allowed to evaporate. The solvent was then removed under reduced pressure. The residue was mixed with water, and the insoluble material was collected by filtration, washed with water and methanol, successively. The brown solid thus obtained was dissolved in toluene (150 m*l*) and the solution was passed through a short column of alumina (15 g). Concentration of the yellow filtrate gave VII_2 as yellow fine needles, mp 253—255°C, 0.394 g (81%). This material was recrystallized twice from toluene to give pure VII_2, mp 256—257°C.

Found: C, 95.47; H, 4.57%. Calcd for $C_{32}H_{18}$: C, 95.49; H, 4.51%. The hydrocarbons prepared by the two different methods gave identical electronic and IR spectra.

Phenanthryl-2-propyn-1-ols(XII). 9-Phenanthryl Derivative(9-XII). A solution of 9-phenanthaldehyde (8.00 g, 0.039 mol) in tetrahydrofuran (80 m*l*) was added over a period of 15 min to a suspension of lithium acetylide (prepared from lithium 0.83 g, 0.12 g atom) in liquid ammonia (200 m*l*) at −50—−55°C. After being stirred for 3 hr at this temperature, stirring was continued for further 3 hr at the temperature of the boiling point of ammonia. Then, ammonium chloride (3 g) was added to the reaction mixture, and the ammonia was allowed to evaporate. A saturated solution of ammonium chloride was added to the residue and the mixture was extracted with benzene. The extract was dried over magnesium sulfate. Evaporation of the solvent under reduced pressure gave an oily material. This material was mixed with benzene (20 m*l*) and was warmed to promote crystallization. The crystals were collected by filtration and were washed with a small amount of benzene to afford light brown tiny cubes, mp 129—133°C, 6.40 g (69%). Concentration of the filtrate gave the second crop, mp 119—124°C, 1.33 g (14%). The material was recrystallized from benzene 5 times to give pure sample, colorless needles, mp 134—135°C.

Found: C, 87.70; H, 5.20%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR: 3380 (OH), 3300 (≡CH), 2100 (C≡C), 1067 (C–O) cm^{-1}.

2-Phenanthryl Derivative(2-XII). To an ice-cooled solution of ethynylmagnesium bromide (prepared from magnesium, 1.80 g, 0.075 g atom, ethylbromide, 8.20 g, 0.075 mol) in tetrahydrofuran (50 m*l*), was slowly added a solution of 2-formylphenanthrene (6.18 g, 0.03 mol) in the same solvent (60 m*l*). The cooling bath was removed then and the mixture was stirred overnight at room temperature. A saturated solution of ammonium chloride was added to the reaction mixture. The aqueous layer was extracted with benzene. The extract was combined with the organic layer, and dried. The oily material obtained by evaporation of the solvent under reduced pressure was mixed with benzene and was warmed to promote crystallization. The crystals thus obtained were washed with benzene-cyclohexane to give light brown fine crystals, 6.50 g (93%). A solution of the crystals in ethyl acetate was passed through a short column of alumina. The crystals obtained by concentrating the filtrate was recrystallized from benzene to afford pure 2-XII, pale yellow tiny cubes, mp 134.5—135°C.

Found: C, 87.92; H, 5.18%. Calcd for $C_{17}H_{12}O$: C,

12) *Cf.* G. Eglinton and A. R. Galbraith, *J. Chem. Soc.*, **1959**, 889.

87.90; H, 5.21%. IR: 3400 (OH). 3290 (≡CH), 2110 (C≡C), 1017 (C–O) cm^{-1}.

3-Phenanthryl Derivative(3-XII). According to the procedure for the preparation of 2-isomer, 3-formylphenanthrene gave 3-carbinol, light brown needles, mp 80—85°C in a yield of 82%. The crude material was recrystallized from benzene-cyclohexane to give pure material, pale yellow needles, mp 82—84°C.

Found: C, 87.37; H, 5.21%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR: 3100—3600 (OH), 3295 (≡CH), 2100 (C≡C), 1056 (C–O) cm^{-1}.

1,6-Di(phenanthryl)-1,6-dihydroxy-2,4-hexadiynes(XIII).

9-Phenanthryl Derivative(9-XIII). Cuprous chloride (0.02 g, 2 mmol), ammonium chloride (0.14 g, 2 mmol) and 2 drops of concentrated hydrochloric acid were added to a solution of the 9-ethynyl carbinol (9-XII, 4.64 g, 0.02 mol) in methanol (80 ml). The mixture was vigorously stirred in oxygen atmosphere at a slightly elevated pressure. Deposition of pale yellow precipitate was observed after 1.5 hr. After being stirred overnight, the precipitate was collected by filtration. The precipitate was washed with methanol, diluted hydrochloric acid, and water, successively, and dried. The pale yellow powder, 3.51 g (76%), mp 210—215°C (dec.) thus obtained was recrystallized 5 times from tetrahydrofuran-benzene to give pure glycol (9-XIII) as colorless fine needles. mp 252—254°C (dec.).

Found: C, 87.99; H, 4.78%. Calcd for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79%. IR: 3400 (OH), 1067 (C–O), 2140, 2250 (C≡C) cm^{-1}.

3-Phenanthryl Derivative(3-XIII). The Glaser oxidative coupling of 3-ethynyl carbinol(3-XII) under the reaction conditions used in the case of 9-isomer afforded 3-XIII as colorless powder in a yield of 66%. The material was recrystallized 3 times from acetone-benzene to yield pure 3-XIII, mp 208—210°C.

Found: C, 87.90; H, 4.78%. Calcd for $C_{31}H_{22}O_2$: C, 88.29; H, 4.79%. IR: 3600—3100 (OH), 2130 (C≡C), 1010 (C–O) cm^{-1}.

2-Phenanthryl Derivative(2-XIII). 2-ethynyl carbinol (2-XII) was converted to di-(2-phenanthryl)-diol(2-XIII) under the reaction conditions used in 3- and 2-isomers. Almost colorless powder (77%) thus obtained was recrystallized thrice from acetone-benzene to yield pure 2-XIII as colorless fine needles, mp 204—206°C (dec.).

Found: C, 88.36; H, 4.84%. Calcd for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79%. IR: 3450—3100 (OH), 1000 (C–O) cm^{-1}.

9,9'-Diphenanthryltriacetylene(VIII$_3$). Formation of the Dichloride (9-XIV). A solution of thionyl chloride (0.36 g, 3 mmol) in pyridine (0.24 g, 3 mmol) was added to a solution of 9-glycol (9-XIII, 0.462 g, 1 mmol) in tetrahydrofuran (15 ml) over a period of 30 min at −20°C, and the mixture was shaken for 30 min.

Dehydrochlorination of 9-XIV. The above-mentioned reaction mixture was added to a suspension of sodium amide (prepared from sodium, 0.40 g, 0.017 g atom) in liquid ammonia (100 ml) under vigorous stirring at −70°C. After 30 min, ammonium chloride (2.0 g) was added to the reaction mixture, and the ammonia was allowed to evaporate. After the solvent had been removed under reduced pressure, a small amount of water was added to the residue. The insoluble material was successively washed with water, methanol, acetone, and benzene, and was dissolved in hot toluene (200 ml). The hot solution was passed through a thin layer of alumina (15 g). The light orange-yellow filtrate was concentrated under reduced pressure to yield VII$_3$ as yellow fine needles, 0.134 g (31%) mp 284—287°C (dec.). This substance was recrystallized from toluene to give pure VII$_3$, mp 285—286°C (dec.).

Found: C, 95.80; H, 4.24%. Calcd for $C_{34}H_{18}$: C, 95.75; H, 4.25%.

3,3'-Diphenanthryltriacetylene (VI$_3$). The procedure used for the preparation of VII$_3$ was applied to the 3-glycol (3-XIII) to give pale yellow fine needles in a yield of 39%, which decomposed at *ca.* 260°C. The material was recrystallized to afford pure VI$_3$, which decomposed at *ca.* 260°C without fusion.

Found: C, 95.71; H, 4.22%. Calcd for $C_{34}H_{18}$; C, 95.75; H, 4.25%.

2,2'-Diphenanthryltriacetylene (V$_3$) Chlorination of 2-glycol(2-XIII) followed by dehydrochlorination according to the reaction conditions used in the preparation of VII$_3$ and VI$_3$ gave pale yellow needles, dec. p *ca.* 270°C in a yield of 11%. This was recrystallized from toluene to give pure V$_3$, pale yellow needles, which decomposed, at *ca.* 270°C without fusion.

Found: C, 95.58; H, 4.22%. Calcd for $C_{34}H_{18}$: C, 95.75; H, 4.25%.

1-(Phenanthryl)-2-butyn-1,4-diol(XV). 9-Phenanthryl Derivative(9-XV). A solution of propargyl alcohol (5.04 g, 0.09 mol) in tetrahydrofuran (20 ml) was added dropwise in an ice-cooled solution of ethylmagnesium bromide in the same solvent (prepared from magnesium, 4.32 g, 0.18 g atom and ethyl bromide 20.0 g, 0.183 mol). After the mixture had been refluxed for 1 hr, it was cooled again with an ice-bath and a solution of 9-formylphenanthrene (9-VIII, 6.18 g, 0.03 mol) in tetrahydrofuran (90 ml) was added under stirring. The reaction mixture was stirred overnight at room temperature. A saturated solution of ammonium chloride was added to the mixture, and the organic layer was separated. The aqueous layer was extracted with benzene. The organic layer was combined with the extract and dried. After evaporation of the solvent, there remained an oily material which was mixed with a small amount of benzene. The crystals deposited on warming the mixture were washed with a small amount of benzene to yield light brown crystals, mp 133—135°C, 7.35 g (93%). The crystals were recrystallized three times from ethanol-cyclohexane to give pure diol, colorless needles, mp 138—139°C.

Found: C, 83.59; H, 5.70%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%. IR: 3350 (OH), 1017 (C–O) cm^{-1}. Recrystallization of the crude crystals three times from benzene afforded colorless needles, mp 104—106°C which contained half mole of benzene as a solvent of crystallization.

Found: C, 83.59; H, 5.70%. Calcd for $C_{18}H_{14}O_2$. 1/2 C_6H_6: C, 82.69; H, 5.69%.

3-Phenanthryl Derivative(3-XV). The above-mentioned procedure was adapted to 3-formylphenanthrene(3-VIII). The yield of crude crystals, light brown leaflets, mp 115—119°C was found to be 89%. The crude material was recrystallized four times from ethanol-benzene to give pure 3-XV, colorless leaflets, mp 122—124°C.

Found: C, 82.62; H, 5.40%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%. IR: 3600—3100 (OH), 1008 (C–O) cm^{-1}.

2-Phenanthryl Derivative(2-XV). According to the same procedure, a slightly impure 2-XV, mp 123—125°C was obtained from 2-formylphenanthrene(2-VIII). The crude material was recrystallized twice from acetone-benzene to afford pure 2-XV, colorless leaflets, mp 126—127°C.

Found: C, 82.37; H, 5.42%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%. IR: 3500—3100 (OH), 1000 (C–O) cm^{-1}.

9-Butadiynylphenanthrene(9-XVII). Formation of Dichloride (9-XVI). A solution of thionyl chloride (5.00 g, 0.042 mol) and pyridine (3.31 g, 0.042 mol) in ether (10 m*l*) was added over a period of 1 hr in a solution of 9-XV (4.200 g, 0.016 mol) in tetrahydrofuran (50 m*l*) under cooling with an ice-salt bath. After the mixture has been stirred for further 1 hr at room temperature, cracked ice was added, and the mixture was extracted with benzene. The extract was washed with water and an aqueous solution of sodium hydrogen carbonate, successively, and dried. The extract was concentrated to *ca.* 20 m*l* under reduced pressure, and the solution was subjected to the following reaction.

Dehydrochlorination of 9-XVI. The above-stated benzene solution of 9-XVI was added over a period of 15 min to a suspension of sodium amide (prepared from sodium 2.3 g, 0.1 g atom) in liquid ammonia (100 m*l*) at −70°C. After the mixture had been stirred for 30 min, ammonium chloride (10 g) was added, and the ammonia was allowed to evaporation. The residue obtained by evaporation of the solvent under reduced pressure was repeatedly digested with petroleum benzine (bp 60—80°C, total 500 m*l*). The benzine solution was percolated through a thin layer of alumina (5 g). Concentration of the colorless filtrate under reduced pressure afforded diacetylene (9-XVII) as colorless fine needles, mp *ca.* 110°C (dec.), 1.664 g (47%). Diacetylene (9-XVII) was found to be extremely unstable substance. The colorless crystals readily turned from blue to violet and then deep brown insoluble material. However, the solution of 9-XVII in benzine could be kept without decomposition in a refrigerator. Diacetylene (9-XVII) gave orange-yellow cuprous and yellow silver acetylides. UV (petroleum ether): λ_{max} (nm): 328.5 (L_a), 360 (L_b).

2-Butadiynylphenanthrene (2-XVII). Hexadiynediol (2-XV) was converted to diacetylene (2-XVII) according to the same reaction sequence under the conditions employed for the preparation of 9-XVII. Extremely unstable diacetylene (2-XVII) was obtained as colorless needles, mp *ca.* 110°C (dec.) in a yield of 50%. The substance gave yellow cuprous and light yellow silver acetylides. UV (petroleum ether): λ_{max} (nm): 314.5 (L_a), 365 (L_b).

3-Butadiynylphenanthrene(3-XVII). This substance was also prepared according to the method used for 9- and 2-isomer. The diacetylene(3-XVII) was obtained as colorless cubes in a yield of 15%. This substance was found to be highly unstable. It began to decompose at *ca.* 60°C and completely decomposed at 98—100°C. Diacetylene (3-XVII) gave orange cuprous and yellow silver acetylides. UV (petroleum ether): λ_{max} (nm): 326.5 (L_a), 362 (L_b).

9,9′-Diphenanthryltetraacetylene(VII$_4$). A mixture of the butadiynyl compound (9-XVII, 1.050 g, 4.65 mmol), cupric acetate monohydrate (10.0 g) and pyridine (50 m*l*) was stirred for 6 hr at 40°C.[12] The insoluble material was collected by filtration, and was washed thoroughly with water, then with a small amount of methanol and acetone. The yellow crystals, 1.018 g (97%). dec. p *ca.* 250°C were recrystallized four times from toluene to give pure tetraacetylene (VII$_4$), which decomposed at *ca.* 255°C without fusion.

Found: C, 95.69; H, 4.41%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

3,3′-Diphenanthryltetraacetylene(VI$_4$). The oxidative coupling of 3-butadiynylphenanthrene(3-XVII) according to the above described procedure afforded yellow needles. dec. p *ca.* 190°C in a yield of 78%. The substance was recrystallized twice from toluene to give pure VI$_4$, yellow needles, which decomposed at *ca.* 200°C without fusion.

Found: C, 95.92; H, 4.02%. Calcd for $C_{36}H_{18}$: C, 95.97; H, 4.03%.

2,2′-Diphenanthryltetraacetylene(V$_4$). According to the procedure used in the cases of 3- and 9-isomers, diacetylene (2-XVII) was converted into tetrayne (V$_4$), yellow needles, 82%, dec. p *ca.* 220°C. The crude crystals in hot toluene were percolated through a thin layer of alumina. Pure V$_4$, yellow needles, which decomposed at *ca.* 220°C without fusion was obtained by concentration of the filtrate.

Found: C, 95.68; H, 3.95%. Calcd for $C_{36}H_{18}$; C, 95.97; H, 4.03%.

Phenanthrypropynals (XXV). 3-Phenanthrylpropynal (3-XXV). To a solution of ethylmagnesium bromide (prepared form magnesium, 2.30 g, 0.09 g atom, ethyl bromide, 13.0 g, 0.12 mol) in tetrahydrofuran (170 m*l*), was added over a period of 20 min a solution of 3-ethynylphenanthrene (3-XXIV, 12.25 g, 0.061 mol) in the same solvent (40 m*l*). After the mixture had been refluxed for 30 min, a solution of dimethylformamide (23.0 m*l*) in the same solvent (40 m*l*) was added under cooling with an ice-salt bath. The reaction mixture turned yellow, and then deposition of colorless crystals took place. The mixture was stirred for 2 hr at room temperature and then for 2.5 hr at 30°C. The mixture was poured into cold 5% sulfuric acid (600 m*l*) and benzene (150 m*l*). The mixture was stirred overnight, and extracted with ether. The extract was washed successively with water and sodium hydrogen carbonate solution, and dried. The oily material obtained by evaporation of the solvent, upon trituration with benzene-cyclohexane (1 : 1, 20 m*l*), gave yellow cubes, mp 130-133°C, 12.23 g (88%). The pure material was obtained by recrystallization of the crude crystals three times from benzene, and once from benzene-cyclohexane as yellow prisms, mp 132—134°C.

Found: C, 88.79; H, 4.43%. Calcd for $C_{17}H_{10}O$: C, 88.67; H, 4.38%. IR: 2840, 2740 (-CHO), 2210, 2180 (C≡C), 1658 (C=O) cm^{-1}.

2-Phenanthrylpropynal (2-XXV). The procedure described in the preparation of 3-aldehyde (3-XXV) was successfully adapted in the preparation of 2-aldehyde (2-XXV). The yellow fine needles, mp 104—108°C obtained in a yield of 62% were recrystallized four times from benzene-cyclohexane to give the pure material, yellow fine needles, mp 109—111°C.

Found: C, 88.62; H, 4.38%. Calcd for $C_{17}H_{10}O$: C, 88.67; H, 4.38%. IR: 2180 (C≡C), 1658 (C=O) cm^{-1}.

1-(Phenanthryl)-1,4-pentadiyn-3-ols (XXVI). 2-Phenanthryl Derivative (2-XXVI). To an ice-cooled solution of ethynylmagnesium bromide (prepared form magnesium, 1.44 g, 0.06 g atom and ethyl bromide, 7.20 g, 0.066 mol) in tetrahydrofuran (70 m*l*), was added a solution of 2-phenanthrylpropynal (2-XXV, 6.45 g, 0.028 mol) in tetrahydrofuran (60 m*l*). The temperature of the reaction mixture was gradually raised to room temperature and stirring was continued overnight. The mixture was hydrolyzed by the addition of a saturated ammonium chloride solution. The organic layer was then separated, and the aqueous layer was extracted with benzene. The extract was combined with the organic layer and was worked up in the usual manner to yield a dark-red oil. On being warmed with benzene (20 m*l*) it gave light brown needles, mp 120—122°C, 5.88 g (82%). The substance as recrystallized three times to give pure alcohol (2-XXVI), colorless needles, mp 121°C.

Found: C, 88.79; H, 4.71% Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%. IR: 3100—3450 (OH), 3295 (≡CH), 2330, 2110 (C≡C) cm^{-1}.

3-Phenanthryl Derivative (3-XXVI). The crude crys-

tals, mp 114—117°C (74%) which were obtained by the procedure described above were recrystallized three times from benzene and once from benzene - methanol to afford pure 3-XXVI as colorless tiny plates, mp 117—118°C.

Found: C, 88.87; H, 4.72%. Calcd for $C_{19}H_{12}O$; C, 89.04; H, 4.72%. IR: 3600—3100 (OH), 3280 (≡CH), 2210, 2110 (C≡C), 1012 (C–O) cm^{-1}.

1,10-Di(Phenanthryl)-1,4,6,9-decatetrayn-3,8-diols (XXVII). 2-Phenanthryl Derivative (2-XXVII). A mixture of 2-phenanthrylpentadiynol (2-XXVI, 2.80 g, 0.011 mol), cuprous chloride (0.35 g), ammonium chloride (0.30 g) and methanol (60 m*l*) was vigorously stirred under oxygen atmosphere at a slightly elevated pressure. After the mixture had been stirred for 48 hr, the solid deposited was collected by filtration. The solid was washed with a small amount of methanol, and then was dissolved in tetrahydrofuran-acetone (1 : 1;20 m*l*). The solution was passed through a short column of silica gel (5 g), and the filtrate was concentrated under reduced pressure to afford crude crystals, 2.40 g (84%), dec. p *ca.* 120°C. The substance was recrystallized from tetrahydrofuran-acetone to yield colorless needles, dec. p *ca.* 125°C. The unstable tetraacetylene glycol turned yellow in a short time.

Found: C, 89.21; H, 4.25%. Calcd for $C_{38}H_{22}O_2$: C, 89.39; H, 4.34%. IR: 3100—3400 (OH), 2235 (C≡C), 1008 (C–O) cm^{-1}.

3-Phenanthryl Derivative (3-XXVI). According to the above procedure, the 3-phenanthrylpentadiynol (3-XXVII) gave light brown crystals, dec. p *ca.* 110°C in a yield of 70%. Recrystallization of this material from acetone-ethanol and then from acetone-benzene afforded rather unstable colorless fine needles, dec. p *ca.* 140°C.

Found: C, 89.47; H, 4.34%. Calcd for $C_{38}H_{22}O_2$: C, 89.39; H, 4.34%. IR: 3600—3100 (OH), 2230 (C≡C), 1010 (C–O) cm^{-1}.

1,10-Di(9-Phenanthryl)-3,4,6,8-decatetrayn-1,10-diol (XIX). Formation of 1-(9-Phenanthryl)-2,4-pentadiyn-1-ol (XVIII). A solution of 1,4-dichloro-2-butyne(7.20 g, 0.059 mol) in ether (10 m*l*) was added over a period of 20 min to a suspension of lithium amide (prepared from lithium, 1.24 g, 0.179 atom) in liquid ammonia (250 m*l*) at −60°C. After having been stirred for 5 min, a solution of 9-formylphenanthrene (9.27 g, 0.045 mol) in tetrahydrofuran (150 m*l*) was added, and the mixture was stirred at −55°C for 1 hr, at −50°C for 1 hr and additional 1.5 hr at −40°C. Ammonium chloride (9 g) was then added to the reaction mixture at −60°C. After ammonia had been allowed to evaporate, water was added to the residue, and was extracted with benzene. Evaporation of the solvent from the dried extract gave a deep brown tarry material, which was re-dissolved in benzene, and then passed through a short column of alumina (7 g). However, no crystalline material could be obtained from the filtrate. The IR spectrum of the crude material indicated the presence of –C≡CH and OH groups. The absorption of C=O was found to be very weak. Owing to the unstable nature of diacetylene carbinol (XVIII), the crude material was subjected to the subsequent reaction.

Oxidative Coupling of Diacetylene Carbinol (XVIII). Cuprous chloride (0.30 g, 3 mmol) and ammonium chloride (0.20 g) were added to a solution of the above-mentioned crude carbinol (XVIII) in methanol (120 m*l*). The mixture was vigorously stirred under oxygen atmosphere at slightly elevated pressure. After having been stirred for 2 hr at room temperature, 2 drops of concentrated hydrochloric acid was added to the reaction mixture to dissolve the deposited cuprous acetylide. Stirring was continued overnight. The insoluble material deposited was washed with a small amount of methanol. The greenish-brown powder thus obtained was dissolved in tetrahydrofuran (60 m*l*) and the insoluble material was removed. The solution was percolated through a thin layer of alumina (10 g). The filtrate was concentrated under reduced pressure, and the tarry residue was mixed with a small amount of benzene. The mixture was warmed to promote crystallization. The crystals were dissolved in acetone and were precipitated by the addition of benzene to give fairly pure crystals, 2.25 g (20% based on 9-formylphenanthrene). The crystals decomposed at *ca.* 175°C without fusion. Owing to the instability of tetraacetylene glycol(XIX), the crude crystals were used in the following reaction.

IR: 3400 (OH), 2200, 2150, 2070 (C≡C), 1063 (C–O) cm^{-1}.

9,9'-Diphenanthrylpentaacetylene(VII_5). Formation of Dichloride(XX). A mixture of thionyl chloride (0.36 g; 3 mmol), pyridine (0.24 g, 3 mmol) and ether (5 m*l*) was added over a period of 20 min to a solution of the crude tetraacetylene glycol (XIX, 0.510 g, 1.0 mmol) in tetrahydrofuran (20 m*l*) at −20°C. The mixture was shaken for 30 min, and was immediately subjected to the following reaction.

Dehydrochlorination of Dichloride(XX). The mixture containing dichloride(XX) was added to a suspension of sodium amide (prepared from sodium, 0.40 g, 0.017 g atom) in liquid ammonia (100 m*l*) at −60°C under vigorous stirring. After 30 min, ammonium chloride (2 g) was added, and ammonia was allowed to evaporate. The residue obtained on removal of the solvent under reduced pressure was mixed with water. The insoluble material was washed successively with water, a small amount of acetone and benzene, and was dissolved in toluene (400 m*l*). The solution was passed through a short column of alumina (15 g). The yellow filtrate was concentrated under reduced pressure to yield orange-yellow needles, 0.213 g (45%). The substance was recrystallized twice from toluene to give pure VII_5, orange-yellow needles. The crystals decomposed at *ca.* at 200°C without fusion.

Found: C, 96.05; H, 3.85%. Calcd for $C_{38}H_{18}$; C, 96.18; H, 3.82%.

3,3'-Diphenanthrylpentaacetylene(VI_5). To a solution of di-(3-phenanthryl)-tetraacetylene glycol (3-XXVII; 0.510 g, 1 mmol) in tetrahydrofuran (15 m*l*), was added at −30°C a mixture of thionyl chloride (3.36 g, 3 mmol), pyridine (0.24 g, 3 mmol) and ether (5 m*l*) over a period of 15 min. The mixture was shaken for additional 5 min, and was added to a suspension of sodium amide (prepared from sodium, 0.40 g, 0.017 g atom) in liquid ammonia (90 m*l*) at −65°C. After having been stirred for 30 min, ammonium chloride (1 g) was added to the mixture, and ammonia was allowed to evaporate. The organic solvent was removed under reduced pressure, and the residue thus obtained was mixed with water. The insoluble material was washed successively with water, methanol, acetone and benzene, and was dissolved in hot toluene (400 m*l*). The hot solution was percolated through a thin layer of alumina (15 g). On cooling the yellow filtrate, orange-yellow needles, 0.276 g (58%) were obtained. The second crop of crystals, 0.029 g (6%) was obtained by the concentration of the mother liquor. The combined crystals were recrystallized from toluene to give pure VI_5, orange-yellow needles. It decomposed at *ca.* 190°C without fusion.

Found: C, 96.27; H, 3.74%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

2,2'-Diphenanthrylpentaacetylene (V_5). According to

the procedure for the preparation of VI_5, the di-(2-phenanthryl)-tetraacetylene glycol(2-XXVII), were converted to V_5, silky yellow needles, in a yield of 22%. The crystals were recrystallized from toluene to afford pure V_5 as bright yellow fine needles. The crystals decomposed at *ca.* 200°C without fusion.

Found: C, 96.42: H, 3.78%. Calcd for $C_{38}H_{18}$: C, 96.18; H, 3.82%.

1-(Phenanthryl)-2,5-hexadiyn-1,4-diols (XXI). 9-Phenanthryl Derivative(9-XXI). A solution of 2,4-pentadiyn-3-ol[13] (3.08 g, 0.039 mol) in tetrahydrofuran (65 m*l*) was added over a period of 20 min to a stirred solution of ethylmagnesium bromide (prepared from magnesium, 2.05 g, 0.086 g atom and ethyl bromide, 10.4 g, 0.095 mol) in tetrahydrofuran (55 m*l*) at a temperature of 20—25°C. After 30 min, a solution of 9-phenanthraldehyde (VIII, R= 9-phenanthryl), (6.00 g, 0.029 mol) in tetrahydrofuran (60 m*l*) was added to the ice-cooled mixture, and the mixture was stirred at room temperature overnight. The reaction mixture was hydrolyzed by the addition of a saturated solution of ammonium chloride. The organic layer was combined with the benzene extract of the aqueous layer, and dried. Evaporation of the solvent gave a viscous oily material. The oily material was warmed with benzene (10 m*l*) to bring about crystallization. The light brown crystals, 6.10 g (74%) mp 135—140°C, obtained by washing with a small amount of cold benzene, were recrystallized three times from methanol-benzene. The colorless fine needles, mp 160—165°C, thus prepared, were re-dissolved in ethyl acetate, and the solution was passed through a short column of alumina to afford pure XXI (R=9-phenanthryl) as colorless fine needles, mp 169—171°C.

Found: C, 83.83; H, 4.90%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR: 3500—3200 (OH), 3295 (≡CH), 2110 (C≡C), 1074, 1030 (C–O) cm^{-1}.

3-Phenanthryl Derivative (3-XXI). The light brown crystalline powder obtained from 3-phenanthraldehyde (3-VIII) according to the procedure used for the preparation of 9-isomer in a yield of 79% was recrystallized from methanol-benzene to yield light brown needles, mp 127—135°C. This material was recrystallized three times from acetone-benzene to give pure 3-phenanthryl diol (3-XXI) as colorless fine needles mp 141—143°C.

Found: C, 83.69; H, 4.96%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR: 3600—3100 (OH), 3295 (≡CH), 2115 (C≡C), 1020 (C–O) cm^{-1}.

2-Phenanthryl Derivative (2-XXI). According to the procedure, 2-phenanthraldehyde (VIII, R=2-phenanthryl) was converted to slightly crude XXI (R=2-phenanthryl), light brown fine crystals, in a yield of 72%. The crystals were recrystallized three times from ethyl acetate-toluene to yield pure specimen as pale yellow leaflets, mp 151—153°C.

Found: C, 84.04; H, 4.92%. Calcd for $C_{20}H_{14}O_2$: C, 83.90; H, 4.93%. IR: 3500—3100 (OH), 3280 (≡CH), 2115 (C≡C), 1020 (C–O) cm^{-1}.

9-Hexatriynylphenanthrene(9-XXIII). Chlorination of Hexadiynediol(9-XXI). To a solution of diol (9-XXI, 1.716 g, 6 mmol) in tetrahydrofuran (16 m*l*) was added over 30 min a mixture of thionyl chloride (2.14 g, 18 mmol), pyridine (1.42 g, 18 mmol) and ether (7 m*l*) at −20°C. The mixture was allowed to reach room temperature, after which it was shaken for 30 min, and was subjected directly to the subsequent reaction.

Dehydrochlorination of Dichloride (9-XXII). The reaction mixture containing dichloride(9-XXII) was added to a vigorously stirred suspension of sodium amide (prepared from sodium, 1.00 g, 0.044 g atom) in liquid ammonia (100 m*l*) at −70°C. After the mixture had been stirred for 45 min, ammonium chloride (4 g) was added, and ammonia was allowed to evaporate. The organic solvent was distilled off under reduced pressure and the residue was digested repeatedly with petroleum ether (bp 60—80°C, total 300 m*l*). The solution was passed through a thin layer of alumina (6 g). A small portion of the pale yellow filtrate was concentrated under reduced pressure to result in the deposition of pale yellow fine needles. Rapid decomposition of the crystals to form black tarry material was observed. Triacetylene (9-XXI, UV (petroleum ether): λ_{max} 352 nm) gave yellow silver and orange cuprous acetylides. Owing to the unstable nature of 9-XXI, the petroleum ether solution was used in the following reaction.

3-Hexatriynylphenanthrene (3-XXIII). A colorless petroleum ether solution of triacetylene (3-XXIII) was obtained from the 3-phenanthryl glycol (3-XXI, 0.860 g, 3 mmol) under the same reaction conditions. Concentration of a small portion of the solution gave extremely unstable colorless cubes, which decomposed immediately to a brown material. Triacetylene (3-XXIII), UV (petroleum ether): λ_{max} 350 nm, gave orange cuprous and yellow silver acetylides. The petrolum ether solution was used directly for the subsequent reaction.

2-Hexatriynylphenanthrene (2-XXIII). 2-Phenanthryl diynediol (2-XXI, 2.00 g, 7 mmol) was converted to a petroleum ether solution of triacetylene (2-XXIII) according to the same procedure. Colorless fine needles obtained by the concentration of a small portion of the solution decomposed to blue insoluble material. Triacetylene (2-XXII, UV (petroleum ether): λ_{max} 342 (L_a), 370 (L_b nm) gave orange cuprous and yellow silver acetylides. The petroleum ether solution was subjected to the following reaction without isolation of 2-XXIII.

9,9′-Diphenanthrylhexaacetylene (VII_6). The petroleum ether solution of 9-hexatriynylphenanthrene (9-XXIII) was mixed with cupric acetate monohydrate (4.0 g) and pyridine (50 m*l*), and the mixture was concentrated to *ca.* 40 m*l* under reduced pressure. After the concentrated mixture had been stirred overnight at room temperature, the mixture was again concentrated to *ca.* 20 m*l* *in vacuo*. The insoluble material was washed with a small amount of methanol and then with water. The crude hexaacetylene, brown powder, 0.101 g (7% based on the diol, 9-XXI), thus obtained, was digested with hot toluene (100 m*l*), and the hot solution was passed through a short column of alumina (5 g). On cooling the orange filtrate, it gave orange fine needles. The crystals were recrystallized twice from toluene to give pure VII_6 as orange fine needles. This substance decomposed without fusion at *ca.* 130°C.

Found: C, 96.30; H, 3.67%. Calcd for $C_{40}H_{18}$: C, 96.36; H, 3.64%.

3,3′-Diphenanthrylhexaacetylene (VI_6). According to the same procedure, the petroleum ether solution of 3-hexatriynylphenanthrene (3-XXIII) gave crude VI_6, as yellow fine leaflets, 0.094 g (13% based on the glycol, 3-XXI). A benzene solution (350 m*l*) of the crude material was percolated through a thin layer of alumina (5 g). The orange yellow filtrate gave 0.056 g of pure VI_6 as orange yellow tiny plates, which decomposed at *ca.* 100°C without fusion.

Found: C, 96.41; H, 3.67%. Calcd for $C_{40}H_{18}$: C, 96.36; H, 3.64%.

2,2′-Diphenanthrylhexaacetylene (V_6). Brown crystalline powder, 0.380 g (22% based on the glycol, 2-XXI),

13) E. R. H. Jones, L. Skatteböl, and M. C. Whiting, *J. Chem. Soc.*, **1956**, 4765.

obtained under similar conditions from the above-mentioned petroleum ether solution of 2-XXIII was dissolved in benzene (300 m*l*). The benzene solution was passed through a short column of alumina (12 g). The deep yellow filtrate was concentrated to *ca.* 100 m*l* *in vacuo* to yield pure V_6 as light orange fine crystals, 0.102 g (6% based on the glycol, 2-XXI), which decomposed without fusion at *ca.* 185°C.

Found: C, 96.15; H, 3.62%. Calcd for $C_{40}H_{18}$; C, 96.36; H, 3.64%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2248—2253 (1971)

The Reaction of Dihalotetramethylbenzenes with Fuming Nitric Acid as a New Convenient Route to Some Dihalotrimethylbenzylic Compounds[1]

Hitomi SUZUKI, Kiyomi NAKAMURA, and Michiko TAKESHIMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 8, 1971)

Products obtained by the nitration of three isomeric dichloro and dibromotetramethylbenzenes with fuming nitric acid have been investigated. 3,6-Dihalo-1,2,4,5-tetramethylbenzene (dihalodurene) gave mainly 3,6-dihalo-2,4,5-trimethylbenzyl nitrate or 1,2-bis(nitrooxymethyl)-3,6-dihalo-4,5-dimethylbenzene, depending on the reaction temperature and the amount of nitrating agent. 4,6-Dihalo-1,2,3,5-tetramethylbenzene (dihaloisodurene) yielded a mixture of 3,5-dihalo-2,4,6-trimethylbenzyl nitrate and 2,6-dihalo-3,4,5-trimethylbenzyl nitrate, the latter in somewhat greater amount. 5,6-Dihalo-1,2,3,4-tetramethylbenzene (dihaloprehnitene) gave 5,6-dihalo-2,3,4-trimethylbenzyl nitrate as the sole nitrooxylation product. The reaction affords a new convenient route to precursors of various polysubstituted benzylic compounds hitherto not easily obtained by ordinary methods. Physical properties of some dihalotrimethylbenzylic compounds (chloride, nitrate, acetate, alcohol, and bisbenzyl ether) have been recorded.

On treatment with fuming nitric acid at low temperature, polyalkylbenzenes and their derivatives undergo side-chain nitrooxylation to give benzyl nitrates.[2-7] A noteworthy feature of this unusual reaction is that the product is usually composed of one isomer of specific orientation. Electron-withdrawing substituent brings about preferential side-chain nitrooxylation on the ortho methyl group, while the electron-releasing group is found to facilitate substitution on the meta methyl group. High positional selectivity, predominant substituent effect, and smooth occurrence of the reaction under mild conditions point to an ionic process.

From an interest in the anomalous nitration of polyalkylated aromatics, we investigated nitration of three isomeric dichloro and dibromotetramethylbenzenes with a view to obtaining further information on the general pattern of side-chain substitution in these systems, and clarifying the scope of synthetic utility of the reaction as a simple route to some polysubstituted benzylic compounds which are otherwise laborious to prepare.

Both dichlorotetramethylbenzenes and dibromotetramethylbenzenes react slowly with fuming nitric acid in dichloromethane at 0°C to give a pale yellow to light brown half-crystalline solid, mostly composed of dihalotrimethylbenzyl nitrates. The bromo compounds appear to be somewhat more reactive than the chloro compounds, and of the three isomeric dihalotetramethylbenzenes, 4,6-dihalo-1,2,3,5-tetramethylbenzene (dihaloisodurene) seems to be the most reactive.

1,2,4,5-Tetramethylbenzene (Durene) Series. 3,6-Dichloro-1,2,4,5-tetramethylbenzene (dichlorodurene) and 3,6-dibromo-1,2,4,5-tetramethylbenzene (dibromodurene) both reacted slowly with fuming nitric acid to give a crystalline solid, the major component of which was either dihalotrimethylbenzyl nitrate, or bis(nitrooxymethyl)dihalodimethylbenzene depending on the amount of nitric acid and the reaction temperature. With the use of three or four equivalent amounts of nitric acid at low temperature, the product was almost exclusively 3,6-dihalo-2,4,5-trimethylbenzyl nitrate. However, when dihalodurene was treated with a large excess of fuming nitric acid in an ice bath and the mixture was left standing for several hours, allowing the temperature of the system to gradually rise to room temperature, the product was a bis(nitrooxymethyl)dihalodimethylbenzene accompanied by some 5-nitro-3,6-dihalo-1,2,4-trimethylbenzene. If the reaction was allowed to proceed for a longer period, the latter compound constituted a significant portion of the product mixture. This product was no doubt derived from the initially formed benzyl nitrate through the replacement of the nitrooxymethyl group by the nitro group. Theoretically, three isomeric bis(nitrooxymethyl)dibromodimethyl-

benzenes can be derived from dibromodurene, and two of them, 1,3-bis(nitrooxymethyl)-2,5-dibromo-4,6-dimethylbenzene (I) and 1,4-bis(nitrooxymethyl)-2,5-dibromo-3,6-dimethylbenzene(II), were prepared from the corresponding bis(chloromethyl)benzenes by treatment with silver nitrate in hot acetonitrile. However, neither of these authentic specimens was found to be identical with the dinitrate obtained from dibromodurene. The bisnitrooxylated product is, therefore, most likely to be 1,2-bis(nitrooxymethyl)-3,6-dibromo-4,5-dimethylbenzene (III), although the authentic specimen is not available yet. This structural assignment is consistent with the observed directing effect of halogen atom and nitrooxymethyl group for the side-chain nitrooxylation of polymethylbenzene derivatives. The combined effect of the ortho/meta directing halogen[3] and the ortho directing nitrooxymethyl group[4] favors structure III over I and II.

Further nitrooxylation of bis(nitrooxymethyl)benzene could not be observed even by the action of a large excess of cold fuming nitric acid for a prolonged period. At somewhat higher temperature, the decomposition of the nitrate or the bis(nitrooxymethyl)-benzene into nitro or carbonyl compounds became prominent. No attempt has been made to identify them.

Chromatography of the crude nitration product on alumina requires some precaution since the active alumina converts the nitrate into bisbenzyl ether and benzyl alcohol during elution with benzene and ethanol. Dichlorotrimethylbenzyl nitrates were more readily decomposed than the bromo compounds. Light petroleum eluted unchanged material and benzyl nitrate, and the light petroleum - benzene mixture eluted bisbenzyl ether and nitro compound. Recovery of benzyl nitrates was usually unsatisfactory. Benzyl alcohol, bis(hydroxymethyl)benzene and unidentified carbonyl compounds were obtained from diethyl ether - ethanol eluates. The relative ratio of these products varied considerably depending on the activity of alumina and length of column.

1,2,3,5-Tetramethylbenzene (Isodurene) Series. 4,6-Dichloro-1,2,3,5-tetramethylbenzene (dichloroisodurene) and 4,6-dibromo-1,2,3,5-tetramethylbenzene (dibromoisodurene) reacted with fuming nitric acid more readily than durene analogs and gave a pale yellow pasty solid, PMR spectra of which showed two methylene peaks due to $-CH_2ONO_2$ at 4.24 and 4.48 τ with relative areas of 55 : 45 for chloro compound, and two peaks of relative intensity 66 : 34 at 4.12 and 4.43 τ for bromo derivative. These nitrates could be separated by fractional crystallization from ethanol. Direct comparison with the authentic specimens identified the benzyl nitrate with methylene proton absorption at higher field as 3,5-dihalo-2,4,6-trimethylbenzyl nitrate(IV), and another nitrate with lower field absorption as 2,6-dihalo-3,4,5-trimethylbenzyl nitrate(V). Attempted chromatographic separation of the product from dichloroisodurene on alumina resulted in nearly complete conversion of the nitrates to benzyl alcohol and bisbenzyl ether, but fairly selective decomposition occurred with the nitrates derived from dibromoisodurene. 2,6-dibromo-3,4,5-trimethylbenzylic product was adsorbed firmly on alumina and only a small portion was usually eluted as nitrate. 3,5-Dibromo-2,4,6-trimethylbenzylic compound was obtained mainly as bisbenzyl ether and alcohol. The structures of these bisbenzyl ethers were established by preparing authentic specimens from the corresponding alcohols. Under the conditions in which dihalodurenes were bisnitrooxylated, dihaloisodurenes were found to yield mononitrates together with a significant amount of nitro and carbonyl compounds.

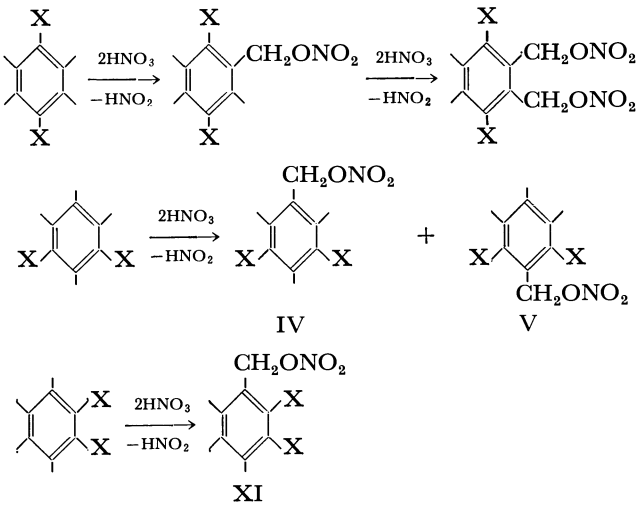

Fig. 1

Both nitrates IV and V derived from dihaloisodurene possess the methyl group at a position para to the nitrooxymethyl group (Fig. 1). The result is in line with the general observation that one of the main factors controlling the ease of side-chain nitrooxylation is the presence of the methyl group at a position para to the alkyl group to be nitrooxylated. This might indicate that the transition state of the anomalous substitution resembles a benzylic compound rather than a methylenecyclohexadiene, since the para methyl group is known to be more effective than halogen atom to delocalize the electron deficiency developed on the benzylic carbon atom during the reaction. The preferred formation of IV and V from dihaloisodurene may be explained as follows:

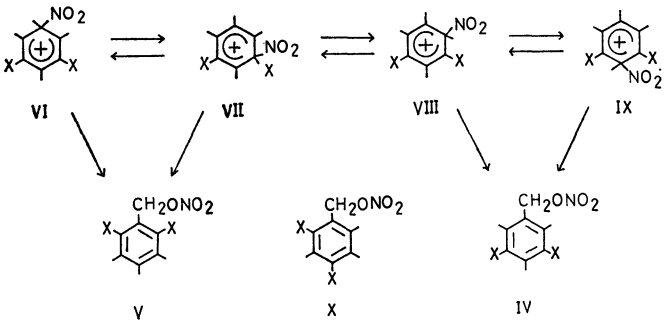

Fig. 2

Electrophilic attack of nitronium ion on dihaloisodurene would lead to an equilibrium mixture of four benzenonium ions VI—IX, in which VI and VII are supposed to predominate since three methyl groups can effectively contribute to the stabilization of these intermediates. Rearrangement of ions VI and VII according to the previously suggested mechanism,[6,7] which assumes migration of the nitro group from the attacking site to the α-carbon of the alkyl group from which the preferential proton removal takes place, will lead to V, because the proton release and subsequent migration of the nitro group would occur preferentially on the methyl group bonded to the more positively polarized ring carbon between two halogen atoms. Transformation of VI and VII into 4,6-dihalo-2,3,5-trimethylbenzyl nitrate(X) would be disfavored since the transition state can not be stabilized as effectively by the para halogen atom as by the para methyl group. On the other hand, less stable ions VIII and IX can be converted into IV more readily owing to the favorable orientation of substituent groups in the ring, the equilibrium being displaced in favor of these ions at the expence of the more stable ions VI and VII.

An alternative possibility may involve the ion-pair path; a proton is removed hyperconjugatively from the alkyl side-chain to form a sort of methylenecyclohexadiene or benzylic intermediate - nitrite ion pair, which will subsequently be converted into the nitrate. An increase in the formation of V relative to IV in going from chlorine to bromine is explained by the greater contribution of ions VI and VII in the equilibrium mixture as well as the easier migration of the nitro group due to the increased nuclear charge and bulkiness of bromine atom.

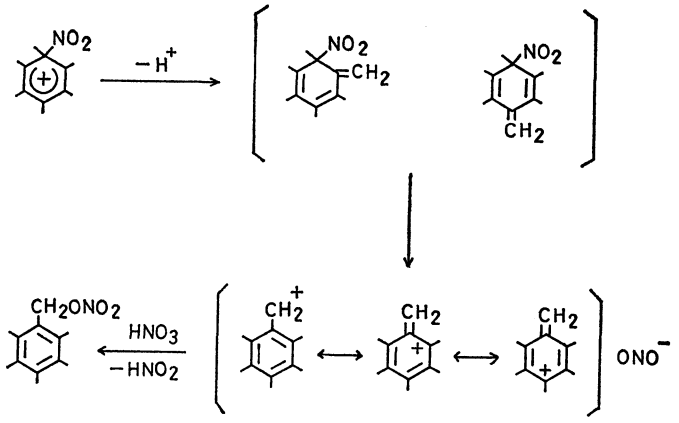

Fig. 3

1,2,3,4-Tetramethylbenzene (Prehnitene) Series. 5,6-Dihalo-1,2,3,4-tetramethylbenzene (dihaloprehnitene) was comparatively stable towards the action of cold nitrating agent, but slowly underwent side-chain nitrooxylation to give only one nitrate in good yield, which could be readily separated from the product mixture by fractional crystallization. The nitrate was identified as 5,6-dihalo-2,3,4-trimethylbenzyl nitrate(XI) by direct comparison with the authentic specimen prepared from 4,5-dihalo-1,2,3-trimethylbenzene through the ordinary sequence. Chromatographic behavior of the nitration product was similar to those obtained from dihaloisodurenes. Nitrate XI does not seem to undergo further nitrooxylation and is liable to suffer extensive decomposition by the action of a large excess of nitrating agent. The product mixture usually contains appreciable amounts of an unidentified crystalline solid which has absorption bands around 1610—1630 and 3400 cm^{-1}. Its structure has not been established yet. Formation of XI in preference to the isomeric 4,5-dihalo-2,3,6-trimethylbenzyl nitrate could be rationalized on the basis of a similar discussion as above.

The results indicate that the side-chain nitrooxylation of dihalotetramethylbenzenes with fuming nitric acid can provide a simple new method for the preparation of dihalotrimethylbenzylic compounds, some of which are laboriously obtained by the ordinary procedure.

Experimental

All melting points were determined with a hot-stage apparatus and are uncorrected. Infrared spectra were run as Nujol on a Jasco DS-402G spectrophotometer and only prominent peaks are recorded. PMR measurements were carried out on a Varian A-60A spectrometer and a JNM-3H spectrometer with carbon tetrachloride as solvent and tetramethylsilane as internal standard.

Dihalotetramethylbenzenes were prepared by halogenation of the corresponding hydrocarbons and purified through chromatography on alumina using light petroleum as eluant.

Authentic specimens of benzylic compounds were prepared essentially by the same sequence; chloride→nitrate, and chloride→acetate→alcohol→bisbenzyl ether. The general procedure is shown below with examples from the compounds of 3,5-dihalo-2,4,6-trimethylbenzylic series. Physical properties of some dihalotrimethylbenzylic compounds are summarized in Table 1.

3,5-Dibromo-2,4,6-trimethylbenzyl Chloride (XII). A crystal of iodine was added to a solution of 2,4,6-trimethylbenzyl chloride[8] (16.9 g) in carbon tetrachloride (50 ml), and bromine (*ca.* 33 g) was introduced dropwise at 0°C. The dibromobenzyl chloride soon began to separate from the mixture. The solvent was partly removed and the precipitate was recrystallized from light petroleum to give white needles (22.5 g, 69%), mp 125—127°C.

Found:C, 36.4; H, 3.3%. Calcd for $C_{10}H_{11}Br_2Cl$: C, 36.8; H, 3.4%.

Other dihalotrimethylbenzyl chlorides were similarly prepared by direct halogenation of the corresponding trimethylbenzyl chlorides. Yields varied from poor to moderate, depending on the structure of the chloride being halogenated. In some cases, a significant amount of unidentified higher halogenated products was formed as a by-product and its purification was tedious.

3,5-Dibromo-2,4,6-trimethylbenzyl Nitrate (XIII). A warm solution of silver nitrate (4.1 g) in acetonitrile (15 ml) was added all at once to a magnetically stirred solution of chloride XII (6.5 g) in acetonitrile (20 ml). The mixture was stirred for several hours, and silver chloride was filtered. After removal of the solvent in a vacuum, the residue was crystallized from light petroleum to give XIII (5.3 g), mp

a) Principal peaks in the regions, 650—1350 and 1500—2000 cm^{-1}. Under certain conditions, benzyl nitrates show another asymmetric frequency band due to ONO_2 group in the 1640—1650 cm^{-1} region (indicated by asterisk). Appearance of this band is often accompanied by a small change in symmetric frequency in 1270—1290 cm^{-1} region.
b) Numerals in parentheses refer the number of methyl groups.

127—128°C.

Found: C, 33.9; H, 3.3%. Calcd for $C_{10}H_{11}Br_2NO_3$: C, 34.0; H, 3.1%.

Other dihalotrimethylbenzyl nitrates were prepared in a similar manner from the chlorides and recrystallized from light petroleum.

3,5-Dibromo-2,4,6-trimethylbenzyl Acetate (XIV). A mixture of chloride XII (9.8 g), silver acetate (5.2 g), and acetic acid (60 ml) was heated under gentle reflux for several hours. Silver chloride was filtered, and the reaction mixture was diluted with water to yield acetate as a white precipitate, which was recrystallized from light petroleum in the form of colorless needles (8.6 g), mp 116—118°C.

Found: C, 41.3; H, 3.9%. Calcd for $C_{12}H_{14}Br_2O_2$: C, 41.2; H, 4.0%.

A similar treatment of other dihalotrimethylbenzyl chlorides with silver acetate gave the corresponding acetates in high yields (75—89%).

3,5-Dibromo-2,4,6-trimethylbenzyl Alcohol (XV). Acetate XIV (3.5 g) was dissolved in a large volume of ethanol, to which was added an aqueous solution of sodium hydroxide (4 g). The mixture was gently refluxed for several hours and then poured into water to give XV (*ca.* 3 g), which was crystallized from boiling ethanol in the form of fine prisms, mp 205—206°C.

Other dihalotrimethylbenzyl alcohols were obtained similarly by analogous hydrolysis of the acetates using aqueous sodium hydroxide. Most dihalotrimethylbenzyl alcohols are only slightly soluble in light petroleum, carbon tetrachloride, benzene, and cold ethanol.

Attempt to prepare dibromotrimethylbenzyl alcohols by reducing dibromotrimethylbenzoic acids with lithium aluminum hydride in tetrahydrofuran proved unsatisfactory, since the bromine atom was partly or completely removed during the reduction.

Bis(3,5-dibromo-2,4,6-trimethylbenzyl) Ether (XVI). A mixture of XV and a catalytic amount of sulfamic acid was heated at 210—220°C in an oil bath. The alcohol melted to a pale yellow oil, and soon solidified to a white crystalline mass, which was taken up in a mixture of dichloromethane and ligroin and chromatographed on a short alumina column to remove any unchanged alcohol. Ether XVI crystallized from hot benzene as white needles and melted at 249—250°C. The yield was nearly quantitative.

Other bisbenzyl ethers were prepared in a similar way. The bromo alcohol needed somewhat higher temperature and longer heating than the chloro compound to complete the reaction.

2,6-Dimethyl-4-bromoaniline (XVII). 2,6-Dimethylaniline (12.1 g) was dissolved into a mixture of concentrated hydrochloric acid (30 ml) and water (220 ml), and the solution was cooled in an ice bath. A rapid stream of air saturated with bromine vapor was introduced with stirring until the solution assumed a distinctly yellow color. About 18—19 g of bromine was required. The bromoaniline hydrochloride came out of the solution as a white precipitate. The reaction mixture was made alkaline with aqueous sodium carbonate and the separated dark oil which soon solidified was filtered and recrystallized from ligroin to give large prisms (16.3 g, 82%), mp 50—51°C (lit,[9] 50—51°C). Acetanilide, mp 199—200°C (lit,[10] 198—200°C).

A similar treatment of 2,3-dimethylaniline gave 4,6-dibromo-2,3-dimethylaniline (mp 56—57°C) and unchanged starting material. The required monobromoaniline was obtained only in a small amount.

*2,5-Dibromo-*m*-xylene (XVIII).* A solution of XVII (20 g) in cold concentrated sulfuric acid (50 ml) was poured onto crushed ice (200 g) and diazotized with sodium nitrite (7.5 g). The resulting solution was filtered and the filtrate was added as rapidly as the foaming permitted to a boiling mixture of copper(I) bromide (7 g), cupper powder (*ca.* 1 g) and 47%-hydrobromic acid (80 ml). The separated black oil was removed by extraction with ether, washed with dilute aqueous sodium hydroxide and dried over anhydrous calcium chloride. The ethereal solution was distilled off to leave a dark oil, which on distillation under reduced pressure gave pale yellow oil (15 g, 57%), bp 120—121°C/15 mmHg (lit,[11] mp 28°C). Some 4-bromo-2,6-dimethylphenol (mp 79—80°C) was obtained as a by-product.

1,3-Bis(chloromethyl)-2,5-dibromo-4,6-dimethylbenzene (XIX).

9) E. Nölting, A. Braun, and G. Thesmar, *Ber.*, **34**, 2259 (1901).
10) E. G. Kleinschmidt and H. Braeuniger, *Pharmazie*, **1969**, 87.
11) J. J. Blanksma, *Rec. Trav. Chim. Pays-Bas*, **25**, 176 (1906).

A warm solution of XVIII (4 g) in chloromethyl methyl ether (*ca.* 5 g) was treated with 60%-fuming sulfuric acid (*ca.* 4—5 g) with vigorous stirring. The reaction proceeded with active liberation of heat and the mixture soon solidified into a black crystalline mass, which was washed with water, dissolved into a mixture of dichloromethane and ligroin, and freed from the polymeric substances through chromatography on a short alumina column. Removal of the solvent, followed by recrystallization of the product from carbon tetrachloride gave XIX (3.5 g, 64%) as long needles, mp 175—176°C.

Found: C, 33.0; H, 3.9%. Calcd for $C_{10}H_{10}Br_2Cl_2$: C, 33.3; H, 2.8%.

By a similar treatment, 2,5-dibromo-*p*-xylene gave *1,4-bis(chloromethyl)-2,5-dibromo-3,6-dimethylbenzene (XX)*, mp 213—215°C.

Found: C, 32.7; H, 2.8%. Calcd for $C_{10}H_{10}Br_2Cl_2$: C, 33.3; H, 2.8%.

1,3-Bis(nitrooxymethyl)-2,5-dibromo-4,6-dimethylbenzene(I). A warm solution of silver nitrate (2.1 g) in acetonitrile (10 m*l*) was added all at once with stirring to a hot solution of XIX (1.8 g) in acetonitrile (40 m*l*). The mixture was stirred with heating for several hours, and silver chloride was separated by filtration. Evaporation of the solvent *in vacuo*, followed by crystallization of the residue from hot ligroin gave white thin plates (2.5 g), mp 130—132°C. IR: 869, 971, 1179, 1278, 1620, and 1633 cm^{-1}, PMR: 7.36 (CH_3), and 4.25 τ (CH_2).

Found: C, 28.9; H, 2.5%. Calcd for $C_{10}H_{10}Br_2N_2O_6$: C, 29.0; H, 2.4%.

The above procedure applied to XX gave *1,4-bis(nitrooxymethyl)-2,5-dibromo-3,6-dimethylbenzene(II)*, mp 186—187°C, as white leaflets. IR: 876, 975, 1176, 1281, and 1628 cm^{-1}, PMR: 7.38 (CH_3) and 4.20 τ (CH_2).

Found: C, 29.0; H, 2.5%. Calcd for $C_{10}H_{10}Br_2N_2O_6$: C, 29.0; H, 2.4%.

General Procedure for Nitration of Dihalotetramethylbenzenes. A suspension of a dihalotetramethylbenzene (0.05 mol) in dichloromethane (50 m*l*) was vigorously stirred and fuming nitric acid (d=1.50) was added dropwise at 0°C over a period of 30 min. The solid part gradually dissolved giving a clear dark brown mixture, which was stirred for some hours and then quenched by being poured into ice water. The organic layer was throughly washed with aqueous sodium hydrogen carbonate and water. Evaporation of the solvent left a yellow to light brown pasty or half-crystalline solid, which was inspected by infrared, PMR, and thin-layer chromatography, and then subjected to chromatographic separation on alumina. Some nitrates were isolated by fractional crystallization of the product mixture from ethanol or ligroin.

Products were identified by elemental analyses, and by infrared and PMR spectra comparison or mixed melting as far as the authentic specimens were available. Typical examples of alumina chromatography are shown below for the nitration products from dibromotetramethylbenzenes.

i) A part (5 g) of light brown crystalline solid obtained from the nitration of dibromodurene (7.3 g) with fuming nitric acid (8 g) was placed on the top of alumina column and eluted with light petroleum to give unchanged starting material (1.2 g) and *3,6-dibromo-2,4,5-trimethylbenzyl nitrate* (0.5 g; Found: C, 33.9; H, 3.0; N, 4.0%. Calcd for $C_{10}H_{11}Br_2NO_3$: C, 34.0; H, 3.1; N, 4.0%). Elution with light petroleum-benzene gave *bis(3,6-dibromo-2,4,5-trimethylbenzyl) ether* (0.6 g; Found: C, 39.8; H, 3.3%. Calcd for $C_{20}H_{22}Br_4O$: C, 40.2; H, 3.7%); with ether-ethanol *3,6-dibromo-2,4,5-trimethylbenzyl alcohol* (1.3 g, Found: C, 39.1; H, 4.3%. Calcd for $C_{10}H_{14}Br_2O$: C, 38.7; H, 4.6%).

A similar treatment of the product (5 g) from the nitration with a large excess of fuming nitric acid at somewhat elevated temperature gave *3,6-dibromo-5-nitro-1,2,4-trimethylbenzene* (0.3 g, mp 198—200°C; Found: C, 33.9; H, 2.8%. Calcd for $C_9H_9Br_2NO_2$: C, 33.4; H, 2.8%) from light petroleum-benzene eluates; small amounts of bisbenzyl ether from benzene eluates; and finally *1,2-bis(hydroxymethyl)-3,6-dibromo-4,5-dimethylbenzene* (1.6 g, mp 225—226°C; Found: C, 37.1; H, 3.8%. Calcd for $C_{10}H_{12}Br_2O_2$: C, 37.0; H, 3.7%) from diethyl ether-ethanol eluates.

Direct crystallization of the latter nitration product from ethanol gave *1,2-bis(nitroxymethyl)-3,6-dibromo-4,5-dimethylbenzene* (mp 121—123°C) as white needles. IR: 847, 868, 940, 1180, 1274, 1280, 1629, and 1640 cm^{-1}, PMR: 7.41 (CH_3) and 4.23 τ (CH_2).

Found: C, 29.1; H, 2.7; N, 6.6%. Calcd for $C_{10}H_{10}Br_2N_2O_6$: C, 29.0; H, 2.4; N, 6.8%.

ii) A light yellow product (5 g) from the nitration of dibromoisodurene was chromatographed on alumina to give the recovered starting material (0.9 g) and *2,6-dibromo-3,4,5-trimethylbenzyl nitrate* (0.5 g, mp 111—112°C; Found: C, 34.3; H, 3.3%. Calcd for $C_{10}H_{11}Br_2NO_3$: C, 34.0; H, 3.1%) from light petroleum eluates. Light petroleum-benzene eluted a mixture of bisbenzyl ethers, most of which was composed of *bis(3,5-dibromo-2,4,6-trimethylbenzyl) ether* (0.3 g, Found: C, 40.6; H, 3.7%. Calcd for $C_{20}H_{22}Br_4O$: C, 40.2; H, 3.7%), and ether-ethanol eluted benzyl alcohol fraction, the major component of which was identified as *3,5-dibromo-2,4,6-trimethylbenzyl alcohol* (1.3 g, Found: C, 38.9; H, 4.2%. Calcd for $C_{10}H_{14}Br_2O$: C, 38.7; H, 4.6%). A greater part of 2,6-dibromo-3,4,5-trimethylbenzylic compounds was lost during elution.

iii) Chromatography of the nitration product from dibromoprehnitene (5 g) gave *5,6-dibromo-2,3,4-trimethylbenzyl nitrate* (0.7 g, Found: C, 34.0; H, 3.4; N, 3.9%. Calcd for $C_{10}H_{11}Br_2NO_3$: C, 34.0; H, 3.1; N, 4.0%) as colorless plates from light petroleum eluates; *bis(5,6-dibromo-2,3,4-trimethylbenzyl) ether* (0.2 g, Found: C, 39.7; H, 3.3%. Calcd for $C_{20}H_{22}Br_4O$: C, 40.2; H, 3.7%) from light petroleum-benzene eluates; an unidentified carbonyl compound from benzene-ether eluates (0.4 g, IR: 1625, 1735, and 3300—3400 cm^{-1}); and finally *5,6-dibromo-2,3,4-trimethylbenzyl alcohol* (1.2 g, Found: C, 39.0; H, 4.3%. Calcd for $C_{10}H_{14}Br_2O$: C, 38.7; H, 4.6%) from ethanol eluates.

By a similar treatment, the product (5 g) from dichloroprehnitene gave *5,6-dichloro*-2,3,4-*trimethylbenzyl nitrate* (0.5 g, Found: C, 45.2; H, 4.3%. Calcd for $C_{10}H_{11}Cl_2NO_3$: C, 45.5; H, 4.2%) and unchanged starting material (0.5 g) from light petroleum eluates. Light petroleum-benzene mixture eluted small amounts of nitro compound and *bis(5,6-dichloro*-2,3,4-*trimethylbenzyl) ether* (0.4 g, Found: C, 58.2; H, 5.5%. Calcd for $C_{20}H_{22}Cl_4O$: C, 57.2; H, 5.3%), and ether eluted an unidentified carbonyl compound (0.6 g, mp 178—179°C; Found: C, 60.8; H, 6.8%; IR: 3400, 1620, 1360, 1270, 1220, 1075, 1040, 1010, 900, 845, and 765 cm^{-1}). *5,6-Dichloro-2,3,4-trimethylbenzyl alcohol* (0.9 g, Found: C, 55.8; H, 5.8%. Calcd for $C_{10}H_{12}Cl_2O$: C, 54.8; H, 5.5%) was obtained as colorless plates from ethanol eluates.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2254—2255 (1971)

The Spectrophotometric Determination of Nickel(II) in a Solution Containing Cobalt(II), Utilizing EDTA and Bismuth as the Masking Reagent and the Demasking Reagent

Katsumi YAMAMOTO, Kousaburo OHASHI, and Ichiro HIRAKO
Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Ibaraki
(Received May 11, 1970)

When hydrogen peroxide is added to a solution mixture of cobalt(II)-EDTA and nickel(II)-EDTA, the former chelate is easily oxidized to the cobalt(III)-EDTA chelate. This mixture in an acidic solution releases nickel(II) upon the addition of a bismuth(III) solution as the result of the nickel(II) in the EDTA chelate being replaced by bismuth(III), because, at pH 2.0, the apparent stability constants of nickel(II)-EDTA and bismuth(III)-EDTA $\log K'$ are 6.1 and 8.6 respectively.[1] Consequently, the exchange reaction between nickel(II)-EDTA and bismuth(III) should thermodynamically proceed almost quantitatively. The cobalt(III)-EDTA chelate does not participate in such an exchange reaction and is not replaced by bismuth(III). When the pH rises above 2.0, the difference in the apparent stability constants gradually decreases; consequently, the exchange is not quantitative. On the other hand, at a pH below 2.0, the formation of the bismuth(III)-EDTA chelate is not complete.

After the above exchange reaction had taken place, 4-(2-pyridylazo)-resorcinol(PAR) was added to the reaction mixture at pH 9.5, and the absorbance of the nickel(II)-PAR chelate was measured at 496 nm.

Bismuth(III) also reacts with PAR under these conditions, but the resulting bismuth(III)-PAR chelate is converted to the bismuth(III)-EDTA chelate by the addition of EDTA. On the other hand, the nickel(II)-PAR chelate, once formed, is stable upon the addition of EDTA.[2]

Thus, trace amounts of nickel(II) in a solution containing cobalt(II) can be determined sensitively by this method, although the procedure for determination is slightly complicated.

Experimental

Apparatus. All the spectrophotometric measurements were made with a Hitachi EPS-3-type recording spectrophotometer, using a 1-cm quartz cell. All the pH measurements were conducted with a Mitamura pH-mV meter.

Reagents. Cobalt and nickel metals with a purity of 99.99% were employed as the perchlorates. A bismuth(III) stock solution was prepared by dissolving GR-grade nitrate salt in a solution containing 1.0 N free nitric acid. Commercial PAR was used as the colorimetric reagent for nickel (II). All the other reagents were GR-grade materials.

Procedure. A series of nickel(II)-EDTA solutions of appropriate concentrations containing cobalt(II)-EDTA were placed in a 10-m*l* measuring flask; 0.5 m*l* of 30% hydrogen peroxide was then added. The pH was maintained at about 8.0 with a 0.2 N sodium hydroxide solution. To completely oxidize the cobalt(II)-EDTA chelate, the reaction mixture was allowed to stand for 15—20 min at 50°C. A 2-m*l* portion of a 5.86×10^{-4} M bismuth(III) was then added, and the pH was maintained at 2.0 with 0.2 N nitric acid and 0.2 N sodium hydroxide so that the exchange reaction proceeded in an acidic solution. The reaction mixture was warmed in a water bath at about 70°C for 40 min to complete the exchange reaction. To destroy the excess hydrogen peroxide, 1 m*l* of a 0.5 M sodium sulfite solution was added. After cooling with ice water to prevent the reversal of the reaction between bismuth(III)-EDTA and nickel(II), 1 m*l* of 0.047 M sodium borate and 1 m*l* of 2.00×10^{-3} M PAR were added. Any excess bismuth(III) present also reacts with PAR. Therefore, after the solution had stood for 5—10 min, a 2-m*l* portion of 2.2×10^{-2} M EDTA was added to convert the bismuth(III)-PAR chelate into the bismuth-(III)-EDTA chelate. Absorbance measurements were made at 496 nm against a solution containing the same concentration of PAR as a blank.

In the above procedure, if the addition of bismuth(III) is omitted and the PAR solution is added directly to the nickel(II)-EDTA complex solution, the nickel(II)-PAR chelate is not formed, for the apparent stability constant of the nickel(II)-EDTA chelate is larger than that of the nickel-(II)-PAR chelate.

Results

Absorption Spectra. The absorption curves of PAR and the nickel(II)-PAR chelate are shown in Fig. 1. PAR shows a maximum absorption at 415 nm, and the reddish nickel(II)-PAR chelate, at 496 nm.

Effect of the Heating Time on the Exchange Reaction. The exchange reaction between the nickel(II)-EDTA chelate and bismuth(III) is very slow at room temperature; it requires 40 min at pH 2.0 and 70°C to proceed quantitatively under the above experimental conditions.

Decomposition of Hydrogen Peroxide. The excess hydrogen peroxide, which destroys the nickel(II)-PAR chelate, must be decomposed before the addition of PAR to a reaction mixture. It was impossible to decompose the hydrogen peroxide completely by heating it for 40 min at 70°C. Thus, sodium sulfite was used to decompose the excess hydrogen peroxide.

Zn(II)	2.80×10^{-4}	70.0	4.00×10^{-6}	3.93×10^{-6}	−1.8

a) Very much interfere

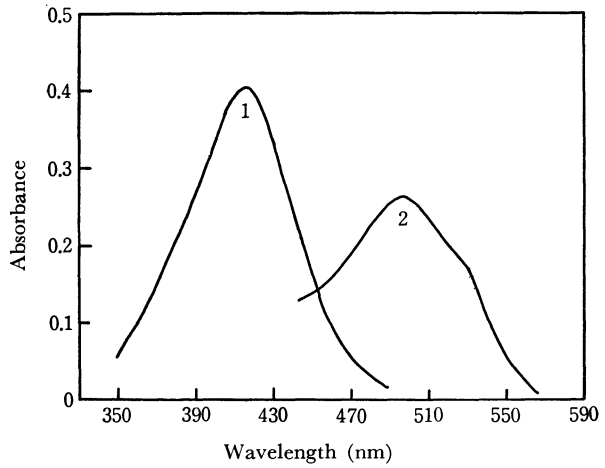

Fig. 1. Absorption spectra of PAR and Ni(II)-PAR chelate.
1. PAR 1.11×10^{-5} M
2. Ni(II)-PAR chelate 3.56×10^{-6} M
pH=9.5

With the addition of 1 ml of 0.5 M sodium sulfite to a reaction mixture, the change in the absorbance was not appreciable.

Concentration of EDTA. Bismuth(III) forms a reddish chelate with PAR, so a large excess of free bismuth(III) in a reaction mixture interferes seriously. Such an interference, however, can be avoided by using EDTA as a masking agent. EDTA displaces PAR easily from the bismuth(III)-PAR chelate. The addition of EDTA is also necessary for the masking of some foreign interfering elements, for example, cadmium(II), copper(II), and zinc(II). A 2-ml portion of 2.2×10^{-2} M EDTA was used as a masking agent.

Determination of Nickel(II). The nickel(II) was determined by the procedure described above. Beer's law was obeyed within the concentration range of 1.95×10^{-6} M to 1.48×10^{-5} M of nickel(II). The molar extinction coefficient was 7.3×10^{4}, and the sensitivity was very high. Table 1 shows the results of determinations in the presence of cobalt(II). When the concentration of the cobalt(II) becomes about ten times as much as the nickel(II), a large error was observed.

Effect of Diverse Ions. The effects of diverse ions on the colorimetric determination of nickel(II) utilizing the nickel(II)-PAR chelate were previously investigated by Shijo.[2] In the present experiments, the authors examined the effect of diverse ions which are highly sensitive in their reactions with PAR. These results are shown in Table 2. It was found that the interference of manganese(II) and copper(II) was very pronounced, but other metal ions did not interfere.

The SCF MO Calculation of the g Value for the H_2NO Radical

Tetsuo MORIKAWA, Osamu KIKUCHI, and Kazuo SOMENO*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

* *Government Chemical Industrial Reseaech Institute, Tokyo, Shibuya-ku, Tokyo*

(Received September 21, 1970)

In our previous papers,[1] an approximate open shell SCF MO method with the CNDO approximation[2] was proposed and applied to quantitative discussions of the electronic structure and ESR parameters of the aliphatic nitric oxide radicals. The results on the g tensor of the H_2NO radical showed that the value of g_{yy}, the principal value of g along the N–O bond, was somewhat unsatisfactory. The present note will show that improved results for the g_{yy} of the H_2NO radical can be obtained by a modification of the evaluation of electron repulsion integrals or bonding parameters.

The principal values of the g tensor for the H_2NO radical, as calculated by Stone's formula,[3] are listed in Table 1. The results are those obtained by the SCF MO CNDO or INDO[5] approximation, where the values of bonding parameters given in the original papers of Pople and Segal[2] were used.[6] A better agreement with the experimental data was obtained by both these calculation methods than the previous one. The value of g_{yy} could be especially improved by the INDO calculation. This is because of the increase in the excitation energy from the non-bonding orbital of the oxygen atom to the odd-orbital and the decrease in spin density on the oxygen atom.

TABLE 1. PRINCIPAL VALUES OF g TENSOR FOR H_2NO

	INDO[a]	CNDO/2[a]	CNDO/2[b]	Exp.[c]
g_{xx}	2.0045	2.0047	2.0050	2.0061
g_{yy}	2.0091	2.0104	2.0113	2.0089
g_{zz}	2.0023	2.0023	2.0023	2.0027
$g_{av.}$	2.0053	2.0058	2.0062	2.0059

a) Bonding parameters used are those in Ref. 2.
b) Results in Ref. 1.
c) Values for di-*t*-butyl nitric oxide in Ref. 4.

The dependence of the g tensor on the molecular geometry of the radical is a subject of importance in the present theoretical study. The g_{yy} of the H_2NO radical is very sensitive to the variation in the N–O bond length and the HNH bond angle, but the g_{yy} is not. The value of g_{yy} obtained by the INDO calculation, for example, changes from 2.0083(1.20 Å) to 2.0119(1.30 Å) at the fixed HNH angle of 120°. This comes from the fact that the oxygen lone-pair orbital, which makes a large contribution to g_{yy}, is very sensitive to these changes in molecular geometry. The theoretical estimation of g tensors must, therefore, be carried out on the basis of a careful examination of the molecular geometry of a radical. For the H_2NO radical, the CNDO or the INDO method gives the minimum energy near the assumed structure of this radical, shown in Fig. 1. As was pointed out by Segal,[7] the CNDO method leads to some success in the evaluation of the equilibrium bond length. Therefore, the present results on the g tensor for the radical assuming the structure are acceptable.

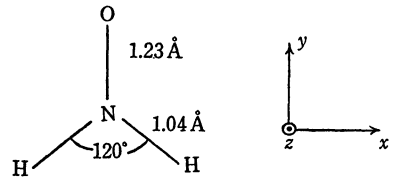

Fig. 1. Assumed stucture of H_2NO.

It may be concluded that the original CNDO/2 and INDO parametrizations give good theoretical results on the g value for the aliphatic nitric oxide radical. However, ambiguity still remains as to the applicability of these methods to other radicals. We have, though, applied the methods to several σ-type radicals and observed that the calculated principal values of the g-tensors of these σ-type radicals show good agreement with the experimental values.[8] Therefore, the theoretical investigation described here may be applicable to the estimation of g values of all other radicals.

The Roles of Thiyl Radicals in the Radiolysis of a Mixed Aqueous Solution of Cysteine and Formate— Hydrogen Abstraction from Formate and the Formation of Carbon Dioxide

Makio MORITA, Katsuro SASAI, Makoto TAJIMA, and Masao FUJIMAKI
Department of Agricultural Chemistry, Faculty of Agriculture, The University of Tokyo, Hongo, Tokyo

(Received October 7, 1970)

Attempts were made to elucidate the role of thiyl radicals in the γ-radiolysis of aqueous solutions containing L-cysteine and formate, and the evidence was obtained for the abstraction of hydrogen and the acceleration of the CO_2 formation from formate by cysteine thiyl radicals.

Experimental

Triply-distilled water (pH 5.0) containing formic acid and cysteine was degassed in Pyrex ampoules and irradiated by a ^{60}CO γ-ray source (dose rate: 9×10^4 rads·h^{-1}, dose: 9×10^4 rads).[1] Amino acids were analyzed on an amino-acid analyzer. The gaseous products were analyzed as has been described.[2] The tritium liberated from ^3H-formate was measured as has been described.[3] The oxalic acid was estimated by measuring the permanganate reduction in acidic media (2 N sulfuric acid) at room temperature. The permanganate was colorimetrically determined at 525 nm. Before the analysis, the cysteine was removed with cation exchange resin.

Results and Discussion

In the radiolysis of aqueous solutions under deaerated and neutral conditions, formate reacts with hydroxyl radicals (OH) to yield carboxyl radicals ($\cdot CO_2^-$) (1), and $\cdot CO_2^-$ dimerized to oxalic acid[4,5] (2):

$$OH + HCO_2^- \xrightarrow{k_1} \cdot CO_2^- \quad (1)$$

$$2\cdot CO_2^- \longrightarrow HCO_2CO_2^- \quad (2)$$

Cystein (CySH) reacts with OH to yield cysteine thiyl radicals (CyS·) (3) and then reacts with e^-_{aq} to yield hydrogen sulfide and alanyl radicals (Cy·)(4). Cy· reacts with another molecule of cysteine to yield alanine (CyH) and CyS· (5). The CyS· produced through both the reactions dimerizes to cystine (CySSCy) (6).[6-8]

$$OH + CySH \xrightarrow{k_3} CyS\cdot \quad (3)$$

$$e_{aq}^- + CySH \longrightarrow Cy\cdot + H_2S \quad (4)$$

$$Cy\cdot + CySH \longrightarrow CyH + CyS\cdot \quad (5)$$

$$2CyS\cdot \longrightarrow CySSCy \quad (6)$$

The other reactions are considered to be less important than the reactions described above.[4-8]

In this investigation we have studied the radiolysis of a mixed solution of formate and cysteine. As is shown in Fig. 1, the yields of hydrogen sulfide and alanine were not affected by the formate. This is because, at pH 5.0, only 0.6—7% of formate exists in its acid form, and this form reacts efficiently with e_{aq}^-.

Hydroxyl radicals (OH) are competed for by the formate ion and cysteine ($k_1=2.9\times10^9$ M^{-1} sec,$^{-1}$[9] $k_3=3\times10^9$ M^{-1} sec^{-1} [10]). However, oxalic acid was not produced at all in the presence of 10^{-3} M cysteine at three concentrations of formate (10^{-3}, 10^{-2}, and 10^{-1} M), as is shown in Fig. 1. This indicates that, at 10^{-3} M, cysteine completely scavenges the $\cdot CO_2^-$ (7):

$$\cdot CO_2^- + CySH \xrightarrow{k_7} HCO_2^- + CyS\cdot \quad (7)$$

If the $\cdot CO_2^-$ is completely converted to CyS·, the OH radicals which have reacted with formate by reaction (1) will also produce CyS· and an unchanged yield of cystine may be anticipated, as is observed in the solution containing 10^{-3} and 10^{-2} M of formate (Fig. 1).

It is well known that thiyl radicals abstract hydrogen from aldehydes.[11] In order to test whether or not

Table 1. ^{3}H-liberation into water from ^{3}H-formate in the γ-radiolysis of its deaerated aqueous solution and addition effect of cysteine on it

Concn. of formate	cpm in 0.5 ml water distilled	
	Without cysteine	With 10^{-3} M cysteine
10^{-3} M	2210	1749
10^{-2} M	2372	13820
10^{-1} M	2699	136562

^{3}H-formate (50 μCi (nominal)/mmol) was used.
dose: 9×10^4 rads.

CyS· abstracts hydrogen of the formate, a tracer experiment using ^{3}H-formic acid was made. As is shown in Table 1, the liberation of tritium from formate to water was almost constant for the three concentrations of formate in the absence of cysteine, but it markedly increased with the concentration of formate in the presence of 10^{-3} M cysteine, the rate of the increase being approximately proportional to the formate concentration. This can be explained by the hydrogen abstraction by CyS· from the formate (8):

$$CyS\cdot + HCO_2^- \xrightarrow{k_8} CySH + \cdot CO_2^- \qquad (8)$$

The reaction is the reverse of (7), and CyS· and $\cdot CO_2^-$ will be mutually converted by (7) and (8). If k_8 is much smaller than k_7, $[\cdot CO_2^-]$ will be much smaller than [CyS·], yielding no oxalic acid. However, the rate of (8) and the rate of the liberation of hydrogen from formate will increase proportionally with the formate concentration, as is observed. As is shown in Fig. 1, the yield of cystine in the presence of 10^{-1} M formate was lowered, while that of carbon dioxide reciprocally increased. This result may be explained as follows: at high formate concentrations, reaction (6) may compete with a reaction of CyS· which produces CO_2. The species which reacts with CyS· to yield carbon dioxide may be the $\cdot CO_2^-$ or the $\cdot CO_2^-$-formate complex.[12]

Electrooxidation of α-Methoxy-γ,γ-Dimethylaconic Acid

Sigeru Torii, Takuya Furuta, Teruo Miyaoka, Hidenori Sako, Hideo Tanaka, and Kenji Uneyama

Department of Industrial Chemistry, Okayama University, Okayama

(Received December 7, 1970)

Recently anodic alkoxylation of alkenes has been investigated extensively.[1] However, few studies have been made on the application of the reaction to cyclic olefins[1] or cyclic α,β-unsaturated carboxylic acids.[2] It is of interest that the acids have two reaction points (olefinic double bond and carboxy group) which may suffer anodic oxidation. Further one-electron oxidation of the acyloxy radical to an acyloxy cation can be possible since decarboxylation of the radical is not favorable.[3] Thus, we have examined the anodic oxidation of α-methoxy-γ,γ-dimethylaconic acid(I) in methanol as a model reaction of α,β-unsaturated cyclic carboxylic acids.

Experimental

Electrolysis of I. A stirred mixture containing 2.2 g of I[4] and 0.2 m*l* of sulfuric acid in 70 m*l* of commercial grade methanol was electrolyzed[5] using 3 cm^2 bright Pt electrodes for 3 hr at 20°C. Anode potential of electrolysis was 2.2±0.1 *vs.* SCE at current density of 0.1 A/cm^2. Under the electrolysis conditions, starting carboxylic acid I was almost completely consumed. The acidic portion (1.36 g) was recrystallized from benzene - ethanol to give 1.06 g of trimethoxy compound II and 0.30 g of IV.

The structural assignment of II was made by elemental analysis and IR and NMR spectra; mp 192.5—193°C, IR (Nujol) 1795 (lactone C=O) and 1760 (COOH) cm^{-1}, NMR (methyl ester) in $CDCl_3$, τ 8.53 (3H, s, CH_3), 8.42 (3H, s, CH_3), 6.50 (3H, s, CH_3O), 6.47 (3H, s, CH_3O), 6.37 (3H, s, CH_3O), 6.21 (3H, s, CO_2CH_3), M^+, *m/e* 262 (methyl ester).

Found: C, 47.99; H, 6.59%. Calcd for $C_{10}H_{16}O_7$: C, 48.39; H, 6.50%.

The structure of IV was assigned by mp, IR spectrum and vpc retention time of its methyl ester compared with authentic samples.[6]

The neutral portion (0.24 g) was fractionated by vpc using a SE-30 column at 150°C to give 0.20 g of carbonate III. The structure of III was established by spectral and elemental analyses; IR (neat) 1780, 1750 (C=O), 1210, 1170, 1130 cm^{-1}, NMR ($CDCl_3$) τ 8.35 (6H, s, gem. CH_3), 6.26 (3H, s, CH_3O), 6.10 (3H, s, CH_3O), M^+-60, *m/e* 172.

Found: C, 46.29; H, 5.43%. Calcd for $C_9H_{12}O_7$: C, 46.59; H, 5.21%.

Electrolysis of II. A mixture of 0.30 g of II and 0.08

5) Electrolyses were carried out by a procedure similar to that described in the paper: A. Takeda, S. Wada, S. Torii and Y. Matsui, This Bulletin, **42**, 1047 (1969).

6) A. Takeda and S. Torii, *Memoirs of School of Engineering, Okayama Univ.*, **1**, 44 (1966).

m*l* of sulfuric acid in 30 m*l* of commercial grade methanol was electrolyzed with a terminal voltage of 15 V at a current density of 0.1 A/cm² (anode cell voltage, 1.95±0.05 *vs.* SCE). After recovery of 0.20 g of unchanged II, 0.05 g of neutral materials obtained was subjected to preparative vpc (SE-30, 3 m, 150°C) to afford 0.03 g of III.

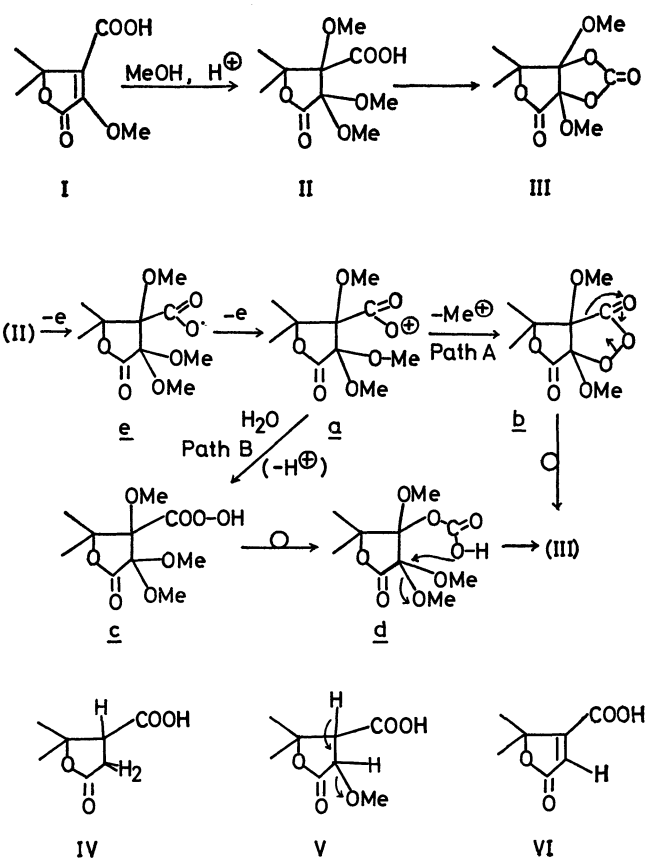
Results and Discussion

Products were α,α,β-trimethoxy-γ,γ-dimethylparaconic acid(II) (36%), terebic acid(IV) (16%), and γ,γ-dimethyl-α,β-carbonyldioxy-α,β-dimethoxybutyrolactone(III) (7.3%). Predominant formation of acidic compounds (II and IV) as compared with neutral compound III indicates that the olefinic double bond in I undergoes oxidation more readily than carboxy group. Trimethoxy compound II would result from two electron oxidation of I followed by methanolysis. Carbonate III would be produced from further oxidation of II, since electrolysis of II in a methanol-sulfuric acid mixture afforded III as the main neutral product.

Table 1. Products and their yields of the anodic oxidation of α-methoxy-γ,γ-dimethylaconic acid (I) in MeOH

Product	I[b]	II	III	IV
Yield[a] (%)	trace	36	7.3	16

a) Yield based on carboxylic acid I.
b) Recovered I.



Scheme 1

A tentative mechanism for the formation of carbonate III is described in scheme 1. Assuming formation of acyloxonium ion **a**[7] in the carbonation reaction of II, one can rationalize the result by postulating the rearrangement of the peroxide intermediates (**b** or **c**), *viz.* (Path A) intramolecular peroxide rearrangement[8] of **b** to III and (Path B) peracid rearrangement of **c** and reclosure of **d** to III. The mechanism of the formation of terebic acid IV can involve the following processes: i) electrochemical reduction of I to V, ii) demethoxylation with the aid of acid, and iii) further reduction of VI.[9] We found that IV was not detected by vpc analysis when I was electrolyzed in an anode compartment separated by a glass filter and VI could be subjected to reduction for a very short period without separation of electrolysis compartments.

Further details of the carbonation mechanism can not be deduced from these preliminary results.

Bis(triphenylphosphine)-π-cyclopentadienyl-cobalt(I) and -rhodium(I)[1]

Hiroshi YAMAZAKI and Nobue HAGIHARA*

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

** The Institute of Scientific and Industrial Research, Osaka University, Yamada-Kami, Suita, Osaka*

(Received January 18, 1971)

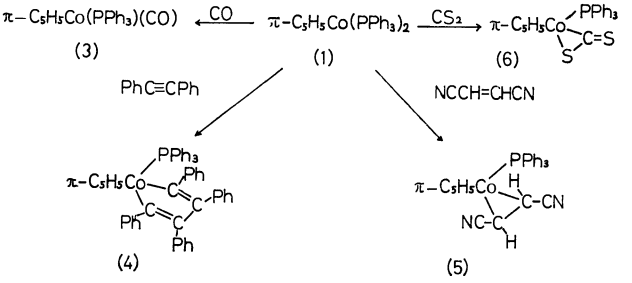
Previously, we have reported the reaction of triphenylphosphine-π-cyclopentadienylcobalt diiodide with isopropylmagnesium bromide in the presence of diphenylacetylene; this afforded acetylene complexes with a π-$C_5H_5Co(PPh_3)$ moiety.[2] In our further study of this reaction, we have found that bis(triphenylphosphine)-π-cyclopentadienylcobalt(I) was the product when the reaction was carried out in the absence of diphenylacetylene.

A recent paper of Rinze *et al.*[3] describes the isolation of the same compound from the reaction of $H_3Co(PPh_3)_3$ or $HN_2Co(PPh_3)_3$ with cyclopentadiene. This report has prompted us to publish our results on the preparation and some reactions of bis(triphenylphosphine)-π-cyclopentadienylcobalt(I) and on the preparation of an analogous rhodium complex.

When triphenylphosphine-π-cyclopentadienylcobalt diiodide in benzene-ether was treated with isopropylmagnesium bromide, favorably in the presence of triphenylphosphine, a red solution resulted. Air-sensitive dark red crystals were isolated from the solution. They melted at 140—143°C with decomposition in a nitrogen-filled capillary tube. The proton NMR spectrum in C_6D_6 showed a singlet at τ 5.55 which was assigned to the five equivalent cyclopentadienyl protons, and complex bands at τ 2.1—3.2 which were assigned to the aromatic protons. On the basis of the elemental analysis, the compound was formulated as π-$C_5H_5Co(PPh_3)_2\cdot C_6H_6$ (**1**). The inclusion of a benzene molecule was confirmed by gas chromatography.

The similar treatment of triphenylphosphine-π-cyclopentadienylrhodium diiodide with isopropylmagnesium bromide in the presence of triphenylphosphine gave dark brown crystals. They are air stable in the solid state and melt at 190°C with decomposition. The infrared spectrum of the compound is almost identical with that of cobalt analogue. The proton NMR spectrum in C_6D_6 showed a singlet at τ 4.96 which was assigned to the five equivalent π-cyclopentadienyl protons and complex bands at τ 2.1—3.1 which were assigned to the aromatic protons. The detailed spectrum of the π-cyclopentadienyl protons consisted of a 1 : 3 : 3 : 1 quartet (J=0.6 Hz) showing the equivalence of ^{31}P and ^{103}Rh nuclei to couple with the protons. Elemental analysis suggested the compound to be π-$C_5H_5Rh(PPh_3)_2\cdot C_6H_6$ (**2**), analogous with the cobalt complex. Upon heating at 140°C for ten minutes under reduced pressure, the crystals turned pale brown and lost a benzene molecule to give an exact analysis for π-$C_5H_5Rh(PPh_3)_3$.

The compound (**1**) readily exchanges one triphenylphosphine with another ligand (L) and gives a complex of the type π-$C_5H_5Co(PPh_3)(L)$. When carbon monoxide was passed through the benzene solution of **1**, triphenylphosphine-carbonyl-π-cyclopentadienylcobalt (**3**)[4] was formed almost immediately; this was also described by Rinze *et al.*[3] The reactions with excess diphenylacetylene and with fumaronitrile afforded triphenylphosphine-π-cyclopentadienyl(tetraphenylcobaltacyclopentadiene) (**4**)[2] and triphenylphosphinefumaronitrile-π-cyclopentadienylcobalt (**5**)[2] respectively.



With carbon disulfide, air-stable dark red crystals with the empirical formula of π-$C_5H_5Co(PPh_3)(CS_2)$ were obtained. In the infrared spectrum of the compound, the ν(C=S) appeared at 1170 and 1155 cm^{-1}, suggesting a structure (**6**) which consists of the bonding of a type similar to that of known carbon disulfide complexes of transition metals.[5]

Studies of the reaction of rhodium compound, **2**, will be described separately.

Experimental

All the reactions were carried out in a nitrogen atmosphere. The melting points were determined on a Yanagimoto hot-stage apparatus unless otherwise stated. The proton NMR spectra were obtained on a Hitachi-Perkin Elmer R-20 spectrometer, with tetramethylsilane as the internal standard. The infrared spectra were obtained with a Jasco DS-402G spectrophotometer.

The compounds π-$C_5H_5Co(PPh_3)I_2$[6] and π-$C_5H_5Rh(PPh_3)I_2$[7] were prepared according to the method described in the literature.

Bis(triphenylphosphine)-π-cyclopentadienylcobalt (1). A slurry of π-$C_5H_5Co(PPh_3)I_2$ (3.2 g) in ether (20 m*l*) and benzene (20 m*l*) was treated with isopropylmagnesium bromide (15 m*l* of a 1-mol ether solution) at room temperature. The resulting red solution was hydrolyzed with aqueous ammonium chloride, and the organic layer was dried with sodium sulfate. After filtration, the solution was concentrated and hexane was added. When the solution was kept in a refrigerator overnight, dark red crystals (1.1 g) were formed.

Found: C, 77.64; H, 5.74%. Calcd for $C_{47}H_{41}P_2Co$ (including a benzene molecule): C, 77.68; H, 5.69%.

In the presence of triphenylphosphine (1.3 g), **1** was obtained in a better yield (1.4 g) by the same procedure.

Bis(triphenylphosphine)-π-cyclopentadienylrhodium (2). According to a procedure similar to that described above, the title compound (1.3 g) was obtained from the reaction of π-$C_5H_5Rh(PPh_3)I_2$ (1.4 g) with isopropylmagnesium bromide (10 m*l* of a 1-mol ether solution) in the presence of triphenylphosphine (1.0 g) and in a mixture of benzene and tetrahydrofurane (1/1, 40 m*l*).

Found: C, 73.15; H, 5.30%. Calcd for $C_{47}H_{41}P_2Rh$ (including a benzene molecule): C, 73.24; H, 5.36%.

The crystals turned pale brown with the loss of the benzene when heated at 140°C under reduced pressure.

Found: C, 71.22; H, 5.15%. Calcd for $C_{41}H_{35}P_2Rh$: C, 71.10; H, 5.09%.

The Reaction of 1 with Carbon Monoxide. Carbon monoxide was passed through the solution of 1 (0.5 g) in benzene (15 m*l*) at room temperature. The red color immediately turned brown. The solution was chromatographed on alumina, with a benzene - hexane as the eluent. The red brown eluate was then concentrated to give red brown crystals of π-$C_5H_5Co(PPh_3)(CO)$ (**3**); mp 142—144°C (in a nitrogen-filled capillary tube (0.1 g). IR (Nujol): ν_{CO} 1915 cm^{-1}. NMR (τ in C_6H_6): 5.38 (singlet, π-C_5H_5).

Found: C, 69.91; H, 4.90%. Calcd for $C_{24}H_{20}OPCo$: C, 69.57; H, 4.87%.

The Reaction of 1 with Excess Diphenylacetylene. A mixture of **1** (1.0 g) and diphenylacetylene (0.9 g) in benzene (20 m*l*) was heated at 60°C for 10 min. The solution was chromatographed on alumina, with benzene as the eluent. The red eluate was then concentrated, and hexane was added to give red-brown crystals (0.9 g). The infrared spectrum of the crystals was identical with that of π-$C_5H_5Co(PPh_3)(PhC{\equiv}CPh)_2$(**4**).

The Reaction of 1 with Fumaronitrile. To a solution of **1** (0.4 g) in benzene (30 m*l*), fumaronitrile (0.1 g) was added at room temperature. After 10 min., the solution was concentrated and chromatographed on alumina, with a benzene - ethyl acetate mixture (**2/1**) as the eluent. After the evaporation of the solvent, the residue was recrystallized with benzene - hexane to give dark red crystals (0.19 g). The infrared spectrum of the crystals was identical with that of π-$C_5H_5Co(PPh_3)(NCCH{=}CHCN)$ (**5**).

The Reaction of 1 with Carbon Disulfide. To a solution of **1** (0.65 g) in benzene (10 m*l*), carbon disulfide (1 m*l*) was added. The resulting dark brown solution was concentrated and chromatographed on alumina, with benzene as the eluent. The chocolate-brown eluate was then concentrated, and hexane was added to give black crystals (0.18 g) of π-$C_5H_5Co(PPh_3)(CS_2)$ (**6**); mp 137—138°C (with decomp.).

Found: C, 62.33; H, 4.36; S, 13.87%. Calcd for $C_{24}H_{20}S_2PCo$: C, 62.55; H, 4.30; S, 13.63%. NMR (τ in $CDCl_3$): 5.50 (singlet, C_5H_5); 2—3 (complex bands, C_6H_5).

Initiation Mechanism of Radiation-Induced Ionic Polymerization of Isobutene Studied by Ion Cyclotron Resonance

Masahiro IRIE, Katsuyuki AOYAGI, Koichiro HAYASHI, Junkichi SOHMA, and Teruo MIYAMAE*

Faculty of Engineering, Hokkaido University, Sapporo

** Japan Electron Optics Laboratory, Akishima, Tokyo*

(Received January 20, 1971)

Radiation induced polymerization of isobutene has been proved to proceed in cationic mechanism in liquid[1] and gas phases.[2] Investigation by high pressure mass spectrometer has been carried out to elucidate the initiation mechanism.[3] However, detailed processes of the ion-molecule reaction in isobutene, such as the role of fragment ions in the initiation, have not yet been made clear because of the difficulty to identity complex ion-molecule reactions by ordinary mass spectroscopy.

Recently, ion cyclotron resonance (ICR) technique has been successfully applied to analysis and interpretation of the complex ion-molecule reactions.[4] In this note we present the results obtained by the ICR study on isobutene and clarify the initiation mechanism of the radiation induced polymerization

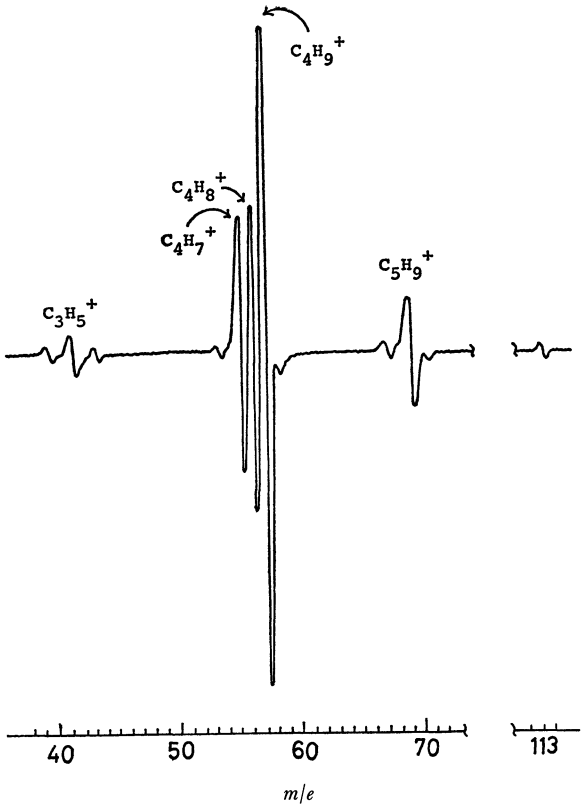

Fig. 1. Ion cycrotron single resonance spectrum of isobutene at 3×10^{-5} Torr.

in gas phase.

The ion cyclotron resonance spectrometer, which was constructed by the Japan Electron Optics Laboratory and utilized in this experiment, was a type similar to the conventional one.[4a] Isobutene was purified by passing it through a column of potassium hydroxide followed by drying with sodium-potassium alloy.

An ion cyclotron single resonance mass spectrum observed at 3×10^{-5} Torr is shown in Fig. 1. Peaks in the spectrum correspond to those obtained at 6×10^{-3} Torr by a high pressure mass spectrometer.[3] The relative intensity of the parent-plus-one ion ($m/e=57$) is about fifty percent of that of total ions at 3×10^{-5}. It should be mentioned that the dimer ion ($m/e=113$) is also observed at this pressure.
Such ICR data indicate that ion-molecule reactions take place at very low pressures.

It was found that abundance of ions depends upon pressure, and the dependence observed from ICR differs from that of high pressure mass spectroscopy.[3] The most remarkable contrast is that relative intensities of $C_4H_8^+$ and $C_4H_9^+$ show minimums at 6.5×10^{-5} and 9×10^{-5} Torr, respectively, though no minimum appears in mass spectroscopy. The intensity of $C_4H_9^+$ decreases with the increase of pressure from 3.0×10^{-5} to 9.0×10^{-5} Torr, but at higher pressures it increases with the increase of pressure. The pressure dependence of $C_3H_3^+$ also differs from that observed by the high pressure mass spectrometer. In contrast to $C_4H_9^+$, formation of $C_3H_3^+$ reaches a maximum at 9×10^{-5} Torr.

The ion-molecule reactions of these ions were studied

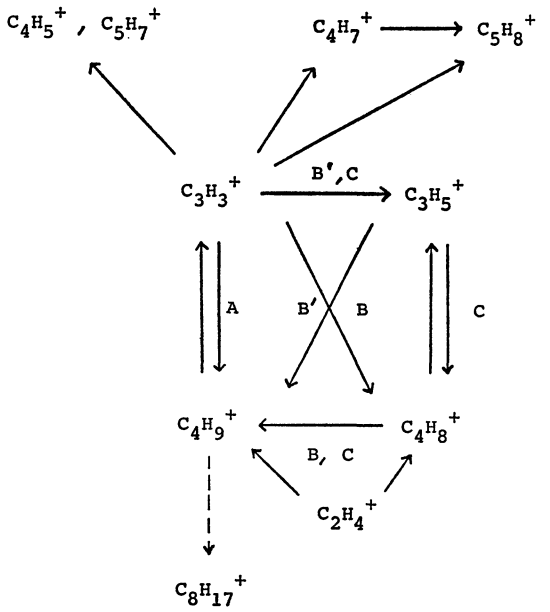

Fig. 2. Reaction scheme in isobutene observed by the ion cyclotron double resonance. Arrows show the ion-molecule reactions with isobutene. Solid arrows mean the reaction demonstrated by the ICR double resonance and broken arrow is a process deduced from the results.

by double resonance experiments. The over-all scheme is summarized in Fig. 2. $C_4H_9^+$ reacts with isobutene through two processes, the addition reaction to form dimer ion ($m/e=113$)[5] and the decomposition reaction to $C_3H_3^+$. The decomposition reaction is a sole process to produce secondary $C_3H_3^+$. Thus, the increase of the intensity of $C_3H_3^+$ with the increase of pressure implies that the decomposition of $C_4H_9^+$ by collision with isobutene into $C_3H_3^+$ is the dominant process at pressure below 9×10^{-5} Torr. Simultaneous appearance of the maximum of $C_3H_3^+$ with minimum of $C_4H_9^+$ at 9×10^{-5} Torr suggests additional paths besides the direct production of $C_4H_9^+$ from $C_3H_3^+$. The paths, including the direct production, are indicated as A, B, B', and C in Fig. 2. Each step of these paths has been confirmed by double resonance experiments. The indirect paths involve one or two intermediates and the reactions through these paths are higher orders, *viz.*, the second order for paths of either B or B', the third order for path C. Since the reactions of the higher orders become effective at higher pressures, contribution of the indirect paths to the production of $C_4H_9^+$ is more enhanced at higher pressures than at lower pressures. The maximum in pressure variation of the formation of $C_4H_9^+$ can be explained by assuming the competition among the reactions through the various paths described in Fig. 2.

$C_4H_9^+$ has been considered to be produced by a proton transfer from the parent ion.[1,2] Study of high pressure mass spectroscopy[3] suggested that a proton transfer from the other primary ions was also important to account for a large intensity of $C_4H_9^+$.

5) We could not confirm the process producing $C_8H_{17}^+$ by the double resonance experiment, because the abundance of $C_8H_{17}^+$ was very small.

The double resonance experiments clearly show that $C_4H_9^+$ is produced from $C_2H_4^+$, $C_3H_3^+$, $C_3H_5^+$, and $C_4H_8^+$. These fragment ions must play important roles in the initiation process of the polymerization induced by γ-irradiation in gas phase, because the ion-molecule chain which starts from *t*-butyl ion ($m/e=57$) is possibly the first step of polymerization.

Dipolar Interaction in TEMPAD Biradical

Jun YAMAUCHI, Teruaki FUJITO,* Akira NAKAJIMA,* Hiroaki O. NISHIGUCHI*, and Yasuo DEGUCHI*

The Institute for Chemical Research, Kyoto University, Uji

** Department of Chemistry, Faculty of Science, Kyoto University, Kyoto*

(Received February 6, 1971)

There have been a number of investigations regarding the magnetic properties of organic solids, especially those of stable free radicals. In addition to the measurement of the paramagnetic susceptibility, the electron spin resonance (ESR) has been used in the study of triplet states of aromatic molecules after the first successful experiments by Hutchison and Mangum[1] and by van der Waals and de Groot.[2] A molecule in a triplet state has degenerate Zeeman levels which are lifted even in the absence of an external magnetic field as a result of dipolar interaction between the unpaired electrons. This dipolar splitting can be obtained in rigid glassy solvents or in diamagnetic host crystals.

When one molecule with a single unpaired electron interacts with another, the problem can be reduced to a question of linear antiferromagnets. Soos adopted the pseudospin method to deal with a linear array of tightly bound electrons which are coupled to their neighbors.[3] In this case, the Hamiltonian can be described as follows:

$$H = \sum \{J(1+d)\boldsymbol{S}_{2i-1}\boldsymbol{S}_{2i} + J(1-d)\boldsymbol{S}_{2i}\boldsymbol{S}_{2i+1}\}, \qquad (1)$$

Where d is an alternation parameter, and J, an exchange integral. Because of the interpair exchange interaction, $J(1-d)$, the triplet states may propagate along the linear chains. These mobile triplet states are called "triplet excitons". The magnetic susceptibilities of $(\phi_3AsCH_3)^+(TCNQ)^-_2$ and $(\phi_3PCH_3)^+(TCNQ)^-_2$ can be well explained if one assumes $d\sim 1$ in Eq. (1).[4] Chesnut and Phillips first observed the ESR spectra of these molecules characterized by fine structure splittings.[5] The dipolar interaction was found by reducing the exchange interaction between triplet excitons at lower temperatures.

The TEMPAD biradical, shown in Fig. 1, has two unpaired electrons in a molecule and may be considered to have a dominant intramolecular spin interaction which forms the triplet state. The weak exchange interaction between the triplet entities may cause the triplet excitons to propagate in the crystal. These facts are confirmed, to some extent, by the magnetic susceptibility measurements.[6] The susceptibility of the TEMPAD biradical is not completely explained by the singlet-triplet model; a slight deviation from the model was observed. It was found that the triplet states in the radical are not actually localized in lattice sites, but are a little mobile because of the weak intertriplet interaction, which presumes the existence of the $J(1-d)$ interaction. However, it has not yet been clarified whether the exchange interaction which causes triplet states is the intra- or inter-molecular interaction. On the other hand, the fine structure arising from the dipole-dipole interaction between electron spins may be observed when the triplet entities are reduced by lowering the temperature. Therefore, we observed the ESR spectra of the TEMPAD biradical at a very low temperature in order to confirm the existence of triplet states and find a zero-field splitting.

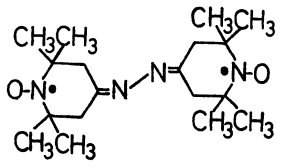

Fig. 1. Structural formula of TEMPAD biradical, bis-(2,2,6,6-tetramethylpiperidine-4-azine)-1,1'-dioxyl.

The sample was prepared from 2,2,6,6-tetramethyl-4-piperidone, following the same process as that of Rassat *et al.*[7] After recrystallization from ether, a pure sample, mp 182°C, was obtained.

The ESR absorption spectra were observed by the use of a JES-S10E type X-band spectrometer with an 80-Hz field modulation. The details of the experiments at very low temperatures will be described

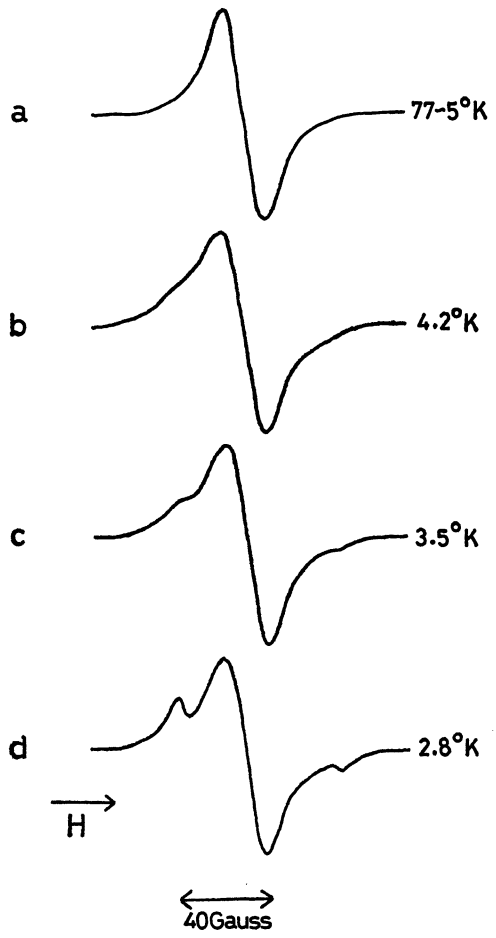

Fig. 2. Temperature dependence of the ESR absorption of a powder of TEMPAD biradical.

elsewhere.[8] The ESR measurements were carried out in powder samples. Fig. 2-a shows an exchange-narrowed Lorentz-type absorption in the higher-temperature region. When the temperature is lowered, the side peaks (Figs. 2-b, c, and d) appear. The newly-appeared doublet can be ascribed to the dipole-dipole interaction between the unpaired electrons. The spacing of the doublet resonances is evaluated as 76.6 gauss. If one assumes a localized spin density, the distance between the unpaired electrons can be calculated from the relation:

$$g\beta\langle 1/r^3\rangle = 38.3,$$

8) J. Yamauchi, This Bulletin, to be published.

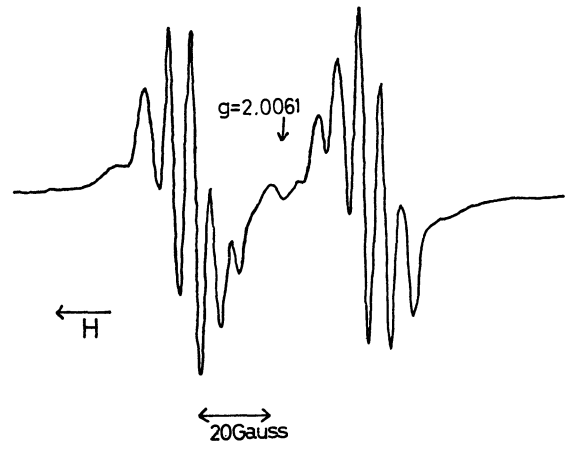

Fig. 3. ESR spectrum of a crystal of TEMPAD biradical diluted in the corresponding diamine for an arbitrary orientation.

where g is a g-factor, β, a Bohr's magneton, and $\langle 1/r^3\rangle$, an average distance between the unpaired electrons. $r\sim 8$ Å is quite well in accord with the distance between the unpaired electrons in a molecule, that is, $r\sim 9$ Å. On the other hand, the doublet splitting is also found at room temperature in the TEMPAD biradical diluted in the corresponding diamine. Although the spectrum, shown in Fig. 3, has not yet been completely analyzed, the dipole-dipole interaction is 40 gauss in order of magnitude; this corresponds to the intramolecular dipole-dipole interaction between the unpaired electrons. Hence, the doublet in Fig. 2 may be ascribed to the intramolecular dipole-dipole interaction.

The triplet-state population at the temperature where the doublet resonance starts to appear can be calculated to be 5% from this relation:

$$\rho = 1/[1+(1/3)\exp(\Delta/kT)],$$

where ρ is the density of the triplets, and $\Delta(\Delta/k = 26.4°K$[6]), the separation between lower singlet and upper triplet states. This phenomenon is similar to the cases of $(\phi_3AsCH_3)^+(TCNQ)_2^-$ and $(\phi_3PCH_3)^+$-$(TCNQ)_2^-$, which also exhibit dipole-dipole interaction at a triplet density of $\rho\sim 0.04$. Therefore, we may conclude that the dipole-dipole interaction can be observed by decreasing the exchange interactions between triplet entities in the solid state and that it can be ascribed to the intramolecular interaction between the unpaired electrons in a molecule.

Preparative and Structural Studies of Kostanecki's Compound

Yasusi YAMAMOTO, Kiyosi KUNO, and Hitosi NOZAKI

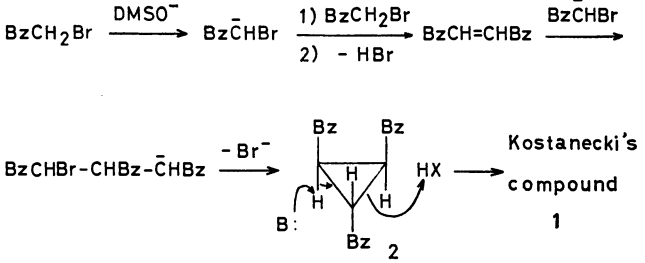
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received February 22, 1971)

Kostanecki and Tambor[1] have reported that the reaction of α-phenoxyacetophenone with sodium in warm xylene gives an orange compound, $(C_8H_6O)_x$, mp 120°C. In 1956, Yates,[2] Wheeler,[3] and their coworkers studied the structure of Kostanecki's compound (**1**) and concluded that this compound was composed of 1,2,3-tribenzoylpropene in equilibrium with the corresponding enol form.

This paper will be concerned with a reaction leading to Kostanecki's compound (**1**) (Scheme 1) as well as with a structural investigation based on the NMR, mass, IR, and UV spectra.

When phenacyl bromide dissolved in dimethyl sulfoxide (DMSO) was treated with a solution of methylsulfinyl carbanion prepared from DMSO and sodium hydride[4] at room temperature, Kostanecki's compound (**1**) was obtained as orange crystals (10%), mp 120—123°C. Meanwhile, we found that a shorter reaction time (1 hr) at room temperature gave 1,2,3-tribenzoylcyclopropane (**2**) (3%) in addition to **1** (7%). The treatment of **2** with the same carbanion afforded **1** (12%), besides a 60% recovery of **2**. A better yield (50%) of **1** was obtained upon the reaction of **2** with the carbanion prepared from cyclopropyl phenyl sulfone and sodium hydride in hexamethylphosphoric triamide (HMPA).



Scheme 1

On the basis of these results, we may explain the formation of **1** as is shown in Scheme 1. Initially, **2** is produced by the indicated route[5] and is then transformed to **1** by the basic ring opening.

The spectrometric properties of **1** have now made it impossible for us to believe in the previous conclusion that **1** is an equilibrium mixture of **1a** and **1b** (Scheme 2). It is proposed that the additional tautomeric isomers, **1c**—**1g**, are all in equilibrium and that the contribution of each structure depends on the phase in which the measurement is made. The **1c** isomer is a hemiacetal of **1b** and is isomerized to **1d** by the allyl-rearrangement of OH in **1c**. The **1e** ion pair is derived from **1c** or **1d** and is transformed to the **1f** salt by the substitution of $^-$OH into another anion, X^-. The innersalt formula **1g** may be proposed to explain the IR spectrum of Kostanecki's compound in the solid state (*vide infra*).

The mass spectra of **1** exhibited the fragment peaks due to the pyrylium ions shown in Scheme 3. The NMR of **1** in $CDCl_3$ (Fig. 1) consisted of a singlet at 4.73 ppm and a complex multiplet at 7.10—8.20 ppm in a ratio of *ca.* 1 : 11. This singlet disappeared upon the addition of MeOD. These results can not be explained by simply assuming **1a** and **1b**.

3) P. E. Devitt, E. M. Philbin, and T. S. Wheeler, *ibid.*, **1956**, 822; Idem., *J. Chem. Soc.*, **1958**, 510.

4) E. J. Corey and M. Chaykovsky, *J. Amer. Chem. Soc.*, **87**, 1345 (1965).

5) This route reminds us of the formation of **2** from sulfonium phenacylide and phenacyl bromide. See Ref 6.

Fig. 1. NMR spectrum of Kostanecki's compound (**1**) in deuterochloroform.

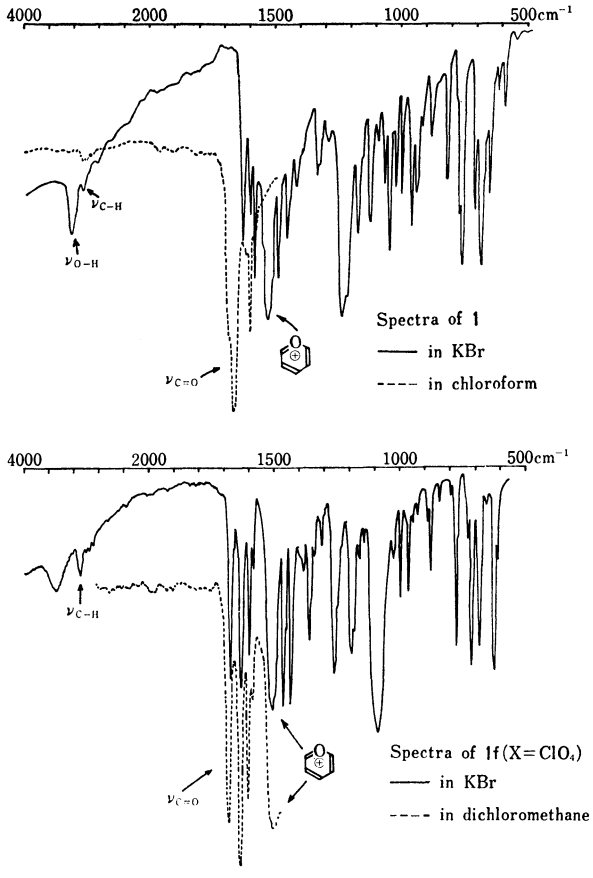

Fig. 2. Comparison of IR spectra of **1** and the pyrylium salt (**1f**) (X=ClO_4) in KBr and chloroform or dichloromethane.

Meanwhile, 2,6-diphenyl-4-benzoylpyrylium perchlorate (**1f**, X=ClO_4) (18%) was obtained as a crystalline solid, mp 233—235°C, upon the treatment of **1** with perchloric acid in chloroform at room temperature. The IR and UV spectra of **1** were compared with those of the **1f** perchlorate (X=ClO_4). The solid state IR of **1** was very analogous to that of the pyrylium perchlorate with the exception of the remarkable difference that the carbonyl band at 1665 cm^{-1} was missing in the IR spectrum of **1** (Fig. 2). As characteristic bands of pyrylium salt and of the hydroxy group were observed in the IR of **1** at 1530 and 3210 cm^{-1} respectively, **1g** can be said to be the best possibility of explaining the structure of **1** in the solid state.

The UV spectrum of **1** in ethanol was almost superimposable on that of the **1f** pyrylium salt (X=ClO_4), as is shown in Fig. 3.

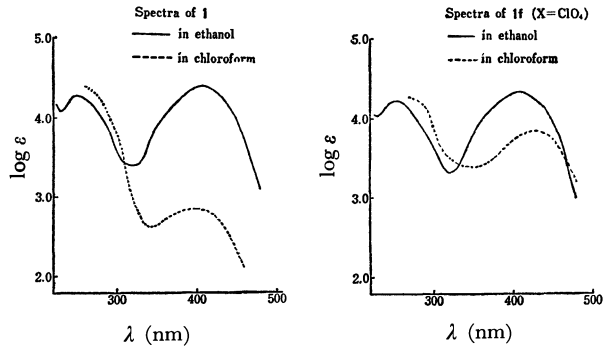

Fig. 3. Comparison of UV spectra of **1** and the pyrylium salt (**1f**) (X=ClO_4) in ethanol and chloroform.

This can be explained by assuming that the major contributing structures of **1** in ethanol are **1e** and/or **1f** (X=OEt); such an assumption is consistent with the disappearance of one proton singlet at 4.73 ppm upon CH_3OD treatment, as has been mentioned above. As is shown in Fig. 3, the absorptions of **1** in chloroform were completely different from those of **1f** (X=ClO_4) and the characteristic strong IR absorption of the pyrylium salt at 1530 cm^{-1} was absent in the spectrum of **1** in chloroform. The **1e**, **1f**, and **1g** structures could, therefore, be excluded in this state; the NMR spectrum (Fig. 1) was consistent with the **1b**, **1c**, and **1d** structures but not with **1a**.

Summarizing these results, we may conclude as follows: (1) The previous assumption of the **1a**⇄**1b** equilibrium is untenable. (2) The solid IR spectrum of **1** can be explained by means of **1g** in view of the absence of the carbonyl absorption. (3) The UV spectrum in ethanol supports the pyrylium salt formula **1e** and/or **1f** (X=OEt). (4) A chloroform solution of **1** gives spectra which are consistent with the **1b**, **1c**, and **1d** structures but not with **1a**, **1e**, **1f**, and **1g**. (5) The **1b**, **1c**, **1d**, **1e**, and **1g** structures are possibly in fast equilibrium, and the contribution of each specific one is controlled by the state in which the measurement is made.

Experimental

All the mps are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University. The NMR spectra were obtained in $CDCl_3$ on a 100 MHz instrument (Varian HA-100 spectrometer) by the courtesy of Toray Co. The mass spectra were obtained on a Hitachi RMU 6D spectrometer by the courtesy of Takeda Chemical Industries, Ltd.

Reaction of Phenacyl Bromide with Methylsulfinyl carbanion. A solution of sodium methylsulfinyl carbanion was prepared under N_2 from sodium hydride (0.72 g, 30 mmol) and dimethyl sulfoxide (DMSO) (40 m*l*). Into this we stirred a solution of phenacyl bromide (3.9 g, 20 mmol) in DMSO (10 m*l*) under ice-cooling over a period of 2 min. The reaction mixture was then stirred at room temperature for 3 hr, poured into water (300 m*l*), acidified with aqueous hydrochloric acid, and extracted with benzene. The evaporation

of the benzene gave a dark-brown oil, to which a small amount of benzene was added again, after which the mixture was allowed to stand overnight. Kostanecki's compound **(1)** was obtained as orange crystals; mp 120—123°C (lit,[1] 120°C) (0.25 g, 10%). Exact mass: 354.127 (base peak), 338.131 (13), 249.092 (94), and 233.099 (19). Calcd for $C_{24}H_{18}O_3$: 354.125, $C_{24}H_{18}O_2$: 338.130, $C_{17}H_{13}O_2$: 249.091, and $C_{17}H_{13}O$: 233.096.

A work-up of the reaction mixture after 1 hr at room temperature gave 1,2,3-tribenzoylcyclopropane **(2)**, mp 216°C (3%), besides **1** (7%). The product, **2**, was identical with an authentic sample.[6]

The Reaction of 1,2,3-Tribenzoylcyclopropane **(2)** *with Carbanion.* A solution of **2** (1.8 g, 5 mmol) in DMSO (20 m*l*) was added to a carbanion solution prepared from sodium hydride (0.14 g, 6 mmol) and DMSO (20 m*l*) under stirring at room temperature. After it had been stirred at room temperature for 3.5 hr, the reaction mixture was treated with water. The precipitating starting material (60%) was removed by filtration. The filtrate was acidified with aqueous hydrochloric acid and extracted with benzene. Concentration gave Kostanecki's compound **(1)** (0.21 g, 12%).[7]

Meanwhile, **2** (1.8 g, 5 mmol) in HMPA (20 m*l*) was treated with a carbanion solution prepared from cyclopropyl phenyl sulfone (4.1 g, 23 mmol) and sodium hydride (0.54 g, 23 mmol) in HMPA (20 m*l*) at 90°C for 24 hr to give **1** (0.89 g, 50%).

Preparation of 2,6-Diphenyl-4-benzoylpyrylium Perchlorate. Kostanecki's compound (0.067 g, 0.19 mmol) was dissolved in chloroform (50 m*l*). To this solution, aqueous perchloric acid (60%) (0.04 m*l*) was added, and the whole mixture was stirred at room temperature for 15 hr. The chloroform solution was dried over anhydrous sodium sulfate and evaporated to yield a yellow oil which solidified upon trituration with ether; mp 233—235°C (17 mg, 18%). The IR spectrum of this solid is shown in Fig 2.

Found: C, 66.1; H, 3.9%. Calcd for $C_{24}H_{17}ClO_6$: C, 66.0; H, 3.9%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2267—2268 (1971)

Magnetic Susceptibilities of Ionic Electron-Donor-Acceptor Complexes

Minoru KINOSHITA, Takamaro MIZOGUCHI, and Hideo AKAMATU
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 24, 1971)

In previous papers, we discussed the magnetic properties of ionic electron-donor-acceptor complexes formed between aromatic diamines and tetracyano-*p*-quinodimethane[1,2] and benzoquinone derivatives.[3] Their magnetic susceptibilities showed large deviations from the Curie law and were explained by the linear chain model of the interacting unpaired electrons on radical ions. We report here the magnetic susceptibilities of the ionic complexes of tetracyanoethylene (TCNE) with *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) and *N,N'*-diphenyl-*p*-phenylenediamine (DPPD).

Tetracyanoethylene is known to be very reactive with aromatic amines.[4] Actually, of the seven amines tested, only the above two were found to give stable solid complexes. The complex of TMPD·TCNE (1 : 1) was precipitated as dark brown microcrystals by mixing cooled solutions (−10°C) of TMPD and TCNE in dichloromethane. The dark violet crystals of DPPD·TCNE (1 : 1) were prepared in a similar manner at −18°C. The complex of TMPD·TCNE turned reddish brown when it was kept in air for two days. The complex of DPPD·TCNE was found to be more stable.

The infrared absorption spectra of these solid complexes indicate that they are essentially of ionic type in their ground states. In the complex of DPPD·TCNE, for example, the C≡N stretching vibration was found at 2150 and 2110 cm^{-1}, while in neutral TCNE[5] it was reported to appear at 2270 and 2240 cm^{-1}. The C-C–C bending and wagging vibrations, observed respectively at 576 and 552 cm^{-1} in neutral TCNE,[5] were found at 510 and 480 cm^{-1} in the complex. These shifts observed upon complex formation are in line with those reported in the change from neutral TCNE to TCNE anion.[6]

The susceptibilities of these complexes were measured with freshly prepared samples by the Faraday method. Their observed molar magnetic susceptibilities are shown in Fig. 1 as a function of temperature. In the higher temperature region, the susceptibility decreased with decrease in temperature. The behavior is similar to that given previously,[1-3] and may be explained in terms of the singlet-triplet model or the linear Ising model. In the former model, the

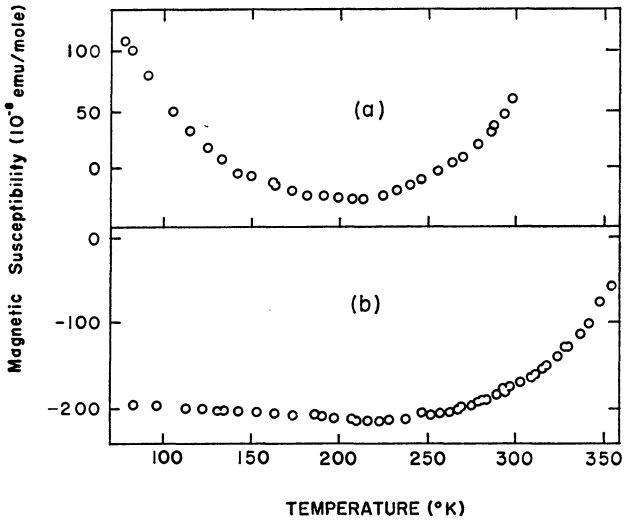

Fig. 1. Temperature dependence of the observed magnetic susceptibilities of (a) TMPD·TCNE and (b) DPPD·TCNE.

susceptibility is expressed by

$$\chi_p = (2Ng^2\beta^2/kT)[3+\exp(\delta/kT)]^{-1} \quad (1)$$

where δ is the singlet-triplet separation and N the Avogadro number, and in the latter by

$$\chi_p = (Ng^2\beta^2/2kT)\exp(-J/kT) \quad (2)$$

where J is the interaction energy of the unpaired electrons. If $\delta, J \gg kT$, these expressions are reduced to

$$\chi_p = C\exp(-E/kT)/T. \quad (3)$$

The intrinsic paramagnetic susceptibilities χ_p of these complexes were obtained after corrections had been made for the diamagnetic part ($\chi_d = -116\times 10^{-6}$ for TMPD·TCNE and $\chi_d = -214\times 10^{-6}$ for DPPD·TCNE) and for the impurity paramagnetism by the procedure described previously.[3] The plots of $\ln(\chi_p T)$ against $1/kT$ gave straight lines. The activation energy E was obtained to be 0.17 eV for TMPD·TCNE and 0.28 eV for DPPD·TCNE. However, the E values thus obtained do not explain the observed susceptibilities. In other words, they yield a very large value for N when substituted into parameter δ or J of the above equations together with χ_p obtained at a certain high temperature. Thus, it is very likely that the parameter δ or J decreases linearly with increase in temperature. On this assumption, the δ-values estimated at various temperatures from Eq. (1) with the obtained χ_p's and with $N=6\times 10^{23}$, were plotted against temperature in Fig. 2. The plots yielded straight lines of the form $\delta=\delta_0+\alpha T$. The values of δ_0 and α obtained from the analysis of Fig. 2 are given in Table 1, where the values for the complexes of chloranil and bromanil[3] are also shown for comparison.

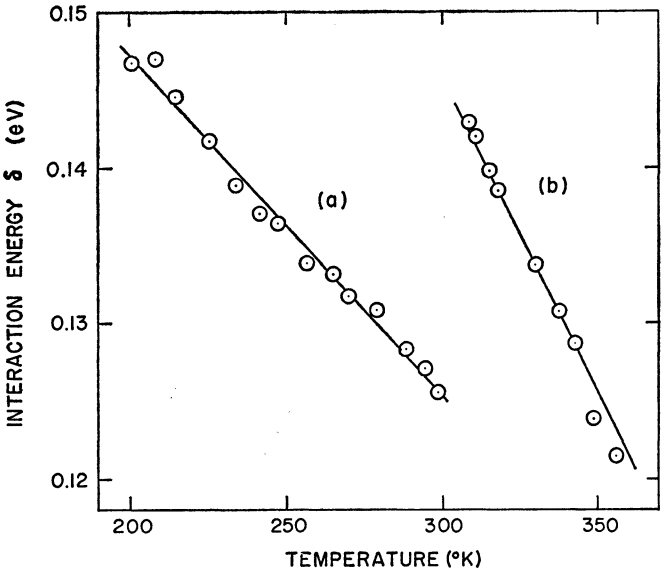

Fig. 2. Variations of the singlet-triplet energy separation δ with temperature for (a) TMPD·TCNE and (b) DPPD·TCNE.

Table 1. Temperature variation of interaction energy

	E (eV)	δ_0 (eV)	$\delta_{300°K}$ (eV)	α (eV/deg)
TMPD·TCNE	0.17	0.16	0.13	-1.9×10^{-4}
DPPD·TCNE	0.28	0.27	0.15	-4.0×10^{-4}
TMPD·*p*-CA	0.34	0.34	0.17	-6.0×10^{-4}
TMPD·*p*-BA	0.21	0.21	0.15	-1.8×10^{-4}
PD·*p*-CA	0.18	0.18	0.15	-0.8×10^{-4}
PD·*p*-BA	0.24	0.24	0.15	-4.4×10^{-4}

In the analysis, the value of δ_0 was expected to agree closely with E. The close agreement can be seen in Table 1. The negative value of α indicates that the interaction between unpaired electrons becomes weaker with the rise of temperature. The value of δ or J is determined by the combination of the exchange interaction of unpaired electrons and the charge-transfer resonance effect.[3] These effects are dependent directly upon the intermolecular spacings. Thus, it is not surprising that the value of $|\alpha|$ thus obtained coincides in order of magnitude with the expansion coefficients of the usual organic compouds. It should be noted that the unit cell dimension of anthracene:*s*-trinitrobenzene complex is known to change by about 2 percent between room temperature and -100°C in the direction of molecular stacking,[7] that is, the average linear expansion coefficient of the complex is also of the order of 10^{-4}.

Magnetic Properties of Aromatic Hydrocarbon-Alkali Metal Salts. II. Anthracene-Alkali Metal Salts

Kimiko MASUDA*, Hiroaki OHYA-NISHIGUCHI, Yasuo DEGUCHI**, and Hideo TAKAKI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received March 2, 1971)

In a previous paper[1] we have reported that the magnetic susceptibility of the solvent-free biphenyl-potassium salt was paramagnetic and that it exhibited a broad maximum at 130±4°K. This susceptibility can be interpreted approximately by this expression:

$$\chi_M = \frac{2Ng^2\beta^2}{kT} \cdot \frac{1}{3+e^{\delta/kT}} \quad (1)$$

which implies the existence of singlet-triplet dimers. The biphenyl-rubidium and biphenyl-cesium systems also obey the above equation rather than Curie-Weiss law in the higher temperature range. The singlet-triplet separations of these salts are very small in comparison with that of the TCNQ radical salts. In order to investigate whether or not the susceptibilities of the aromatic hydrocarbon radical salts follow the singlet-triplet dimer model, we have measured the static magnetic susceptibilities and the EPR absorption of solid complexes composed of anthracene with sodium, potassium, rubidium, and cesium. In this paper we will discuss qualitatively the structures of the anthracene anion radical solids in comparison with those of the corresponding TCNQ radical salts.

Experimental

These powder salts were prepared in the same way in the previous paper.[1] Anthracene of the scintillation-counter grade was used without further purification. The anthracene was reduced with potassium or sodium in tetrahydrofuran, and with rubidium or cesium in dimethoxyethane, which could dissolve these ion pairs better than tetrahydrofuran. These solutions were then evacuated *in vacuo*, and powder crystals were precipitated. The anion radical salts were titrated with a standard oxalic acid solution, using phenolphtalein as the indicator. The ratios of alkali metal to anthracene were 0.9±0.1 for potassium, rubidium, and cesium. Three samples were obtained for sodium anthracene complexes: An–$Na_{0.7}$, An–$Na_{1.0}$, and An–$Na_{1.5}$. (These formulas represent the complexes in which the ratios of sodium to anthracene are 0.7, 1.0, and 1.5 respectively). Although Holmes-Walker and Ubbelohde[2] have reported their findings as to the magnetic susceptibility and conductivity of An–$Na_{2.02}$ synthesized in diethyl ether, we could obtain it in tetrahydrofuran. The solids were brown for An–Na and blue-black for the other alkali metal complexes.

Results and Discussion

Temperature Dependence of Magnetic Susceptibility. The measured paramagnetic susceptibilities of the radical salts on 1 mol of anthracene (χ_M) are shown in Fig. 1 as a function of the temperature. The diamagnetic contribution was calculated by Pascal's method ($\chi_M^{An-Na} = -1.37$, $\chi_M^{An-K} = -1.45$, $\chi_M^{An-Rb} = -1.53$, and $\chi_M^{An-Cs} = -1.65 \times 10^{-4}$ emu/mol). The magnetic susceptibility of An–K varies with the temperature and exhibits a broad maximum (T_c), as is shown in Fig. 1, which gradually shifts to a higher temperature as the solvent residual in the solid sample decreases. The T_c of An–K (IV), which was evacuated for about one day, is estimated to be 135±5°K. However, in the case of An–K(III) evacuated for about 2 days the susceptibility passes through its maximum at 165±5°K and the maximum susceptibility decreases in comparison with (IV). The shifts of the maximum point may be due partly to the mixing of the susceptibility of the monomer with that of the dimer and partly to the presence of a

residual solvent between anion radicals. Using the value for T_c=165°K determined from the experiment, we can estimate the singlet-triplet separation to be 0.0231 eV. The comparison of this result with the cases of biphenyl-K (0.0182 eV) and *meta*-terphenyl-K (0.0252 eV)[3] indicates that the singlet-triplet separations in the aromatic hydrocarbon anion(Ar)–K complexes do not vary in the order of magnitude. The singlet-triplet separation of the dimer may depend on the distance between the two constituent radicals; therefore, the small difference implies that the distance between the two anion radicals of these Ar–K complexes is of the same order of magnitude. It is instructive to compare the singlet-triplet separations of Ar–K and that of K(TCNQ) (0.2 eV),[4] since both salts are 1 : 1 complexes of the organic compounds and potassium. The large difference implies that the two anion radicals in Ar–K complexes are more separated from each other than in the case of K(TCNQ). As was suggested in the previous paper,[1] the difference in the singlet-triplet separations may indicate the existence of a potassium cation between the two radicals constituting the An–K complexes; the two spins interact indirectly, while the TCNQ anions in the K(TCNQ) complexes couple directly. The magnetic susceptibilities of the three samples of anthracene sodium complexes are very small and change little with the temperature or with various alkali metal concentrations. If one assumes the singlet-triplet dimer model, An–$Na_{1.0}$ and An–$Na_{0.7}$ could be attributed to the low-temperature range ($kT/\delta<1$). The small χ_M of An–$Na_{1.5}$ is probably due to its compositions containing dinegative ions and dimer clusters. The magnetic susceptibilities of An–Rb and An–Cs salts increase as the temperature decreases down to 77°K and do not show any maximum. They would be more suitable for the higher-temperature range ($kT/\delta>1$) of Eq. (1) than the same temperature range of the Curie-Weiss law on condition that $\delta_{An-Na}>\delta_{An-K}>\delta_{An-Rb}>\delta_{An-Cs}$.

Electron Paramagnetic Resonance Absorption. We have also observed the electron paramagnetic resonance of alkali metal complexes of anthracene. The EPR spectra of these salts changed with different alkali metals and with the temperature, as is shown in Fig. 2. The EPR spectrum of An–K salt which was evacuated for 2 days *in vacuo* exhibits an exchange-narrowed single line (1.8 G) broader than that (1.0 G) of the An–K which was evacuated for 2 hr, and the line width changed little with the temperature. The EPR spectra of An–Na exhibit an exchange-narrowed sharp single line comparatively broader than that of An–K, and the line width changed little with temperature. The EPR spectra of An–Cs salt exhibits a broad single line, and the line width increases with the temperature up to 28 gauss. These phenomena can also be seen in the cases of Bp–Cs and cupric acetate monohydrate.[5] The absorption of An–Rb varies from one sample to another. The EPR spectrum of An–Rb, which was evacuated for 1 hr, shows two lines at room temperature; one of them is sharp, and the other, comparatively broad. When the solvent was introduced to this sample, these two lines coalesced into a single sharp line. The EPR spectrum of An–Rb evacuated for 2 days shows a single lines at 77°K, one of them sharp, and the other, very broad. This broad line may correspond to the absorption of dimer clusters, and the other, to the single spin, as was seen in the cases of Bp–K and Bp–Rb.

Study on Scrambling in Decomposition of Labeled Acetyl Benzoyl Peroxide

Michio KOBAYASHI, Hiroshi MINATO, and Ryuki HISADA

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received March 8, 1971)

Acetyl benzoyl peroxide [acetyl-^{18}O] and acetyl benzoyl peroxide [benzoyl-^{18}O] were decomposed in 0.1 M benzene solutions at 78° for 160 min (48% decomposition; its half life, determined by gas evolution, was 168 min.), and the undecomposed ABP-^{18}O was recovered and purified. The contents of oxygen-18 at the acetyl or benzoyl carbonyl were determined by converting the recovered ABP-^{18}O into acethydrazide or benzhydrazide. The results are shown in Table 1 and 2.

TABLE 1. OXYGEN-18 ANALYSIS OF ACETYL BENZOYL PEROXIDE [BENZOYL-^{18}O]

Sample	^{18}O excess atom %	
	Found	Calcd
$PhCON_2H_3$ derived from the starting ABP-^{18}O[a]	0.901[b]±0.007	(0.901)
$PhCON_2H_3$ derived from the recovered ABP-^{18}O	0.892[b]±0.016	0.901
Products of Decomposition		
$PhCO_2H$	0.466	0.451
$PhCO_2CH_3$	0.428	0.451
CO_2	0.196	—

a) When the starting ABP-^{18}O itself was directly subjected to pyrolysis, the ^{18}O excess atom % of the carbon dioxide formed was 0.252 %.
b) The average of the values obtained by two experiments.

TABLE 2. OXYGEN-18 ANALYSIS OF ACETYL BENZOYL PEROXIDE [ACETYL-^{18}O]

Sample	^{18}O excess atom %	
	Found	Calcd
$CH_3CONHN{=}CHPh$ derived from the starting ABP-^{18}O[a]	1.228	(1.228)
$CH_3CONHN{=}CHPh$ derived from the recovered ABP-^{18}O	1.169[b]+0.029	1.228
Generated CO_2 during decomposition	0.363[b]±0.003	—

a) When the starting ABP-^{18}O itself was directly subjected to pyrolysis, the ^{18}O excess atom % of the carbon dioxide formed was 0.365 %.
b) The average of the values obtained by two experiments.

Data in Table 1 and 2 indicate that scrambling of acetyl oxygen-18 appears to take place to small extent and that of benzoyl oxygen-18 was much less; these findings are in parallel with the results that scrambling of the labeled acetyl peroxide was extensive[1] whereas that of the labeled benzoyl peroxide was very small.[2,3]

Recently Goldstein and Judson[4] reported that oxygen scrambling of acetyl peroxide in isooctane was much more extensive than that in cumene. Therefore it is possible that scrambling of ABP is greater in solvents other than aromatic solvents. Further investigation is desirable in order to establish whether or not scrambling of the label of ABP is much affected by solvents.

Experimental

Benzaldehyde-^{18}O. A solution of 31 g of benzylideneaniline (0.17 mol) in 150 ml of ether was mixed with 11.0 g of ^{18}O-enriched water (1.3 atom % excess oxygen-18) and 19.7 g of concentrated sulfuric acid. After hydrolysis was complete, precipitates formed were filtered and the ether was evaporated under reduced pressure. The residue was distilled under reduced pressure, and 11.5 g of benzaldehyde-^{18}O was obtained at 61.0—63.5°C/14 mmHg.

Acetic anhydride-^{18}O. The method described by Oae, Kitao, and Kitaoka was used with some modification.[5] To a solution of 250 ml of anhydrous ethanol and 40 g of water enriched with 1.3 atom % excess oxygen-18, 23 g of sodium metal (1 mol) was added slowly with cooling. To this solution 41 g (1 mol) of acetonitrile was added, and the mixture was refluxed for 4 days. After hydrolysis was completed, the solvent was evaporated and the white crystals obtained was heated under reduced pressure until they melted. Sodium acetate formed amounted to 75.5 g (92%).

Then, 41 g (0.5 mol) of sodium acetate-^{18}O was treated with 89 g (0.75 mol) of thionyl chloride, and distillation yielded acetyl chloride-^{18}O (32.1 g; 82%). A mixture of 32.1 g (0.41 mol) of acetyl chloride-^{18}O and 34.5 g (0.42 mol) of sodium acetate-^{18}O was let to react at 140°C for 3 hr. Distillation of the mixture and the redistillation of the distillate yielded 24.5 g (57%) of acetic anhydride-^{18}O at 135—139°C.

Acetyl Benzoyl Peroxide [Acetyl-^{18}O] and Acetyl Benzoyl Peroxide [Benzoyl-^{18}O]. The method described by Juračka and Chromeček was used with some modification.[6] To a mixture of 10.6 g (0.1 mol) of benzaldehyde-^{18}O or benzaldehyde, 24.5 g (0.24 mol) of acetic anhydride or acetic anhydride-^{18}O and 6.3 g of magnesium carbonate, oxygen gas was bubbled for 7 hr at 40°C. After the reaction was over, 400

5) S. Oae, T. Kitao, and Y. Kitaoka, *ibid.*, **84**, 3359 (1962).
6) F. Juračka and R. Chromeček, *Chem. Prumysl.*, **6**, 27 (1956); A. Yamamoto, N. Inamoto, H. Morikawa, and O. Simamura, Abstracts of the 19th Anual Meeting of the Chemical Society of Japan, 3F202, 113 (1966).

m*l* of cold water was added and the mixture was extracted with 100 m*l* of ether. The ether extract was washed with a 5% sodium hydrogen carbonate solution and water, and then dried over anhydrous magnesium sulfate. Evaporation of the ether under reduced pressure yielded yellowish white crystal . After three recrystallization from *n*-hexane 11.8—12.5 g of white crystals was obtained (65—70%); mp 37.5—38.0°C.

Decomposition of ABP-^{18}O in benzene. A 0.1 mol/*l* solution of ABP-benzoyl-^{18}O or ABP-acetyl-^{18}O in benzene was degassed, and then decomposed for 160 min at 78°C. The carbon dioxide evolved was measured by a gas buret, and then collected in a liquid nitrogen trap and analyzed for excess oxygen-18.

About 40% of benzene was removed from the reaction mixture under reduced pressure. The benzene solution was washed with a 5% sodium hydrogen carbonate solution, which upon acidification yielded precipitates of benzoic acid. The benzene solution was washed further with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure. When the residue was distilled *in vacuo* at room temperature, methyl benzoate was present in the distillate. The residue was recrystallized twice from *n*-hexane, and white crystals of undecomposed ABP were recovered.

Determination of Oxygen-18 Contents. (1) Oxygen-18 Content in Benzoyl Oxygen of ABP: To an ice-cooled solution of 1.5—2.0 g of anhydrous hydrazine and 15 m*l* of dry benzene a solution of 1.5—2.0 g of ^{18}O-enriched ABP in 15 m*l* of dry benzene was added drop by drop. Benzene and unreacted hydrazine were evaporated from the reaction mixture under reduced pressure, and other volatile compounds were removed under a reduced pressure of 8×10^{-4} mmHg at 70°C. The residue was recrystallized from benzene, and the crystals obtained were further purified by repeating recrystallizations three times from ether. The benzhydrazide-^{18}O obtained melted at 109—111°C (lit,[7] 112.5°C). This sample was converted by pyrolysis to carbon dioxide, which was subjected to mass spectrometric analysis for the determination of the oxygen-18 content in the benzoyl oxygen of ABP.

(2) Oxygen-18 Content in Acetyl Oxygen of ABP: In a way similar to that described above in (1) ^{18}O-enriched ABP was let to react with anhydrous hydrazine. After benzene and unreacted hydrazine were removed under reduced pressure, the residue was subjected to distillation at 40°C under a reduced pressure of 8×10^{-4} mmHg. The distillate was dissolved in dichloromethane, and freshly distilled benzaldehyde was added to this solution. The dichloromethane was removed under reduced pressure and the residue was recrystallized three times from ether. *N*-Benzylideneacethydrazide obtained melted at 134—135°C (lit,[8] 134°C). This sample was converted to carbon dioxide, which was analyzed for the determination of the oxygen-18 content in the acetyl oxygen of ABP.

(3) Mass-spectrometric Determination of Oxygen-18 Content. Samples of ABP, benzhydrazide, *N*-benzylideneacethydrazide, benzoic acid, and methyl benzoate were converted by the method of Rittenburg and Ponticorvo[9] to carbon dioxide, and the peak ratio 44/46 was determined by use of a Hitachi RMU-6E Type mass spectrometer.

On the Crystal Structure of Methane in Phase II

Masao HASHIMOTO, Michiko HASHIMOTO*, and Taro ISOBE
The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received March 12, 1971)

It is well known that there are two kinds of second-order phase transitions in solid methane, at 4.20°K and at 8°K. The most likely explanation of these transitions is that these are changes in the molecular orientation[1], but their exact mechanism and the structure of the each phase are still ambiguous.

X-Ray diffraction studies[2-4] show that the carbon atoms occupy *fcc* positions over the whole temperature range from 4.2 to 80°K. For the *fcc* carbon lattice, there are several possible structures, differing in the relative orientations of their molecules.

The IR and Raman spectra[5,6] of Phase II(20.4> T°K>8) were explained by postulating sites of either C_{2v} or D_2 structures.

Kimel *et al.*[7] have calculated the cohesive energy of crystalline methane for various possible structures using a potential function consisting of repulsive and attractive interactions between non-bonded atoms. They found that the tetragonal structures of the D_{3d} symmetry have the best paking.

In a previous work,[8] we found, for the C_2H_2 crystal, that the pair-potential calculation makes it possible to determine the space group when the crystal system and the lattice constants are already known.

In the present note, we will see, for the crystalline methane, that if the distance between the nearest two molecules is known, it is possible to determine not only the crystal system, but also the space group. This finding is very interesting, since the mechanism of

molecular condensation or crystallization can now be explained by means of pair-interaction potentials. All the computational work in this note were done at the Computer Center of Tohoku University using NEAC-2200-500 computer system.

Intermolecular Potential

Assuming the spherical symmetry of the component atoms of the methane molecule, the following equation was used to calculate the pair-potential energy:

$$v(r) = \sum_j (a_j \exp(-b_j r_j)/r_j d_j - c_j/r_j^6), \qquad (1)$$

where the summation, j, is extended to all the interatomic pairs of the two molecules. The a_j, b_j, c_j, and d_j parameters have been determined by several authors[9,10] so as to give the best agreement with the experimental results (see Table 1).

The relative orientation of the two interacting molecules is defined as is shown in Fig. 1.

Table 1. Set of parameters in Eq. (1)
set a: Ref. 9; set b: Ref. 10

atom-atom	set	a×10⁻³	b	c	d
C···C	a	237.0	4.32	298.0	0.0
	b	408.0	0.0	373.0	12.0
C···H	a	31.4	4.20	121.0	0.0
	b	205.0	0.0	133.0	12·0
H···H	a	6.60	4.08	49.2	0.0
	b	4930.0	0.0	51.5	12.0

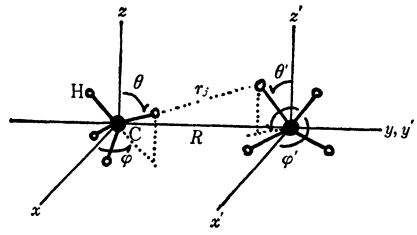

Fig. 1. The geometrical representation of two interacting methane molecules.

Calculation and Results

Figs. 2 and 3 indicate the $v(r)$ when $\varphi'=270°$ and $\theta'=0°$. Among the $v(r)$ values for various θ' and φ', those given in Figs. 2 and 3 have the deepest minimum. Since the methane molecule has a tetrahedral symmetry, there are twelve such minima about each methane molecule. Their centers of gravity form a face-centered cubic lattice. In each molecule three C–H bonds are placed nearly parallel to the a, b, and c cubic axes, and the remaining one, parallel to the direction of the body diagonals (see Fig. 4). This structure belongs to the T^4-$P2_13$ space group and is just the one suggested by Nagamiya[11].

Recently Savoie *et al.*[12] have proposed the T^4-$P2_13$ space group for the structure of Phase II on the basis of the far infrared data. This is also consistent with our results.

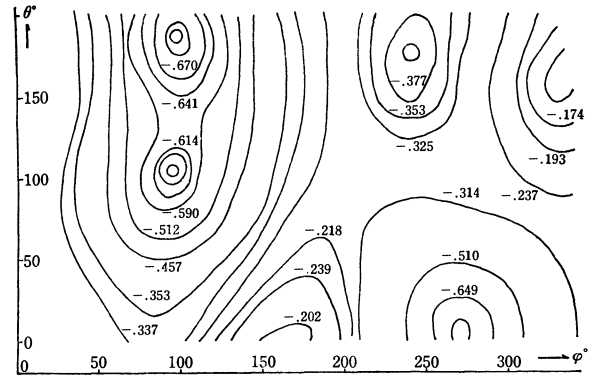

Fig. 2. θ-φ dependency of the pair potential using set b, in kcal/mol.

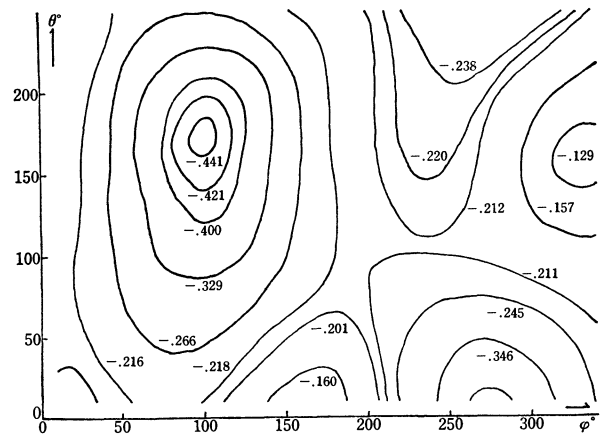

Fig. 3. θ-φ dependency of the pair potential using set a, in kcal/mol.

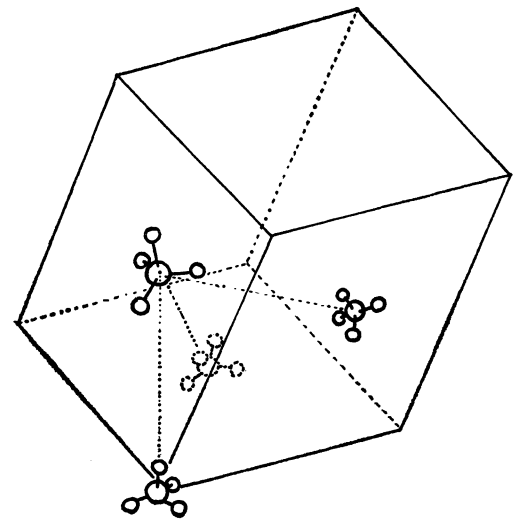

Fig. 4. The orientation of molecules that minimizes the pair potential when R=4.16 Å.

11) T. Nagamiya, *Progr. Theor. Phys.* (Kyoto), **6**, 702 (1951).
12) R. Savoie and R. P. Fourier, *Chem. Phys. Lett.*, **7**, 1 (1970).

The summation of $v(r)$ over the twelve nearest neighbours is 5.9 kcal/mol; this is roughly comparable with twice the sublimation energy of solid methane[13] at 0°K, 4.4 kcal/mol.

It may be suggested that the mechanism of the phase transition is a rotational one from the double minima in Fig. 2, but it is still ambiguous, for there are no such minima in Fig. 3. The validity of the parameters of Eq. (1) must be studied further.

The Radiolysis of Liquid Nitrogen Containing Hydrocarbons. III. Nitrile Formation from Solutions of Alkanes

Takefumi OKA, Tadashi SHINDO, and Shin SATO
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received March 15, 1971)

Recently, the radiolysis of liquid nitrogen containing simple olefins has been investigated in our laboratory in order to elucidate the mechanism of the reactions of nitrogen atoms with olefins.[1-3] In these studies, various nitrogenous compounds, such as hydrogen cyanide, acetonitrile, and propionitrile, were observed as products. The formation of these products was first attributed to the reactions of nitrogen atoms with olefins. However, a more detailed study showed that some of these products are formed by the reactions of alkyl radicals with nitrogen atoms.

In the study of the gas-phase reactions of active nitrogen with hydrocarbons, Safrany *et al.* showed that the reactions of nitrogen atoms with alkyl radicals do not produce nitriles, but hydrogen cyanide and ammonia.[4]

The present note will report the results of the radiolysis of liquid nitrogen containing simple alkanes and will discuss the mechanism of the formation of some of the nitrogenous products.

Experimental

Methane, ethane, and propane of a pure grade obtained from the Takachiho Trading Co. were used after bulb-to-bulb distillation. The samples were prepared and irradiated, and the products were analyzed as has been previously described.[2] Most of the samples were in ten-m*l* portions and were irradiated by ^{60}Co γ-rays for one hour at a dose rate of 0.9×10^{6} R/hr.

Results

Propane. The observed products were acetonitrile, a trace of propionitrile, ethane, ethylene, isobutane, *n*-butane, 2,3-dimethylbutane and/or 2-methylpentane, *n*-hexane, an unspecified basic compound and a non-volatile product. Hydragen cyanide and propylene were not observed. All the volatile products increased linearly with the irradiation time up to two hours, the initial concentrations of propane used being 1×10^{-4} and 6×10^{-4} in the mole fraction. The *G*-values of acetonitrile and hexanes are shown in Fig. 1 as a function of the concentration of propane. The *G*-value of acetonitrile (0.08) seems to be independent of the concentration of propane, while those of the hexanes are dependent on it. This feature is similar to those observed when ethylene and propylene are used as solutes.[2,3]

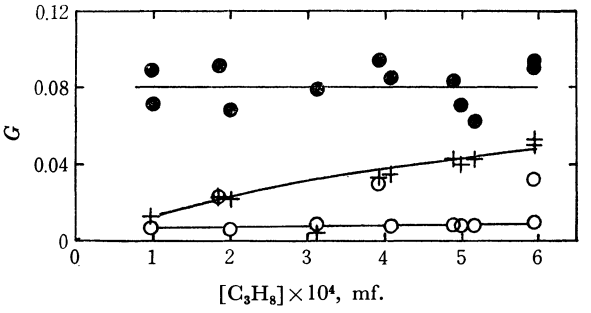

Fig. 1. *G*-values of acetonitrile (●), 2,3-dimethylbutane and/or 2-methylpentane (+) and *n*-hexane (○) as a function of the concentration of propane.

The presence of basic products was ascertained by the following method. After introducing hydrogen chloride onto a volatile product condensed at the temperature of liquid nitrogen, the system was warmed to room temperature. White particles were thus obtained. An aqueous solution of this solid was colored by the Nessler reagent. The non-volatile product was also soluble in water and was colored by the same reagent. The color observed for both solutions was similar to that when ammonium chloride was treated in the same manner. These three solutions showed similar absorption spectra in the region of 350 to 450 mμ. This result suggests that both volatile and non-volatile products contain basic nitrogenous compounds. However, they do not seem to be amines because ethyl and methyl amines have very weak absorptions in the wavelength region examined. Moreover, the volatile product is not simply ammonia, because the absorption at 430 mμ of the aqueous solu-

tion increased gradually with the elapsed time for 30 min after preparation. Such a behavior cannot be observed with the solution of ammonium chloride. Every effort we have made hitherto has failed to identify these basic products.

Ethane. The observed products were acetonitrile (G=0.025), hydrogen cyanide (G~0.001), propane (G~0.08), acetylene (G~0.01), and *n*-butane (G~0.04). The basic products were not examined.

Methane. The nitrogenous product observed was hydrogen cyanide (G=0.07). The other products were not analyzed.

Discussion

In a study of the reactions of active nitrogen with alkanes, it was reported that nitrogen atoms in its ground state do not react with methane and ethane at room temperature.[4] The nitrogenous compounds observed in the present study, therefore, may not result from the reactions of nitrogen atoms in its ground state with alkanes. The following processes can be considered for the formation of nitrogenous compounds:

a) The reactions of nitrogen atoms in its ground state with alkyl radicals, which are eventually formed by the reactions of excited nitrogen molecules or nitrogen molecule ions with alkanes:

$$RH + N_2^* \rightarrow R\cdot + H + N_2$$

b) The reactions of electronically-excited nitrogen atoms(^{2}D) with alkane molecules, and

c) The reactions of nitrogen atoms with olefins of impurities or products.

Case c) can, though, be ruled out on the basis of the following facts; 1) In the cases of ethane and propane, propylene is not a product; if formed, it gives rise to acetonitrile in the reaction with nitrogen atoms.[2] 2) The acetonitrile observed in the case of propane was a primary product. 3) The propane used contained no propylene as an impurity.

Case b) cannot be denied by the experimental facts. However, N(^{2}D) can be expected to form ammonia or amines rather than cyanides in reactions with alkanes, judging from the reactions of O(^{1}D),[5] S(^{1}D),[6] C(^{1}S),[7] and nitrene[8] with alkanes.

Case a), which is most likely, can explain the experimental results as follows; if the most abundant alkyl radicals are taken account of in each system, in the case of methane:

$$CH_3 + N \rightarrow HCN + 2H, \quad (1)$$

in the case of ethane:

$$C_2H_5 + N \rightarrow CH_3CN + 2H, \quad (2)$$

and in the case of propane:

$$iso\text{-}C_3H_7 + N \rightarrow CH_3CN + CH_3 + H. \quad (3)$$

These reactions have already been proposed to explain the formation of a part of the cyanides obtained in the radiolysis of liquid nitrogen containing olefins.[2-3] In the gas phase, it was suggested by Safrany and Jaster that these reactions produce HCN or NH.[4] This apparent disagreement may be due to the difference in deactivation.

The basic products observed might be imines, whose formation has been suggested in the thermolysis and photolysis of methylazide.[8] Obviously, further investigations are needed.

On Liquefaction Caused by the Trituration of Pairs of Solid Compounds

Tominosuke KATSURAI, Sadao MATSUO*, and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Tokyo

** Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo*

(Received March 16, 1971)

Many pairs of solid compounds are known to give rise to liquefaction when they are brought into contact. Liquefaction is accelerated by trituration. The mode of liquefaction is of interest as an irreversible change which takes place in the contact area of two different phases. Features common to the liquefaction are twofold, *viz.*, either one or both of the solid compounds are hydrated, and the process is endothermic.[1-5]

This note deals with our search for new pairs for liquefaction and the results obtained. Since we had so far no guiding principle for selection of the pairs, we simplified the situation by choosing pairs consisting of (a) a hydrated inorganic salt and (b) an organic compound without water of crystallization (except oxalic acid). (a) is considered to supply the water necessary for liquefaction and (b) to make (a) liberate the water. Most of the salts (a) were sulfates because they are not hygroscopic but some chlorides were also tried. Chloral hydrate was taken up for the sake of comparison. For (b) we chose compounds which are able to form hydrogen bonds with water and seem to influence the structure of water. Simple amino-acids, urea,[6] acetamide which is structurally similar to urea and a series of organic acids were selected, in order to see if the change in structure might influence the mode of liquefaction.

Pairs of compounds consisting of one each from (a) and (b) were triturated in a porcelain mortar by hand for 10 min and the resulting changes were observed. Commercial products of the best grade were used. Roughly the same weights for each compound were taken. The molar ratio was made to be that of integers, *e.g.*, 5 g of $CuSO_4 \cdot 5H_2O$ and 4.8 g of urea make the ratio 1 : 4. The results are summarized in Table 1.

We see that there is no general, all-embracing rule for the occurrence of liquefaction. However, we note several interesting facts and rules. Of (a), $Na_2SO_4 \cdot 10H_2O$ undergoes liquefaction to the greatest extent, and $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ none.[7] On the other hand, $Fe_2(SO_4)_3 \cdot (NH_4)_2SO_4 \cdot 24H_2O$ undergoes liquefaction very easily with several organic compounds. Of (b), polar and highly water-soluble compounds favor liquefaction, *viz.*, urea, acetamide, malonic acid, malic acid, citric acid,[8] tartaric acid and chloral hydrate. Non-polar and water-insoluble compounds have no ability to give rise to liquefaction. This is exemplified by succinic acid and fumaric acid. Isomers differ in their behavior toward liquefaction as in the cases of α-alanine and β-alanine, and maleic acid and fumaric acid.

From the results so far obtained, we might prescribe the following not rigorous but practical tests to find new pairs for liquefaction. (1) Triturate a salt from (a) with urea. If liquefaction takes place, another compound belonging to (b) which gives rise to liquefaction on being triturated with (a) can be found. If liquefaction does not take place, no (b) can be found. (2) Triturate a compound from (b) separately with $Na_2SO_4 \cdot 10H_2O$ and $Fe_2(SO_4)_3 \cdot (NH_4)_2SO_4 \cdot 24H_2O$. If liquefaction takes place, another salt belonging to (a) which gives rise to liquefaction on being triturated with (b) can be found. If not, no (a) can be found.

In certain pairs, one compound of the pair can be liquefied without being kept in contact with the other. Equivalent amounts of $Na_2SO_4 \cdot 10H_2O$ and urea, each pulverized, were put into separate branches of a bifurcated glass tube. The tube was evacuated while they were being cooled with Dry Ice and then let to stand at room temperature. Urea liquefied in less than ten days. In the case of the pair $MgSO_4 \cdot 7H_2O$ and urea, the latter did not liquefy, although the pair liquefies on trituration. In the case of $FeCl_3 \cdot 6H_2O$ and acetamide, both became wet.

Sometimes we come across pairs which on trituration give rise to chemical changes. They are exemplified by the evolution of SO_2 in the pair $Na_2S_2O_3 \cdot 5H_2O$ and citric acid, and by that of HCl in the pair $AlCl_3 \cdot 6H_2O$ and citric acid or tartaric acid, as well as by the change of color to a deep bluish violet in the pair $CuSO_4 \cdot 5H_2O$ and glycine. We realize here the necessity of giving attention to possible solid-phase reactions such as ion exchange[9] and the formation of complex compounds.

SHORT COMMUNICATIONS

Photodecomposition of Azidoformate in Alkyl Sulfides. I

Wataru ANDO, Nobukuni OGINO, and Toshihiko MIGITA
Department of Chemistry, Gunma University, Kiryu, Gunma
(Received March 1, 1971)

The reaction of azidoformate in alkyl sulfides under photolytical conditions has received little attention. We wish to describe the formation of a stable iminosulfurane by photoinduced reaction of methyl azidoformate with alkyl sulfides, and some properties of singlet and triplet carbomethoxynitrene in alkyl sulfides.

Irradiation of a solution of 1 mmol methyl azidoformate in 10 mmol of alkyl sulfide was carried out in quartz vessels under nitrogen atmosphere with a high pressure mercury lamp for one hour. *N*-Methoxycarbonylalkyliminosulfuranes (I—III) were obtained as pale yellow liquids in 40—60% yields by passing the reaction mixture through a silica gel column using ethyl ether, then methanol-ethyl ether (1 : 4) as eluting solvents. The structures of the sulfuranes are determined by comparison of their spectra with those of authentic samples.[1]

Product patterns resulting in photosensitized reaction of azidoformate with sulfides are quite different from those in direct photolysis.

$$N_3CO_2CH_3 + R_2S \xrightarrow{h\nu} R_2\overset{\oplus}{S}-\overset{\ominus}{N}CO_2CH_3 \quad 40—60\%\ \text{yields}$$

I, $R=CH_3$;
II, $R=C_2H_5$;
III, $R=i\text{-}C_3H_7$

A mixture of methyl azidoformate and alkyl sulfides (molar ratio 1 : 10) in Pyrex tubes was irradiated with a high pressure mercury lamp in the presence of acetophenone as triplet sensitizer.[2,3] Methyl carbamate was obtained as a major product (56% yield). Formation of alkyliminosulfuranes was not recognized from the NMR spectrum.

These results indicate that the triplet nitrene cannot be an intermediate of the formation of imonosulfuranes, analogous to the behaviors of carbene towards sulfur containing molecules.[4,5] This suggests a mechanism of iminosulfurane formation in which a singlet carbomethoxynitrene attacks an unshared electron pair on the sulfur atom of alkyl sulfides.

Competitive reactions of dimethyl sulfide and *cis*-4-methyl-2-pentene towards the nitrene derived by the direct photolysis of methyl azidoformate were carried out. The results listed in Table 1 show the following tendencies in the relative rate between addition and iminosulfurane (I) formation, and in the stereochemistry of the addition to olefin. First, the relative rate constant of iminosulfurane (I) formation to addition k_s/k_o gradually decreased as the initial ratio of olefin and sulfide decreased. Secondly, although the yields of total aziridines decreased, the relative ratio of *trans* isomer increased as the initial concentration of sulfide increased. Even in the reaction with olefin alone, a considerable amount of *trans* aziridine was formed (*cis* : *trans*=2 : 1), that is to say, the addition is not strictly stereospecific. These tendencies can be best explained by assuming that the reaction of the singlet nitrene with solvent molecules competes with the intersystem crossing of the singlet to the triplet, and that the singlet adds to olefin stereospecifically and reacts with dimethyl sulfide giving iminosulfurane, while the triplet adds to olefin nonstereospecifically and reacts with the sulfide less easily without giving iminosulfurane. Increase in the initial concentration of sulfide will decrease the amount of aziridine derived from the singlet. This will diminish the probability of the intersystem crossing to give a less amount of the triplet nitrene and lower yields of the *trans* aziridine.

3-*O*-Benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylopyranose

Saburo INOKAWA, Yoshimi TSUCHIYA, Kuniaki SEO,* Hiroshi YOSHIDA, and Tsuyoshi OGATA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

* *Department of Applied Chemistry, Numazu Technical College, Ohoka, Numazu*

(Received March 18, 1971)

There has been a great deal of activity in recent years in connection with the syntheses of sugar analogs with nitrogen or sulfur in the hemiacetal ring.[1] Concerning sugar analogs with phosphorus in the ring, however, only one short report has been published, by Whistler and Wang,[2] who prepared 5-deoxy-3-*O*-methyl-5-(phosphinyl)-D-xylopyranose and 5-deoxy-3-*O*-methyl-5-(hydroxyphosphinyl)-D-xylopyranose in poor yields.

The present paper will report on the synthesis of 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylopyranose in 27% yield from **1**.

As a starting material, we used 3-*O*-benzyl-5-deoxy-5-iodo-1,2-*O*-isopropylidene-α-D-xylofuranose (**1**) (mp 76—76.5°C,[3] $[\alpha]_D^{14}$ −59.8° (*c* 4.5, acetone)), which has been prepared from 3-*O*-benzyl-1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranose through the sequence of 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucofuranose, 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-xylofuranose, and 3-*O*-benzyl-5-*O*-tosyl-1,2-*O*-isopropylidene-α-D-xylofuranose. The Michaelis-Arbuzov reaction of **1** with diethyl ethylphosphonite gave, in an 87% yield, 3-*O*-benzyl-5-deoxy-5-(ethoxyethylphosphinyl)-1,2-*O*-isopropylidene-α-D-xylofuranose (**2**) (bp 105—110°C/10^{-2}—10^{-3} mmHg, syrup, $[\alpha]_D^{14}$ −15.3° (*c* 3.9, chloroform)). The reduction of **2** with lithium aluminum hydride, followed by oxidation with air, afforded, in an 85% yield, 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-1,2-*O*-isopropylidene-α-D-xylofuranose (**3**) (bp 120—130°C/10^{-2}—10^{-3} mmHg, syrup, $[\alpha]_D^{15}$ −34.5° (*c* 4.6, chloroform)). The structure of **3** was established by studies of the PMR and IR spectra. The PMR spectrum (chloroform-*d*) showed a characteristic J(P–H) value[4] of 462 Hz at τ 3.1 (one-proton multiplet, disappearing upon the addition of D_2O). The IR spectrum showed the absorption of a P–H group at 2350 cm^{-1} and that of a P=O group at 1260 and 1220 cm^{-1}. The methanolysis of **3** in a methanol solution containing hydrochloric acid did not afford a methyl glycoside with phosphorus in the ring, but methyl 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylofuranoside (syrup) (**4**) in an 82% yield. The PMR spectrum (chloroform-*d*) showed a J(P–H) value of 462 Hz at τ 3.1 (one-proton multiplet, disappearing upon the addition of D_2O), and the IR spectrum showed the absorption of a P–H group at 2350 cm^{-1}. The structure of **4** was then identified as a methyl furanoside. On the hydrolysis of **3** in 50% aqueous methanol containing sulfuric acid (2 N), two major spots (R_f 0.70 and 0.55) and one minor spot (R_f 0.15) could be observed on a thin-layer chromatogram (chloroform-methanol, 5 : 1 v/v). The constitution of the two major components was about 1 : 1. The component **5**, with R_f 0.70, was easily separated, in a 45% yield, from the mixture by extraction with chloroform. The PMR spectrum (chloroform-*d*) showed a J(P–H) value of 462 Hz at τ 3.1 (one-proton multiplet, disappearing upon the addition of D_2O), and the IR spectrum showed the absorption of a P–H group at 2350 cm^{-1}. The component **5** was then identified as 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylofuranose (syrup). The component **6**, with R_f 0.55, was separated, in a 37% yield, by alumina-column chromatography (chloroform-methanol, 5 : 1 v/v). In the PMR (dimethyl sulfoxide-d_6) and IR spectra of **6**, the absorption showing the presence of a P–H group completely disappeared and the absorption of a one-proton multiplet at τ about 5 assigned to H-1 appeared. Moreover, by the treatment of **5** with 2 N sulfuric acid, half of the **5** was led to **6**. Therefore, **6** was identified as 3-*O*-benzyl-5-deoxy-5-(ethylphosphinyl)-D-xylopyranose (syrup, $[\alpha]_D^{11}$ −7.0° (*c* 2.6, methanol)).

The Formation of $N_3P_3(NH_2)_6 \cdot H_2O$ and $N_3P_3(NH_2)_6 \cdot HCl$ from the Reaction Product between $(NPCl_2)_3$ and Ammonia

Etsuro KOBAYASHI

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

(Received March 19, 1971)

In the course of the synthesis research into $N_3P_3(NH_2)_6 \cdot H_2O$ as a fireproof material, some experiments have been made on the reaction between $(NPCl_2)_3$ and liquid ammonia, a new adduct, $N_3P_3(NH_2)_6 \cdot HCl$, was found to be formed. The reaction conditions for the formation and the characteristics of the adduct have been investigated.

Previous studies have indicated that an ammonolysis of phosphonitrilic chlorides takes place very slowly.[1] Audrieht and Sowerby[2] have also reported that the complete replacement of the chlorine atoms in the phosphonitrilic chlorides could be achieved within 48 hr. However, in this study, the reaction between $(NPCl_2)_3$ and a large excess of liquid ammonia has been completed within several hours in an autoclave with an electro-magnetic stirrer, and the rate of reaction was accelerated by the addition of dioxane as the solvent to this reaction system. The reaction product is a mixture of $N_3P_3(NH_2)_6$ and NH_4Cl.

It has been reported that the addition of ethanol to an aqueous solution of the reaction product causes the precipitation of $N_3P_3(NH_2)_6 \cdot H_2O$.[3] However, the author found the following facts when he used this separation procedure.

After the ammonia involved in the reaction product was completely excluded under reduced pressure, the product was dissolved in water. The adduct, $N_3P_3(NH_2)_6 \cdot HCl$, was then precipitated by the addition of ethanol to the aqueous solution.

Found: P, 34.2; N, 46.5; Cl, 12.6%; P : N : Cl atomic ratio, 3.0 : 9.0 : 1.0. Calcd for $N_3P_3(NH_2)_6 \cdot HCl$: P, 34.73; N, 47.12; Cl, 13.25%.

The analyses of the typical products did not give the $N_3P_3Cl_{6-n}(NH_2)_n$ formula, but $N_3P_3(NH_2)_6 \cdot HCl$. Therefore, the formation reaction may be expressed by the following equation:

$$N_3P_3(NH_2)_6 + 6NH_4Cl \rightleftharpoons N_3P_3(NH_2)_6 \cdot HCl + 5NH_4Cl + NH_3$$

The equation was also confirmed by an examination of the reaction between $N_3P_3(NH_2)_6 \cdot H_2O$ and commercial ammonium chloride, and the heat of reaction was 1.24 kcal/mol (endothermic).

It is known[4] that the basicity of some aninophosphazens is comparable with that of parent amines, and adducts ($N_3P_3(NHR)_6 \cdot HCl$, where R is aliphatic amines) are formed with one molecule of hydrogen chloride even in the presence of ammonia. However, with the $N_3P_3(NH_2)_6 \cdot HCl$ adduct, it is considered that the molecule of hydrogen chloride can be removed with ammonia. In fact, $N_3P_3(NH_2)_6 \cdot H_2O$ was formed by the addition of ethanol to a reaction product solution that contained an excess amount of ammonia for the neutralization of hydrogen chloride in $N_3P_3(NH_2)_6 \cdot HCl$.

Found: P, 38.4; N, 51.7; Cl, 0.4%; P : N : Cl atomic ratio, 3.0 : 8.9 : 0.0. Calcd for $N_3P_3(NH_2)_6 \cdot H_2O$: P, 37.30; N, 50.61%.

Both compounds, $N_3P_3(NH_2)_6 \cdot H_2O$ and $N_3P_3(NH_2)_6 \cdot HCl$, are composed of a white crystalline powder, both dissolve in water (hydrate: the solubility at 25°C is 11.2 g anhydride/100 g soln; chloride: because of its high solubility, it could not be measured), but are insoluble in various organic solvents. The compounds showed their own characteristic IR absorption bands, as is shown in Fig. 1. Their DTA curves are distinguished from each other, and they were both converted by heating to phospham, which has an excellent flame resistance.

Nuclear Magnetic Resonance Spectra of Carbanions. VIII.[1] α-Picolyllithium

Kazuyori KONISHI, Kensuke TAKAHASHI,[2] and Ryuzo ASAMI

Department of Synthetic Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya

(Received April 14, 1971)

The pmr spectra of the benzyl-type carbanions containing hetero atoms have not yet been reported as far as we know. We have recently observed the pmr spectra of α-picolyllithium in THF solutions. α-Picolyllithium was prepared from 6.35 mmol of α-picoline in contact with 6.05 mmol of phenyllithium in THF in a vacuum. A typical spectrum of α-picolyllithium is given in Fig. 1. One strong impurity signal is observed at 7.31 ppm; it is due to benzene. The other signals can be easily assigned by means of their intensities and structures except for some small impurity signals. The observed chemical shifts are given in Table 1, along with those of α-picoline and benzyllithium for comparison, taking the solvent peak at 1.79 ppm as a reference. The chemical shifts for the 0.22 and 0.58 mol/*l* solution of the carbanion were consistent within the limits of experimental error (±0.03 ppm). The coupling constants between the ring protons are $J_{34}=9.0$, $J_{35}=1.5$, $J_{36}=1.0$, $J_{45}=6.5$, $J_{46}=1.9$, and $J_{56}=5.5$ Hz, as evaluated from the first-order analysis for a 0.22 mol/*l* solution of the carbanion in THF. The data are compared with those of benzyllithium reported by Sandel and Freedman.[3] The ring protons of α-picolyllithium are more shielded than those of benzyllithium except for the 6-hydrogen, which is strongly affected by the nitrogen atom. The extra charge transferred from lithium to the pyridine ring in α-picolyllithium can be evaluated from the chemical shifts, using the procedures in a previous report.[4] The charges are -0.16_5, -0.15, -0.22, and -0.15 in units of the absolute value of the charge of an electron for the 3-, 4-, 5-, and 6-carbons respectively, taking picoline as the reference compound. There is a question of the magnitude of the proportional coefficient of the 10 ppm/electron, used for the charge estimation.[5] However, we can compare the extra charges transferred from lithium to the aromatic ring of the carbanions relatively. It is estimated that the more shielded the aromatic protons in the carbanions, the more stable the carbanions become. The extra charges are more transferred from lithium to the aromatic ring in α-picolyllithium than that in benzyllithium.[3] Therefore, the ionic nature of the metal-carbon bond in α-picolyllithium may be larger than that in benzyllithium, and α-picolyllithium may be more stable than benzyllithium. The methylene protons of α-picolyllithium are less shielded than the methyl protons of α-picoline. This tendency may be ascribed to the hybridization change in the α-carbon atom from sp^3 in α-picoline to near-sp^2 in α-picolyllithium, as was reported before in the α-methylstyrene dimer dianion.[4] The line width of the methylene proton signal is broader than the other ring proton signals in α-picolyllithium. Three reasons explaining this broadening may be considered. They are the nitrogen quadrupole relaxation effect, the coupling with ring protons, and the nonequivalency of the two methylene protons. The last reason seems to be most probable. Further studies are now in progress.

Oxidation of Propylene over Cu(II)-Y Molecular Sieve under High Steam Concentration[1]

Isao Mochida, Shinji Hayata, Akio Kato, and Tetsuro Seiyama
Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka
(Received April 22, 1971)

In a previous paper,[2] it was reported that acrolein was formed from propylene over the Y molecular sieve ion-exchanged with cupric ion (Cu(II)-Y) in the presence of steam. As the molecular sieve is highly acidic, it is expected to play a bifunctional catalytic role for the synthesis of acetone from propylene through hydration and dehydrogenation under adequate conditions.

In the present study, reactions of propylene over this catalyst under high steam concentration was carried out using a flow reactor with a fixed catalyst bed. Feed and product compositions were analyzed by gas-chromatography. The procedures were similar to those reported by Ogasawara *et al.*[3]

The results obtained in the absence of oxygen (Fig. 1) indicate that isopropanol and acetone can be formed in place of another. This suggests that acetone is formed from propylene *via* hydration and dehydrogenation. The maximum yield of acetone was 1.3% at 315°C, where the yield is defined by (product moles)/(propylene fed).

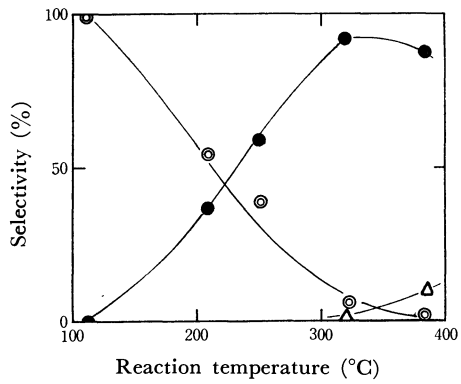

Fig. 1. Selectivity of products over Cu(II)-Y without oxygen.
Cu(II)-Y: 4 g. Reactant gas composition, C_3H_6:H_2O=1:20.
●: acetone, ◎: isopropanol, △: ethylene.

The results in the presence of oxygen are shown in Fig. 2. The main products other than carbon dioxide were isopropanol below 200°C, acetaldehyde at around 250°C and acetone above 450°C. It should be mentioned that acrolein was the main product under low steam concentration.[2] The maximum yields of acetaldehyde and acetone were 1.0 and 0.7%, respectively.

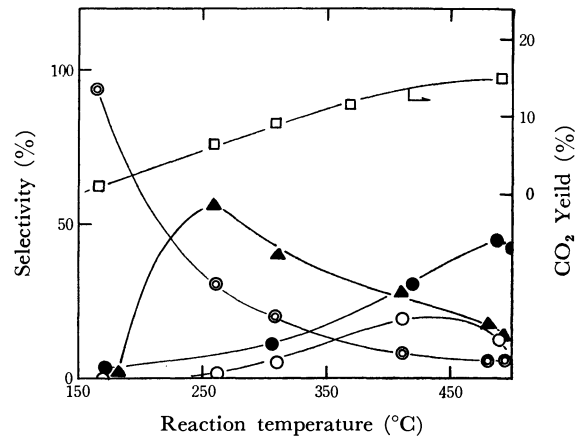

Fig. 2. Selectivity of propylene oxidation over Cu(II)-Y in the presence of oxygen (selectivity is based on products excluding carbon dioxide).
Cu(II)-Y: 2.7 g. Reactant gas composition, C_3H_6:O_2:H_2O =1:1:20.
□: CO_2 yield, ●: acetone, ◎: isopropanol, ▲: acetaldehyde, ○: acrolein.

Moro-oka *et al.*[4] and Ogasawara *et al.*[3] reported selective oxidation of propylene into acetone on molybdena catalysts. Backer and Carrick reported the oxidative cleavage of olefinic double bond on chromia catalyst.[5] From their results and ours, formation routes for acrolein, acetaldehyde, and acetone can be described as follows:

A Novel Bis(dimethylglyoximato)cobalt(III) Complex with a *cis*-Configuration

Nobufumi MAKI

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received April 28, 1971)

Numerous cobalt(III) complexes of the *trans*-[CoX_2-$(dgH)_2$] type[1] have been reported, but the corresponding *cis*-isomers have not yet been synthesized. The steric condition arising from the extremely stable square-planar structure of the [$Co(dgH)_2$] type with a pair of hydrogen bonds is the reason why the formation of *cis*-isomers is so difficult. Nakahara,[2] however, has prepared the [$Co(dgH)_3$]·5/2 H_2O complex in a strongly basic solution for the rupture of the hydrogen bonds. The present communication will describe one of our attempts to prepare three new compounds of a cis-type involving an ethylenediamine, [$Co(dgH)(dgH_2)en$]Cl_2·$2H_2O$, [$Co(dgH)(dgH_2)en$]-Br_2·$2H_2O$, and [$Co(dgH)_2en$]ClO_4·1/3 H_2O.

Thirty grams of the [Co en_3]Cl_3·$3H_2O$ complex[3] were completely dissolved in 850 m*l* of water at 80°C. To this solution we then added 45.7 g of Na_2dg·$8H_2O$. The solution was directly heated to the boil (100°C) for 3 hr, and finally it was concentrated to 130 m*l*. On heating, the orange-yellow color of the solution soon turned dark brown, but no deposition of metallic cobalt was observed during the reaction. After the solution had been cooled in ice, sodium chloride precipitates formed and were filtered off. To the filtrate (130 m*l*), 36 m*l* of 35% HCl were added under ice-cooling. Then, brown crystals were deposited from the solution; these crystals were separated by filtration and washed with a small amount of cold water, ethanol, and ether. The yield was 34% of the theory. The purifications were carried out as follows: the crude complex (14 g) was dissolved in a requisite small amount of a 0.5 M NaOH solution (110 m*l*). After the filtration of the solution, the complex was precipitated again by stirring in 36 m*l* of HCl (25%), drop by drop, at 0°C. This procedure was repeated three times. The complex was then dried on $CaCl_2$ under 1 atmosphere. Found: Co, 18.72; C, 26.58; N, 18.83; H, 6.31; Cl, 15.74%. Calcd for [$Co(dgH)$-$(dgH_2)en$]Cl_2·$2H_2O$: Co, 18.89; C, 26.27; N, 18.38; H, 5.95; Cl, 15.51%.

The bromide and perchlorate of the complex were likewise precipitated by adding the corresponding acid (30—35%) instead of hydrochloric acid to the basic filtrate. The purification procedure was quite the same as above. Found: Co, 10.65; C, 21.53; N, 15.78; H, 5.11; Br, 29.15%. Calcd for [$Co(dgH)$-$(dgH_2)en$]Br_2·$2H_2O$: Co, 10.79; C, 21.99; N, 15.39; H, 4.98; Br, 29.26%. Found: Co, 12.78; C, 26.05; N, 18.71; H, 4.89; Cl, 8.03%. Calcd for [Co-$(dgH)_2en$]ClO_4·1/3 H_2O: Co, 12.96; C, 26.42; N, 18.48; H, 5.03; Cl, 7.80%.

The molar ratio of the halide ion to the complex cation was also examined by volumetric analyses; the results established an approximately 2 : 1 ratio for both the halide ions. The aqueous solutions of these compounds are strongly acidic with pH-values ranging from 0 to 1.2. Therefore, the DC polarograms of these compounds were almost in accord with the hydrogen waves in aqueous solutions. On the other hand, the results of examining them in DMSO revealed this complex to take a *cis*-configuration.[4]

Figure 1 shows the absorption spectra of *cis*-bis-(dimethylglyoximato)ethylenediaminecobalt(III) and its related complexes in the visible and ultraviolet regions. Although its first *d–d* band is partly overlapped with the charge-transfer band due to the oxime ligands, it seems likely that the first band shifts to a shorter wavelength in the following sequence of complexes: [Co en_3]$^{3+}$, [$Co(dgH)_2en$]$^+$, [$Co(dgH)_3$].

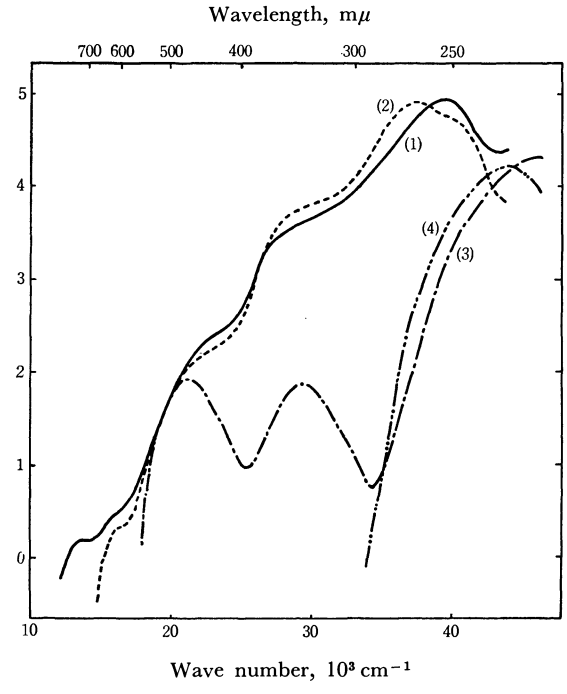

Fig. 1. Absorption spectra of *cis*-bis(dimethylglyoximato)-cobalt(III) and its related complexes: (1) —— *cis*-[$Co(dgH)_2$-en]ClO_4·1/3 H_2O in 0.1 N NaOH; (2) ---- *dl*-[$Co(dgH)_3$]·5/2 H_2O in 0.1 N NaOH; (3) ——— *dl*-[Co en_3]Cl_3 in H_2O; (4) ——— Na_2dg·$8H_2O$ in H_2O.

Since the pmr spectrum of the *cis*-[$Co(dgH)$-$(dgH_2)en$]Cl_2·$2H_2O$ complex in 99.7% D_2O shows that the broad band at 2.9 ppm downfield from DSS is in the same position as the single broad CH_2 band in the spectrum of [Co en_3]$^{3+}$, this band adjacent to the peak of CH_3-group may be assigned to the CH_2-group; this suggests the presence of an ethylenediamine bound to the cobalt.

Phosphorylation by Oxidation-Reduction Condensation.[1] Preparation of Active Phosphorylating Reagents

Teruaki MUKAIYAMA and Mitsunori HASHIMOTO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

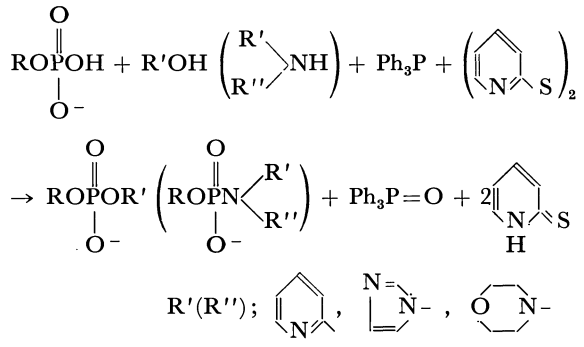
(Received April 30, 1971)

Active phosphorylating reagents such as imidazolylphosphonate,[2,3] 2-pyridyl ester of phosphoric acid,[4,5] and phosphoramidate,[6] especially phosphoromorpholidate,[7] are considered to be important intermediates in nucleotide synthesis. In the present experiment, the preparation of these active phosphorylating reagents such as imidazolylphosphonate, 2-pyridyl ester of phosphoric acid and phosphoromorpholidate by the oxidation-reduction condensation reaction[1] was studied.

First, the preparation of imidazolylphosphonate was attempted. In a typical reaction, triphenylphosphine (2 mmol) was added rapidly into a mixture of *p*-chlorophenyl dihydrogen phosphate (1 mmol), imidazole (5 mmol), triethylamine (1 mmol) and 2,2'-dipyridyl disulfide (2 mmol) in 5 m*l* of THF at room temperature. After stirring for 20 min, acetone solution of sodium iodide (1.5 mmol) was added to the reaction mixture and cooled down to 0°C. After being kept standing for 1 hr at 0°C, the precipitated white needle crystals were filtered off and washed with cold acetone. After removal of the solvent *in vacuo*, the sodium salt of *p*-chlorophenyl imidazolylphosphonate was obtained in a quantitative yield. UV: λ_{max} 270 mμ.

Found: C, 38.50; H, 2.51; N, 10.00%. Calcd for $C_9H_7O_3N_2PClNa$: C, 38.53; H, 2.52; N, 9.99%.

In the case of adenosine 5'-monophosphate, DMF was used in place of THF in the above experiment, and the corresponding adenosine 5'-imidazolylphosphonate was obtained in a quantitative yield without producing symmetrical pyrophosphate (AppA). *p*-Chlorophenyl-2-pyridyl phosphate was isolated as its cyclohexylammonium salt from *p*-chlorophenyl dihydrogen phosphate and 2-hydroxypyridine in high yield according to the following procedure. *p*-Chlorophenyl dihydrogen phosphate (1 mmol) was allowed to react with 2-hydroxypyridine (5 mmol), triphenylphosphine (2 mmol) and 2,2'-dipyridyl disulfide (2 mmol) in THF at room temperature for 3 hr. Cyclohexylamine (1.5 mmol) was then added to the reaction



mixture cooled in an ice-bath and kept standing for 2 hr. The precipitated crystals were filtered off, washed with cold THF and dried *in vacuo*. The corresponding cyclohexylammonium salt of *p*-chlorophenyl-2-pyridyl phosphate, mp 164°C, was obtained in 80% yield. UV: λ_{max} 262 mμ.[8] Found: C, 52.95; H, 5.85; N, 7.40%. Calcd for $C_{17}H_{22}O_4N_2ClP$: C, 53.10; H, 5.76; N, 7.29%.

Next, it was found that adenosine 5'-phosphoromorpholidate, an important intermediate in the synthesis of pyrophosphates such as FAD (flavin Adenine dinucleotide), was obtained in a quantitative yield by this method. Triphenylphosphine (2 mmol) was added into the suspended DMF solution of adenosine monophosphate (1 mmol), morpholine (5 mmol), triethylamine (1 mmol) and 2,2'-dipyridyl disulfide (2 mmol) at room temperature. After the mixture was stirred for 1 hr, the suspended solution turned clear. By this time, paper chromatography and paper electrophoresis showed the presence of only one spot corresponding to adenosine 5'-phosphoromorpholidate. Determination by UV absorption after separation with paper chromatography showed that the adenosine 5'-phosphoromorpholidate was obtained in a quantitative yield. $\lambda_{max}^{pH\,7}$ 260 mμ (ε 1.59×10^4). R_f 0.41, isopropanol - concd. ammonium hydroxide - water (7 : 1 : 2).

In conclusion, it is noted that the present oxidation-reduction condensation produces active phosphorylating reagents such as imidazolylphosphonate, 2-pyridyl ester of phosphoric acid and phosphoromorpholidate in high yields in a short reaction time by simply mixing triphenylphosphine, 2,2'-dipyridyl disulfide and phosphate with imidazole, 2-hydroxypyridine or morpholine, respectively.

The authors wish to express their hearty thanks to Dr. Tsujiaki Hata for his advice.

A Useful Method for Reductive Fission of Sulfides and Its Application to Carbon-Carbon Bond Formation

Teruaki MUKAIYAMA, Koichi NARASAKA, Kazuo MAEKAWA, and Masayasu FURUSATO
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received June 11, 1971)

In connection with the activation of bivalent sulfur compounds with $CuCl_2$,[1] we report useful methods for both reductive fission of sulfides with $CuCl_2$-$LiAlH_4$ and carbon-carbon bond forming reaction with the use of allyl 2-pyridyl sulfide. The present work was investigated anticipating that the reductive fission of sulfides would proceed in the presence of $CuCl_2$ by an attack of a hydride generated from metal hydrides. As expected, the reduction proceeded effectively by the combined use[2] of $CuCl_2$ and $LiAlH_4$ as follows. First, 2 mol of $CuCl_2$ and 4 mol of $LiAlH_4$ were stirred for 1 hr in tetrahydrofuran under argon atmosphere (black precipitate appeared immediately), then diphenylmethyl phenyl sulfide(I) was added and the reaction mixture was refluxed for 3 hr. After successive hydrolysis, diphenylmethane was obtained in 73% yield. Similarly, benzophenone ethylenemercaptole (II) was reduced with 4 mol of $CuCl_2$ and 8 mol of $LiAlH_4$ under the same conditions to give diphenylmethane in 42% yield. The yield of diphenylmethane was increased to 84% when II was reduced with 4 mol of $CuCl_2$, 4 mol of $ZnCl_2$ and 16 mol of $LiAlH_4$ in the above experiment.

$$Ph_2CHSPh\ (I) \xrightarrow[3\text{ hr }94\%]{2CuCl_2+4LiAlH_4} Ph_2CH_2$$

$$p\text{-MeO-}C_6H_4CH(SEt)Ph \xrightarrow[3\text{ hr }73\%]{CuCl_2+2LiAlH_4} p\text{-MeO-}C_6H_4CH_2Ph$$

$$Ph_2C\begin{matrix}S\\S\end{matrix}\ (II) \xrightarrow[3\text{ hr }84\%]{4CuCl_2+4ZnCl_2+16LiAlH_4} Ph_2CH_2$$

For the reductive fission of sulfides, some methods have been noted.[3] However, unfavorable side reactions such as reduction of aromatic ring or carbon-carbon double bond generally accompany the desired reductive fission of carbon-sulfur bond. With the $CuCl_2$-$LiAlH_4$ method, the reductive fission of sulfides proceeded selectively with no such side reactions.

A new synthetic route for carbon-carbon bond formation involving the alkylation of allyl 2-pyridyl sulfide and a subsequent reductive fission of 2-thiopyridyl group from the alkylated products by the above mentioned reduction, was established. Selective alkylation of allyl 2-pyridyl sulfide was tried starting from the lithium salt. The alkylation of allylic phenylsulfides was reported by Biellmann and Ducep.[4] By introduction of 2-pyridyl group instead of phenyl group, it was expected that side reactions, such as a migration of double bond and a *cis-trans* isomerization, would be minimized by the effect of the stable five membered chelate ring formation of the carbanion. Actually, allyl 2-pyridyl sulfide (III) was easily converted into their carbanion with C_6H_5Li in tetrahydrofuran at −25——15°C. Subsequent alkylation with alkyl halides afforded the alkylated products in good yields after purification by silica gel column chromatography and distillation as shown in the Table. Analysis by vpc indicated that the products selectively contained α-alkylated products (IV) in 92—95% as shown in parentheses.

Reductive fission of 2-pyridyl group from the alkylated product (IV) proceeds successfully according to the following procedure with the use of $CuCl_2$-$LiAlH_4$; Treatment of IV with 4 mol of $CuCl_2$ and 8 mol of $LiAlH_4$ in tetrahydrofuran for 4 hr at room temperature, followed by distillation gave α-olefins (V), estimated to be 93% pure by vpc, in good yields.

The Photoinduced Substitution Reaction of 2-Quinolinecarbonitrile

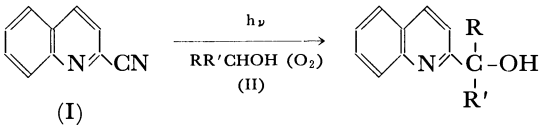
Norisuke HATA, Isao ONO, and Seiichi OGAWA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

(Received May 6, 1971)

Recently, there has been considerable interest in photochemical alkylations of *N*-heterocyclic compounds.[1,2] However, photochemical hydroxyalkylations have been reported only in the case of quinoline by Stermitz *et al.*[2]; there, ultraviolet irradiations of the quinoline in ethanol solution gave the 2-(1-hydroxyethyl)quinoline in a 20% yield. In the present investigation, the authors found an interesting photochemical substitution reaction of 2-quinolinecarbonitrile in alcoholic solvents, affording 2-(1-hydroxyalkyl)-quinoline.

A solution of 0.8 g of 2-quinolinecarbonitrile in an alcoholic solvent (350 m*l* of ethanol, 1-propanol, or 2-propanol) in a Pyrex vessel was irradiated with a 250-W high-pressure mercury lamp for 18 hr while oxygen was bubbled in. After the removal of the solvent under reduced pressure, the residue was chromatographed on a silica-gel column by elution with a mixture of *n*-hexane and diethyl ether (1 : 1). The melting points and the yields of the main products thus obtained are given in Table 1. The UV spectra of these compounds were quite similar to that of quinaldine. The IR spectra of the products in KBr showed a peak at 3300 cm^{-1} (ν_{O-H}) and no absorption at 2230 cm^{-1} characteristic of the C≡N group. In addition to the UV and IR spectra, the structural determinations of the products were made on the basis of the NMR and mass spectra as well as by means of elemental analyses; the results are summarized in Table 1. It was concluded from these results that the quinolinecarbonitrile (I) changed photochemically in alcoholic solvents(II) to give 2-(1-hydroxyalkyl)-quinoline (III) as follows:



(I) (III)

IIa and IIIa: R=CH_3, R'=H
IIb and IIIb: R=C_2H_5, R'=H
IIc and IIIc: R=CH_3, R'=CH_3

When the irradiation was carried out where nitrogen was bubbled in instead of oxygen, the solution became reddish violet and two main products were separated: one was the product (III), while the other was unidentified. In the presence of piperylene as a triplet quencher,[3] however, no such coloration occurred and only the photoproduct (III) was obtained as a main product. These facts suggest that the lowest triplet state of 2-quinolinecarbonitrile is not responsible for the photochemical conversion (I)→(III).

Further studies are now in progress and will be reported soon.

3) It was estimated, from the first maximum of the phosphorescence spectrum (484 nm) in ethanol at 77°K, that the lowest triplet state of 2-quinolinecarbonitrile has an excitation energy of about 59 kcal·mol^{-1}.

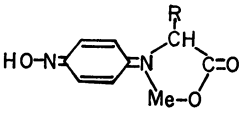
A Stereospecific Racemization Catalyst for Amino Acid[1]

Kazuhiro HIROTA and Yoshiharu IZUMI

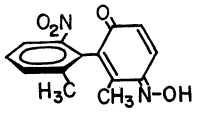
Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Receied May 7, 1971)

It is known that pyridoxal, salicylaldehyde, *o*- or *p*-nitrosophenol, and aurintricarboxylic acid catalyze[2-6] non-enzymatically, in alkaline media, the racemization of optically-active amino acid in the presence of a metal ion. These reactions involve the formation of the chelate compounds of a Schiff base, which compounds promote the release of the proton at the α-carbon of the amino acid and the racemization of the amino acid. A possible chelate structure in *p*-nitrosophenol (*p*-quinoneoxime), as an example, is shown in I.



(I)



(II) (oxime type)

Therefore, when the optically-active asymmetric structure is introduced to the catalyst, it could bring about differences in the stabilities or in the rates of the formation of these chelates with a metal ion between L- and D-amino acids. Those differences could appear as differences in the racemization rates between L- and D-amino acids. Therefore, we wish to report here the first observation of the stereospecific racemization reaction for amino acid with the hindered biphenyl, (S)-2′-nitro-2-hydroxy-5-nitroso-6,6′-dimethylbiphenyl(II).[7] The racemization activities of the catalyst for L- and D-alanine respectively were studied in the presence of the cupric ion.

The procedure for the racemization reaction was as ollows; the reaction mixtures containing L- or D-alanine (0.5 mmol), cupric sulfate pentahydrate (0.05 mmol), and the catalyst (II) (0.0125 mmol) were adjusted to pH 10 with sodium hydroxide to make a total volume of 0.5 m*l* with water, and then the mixture was shaken in a sealed tube at 31° or 40°C. After the reaction, 6 N hydrochloric acid (0.5 m*l*) was added to stop the racemization reaction. The determination of the ratio of L- and D-alanines was performed as follows; the reaction mixtures were centrifuged to precipitate the used catalyst, and the supernatants were dried up. After the residues had been converted into l-menthyl D- and L-trifluoroacetylalaninates, the ratio of L- and D-alanines was determined by means of gas chromatography. Careful measurements, compared with the calibrated curve, led us to an estimated error of ±0.5%.

The catalytic activities for L- and D-alanines are compared in Table 1 in terms of the contents of the racemized D- and L-alanines and the difference between the two. Though the racemic catalyst, of course, showed no difference in the catalytic activities between L- and D-alanines, II possessed some stronger activities for L-alanine than for D-alanine. The difference in the catalytic activity lay in the range from 3.0 to 5.0% in the contents of L- and D-alanines racemized from the D- and L-alanines substrates respectively. Such a catalytic property may serve as a model for the high stereospecificities often observed in the interactions of metallo-enzymes and their substrates. A stereochemical relationship between the catalyst and substrate will be discussed in a presentation of a molecular model in This Bulletin in the near future.

TABLE 1. RACEMIZATION ACTIVITY OF THE CATALYST

Configuration of catalyst	Substrate	Exp. 1.		Exp. 2		Exp. 3	
		D- or L-ala. content (%)[b]	Difference[c]	D- or L-ala. content (%)	Difference	D- or L-ala. content (%)	Difference
Racemic	L-alanine	D : 20.4	0.6	D : 28.5	0.5	D : 34.0	0.5
	D-alanine	L : 19.8		L : 29.0		L : 34.5	
S	L-alanine	D : 20.1	3.2	D : 26.2	5.0	D : 29.5	3.0
	D-alanine	L : 16.9		L : 21.2		L : 26.5	

Reaction mixture (0.5 m*l*) containing 0.5 mmol alanine, 0.05 mmol $CuSO_4 \cdot 5H_2O$ and 0.0125 mmol catalyst (II) was shaken at pH 10.0.

a) Racemization conditions were as follows:
Exp. 1: at 31°C for 162 hr. Exp. 2: at 31°C for 168 hr. Exp. 3: at 40°C for 72 hr.

b) Content of D- or L-alanine after the racemization reaction.

c) Difference between contents of L- and D-alanines racemized from D- and L-alanines, respectively.

7) II was derived from (S)-2′-nitro-2-amino-6,6′-dimethylbiphenyl; its diazonium salt was hydrolyzed to the phenol derivative, and then treated with sodium nitrite. The method will be reported in detail in the near future.

Hydrogen Abstraction of Excited Benzophenone in *N,N*-Dimethylaniline and 2-Methyltetrahydrofuran Solution at Low Temperature

Satoshi ARIMITSU* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 13, 1971)

Photochemical reactivities of aromatic ketones have been studied extensively,[1-5] Porter and his co-workers found that photoreduction of benzophenone in isopentane does not occur at temperatures 77°K—108°K, but proceeds above 108°K.[4] We wish to report that it occurs easily in a mixed glass of aromatic amine and ether at 77°K. Benzophenone (5×10^{-3} M) in a degassed mixture of *N,N*-dimethylaniline (DMA) and 2-methyltetrahydrofuran (2MTHF), about 1 : 3 by volume, at 77°K was photolysed in the region 350—400 nm through a glass filter with a high pressure mercury lamp for 10—30 sec. The results are shown in Fig. 1. The spectrum (appearing from 500 to 570 nm in curve d) is nearly in agreement with that of the ketyl radical at room temperature (curve e).[3,4] No ketyl radical was found by the photolysis of benzophenone in a 2MTHF matrix at 77°K.

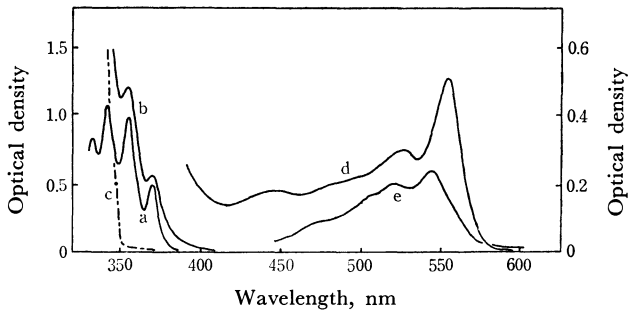

Fig. 1. a) Absorption spectrum of benzophenone in 2MTHF at 77°K. b) Absorption spectrum of benzophenone in DMA and 2MTHF at 77°K. c) Absorption of DMA and 2MTHF at 77°K. d) Absorption of sample used in b) after irradiation. e) Absorption of the ketyl radical obtained by flash illumination of a solution at room temperature.

The electronic spectrum of benzophenone in the DMA-2MTHF matrix shown by curve b suggests that an electron donor-acceptor complex is formed between benzophenone as an electron acceptor and DMA as a donor at 77°K. Therefore, it is suggested that the photochemical reactivity of benzophenone is activated significantly in the excited state of benzophenone-DMA complex. The ketyl radical appears also in a mixed matrix of DMA and trichlorotrifluoroethane, the latter having no hydrogen atom to abstract. This result definitely indicates that the ketyl is produced as a result of intermolecular hydrogen transfer from DMA to benzophenone. Thus, the absorption band at near 445 nm can be ascribed to DMA radical $\left(\phi\text{-N}\langle\begin{matrix}\dot{C}H_2\\CH_3\end{matrix}\right)$.[6]

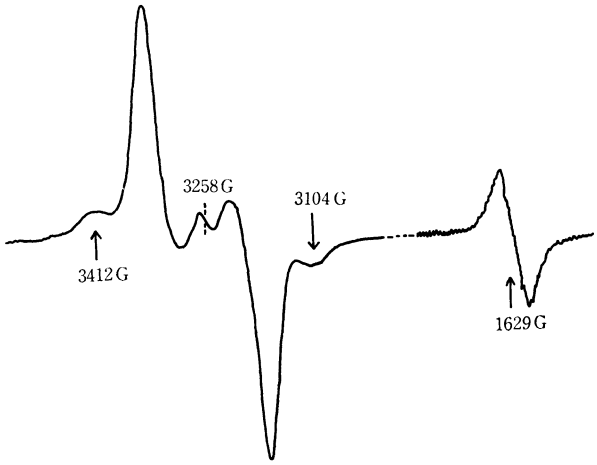

Fig. 2. ESR spectrum of benzophenone in DMA-2MTHF irradidiated at 77°K: (ν=9136 MHz.).

When benzophenone in a DMA-2MTHF matrix was irradiated at 77°K, an ESR spectrum was obtained as shown in Fig. 2. A weak absorption ascribable to the $\Delta m=2$ transition of a radical pair in a triplet state was found at 1629 gauss. A stronger spectrum which consists of two pairs of lines with a separation of 176 and 308 gauss appeared symmetrically with respect to the magnetic field strength of 3258 gauss. From the ESR spectrum we can immediately estimate the D value or the fine structure constant of the radical pair to be 154 gauss, and the average distance between the interacting radical 5.6_4 Å by using a point-spin-density approximation.[7] This result might be the first one indicating the presence of two photo-chemically formed unstable radicals which lie close to each other and form a combined triplet (S=1) state.

The Production of New Carbonyl- and Thiocarbonyl-stabilized Phosphonium Ylids by the Reaction of the Triphenylphosphonium Methylid with *O*-Alkylxanthates

Hiroshi YOSHIDA, Hironori MATSUURA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received May 17, 1971)

The reaction of phosphonium alkylids with *S*-alkyl thiolcarboxylates yields phosphonium acylalkylids in good yields.[1] However, no worker has reported on the reaction of dialkylcarbonates with phosphonium alkylids. In this communication, the reaction of triphenylphosphonium methylid (**1**) with *O*-alkylxanthates (**2**) to give new carbonyl- and thiocarbonyl-stabilized phosphonium ylids will be treated.

The reaction of **1** with a two fold amount of **2** was performed in toluene under a nitrogen atmosphere at various temperatures. The product was then purified by recrystallization from petroleum ether-ethyl acetate or by column chromatography. The structure of the product was confirmed by elemental analysis, NMR, IR and a Wittig reaction with benzaldehyde.

As Table 1 shows, the reaction at room temperature yields only thiocarboalkoxymethylene triphenylphosphorane (**3**); however, the reaction at 130°C yields **3** or **4**, or a mixture of the two. The alkyl groups attached to the ylids, **3** and **4**, are the *O*-alkyl groups of the starting xanthates, **2**.

TABLE 1. THE REACTION OF **1** WITH **2** IN TOLUENE

2		Reaction condition		Yield (%)	
R	R′	Temp. (°C)	hr	**3**(R)[a]	**4**(R)[a]
Me	Me	room temp.	24	38	—
		130	3.5	—	46
Me	Et	130	3	—	47
Et	Me	room temp.	24	41	—
		130	3	53[b]	
Et	Et	130	3	59[b]	
i-Pr	Me	130	3	56	—

a) The same group as the *O*-alkyl R of the xanthate **2**.
b) Nearly equimolar mixture of **3** and **4**.

Mps: **3** (R=Me) 164—165.5, **3** (R=Et) 137—139, **3** (R=*i*-Pr) 155—156.5, **4** (R=Me) 220—221, **4** (R=Et) 177—182°C.

The formation of **4** did not result from a intramolecular thion-thiol rearrangement of **3** similar to the Schönberg rearrangement,[2] since **3** (R=Me, Et, *i*-Pr) remained unchanged on heating at 130°C for a few hours. On the other hand, reaction **3** (R=Et) with **2** (R=R′=Me) gave, almost quantitatively, **4** (R=Me) and methyl ethyl dithiolcarbonate.

It is known that carboalkoxy ylids undergo alkylation with a variety of alkyl halides to afford normal alkylated ylids (alkylation on carbanion);[3] however, alkylation with triethyloxonium fluoroborate does not yield normal alkylation products (alkylation on carbonyl oxygen).[4] The alkylation of **3** with methyl and ethyl iodides yields exclusively an *S*-alkylated product.[5] Thus, the formation of **4** may be from the alkylation of **2** to the highly-polarized thiocarbonyl sulfur of **3**. The present authors have previously reported that **2** reacts with tertiary amines as an alkylating reagent and that the reactivity decreases in the order: Me≫Et>*n*-Pr≫*i*-Pr.[6] This order agrees well with that of the yield of **4** at 130°C (Table 1). Thus, the reaction of **1** with **2** to give **3** and/or **4** may be pictured as follows:

The physical and chemical properties of **3** and other analogs will be published later.

The Single-crystal Absorption Spectra of the Basic Rhodo Chromic Perchlorate

Akio URUSHIYAMA, Masayoshi NAKAHARA, and Yukio KONDO

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo

(Received May 27, 1971)

In several spectroscopic studies [1-5] concerned with the binuclear complexes of chromium(III), it has been found that the basic rhodo chromic complex, $[(NH_3)_5Cr\text{-}O\text{-}Cr(NH_3)_5]^{4+}$, shows some unfamiliar sharp absorption bands in the near-ultraviolet region. Previously, one of the present authors (Y. K.) has reported[6] that these sharp bands are strongly polarized. Recently, the crystal structure of the basic rhodo chromic chloride has been determined.[7,8] In the present communication, the polarized absorption spectra of the basic rhodo chromic complex salt related to the orientation of the dimeric unit will be reported.

The basic rhodo chromic complexes are situated on the centers of symmetry in the orthorhombic (space group *Pbca*) system of the chloride crystal, and the chromium atoms are located at $x=\pm0.62$, $y=\pm1.11$, and $z=\pm1.27$ (Å) if we take the point of origin as the symmetry center.[7] Unfortunately, the crystals, although they exhibit a dichroism (blue—through the light polarized parallel to the *a* axis, greenish blue—parallel to the *c* axis), are unsuitable for study by means of the microspectroscopic technique because of their shapes. However, a similar dichroism can be observed more distinctly on the thin plates of the perchlorate crystals, which *are* suitable for the microspectroscopic study. As the color of the chloride crystals has been related to the orientation of the complex, it seems reasonable to say that the absorption parallel to the four-fold rotation axis of the complex contributes greatly to the polarized absorption spectrum along the extinction direction of the perchlorate crystal, which shows greenish blue with the polarized light having the parallel electronic vector.

For the measurement of the absorption spectrum of the single crystal of microsize, an apparatus was constructed using a Hitachi EPS-3T spectrophotometer and a Nippon Kogaku POH polarizing microscope, together with two Olympus MO90 reflecting-type objectives (×90). The polarized absorption spectra of the basic rhodo chromic perchlorate are shown in Fig. 1.

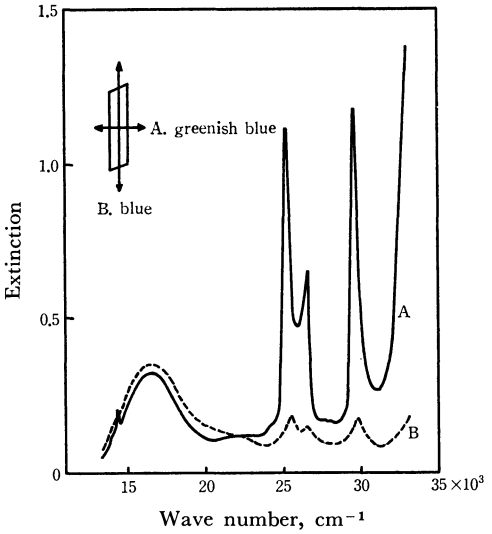

Fig. 1. Polarized absorption spectra of the basic rhodo chromic perchlorate.

It was found that: (i) the characteristic sharp absorption bands at 14320 cm^{-1} and in the near-ultraviolet region are all polarized along the four-fold rotation axis of the complex; (ii) the broad band in the 16600 cm^{-1} region seems to be slightly reduced in intensity along the four-fold rotation axis; (iii) the position of the absorption maxima of two broad bands, *i. e.*, 16600 cm^{-1} and 22000 cm^{-1}, seem to correspond to that of the so-called "first band" of the octahedrally-coordinated $Cr(III)O_6$ and $Cr(III)N_6$ types of complexes, respectively; (iv) the so-called "second band" of the *d–d* transition is obscure; and (v) as the total of the integrated intensities of the sharp bands in the near ultraviolet region is almost comparable to that of the band at 16600 cm^{-1}, the intensities of these bands are not so large as the ordinary charge-transfer absorption band shows. The characterization of the absorption bands of the basic rhodo chromic complex is very complicated. However, the assignment of the bands should be consistent with the results of the polarized spectroscopy. Further measurements at low temperatures are now in progress.

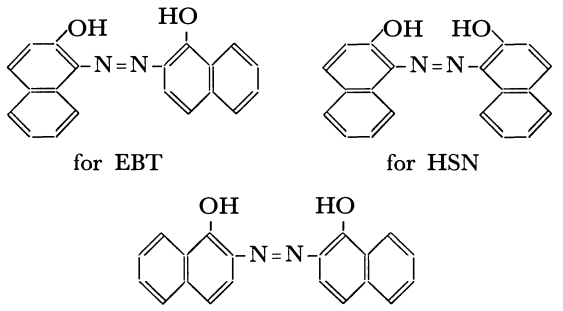
1,1′-Dihydroxy-2,2′-azonaphthalene-4,4′-disulfonic Acid as a New Reagent for Magnesium

Yasuko NODA* and Haruo MIYATA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received May 31, 1971)

Eriochrome Black T (EBT) has been used exclusively as the metallochromic indicator in the chelatometric titration of magnesium with EDTA. Also, Patton and Reeder's dye (HSN, 2-hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-3-naphthoic acid) has been used for calcium. The acid dissociation constants of these indicators are 6.3 and 11.6 for EBT,[1] and 9.2_6 and 13.6_7 for HSN[2] respectively, as pK_a values; the skeletal structures are as follows:



Structure 1

We expected that the pK_a values of the reagent with a skeletal structure such as Structure 1 would be lower than those of EBT or HSN, and that the conditional stability constant for its magnesium chelate would be higher. Therefore, 1,1′-dihydroxy-2,2′-azonaphthalene-4,4′-disulfonic acid[3] was synthesized as a reagent for magnesium from the diazotized 2-amino-1-naphthol-4-sulfonic acid, which was coupled with 1-naphthol-4-sulfonic acid. The pK_a values of this reagent are 5.0 and 11.1. A color change from blue to red upon treatment by this reagent with the magnesium ion is very sharp at pH 10. The absorption spectra of the reagent and its magnesium chelate are shown in Fig. 1. The absorption spectrum of calcium chelate at pH 7.7 is almost the same as that of the reagent itself at pH 6.46 (Curve 2) in Fig. 1. The existence of a 1-to-1 chelate was verified by the continuous-variation method, its conditional stability constant, K', and the stability constant, K, are listed in Table 1.

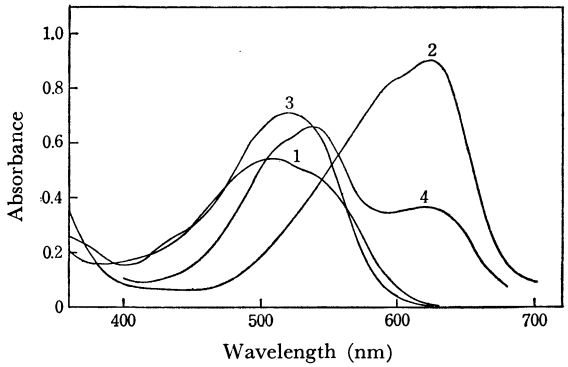


Fig. 1. Absorption spectra of the reagent and its magnesium chelate: 1 at pH 1.71; 2 at pH 6.46; 3 at pH 13; and 4 (magnesium chelate) at pH 7.69.
reagent concentration: 2.46×10^{-5} M
magnesium concentration, 2.46×10^{-3} M

By a comparison of these data, it was found that the reagent is a valuable indicator for the chelatometric titration of the magnesium ion at pH 10, and that also, it can be used in the colorimetric determination of magnesium in the presence of the calcium ion. Further details on the magnesium chelate will be reported elsewhere.

The Magneto-Optical Rotatory Dispersion of Benzophenone in the $S_0 \rightarrow T$ (n-π^*) and the $S_0 \rightarrow S_1$ (n-π^*) Absorption Regions

Yoshiya TAKENOSHITA and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received September 24, 1970)

The magneto-optical rotatory dispersion (MORD) of benzophenone has been measured in the spectral regions corresponding to its $S_0 \rightarrow S_1$ (n-π^*) and $S_0 \rightarrow T$ (n-π^*) absorption systems. The abnormal MORD in the $S_0 \rightarrow T$ absorption region has not always been observed, contrary to the results by Shashoua, only the normal MORD has always been observed. The MORD in the $S_0 \rightarrow S_1$ (n-π^*) absorption region changes its sign at about 340 mμ and is classified as a positive ($B+C/kT$) type, according to Stephens *et al.* It has been concluded that the MORD of the $S_0 \rightarrow S_1$ transition of benzophenone occurs as a result of the n,π^* state, S_1, being mixed with the B_{2u}-analogue state, S_3, and that then the S_1 state interacts magnetically with the S_3 under an external magnetic field.

Shashoua observed the MORD of benzophenone in 1960[1] and acetophenone in 1964[2] in the spectral regions corresponding to the absorption systems of these compounds. The electronic structure of benzophenone has been investigated in detail by analyses of its absorption and emission spectra.[3,4] It is well known that the lowest excited singlet state, S_1, and the lowest triplet state, T, are both of the n-π^* type.[5,6]

Some aspects of the magnetic field on the $S_0 \rightarrow T$ transition have been studied.[7,8] More recently, Eberhardt *et al.* studied the magnetic rotation spectra of the $S_0 \rightarrow T$ absorption of several small organic compounds.[9] Therefore, it seems that the MORD in the $S_0 \rightarrow T$ absorption region should be observed, and the experiments by Shashoua seem to support this idea. However, the f value of the $S_0 \rightarrow T$ absorption of benzophenone has been reported to be 0.6×10^{-7}, [10] and this region is overlapped by the tail of the strong $S_0 \rightarrow S_1$ absorption. Therefore, there remain some questions as to the reality of the observation of the MORD in the $S_0 \rightarrow T$ region of aromatic carbonyl compounds by Shashoua. Accordingly, we undertook an MORD experiment with benzophenone in the region of its $S_0 \rightarrow T$ absorption spectrum and also studied the rotatory dispersion in the spectral region of its $S_0 \rightarrow S_1$ absorption.

Experimental

A Shimadzu spectrophotometer, model QR-50, with an accessory for the observation of natural optical rotation was modified in order to observe the magnetic optical rotation. The light source was a 500-W Xe-lamp. The magnetic field was produced with an electric magnet, its field strength being 5080 gausses at 5.0 A d.c. The strength of the field was determined form Verdet's constant (min.gauss^{-1}.cm^{-1}) of water.[11]

When $\varepsilon(\nu)$ stands for the rotation of a light frequency, ν, of two quartz plates (0.20 cm in total width) and $V(\nu)$, for that of the quartz plates plus a sample with a total optical path of 1.20 cm, the rotation of a sample, $\theta(\nu)$, can be expressed as follows:

$$\theta(\nu) = V(\nu) - \varepsilon(\nu) + \delta(\nu) \quad (1)$$

where δ is the dispersion of air exchanged for the sample (it will be neglected in this experiment). The average experimental error was $\pm 0.005°$ degrees.

For the measurement of the MORD in the $S_0 \rightarrow T$ absorption region, two solutions, consisting of 3.08% and 3.14% of benzophenone in ethanol, and a solution of 1.88% in cyclohexane were used, while for the measurement of the MORD in the $S_0 \rightarrow S_1$ absorption region, a solution of 0.1916% benzophenone in ethanol was used at 10°C, its density being 0.799 g/cc.

Results and Discussion

The magnetic rotation angle (degree) of benzophenone has been measured in the spectral region between 340 and 480 mμ, which corresponds to its $S_0 \rightarrow S_1$ and $S_0 \rightarrow T$ absorption regions. The rotation angles of the samples in the latter region, which were calculated with Eq. (1) for each wavelength, are plotted against the wavelength in Fig. 1, in which, for the sake of comparison, Shashoua's data are also plotted.

It is necessary to use the specific magnetic rotation or the molar magnetic rotation in order to discuss the dispersion phenomenon in detail. The specific magnetic rotation, $[\theta]$, of a solution and the molar magnetic rotation, $[\alpha]_M$ of a solute are defined as follows:[12-14]

$$[\theta] = H\theta/\rho \quad (2)$$

$$[\alpha]_M = (10M/100k)([\theta] - k_s[\beta]) \quad (3)$$

where $[\alpha]_M$ is defined in the same way as the natural

optical activity;[15] H is the strength of a magnetic field; ρ, the density of a solution; M, the molecular weight of the solute; k and k_s, the grams of the solute and the solvent respectively, and β, the specific rotation of the solvent. The MORD values in the region corresponding to the $S_0\rightarrow T$ and the $S_0\rightarrow S_1$ absorptions of benzophenone are shown in Fig. 2.

A. $S_0\rightarrow T$ Absorption Band. The 0–0 band of the phosphorescence spectrum of benzophenone was observed at 24,185 cm^{-1},[4] while the absorption maximum of its $S_0\rightarrow T$ transition was located at 24,300 cm^{-1}.[10] Shashoua observed an abnormal dispersion at 420 mμ[1] which he interpreted as due to the $S_0\rightarrow T$ absorption, since there is no other absorption in the region. As the interaction between a molecule in the triplet state and a magnetic field is proportional to the strength of the field, H, the MORD of benzophenone has been observed in the spectral region corresponding to the $S_0\rightarrow T$ absorption under a magnetic fields almost the same in strength and seven times as strong as that used by Shashoua. We observed no abnormal dispersion near 420 mμ in an alcoholic solution, even under 8000 gausses, nor did we do so in cyclohexane. That the rotation angles in a solution decrease in the three curves near 390 mμ to shorter wavelengths may be ascribed to experimental error, since the absorption coefficient of benzophenone increases abruptly in that region because of the presence of the $S_0\rightarrow S_1$ absorption and since the light that comes through the sample is naturally decreased in intensity. This makes the slit-width of the excitation monochromator wider and, accordingly, the measurement becomes less accurate. Therefore, it may be concluded no abnormal dispersion is observable in the $S_0\rightarrow T$ absorption region within the limits of our experiment. As is shown in Fig. 2, the molecular rotatory dispersion in the region from 390 to 430 mμ is too flat to be explained by either formula, $[\alpha]_M=A\nu^2/(\nu_0^2-\nu^2)^2$ or $[\alpha]_M=B\nu^2/(\nu_0^2-\nu^2)$.[8] Since the slope of the dispersion curve is small and the dispersion is constant at each wavelength in this region, the dispersion should be interpreted as a result of dispersions due to absorptions in the shorter wavelengths. Therefore, even if the rotation of the $S_0\rightarrow T$ transition were observable, it would be included within the limits of experimental error.

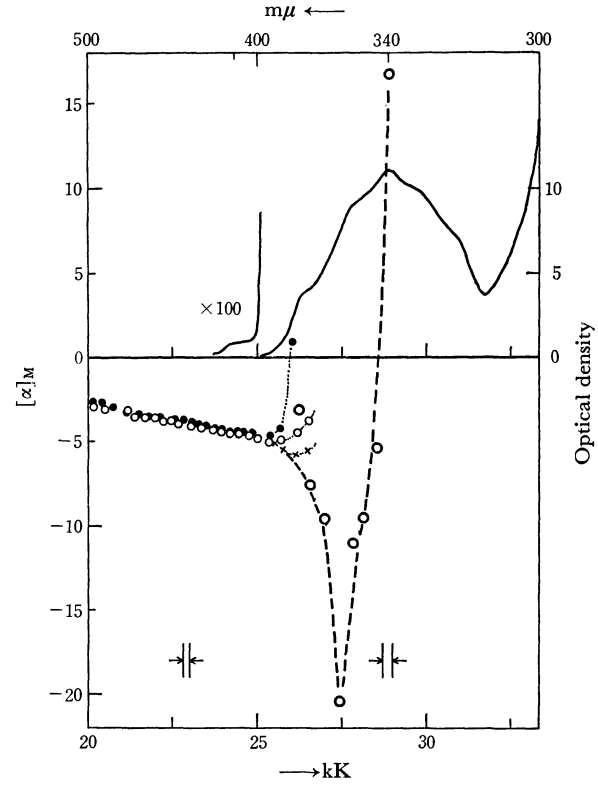

Fig. 2. The MORD and the absorption spectrum of benzophenone ○○○....., ●●●....., -⊙-⊙- in alcohol; ...×... ...×... in cyclohexane.

Theoretically speaking, the dispersion due to the $S_0\rightarrow T$ absorption could be classified as to the A-type.[16] It is, however, impossible to discuss quantitatively the order of the magnitude of the MORD of the $S_0\rightarrow T$ transition according to the results of this experiment. It should be noted that no abnormal MORD, but only a normal MORD, is observed in this region.

B. n–π^* ($S_0\rightarrow S_1$) Absorption Band. The absorption spectrum of benzophenone between 390 and 310 mμ is shown in Fig. 2. The MORD of the n–π^* absorption

15) C. Djirassi, "Optical Rotatory Dispersion," McGraw Hill Co., New York (1960).

16) M. Kimura, H. Kondo, and S. Hattori, *J. Phys. Soc. Jap.*, **20**, 1778 (1965).

region corresponding to the wavelength of the absorption maximum changes in sign at about 340 mμ, it may be interpreted as an I type, according to Shashoua,[2] or as a positive $(B+C/kT)$ type, according to Stephens *et al.*[17] As benzophenone is diamagnetic in the ground state, C is equal to zero.

Then, assuming a damped-oscillator model, according to Stephens *et al.*,[17,18] one obtains the following values:

$$[\alpha]_{M\,max} = 10 - 20\,\text{deg}\cdot l/\text{m.mol},\ \Gamma_{01} = 1.1 - 0.9\,\text{kK},$$

$\omega_{01}=28.7$ kK,

therefore, $B(S_0\rightarrow S_1)=1.8-1.5\times10^{-2}d^2\beta/\text{cm}^{-1}$ where Γ means a damping constant; ω_{01}, an energy difference in cm^{-1} between the S_0 and S_1 states, d, a dipole moment in Debye units, and β, a Bohr magneton.

According to theory of the Faraday effect, the B term has been given as follows:

$$B(S_0\rightarrow S_1) = \sum_{k\neq1} \boldsymbol{M}_{1k}\cdot(\boldsymbol{R}_{01}\times\boldsymbol{R}_{k0})/(\omega_k-\omega_1) + \sum_{k\neq0} \boldsymbol{M}_{k0}\cdot(\boldsymbol{R}_{01}\times\boldsymbol{R}_{1k})/\omega_k, \quad (4)$$

where the subscripts 0, 1, and k mean the ground, the n, π^* excited, and the kth excited states respectively, and where M and R stand for a magnetic and an electric dipole moment vector respectively.

It has recently been reported by Hoffman *et al.*[19] that the both phenyl rings of benzophenone are twisted out of the >C=O plane by 38° from the CNDO–MO calculations. Therefore, it is reasonable to discuss those states with C_2 symmetry. Therefore, the $S_0\rightarrow S_1$ transition is allowed in itself. Vala and Tanaka[20] pointed out, on the basis of their study of the polarized absorption spectra of the 4,4′-dichlorobenzophenone crystal, that there are four states in the 300—230 mμ region, that is, two CT states and two B_{2u}-analogue states, and that the transition moments from the ground state to the one of the former and to the one of the latter are parallel to the z or C=O axis. The order of these four states and the polarization data of these transitions would seem to be inconsistent with the polarization spectra reported by Shimada and Goodman.[5] However, if it is taken into account that these two sets of results are not essentially inconsistent with each other because of the difference in the experimental conditions, it may be concluded that the S_3 state corresponds to one of the B_{2u}-analogues and that the $S_0\rightarrow S_3$ involves two components parallel to the x and the z axes. (By the way, S_2 corresponds to one of the CT states.) Therefore, one obtains:

$$B(S_0\rightarrow S_1) = \sum^{B}\{M^y_{1k}R^z_{01}R^x_{k0}-M^x_{1k}R^z_{01}R^y_{k0}\}/(\omega_k-\omega_1) + \sum^{B}\{M^y_{k0}R^z_{01}R^x_{1k}-M^x_{k0}R^z_{01}R^y_{1k}\}/\omega_k. \quad (5)$$

The R^y_{k0} and R^y_{1k} matrix elements[21] are much smaller than R^x and R^z. As for the R^y_{1k} matrix element, although the S_k–S_1 transitions are not always negligible, the k states must be transformed like the x-coordinate. Therefore, the M^y_{k0} magnetic monents are nearly equal to zero. The main terms of $B(S_0\rightarrow S_1)$ are, then, as follow:

$$B(S_0\rightarrow S_1) = M^y_{13}R^z_{01}R^x_{30}/(\omega_3-\omega_1) + (\text{the similar terms for } k>3). \quad (6)$$

When $\omega_1=26.58$ kK, $\omega_3=39.00$ kK, $f_{10}=0.0029$, and $f_{30}=0.42$, assuming that $|R^z_{01}R^x_{30}|=(|R^z_{01}|^2\cdot|R^x_{30}|^2)^{1/2}=(f_{10}\cdot f_{30}/\omega_1\omega_3)^{1/2}$ and $|M^y_{13}|=10^{-1}-10^{-2}$, the order of the magnitude of the triple scalar products is $10^{-3}-10^{-4}$. It may be said that this order of magnitude is considerably close to our experimental value of $B(S_0\rightarrow S_1)$.

Finally, it can be concluded from the above discussions of the C_2 approximation that the MORD of the $S_0\rightarrow S_1$ transition (n–π^* absorption) of benzophenone occurs as a result of the perturbing state, S_3, being mixed into the S_1 state; then, the magnetic dipole transition is allowed through the magnetic dipole interactions between the S_3 and the S_1 states by the perturbation of the external magnetic field.

Although benzophenone is not a good example for discussing the properties of aromatic molecles by means of the MORD observation, it should be noted that some interesting characteristics of the MORD of benzophenone have been discussed. However, it is impossible to go further until more detailed data are accumulated.

The authour wish to thank Professors On Matumura and Yoshio Shibuya of the Department of Physics, Kyushu University, for providing them with the electric magnet.

Cleaning Effects of the Reactant in the Liquid-phase Isomerization of *m*-Xylene over a Silica-Alumina Catalyst under Pressure

Haruo TAKAYA, Naoyuki TODO, Tadasuke HOSOYA, Toshio MINEGISHI
Mikio YONEOKA,* and Hideki ŌSHIO**

The Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo
**Japan Gas-Chemical Company, Inc., Niigata Laboratory Enoki-cho, Niigata*
***The Research Laboratory, Central Glass Company, Ltd., Imafuku, Kawagoe-shi, Saitama*

(Received November 11, 1970)

The activity of silica-alumina catalyst in the isomerization of *m*-xylene was measured at the temperatures of 290°C, 320°C, 380°C, and 430°C in the liquid phase under a pressure of 300 kg/cm². The observed activities were considerably higher than those in vapor-phase reactions, moreover even after 20 days practically no decline in the activity was observed except for the measurements at 430°C. This superior ability of the catalyst in the liquid phase can be ascribed to the cleaning effect of the liquid reactant: in the liquid-phase reaction the high-boiling by-product, which, in vapor-phase reactions, diminishes the activity because of its strong adsorptivity on the surface sites, is successively dissolved in the reactant; therefore, more surface sites are constantly available for the isomerization. This interpretation was substantiated by the following results: 1) when the reaction was operated in the liquid phase, about eighteen times as much high-boiling by-product was obtained as in the vapor phase; 2) the activity in the liquid-phase reaction was much higher than that in the vapor phase; 3) the decreased activity caused by the interruption of the flow was regenerable when the flow was resumed; 4) the addition of the high-boiling by-product to the reactant *m*-xylene resulted in a considerable decrease in the activity. In addition, the identification of the components in the high-boiling by-products was carried out by means of mass and NMR spectroscopic studies.

In earlier papers, the present authors reported on the effect of pressure on the equilibrium composition of xylene isomers[1] as well as on the rate of the isomerization of *m*-xylene over a silica-alumina catalyst.[2] In these studies it was found that the silica-alumina catalyst revealed considerably higher activity in the liquid-phase reactions than in the vapor-phase reactions. Such an enhanced activity in the liquid-phase reactions can not be explained in terms of the increase in the coverage of xylenes on active sites, since the coverage is already high at atmospheric pressure.[3]

It was presumed from the charactersistic coloration of the products that the enhanced activity in the liquid-phase reaction is caused by the cleaning effect of the liquid reactant; in the liquid-phase reaction, the high-boiling by-product, which, in the vapor-phase reaction diminishes the catalyst activity because of its strong adsorptivity on the surface sites, is successively dissolved in reactant liquid xylenes; therefore, more surface sites are constantly available for the isomerization reaction. The purpose of this study is to confirm the above presumption.

Experimental

As is shown in Fig. 1, the equipment for carrying out continuous liqid-phase xylene isomerization under high pressure consisted of a pressure vessel, 3, containing a catalytic reactor, 4, and auxiliary equipment including pumps for xylene, 1 and 2, a pressure regulator, 5, and a product receiver, 6. All the equipment in contact with the process fluid was made of 18–8 stainless steel. The reactor placed on the lower flange, 7, of a pressure vessel, 1, had two porous sintered 18–8 stainless steel disks fixed by gland nuts, 10, serving to hold it steady as the catalyst bed. The pressure vessel was closely wound with nichrome resistance wire in three separate sections, 11, 12, and 13, to maintain isothermal conditions in the catalyst bed. The entire length of the reactor was covered with asbestos cloth for insulation, 15. The reaction temperature was measured with chromel-alumel theremocouples, 16 and 17, inserted in 18–8 stainless steel pipes, 18 and 19. In this way the temperature of the catalyst bed was controlled within 0.25°C of the desired temperature.

a) TMB: Trimethylbenzene

In preparation for a series of runs, a weighed amount of catalyst was charged into the reactor in a dry box and moistened with *m*-xylene; then the reactor was placed in the pressure vessel. To make a run, *m*-xylene was passed through the reactor at a desired rate of 2 to 24 g/h under a pressure of 300 kg/cm², and then the reactor was heated to the desired temperature.

The catalyst was Nikki N633L silica-alumina crushed to a diameter of 1—1.4 mm or powdered Nikki N633L silica-alumina; both of these had been calcined at a temperature of 500°C for 20 hours. The purity of the *m*-xylene used as a reactant (produced by the Japan Gas-Chemical Co., Inc.) was 99.6 percent, as is shown in Table 1.

The product was analyzed by gas chromatography at 57°C. The column used for this measurement was 4 m in length and 1 mm in dia., and was packed with 5% bentone 34+ 5% DIDP on diasolid L (100—200 mesh).

In order to confirm the inhibiting effects of the high-boiling by-products on catalyst activity and to identify the components, the reaction products were fractionated under a pressure of 6—8 mm Hg and separated into several fractions. The components of the thus fractionated products were analyzed by means of a Hitachi double-beam mass spectrometer and a Varian-type NMR spectrometer. The mass spectra were obtained at ionization voltages as low as 15 V in order to allow only the parent peaks of the components to appear.

Results and Discussion

Activity of Powdered Silica-Alumina in the Liquid-phase Reaction. A heterogeneous catalytic reaction is considered to proceed in a series of mass transfer and kinetic steps. It has already been shown, however, that, in the liquid-phase isomerization of xylene, the kinetic steps are rate-determining up to the temperature of 380°C when powdered silica-alumina is used.

The results obtained at reaction temperatures of 290°C, 320°C, and 380°C under a pressure of 300 kg/cm² are shown in Table 2 and Fig. 2. It has been well recognized, in a study to follow the variation in the catalyst activity, that the variation is insensitive if the reaction has been equilibrated. Therefore, in this experiments the contact times, *W*/*F* (g-cat·h/g), were lowered with an increase in the reaction temperature so as to keep the *p*- and *o*-xylene contents in the products in the region of 0.12 to 0.15. In Fig. 2, the catalyst activities for isomerization and disproportionation are represented by the contents of *p*-xylene and toluene

Temperature	Toluene	*p*-Xylene	*m*-Xylene	*o*-Xylene	TMB[a)]	*W*/*F* g-cat·h/g
320°C	1.6	11.5	71.5	9.3	1.8	2.4×10^{-1}
380°C	0.5	12.2	74.9	9.9	0.5	1.5×10^{-2}
430°C	4.5	14.5	62.4	12.9	5.3	7.4×10^{-3}

respectively, since these contents are nearly equal to those of *o*-xylene and trimethylbenzene respectively. It is clear from this figure that, in each of the three cases, but not at 430°C, practically no decline in the catalyst activity for the isomerization of *m*-xylene was observed, even after 20 days.

From Table 2 it can be seen that the ratio of the toluene content to the *p*-xylene content decreased with the reaction temperature. This result is consistent with the fact that the activation energy for the disproportionation over H–Y zeolite is smaller than that for the isomerization.[4]

Activity of Granular Silica-Alumina in the Liquid-phase Reaction. In Fig. 3 and Table 3, the results obtained by using a granular silica-alumina catalyst (1—1.4 mm in dia.) are shown. Figure 3 indicates that the activity decline did not occur at the temperature of 380°C. However, at the temperature of 430°C a gradual and comparatively large decline was observed; furthermore, the initial ratio of the toluene content to the *p*-xylene content increased considerably.

In an earlier paper[2] it was shown that the ratio of toluene to *p*-xylene increased with the contact time. Therefore, the remarkable increase in the disproportionation products at a higher temperature, such as 430°C, may be partially connected with the appearance of the contribution of the diffusion step to the reaction rate. Under such reaction conditions, the high-boiling by-product may accumulate, since its diffusion rate from the pores will be slower than the accelerated rate of the formation of the high-boiling by-product. This will be the cause of the decline in activity at 430°C.

Activity of Silica-Alumina in Vapor-phase Reactions at Atmospheric Pressure. In contrast with the results obtained in the liquid-phase reaction described above, it has been reported by many workers that, in the vapor-phase reaction, a steep decline in activity is unavoidable.[3,5] In order, therefore, to get information about the characteristic difference between the reaction in the liquid phase under high pressures and that in the vapor phase at atmospheric pressure, the following measurements were carried out. The reaction was operated at 292°C under a pressure of 300 kg/cm²; then the temperature was raised to 378°C at atmospheric pressure and kept at this temperature for 48 hr. After that, the reaction temperature was lowered again to 292°C and the pressure was increased to the initial pressure of 300 kg/cm². The activity indicated by the produced *p*-xylene is shown in Fig. 4. One of the most characteristic features in the vapor-phase isomerization is that the activity decreases steeply from 0.94 g/h g-cat. (B in Fig. 4) to 0.43 g/h·g-cat. (C in Fig. 4).

In addition, it must be noted that the observed activity in the vapor-phase reaction is much lower than that in the liquid-phase reaction. The vapor-phase reaction was carried out at a much higher temperature, at which a sufficient change in activity is observable, than that in the liquid phase. The comparison of the activities between the two reactions was made by the following procedure. As was reported in a preceding paper,[2] in the liquid-phase reaction under pressures the coverage of xylenes on surface sites is 1.0 and the observed activation energy for the isomerization from *m*-xylene to *o*-xylene is 37 kcal/mol, so long as the reaction temperatures are 380°C or less. Thus, the rate calculated for the isomerization from *m*- to *p*-xylene at 380°C by using this activation energy amounts to 76 times that at 292°C. On the other hand, the observed ratio of the rate for the vapor-phase reaction at 378°C to that for the liquid phase at 292°C is only 8.8. It is evident from the comparison that the activity of the silica-alumina catalyst in the liquid phase under a high pressure is much higher than that in the vapor phase.

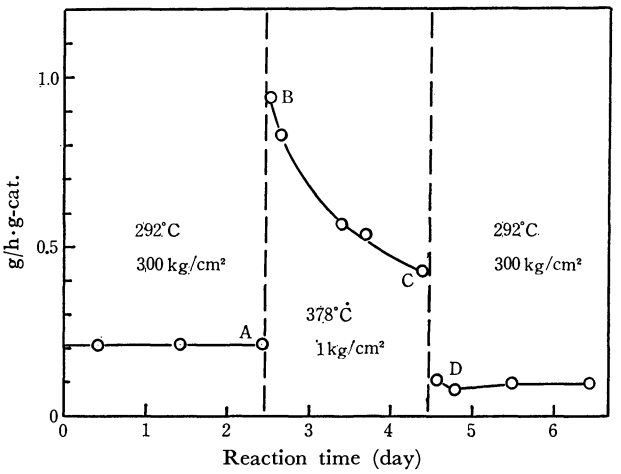

Fig. 4. Activity of silica-alumina in the vapor-phase reaction at atmospheric pressure.

Effect of the Interruption of the Flow on the Activity. As was described in the foregoing paragraph, an increase either in the contact time or in the reaction temperature tended to have the same effects on the

product distribution and on the activity of the catalyst. In order, therefore, to get more detailed information about the effect of the product distribution on the decline in the activity, as an extreme case the flow of the feed was interrupted for 5 hr in the course of a stationary reaction at 320°C under 300 kg/cm²; the consequent variations in the activity and in the product distribution were followed. As is shown in Fig. 5, the *p*-xylene content decreased from a value of 16.6% before the interruption of the flow (A in Fig. 5) to 6.6% immediately after the resumption of the flow (B_2 in Fig. 5), and was then restored to an incomplete level of 14.7% after a two-day reaction. The compositions of the products at the representative points shown in Fig. 5 are tabulated in Table 4. From a comparison of the composition at 1.5 hr after the resumption of the flow (B_1) with those at A and C, it can be seen that the interruption of the flow results in an extraordinary increase in the disproportionation products and unidentified high-boiling by-products. On the basis of these results, it can be considered that the unidentified products, X, presumed to be responsible for retarding the isomerization, were accumulated on the surface sites of the catalyst during the interruption of the flow and were then eluted into the reactant solution after the resumption of the flow.

○: *p*-Xylene. ●: *o*-Xylene. △: Toluene.

The Effect of High-boiling By-products on the Activity. An experiment was carried out at 400°C under a pressure of 300 kg/cm², where the high boiling by-products could be produced in high yields. The total product after 9 days' operation, 1000 g, was distilled under a reduced pressure of 6—8 mmHg in the temperature ranges of 100—125°C (fraction 1), 125—150°C (fraction 2), and 150—200°C (fraction 3). The yields of these fractions and the residue are shown in Table 5.

Figures 6 and 7 show, respectively, the effects of the addition of fraction 2 and the residue on the activities; *m*-xylene solutions containing 2 weight percent of fraction 2 and 1 weight percent of the residue were passed through the catalyst bed for 4 hr in the course of a stationary reaction, using pure *m*-xylene as the reactant at 280°C under a pressure of 300 kg/cm². From Fig. 6 it is obvious that, by the addition of a minute quantity of the fraction 2, the *p*-xylene and *o*-xylene contents diminished and the toluene content increased. The varied contents were, however, restored to levels of about 90 percent of the initial values 4 days after the reactant was changed to pure *m*-xylene. As to the experiment with using a *m*-xylene solution containing 1 weight percent of the residue, the effect differed from that of fraction 2, as is shown in Fig. 7, the contents of *p*-xylene and *o*-xylene diminished to values less than half of the initial contents, whereas

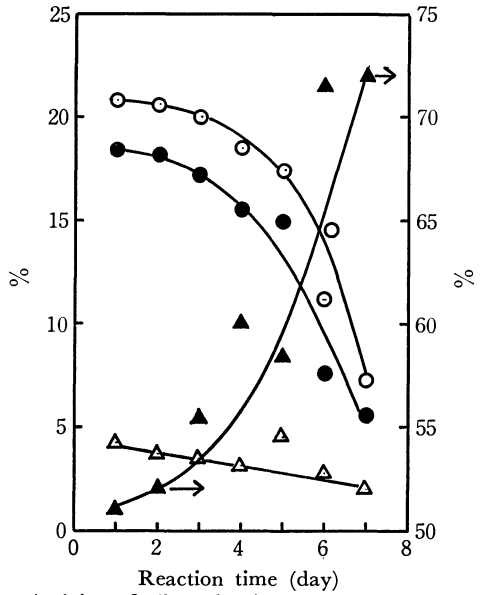

Fig. 8. Activity of silica-alumina at atmospheric pressure. W/F=0.5 h.

	1st day	2nd	3rd	4th	5th	6—7th
Reaction temperature(°C)	430	440	450	460	490	500

○: *p*-Xylene. ●: *o*-Xylene. ▲: *m*-Xylene. △: Toluene.

the toluene content was unaltered. Moreover, in this case, the reduced contents of *p*- and *o*-xylene were scarcely restored even 4 days after the reactant had been changed to pure *m*-xylene. The results clearly indicate that the high-boiling by-products have an inhibiting effect on the isomerization of *m*-xylene.

In contrast to the case of the liquid-phase isomerization under high pressure, only 1 g of high-boiling by-products could be separated from the product (800 g) obtained by 7 days reaction operated at a temperature above 430°C under atmospheric pressure. This result, when considered in connection with the remarkable decline in activity shown in Fig. 8, indicates that, in the vapor-phase isomerization high-boiling by-products are not easily desorbed from the catalyst surface, but are accumulated on the surface, this accumulation results in a large decline in the activity and in the low activity in the vapor-phase reaction.

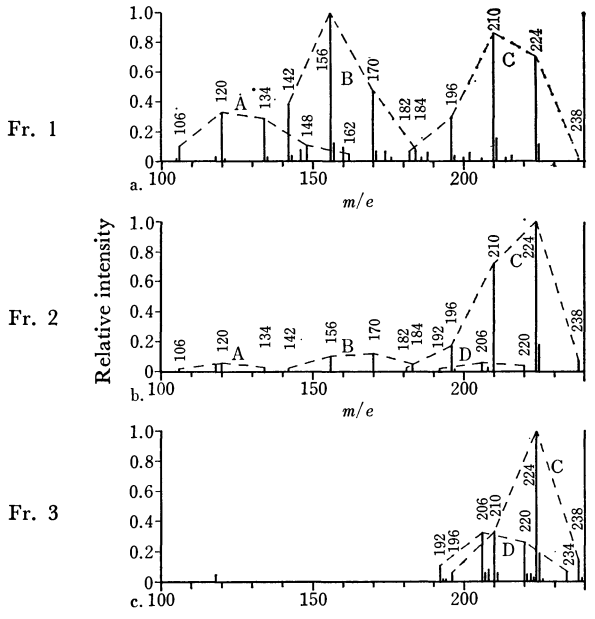

Fig. 9. Mass spectra of the fractions 1, 2 and 3.
A: Polymethylbenzene. B: Polymethylnaphthalene.
C: Polymethyldiphenylmethane. D: Polymethylanthracene or Polymethylphenanthrene.

Identification of High-boiling By-products. Figure 9 shows the mass spectra of the fractions 1, 2, and 3. It can be seen that all the spectra consist of several homologous series of the parent peaks: the successive peaks in a homologous series differ in mass number by 14, corresponding to the replacement of a hydrogen atom by a methyl group.

In the fractions 1 and 2, three series of polymethyl compounds were observed: A and B correspond to polymethylbenzene and polymethylnaphthalene respectively, while C corresponds to polymethyldiphenyl, polymethyldiphenylmethane, or polymethyldiphenylethane. The D series in the fractions 2 and 3 was identified as polymethylanthracene or polymethylphenanthrene.

Table 5. High-boiling by-products separated from the products (1000 g) of the reaction at 400°C under a pressure of 300 kg/cm². Distillation pressure: 6–8 mmHg

Fraction number	Temperature range (°C)	Yield (g)
1	100—125	3.2
2	125—150	14.7
3	150—200	3.0
Residue		1.4

As is shown in Table 5, the yield of fraction 2 amounts to 70 percent of total high-boiling by-products.

Therefore, the studies were concentrated upon the more accurate identification of the possible components of the main series, C. For this purpose, the fraction 2 was analyzed by means of NMR spectroscopy. The observed spectrum shows that all the polymethyl compounds have a methylene group in their structures. Moreover, the ratio of the number of the hydrogen atom in the methyl group to that in the methylene group was 6.5, and the ratio of the number of the hydrogen atom bound to the aromatic ring to that in the methylene group was 4.0. These findings imply

Table 6. Ratios of numbers of hydrogen atoms in the methyl group and bound with aromatic rings to that in methylene groups

	$-CH_2-$	$-CH_3-$	$-H$
The observed ratio for the fraction 2	1	6.5	4

The calculated ratios from the formulas

Mass number	Polymethyldiphenylmethane			Polymethyldiphenylethane		
	$-CH_2-$	$-CH_3$	$-H$	$-CH_2-$	$-CH_3$	$-H$
196	1	3	4	1	0.75	2.25
210	1	4.5	3.5	1	1.5	2
224	1	6	3	1	2.25	1.75

that the existence of polymethyldiphenyl should be excluded. Thus, the component must be either polymethyldiphenylmethane or polymethyldiphenlethane. The ratios calculated from the formulas of these compounds are also shown in Table 6. The agreement between the calculated and observed values is not satisfactory. However, it seems to be reasonable to say that the main component in the C series is polymethyldiphenylmethane rather than polymethyldiphenylethane, when one takes into account the fact that minute amounts of the compounds which have no methylene group, such as polymethylnaphthalene and polymethylanthracene, raise both the ratios.

We are very grateful to Dr. Yamamoto for his help in the measurements of the NMR spectra and to Dr. Fukuda for his help in the measurements of the mass spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2301—2308 (1971)

Linear Antiferromagnetic Interaction in Organic Free Radicals

Jun YAMAUCHI
The Institute for Chemical Research, Kyoto University, Uji
(Received December 26, 1970)

The static magnetic susceptibilities from 1.8°K to 300°K, and the ESR spectra from 1.5°K to 300°K, of several organic free radicals have been measured on powder samples. The broad maxima in the susceptibility which indicate the antiferromagnetic interaction and the broadening of the ESR absorption lines have been observed. The data are analysed on the basis of the linear Heisenberg model and shown to be consistent with the one-dimensional magnetic chain model of isotropic exchange interaction. Discussions are made of the grounds of susceptibility, the ESR, and the specific heat measurements. In addition to a short-range ordering of spins, the possibility of long-range ordering is also discussed in two radicals, BDPA-Bz and *p*-Cl-BDPA, on the basis of discontinuities in the slope of susceptibility, the rapid broadening of the ESR linewidth, and the disappearance of the ESR absorption.

Since the beginning of the history of free radical chemistry in 1900 when Gomberg published his discovery of the first stable radical, triphenylmethyl[1] a number of stable radicals have been prepared and investigated by means of modern techniques.[2] It is now possible to detect, and even to study, extremely unstable free radicals. As it is our purpose to examine the exchange interaction between unpaired electrons, the present study is confined to the stable radicals which can be obtained in a substantial concentration. A free radical is, as is well known, an atom, molecule or complex which contains one or more unpaired electrons. In the present paper we are concerned exclusively with organic free radicals which have one unpaired electron on each molecule.

The magnetic properties of the organic free radicals have attracted much interest in recent years. Although the radical molecules constituting the solid are quite complicated, the solid itself can be simply regarded as an array of molecules, each containing one unpaired electron in its highest filled orbital. At first sight it seems that the paramagnetic susceptibility can be described by the Curie law: $\chi_e = Ng^2\beta^2S(S+1)/3kT$, which can be applied to the radical solids with N spins of $S=1/2$. For all radicals measured above 77°K, however, this simple relation does not hold; the deviation apparently can be explained by the Curie-Weiss law with negative Weiss constants, which imply an antiferromagnetic exchange interaction between the unpaired electrons. Some of the ion-radical salts and charge-transfer complexes exhibit an anomalous paramagnetism which can be interpreted in terms of an exchange-coupled pair model.[3] This anomalous paramagnetism arises from strong exchange coupling between the unpaired electrons on adjacent molecules, each pair forming a lower singlet state and an upper triplet state. As the temperature is lowered, the singlet level becomes increasingly populated at the expense of the triplet level, so that the susceptibility decreases. The molar susceptibility for the singlet ground state dimers, each having a triplet state lying at an energy, Δ, above this ground state, is given as:

$$\chi = (Ng^2\beta^2S(S+1)/3kT)[1+(1/3)\exp(\Delta/kT)]^{-1}, \quad (1)$$

where $S=1$. In the ion-radical salts or charge-transfer complexes, the charged diamagnetic molecules may be considered to play an important role in forming dimers. For the sake of simplicity, we will limit ourselves to the radicals which are electrically neutral. The unpaired electron occupies a molecular orbital spreading over a whole molecular framework. According to the investigation of the hyperfine splittings of nitroxide radicals

like TANOL,[4] the unpaired electron is exclusively localized on the N–O bond.[5] On the other hand, BDPA[6] has delocalized spin densities, even on the carbon atoms of biphenylene.[7,8] We studied the magnetic properties of two types of radicals in order to ascertain how the exchange interaction between the unpaired electrons would be affected by the delocalization of an unpaired electron. The stable radicals studied here are the following compounds.

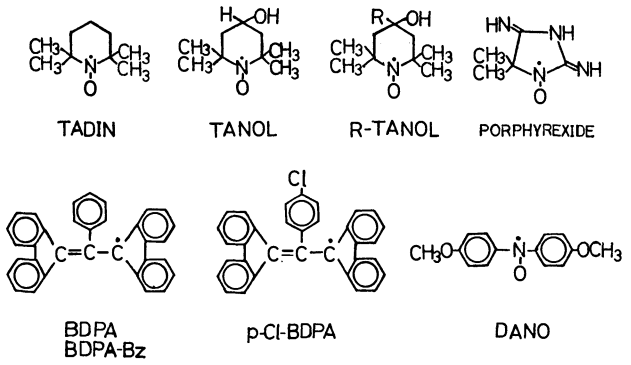

Fig. 1. Molecular structures of the radicals.

In many stable neutral radicals the susceptibility deviates from the Curie-Weiss law at low temperatures and shows a broad maximum. Rozantsev *et al.* have observed the temperature dependence of the intensities of the ESR spectra of TANOL and found a broad maximum in the intensities near 6°K.[9] The susceptibility had previously been measured by several investigators,[10,11] and a broad maximum at 6.5°K had been found. They suggested that this behavior of the paramagnet could be well described by the Heisenberg one-dimensional model with isotropic antiferromagnetic interaction. The magnetic susceptibility of BDPA-Bz has been measured above the temperature of liquid nitrogen by Duffy[12] and in the helium region by Edelstein *et al.* and by Pake *et al.*[13] Hamilton *et al.*[14] have used the proton Knight shift to measure the susceptibility and also measured the specific heat. They obtained the maximum susceptibility at 5.7°K and explained the phenomena tentatively. However, the accuracy of the measurements and the methods of analysis do not seem satisfactory.

Organic free radicals have plate-like structure of a low symmetry and condense into a crystalline solid with a small coordination number, as may be seen from the X-ray analysis of several radicals.[15–17] Therefore, the radicals may form a magnetic chain or plane different from that of the three-dimensionally interacting spin system. Since the distance between chains or planes is presumed to be much greater than the distance between nearest molecules in the chain or plane, the exchange coupling between nearest-neighbor electrons in different chains or planes is much weaker than that between nearest-neighbor electrons in the same chain or plane. The orbital occupied by the unpaired electrons is the $2P_z\pi$ - orbital, which has a uniaxial angular dependence. Therefore, we conjecture that organic free radicals are more likely to form a "magnetic chain" than a "magnetic plane."

From the theoretical point of view, the one-dimensional model of spin interaction is of considerable interest since it admits of an exact solution under certain simplifications which are actually possible in some cases. The magnetic behavior has several features different from that of usual three-dimensional spin systems.

The susceptibility and ESR measurements of several neutral stable radicals using a magnetic torsion balance and an ESR spectrometer at low temperatures were carried out in order to examine the exchange interaction and spin correlation in organic free radicals and in order to compare the observed values with the theoretically calculated ones. Later, more quantitative interpretations of the magnetic behavior will be made using the data published previously.

Experimental

The radical TANOL and its derivatives were prepared through the oxidation of the corresponding amine of 4-substituted 2,2,6,6-teramethylpiperidine following the process of Rozantsev.[18] They were purified a few times through recrystallization from ethereal alcohol. The details of the synthesis have been published elsewhere.[19] The samples of BDPA and its derivatives were prepared according to the procedures of Koelsch[20] and of Kuhn and Neugebauer.[8] After recrystallization from a benzene-benzine solutions, the melting points were found to agree well with the values in the literature. The results of the elementary analysis of carbon, hydrogen and nitrogen of each sample corresponded closely to the calculated values. As reported by Kuhn *et al.*, the radical solid BDPA complexes readily with such solvent molecules as benzene and acetone. BDPA with 1 mol of benzene will hereafter be abbreviated as BDPA-Bz, and BDPA containing no benzene molecule, as BDPA. BDPA-Bz was heated *in vacuo* at about 90°C for several hours; BDPA was thus obtained. BDPA, whose data have been published previously, is suspected to contain 1 mol of crystal benzene.

The susceptibility measurements were done, by means of a magnetic torsion balance described elsewhere,[21] on powder

samples of about 100—50 mg in a field of 8.8 KOe. The measurements on all the samples were carried out in the temperature region attainable by pumping of liquid helium. No ferromagnetic impurities were found in any samples by checking the field dependence of magnetization up to 12 KOe at 4.2°K. The temperatures were measured with a carbon resister and an AuCo-Cu thermocouple calibrated by measuring the magnetic susceptibility of manganese Tutton salt and the vapor pressures of liquid helium, liquid hydrogen, and liquid nitrogen.

The ESR absorption spectra were observed between 1.5°K and 77°K using a JES-S1OE-type X-band spectrometer with an 80 Hz field modulation. The cavity with the TE_{102} mode was immersed in a liquid helium bath. The temperatures were measured with a carbon resister and an AuCo-Cu thermocouple attached to the cavity wall. An aqueous solution of peroxylamine disulfonate was used as a standard for the estimation of the *g*-value at room temperature. The magnetic field was calibrated from a hyperfine splitting of Mn^{2+} in MgO.

Results

Susceptibility. The data have been corrected for diamagnetism using Pascal's constants.[22] The calculated diamagnetic contribution is listed in Table 1. The absolute molar susceptibility, χ_M, corrected for diamagnetism, was compared with various theoretical calculations. All the radicals discussed here obey the Curie-Weiss law with a negative Weiss constant, θ, in a relatively high temperature region. The radical concentration of each sample, as determined from the susceptibility, was found to be nearly 100% within the limit of experimental accuracy. At lower temperatures, the molar susceptibility, however, deviates from the Curie-Weiss law and reaches a broad maximum at the T_m temperature. The values θ, T_m, and χ_{max} (the maximum susceptibility at T_m) of each sample are summarized in Table 1. When the temperature is decreased further, the susceptibility decreases comparatively slowly towards a finite susceptibility at $T=0$°K, $\chi_{T=0}$. The values $\chi_{T=0}$ in Table 1 are roughly estimated by the extrapolation of the χ_M-T curve. Figures 2—4 show the molar susceptibilities of the radicals.

ESR. ESR measurements were carried out in powder samples. The *g*-values were practically isotropic and were close to the free electron *g*-factor in all radicals; the latter factor is used in the theoretical

calculation of susceptibility. The ESR absorption spectrum in each sample shows a single line which has an exchange-narrowed Lorentz shape. The linewidth, which was taken to be the peak-to-peak linewidth of the first derivative of the absorption spectrum, started to increase rapidly as the temperature was decreased below T_m, where the susceptibility went through a broad maximum. The ESR lines of all the radicals except *p*-Cl–BDPA[23] can be observed above the temperature of 1.8°K; the ESR line of *p*-Cl–BDPA broadens out and disappears as the temperature approaches 2.8°K from higher temperatures. Figures 5—7 show the temperature dependence of the linewidths of the radicals.

Discussion

Susceptibility. It may be conjectured that the neutral organic free radicals, unlike ion-radical salts, have little tendency to form dimers. This fact is confirmed by a comparison of the experimentally-obtained susceptibility with that of the dimer model described by Eq. (1). If one enumerates the energy separation between singlet and triplet states, Δ, of Eq. (1) from the following relation;

$$\Delta/k = 1.60T_m, \tag{2}$$

Eq. (1) will reproduce qualitatively the experimental results of susceptibility, but the magnitude of the paramagnetic susceptibility differs from the observed value. The theory predicts a much larger value, χ_{max}, at T_m than the observed one; besides the deviation of the susceptibility becomes larger as the temperature is decreased below T_m. For instance, χ_{max} in TANOL is equal to 226×10^{-4} emu/mol; this is in contrast to the theoretical χ_{max} value of 298×10^{-4} emu/mol calculated from Eqs. (1) and (2) using T_m=6.5°K. Therefore, it may safely be said that no pairing of electron spins in the radicals and no dimerization of molecules occur.

Edelstein has successfully employed the linear Ising model for the qualitative interpretation of the susceptibilities of BDPA–Bz and PAC.[24] The Ising models are theories treating spatially-localized spins between which the exchange coupling is represented as $-2JS_{iz}S_{jz}$. Although Stout and Chisholm have treated the small interactions between Ising chains in $CuCl_2$ by introducing a molecular field,[25] organic free radicals have never been observed to have so large an anisotropic character. In fact, all organic free radicals have nearly isotropic *g*-values, so that the linear Ising model does not explain our results quantitatively. Therefore, we presume that it is not adequate to discuss the magnetic properties of organic free radicals on the basis of Ising models.

Soos *et al.* have analysed the temperature dependence of the magnetic susceptibility by treating the system as an alternating one-dimensional chain of Heisenberg spins;[26] the Hamiltonian is given by:

$$H = \sum_{i=1}^{N/2}\{J(1+d)S_{2i-1}S_{2i} + J(1-d)S_{2i}S_{2i+1}\}, \tag{3}$$

where $J(1+d)$ and $J(1-d)$ are the exchange constants between neighboring spins and where d is a parameter that represents the degree of alternation. Unfortunately, the theoretical susceptibility results do not agree with the more exact treatments for the limiting cases of d=1 and d=0. Recently Duffy and Barr obtained the exact eigenvalue spectrum and thermodynamic prop-

erties of the same Hamiltonian as Eq. (3) and compared their results with the experimental results.[27] They fitted the susceptibility data with success in ion-radical salts, charge-transfer complexes, and only PAC and doubly-nitrated DPPH among neutral radicals. When $d \neq 0$, that is, in an intermediate alternation, there is an excited state with an energy gap from the ground state at $T=0$°K, so the susceptibility decreases exponentially as $T \to 0$°K. These schemes fail to explain a finite susceptibility at $T=0$°K unless $d=0$.

Previous to these investigations, theoretical calculations of the thermodynamic properties of one-dimensional long chains with isotropic and anisotropic interactions were made by Griffiths[28] and by Bonner and Fisher.[29] The corresponding spin Hamiltonian is given by:

$$\boldsymbol{H} = -2J\sum_{i=1}^{N}\{\boldsymbol{S}_{iz}\boldsymbol{S}_{i+1z}+\gamma(\boldsymbol{S}_{ix}\boldsymbol{S}_{i+1x}+\boldsymbol{S}_{iy}\boldsymbol{S}_{i+1y})\}, \quad (4)$$

which reduces to the Ising case when $\gamma=0$ and to the Heisenberg case when $\gamma=1$. Bonner and Fisher also estimated the behavior of susceptibility and specific heat for $N \to \infty$. The susceptibility for a pure antiferromagnetic Heisenberg chain displays a round maximum, and the corresponding specific heat exhibits an anomaly of the Schottky type. One of the crystalline solids which clearly exhibit antiferromagnetic linear chain behavior is $Cu(NH_3)_4SO_4 \cdot H_2O$, whose magnetic quantities can be explained qualitatively and also quantitatively in terms of this model, since each Cu^{2+} ion couples within a –O–Cu–O–Cu–O– chain and since interactions between chains are negligible.[30]

Organic free radicals have a plate-like structure of low symmetry with a small coordination number. Thus, the radicals may be expected to form magnetic chains, as has already been described in the introduction. Therefore, it is reasonable to analyse and discuss the results using the theory of the one–dimensional Heisenberg model based on Bonner and Fisher's calculations, which will be briefly summarized in the case of isotropic Heisenberg interaction with $\gamma=1$ and $N \to \infty$ in Eq. (4). The susceptibility displays a rounded maximum of height:

$$\chi_{max}/(g^2\beta^2/|J|) = 0.07346 \quad (5)$$

at

$$kT_m/|J| = 1.282. \quad (6)$$

The corresponding specific heat shows a Schottky-type anomaly associated with the broad susceptibility maximum and goes through the maximum of height:

$$C_{max}/Nk = 0.350 \quad (7)$$

at

$$kT_{mc}/|J| = 0.962. \quad (8)$$

It is worth remarking that χ_M can approach a finite nonzero value, $\chi_{T=0}$, at $T=0$°K, as there is no energy gap between the ground state and the first excited states when $\gamma=1$ and $N \to \infty$. $\chi_{T=0}$ is given by the following relation with the parameter J:

$$\chi_{T=0}/(g^2\beta^2/|J|) = 0.05066. \quad (9)$$

One can obtain the J parameter in Eq. (4) from several relations, (5), (6), (8), and (9). Assuming the J value from the T_m value experimentally obtained with the use of the (6) relation, we can evaluate the χ_M, χ_{max}, and $\chi_{T=0}$ values, which are dependent on the manner of evaluating J. On the other hand, the $\chi_{max}/\chi_{T=0}$ and T_m/T_{mc} ratios are independent of the J parameter and are equal to 1.45:1 and 1.33:1 respectively.

TANOL System: The temperature dependence of the magnetic susceptibilities of TANOL and TADIN[31] have been reported by several investigators.[10,11,32] In the case of TANOL, the exchange parameter was obtained as $|J|/k=5.0$°K; this agrees well with that obtained from the $\theta=2zJS(S+1)/3k$ relation with a nearest-neighbor parameter of $z=2$, with $S=1/2$, and with the Weiss constant $\theta=-6.0$°K. The χ_{max} value, 218×10^{-4} emu/mol, thus obtained from Eq. (5) is in good agreement with the experimental value, $\chi_{max}=226\times10^{-3}$ emu/mol. $\chi_{T=0}$ was then evaluated to be 180×10^{-4} emu/mol by extrapolation, while the same value can also be expected from Eq. (9). The Heisenberg linear chain for $N \to \infty$ and $\gamma=1$ predicts the theoretical ratio of $\chi_{max}/\chi_{T=0}=1.45$. On the other hand, the observed ratio, $\chi_{max}/\chi_{T=0}$, is equal to 1.3 (Table 1); this is in quite good accord with the theory. It may be said, therefore, that the spins in TANOL interact one-dimensionally with each other and that the interaction is isotropic in the sense of Heisenberg exchange interaction. A precise determination of the crystallographic structure of TANOL is monoclinic: $a=7.052\pm0.010$ Å, $b=14.081\pm0.018$ Å, $c=5.780\pm0.010$ Å, and $\beta=118°40'\pm10'$. The molecules are aggregated by the hydrogen bond and form chains parallel to the a-axis.[16] However, it is difficult to conclude whether the direction of linear exchange interaction is along the direction of hydrogen bonding or along the c-axis, where the lattice constant is the shortest. We are now engaged in clarifying this point.

The susceptibility of TADIN shows a broad maximum at $T_m=2.3$°K, after which χ_M decreases slowly towards a constant susceptibility. $J/k=-1.8$°K, which is obtained by following the same procedure as has been described above, reproduces well the experimental susceptibilities, χ_M, χ_{max}, and $\chi_{T=0}$. The $\chi_{max}/\chi_{T=0}$ ratio, 1.3:1, is also in good accord with the theory. Therefore, TADIN is considered to be a one-dimensional Heisenberg antiferromagnet.

The susceptibilities of TANOL derivatives (R= methyl, ethyl, phenyl, and cyclohexyl in Fig. 1) exhibit no broad maxima in the temperature range as low as 1.8°K, but deviate slightly from the Curie-Weiss law below about 4°K. The Weiss constants were found to be about 0°K (methyl and ethyl derivatives), −1°K (phenyl derivative), and −2.5°K(cyclohexyl derivative). The bulkier a substituent a radical has, the larger the Weiss constant becomes, but the exchange interactions are less than 1.5°K. The fact that TANOL has such a large exchange interaction as compared with those of TANOL derivatives may be ascribed either to the difference in the lattice distance of the crystal

axis along which the magnetic chains are formed or to the difference in the strength of the hydrogen bond, which was found out by studying the infrared absorption spectra in Nujol. The details of this ascription will be published elsewhere.[33]

BDPA System: The molar susceptibility of BDPA-Bz, shown in Fig. 3, exhibits a broad maximum at $T_m=5.6$°K. χ_{max} and $\chi_{T=0}$ are obtained as 199 and 150×10^{-4} emu/mol respectively. Considering $\chi_{max}/\chi_{T=0}=1.3$ and the temperature dependence of the susceptibility in the especially low temperature region, the data can also be well explained in terms of the Hamiltonian ($N\to\infty$ and $\gamma=1$) described above. Thus, we obtain $J/k=-4.4$°K. If one excludes benzene molecules from BDPA-Bz by heating, the exchange interaction becomes larger, going from −4.4°K to −8.5°K. This radical, BDPA, also shows a susceptibility decreasing towards a finite susceptibility at $T=0$°K after $T_m=10.9$°K. However, the $\chi_{max}/\chi_{T=0}$ ratio, 1.7:1, is larger than the theoretical one, since $\chi_{max}=153\times10^{-4}$emu/mol is a little larger than the theoretical $\chi_{max}=130\times10^{-4}$ emu/mol. Thus, BDPA also has a one-dimensional Heisenberg interaction like BDPA-Bz. This fact can be understood by assuming that the removal of benzene molecules does not affect the spin structure in BDPA-Bz, but causes a stronger exchange interaction.

The data of *p*-Cl-BDPA are similar to those of BDPA-Bz, as is shown in Fig. 4 and summarized in Table 1. Therefore, the magnetic properties of *p*-Cl-BDPA are similar to those of BDPA-Bz. However, a discontinuity in the slope of susceptibility was found at about 2.8°K, after which the susceptibility rises again. This rise in the susceptibility has also been found in the neighborhood of 1.7°K in BDPA-Bz.[13] Such a discontinuity in *p*-Cl-BDPA indicates that there may be a phase transition into an antiferromagnetic state. This will be discussed below, together with the data of ESR measurements.

In the magnetic properties of BDPA-Bz and *p*-Cl-BDPA, there is a slight but significant difference between experiment and theory; that is, χ_{max} is lower than the theoretically-predicted value. At first sight, the radical concentration seems to become lower as the temperature is lowered. At T_m an assumed concentration decreases to 80% in both radicals. However, this is not due to a poor radical concentration, as one can understand from the facts that: 1)if the radical has a low concentration, the amount of the deviation of susceptibility is constant at all temperatures, 2) the radical concentrations of BDPA-Bz and *p*-Cl-BDPA are equal to above 100% if we estimate them from the susceptibility about 77°K, and 3) BDPA after the heat treatment of BDPA-Bz has about a 100% radical concentration in all temperature ranges. Although this effect is not completely accountable for at present, it may be associated with the electronic properties of allyl radicals, which behave as semiconductors,[34] as has been pointed out by Fedders and Kommandeur.[35]

ESR. The distinct character of linear magnetic chains is the development of short-range magnetic ordering without a definite transition to long-range ordering at low temperatures. The short-range magnetic ordering developed remarkably near T_m can be observed in the increase in the ESR linewidth below T_m. The data are illustrated in Figs. 5—7. The linewidth of each sample increases with the lowering of the temperature below T_m. Recently, the temperature dependence of the exchange-narrowed ESR linewidth of linear antiferromagnetic chains with the anisotropic exchange coupling was calculated by Kawasaki, using the double-time Green function method.[36] She found the following relation:

$$\Delta H/\Delta H_\infty = AT^{-1/4} \tag{10}$$

in the vicinity of 0°K, where ΔH_∞ is the linewidth at an infinite temperature and where A is a constant. The observed linewidth *versus* temperature below 77°K can be fitted to the following empirical relation:

$$\Delta H = \alpha \exp(\beta T_m/T) \tag{11}$$

where α and β are constant and where α may imply ΔH_∞. The α and β values of each sample are summarized in Table 2. We cannot fit the data with the relation (10) over a wide temperature region, even when the other exponents are applied. The broadening of the resonance may be attributed to an increase in the correlation time of the exchange motion because of magnetic ordering below the temperature of the susceptibility maximum. This pronounced increase in the linewidth of the paramagnetic resonance provides additional support for the present interpretation made from the susceptibility data.

Table 2. Parameters of temperature dependent linewidth: $\Delta H=\alpha\exp(\beta T_m/T)$

	T_m (°K)	α (Gauss)	β
TANOL	6.5	8.4	0.20
TADIN	2.3	8.2	0.48
BDPA-Bz	5.6	2.8	0.28
BDPA	10.9	3.5	0.49
p-Cl-BDPA	5.6	1.6	0.51

In *p*-Cl-BDPA the relation (11) holds above 4°K. The intensities of the ESR spectra decrease immediately below 4°K, and simultaneously the ESR linewidths broaden out. The disappearance and the broadening of the lines may be attributed to the coupling between neighboring chains, which induces a spontaneous magnetization. This phenomenon may imply the onset of long-range ordering, as it may be considered that the subsequent rapid increase in linewidth is the result of the critical fluctuation of electron spins in the neighborhood of the transition temperature.

In the case of BDPA-Bz, the ESR signal is so feeble that we cannot observe an absorption at about 1.6°K. This fact is probably related to the specific heat anomaly at 1.78°K[14]

Specific Heat. According to the specific heat measurements of TANOL[37] and BDPA-Bz,[14] Schottky-type anomalies associated with the broad maximum susceptibility have been obtained at 4°K and 3°K respectively. The anomalies are predicted by the one-dimensional Heisenberg model. The maximum specific heat in TANOL is nearly what is expected from Heisenberg chains rather than from Ising chains, although in BDPA-Bz it is much smaller. This discrepancy in magnitude might be explained by assuming some type of electronic band structure.[35] The ratio of T_m to T_{mc} is unconnected with the exchange integral, J, and is equal to 1.3 for Heisenberg chains and to 2.4 for Ising chains. The observed T_m/T_{mc} ratios 1.6:1(TANOL) and 1.7:1(BDPA-Bz), deviate a little from the theoretically predicted ratio. The agreement with the theory is not so bad, however, if one takes into account of the accuracy of T_{mc}. Thus, the results of the specific heat measurements of TANOL and BDPA-Bz are not contradictory to the interpretation from the susceptibility measurements.

Other Radicals. The magnetic properties of other radicals will be discussed briefly below.

In porphyrexide the magnetic properties can be explained by the Ising model rather than by the linear Heisenberg model.[38] This is probably because the radical has a very small amount of anisotropy, which reduces the Heisenberg-type magnetic properties to Ising-type ones. The effect of this anisotropy was found in the temperature dependence of the ESR linewidth.[39]

The susceptibility data of DANO (di-*p*-anisylnitroxide) were shown by Duffy *et al*[40] to be consistent with the nearest-neighbor antiferromagnetic Heisenberg exchange of a quadratic layer lattice, because the radical is a magnetically layered crystal, as may be infered from the X-ray crystallographic study of Hanson.[15] However, as is shown in Table 1, $\chi_{max}/\chi_{T=0}$ and T_m/T_{mc} (T_{mc}=3°K) are in good agreement with the linear Heisenberg model. This radical presumably has a one-dimensional interaction, for it is possible that the radical forms a magnetic chain instead of a magnetic quadratic layer. This may be understood by taking into account the fact that the molecular orbitals of the unpaired electrons have a uniaxial angular dependence.

Exchange Interaction Mechanism. The exchange interaction originates from an overlap of the wave functions of the unpaired electrons. In compounds of transition ions, *d*-orbitals spread spatially in several directions so that magnetic planes can be formed. On the other hand, in organic free radicals the wave functions are described by $p_z\pi$-orbitals which have a uniaxial angular dependence. The exchange mechanism may be such that the interaction between unpaired electrons takes place through the overlap of the π-orbitals, as is shown in Fig. 8. Therefore, it may be understood that the neutral organic free radicals are one-dimensional antiferromagnets.

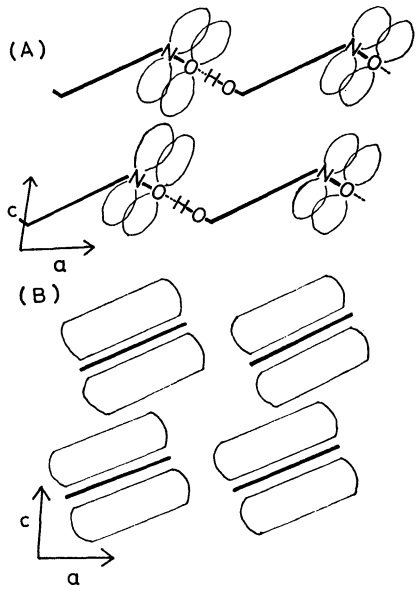

Fig. 8. Presumed exchange interaction mechanism between the unpaired electrons localized on N–O bonds (A) and between the delocalized unpaired electrons (B).
—: radical molecule, (⬭): π electron cloud.

Possible Existence of Long-range Ordering. It is well known theoretically[41] that the isolated magnetic linear chains do not have any magnetic phase transition but a broad maximum susceptibility, and that, in the presence of a small interaction between chains there occurs a magnetic transition from the short-range ordered state to the long-range ordered state in the lower temperature region. A sharp cooperative transition in organic free radicals has never been observed, although phase transitions associated with crystal deformation have been found.[42] There is a possibility for neutral organic free radicals to go into a long-range ordered state, since the interaction between chains cannot always be neglected. The data on BDPA-Bz and *p*-Cl-BDPA are considered to imply a long-range order at the Néel temperature of 1.78°K and 2.8°K respectively, because of: 1) the discontinuities of $d\chi_M/dT$ found at 1.7°K in BDPA-Bz[13] and 2.8°K in *p*-Cl-BDPA, 2) the rapid broadening and subsequent disappearance of the ESR absorption lines, and 3) the specific heat anomaly at 1.78°K in BDPA-Bz.[14] The long-range order in other radicals would be found if experiments were performed at lower temperatures.

Conclusion

The magnetic properties of neutral organic free radicals have been discussed qualitatively and quantitatively

on the basis of a linear Heisenberg model and on the basis of the following data: 1) the qualitative behavior of χ_M, 2) χ_{max} at T_m, 3) finite $\chi_{T=0}$, 4) $\chi_{max}/\chi_{T=0}$, 5) the Schottky-type anomaly of specific heat, 6) T_m/T_{mc}, and 7) the ESR linewidth. Although the interpretations may be tentative, except in the cases of TANOL and BDPA-Bz, for lack of data from crystal-structure and/or specific-heat measurements, the data on magnetic susceptibility, ESR linewidth, and specific heat are consistent with the linear Heisenberg antiferromagnetic exchange model in neutral organic free radicals. In comparison with a strong exchange interaction in a chain, the magnetic interaction between the chains is estimated to be very weak; thus, the neutral organic free radicals may be considered to be suitable crystals for studying the short-range order effect of the magnetic transition process.

The author is much obliged to Professor H. Takaki and Professor Y. Deguchi for a continuous encouragement throughout this work and also indebted to Dr. H. O. Nishiguchi, Dr. M. Mekata, and members of the laboratory for illuminating discussions. Thanks are also due to Mr. T. Fujito for a hearty cooperation in experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2308—2312 (1971)

An Acoustical Study of the Kinetics of Intermolecular Hydrogen Bonding and the Applicability of the Hammett Rule

Tatsuya YASUNAGA, Sadakatsu NISHIKAWA, and Nobuhide TATSUMOTO
Department of Chemistry, Fraculty of Science, Hiroshima University, Hiroshima

(Received January 23, 1971)

Rate and equilibrium constants for the hydrogen-bond dimerization of benzoic acid and meta- and para-substituted compounds in *N,N*-dimethylformamide have been determined by the measurement of the ultrasonic absorption in the 15—95MHz frequency range at 20°C, and the Hammett rule for the rapid monomer-dimer reaction has been examined. The forward and backward rate constants are 0.67×10^8 sec^{-1} and 2.8×10^7 sec^{-1} M^{-1} for para-toluic acid, 0.90×10^8 sec^{-1} and 1.9×10^7 sec^{-1} M^{-1} for meta-toluic acid, 1.6×10^8 sec^{-1} and 1.5×10^7 sec^{-1} M^{-1} for benzoic acid, 2.1×10^8 sec^{-1} and 2.4×10^7 $sec^{-1}M^{-1}$ for para-chlorobenzoic acid, and 3.3×10^8 sec^{-1} and 1.6×10^7 $sec^{-1}M^{-1}$ for metachlorobenzoic acid respectively. The forward and backward activation enthalpies for benzoic acid are 8.4 kcal/mol and 3.3 kcal/mol respectively. Using the substituent constants in Jaffe's table, the reaction constants in the Hammett rule are calculated to be 1.2 and −0.33 for the forward and backward reactions respectively.

There have been many reports[1] about the association of benzoic acid in nonassociated solvents. Maier and his coworker[2] found an excess absorption in carbon tetrachloride solutions of benzoic acid; they attributed this absorption to a perturbation of the equilibrium between the monomer and the hydrogen-bonding dimer of benzoic acid.

On the other hand, the Hammett rule, which is often used to account for the effect of substituents on aromatic compounds, has been used in studying the reaction of hydrolysis, acid dissociation, and so on.[3,4] The Hammett rule is characterized by a parameter which is independent of the reaction system, depending only on the substituents. It may be expected that the rule would hold true also for the rapid association and dissociation reactions for benzoic acid and meta- or para-substituted compounds. The ultrasonic absorption method, which provides a means of determining the rate constants for a reaction occurring in such a short time as shorter than 10^{-7} sec, seems to be very useful for examining the Hammett rule for this reaction.

Rassing and his coworkers[5] have already studied the Hammett rule for several para-substituted benzoic acids, but their measurements were limited to a few frequencies.

In this paper, we will present the ultrasonic absorption results for various meta- and para-substituted benzoic acid compounds and will evaluate the thermodynamic and kinetic values associated with the dimerization reaction.

Experimental

The ultrasonic absorption measurements were carried out in the frequency range from 15 to 95 MHz using the pulse technique which had been developed in our laboratory.[6] The cell was improved to prevent the dissolving of the binding materials into the solution by covering the transducer with a fused quartz plate 2 mm thick. The chemicals used were benzoic acid, meta-, para-toluic acids, meta-, para-chlorobenzoic acids, aniline, and methyl benzoate as solutes and *N,N*-dimethylformamide (DMF) as the solvent. These were all of the purest grade obtainable and were used without further purification. The measurements were made at various

temperatures for benzoic acid and at 20°C for the other compounds.

Results and Discussion

Figures 1—5 show the ultrasonic absorption spectra in *N,N*-dimethylformamide solutions of benzoic acid, meta-, para-toluic acids, and meta- and para-chlorobenzoic acids at 20°C. These spectra can be represented by the following formula for a single relaxation:

$$\alpha/f^2 = \frac{A}{1 + (f/f_r)^2} + B \qquad (1)$$

where α is the absorption coefficient, f is the frequency, f_r is the relaxation frequency, and A and B are constants. Table 1 shows the ultrasonic parameters for these solutions.

As is shown in Fig. 6, the excess absorption was not observed in the pure solvent, *N,N*-dimethylformamide, or in the solutions of aniline or of methyl benzoate in the frequency range used in this experiment.

These results lead us to the conclusion that the

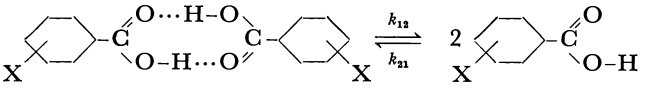
excess absorption is associated with the reaction the site of which exists in the carboxyl group of benzoic acid and its substituted compounds. It has been reported[1] that the equilibrium between the monomer and the dimer formed by the intermolecular hydrogen bonding between the carboxylic proton and carbonyl oxygen exists in the solution of benzoic acid. Provided that the ultrasonic absorption is ascribed to the monomer-dimer reaction, the reaction scheme can be written as:



(2)

where k_{12} and $_{21}$ are the forward and backward reaction rate constants respectively and where X is meta- or para-substituent. Then, the rate equation can be represented by:

$$\frac{d[A_2]}{dt} = k_{21}[A_1]^2 - k_{12}[A_2] \quad (3)$$

where $[A_1]$ and $[A_2]$ are the concentrations of the monomer and the dimer respectively. The relation between the relaxation frequency, f_r, and the total concentration, $[C_0]$, is expressed by the following equation:

$$(2\pi f_r)^2 = (1/\tau)^2 = 8k_{12}k_{21}[C_0] + k_{12}^2 \quad (4)$$

where τ is the relaxation time.

Figure 7 shows the experimental plots of $(2\pi f_r)^2$ *vs.* $[C_0]$ for five compounds; the linearity of these plots confirms our assumption that the ultrasonic absorption is associated with the monomer-dimer reaction. The values of k_{12} and k_{21} were obtained from the intercept

TABLE 2. THE KINETIC VALUES OBTAINED FROM ULTRASONIC ABSORPTION SPECTRA AND SUBSTITUENT CONSTANTS

Compound	k_{12}, 10^8 sec^{-1}	k_{21}, 10^7 sec^{-1}M^{-1}	*K*, M	σ
p-Toluic acid	0.67	2.8	2.4	−0.170
m-Toluic acid	0.90	1.9	4.8	−0.067
Benzoic acid	1.6	1.5	10	0
p-Chlorobenzoic acid	2.1	2.4	9.3	0.227
m-Chlorobenzoic acid	3.3	1.6	20	0.373

and the slope of the curve in Fig. 7, while the equilibrium constant, K, was calculated by $K=k_{12}/k_{21}$. These values are listed in Table 2.

According to Eyring's rate theory, the rate constant can be written as:

$$k_i = \kappa\frac{kT}{h}\exp\left(-\frac{\Delta F_i^*}{RT}\right) = \kappa\frac{kT}{h}\exp\left(-\frac{\Delta H_i^*}{RT}+\frac{\Delta S_i^*}{R}\right) \quad (5)$$

where k_i is the rate constant, κ is the transmission coefficient, k is the Boltzmann constant, T is the absolute temperature, R is the gas constant, ΔF_i^* is the activation free energy, ΔH_i^* is the activation enthalpy, and ΔS_i^* is the activation entropy. Figure 8 shows the plots of $\ln k_i/T$ *vs.* $1/T$ for benzoic acid. Figure 9 shows the activation enthalpies which were calculated from the slopes in Fig. 8; it also shows the enthalpy change obtained through the difference between the activation enthalpies for the forward and backward reactions.

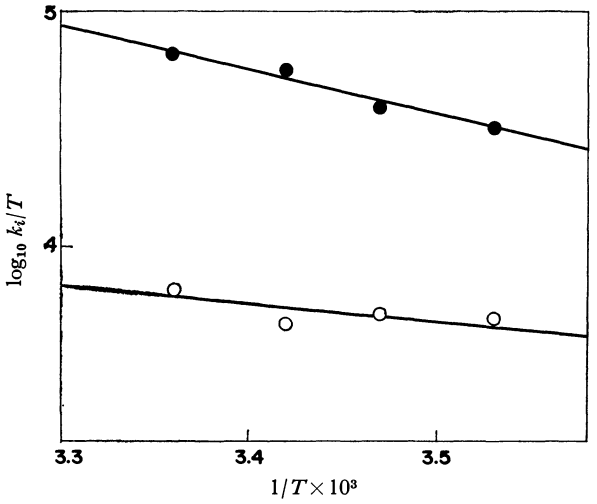

Fig. 8. Dependence of $\log k_i/T$ on $1/T$ for benzoic acid: ●, k_{12}; ○, k_{21}.

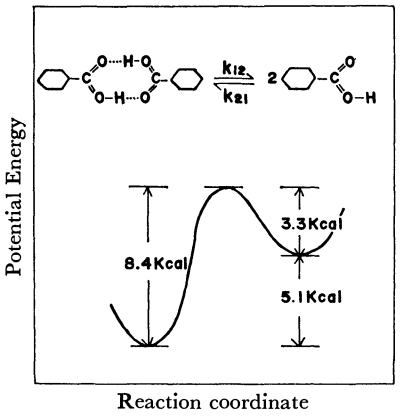

Fig. 9. Energy potential curve for monomer-dimer reaction in DMF solution of benzoic acid.

Now, provided that k_0 and k_j are the rate constants for the reaction in the unsubstituted compound and in a compound substituted in meta- or para-positions respectively relative to the carboxyl group, the following expression can be derived from Eq. (5):

$$\ln\frac{k_j}{k_o} = \frac{\Delta F_o^* - \Delta F_j^*}{RT} = \sigma\rho \quad (6)$$

where ΔF_o^* and ΔF_j^* are the activation free energies for benzoic acid and substituted compounds respectively. Equation (6) shows the well-known Hammett rule. σ is the substituent constant, which depends only on the nature and position of the substituent, X, and ρ is the reaction constant, which depends on the reaction, the condition under which it takes place, and the nature of the side chain.

In Fig. 10 the rate constants for the five compounds which were obtained in this experiment are plotted against the values of σ found in Jaffe's table.[7] The values of the reaction constants, ρ, obtained from the slope in Fig. 10 are 1.2 for the dissociation and −0.33 for the association in this reaction system.

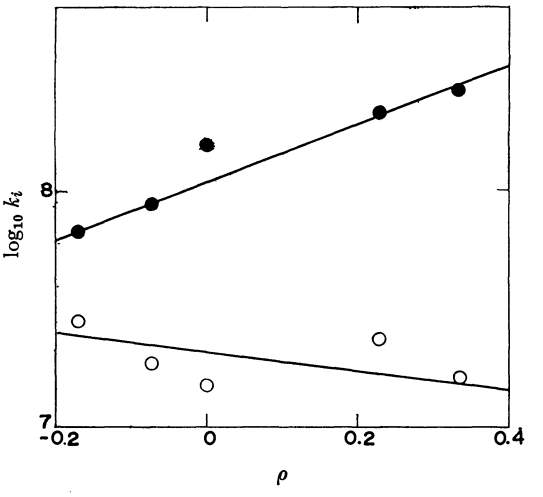

Fig. 10. The relation between the rate constant and the substituent constants: ●, k_{12}, ○, k_{21}.

As is shown in Fig. 7, the dependence of the relaxation frequency on the concentration shows that the excess absorption may be attributed to the perturbation of the equilibrium between the monomer and the dimer of benzoic acid or substituted compounds. The value of enthalpy change for benzoic acid, 5.1 kcal/mol, is small, as the breakage of the two hydrogen bonds in the dimer.[2,8] Borucki,[9] however, has reported that the enthalpy change in the monomer-dimer reaction for bonzoic acid in a polar solvent is smaller than that in a nonpolar solvent. The value, therefore, seems to be reasonable for the enthalpy change for the hydrogen bonding.

Figure 10 shows that the Hammett rule can be applied to the hydrogen-bonding reaction of meta- and para-substituted compounds of benzoic acid. According to previous theoretical studies of the Hammett rule,[3,10,11] σ can be correlated with the electron density.

8) W. Maier, *Z. Elektrochem.*, **64**, 132 (1960).
9) L. Borucki, *Ber. Bunsenges. Physik. Chem.*, **71**, 504 (1967).
10) H. H. Jaffe, *J. Chem. Phys.*, **20**, 279 (1952).
11) H. H. Jaffe, *ibid.*, **21**, 415 (1953).

When the tendency of substituents to be electron donors increases and when the electron density at the reaction site becomes high, σ becomes more negative. As can be seen in Fig. 10, in the compound of which σ is great, *i.e.*, in which the electron density at the reaction site is low, the hydrogen bond in the dimer is weak and the rate of dissociation is fast, while in that of which σ is small, *i.e.*, in which the electron density is high, the bond is strong and the rate is slow. On the other hand, the reaction constant for the association is negative, and the activation enthalpy for the association is increased with σ. That is, the monomeric state is stabilized and the rate of association is decreased with an increase in σ. Consequently, the rates for the formation and breakage of hydrogen bonds in these compounds depend on the electron density at the reaction sites.

** The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo*

(Received January 26, 1971)

The electronic structures of various transition metal complexes with 2,2′-bipyridyl in low oxidation states are studied theoretically by the composite system method. The results show that the excess electrons are not localized on the metal ion but are transferred to some extent to the ligand antibonding π-molecular orbitals with the lower oxidation states of complex ions. The present theory can explain reasonably and systematically the observed magnetic moments and ESR spectra of the complexes, the simple one-electron treatment being inappropriate for a theoretical explanation of their magnetic properties. According to the present treatment, their electronic absorption spectra can be explained satisfactorily from a qualitative point of view as the overlapping of the π–π^* transition bands in the ligands with the metal-ligand charge-transfer transition bands.

A number of transition metal complexes in low oxidation states have been synthesized. In particular, the tris(2,2′-bipyridyl) complexes in various oxidation states have been synthesized for the iron-series transition metals and their magnetic properties have been investigated.[1–10] König studied their ESR spectra,[11] assuming that the excess electrons are localized completely on the metal ion. Hall and Reynolds explained the g value obtained by the ESR measurement for $[Fe(bip)_3]^0$ [12] on the same assumption. However, in view of the metal-ligand interaction, this assumption may not always be appropriate. In fact, their measurement of the electronic absorption spectrum[9,10] of $[Fe(bip)_3]^0$ indicates that most of the excess electrons delocalize to the bipyridyl π-electron systems, and their ESR and electronic absorption studies give different conclusions on the excess electron distribution of the same complex. This contradiction must be solved.

The present study has been undertaken to understand more extensively the electronic structures of tris(2,2′-dipyridyl) complexes in low oxidation states and to solve several problems on their magnetic and optical properties from the theoretical point of view. In particular, the distribution of "excess electrons" in the ground states of these complexes seems to be interesting in connection with their magnetic properties and with their oxidation-reduction abilities.

General Background of the Present Theoretical Consideration

The metal complexes in lower oxidation states treated in the present study are summarized in Table 1 together with those in ordinary oxidation states. We have adopted the two quantities to characterize the isoelectronic series;[13] namely, N_π, the total numbers of the metal $3d\pi$ electrons plus the π electrons in ligand

12) The tris-(2,2′-bipyridyl) complex is abbreviated to $[Me(bip)_3]^Q$, where Me=metal and Q is the charge on the complex.

13) The ligand-to-metal π-electron transfer is not taken into account in the present treatment. Therefore, N_π may be considered as the number of metal $3d\pi$ electrons when there is no π-electron transfer from the metal to ligands.

Table 1. $[Me(bip)_3]^Q$ Complexs in various oxidation states[a,b]

Q	N[c]						
	15	16	17	18	19	20	21
−2				Ti 0		Cr 2	
−1			Ti 1	V 0	Cr 1	Mn 3	Fe p
0	Sc 1	Ti 0	V 1	Cr 0	Mn 3	Fe p	Co 1
1		V 2	Cr 1			Co	
2	V 3	Cr 2	Mn 5	Fe 0	Co 4	Ni 2	
3	Cr 3	Mn	Fe 1	Co 0			

a) The synthesis and magnetic moment are described in Refs. 1—10.
b) The number in each site indicates the number of unpaired electrons deduced from the observed magnetic moment. The notation "p" denotes that the complex is paramagnetic but its magnetic moment has not been measured.
c) $N=N_\pi+N_\sigma$, where N_π is the total number of electrons in the $3d\pi$ and ligand antibonding π-orbitals and N_σ is the total number of electrons in the metal σ ($3d\sigma$, $4s$, $4p\sigma$) and ligand σ lone-pair orbitals

antibonding MO's, and Q, the charge of the complex as a whole.

The theoretical method is similar to that developed previously for the metal chelate compounds containing organic unsaturated molecules as ligands.[14-17] It is based on the composite-system method in which the π-electron system of the complex is divided into the metal and three ligand molecules. Thereafter, the interaction among the four components is considered by the configuration interaction among the ground, locally-excited and charge-transfer (CT) configurations. The π-electron wavefunctions and energy integrals for the ligand molecule were obtained previously by use of the SCFMO–CI method considering the effect of electrostatic potential field caused by the metal ion.[15] The metal-ligand resonance integral β necessary for the configuration interaction calculations is determined by the equation

$$\beta = -S_{MN}(I_M+I_N)/2 \qquad (1)$$

where I_M and I_N are the ionization potentials of the metal $3d\pi$ AO and the nitrogen $2p\pi$ AO, respectively, and S_{MN} is the overlap integral between these two AO's.

We assume that the complex has a D_3 symmetry as illustrated in Fig. 1. This geometrical configuration has been established for the ordinary tris-complexes[18,19]

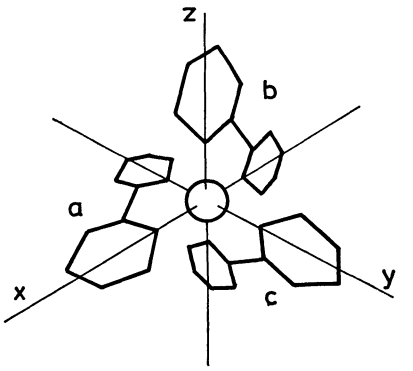

Fig. 1. The geometrical structure of tris-(2,2′-bipyridyl) complexes.

and also for some complexes in lower oxidation states.[20]

The π-Electron Distribution

First of all, we examine the magnetic properties of a series of complexes of $N_\pi=4$ on the assumption that the excess electrons are localized completely on the metal $3d\pi$ AO's. The calculation has been made by taking the ground configuration and the CT configurations in which a metal $3d\pi$ electron is moved to φ_7, the lowest vacant MO of a ligand, and by constructing spin-orbitals.[15] The result shows[21] that the lowest state is commonly ^3E for $[Cr(bip)_3]^{2+}$, $[V(bip)_3]^+$ and $[Ti(dip)_3]^0$. The result is independent of the metal-to-

ligand CT energy which is taken as a parameter. Thus the theory can not explain the observed magnetic susceptibilities which indicate spin-triplet and -singlet states for the chromium and titanium complexes, respectively.[22]

Similarly, for the $N_\pi=3$ series, the theory predicts the $^4A_2$ ground state commonly for $[V(bip)_3]^{2+}$, $[Ti(bip)_3]^+$ and $[Sc(bip)_3]^0$, whereas the experimental results indicate quartet and doublet states for the ground states of the vanadium and scandium complexes, respectively[8,23] Hence, the assumption that the excess electrons are localized in the metal $3d\pi$ AO's seems inappropriate.

In connection with the above-mentioned discussion, we examine in detail the distribution of excess electrons for the isoelectronic series of $N_\pi=4,5$, and 8. Details of the calculation are summarized in the Appendix.

The calculated energies of various electron distributions for the $N_\pi=4$ series are shown in Fig. 2 for $N_{3d\sigma}=2$ as the function of Q[24]. Here $N_{3d\sigma}$ represents the number of electrons on the metal $3d\sigma$ AO's donated from $\chi_{N\sigma}$'s, the nitrogen lone pair AO's, through the σ-type dative bonds. Hence, each $\chi_{N\sigma}$ possesses $+N_{3d\sigma}/6$ positive hole. The figure does not show absolute values of energies, but relative ones taking the $N_{3d\pi}=4$ case as the standard. Here $N_{3d\pi}$ denotes the number electrons on the $3d\pi$ AO's; *i.e.*, $N_\pi-N_{3d\pi}$ electrons are on the ligand antibonding MO's. Although the estimated energy values are rough (probably with errors of a few eV's; see Appendix I for the detail), Fig. 2 clearly shows that most of the excess electrons are transferred to the ligand antibonding MO's for the lower Q values and that they are gradually concentrated to the metal $3d\pi$ AO's as Q increases. For instance, as shown in Fig. 2, three of the excess electrons in $[Ti(bip)_3]]^0$ are in the ligand antibonding MO's so that this substance may be thought to be the complex of bipyridyl anion radicals with $Ti^{3+}[(3d\pi)^1]$. The net charge on the metal is $+1$ since $N_{3d\sigma}=2$. On the other hand, the excess electrons in the chromium complex are almost completely localized in the metal $3d\pi$ AO's so that it seems to be an ordinary complex of neutral bipyridyl molecules with $Cr^{2+}[(3d\pi)^4]$ ion, the net charge on the metal being 0 since $N_{3d\sigma}=2$. Similarly, $[V(bip)_3]^+$ can be regarded as the metal complex with a neutral bipyridyl molecule and the two anion radicals.

Similar results are obtained for the isoelectronic series of $N_\pi=5$ and 8. The former is illustrated in Fig. 3. In contrast to the other complexes of the $N_\pi=5$ series,[1,2,4a,25] $[Mn(bip)_3]^{2+}$ has a high spin ground state with five

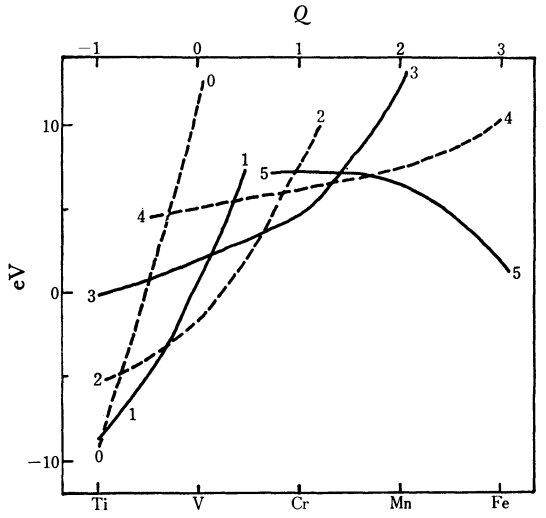

Fig. 3. Energies of the $N_\pi=5$ series of complexes with $N_{3d\sigma}=2$. The numbers in the figure represent the $N_{3d\pi}$ values.

unpaired electrons, two of them occupying probably the $3d\sigma$ orbitals.[26] As can be seen in Fig. 3, the lowest energy for the low spin configuration is relatively higher for this complex than for the others. Hence, stabilization through the exchange interaction may predominate, making the high spin state lower than the low spin state with $N_\pi=5$.

In the case of the isoelectronic series of $[Fe(bip)_3]^0$ corresponding to $N_\pi=8$, if the excess electrons are localized on the metal, two of them should occupy the $3d\sigma$ AO's since the $3d\pi$ AO's can receive at most six electrons (case I). On the other hand, if we put all 8 electrons in the π-electron system, at least two of them should occupy the ligand antibonding MO's (case II). In the former case, the $6-N_{3d\pi}$ electrons occupy the antibonding π MO's and $N_{3d\sigma}=2+n$, where n is the number of electrons transferred from $\chi_{N\sigma}$'s. In the latter case, the $8-N_{3d\pi}$ electrons are in the ligand antibonding MO's and $N_{3d\sigma}$ is just the electron number transferred from $\chi_{N\sigma}$'s. At the present stage, we can not conclude which case takes place actually for $[Fe(bip)_3]^0$ since we can not know the relative energies among the states with different $N_{3d\sigma}$ values. This problem is discussed later.

The Nature of the Ground State

Now we examine the nature of the ground states of the complexes in more detail on the basis of electron distribution. In the following calculation, the exchange interaction between $3d\pi$ AO's and the interaction with the lowest CT configurations are taken into account strictly.

$N_\pi=4$ Series. Assuming $N_{3d\sigma}=2$, the lowest enregy (ground) configuration of $[Ti(bip)_3]^0$ is that with $N_{3d\pi}=1$ as shown in Fig. 2. The second lowest is that with $N_{3d\pi}=0$. The configuration-interaction calculation is performed by considering eight triplet and six singlet ground configutations with $N_{3d\pi}=1$ and four triplet and three singlet CT configurations with

22) A. Earnshow, L. F. Larkworthy, K. C. Patel, K. S. Patel, R. C. Carlin, and E. G. Terezakis, *J. Chem. Soc.*, **A**, **1966**, 511.

23) N. Elliott, *J. Chem. Phys.*, **46**, 1006 (1967).

24) We do not treat explicitly the σ-electron system. However, the previous study[15] on $[Fe(bip)_3]^{2+}$ indicates that the $N_{3d\sigma}$ value of ~ 2 is appropriate for explaining the observed electronic absorption spectrum. For instance, the lowest configuration of $[Ti(bip)_3]^0$ is that with $N_{3d\pi}=2$ if we assume $N_{3d\sigma}=0$. This indicates that the net charge on the metal is $+2$. By an analogy with $[Fe(bip)_3]^{2+}$, at least two electrons should be transferred from $\chi_{N\sigma}$ to the $3d\sigma$ AO's. From this point of view, we adopt tentatively $N_{3d\sigma}=2$.

25) B. N. Figgis, J. Lewis, F. E. Mabbs, and G. A. Webb, *J. Chem. Soc.* **A**, **1966**, 422.

26) F. H. Burstull and R. S. Nyholm, *J. Chem. Soc.*, **1952**, 3570.

$N_{3d\pi}=0$. The energies of all the ground configurations which are equal to one another are taken as reference. The energies for all the CT configurations are commonly equal to E_{CT}, the CT energy from the $3d\pi$ AO to φ_7, and are taken as a parameter. All the off-diagonal matrix elements are determined by the quantity $B=C_{7N}\beta_{MN}$. The core resonance integral β_{MN} is given by the aid of Eq. (1) to be -1.87 eV by assuming the electron configuration of $[(3d\pi)^1(3d\sigma)^2]$ for Ti^+. C_{MN} is the coefficient of the $2p\pi$ AO of nitrogen in φ_7 and is determined to be -0.3886 by the previous calculation.[15,27]

The lowest state is shown in Fig. 4a for each spin and symmetry species of $[Ti(bip)_3]^0$. The ground state is $^1A_1$, being about 0.1 eV lower than the second lowest state, ^3E, within the reasonable range of E_{CT}. This result can explain the observed magnetic susceptibility.[1]

By taking three triplet and six singlet ground configurations with $N_{3d\pi}=4$ and twenty seven triplet and twenty four singlet CT configurations with $N_{3d\pi}=3$, a similar calculation has been made for $[Cr(bip)_3]^{2+}$.

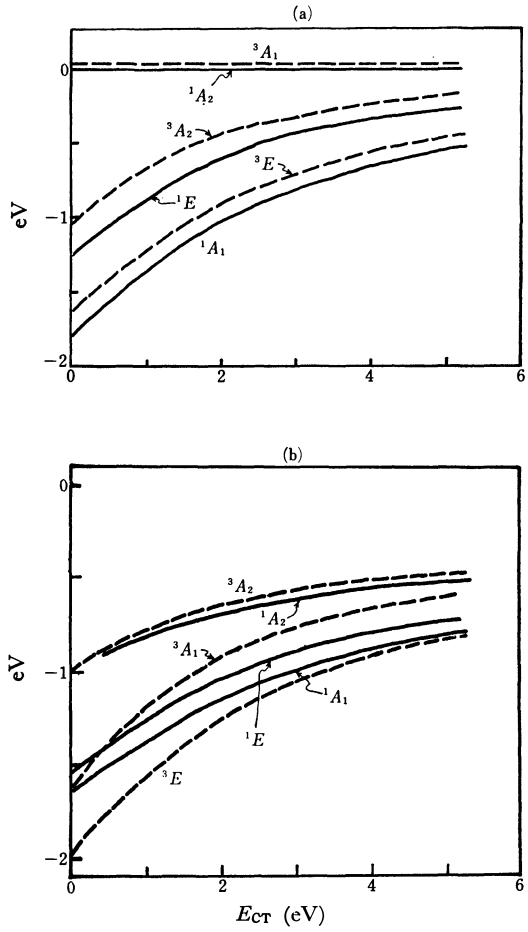

Fig. 4. Lower electronic states of the $N_\pi=4$ series of complexes. (a) $[Ti(bip)_3]^0$ and (b) $[V(bip)_3]^+$.

27) This is the value determined for the free bipyridyl molecule.[15] It varies with the change in the electron distribution, but the effect is not large: for instance, $C_{7N}=-0.3185$ if the potential field of the dipositive metal ion is taken into account.[15] The change in the β value is also not large because of the mutual cancellation of the changes in S_{MN} and I_{Me}; for instance, $\beta=-1.69$ eV if we assume $Ti^0[(3d\pi)^4]$.

The oxidation state of the metal is assumed to be $Cr^0[(3d\pi)^4(3d\sigma)^2]$ and β is estimated to be -1.26 eV. In addition, a new quantity K, the exchange integral between the two $3d\pi$ AO's, appears in the matrix elements[28] and is estimated to be 0.41 eV. The theoretical result predicts that the ground state ^3E is lower by $\sim$1 eV than the second lowest one. This is coincident with the observation.[22]

The ground state of $[V(bip)_3]^+$ is calculated by considering the fifty one ground and forty five CT configurations for $N_{3d\pi}=2$ and 3, respectively. Assuming the electron configuration of $[(3d\pi)^2(3d\sigma)^2]$ for V^+, we estimate β and K to be -1.63 and 0.513 eV, respectively. The lowest state is ^3E, as is shown in Fig. 4b. Perthel[29] obtained the effective magnetic moment of 2.80 Bohr magneton for $V(bip)_3I\cdot(1/2)py$, where py=pyridine. This value is close to that due to two unpaired electron spins, indicating the triplet ground state. On the other hand, König *et al.* could not observed the ESR signal of this substance in solution.[30,31] The reason why the ESR signal can not be observe at room temperature may probably be due to the fact that the orbitally degenerate ground state ^3E causes a large anisotropy in the g value and the hyperfine splitting, giving rise to a fairly short relaxation time.[32]

$N_\pi=5$ *Series.* A similar calculation has been made for $[Ti(bip)_3]^-$ by taking the ground and CT

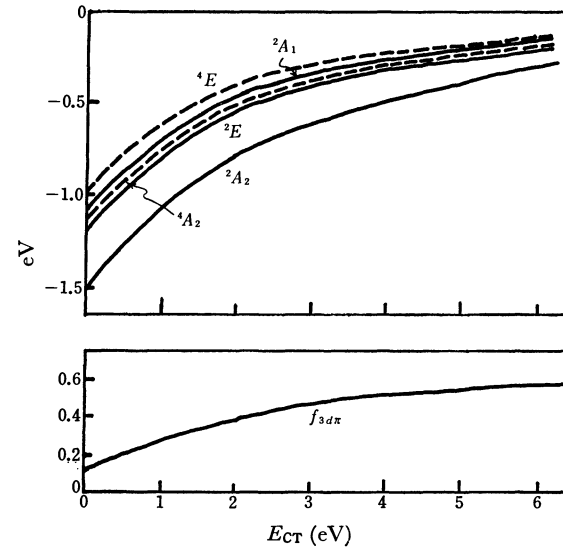

Fig. 5. Lower electronic states and spin densities on the $3d\pi$ AO's for $[V(bip)_3]^0$.

28) The E_{CT} value contains only the averaged spin interaction as is mentioned above. The $3d\pi$ exchange intergral K brings about the actual spin interaction in a rigorous manner.

29) R. Perthel, *Z. Phys. Chem.*, **211**, 74 (1959).

30) E. König, H. Fischer, and S. Herzog, *Z. Naturforsch.*, **18b**, 432 (1963).

31) S. Herzog, *Z. anorg. allg. Chem.*, **294**, 155 (1958).

32) König *et al.* suggested that the spin-orbit interaction gives a singlet ground state on the assumption that the excess electrons are localized on the metal. Hence, the ESR signal can not be observed if the substance is completely in the singlet ground state. This may hold as very low temperatures but not at room temperature. For, if the lowest state is singlet as they pointed out, a triplet state lies a little higher. The splitting is probably comparable to or smaller than the thermal energy at room temperature.

configurations with $N_{3d\pi}=0$ and 1, respectively. The result shows that the lowest state is $^2A_2$, being lower by about 0.3 eV than the second lowest one, ^2E. The $[V(bip)_3]^0$ complex is calculated to be also in the $^2A_2$ ground state by considering the ground and CT configurations with $N_{3d\pi}=2$ and 1, respectively. By assuming the electron configuration of $[(3d\pi)^2(3d\sigma)^2]$ for V^+, β and K are estimated to be -1.50 and 0.51 eV, respectively. The $[Cr(bip)_3]^+$ complex is shown to be in a $^2A_1$ ground state by the calculation taking into account the ground and CT configurations with $N_{3d\pi}=3$ and 4, respectively. The electron configuration of Cr^+ is assumed to be $[(3d\pi)^3(3d\sigma)^2]$ and the β and K values are evaluated to be -1.36 and 0.58 eV, respectively. All these results can explain the observed magnetic properties[1,2,4a] which indicate commonly the doublet ground state for the three substances. The lowest state for each spin and symmetry species is shown for the vanadium complex in Fig. 5.

Analysis of the ESR Data for the $N\pi=5$ Series

Let us examine the ESR data observed by König[11] on the basis of our theoretical results. The bonding and antibonding MO's constructed from the 4s AO (χ_{4s}) and the ligand σ AO's can be written as follows:[33]

$$\varphi = C_1\chi_{4s} + C_2\sum_l \tag{2}$$

$$\varphi^* = C_1'\chi_{4s} - C_2'\sum_l, \tag{3}$$

where $\sum_l$ is the symmetric linear combination of the nitrogen σ lone-pair AO's. The hyperfine coupling constant A_{Me} due to the metal nucleus can be represented approximately as

$$A_{Me} = A_{Me}^p + A_{4s}, \tag{4}$$

where

$$A_{Me}^p = [A_0^p + (\rho_{4s}^0/2)A_{4s}^p]f_{3d\pi} \tag{5}$$

and

$$A_{4s} = A_{4s}^0 f_{4s}. \tag{6}$$

Here A_0^p represents the hyperfine interaction due to the spin polarization of 1s, 2s, and 3s electrons produced by an unpaired electron on the 3$d\pi$ AO's. A_{4s}^p is a similar constant for a pair of 4s electrons. A_{4s}^0 represents the hyperfine interaction caused by an unpaired electron on χ_{4s}. The quantities $f_{3d\pi}$ and f_{4s} represent the spin densities on the 3$d\pi$ AO's and χ_{4s}, respectively. The latter represents only the electron spin transferred from the 3$d\pi$ AO's; that is, it does not include the 4s spin produced by exchange polarization.[34] The quantity ρ_{4s}^0 is written approximately as[35]

$$\rho_{4s}^0 = 2C_1^2 \tag{7}$$

Similarly, the hyperfine coupling constant due to the nitrogen nucleus can be written as

$$A_N = A_N^p + A_{2s} \tag{8}$$

where

$$A_N^p = A_{N0}^p f_{N\pi} \tag{9}$$

and

$$A_{2s} = A_{2s}^0 f_{2s}^N \tag{10}$$

A_{N0}^p represents the hyperfine coupling due to the spin polarization of nitrogen 1s and 2s electrons caused by an unpaired electron on the 2$p\pi$ AO. A_{2s}^0 represents the hyperfine coupling due to a spin on the 2s AO transferred from the metal 3$d\pi$ AO's. The quantities $f_{N\pi}$ and f_{2s}^N are the spin densities on the nitrogen 2$p\pi$ and 2s AO's respectively. The latter does not contain the electron spin induced through spin polarization.

By a combination of the above-mentioned relations with the expressions for spin densities given in Appendix II and with the observed coupling constants $|A_{Me}|=83.5$ and $|A_N|=2.3$ Gauss,[11] we can calculate the spin and electron densities in $[V(bip)_3]^0$ for a given value of E_{CT}.[36] The results are summarized in Table 2.

We can obtain solutions only for positive A_{Me} and A_N.

Table 2. Results of analysis of ESR data for $[V(bip)_3]^0$ and $[Cr(bip)_3]^+$ [a]

	$[V(bip)_3]^0$		$[Cr(bip)_3]^+$	
	$E_{CT}=$ 0(eV)	$E_{CT}=$ 5(eV)	$E_{CT}=$ 0(eV)	$E_{CT}=$ 1.3(eV)
f_{4s}	0.11	0.16	0.14	0.15
$f_{3d\pi}$	0.19	0.63	1.61	1.69

$A_0^P f_{3d\pi}$	−20.2	−67.3	38.3	40.2
$A_{4s}^P(\rho_{4s}^0/2)f_{3d\pi}$	4.6	0.6	−0.1	0.0
A_{4s}	99.1	150.1	−60.3	−62.6
A_N^P	−0.8	−0.4	0.5	0.6
A_{2s}	3.1	2.7	2.5	2.5

a) The quantities in the first column are defined in the text and Appendix. The coupling constants are all given in the Gauss unit.

33) The following orthonormality conditions hold;

$$C_1^2 + C_2^2 + 2C_1C_2S = 1,$$
$$C_1'^2 + C_2'^2 - 2C_1'C_2'S = 1$$

and

$$C_1C_1' - C_2C_2' - (C_1C_2' - C_1'C_2)S = 0,$$

where S is the overlap integral between χ_{4s} and $\sum_l$, and is calculated to be 0.685 by use of the Slater AO for the nitrogen and four-terms function for χ_{4s}[J. W. Richardson, W. C. Nieuwpoort, R. R. Powell, and W. F. Edgell, *J. Chem. Phys.*, **36**, 1057 (1962)].

34) It is possible at least to a first-order approximation to divide the 4s spin density into f_{4s} and the spin density produced by the spin polarization effect.

35) The quantity ρ_{4s}^0 is the spin-paired electron density when we disregard the effect of the unpaired electrons of the 3$d\pi$ AO's. We ignore the contribution to ρ_{4s}^0 from the antibonding MO φ^*. It is also to be noted that this quantity differs in the definition from the density ρ_{4s}^0 defined in Eq. (11). The former is the net atomic population whereas the latter is the gross population.

36) The following values are adopted for the basic coupling constants (in Gauss);

$$A_0^p = -106.6, \quad A_{4s}^p = 91.57,$$
$$A_{4s}^0 = 923.1, \quad A_{N0}^p = -25,$$
$$A_{2s}^0 = 546.1$$

The A_{4s}^0, A_{N0}^p and A_{2s}^0 values are taken from Ref. 11. The others are newly estimated by extrapolations from the theoretical results of Watson and Freeman [*Phys. Rev.*, **123**, 2027 (1961)].

In this table, the 4*s* electron densities due to the electrons in φ and φ^* are defined as

$$\rho_{4s}^{b} = 2(C_1^2 + C_1C_2S) \quad (11)$$

and

$$\rho_{4s}^{a} = \gamma^2(C_1'^2 - C_1'C_2'S) \quad (12)$$

respectively, where γ is defined by Eq. (A9) in Appendix. The spin and electron densities thus determined seem to be reasonable for the E_{CT} values of 0 to 5 eV.

As can be seen from Table 2, A_{Me} is determined predominantly by the spin density on the 4*s* AO. Spin polarization causes only a minor effect. A_N is determined by the spin density on the 2*s* AO which transferred from the $3d\pi$ AO's through the trigonal field mixing. The spin polarization caused by the odd electron on the nitrogen $2p\pi$ AO also brings about a minor effect.

A similar analysis can be applied to $[Cr(bip)_3]^+$. By use of the value $S=0.736$ and of the observed coupling constants[11] $|A_{Me}|=21.8$ and $|A_N|=3.05$ Gauss, we can obtain the spin and electron distributions as functions of E_{CT}. The solution can be obtained only for $A_{Me}<0$ and $A_N>0$ and $E_{CT}\leq 1.3$ ev. The results of $[Cr(bip)_3]^+$ are also summarized in Table 2, and show some new aspects differing from those of the vanadium complex. The spin density on the $3d\pi$ AO's amounts to 1.6 in line with the fact that the spin density on the ligand π-electron systems is negative. This may be a little striking but is not an unexpected result. It can also be seen that the contribution of the 4*s* AO to the dative bonding is smaller than that of the vanadium complex.

$[Ti(bip)_3]^-$ gives no hyperfine structure.[11] This can be explained on the basis of the present theoretical result that the metal has almost no $3d\pi$ electron. The spin density f_{2s} also vanishes since $f_{3d\pi}\simeq 0$. A_N^p is non-vanishing but is probably very small as is observed for the vanadium and chromium complexes. In fact, it should not exceed 1/3 of the nitrogen hyperfine coupling constant of the bipyridyl anion radical,[37-39] since an unpaired electron is distributed on these ligand molecules. Therefore, it seems to be reasonable that the titanium complex exhibits no hyperfine structure.[40]

Electronic Absorption Spectra

Few experimental studies on electronic absorption spectra of metal complexes in lower oxidation state have been made, except for those $[Fe(bip)_3]^0$ and $[Fe(bip)_3]^-$ reported by Reynolds and co-workers.[9,10] Recently, however, Torii, Kobayashi, and their co-workers studied the electronic absorption spectra of a number of complexes in low oxidation states.[41,42] König and Herzog have also studied the electronic absorption spectra of the titanium, vanadium, and chromium complexes in various oxidation states.[43]

As was already mentioned, some ligands of the lower oxidation state complexes can be seen as the bipyridyl anion radicals or its dinegative ions. From this point of view, the π-electron structures of the anion radical and the dinegative ion of 2,2'-bipyridyl are examined theoretically in addition to that of the neutral bipyridyl studied previously.[15] The π-electron structure of the anion radical in the cis form was calculated by the SCFMO-CI method for the open shell system,[44] by taking a hundred singly and doubly excited configurations in the configuration interaction calculation.[45] The results are summarized in Table 3, showing a fairly good agreement with the observation for Na(bip) (sodium bipyridyl) in tetrahydrofuran.[10,39]

40) König attributed this to the smaller natural abundance of the titanium isotopes with nuclear spins. However, this seems to be unreasonable since the natural abundances do not differ so much between the titanium and chromium isotopes, the hyperfine structure due to the metal being observed for the latter. It is also not reasonable to attribute it to the short relaxation time since the ground state of $[Ti(bip)_3]^-$ is not degenerate and the separation from the lowest excited state is almost the same as that of $[V(bip)_3]^0$.

The length indicates the oscillator strength value in an arbitrary scale. The band position predicted for the CT transition is indicated by an arrow for each substance. (a) —$[V(bip)_3]^0$ and ---$[Ti(bip)_3]^0$. The theoretical result is that of bip^-. (b) —$[Cr(bip)_3]^+$, ---$[V(bip)_3]^+$ and ···$[Fe(bip)_3]^0$. The theoretical result is the weighted average of the calculations for bip^0 and bip^-. (c) $[Ti(bip)_3]^-$. The theoretical result is the 1:2 average of the calculations for bip^- and bip^{2-}.

result is shown in Table 4, together with the transition energies measured with Li_2(bip) (dilithium bipyridyl) in tetrahydrofuran[42]

The electronic absorption spectra[41,43] of $[V(bip)_3]^0$ and $[Ti(bip)_3]^0$, which can be considered as the metal complex with three bip^-, are shown in Fig. 6a together with the theoretical result for bip^-. The position of the lowest CT transition band predicted theoretically is indicated by an arrow. In the present theoretical study, we ignore the dipole interaction between the π–π^* transitions in different ligands and also the interaction of CT transition with the ligand π-π^* transition. This means that we disregard the splitting of each band due to the above-mentioned interactions. Therefore we confine ourselves to a qualitative comparison of the theoretical and observed results.

As is shown in Fig. 6a, the electronic absorption spectra of $[V(bip)_3]^0$ and $[Ti(bip)_3]^0$ are at least qualitatively explained by the overlapping of the π–π^* transition bands of bip^- and the metal-ligand π-electron transfer ones. The observed bands in the energy region lower than 10 kK are ascribed to the ligand π–π^* transitions (to V_1 and V_2 of Table 3). The bands in 10—20kK region can be due to the mixture of the CT transition and the ligand π–π^* transition to V_3. The 26 kK and 30 kK bands of titanium and vanadium complexes, respectively, are due to the ligand π–π^* transition to V_0 corresponding to the strong 26 kK band observed for Na(dip).[39]

In Fig. 6b are shown the electronic absorption spectra[30,41-43] of $[Cr(bip)_3]^+$, $[V(bip)_3]^+$,and $[Fe(bip)_3]^0$ which can approximately be considered to be the metal complex with a dip^0 and two dip^-. The corresponding theoretical prediction shown in Fig. 6b is the weighted average of the calculated band intensites for dip^0 and dip^-. The absorption bands of $[V(bip)_3]^+$ are well interpreted as the 1:2 mixture of the bip^0 and bip^- spectra except for the 10—12 kK band which can be ascribed to the metal-ligand CT transition on the basis of the present theoretical study. In the spectrum of $[Cr(bip)_3]^+$, the 6—8 kK band may be due to two transitions; the CT transition from φ_7 of bip^- to the $3d\pi$ AO's and the lowest π–π^* transition of bip^-. The other transitions can be well interpreted as the overlapping of the local excitations in bip^0 and bip^-.

Concerning $[Fe(bip)_3]^0$ there are two possibilities, cases I and II, as already mentioned. If we assume $N_{3d\sigma}=2$, both cases give the ground state in which two excess electrons are located on the ligands and the CT state about 3 eV about it. The CT directions differ for cases I and II; namely, from φ_7 to $3d\pi$ for the former and from $3d\pi$ to φ_7 for the latter. The absorption spectra of this complex and free bip^- are somewhat similar to each other, but differ significantly in their relative intensity ratios. This indicates a fairly strong perturbation affecting the bip^- electronic structure. In case II, the CT from $3d\pi$ to φ_7 can interact with the π–π^* transitions in bip^0 but not with those in bip^-. On the other hand, the CT transition predicted for case I can interact only with the π–π^* transitions of bip^-. Hence, the latter case seems to be more suitable to explain the relative intensities of the bands below 30 kK. It is difficult to determine the bip^-/bip^0 ratio in

the complex because of a strong disturbance by the absorption band of the dissociated free bip in the region above 30 kK. The absorption spectrum of the complex strongly perturbed by the CT interaction, however, may be explained by the overlapping of the absorption spectra of bip^- and bip^0 in a 2:1 ratio. This is because, according to a rough estimate of the ground state energy, the electron configuration in this ratio is most stable.

The absorption spectrum[42] of $[Ti(bip)_3]^-$ is shown in Fig. 6c, together with the theoretical prediction of the weighted average of the calculated intensities for bip^- and bip^{2-} in the 1:2 ratio. The correspondence seems to be fairly good if the 12 kK band is ascribed to the transition to the CT state which is predicted to lie about 1 eV above the ground state.

Discussion

The electron distribution of the ground state determined above indicates that excess electrons are localized on the metal for the complexes with a large Q value and are gradually transferred to the ligand π-electron systems as Q decreases. Hence, we can not distinguish the complexes in lower oxidation states clearly from those in normal oxidation states. Moreover, the term "oxidation state" should be considered as the charge on the complex as a whole and should not be directly related to the oxidation state of the metal ion only.

In this connection, it seems to be interesting to examine how many electrons move when an electron is added to the normal complex. For instance, adding an electron to the π-electron system of $[Cr(bip)_3]^{2+}$ in which four π electrons are localized on the metal, we find about two electrons in the ligand antibonding MO's; that is to say, the addition of an electron induces not only its delocalization to the ligands but also the transfer of another electron which is originally in the metal. A similar tendency can be found for the vanadium complex. Adding an electron to $[V(bip)_3]^{2+}$ in which three electrons are localized in the metal, we find two electrons in the $3d\pi$ AO's and the other two in the ligands. Adding another electron, we find two electrons in the metal and the other three in the ligands. This general tendency can be understood as follows; an electron in φ_7 repels the $3d\pi$ electron resulting in the reduction of the metal ionization potential whereas it lifts the orbital energies of the ligands to reduce their electron affinities. The former effect is fairly larger since the metal-ligand average distance is shorter than the interligand average distance. Hence, the addition of an electron makes the transfer of metal $3d\pi$ electron easier. For lower Q values, this tendency reaches a saturation since the metal ionization potential decreases rapidly with the decreasing net charge on the metal.

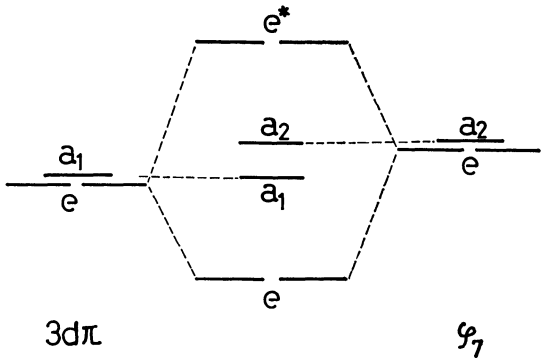

Fig. 7. The energy level diagram.

The magnetic behaviour of the ground state seems to be interpreted by the composite-system treatment adopted in the present work. The one-electron-orbital model adopted so far to the interpretation of the ESR result seems to be inappropriate for the low oxidation metal complexes under consideration. According to this model illustrated in Fig. 7, an unpaired electron of the $N_{3d\pi}=5$ complex should occupy the a_1 or a_2 orbital and should be localized completely on the metal or ligand, respectively. This is in serious disagreement with the present result which indicates an extensive delocalization of the unpaired electron both on the metal and ligands. The contradiction can be ascribed to the fact that the simple one-electron-orbital model completely ignores the strong exchange polarization of the e-orbital electrons due to the unpaired electron in the a_1 or a_2 orbital.

Tetrazakis and Carlin[46] explained the magnetism of $[Cr(bip)_3]^{2+}$ on the basis of the theory[47] presented by Figgis *et al.*, giving the trigonal splitting $\Delta\sim630$ cm^{-1} ($^3A_2$ is lower) and the orbital delocalization factor $k\sim0.6$. Although the k value seems to be consistent with the present result in which the metal-ligand CT configurations lie very close to the ground configurations, the Δ value is in serious disagreement with ours: $\Delta\sim-10^4$ cm^{-1} (^3E is lower). Since φ_7 is symmetric with respect to the bipyridyl molecule, it can not interact with the $3d\pi$ orbitals, whereas the e-symmetry orbital can interact with them. Hence, the result of Figgis *et al.* that Δ is positive (that is, the a_1 orbital is lower) is incorrect.

Next, we examine the magnetic property of $[Fe(bip)_3]^0$ qualitatively on the basis of Fig. 7. Although the one-electron-orbital model is inappropriate for quantitative treatment, it may be useful for the qualitative discussion of the spin state. By an analogy with the results for the $N_{3d\pi}=4$ and 5 series, the metal-ligand CT interaction is probably strong for this case with a low Q value. Hence the e^* orbital should lie far apart from the a_1 and a_2 orbitals, so that, in case II, the eight π electrons occupy the e, a_1, and a_2 orbitals, resulting in a spin singlet ground state. This is in contradiction to the observation. On the other hand, in case I, the six π electrons may occupy the e, a_1, and a_2 orbitals if the $3d\pi$ AO and ligand antibonding MO of the a_1 and a_2 symmetry, respectively, are close to each other. We have four unpaired electrons, two in the a_1 and a_2 orbitals and two in the σ orbitals of the e symmetry, with a spin quintet ground state. Thus examination of both the magnetism and the electronic absorption spectrum supports case I. Another supporting fact is that the substance readily decomposes to bipyridyl and iron on heating.[6] This can be understood as due to the weak σ-dative bonding caused by partial occupation of

46) E. G. Tetrazakis and R. L. Carlin, *Inorg. Chem.*, **6**, 2125 (1967).

the σ-antibonding MO's.

$[Mn(bip)_3]^-$ which is isoelectronic with $[Fe(bip)_3]^0$ shows a magnetic moment of 3.71 Bohr magneton.[3] This can not be explained on the basis of the even number of unpaired electrons. The substance should be considered as a mixture of the spin quintet and triplet species. The situation can be understood by the energy level scheme shown in Fig. 7. If the a_1 and a_2 orbitals are close to each other as for the iron complex, we have four unpaired electrons, and thus a spin quintet ground state. If a stronger metal-ligand interaction makes the a_1 and a_2 orbitals split, all the π electrons should be paired and we have the spin triplet ground state because of the unpaired electrons in the σ-antibonding orbitals. We have a mixture of the two species if the separation between the a_1 and a_2 orbitals is comparable with the exchange integral between the two $3d\pi$ AO's. The electron distribution in case II gives no reasonable explanation also for this complex.

$[Cr(bip)_3]^{2-}$ has two unpaired electrons.[4b] This is understood as predominance of the triplet state because of the large a_1–a_2 separation. Thus, for this isoelectronic series, the iron, manganese and chromium complexes, together with well-known $[Ni(bip)_3]^{2+}$, have two unpaired electrons in the σ-antibonding orbitals, in addition to those in the π-electron system.

The authors are deeply indebted to Prof. Hiroshi Kobayashi and Dr. Yasuo Torii of the Tokyo Institute of Technology for valuable discussion and for use of the spectral data before publication.

Appendix I

Here we will show the method calculating the energies for various π-electron distributions given in Figs. 2 and 3. Let us take $[Ti(bip)_3]^0$, $N_\pi=4$, as an example.

If we take the energy of the electron configuration $N_{3d\pi}=4$ and $N_{3d\sigma}=0$ as a reference, the energy of the configuration $N_{3d\pi}=3$ and $N_{3d\sigma}=0$ is just the CT energy to remove an $3d\pi$ electron to the lowest vacant MO φ_7 of one of the ligands (say, ligand a);

$$E(3,0) = I_{Me} - A_L - 3V_{MQ} + 2V_{OQ} - V_{MO} \quad \text{(A1)}$$

where the configurational energy is represented as $E(N_{3d\pi}, N_{3d\sigma})$. I_{Me} and A_L are the valence state ionization potentials corresponding to the ionization process $Ti^0[(3d\pi)^4]\rightarrow Ti^+[(3d\pi)^3]$ and the electron affinity of the ligand, respectively. V_{MQ}, V_{OQ}, and V_{MO} are, respectively, the electrostatic interaction energies between a $3d\pi$ electron and the formal charges due to π electrons on each ligand, between an electron in φ_7 of a ligand and the formal charges on one of the other ligands, and between $3d\pi$ electron and an electron in φ_7 of a ligand. I_{Me} is estimated to be 3.01 eV from the observed atomic term values by averaging all spin interactions. By the aid of SCF calculation for the free 2,2′-bipyridyl molecule, the following results are obtained: $A_L=0.02$,[48] $V_{MQ}=1.00$, $V_{OQ}=0.25$ and $V_{MO}=4.98$ (all in eV), and, therefore, $E(3,0)=-4.51$ eV. A_L is evaluated from the calculated φ_7 orbital energy ($\varepsilon_7=-1.72$ eV) of the ligand by the following equation;[48]

$$A_L = -\varepsilon_7 - 1.7 \quad \text{(A2)}$$

Next, we evaluate the energy of the configuration $N_{3d\pi}=2$ and $N_{3d\sigma}=0$. By considering the process to remove an electron from the ligand antibonding MO of the configurations $N_{3d\pi}=2$ to the $3d\pi$ AO, we have

$$E(3,0) = E(2,0) + I_L - A_{Me}^{\pi}(2,0) - V_{OO} + V_{MO} + 3V_{MQ} \quad \text{(A3)}$$

where I_L is the ionization potential necessary for removing a ligand antibonding-orbital electron, being equivalent to A_L defined above. In this case, A_L is evaluated to be 7.26 eV by Eq. (A2), since ε_7 is calculated to be −8.955 eV by the SCF MO calculation including the potential field caused by the metal charge (the net charge on the metal is +2 for $N_{3d\pi}=2$ and $N_{3d\sigma}=0$).[15] $A_{Me}^{\pi}(m,n)$ is the electron affinity of metal corresponding to the process $Ti^Q[(3d\pi)^m(3d\sigma)^n]\rightarrow Ti^{Q-1}[(3d\pi)^{m+1}(3d\pi\sigma)^n]$ where $Q=4-(m+n)$. $A_{Me}(m,n)$ is also defined in a similar manner. V_{OO} is the interaction between electrons in the lowest vacant MO's of different ligands and calculated to be 2.87 eV. V_{MO} and V_{MQ} have the same meanings as before and are calculated by use of the SCF MO's obtained by taking into account the potential field of the metal ion. Hence,[49]

$$E(2,0) = E(3,0) - 6.21 = -10.63\text{eV}. \quad \text{(A4)}$$

The configuration $N_{3d\sigma}=2$ and $N_{3d\sigma}=1$ can be produced from $N_{3d\pi}=2$ and $N_{3d\pi}=0$ by removing an electron from one of the MO's $\varphi_{N\sigma}$ constructed from the σ-lone pair AO's of nitrogens to the metal $3d\pi$ AO's.

$$E(2,1) = E(2,0) + I_\sigma - A_{Me}^{\sigma}(2.0) + V_{SQ} - 2V_{SO} + V_{MS} + 2V_{MO} - 3V_{MQ} \quad \text{(A5)}$$

where I_σ is the ionization potential to remove an electron from $\varphi_{N\sigma}$ and is taken to be 10.35 eV from the corresponding ionization potential of pyridine.[50] $A_{Me}^{\sigma}(2,0)$ is estimated to be 3.04 eV. V_{SQ}, V_{SO}, and V_{MS} are the interaction of an electron in $\varphi_{N\sigma}$ with the formal charge distributions in the π electron systems of three ligands with an electron in φ_7 and with a $3d\pi$ electron, respectively. They are estimated to be −8.35, 4.41, and 8.46 eV, respectively, by use of the SCF MO obtained by taking into account the potential field of the metal ion.[15] The interatomic interaction within a ligand molecule is calculated by use of the Slater AO's, whereas the interactions between different ligands and between the metal and ligand are calculated by use of the point-charge approximation. By use of these quantities, $E(2,1)$ is evaluated to be −2.17 eV.

The configuration with $N_{3d\pi}=2$ and $N_{3d\sigma}=2$ is produced from that with $N_{3d\pi}=2$ and $N_{3a\sigma}=1$ by removing another electron from $\varphi_{N\sigma}$ to $3d\sigma$ AO;

$$E(2,2) = E(2,1) + I_\sigma^+ + V_{SQ} - 2V_{SO} - A_{Me}^{\sigma}(2,1) - V_{MS} + 2V_{MO} - 3V_{MQ} \quad \text{(A6)}$$

where $I\sigma^+$ is the second ionization potential of $\varphi_{N\sigma}$ and estimated to be 15.87 eV correcting $I\sigma$ with respect to the electrostatic interaction between the nitrogen σ lone-pair AO's. The other quantities have the same meanings as before, and are calculated by use of the SCF MO's obtained putting a

48) We employ the correction of 1.7 eV.[16,17]

49) The energy $E(2,0)$ may be obtained by considering the process removing $3d\pi$ electron in the configuration $N_{3d\pi}=3$ to the ligand vacant MO. We employ here, however, the reverse CT process in order to utilize the previously obtained MO's for, ligand under the influence of dipositive metal ion.

50) M. I. Al-Jaboury and D. W. Turner, *J. Chem. Soc.*, **1964**, 4438; E. Clementi, *J. Chem. Phys.*, **46**, 4731, 4737 (1967); J. L. Whitten *et al.*, *ibid.*, **48**, 953 (1968); J. Del Benne and H. H. Jaffe, *ibid.*, **48**, 1811 (1968); M. A. El-bayoumi and O. S. Khalil, *ibid.*, **47**, 4863 (1967).

positive charge on the metal and $+1/6$ hole on each nitrogen σ AO. $E(2,2)$ is thus estimated to be 4.04 eV.

The estimated energy of each electron configuration should not be considered to be the energy of the actual state for the following reasons: (i) The energy change due to resonance interaction is not taken into account, (ii) the spin interaction is averaged out, and (iii) the stabilization due to electron rearrangement accompanied by electron transfer is not taken into account. Although the resonance and spin interactions are ignored in the estimation of electron distribution, they are taken into account in the calculation of the magnetic property of the ground state. Hence, we discuss here the third point. We evaluate the energy of the $N_{3d\pi}=3$ and $N_{3d\sigma}=0$ distribution to be 4.51 eV below the reference state with $N_{3d\pi}=4$. This is just the CT energy including no electron rearrangement effect. If we denote the stabilization due to the effect as Δ_1 (taken as positive), the absolute energy should be $-4.51-\Delta_1$ as illustrated in Fig. 8a. Similarly, the CT

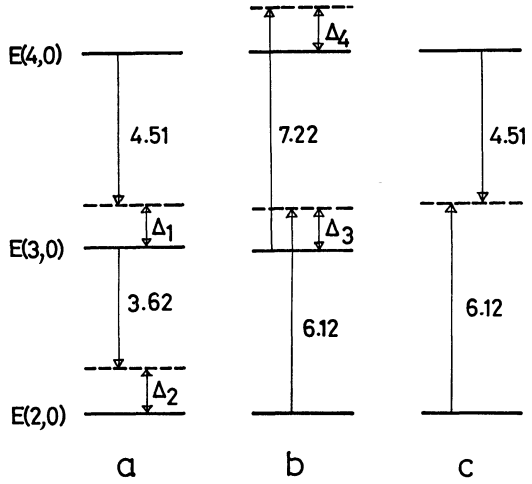

Fig. 8. The energy estimation for some electron distributions of $[Ti(bip)_3]^0$.

energy from the $N_{3d\pi}=3$ system to the $N_{3d\pi}=2$ system is calculated to be -3.62 eV on the basis of the electron distribution of the $N_{3d\pi}=3$ system. If we put the rearrangement energy of the $N_{3d\pi}=2$ system as Δ_2, the absolute energy of this system is $-(4.51+\Delta_1+3.62+\Delta_2)$. If we start from the $N_{3d\pi}=2$ system, we obtain the absolute energy of the $N_{3d\pi}=4$ system as $(6.12-\Delta_3+7.22-\Delta_4)$ above the former, as is illustrated in Fig. 8b. Since the relation

$$(4.51+\Delta_1+3.62+\Delta_2) = (6.12-\Delta_3+7.22-\Delta_4)$$

should hold, we obtain

$$\Delta_1 + \Delta_2 + \Delta_3 + \Delta_4 = 5.21 \text{ eV}.$$

Assuming $\Delta_1\simeq\Delta_2\simeq\Delta_3\simeq\Delta_4=\Delta$, the absolute value of the $N_{3d\pi}=2$ system is estimated to be $-4.51-3.62-2\Delta=-10.74$ eV. As illustrated in Fig. 8c, the corresponding energy can be evaluated by adding the energy of the $N_{3d\pi}=3$ distribution based on the $N_{3d\pi}=4$ to that based on the $N_{3d\pi}=2$. The sum $4.51+6.12=10.63$ eV, is very close to the estimated absolute energy given above. The energy of the $N_{3d\pi}=3$ system is obtained as -4.51 and -7.22 eV by calculations based on the distributions $N_{3d\pi}=4$ and 3, respectively. The absolute value can be estimated as $-4.51-\Delta=-5.8$ eV. Thus the electron rearrangement effect amounts to ± 1.3 eV for this state.

Appendix II

The ground state of $[V(bip)_3]^0$ is represented by the wavefunction

$$\Psi(^2A_2) = A_1\Psi_1 + A_2\Psi_2 + A_3\Psi_3 + B_1\Psi_1' + B_2\Psi_2' + B_3\Psi_3' \quad \text{(A7)}$$

where Ψ_1, Ψ_2, and Ψ_3 are the configurational wavefunctions with $N_{3d\pi}=2$ and Ψ_1^1, Ψ_2^1 and Ψ_3^1 are those of the CT configurations with $N_{3d\pi}=1$. The coefficients A_i's and B_i's have been determined by the calculation described in Appendix I.

Considering the mixing of the $3d\pi$ and $4s$ orbitals due to the trigonal field we have

$$\Psi'(^2A_2) = \Psi(^2A_2) - \gamma[A_1\sum\nolimits_2 + (3)^{-1/2}A_2(\sum\nolimits_1-(2)^{1/2}\sum\nolimits_4) - (2/3)^{1/2}A_3(\sum\nolimits_1-(2)^{1/2}\sum\nolimits_3) \quad \text{(A8)}$$

where $\sum_1$ to $\sum_4$ are the wavefunctions of the CT $(4s\rightarrow\varphi^*)$ configurations belonging to the $^2A_2$ symmetry.[51] The coefficient γ determines the extent of mixing and may be expressed as

$$\gamma = (C_1'/\Delta E)\langle\chi_{3d\pi}|\mathbf{V}_{tr}|\chi_{4s}\rangle \quad \text{(A9)}$$

where ΔE is the energy of electron transfer from $3d\pi$ to $4s$ and $\mathbf{V}_{tr}$ is the trigonal electrostatic field.

By use of this wavefunction, the spin densities can be expressed by their definitions as follows.

$$\begin{aligned}
f_{4s} &= (2/3)\gamma^2C_1'^2(A_2^2+2A_3^2)\\
f_{3d\pi} &= (2/3)A_2^2 + (14/27)A_3^2 - (1/3)B_1^2 + B_2^2 - (1/3)B_3^2 + (2/3)\gamma^2(A_2^2+2A_3^2)\\
f_{2s} &= (1/27)\gamma^2C_2'^2(A_2^2+2A_3^2) \quad \text{(A10)}\\
f_{L\pi} &= A_1^2 + (1/3)A_2^2 + (13/27)A_3^2 + (4/3)(B_1^2+B_3^2) + \gamma^2[A_1^2-(1/3)A_2^2-(2/3)A_3^2]\\
f_{N\pi} &= (1/3)(C_{7N})^2f_{L\pi}
\end{aligned}$$

where $f_{L\pi}$ represents the sum of the spin densities in the π-electron systems of three ligands.

The ground state wavefunction Ψ for $[Cr(bip)_3]^+$ can also be represented by Eq. (A7) except that the configurational wavefunctions Ψ_1 to Ψ_3 are those of $^2A_1$ with $N_{3d\pi}=3$ and Ψ_1' to Ψ_3' are those of $^2A_1$ with $N_{3d\pi}=4$. The interaction with the $4s$ AO can be written as

$$\Psi'(^2A_1) = \Psi(^2A_1) + (3)^{1/2}\gamma[A_1\sum\nolimits_1' + A_2\sum\nolimits_2' - A_3\sum\nolimits_3'] \quad \text{(A11)}$$

where $\sum_1'$ to $\sum_3'$ are the wavefunctions for the CT configurations corresponding to the electron transfer from the $3d\pi$ AO's to φ^*. The spin densities are expressed as

$$\begin{aligned}
f_{4s} &= (1/3)(A_1^2+A_2^2+5A_3^2)\gamma^2C_1'^2,\\
f_{3d\pi} &= (1/3)[A_1^2+A_2^2+5A_3^2+4(B_1^2+B_3^2)] + (2/3)\gamma^2[A_1^2+A_2^2+5A_3^2],\\
f_{2s} &= (1/54)(A_1^2+A_2^2+5A_3^2)\gamma^2C_2'^2, \quad \text{(A12)}\\
f_{L\pi} &= (1/3)[2(A_1^2+A_2^2-A_3^2)-(B_1^2-3B_2^2+B_3^2) + 2(A_1^2+A_2^2-A_3^2)\gamma^2],\\
f_{N\pi} &= (1/3)(C_{7N})^2f_{L\pi}
\end{aligned}$$

51) The electron transfers from φ to $3d\pi$ and to the vacant MO of ligand are ignored since their energies lie probably fairly higher than that of the electron transfer $3d\pi\rightarrow\varphi^*$.

Electron-transfer Phenomena in Some Three-dimensional Complex Thiocyanate Semiconductors

Masao HASHIMOTO,* Shichio KAWAI, and Ryôiti KIRIYAMA
Institute of Scientific and Industrial Research Osaka University, Suita-shi, Osaka
(Received February 3, 1971)

Measurements of the electrical conductivity, the photoconductivity, the electronic spectra, and the magnetic susceptibility were carried out with powder samples of $CuHg(SCN)_4$ and $(Cu_xZn_{1-x})Hg(SCN)_4$. The electrical conductivity (σ) of the compounds has been found to obey the usual exponential equation of electrical conduction, $\sigma=\sigma_0\exp(-E_t/KT)$. It was found that there was a close relation between the photocurrent spectra and the electron-transfer bands in both compounds. In terms of the band model, the nature of the semiconductivity and the photocurrent in their intrinsic region are discussed in connection with the electron-transfer phenomena.

The $M(II)Hg(SCN)_4$ series of compounds has been known for many years.[1] In $ZnHg(SCN)_4$ the zinc ion is surrounded by a slightly distorted tetrahedron of four nitrogen atoms,[2-4] while green $CuHg(SCN)_4$ has a quite different structure,[5] in which copper ions are surrounded octahedrally by four nitrogens and two sulfurs. However, their polymeric structure are similar. The structure of mixed crystals of $(Cu_xZn_{1-x})Hg(SCN)_4$ composition, with x smaller than 0.22, is also isomorphous with $ZnHg(SCN)_4$, and their color changes from pale pink to dark purple depending on the relative concentration of Zn^{2+} and Cu^{2+}.[6] The color of the mixed crystals is caused by the intense electron-transfer bands at about 330 and 550 mμ; green $CuHg(SCN)_4$ has also an electron-trasfer band at about 430 mμ.[6]

The present experiments were undertaken in order to elucidate the relation between the electron-trasfer phenomena and the semiconduction in inorganic complex salts with a three-dimensional framework. Braterman *et al.* have investigated the electrical conductivity of some complex cyanides and found no equality between the activation energy for the semiconduction and the optical absorption energy of the electron-transfer band.[7] Our present results, however, will show that the mechanism of intrinsic semiconduction in $CuHg(SCN)_4$ and $(Cu_xZn_{1-x})Hg(SCN)_4$ is closely related to the nature of their electron-transfer bands.

Experimental

Materials. The green compound, $CuHg(SCN)_4$, was prepared by mixing aqueous solutions of copper(II) sulfate and potassium mercury tetrathiocyanate. The precipitate was filtered off, washed with cold water, and dried at about 100°C in an air thermostat. The crystalline powder of $ZnHg(SCN)_4$ was obtained by a similar method of preparation. The purple mixed compounds $(Cu_xZn_{1-x})Hg(SCN)_4$ were prepared by adding mixed aqueous solutions of zinc and copper sulfate to aqueous solutions of potassium mercury tetrathiocyanate. The mole fractions of the copper ion in the products were assumed to be the same as those of the starting mixed solutions. All the materials thus obtained were identified by means of an X-ray diffractometer using Cu$K\alpha$ radiation.

Electrical Conductivity. The electrical conductivity measurements were carried out in a vacuum with pellets of the compounds. The electrode assembly used for our measurements is shown in Fig. 1. The electrical current at a constant field strength was measured with a Toa Dempa Model PM 18 microvolt-ammeter, capable of measuring currents down to 10^{-12} A. The field strengths were in the region between 100 to 450 V/cm. In order to prevent thermal decomposition under these experimental conditions, the measurements were carried out at temperatures below about 420°K.

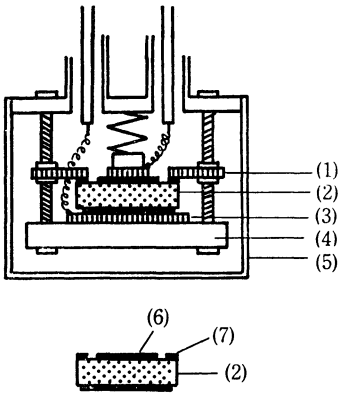

Fig. 1. Electrode assembly.
(1) Copper ring(guard electrode), (2) Specimen, (3) Copper plate, (4) Steatite, (5) Shield box, (6) Central electrode (evapolated gold), (7) Guard electrode(evapolated gold)

For the measurements of the photocurrent, a DC electric field was applied between the guard electrode and the central electrode of a pellet (Fig. 1). The surface between these two electrodes was then exposed to light. The photoconductivity was excited by a monochromatic light from a quartz prism monochrometer. A xenon-lamp was employed as the light source. The photocurrent was measured with the microvolt-ammeter mentioned above at field strengths ranging from 100 to 450 V/cm. The measurements were carried out at room temperature over the 380—1000 mμ spectral region. On the assumption that the photoconductivity is

linearly related to the intensity of the light, the spectral response of photocurrent was determined; that is, the measured values of the photocurrent were divided by the relative intensity of the light.

Electronic Spectra. The diffuse reflectance (R_d), *i.e.*, the ratio of the quantity of light reflected by a powdered sample to the quantity of light reflected by magnesium carbonate, was measured with a Shimadzu Spectrophotometer, with its integration attachment, in the visible region. In presenting the data of the reflectance measurements, it seems convenient to use Kubelka and Munk's expression,[8] $f(R_d)=(1-R_d)/2R_d$, for there is a certain parallel between this quantity and the extinction coefficient of the crystal.

Magnetic Susceptibility. The magnetic susceptibility of $ZnHg(SCN)_4$ and $(Cu_xZn_{1-x})Hg(SCN)_4$ were obtained by the Gouy method in the temperature range from 118 to 300°K. The Gouy tube was calibrated with a standard aqueous solution of nickel(II) chloride. The diamagnetic corrections were estimated from the observed magnetic susceptibility of $ZnHg(SCN)_4$.

Results

Electrical Conductivity. The electrical conductivity (σ) of the compounds was found to obey the usual exponential relation to the temperature:

$$\sigma = \sigma_0 \exp(-E_t/kT),$$

where σ_0 is a constant and where E_t is the thermal activation energy for the electrical conduction. The values of the specific conductivity at about 373°K (σ_{373}) are listed in Table 1, together with the thermal activation energy (E_t) as calculated from $\log\sigma$ *vs.* $1/T$ plots. It can be seen in Fig. 2 that the $\log\sigma$ *vs.* $1/T$ plots of $(Cu_xZn_{1-x})Hg(SCN)_4$ give two strainght lines, with a break around 393°K. The two notations, E_t^e and E_t^i, in Table 1 denote the activation energy for the lower (extrinsic) and the upper (intrinsic) part of the break respectively.

Table 1. Specific conductivity at 373°K (σ_{373}) and thermal activation energy measured with pellets of $(Cu_xZn_{1-x})Hg(SCN)_4$

x	σ_{373} $\mho$/cm	E_t^e eV	E_t^i eV
0.0	1.8×10^{-14}	1.2	1.6
0.03	3.3×10^{-13}	1.1	1.6
0.1	7.7×10^{-12}	0.9	1.5
0.2	9.3×10^{-11}	0.6	1.6
1.0	1×10^{-10}	—	2.2

It is noticeable that the conductivity of (Cu_xZn_{1-x})-$Hg(SCN)_4$ increases with an increase in the copper concentration. This shows that the increase in the copper concentration causes an increase in the number of charge carriers required for electrical conduction. Furthermore, the value of E_t^e gradually increases with a decrease in the copper concentration, while the value of E_t^i is almost constant, regardless of the relative concentrations of Cu^{2+} and Zn^{2+}. The lower activation energy (E_t^e) must result from the presence of lattice imperfections introduced by the doping of copper ions in the $ZnHg(SCN)_4$ lattice.

(a), x=0.2; (b), x=0.1; (c), x=0.03; (d), x=0

Electronic Spectra. In order to clarify the relation between the electrical conductivity and the depth of the characteristic color of $(Cu_xZn_{1-x})Hg(SCN)_4$, the electronic spectra of a series of the mixed crystals were measured in the visible region. Our results, obtained by diffuse reflectance (Fig. 3), are essentially in agreement with the spectrum of $(Cu_{0.14}Zn_{0.86})Hg(SCN)_4$ reported by Forster *et al.*[6] The band at 560 mμ has been identified as an electron-transfer band. It can be seen in Fig. 3 that the absorbance of the spectra

a), x=0.2; b), x=0.1; c), x=0.03; d), x=0.003; e), x=0.

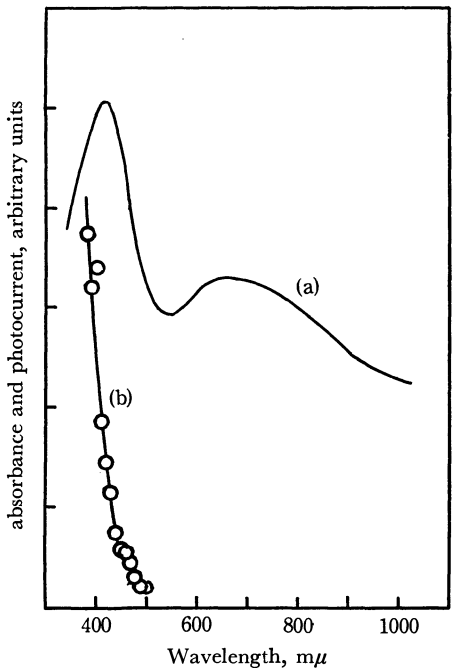

Fig. 4. Absorption and photocurrent spectra of $CuHg(SCN)_4$. (a), absorption spectrum(Ref. 6); (b), photocurrent spctrum.

increases with an increase in the copper concentration. This must be closely related to the fact that the electrical conductivity increases with an increase in the copper concentration.

Photocurrent Spectra. It seems to be of paticular interest that the inorganic complex salts, $CuHg(SCN)_4$ and $(Cu_xZn_{1-x})Hg(SCN)_4$, exhibit photoconductivity.

The photocurrent spectrum of $CuHg(SCN)_4$ is shown in Fig. 4, together with its electronic spectrum. The threshold energy of the photocurrent (E_o) is about 2.8 eV, slightly larger than the energy of the absorption edge of the electron-transfer band with its absorption peak at about 430 mμ. Although the threshold energy of the photocurrent (E_o) does not agree well with the energy of the absorption edge of the band at about 430 mμ, the photoconductivity response found for $CuHg(SCN)_4$ may be caused by the electronic transitions associated with the electron-transfer band at 430 mμ.

The photocurrent spectra of $(Cu_{0.03}Zn_{0.97})Hg(SCN)_4$, $(Cu_{0.1}Zn_{0.9})Hg(SCN)_4$, and $(Cu_{0.2}Zn_{0.8})Hg(SCN)_4$ are shown in Fig. 5, together with the electronic spectrum. What is evident on comparing the photocurrent and electronic spectra is that the photocurrent spectra are closely related to the electron-transfer band with its absorption edge at about 450 mμ. It is noticeable that the threshold values of the photocurrents are almost equal to about 450 mμ (E_o=2.8 eV) for all these three compounds. However, the tail of the photocurrent spectrum of $(Cu_xZn_{1-x})Hg(SCN)_4$ in the 450—600 mμ region seems to shift to the long-wavelength side, depending on the relative concentrations of Cu^{2+} and Zn^{2+}. As well as the thermal activation energy for electrical conduction in the extrinsic region (E_i^e), these tails are associated with the electronic levels of several sorts of lattice imperfections, which were probably introduced by the doping of Cu^{2+} in the $ZnHg(SCN)_4$ lattice.

Table 2. Effective magnetic moment (μ_{eff}) of Cu(II) in $(Cu_xZn_{1-x})Hg(SCN)_4$ lattice at room temperature

Compound	μ_{eff} B.M.
$(Cu_{0.1}Zn_{0.9})Hg(SCN)_4$	2.0
$(Cu_{0.2}Zn_{0.8})Hg(SNC)_4$	1.9

Magnetic Moments. The magnetic susceptibility of the mixed crystals, $(Cu_xZn_{1-x})Hg(SCN)_4$, obeys the Curier-Weiss law fairly well over the temperature range from 118 to 283°K, with quite a small Weiss constant. The values of the effective magnetic moments (μ_{eff}) of Cu(II) in $(Cu_xZn_{1-x})Hg(SCN)_4$ are listed in Table 2. Figgis has shown that Cu(II) in a perfectly regular tetrahedral environment should have an effective moment of about 2.2 B.M.[9] However, it is well established by measurements that the μ_{eff} of Cu(II) is 1.96—2.00 B.M. for Cs_2CuCl_4, 1.91 B.M. for $(Ph_3MeAs)_2CuCl_4$, and 1.96 B.M. for $(Ph_3MeAs)_2CuBr_4$.[10] In Cs_2CuCl_4, the values of the two Cl–Cu–Cl bond angles are 120° and 104°.[11] The value of μ_{eff} of Cu(II) in $(Cu_{0.1}Zn_{0.9})Hg(SCN)_4$ in this case is almost equal to that in Cs_2CuCl_4. Therefore, the degree of distortion of the CuN_4 tetrahedron in $(Cu_xZn_{1-x})Hg(SCN)_4$ may be expected to be almost identical with that of the $CuCl_4$ tetrahedron in Cs_2CuCl_4. In fact, $ZnHg(SCN)_4$ is isomorphous with $CoHg(SCN)_4$,[2] where the N–Co–N bond angles are 118° and 106°.[3,4] The degree of distortion in $(Cu_{0.2}Zn_{0.8})Hg(SCN)_4$ may larger than that in $(Cu_{0.1}Zn_{0.9})Hg(SCN)_4$, judging from the value of μ_{eff} found for $(Cu_{0.2}Zn_{0.8})Hg(SCN)_4$. Consequently, it follows that the mixed crystal with a higher copper concentration will include a greater amount of lattice imperfections caused by Cu^{2+} doping.

Discussion

Here, we will propose a qualitative discussion of the semiconducting nature of the three-dimensional complex salts studied. However, our discussion will be confined to the case of intrinsic semiconduction, because the experimental data are not sufficient to clarify the latttice imperfections which affect the extrinsic semiconduction in the lower-temperature range.

Measurements of the electrical conductivity and its temperature dependence showed that $CuHg(SCN)_4$ and the mixed crystal, (Cu, Zn)$Hg(SCN)_4$, were semiconductors with quite low conductivities. In the case of the mixed crystals, it may be concluded, from a comparison of their photocurrent spectra with their electronic spectra, that the charge carriers for the intrinsic semiconduction originate from electronic transitions associated with the electron-transfer band at about 330 mμ. It may be seen in Fig. 2 that the intrinsic conductivity of the mixed crystals increases with an increase in the copper concentration. This may be due to the increase in the number of charge carriers. In this case, the absorbance of the electron-transfer band at 330 mμ may be expected to increase. Unfortunately, our spectral data are restricted to the visible region; therefore, the compositional dependence of the absorbance of the band at 330 mμ is obscure.

In general, the electron-transfer processes are of two types: the transfer of an electron from an orbital mainly localized on the ligand(s) to an orbital mainly localized on the metal (abbreviated L→M), and the transfer of an electron in the opposite direction (abbreviated M→L).[12] Forster *et al.* have suggested that the electron-transfer bands of the mixed crystals are analogous to those found for $CuCl_4^{2-}$ and $CuBr_4^{2-}$.[6,13,14] This implies that the electron-transfer bands of the mixed crystals are of the L→M type. If it is possible to consider that the electron-transfer bands of the mixed crystals and $CuHg(SCN)_4$ are of the L→M type, a reasonable account for the intrinsic semiconduction of these compounds may be given on the assumptions that the charge carriers are positive holes originating from the electron transfer from thiocyanate to the copper ion and that the holes are conducted through a valence band formed by electronic levels of thiocyanate ions. This mechanism of semiconduction may well account for the fact that, in the case of the mixed crystals, only the higher-energy electron-transfer band is responsible for the photocurrent; that is, if the lower energy electron-transfer band arises from electronic transitions involving localized orbitals, such as nonbonding orbitals of the ligand, the positive holes in such orbitals are likely to be localized in the ligand, therefore making no contribution to the electrical conductivity. In fact, Ferguson has pointed out that the lowest-energy electron-transfer band of $CuCl_4^{2-}$ probably arises from transitions involving orbitals which are nonbonding in T_d symmetry.[13]

The thermal activation energy (E_t) is related to the optical energy (E_o) by the following expression:

$$E_o/E_t = \varepsilon_s/\varepsilon_o,$$

where ε_s and ε_o are the static and high-frequency dielectric constants respectively. If the interatomic bonding is ionic, E_t is smaller than E_o. For the complex salts studied, the values of E_t^i obtained from $\log\sigma$ *vs.* $1/T$ plots are smaller than the values of E_o obtained from the threshold values of the photocurrent and electronic spectra. This suggests that the chemical bonds between copper and thiocyanate ions are most likely to be electrostatic.[15] Furthermore, the extremely low conductivities of these complex salts may well be due to the strong ionic character of the chemical bonds.

Elimination Reaction on Solid Acid Catalysts. IV.* A δ_R LFER Study of the Esterification of Alcohols with Carboxylic Acids over Solid Acid Catalysts

Isao MOCHIDA, Yasuhide ANJU, Akio KATO, and Tetsuro SEIYAMA
Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka
(Received February 6, 1971)

The esterification between eight alcohols and seven carboxylic acids was studied over sodium-poisoned silica-alumina at 250°, using a microcatalytic gas chromatographic technique, in order to elucidate the mechanism of the esterification on a solid acid catalyst on the basis of a LFER (Linear Free-Energy Relationships) approach. Alcohols showed fairly close reactivities for the esterification with acetic acid, whereas, for the olefin formation by intramolecular dehydration and ethylether formation with ethanol, their reactivity varied very much according to the kind of alcohol. In contrast, the reactivities of carboxylic acids for the esterification varied with the structure and were correlated with E_s, Newman's steric-effect parameter, as was observed in the homogeneous acid catalysis, although the reactivity difference under the present conditions was small indeed. It is probably due to the elevated reaction temperature. No ethylacetate, but only thiolacetate, was found in the reaction of acetic acid with ethanethiol. From these facts, it may be concluded that the esterification over a solid acid catalyst may proceed through the attack of an oxonium ion from a carboxylic acid on an adsorbed alcohol, in the manner similar to that in the homogeneous acid-catalyzed esterification.

In a previous paper,[1] two possible mechanistic schemes for the esterification of ethanol with acetic acid were discussed:

Mechanism 1: $C_2H_5^+ + CH_3C(OH)_2^+ \longrightarrow CH_3C(O)OC_2H_5 + 2H^+$

Mechanism 2: $CH_3C(OH)_2^+ + C_2H_5OH_2^+ \longrightarrow CH_3C(O)OC_2H_5 + H_3O^+ + H^+$

One is the attack of the ethyl carbonium ion originating from ethanol on the oxygen atom of the adsorbed acetic acid (Mechanism 1), while the other is that of the oxonium ion from acetic acid on the adsorbed ethanol (Mechanism 2). The δ_C effect (the effect of the nature of the catalyst on the reaction rate),[2] poisoning effect, the kinetic study and a comparison with the dehydration of ethanol on the same catalyst[1,3] all indicate that Mechanism 2 is more probable in the heterogeneous esterification as well as in the homogeneous one.

A study of the dependence of the reactivity upon the reactant structure may give further information about the proposed reaction mechanism. Newman[4] argued the importance of the steric factors of carboxylic acids in homogeneous reactions on the basis of such an approach. In the present study, the mechanism of the esterification on the solid acid catalyst was considered on the basis of the δ_R (the effect of the nature of the reactants on the reaction rate) LFER,[2] using eight alcohols and seven carboxylic acids. A discussion from the same viewpoint was made of the comparisons between the esterifications and the dehydrations of these alcohls. The discrimination between the above two reaction mechanisms may be possible by determining the origin of the ethereal oxygen of the ester. For this purpose, the esterification of ethanethiol with acetic acid may be an adequate system if a common reaction mechanism can be assumed for both alcohols and thiols. An esterification of ethanethiol with acetic acid was, then, studied on the solid acid catalyst. Such a study was attempted in the homogeneous reactions, and the attack of the oxonium ion from benzoic acid was established.[5]

Experimental

Reagents. The alcohols in Table 1 were obtained from the Wako Junyaku Co. The carboxylic acids were obtained from the Tokyo Kasei Co. The ethanethiol was obtained from Nakarai Chemicals, Ltd. All of them were of a E.P. grade except for the ethanol, which was of a G.R. grade.

Catalysts. The catalysts in this work were silica-alumina (13% Al_2O_3) of Japan Cat., a cracking catalyst of the Shokubai Kasei Co. (abbreviated to SA), and the same catalyst impregnated with 0.4 meq Na/g(abbreviated to SA–Na). They were calcined at 550° for 8 hr in the atmosphere.

Apparatus and Procedures. For esterifications of alcohols with carboxylic acids and dehydrations of the mixed alcohols, the reaction temperature was 250°C. For the condensation reaction of ethanethiol with acetic acid, it was 300°C. The rates were calculated from the conversion measured by means of the microcatalytic gas-chromatographic technique.[1,3,6] Polyethylene glycol(PEG 1500) was used in an analytical column except in the esterifications of 2-ethyl-*n*-butyric acid and isovaleric acid with ethanol. In these cases, Tween 80+20% H_3PO_4 was used. A carboxylic acid and an alcohol were mixed in equimolar quantities. A fixed quantity (3.4×10^{-2} mmol) of the homogeneous mixture was injected in every run. The conversions of alcohols were kept below 10% except for *tert*-butanol. The same procedure was used for the reaction of mixed alcohols. The rate was expressed by the unit of mmol·ml/g·min. The details of the experiments were described in previous papers.[1,3]

Results and Discussion

δ_R *Effect as to Alcohols.* The mixture of an alcohol and an acetic acid gave an olefin and an ester without an ether on SA–Na at 250°C. The reactivities of eight alcohols, ROH, are compared in Fig. 1, where the rates of esterification and dehydration into olefin are plotted against Taft's σ^* for the R group. The σ^* values are defined as measures of the inductive electron-withdrawing power of an atom or group of atoms in a molecule. The values of σ^* were taken from the literature.[7] The reactivities of alcohols for the intramolecular dehydration to olefin varied very much amoung the alcohols, whereas those for esterification remained fairly constant. The large dependence of the dehydration rate upon σ^* may mean that the electron-releasing ability of the alkyl group is important in the intramolecular dehydration. Such results have also been reported in the absence of acetic acid.[8] The reactive alcohols tend to proceed into their intramolecular dehydration rather than into their intermolecular esterification, as has been observed in the metal sulfate supported by silica gel.[9] This fact may be understood if we remember that the intermediate from the alcohol with a high tendency to give the carbonium ion is too reactive to stay on the catalyst for the ester formation without being converted into olefin. The distinct difference in the reactivity tendencies suggests different rate-detarmining steps for these intra- and intermolecular reactions.

The ether formations through intermolecular reactions between ethanol and various alcohols were measured on SA–Na at 250°C. The rates are compared with those of acetate formations through the intermolecular reactions of alcohols with acetic acid in Table 1. For primary and secondary alcohols, the rates of the esterifications were much larger than those of the ethyl-ether formations.

The rates of ether formation with ethanol increase in this order of the ease of the formation of the corresponding carbonium ion from alcohols: primary <secondary<tertiary. This indicates a carbonium ion mechanism for the ether formation, in which ethanol is attacked by the carbonium ion from higher alcohol. If the esterification proceeds through a mechanism accompanying carbonium ions from alcohols, the ether formation will be faster than the esterification because more basic ethanol will have a larger susceptibility to the carbonium ion than that of acetic acid. The rates observed, however, do not agree with this expectation for primary and secondary alcohols. Therefore, the carbonium ion formation from alcohols

TABLE 2. DEPENDENCE OF THE ESTERIFICATION REACTIVITY ON THE STRUCTURE OF CARBOXYLIC ACID

Reaction temperature (°C)	s[a)]	Numbers of carboxylic acids used for analysis
20	1.03 ± 0.01	16
30	0.99 ± 0.01	17
40	0.93 ± 0.03	19

a) $\log(k/k_0)=s\,E_s$, where k and k_0 are the rate constants of esterification of ethanol with carboxylic acid and acetic acid, respectively.
Kinetic data were obtained from Ref. 12.

should be abandoned and Mechanism 2 seems more probable for the esterification.

For *tert*-butanol, the rate of mixed-ether formation was larger than that of esterification. A different mechanism should be supposed for the esterification of *tert*-butanol in the heterogeneous reaction as well as in the homogeneous reaction.[10)]

δ_R Effect as to Carboxylic Acids. The rates of the esterifications of ethanol with some carboxylic acids on SA–Na at 250°C are shown in Fig. 2 as a function of E_s,[11)] which is thought to represent the steric factor of the substituent. Newman[12)] proposed a sixtet rule for the reactivities of carboxylic acids in the homogeneous esterification, and stressed the importance of the steric factor in this reaction. The analysis of his data at 20, 30, and 40°C showed good correlations with the E_s of the carboxylic acid as is shown in Table 2 and Fig. 2. Large differences in the reactivities were observed. In the heterogeneous catalysis of the present study, a linear correlation was also found, as is shown in Fig. 2, although the kind of carboxylic acids has a smaller effect on the reactivity for esterification. The dependency of the esterification rate on the structure of carboxylic acids decrease with an increase in the reaction temperature in the homogeneous reaction, as may be seen in Table 2. Thus, the smaller reactivity differences among carboxylic acids in the present study may be explained by the reduction of the steric-effect at the higher reaction temperatures. It is interesting that the steric effect was small at the reaction of 250°C in spite of the expectation that the effect might be large on the solid catalyst surface. At any rate, such results do not conflict with Mechanism 2 and suggest, rather, the continuity of the reaction mechanism in homogeneous and heterogeneous acid-catalyzed reactions.

Reaction of Acetic Acid and Ethanethiol. It has been known that the thiol reacts with benzoic acid to produce thiol benzoate in an acidic medium.[5)] Whether or not the ester thus produced contains the sulfur atom may give information on the mechanism of esterifications. In the reaction of acetic acid with ethanethiol on SA at 300°C, no ethylacetate except thiol acetate was found by the use of the gas chromatograph.[13)] The further identification of thiol acetate was done by means of IR and MS analyses of the trapped sample. The existence of ethylthioacetate without ethylacetate in the product may support Mechanism 2; in this case, the carbon atom of the carbonyl group in the acetic acid, which is positively polarized, may attack the sulfur atom of thiol. The fact that the reactivity of thiol is lower than that of ethanol may be easily deduced by the above reaction mechanism because of the small basicity of the sulfur atom, as estimated from the value of electronegativity.[14)] In fact, the reactivity of thiol was only a tenth of that of ethanol.

All the above results suggest that the esterification over the solid acid catalyst may proceed through an attack of the oxonium ion from carboxylic acid on an adsorbed alcohol, in a manner similar to that in the homogeneous acid-catalyzed esterification.

Our thanks are due to Professor Yukio Yoneda of the University of Tokyo for generously providing us with a program of the least-square means. The electronic computaion was carried out on a FACOM 230–60 of the Computer Center of Kyushu University. We are also grateful to Mr. Hozumi Futada for his analysis by means of a Mass Spectrometer.

Mixed Monolayers of Poly(methyl acrylate) and Its Saponified Polymer

Seiichiro HIRONAKA,* Takashi KUBOTA, and Kenjiro MEGURO
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo
(Received February 20, 1971)

A film balance study of the mixed monolayers with various ratios of poly(methyl acrylate) and its saponified polymer or of the monolayers themselves was carried out on distilled water, and the mixed monolayers were compared with individual monolayers of the saponified polymers. These mixed monolayers expanded more than individual saponified polymers at the same degree of saponification, giving larger limiting areas. Their limiting areas deviated from the linearity between the limiting area and the degree of saponification, in contrast to the fact that the limiting areas of individual monolayers decreased linearly with an increase in the degree of saponification. This fact can be considered to be due to interactions between the side chains of the ploymers.

Recently, many studies of the mixed monolayers have been reported.[1-3] However, there have been few studies of the mixed monolayers of polymers.[4-6]

In general, when mixtures of two insoluble substances are spread on the water surface, it can be considered that they form either individual monolayers without two components' mixing or an ideal surface mixture by their complete mixing with one another. Mixtures of analogous compounds give the linear relation between the limiting area and the ratio of mixing and the existence of stoichiometric interaction, that is, the additivity of the film areas and the surface potentials. La Mer *et al.* have reported the ideal surface behavior of the mixed monolayers by studying the rate of the evaporation of water through the mixed monolayers.[1] Crisp has shown that the areas and the surface potentials of the mixed monolayers of poly(vinyl acetate) and poly(vinyl alcohol) were linear averages of the individual pure monolayers.[4] However, Labbauf has suggested that the areas obtained for the mixed monolayers of poly(ethyl acrylate) and poly(vinyl acetate) deviated largely, both positively and negatively, from the linear average values.[7]

In this investigation, we have studied the mixed monolayers of poly(methyl acrylate) and its saponified polymers, or the monolayers themselves, and discussed the two-dimensional behavior of polymers in terms of the deviation from the linearity of their limiting areas and the degrees of saponification.

Experimental

Monomer. Methyl acrylate (supplied by Toagosei Co., Ltd.) was used for radical polymerization. It was purified by distillation under reduced nitrogen atomosphere after its inhibitor had been removed by washing it with 5% sodium hydroxide aqueous solution and distilled water and after it had been dehydrated with silicon dioxide.

Polymerization. Poly(methyl acrylate) was prepared by radical polymerization, with α,α'-azobisisobutyronitrile as the initiator, in benzene at 50°C under a flow of nitrogen gas. The polymer thus obtained was purified by reprecipitation from its acetone solution into a large excess of methanol. The average molecular weight of this polymer, as determined by the measurement of the viscosity, was 659000.

Saponification. The saponifications of poly(methyl acrylate) were carried out in a homogeneous system of an acetone-water mixture (5:2 by volume), with sodium hydroxide as the catalyst, at 50°C until all the sodium hydroxide was consumed.[8] After the reaction, the saponified polymers were washed with a hydrochloric acid aqueous solution. They were purified by reprecipitation from an acetone solution into water, methanol, and ethyl ether. The saponification was confirmed by a study of the infrared spectra, while the degrees of saponification (mol%) of these polymers were determined by the elementary analyses to be 13.48, 24.16, and 48.34 mol%.

Surface-pressure Measurement. A modified Wilhelmy-type film balance was used to measure the surface pressure.[9] The film balance was enclosed in the chamber to allow thermostatic control at 20.0±0.2°C. The water in the trough was kept at 20.0±0.2°C by circulating water from a thermostat bath. The distilled water used as the substrate was in the range of pH 5.0—6.0. The trough was coated with highly pure, hard paraffin wax. The sensitivity of the torsion wire was about ±0.1 dyn/cm.

The monolayers were spread on the substrate from a mixed spreading solution of acetone-benzene (1:1 by volume) by means of an "Agla" microsyringe. Various organic liquids were examined as the spreading solvent, but the best was an acetone-benzene mixture (1:1 by volume).

Thirty minutes were allowed for the solvent to evaporate before compression was started. Every reading of the surface pressure was carried out after the films had been left for 5 min. after their compression. The rate of compression was 7.5 cm²/min.

Results and Discussion

The surface pressure measurements for all the polymers were repeated at least several times; their results were reproducible within the limits of experimental er-

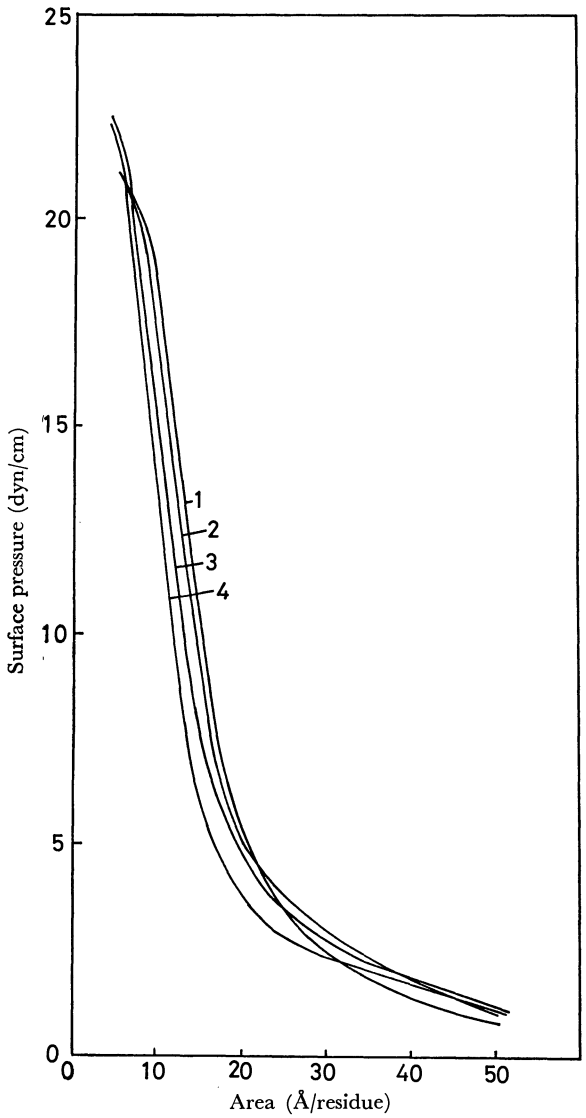

Fig. 1. The surface pressure-area isotherms of poly (methyl acrylate) and its saponified polymer on distilled water.
1– poly(methyl acrylate); 2– 13.93 mol% saponified polymer; 3– 24.16 mol% saponified polymer; 4– 48.34 mol% saponified polymer.

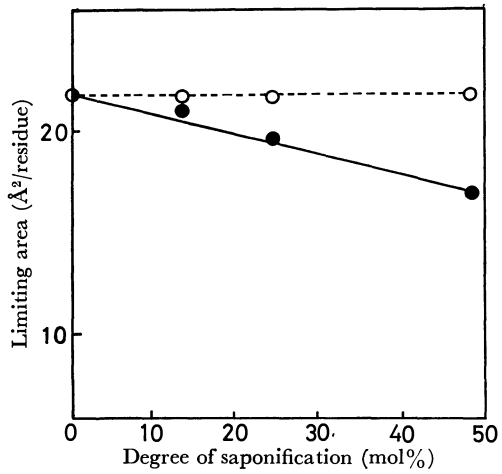

Fig. 2. The limiting areas of the saponified polymer *vs.* the the degree of saponification. ○: theoretical; ●: experimental; ◑: poly(methyl acrylate).

ror of the ±0.1 Å²/residue.

The surface pressure-area isotherms for poly(methyl acrylate) and its saponified polymers on distilled water are shown in Fig. 1. The limiting area obtained for poly(methyl acrylate) was 21.6 Å²/residue which corresponded well to 21.5 Å²/residue by Crisp.[10] This fact suggests that our sample is just the same as Crisp's. The limiting area for each saponified polymer was smaller than that of poly(methyl acrylate), and the theoretical values were calculated as follows. By using the limiting areas of 21.5 Å² per methyl acrylate residue and 22.0 Å² per acrylic acid residue reported by Crisp,[10] the theoretical value (A_t) of the saponified polymer when all the residues of the polymer were oriented on the water surface was calculated by this equation:

$$A_t = 21.5\left(1-\frac{X}{100}\right) + 22.0\frac{X}{100} \qquad (1)$$

where X is the degree of saponification (mol %).

Figure 2 shows the limiting area of the saponified polymer *vs.* the degree of saponification. The experimental and theoretical limiting areas for each saponified polymer are listed in Table 1. The limiting areas decreased linearly with an increase in the degree of saponification, but deviated from the ideal linearity of Eq. (1). It is considered that some of the hydrophilic residues of the polymer are submerged into the water phase by compressing the films,[11] and that the higher the degree of saponification, the larger the decrease in the limiting area.

Table 1. The limiting areas of poly(methyl acrylate) and its saponified polymer on distilled water

Sample	Limiting Area (Å²/residue)	
	Experimental	Theoraretical (by Crisp)
Poly(methyl acrylate)	21.6	21.5
13.93 mol% saponified polymer	21.0	21.65
24.16 mol% saponified polymer	19.5	21.69
48.34 mol% saponified polymer	16.8	21.79

The surface pressures of the mixed monolayers of poly(methyl acrylate) and the 48.34 mol% saponified polymer (mixed monolayers of the A series) and the 13.48 mol% and 48.34 mol% saponified polymers (mixed monolayers of the B series), mixed in various ratios, were measured under the same conditions as were used the individual monolayers. The surface pressure-area isotherms obtained for the mixed monolayer of the B series are shown in Fig. 3. The mixed monolayers expanded much more than the individual monolayers and gave larger limiting areas. Furthermore, these limiting areas were larger than those of the individual monolayers at almost the same degree of saponification. The mixed monolayers of the A series showed the same inclinations.

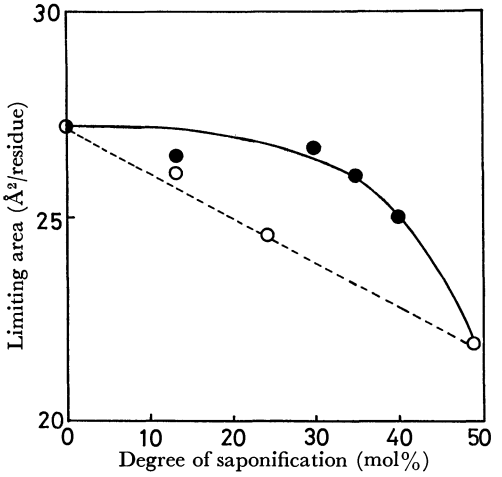

Fig. 4. The limiting areas of mixtures of poly(methyl acrylate) and 48.34 mol% saponified polymer *vs.* the degree of saponification by mixing. ○: pure saponified polymer; ●: mixed polymer; ◑: poly(methyl acrylate).

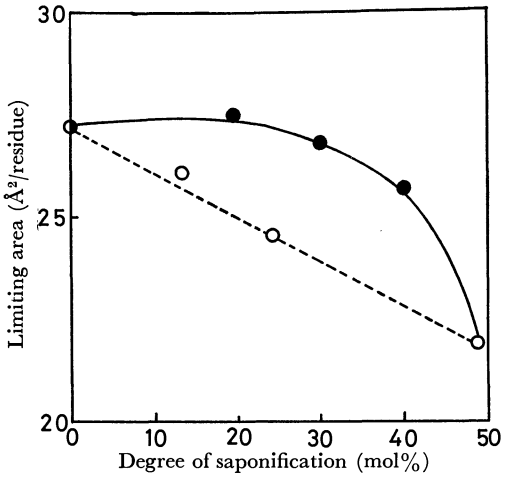

Fig. 5. The limiting areas of mixtures of 13.93 mol% saponified polymer and 48.34 mol% saponified polymer *vs.* the degree of saponification by mixing. ○: pure saponified polymer; ●: mixed polymer; ◑: poly(methyl acrylate).

The behavior of the ideal surface mixtures is generally exhibited by mixtures of close members of a homologous series.[1,4,12] The plots of the limiting areas of the mixed monolayers *vs.* the degrees of saponification by mixing are given in Figs. 4 and 5. If these mixed monolayers form the ideal surface solution, the plots should have the ideal mixing linearity, that is, the linearity between the limiting areas and the degrees of saponification obtained for the individual monolayers. However, the results of A and B series deviated largely and positively from the ideal mixing linearity and behaved like the nonideal surface solutions. This fact suggests that the behavior and orientations of the mixed monolayers are different from those of the individual monolayers. The individual monolayers have such orientations as some of their hydrophilic groups are submerged into the bulk, while one or two of them are hung with such hydrophobic anchors as methyl acrylate residues and so remain on the water surface. Therefore, they have limiting areas smaller than the theoretical values. On the other hand, with regard to the mixed monolayers, it is considered that the two component polymers have interactions between each other's sidechains, though they consist of binary mixtures of homologous polymers, and that the interactions exceed the decrease in the areas because of the submergence of some of the hydrophilic groups. Furthermore, it is conceivable that the dissociation of the hydrophilic groups facilitates this interaction between sidechains. As evidence for these suggestions, the mixed monolayers were more expanded and unstable than the individual monolayers at all surface pressures. Specially, at low surface pressures, the mixed monolayers were much more expanded than the individual monolayers. This suggests that the molecules of polymers have larger spaces for their free movements because of the interactions.

12) M. L. Robbins and V. K. La Mer, *J. Colloid Sci.*, **15**, 123 (1960).

Conclusion

Although the individual monolayers gave smaller limiting areas than the theoretical values because some of hydrophilic groups are submerged into the bulk, they exhibited a linearity between the limiting area and the degree of saponification. The mixed monolayers did not show the behavior of the ideal surface mixtures in spite of their consisting of close members of a homologous series, and their limiting areas deviated largely and positively from the ideal linearity upon mixing. These unexpected results suggest an interaction between sidechains of two component polymers which exceeds the decrease in the areas as a result of the submergence of some of the hydrophilic groups.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2332—2339(1971)

Topological Index. A Newly Proposed Quantity Characterizing the Topological Nature of Structural Isomers of Saturated Hydrocarbons

Haruo Hosoya

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo

(Received February 27, 1971)

A topological index Z is proposed for a connected graph G representing the carbon skeleton of a saturated hydrocarbon. The integer Z is the sum of a set of the numbers $p(G,k)$, which is the number of ways in which such k bonds are so chosen from G that no two of them are connected. For chain molecules Z is closely related to the characteristic polynomial derived from the topological matrix. It is found that Z is correlated well with the topological nature of the carbon skeleton, *i.e.*, the mode of branching and ring closure. Some interesting relations are found, such as a graphical representation of the Fibonacci numbers and a composition principle for counting Z. Correlation of Z with boiling points of saturated hydrocarbons is pointed out.

There are three conventional methods for distinguishing the carbon skeletons of the structural isomers of saturated hydrocarbons, which may or may not contain a ring or rings as illustrated in Fig. 1.

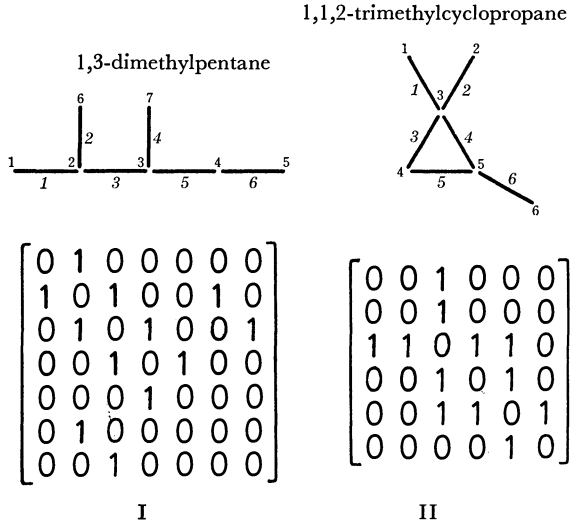

Fig. 1. Three conventional methods for characterizing the carbon skeletons of saturated hydrocarbons.

i) A systematic naming system in which the size of the ring and the sites of the branching are specified for the longest chain or largest ring.

ii) A graph in which each point corresponds to a carbon atom and the numbers of the attached hydrogen atoms are automatically determined so that each carbon atom satisfies the tetra-valency.

iii) A topological matrix in which the values of the off-diagonal elements 1 and 0 are respectively assinged to the bond and no-bond for the pairs of carbon atoms.

These three methods are equivalent to each other in the topological sense. Topology has contributed to the development of chemistry, *e.g.*, in predicting the numbers of the structural isomers,[1-4] by way of the so-called chemical inference using the structural formulae, through the electronic therories such as the Hückel molecular orbital, valence bond and free electron theories.[5] It has also been shown that some thermodynamic properties such as boiling point are correlated well with the topological nature of the compounds,[6,7] while sophisticated quantum mechanical calculations have been unsuccessful.

In this report a topological index Z is defined and proposed as a fourth candidate for classifying saturated hydrocarbons with respect to their topological nature. Although it does *not* necessarily give the structure of the isomer, it is roughly dependent on the topological

nature of a molecule, *i.e.*, the size and mode of branching and ring closure. It was also found to correlate well with the boiling point. This magic number Z is enumerated just from the carbon skeleton G of a given saturated hydrocarbon, and is of chemical and mathematical interest.

Theoretical

First, a brief summary of theoretical background is given as premises.[8,9] It seems that most of the formulations and algorithms developed in this paper have not yet been proposed in chemistry or in graph theory.[10]

Premises. A graph G consists of points (vertices or atoms) and lines (edges or bonds). We consider only connected non-directed graphs in which every point has at least one and at most four neighbors, and no loop (a line joining a point to itself) and no multiple lines (double or triple bonds) are involved. With these restrictions the graph is equivalent in a topological sense to the carbon skeleton of a saturated hydrocarbon or, in some cases, an unsaturated hydrocarbon. Distinction between σ- and π-electrons or between single and multiple bonds are meaningless for the moment.

Graphs are grouped into trees and non-trees depending upon whether they contain cycles (rings) or not. Chemically speaking, trees are chain hydrocarbons and non-trees cyclic ones.

An adjacency matrix $\boldsymbol{A}$ for graph G is defined in graph theory as a square matrix with the following elements:

$$a_{ij} = \begin{cases} 1 & \text{if the points } i \text{ and } j \text{ are neighbors,} \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

The order of $\boldsymbol{A}$ is the number of the points in G. Ham and Ruedenberg[11] called it a topological matrix. Since then a number of interesting relations have been derived.[5] It is obvious that the matrix characters of $\boldsymbol{A}$ are independent of the way of numbering the atoms.

The power series expansion, with respect to X, of the determinant $|X\boldsymbol{E}+\boldsymbol{A}|$ for graph G is called a characteristic polynomial, where $\boldsymbol{E}$ is a unit matrix of the same order N as $\boldsymbol{A}$.[12]

$$P_G(X) = \det|X\boldsymbol{E}+\boldsymbol{A}| = \sum_{i=0}^{N} f_i X^{N-i} \quad (2)$$

A secular determinant giving the Hückel molecular orbitals for the π-electrons of an unsaturated hydrocarbon is reduced to the same form as above. Besides the standard but iterative methods of Laplace, Newton, and Frame, useful graphical techniques of the expansion of $P_G(X)$ by use of recursion formulae were given by Heilbronner.[13]

Definition of Topological Index. Consider a graph or structure G with N carbon atoms. The topological index Z is defined stepwise as follows.

Definition 1 (*Non-adjacent number*): A non-adjacent number $p(G,k)$ is the number of ways in which k bonds are so chosen from G that no two of them are connected, $p(G,0)$ being unity and $p(G,1)$ the number of the bonds.

Definition 2 (*Z-counting polynomial*):

$$Q_G(Y) = \sum_{k=0}^{m} p(G,k) Y^k \quad (3)$$

Definition 3 (*Topological index*):

$$Z_G = \sum_{k=0}^{m} p(G,k) = Q_G(1) \quad (4)$$

where m is the maximum number of k for G.

Note that $p(G,m)$ is equal to the number of Kekulé structures for an unsaturated hydrocarbon in which each atom forming the carbon skeleton G supplies one electron to the π-system.[14] The Z-counting polynomial is introduced as a proof technique and is actually used in Appendix.[16] Unless confusion occurs the suffix G for Z, $P(X)$ and $Q(Y)$ may be omitted.

Let us take two compounds I(tree) and II(non-tree) in Fig. 1 as examples and enumerate these quantities. For convenience the bonds are numbered in italics. For both the compounds $p(G,0)=1$ and $p(G,1)=6$. The following pairs of bonds are the entries of $p(G,2)$:

I: *1-4*, *1-5*, *1-6*, *2-4*, *2-5*, *2-6*, *3-6*, and *4-6*,
II: *1-5*, *1-6*, *2-5*, *2-6*, and *3-6*.

Hence $p(I,2)=8$ and $p(II,2)=5$. For I there are two possible ways of choosing three bonds in which no two of them are connected, *i.e.*, *1-4-6* and *2-4-6*. However, for II one can not choose such combination. We have then $p(I,3)=2$ and $p(II,3)=0$. All other $p(G,k)$ values for $k>3$ are zero and we obtain

$$Q_I(Y) = 1 + 6Y + 8Y^2 + 2Y^3, \qquad Z_I = 17$$
$$Q_{II}(Y) = 1 + 6Y + 5Y^2, \qquad Z_{II} = 12.$$

Relation with Characteristic Polynomial. The characteristic polynomials of I and II are obtained as follows by decomposing the secular determinants.

$$P_I(X) = X^7 - 6X^5 + 8X^3 - 2X$$
$$P_{II}(X) = X^6 - 6X^4 + 2X^3 + 5X^2.$$

Note that for I, i) the power to X decreases by two and ii) the absolute values of the coefficents of $P(X)$ are identical to the set of numbers $p(G,k)$ or the coefficients of the Z-counting polynomial $Q(Y)$. For any tree these two characteristics are observed without exception.[17] i) is proved by the pairing theorem[18]

for the Hückel molecular orbitals of alternant hydrocarbons, since a tree is alternant. Although ii) appears to be obvious, it seems to have never been stated explicitly. This relation is worthy of being restated as a theorem.

Theorem 1: The characteristic polynomial of a tree T is given by

$$P_T(X) = \sum_{k=0}^{m} (-1)^k p(T, k) X^{N-2k} \quad (5)$$

where m is the largest number of bonds disconnected to each other in T.

On the other hand, for non-tree graphs as II the above-mentioned relationship no longer holds, but is contaminated with the terms representing the size and branching mode of the rings.

Normal Paraffins. Denote a normal paraffin with N carbon atoms (n-N-ane) by $\bar{N}$. By induction it can be shown that

$$p(\bar{N}, k) = {}_{N-k}C_k = (N-k)(N-k-1)\cdots(N-2k+1)/k! \quad (k \neq 0) \quad (6)$$

$$P_{\bar{N}}(X) = \sum_{k=0}^{m} (-1)^k {}_{N-k}C_k X^{N-2k} \quad (7)^{19}$$

The interger m can be expressed as $m=[N/2]$, where a pair of square brackets are, after Gauss, the greatest integer not exceeding the real number in them.

As an example, for n-heptane one obtains $p(\bar{7},0)=1$, $p(\bar{7},1)=(7-1)/1=6$, $p(\bar{7},2)=(7-2)(7-3)/2\cdot1=10$, $p(\bar{7},3)=(7-3)(7-4)(7-5)/3\cdot2\cdot1=4$, and $p(7,k)=0$ for $k>3$, and $Z_7=1+6+10+4=21$, and

$$P_{\bar{7}}(X) = X^7 - 6X^5 + 10X^3 - 4X.$$

From the sets of $p(\bar{N},k)$ the following progression $\{Z_{\bar{N}}\}$ can be obtained.

N:	1	2	3	4	5	6	7	8	⋯
$Z_{\bar{N}}$:	1	2	3	5	8	13	21	34	⋯

The series $\{Z_{\bar{N}}\}$ recurs as

$$Z_{\bar{N}} = Z_{\bar{N-1}} + Z_{\bar{N-2}} \quad (N \geq 3) \quad (8)$$

This is just the Fibonacci series[20] and is given by the Binét formula[21]

$$Z_{\bar{N}} = \left\{ \left(\frac{1+\sqrt{5}}{2}\right)^{N+1} - \left(\frac{1-\sqrt{5}}{2}\right)^{N+1} \right\} \Big/ \sqrt{5} \quad (9)$$

Relation (8) can be proved from the definition of the topological index and the well-known recursion formula for $P_{\bar{N}}(X)$:[13]

$$P_{\bar{N}}(X) = X \cdot P_{\bar{N-1}}(X) - P_{\bar{N-2}}(X) \quad (N \geq 3) \quad (10)$$

Branched Paraffins. For branched paraffins $P(X)$ obtained from Eq. (5) without tedious effort of decomposing the determinant $|XE+A|$. The results for the lower members of normal and isomeric paraffins are given in Table 1 in the increasing order of the topological

index Z. Note the numbering character of Z. All the possible isomeric saturated hydrocarbons from methane to n-hexane are found to be "numbered" with Z except for neopentane which has the same Z value 5 as n-butane leaving the compound-6 blank. The Z value of 2,2,3-trimethylbutane, 13, is the same as that of n-hexane and the nine isomers of heptane are nicely "numbered" up to 21. For eighteen isomers of octane, numbering from 17 to 34 is a little disordered and redundancy increases very smoothly with N, since it is an outcome of a different way of partitioning a given interger Z into a set of $p(G,k)$'s.

Let us take a closer look at the $p(G,k)$ values. To all the isomers with the same number of carbon atoms the values of $p(G,0)$ and $p(G,1)$ are common by difinition. If one defines the decrement of the $p(G,k)$ value of an isomeric N-ane relative to the normal N-ane as

$$\delta p(N, k) = p(\bar{N}, k) - p(N, k), \tag{11}$$

we find additive contributions to the value of $\delta p(N,2)$ by the branching as

$$\delta p(N, 2) = (\text{Number of tertiary carbon atoms}) + 3(\text{Number of quarternary carbon atoms}). \tag{12}$$

Although higher members of $\delta p(N,k)$'s have similar additive relations, fairly complicated crowdness corrections are necessary, *e.g.*, terms which are functions of the number of adjacent pairs of tertiary and quarternary carbon atoms. Anyway a general trend of the lowering of the resultant Z value by the branching is thus evident.

Composition Principle for Z. In order to study the above problem quantitatively, the composition principle for enumerating the Z values of branched hydrocarbons is given as a theorem.

Theorem 2: The Z value of a given graph G is calculated as

Z_G = (Product of the Z values for the graphs G_1 and G_2 derived from G by cutting a bond b) + (Product of the Z values for all the graphs $G_{i1}, G_{i2}, \cdots$ $(i=1, 2)$ derived from G_1 and G_2 by cutting all the bonds incident to b in the *original* graph G).[22]

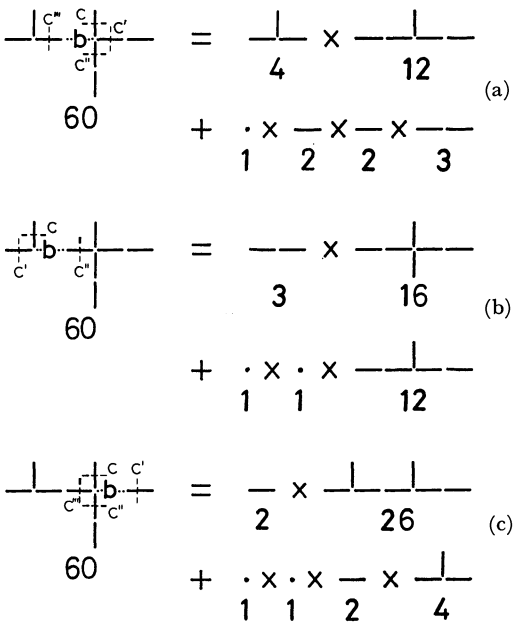

Fig. 2. Examples of the composition principle for the topological index Z. Bond b is cut first and then bonds c,c',.... Three different choices of b give the same Z value.

22) For ring compounds one can choose a bond whose deletion gives rise to one graph G_1 (=G-b) instead of generating two fragmental graphs. In this case read the first term in Theorem 2 as (The Z value of the graph G_1 derived from G by cutting a bond b).

See Fig. 2 for explanation. Graph G may be called 2,4-dimethyl-4-ethylhexane. Choose any one bond say bond b in Fig. 2a and cut it. The graph G is divided into isobutane and 3-methylpentane, whose Z values are, respectively, 4 and 12, giving the product 48. Then cut all the bonds c, c′, c″, and c‴ which *were* incident to bond b in the original graph G. The resultant graphs are one methane ($Z=1$), two ethanes ($Z=2\times2$) and one propane ($Z=3$), giving the product of Z's as 12. The Z value of the graph G is the sum of 48 and 12, namely 60. It should be confirmed that the Z value is uniquely obtained independent of the choice of bond b in the first step. This is actually the case as illustrated in Figs. 2b and 2c.

If one cuts the terminal bond of n-N-ane and applies Theorem 2, the recursion formula (8) is obtained, while if the jth bond is chosen the following equation is obtained.

$$Z_{\overline{N}} = Z_{\overline{j}} \cdot Z_{\overline{N-j}} + Z_{\overline{j-1}} \cdot Z_{\overline{N-j-1}} \qquad (13)^{23)}$$

A general proof of Theorem 2 is given in the Appendix. It is also shown that this composition principle can be applied to ring compounds (*vide infra*). If we neglect the second term of the right-hand side of Theorem 2, and if necessary apply Theorem 2 successively, we get the following theorem.

Theorem 3: If graph G is decomposed into a set of fragmental subgraphs G_1, G_2, ···by deleting a set of bonds b, c,···(G−b−c−···$=G_1+G_2+\cdots$, $G_1 \cap G_2=0$, ···), then

$$Z_G > Z_{G_1} Z_{G_2} \cdots.$$

Especially for a n-N-ane we get

$$\begin{aligned} Z_{\overline{N}} &> Z_{\overline{i}} \cdot Z_{\overline{N-i}} \\ Z_{\overline{N}} &> Z_{\overline{i}} \cdot Z_{\overline{j}} \cdot Z_{\overline{N-i-j}} \\ Z_{\overline{N}} &> Z_{\overline{i}} \cdot Z_{\overline{j}} \cdot Z_{\overline{k}} \cdot Z_{\overline{N-i-j-k}} \quad \text{and the like.} \end{aligned} \qquad (14)$$

The ralations are derived also from Eq. (13). By the aid of these composition principles let us study the regularities in the lowering of Z values by branching.

First consider a series of 2-methyl-($N-1$)-ane (Fig. 3a, $j=2$), in which a branch of a unit length is attached to the second atom counting from one end of a linear chain composed of ($N-1$) atoms. Application of Theorem 2 to this graph gives the general expression

$$Z_{2m-N} = Z_{\overline{N-1}} + Z_{\overline{N-3}} \quad (N \geq 3) \qquad (15)$$

where $2m$-N stands for the 2-methyl substituted isomer of N-ane. Generally for j-methyl substituted isomers we get

$$Z_{jm-N} = Z_{\overline{N-1}} + Z_{\overline{j-1}} \cdot Z_{\overline{N-j-1}} \quad (N-1 \geq j \geq 2) \qquad (16)^{24)}$$

Similarly for j,j-dimethyl-($N-2$)-ane ($N-2 \geq j \geq 2$,

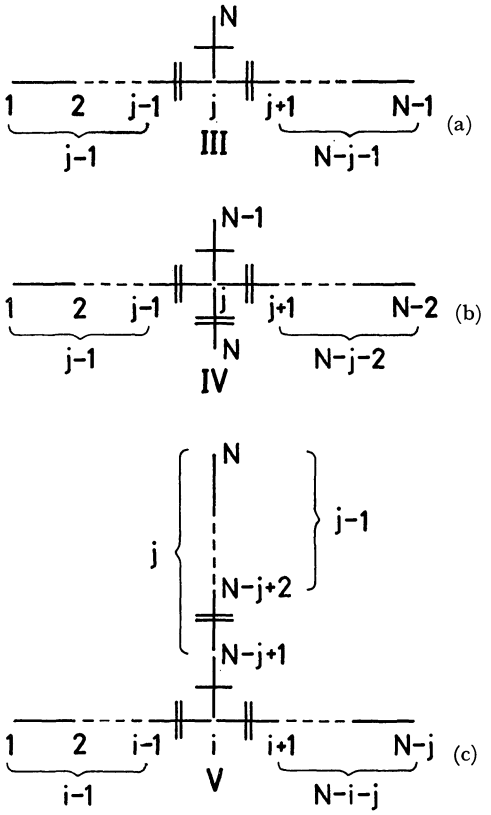

Fig. 3. Application of the composition principle to three different classes of branched hydrocarbons. A single line and two parallel lines dissecting bonds, represent the first and second cutting processes, respectively.

Table 2. Effect of branching on the $p(G,k)$ and Z values of decane isomers

Type[a]	j	Graph (G)	$p(G,k)$[b] $k=2$	3	4	5	Z_G

	2		27	32	13	1	83
	3		27	32	12	0	81

a) See the corresponding structures in Fig. 3 with N=10 and $i=4$ (for V).
b) For all the graphs $p(G,0)=1$ and $p(G,1)=9$.

23) This is also proved by the known relation for $P(X)$,[13] *viz.*,
$$P_{\overline{N}}(X) = P_{\overline{j}}(X)P_{\overline{N-j}}(X) - P_{\overline{j-1}}(X)P_{\overline{N-j-1}}(X) \qquad (13')$$
or $$Q_{\overline{N}}(Y) = Q_{\overline{j}}(Y)Q_{\overline{N-j}}(Y) + Y \cdot Q_{\overline{j-1}}(Y)Q_{\overline{N-j-1}}(Y) \qquad (13'')$$

24) The corresponding expressions for the Z-counting and characteristic polynomials are as follows.
$$Q_{jm-N}(Y) = Q_{\overline{N-1}}(Y) + Y \cdot Q_{\overline{j-1}}(Y)Q_{\overline{N-j-1}}(Y) \qquad (16')$$
$$P_{jm-N}(X) = X \cdot P_{\overline{N-1}}(X) - P_{\overline{j-1}}(X)P_{\overline{N-j-1}}(X) \qquad (16'')$$
$$Q_{jjm-N}(Y) = Q_{\overline{N-2}}(Y) + 2Y \cdot Q_{\overline{j-1}}(Y)Q_{\overline{N-j-2}}(Y) \qquad (17')$$
$$P_{jjm-N}(X) = X \cdot P_{\overline{N-2}}(X) - 2 \cdot P_{\overline{j-1}}(X)P_{\overline{N-j-2}}(X) \qquad (17'')$$
$$Q_{ji-N}(Y) = Q_{\overline{i}}(Y)Q_{\overline{N-i}}(Y) + Y \cdot Q_{\overline{i-1}}(Y)Q_{\overline{j-1}}(Y)Q_{\overline{N-i-j}}(Y) \qquad (18')$$
$$P_{ji-N}(X) = X \cdot P_{\overline{i}}(X)P_{\overline{N-i}}(X) - P_{\overline{i-1}}(X)P_{\overline{j-1}}(X)P_{\overline{N-i-j}}(X) \qquad (18'')$$

denoted by *jjm-N*) series, we get (Fig. 3b)

$$Z_{jjm-N} = Z_{\overline{N-2}} + 2Z_{\overline{j-1}} \cdot Z_{\overline{N-j-2}} \quad (N-2 \geq j \geq 2) \quad (17)^{24)}$$

The result for the compound in which a chain of j atoms is attached to the ith position of n-$(N-j)$-ane is as follows.

$$Z_{ij-N} = Z_{\overline{j}} \cdot Z_{\overline{N-j}} + Z_{\overline{i-1}} \cdot Z_{\overline{j-1}} \cdot Z_{\overline{N-i-j}} \quad (N-j \geq i \geq 1) \quad (18)^{24)}$$

Examples of the calculated results are shown in Table 2 for decane isomers ($N=10$). Note the zig-zag variation of the Z values within a series of compounds and an interesting pattern of the $p(G,k)$ values. By successive applications of Eqs. (8), (13), and (14) to Eqs. (16)—(18), the following inequality is obtained.

$$Z_{\overline{N}} > Z_{jm-N}, Z_{jjm-N}, Z_{ji-N} \quad (19)$$

More generally this can be stated as a theorem.

Theorem 4: The value Z of the normal compound is the largest among the isomers with the same number of carbon atoms.

Table 3. Topological properties of cyclo-*N*-anes

N	$P(X)$	$Q(Y)$	Z
3	X^3-3X+2	$1+3Y$	4
4	X^4-4X^2	$1+4Y+2Y^2$	7
5	X^5-5X^3+5X+2	$1+5Y+5Y^2$	11
6	$X^6-6X^4+9X^2-4$	$1+6Y+9Y^2+2Y^3$	18
7	$X^7-7X^5+14X^3-7X+2$	$1+7Y+14Y^2+7Y^3$	29
8	$X^8-8X^6+20X^4-16X^2$	$1+8Y+20Y^2+16Y^3+2Y^4$	47

Cycloparaffins. For compounds with one or more rings, simple correlation between the $p(G,k)$'s and the coefficients of the characteristic polynomials is not always observed. $P(X)$, $Q(Y)$, and Z for the lower members of cyclo-*N*-ane (denoted by N^0) are given in Table 3. The coefficeints in $Q(Y)$ are systematically obtainable as

$$\begin{aligned} Q_{N^0} &= \sum_{k=0}^{m} ({}_{N-k}C_k \cdot N/(N-k))Y^k \\ &= 1 + NY + N(N-3)/2 \cdot Y^2 \\ &\quad + N(N-4)(N-5)/3! \cdot Y^3 \\ &\quad + N(N-5)(N-6)(N-7)/4! \cdot Y^4 + \cdots \end{aligned} \quad (20)$$

For ring compounds, however, no one-to-one correspondence between the coefficients of $P(X)$ and $Q(Y)$ exists.

For Z_{N^0} values the following two relations are found.

$$Z_{N^0} = Z_{\overline{N}} + Z_{\overline{N-2}} \quad (N \geq 3) \quad (21)$$

$$Z_{N^0} = Z_{N-1^0} + Z_{N-2^0} \quad (N \geq 5) \quad (22)$$

Note that Eq. (21) is a special case of Theorem 2 and the recursion formula (22) can be derived from Eq. (21). The series $\{Z_{N^0}\}$ form another family of the Fibonacci series, which can be expressed as

$$Z_{N^0} = \left(\frac{1+\sqrt{5}}{2}\right)^N + \left(\frac{1-\sqrt{5}}{2}\right)^N \quad (23)^{25)}$$

25) For computer calculation one can use the Gaussian expression.

$$Z_{N^0} = \left[\left(\frac{1+\sqrt{5}}{2}\right)^N + 0.5\right]. \quad (23')$$

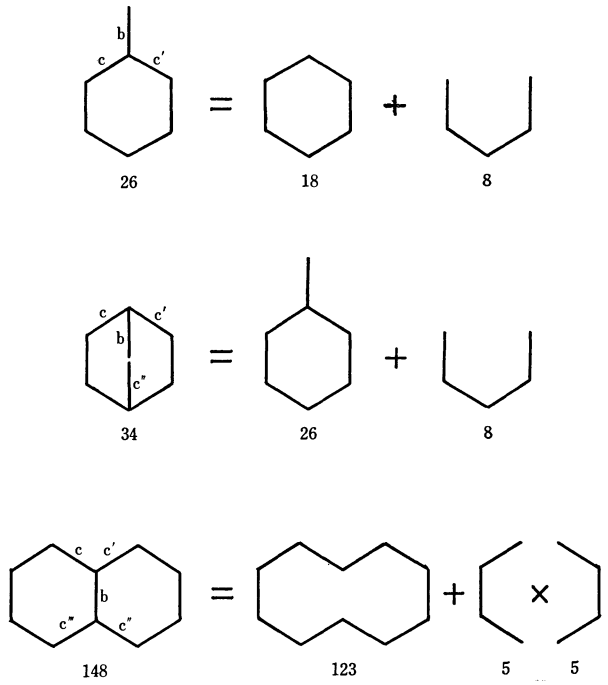

Fig. 4. Examples of application of the composition principle to ring compounds. The letters b, c,··· have the same meaning as in Fig. 2.

a) The numbers refer to the graphs in Chart 1.
b) The number of the carbon atoms with i neighboring carbon atoms. Namely, the numbers of quarternary, tertiary, secondary, and primary carbon atoms.
c) The data were taken from the reference in Table 1.

The composition principle (Theorem 2) can also be applied to complicated cycloparaffin derivatives as illustrated in Fig. 4. In Table 4 are given the topological indices of all the possible isomers of mono-

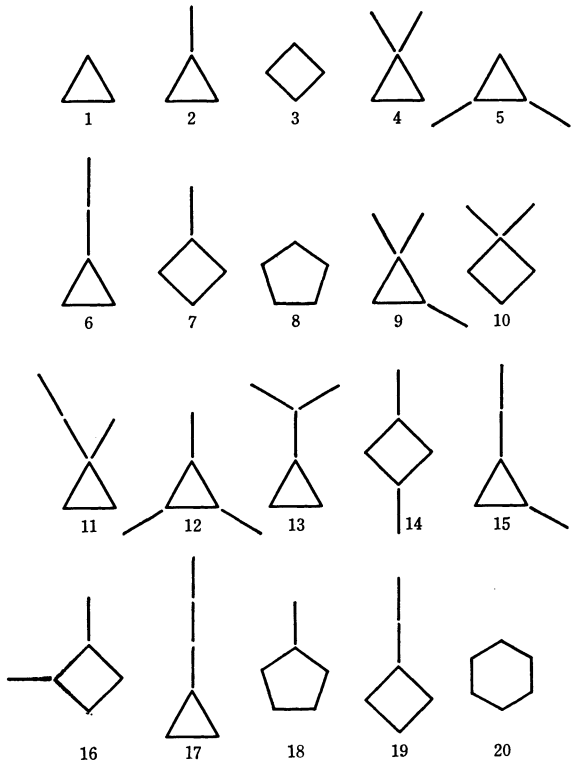

Chart 1

cyclic hydrocarbons with the carbon numbers from three to six.

The numbers of quarternary, tertiary, secondary, and primary carbon atoms for each graph are also shown. It is interesting to note that if one reads a set of the four integers for each graph as a four-digit integer it decreases as the Z value increases as long as the isomers of the same carbon number are compared. This suggests, though qualitatively, that the topological index for ring compounds also decreases with branching. This sort of calculation can be extended to higher members of the series and polycyclo compounds.[26]

Discussion

Comparison with Other Studies. Wiener proposed a path number w (Wiener number), which is the total number of bonds between all pairs of carbon atoms.[6] For example the w value of compound I in Fig. 1 is 46. This quantity turns out to be the half sum of the off-diagonal elements of a distance matrix **D** whose element d_{ij} is a number of bonds for the shortest path between atoms i and j.[27] Although it increases with carbon number and decreases with branching, no systematic relations such as recursion formula and composition principle, are found except for normal paraffins ($w=(n^3-n)/6$).

In ralation to the Wiener number, Altenburg proposed a polynomial $\sum_i n_i a_i$ for a carbon skeleton where n_i is the number of pairs of atoms whose distance is a_i or i C–C bonds.[28] The expression for compound I is $6a_1+7a_2+6a_3+2a_4$.[29]

Note that

$$w = \sum_i i \cdot n_i \tag{24}$$

For I we get $w=6\times1+7\times2+6\times3+2\times4=46$. As in the case of w, it is difficult to find useful relations for this polynomial expression.

Relation to Boiling Points. It was found that the boiling points of a number of saturated hydrocarbons are correlated fairly well with Z values. It is well known that for *non*-polar molecules the heavier the molecule the higher the boiling point becomes and the more the molecule is branched the lower the boiling point. The Z value has these characteristics. A number of empirical equations have been proposed to estimate the boiling points of a series of structural isomers by use of structural parameters and other physical quantities.[6,7,28,30,31] However, all of them require from three to six parameters and tedious calculations. In our case only one parameter is required. We can show that many empirical rules on the relation between boiling points of saturated hydrocarbons and structures of carbon skeleton are proved if we admit an empirical equation relating the Z value and boiling point. Of the physical and thermochemical quantities boiling point seems to have the best correlation with the topological index. It is also worth mentioning that of the quantities studied boiling point is the only quantity whose upper or lower limit for the isomeric compounds is the value of the normal compound.

It must be remembered that the topological index is defined for a topological graph which has nothing to do with distances, angles, steric strain, or hindrance. Therefore, without substantial modification, the value Z alone can not account for the difference in physical quantities of geometrical isomers such as *cis*- and *trans*-1,2-dimethylcyclopropane, nor for the overcrowded effect expected for compounds having vicinal quarternary carbon atoms. In this sense the proposed quantity Z is a kind of "index" for problems which are expected to be dependent on the topological nature of the skeleton of a system like a molecule.

Appendix

Proof of Theorem 2. Given three bonds a, b, and c and three graphs A, B, and C, a larger graph L is constructed as in Fig. 5a. It may be expressed as

$$\mathrm{L} = (\mathrm{A}+\mathrm{a}) + (\mathrm{B}+\mathrm{b}) + (\mathrm{C}+\mathrm{c}).$$

Similarly let us have

$$\mathrm{M} = (\mathrm{D}+\mathrm{d}) + (\mathrm{E}+\mathrm{e}) + (\mathrm{F}+\mathrm{f}).$$

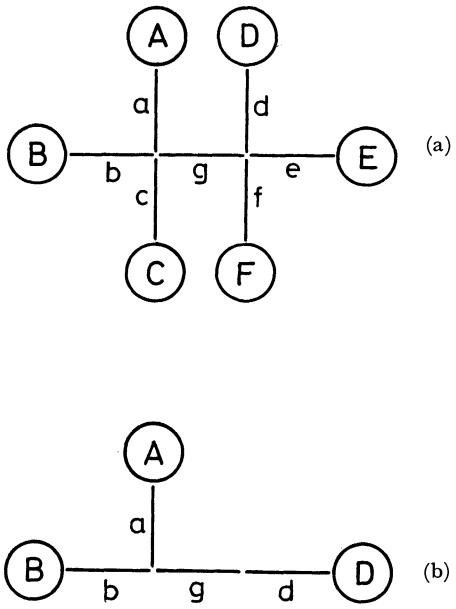

Fig. 5. Explanation for the proof of Theorem 2. The subgraphs A, B,···F are disconnected with each other.

By joining the graphs L and M with a bond g, a graph G can be constructed:

$$G = L + g + M$$

Now consider a number $p(G,k)$ for the graph G, the number of ways in which such k bonds are chosen from G that no two of them are connected. Each combination either includes or excludes the bond g. Since Z_G is the sum of $p(G,k)$'s, it is also divided into two parts, namely, g-including and g-excluding. It may be formulated as

$$Z_G = Z_G(+g) + Z_G(-g). \tag{A1}$$

Let us expand the following polynomial product,

$$\begin{aligned} Q_L(Y)Q_M(Y) &= \sum_{j=0}^{m_L}\sum_{k=0}^{m_M} p(L,j)p(M,k)Y^{j+k} \\ &= (0,0)+\{(0,1)+(1,0)\}Y \\ &\quad + \{(0,2)+(1,1)+(2,0)\}Y^2 + \cdots \\ &\quad + \{\cdots+(m_L, m-m_L)+\cdots \\ &\quad + (m-m_M, m_M)+\cdots\}Y^m \end{aligned} \tag{A2}$$

where the following abbreviated symbol is adopted:

$$(j,k) = p(L,j)p(M,k). \tag{A3}$$

The cofficient of Y^i in thr far right-hand side of Eq. (A2) is equal to the number of ways in which such i bonds are chosen from the graph G−g (or L+M) that no two of them are connceted. Hence

$$Z_G(-g) = Q_L(1)Q_M(1) = Z_L Z_M. \tag{A4}$$

On the other hand, the coefficients in the following product of the polynomials *multiplied* by Y are the contributions of the g-including combinations.

$$\begin{aligned} Q_{ABC}(Y)Q_{DEF}(Y)Y &= \sum_{j=0}^{m_{ABC}}\sum_{k=0}^{m_{DEF}} p(ABC,j)p(DEF,k)Y^{j+k+1} \\ &= (0,0)Y + \{(0,1)+(1,0)\}Y^2 \\ &\quad + \{(0,2)+(1,1)+(2,0)\}Y^3 \\ &\quad + \cdots + \{\cdots+(m_{ABC}, m-m_{ABC}-1)+\cdots\}Y^m, \end{aligned} \tag{A5}$$

where

$$\begin{aligned} ABC &= L - (a+b+c), \\ DEF &= M - (d+e+f), \end{aligned}$$

and

$$(j,k) = p(ABC,j)p(DEF,k). \tag{A6}$$

Thus we obtain

$$\begin{aligned} Z_G(+g) &= \{Q_{ABC}(Y)Q_{DEF}(Y)Y\}_{Y=1} \\ &= Q_{ABC}(1)Q_{DEF}(1). \end{aligned} \tag{A7}$$

Since the subgraphs A, B, and C in ABC are not connected to each other, the polynomial $Q_{ABC}(Y)$ is equal to the product of the constituent $Q(Y)$'s.

$$Q_{ABC}(Y) = Q_A(Y)Q_B(Y)Q_C(Y) \tag{A8}$$

Similarly we have

$$Q_{DEF}(Y) = Q_D(Y)Q_E(Y)Q_F(Y). \tag{A9}$$

Therefore we obtain

$$\begin{aligned} Z_G(+g) &= Q_A(1)Q_B(1)Q_C(1)Q_D(1)Q_E(1)Q_F(1) \\ &= Z_A Z_B Z_C Z_D Z_E Z_F \end{aligned} \tag{A10}$$

and

$$Z_G = Z_L Z_M + Z_A Z_B Z_C Z_D Z_E Z_F. \tag{A11}$$

Note that in the derivation no special restriction was imposed on the number of the subgraphs incident to the bond g. Thus for the system G′ as in Fig. 5b we obtain

$$Z_{G'} = Z_{L'}Z_{M'} + Z_A Z_B Z_D \tag{A12}$$

where

$$\begin{aligned} L' &= (A+a) + (B+b) \\ M' &= D + d \\ G' &= L' + g + M'. \end{aligned}$$

In this case, however, Eq. (A12) is already implied by Eq. (A11) if we consider graphs C, E, and F to be null and assume their Z values to be unity. This is consistent with the relation $Z_{\bar{0}}=1$ obtained from Eq. (9).

Extension of this theorem into ring compounds is approved if we note that a ring is formed by connecting any two of the subgraphs A, B,···F in the graph G.[22]

An Investigation of the Decomposition of the Intermediate Ions Produced by Electron Impact. I. $C_7H_7^+$ Ions from Several Substituted Toluenes

Susumu TAJIMA, Yoshio NIWA, Masahiko NAKAJIMA,* and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo

**Mitsubishi Petrochemical Co., Ltd., Amicho, Inashiki-gun, Ibaragi*

(Received March 2, 1971)

The decomposition of the $C_7H_7^+$ ions produced by electron impact from toluene, *o*-, *m*-, *p*-xylene, *o*-, *m*-, *p*-chlorotoluene, *o*-, *m*-, *p*-methylbenzoic acid, *p*-nitrotoluene, and *p*-methylacetophenone has been investigated. By the determination of the relative abundances of normal and metastable ions, these $C_7H_7^+$ ions are shown to be identical in structure, except for the $C_7H_7^+$ ion from *p*-nitrotoluene. The relative rates of decomposition of these ions are compared in terms of the relative abundances of the ions $65^+/91^+$ ($=R$) and $46.5^*/91^+$ ($=R^*$) (where 46.5* is the abundance of the metastable ion for the $91^+ \rightarrow 65^+ + 26$ decomposition; 91^+ and 65^+ denote the abundance of ions at *m/e* 91 and 65 respectively). Further, using the internal energy, the relative rates are estimated by comparing their R and R^* values with the IRE curve (*i.e.*, R and R^* *versus* the bombarding electron energy) for *p*-methylacetophenone (PMAP), which was used as the standard compound.

By the quasi-equilibrium theory (QET),[1] the rate constant, k, for the decomposition of an ion produced by electron impact varies with the internal energy, E, according to Eq. (1):

$$k(E) = \nu(1-\varepsilon_0/E)^{n-1} \quad (1)$$

where ν is a frequency factor, where ε_0 is the activation energy for the decomposition, and where n is the number of effective harmonic oscillators of which the compound is assumed to be composed. Many authors have explained the influence of ν,[2] E,[3,4] and n[5] in the equation on the rate of the decomposition of the ions produced by electron impact. McLafferty *et al.*,[6] Cooks *et al.*,[7] and Jennings and Futrell[8] have studied the relative rates of the decomposition of a common intermediate ion, X^+, from different precursors. They investigated the following reaction:

$$M^+ \longrightarrow X^+ \xrightarrow{m^*} A^+ \quad (2)$$

where M^+ is a different precursor ion, where X^+ is a common intermediate ion, and where m* is the metastable ion for the $X^+ \rightarrow A^+$ decomposition. They investigated the relative rates of the decomposition of X^+ in terms of such ratios of abundances of ions as X^+/A^+, X^+/m^*, and/or m^*/A^+; then, using QET, they explained the relative rates qualitatively by the degrees of vibrational freedom in M^+ or the apparent heat of formation, which was assumed to be associated with the internal energy, E, for X^+.

In this paper, the rates of decomposition of $C_7H_7^+$ ions produced from certain toluene derivatives substituted by electron-withdrawing substituents are investigated. In the mass spectra of these toluene derivatives, the $C_7H_7^+$ ion is very prominent, and the ion decomposes successively through the $C_7H_7^+$ (*m/e* 91) $\xrightarrow{m^*(m/e\ 46.5)}$ $C_5H_5^+(m/e\ 65) + C_2H_2$ process, with the metastable peak at *m/e* 46.5. On the base of QET, we will examine the decomposition of the $C_7H_7^+$ ions as a function of the internal energy, E. The procedure is as follows: 1) the relative ion abundances ($65^+/91^+ = R$, $m^*/91^+ = R^*$) for the $C_7H_7^+$ ion produced by electron impact from *p*-methylacetophenone (PMAP) are measured; 2) the "ion abundance ratio efficiency curve" (IRE curve), which gives the relation of R and R^* to the electron accelerating voltage (V_e), is plotted; 3) the structure and the internal energy, E, of the $C_7H_7^+$ ions from substituted toluenes are estimated from these curves, *i.e.*, by comparing the R and R^* values obtained from each compound.

Experimental

The mass spectra were obtained by voltage scanning with a CEC 21-103C mass spectrometer. The V_e was measured with a potentiometer of Leeds & Northrup Co., Ltd. The electron-trap current was 10 μA. The temperatures of the ion source and the sample manifold were 250 and 125°C respectively.

With scanning, the voltage applied to the repeller electrodes varies in proportion to the ion-accelerating voltage. Because the bombarding electron energy is known to be affected by the repeller voltage,[9,10] it is desirable to measure the abundances of the *m/e* 91, *m/e* 65, and *m/e* 46.5 ions under the same ion-accelerating voltage, so that the effect of the repeller voltage on V_e can be nearly the same for all the ions studied. In this study, the optimum ion-accelerating voltage

for the most intense metastable peak was obtained first, and then all the ions were measured under this same accelerating voltage by adjusting the magnetic field.

The 180° mass spectrometer used does not have the field-free region in front of the magnetic analyser; however, it is known that the apparent mass (m*) of the metastable ion can be obtained by means of the same equation ($m^* = A^2/X$) as is used with other sector-type mass spectrometers.[11,12] The metastable ion-abundance measurements were based on the peak heights for the data.

All the samples studied were of a research grade, were obtained from Tokyo Kasei Co., Ltd., and were used without further purification upon checking the purity with the mass spectrometer. The ion abundances of the *m/e* 91, *m/e* 65, and *m/e* 46.5 of PMAP were measured at 1.0 eV intervals of the bombarding-electron energy. The abundances of these ions from the other compounds studied were measured at V_e= 20.0 eV. The probable error in the measurement of V_e is estimated to be less than ± 0.2 eV.

Results and Discussion

The "IRE curves" for PMAP are given in Fig. 1. The ordinates denote R and R^* ($\times 100$); hereafter, these curves will be termed the "R-standard curve" and the "R^*-standard curve" respectively. According to QET, the rate constant, k, for the decomposition of an ion is given by Eq. (1). An ion has its own distribution function of the internal energy, E, and an ion with a particular internal energy decomposes with a rate constant corresponding to the internal energy. For the decomposition of ions identical in structure, the rate constant, k, increases with an increase in the internal energy, E, of the ion, as can be seen from Eq. (1), since the frequency factor, ν, the activation energy, ε_0, and the number of harmonic oscillators, n, are the same for ions identical in structure.

For simplicity, it is assumed that all the X^+ ions are produced at the same time in the ionization chamber and that the A^+ ions do not decompose further. The latter assumption is reasonable when a low electron energy is used. Then, the intensities of the various ions in Eq. (2) are given by:[13]

$$I(X^+) = \int_0^{\varepsilon_0} P(E)\mathrm{d}E + \int_{\varepsilon_0}^{\infty} P(E)\exp\{-k(E)t_4\}\mathrm{d}E \quad (3)$$

$$I(A^+) = \int_{\varepsilon_0}^{\infty} P(E)[1-\exp\{-k(E)t_1\}]\mathrm{d}E \quad (4)$$

$$I(\mathrm{m}^*) = \int_{\varepsilon_0}^{\infty} P(E)[\exp\{-k(E)t_2\}-\exp\{-k(E)t_3\}]\mathrm{d}E \quad (5)$$

where $P(E)$ is the number of X^+ with the internal energy, E, (internal energy distribution function). In the above equation, we assumed further that the X^+ ions created at $t=0$ reach the exit slit in the ion source at time t_1, the field-free region at time t_2, the magnetic field at time t_3, and the end of the magnetic field at time t_4. R and R^* are given by:

$$R = I(A^+)/I(X^+) \quad (6)$$

$$R^* = I(\mathrm{m}^*)/I(X^+) \quad (7)$$

From Eqs. (1), (6), and (7), R and R^* can be treated as function of the internal energy, E.

Using, for simplicity, the expressions for $I(X^+)$, $I(A^+)$, and $I(m^*)$ given by Chupka[5] instead of Eqs. (3)—(5), the relations of R and R^* to the rate constant, k, calculated by a FACOM 270-30 computer are shown in Fig. 2. In this calculation, we used $t_1=t_2=2.5$ μsec, $t_3=3.3$ μsec, and $t_4=9.5$ μsec. These times were estimated from the dimensions of the mass spectrometer used in this study and from the conditions of measure-

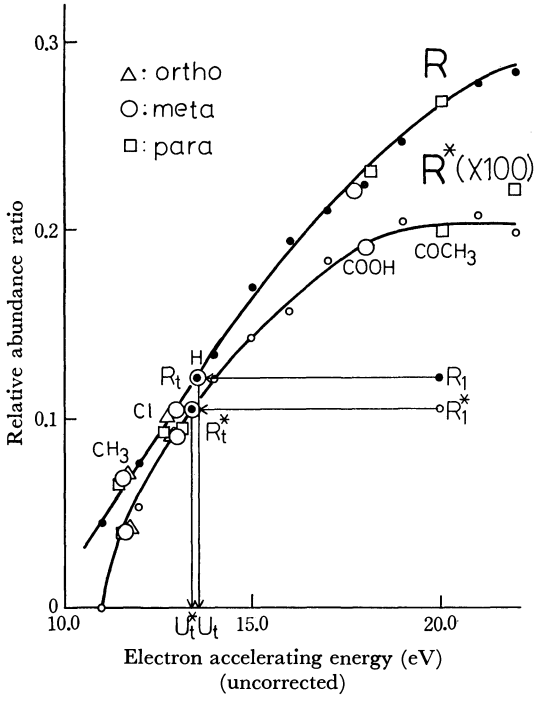

Fig. 1. IRE curves for *p*-methylacetophenone and relative abundance ratios of each compound at V_e=20.0 eV.

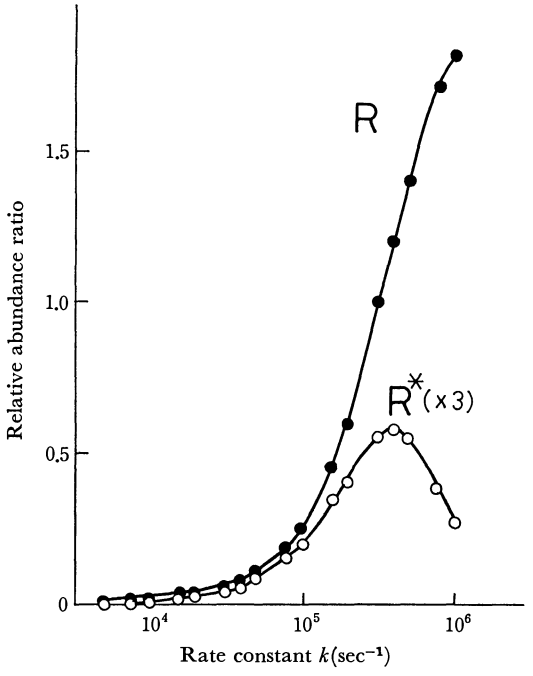

Fig. 2. Calculated relative abundance ratios $65^+/91^+$ and $m^*/91^+$ *vs.* rate constant k by using Chupka's equations.[5]

11) N. D. Coggeshall, *ibid.*, **37**, 2167 (1962).
12) A. S. Newton, *ibid.*, **44**, 4015 (1966).

ment. The internal energy of the parent ion, M^+, increases with an increase in V_e, so the internal energy, E, of X^+, produced by the decomposition of M^+, will also increase with an increase in V_e. Consequently, the greater the V_e value, the greater the average rate constant, $\bar{k}$. The behavior of R and R^* with V_e in Fig. 1 can be explained qualitatively when the curves in Fig. 1 are compared with those in Fig. 2, assuming k values lower than 5×10^5 sec^{-1}. The X^+ produced by the decomposition of M^+ from PMAP at a given V_e will have an internal energy corresponding to the V_e. The ion abundances related to the decomposition of X^+ give R and R^* values corresponding to the ordinates in Fig. 1. Thus, R and R^* can be taken as measures of the internal energy of X^+ in the sense mentioned above. The corresponding values on the abscissa show the internal energy of X^+ in this measure. When the average internal energy of X^+ is estimated in this measure, the R and R^* obtained for the X^+ must lie on a line perpendicular to the abscissa. In this study, we used the IRE curves for PMAP as a measure of the internal energy of the $C_7H_7^+$ ions from various compounds.

TABLE 1. RELATIVE ABUNDANCE RATIOS $65^+/91^+(R)$ AND $m^*/91^+(R^*)$ IN THE MASS SPECTRA OF EACH SUBSTITUTED TOLUENE AT $V_e=20.0$ eV

Substituent	R	$R^*(1\times00)$
H	0.122	0.105
o-CH_3	0.071	0.053
m-CH_3	0.068	0.048
p-CH_3	0.065	0.048
o-Cl	0.104	0.095
m-Cl	0.108	0.095
p-Cl	0.095	0.094
o-COOH	0.304	0.221
m-COOH	0.221	0.189
p-COOH	0.230	0.220
p-$COCH_3$	0.269	0.200
p-NO_2	0.460	0.491

In order to investigate the structure and the internal energy of the $C_7H_7^+$ ion from each substituted toluene, the R and R^* values for each compound in Table 1 have been compared with the standard curves. The data in Table 1 were measured at $V_e=20.0$ eV, because the abundance of the m/e 46.5 metastable ion peak was masked by other normal peaks (for example, by the m/e 47 peak) and the abundance of the metastable ion could not be determined exactly when V_e was higher.

The effective internal energy from every compound in Table 1 was estimated as follows. The R and R^* values were determined experimentally for each compound at $V_e=20.0$ eV. Two lines were drawn parallel to the abscissa from points on the ordinate corresponding to the R and R^* values. R_1 and R_1^* were determined where the lines intersected the R- and R^*-standard curves respectively. When perpendiculars passing through these points were drawn, the feet, U and U^*, were found to coincide within the limits of experimental error. The value of V_e corresponding to the feet was assumed to be a measure of the internal energy in the sense mentioned above. For example, in the case of toluene, the two feet are denoted as U_t and U_t^* in Fig. 1. U_t and U_t^* are found to be 13.6 and 13.4 eV respectively. This suggests that the structure and the internal energy distribution of the $C_7H_7^+$ ions from toluene at $V_e=20.0$ eV correspond to those of the $C_7H_7^+$ ions from PMAP at about $V_e=13.5$ eV. That is, if the structure and the internal energy distribution of the $C_7H_7^+$ ions from toluene at $V_e=20.0$ eV are identical with those of the $C_7H_7^+$ ions from PMAP at $V_e=13.5$ eV, ν, ε_0, and n in Eq. (1), and $P(E)$ in Eqs. (3)—(5) will be the same, respectively, for each of the $C_7H_7^+$ ions from the two compounds. Therefore, the relation between R_t and R_t^* in toluene is exactly the same as the relation between R and R^* in PMAP, and U_t will agree with U_t^*. If the $C_7H_7^+$ ions from toluene were not identical in structure and/or in internal energy with those from PMAP, ν, ε_0, and n in Eq. (1) would be different for these ions and $P(E)$ in Eqs. (3)—(5) would also be different. Therefore, the relation between R_t and R_t^* in toluene will differ from that in PMAP, and U_t will not generally coincide with U_t^*. The U and U^* values for other compounds in Table 1 coincide with each other within the limits of experimental error, as can be seen in Fig. 1. Therefore, the $C_7H_7^+$ ions produced from these compounds at $V_e=20.0$ eV have the same structure and internal energy distribution as the $C_7H_7^+$ ion produced from PMAP at each corresponding V_e. By using the isotope labelling technique, Meyerson *et al.*[14] have reported that the $C_7H_7^+$ ions from toluene, p-xylene, and p-chlorotoluene are "tropylium ions." Thus, the $C_7H_7^+$ ions produced from the compounds in Table 1 and PMAP in the V_e range of the present investigation can be inferred also to be tropylium ions which have various effective internal energies, as is indicated in Table 2.

TABLE 2. THE ELECTRON ACCELERATING VOLTAGE (U), AT WHICH THE INTERNAL ENERGY DISTRIBUTION OF THE $C_7H_7^+$ ION FROM PMAP IS EQUAL TO THAT OF THE $C_7H_7^+$ ION FROM EACH COMPOUND AT $V_e=20.0$ eV

Compound	U(eV)
Toluene	13.5
Xylene	11.8
Chlorotoluene	13.0
Methylbenzoic acid	~18.0

In the case of p-nitrotoluene, we could not plot the R and R^* in Fig. 1 because these values were too high in comparison with the values of the other compounds. When the IRE curves of p-nitrotoluene are regarded as the standard curves instead of that of PMAP, U does not agree with the U^* value in other compounds. These facts suggest that the structure of the $C_7H_7^+$ ion from p-nitrotoluene is not identical with that of the $C_7H_7^+$ ions from the other compounds studied here.

Beynon *et al.*[15] have studied in detail the decomposition mechanism of nitrobenzene derivatives by electron impact. They have explained that the compounds decompose to fragment ions through some complicated intermediates. Recently, Westwood *et al.*[16] have reported the difference between the decomposition mechanism of *p*-nitrobenzene derivatives and that of *m*-isomers. One reason why the structure of the $C_7H_7^+$ ion from *p*-nitrotoluene is not identical with that of the $C_7H_7^+$ ions from other compounds may be these complicated decomposition processes.

From Table 1 it may be seen that while the *U* values for compounds with different substitutents differ from one another, the *U* values for the *o*-, *m*-, *p*-isomers containing the same set of substituents are nearly the same, except for methylbenzoic acid. This indicates that the internal energy distribution of the tropylium ion is affected by the species of substituents and not by the position of the substituents. The *U* values obtained for compounds in Table 1 are shown in Table 2. For example, in the case of toluene, the internal energy distribution of the $C_7H_7^+$ ion obtained at V_e=20.0 eV corresponds to that of the $C_7H_7^+$ ion from PMAP at about V_e=13.5 eV. One reason why the *U* values for *o*-, *m*-, *p*-methylbenzoic acid are distributed over a rather wide range compared to the case of the other compounds may be that the *R* and *R** values of methylbenzoic acid are in a relatively insensitive portion of the bombarding electron energy. In such a range, a slight error in measurement of ion abundances will result in a rather large spread in the corresponding electron energy. According to the results given in Table 2, the order of the internal energy of the $C_7H_7^+$ ions produced by the electron bombardment of the 20.0 eV energy is: methylacetophenone≃methylbenzoic acid> toluene>chlorotoluene>xylene. This order reveals an approximate tendency for the amount of the internal energy of the $C_7H_7^+$ ion from the compound to be larger as the electron-withdrawing property of the substituent is stronger.

Recently, Gross and McLafferty[17] have reported that substituted benzophenone, $Y\phi CO\phi$, with a weaker $Y\phi$-$CO\phi$ bond (ϕ and Y representing a benzol ring and a substituent respectively), yields the less energetic benzoyl ion when bombarded by electrons. On the contrary, Shapiro *et al.*[18] have indicated that substituted benzamide, described as $Y\phi NHCO\phi$, with a stronger $Y\phi NH$-$CO\phi$ bond, yields the less energetic benzoyl ion. Based on the information about the competing fragmentation of benzophenone, they have explained[18] the results of Gross and McLafferty.[17] It has been shown recently[19] that, when bombarded by electron, a disubstituted benzene, A-ϕ-Y (A being a common substituent for a series of compounds), gives a larger value of the summation of ions ($A\phi^+ + Y^+$) when the substituent Y has a stronger electron-withdrawing property. If this result is understood to indicate that the summation of the ions increases as the bond strength between the substituent, Y, and the aromatic moiety decreases, and if it is assumed that all of the molecular ions studied here have nearly the same internal energy distribution, the compound possessing a weak bond between the substituent, Y, and the aromatic moiety will leave a large internal energy to the $A\phi^+$ ion, *i.e.*, the tropylium ion in the present investigation. That is, as the energy spent to break the $(A\phi\text{-}Y)^+$ bond is smaller, a larger internal energy is left in the residual $A\phi^+$ ion. If this simple explanation is accepted, the relationship between the amount of internal energy of the $C_7H_7^+$ ions corresponding to $A\phi^+$ ions and the electron-withdrawing property of the substituents can be explained qualitatively in accordance with the conclusions of Shapiro *et al.*[18] Like the compounds studied by Shapiro *et al.*,[18] the molecular ions of the compounds in Table 1 do not undergo competing reactions to any appreciable extent, and they decompose almost exclusively into $C_7H_7^+$ ions at any ionizing energy.

In addition to the two parameters used in this study, the m^*/A^+ parameter is used by many authors to obtain the relative rate constant, *k*, for the decomposition. When the internal energy of X^+ for PMAP is smaller with a decrease in the V_e, this parameter is less reliable, since both the numerator, m*, and the denominator, A^+, are very small in this V_e region. Therefore, the m^*/A^+ parameter was not used in this study.

Conclusions

A procedure for investigating the identity of an ion produced by electron bombardment in mass spectrometry is proposed. "IRE curves" are first obtained for a standard compound, and the ion abundance ratio *R* and *R** from the comound to be studied is compared with the standard curve. By this procedure, the identity of the ion can be checked and the internal energy imparted to the ion can be estimated semiquantitatively.

The $C_7H_7^+$ ions from various toluene derivatives were investigated by this method. While the $C_7H_7^+$ ions from isomeric compounds possessing the same combination of substituents (Table 1) contain nearly equal amounts of internal energy, the $C_7H_7^+$ ions from compounds containing different sets of substituents contain quite different amounts of internal energy. The amount of internal energy contained by the ion from derivatives of toluene increases as the electron-withdrawing property of the substituent other than CH_3 increases.

The authors wish to thank Akio Hashizume and Nobuhide Wasada of this Institute for their valuable discussions.

Microwave Spectrum, Barrier Height to Internal Rotation of Methyl Group, and Dipole Moment of 3-Methylfuran

Teruhiko OGATA and Kunio KOZIMA

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 13, 1971)

The microwave spectrum of 3-methylfuran was measured in the frequency region from 8.2 to 30 GHz. By observing the *A-E* splittings due to the hindering rotation of the methyl group, the barrier height was determined to be 1.09 kcal/mol. The value is nearly the same as that of 2-methylfuran. The dipole moment was determined to be 1.03 D, which is a little larger than that of furan.

A few studies of the potential barrier to the internal rotation of the methyl group which is attached to a heterocyclic five-membered ring have recently been carried out by measuring the microwave spectra.[1-3] The barrier height to the rotation of the methyl group of 2-methylfuran was determined by Norris and Krisher[1] to be 1190 cal/mol.

Since the difference in the position of the methyl group which is attached to the furan ring may be expected to affect the value of the barrier height, it seemed that it would be interesting to determine the value for 3-methylfuran.

Experimental

The sample of 3-methylfuran was prepared and purified according to the method of Cornforth.[4] The infrared spectrum of 3-methylfuran thus obtained agreed with that previously reported.[5] The purity was checked with a vapor-phase chromatograph obtained by means of a 4-m column of dioctyl phthalate coated on celite. Runs at 120°C indicated only one component in the sample.

The microwave spectrum was investigated in the frequency region from 8.2 to 30 GHz by using a conventional 100-kHz Stark modulation spectrometer.[6] The measurements were made at about −20°C by using a 6-m absorption cell.

Results and Discussion

Microwave spectrum. In order to assign the absorption lines, the preliminary rotational constants were calculated by using the r_s-structure of furan obtained by Bak *et al.*[7] and the usual values of the bond lengths and the bond angles for the methyl group. By assuming a pseudo-rigid rotor approximation, the transition frequencies were calculated from the preliminary rotational constants. The lines of the *a*- and *b*-type transitions could be found quite close to their predicted frequencies and were assigned by their Stark patterns. The intensities of the *b*-type lines are weaker than those of the *a*-type lines. By considering the Stark patterns and the intensities, several pairs of the lines, which are separated by about few MHz, could be identified as doublets due to the transitions of the *A*- and the *E*-levels caused by the hindering rotation of the methyl group. The observed frequencies of the *a*- and *b*-type transitions of the *A*-levels for the vibrationally-ground state are shown in Table 1. The pseudo-rigid rotational constants for the *A*-levels were determined so as to get the best fit between the observed and the calculated frequencies by the use of the least-squares method. The constants thus obtained are shown in Table 2. By

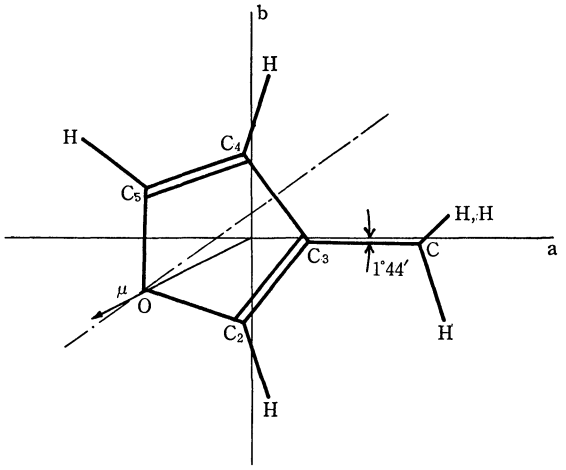

Fig. 1. Molecular structure and dipole moment of 3-methylfuran.

Molecular Structure and Internal Rotation. In order to determine the molecular structure, some of the molecular parameters were assumed by using the r_s-structure described above with the additional assumptions that all the C-H bond lengths and all the valency angles of the methyl group were 1.090 Å and 109°28′ respectively. These assumed values are listed in Table 3, in which the number attached to the symbol of each atom is shown in Fig. 1. By using these parameters, the angle of $\angle C_4C_3(CH_3)$ and the bond length of C_3–CH_3 were determined so as to get a good fit between the calculated rotational constants and the observed constants of A_A, B_A, and C. The results are shown in Table 3. Although it should be taken into account that the observed values of A_A and B_A are affected by the contribution of the hindering rotation of the methyl group, it is certain that the differences between these rotational constants and the unperturbed values of A and B are small enough to affect the molecular parameters determined above. From Table 3 it can be seen that the change in the structure of the furan ring caused by the substitution of the methyl group in the 3-position is negligible.

The potential energy function of the hindering rotation of the methyl group for this molecule may be expressed as usual by the following equation:

$$V(\alpha) = \frac{V_3}{2}(1-\cos 3\alpha) + \frac{V_6}{2}(1-\cos 6\alpha) + \cdots$$

where α is the relative angle of the internal rotation and where V_3 and V_6 are the potential constants. In this paper only the V_3 term is considered, for the V_6 term would introduce only a minor correction in the value of V_3.

The Hamiltonian can be written in the following manner:

$$H_A = A_A P_z^2 + B_A P_y^2 + C P_x^2$$

and

$$H_E = A_E P_z^2 + B_E P_y^2 + C P_x^2 + F W_{0E}^{(1)} \mathscr{P} + F W_{0E}^{(3)} \mathscr{P}^3$$

where

$$F = \hbar^2/2rI_a, \qquad r = 1 - \sum_{g=a,b} \lambda_g^2 I_a/I_g$$
$$\alpha = \lambda_a I_a/I_a, \qquad \beta = \lambda_b I_a/I_b$$
$$\mathscr{P} = \alpha P_z + \beta P_y$$
$$A_\sigma = A + F\alpha^2 W_{0\sigma}^{(2)}, \quad B_\sigma = B + F\beta^2 W_{0\sigma}^{(2)} \quad (\sigma = A \text{ or } E)$$

The notations have the same meanings as in Hershbach's paper.[8] The table of Hayashi and Pierce[9] was the source for the values of the perturbation coefficients, $W_{v\sigma}^{(n)}$. From the assigned transitions of the A- and E-levels, a rough estimate of the value of s, a parameter of the Mathieu equation, could be made. By using this value of s and the internal-rotation parameters shown in Table 4, the transition frequencies of the E-levels were calculated for the transitions which have large A-E splittings; the lines of the E-levels were found near the calculated frequencies and consequently assigned. Then, the accurate value of s was determined so as to give the best fit to the observed A-E splittings by means of the least-squares method, using a HITAC-5020 computer of the Computer Center of Tokyo University. The transition frequencies, ν_E, of the E-levels thus assigned and the A-E splittings, $(\nu_A-\nu_E)_{obs}$, are listed in Table 5, together with the calculated values of $(\nu_A-\nu_E)_{calc}$ which were obtained by using the cor-

a) Experimental uncertainty in the frequency measurements is ±0.1 MHz.

rected value of s. For the transitions in which the A-E splitting is less than 0.3 MHz, the splittings could not be measured; such transitions are shown by the dotted lines in the third column of Table 5. By using the Hamiltonian H_E mentioned above, the calculations were made by taking into account the terms of $FW_{oE}^{(1)}\mathscr{P}$ and $FW_{oE}^{(3)}\mathscr{P}^3$. The values shown in parentheses in the last column of Table 5 were tentatively calculated by neglecting the $FW_{oE}^{(3)}\mathscr{P}^3$ term. It can be seen that this neglect does not affect the result beyond the limits of experimental error. The determined value of s and the differences in A_A-A and B_A-B are shown in Table 4.

The value of V_3 calculated from the value of s is 1088±3 cal/mol. The uncertainty in the barrier arises primarily from the uncertainty in the assumed value of I_a. This assumed value, however, may be fairly reasonable, because the pseudo-inertial defect, $\Delta'=I_a-(I_a+I_b-I_c)$, is calculated to be 0.084 amu·Å^2, not very different from the value of 0.0458 amu·Å^2 [7] of the inertial defect of furan, where the unperturbed moments of inertia of 3-methylfuran, I_a, I_b, and I_c, are 56.8423 amu·Å^2, 150.101 amu·Å^2, and 203.837 amu·Å^2 respectively.

The barrier height of 3-methylfuran is not very different from that of 2-methylfuran, which is 1190 cal/mol.[1]

Dipole Moment. The dipole moment of 3-methylfuran for the ground vibrational state was determined from the second-order Stark effects of the $1_{01}\rightarrow 2_{02}$, $2_{02}\rightarrow 3_{03}$, $3_{03}\rightarrow 3_{12}$, and $4_{04}\rightarrow 4_{13}$ transitions of the A-level. The dipole moment and the observed and calculated Stark coefficients are given in Table 6.

TABLE 6. STARK EFFECT AND DIPOLE MOMENT OF 3-METHYLFURAN[a]

Transition		Stark coefficient (MHz(kV/cm)$^{-2}$) Observed	Calculated

	$\mu_a=0.91\pm0.01$ D		
	$\mu_b=0.48\pm0.03$ D		
	$\mu=1.03\pm0.02$ D		

a) The absorption cell was calibrated by using the $J=1\rightarrow 2$ transition of OCS, taking the dipole moment of OCS as 0.7152 D.[10]

The difference of 0.97 D between the dipole moment of tetrahydrofuran (1.63 D)[11] and that of furan (0.661 D)[12] is mainly due to the π-moment, μ_{mig}, caused by the migration of the π-electron of the oxygen atom in the furan ring. The μ_{mig} was calculated by Nagakura and Hosoya[13] to be 0.61 D and by Pujol and Julg[14] to be 0.89 D, pointing from a positive oxygen atom "up" the C(3)–C(4) bond. Therefore, it is certain that the direction of the total moment of furan is opposite to that of the μ_{mig}. Furthermore, it is known[15] that the moment, μ_b, along the b principal axis of the *trans* isomer of furfural is markedly smaller than that of the *cis* isomer. This fact is evidence in favor of this view. Based on the rule of vector addition for dipole moments, a relation among the dipole moment, μ, of 3-methylfuran, the μ_f value of the parent molecule, and the difference, μ_d, between the group moment of CH_3–C(sp^2) and the bond moment of H–C(sp^2) can be easily written as follow:

$$\frac{\sin(\theta+\varphi)}{\mu}=\frac{\sin\theta}{\mu_f}=\frac{\sin\varphi}{\mu_d}$$

where θ is the angle between μ and the C–CH_3 axis and φ, the angle between μ and the C_2 symmetry axis of the ring.

There are four possibilities for the direction of the experimentally-determined value of μ. However, by taking into account the fact that the value of μ_d is usually near 0.3 D,[16] only the direction shown in Fig. 1 is found to be possible. For this case, the θ and φ angles are 29±2° and 9±2° respectively. From the above relation we can calculate $\mu_f=0.80\pm0.06$ D and $\mu_d=0.27\pm0.04$ D, which points the negative end towards the C-atom of the ring. The values of μ_f and μ_d are resonable.

CNDO Calculations of Electronic Structures and Spectra of Nonalternant Conjugated Hydrocarbons

Akio TAJIRI,* Naoto OHMICHI, and Takeshi NAKAJIMA
Department of Chemistry, Tohoku University, Katahira, Sendai
(Received March 16, 1971)

The energetically most favorable geometrical structures with respect to C–C bond-length variation of fundamental nonalternant conjugated hydrocarbons have been examined using CNDO/2 approximation with its original parameterization. It was found that all the molecules examined should exhibit a marked bond alternation, accompanied with a molecular-symmetry reduction in the case of pentalene and heptalene. The predicted molecular dipole moments are in good agreement with the available experimental values. The electronic spectra have been calculated using a modified version of the CNDO/2 method proposed by Del Bene and Jaffe, with a new parameterization. The results are found to be in good agreement with experiment.

Bond distortions in the ground states of certain nonalternant conjugated hydrocarbons have drawn considerable theoretical attention in late years. It was noticed[1–3] that heptalene (IX, Fig. 1) shows no energy minimum for the D_{2h} symmetry suggested by the superposition of the two Kekule-type resonance structures, but has a lower energy if it takes an unsymmetrically-distorted nuclear arrangement that corresponds to either of the resonance structures and exhibits a strong bond alternation of a C_{2h} type in its periphery. The experimental information[4] agrees with this in indicating that π-electrons in this molecule are strongly localized in "double" bonds, rather than uniformly delocalized over the entire molecule.

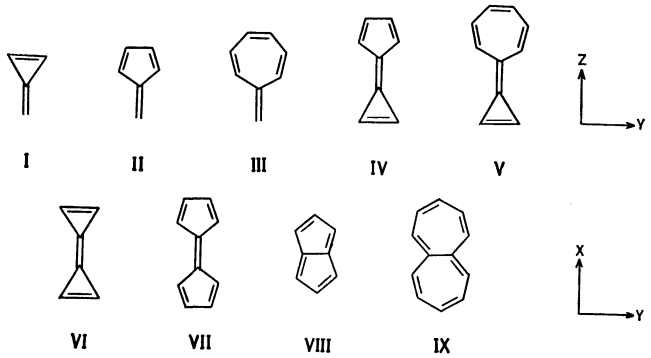

Fig. 1. Carbon skeletons and choice of axes for nonalternant hydrocarbons.

Theoretical justifications for such anomalous phenomena have been attempted by several authors.[1–3,5,6] Making allowance for the effects of σ-bond compression, they have succeeded in predicting that an unsymmetrical configuration resembling either of the two Kekule-type structures is actually energetically favored as compared with the fully symmetrical one. Binsch *et al.*[7–11] and Nakajima *et al.*[12,13] have recently developed a general theory of double-bond fixation in conjugated molecules and shown that bond alternations in certain nonalternant hydrocarbons are obtained theoretically as the energetically most favorable distortion rather than a presumed type of bond distortion.

In all the treatments so far made of the bond distortions in nonalternant hydrocarbons, however, complete σ-π separation has been assumed. That is, the total energy of a conjugated molecule is assumed to be the sum of the π-electron energy and the σ-core energy which may be regarded as the sum of the independent contributions from the C–C σ-bonds. The individual contributions of the σ-bonds have been approximated by a quadratic function of the bond-distance variation. The approximation used in computing the σ-core energy is not consistent with the molecular-orbital approximation used in calculating the π-electron energy.

It is the purpose of this paper to examine the ground-state geometries and electronic properties and the electronic spectra of certain fundamental nonalternant hydrocarbons by means of an all valence-electron molecular-orbital method, in which π-electrons and σ-electrons are treated with the same approximation.

Method of Calculation

The method used for predicting the energetically most favorable geometrical structures with respect to C–C bond-length variation is the semiempirical self-consistent all valence-electron molecular-orbital theory in the framework of the CNDO/2 approximation pro-

posed by Pople and his coworkers.[14-16]

Although it is known[16,17] that the CNDO/2 approximation successfully predicts geometrical structures, *viz.*, equilibrium bond angles and bond lengths of a variety of molecules, it is inadequate for the calculation of the energy quantities such as dissociation energy and excitation energy. For small molecules, the bonding energies calculated by use of the Pople-Segal bonding parameters are higher than the experimental by factors 3—8.[18]

A modification along this line of the Pople-Segal CNDO/2 theory has recently been made by Sichel and Whitehead.[18,19] Using the CNDO approximation, they have developed a semiempirical SCF MO method with atomic parameters derived from atomic valence-state energies, interatomic electron-repulsion integrals calculated by use of the semiempirical formulas and bonding parameters calibrated by use of the bonding energies of binary hydrides. Bonding energies calculated using these parameters for various small molecules were found to be in much better agreement with experiment than those calculated from the Pople-Segal CNDO/2 theory.

When used for the prediction of the energetically most favorable geometrical structures of conjugated molecules, however, the parameterization proposed by Sichel and Whitehead turns out to be less satisfactory and, in certain cases, completely inadequate. As an example, the equilibrium C–C bond length for ethylene predicted with their parameterization is smaller than 1.20 Å, and is considerably shorter than that (1.320 Å) predicted with the Pople-Segal CNDO/2 method and the experimental value (1.339 Å). For benzene, the SCF iterative procedure with the Sichel-Whitehead parameterization leads to the loss of the initially assumed D_{6h} symmetry for its ground state. This unexpected result arises mainly from the fact that because of the too small values of bonding parameters proposed by Sichel and Whitehead, the orbital-intermingling occurs between the initially chosen bonding and antibonding molecular orbitals in the course of the iterative procedure.

Recently, some modifications of the CNDO/2 procedure have been attempted by several authors[20-26] aiming at making it useful for predicting and interpreting spectroscopic data. Of these, the approximation proposed by Del Bene and Jaffé[21-24] is most noteworthy, the essential modification involving the use of reduced electron-repulsion integrals instead of theoretical ones and introduction of a new empirical parameter κ to differentiate resonance integrals between σ-type orbitals from those between π-type orbitals. The value of κ and bonding parameters have been adjusted so as to give the most consistent spectroscopic data for benzene, pyridine, and diazines.

However, Del Bene-Jaffé's approximation with the original parameterization does not work well for the prediction of electronic spectra of saturated molecules. For methane and ethane, it gives the lowest excitation energies higher by 3—4 eV than the experimental values. Of course, it is desirable to be able to treat conjugated molecules and saturated molecules at the same time using a single parameterization.

For the discussion of electronic spectra, we use the Del Bene-Jaffé-type modified CNDO/2 method with the values of κ and bonding parameters, β_C^0, β_H^0, readjusted, so that they may give the most consistent spectroscopic data in methane, ethylene and benzene.[27] The values chosen for β_C^0, β_H^0, and κ are -15.0 eV, -8.0 eV, and 0.75, respectively. One-center and two-center electron-repulsion integrals were evaluated with Sichel-Whitehead's formula and Mataga-Nishimoto's formula,[28] respectively, and the local core matrix elements with Sichel-Whitehead's formula.

It should be added that the Del Bene-Jaffé-type method with the present parameterization is inadequate for the prediction of the ground-state geometrical structures. If the internuclear potential energy, V_{AB}, is written as[18]

$$V_{AB} = Z_A Z_B \gamma_{AB}$$

where Z and γ are the atomic core charge and the atomic electron-repulsion integral, the equilibrium C–C bond length r_e for ethylene is predicted to be zero. On the other hand, the use of the point-charge approximation for V_{AB} gives to an infinitely large r_e for ethylene. Another formula available for V_{AB} is that recommended by Dewar and Klopmann:[29]

$$V_{AB} = \frac{Z_A Z_B}{r_{AB} + a}$$

However, the use of this formula with the value of a adjusted so as to reproduce the experimental r_e for ethylene unexpectedly results in the ground state of benzene being of D_{3h} symmetry.

We therefore used the CNDO/2 method with its original parameterization to predict the geometrical structures of nonalternant hydrocarbons, and the Del Bene-Jaffé-type modified CNDO/2 method with the new parameterization to discuss electronic spectra.

We made the following assumptions for prediction of the energetically most favorable ground-state geometry of each molecule.

(a) Only C–C bond distances were varied and the C–H bond distances were kept constant (1.00 Å), assuming the molecule to be planar.

(b) The internuclear distances between nonneighboring atoms were all kept constant and estimated assuming all the rings to be regular polygons.

(c) Starting from the nuclear arrangement in which all the C–C bond lengths are assumed to be equal, the C–C bonds corresponding to the double bonds in the Kekule-type structure were shortened and, at the same time, all the remaining C–C bonds lengthened in the same amount.

In calculating electronic spectra, configuration mixing of the singly excited states is partially included; the number of the configuration interactions considered is 28 for I, II, and VI (Fig. 1) and 55 for other molecules.

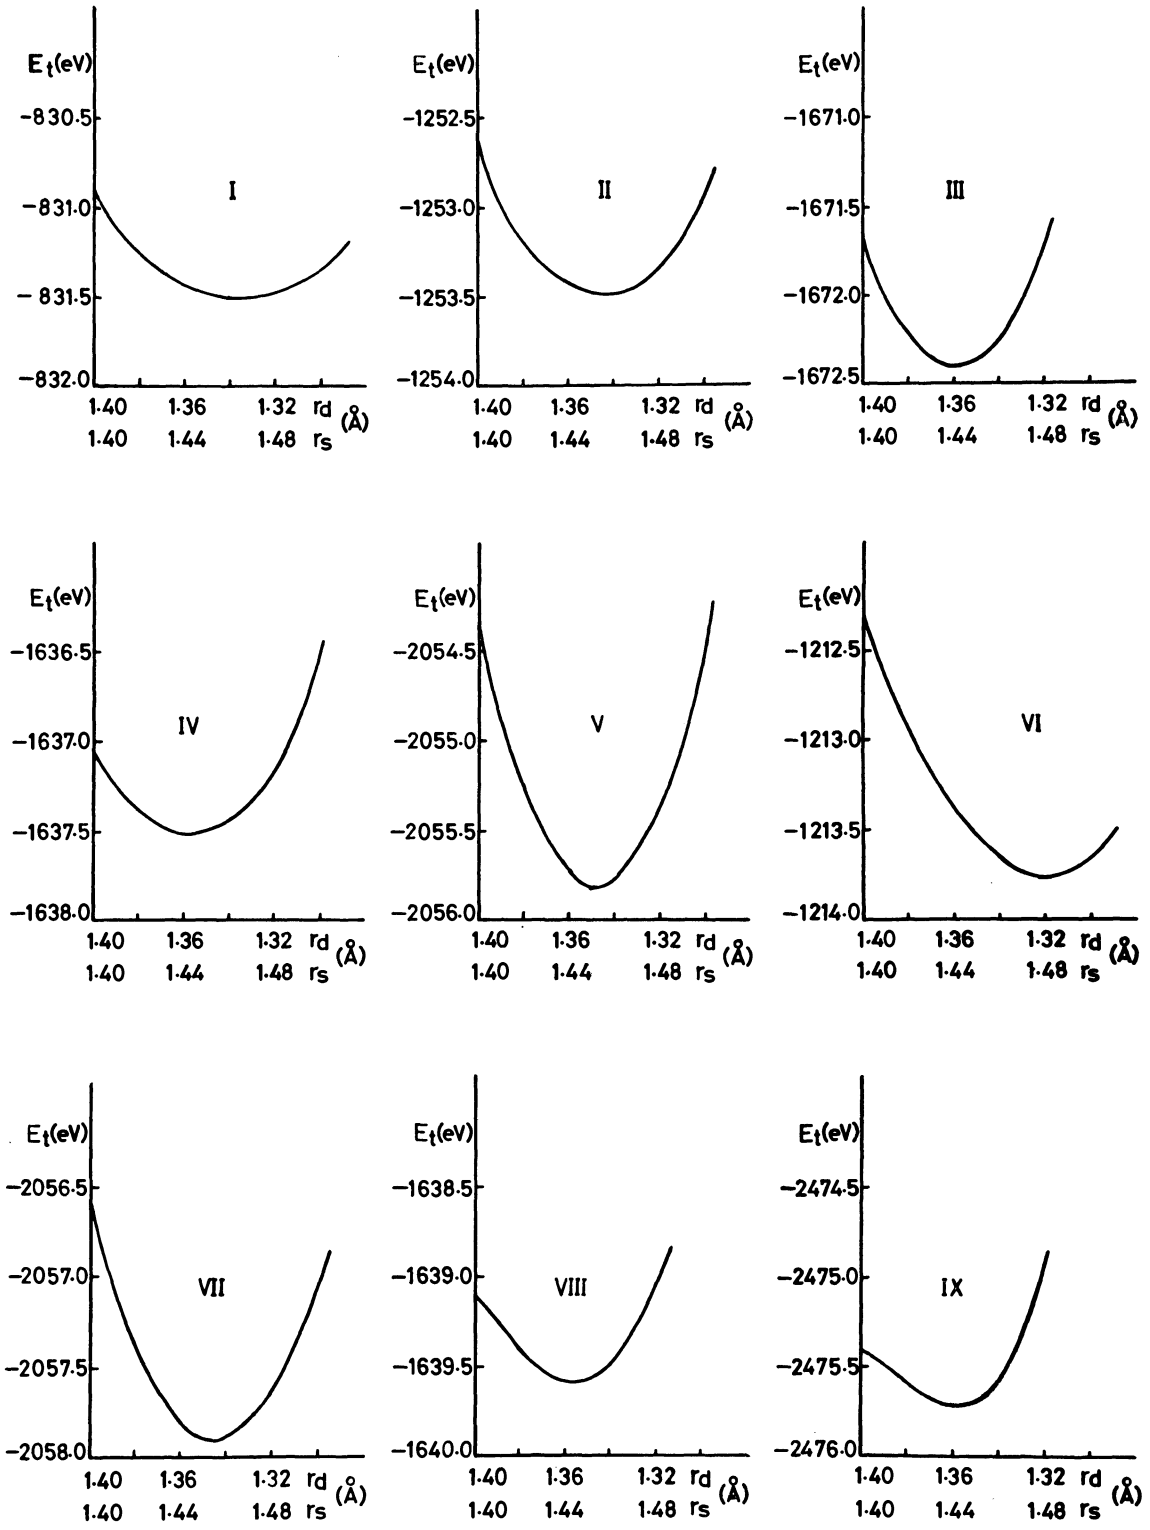

Fig. 2. Variations of total energies with C–C bond lengths. r_d and r_s mean the C–C bond lengths corresponding to the double bonds and single bonds, respectively, in the Kekulé-type structure.

Results and Discussion

Ground-State Properties. The nonalternant hydrocarbons examined are triafulvene (I), fulvene (II), heptafulvene (III), calicene (IV), triaheptafulvalene (V), triafulvalene (VI), fulvalene (VII), pentalene (VIII) and heptalene (IX) (Fig. 1). In Fig. 2, the total energies calculated for these molecules are plotted against the C–C bond-distance variation. All the curves exhibit an energy minimum at about 1.32—1.36 Å for the shorter bonds and 1.44—1.48 Å for the longer bonds, showing an agreement with the results of previous investigations[1–3,5,7,9,11,30] where in these nonalternant hydrocarbons a distorted structure in which a marked double-bond fixation exists is energetically favored as compared with the fully delocalized one. It should be noted that in pentalene (VIII) and heptalene (IX), such a bond distortion is accompanied with molecular-symmetry reduction from D_{2h} to C_{2h}. The stabilization energies which favor the C_{2h} structure for VIII and IX are calculated to be 11.04 and 6.90 kcal/mole, respectively.

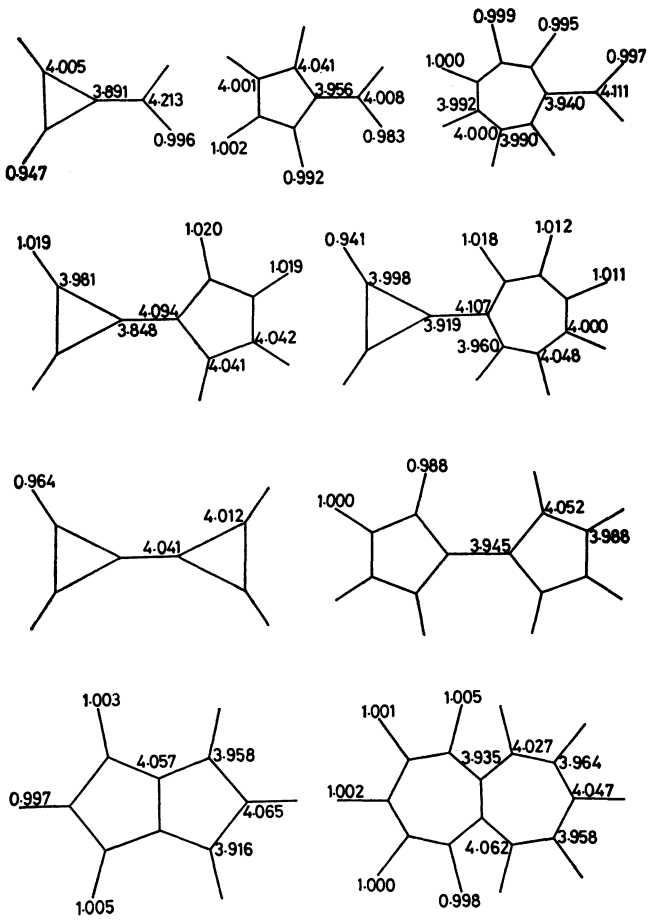

Fig. 3. Total atomic populations.

The total atomic populations calculated using the energetically most favorable set of C–C bond distances are shown in Fig. 3. The dipole moments calculated from these data for I, II, III, IV, and V are 2.12, 0.61, 0.98, 5.45, and 3.71 D, respectively. As for II, a dipole moment of 1.2 D[31] or 1.1 D[32] has, until recently, been adopted as the experimental value. Brown *et al.*[33] have measured the Stark effect of II and reported a dipole moment of 0.44 ± 0.02 D, which is considerably smaller than the experimental estimation. They have also calculated the dipole moment of II using the CNDO/2 procedure and obtained a theoretical value 0.89 D. The discrepancy between their value and ours seems to arise from the difference in the geometrical structures adopted. Our value obtained using the set of bond distances at which the total energy is minimized should in principle be more plausible and actually is reasonably near the new experimental value.

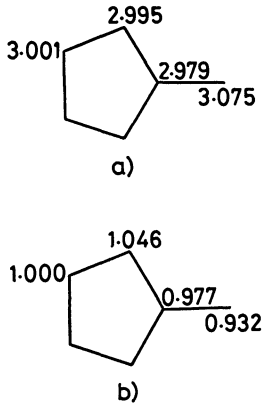

Fig. 4. Electron densities in fulvene: a) σ-electron densities; b) π-electron densities.

In Fig. 4, σ-electron and π-electron charge densities of II are shown separately. The π-electron distribution shows that the 5-membered ring is charged negatively, as is expected from the aromatic sextet rule. On the other hand, the σ-electron distribution reveals that the σ framework of the 5-membered ring is charged positively and the dipole moment due to σ charge has the direction opposite to that due to π charge. However, the dipole moment due to σ electrons (0.19 D) is completely masked by that due to π electrons (0.80 D), and the total dipole moment is such that the 5-membered ring is charged negatively. Such is the case with other polar molecules, I, III, IV, and V.

The theoretical dipole moments for III and IV are in good agreement with the experimental values 0.7 D[34] and 5.6—6.1 D,[30] respectively.

The dipole moment of I is predicted to be considerably larger than that of III, which means that the electron releasing power of the 3-membered ring is appreciably greater than that of the 7-membered ring. This fact is reflected in the appreciable dipole moment calculated for V; the dipolar structure of this molecule is such that the negative pole is directed towards the 7-

h) Reference 4.

jima *et al.*[35] (5.61 eV), and Meyer[36] (5.08 eV) using the π-electron approximation, but in good agreement with the value (4.3 eV) calculated by Yamaguchi *et al.*[37] using the variable bond-length SCF CI π-MO method in which the effects of the bent bonds in the 3-membered ring are taken into account. Unfortunately, there are at present no experimental spectral data available for a direct comparison of theory and experiment.

In fulvene (II) and heptafulvene (III), the lowest $\pi \rightarrow \pi^*$ transition (B_2) polarized along the short axis and the next one (A_1) polarized along the long axis are well separated in energy. On the other hand, in calicene (IV) and fulvalene (VII), these two transitions are predicted to be very close in energy. This is in agreement with the experimental data.

In heptalene (IX), the agreement between theory and experiment is less satisfactory, the predicted transition energies being found to be fairly small as compared with the observed values. This may be attributed to a nonplanar conformation, possible in this molecule owing to the steric repulsion between the ortho hydrogen atoms.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2352—2355(1971)

Molecular Structure of Piperazine as Studied by Gas Electron Diffraction

Akimichi YOKOZEKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 24, 1971)

A study of piperazine by means of gas electron diffraction has given the following structural parameters (the r_g distances and the angles based on the r_α structure) with estimated limits of error: C–C=1.540±0.008 Å, C–N=1.467±0.004 Å, ∠C–C–N=110.4 ±0.8°, ∠C–N–C=109.0 ±0.8°, C–H=1.110±0.008 Å and ∠H–C–H=109.$_1$±5°; the molecule takes a chair conformation. The C–C distance is nearly equal to that in cyclohexane, and the C–N–C angle is slightly smaller than the C–C–N angle. These angles agree with those predicted by an SCF-CNDO/2 method.

In succession of the studies of triethylenediamine[1] and ethylenediamine,[2] the molecular structure of diethylenediamine (piperazine: Fig. 1) has now been

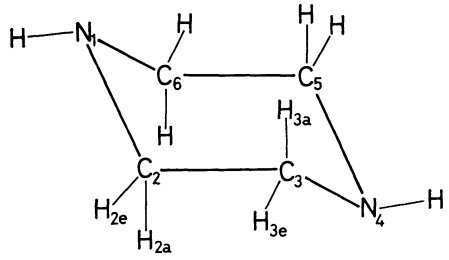

Fig. 1. The numbering of piperazine.

investigated by means of gas electron diffraction. Previous studies of this molecule (electron diffraction,[3] infrared,[4,5] and Raman[6]) showed that this molecule had a chair conformation (C_{2h} symmetry) analogous to cyclohexane. Davis and Hassel[3] reported that the C–N and C–C bond distances were 1.471 and 1.527 Å, respectively, the latter being claimed to be equal to that of cyclohexane, which they studied at the same time, 1.528 Å. However, their C–C distances are found to be about 0.013 Å shorter than that determined by a recent study of cyclohexane.[7] Furthermore, in comparison with the C–C distance in ethylenediamine,[2] 1.545±0.008 Å, their C–C distance seems to be questionably short. Their C–N distance and the C–C–N bond angle, on the other hand, seem to agree with those in ethylenediamine. The present paper reports on a reinvestigation of the piperazine structure and a comparison with those of analogous molecules.

Experimental

Anhydrous piperazine (Guaranteed Reagent, above 99% pure) was purchased from the Tokyo Chemical Industry Co., Ltd. Diffraction photographs were taken on Fuji Process Hard plates at 130°C using a high-temperature nozzle assembly[1] with an apparatus equipped with an r^3-sector.[8] The accelerating voltage (stabilized to within 0.01%) and the beam current were about 40 kV and 0.44 μA, respectively.

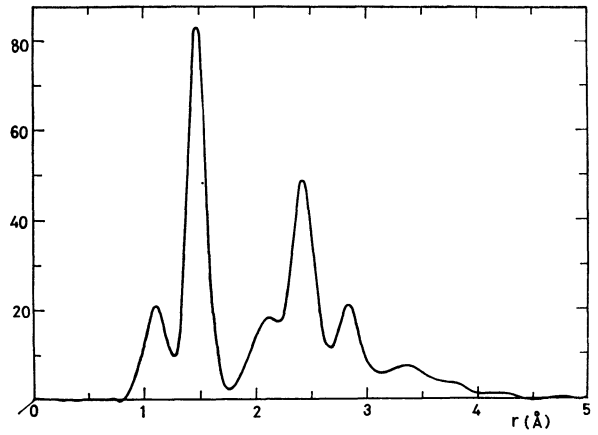

Fig. 3. Experimental radial distribution curve for piperazine with a damping factor of $\exp(-0.00014q^2)$.

The exposure times were about 150 and 60 sec for camera lengths of 113.69 and 249.06 mm. The vapor pressure of the sample at 130°C was estimated to be 70±30 Torr. The vacuum in the diffraction chamber was about 6×10^{-5} Torr during the exposure. In order to obtain correct scales of the diffraction patterns, photographs of reference gases (N_2 and CO_2 for the long and short camera lengths, respectively) were taken in experimental conditions similar to those for the sample, and the scale factors were calibrated to within 0.07% with reference to the r_a(C=O), 1.1646 Å,[8] and r_a(N-N), 1.1007 Å.[9] The photographic densities (0.19 to 0.57) of four plates for each camera length were measured at the intervals of integral q values with a digital microphotometer.[10] Experimental and theoretical molecular intensities and radial distribution function[11] are shown in Figs. 2 and 3, respectively.[12] Most of the calculations were performed by the use of a HITAC-5020E computer in the Computer Centre of the University of Tokyo.

Analysis

Mean Amplitudes of Vibration. The root-mean-square amplitudes and shrinkage corrections for thermal vibration[13] (at 130°C) were obtained from a normal-coordinate analysis by the use of the Urey-Bradley force constants estimated from those for cyclohexane[14]

and amides[15] (Table 1). The calculation was based on a C_{2h} structure with an equatorial N–H bond (see next subsection). The vibrational frequencies of piperazine calculated in this way are compared in Table 2 with observed infrared and Raman frequencies,[4,6] to which a tentative assignment, similar to that of Hendra and Powell,[5] was made. The mean amplitudes and vibrational corrections obtained here are listed in Table 3. The vibrational corrections and some of the mean amplitudes were used as fixed constants in the least-squares analysis.

Determination of Molecular Structure. The radial distribution curve has confirmed a chair (C_{2h}) conformation of the piperazine skeleton but has given no evidence as to the orientation of the N–H bonds (equatorial and/or axial). In this connection, Katritzky *et al.*[16,17] reported from the measurements of the dipole moments and the infrared NH-overtone spectra of piperidine that the N-hydrogen atom prefers the equatorial position in the gas phase and in non-interacting solvents with the ΔG^0 of 0.4—0.5 kcal/mol.

In order to determine the structural parameters, the following assumptions about the hydrogen positions were made for the r_a structure[18] of C_{2h} symmetry.

18) K. Kuchitsu, T. Fukuyama, and Y. Morino, *J. Mol. Structure*, **1**, 463 (1968).

(1) The N–H bonds are equatorial, and the C–N–H angle is equal to that in dimethylamine, 108.8°.[19]

(2) The N–H bond distance is equal to that in ammonia, r_g (N–H) = 1.0302 Å.[20]

(3) The C–C–N plane is perpendicular to the H–C–H plane and bisects the H–C–H bond angle, and *vice versa*.

By taking into account the above geometrical constraints, the total number of the independent parameters was reduced to six: the C–N, C–C and C–H distances, and the C–C–N, C–N–C and H–C–H angles. They were determined, together with an index of resolution and several mean amplitudes, by a least-squares analysis on the molecular intensity curves. The error matrix[21] is listed in Table 4, and the most probable values of the structural parameters and the mean amplitudes are given in Tables 5 and 6 with estimated limits of error including random and systematic errors. The experimental systematic uncertainties in the scale factor and sector imperfection[18] were estimated to be 0.08% in total, while those due to the geometrical constraints mentioned above were estimated to be of the order of random standard errors, since moderate changes in the assumed values had no effect on the most probable values beyond their random standard deviations. The systematic errors in the mean amplitudes were estimated to be 5%,[18] within which the observed mean amplitudes agree with the calculated values. This justifies the above estimation of the force constants; in addition, the systematic errors caused by the use of constant parameters for some of the mean amplitudes seem to have little effect.

Discussion

The structural parameters determined in the present study are compared in Table 7 with those of related compounds studied by gas electron diffraction. The C–C distance, 1.540±0.008 Å, is significantly longer than that reported previously by Davis and Hassel,[3] 1.527±0.005 Å, and is essentially equal to that in cyclohexane,[7] 1.540 Å, and in ethylenediamine,[2] 1.545±0.008 Å, whereas that in triethylenediamine[1] is about 0.02 Å longer, as has been discussed in Ref. 2. The C–N distances in the three molecules are essentially equal to one another and are similar to that in methylamine, 1.467±0.002 Å.[22] In this connection, the C–N distance in dimethylamine is measured to be r_g = 1.455±0.002 Å,[23] r_s = 1.466±0.005 Å,[19] while that in trimethylamine is r_g = 1.454±0.002 Å,[23] r_s = 1.451±0.003 Å.[24] As for bond angles, piperazine, ethylenediamine and triethylenediamine have nearly equal C–C–N angles of about 110°. They are slightly smaller than the C–C–C angles observed in cyclohexane (111.4°)[7] and in normal alkanes (*e.g.*, butane, 112.2°).[25] The C–N–C bond angle, 109.0°±0.8°, supersedes that reported in Ref. 3, 112.6°±0.5°. The hydrogen parameters (C–H and ∠H–C–H) determined in the present study seem to be compatible with those in cyclohexane.[7]

a) Present study.
b) Ref. 1.
c) Ref. 2.

A conformational analysis[2] by the use of a CNDO/2 program[26] written by Segal[27] was made with the C–C–N and C–N–C angles varied from 100° to 120° in step of 0.5°. Other structural parameters were set equal to the values determined above. A set of ∠C–C–N = 110.5° and ∠C–N–C = 109.5° gave the minimum energy, and hence, the calculation is in agreement with the present experiment.

Structures of Norbornane and Norbornadiene as Determined by Gas Electron Diffraction

Akimichi YOKOZEKI and KOZO KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 30, 1971)

The structures of norbornane and norbornadiene in the gas phase have been investigated by electron diffraction. For the most probable models the r_g bond lengths and the bond angles (based on the r_a structure) with estimated limits of error are as follows: For norbornadiene: C_1–C_2=$1.535_4\pm0.007$ Å, C_2=C_3=$1.343_2\pm0.003$ Å, C_1–C_7=$1.57_3\pm0.01_4$ Å, $\angle C_1$–C_7–C_4=$94.{}_1\pm3.{}_0°$, and θ (the dihedral angle between the C_1–C_2–C_3–C_4 and C_4–C_5–C_6–C_1 planes)=$115.{}_6\pm2.{}_2°$; For norbornane: C–C(average)=$1.548_8\pm0.003$ Å, C_1–C_2=$1.53_9\pm0.01_2$ Å, C_2–C_3=$1.55_7\pm0.02_5$ Å, C_1–C_7=$1.56_0\pm0.02_4$ Å, $\angle C_1$–C_7–C_4=$93.{}_1\pm1.{}_7°$, and θ=$113.{}_1\pm1.{}_8°$. The frame structures of these molecules are similar to each other except for the C_2–C_3 bond distances. All the C–C–C valence angles are appreciably smaller than the tetrahedral angle ($\angle C_1$–C_7–C_4 in particular). The C_1–C_7 bridge bonds appear to be longer than the normal C–C single bond. The above structures are compared critically with those reported so far by other investigators. A method for estimation of systematic errors in the structural parameters derived from a least-squares analysis with fixed mean vibrational amplitudes is discussed.

Norbornane (bicyclo[2.2.1]heptane), norbornadiene (bicyclo[2.2.1]hepta-2,5-diene) (Fig. 1), and their

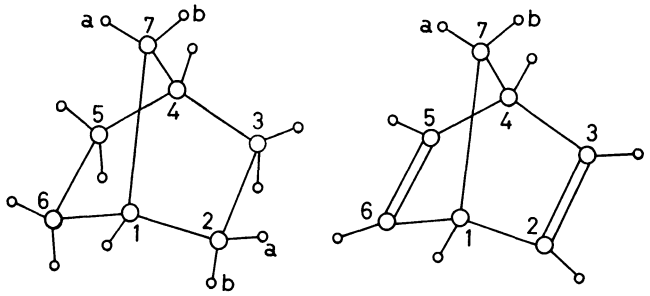

Fig. 1. The numbering of norbornane (left) and norbornadiene (right).

derivatives have been investigated in detail by physical and chemical methods with particular attention to the effect of intramolecular strain. Extensive studies by X-ray diffraction[1] have shown that the carbon bond angles in analogous molecules with camphane frameworks are less than the tetrahedral angle. Particularly striking is the value reported for the angle at the methylene bridge ($\angle C_1$–C_7–C_4: 93°—96°), so that the skeleton must be strained considerably. Theoretical calculations of the geometrical parameters and the conformational energy of norbornane also indicate the above trend.[2-6] The total strain energies in norbornane and norbornadiene, as measured by the heats of combustion and hydrogenation, are 18.4 and 29.0 kcal/mol, respectively.[7] Further support for this strain is given by NMR studies,[8] by which an unusual behavior of the rings toward the magnetic shielding and the proton coupling constants was observed and ascribed to the *p*-character of the C–C bonds in the strained rings. Chemical reactivities such as their high rates of solvolysis are also considered to be closely related to the above-mentioned characteristics.[9]

The present study was initiated to obtain as precise information as possible on the gas-phase structures of these molecules by electron diffraction so as to shed light on the strain effect. Several independent studies of electron diffraction,[10-13] including our preliminary report,[14] have recently been published. However, some of the internuclear distances and angles contained significant discrepancies with one another. In order to examine the origin of these discrepancies, a further analysis has here been carried out by making a critical comparison of the experimental data.[15] In addition, care has been taken in the estimation of uncertainties, particularly that of the systematic errors originated in the theoretical mean amplitudes of vibration used in the analysis.

Experimental

Diffraction photographs were taken on Fuji Process Hard plates at 20°C with an apparatus equipped with an r^3-sector.[16]

The vapor pressure of norbornane was about 20 Torr, and that of norbornadiene was about 40 Torr. Purified samples of norbornane and norbornadiene were kindly provided by Drs. Hiroshi Tanida and Kazuo Tori of Shionogi Research Laboratory. The vacuum was kept under 5×10^{-5} Torr while the sample gas was introduced into the chamber through a nozzle of 0.2 mm diameter. The beam current was about 0.21 μA. The accelerating voltage (about 40 kV) was stabilized within 0.01% during the experiment, and the electron wavelength was calibrated to within 0.07% with reference to the r_a(C=O) bond length of carbon dioxide, 1.1646 Å.[16] The camera lengths were measured to be 107.77 ± 0.01 and 243.22 ± 0.01 mm. The exposure times were about 210 and 60 sec for the shorter and longer camera lengths, respectively, for norbornane, and about 80 and 40 sec for norbornadiene. The photographs were developed at 20°C for 5 min with FD-131 developer diluted twice.

Four plates for each camera length were used for intensity measurements. The optical densities of the plates were measured at the intervals of integral q values (from 17 to 120 and 15 to 60 for the shorter and longer camera lengths, respectively) using an integrating digital microphotometer.[17] The optical densities thus obtained (0.09 to 0.52), were in the range where the densities were found to be proportional to the electron intensities. Most of the calculations were carried out on a HITAC-5020E computer in the Computer Centre of the University of Tokyo.

Analysis

The molecular intensities, $qM(q)$, were obtained from the observed total intensities by the usual procedure[18]; they are illustrated in Fig. 2.[19] Molecular intensites obtained from different photographic plates deviated from one another randomly by about 0.25.

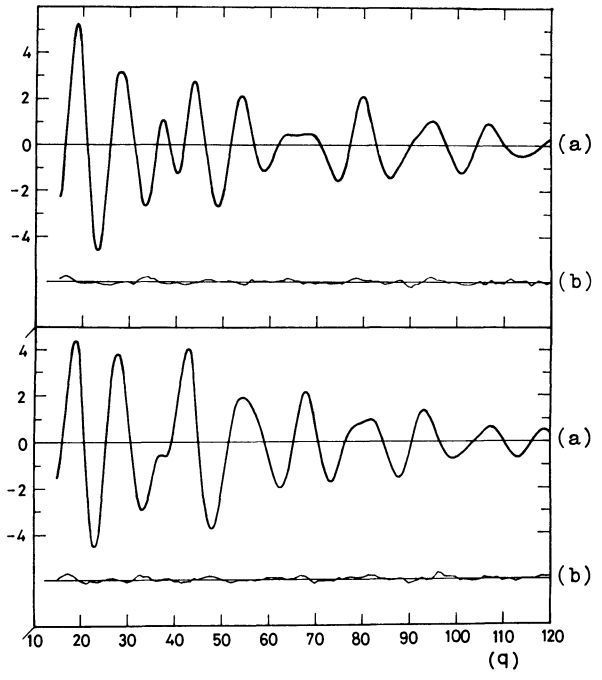

Fig. 2. Molecular intensity curves $qM(q)$ of norbornadiene (upper) and norbornane (lower). (a): best-fit theoretical; (b): experimental minus theoretical.

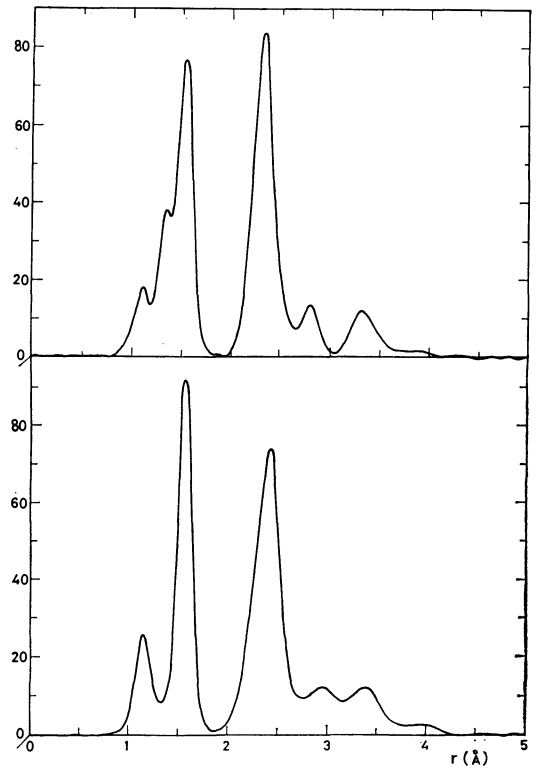

Fig. 3. Experimental radial distribution curves of norbornadiene (upper) and norbornane (lower) with a damping factor of $\exp(-0.00016q^2)$.

Radial Distribution Curves. Modified radial distribution (RD) curves obtained from the molecular intensity curves with a damping factor of $\exp(-0.00016q^2)$ are shown in Fig. 3.

Norbornadiene: Three peaks located in 1—2 Å correspond to the bonded pairs with their maximum positions for C–H at 1.11 Å, C=C at 1.33 Å, and C–C at 1.54 Å. The C–H and C–C peaks are composed of two nonequivalent atom pairs. The peaks in 2—3 Å contain all nonbonded C–C and some of the nonbonded C–H and H–H pairs. In spite of the considerable overlapping of peaks, the RD contour in this region was found to be sufficiently sensitive to determine the carbon skeleton structure. The lower peak at 2.8 Å is almost completely made of the C_2–C_5 and C_3–C_6 pairs, and hence, it affords a good measure of the dihedral angle θ between the C_1–C_2–C_3–C_4 and C_4–C_5–C_6–C_1 planes. A preliminary analysis of this peak showed that θ was about 116°, and from the 2.35 Å peak that $\angle C_1$–C_7–C_4 and $\angle C_1$–C_2–C_3 were about 91° and 107.5°, respectively. The peak in 3—4 Å is made of several nonbonded C···H and H···H pairs. The result of the above analysis was used as a starting model in a least-

squares refinement on molecular intensities.

Norbornane: The first peak of the RD curve corresponds to the bonded C–H distances, the average value of which is 1.11 Å. The second peak at 1.55 Å contains three closely-spaced nonequivalent C–C pairs. Being analogous to norbornadiene, the peaks in 2—3 Å correspond to nonbonded C···C, C···H, and H···H pairs. If the skeleton has C_{2v} symmetry, the longer distance of the C_2–C_5 and C_3–C_6 should correspond to the peak at 2.9 Å. Since all attempts to account for the RD peaks in terms of a C_2 structure were unsuccessful, a C_{2v} structure was favored.

TABLE 1. ESTIMATED FORCE CONSTANTS FOR NORBORNANE AND NORBORNADIENE[a]

K(C–C)	2.3	H(C–C–C)	0.32	F(C–C–C)	0.20
K(=C–C)	3.0	H(C–C=C)	0.25	F(C–C=C)	0.35
K(C=C)	7.4	H(C–C–H)	0.225	F(C–C–H)	0.41
K(C–H)	4.1	H(C=C–H)	0.21	F(C=C–H)	0.36
K(=C–H)	4.3	H(H–C–H)	0.40	F(H–C–H)	0.18
Y(=C–C)	0.16	Y(C=C)	0.50	Y_{cis}(C–C)	0.11
Y(C–C) *gauche*	0.15	W(C=C–H)	0.35		

a) Estimated force constants taken from those for cyclohexane[23] and several olefins (butene, pentene, *etc.*),[24] The torsional (Y) and wagging (W) force constants are in md·Å, and the others are in md/Å units.

a) For 20°C. The H·····H pairs are not listed.

Least-Squares Refinements on Intensity Curves. The intensity curve was fitted to the corresponding theoretical expression by a least-squares method with a preset weight function.[20] The mean amplitudes and shrinkage corrections of vibration[21] for all the internuclear distances were calculated on the basis of an estimated force model using the Urey-Bradley force field,[22] to which force constants for simple molecules with analogous geometrical arrangements (cyclohexane,[23] pentene, butene, *etc.*)[24] were transferred (listed in Table 1). A detailed procedure for the calculations is given elsewhere.[21] Numerical results are listed in Tables 2 and 3; they were used as fixed constants in the analysis. Systematic errors due to this constraint are examined in later sections. The asymmetry parameters κ for the bonded C–H were estimated to be 1.0×10^{-5} Å^3 and used as constants.[25]

Choice of Independent Parameters. Norbornadiene: This molecule is expected to have a C_{2v} structure. The RD analysis and a preliminary least-squares analysis on the intensity curves showed that the equilibrium structure of this molecule belongs to this symmetry. Thus the total number of independent parameters is twelve. In order to make the analysis easier, the following additional assum tions were taken into account.

1) The C–C–H angles are equal at the bridgehead, *i.e.*, $\angle$H–C_1–C_2=$\angle$H–C_1–C_6=$\angle$H–C_1–C_7.

2) All the C(sp^3)–H bond distances are equal.

3) The C(sp^2)–H bond distances are equal to that in ethylene, r_a=1.0896 Å.[26]

4) The vinylene group (C_1–CH=CH–C_4) is planar. These assumptions reduced the number of independent parameters to eight. Regarding the skeleton structure, three distances (C_1–C_2, C_2=C_3, and C_1–C_7) and two angles ($\angle C_1$–C_7–C_4 and θ defined above) were chosen. The parameters for hydrogen positions were $\angle$H–C_7–H, $\angle$C=C–H and the (weighted-average) C(sp^3)–H distance.

Norbornane: As mentioned in the preceding subsection, a C_{2v} structure was favored for this molecule, in which the structure are defined by fifteen independent parameters. Additional assumptions on the r_a structure[21,27] were as follows.

1) The H–C_2–H plane is perpendicular to the C_1–C_2–C_3 plane and bisects the C_1–C_2–C_3 angle, and *vice*

20) Y. Morino, K. Kuchitsu, and Y. Murata, *Acta Crystallogr.*, **18**, 549 (1965).

27) G. Dallinga and L. H. Toneman, *J. Mol. Structure*, **1**, 11 (1967); K. Kuchitsu, T. Fukuyama, and Y. Morino, *ibid.*, **1**, 463 (1968).

versa.

2) The C–C–H angles are equal at the bridgehead, *i.e.*, $\angle H\text{–}C_1\text{–}C_2 = \angle H\text{–}C_1\text{–}C_6 = \angle H\text{–}C_1\text{–}C_7$.

3) All the C–H bond distances are equal.

4) All the H–C–H bond angles are equal.

Thus the number of independent parameters was reduced to seven. For the skeleton structure, three non-equivalent carbon-carbon distances, C_1–C_2, C_2–C_3, and C_1–C_7, and two angles, $\angle C_1\text{–}C_7\text{–}C_4$ and θ, were chosen as parameters. For hydrogen positions, a weighted-average C–H bond distance and the H–C–H angle were varied. In our earlier report,[14] the C_1–C_2 and C_2–C_3 distances were assumed to be equal, but this constraint has been released in the present analysis.

Results of the Analysis. The above analysis led to the most probable parameters with random standard

Table 4. Least-squares results for norbornadiene and norbornane[a]

Independent parameters	Norbornadiene I	Norbornadiene II	Norbornane
C_1——C_2	$1.533_2 \pm 0.001_4$	$1.532_9 \pm 0.001_3$	$1.536_2 \pm 0.002_9$
C_2——C_3	$1.338_7 \pm 0.001_2$	$1.338_3 \pm 0.001_1$	$1.552_7 \pm 0.008_7$
C_1——C_7	$1.571_1 \pm 0.003_1$	$1.571_2 \pm 0.003_0$	$1.557_9 \pm 0.008_6$

k								92

a) Error matrix for the independent parameters. Units (10^{-4}) for the distances are Å, those for the angles are rad., and the index of resolution k is dimensionless.

errors shown in Table 4. The corresponding error matrices[28] are listed in Tables 5 and 6. Two alternative sets of solutions were obtained for norbornadiene. In particular, the C_1–C_7–C_4 angle converged to I 92.2°±0.4° and II 96.0°±0.2°, depending on the initial values of the analysis; any initial value smaller than 94° led to solution I, while any of those larger than that led to solution II. Changes in the other parameters due to correlation with the C_1–C_7–C_4 parameter were within about three times the corresponding random standard errors (see Table 4). These alternative solutions (I and II) were equally probable, since the variances $([V^*PV/(n-m)]^{1/2})$ for the solutions were 0.106 and 0.105, respectively. In this connection, the differences in the observed and the most probable theoretical intensities were similar to those among the observed intensities derived from different photographic plates. Accordingly, the variances derived from the above analysis did not provide a clearcut criterion on the resolution of this ambiguity. This problem is further investigated in the following section.

Estimation of Systematic Errors. For some of the parameters, systematic errors due to the uncertainties in the mean amplitudes fixed in the analysis are more important than the random standard errors. In other words, a unique determination of the structure depends critically on the correctness of the estimated amplitudes.[18] In order to investigate this problem, the following method has been considered.

Suppose a probability of finding a set of correct estimates of the mean amplitudes between l_1, l_2,···and $l_1+\mathrm{d}l_1$, $l_2+\mathrm{d}l_2$,··· is represented by $w(l)\mathrm{d}l \equiv w(l_1, l_2,\cdots)\cdot \mathrm{d}l_1\mathrm{d}l_2\cdots$. This function is not necessarily a Gaussian, nor may be symmetric about the most probable set. In principle, this function can be estimated if a probability of finding correct estimates of the force constants K, $w(K)\mathrm{d}K$, is known. In reality, an order-of-magnitude estimation of $w(l)$ is barely practicable, but it seems to be sufficient for the present purpose.

When a least-squares technique is applied to the molecular intensity with mean amplitudes fixed at l_1, l_2,···, the most probable estimates of the variable parameters, x_1, x_2,··· and their standard errors depend on l parametrically and constitute a probability distribution of the estimate, $W(x;l)\mathrm{d}x$; this function should conform, at least approximately, to a multidimensional Gaussian. The uncertainties in the mean amplitudes fixed in the analysis smear this error distribution in such a way that the total distribution, $P(x)\mathrm{d}x$, is a folding of the $W(x;l)$ and $w(l)$ functions,

$$P(x)\mathrm{d}x = \int W(x;\, l)w(l)\mathrm{d}l\mathrm{d}x, \qquad (1)$$

from which the systematic uncertainties from this origin in the x parameters may be estimated. The above equation can be integrated if analytical functions are assumed for $W(x;l)$ and $w(l)$; otherwise a numerical method may be used. Since a non-random problem is dealt with, the present analysis cannot have a full statistical significance. However, one may still apply the criterion of least squares to an automatic searching for a *plausible* set of parameters and their *possible uncertainties*.

In the present problem, the $w(l)$ function was estimated from our past experience: For simple molecules, errors in the experimental mean amplitudes are less than 10%, and those in the values calculated from assumed force fields are of a similar order. Usually, experimental and theoretical mean amplitudes for bonded atom pairs have smaller uncertainties than those for nonbonded atom pairs. Therefore, the uncertainties in the calculated mean amplitudes (Tables 2 and 3) were assumed to be 10 and 20% for bonded and nonbonded atom pairs, respectively.[29] The $w(l)$ function was assumed to be a product of individual probabilities, $w(l) = \prod_i w_i(l_i)$, where $w_i(l_i)$ were assumed to be independent of each other, constant in the ranges mentioned above and vanishing outside. Equation (1) was calculated by an approximate Monte-Carlo method. A set of the mean amplitudes l_i were prepared randomly by use of a function

$$l_i = l_{i0}\{1+2c_i(r-0.5)\}, \qquad (2)$$

where c_i is the estimated uncertainty in the theoretical amplitude l_i (10 or 20%), l_{i0} is given in Tables 2 and 3, and r is a set of uniform random numbers (0.0—1.0) generated by a program G5/TC/RUNI[30] in the program library of the Computer Centre of the University of Tokyo. Least-squares analyses were carried out with more than 20 sets of the fixed mean amplitudes sampled by Eq. (2) for either molecule. The resulting ranges Δ for the most-probable parameter values are listed in Table 7 together with their random standard errors

TABLE 7. ESTIMATION OF ERRORS

Independent parameters	Norbornadiene		Norbornane	
	σ_r[a]	$\Delta/2$[b]	σ_r	$\Delta/2$
(C——C)$_{av}$	···	···	0.001_0	0.001

b) The r_g distances converted from the r_α distances given in Ref. 14.
c) Distances (r_g) are estimated by adding 0.0018 Å to the C–C distance and also 0.0055 Å to the C–H distances reported in the references (probably r_α).

count. They are listed in the first columns of Tables 8 and 9 accompanying the most probable parameters. For some of the parameters (*e.g.*, the C=C distance in norbornadiene), the P distributions seem to be essentially equal to the W distributions, whereas for other parameters (*e.g.*, the C_1–C_7–C_4 and θ angles) the W functions are broadened into the P functions so that the uncertainties in the parameter values originate entirely from the choice of the mean amplitudes.

For norbornadiene, the most-probable estimates of the C_1–C_7–C_4 parameter obtained in the above analyses scattered from 92° to 96°, whereas the values did not always depend on the starting parameters as mentioned in the preceding subsection. Since the error surface seems to have a broad minimum around 94° with respect to this parameter, a simple average over the estimated P distribution was taken as the final estimate of this parameter.

Despite the large uncertainties in the individual C–C bond distances mentioned above, their weighted-average values have been determined with much better accuracy. The C–C distance in norbornadiene has also been obtained uniquely without serious correlation with the mean amplitudes.

Comparison with Previous Results. The experimental values reported in the literature[10–14] are compared with the present results in Tables 8 and 9, where our preliminary results in the earlier communication[14] (r_α structures[21,27]) have been revised within their limits of error by taking into account the multiminimum solutions discussed above and the systematic errors due to the fixed mean amplitudes in the least-squares refinements.

Some of the parameters reported by other authors contradict one another beyond the quoted uncertainties. Possible sources of the discrepancies are considered to be (A) differences in the experimental intensity curves and (B) those in how the mean amplitudes are treated in the analysis.

Norbornadiene: The results obtained here are similar to those in Ref. 11 except for the scale. The double bond distance affords a good measure of the scale, since this distance can be determined with little ambiguity. The C=C distance determined here is in good agreement with that reported in Ref. 13b, whereas a scaling error of about 1% is involved in those of Refs. 10 and 11. On the other hand, the principal origin of the difference between the present structure and that of Ref. 13b is to be sought in source (B), since the experimental molecular intensity of Dallinga and Toneman[13b] agrees with ours to within the reproducibility of the observed intensity ($\Delta qM(q)\lesssim0.25$), and yet their results differ significantly from any of the others: (1) Their C_1–C_2 bond distance is longer than the C_1–C_7 distance, contrary to the results of all the other authors, and (2) their C_1–C_7–C_4 angle is much larger than those determined by the others.

The choice of the mean amplitudes seems to be responsible for the difference between Dallinga's results and ours. They adopted the mean amplitudes in cyclohexadiene, butadiene, *etc.* with no discrimination among the nonequivalent pairs and used them as fixed

constants: all the C–C amplitudes equal to 0.052 Å, all the nonbonded C···C amplitudes equal to 0.066 Å, all the nonbonded C···H amplitudes equal to 0.084 Å, and so forth. According to our estimates given in Table 2, however, significant differences exist among the amplitudes for nonequivalent pairs: For example, nonbonded C···C and C···H amplitudes range from 0.058 Å to 0.077 Å and from 0.094 Å to 0.140 Å, respectively. Judging from our finding discussed in the preceding subsection, their assumptions probably give rise to considerable systematic errors in their structural parameters. In fact, a theoretical molecular intensity curve based on their structural parameters and our theoretical mean amplitudes (Table 2), instead of their estimated amplitudes, deviates from our experimental curve beyond the uncertainties in the measurement. Furthermore, when some of the mean amplitudes were varied indiscriminately in the analysis of our intensity, a result similar to Dallinga's was obtained: C_1–C_2=1.558 Å, C_1–C_7=1.528 Å, $\angle C_1$–C_7–C_4=97° and θ=112°; however, the amplitudes obtained in this analysis seemed physically unrealistic: The C_1–C_2 (0.0600±0.0035 Å) and C_1–C_7 (0.0450±0.0028 Å) amplitudes are much too large and too small, respectively, and the $C_1\cdots C_3$ nonbonded amplitude (0.052±0.0022 Å) was similar to that of a bonded pair. After all, Dallinga's parameters seem to be one of the multisolutions resulting from a questionable choice of the mean amplitudes.

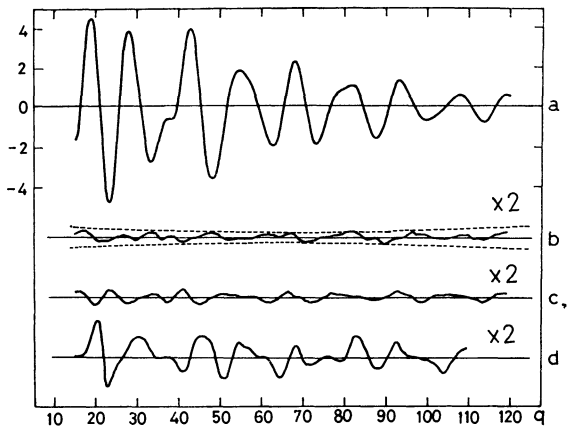

Fig. 4. Comparison of the experimental molecular intensity curves $qM(q)$ for norbornane. a: Present study; b: $[qM(q)_{exp}-qM(q)_{calc}]\times 2$ for the present measurement, where broken lines indicate the uncertainty level; c: [Curve a$-qM(q)$ measured by Dallinga and Toneman (Ref. 13a)]×2; d: [Curve a$-qM(q)$ measured by Chiang *et al.* (Ref. 12)]×2.

Norbornane: Our results are in good agreement with Dallinga's,[13a] except that the order of the C_2–C_3 and C_1–C_7 bond lengths is reversed, whereas Chiang's results[12] deviate from the others in the C–C weighted-average and θ; the C–C average is about 0.01 Å (see footnote c of Table 9) longer than the others, and the θ is about 4° smaller. The discrepancy in the C–C average seems to be a scaling error of about 0.5%. In this connection, experimental molecular intensity curves[12,13a,15] are compared in Fig. 4. Dallinga's curve agrees with ours to within the experimental uncertainties illustrated in Fig. 4 as broken lines, whereas Chiang's curve deviates significantly.[31] Therefore, the difference between Chiang's results and the others appears to be due to source (A), while that between Dallinga's results and ours is due to source (B). The differences between the individual C–C bond distances (C_1–C_2, C_2–C_3, and C_1–C_7) are within the estimated systematic errors due to the uncertainties in the mean amplitudes used in the analysis (see preceding section), so that it seems to be a hard problem at the present stage to discriminate the individual C–C bond distances unambiguously by electron diffraction alone. Additional information such as the rotational constants determinable from microwave spectroscopy may provide an effective solution of this problem.[27]

Discussion

Molecular Structure. The final results are listed in the first columns of Tables 8 and 9 with estimated limits of error including random and systematic errors.

The frame structure of norbornadiene is similar to that of norbornane, except that the C=C double bond distance seems to be slightly longer than that in ethylene (r_g=1.337 Å).[26] The C_1–C_2 bond distance is found to be about 0.03 Å longer than the C–C single bond adjacent to a C=C double bond (*e.g.*, 1.501 Å (r_s) in propylene[32]), and the C_1–C_7 bridge bond distance is about 0.03 Å longer than that in cyclohexane, 1.540 Å (r_g).[33] These lengthenings seem to indicate the effect of strong intramolecular strain, which also makes the C_1–C_7–C_4 angle decrease from the tetrahedral angle by more than 15°. Analogously, the C_1–C_2=C_3 angle is about 18° smaller than the C–C=C angle in *cis*-2-butene (*ca.* 125°),[34] whereas the C=C–H angle, 124°, seems to be normal.

For norbornane, the average value of the C–C bond distance, 1.548_8±0.003 Å, is about 0.01 Å longer than the normal single bond distance. Probably, this lengthening is due to the C_1–C_7 and C_2–C_3 bonds; they appear to be about 0.02 Å longer than the C_1–C_2 distance, though the differences are within their limits of error. The $C_1\cdots C_4$ distance, 2.26Å, is nearly equal to or a few hundredths of an angstrom shorter than that in norbornadience; the corresponding distances in the bicyclo-[2.2.2]-compounds (octane, octene, and octadiene) are about 0.3 Å longer.[29] All the C–C–C angles (the C_1–C_7–C_4 in particular), except for the C_2–C_1–C_6 angle (108.6°), are appreciably smaller than the tetra-

31) It is likely that the difference in the diffraction intensities obtained by Chiang *et al.*[12] from those obtained by Dallinga[13a] and in the present study (shown in Fig. 4) is due to the samples rather than to the apparatuses, since Chiang *et al.* found no essential difference between the intensity patterns taken at Cornell University and at the University of Oslo (by Bohn) by the use of portions of the same sample. (S. H. Bauer, private communication, April, 1971).

TABLE 10. COMPARISON OF THE EXPERIMENTAL AND THEORETICAL STRUCTURES FOR NORBORNANE

Parameters	Obsd[a]	Calcd[b]					
		A	B	C	D	E	F
$(C—C)_{av}$	1.549	1.538	1.541	1.521			
$C_1—C_2$	1.53_9	1.534	1.543	1.520			
$C_2—C_3$	1.55_7	1.534	1.547	1.526			
$C_1—C_7$	1.56_0	1.551	1.531	1.513			
$\angle C_1$-C_7-C_4	$93._1°$	92.8°	93.9°	93.7°	92.0°	94—96°	93.0°
$\angle C_1$-C_2-C_3	$103._3°$	103.4°	102.9°	103.0°	103.0°	104°	103.0°
θ	$113._1°$	114.3°	110.1°	114.8°	113.9°	109°	113.0°

a) Observed structure determined in the present study (see Table 9). The C_1-C_2-C_3 angle was calculated from the independent parameters.

b) Theoretical structures calculated by a conformational analysis of the SCF-MINDO (A) or the strain-relief scheme (B—F). A: Ref. 6; B: Ref. 5; C: Ref. 4; D: Ref.2; E: Ref. 3; F: Present study (see text).

hedral angle. As discussed below, those anomalous values are consistent with the predictions based on the calculation of strain on bond angles and the interaction of the nonbonded C···C, C···H, and H···H atoms. X-ray observations[1] on similar angles in certain derivative molecules in the crystal phase are also in line with the above findings. Therefore, the angular distortions found in crystals should primarily be of intramolecular origin rather than of intermolecular origin.[18]

Intramolecular Strain. A calculation was made to account for the striking features in the skeletons of these molecules discussed above by means of a minimization of empirical strain energy.[29] A modified Urey-Bradley field similar to that developed by Jacob *et al.*[35] was employed with a "softer" set of nonbonded potential functions taken from Hendrickson's papers.[36] The force constants for the C–C–C and C–C=C angles were assumed to be equal to each other, 0.687 md·Å, and the equilibrium values for the former and the latter angles were chosen to be the tetrahedral and trigonal angles, respectively, while the torsional constant was taken from the height of the rotational barrier for ethane, 2.93 kcal/mol[37] for the carbon-carbon single bond. The analyses were made with bond lengths fixed to the values observed in the present work, and angular parameters for the skeleton were varied simultaneously in order to minimize the potential energy. The results, listed in the last column of Tables 8 and 10, account for the experimental values. Similar predictions made by other researchers[2-6] for norbornane, compared in Table 10, agree essentially with the present results in spite of the difference in the force fields and in the schemes, except that the dihedral angles θ in Refs. 3 and 5 are too small.

In order to account for the observed lengthening in the C–C bonds, bond lengths for the norbornane skeleton were varied in the above conformational analysis, where the stretching force constant and the equilibrium distance of the C–C bond were taken as 2.2 md/Å and 1.533 Å, respectively. The analysis resulted in all the C–C bond distances (C_1–C_2, C_2–C_3, and C_1–C_7) longer than 1.6 Å. This absurdity is no doubt due to the strong nonbonded repulsion assumed among the carbon atoms, since the mean next-to-bonded C···C distance of 2.412 Å is substantially shorter than the average value of 2.545Å in normal alkanes.[38] Gleicher and Schleyer[5] ignored those interactions of the 1–3 type in summing up all the nonbonded interactions, because they used a modified valence force field. The calculation made by Allinger *et al.*[4] is based on a similar scheme. However, neither prediction of the bond lengths, compared in Table 10, is in agreement with the observation. On the other hand, a conformational analysis made by Boder and Dewar[6] for norbornane by a semiempirical SCF-MO (MINDO/2) method predicted the C_1–C_7 distance to be longer than C_1–C_2 and C_2–C_3 distances, although their C–C weighted average was about 0.01 Å shorter than the observed value. According to another prediction of Dallinga and Ros[39] on the basis of an iterative extended Hückel method, the C_1–C_7 and C_1–C_2 distances for norbornane are practically equal and about 0.03 Å shorter than C_2–C_3. Therefore, a fully quantitative prediction of bond lengths in such bicyclic compounds seems to be beyond the reach of our control at the present stage.

The authors wish to thank Professor Emeritus Yonezo Morino for his continual encouragement and Drs. Hiroshi Tanida and Kazuo Tori of the Shionogi Research Laboratory for the samples used in this work. They are also indebted to Professor S. H. Bauer of Cornell University and Dr. G. Dallinga of Koninklijke/Shell-Laboratorium, Amsterdam for sending their experimental intensity curves and for their helpful discussions.

Magnetic and Thermal Properties of Crystals Including Isolated Clusters. II. Heat Capacity of $Co_3(C_5H_5)_3S_2$ from 15 to 270 K and Mechanism of Phase Transition[1]

Michio SORAI, Akio KOSAKI, Hiroshi SUGA, Syûzô SEKI,
Toshikatsu YOSHIDA,* and Sei OTSUKA*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka
**Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

(Received March 31, 1971)

Heat capacity of $Co_3(C_5H_5)_3S_2$ was measured between 15 and 270 K. A phase transition was discovered at 192.5±0.1 K with the transition enthalpy and the entropy of 5253.4 J mol^{-1} and 28.894 J K^{-1} mol^{-1}, respectively. The transition entropy is well described as the sum of the configurational entropy of $R\ln 4$ due to cyclopentadienyl rings and the magnetic contribution of $R\ln 8$ due to cyclopentadienyl rings and the magnetic contribution of $R\ln 4$. The transition behavior is satisfactorily accounted for in the whole temperature region investigated in terms of the cooperative coupling between the orientational motion of the rings and the electronic states of a molecule on the basis of the Chesnut exciton model modified by the present authors. The model proposed here is to take both the temperature dependences of the energy parameters and the inversion of the spin state at higher temperatures into account. The measurements of infrared spectra and proton magnetic resonance were made as a function of temperature. These results are favorable to the present model. The electron spin resonance experiment also confirmed the present model.

In the course of our systematic magnetic and thermal investigations of isolated clusters, we reported, as series I,[2] the magnetic interaction of a trinuclear complex compound, $[Cr_3O(CH_3COO)_6(H_2O)_3]Cl\cdot 6H_2O$, which is one of the typical coordination compounds of the Werner-type with the spin quantum number of 3/2 per each Cr^{3+} ion. In this paper we will deal with magnetic and thermal properties of a trinuclear organometallic compound, $Co_3(C_5H_5)_3S_2$ [tris-(π-cyclopentadienylcobalt) disulfide].

Crystalline $Co_3(C_5H_5)_3S_2$, which was newly synthesized by two of the present authors (T.Y. and S.O.) and others,[3] consists of discrete molecules with the configuration shown in Fig. 1. The cobalt and sulfur atoms form a regular trigonal bipyramid with the cyclopentadienyl rings stereochemically disposed about the cobalt atoms such that lines passing from the center of the equilateral cobalt triangle through the cobalt atoms intersect the centroids of the cyclopentadienyl rings.[4] The magnetic susceptibility measured by two of the present authors (T.Y. and S.O.) and others[4] showed a maximum at 215 K. Above this temperature the susceptibility obeyed the Curie-Weiss law, but below 215 K it decreased rapidly reaching near zero at about 130 K. The effective magnetic moment μ_{eff} calculated from the susceptibility was found to be independent of temperature above 215 K and the average value of μ_{eff} was 2.53 B.M. Below this temperature, however, the μ_{eff} decreased gradually to zero at about 130 K. From the comparison of these values with the theoretical ones based on the orbital-quenched model and also from the simple molecular orbital treatment, it was proposed[4] that the magnetic property of the present compound may be explained by a ground singlet state at the low temperatures followed by a thermally accessible triplet state above 215 K.

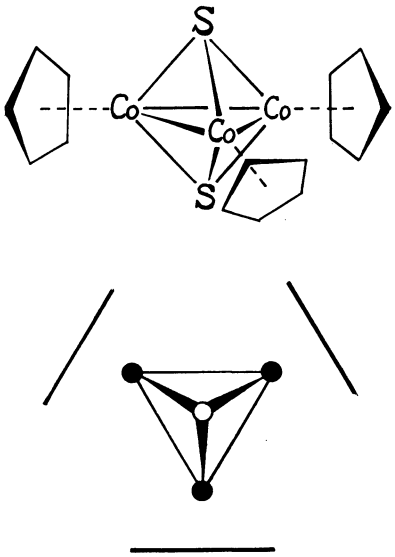

Fig. 1. Molecular configuration of $Co_3(C_5H_5)_3S_2$ (after Ref. 4).

The susceptibility maximum at about 215 K is suggestive of some cooperative effects in the present crystal. It should be, however, remarked here that unlike the preceding salt, $[Cr_3O(CH_3COO)_6(H_2O)_3]Cl\cdot 6H_2O$, the direct covalent bonds are formed among three metal atoms within a cluster and hence the cobalt atoms do not exist as ionic states in the present compound. The study of the magnetism accompanied by electronic excitation is somewhat difficult compared with that of the magnetism only due to spin states. The cooperative effects in such a system have not been fully investigated. One of the scare examples is the phenomenological theory for some dense magnetic excition systems by Chesnut,[5] who described successfully the gross aspects of the observed anomalous behaviors in some

organic free-radical salts in terms of the relatively high exciton concentrations.

The purposes of the present paper are to measure the heat capacity and the related properties between 15 and 270 K and to clarify whether any cooperative phenomenon does exist or not in the present cluster system. As a result a heat capacity anomaly was discovered at 192.5 K with a large amount of the transition entropy unexpected solely from the magnetic contribution due to the old energy schemes.[4]

In order to get more insight into the mechanism of the phase transition we gave attention to the motional behavior of the cyclopentadienyl rings in a crystalline state. The physical properties of ferrocene, $Fe(C_5H_5)_2$, are favorably compared with those of the present crystal.

The transition behavior is satisfactorily accounted for in terms of the cooperative coupling between the orientational motion of the cyclopentadienyl rings and the electronic states on the basis of the Chesnut exciton model modified by the present authors.

Experimental and Results

Material. The present substance was prepared by the method[3] previously described and was recrystallized from a mixture of benzene and *n*-hexane to give dark prism crystals. The results of elementary analysis have been shown in the previous paper.

Heat Capacity. The heat capacity of $Co_3(C_5H_5)_3S_2$ crystal was measured by an adiabatic calorimeter[6] in the temperature range from 15 to 270 K. The

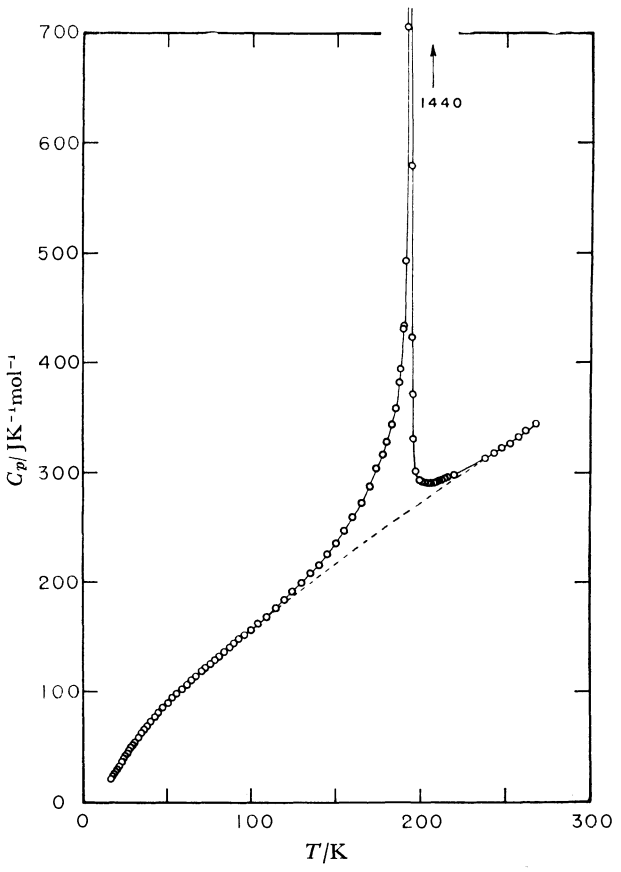

Fig. 2. The heat capacity of $Co_3(C_5H_5)_3S_2$ in the region from 15 to 270 K. Broken line indicates the "normal" heat capacity.

Table 1. The heat capacity of $Co_3(C_5H_5)_3S_2$ (Molecular weight 436.214).

6) T. Matsuo, H. Suga, and S. Seki, *J. Phys. Soc. Jap.*, **30**, 785 (1971).

calorimeter cell contained 11.0344 g (=0.0252958 moles) of the sample and a small amount of helium gas to aid in heat transfer. As this substance is thermally stable but sensitive to air, all treatments were carried out in a dry-box under a stream of dried nitrogen gas.

The results of heat capacity measurements are summarized in Table 1 and plotted in Fig. 2. As can be seen from the figure at heat capacity anomaly was discovered reproducibly at 192.5 ± 0.1 K. This phase transition may be nonisothermal or of second-order because the time required for thermal equilibration after an energy input was not affected by the transition phenomenon. The heat capacity peak is very sharp in the vicinity of the transition point but the tail of excess heat capacity extends down to rather low-temperature side. It is therefore difficult to determine uniquely the enthalpy and the entropy of transition. A dashed line indicated at the base of the transition peak in Fig. 2 is a tentative but plausible curve which separates the excess heat capacities from the overall ones. The enthalpy and the entropy of transition calculated by use of this "normal" heat capacity were found to be 5253.4 $J\,mol^{-1}$ and $28.894\,JK^{-1}mol^{-1}$, respectively.

One of the most interesting features of this crystal that has come to light in the present thermal study is the large amount of transition entropy. The detailed discussions will be given in the next section where the entropy will be related to the mechanism of phase transition.

Infrared Absorption Spectra. The infrared absorption spectra of this substance were obtained by a Grating-type Infrared Spectrophotometer Model DS-402G (Japan Spectroscopic Co., Ltd.) in the range between 4000 and 400 cm^{-1} and by a Spectrophotometer No. FIS-001 (Hitachi Ltd.) in the range from 500 to 80 cm^{-1} at the temperatures of 295 and 120 K, respectively. For the sake of comparison the infrared spectra of ferrocene were also recorded on the same spectrophotometers. The nujol mull method was employed for the preparation of the samples.

In Figs. 3 and 4 the far-infrared spectra of $Co_3(C_5H_5)_3S_2$ and $Fe(C_5H_5)_2$ crystals are shown respectively in the range from 500 to 80 cm^{-1}. In both crystals many new absorption peaks were observed below each phase transition point.

Proton Magnetic Resonance. The proton magnetic resonance absorption spectra of the present substance

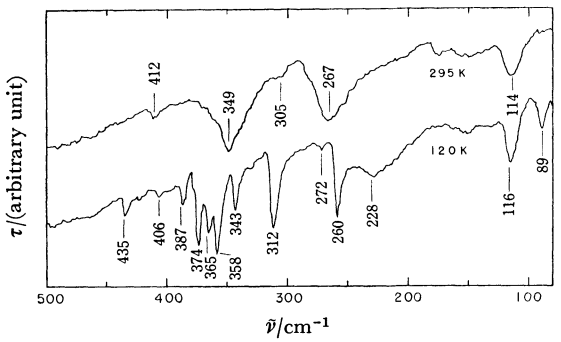

Fig. 3. The far-infrared spectra of $Co_3(C_5H_5)_3S_2$ in the region from 500 to 80 cm^{-1} at the temperatures of 295 and 120 K, respectively.

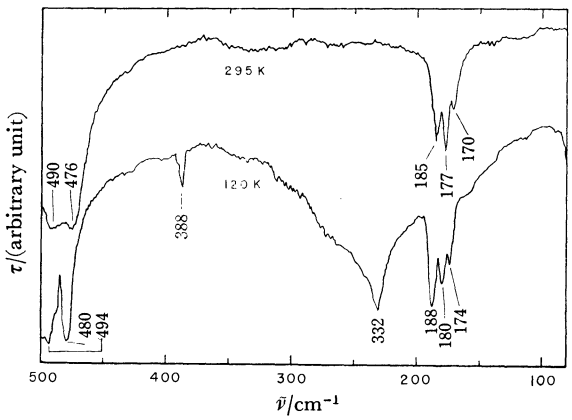

Fig. 4. The far-infrared spectra of $Fe(C_5H_5)_2$ in the region from 500 to 80 cm^{-1} at the temperatures of 295 and 120 K, respectively.

were obtained at a frequency of 21.4 MHz with a broad-line NMR Spectrometer Type BL-1 No. 2004 (Japan Electron Optics Laboratory Co., Ltd.) at 77 K and at room temperature.

The absorption peaks were symmetrical on both sides of the first derivative line. The line width changed from 3.1 gauss at 77 K to 2.6 gauss at room temperature. The second moments of the absorption curves obtained graphically were independent of temperature within the experimental errors between 77 K and room temperature. The average value of the second moment was 0.17 $gauss^2$. This value is not so accurate because the field modulasion amplitude employed here was rather large. It is, however, conceivable that the motional narrowing takes place already at a temperature as low as 77 K.

Phenomenological Nature of Phase Transition

The phase transition discovered at 192.5 K is obviously associated with some magnetic interactions, as revealed from the magnetic susceptibility measurement.[4] As was mentioned briefly in the preceding section, the entropy of transition has a large value of $28.894\,J\,K^{-1}mol^{-1}$ and cannot be explained solely by the magnetic contribution based on the thermal excitation of electrons in a molecule from a ground singlet state to an excited triplet state. In this energy scheme the magnetic entropy required for thorough excitation of electrons will be at most $R\ln 4$ ($=11.526\,J\,K^{-1}mol^{-1}$).

On the other hand, some insights into the nature of phase transition may be gained from a closer examination of the molecular and the crystal structures of the present substance. According to the results of X-ray diffraction analysis[4] the crystal belongs to the hexagonal system at room temperature. Its unit cell contains two chemical units and the space group is found to be $P6_3/m$ or $P6_3$. It is also indicated that the cyclopentadienyl ring is accurately coplanar. While there is no constraint imposed by crystal symmetry, the molecule itself has a point group symmetry of D_{3h}. This site symmetry may be accounted for by either a free rotation of or by a twofold orientational disorder

of each cyclopentadienyl ring.

It is, however, possible to exclude the case of free rotation in the present crystal as compared with the case of ferrocene crystal. In a gas phase a ferrocene molecule belongs to a symmetry of $D_{\infty h}$ indicating that no appreciable barrier to free or only slightly hindered rotation of the cyclopentadienyl rings exists.[7] According to Dunitz, Orgel, and Rich,[8] however, the D_{5d} configuration of ferrocene found in the solid state must arise from intermolecular interactions, where the repulsive interaction between hydrogen atoms belonging to adjacent molecules plays a dominant role. Edwards, Kington, and Mason[9] measured the heat capacity of ferrocene crystal, which is diamagnetic, and found a phase transition at 163.9 K with a secondary small C_p maximum at 169 K. On the assumption that each cyclopentadienyl ring can take up two orientations in the room temperature phase, one of which may be obtained by a rotation through 36° in the plane of the ring, they successfully accounted for the observed transition entropy of $R\ln 1.89$ as the twofold orientational disorder.

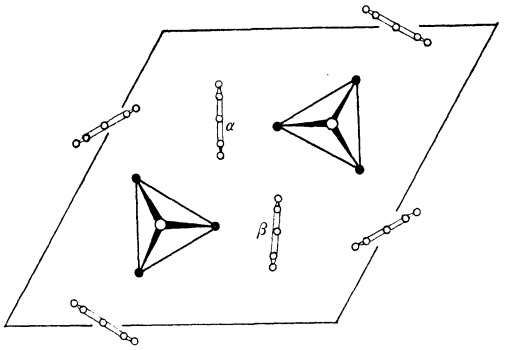

Fig. 5. A projection on the (001) plane of the crystal structure of $Co_3(C_5H_5)_3S_2$ (after Ref. 4).

Similar arguments may be applied to the present crystal, because the packing[4] of cyclopentadienyl rings belonging to different molecules, which are indicated for example as α and β in Fig. 5, has a close resemblance to that of ferrocene crystal along with the *c*-axis. As is the case of ferrocene we assumed that each cyclopentadienyl ring of $Co_3(C_5H_5)_3S_2$ can take up two orientations in the room temperature phase. But the difference from ferrocene is that the present compound has three cyclopentadienyl rings per one molecule. We further assumed that the interactions among three rings belonging to the same molecule would be negligible as each ring is separated far from the other two by a large core of cobalt and sulfur atoms. On these assumptions the number of energetically equivalent configurations attainable for one molecule may be eight ($=2^3$) and the configurational entropy due to the order-disorder phenomenon of the cyclopentadienyl rings amounts to $R\ln 8$. The observed transition entropy of 28.894 $JK^{-1}mol^{-1}$ is satisfactorily explained by the sum of this configurational entropy of $R\ln 8$ and the magnetic contribution of $R\ln 4$, which gives the value of 28.815 $JK^{-1}mol^{-1}$.

Strong evidences for the assumption that the ordering processes of cyclopentadienyl rings may be concerned in the phase transition can be obtained from the measurements of proton magnetic resonance and infrared spectra of this crystal as a function of temperature. As was mentioned in the previous section, the proton magnetic resonance of the present compound showed the motional narrowing already at a temperature as low as 77 K. And this fact is favorably compared with the case of ferrocene crystal[10] where the motional narrowing also takes place at 77 K and the activation energy for the reorientation is found to be as low as 2.3 kcal mol^{-1}. On the other hand, many new absorption peaks were observed in the infrared spectra of both the present substance and ferrocene below each phase transition point (see Figs. 3 and 4). Although we have not yet completed the assignments to these new peaks, it is likely that they are arising from fundamental and/or lattice bands due to some ordering processes of cyclopentadienyl rings below each phase transition point.

Modified Exciton Theory

In order to make more quantitative arguments about the mechanism of phase transition the phenomenological theory by Chesnut[5] based on the exciton model will be applied directly to the present system in the first half of this section, and in the latter half we will modify this exciton model to achieve the closest agreement between theory and experiment.

According to Chesnut[5] we imagine a system of N molecules, n of which are excited to a triplet state of energy $\varepsilon_0>0$. The mobile excited states will be referred to hereafter as "particles" and the system will be described as one with a particle (exciton) density $\rho=n/N$. The particle entropy of the system may be written as

$$\sigma/Nk = \rho\ln 3 - \rho\ln\rho - (1-\rho)\ln(1-\rho), \qquad (1)$$

and for the Helmholtz energy of the system Chesnut proposed the form as

$$A/N = \varepsilon_0\rho + \frac{1}{2}\varepsilon_1\rho^2 - kT[\rho\ln 3 - \rho\ln\rho - (1-\rho)\ln(1-\rho)], \qquad (2)$$

where $\varepsilon_0\rho$ represents the sum of the single-particle energies and the additional term quadratic in ρ may be attributable to an effective particle-particle interaction. The equilibrium value of ρ, which is obtained by minimizing A with respect to ρ, satisfies the following condition,

$$\rho = \left[\frac{1}{3}\exp(\varepsilon_0+\varepsilon_1\rho)/kT+1\right]^{-1}. \qquad (3)$$

The solution(s) of Eq. (3) must subject to another minimum condition,

$$\frac{1}{N}\frac{\partial^2 A}{\partial\rho^2} = \varepsilon_1 + \frac{kT}{\rho(1-\rho)} > 0. \qquad (4)$$

On the other hand, the triplet excitation density ρ may be determined from the succeptibility measurement by using the following relation,

$$\chi = \frac{2Ng^2\mu_B^2}{3kT}\left[\frac{1}{3}\exp(\Delta E_{eff}/kT)+1\right]^{-1} \quad (5)$$

and

$$\rho = \left[\frac{1}{3}\exp(\Delta E_{eff}/kT)+1\right]^{-1}, \quad (6)$$

where ΔE_{eff} is the effective energy gap between the singlet and the triplet state, g the elctron g-factor and μ_B the Bohr magneton. The temperature dependence of ΔE_{eff} is obtainable from Eqs. (3) and (6);

$$\Delta E_{eff} = \varepsilon_0 + \varepsilon_1\rho. \quad (7)$$

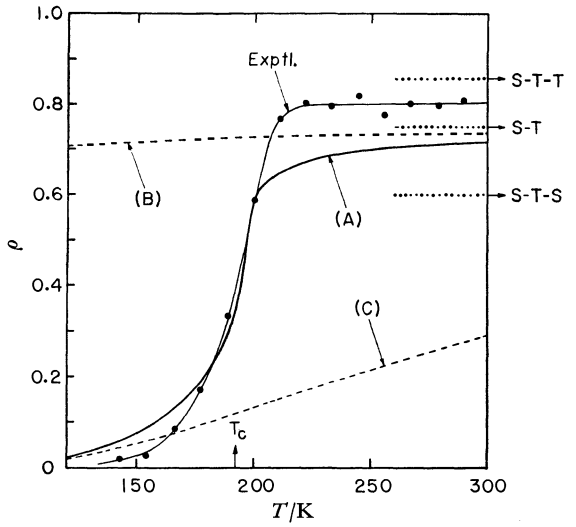

Fig. 6. Observed (curve drawn through black dots) and calculated values of the exciton density *versus* temperature for $Co_3(C_5H_5)_3S_2$. The values of energy parameters ε_1 and ε_0 used for the curves (A), (B), and (C) are indicated in the text.

The exciton density calculated from the succeptibility[4] of the present crystal is compared in Fig. 6 with the theoretical ones derived from Eq. (3). Curve (A) in this figure is corresponding to the best fit, the parameters of which were determined by trials and errors to be ε_0=0.05140eV and ε_1=−0.06559eV. Curves (B) and (C) are the ones in which the attractive interaction between particles is neglected; *i.e.*, ε_0=0.05140eV and ε_1=0 for curve (B) and ε_0=0.00221eV and ε_1=0 for curve (C). These two curves do not account for the experimental one at all. Three horizontal dotted lines indicated at the right-hand-side in Fig. 6 with the symbols *S*-*T*, *S*-*T*-*T* and *S*-*T*-*S* are respectively the limiting values of ρ in the case of $kT\to\infty$, where *S* means a singlet state, *T* a triplet state and a sequence of energy states are indicated as ground state - first excited state - second excited state.

In Fig. 7 the entropy of phase transition is compared with this model. The magnetic contribution estimated from Eq. (1) and the curve (A) in Fig. 6 exceeds the experimental entropy below about 165 K and hence the configurational entropy becomes negative below this temperature. We cannot accept such a feature from a physical reality.

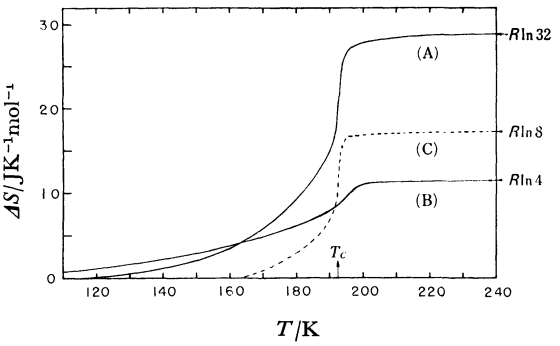

Fig. 7. The entropy of phase transition *versus* temperature for $Co_3(C_5H_5)_3S_2$. Curve (A) is the experimental value obtained from the heat capacity measurement. Curve (B) is the magnetic contribution calculated from Eq. (1) and the curve (A) in Fig. 6. Curve (C) is the configurational entropy determined by subtracting the value of curve (B) from that of curve (A) at respective temperature.

Apart from the details, however, this model is able to describe the gross aspects of the observed magnetic behavior. Then we attempt to modify this exciton model so that the closest agreement may be obtainable. As to the Chesnut model the energy parameters ε_1 and ε_0 are assumed to be independent of temperature. But this is not the case because a real system will be affected by thermal expansion. Moreover, the exciton density ρ determined from the experiment exceeds above near 208 K the limiting value of 0.75 based on the energy scheme of a ground singlet state followed by an excited triplet state (see Fig. 6). This feature may be interpreted either by considering a system with additional multi-degenerate state(s) above the first excited state such as *S*-*T*-*T* or by inverting the degeneracy of a ground and an excited state above 208 K. The latter model based on the inversion in the spin state seems to be more favorable to the present system as will be mentioned in the next section.

We modify the Chesnut exciton theory so as to take account of both a temperature dependence of the energy parameters and the inversion in the spin state above 208 K. In this model one of the energy parameters is eliminated by the condition: When ρ=3/4, $\Delta E_{eff}=\varepsilon_0(T)+\rho\varepsilon_1(T)=0$, then

$$\left.\begin{aligned}\varepsilon_0(T) &= -3\varepsilon_1(T)/4\\ \text{and}\qquad \Delta E_{eff} &= \varepsilon_1(T)\left(\rho-\frac{3}{4}\right).\end{aligned}\right\} \quad (8)$$

The temperature dependences of ε_1 and ε_0 were obtained by fitting Eqs. (3) and (8) to the experimental values of ρ. The results are shown in Fig. 8. Appreciable but different temperature dependences were found below and above the transition point. The following linear dependences were assumed:

$$\varepsilon_1/k = \begin{cases}184.0 - 6.471T & (T > T_c),\\ -1626 + 4.4T & (T < T_c).\end{cases} \quad (9)$$

On this assumption the temperature dependence of the exciton density except for the vicinity of the transition point is satisfactorily accounted for (see Fig. 9). As is shown in Fig. 10, the transition entropy obtained from

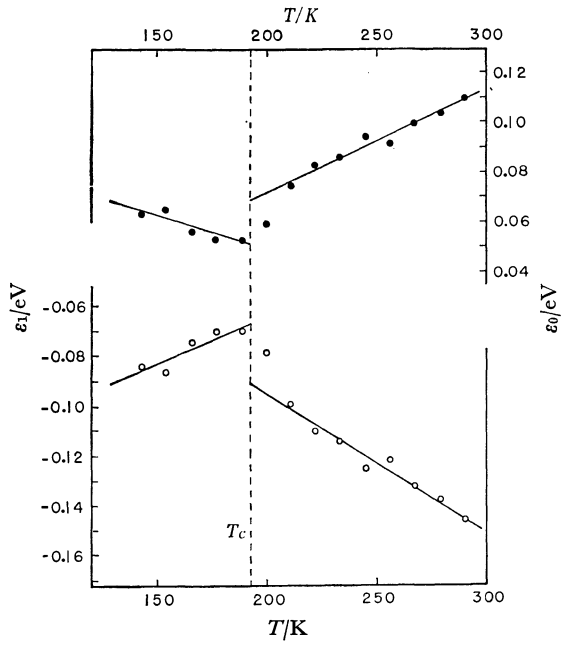

Fig. 8. The temperature dependences of the energy parameters ε_1 and ε_0 for $Co_3(C_5H_5)_3S_2$. Open and solid circles are the observed values. The straight lines are formulated in Eq. (9).

our heat capacity measurement is also well explained in the whole temperature region as the sum of the magnetic contribution derived from the present model and the configurational entropy due to the cyclopentadienyl rings. The effective energy gap ΔE_{eff} between a singlet and a triplet state is shown in Fig. 11 as a function of temperature. As can be seen from this figure, consideration of temperature dependence of the energy parameters well accounts for the actual behavior.

We have so far regarded the dominant origin of the temperature dependence of ε_1 and ε_0 as existing thermal expansion of real crystal but a remarkable difference in temperature dependence between both sides of the transition point will be a further problem.

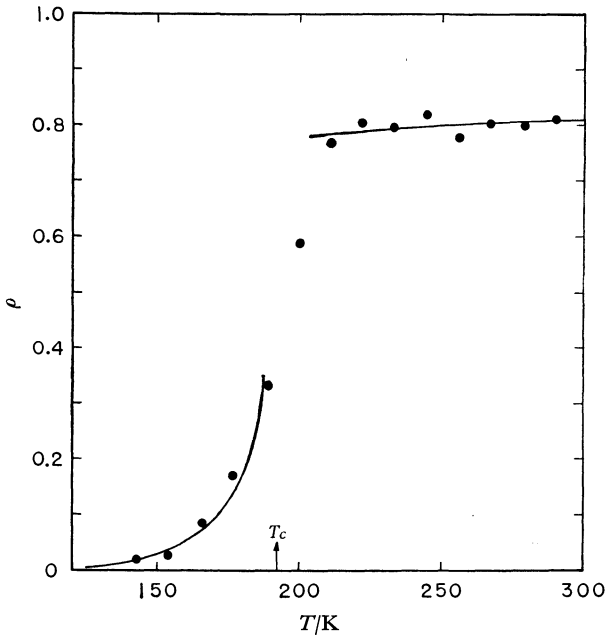

Fig. 9. Comparison of the exciton density between the observed (solid circle) and the calculated values (solid lines) based on the present model.

Mechanism of Phase Transition

In this section we will present a physical picture for the temperature dependence of ΔE_{eff} and also for the inversion of spin state. In doing this, it is convenient to make arguments based on the electronic configuration of the present cluster molecule[4] and that of the nickel congener,[11] $Ni_3(C_5H_5)_3S_2$, derived from a simple molecular orbital scheme.

As we are interested in a relation between the electronic state and the spin state, our discussion will be

11) H. Vahrenkamp, V. A. Uchtman, and L. F. Dahl, *J. Amer. Chem. Soc.*, **90**, 3272 (1968).

confined to four truncated anti-bonding orbitals involved in the 3*d* orbitals of the cobalt atoms. According to Otsuka *et al.*,[4] the d_{z^2} orbitals of three cobalt atoms combine to give doubly degenerate anti-bonding orbitals $e'^*(d_{z^2})$, $(2\phi_1-\phi_2-\phi_3)/\sqrt{6}$ and $(\phi_2-\phi_3)/\sqrt{2}$. Here, ϕ_i is the d_{z^2} orbital of the *i*th cobalt atom and the coordinate axes at each cobalt atom are so chosen that the *z*-axis points to the centroid of the equilateral cobalt triangle, the *x*-axis lies in the triangle plane and the *y*-axis completes right-handed coordinate system. Similarly the $d_{x^2-y^2}$ orbitals give rise to two anti-bonding orbitals $e'^*(d_{x^2-y^2})$. The d_{xy} and the d_{zx} orbitals bring about non-degenerate anti-bonding orbital $a_1''^*(d_{xy})$ and $a_2'^*(d_{zx})$, respectively. Of all the valence electrons only eight electrons are accomodated in these anti-bonding orbitals. While it is not possible to settle the relative energy levels among these orbitals beyond the point of speculation, Otsuka *et al.* suggested that the configuration in the ground state will be $e'^*(d_{x^2-y^2})^4$, $e'^*(d_{z^2})^4$ leaving $a_1''^*(d_{xy})^0$ and $a_2'^*(d_{zx})^0$ vacant. Here, the superscript indicates the number of electrons accomodated in each anti-bonding orbital. Although their qualitative approach does not tell which orbital comes higher among the e'^* orbitals or among $a_1''^*$ and $a_2'^*$ orbitals, this energy scheme does not conflict with the gross aspect of magnetic behavior and with the bonding scheme[11] in the nickel congener.

It should be noticed here that the phase transition in the present crystal is satisfactorily accounted for by the sum of both configurational and magnetic contribution, the cooperative effect obviously arises from the gear-motion of cyclopentadienyl rings in the lattice. As was pointed out by Chesnut,[5] no cooperative phase transition may result in such a magnetic system as the present crystal where a discontinuity is not observed in the magnetic susceptibility curve. It is, however, possible to suppose that a cooperative coupling is still present between rotational motion of the cyclopentadienyl rings and the electronic state of a molecule. The existence of such a cooperative coupling is secured by the fact that the magnetic behavior can only be explained by varying the energy gap ΔE_{eff} with temperature and by introducing the inversion of spin state at higher temperatures.

We propose the following energy schemes as is shown in Fig. 12: (1) The energy levels of the $e'^*(d_{x^2-y^2})$ and the $a_1''^*(d_{xy})$ orbitals will not depend on temperature as the orbital overlap between these and the π-orbitals of each cyclopentadienyl ring is negligible. (2) The $e'^*(d_{z^2})$ level is also nearly independent of temperature. Although the small overlap exists, the reorientational motion of the ring will scarcely affect the energy state of this orbital because the overlapping is nearly symmetrical around each *z*-axis. (3) The $a_2'^*(d_{zx})$ will be sensitive to the motional behavior of the ring. Frequent reorientation of the ring would lead to almost complete smearing of the electron density around the circle formed by the rotating group. Hence the energy of this orbital will decrease with increasing reorientational motion of the ring. (4) The level-crossing is assumed to take place between the $a_2'^*(d_{zx})$ and the $e'^*(d_{z^2})$ at a certain temperature T^* and thus the inversion of spin state occures above T^*. In the present crystal the value of T^* is 208 K which is slightly higher than the phase transition point. Favorable evidence for the inversion of spin state is also obtained from the preliminary experiment of electron paramagnetic resonance by Kuwata,[12] who measured the absorption intensity and the line width as a function of temperature. (5) The physical meaning of ΔE_{eff} differs

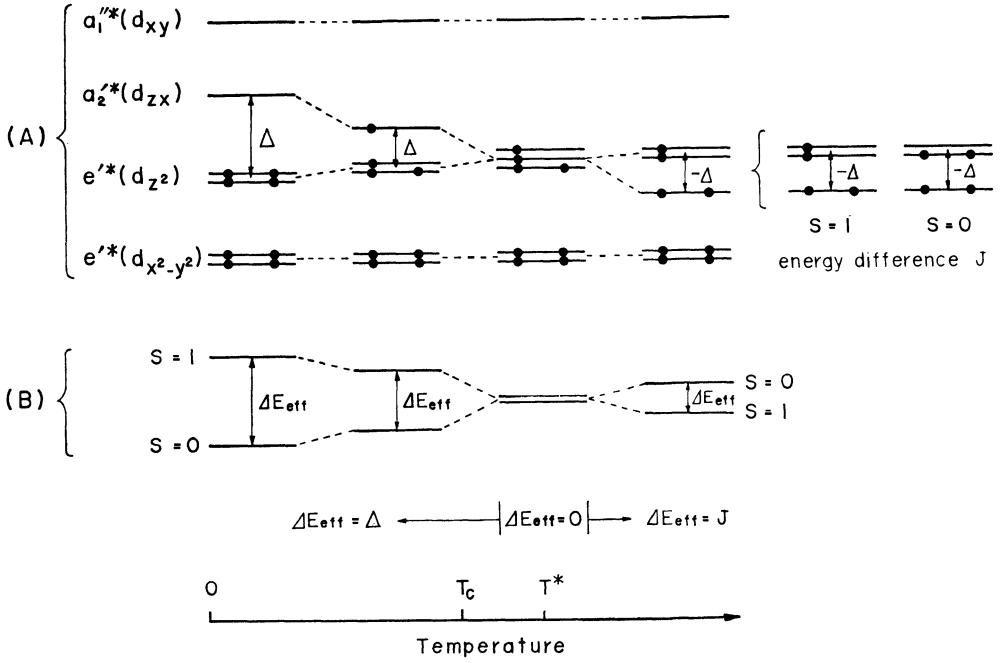

Fig. 12. Temperature dependence of (A) the electronic and (B) the spin states for $Co_3(C_5H_5)_3S_2$. The meanings of the molecular orbital symbols corresponding to each irreducible representations are indicated in the text.

12) K. Kuwata: private communicatoin (to be published).

from each other below and above T^*. ΔE_{eff} is equivalent to the level-spacing between the ground and the excited electronic states below T^*. Above T^*, on the other hand, ΔE_{eff} corresponds to the intra-J based on Hund's rule. The intra-J is in general almost independent of temperature. This fact really coincides with the present result as is shown in Fig. 11.

Conclusion

In the preceding sections of this paper we have shown the possibility of explaining the observed phase transition phenomenon of $Co_3(C_5H_5)_3S_2$ crystal based on the cooperative coupling between reorientational motion of the cyclopentadienyl rings in the lattice and the electronic state of a molecule. Magnetic behavior can be well described by introducing both the temperature dependences of the energy paramaters (ε_1 and ε_0) and the inversion of spin state at higher temperatures to the excition model derived by Chesnut.

Although the present model does not conflict with the existing experimental results, a possible model including the effects of higher excited states is still remaining. More rigorous calculation of molecular orbitals is necessary to gain more quantitative insight into the electronic state of the present crystal.

Heat capacity measurement of the nickel congener $Ni_3(C_5H_5)_3S_2$, will provide a useful information to judge the validity of the present arguments. Molecular and crystal structures of this compound are isomorphous with the present substance. This molecule, however, contains three more electrons compared with $Co_3(C_5H_5)_3S_2$ to give one unpaired electron in the ground electronic state.[11] So far as the energy scheme shown in Fig. 12 is adopted, anomalous magnetic behavior will not be expected for the nickel compound except for weak intercluster interactions. Even if a phase transition be observed in the nickel compound, such a phase transition would result solely from a configurational effect of cyclopentadienyl rings and the transition entropy would amount to only $R\ln 8$.

The authors would like to express their sincere thanks to Dr. Keiji Kuwata for informing the results of his ESR studies prior to publication and for his valuable discussions. Thanks are also extended to Mr. Shinichi Ishikawa for taking the infrared spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2371—2378(1971)

A General Matrix Method for Treating Elastic Constants of Molecular Crystals; Application to Orthorhombic Polyethylene

Yuji SHIRO and Tatsuo MIYAZAWA*

Faculty of Education, Hiroshima University, Shinonome, Hiroshima

**Institute for Protein Research, Osaka University, Kita-ku, Osaka*

(Received April 21, 1971)

A general method is developed for treating elastic constants of molecular crystals, with the ***B*** matrices as commonly used in normal-coordinate treatments. Equations are written in matrix forms, convenient for calculating elastic constants from intramolecular and intermolecular force field and are readily programed for electronic computations. Partial derivatives of elastic constants with respect to force constants are also derived, for least-square adjustments of force fields with reference to experimental elastic constants as well as vibrational frequencies. Matrix treatments of elastic constants are much simplified by the use of crystal symmetry, just as are treatments of normal vibrations. The matrix methods are explained for the example of orthorhombic polyethylene.

Normal coordinate treatments of molecular vibrations are useful for vibrational assignments of infrared and Raman spectra of polyatomic molecules. The ***GF*** matrix method derived by Wilson[1] is commonly used in treating molecular vibrations. Inverse-kinetic energy matrices (***G***) are constructed from ***B*** matrices, transformation matrices from Cartesian coordinates to intramolecular coordinates including bond-stretching, angle-bending[2] and internal-rotation coordinates.[3]

B matrices are also useful for treating normal vibrations of molecular crystals, where intermolecular coordinates are used together with intramolecular coordinates. In a previous paper,[4] applications of the ***GF*** matrix method were explained for factor-group vibrations of crystal lattices. Intermolecular and intramolecular force constants may be adjusted with reference to infrared and Raman frequencies observed for molecular crystals. However, too often, a unique set of force constants can not be obtained, because the number of observed frequencies is smaller than the number of force constants. In these cases, it is a common practice to assume certain type of potential functions.[2] Never-

theless, it is desirable to refer to additional experimental data that depend on force constants of crystals. For many inorganic crystals and some organic molecular crystals,[5] elastic constants have been measured and serve as useful data for studying force fields of crystals.

A general relation between force constants and elastic constants was discussed by Born and Huang.[6] However, in practical numerical treatments of elastic constants of molecular crystals together with their vibrational frequencies, it is important to formulate the transformation from the potential energy matrix ($\boldsymbol{F}$) to the elastic constant matrix ($\boldsymbol{C}$). This transformation may be derived with the $\boldsymbol{B}$ matrices as used in normal-coordinate treatments. Accordingly, in the present study, a general matrix method was developed for treating elastic constants from force fields of molecular crystals. Furthermore, partial derivatives of elastic constants with respect to force constants were derived and were formulated in matrix equations.

Energy Density due to Homogeneous Deformation

The potential energy (V) of a crystal lattice may be expressed in terms of an appropriate internal-coordinate vector ($\boldsymbol{R}$),

$$V = \frac{1}{2}\tilde{\boldsymbol{R}}\boldsymbol{F}_{\mathrm{R}}\boldsymbol{R} \tag{1}$$

where a tilde denotes transposed matrix or vector and $\boldsymbol{F}_{\mathrm{R}}$ is the potential energy matrix associated with the $\boldsymbol{R}$ vector.[1] For a crystal of N unit cells, the energy density (ε) is given as,

$$\varepsilon = \frac{1}{2}\tilde{\boldsymbol{R}}\boldsymbol{F}_{\mathrm{R}}\boldsymbol{R}/Nv \tag{2}$$

where v is the volume per unit cell.

A unit cell of a crystal lattice may be denoted with an index vector $\boldsymbol{L}$ with integral components (h,k,l), so that the internal-coordinate vector ($\boldsymbol{R}$) is expressed as

$$\boldsymbol{R} = \begin{bmatrix} \vdots \\ \boldsymbol{R}(\boldsymbol{L}) \\ \vdots \end{bmatrix} \tag{3}$$

where $\boldsymbol{R}(\boldsymbol{L})$ is the internal-coordinate subvector for the unit cell $\boldsymbol{L}$. If such a crystal is subjected to a homogeneous deformation, the resulting structure remains a perfect lattice and $\boldsymbol{R}(\boldsymbol{L})$ is actually independent of $\boldsymbol{L}$. Accordingly, the internal-coordinate vector ($\boldsymbol{R}$) may be transformed into the internal symmetry-coordinate vector ($\boldsymbol{R}^0$),

$$\boldsymbol{R}^0 = N^{-1}\sum_{\boldsymbol{L}}\boldsymbol{R}(\boldsymbol{L}) \tag{4}$$

The $\boldsymbol{R}^0$ coordinates are symmetric with respect to translational symmetry operations. A corresponding transformation need be carried out on the potential energy matrix ($\boldsymbol{F}_{\mathrm{R}}$), yielding

$$\boldsymbol{F}_{\mathrm{R}}{}^0 = \sum_{\boldsymbol{\lambda}}\boldsymbol{F}_{\mathrm{R}}(\boldsymbol{\lambda}) \tag{5}$$

where $\boldsymbol{F}_{\mathrm{R}}(\boldsymbol{\lambda})$ is the potential-energy submatrix, associated with the $\boldsymbol{R}(\boldsymbol{L})$ vector and the $\boldsymbol{R}(\boldsymbol{L}+\boldsymbol{\lambda})$ vector. Equation (2) is written as

$$\varepsilon = \frac{1}{2}\sum_{\boldsymbol{L}}\tilde{\boldsymbol{R}}^0\sum_{\boldsymbol{\lambda}}\boldsymbol{F}_{\mathrm{R}}(\boldsymbol{\lambda})\boldsymbol{R}^0/Nv = \frac{1}{2}[\tilde{\boldsymbol{R}}^0\boldsymbol{F}_{\mathrm{R}}{}^0\boldsymbol{R}^0]/v \tag{6}$$

and the energy density is now expressed with a finite number of internal symmetry-coordinates ($\boldsymbol{R}^0$). The $\boldsymbol{F}_{\mathrm{R}}{}^0$ matrix may also be used for treating infrared and Raman-active normal vibrations of molecular crystals.

Elastic Strain

In a homogeneous deformation of a crystal lattice, the displacement of the mth atom in the cell ($\boldsymbol{L}$) is given[7] as

$$\xi_\alpha(\boldsymbol{L}, m) = \sum_\beta U_{\alpha\beta}X_\beta(\boldsymbol{L}, m) + \rho_\alpha(m) \qquad (\alpha, \beta = x, y, \text{or } z) \tag{7}$$

where $U_{\alpha\beta}$ is external deformation parameter, $\boldsymbol{X}(\boldsymbol{L},m)$ is the position vector (column) of the mth atom of the cell ($\boldsymbol{L}$). The first term of the right side of Eq. (7) is due to the external deformation that is uniform throughout the crystal (even within a unit cell). The second term, $\boldsymbol{\rho}(m)$, is the internal strain vector of the mth atom that is common to every unit cell.

Now, for a crystal containing n atoms per unit cell, Eq. (7) may be reduced into a matrix form,

$$\tilde{\boldsymbol{\xi}}(\boldsymbol{L}) = \boldsymbol{P}(\boldsymbol{L})\boldsymbol{U} + \boldsymbol{\rho} \tag{8}$$

where

$$\tilde{\boldsymbol{\xi}}(\boldsymbol{L}) = [\xi_{\mathrm{x}}(\boldsymbol{L}, 1)\ \xi_{\mathrm{x}}(\boldsymbol{L}, 2)\ \cdots\ \xi_{\mathrm{x}}(\boldsymbol{L}, n)\ \xi_{\mathrm{y}}(\boldsymbol{L}, 1)\ \xi_{\mathrm{y}}(\boldsymbol{L}, 2)\ \cdots\ \xi_{\mathrm{y}}(\boldsymbol{L}, n)\ \xi_{\mathrm{z}}(\boldsymbol{L}, 1)\ \xi_{\mathrm{z}}(\boldsymbol{L}, 2)\ \cdots\ \xi_{\mathrm{z}}(\boldsymbol{L}, n)] \tag{9}$$

$$\tilde{\boldsymbol{P}}(\boldsymbol{L}) = \begin{bmatrix} \boldsymbol{X}(\boldsymbol{L}, 1) & \boldsymbol{X}(\boldsymbol{L}, 2) & \cdots & \boldsymbol{X}(\boldsymbol{L}, n) & 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & \boldsymbol{X}(\boldsymbol{L}, 1) & \boldsymbol{X}(\boldsymbol{L}, 2) & \cdots & \boldsymbol{X}(\boldsymbol{L}, n) & 0 & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & 0 & \boldsymbol{X}(\boldsymbol{L}, 1) & \boldsymbol{X}(\boldsymbol{L}, 2) & \cdots & \boldsymbol{X}(\boldsymbol{L}, n) \end{bmatrix} \tag{10}$$

$$\tilde{\boldsymbol{U}} = [U_{\mathrm{xx}}\ U_{\mathrm{xy}}\ U_{\mathrm{xz}}\ U_{\mathrm{yx}}\ U_{\mathrm{yy}}\ U_{\mathrm{yz}}\ U_{\mathrm{zx}}\ U_{\mathrm{zy}}\ U_{\mathrm{zz}}] \tag{11}$$

$$\tilde{\boldsymbol{\rho}} = [\rho_{\mathrm{x}}(1)\ \rho_{\mathrm{x}}(2)\ \cdots\ \rho_{\mathrm{x}}(n)\ \rho_{\mathrm{y}}(1)\ \rho_{\mathrm{y}}(2)\ \cdots\ \rho_{\mathrm{y}}(n)\ \rho_{\mathrm{z}}(1)\ \rho_{\mathrm{z}}(2)\ \cdots\ \rho_{\mathrm{z}}(n)] \tag{12}$$

From the displacement vector ($\boldsymbol{\xi}$), the internal coordinate vector ($\boldsymbol{R}$) may be written as shown below, with the transformation matrix ($\boldsymbol{B}$)[1].

$$\boldsymbol{R} = \boldsymbol{B}\boldsymbol{\xi} \tag{13}$$

For a crystal under a homogeneous deformation, unit cells are all equivalent with one another and accordingly, the internal coordinate vector $\boldsymbol{R}(\boldsymbol{L})$ of the cell ($\boldsymbol{L}$) is given as

$$\boldsymbol{R}(\boldsymbol{L}) = \sum_{\boldsymbol{\lambda}}\boldsymbol{B}(\boldsymbol{\lambda})\boldsymbol{\xi}(\boldsymbol{L}+\boldsymbol{\lambda}) \tag{14}$$

5) K. H. Hellwedge, in Landolt-Boernstein Phys. Chem. Tables, new series, Group III-Vol. 1, Springer-Verlag, Berlin (1966), p. 1—39.

6) M. Born and K. Huang, "Dynamical Theory of Crystal Lattices," Oxford University Press, London (1954), Chapter III.

7) A. E. H. Love, "Mathematical Theory of Elasticity," Cambridge University Press, Cambridge (1934).

where $\boldsymbol{\lambda}$ is a difference-index vector and the $\boldsymbol{B}(\boldsymbol{\lambda})$ submatrix is independent of $\boldsymbol{L}$. On substituting Eq. (8) into Eq. (14), the $\boldsymbol{R}^0$ vector is now written as a sum of the terms due to external deformation ($\boldsymbol{U}$) and internal strain vector ($\boldsymbol{\rho}$),

$$\boldsymbol{R}^0 = \boldsymbol{R}(\boldsymbol{L}) = \boldsymbol{D}_U\boldsymbol{U} + \boldsymbol{B}_\rho\boldsymbol{\rho} \tag{15}$$

$$\boldsymbol{B}_\rho = \sum_{\boldsymbol{\lambda}}\boldsymbol{B}(\boldsymbol{\lambda}) \tag{16}$$

$$\boldsymbol{D}_U = \sum_{\boldsymbol{\lambda}}\boldsymbol{B}(\boldsymbol{\lambda})\boldsymbol{P}(\boldsymbol{L}+\boldsymbol{\lambda}) \tag{17}$$

It may be remarked that, under a homogeneous deformation, the transformation matrix ($\boldsymbol{D}_U$) for deformation parameters, is independent of the choice of cell ($\boldsymbol{L}$). A general method for calculating $\boldsymbol{D}_U$ matrix elements for bond-stretching, angle-bending and torsional coordinates is described in Appendix I.

Internal displacement coordinates, $\rho_\alpha(m)$, of Eq. (15) are not all independent, since the mass-weighted linear combinations, $\sum_m M(m)\rho_\alpha(m)/\sum_m M(m)$, give overall-translation coordinates ($\alpha=x$, y, and z) of the crystal. Accordingly, after an appropriate orthogonal transformation, the columns of the $\boldsymbol{B}_\rho$ matrix associated with these three redundant coordinates may be reduced to zero. In treating elastic constants, these redundant coordinates are deleted and remaining $3n$–3 internal displacements are used. However, the generality of the treatment of elastic constants may well be retained by deleting internal displacement coordinates [$\rho_x(m)$, $\rho_y(m)$, and $\rho_z(m)$] of any single atom (m), in place of the actual "overall-translation" coordinates.

Elastic Constant Matrix

The deformation parameters ($\boldsymbol{U}$) of Eq. (7) actually are not independent of "overall-rotation" modes of the crystal lattice. Accordingly, for deriving the elastic constant matrix ($\boldsymbol{C}$), it is necessary to introduce σ parameters as follows,

$$\begin{aligned}
\sigma_1 &= U_{xx} \quad \sigma_4 = U_{yz} + U_{zy} \quad \sigma_7 = U_{yz} - U_{zy} \\
\sigma_2 &= U_{yy} \quad \sigma_5 = U_{zx} + U_{xz} \quad \sigma_8 = U_{zx} - U_{xz} \\
\sigma_3 &= U_{zz} \quad \sigma_6 = U_{xy} + U_{yx} \quad \sigma_9 = U_{xy} - U_{yx}
\end{aligned} \tag{18}$$

For a homogeneous deformation, σ_1—σ_6 are external strain parameters whereas σ_7—σ_9 are "overall-rotation" parameters for the x, y, and z axes.[7]

The energy density (ε) may be expressed in terms of σ parameters, after the reverse transformation,

$$\boldsymbol{U} = \boldsymbol{T}_\sigma\boldsymbol{\sigma} \tag{19}$$

However, since the energy density (ε) is independent of "overall-rotation" parameters σ_7—σ_9, the last three columns of the transformation matrix ($\boldsymbol{T}_\sigma$) are redundant and accordingly σ_7—σ_9 will be left out of the external strain-parameter vector ($\boldsymbol{\sigma}$),

$$\tilde{\boldsymbol{\sigma}} = [\sigma_1\ \sigma_2\ \sigma_3\ \sigma_4\ \sigma_5\ \sigma_6] \tag{20}$$

$$\boldsymbol{T}_\sigma = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & \frac{1}{2} \\
0 & 0 & 0 & 0 & \frac{1}{2} & 0 \\
0 & 0 & 0 & 0 & 0 & \frac{1}{2} \\
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & \frac{1}{2} & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{1}{2} & 0 \\
0 & 0 & 0 & \frac{1}{2} & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0
\end{pmatrix} \tag{21}$$

On substituting Eq. (19) into Eq. (15), the $\boldsymbol{R}^0$ vector is rewitten as,

$$\boldsymbol{R}^0 = \boldsymbol{D}_\sigma\boldsymbol{\sigma} + \boldsymbol{B}_\rho\boldsymbol{\rho} \tag{22}$$

where

$$\boldsymbol{D}_\sigma = \boldsymbol{D}_U\boldsymbol{T}_\sigma = [\sum_{\boldsymbol{\lambda}}\boldsymbol{B}(\boldsymbol{\lambda})\boldsymbol{P}(\boldsymbol{L}+\boldsymbol{\lambda})]\boldsymbol{T}_\sigma \tag{23}$$

From Eqs. (6) and (22), the energy density(ε) is derived as,

$$\varepsilon = \frac{1}{2}[\tilde{\boldsymbol{\sigma}}\tilde{\boldsymbol{D}}_\sigma + \tilde{\boldsymbol{\rho}}\tilde{\boldsymbol{B}}_\rho]\boldsymbol{F}_R{}^0[\boldsymbol{D}_\sigma\boldsymbol{\sigma} + \boldsymbol{B}_\rho\boldsymbol{\rho}]/v \tag{24}$$

However, the internal strain vector ($\boldsymbol{\rho}$) is related to the external strain parameters (σ),

$$\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\boldsymbol{B}_\rho\boldsymbol{\rho} + \tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\boldsymbol{D}_\sigma\boldsymbol{\sigma} = 0 \tag{25}$$

so that the energy density (ε) is minimized with respect to internal strains ($\boldsymbol{\rho}$). Accordingly, the $\boldsymbol{\rho}$ vector given in Eq. (25) is put into Eq. (22) and the internal symmetry coordinates are now expressed in terms of the external strain parameters,

$$\boldsymbol{R}^0 = \boldsymbol{H}_\sigma\boldsymbol{\sigma} \tag{26}$$

where

$$\boldsymbol{H}_\sigma = \{\boldsymbol{E} - \boldsymbol{B}_\rho[\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\boldsymbol{B}_\rho]^{-1}\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\}\boldsymbol{D}_\sigma \tag{27}$$

The energy density is now derived as

$$\varepsilon = \frac{1}{2}\tilde{\boldsymbol{\sigma}}\tilde{\boldsymbol{H}}_\sigma\boldsymbol{F}_R{}^0\boldsymbol{H}_\sigma\boldsymbol{\sigma}/v = \frac{1}{2}\tilde{\boldsymbol{\sigma}}\boldsymbol{C}\boldsymbol{\sigma} \tag{28}$$

and the elastic constant matrix is thus derived as

$$\boldsymbol{C} = \tilde{\boldsymbol{H}}_\sigma\boldsymbol{F}_R{}^0\boldsymbol{H}_\sigma/v \tag{29}$$

On substituting Eq. (27) into Eq. (29), the elastic constant matrix is also written as,

$$\boldsymbol{C} = \{\tilde{\boldsymbol{D}}_\sigma\boldsymbol{F}_R{}^0\boldsymbol{D}_\sigma - \tilde{\boldsymbol{D}}_\sigma\boldsymbol{F}_R{}^0\boldsymbol{B}_\rho[\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\boldsymbol{B}_\rho]^{-1}\tilde{\boldsymbol{B}}_\rho\boldsymbol{F}_R{}^0\boldsymbol{D}_\sigma\}/v \tag{30}$$

The elastic stress vector ($\boldsymbol{S}_\sigma$) is now given as

$$\boldsymbol{S}_\sigma = \boldsymbol{C}_\sigma \tag{31}$$

and, therefore, when an elastic stress is applied to a crystalline lattice, the internal coordinate vector $\boldsymbol{R}^0$ is derived as

$$\boldsymbol{R}^0 = \boldsymbol{H}_\sigma\boldsymbol{\sigma} = \boldsymbol{H}_\sigma\boldsymbol{C}^{-1}\boldsymbol{S}_\sigma \tag{32}$$

Partial Derivatives of Elastic Constants

The potential energy submatrices, $\boldsymbol{F}_R(\boldsymbol{\lambda})$, have been shown to be useful for calculating elastic constants of molecular crystals. Accordingly, experimental elastic constants as well as vibrational frequencies may be referred to in adjusting force fields or force constants of

crystals. For least-square adjustments,[8] however, it is necessary to formulate partial derivatives of elastic constants with respect to force constants.

The potential-energy matrix ($\boldsymbol{F}_R^0$) may be expressed as a sum of matrices associated with force constants, $K(h)$,

$$\boldsymbol{F}_R^0 = \sum_h \boldsymbol{A}(h)K(h) \tag{33}$$

and accordingly

$$\Delta\boldsymbol{F}_R^0 = \sum_h \boldsymbol{A}(h)\Delta K(h) \tag{34}$$

Then, as proved in Appendix II, the derivatives of elastic constants with respect to force constants are expressed as,

$$\partial C_{ij}/\partial K(h) = [\tilde{\boldsymbol{H}}_\sigma \boldsymbol{A}(h)\boldsymbol{H}_\sigma]_{ij}/v \tag{35}$$

It may be seen that an elastic constant (C_{ij}) is expressed as a linear combination of partial derivatives $\partial C_{ij}/\partial K(h)$. Thus, from Eqs. (29), (33), and (35),

$$\begin{aligned} C_{ij} &= \{\tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R^0 \boldsymbol{H}_\sigma/v\}_{ij} \\ &= \sum_h \{[\tilde{\boldsymbol{H}}_\sigma \boldsymbol{A}(h)\boldsymbol{H}_\sigma]_{ij}/v\}K(h) \\ &= \sum_h \{\partial C_{ij}/\partial K(h)\}K(h) \end{aligned} \tag{36}$$

This equation may be rewritten as

$$\sum_h [\partial C_{ij}/\partial K(h)]K(h)/C_{ij} = 1 \tag{37}$$

so that each term represents the fractional contribution of the hth potential term to the elastic constant (C_{ij}).

The equations for elastic constants, Eqs. (26), (28), (29), (35), (36), and (37), correspond closely with the equations for normal vibrations,[1,9]

$$\boldsymbol{R} = \boldsymbol{L}\boldsymbol{Q} \tag{38}$$

$$\boldsymbol{V} = \frac{1}{2}\tilde{\boldsymbol{Q}}\boldsymbol{\Lambda}\boldsymbol{Q} \tag{39}$$

$$\boldsymbol{\Lambda} = \tilde{\boldsymbol{L}}\boldsymbol{F}\boldsymbol{L} \tag{40}$$

$$\partial\lambda(a)/\partial K(h) = [\tilde{\boldsymbol{L}}\boldsymbol{A}(h)\boldsymbol{L}]_{aa} \tag{41}$$

$$\lambda(a) = \sum_h [\partial\lambda(a)/\partial K(h)]K(h) \tag{42}$$

$$\sum_h [\partial\lambda(a)/\partial K(h)]K(h)/\lambda(a) = 1 \tag{43}$$

where $\boldsymbol{L}$ is the eigenvector matrix, $\boldsymbol{Q}$ is normal-coordinate vector, $\boldsymbol{\Lambda}$ is diagonal frequency-parameter matrix, and $\lambda(a)$ is the ath frequency-parameter (squared angular frequency).

Partial derivatives of elastic constants [Eq. (35)] and frequency parameters [Eq. (41)] may now be used for least-square adjustments[8] of force constants of molecular crystals with reference to experimental elastic constants and vibrational frequencies.

Symmetry Treatments

Treatments of elastic constants may be simplified by the use of factor-group symmetry, just as are treatment of normal vibrations.[1] By an appropriate orthogonal transformation, new symmetry-coordinate vectors are set up,

$$\boldsymbol{R}_s^0 = \boldsymbol{T}_R \boldsymbol{R}^0 \tag{44}$$

$$\boldsymbol{\rho}_s = \boldsymbol{T}_\rho \boldsymbol{\rho} \tag{45}$$

and the potential-energy matrix ($\boldsymbol{F}_R^0$) is transformed accordingly,

$$\boldsymbol{F}_{Rs}^0 = \boldsymbol{T}_R \boldsymbol{F}_R^0 \tilde{\boldsymbol{T}}_R \tag{46}$$

$$\boldsymbol{A}_s(h) = \boldsymbol{T}_R \boldsymbol{A}(h) \tilde{\boldsymbol{T}}_R \tag{47}$$

From Eqs. (22), (44), and (45),

$$\boldsymbol{R}_s^0 = \boldsymbol{D}_{s\sigma}\boldsymbol{\sigma} + \boldsymbol{B}_{s\rho s}\boldsymbol{\rho}_s \tag{48}$$

where

$$\boldsymbol{D}_{s\sigma} = \boldsymbol{T}_R \boldsymbol{D}_\sigma \tag{49}$$

$$\boldsymbol{B}_{s\rho s} = \boldsymbol{T}_R \boldsymbol{B}_\rho \tilde{\boldsymbol{T}}_\rho \tag{50}$$

After defining

$$\begin{aligned} \boldsymbol{H}_{s\sigma} &= \boldsymbol{T}_R \boldsymbol{H}_\sigma \\ &= [\boldsymbol{E} - \boldsymbol{B}_{s\rho s}[\tilde{\boldsymbol{B}}_{s\rho s}\boldsymbol{F}_{Rs}^0 \boldsymbol{B}_{s\rho s}]^{-1}\tilde{\boldsymbol{B}}_{s\rho s}\boldsymbol{F}_{Rs}^0]\boldsymbol{D}_{s\sigma} \end{aligned} \tag{51}$$

the internal symmetry coordinate vector ($\boldsymbol{R}_s^0$) is expressed as,

$$\boldsymbol{R}_s^0 = \boldsymbol{H}_{s\sigma}\boldsymbol{\sigma} \tag{52}$$

$$= \boldsymbol{H}_{s\sigma}\boldsymbol{C}^{-1}\boldsymbol{S}_\sigma \tag{53}$$

and the elastic constant matrix ($\boldsymbol{C}$) is derived as

$$\boldsymbol{C} = \{\tilde{\boldsymbol{H}}_{s\sigma}\boldsymbol{F}_{Rs}^0 \boldsymbol{H}_{s\sigma}\}/v \tag{54}$$

$$\begin{aligned} &= \{\tilde{\boldsymbol{D}}_{s\sigma}\boldsymbol{F}_{Rs}^0 \boldsymbol{D}_{s\sigma} \\ &\quad - \tilde{\boldsymbol{D}}_{s\sigma}\boldsymbol{F}_{Rs}^0 \boldsymbol{B}_{s\rho s}[\tilde{\boldsymbol{B}}_{s\rho s}\boldsymbol{F}_{Rs}^0 \boldsymbol{B}_{s\rho s}]^{-1}\tilde{\boldsymbol{B}}_{s\rho s}\boldsymbol{F}_{Rs}^0 \boldsymbol{D}_{s\sigma}\}/v \end{aligned} \tag{55}$$

Partial derivatives of elastic constants with respect to a force constant are given as,

$$\partial C_{ij}/\partial K(h) = [\tilde{\boldsymbol{H}}_{s\sigma}\boldsymbol{A}_s(h)\boldsymbol{H}_{s\sigma}]_{ij}/v \tag{56}$$

The elastic constants of a symmetry species may be treated by the use only of relevant strain parameters (σ). For the example of orthorhombic crystals with the factor-group D_{2h}, strain parameters σ_1, σ_2, and σ_3 belong to the a_g species, and σ_4, σ_5, and σ_6 belong to the b_{1g}, b_{2g}, and b_{3g} species, respectively. $\boldsymbol{F}_{Rs}^0$, $\boldsymbol{A}_s(h)$ and $\boldsymbol{B}_{s\rho s}$ matrices are commonly used for treating normal vibrations and elastic constants belonging to the same symmetry species.

Finally it may be remarked that, before inverting the matrix of $[\tilde{\boldsymbol{B}}_{s\rho s}\boldsymbol{F}_R^0 \boldsymbol{B}_{s\rho s}]$ in Eqs. (51) and (55), the columns of the $\boldsymbol{B}_{s\rho s}$ matrices associated with "overall-translation" displacements, if any, need be deleted. Fortunately, however, for factor groups having the inversion operation, elastic strains belong to *gerade* species whereas "overall-translation" displacements belong to *ungerade* species. Accordingly, the $\boldsymbol{B}_{s\rho s}$ matrices associated with "overall-translation" displacements are separated, because of the inversion symmetry, from the $\boldsymbol{B}_{s\rho s}$ matrices as used for elastic properties.

Application to Polyethylene Crystal

The crystal structure of the orthorhombic polyethylene (Pnam-D_{2h}^{16}) was analysed by Bunn.[10] Two molecular chains pass through a unit cell along the c axis and there are four methylene groups per unit cell, with the lattice constants of $a_0=7.40$, $b_0=4.93$, and $c_0=2.54$ Å. The position vectors (Å) of four carbon atoms are

10) C. W. Bunn, *Trans. Faraday Soc.*, **35**, 482 (1939).

$$\boldsymbol{X}(1) = \begin{bmatrix} -0.281 \\ -0.320 \\ -0.635 \end{bmatrix} \qquad \boldsymbol{X}(2) = \begin{bmatrix} 0.281 \\ 0.320 \\ 0.635 \end{bmatrix}$$

$$\boldsymbol{X}(3) = \begin{bmatrix} 3.419 \\ 2.785 \\ -0.635 \end{bmatrix} \qquad \boldsymbol{X}(4) = \begin{bmatrix} 3.981 \\ 2.145 \\ 0.635 \end{bmatrix}$$

In the previous study,[11] the frequency distribution and specific heat of the orthorhombic polyethylene crystal were treated with skeletal approximation; methylene groups were regarded as united atoms. The Urey-Bradley field[12] was used as the intramolecular force field, with the bond-stretching terms $[K_r(\Delta r)^2/2]$, angle-bending terms $[K_\phi(\Delta\phi)^2/2]$, repulsion terms $[K_q(\Delta q)^2/2]$ and internal-rotation terms $[K_t(\Delta t)^2/2]$ (see Fig. 1 for intramolecular coordinates). The intermolecular force field was expressed as a sum of three types of stretching terms, $P_1(\Delta p_1)^2/2$, $P_2(\Delta p_2)^2/2$, and $P_3(\Delta p_3)^2/2$, corresponding to intermethylene contacts of p_1=4.12, p_2=4.18, and p_3=4.57 Å, respectively. The intermethylene-stretching coordinates per unit cell are shown in Figs. 1 and 2 and are also listed below,

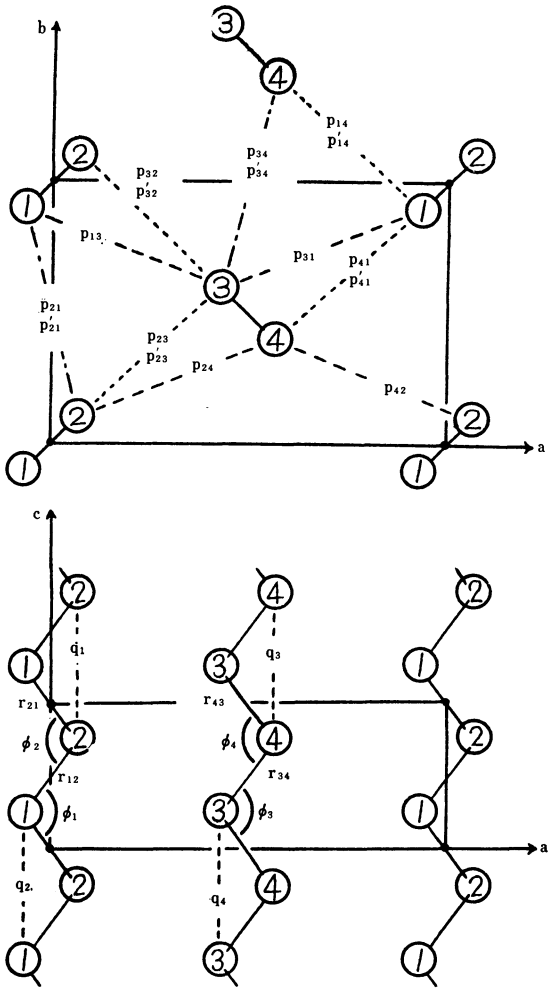

Fig. 1. Internal coordinates (*ab* and *ac* planes).

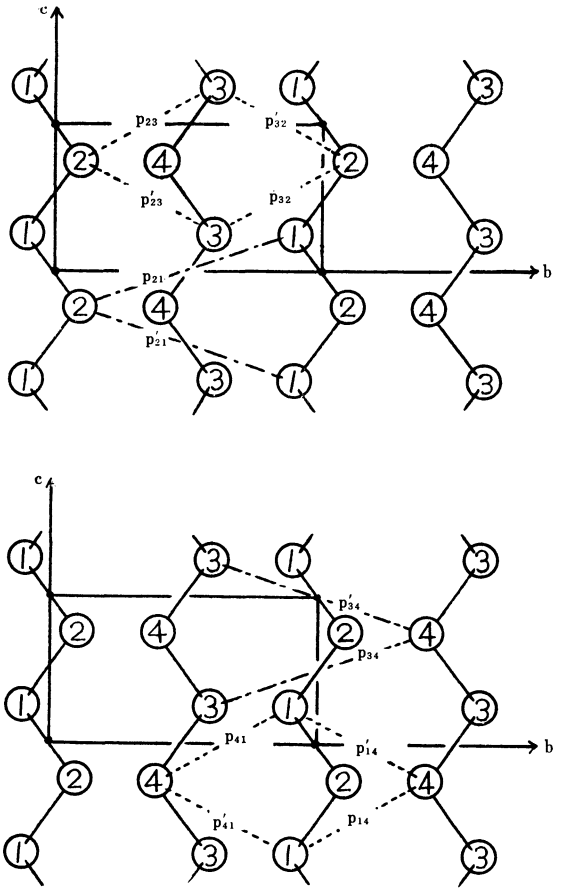

Fig. 2. Internal coordinates (*bc* plane).

Δp_1: Δp_{24}, Δp_{31}, Δp_{42}, and Δp_{13}
Δp_2: Δp_{23}, Δp_{41}, $\Delta p'_{23}$, $\Delta p'_{41}$, Δp_{32}, Δp_{14}, $\Delta p'_{32}$, and $\Delta p'_{14}$
Δp_3: Δp_{21}, $\Delta p'_{21}$, Δp_{34}, and $\Delta p'_{34}$

The intramolecular and intermolecular force constants were adjusted[11] as K_r=4.0 md/Å, K_ϕ=0.59 md Å/rad², K_q=0.35 md/Å, K_t=0.047 md Å/rad², $P_1=P_2$=0.025, and P_3=0.003 md/Å. These force constants were used in the present study of the elastic constants of polyethylene.

The internal coordinate vector ($\boldsymbol{R}$) of the crystal lattice was transformed, with translational operations, into the $\boldsymbol{R}^0$ vector with twenty-eight components,

$$\tilde{\boldsymbol{R}}^0 = [\Delta r_{12}{}^0, \Delta r_{21}{}^0, \Delta r_{43}{}^0, \Delta r_{34}{}^0, \Delta\phi_1{}^0, \Delta\phi_2{}^0, \Delta\phi_3{}^0, \Delta\phi_4{}^0, \Delta q_1{}^0, \Delta q_2{}^0, \Delta q_3{}^0, \Delta q_4{}^0, \Delta p_{24}{}^0, \Delta p_{31}{}^0, \Delta p_{42}{}^0, \Delta p_{13}{}^0, \Delta p_{23}{}^0, \Delta p_{41}{}^0, \Delta p'_{23}{}^0, \Delta p'_{41}{}^0, \Delta p_{32}{}^0, \Delta p_{14}{}^0, \Delta p'_{32}{}^0, \Delta p'_{14}{}^0, \Delta p_{21}{}^0, \Delta p'_{21}{}^0, \Delta p_{34}{}^0, \Delta p'_{34}{}^0]$$

Internal-rotation coordinates (Δt) were deleted because they are antisymmetric with respect to the inversion symmetry and are redundant in treating elastic constants which belong to *gerade* species.

According to the factor-group symmetry of D_{2h}, the $\boldsymbol{R}^0$ vector was then transformed into symmetry-coordinate vectors ($\boldsymbol{R}_s{}^0$) for the symmetry species of elastic constants;

$$\tilde{\boldsymbol{R}}_s{}^0(a_g) = [R_s{}^0(1), R_s{}^0(2), R_s{}^0(3), R_s{}^0(4), R_s{}^0(5), R_s{}^0(6)],$$
$$\tilde{\boldsymbol{R}}_s{}^0(b_{1g}) = [R_s{}^0(7), R_s{}^0(8), R_s{}^0(9)],$$
$$\tilde{\boldsymbol{R}}_s{}^0(b_{2g}) = [R_s{}^0(10), R_s{}^0(11), R_s{}^0(12)],$$
$$\tilde{\boldsymbol{R}}_s{}^0(b_{3g}) = [R_s{}^0(13), R_s{}^0(14), R_s{}^0(15), R_s{}^0(16), R_s{}^0(17)].$$

The potential-energy matrix ($\boldsymbol{F}$) was transformed accordingly as,

$$\boldsymbol{F}_{Rs}{}^0(a_g) = \begin{pmatrix} K_r & 0 & 0 & 0 & 0 & 0 \\ 0 & K_\phi & 0 & 0 & 0 & 0 \\ 0 & 0 & K_q & 0 & 0 & 0 \\ 0 & 0 & 0 & P_1 & 0 & 0 \\ 0 & 0 & 0 & 0 & P_2 & 0 \\ 0 & 0 & 0 & 0 & 0 & P_3 \end{pmatrix} \quad (57)$$

$$\boldsymbol{F}_{Rs}{}^0(b_{1g}) = \boldsymbol{F}_{Rs}{}^0(b_{2g}) = \begin{pmatrix} K_r & 0 & 0 \\ 0 & P_2 & 0 \\ 0 & 0 & P_3 \end{pmatrix} \quad (58)$$

$$\boldsymbol{F}_{Rs}{}^0(b_{3g}) = \begin{pmatrix} K_r & 0 & 0 & 0 & 0 \\ 0 & K_\phi & 0 & 0 & 0 \\ 0 & 0 & P_1 & 0 & 0 \\ 0 & 0 & 0 & P_2 & 0 \\ 0 & 0 & 0 & 0 & P_3 \end{pmatrix} \quad (59)$$

The internal strain vector $\boldsymbol{\rho}$ [Eq. (12)] of carbon atoms was also transformed into internal symmetry-strain vectors ($\boldsymbol{\rho}_s$) for the symmetry species of elastic constants,

$$a_g \text{ species}: \rho_s(1) = [\rho_x(1) - \rho_x(2) + \rho_x(3) - \rho_x(4)]/2$$
$$\rho_s(2) = [\rho_y(1) - \rho_y(2) - \rho_y(3) + \rho_y(4)]/2 \quad (60)$$
$$b_{1g} \text{ species}: \rho_s(3) = [\rho_z(1) - \rho_z(2) - \rho_z(3) + \rho_z(4)]/2 \quad (61)$$
$$b_{2g} \text{ species}: \rho_s(4) = [\rho_z(1) - \rho_z(2) + \rho_z(3) - \rho_z(4)]/2 \quad (62)$$
$$b_{3g} \text{ species}: \rho_s(5) = [\rho_x(1) - \rho_x(2) - \rho_x(3) + \rho_x(4)]/2 \quad (63)$$
$$\rho_s(6) = [\rho_y(1) - \rho_y(2) + \rho_y(3) - \rho_y(4)]/2 \quad (64)$$

The $\boldsymbol{B}_{s\rho s}$, $\boldsymbol{D}_{s\sigma}$, and $\boldsymbol{H}_{s\sigma}$ matrices were calculated, as shown in Tables 1—4, from $\boldsymbol{B}(\boldsymbol{\lambda})$ and $\boldsymbol{P}(\boldsymbol{L}+\boldsymbol{\lambda})$ submatrices, with Eqs. (16), (21), (23), (49), (50), and (51). Finally, with Eq. (54), the elastic constants were calculated as,

a_g species : $C_{11}=0.022_0$, $C_{22}=0.007_5$, $C_{33}=0.243$
$C_{23}=0.002_6$, $C_{31}=0.003_8$, $C_{12}=0.009_8$ md/Å^2

b_{1g} species: $C_{44}=0.001_5$ md/Å^2

b_{2g} species: $C_{55}=0.002_7$ md/Å^2

b_{3g} species: $C_{66}=0.012_6$ md/Å^2

Young's moduli of orthorhombic polyethylene were calculated as

$$E_a = 1/(C^{-1})_{11} = 0.009$$
$$E_b = 1/(C^{-1})_{22} = 0.003$$
$$E_c = 1/(C^{-1})_{33} = 0.243 \text{ md/Å}^2$$

In comparisn, Young's moduli measured at room temperature[13] are E_a=0.005, E_b=0.004, and E_c=0.235 md/Å^2. It may be remarked that the Young's modulus along the c axis (E_c) is due to the intramolecular force field and is much higher than the values of E_a or E_b which are due to intermolecular contacts. Finally, partial derivatives of elastic constants with respect to force constants were calculated with Eqs. (33), (47), and (56). The fractional distribution of potential terms is shown in Table 5.

The elastic constant along the c axis (C_{33}) is due to the intramolecular potential terms, K_r(22%), K_ϕ(38%), and K_q(40%), and the contributions of intermethylene terms (P_1, P_2, and P_3) are negligible. The elastic

constant along the b axis (C_{22}) is largely due to the P_3 contacts (52%) which are nearly parallel to the b axis (see Figs. 1 and 2). The elastic constant along the a axis (C_{11}) is predominantly due to the P_1 contacts (83%) which are nearly parallel to the a axis (see Fig. 1). On the other hand, P_2 contacts are nearly parallel to body-diagonals of unit cells and, in fact, make greatest contributions to the elastic constants of C_{44}, C_{55}, and C_{66}.

Conclusion

In a previous paper by Walmsley,[14] a method for treating elastic constants of molecular crystals is presented, where molecules are regarded as rigid bodies and the potential energy is expressed as a sum of terms each due to the interaction of a different pair of molecules. However, a general method worked out in the present study for treating elastic constants is applicable to general force fields. For molecular crystals, molecules need not be regarded as rigid bodies and internal strains within molecules may also be taken into account.

14) S. H. Walmsley, *J. Chem. Phys.*, **48**, 1438 (1968).

The present equations for elastic constants are written in matrix form and are readily programed for electronic computation. Factor-group symmetry operations may be applied in refined treatments of elastic properties. Also, elastic constants and normal vibrations may be treated together, and derivatives for elastic constants and normal vibration frequencies may be used together for least-square adjustments of force constants with reference to experimental elastic constants and vibrational frequencies.

The authors wish to express their thanks to Prof. Hiromu Murata and Dr. Michiro Hayashi of Hiroshima University for their discussions and to Dr. Hiromu Sugeta and Dr. Teizo Kitagawa of Osaka University for part of numerical calculations and discussions.

Appendix I Transformation Matrix ($\boldsymbol{D}_U$)

For the elastic constants of molecular crystals, it is necessary to derive $\boldsymbol{D}_U$ matrix elements [Eq. (17)] associated with bond-stretching, angle-bending, and torsional coordinates. Explicit equations for each of these coordinates may be derived by the use of relevant $\boldsymbol{s}_i$ vectors[1] of the atoms (i) involved,

$$\boldsymbol{s}_i = [B_{xi}\ B_{yi}\ B_{zi}] \tag{A1}$$

After defining the position vector $X(i)$ of the ith atom,

$$X(i) = [X(i)\ Y(i)\ Z(i)] \tag{A2}$$

the row vector $\boldsymbol{D}_U$ for an internal coordinate may be derived from Eqs. (10) and (17),

$$\begin{aligned}\boldsymbol{D}_U &= \sum_i [B_{xi}X(i)\ B_{xi}Y(i)\ B_{xi}Z(i)\ B_{yi}X(i)\ B_{yi}Y(i)\\ &\qquad B_{yi}Z(i)\ B_{zi}X(i)\ B_{zi}Y(i)\ B_{zi}Z(i)]\\ &= \sum_i [\boldsymbol{s}_i \times \boldsymbol{X}(i)]\end{aligned} \tag{A3}$$

where $\times$ denotes a direct product.

For the stretching coordinate (Δr_{ij}) of the bond i—j, the $\boldsymbol{s}$ vectors are expressed by the unit vector from the atom j toward i,

$$\begin{aligned}\boldsymbol{s}_i &= \boldsymbol{e}_{ji}\\ \boldsymbol{s}_j &= -\boldsymbol{e}_{ji}\end{aligned} \tag{A4}$$

Accordingly, the $\boldsymbol{D}_U$ vector is derived as

$$\boldsymbol{D}_U(\Delta r_{ij}) = \boldsymbol{e}_{ji} \times \boldsymbol{X}(i) - \boldsymbol{e}_{ji} \times \boldsymbol{X}(j) = \boldsymbol{e}_{ji} \times \boldsymbol{r}_{ji} \tag{A5}$$

where $\boldsymbol{r}_{ji}$ is the vector from the atom j to i,

$$\boldsymbol{r}_{ji} = \boldsymbol{X}(i) - \boldsymbol{X}(j) \tag{A6}$$

For the bending coordinate ($\Delta\phi_{ijk}$) of the bond angle i–j–k, the $\boldsymbol{s}$ vectors may be expressed as,

$$\begin{aligned}\boldsymbol{s}_i &= \boldsymbol{p}_{ji}/r_{ji}\\ \boldsymbol{s}_j &= -\boldsymbol{s}_i - \boldsymbol{s}_k\\ \boldsymbol{s}_k &= \boldsymbol{p}_{jk}/r_{jk}\end{aligned} \tag{A7}$$

where the unit vectors $\boldsymbol{p}_{ji}$ and $\boldsymbol{p}_{jk}$ are perpendicular to $\boldsymbol{e}_{ji}$ and $\boldsymbol{e}_{jk}$, respectively, and point in the positive bending direction. Accordingly, the $\boldsymbol{D}_U$ vector is derived as

$$\begin{aligned}\boldsymbol{D}_U(\Delta\phi_{ijk}) &= \boldsymbol{s}_i \times r_{ji} + \boldsymbol{s}_k \times r_{jk}\\ &= \boldsymbol{p}_{ji} \times \boldsymbol{e}_{ji} + \boldsymbol{p}_{jk} \times \boldsymbol{e}_{jk}\end{aligned} \tag{A8}$$

For the torsional coordinate ($\Delta\tau_{ijkl}$) of the dihedral angle i–j–k–l, the $\boldsymbol{s}$ vectors may be expressed as

$$\begin{aligned}\boldsymbol{s}_i &= \boldsymbol{p}_{kji}/r_{ji} \sin\phi_{kji}\\ \boldsymbol{s}_j &= -\boldsymbol{s}_i + \boldsymbol{p}_{kji}\cos\phi_{kji}/r_{kj}\sin\phi_{kji} - \boldsymbol{p}_{jkl}\cos\phi_{jkl}/r_{jk}\sin\phi_{jkl}\\ \boldsymbol{s}_k &= -\boldsymbol{s}_l + \boldsymbol{p}_{jkl}\cos\phi_{jkl}/r_{jk}\sin\phi_{jkl} - \boldsymbol{p}_{kji}\cos\phi_{kji}/r_{kj}\sin\phi_{kji}\\ \boldsymbol{s}_l \boldsymbol{p} &= {}_{jkl}/r_{kl}\sin\phi_{jkl}\end{aligned} \tag{A9}$$

where the unit vectors $\boldsymbol{p}_{kji}$ and $\boldsymbol{p}_{jkl}$ are perpendicular to the planes of bond angles ϕ_{kji} and ϕ_{jkl}, respectively, and point in the positive torsional direction. Accordingly, the $\boldsymbol{D}_U$ vector is derived as

$$\begin{aligned}\boldsymbol{D}_U(\Delta\tau_{ijkl}) &= \boldsymbol{p}_{kji} \times (\boldsymbol{e}_{ji} + \boldsymbol{e}_{kj}\cos\phi_{kji})/\sin\phi_{kji}\\ &\quad + \boldsymbol{p}_{jkl} \times (\boldsymbol{e}_{kl} + \boldsymbol{e}_{jk}\cos\phi_{jkl})/\sin\phi_{jkl}\end{aligned} \tag{A10}$$

Appendix II Derivation of $\partial C_{ij}/\partial K(h)$

From Eqs. (29) and (34),

$$\Delta\boldsymbol{C} = [\tilde{\boldsymbol{H}}_\sigma \Delta \boldsymbol{F}_R{}^0 \boldsymbol{H}_\sigma + \Delta\tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R{}^0 \boldsymbol{H}_\sigma + \tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R{}^0 \Delta \boldsymbol{H}_\sigma]/v \tag{A11}$$

Also from Eq. (27)

$$\Delta \boldsymbol{H}_\sigma = -\boldsymbol{B}_\rho \Delta\{[\tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho]^{-1} \tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0\} \boldsymbol{D}_\sigma \tag{A12}$$

and

$$\begin{aligned}\tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R{}^0 \Delta \boldsymbol{H}_\sigma &= -\tilde{\boldsymbol{D}}_\sigma \{\boldsymbol{E} - \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho [\tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho]^{-1} \tilde{\boldsymbol{B}}_\rho\} \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho\\ &\quad \times \Delta\{[\tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho]^{-1} \tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0\} \boldsymbol{D}_\sigma\end{aligned} \tag{A13}$$

However, since

$$\{\boldsymbol{E} - \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho [\tilde{\boldsymbol{B}}_\rho \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho]^{-1} \tilde{\boldsymbol{B}}_\rho\} \boldsymbol{F}_R{}^0 \boldsymbol{B}_\rho = 0 \tag{A14}$$

the matrix $\tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R{}^0 \Delta \boldsymbol{H}_\sigma$ and the transposed matrix $\Delta \tilde{\boldsymbol{H}}_\sigma \boldsymbol{F}_R{}^0 \boldsymbol{H}_\sigma$ in Eq. (A11) are both reduced to zero, leaving

$$\Delta\boldsymbol{C} = \{\sum_h [\tilde{\boldsymbol{H}}_\sigma \boldsymbol{A}(h) \boldsymbol{H}_\sigma] \Delta K(h)\}/v \tag{A15}$$

Accordingly, the partial derivative of the elastic constant (C_{ij}) with respect to the force constant $K(h)$ is given by Eq. (35) in the main text.

A Fermi Resonance with ν_6 of Acetonitrile

Hiroatsu MATSUURA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 30, 1971)

The rotation-vibration spectrum of ν_6 of acetonitrile measured by Nakagawa *et al.* has been reanalyzed by taking account of the Fermi resonance between the states $|v_6=1>$ and $|v_7=1, v_8=1>$. The previous assignment of Q branches by Amat *et al.* has been revised on the basis of the obtained values of band constants. The following band constants have been determined for the ν_6 band: $\nu_0=1447.9$ cm^{-1}, $\zeta=-0.305$ and $\alpha^A=0.046$ cm^{-1}. From the value of the resonance operator, the magnitude of the cubic force constant k_{678} has been estimated to be about 30 cm^{-1}.

Rotation-vibration spectra of acetonitrile CH_3CN have been studied by Parker, Nielsen, and Fletcher[1] and Nakagawa and Shimanouchi,[2] and anomalous rotational structures have been found in the ν_6 perpendicular band. Amat and Nielsen[3] interpreted the anomaly to be due to the Fermi resonance between the states $|v_6=1>$ and $|v_7=1, v_8=1>$ and made an assignment of observed Q branches. In the present study, the ν_6 band region in the spectra of Nakagawa and Shimanouchi[2] was reanalyzed and Amat's assignment was revised on the basis of the obtained values of band constants.

Spectral Analysis and Discussion

As shown in Fig. 1, the observed spectrum in the region 1300—1600 cm^{-1} consists of two series of Q branches (ν^+ and ν^-), higher- and lower-wave number components of the Fermi doublet. We have three possible vibrational states which can be coupled with and perturb the $|v_6=1, l_6=\pm1>$ state through Fermi-resonance operators; namely $|v_7=1, l_7=\mp1, v_8=1, l_8=\mp1>$, $|v_8=4, l_8=\mp2>$ and $|v_8=4, l_8=\pm4>$, which have rotation-vibration energies close to that of the $|v_6=1, l_6=\pm1>$ state. It has become evident, from the obtained values of the band constants, that the perturber is the $|v_7=1, l_7=\mp1, v_8=1, l_8=\mp1>$ state. In assigning observed Q branches, however, there are two possible K-numberings (Assignment I and Assignment II) as shown in Table 1; they differ in the assigned $K\Delta K$ numbers by one in the ν^- component. Assignment II corresponds to Amat's assignment.[3] Analyses of the band system were made according to the two assignments.

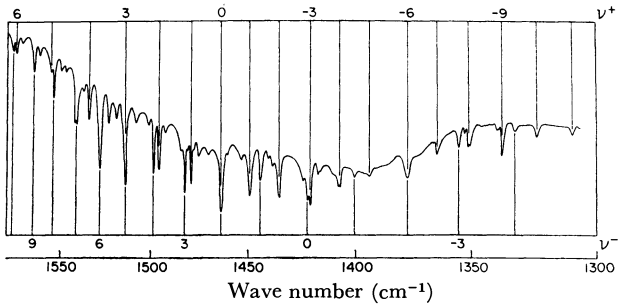

Fig. 1. Infrared spectrum of the ν_6 region of CH_3CN (Ref. 2). Numbers shown above and below the spectrum are $K\Delta K$ numbers for ν^+ and ν^- according to Assignment I.

In calculating the unperturbed band constants, the following matrix was set up for each K value

$$\begin{bmatrix} E^0(v_6=1, l_6=\pm1, K) & W \\ W & E^0(v_7=1, l_7=\mp1, v_8=1, l_8=\mp1, K) \end{bmatrix},$$

where E^0 denotes the unperturbed energy and W the matrix element of the Fermi-resonance operator. The unperturbed band constants and the resonance operator were determined by solving the above matrix and fitting observed wavenumbers to the wave number equation by the method of least squares. The results are given in Table 2. The values of ν_0, ζ, and α^A ($=A''-A'$) were calculated by assuming $B'=B''=0.3068$ cm^{-1} and $A''=5.280$ cm^{-1}.[4] From the ζ_7 value (0.422)[2] and the ζ value $[-(\zeta_7+\zeta_8)]$ of the $\nu_7+\nu_8$ band, we obtain $\zeta_8=0.863$ for Assignment I and $\zeta_8=0.764$ for Assignment II. Venkateswarlu *et al.*[5] have obtained $\zeta_8=0.88$ from microwave studies. The good agreement between the ζ_8 value for Assignment I and the microwave value is an evidence that favors Assignment I. From the ζ_6 and ζ_8 values of the present study and the ζ_5 and ζ_7 values previously determined,[2] we can check the ζ-sum rule ($\sum_t \zeta_t = 1+B/2A$); $\sum_t \zeta_t=1.042$ for Assignment I and $\sum_t \zeta_t=0.898$ for Assignment II, while $1+B/2A=1.029$. Agreement between the left- and right-hand sides is much better for Assignment I than for Assignment II.

Values of the rotation-vibration coupling constant α^A for localized vibrations, *e.g.* CH_3 stretching and CH_3 bending vibrations of CH_3X and CH_3CN, are expected to be similar for the same vibrational modes.[6,7] α^A values for the CH_3 rocking, and CH_3 asymmetric stretching vibrations of CH_3CN are, in fact, close to the corresponding values for CH_3Cl, CH_3Br and CH_3I. The α^A value for ν_6 of CH_3CN (CH_3 asymmetric deformation) was determined to be 0.046 cm^{-1} for Assignment I and 0.028 cm^{-1} for Assignment II. The former is much closer than the latter to the corre-

a) More likely assignment.
b) Observed wave number (cm^{-1}).
c) $\Delta\nu=\nu_{obs}-\nu_{calc}$.
d) Omitted from the least squares calculation.

sponding values[8,9] of 0.048 cm^{-1}, 0.048 cm^{-1} and 0.046 cm^{-1} determined for CH_3Cl, CH_3Br, and CH_3I, respectively. This is another basis for preferring Assignment I to Assignment II.

By comparing the results obtained for both assignments, it is now concluded that Assignment I is a more likely alternative; the results for Assignment I will therefore be used in subsequent parts of this paper. The better agreement between the observed and calculated wavenumbers for Assignment I than Assignment II (see Table 1) may also support this conclusion. In order to check the conclusion, approximate intensity ratios of the Q branches for the ν^+ and ν^- components with the same $K\Delta K$ numbers were calculated for the two assignments. However, a definite comparison could not be made due to overlapping of some of the Q branches and another kind of perturbation.

The unperturbed band origin of ν_6 was determined to be 1447.9 cm^{-1}. This wave number is about 6 cm^{-1} lower than the wave number[1,2] previously obtained without taking account of the Fermi resonance. From the wave number of the band origin for $\nu_7+\nu_8$ and those for ν_7 and ν_8,[2] the anharmonic term[10] $x_{78}+x_{l_7l_8}=-0.8$ cm^{-1} is obtained.

Assuming that the Fermi-resonance operator W is

TABLE 2. BAND CONSTANTS OF THE ν_6 AND $\nu_7+\nu_8$ BANDS OF CH_3CN IN cm^{-1}

Constant	Assignment I[a]		Assignment II	
	ν_6	$\nu_7+\nu_8$	ν_6	$\nu_7+\nu_8$

determined by the following anharmonic term of the intramolecular potential

$$V = hck_{678}[q_{6a}(q_{7a}q_{8a}-q_{7b}q_{8b}) - q_{6b}(q_{7a}q_{8b}+q_{7b}q_{8a})],$$

we find the following non-zero matrix element

$$\langle v_6, l_6, v_7, l_7, v_8, l_8 | V/hc | v_6-1, l_6\pm1, v_7+1, l_7\pm1, v_8+1, l_8\pm1\rangle$$
$$= \pm(1/4\sqrt{2})k_{678}[(v_6\mp l_6)(v_7\pm l_7+2)(v_8\pm l_8+2)]^{1/2}.$$

Accordingly, from the $|W|$ value obtained in the present analysis, the magnitude of the cubic force constant k_{678} is estimated to be $|k_{678}|=2|W|=31$ cm^{-1}.

It has been found in the course of the analysis that there is another kind of perturbation, though much weaker than the one described above, for ${}^PQ_6-{}^PQ_8$ in the ν^+ component; the observed wave numbers deviate systematically from the calculated wave numbers (see Table 1). Amat and Nielsen[3] explained it as due to a Coriolis interaction between the states $|v_3=1\rangle$ and $|v_6=1\rangle$. The observed wavenumbers for these Q branches were omitted in determining the band constants given in Table 2.

The author wishes to thank Dr. Ichiro Nakagawa, the University of Tokyo, for providing the author with a copy of his original spectrum and for his valuable discussions. The author is also grateful to Professor Tatsuo Miyazawa, Osaka University, for his helpful discussions.

After this work was completed, the author has been informed by Professor. G. Amat that J. L. Duncan, D. Ellis, and I. J. Wright [*Mol. Phys.*, **20**, 673 (1971)] independently studied the same subject and obtained essentially the same results.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2381—2386 (1971)

The Formation Constants and Composition of Tetraethylenepentaamineheptaacetato Nickel(II) Complexes measured by a Potentiometric Titration Method

Yoshitaka MASUDA, Yukiko HIRAI, and Eiichi SEKIDO

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

(Received October 14, 1970)

Stability constants for nickel(II) complexes of tetraethylenepentaamineheptaacetic acid (TPHA: H_7L) were determined by the pH titration method. In an aqueous solution ($\mu=0.1$) three uninuclear complex species, NiH_2L, NiHL, and NiL, and a binuclear compound, Ni_2L seem to exist. The structures of uni- and bi-nuclear chelates are discussed with their visible absorption spectra. Formation of the hydroxo complex was not observed on the titration curves. In the present investigation no evidence was found for species of Ni_2HL either. The formation constants of the complexes stated above have been calculated as follows, (at 25 ± 0.1°C). $\log K_{ML}=16.18$, $\log K_{MHL}=10.00$, $\log K_{MH_2L}=6.16$, $\log K_{M_2L}=17.35$ and $\log K_{ML_2}=27.78$.

Ethylenediaminetetraacetic acid (EDTA) and many related polyaminopolycarboxylic acids form metal complexes which exist over a wide pH range, and have high stability constants. Among them, triethylenetetraminehexaacetic acid (TTHA, H_6L) has been shown as an interesting complexing agent by some workers. Přibil and co-workers[1] studied its analytical usefulness as a titrant for many metal ions. It is noteworthy that the equilibrium of complexation for mono- and diprotonated forms of uni-nuclear chelates have been investigated by Martell and Bohigian.[2] They also reported that there are some differences between the structure of the complex of alkaline-earth metals and that of transition metals. Further, Koryta and Kopanica[3] have undertaken the investigation of the polarographic behavior of cadmium(II)-TTHA complex. They reported that CdH_2L^{2-} species exists over a wide pH range and the logarithm of its formation constant is given as 10.36 at 25°C.

Recently, it has been found further that a new multi-dentate ligand,[4] TPHA (tetraethylenepentaamineheptaacetic acid H_7L) forms complexes with many transition metals. However, there are few equilibrium data for this new ligand in the literature. The acid dissociation constants of free TPHA have been first determined by Dyatrova[5] by a potentiometric titration method. Aihara, Kida, and Misumi[6] studied the reactions of the lanthanide(III) ion with TPHA. No stability constant data have been published for the transition metal chelates of this ligand. In this paper, are reported the stability constants of nickel(II)-TPHA complexes determined potentiometrically by a similar method to Bohigian and Martell's[2] and by deriving new equations for calculation.

Experimental

Hitachi-Horiba model P pH meter fitted with extension glass and calomel electrode was calibrated with standard buffer solutions of pH 4.10 and 7.00. Actual hydrogen ion concentration was determined on the basis of the data tabulated by Harned and Owen.[7]

Reagent. The chemical formula of synthesized TPHA ligand[4] was given by $C_{33}H_{27}N_5O_{14}\cdot 4HCl\cdot 2H_2O$. The TPHA solution was standardized by the titration with a standard thorium nitrate solution. Standard carbonate-free potassium hydroxide solution was prepared as follows. G. R. potassium hydroxide (7.0 g) and G. R. barium chloride (2 g) were dissolved in demineralized water. The solution was set aside for a few days at ordinary temperature in a 1000 m*l* Erlenmyer flask. Excess of barium chloride in the solution was removed by passing the solution through a column of potassium-type cation exchange resion "Dowex 50-X12" (100—200 mesh). The resulting carbonate free potassium hydroxide solution was stored in a polyethylene bottle and protected from the atmosphere by a soda lime tube.

The potassium hydroxide solution was standardized by potentiometric titration with potassium phthalate solution. The solution of nickel nitrate was standardized titrimetrically by the EDTA procedure,[8] and was stored under pure nitrogen gas. Potassium nitrate was used to make the ionic strength to 0.1. Demineralized water free from carbonate was used in all the titrations.

Procedure. The experimental method consists of potentiometric titration of the hepta basic acid, TPHA, with potassium hydroxide solution in the absence and the presence of the nickel(II) ion at 1:1, 2:1, 1:2, and 3:1 molar ratios of metal ion to ligand. All titrations were carried out in a double walled glass titration cell of 200 m*l* capacity. The temperature was controlled to 25±0.1°C by circulating water through the double wall cell and the ionic strength of the solution were maintained constant at 0.10. Nitrogen free from carbon dioxide was continuously passed through the system in the titration cell. After each addition of aliquots of alkali titrant (0.05 m*l*), the solution was stirred with a magnetic stirrer and was allowed to stand for 3 min to attain equilibrium. The titrations were carried out from an initial pH 2.5 to 10.5.

Calculations

The values of the dissociation constants of TPHA (H_7L) obtained by Dyatrova[5] were used in this work, namely, pK_1, 9.95; pK_2, 8.85; pK_3, 5.56; pK_4, 3.82; pK_5, 2.79. The calculations were carried out in the range of a=3—6, where a is the equivalent base added per mole of ligand (above pH 2.9). The influence of pK_6 and pK_7 was not observed at all. The equations can be derived by modifying Martell's.[2] The following equilibria were considered for the calculation of stability constants for the ligand, H_7L and the metal ion, M^{2+}.

$$M + L \rightleftharpoons ML \qquad K_{ML} = [ML]/[M][L] \qquad (1)$$

$$M + HL \rightleftharpoons MHL \qquad K_{MHL} = [MHL]/[M][HL] \qquad (2)$$

$$MHL \rightleftharpoons ML + H \qquad K^{H}_{MHL} = [ML][H]/[MHL] \qquad (3)$$

$$M + H_2L \rightleftharpoons MH_2L \qquad K_{MH_2L} = [MH_2L]/[M][H_2L] \qquad (4)$$

$$MH_2L \rightleftharpoons MHL + H \qquad K^{H}_{MH_2L} = [MHL][H]/[MH_2L] \qquad (5)$$

$$M + H_3L \rightleftharpoons MH_3L \qquad K_{MH_3L} = [MH_3L]/[M][H_3L] \qquad (6)$$

$$MH_3L \rightleftharpoons MH_2L + H \qquad K^{H}_{MH_3L} = [MH_2L][H]/[MH_3L] \qquad (7)$$

Equations describing the total analytical concentration of metal ion (T_M), total ligand concentration (T_L), and electroneutrality can be written as follows.

$$T_L = \sum_{j=1}^{7}[H_jL] + [L] + [MHL] + [MH_2L] \qquad (8)$$

$$T_M = [M] + [MHL] + [MH_2L] \qquad (9)$$

$$T_H = (7-a)T_L = [H] - [OH] + \sum_{j=1}^{7} j[H_jL] + [MHL] + 2[MH_2L] \qquad (10)$$

From Eqs. (2), (3), (4), (5), (8), (9), and (10), Eqs. (11) and (12) are obtained.

$$[H_2L] = \frac{\{(6-a)T_L-[H]+[OH]\}K^{H}_{MH_2L}+\{(5-a)T_L-[H]+[OH]\}[H]}{(P-S)K^{H}_{MH_2L}+[H](P-2S)} \qquad (11)$$

$$K_{MH_2L} = \{(6-a)T_L-[H]+[OH]-[H_2L](P-S)\}/[H_2L]^2\cdot S \qquad (12)$$

where

$$P = 2 + K_2^{H}/[H] + \sum_{i=1}^{5}(i+2)[H]^i/\prod_{z=3}^{i+2}K_z^{H}$$

and

$$S = 1 + K_2^{H}/[H] + K_1^{H}K_2^{H}/[H]^2 + \sum_{i=1}^{5}[H]^i/\prod_{z=3}^{i+2}K_z^{H}$$

K_z^{H} may be defined as the zth acid dissociation constant of the TPHA ligand. $K_z^{H}=[H_{z-1}L][H]/[H_zL]$, $z=1, 2, \cdots, 7$.

The calculation of the stability constants of MHL and ML was made by a graphical method. A series of values for pK^{H}_{MHL} were assumed and corresponding values for K_{MHL} calculated from the following equations.

$$[HL] = \frac{[H]\{(6-a)T_L-[H]+[OH]\}+K^{H}_{MHL}\{(7-a)T_L-[H]+[OH]\}}{[H](Y-X)+Y\cdot K^{H}_{MHL}} \qquad (13)$$

$$K_{MHL} = \{(7-a)T_L-[H]+[OH]-[HL]\cdot Y\}/[HL]^2X \qquad (14)$$

where

$$X = 1 + K_1^{H}/[H] + \sum_{i=1}^{6}[H]^i/\prod_{z=2}^{i+1}K_z^{H}$$

and

$$Y = 1 + \sum_{i=1}^{6}(i+1)[H]^i/\prod_{z=2}^{i+1}K_z^{H}$$

When the resulting values of $\log K_{MHL}$ are plotted against the assumed values of pK^{H}_{MHL}, intersecting lines are obtained. The fact that all the lines obtained from different points on the titration curve intersect at one point indicates the existence of a set of unique values for $\log K_{MHL}$ and pK^{H}_{MHL}, which will satisfy the assumed reaction at any point along the titration curve in a certain range of a values. The values for $\log K_{ML}$ are calculated from Eq. (15).

$$K_{ML} = K^{H}_{MHL}\cdot K_{MHL}/K_1 \qquad (15)$$

where K_1 is the first acid dissociation constant of the

8) K. Ueno, "Chelatometric Titration" (reprinted 12), Nankodo, Kyoto, (1967), p. 287.

ligand TPHA. The value of K_{MHL} is obtained in the same fashion on the process of the log K_{ML}. In a similar fashion, equations for the stability constant of the triprotonated TPHA complex can be obtained. The following equations for stability constant of the binuclear chelate compounds are derived.

$$[L] = \{(7-a)T_L - [H] + [OH]\}/Y' \quad (16)$$

$$K_{M_2L} = \{T_L - [L]X'\}/4[L]^3X'^2 \quad (17)$$

where

$$X' = 1 + \sum_{i=1}^{7}[H]^i/\prod_{z=1}^{i}K_z^H$$

and

$$Y' = \sum_{i=1}^{7}i[H]^i/\prod_{z=1}^{i}K_z^H$$

To calculate the formation constants of hydroxo complexes, the average number of hydroxide ions bound to the metal ion is described by

$$\bar{n}_{OH} = \frac{T_{OH} - [OH]}{T_M} = \frac{[M(OH)L] + 2[M(OH)_2L]}{[ML] + [M(OH)L] + [M(OH)_2L]} \quad (18)$$

T_{OH} represents concentration of the hydroxide ion added to any point along the titration curve. The relationship between $\bar{n}_{OH}$ and [OH] was equivalent to that between $\bar{n}_L$ and the free ligand concentration [L].[9] From a plot of $\bar{n}_{OH}$ *vs.* pOH, the formation constant of mono hydroxide complex was calculated as first approximation ($\bar{n}_{OH}=0.5$).

The extent of 1:2 chelate formation can be characterized by the complex formation function or the average co-ordination number introduced by Bjerrum.

$$\bar{n}_L = \frac{[ML] + 2[ML_2]}{[M] + [ML] + [ML_2]} = \frac{K_{ML}[L] + 2K_{ML_2}[L]^2}{1 + K_{ML}[L] + K_{ML_2}[L]^2} \quad (19)$$

[L] can be obtained by Eq. (16).

From some points along the titration curve, the values for $\bar{n}_L$ are plotted against [L]. $\log K_{ML}$ and $\log K_{ML_2}$ may be determined from values of pL at $\bar{n}_L$ values of 0.5 and 1.5 on the plot of $\bar{n}_L$ *vs.* pL.

Results and Discussion

Potentiometric pH Curves. The potentiometric titration curves of TPHA and of mixtures of nickel(II) and TPHA (1:2, 1:1, 2:1, and 3:1) are shown in Fig. 1. The titration curve of the acid (TPHA) points out two steps, that is, it appears as a well-defined inflextion at a between 4 and 5 involving the dissociation of the acid species, H_3L and H_2L and as a less distinction inflextion at a above 5 involving the dissociation of HL acid species. It is seen that this small inflextion is due to the least mutual electrostatic repulsion between the protonated amino groups. A 1:1 mixture of nickel(II) and acid (TPHA) exhibits a well-defined inflextion at $a=5.75$, whereas a 2:1 mixture shows one steep inflextion at $a=6.75$. In the case of a 1:1 mixture of nickel(II) and TPHA, inflextion is not seen exactly at $a=5$, $a=6$, and $a=7$. Although an explanation for this fact is not found, it may be suggested that sites of nickel(II) are not saturated for arrangement of TPHA ligand. The titration curve of 3:1 mixture of nickel(II) and TPHA is similar to the 2:1 curve up to $a=6.75$. This shows that metal ions more than two can't be bound to one TPHA molecule. Further addition of potassium hydroxide results in the formation of nickel hydroxide. The buffer region for $a>6.75$ is consistent with the pH region where the nickel(II) hydroxide is precipitated. This was checked by separate titrations of the corresponding nickel nitrate solutions in absence of TPHA.

The 1:1 curve indicates the formation of a protonated nickel chelate below $a=4.5$ and the formation of the hydroxo complex was not observed on those curves. These experiments indicate the presence of the complexes; MH_3L, MH_2L, MHL, ML, M_2L, and ML_2. From the knick of the titration curves at $a=4$, the following reaction is considered.

$$Ni^{2+} + H_7L + 4OH^- \rightleftharpoons NiH_3L + 4H_2O$$

At $a=5$ and $a=6$, the following reactions take place.

$$Ni^{2+} + H_7L + 5OH^- \rightleftharpoons NiH_2L + 5H_2O$$

$$Ni^{2+} + H_7L + 6OH^- \rightleftharpoons NiHL + 6H_2O$$

Above $a=6$, the following reaction takes place.

$$NiHL + OH^- \rightleftharpoons NiL + H_2O$$

In the 2:1 mixtures a binuclear complex is obviously predominant:

$$2Ni^{2+} + H_7L + 7OH^- \rightleftharpoons Ni_2L + 7H_2O$$

The Ionization of TPHA. Figure 2 shows the percentage of variously dissociated forms of the ligand, TPHA, at various pH's. The percentages have been calculated from Eq. (20) and by using Dyatrova's data of the dissociation constants[5] of TPHA. It has been assumed that pK_7 and pK_6 should be 2.0 and 2.5, respectively.

$$T_L = [H_7L] + [H_6L] + [H_5L] + [H_4L] + [H_3L] + [H_2L] + [HL] + [L] \quad (20)$$

For the sake of simplicity for calculation, a parameter D was introduced (Eq. (21)).

$$D = [H]^7/\alpha_7 + [H]^6/\alpha_6 + [H]^5/\alpha_5 + [H]^4/\alpha_4 + [H]^3/\alpha_3 + [H]^2/\alpha_2 + [H]/\alpha_1 + 1 \quad (21)$$

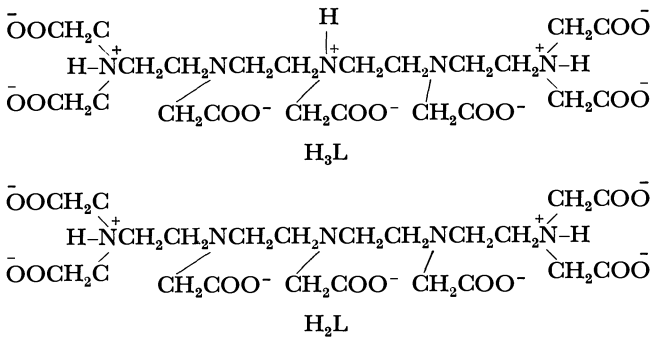
which α's indicate dissociation constants of TPHA ligand. Each of the distribution ratio may be represented by Eq. (22).

$$\begin{aligned} &[L]/T_L = 1/D & &[HL]/T_L = [H]/D\alpha_1 \\ &[H_2L]/T_L = [H]^2/D\alpha_2 & &[H_3L]/T_L = [H]^3/D\alpha_3 \\ &[H_4L]/T_L = [H]^4/D\alpha_4 & &[H_5L]/T_L = [H]^5/D\alpha_5 \\ &[H_6L]/T_L = [H]^6/D\alpha_6 & &[H_7L]/T_L = [H]^7/D\alpha_7 \end{aligned} \quad (22)$$

Below pH 3 three species, H_7L, H_6L, and H_5L are present in the solution in the absence of metal ions. In the range of pH 3.0 to 4.0, H_4L species is obviously predominant and in the range of pH 3.8 to 5.5, H_3L species is predominant. The percentage of H_2L species attained maximum value, 96% at the pH 7.0. The H_2L and HL species exist over the wide range from 4.5 to 9.8 and from 7.0 to 10.0 respectively. At pH$\geq$ 8.0, the percentage of the L species increased with increasing pH. In this range of pH, TPHA acts as a

9) J. Bjerrum, "Metal Ammine Formation in Aqueous Solution," E. Christensen, 2nd ed., P. Hasse and Son, Copenhagen (1957), p. 123.

diprotic acid. According to the diagram previously described, the species H_3L and H_2L, exist in a wide pH range. From infrared studies with respect to the structures of EDTA and DTPA,[10] the structures of the species, H_3L and H_2L will be inferred as follows.



H_3L

H_2L

Graphical Solution for Stepwise Equilibrium Constants, K_{MHL} and pK^H_{MHL}, K_{MHL} and $pK^H_{MH_2L}$. The resulting values of log K_{MHL} were plotted against the assumed values of pK^H_{MHL} to give the intersecting curves shown in Fig. 3. (refer to Eqs. (13) and (14)). All curves obtained from the different points on one titration curve for the 1:1 Ni(II)–TPHA system intersect at one point, as shown in Fig. 3. This fact indicates the existence of a set of unique values for K_{MHL} and pK^H_{MHL}. The values for $\log K_{MHL}$ and pK^H_{MHL} are found to be 9.90_0 and 3.77_5, respectively.

In a similar fashion the value of log K_{MH_2L} was also determined (refer to Eqs. (11) and (12)). From the graphical determination of $pK^H_{MH_2L}$ and $\log K_{MH_2L}$, intersection of the resulting curves gives the values of

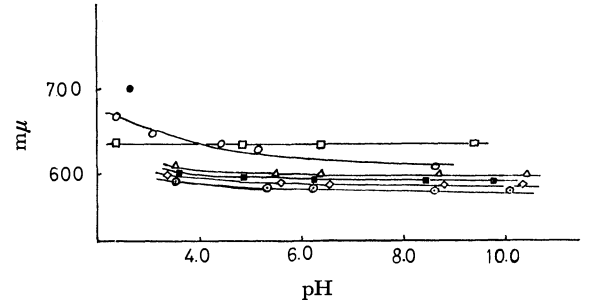

Fig. 6. Displacement of absorption maximum of nickel(II)-polyaminocarboxylic acid chelates (1:1) as a function of pH. polyaminocarboxylic acid; (□) NTA, (○) IDA, (△) EDTA, (■) TPHA, (◇) TTHA, (⊙) DTPA.
(●) nickel(II) perchlorate solution.

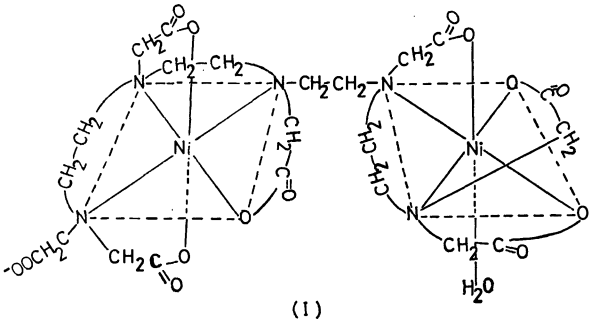
the equilibrium constants. For nickel(II), the values, $pK^{H}_{MH_2L}=3.275$ and $\log K_{MH_2L}=6.16$ were found (see Fig. 4). The value, $\log K_{MH_2L}=5.40$ calculated by using Eqs. (21) and (20) was less than the value of graphical solution. The disagreement between calculated and graphical solutions is due to the presence of species other than MH_2L and MHL complexes assumed for stepwise equilibrium constants. The value of $\log K_{MH_3L}$, 5.26 on the limiting range of pH measurement (3.0) was obtained.

Stability Constants of log K_{M_2L} and log K_{ML_2}. The stability constants of the complexes were calculated as described above (refer to Eqs. (16) to (17) and to Eq. (19)). The results are also given in Table 1.

The Percentages of the Species. Nickel(II) and TPHA form a normal and protonated complexes as described above. In Fig. 5. the percentages of the species, MH_2L, MHL, and ML in the solution of 1:1 mixtures of nickel(II) and the ligand, TPHA, are plotted as a function of a. Figure 5 clearly demonstrates the difference in the stabilities of MH_2L, MHL, and ML. It was shown that the MH_2L complex is present in the range between $a=1.0$ and $a=5.0$. The percentage of this species has a maximum value (70%) at $a=3.8$, while the MHL species is present from $a=2.0$ to $a=5.5$, although a maximum value at $a=4.6$ is only 11 pecent. However, the ML species predominated at $a\geq5.0$. An intersecting point of lines representing the species MH_2L and ML was observed at $a=4.4$. A similar behaviour is indicated for lines representing the species MHL, and MH_2L, too. Below $a=3$, the species other than MHL, MH_2L, and ML, such as triprotonated species, also exists. In the present investigation no evidence was found for species of M_2HL and ML(OH).

Stability Constants and the Structures of Nickel(II)-TPHA Complexes. The stability constants of the uninuclear nickel(II)-complexes with EDTA, DTPA, and TTHA were reported by several authors.[2,11,12] Table 1 shows the stability constants of nickel(II) complexes with TPHA. The stability constant of the 1:1 nickel(II)-TPHA normal complex is lower than the corresponding constants of the EDTA, DTPA, and TTHA chelates by 2—3 logarithmic units. The chelate effect of 1:1 nickel(II)-TPHA complex may be lowered by the following reasons: 1) the presence of a number of ligand atoms which do not bind to nickel(II), 2) the steric forces of some kinds, that is, steric strain, and 3) diminution of the degree of freedom in molecular rotation of the ligand molecules by chelation.

The stability constants of di- and mono-protonated complex are also calculated (refer to Table 1). As nickel(II) has the co-ordination number of six in spite of TPHA having twelve open positions for the co-ordination, polynuclear chelates may be formed. It is found that TPHA ligand does not bind to metals more than two and that binuclear hydrogen or hydroxo complex does not exist as the results of potentiometric titration under the given condition. The normal binuclear complex is more stable than uninuclear one. Possible structure of M_2L is indicated as follows. This fact may be explained in terms of binding of the functional donor groups in TPHA ligand inlayed with sites of two nickel(II) in the binuclear complex.



(I)

Six donor groups combined with nickel(II) are arranged in an octahedral configuration. Nickel(II)-TPHA complex can involve carboxylate and nitrogen donors combination, which satisfy co-ordination sites of nickel(II). In the extreme case, three different arrangements for the normal uninuclear complex are

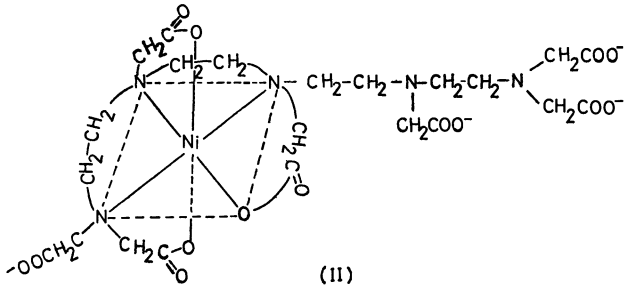
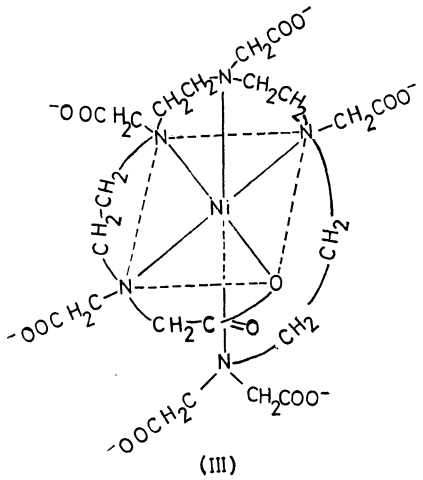
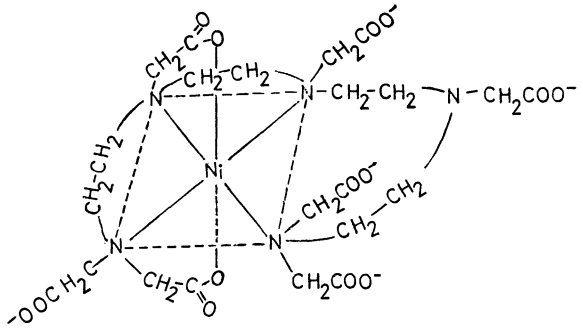
considered as formulae II, III, and IV. In formula II, nickel(II) is co-ordinated with three nitrogen and three carboxylate donors, in formula III with five nitrogen donors and in formula IV with three nitrogen atoms and remote nitrogen donor having the high basicity.



(II)



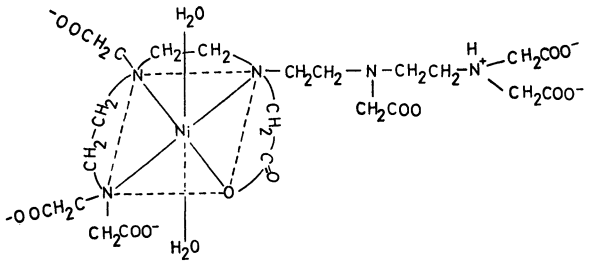
(III)



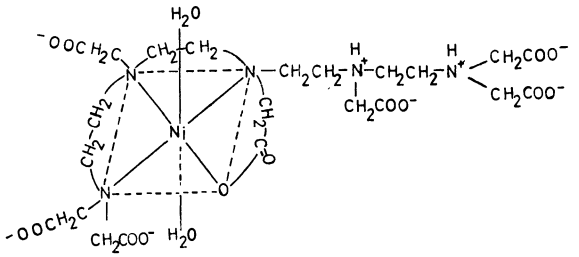
(IV)

A comparison of the visible absorption spectra of nickel(II)-polyaminocarboxylic acid complexes shows that the maxima are shifted to shorter wavelength as the number of co-ordinated nitrogen atoms increases. This fact suggests that the ligand field effect becomes powerful as the number of co-ordinated nitrogen atoms increases. However, for the nickel(II)-TPHA complex, the shift of the absorption maximum to shorter wavelength is smaller than for the DTPA complex with a rearrangment of donor groups involving three nitrogens and three caboxylate groups. It may be considered that the structure (II) is most probable one and is consistent with the reason mentioned before. On account of the ligand field strength and potential basicity of nitrogen atom of remote terminal amino group, the structure (IV) may be also present.

The following structures for mono- and diprotonated complexes may be suggested. More probable arrangements would involve co-ordination of metal ion by three nitrogen atoms and one carboxylate donor group, and un-co-ordinated groups exist in the structure as a terminal nitrogen atom remaining a proton and as carboxylate ion (refer to V and VI).



(V)



(VI)

Details concerning both the lack of a marked difference in behavior of the transition metal complexes and general validity of the Irving-William order will be reported in subsequent papers.

(Received December 22, 1970)

The cobalt(II)-acetylacetonate complex and the nickel(II)-acetylacetonate, -glutamate, -aspartate and -iminodiacetate complexes were found to give kinetic waves due to the dissociation of these complexes at the electrode surface preceding the electron-transfer step. From the experimental examination of the nature of the kinetic current and a theoretical consideration, the mechanism and the rate constants of the dissociation of these complexes at the mercury-electrode surface were determined. The dissociation reactions were found to proceed through the following mechanism:

$$MX_2^{2-2m} \rightleftharpoons MX^{2-m} + X^{m-} \quad \text{rapid}$$

$$MX^{2-m} \underset{k_d}{\rightleftharpoons} M^{2+} + X^{m-} \quad \text{slow}$$

$$M^+ + 2e^- + Hg = M(Hg)$$

The rate constants, k_d's, for the dissociation reactions of cobalt(II)-acetylacetonate complex and of nickel(II)-acetylacetonate, -glutamate, -aspartate, and -iminodiacetate complexes at 25°C were estimated to be 9.3_0, 0.56, 0.69, $1.2_1 \times 10^{-2}$, and 2.5×10^{-4} sec^{-1} respectively. From a comparison of the rate constants, the dissociation of nickel(II)-aminopolycarboxylate complexes was concluded to proceed invariably through a reaction intermediate in which the leaving aminopolycarboxylate anions is bonded to the nickel(II) ion through one nitrogen and one oxygen atoms (Glycinate intermediate). In the formation reactions of cobalt(II)- and nickel(II)-acetylacetonate complexes in a 1:1 ratio, the dissociation of coordinated water from the metal(II) ion is rate-determining (water-loss mechanism).

Previously,[1,2] we reported that the cadmium(II)-EDTA complex in an acetate buffer solution and the zinc(II)-NTA complex in an ammonia buffer solution give kinetic waves due to the dissociation of these complexes preceding the electron-transfer step at the electrode surface; we then thoroughly investigated the nature of these kinetic waves from both theoretical and experimental viewpoints and determined the rates and the mechanism of the dissociation reactions of cadmium(II)-EDTA and zinc(II)-NTA complexes. Quite similar phenomena could also be observed in the polarography of the cobalt(II)-acetylacetonate (ACAC) complex and in that of the nickel(II)-ACAC, -glutamate (Glut), -aspartate (Asp) and -iminodiacetate (IDA) complexes. In this paper, we will study systematically the nature of the kinetic waves due to the dissociation of these complexes from both theoretical and experimental viewpoints, and will determine the mechanism and the rates. From a comparison of rate constants for the dissociation of the nickel(II)-aminopolycarboxylate complexes with those estimated on the basis of the proposed reaction intermediate, the structures of the reaction intermediates will be determined in detail. The mechanism of the formation reactions of 1:1 ratio cobalt(II)- and nickel(II)-ACAC complexes will also be discussed.

Experimental

Reagents. Standard nickel(II) and cobalt(II) nitrate solutions were prepared by dissolving known amounts of metallic nickel and cobalt (99.99% pure) in dilute nitric acid (1+1), and by then removing the excess nitric acid by distillation under reduced pressure. L-Glutamic acid (Glut), L-aspartic acid (Asp) and iminodiacetic acid (IDA) were recrystallized from their aqueous solutions by adding pure ethanol and hydrochloric acid. The acetylacetone used was purified twice by distillation under reduced pressure. The standard solutions of Glut, Asp, and IDA were prepared by dissolving known amounts of recrystallized Glut, Asp, and IDA in redistilled water. All the other chemicals used were of analytical-reagent grades and were used without further purification.

Apparatus and Experimental Procedures. All the DC current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane[3] or a Yanagimoto pen-recording polarograph PA-102. The characteristic feature of the dropping mercury electrode (DME) used in this study was described previously.[4] A saturated calomel electrode (SCE) with a large area was used as the reference electrode and was connected to the cell solution through a Hume and Harris-type salt bridge.[5] The pH value of the solution was measured with a glass electrode pH meter (a Hitachi-Horiba F-5). The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution. The ionic strength of the solution was adjusted to 0.20 by adding an appropriate amount of pure sodium perchlorate or potassium nitrate. To keep the solution's pH constant, a sodium acetate-acetic acid mixture in the nickel-

(II)-IDA system and a potassium dihydrogen phosphate-disodium hydrogen phosphate mixture in the nickel(II)-ACAC and -Asp systems were used. In the cases of the nickel(II)-Glut and cobalt(II)-ACAC systems, no buffer mixture was used, for the sample solution always contained a large excess of uncomplexed Glut or ACAC, and, hence, was considered to have a sufficient buffer capacity over the entire pH range covered ($7.80<pH<9.00$ in the cobalt(II)-ACAC system, $8.50<pH<9.30$ in the nickel(II)-Glut system).

Results and Discussion

Polarographic Behavior of Nickel(II) and Cobalt(II) Ions in Acetylacetonate Solutions. As is shown in Fig. 1, both nickel(II) and cobalt(II) ions in acetylacetonate solutions exhibited the polarographic steps at potentials where the aquo complexes of these metal(II) ions will give polarographic waves due to their reduction even under the experimental conditions where, from the thermodynamic point of view,[6] all the metal(II) ions may be considered to exist as acetylacetonate complex. The second wave of the nickel(II)-ACAC complex may correspond to its direct reduction. Its limiting current was proportional to the square root of the effective pressure of mercury. At lower solution pH's, the polarographic step corresponding to the direct reduction of cobalt(II)-ACAC complex could also be observed, but this step merges in the base current at higher pH's. The limiting current of the reduction wave of the cobalt(II)-ACAC complex and that of the first wave of the nickel(II)-ACAC complex were almost independent of the effective pressure of the mercury column within the limits of experimental error. Some typical data are given in Table 1. This fact clearly implies that both limiting currents are kinetic-controlled in nature. The polarogram of the cobalt(II)-ACAC complex and the first wave of the nickel(II)-ACAC complex gave linear log-plots ($\log(i/(i_1-i))$ *vs.* E_{dme}) with slopes of about 54 and 57 mV respectively, thus indicating an irreversible two-electron reduction. The results are not shown here. The reduction wave-height of the cobalt(II) ion in the ACAC solution was found to decrease with an increase in the solution's pH or with the concentration of uncomplexed ACAC. In the nickel(II)-ACAC system, although the total wave-height was almost constant under the present experimental conditions, the height of the first wave also decreased with an increase in the solution's pH or in the concentration of uncomplexed ACAC. Considering that the concentration of the deprotonated ACAC anion increases with an increase in the solutions' pH all the facts given above indicate that the first wave of the nickel(II)-ACAC complex and the polarographic step of the cobalt(II)-ACAC complex can be ascribed to the reduction of the uncomplexed metal(II) ion or a lower ACAC complex liberated by the dissociation of nickel(II) and cobalt(II) complexes of ACAC at the mercury electrode surface proceding the electron-transfer step.

Since all the systems studied in this paper contained a large excess of uncomplexed ACAC over the metal(II) ion, the dissociation of metal(II)-ACAC complexes can be treated as a psuedo-first-order reaction. Therefore, as both metal(II) ions form 1:1- and 1:2-ratio ACAC complexes under the present experimental conditions, the reaction mechanism can be written in a simpler form as (A) or (B):

75.0	1.67_3	6.69_3	0.775

$$(A)\quad \begin{cases} A \underset{}{\overset{K_{1a}}{\rightleftharpoons}} B & \text{rapid} \quad (1) \\ B \underset{k_{2a}}{\overset{\vec{k}_{2a}}{\rightleftharpoons}} O & \text{slow} \quad (2) \\ O + 2e^- \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftharpoons}} R & (3) \end{cases}$$

$$(B)\quad \begin{cases} A \underset{\overleftarrow{k}_{1b}}{\overset{\vec{k}_{1b}}{\rightleftharpoons}} O & \text{slow} \quad (4) \\ O + 2e^- \underset{\overleftarrow{k}}{\overset{\vec{k}}{\rightleftharpoons}} R & (3') \end{cases}$$

For the mechanims (A), where (3) is rapid in a polarographic sense, we previously[1] derived the general relations of the limiting current and the current-voltage curve by taking into consideration the diffusion processes of A and B from the bulk of the solution to the electrode surface and that of R from the mercury surface to the inside of mercury, and by assuming the conditions of the stationary state with respect to the concentrations of A, B, O, and R at the electrode surface. Equation (25) in Ref. 1 is applicable to the present systems, in which the (3) process is irreversible, without making any modification. That is, we can use the following relation to examine the nature of the limiting current:

$$\frac{1}{i_l} = \frac{1}{2AF \cdot K_{2a} \cdot D^{1/2} \cdot \vec{k}_{2a}^{1/2} \cdot C_B^0} + \frac{1}{2AF \cdot K^D \cdot C^0} \quad (5a)$$

where C^0 is equal to $C^0_A + C^0_B$ and where all the symbols used have the same meanings as in the previous paper.[1] As is clear from the log-plot slopes, the electron-transfer process (3) is assumed to be irreversible, *i.e.*, $\vec{k} \gg \overleftarrow{k}$, in the present systems. Therefore, Eq. (27) in Ref. 1 should be replaced by the (6_a) relation:

$$E = \text{constant} - \frac{0.0591}{2\alpha} \log \frac{i}{i_l - i} - \frac{0.0591}{4\alpha} \log \overleftarrow{k}_{2a} \quad (6a)$$

For the (B) mechanism, where (3′) is irreversible in nature, we had already derived the theoretical relations for the limiting current and for the current voltage curve.[2] The relations, (16) and (18) or (20), in Ref. 2 can be used without any modification. Thus, for the (B) reaction mechanism we can derive the following two relations:

$$\frac{1}{i_l} = \frac{1}{2AF \cdot K_{1b}^{1/2} \cdot D^{1/2} \cdot \vec{k}_{1b}^{1/2} \cdot C_A^0} + \frac{1}{2AF \cdot K^D \cdot C_A^0} \quad (5b)$$

$$E = \text{constant} - \frac{0.0591}{2\alpha} \log \frac{i}{i_l - i} - \frac{0.0591}{4\alpha} \log \overleftarrow{k}_{1b} \quad (6b)$$

Provided that the other experimental conditions are kept constant, both the polarographic wave of the cobalt(II)-ACAC complex and the first step of the nickel(II)-ACAC system gave excellent linear relations between $1/i_l$ and the $(1+K'_2[X]_f)[X]_f^{1/2}$ value or the $(1+K_2' \cdot [X]_f)/(\alpha_H)_X^{1/2}$ value. Typical results are shown in Figs. 2, 3, and 4. Here, $(\alpha_H)_X$ denotes the apparent (α_H) value of acetylacetone, defined as $1+5\cdot[H^+]/K_a$; K_a, the dissociation constant of the tautomeric enol acetylacetone; $[X]_f$, the concentration of uncomplexed acetylacetone, and K_2', the conditional second successive formation constant of the acetylacetonate complex. The aqueous equilibrium keto : enol ratio was assumed to be approximately four to one.[7] The keto: enol ratio 4:1 suggests that if the ketonization rate of the

enol ACAC, which is the initial product of the protonization of the ACAC anion, is slow, the ACAC anion concentration at the electrode surface will increase with an increase in the current, especially at lower ACAC concentrations. The rapid ketonization was confirmed by following the change in the absorbance at 270 mμ (the absorption maximum of the enol form). When perchloric acid was added to an ACAC solution of pH 10.5, the absorbance decreased so rapidly that we could not determine the ketonization rate exactly by using a conventional method. Since the $[X]_f/(\alpha_H)_X$ and $[M]_t/(1+K_2'\cdot[X]_f)$ values correspond to the concentration of uncomplexed ACAC anion and the bulk concentration of a 1:1 ratio metal(II)-ACAC complex, the above findings evidently show that the reaction mechanism for the first wave of the nickel(II)-ACAC complex can be expressed as:

$$I_a \begin{cases} MX_2^{2-2m} \overset{K_1}{\rightleftharpoons} MX^{2-m} + X^{m-} & \text{rapid} \quad (7) \\ MX^{2-m} \underset{k_f}{\overset{k_d}{\rightleftharpoons}} M^{2+} + X^{m-} & \text{slow} \quad (8a) \\ M^{2+} + 2e^- + Hg = M(Hg) & (9) \end{cases}$$

where X^{m-} means the ACAC anion. For the above reaction mechanism, Eqs. (5a) and (6a) can be rewritten as:

$$\frac{1}{i_l} = \frac{K_1^{1/2}\cdot(1+K_2'\cdot[X]_f)\cdot[X]_f^{1/2}}{2AF\cdot D^{1/2}\cdot k_d^{1/2}\cdot[M]_t\cdot(\alpha_H)_X^{1/2}} + \frac{1}{2AF\cdot K^D\cdot[M]_t} \quad (10a)$$

$$E_{1/2} = \text{constant} - \frac{0.0591}{4\alpha}\log\frac{[X]_f}{(\alpha_H)_X} \quad (10b)$$

As was discussed in the previous paper,[1] theoretically the $2AF\cdot D^{1/2}$ and $2AF\cdot K_d$ values in Eq. (10_a) are identical to $2.51\times10^5\cdot m^{2/3}\cdot t^{2/3}$ and $2\times6.07\times10^4\cdot m^{2/3}\cdot t^{1/6}\cdot D^{1/2}$ respectively. $[M]_t$ in Eq. (10a) signifies the total concentration of the metal(II)-ACAC complex and K_1, the formation constant of a 1:1 ratio metal(II)-ACAC

complex. Equation (10a) suggests that $\Delta E_{1/2}/\Delta\log [X]_f$ and $\Delta E_{1/2}/\Delta \log (\alpha_H)_X$ should be $-0.0591/4\alpha$ and $0.0591/4\alpha$ V respectively. These relations were also examined by using some typical data. The results are shown in Table 2. The agreement between the observed value and that calculated with the aid of Eq. (10b) can be regarded as satisfactory. On the other hand, if the reaction mechanism is written as:

$$I_b \begin{cases} MX_2^{2-2m} + H^+ \rightleftharpoons MX^{2-m} + HX^{1-m} & \text{rapid} \\ MX^{2-m} + H^+ \rightleftharpoons M^{2+} + HX^{1-m} & \text{slow} \\ M^{2+} + 2e^- + Hg = M(Hg) \end{cases}$$

the plot of $1/i_l$ agaist the $(1+K_2'\cdot[X]_f)/(\alpha_H)_X^{1/2}\cdot[H^+]^{1/2}$ value should yield a straight line at a constant $[X]_f$. The curves given in Figs. 3 and 4 completely eliminated the above reaction mechanism. By using the D value of 7.4×10^{-6}, the k_d values for the cobalt(II) and nickel(II)-ACAC complexes were estimated from the slopes of the linear relations shown in Figs. 2, 3, and 4 and listed in Table 3. In both systems, the k_d value determined from the slopes of the linear relation between $1/i_l$ and $(1+K_2'\cdot[X]_f)/(\alpha_H)_X^{1/2}$ agreed well with that determined from the slope of the linear relation between $1/i_l$ and $(1+K_2'\cdot[X]_f)\,[X]_f^{1/2}$. A phosphate buffer used in the nickel(II)-ACAC system to keep the solution pH constant had no effect on the rate of dissociation of the nickel(II)-ACAC complex. Although the K_3 value for the nickel(II)-ACAC complex has been reported by Izatt *et al.*,[8] the possibility of the formation of a 1:3 ratio nickel(II)-ACAC complex could be eliminated by the ion-exchanger test. Under the present experimental conditions, no nickel(II) ion was adsorbed at either the cation or anion exchanger.

	2.8×10^{-4} [10]		

Polarographic Behavior of Nickel(II) Ions in Glutamate, Aspartate, and Iminodiacetate Solutions. As in the cases of the metal(II)-ACAC complexes studied in this paper, the nickel(II) ions in glutamate, aspartate, and iminodiacetate solutions also gave kinetic waves as a result of their dissociation at the electrode surface. Some typical polarograms of the nickel(II)-Asp and -IDA complexes are shown in Fig. 5. Although the polarogram is not shown here, the nickel(II)-Glut complex also gave the two polarographic steps. The limiting currents of the first waves of the nickel(II)-Glut and -Asp complexes and the reduction step of the nickel(II)-IDA complex were almost independent of the effective pressure on the DME, indicating their kinetic nature

(the results are not shown). The second step observed in the nickel(II)-Glut and-Asp systems may be ascribed to the direct reduction of the nickel(II)-Glut and -Asp complexes. In both systems, the total wave-height was almost constant under the present experimental conditions and was exactly proportional to the square root of the effective pressure on the DME. In the case of the nickel(II)-IDA complex, however, the polarographic step corresponding to the direct reduction of the nickel(II)-IDA complex could not be observed (Fig. 5). This

can be ascribed to the inertness of the nickel(II)-iminodiacetate complex. The first waves of the nickel(II)-Glut and -Asp complexes and the reduction wave of the nickel(II)-IDA complex gave linear log-plots with slopes falling in the range from 65 to 75 mV. As in the cases of the cobalt(II)- and nickel(II)-ACAC complexes, all three waves invariably gave linear relations between $1/i_l$ and $(1+K_2'\cdot[X]_f)\cdot[X]_f^{1/2}$ or $(1+K_2'\cdot[X]_f)/(\alpha_H)_X^{1/2}$, with intercepts corresponding to the reciprocal of the total wave-height. Here, K'_2 means the conditional second successive formation constant; $[X]_f$, the concentration of uncomplexed Glut, Asp, or IDA, and $(\alpha_H)_X$, the (α_H) value of Glut, Asp, or IDA. The results are shown in Figs. 6, 7, and 8. The linear relations found in the nickel(II)-Glut and -Asp systems evidently imply that the electrode reaction mechanism for the first waves of these complexes is also given by (I_a), and that the concentration dependence of the half-wave potential is also given by Eq. (10b). Some typical results obtained in the nickel(II)-Asp system are given in Table 4. The shifts of the half-wave potential, as

50.0	−1.118	−24.1	−29

calculated with the acid of Eq. (10b) agreed well with those determined experimentally. As we observed in the acetylacetonate system, curves obtained by plotting the $1/i_l$ against the $(1+K_2'\cdot[X]_f)/(\alpha_H)^{1/2}\cdot[H^+]_X^{1/2}$ also eliminate the proton-assisted reaction mechanism. From the slopes of the linear relations shown in Fig. 6 and 7, the k_d values for the dissociation of the 1:1 ratio nickel(II)-Glut and -Asp complexes were determined to be 1.2_0 (30°C) and $1.2_1\times10^{-2}$ sec^{-1} (25°C) respectively.

As in the case of the nickel(II)-ACAC system, a phosphate buffer mixture had no effect on the wave-height of the nickel(II)-Asp complex. An acetate buffer, however, had a remarkable effect on the wave-height of the nickel(II)-IDA complex. The wave-height was increased remarkably by increasing the concentration of an acetate ion. This indicates that the acetate anion effectively assists the dissociation of the nickel(II)-IDA complex at the electrode surface. Judging from the magnitude of the formation constant of the nickel(II)-acetate complex,[9] an acetate anion can not participate in the formation of a mixed ligand complex of the nickel(II) ion involving an IDA anion under the present experimental conditions. Therefore, the ace-

9) N. Tanaka and K. Kato, This Bulletin, **32**, 516 (1959).

tate ion will help only the dissociation of a 1:1 nickel-(II)-IDA complex at the electrode surface. If the dissociation of a 1:1 nickel(II)-IDA complex proceeds through both the (8b) and (8a) reaction pathways, one can derive Eq. (11) for the limiting current:

$$NiX^0 + Ac^- \overset{(k_d)_{Ac}}{\rightleftharpoons} Ni(Ac)^+ + X^{2-} \quad (8b)$$

$$\frac{1}{i_l} = \frac{K_1^{1/2}\cdot(1+K_2'\cdot[X]_f)\cdot[X]_f^{1/2}}{2AF\cdot D^{1/2}\cdot(k_d^{1/2}+(k_d)_{Ac}^{1/2}\cdot K_{NiAc}^{1/2}\cdot[Ac^-])(\alpha_H)_X^{1/2}\cdot[Ni]_t} + \frac{1}{i_d} \quad (11)$$

where K_{NiAc} denotes the first formation constant of the nickel(II)-acetate complex; $[Ac^-]$, the concentration of the uncomplexed acetate ion, and $[Ni]_t$, the total concentration of the nickel(II)-IDA complex, and where i_d corresponds to the $2AF\cdot K^D\cdot[M]_t$ value in Eq. (10a). From Eq. (11), one can easily derive the following relation.

$$\frac{i_d i_l}{i_d - i}\times\frac{(1+K_2'\cdot[X]_f)\cdot[X]_f^{1/2}}{(\alpha_H)_X^{1/2}} = 2AF\cdot D^{1/2}\cdot[Ni]_t(k_d^{1/2}+(k_d)_{Ac}^{1/2}\cdot K_{NiAc}^{1/2}\cdot[Ac^-]) \quad (12)$$

This relation indicates that the plot of the left-hand side of Eq. (12) against $[Ac^-]$ will give a linear relation, the slope and intercept of which correspond to $2AF\cdot D^{1/2}\cdot[Ni]_t\cdot(k_d)_{Ac}^{1/2}\cdot K_{NiAc}^{1/2}$ and $2AF\cdot D^{1/2}\cdot[Ni]_t\cdot k_d^{1/2}$ respectively, if the dissociation of a 1:1 ratio nickel(II)-IDA complex at the electrode surface proceeds through the two reaction pathways, (8a) and (8b). The above relation was examined by using some typical experimental data. As is shown in Fig. 9, a fairly good linear relation could be obtained. From the slope and intercept of the linear relation in Fig. 9, the $(k_d)_{Ac}$ and k_d values at 30°C were determined to be 3.8×10^{-4} and $3._9\times10^{-4}$ respectively. In a similar way, the k_d value of the nickel(II)-Asp and Glut complexes at 15°C were also determined (Table 3). The k_d value for the nickel(II)-IDA complex determined in this study agrees well with that reported by Bydalek and Constant.[10] This agreement also supports the present author's explanation.

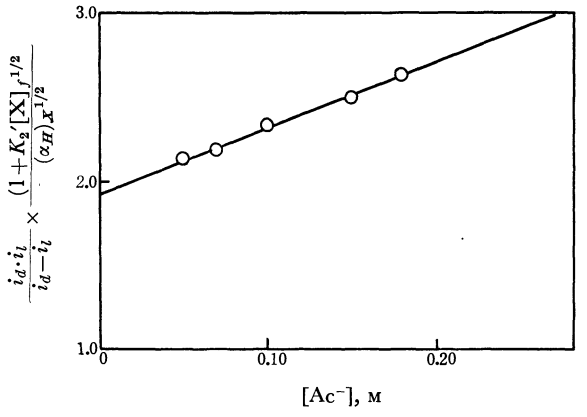

Fig. 9. The plot of $i_d\times i_l\ (1+K_2'[X]_f)[X]_f^{1/2}/(i_d-i_l)\cdot(\alpha_H)_X^{1/2}$ against the acetate ion concentration
The Ni(II) concentration=2.0 mM, 30°C, pH=5.40
The concentration of uncomplexed IDA=20.0 mM

From the $K_1=k_f/k_d$ relation, the formation rate constant, k_f, of the 1:1 ratio cobalt(II)-ACAC complex and that of the 1:1 ratio nickel(II)-ACAC complex were determined to be 6.4×10^5 and 1.7×10^5 $M^{-1}\cdot sec^{-1}$ respectively. These values are nearly identical with the characteristic water exchange rate constants of these metal(II) ions.[11] This fact indicates that, in the formation reaction of both cobalt(II)- and nickel(II)-ACAC complexes with a 1:1 ratio, the dissociation of water from the metal(II) aquo ion is the rate-determining step. The finding that, in the formation of the 1:1 cobalt(II)-ACAC complex, the dissociation of water from the cobalt(II) ion is the rate-determining step is contrary to the prediction of Pearson and Anderson[12] that the steric rearrangement of the ligand will provide the main activation energy barrier (sterically controlled substitution, SCS mechanism) in the formation of a six-membered chelate ring of the cobalt(II) complex. The k_f value for the 1:1 nickel(II)-ACAC complex is slightly larger than the characteristic water-exchange rate constant of the nickel(II) ion. However, this value can also be taken as evidence for the usual water exchange mechanism. Although Pearson and Moor[13] mentioned that the complexation reaction of neutral enol ACAC with the nickel(II) ion is very slow, and explained this slow reaction in terms of the SCS mechanism, there is, as yet, no satisfactory explanation for the distinct difference in the reaction rate between enol ACAC and its anion.

Generally, it is very hard to believe that, in the dissociation of nickel(II)-aminopolycarboxylate complexes, all three bond breakages are involved in the rate-determining step. Furthermore, as the nickel(II)-oxygen bond (carboxylate) breakage is much faster than

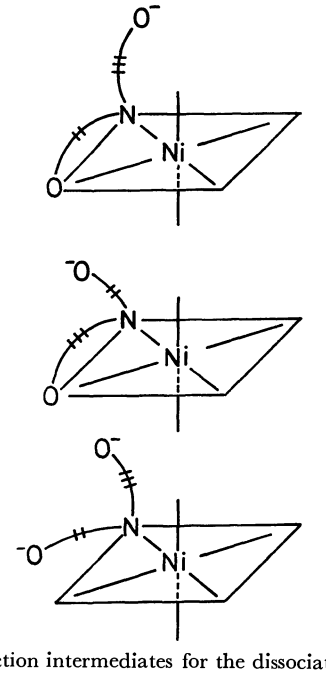

Fig. 10. Reaction intermediates for the dissociation of nickel-(II)-aspartate complex.

10) T. J. Bydalek and A. H. Constant, *Inorg. Chem.*, **4**, 833 (1965).

11) M. Eigen, *Ber. Bunsenges. Physik. Chem.*, **67**, 753 (1963).
12) R. G. Pearson and O. P. Anderson, *Inorg. Chem.*, **9**, 39 (1970).
13) R. G. Pearson and J. W. More, *ibid.*, **5**, 1523 (1966).

the nickel(II)-nitrogen bond (amine) breakage,[14] at least the nickel(II)-nitrogen bond breakage should be involved in the rate-determining step. Therefore, in the case of the nickel(II)-Asp complex, the dissociation can be expected to proceed through one of the following three reaction intermediates (Fig. 10). Here, one can eliminate the I_b reaction intermediate because the six-membered chelate ring is much more labile than the five-membered chelate ring in the substitution reaction of the nickel(II) ion complex. As was discussed by Rorabacher and Margerum,[15] the observed rate constant for the dissociation of the nickel(II)-aspartate complex can be related to the rate constant of the rate-determining step, k_{rds}, and the stability constant of the reaction intermediate prior to the rate-determining step, K_{int}, in the following manner:

$$k_d = \frac{k_{rds} \cdot K_{int}}{K_{MX}} \qquad (13)$$

Here, K_{MX} is the formation constant of the nickel(II)-Asp complex with a 1:1 ratio. With the aid of the above relation, we calculated the k_d values for two reaction intermediates, I_a and I_c. The k_d values calculated for these two reaction intermediates were $1.1_4 \times 10^{-2}$ and 4.5×10^{-3} sec^{-1} respectively. The k_d value estimated on the basis of I_a agrees better with the observed rate constant. In the calculation, the *N*-ethylglycinate and ammine complexes were used as models, and the electrostatic contribution was taken into consideration. The k_{rds} values[16] reported by Hammes and Steinfeld and by Margerum *et al.* were used.

Equation (13) also suggests that, if the dissociation of the nickel(II)-Glut and -IDA complexes proceeds through the glycinate reaction intermediate, as in the case of nickel(II)-Asp complex, the dissociation rate constant should be inversely proportional to the stability constant. The ratio of k_d was compared with that of the reciprocal of the stability constant, K_{MX}^{-1}. The results are shown in Table 5. In the case of the nickel-(II)-IDA system, the statistical factor was also taken into account. The agreement between the k_d ratio and the K_{MX}^{-1} ratio can be regraded as satisfactory. This agreement evidently implies that all three nickel(II)-aminopolycarboxylate complexes studied in this paper dissociate invariably through the reaction intermediate in which the leaving aminopolycarboxylate anion is bonded to the nickel(II) ion through the five-membered glycinate chelate ring, and that, in the dissociation of the nickel(II) ion complex, the six- and seven-membered chelate rings are much more labile than the corresponding five-membered chelate ring.

TABLE 5. RATIOS OF k_d AND K_{MX}^{-1}

System	k_d ratio	K_{MX}^{-1} ratio	log K_{MX} (μ=0.20)

Mixed-ligand Complexes of Copper(II). I. An ESR Study of Coordination Bonding[1]

Hiroshi YOKOI, Masaki OTAGIRI, and Taro ISOBE

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received January 13, 1971)

The sample solutions were prepared by mixing equal volumes of any two of the 1.00×10^{-2} mol/*l* solutions of the 1:2 complexes of copper(II) with ethylenediamine, *N,N*-dimethylethylenediamine, *N,N*-diethylethylenediamine, 1,3-diaminopropane, L-alanine, L-serine, *N,N*-diethylglycine, and *β*-alanine, where an equivolume mixture of water and methanol was used as the solvent. The X-band ESR measurements for these sample solutions were carried out at the temperature of liquid nitrogen. The observed ESR line shapes showed that only the mixed-ligand complexes are formed almost quantitatively in all the solutions except two: equivolume mixtures of the two complex solutions of ethylenediamine and *β*-alanine and those of ethylenediamine and *N,N*-dimethylglycine, in which the coexistence of two or more complex species was clearly demonstrated. The ESR line shapes and, furthermore, the intensities of the visible absorption indicated that the symmetry of the ligand field of the mixed-ligand complexes is as axial as that of the parent complexes. The ESR experimental results showed that the $g_{//}$ value of a mixed-ligand complex almost equals the mean of the $g_{//}$ values of its two parent complexes, but that there is not such a clear correlation between their $A_{//}$ values. It was interestingly concluded from the determined g values that the covalency of the metal-ligand bonds of a mixed-ligand complex are intermediate in degree between those of its two parent complexes.

Studies of mixed-ligand complexes from various angles have become very important in recent years, since mixed-ligand complexes occur during transition states of metal-ion-catalyzed reactions,[2] since they are important in analytical chemistry,[3] and since they can be regarded as models for metalloenzyme-substrate complexes.[4,5] Investigations of their stability in solutions, furthermore, are considered to be important in establishing a more advanced theory as to the stability of metal-ion complexes. Most studies of mixed-ligand complexes have so far been concerned with their stability.[6-10]

Recently, Farona *et al.* published a paper about the coordination bonding of mixed-ligand complexes, an investigation where various *β*-diketone chelate complexes of copper(II) were prepared and studied by the infrared, visible absorption, and ESR methods in connection with the parent complexes.[11] The ESR technique is effective in obtaining useful information about coordination, namely, about the strength and symmetry of the ligand field, in copper(II) complexes.[12] The purpose of this paper is to investigate more systematically the coordination of mixed-ligand complexes in connection with that of the parent complexes, using the ESR method, and using as the parent complexes the 1:2 chelate complexes of copper(II) with ethylenediamine, its alkyl derivatives, 1,3-diaminopropane, and various amino acids.

Experimental

Materials. The sample complexes, which were used as parent complexes in this study, were prepared according to the methods in the literature,[13,14] were recrystallized from water or methanol, and were identified by elemental analysis.[15-17] They are listed in Table 1. All of the reagents used were commercially available.

ESR and Optical Measurements. 1.00×10^{-2} mol/*l* solutions of the complexes listed in Table 1 were prepared by using an equivolume mixture of water and methanol as the solvent. These solutions were directly used as the samples of the parent complexes themselves, while equal volumes of any two of them were mixed and used as the samples of the mixed-ligand complexes. The ESR spectra of these samples were measured at the temperature of liquid nitrogen with a Hitachi X-band ESR spectrometer, Model MES-4001, equipped with a 100 kHz field modulation unit. The field was calibrated with an NMR probe and then with a benzene solution of vanadyl acetylacetonate. Some of the observed ESR spectra are shown in Figs. 1—4. The optical absorption spectra were measured at room temperature for the same sample solutions with a Hitachi spectrophotometer, Model

Results and Discussion

Complex Species in Solution. When two kinds of copper(II) complexes with bidentate ligands are dissolved to make a solution, the following equilibrium is generally established in the solution:[6-8)]

$$CuA_2 + CuB_2 \rightleftharpoons 2CuAB \quad (1)$$

$$K = \frac{[CuAB]^2}{[CuA_2][CuB_2]} \quad (2)$$

where CuA_2 and CuB_2 represent parent complexes, and CuAB, a mixed-ligand complex. The relative amounts of the three complexes in the solution, therefore, vary according to the *K* value.

The ESR line shape of a single complex species of copper(II) complexes in the rigid solution has been

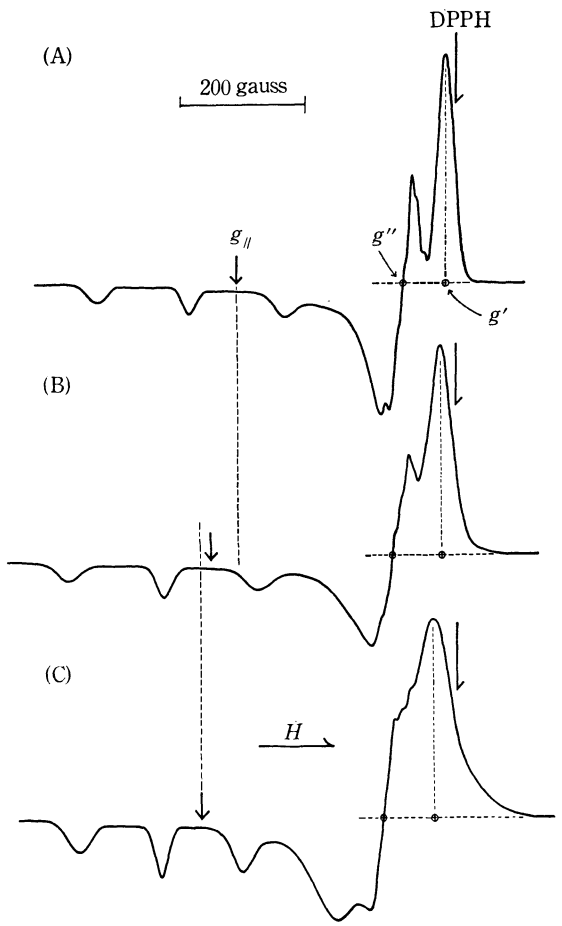

Fig. 3. The X-band ESR spectra of solution samples (measured at 77°K, Solvent: an equivolume mixture of water and methanol).

studied by several authors.[18,19] If two different complex species of copper(II) complexes coexist independently in the solution, the observed ESR spectrum will be made up of the superposition of their individual ESR spectra. Judging from the line shape, the ESR spectra of (B) in Figs. 1—3 can be said to be almost all due to a single complex species; furthermore, the absorption lines are different in position from those of the parent complexes. It can, therefore, be concluded that almost all the (B) spectra of Figs. 1—3 are due to mixed-ligand complexes; only mixed-ligand complexes are formed quantitatively in these systems. Such is the case with all the other sample solutions except two. The ESR spectra of these two exceptional solutions are shown in Fig. 4; the details in these cases will be discussed in the next paper of this series.[20] The line shapes in Fig. 4 clearly demonstrate that two or more complex species coexist in these solutions; this can, in short, be attributed to the comparatively small K values. However,

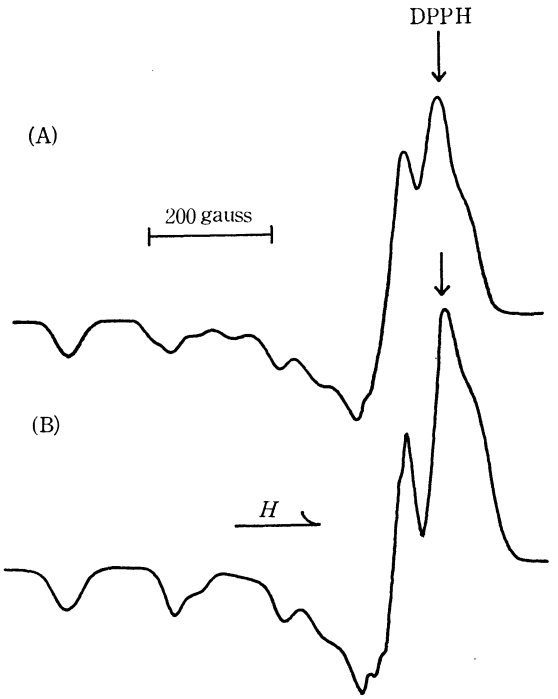

Fig. 4. The X-band ESR spectra of solution samples (measured at 77°K, Solvent: an equivolume mixture of water and methanol).

whether or not this ESR method is effective for the identification of two or more complex species in the solution depends upon the degree of separation between the absorption lines of different complex species, their line widths, and the value of K. If the K value is more than about 20, the identification of the parent complexes seems to be almost impossible for solutions with such broad line widths and such small line separations as those shown in Figs. 1—3.[20]

Symmetry of Ligand Field. When the three principal g values are designated in the order of increasing magnitude as g_1, g_2, and g_3, the axial symmetry of ligand field means that $g_1=g_2<g_3$. All the observed ESR spectra of mixed-ligand complexes were similar to each other in absorption line shape, as the several ESR spectra shown in Figs. 1—3 show; they all have an intense absorption line in the high-field part and three or four very weak absorption lines in the low-field part. It can be concluded from a theoretical consideration of the ESR line shape that the copper(II) complexes showing this type of line shape are of axial or near axial symmetry in the ligand field; all the mixed-ligand complexes dealt with in this study are approximately square-planar (tetragonal) complexes in a solution.[18,19]

When the g values at the positions of the two circles in Figs. 1 and 3 are designated as g' and g'', whose values are listed in Tables 2 and 3, these g values may be used as a measure in comparing the symmetry of the ligand field between the mixed-ligand complexes and the parent complexes, although this method of comparison is accompanied by somewhat complicated factors due to the hyperfine and extra-hyperfine structures.[17,18]

a) The sample solution of two numbers hyphened together represents an equivolume mixture of the solutions of the numbers referred to in Table 1.
b) Those g values correspond to the ones at the positions shown in Figs. 1 and 3.
c) The numbers in parentheses represent the ones of pure mixed-ligand complexes determined by spectrophotometrical analysis, which will be described in our next paper of this series.[20)]
d) The ESR data could not be obtained for this mixed-ligand complex.

$\Delta g'$ and $\Delta g''$ are defined as follows:

$$\Delta g' = g'(\mathrm{M}) - g'(\mathrm{P_s})$$

$$\Delta g'' = g''(\mathrm{P_l}) - g''(\mathrm{M})$$

where $g'(\mathrm{M})$ and $g''(\mathrm{M})$ are the g' and g'' values respectively of a mixed-ligand complex, and where $g'(\mathrm{P_s})$ is the smaller value of the two g's of its parent complexes, and $g''(\mathrm{P_l})$, the larger value of the two g''s of the parent complexes. This, therefore, means that if $\Delta g' > 0$ and $\Delta g'' > 0$ for a mixed-ligand complex, the intense

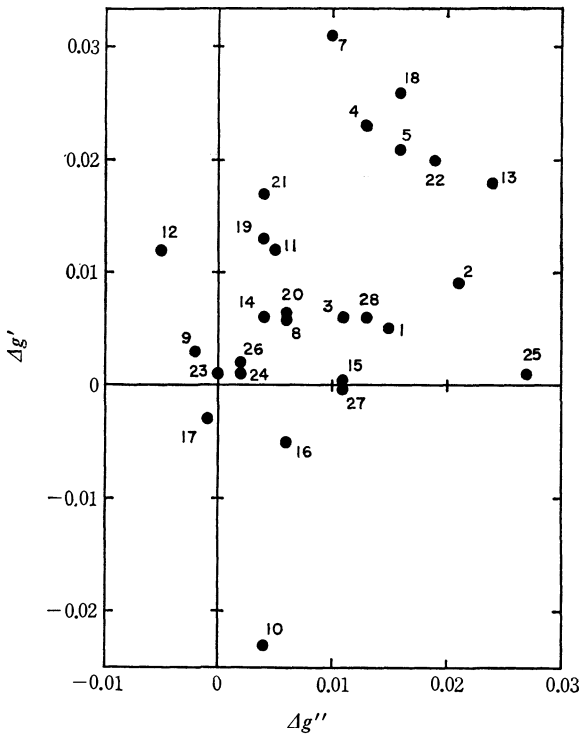

Fig. 5. A plot of $\Delta g'$ against $\Delta g''$ for mixed-ligand complexes (the description of $\Delta g'$ and $\Delta g''$ is given in the text, and the number of each point on the figure is the one referred to in Table 3).

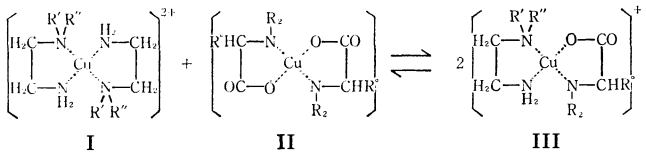
absorption line in the high-field part of the complex appears at a position intermediate between those of its parent complexes. The experimental results are shown in Fig. 5, where most of the mixed-ligand complexes appear in the plus range of both $\Delta g'$ and $\Delta g''$. This fact indicates that the axial symmetry of the ligand field for the mixed-ligand complexes is kept at least in almost the same degree as for their parent complexes. This result is also supported by the intensity data of the visible absorption spectra. As may be seen in Tables 2 and 3, the $\varepsilon_{\lambda max}$ values of almost all the mixed-ligand complexes were intermediate between those of the corresponding two parent complexes, and none of the sample solutions had abnormal band widths; the dipole strengths of transition of the mixed-ligand complexes were intermediate between those of the parent complexes. The details will soon be published elsewhere. This spectral fact suggests that the mixed-ligand complexes are not much lower in the symmetry of their ligand fields than are the parent complexes, since it has generally been believed that the intensity of the visible absorption spectrum of a copper(II) complex always increases as the symmetry of the ligand



I II III

Fig. 6. A schematically represented example of the equilibrium of Eq. (1).

Table 4. Symmetry

Copper-(II) complex[a)]	Coordination groups	Assumed ligand field	Actual ligand field[b)]
I	D_{2h}	D_{2h}	near axial
II	D_{2h}	D_{2h}	near axial
III	no symmetry	no symmetry	near axial

a) The numbers of the copper(II) complexes are the ones referred to in Fig. 6.
b) Judged from the observed ESR line shapes.

field of the complex descends.[21,22]

When a typical representative example of Eq. (1) is schematically shown in Fig. 6, therefore, the symmetries of the coordinating groups and ligand field for each of the complexes in it can be expressed as is shown in Table 4. Accordingly, the symmetry of the ligand field does not coincide with the apparent symmetry of the coordinating groups, and the symmetry of the ligand field of the planar copper(II) complexes seems to be kept in a high degree, regardless of the different kinds of coordinating groups.

$g_{//}$ *and* $A_{//}$. According to the ligand field theory of a tetragonal copper(II) complex (D_{4h} symmetry assumed), the following antibonding molecular orbitals, in the order of increasing energy, can be formed for the "hole" configuration[23-25]:

$$\begin{aligned}
\varphi_{b_{1g}} &= \alpha d_{x^2-y^2} - \alpha' \phi_L(x^2-y^2) \\
\varphi_{b_{2g}} &= \beta_1 d_{xy} - \beta_1' \phi_L(xy) \\
\phi_{a_{1g}} &= \alpha_1 d_{z^2} - \alpha_1' \phi_L(z^2) \\
\varphi_{e_g} &= \begin{cases} \beta d_{xz} - \beta' \phi_L(xz) \\ \beta d_{yz} - \beta' \phi_L(yz) \end{cases}
\end{aligned} \tag{3}$$

In each of the wavefunctions, the ϕ_L in the second term on the right-hand side represents the ligand orbital which can be mixed with the copper d orbital expressed in the first term. The magnetic parameters can then be expressed approximately as follows:

$$\begin{aligned}
g_{//} &= 2 - \frac{8\lambda}{\Delta E_{xy}}(\alpha^2\beta_1^2 - f_1) \\
g_{\perp} &= 2 - \frac{2\lambda}{\Delta E_{xz}}(\alpha^2\beta^2 - f_2)
\end{aligned} \tag{4}$$

$$\begin{aligned}
A_{//} &= P\left[-\frac{4}{7}\alpha^2 - \kappa + (g_{//}-2) + \frac{3}{7}(g_{\perp}-2) + f_3\right] \\
A_{\perp} &= P\left[\frac{2}{7}\alpha^2 - \kappa + \frac{11}{14}(g_{\perp}-2) + f_4\right]
\end{aligned} \tag{5}$$

where $P=2\gamma\beta_0\beta_N\langle d_{x^2-y^2}|r^{-3}|d_{x^2-y^2}\rangle$, $\Delta E_{xy}=E_{xy}-E_{x^2-y^2}$, and $\Delta E_{xz}=E_{xz}-E_{x^2-y^2}$, and where f_1—f_4 are small and almost constant values for a variety of copper(II) complexes ($f_1, f_2 \leq 0.04$, $f_3 \leq 0.03$, and $f_4 \leq 0.005$).[15,24,25]

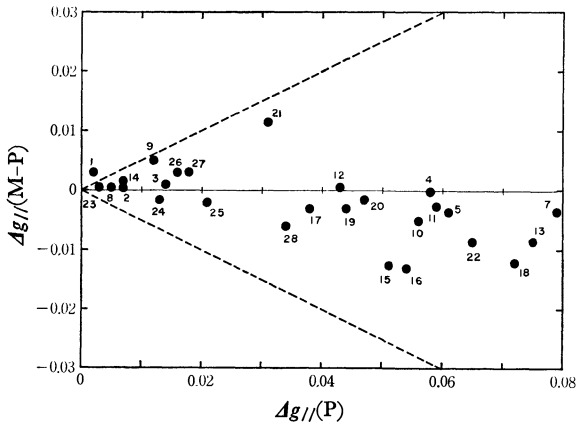

Fig. 7. A plot of $\Delta g_{//}$(M–P) against $\Delta g_{//}$(P) for mixed-ligand complexes.
$\Delta g_{//}(\mathrm{M-P}) = g_{//}(\mathrm{M}) - 1/2(g_{//}^{P_1} + g_{//}^{P_2})$
$\Delta g_{//}(\mathrm{P}) = |g_{//}^{P_1} - g_{//}^{P_2}|$
where $g_{//}$(M), $g_{//}^{P_1}$, and $g_{//}^{P_2}$ are the $g_{//}$ values of a mixed ligand complex, and its two parent complexes, P_1 and P_2, respectively. The numbers for the mixed-ligand complexes in Table 3 are employed on this figure.

The experimentally-determined $g_{//}$ and $A_{//}$ values are listed in Tables 2 and 3. The correlation between the $g_{//}$ values of the mixed-ligand complexes and those of the parent complexes is shown in Fig. 7, where, for a mixed-ligand complex, the absolute difference between the $g_{//}$ values of its two parent complexes, $g_{//}^{P_1}$ and $g_{//}^{P_2}$, is indicated on the abscissa ($\Delta g_{//}$(P)), and the difference between the $g_{//}$ value of the mixed-ligand complex, $g_{//}$(M), and the mean of $g_{//}^{P_1}$ and $g_{//}^{P_2}$, on the ordinate ($\Delta g_{//}$(M–P)). The dotted lines on this figure express the $g_{//}$ values of two parent complexes against any point of the abscissa. If $\Delta g_{//}$ (M–P)$=0$ for a mixed-ligand complex, accordingly, its $g_{//}$ value exactly equals the mean of the two $g_{//}$ values of its parent complexes. This figure clearly shows that the $g_{//}$ values of the mixed-ligand complexes dealt with here are almost equal to the average $g_{//}$ values of the parent complexes.

As to the $A_{//}$ value, a graph was prepared in a similar manner; it is shown in Fig. 8. This figure, however, shows that the points scatter over a considerably wide range, and such a regularity as is indicated for the $g_{//}$

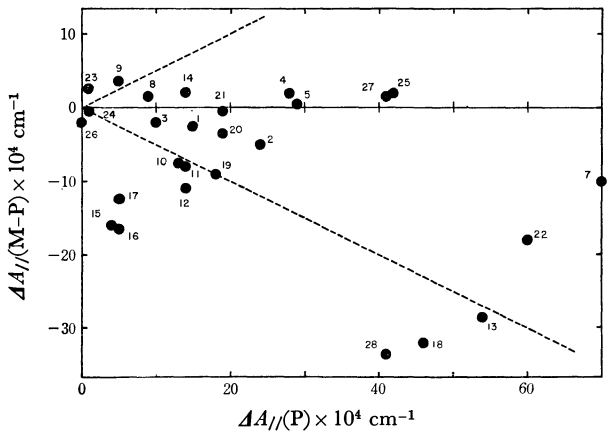

Fig. 8. A plot of $\Delta A_{//}$(M–P) against $\Delta A_{//}$(P) for mixed-ligand complexes ($\Delta A_{//}$(M–P) and $\Delta A_{//}$(P) are expressed in the similar equations to $\Delta g_{//}$(M–P) and $\Delta g_{//}$(P) respectively).

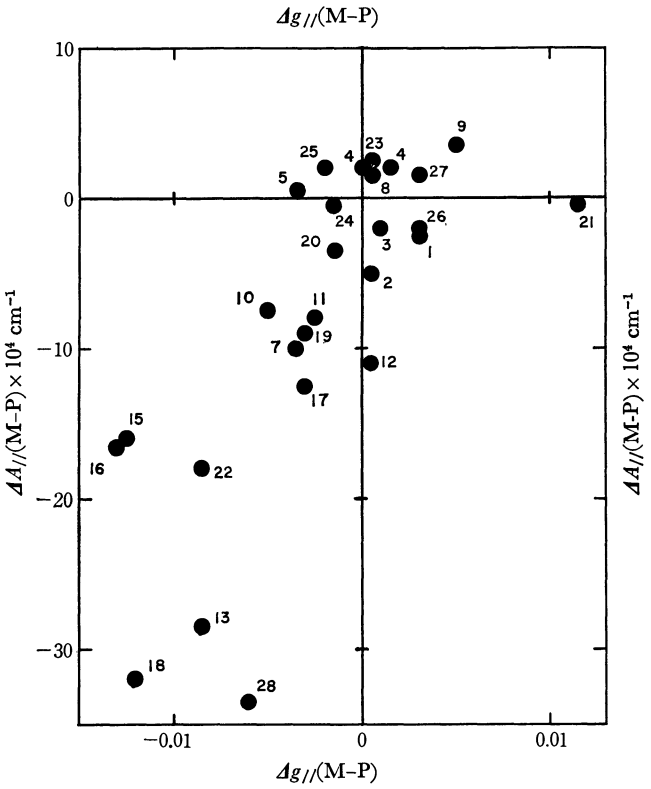

Fig. 9. A plot of $\Delta A_{//}$(M–P) against $\Delta g_{//}$(M–P) for mixed-ligand complexes.

value is difficult to find. As an experiment, $\Delta A_{//}$ (M–P) was plotted against $\Delta g_{//}$(M–P) (cf. Fig. 9). A rough tendency for $\Delta A_{//}$(M–P) to decrease with the decrease of $\Delta g_{//}$(M–P) seems to be found in this figure, but this tendency can not be understood only in terms of Eqs. (4) and (5) at the present stage.

Coordination Bonding. At present, the hyperfine parameters are less rigorously related to the structure than are the g values, since the hyperfine parameters depend in complicated ways upon the core spin polarization and, furthermore, upon the $4s$ orbital spin polarization and the p-electron admixture, and since a definite relation between these effects and the covalency of metal-ligand bonds has not yet been established.[26–32] It seems, accordingly, that much reliance can not be placed on Eq. (5). The degree of the covalency, therefore, is estimated only from the g values in this work.

Equation (4) is rewritten as follows:

$$g_{//} = 2 - \frac{8\lambda k_{//}^2}{\Delta E_{xy}} \qquad (6)$$

where $k_{//}^2$ is the orbital reduction factor, relating to the bonding parameters, mainly α^2 and β_1^2. The ligand-field energy of ΔE_{xy} must, then, be estimated in order to determine the value of $k_{//}^2$ from Eq. (6). However, it is not easy to estimate this energy value exactly for the copper(II) complexes with a single broad absorption band in the visible region. Amines and amino acids are arranged in a near position in the spectrochemical series.[33] It seems, therefore, quite likely that all the complexes employed here are similar in the spacing of the energy levels of the *d*-orbitals. Accordingly, we assumed in this study that the ratio of the energy value of ΔE_{xy} to that of the wavelength of maximum absorption is almost constant for the complexes. The observed wavelengths of λ_{max} for all the 1—28 solutions listed in Table 3 except for the 6 and 7 solutions are considered to be nearly equal to those of mixed-ligand complexes themselves, as has been demonstrated in Table 3 by some examples, since the values of K are quite large for those mixed-ligand complexes, which we will discuss in the next paper in this series.[20] The above-mentioned assumption is the same as that the energy of λ_{max} may be directly used in comparing the complexes with each other in terms of the relative values of $k_{//}^2$. The $k_{//}^2$ values thus determined from Eq. (6) for all the mixed-ligand complexes are illustrated graphically in Fig. 10 in a manner similar to that in Figs. 7 and 8. The dotted lines on Fig. 10 also represent the two $k_{//}^2$ values of the parent complexes. It is clear in this figure that most of $k_{//}^2$ values of the mixed-ligand complexes are very close to the mean of the $k_{//}^2$ values of the corresponding parent complexes. It can, furthermore, easily be understood on a simple calculation that, even if the ligand-field energies of the mixed-ligand complexes vary widely from those of the parent complexes, most of the mixed-ligand complexes become intermediate in $k_{//}^2$ value between the parent complexes. Although $k_{//}^2$ is connected with the in-plane bondings, such may be the case with the out-of-plane bondings, judging from the results shown in Fig. 5.

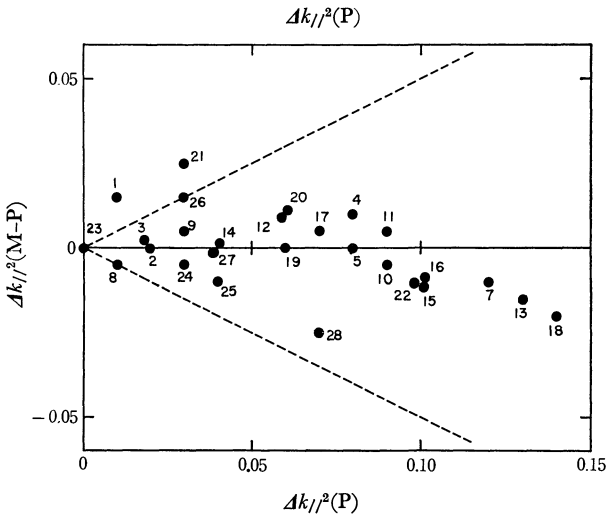

Fig. 10. A plot of $\Delta k_{//}^2$(M–P) against $\Delta k_{//}^2$(P) for mixed-ligand complexes ($\Delta k_{//}^2$(M–P) and $\Delta k_{//}^2$(P) are expressed in the similar equations to $\Delta g_{//}$(M–P) and $\Delta g_{//}$(P) respectively).

All the above facts suggest that, as to the metal-ligand bonds, the covalency of a mixed-ligand complex is close in degree to the mean of those of the parent complexes. It follows in Eq. (1) that, when the M–A bond is stronger than the M–B bond in the parent complexes, the M–A bond becomes weaker and the M–B bond stronger in the mixed-ligand complex than in the parent complexes; that is, the M–A and M–B bonds become close together in bond strength in a mixed-ligand complex.

Mixed-ligand Complexes of Copper(II). II. A Study of Dismutation Constants

Hiroshi Yokoi, Masaki Otagiri, and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received January 27, 1971)

The dismutation constants for mixed-ligand complexes of copper(II) involving, as bidentate ligands, ethylenediamine, L-alanine, β-alanine, and *N,N*-dimethylglycine were determined at two or three temperatures by both the spectrophotometric and ESR methods, and the thermodynamic constants were then derived from those data. It was found for these systems that the entropy change plays a main role in governing the equilibrium between a mixed-ligand complex and its parent complexes, and that the differences in the dismutation constants among the mixed-ligand complexes are due to the small but different values of the enthalpy term.

When two kinds of stable copper(II) complexes with bidentate ligand (A and B) are dissolved in a solvent, the following kind of equilibrium is generally established in the solution:

$$CuA_2 + CuB_2 \rightleftharpoons 2CuAB \quad (1)$$

$$K = \frac{[CuAB]^2}{[CuA_2][CuB_2]} \quad (2)$$

The reciprocal of K is designated by Watters *et al.* as the dismutation constant.[1] The studies of the equilibrium and of the coordinate bond for the mixed-ligand complexes seem to be important in coordination chemistry and in biochemistry, since these studies are concerned with extending such a fundamental concept as soft and hard acids and bases,[2] and since the mixed-ligand complexes are regarded as models for metalloenzyme-substrate complexes.[3,4] Furthermore, the complexes are important in analytical chemistry and in synthetic reactions catalyzed by metal ions.[5,6] Many studies of mixed-ligand complexes have been mainly concerned with their stability.[1,7-10]

In a previous paper,[11] we reported on an ESR study of the coordinate bond for mixed-ligand complexes with comparatively large K values, using, as bidentate ligands, ethylenediamine, its analogues, and amino acids. We pointed out that, for the two systems with ethylenediamine and β-alanine as A and B in Eq. (1) and with ethylenediamine and *N,N*-dimethylglycine, two or three complex species can clearly be identified from the ESR spectra in the solution, since the K values of these systems are comparatively small. The purpose of this paper is to investigate in full detail, by the use of both the spectrophotometric and ESR techniques, what factors govern the above-mentioned equilibrium, using as the parent complexes the 1:2 complexes of copper(II) with ethylenediamine, L-alanine, β-alanine, and *N,N*-dimethylglycine.

Experimental

The copper(II) complexes employed in this work, which had been prepared and purified in a previous work,[11] were $[Cu(en)_2](ClO_4)_2$, $[Cu(L\text{-}Ala)_2]$, $[Cu(\beta\text{-}Ala)_2]\cdot 6H_2O$, and $[Cu(dmg)_2]\cdot 3H_2O$, where en, L-Ala, β-Ala, and dmg are ethylenediamine and the anions of L-alanine, β-alanine, and *N,N*-dimethylglycine respectively. The sample solutions for the ESR and optical absorption measurements were 1.00×10^{-2} mol/l solutions of these four complexes and mixtures of any two of the solutions at various volume ratios, with an equivolume mixture of water and methanol being used as the solvent.

The ESR spectra of these sample solutions were measured at the temperature of liquid nitrogen with a Hitachi X-band ESR spectrometer, Model MES-4001, equipped with a 100 kHz field modulation unit. The field was calibrated with an NMR probe, and then with a benzene solution of vanadyl acetylacetonate. The optical absorption spectra were measured at temperatures of 20 and 50°C with a Hitachi spectrophotometer, Model EPS-3T, in the range from 340 to 700 mμ, using 10-mm quartz cells.

Results

The 1.00×10^{-2} mol/l solutions (solvent: an equivolume mixture of water and methanol) of $[Cu(en)_2](ClO_4)_2$, $[Cu(L\text{-}Ala)_2]$, $[Cu(\beta\text{-}Ala)_2]\cdot 6H_2O$, and $[Cu(dmg)_2]\cdot 3H_2O$ will hereafter be designated as Systems

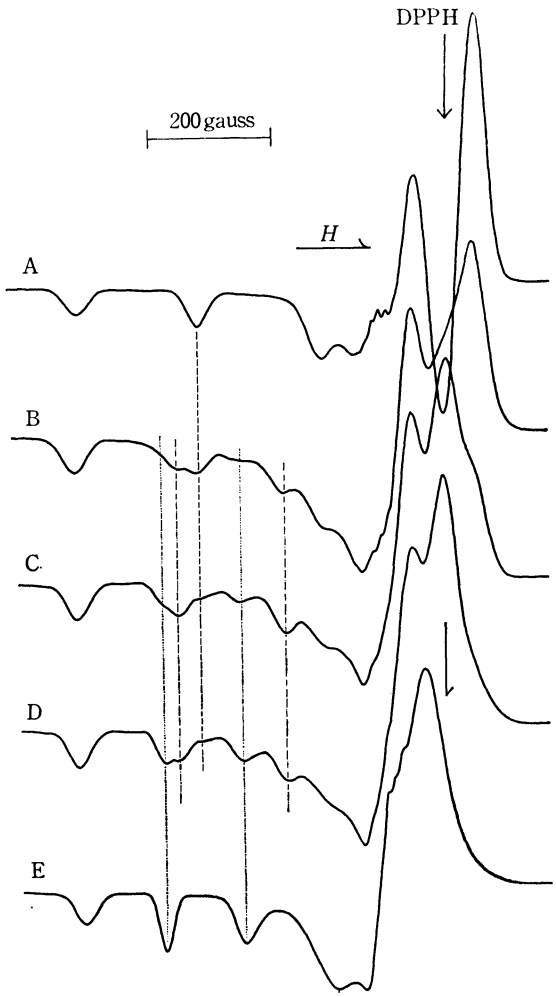

Fig. 1. The X-band ESR spectra (measured at 77°K, 1.00×10^{-2} mol/l per copper atom, Solvent: an equivolume mixture of water and methanol) of the mixed solutions of $[Cu(en)_2]^{2+}$ and $[Cu(\beta\text{-Ala})_2]$ at the following molar ratios: (A) 1 : 0, (B) 2 : 1, (C) 1 : 1, (D) 1 : 2, and (E) 0 : 1. Each of the vertical lines shown at the low field part locates an absorption line due to one of the three molecular species.

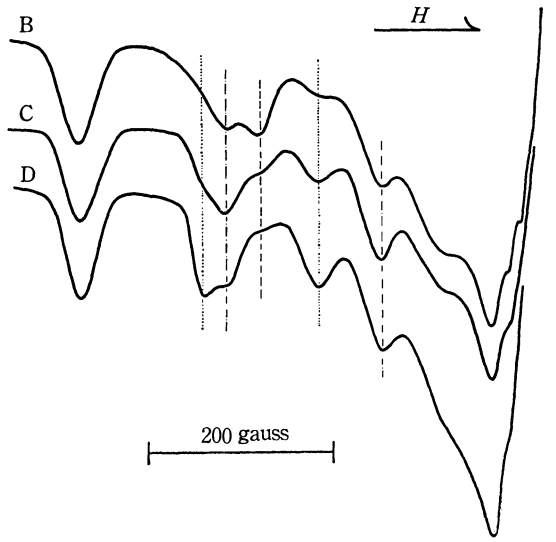

Fig. 2. Some of the enlarged ESR spectra of Fig. 1 at the low field part (the spectral names and the vertical lines are those referred to in Fig. 1).

I, II, III, and IV. The mixture of I and II, for example, is described as System I–II, and the volume ratio in the mixture is affixed to this expression in parentheses.

Determination of K by ESR. The ESR spectra of Systems I–II (1:1) and II–III (1:1), measured at the temperature of liquid nitrogen, which had already been presented in a previous paper,[11] indicated that the mixed-ligand complexes are almost quantitatively formed in the solution of these systems, and it was expected that the K values for these systems would be comparatively large. Attention must, however, be paid to the fact that the K values under discussion are determined at a certain temperature immediately before the sample solutions freeze in liquid nitrogen (sample glass tubes about 4 mm in diameter are directly immersed in liquid nitrogen in this study). Since the exact freezing temperature of these solutions on such rapid cooling is unknown, the temperature was assumed to be about −100°C in this work.[12] On the other hand, it was reported in a previous paper that the ESR spectra of Systems I–III (1:1) and I–IV (1:1) are not due to a single complex species, suggesting that the K values of these systems are remarkably small as compared with those of other systems.[11] In this study we made an attempt to determine the K values for these two systems from the ESR spectra, as will be described below.

The ESR spectra of System I–III at various volume ratios are shown in Fig. 1, while the enlarged spectra in the low-field part of Fig. 1 are shown in Fig. 2. These two figures clearly indicate that the ESR spectra are made up of the superposition of three different spectra; three complex species coexist in System I–III. It can easily be understood that the three complex species correspond to the two parent complexes and one mixed-ligand complex. If the molar ratio of these three complexes can be properly estimated from the ESR spectra, the K value can be calculated using Eq. (2). The hyperfine absorption lines of $I_z=-1/2$ for the three complexes appear near the base line in the low-field part, this fact being a factor in attaining greater accuracy in the following analysis, and the lines are superposed to a moderate extent upon each other, whereas the absorption lines of $I_z=-3/2$ overlap to too complete a degree to be analyzed. The most reasonable method for analyzing the ESR spectra with the aim of determining the molar ratio, therefore, seems to consist in resolving the spectral part of the overlapping absorption lines of $I_z=-1/2$ into the corresponding three components, and then in properly deriving the molar ratio from the resolved spectra.

It was assumed that the observed ESR line shape can

12) The freezing temperature of the equivolume mixture of water and methanol is −47°C ("The Merck Index," eighth edition ed. by P. G. Stecher, Merck & Co., Inc., New Jersey, U.S.A. (1968), p. 671). The freezing temperature of the sample solutions under discussion, however, is considered to be further lowered to a very large extent on such extremely rapid cooling as we adopted, since it has been reported that, when the cooling rate is increased, the freezing temperature of water is lowered owing to the phenomenon of supercooling (I. E. Kuhns and B. J. Mason, *Proc. Roy. Soc.* (London), **A302**, 437 (1968)).

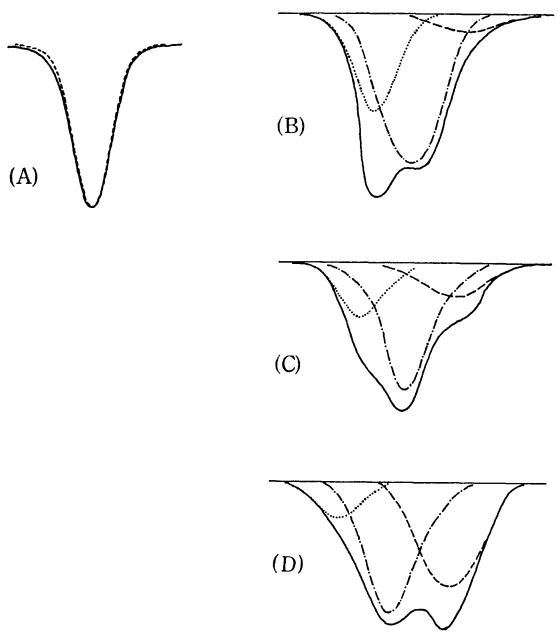

Fig. 3. The overlapping hyperfine absorption lines of $I_z=-1/2$ resolved into three components by the Gaussian analysis for the mixed solutions of $[Cu(en)_2]^{2+}$ and $[Cu(\beta\text{-Ala})_2]$ at the following molar ratios: (A) 0 : 1, (B) 1 : 2, (C) 1 : 1, and (D) 2:1.

be approximated by the following Gaussian curve:

$$S_i(H) = b\exp(-a^2(H_i^\circ - H)^2)$$
$$a = \sqrt{2}/\Delta H_i^{msl},$$
$$b = \sqrt{2/\pi}/\Delta H_i^{msl},\ \Delta H_i^{msl} = \Delta H_i/1.386$$

where ΔH_i is the half-width; ΔH_i^{msl}, the separation between the points of the maximum and minimum slopes, and H_i°, the magnetic field at the center of an absorption line, i. In order to check whether or not the Gaussian curve can simulate the observed absorption lines of $I_z=-1/2$ with a good approximation, the observed absorption line of System III was compared with a Gaussian curve; the results are shown in Fig. 3 (A). This figure suggests that the observed spectra can be analyzed by the Gaussian curves with a fairly good approximation.

The values of ΔH_i for the absorption lines of $I_z=-1/2$ of $[Cu(en)_2]^{2+}$ and $[Cu(\beta\text{-Ala})_2]$ were determined from their ESR spectra to be 17 and 12.5 gauss respectively. Some of the results obtained by this analysis are shown in Fig. 3, using 15 gauss as the ΔH_i value of the mixed-ligand complex. It is, furthermore, assumed that the molar ratio of the three complexes is approximately proportional to the ratio of the integrated intensities of the corresponding resolved Gaussian curves. This seems to be a reasonable assumption, since the three complexes are not extremely different from each other in their magnetic parameters. The ESR spectra of System I–IV, some of which are shown in Fig. 4, were analyzed in a similar way. The analysis for this system, however, was more difficult than for

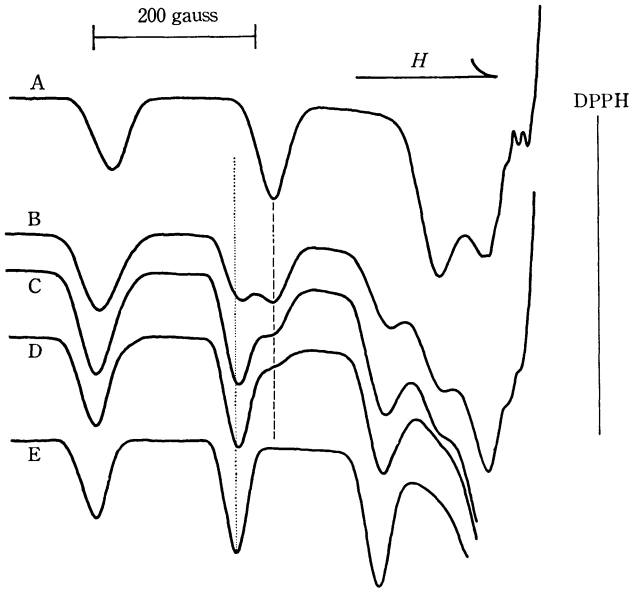

Fig. 4. The X-band ESR spectra (measured at 77°K, 1.00×10^{-2} mol/l per copper atom, Solvent: an equivolume mixture of water and methanol) of the mixed solutions of $[Cu(en)_2]^{2+}$ and $[Cu(dmg)_2]$ at the following ratios: (A) 1 : 0, (B) 2 : 1, (C) 1 : 1, (D) 1 : 2, and (E) 0 : 1. The absorption line of $I_z=-1/2$ of the mixed ligand complex, the location of which is not apparent in the line shape, appears between the two vertical dotted lines on the figure.

System I–III, since the magnetic parameters of the three complexes for the former system were closer to each other and its K value was much smaller. It seems, therefore, that the error accompanying this analysis in System I–IV will inevitably become larger. All the results obtained are listed in Tables 1 and 2, together with the calculated values of $\log K$. It seems that much reliance can be placed on this ESR method, since the determined values of $\log K$ were held constant to a considerable extent for all the mixtures at various volume ratios.

Determination of K by Optical Absorption. The values of K were also determined at temperatures of 20 and 50°C by optical absorption measurements according to the Kida method.[7] Some of the observed spectra for Systems I–II and I–III are shown in Figs. 5 and 6 respectively. The spectral measurements for System II–III was carried out only at 20°C in a similar way; an especially careful experiment was required in order to obtain the exact isosbestic points, since the parent complexes are comparatively close to each other in the wavelength and the intensity of the maximum absorption. All the results obtained are listed in Tables 3—6, together with the calculated values of $\log K$.

Discussion

All the values of log K are summarized in Table 7; the values of K for Systems I–II, I–III, I–IV, and II–III are about 26, 6, 1, and 17 respectively. The K values of the second and third systems are comparatively smaller than those of the others. This is consistent with the following ESR result: the coexistence of three complex species for Systems I–III and I–IV was clearly established by a study of their ESR spectra. On the other hand, for Systems I–II and II–III the ESR absorption lines due to the parent complexes are very

Table 7. The value of log K

Temperature (°C)	System[a] I–II	I–III	I–IV	II–III
50	1.38±0.02	0.80±0.03	0.15±0.03	——
20	1.44±0.02	0.78±0.04	0.14±0.03	1.24±0.03
ca. −100[b]	——	0.79±0.10	−0.45±0.15	——

a) Systems I–II, I–III, I–IV, and II–III were designated as the mixed solutions of $[Cu(en)_2]^{2+}$ and $[Cu(L\text{-}Ala)_2]$, of $[Cu(en)_2]^{2+}$ and $[Cu(\beta\text{-}Ala)_2]$, of $[Cu(en)_2]^{2+}$ and $[Cu(dmg)_2]$, and of $[Cu(L\text{-}Ala)_2]$ and $[Cu(\beta\text{-}Ala)_2]$ respectively.
b) See the text.

difficult to detect in the spectra; only the mixed-ligand complexes are almost quantitatively formed for Systems I–II and II–III.[11] It is, furthermore, interestingly shown in the table that the values of log K determined by both the optical absorption and ESR methods are almost equal to each other for System I–III and are comparable in their order for System I–IV. These results suggest that the value of K does not depend largely upon the temperature and that this ESR method is an excellent one for determining the K values.

Kida definded log K_{stab} as follows:[7,8]

$$\log K_{stab} = \log K - \log K_{stat}$$

where K_{stat} is the value of K when the three complexes in Eq. (1) are distributed entirely statistically or randomly. Under these conditions, K_{stat} is equal to 4: accordingly, log K_{stat}=0.60. If log K_{stab} is positive for a system, the mixed-ligand complex is more stable than can be expected statistically. Kida pointed out that log $K_{stab}>0$ generally holds for such an equilibrium as is expressed in Eq. (1) by reason of the fact that both the electrostatic effect and the effect of the σ-covalency of the coordinate bond serve to promote the formation of a mixed-ligand complex.

The values of log K_{stab} are positive for all the systems except one, as may be seen in Table 7, but their values are quite different. It is important for us to investigate the reason for such different values, although it is not easy to do so at the present stage because of the insufficiency of data of this kind. The question whether or not the promotive formation of a mixed-ligand complex depends upon its stabilization in bond energy will, however, be answered by the experimental study of the temperature dependence of log K. log K is expressed as follows:[13]

$$\log K = \frac{1}{2.30R}\left(-\frac{\Delta H}{T} + \Delta S\right) \qquad (3)$$
$$\Delta S = \Delta S_r + \Delta S_s$$

where ΔS_s is the entropy term of log $K_{stat}=\Delta S_s/2.30R$ =0.60 concerning the statistical distribution among the three complexes in Eq. (1) and where ΔS_r is designated as the summation of all the other unknown entropy terms. The error inherent in the ESR method of determining the K values may be somewhat larger than in the optical absorption method, mainly because of the assumed proportionality between the molar ratio of the three complexes and the ratio of the integrated intensities of the corresponding resolved Gaussian curves and because of the troublesome nature of the Gaussian analysis itself. Accordingly, it seems reasonable that the errors, which are ±0.04 in Tables 1 and 2, were increased properly as much as about twofold for System I–III and about fourfold for System I–IV in Table 7. These increased errors, however, are, after all, counterbalanced from the point of view of the temperature dependence of log$K$ because of the very low temperature at which the K values are determined by the ESR method.

The thermodynamic constants were derived from the data in Table 7; they are listed in Table 8. The results in Table 8 indicate that the entropy change plays a main role in governing the equilibrium for all the systems. It is, furthermore, an interesting finding that the entropy values are almost constant for these systems, any one of which is concerned with ethylenediamine (as A in Eq. (1)) and amino acid (as B). On the other hand, the ΔG°_{293} values of the three systems are different from each other, and the enthalpy terms, whose values were different, are considered to be responsible for the differences in the value of ΔG°_{293}. Since the enthalpy term is related to the bond energies, the above-mentioned fact is consistent with Kida's proposal that the promotive formation of a mixed-ligand complex depends upon the electrostatic effect and also upon the effect of the σ-covalency of the coordinate bond. The enthalpy changes listed in Table 8 are comparatively small, especially for System I–III. This finding agrees with the ESR result already reported in a previous paper; the Cu–A and Cu–B bonds in Eq. (1) become close to each other in bond strength in the mixed-ligand complex, and there is an accompanying internal compensation for the bond energies.[11] A further study of the relations between these thermodynamic functions and the kinds of mixed-ligand complexes, or the other physico-chemical properties of the complexes, is now in progress. It is clear that all these data are fundamentally important for the structural estimation of the metalloenzyme-substrate complexes and for understanding their reaction mechanisms.

Table 8. Thermodynamic constants

The Relation between the Volatilization Rates of Chlorine and Bromine Compounds from Volcanic Rocks on Heating

Kazuyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 23, 1971)

Experiments on the volatilization rate of chlorine and bromine compounds from volcanic rocks were made at temperatures above 770°C in a stream of nitrogen, both in the presence of water vapor and without it. The rate of volatilization have been studied by following the change in the retained chlorine and bromine contents as a function of the heating time. Their contents retained in rocks during heating were estimated indirectly by determining their amounts evolved from rocks. The chlorine compounds are more volatile than those of bromine, regardless of the rock type. However, the difference in their volatility becomes quite small in the presence of water vapor. This fact suggests that there is little difference in the volatility between chlorine and bromine compounds in the presence of much water vapor, so the Br/Cl ratio in magma does not change very much during the crystallization process.

Sugiura[1] reported that the bromine and chlorine contents of volcanic rocks ranged widely, but that the Br/Cl ratios were to be found in a relatively narrow range, mostly from 1×10^{-3} to 6×10^{-3} by weight, regardless of the rock type. The present author and his co-workers determined the halogen contents of volcanic rocks.[2] Their Br/Cl ratios also fell in a narrow range, regardless of their contents in the rocks and of the rock type. These findings may show the close similarity between the volatilization rates of chlorine and bromine compounds, because the distribution of halogens in volcanic rocks is largely determined by their volatilization. Several studies of the volatilization of halogen compounds were carried out by heating volcanic rocks. Yoshida[3] and Yoshida *et al.*[4,5] studied the fractionation of halogen compounds through the process of volatilization and sublimation by determining their contents in the gases and sublimates obtained by heating rocks. Iwasaki and Katsura[6] carried out an experimental study of the volatilization rate of chlorine compounds from basaltic rock melts, neglecting the effect of water vapor. From the experimental results on the liberation of chlorine and fluorine compounds in the presence of water vapor, Sugiura[7] suggested that the distillation process of halogens with water vapor determines the distribution of halogens in volcanic rocks more than does the chemical and mineralogical nature of the rocks.

No attempt has, however, yet been made to study the rates of volatilization of bromine compounds from volcanic rocks on heating; this has been because of the lack of a suitable analytical method for the determination of bromine. The objective of the present paper is to make clear the relation between the rates of volatilization of chlorine and bromine compounds from volcanic rocks on heating. The experiments on the liberation of their compounds from volcanic rocks were made by heating rocks in a stream of nitrogen, both in the presence of water vapor and without it.

Experimental

Materials. The rock samples used in this study are listed in Table 1, together with their chlorine and bromine contents. The chlorine in rocks was determined by the method of Iwasaki *et al.*[8] with some improvements, while the bromine in the rocks was determined by the method of Takahashi *et al.*[9] Reagent-grade chemicals and redistilled water were used throughout this work.

Apparatus and Procedure. The apparatus used in this study is shown in Fig. 1. The method of generation of the water vapor was the same as that described by Sugiura.[7] The temperature of the furnace was kept constant within ±10°C and measured by a pyrometer with a platinum-platinum, 10% rhodium thermocouple. Two absorption vessels were connected to the three-way cock separately, each containing about 40 m*l* of water and 5 g of potassium hydrox-

ide. From 3 to 4 g of a finely-powdered sample, placed in a platinum boat, was inserted in the silica glass tube and then placed in the center of the furnace at a given temperature. Nitrogen gas freed of halogens by sodium hydroxide pellets was then allowed to flow through at a fixed flow rate of about 360 ml/min. The halogen compounds which were liberated from the sample were absorbed by the solution in the absorption vessel. After various periods of heating, the three-way cock was turned in order to trace the change in the amounts of chlorine and bromine evolved as a function of the heating time. After the solution in each absorption vessel has been adequately diluted, an aliquot of the solution was used for the determination of bromine. Another portion was used for the determination of chlorine after oxidizing the sulfide by heating the solution with a small amount of hydrogen peroxide. The chlorine was determined by the mercuric thiocyanate method[10] with some improvements, while the bromine was determined by a modification of the method reported in a previous paper.[9] The amounts of chlorine and bromine deposited on the inside surface of the silica-glass tube and the cock on the outgassing of the rocks were small enough to be neglected; the bromine was less than 5% of the total amount of bromine evolved from rocks, and the chlorine, less than 2% of the total amount of chlorine evolved.

Results and Discussion

The Rates of Volatilization of Chlorine and Bromine Compounds from Volcanic Rocks on Heating. The results of experiments conducted at different temperatures and at various heating times are shown in Figs. 2 and 3. In Figs. 2 and 3, only the results for basalt from Miyake-jima are presented, because the shapes of the curves for this basalt are very similar to those for all the other rocks used in this study. Figure 2 shows the change in the ratio (%) of the volatilized chlorine content to the original chlorine content with the heating time at different temperatures, both in the presence and absence of water vapor. Figure 3 shows the change in the ratio of the volatilized bromine content to the original bromine content, as in the case of chlorine. From the results shown in Figs. 2 and 3, it is evident that the rates of volatilization of chlorine and bromine compounds are remarkably fast in the initial heating

period, and that then the rates become slow. The liberation of their compounds from the rocks becomes remarkably difficult as soon as they begin to melt. The basaltic sample from Miyake-jima begins to melt after several minutes in the furnace at 1170°C. The chlorine and bromine compounds tend to volatilize more easily in the presence of water vapor than without it. There is an especially striking difference in the rate curves of the liberation of bromine compounds in nitrogen and in a N_2-H_2O mixture. Figure 3 shows that the bromine compounds are much more easily liberated in the N_2-H_2O mixture.

The kinetics of the volatilization of the chlorine and bromine compounds is very complex because a rock is a multicomponent and inhomogeneous system. According to Iwasaki *et al.*[11] and the results of the pH measurements, which are not listed in this paper, the chemical form of the chlorine evolved is mostly hydrogen chloride. This would be the case for bromine, also. For this reason, it is evident that water in rocks plays an important role in the kinetics of the volatilization of their compounds.

The Relation between the Rates of Volatilization of Chlorine and Bromine Compounds from Rocks on Heating.
Figures 4, 5, and 6 show the relation between the percentage fractions of retained chlorine and bromine in rocks during heating, both in the presence of water vapor and in its absence. $[Cl]_{rock}$ and $[Br]_{rock}$ represent the percentage of the retained chlorine and bromine contents respectively in relation to their original contents. The chlorine compounds are remarkably easier to release than those of bromine on heating in the absence of water vapor, regardless of the rock type. The plots of log $[Br]_{rock}$ *vs.* log $[Cl]_{rock}$ all yield approximately straight lines except for basalt. The ratio of the volatility of chlorine compounds to that of bromine compounds, k, was defined by the equation:

$$(-d[Cl]_{rock}/[Cl]_{rock}dt)/(-d[Br]_{rock}/[Br]_{rock}dt) = k.$$

From the slopes of the straight lines, the volatility ratios obtained for andesite from Sakura-jima, liparite from Kozu-shima, and obsidian from Imari on heating at 950°C in N_2 are 3.9, 4.3, and 3.4 respectively.

The Br/Cl ratio in rocks increases with an increase in the duration of heating because of the higher volatility of chlorine compounds. In other words, the lower the chlorine content retained in rocks on heating, the larger the $(Br/Cl)_{retained}$ ratio. It is interesting to note that these observations are similar to the relation between the Br/Cl ratio and the chlorine content of ordinary chondrites reported by Goles *et al.*[12] The Cl/Br ratio in ordinary chondrites increases rapidly with an increase in the chlorine content. The thermal history of meteorites seems to have a large influence on the abundance of chlorine and bromine in them.

On the other hand, the difference in volatility between chlorine and bromine compounds becomes remarkably small in the presence of water vapor. The effect becomes even stronger with an increase in the water-vapor pressure, and each curve in the log-log relation in Figs. 4, 5, and 6 gradually approaches the broken line which shows the case in which there is no difference in volatility between chlorine and bromine compounds.

The chlorine and bromine contents of magma are considered to decrease rapidly during cooling because of the volatilization of their compounds. Provided that the Br/Cl ratio in any magma is approximately constant and that chlorine and bromine do not enter into the rock-forming minerals in volcanic rocks, the ratio of the retained bromine to the retained chlorine in magmas can be determined by means of the difference in volatility between their compounds. If the chlorine compounds are more volatile than that of bromine under natural conditions, the Br/Cl ratio in rocks will increase as their contents decrease. As can be seen in Fig. 7, the Br/Cl ratios in volcanic rocks fall in a narrow range,

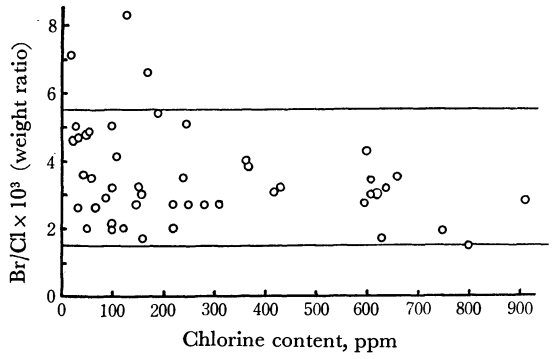

Fig. 7. Relationship between Br/Cl ratio and Cl content in volcanic rocks.

mostly from 1.5×10^{-3} to 5.5×10^{-3} by weight, regardless of the chlorine content and the rock type. This fact seems to result from the close similarity between the volatilities of chlorine and bromine compounds during the cooling process of magma under hydrous conditions.

In order to obtain information on the volatilities of chlorine and bromine compounds from magma, the data on the Br/Cl ratio in volcanic gases may be important. The data in high-temperature volcanic gases are especially required because the chlorine and bromine compounds in low temperature volcanic gases are fractionated by means of the process of sublimation and by other phenomena. For example, Mizutani[13] and Yoshida *et al.*[4] pointed out that bromine is strongly enriched in ammonium chloride as volcanic sublimate. From the results of heating experiments on the rocks, Yoshida *et al.*[4] showed also that bromine is deposited more easily than chlorine. The data on the chlorine and bromine contents in volcanic gases are insufficient. Sugiura *et al.*[14] and Honda[15] determined the Br/Cl ratios in volcanic gases from several active volcanoes in Japan. The Br/Cl ratios in gases with temperatures above 300°C are $(1—2)\times10^{-3}$ by weight. This value is a little smaller than that in volcanic rocks. According to Sugiura,[1] however, the Br/Cl ratios in the volcanic gases are nearly the same as those in volcanic rocks at each volcano studied. From these facts, it seems likely that there is little difference in volatility between chlorine and bromine compounds under magmatic conditions.

As has often been pointed out, water vapor which is believed to be ubiquitous in magma plays an important role in the volatilization of halogen compounds.[7,16,17] According to the very simple thermodynamic calculations of Kogarko and Ryabchikov,[17] reactions between water vapor and metal halides at high temperature yield volatile hydrogen halides. In the present study, the addition of water vapor slightly affected the volatilization of chlorine compounds, while it greatly affected that of bromine compounds. This suggests that water vapor formed in rocks on heating reacts with chlorine compounds more effectively than with bromine compounds through the process of the rapid escape of water vapor.

Conclusion

The chlorine compounds are more volatile than those of bromine on heating without water vapor, regardless of the rock type, so the lower the content of retained chlorine during heating, the larger the Br/Cl ratio in rocks. This relation is consistent with the correlation of the Br/Cl ratio with the chlorine content in ordinary chondrites. The difference in volatility between their compounds tend to become noticeably smaller in the presence of water vapor. This fact, and the close relation between the abundance of chlorine and that of bromine in volcanic rocks, show that the ratio of the volatilization loss of chlorine to that of bromine is nearly constant during the cooling process of hydrous magma.

The author wishes to express his hearty thanks to professor Iwaji Iwasaki of Tōhō University, and to Dr. Takejiro Ogawa, and Dr. Minoru Yoshida of the Tokyo Institute of Technology, for their many valuable discussions and suggestions during this study.

The Crystal Structure of Perchlorato-bis(2,2′-bipyridine)-copper(II) Perchlorate, $[Cu(ClO_4)(bipy)_2]ClO_4$

Hisayoshi NAKAI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received January 25, 1971)

The structure of bis(2,2′-bipyridine)copper(II) perchlorate, $Cu(bipy)_2(ClO_4)_2$, has been determined from three-dimensional X-ray data collected by the photographic method. The compound forms triclinic crystals with $a=7.44(1)$, $b=14.93(1)$, $c=15.32(1)$ Å, $\alpha=136.3(0.1)$, $\beta=103.7(0.1)$, $\gamma=83.2(0.1)°$, and $Z=2$ in the space group $P\bar{1}$. The structure was solved by the usual Patterson and Fourier techniques and was refined by the least-squares method to an R value of 0.134. The crystal is composed of an infinite chain of $[Cu(ClO_4)(bipy)_2^+]_\infty$ and ClO_4^-; a perchlorate ion in the chain bridges two adjacent copper atoms through its two oxygen atoms. Roughly speaking, the coordination polyhedron around the copper atom is a tetragonally-distorted octahedron; the four nitrogen atoms of bipyridine molecules are arranged in a flattened tetrahedral manner (average Cu–N=1.99 Å), the least-squares plane of these atoms making an equatorial plane, while the polar positions are occupied by the two oxygen atoms of perchlorate anions, the Cu–O distances being 2.45 and 2.73 Å. The two pyridine rings are twisted slightly to each other in both of the bipyridine molecules; the dihedral angle between the pyridine planes is 13° in one bipyridine ligand and 4° in the other.

It is well known that the copper(II) ion can give numerous bis-bipyridine complexes with the general formula of $Cu(bipy)_2X_2\cdot nH_2O$.[1] In these complexes, however, two bipyridine molecules have to overcome a great difficulty; in case they take a completely coplanar arrangement around the Cu atom, there is severe steric interference between the hydrogen atoms on the 6- and 6′-carbon atoms of the two bipyridine molecules (Fig. 1). In fact, no such coplanar disposition of bipyridine molecules has been found for the bis-bipyridine metal complexes, including even the copper(II) complexes,[2-4] in which the bipyridine molecules are most likely to be on a plane.

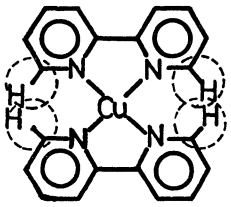

Fig. 1

The author has been very interested in the structure of bipyridine-copper(II) complexes, and has been attempting the crystal-structure analyses of a series of bis-bipyridine complexes in order to elucidate the disposition of the two bipyridine ligands around the copper(II) ion as well as the conformation of the bipyridine molecule in the complex. One of the results ($[Cu(NO_3)(bipy)_2]NO_3\cdot H_2O$) has already been reported briefly.[3] In this paper, the crystal structure of $Cu(bipy)_2(ClO_4)_2$ will be dealt with.

Experimental

The crystals of $Cu(bipy)_2(ClO_4)_2$ were prepared by Jaeger's method[5] and were recrystallized from a water-methanol mixture.

The lattice constants at room temperature were determined from $(h0l)$, $(0kl)$, and $(hk0)$ reflection data recorded on Weissenberg photographs on which the aluminum powder diffraction lines were superimposed for calibration. Cu$K\alpha$ radiation ($\lambda=1.5418$ Å) was used throughout the diffraction study. The density of the compound was determined by floatation in a benzene-bromoform mixture. Of the two possible triclinic space groups, $P\bar{1}$ and $P1$, the former was chosen initially; this choice was confirmed by the successful solution and refinement of the structure. The crystal data are listed in Table 1.

Table 1. Crystal data

$Cu(bipy)_2(ClO_4)_2$		
Triclinic		
$a=7.44\pm0.01$,	$b=14.93\pm0.01$,	$c=15.32\pm0.01$Å
$\alpha=136.3\pm0.1$,	$\beta=103.7\pm0.1$,	$\gamma=83.2\pm0.1°$
$Dm=1.68$ g/cm^3,	$Dc=1.69$ g/cm^3	
$Z=2$, Space group $P\bar{1}$		
Linear absorption coefficient for Cu$K\alpha$, $\mu=40.2$ cm^{-1}		

The intensity data of the $0kl$—$4kl$, $h0l$, and $hk0$ reflections were collected from crystals with dimensions of $0.15\times0.15\times1.0$ mm by the multiple-film equi-inclination techniques. The intensity scale was prepared from the same crystal and was used for the visual estimation of the 3064 independent reflcetions, but the intensities of 792 of them were too weak to be measured and so were assumed to be zero.

After the intensity data had been corrected for Lorentz-polarization effects and spot extension, the structure factors were placed on a common arbitrary scale by internal correlation. No absorption correction was made, for it was estimated that the maximum effect of absorption on the intensity was, at most, 15 per cent.

Structure Determination

The position of the copper atom was readily determined from the three-dimensional Patterson maps. A first Fourier synthesis, phased on the Cu atom, clearly gave the atomic positions of one bipyridine ligand and those of the coordinating ClO_4^- ion. The coordinates of the remaining non-hydrogen atoms were obtained from the subsequently-synthesized Fourier maps. In these diagrams, the electron-density distribution of the uncoordinating ClO_4^- ion was evidently indicative of its tetrahedral configuration, but was much more diffuse than that of the coordinating ClO_4^- anion. The crystal structure was refined by a block-diagonal least-squares method. Throughout the least-squares calculations, the following weighting scheme was employed:

$$w = 0.2, \text{ if } F_o \leq F_{\min} \ (= 0.5 = 0.01 \times F_{\max})$$

and

$$w = 1.0, \text{ if } F_{\min} < F_o.$$

The atomic scattering curves were taken from the International Tables for X-ray Crystallography, Vol. III,[6] the real part of the anomalous dispersion correction ($\Delta f' = -2.1$) being applied for the neutral copper atom. After three cycles of the refinements, the conventional R value was 0.17 for 2272 non-zero reflections. Three more cycles of the refinements with anisotropic thermal parameters for only the heavier atoms of Cu, Cl(1) and Cl(2) reduced the R value to 0.15. At this stage, the average isotropic temperature factor of the oxygen atoms of the uncoordinating ClO_4^- ion rose to 19 Å^2. In the further refinement, the anisotropic thermal parameters were introduced, in addition to the heavier atoms mentioned above, to the oxygen atoms of the uncoordinating ClO_4^- ion. The R value was improved to 0.134 by three cycles of the least-squares calculations. In the last cycle of the calculations, the maximum shift in any parameter was less than one-eighth of its estimated standard deviation. The final atomic coordinates and temperature factors are listed in Table 2.

Results and Discussion

The crystal structure of $Cu(bipy)_2(ClO_4)_2$ viewed down the a-axis is shown in Fig. 2, while the bond lengths and angles, together with their estimated standard deviations, are presented in Table 3. The crystal is composed of the perchlorate ion and an infinite chain of $[Cu(ClO_4)(bipy)_2^+]_\infty$ in which a ClO_4^- ion bridges two adjacent copper atoms. A schematic drawing of a part of the infinite chain is shown in Fig. 3.

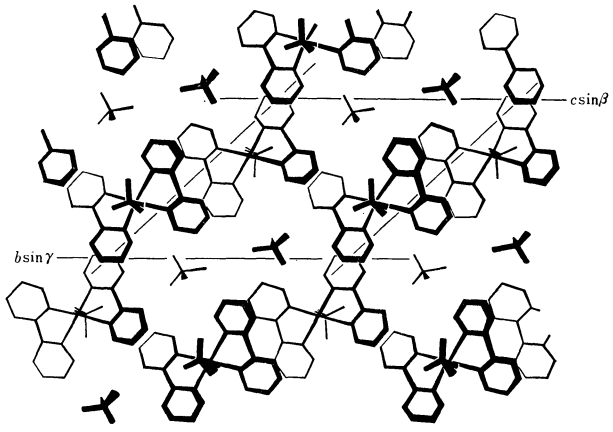

Fig. 2. a-axis projection of the crystal structure.

Cu	−0.03 Å		

In the complex cation the two Cu–O bond lengths are not equal; one is 2.73 Å, and the other, 2.45 Å. It is worthy of note that these values are within the range of 2.2—2.9 Å, the range[7] which is known as the axial Cu–O distance in the tetragonally-distorted octahedral geometry of Cu(II). Four nitrogen atoms of the bipyridine ligands are arranged around the copper atom in a flattened tetrahedral manner (Cu–N= 1.99 Å on the average); the copper atom lies almost on the least-squares plane defined by these nitrogen atoms, and the Cu–O bonds are approximately normal to this plane. This is attributable to the steric interference between the chelating ligands; since the $Cu(bipy)_2^{2+}$ moiety, as has been stated in the introduction, can not have a strictly coplanar structure, the two bipyridine molecules are forced to slant against one another, giving rise to the tetrahedral arrangement of their

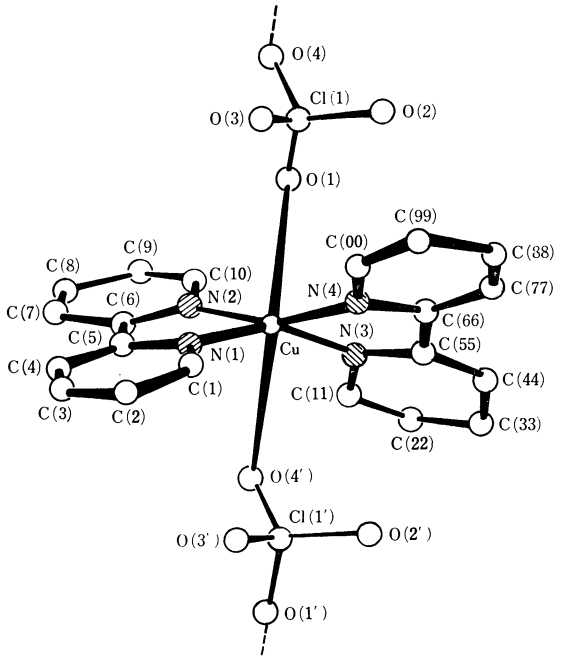

Fig. 3. A schematic drawing of a part of the infinite chain, $[Cu(ClO_4)(bipy)_2^+]_\infty$.

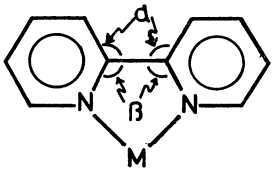
nitrogen atoms. The dihedral angle between the $Cu \begin{matrix} N(1) \\ N(2) \end{matrix}$ and $Cu \begin{matrix} N(3) \\ N(4) \end{matrix}$ planes is 37°.

As has been mentioned above, the axial Cu–O bonds are considerably longer than the Cu–N bonds; therefore, it is uncertain whether, in the strict sense, the oxygen atoms are in bonding with the copper atom or not. On the basis of the IR spectrum of $Cu(en)_2(ClO_4)_2$,[7] Hathaway and his coworkers inferred that the perchlorate anion is in "semi-coordination"[8] with the copper atom, irrespective of the Cu–O distance of 2.61 Å.[9] In the present compound, the distance of 2.45 Å between Cu and O(1) is significantly shorter than the Cu–O bond length in the ethylenediamine complex; hence, O(1) must be coordinated to Cu. Hathaway *et al.* investigated $Cu(bipy)_2(ClO_4)_2$, too. According to them, this compound gives a single broad reflectance band with a low intensity at 15.1×10^3 cm^{-1}, which is suggestive of a more tetragonally-distorted structure with an approximate center of symmetry, while it shows a single strong band at 1088 cm^{-1} and a weak band at 930 cm^{-1}, neigher of which is any evidence that ClO_4^- is coordinated or even semi-coordinated to Cu. Thus, they concluded that the compound should be formulated as $[Cu(bipy)_2](ClO_4)_2$ and that the complex cation has an essentially planar structure, although the two bipyridine ligands are twisted mutually by 10—30° towards a tetrahedral coordination This is not entirely in agreement with the result obtained in the present study regarding the aspect of the coordination of the ClO_4^- ion.

It should be remembered that the coexistence of the coordinating and uncoordinating ClO_4^- ions in the crystal would obscure the vibrational spectrum originating from the perchlorate anion and would make it difficult for them to establish the bonding feature of the anion. Considering such a situation as well as the presence of an approximate center of symmetry,[10] the present author should like to draw the following conclusion: having an appreciable influence on the chromophore $[CuN_4O(1)]$ with no center of symmetry, O(4') is possibly in "semi-coordination" with the copper atom, completing a distorted octahedron, though the Cu–O(4') distance is considerably longer than that of Cu–O(1). Thus, the complex could be regarded as hexa-coordinative.

The bipyridine ligands are not on a plane, but each individual pyridine ring is planar within the value of 0.03 Å. The pyridine rings of the bipyridine molecule are slightly twisted about the 2,2'-carbon bond by 13° and 4° for the molecules defined by N(1) and N(2) and by N(3) and N(4) respectively. Furthermore, the bond angle of α (123°) is larger than that of β by 7°, on the average. Although this value is not highly significant in view of its standard deviation, a similar difference in these bond angles (5—10°) is also observed in the crystal structures of the 2,2'-bipyridine molecule[11] and the bis-bipyridine complexes.[2-4,12]



The average Cl–O bond length and O–Cl–O angle of the bridging ClO_4^- ion are 1.45 Å and 109.5° respectively, while those of the uncoordinating ClO_4^- anion are less accurate and can not be discussed in detail because of the distorted arrangement in the crystal lattice. The closest approach of the uncoordinating perchlorate ion to the bipyridine ligand is 3.25 Å between the O(11) and C(88) $[x, y, 1+z]$. This value is comparable with the O–C distance (3.24 Å) found in $[Cu(ONO)(bipy)_2]NO_3$.

The author wishes to thank Professor H. Kuroya, Dr. S. Ooi and Dr. Y. Kushi for their kind advices and encouragements throughout the present work. The author is also greatly indebted to Mr. K. Hirotsu, who adapted the HBLS-IV computer program[13] to the FACOM 270-30 computer at Osaka City University and granted me his kind permission of using it.

Stability Constants of Alkaline Earth Metals with *o*-Arsono-*o'*-hydroxy Azo Compounds

Kenyu KINA and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received February 25, 1971)

The acid dissociation constants of the *o*-arsono-*o'*-hydroxy azo compounds, and their chelate stability constants with alkaline earth metals, have been measured by the pH titration method at an ionic strength of 0.10 and at 25.0±0.1°C. These azo compounds were synthesized by the coupling reaction of diazotized *o*-aminophenylarsonic acid with naphthol sulfonates. As the coupling components, 1,8-dihydroxynaphthalene-3,6-disulfonic acid (chromotropic acid), 2-hydroxynaphthalene-3,6-disulfonic acid (R acid), and 1-hydroxynaphthalene-3,6-disulfonic acid were used. *o*-Arsonophenylazochromotropic acid (Neo-Thorin) formed the most stable chelates. It was concluded that the stabilization of the metal chelate ring of the Neo-Thorin was due to a quasi-aromaticity of the six-membered ring which was produced by the hydrogen bond between two naphtholic hydroxyl groups of chromotropic acid. The metal chelate stability order, Mg>Ca>Sr>Ba, is parallel to the reciprocal of the ionic radii of the metal ions.

According to Emi *et al.*,[1] the limit of the identification of the *o*-arsono-*o'*-hydroxy azo compounds depends of the coupling components rather than on the diazo components. Especially, the azo compounds of the chromotropic acid and the *R* acid, namely Neo-Thorin and thorin, are well-known as colorimetric reagents for Thorium. In general, the relation between the basicity of the coordinating site of the similar ligand and the metal chelate stability constants should present a good linearity from the standpoint of the Lewis acids and bases. The stability constants of the chelates which we have investigated, however, vary inversely with the basicity of the ligands. This result suggests the presence of a more significant factor than basicity. In this report, we will discuss these chelate systems from the electronic and structural points of view.

Experimental

Reagents. The azo compounds, 2-(2-arsonophenylazo)-1,8-dihydroxynapthalene-3,6-disulfonic acid disodium salt [Neo-Thorin], 1-(2-arsonophenylazo)-2-hydroxynaphthalene-3,6-disulfonic acid disodium salt [Thorin], and 2-(2-arsonophenylazo)-1-hydroxynapthalene-3,6-disulfonic acid disodium salt, were synthesized by the coupling reaction of diazotized *o*-aminophenylarsonic acid with the corresponding coupling components. These azo compounds were obtained as fine crystals.

In addition, a number of azo compounds for example, N.W. acid, and F acid, were obtained by the use of hydroxynaphthalene monosulfonic acid. These compounds, however, were not studied in this investigation because of their low solubility. A carbonate-free potassium hydroxide solution was prepared by the ion exchange method and was standardized titrimetrically against potassium hydrogen phthalate.

Reagent Solutions. The stock solutions of these ligands were standardized by potentiometric titration with standard 0.10 N potassium hydroxide. The stock solutions of magnesium, calcium, strontium, and barium were prepared by dissolving $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $Sr(NO_3)_2$, and $Ba(NO_3)_2$ of a guaranteed-reagent grade in distilled water. The concentration of the former two solutions was determined by chelatemetric titration,[2] while the concentration of the latter two was determined by the usual gravimetric method.

pH Titration Method. The measurements were carried out by the use of a micro-titration apparatus. The temperature was kept at 25.0±0.1°C throughout the titration by the circulation of water through a jacketed titration vessel with a capacity of 5 m*l*, and the ionic strength of the solutions was adjusted to 0.10 with potassium nitrate. Alkali was added from a calibrated 0.50 m*l* micrometer syringe to the solution in an atmosphere of nitrogen. The hydrogen-ion concentration was measured with an HRL-Model P pH meter (made by the Horiba Instruments Inc., Kyoto) equipped with a combined glass electrode (Metrohm, EA-125 U-type, Herisaw, Switzerland). The observed pH meter readings were converted into the actual hydrogen-ion concentrations by comparing them with the stoichiometric dissociation constant of acetic acid, which was obtained by titrating it before and after each measurement.[3] The pH ($-\log[H^+]$) region above 11.0 was calibrated by measurements of the KOH solution.[4]

Results and Discussion

Calculation of Acid Dissociation Constants and Chelate Stability Constants. The equilibria and the dissociation constants involved are:

$$H_3L \rightleftharpoons H_2L + H, \quad K_{a1} = [H][H_2L]/[H_3L],$$
$$H_2L \rightleftharpoons HL + H, \quad K_{a2} = [H][HL]/[H_2L],$$
$$HL \rightleftharpoons L + H, \quad K_{a3} = [H][L]/[HL],$$

where the ionic charge was neglected for the sake of convenience. The titration curve shows a well-defined inflection at $a=1$; therefore, the first dissociation step of this triprotic acid can be treated separately form the last two steps. The region before $a=1$ was treated as monoprotic acid, while after $a=1$ it was treated as diprotic acid. In general, the following relationship represents the step-by-step acid dissociation constant of the polyprotic acid:

1) K. Emi, K. Tôei, and K. Furukawa, *Nippon Kagaku Zasshi*, **79**, 681 (1957).

2) K. Ueno, "Chelatemetric Titration" (in Japanese), Nankodo, Tokyo (1967).

3) C. F. Richard, R. L. Gustafson, and A. E. Martell, *J. Amer. Chem. Soc.*, **81**, 1033 (1959).

4) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions," 3rd. Ed., Reinhold Publ. Corp., N. Y. (1958), p. 752.

$$\sum_{i=1}^{n} \frac{iT_L - f}{f[H]^i} K_{a1} \cdot K_{a2} \cdot \cdots \cdot K_{ai} = 1,$$

$$f = (T_{OH} + [H] - [OH]),$$

where T_L represents the total concentration of ligand species and where T_{OH} represents the total concentration of the base added to the system. In all the calculations, the concentrations were corrected for the volume change resulting from the addition of the potassium hydroxide solution; the calculation formula of the monoprotic acid is as follows:

$$\frac{T_L - f}{f[H]} K_{a1} = 1,$$

while in the case of diprotic acid it is as follows:

$$\frac{2T_L - f}{f[H]^2} K_{a1}K_{a2} + \frac{T_L - f}{f[H]} K_{a1} = 1.$$

From the above equation, the dissociation constants, $K_{a1}K_{a2}$ and K_{a1}, were calculated by solving the simultaneous equation from two points on the ligand-only titration curve.

The chelate stability constants were calculated by means of the following equations:

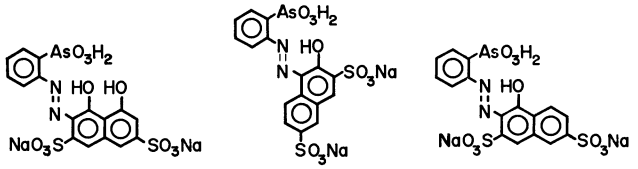
$$K_{ML} = (T_L - F)/[L](F + T_M - T_L).$$

where

$$L = (3T_L - T_{OH} - [H] + [OH])/[H]/K_{a3} + 2[H]^2/K_{a3}K_{a2} + 3[H]^3/K_{a3}K_{a2}K_{a1},$$

$$F = [L]\{1 + [H]/K_{a3} + [H]^2/K_{a3}K_{a2} + [H]^3/K_{a3}K_{a2}K_{a1}\},$$

and where T_M represents the total concentration of the metal species. All the calculations were carried out by using an NEAC-2203 computer (The Nippon Electric Co., Ltd.) of the Electronic Computer Center of Okayama University. The *o*-arsono-*o'*-hydroxy azo compounds are numbered as follows:



I II III

Titration Curves. The pH titration curves are illustrated in Figs. 1—3 for *o*-arsono-*o'*-hydroxy azo compounds, both on chelate systems and for each ligand alone. The dissociation constants, pK_{a1} and pK_{a2}, of phenylarsonic acid have been reported to be 3.39 and 8.25 respectively,[5] the clear inflections at $a=1$ and $a=2$, therefore, correspond to the dissociation of two arsonic protons. The pK_a value of an naphthlic proton is of an order of magnitude of 10, and this proton gives no inflection after $a=2$. The titration curve in the presence of a metal ion shows a lower pH value than in the presence of the ligand only. Such a depression of the titration curves indicates the formation of metal chelate species. The chelate stability order, Mg>Ca>Sr>Ba, can be readily

TABLE 1. ACID DISSOCIATION CONSTANTS OF *o*-ARSONO-*o'*-HYDROXY AZO COMPOUNDS AND STABILITY CONSTANTS OF THEIR CHELATES
(t=25.0±0.10°C; μ=0.10 by KNO_3)

Ligand	Acid dissociation constants				Stability constants, log K_{ML}			
	pK_{a1}	pK_{a2}	pK_{a3}	pK_A	Mg	Ca	Sr	Ba
I	2.93	7.65	10.15	20.73	5.57	5.20	4.39	4.22
II	3.44	7.86	10.80	22.10	5.20	4.17	2.87	—
III	3.09	8.05	11.40	22.54	5.35	3.50	2.0	1.8

where $K_{a_1}=[H][H_2L]/[H_3L]$, $K_{a_2}=[H][HL]/[H_2L]$, $K_{a_3}=[H][L]/[HL]$, $K_{ML}=[ML]/[M][L]$.
— not measurable owing to precipitation

expected from the extent of the depression of pH. Evidently, Compound I formed a more stable chelate with Ca, Sr, and Ba than did the other two.

Acid Dissociation Constants. In Table 1, the pK_{a1} and the pK_{a2} values correspond to the dissociation of the arsonic group, while the pK_{a3} value corresponds to the dissociation of the naphtholic hydroxyl group. The overall acidity of the ligands is defined as the sum of the dissociation constants, $pK_A=(pK_{a1}+pK_{a2}+pK_{a3})$; therefore, the larger the pK_A value, the more basic the ligand. The basicity of the ligand increases as follows: Compound I<Compound II<Compound III. As Fig. 4 shows, there exists a strong hydrogen bond between the two oxygen atoms of the Compound I; this naphtholic hydroxyl group, therefore, does not dissociate under ordinary experimental conditions.[5] The pK_{a3} which corresponds to the dissociation of the first hydroxyl proton of Compound I is 10.15, a value lower than those of Compounds II and III. This higher acidity is also attributed to a strong intramolecular hydrogen bonding, which could stabilize the deprotonated anion. Actually, Compound II shows a higher basicity, because it can not form any hydrogen bond such as shown in Fig. 4.

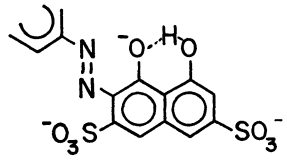

Fig. 4. Structure of hydrogen bonding.

Stability Constants. The chelate stability constants are also listed in Table 1. The stability constant of Compound II with the barium ion was not obtained because of precipitation. In general, the alkaline earth metals form an ionic coordination bond; the relation of the stability constants, $\log K_{ML}$, to the reciprocal of the ionic radii, $1/r$, of alkaline earth metals is given in Fig. 5. The stability constants increase with a decrease in the ionic radii; that is, the decrease in the order of the metal chelate stability is as follows: Mg>Ca>Sr>Ba. The stability order relation to the ligands, except the Mg chelates, is as follows: Compound I>Compound II>Compound III. According to the concept of Lewis acids and bases, the strong basic ligand would form the more stable chelate compound. However, the metal chelate stability constants of these compounds vary inversely with the basicities of the ligands.

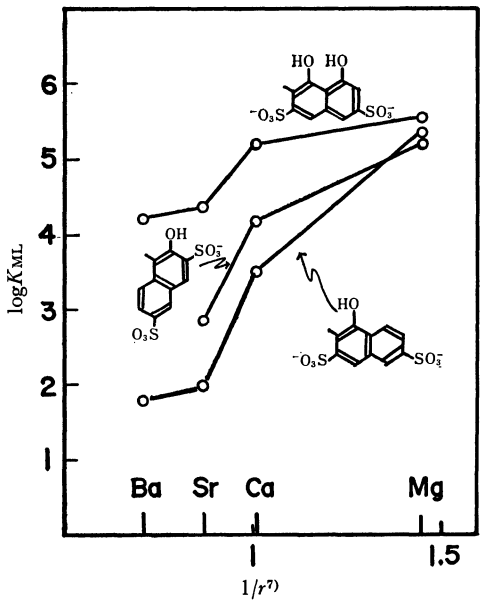

Fig. 5. Relation between $\log K_{ML}$ of the chelate of *o*-arsono-*o'*-hydroxy azo compounds and the reciprocal of the ionic radii.[7]

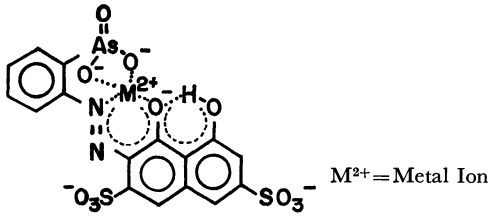
Such a difference depends largely on the nature of the naphtholic hydroxyl group. The chelate structure of Compound I may be as follows:



From the results of the measurement of the visible spectra of the free ligand, the λ_{max} values of Compounds I, II, and III are 505 mμ, 484 mμ, and 484 mμ, respectively; thus, Compound I indicates a bathochromic shift. This bathochromic effect of Compound I may be caused by the six-membered hydrogen bond ring acquiring a quasi-aromaticity which is similar to that of β-diketone derivatives.[6] As was shown in the above scheme, such a quasi-aromaticity is extremely advantageous for the stabilization of the six-membered chelate ring by means of the resonance effect.

TABLE 2. ACID DISSOCIATION CONSTANTS AND STABILITY CONSTANTS OF THE METAL CHELATES OF THE CATECHOL DERIVATIVES[8]

Ligand	pK_a	pK_a	Zn		Cu	
			$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$
Catechol	9.13	11.59	8.46	6.78	12.52	9.66
Catechol-4-sulfonate	8.26	12.16	9.40	7.20	13.29	10.23
Tiron	7.54	12.23	10.19	8.33	13.99	11.17

where $K_1=[ML]/[M][L]$, $K_2=[ML_2]/[L][ML]$

In the cases of Compounds II and III, they have lower $\log K_{ML}$ values than does Compound I because such an effect (the resonance effect) is absent. In the chelate system in which the resonance effect exerts a significant influence upon the chelate stability, the presence of a substituent group that increases the electron density of the donor atoms results in a decrease in the stability of the chelate ring. For example, the stability of the acetoacetic ester chelate is lower than that of the acetylacetone chelate. This has been explained on the basis of the electron-donating behavior of the ester group.[9] On the contrary, such a chelate system is stabilized by the presence of a electron-withdrawing group. A typical example of this can be seen in the Tiron. As Table 2 shows, the zinc or copper chelate of the Tiron is more stable than that of catechol or catechol-4-sulfonate, though the Tiron is less basic than the others. This phehomena shows that the localized electron on the oxygen atoms is dispersed by the sulfonate group; that is, such a stabilization may be due to the electron delocalization. From the structrural point of view, Compound II has a sulfonate group adjacent to the naphtholic hydroxyl group, as does the Tiron; therefore, Compound II forms a more stable chelate with Ca and Sr than does Compound III. This stabilization of the chelate ring may be the sulfonate group. As has been mentioned above, the main factor influencing the chelate stability is the nature of the naphtholic hydroxyl group with respect to calcium, strontium, and barium. On the other hand, the order of decrease in the stability constants of magnesium chelates is as follows: Compound I>Compound III>Compound II, although there is little difference among them. This order differs from the above-mentioned order. As is shown in Fig. 5, the magnesium ion has a much smaller ionic radius than those of calcium, strontium, and barium. Its chelating behavior, therefore, differs from that of the other alkaline earth metals. The stabilities of magnesium chelates are not greatly affected by the nature of the naphtholic hydroxyl group, but they are affected by its small ionic radius.

Analytical Study of the Lead Ion-selective Ceramic Membrane Electrode

Hiroshi HIRATA and Kenji HIGASHIYAMA

Wireless Research Laboratory, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka

(Received February 27, 1971)

The lead(II) ion-selective ceramic membrane electrode developed by sintering a mixture of lead, silver, and cuprous sulfides showed sensitivity, selectivity, and other response characteristics well suited to analytical utilization. The Nernstian slope was obtained over a concentration range from 10^{-1} to 10^{-6}M Pb^{2+} in activity, and the analytical range had a concentration of 10^{-1}—10^{-7}M when the membrane contained less than 30 wt% of cuprous sulfide and more than 1 wt% of lead sulfide. Among the common ions, silver, cupric, mercury(II), ferric, sulfide and iodide ions interfered seriously. About 10 times as many cadmium and bromide ions and more than 1000 times as many alkali metal, alkaline earth metal, zinc, aluminum, nickel, manganese(II), cobalt, and nitrate ions did not interfere with the lead ion, however. The electrode potentials did not change over a pH range from 2 to the pH at which the precipitation of lead hydroxide occurred. The electrode was safely used at temperatures from 0 to 95°C, and the potentials of the membrane satisfied the Nernstian equation within the limits of experimental error. The membrane electrode responded to activity changes very quickly: the rate of those changes was twice that in a lead sulfide-silver sulfide two-component ceramic electrode. A continuous potential measurement for 5 months promised long-term stability and accuracy. The rapid response rate and the long lifetime suggest that the continuous monitoring of some changing systems is feasible.

Ion-selective solid-state membrane electrodes can be classified conveniently into the following main groups: a single crystal membrane electrode, such as a fluoride ion-selective europium-doped lanthanum fluoride electrode:[1] a compacted polycrystalline electrode, where the membrane consists of a disc of a water-insoluble active material: a heterogeneous-membrane electrode, the so-called Pungor type, in which the active material is impregnated in an inert binder or matrix such as silicone rubber, and a glass electrode similar in principle and structure to a conventional glass pH electrode.[4]

For the lead ion-selective solid-state membrane electrode, a compacted polycrystalline electrode[5] has recently been developed by Orion Research, Inc.: here the membrane consists of lead sulfide incorporated with silver sulfide. A lead sulfide-impregnated silicone rubber membrane electrode[6] has since been prepared.

No electrode membrane has, however, yet been obtained by a sintering process, although a halide ion-sensitive electrode membrane was made by casting silver halide[7] and/or by hot-pressing a mixture of silver halide and a powdered thermoplastic polymer.

In our laboratory, a new type of cuprous sulfide ceramic membrane electrode which can be used for the measurement of cupric ion activity[9] has been prepared, and subsequently a lead sulfide ceramic electrode membrane incorporated with silver and cuprous sulfides has been developed.[10] The lead ion-selective electrode membrane obtained by a hot-pressing method permited lead-ion determination over a concentration range from 10^{-1} to 10^{-7} mol/*l*. In a previous paper, the relationship of the potential *vs.* the concentration curves and the compositions of the ceramic membranes was described. The present work was undertaken to provide some quantitative information regarding the analytical usefulness of a ceramic membrane electrode containing a mixture of lead, silver, and cuprous sulfides as the membrane for measuring the lead-ion concentration.

Experimental

Apparatus. An Orion model 801 digital pH meter was used for all the potentiometric measurements. The reference electrode was a Horiba Seisakusho model 2530-05T saturated calomel electrode to prevent contamination from a test solution.

The electric furnace for the preparation of the raw materials and the hot-pressing apparatus for making an electrode membrane were the same as previously reported.[10]

Chemicals. The lead, silver, copper, and sulfur were commercially-available materials, as pure as possible. The raw materials, PbS, Ag_2S, and Cu_2S, for preparing the membranes were obtained by the direct reaction of the corresponding metal with sulfur, as has previously been described.[10]

A stock solution of the 0.1M Pb^{2+} ion was prepared by direct weighing from Nakarai reagent-grade $Pb(NO_3)_2$ and was stored in polyethylene reagent bottles. A series of standard solutions of the lead ion was prepared by the suitable dilution of the stock solution, keeping the ionic strength of 0.1M by the addition of appropriate volumes of a 1M sodium nitrate solution. All the other chemicals were of Nakarai reagent grade and were used without further purification. The nitric acid and sodium hydroxide solutions were used to adjust the pH of the standard solutions. All the solutions were prepared from water which had been both deionized and distilled.

Preparation of the Ceramic Membrane. The ceramic membrane was obtained by the following two methods:

(1) A mixture of lead, silver, and cuprous sulfides was compressed and then sintered at 350—500°C for 3 hr in a hydrogen sulfide gas stream, and

(2) A mixture of lead, silver, and cuprous sulfides was

4. insulator (epoxy resin) 5. cap

compressed and subsequently hot-pressed at 350—400°C for 2 hr under a pressure of 3—7 ton cm^{-2}.

Preparation of the Electrode. A cross-section of the lead(II) ion-selective ceramic membrane electrode is shown in Fig. 1. The ceramic membrane was fastened directly with a leading wire, and then mounted with epoxy resin adhesive in a stem of unbreakable epoxy resin, which is highly resistant to acids, bases, and organic solvents. The internal electrode and solution which are commonly used in usual selective electrodes, such as a glass pH electrode or a liquid ion-exchanger electrode, were eliminated in order to avoid any internal contamination of the membrane and in order to simplify the structure of the electrode. Then, the membrane surface was polished with diamond paste and washed with an ultrasonic wave cleaner.

Procedure. Potentiometric measurements for drawing the calibration curves were carried out in the conventional manner. The potentials developed by the membrane electrode were measured at 25.0 ± 0.1°C with a saturated calomel electrode as the reference electrode. Magnetic stirring was employed. The electrode potentials were attained rapidly, and in every case the equilibrium potentials were read within 2 min after the immersion of the electrodes into the standard solution. The reproducibility for different solutions with the same lead-ion concentration was within ± 0.5 mV if the electrode surface was kept clean and the stirring rate was constant.

Dynamic response curves were obtained after the rapid concentration or dilution of the standard solution by the addition of more concentrated lead nitrate or 0.1 M sodium nitrate solutions. In all cases, the resulting potentials *vs.* time curves were smooth and reproducible after the initial mixing period (the pH and ionic strength were kept constant).

Results and Discussion

Response of the Membrane Electrode to the Lead(II) Ion. In general, the mechanism of the response of solid-state electrodes is not so well understood as that of glass or liquid ion-exchanger membrane electrodes; by an analogical consideration of the glass membrane electrode, the ion-exchange theory[11] has been applied directly to the solid-state membrane electrode. Pungor[3] demonstrated with radiochemical methods that the rate of the iodide-ion exchange at the membrane-solution interface was very fast when a silver iodide-impregnated silicone rubber membrane was used. Buck[12] has presented such a theory assuming a rapid, reversible ion exchange at the membrane interfaces and mobile defects within the membrane crystal. While it is at least highly probable that these are necessary conditions for the operation of a solid-state ion-selective membrane electrode, experimental evidence supporting this theory has not been available for many solids now in use as membrane materials. It is especially very difficult to adapt this theory to a complicated mixed crystalline membrane electrode such as the present ceramic membrane electrode.

On the operation mechanism for an electrode such as a silver sulfide - cupric sulfide - compacted membrane electrode, Rechnitz *et al.*[13] suggested that this membrane was an ionic conductor which allowed the silver ion to pass and that this electrode transported the charge by the movement of silver ions, but the potential was determined indirectly by means of the availability of S^{2-}, which, in turn, was fixed by the activity of the divalent metal in contact with the membrane. Certainly, a pure lead sulfide ceramic membrane, in which no trace of silver could be detected by qualitative emission spectroscopy, as has previously been reported, proved non-responsive to the lead ion, but an impure lead sulfide ceramic membrane containing less than 0.01 wt% of silver was rather more sensitive than a pure one, and a membrane with 1% of silver sulfide added exhibited 27 mV for each ten-fold change in the lead-ion activity. Nevertheless, a very pure lead sulfide-impregnated silicone rubber membrane electrode was readily sensitive to lead ion activity without any trace of silver sulfide and showed sufficient selectivity among other cations or anions in spite of the fact that pure lead sulfide was not an ionic but an electronic semiconductor.

Recently, Brand and Rechnitz[14] have made impedance measurements of the electrode membranes. In the case of an electrode fabricated from a compacted disc containing a mixture of lead and silver sulfides, it was found that there was no net ion transport across the membrane cell, and that charges were built up at the membrane-solution interface, producing a capacitative effect. Such ion-blocking at the interface includes the absence of an ion-exchange reaction (ionic conduction within the membrane) or the absence of a charge-transfer reaction (electronic conduction within the membrane).

However, it is quite difficult, from the above point of view, to clarify the specific ion-selectivity and the effect of incorporation by silver sulfide.

Further investigations of the mechanism of the mixed crystalline membrane electrode were not, however,

carried out in the present study.

Calibration Curves. The experimental cell can be represented as:

$$\text{Lead ion-sensitive electrode} \left| \begin{matrix}\text{test solution} \\ \mu=0.1\ (NaNO_3)\end{matrix} \right\| 0.1\text{M } NaNO_3 \left| \text{SCE} \right.$$

The potential of this cell is given by:

$$E = \text{constant} + 2.303(RT/2F) \log a_{Pb^{2+}},$$

where the "constant" is the sum of the potentials at the leading wire-membrane contact interface, the saturated calomel electrode and the liquid-junction potential between a test solution and the reference electrode, and the potential across the membrane, when the silver-ion activity in the test solution is unity. Since the measurements were carried out at a constant ionic strength of 0.1 M, the junction potential was kept approximately constant.

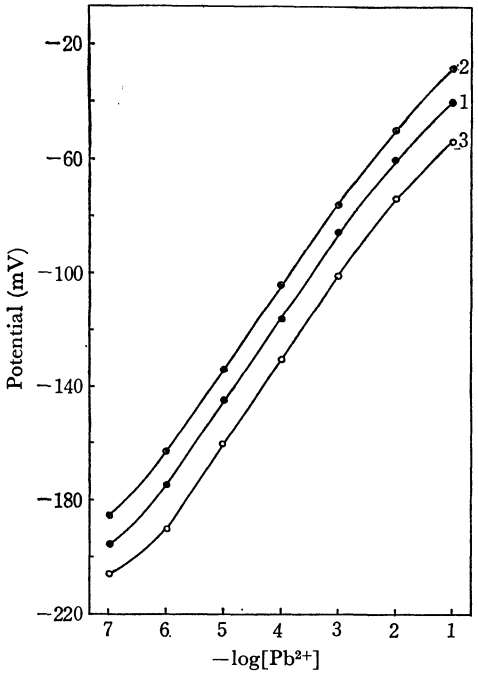

Fig. 2. Potential *vs.* concentration curves for the membranes prepared by hot-pressing method (at 370°C, for 2hr and under a pressure of 7 ton cm^{-2}).

1. PbS 30% Ag_2S 65% Cu_2S 5%
2. PbS 50% Ag_2S 40% Cu_2S 10%
3. PbS 80% Ag_2S 16% Cu_2S 4%

The actual potential of the ceramic membrane electrode *vs.* the saturated calomel electrode as a function of the lead-ion concentration is demonstrated in Fig 2. A straight line has been drawn, over a range of lead-ion activities from 10^{-1} to 10^{-6}M, with a slope of 29.5 mV per log [Pb^{2+}] unit. This value is in agreement with that predicted by the Nernst relationship. The experimental results suggest that the ceramic electrode membrane material used in the indicator electrode and the applied sintering process were very effective. Moreover, the analytical range of this electrode, as depicted in Fig. 2, was a concentration of 10^{-1}—10^{-7} mol/*l*.

Dynamic Response Characteristics. When an ion-selective membrane electrode is utilized for the concentration control of a reaction process or as an indicator electrode in the potentiometric titration, the dynamic-response characteristic is a very important factor. The response characteristics of the lead ion-sensitive membrane electrode were evaluated by exposing the electrode to a rapid change in lead-ion concentration (approximately twofold) and by recording the resulting e.m.f. *vs.* time function. The dynamic-response experiment was carried out with hot-pressed ceramic membranes containing 30, 50, and 80 wt% of lead sulfide. Some of the resulting response curves typical of the results obtained, are represented in Fig. 3.

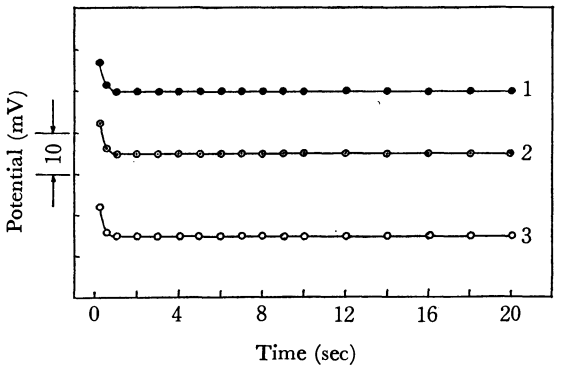

Fig. 3. Dynamic response curves.
Membranes for the curves 1, 2, and 3 are identical with those numbered in Fig. 2 in the compositions and preparation conditions respectively.

All the curves were smooth and of an identical shape; the expected (on the basis of calibration curves) e.m.f. value was attained in all cases. The response half-time $t_{1/2}$ of the electrode used depends on the stirring method, the efficiency of the solution mixing, and the cleanliness of the electrode surface, but it is independent of the initial lead-ion concentrations over the entire range studied. The response half-times obtained are of an order of less than one second for the present experimental conditions and are probably determined mainly by the mixing efficiency. Since the electrode used is an extremely low-solubility ceramic ionic semiconductor (the electrical resistance is less than 100 ohm-cm), the rapid response to changes in the lead-ion concentration is not unexpected. The high response rate of this electrode suggests that a continuous monitoring of lead-ion activities in aqueous solutions would be feasible.

Influence of pH. Figure 4 shows the influence of the pH on the lead ion-selective ceramic membrane electrodes in 10^{-2}, 10^{-4}, and 10^{-6}M Pb^{2+} solutions. The potentials did not change at pH values below 6.5. They did, however, decrease sharply when the pH increased above 6.5, for the precipitation of $Pb(OH)_2$ occurred. Of course, the pH at which the precipitation begins depends on the concentration of the lead ion. The resulting curves in Fig. 4 also show that the measurable pH range is independent of the lead-sulfide content in the membrane. However, the membrane containing much more than 50% of lead sulfide dissolved and the potential become unstable at a lead-ion concentration lower than 10^{-6} mol/*l*, when it was

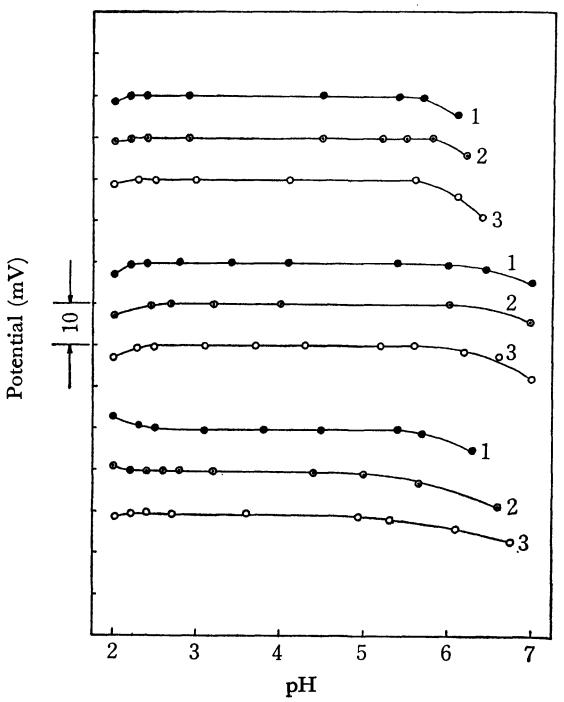

Fig. 4. Influence of the pH.
Membranes corresponding to the numbers of the curves are the same as those of Fig. 2 in their preparation conditions and compositions.

exposed in a solution with a pH below 2 for a long time.

Selectivity. No electrode is entirely selective towards a particular ion, and the presence of other ions may seriously impair electrode performance. It is, therefore, important to be aware of such interferences. An approximate selectivity constant can be derived experimentally from the ratio of ionic concentrations where the interfering ion causes deviation from the expected theoretical ($2.303\,RT/2F$) slope.[3]

Tests of the effects of several ions *e.g.* Ag^+, Cu^{2+}, Hg^+, S^{2-}, Fe^{3+}, I^-, Cd^{2+}, Br^-, alkali metal, alkaline earth metal, Zn^{2+}, Al^{3+}, Ni^{2+}, *etc.* on the lead ion-selective ceramic membrane prepared by the hot-pressing method were made in solutions containing 10^{-4}M of lead ions. The concentration ratios of common ions to lead ion were varied from 1 to 1000, Among the common ions, silver, cupric, mercury(I), ferric, sulfide, and iodide ions interfered seriously. About 10 times as many cadmium and bromide ions and more than 1000 times as much alkali metal, alkaline earth metal, zinc, aluminum, nickel, manganese(II), cobalt, and nitrate did not interfere with the lead ion. The lead-sulfide content in the ceramic membrane was independent of the selectivity in the present experimental range.

The numerical selectivity ratios of the electrode for the lead ion with respect to these common ions were not evaluated, but, in view of this finding, it is clear that this electrode is well suited for the selective analytical measurement of lead-ion activity in a wide variety of practical systems.

Effect of the Temperature. The electrode was safely used at temperatures from 0 to 95°C, and the potentials of the membrane satisfied the Nernstian equation within the limits of experimental error.

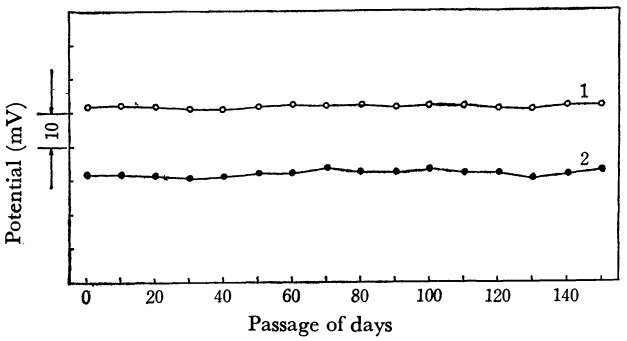

Fig. 5. Long term stability of the membranes hot-pressed at 370°C, for 2hr and under 7 ton cm^{-2}, containing
1. PbS 30% Ag_2S 65% Cu_2S 5%
2. PbS 50% Ag_2S 40% Cu_2S 10%

Lifetime. A continuous potential measurement was made using a hot-pressed ceramic membrane electrode in a specially-designed sample circulation cell. Figure 5 demonstrates that the ceramic membrane electrode had a very long lifetime and that the long-term stability and accuracy was well suited to the continuous monitoring of lead-ion activities in an aqueous solution in relation to the rapid response to changes in the lead-ion concentrations.

The authors thank Drs. S. Kisaka, K. Sugihara, and S. Hayakawa for their encouragement in this work. Thanks are also due to Messrs. T. Miyazawa and H. Yamao for X-ray analysis and microscopic photograph of the electrode membrane.

The Preparation and Absorption Spectra of the Geometrical Isomers of Carbonatoglycinatodiamminecobalt(III)[1]

Shuji KANAZAWA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 1, 1971)

Three geometrical isomers of the $[CoCO_3(gly)(NH_3)_2]$ complex, the *mer*(*cis*-diammine)-, *mer*(*trans*-diammine)-, and *fac*-isomers, have been isolated from a reaction mixture of the *cis*-$[Co(CO_3)_2(NH_3)_2]^-$ ion with glycine by means of a study of the solubility difference and by means of ion-exchange chromatography. These isomers have been characterized by the absorption spectra, the PMR spectra, and the infrared spectra. The absorption spectrum of the *mer*(*trans*)-isomer is of special interest, and there is a clear shoulder in the second absorption band region which may be due to the splitting of the second band.

Recently there has been interest in the absolute configurations of the *tris*(α-amino-acid) complexes of cobalt(III)[2-5] and also their stereoselectivities.[4,6,7] In preparing such complexes, it has been recognized that the method using the tricarbonatocobaltate(III) anion as the starting material is of use in the preparation of possible isomers for a *tris*(α-amino-acid) complex.[3,4,7,8] In the present work we undertook to use the dicarbonatodiamminecobaltate(III) anion[9,10] in the preparation of the carbonatoglycinatodiamminecobalt(III) complex. This complex, like the *tris*(amino-acid) complexes, belongs to the general type of $[CoN_3O_3]$ and is expected to have three geometrical isomers, two of *mer* and one of *fac*. We succeeded in obtaining the three isomers from a reaction mixture of the starting material with glycine by studying the solubility difference and by ion-exchange chromatography. The isomers obtained were characterized mainly by the electronic absorption and proton magnetic resonance spectra. By the way, the corresponding ethylenediamine complexes of the [Cogly(chelate)en] type (the chelate represents CO_3^{2-}, $C_2O_4^{2-}$ or the malonate ion) have already been synthesized by Matsuoka *et al.*[11]

Experimental

Preparation. In a solution of 4 g (0.015 mol) of potassium *cis*-dicarbonatodiamminecobaltate(III)[9,10] in 10 m*l* of water, an equimolar amount (1.2 g) of glycine was dissolved. The mixture was then stirred at room temperature for 10—12 hr. During this reaction, a considerable amount of fine red crystals were precipitated. The crystals were collected by filtration and recrystallized from water containing a small amount of potassium bicarbonate. A portion of the filtrate was added to a cation-exchange column containing 100—200 mesh Dowex 50W×8 resin in the sodium form (diameter, 4.5 cm; resin height, 25 cm). When water was passed through the column at a rate of about 10 m*l*/min, four red-violet bands appeared. The first band consisted of negatively-charge complexes, such as $[Co(CO_3)_2(NH_3)_2]^-$ and $[CoCO_3(gly)_2]^-$. The other three bands were isomers of the desired complex; hence, they were collected in three fractions. The fractions were conveniently numbered Nos. 1—3 in the descending order of the bands. This chromatographic separation was repeated several times in order to treat all the reacted solution. Each fraction was then concentrated to a small volume under reduced pressure at about 40°C. When a small amount of ethanol was added to the concentrate and the whole was kept in a refrigerator for one day, the desired material was precipitated. Recrystallization was done from water containing a small amount of potassium bicarbonate. The compound which had precipitated during the process of reaction was identical with that obtained from the No. 2 fraction, and the former by far exceeded the latter in yield (1 g for the former, and 0.2 g for the latter). For the other compounds, the yields were 0.4 g from the No. 1 fraction and and 0.6 g from the No. 2 fraction.

Found for the complex from No. 1: C, 14.65; H, 4.82; N, 17.12. Calcd for $[CoCO_3(C_2H_4NO_2)(NH_3)_2]\cdot H_2O$: C, 14.70; H, 4.90; N, 17.15%.

Found for the complex from No. 2: C, 13.96; H, 4.94; N, 15.96. Calcd for $[CoCO_3(C_2H_4NO_2)(NH_3)_2]\cdot 2H_2O$: C, 13.70; H, 5.30; N, 15.97%.

Found for the complex from No. 3: C, 14.60; H, 4.51; N, 17.25. Calcd for $[CoCO_3(C_2H_4NO_2)(NH_3)_2]\cdot H_2O$: C, 14.70; H, 4.90; N, 17.15%.

Measurements. The absorption spectra were usually measured with a Hitachi EPU-2A spectrophotometer, but sometimes with a Cary-14 spectrophotometer by way of precaution. The infrared spectra were measured as KBr disks with a Jasco DS-301 spectrometer (4000—700 cm^{-1}) and also with a Hitachi EDI spectrometer (700—250 cm^{-1}). The proton magnetic resonance (PMR) spectra were recorded on a JEOL C-60H spectrometer operating at 60 Mc/sec. The spectra were measured in deuterated trifluoroacetic acid, using tetramethylsilane as the internal standard. The molar conductivity was measured with a Universal Bridge BV-Z-12A, using a 5×10^{-3}M aqueous solution. The absorption spectra of a single crystal were measured through the good offices of Professor Y. Kondo of Rikkyo University.

Results and Discussion

Although the chromatographic behavior described in the experimental section was evidence for the non-

charged species, the molar conductivities of the isomers gave additional proof of the fact. The molar conductivity values were 6 for the isomer from the No. 1 fraction, 8 for that from No. 2 fraction, and 10 mho cm^{-1} for that from the No. 3 fraction.

Three possible geometrical isomers for the present complex are shown in Fig. 1. The first one has two NH_3 groups in the *cis* position and three N (or O) atoms in the *cis-trans* positions (a); the second one has two NH_3 in the *trans* position and three N atoms in the *cis-trans* positions (b), and the third one has two NH_3 in the *cis* position and three N atoms in the *cis-cis* positions (c). Hereafter, these will be represented as the *mer*(*cis*)-, *mer*(*trans*)-, and *fac*-isomers respectively. Furthermore, the three isomers will also be represented as No. 1, No. 2, and No. 3 isomers according to the fraction number. In order to assign these possible structures to the isolated isomers, the data from the absorption, PMR, and IR spectra were used.

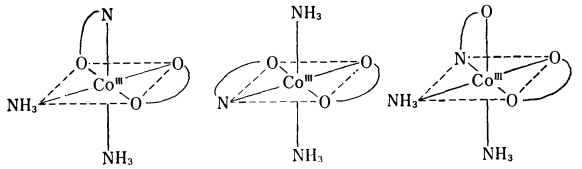

Fig. 1. Possible isomers.

Absorption Spectra. The absorption spectra of the three isomers in aqueous solutions containing potassium bicarbonate are shown in Fig. 2. The spectrum of the No. 3 isomer shows the first absorption band (ν_1) at 56.2×10^{13} sec^{-1} (log ε=2.04) and the second band (ν_2) at 80.1×10^{13} sec^{-1} (log ε=2.13). These values are very similar to those for the known *fac*(N)-[$CoCO_3$-(gly)en][11] (ν_1=56.6 (2.17), ν_2=80.4 (2.13)). This fact indicates that the No. 3 isomer can be assigned to the *fac*-form. When the spectrum of the No. 1 isomer is compared with that of the known *mer*(N)-[$CoCO_3$-(gly)en],[11] the ν_1 and ν_2 values for the former are, in some extent, smaller than those for the latter; for the present isomer, ν_1=54.2 (2.03) and ν_2=79.5 (2.25); for comparison, ν_1=56.6 (2.07) and ν_2=81.1 (2.17). However, the spectrum is very similar to that of the familiar *mer*-[Co(gly)$_3$] isomer[12,13] and exhibits a lower intensity in the first band (half width=*ca.* 12.5×10^{13} sec^{-1}) than in the second band.[14] From these facts, the structure of this No. 1 isomer can be regarded as either one of the two *mer*-forms.

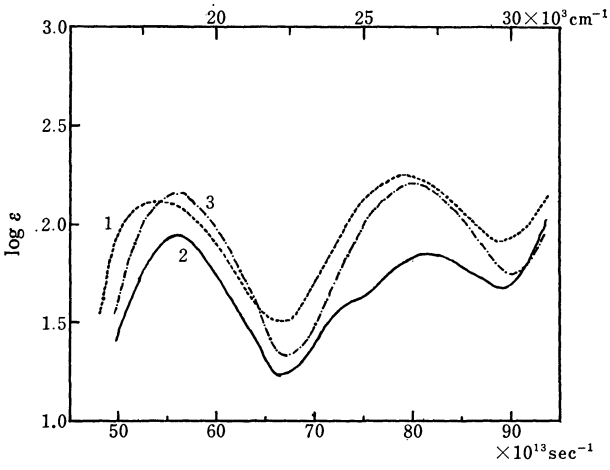

Fig. 2. Absorption spectra of the isomers in $KHCO_3$ aqueous solution.
1) *mer*(*cis*) ····· (No. 1)
2) *mer*(*trans*) —— (No. 2)
3) *fac*-isomer ·-·-· (No. 3)

The absorpsion spectrum of the No. 2 isomer shows a shoulder in the second absorption band region (ν_1= 56.0 (1.93), sh=74.8 (1.6), ν_2=81.8 (1.85)). Apart from this shoulder, the isomer is regarded as another *mer*-from on the basis of the broadened first absorption band (half width=*ca.* 11.2×10^{13} sec^{-1}).

It is a very interesting fact that such a shoulder appears in the second absorption band region. Splittings of the first absorption band are widely observed in *mer*-isomers of the *tris*(amino-acid) complexes and also in *trans*-isomers of dihalogenotetraammine-type complexes, and can be understood with the aid of a ligand field theory, such as Yamatera's prediction.[15] The splitting of the second band has, however, never been observed in the solution spectra of cobalt(III) complexes,[16] although such splitting has been observed in the crystal spectra for some complexes of cobalt-(III).[17]

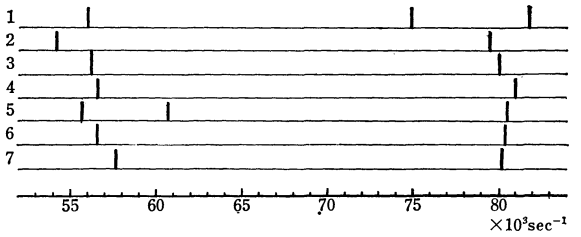

Fig. 3. Experimental band positions for [Co N_3O_3]-type complexes.
1. *mer*(*trans*)-[$CoCO_3$gly$(NH_3)_2$] (No. 2)
2. *mer*(*cis*)-[$CoCO_3$gly$(NH_3)_2$] (No. 1)
3. *fac*-[$CoCO_3$gly$(NH_3)_2$] (No. 3)
4. *mer*-[$CoCO_3$(gly)en][9]
5. *mer*-[Cogly$_3$][11]
6. *fac*-[$CoCO_3$glyen][9]
7. *fac*-[Cogly$_3$][11]

In Fig. 3 the experimental band positions for the present three and some related complexes are schematically represented. It seems to be unreasonable to regard the shoulder concerned as a component of the first band, because only a partial splitting or a braodened shape of the first band is observed in the other *mer*-isomers. When the second band maxima are compared among these isomers, it is noticed that the value (81.8) for the No. 2 isomer is considerably higher than those for the other isomers (80—81$\times10^{13}$ sec^{-1}).

Original soln. ——
Acidified soln. -·-·-
Alkalined soln. ·····

Furthermore, the intensity of the ν_2 band (ε=70.5) is considerably smaller than that of the ν_1 band (ε=95.8). From these facts, we can now assume the splitting of the second band for this isomer.

When the absorption spectrum of a solution of the No. 2 isomer acidified with perchloric acid was measured (Fig. 4(a)), the above-mentioned shoulder disappeared and the ν_1 band was observed at a considerably longer wavelength (at 54.7×10^{13} sec^{-1}), contrary to expectations of the positions of the CO_3^{2-} and H_2O ligands in the spectrochemical series. When the acidified solution was again alkalined with a large amount of potassium bicarbonate, the spectrum of the resulting solution was identical with that of the original solution. The spectra for the acidified solutions of the other two isomers showed some shifts of the ν_1 bands to the shorter-wavelength side (Fig. 4(b) and (c)). The spectra for the solutions again alkalined returned to the same spectra as in the original solutions. These facts suggest a configuration retention of these isomers in the process of acid hydrolysis.

The absorption spectra of a single crystal for the No. 2 isomer are shown in Fig. 5. The dichroism of this complex is clearly observed in the first absorption band region. Both of the polarized lights are strongly absorbed in the second band region, but the relative intensities of the two maxima differ for the two directions of the light.

PMR Spectra. Because of the limited solubility of the present compounds in water and because of the instability of their aqueous solutions, the samples for

the measurement were dissolved in deuterated trifluoroacetic acid. On the assumption of the configuration retention in the process of acid hydrolysis, the PMR spectra, which are shown in Fig. 6, will now be discussed.

The spectrum on the No. 1 isomer shows two peaks due to the two NH_3 groups, at 5.1 and 5.8 ppm, and also a peak due to a NH_2 group of the chelated glycinate at 3.5 ppm (b). The integrated ratio of these three peaks is estimated to be 3:3:2, corresponding to the proton numbers concerned. This indicates the existence of two NH_3 groups in different environments; from this fact, this isomer can be identified as the *mer(cis)*-isomer. The spectrum on the No. 2 isomer shows two peaks, due to the NH_3 group and the NH_2 group, at 5.2 and 4.5 ppm respectively (a). From the area ratio of about 3:1, we can now judge this isomer to be the *mer(trans)* one. The spectrum of the No. 3 isomer exhibits one peak of the NH_2 protons at 4.6 ppm and one broad pattern at 5.7—6.4 ppm which may be resolved into three peaks due to the two different NH_3 groups and the one CH_2 group of the chelated glycinate

(c). These results would seem to support the previous conclusion that this isomer is of the *fac*-form.

Infrared Absorption Spectra. The spectra of the present three isomers are shown in Fig. 7. It is clear that the carbonate ion in each isomer coordinates to central cobalt atom as a bidentate ligand, because of the presence of the characteristic sym. ν(C–O), asym. ν(C–O), and sym. ν(C=O) bands at about 1020, 1280, and 1600 cm^{-1} respectively.[18] It is also clear that the glycinate ion coordinates as a bidentate ligand, because of the presence of the band near 1600 cm^{-1} as well as the absence of the deformation band of the $-NH_3^+$ group near 1500 cm^{-1}.[19]

When the spectra in the 700—1400 cm^{-1} region are compared among the three isomers, the spectrum of the *mer*(*trans*)-isomer reveals the simplest pattern and all of the bands are attributable to the CH_2 and NH_2 waggings (1350—1300 cm^{-1}), the CH_2 twisting (1200—1180 cm^{-1}), and the NH_2 and CO_3 out-of-plane rockings (850—800 cm^{-1}). The infrared spectrum of a lower symmetry complex, in general, exhibits a more complicated pattern than that of the related higher-symmetry complex.[20,21] From this point of view, it can be said that the No. 2 isomer has a *trans* configuration with respect to the coordinated NH_3 groups, whereas the No. 1 isomer has a *cis* configuration.

Functional Group Analysis by Gas Chromatography. IV.[1] Pyrolytic Reaction of Carboxylic Acids in Sulfur Vapor

Tadashi HARA and Susumu ITO

Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received March 8, 1971)

This paper deals with a quantitative gas chromatographic analysis of the product evolved by the pyrolytic reaction between carboxylic acid and sulfur vapor. About 10 mg of carboxylic acid was mixed with 2—3 g sulfur and made to react at 1000—1100°C for 10min. The gaseous product was taken in a gas sampler and subjected to gas chromatography. Carbon dioxide was produced from the carboxyl group, carbon disulfide from carbon, hydrogen sulfide from hydrogen and nitrogen molecule from nitrogen. The peak area ratios of carbon disulfide and hydrogen sulfide to carbon dioxide were found in the gas chromatogram with glycine as a standard substance, and the other carboxylic acids were analyzed on the basis of the relation between the peak area ratio and the chemical composition of glycine. Aliphatic and aromatic carboxylic acids gave satisfactory resuls by this method, but not pyridine carboxylic acid. Weighing a definite amount of sample is not needed in this method. Information concerning the chemical composition as well as the functional group of a carboxylic acid can be obtained.

Studies have been carried out synthetically and kinetically pertaining to the reaction between sulfur and organic compounds, especially aliphatic hydrocarbons in a gaseous phase.[2-7] However, none of them has been applied to the analysis of an organic compound.

In a conventional elementary analysis, the sample is subjected to combustion in an oxygen stream and converted into water and carbon dioxide, the water being determined gas-chromatographically with difficulty. Though the method is effective for knowing the chemical composition of the sample, it does not offer

any information about the functional group. We proposed a new method,[1] in which organic compounds were subjected to pyrolysis in sulfur vapor and the reaction products were analyzed gas-chromatographically. We could determine the chemical composition as well as the functional group.

We investigated the pyrolysis of carboxylic acids in sulfur vapor, in which the reaction products such as hydrogen sulfide, carbon dioxide and carbon disulfide are determined by means of gas chromatography. Since the carboxyl group is quantitatively converted into carbon dioxide, the reaction products other than carbon dioxide are represented on the basis of the amount of carbon dioxide.

Experimental

Reagents. Since commercial crystalline sulfur (analytical grade) contains carbon disulfide, it was dried at 90°C for 24 hr, pulverized and dried again. The other reagents were either of analytical grade, or purified. Helium was of commercial grade.

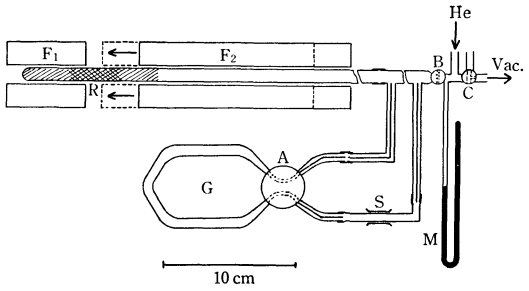

Fig. 1. Apparatus.
F_1,F_2: Electric furnace, G: Gas sampler,
S: Stroke pump, M: Manometer,
R: Reaction tube

Procedure. Two to three grams of powdered sulfur was divided into three portions, the first being charged into a 10 mm diam. × 400 mm quartz tube R with a closed end (Fig. 1). The second is mixed with about 10 mg of sample and charged into the tube, followed by the third portion. The tube was connected to the circulating system with rubber and evacuated through the cocks B and C, followed by replacement of air by helium.

The electric furnaces F_1 and F_2 were held at 750—800°C and 1000—1100°C, respectively. F_2 was placed at a certain position. After three minutes F_1 was placed at another position. F_2 is gradually moved. After completion of the reaction, cock A was closed and the gas sampler separated from the system, followed by gas chromatographic determination of the reaction products.

The reaction temperature was calibrated by a model experiment and maintained within a definite range.

The gas chromatogram was obtained with a Yanagimoto GCG-5DH gas chromatograph under the following conditions: A 2 m stainless steel column was charged with silica gel (60—80 mesh), and held at 100°C. Helium was flowed at the rate of 40 m*l* He/min, and the separated substances were detected with a thermal conductivity detector. The peak area in the gas chromatogram was approximated by the half-width method.

Results and Discussion

Effect of Reaction Temperature. In order to examine the effect of reaction temperature on the products, a dibasic aliphatic acid was treated at 800—850°C and 1000—1100°C, and the mole ratios of hydrogen sulfide or carbon disulfide to carbon dioxide were estimated. The results are shown in Fig. 2. The abscissa represents the theoretical mole ratios of hydrogen or carbon to the carbon dioxide based on the –COO– in the carboxylic acid, and the ordinate represents the experimental peak area ratios of hydrogen sulfide or carbon disulfide to carbon dioxide. The amount of carbon disulfide increased at higher temperature while that of hydrogen sulfide was independent of the reaction temperature. Though the amount of carbon disulfide was expected to increase with the rise of temperature, the reaction temperature was kept at 1000—1100°C since hydrogen sulfide had been reported to decompose at temperatures higher than 1000°C in accordance with the following reaction[8]:

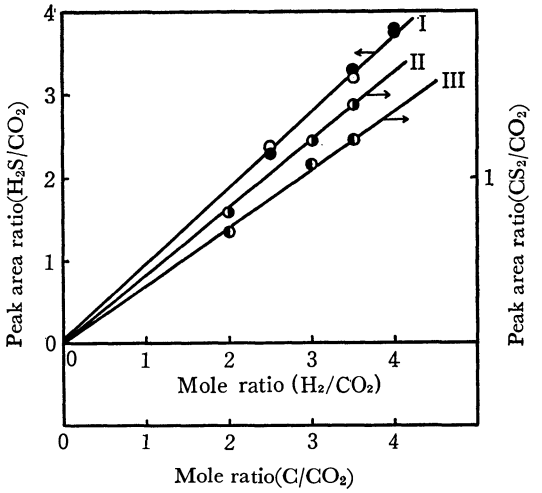

Fig. 2. Relationship between peak area ratios and mole ratios
I: H_2S, II, III: CS_2
○, ◐: 800—850°C, ●, ◑: 1000—1100°C

$$2H_2S \longrightarrow 2H_2 + S_2$$

Hydrogen sulfide was also produced by the reaction between hydrogen and sulfur at 1000—1100°C. Decomposition of hydrogen sulfide at the same temperature thus seems to be negligibly small in the presence of an excess sulfur. This is supported by the equilibrium constant for the reaction $H_2 + {}^1/_2\, S_2 \rightleftharpoons H_2S$, in which $K = P(H_2S)/P(H_2) \times P(S_2)^{1/2}$, and the values of log K are 1.305 at 1218°K and 0.964 at 1338°K.[9]

It is evident that the amount of hydrogen sulfide and carbon disulfide are proportional to the number of hydrogen and carbon atoms in the compounds such as adipic, suberic and azelaic acids.

Effect of Catalyst. Catalysts such as alumina,[5]

8) A. J. Owen, K. W. Sykes, and D. J. D. Thomas, *Trans. Faraday Soc.*, **49**, 1207 (1953).

9) "International Critical Tables," Vol. 7, ed. by E. D. Washburn, Mcgraw-Hill Book Co., Inc., New York and London (1930), p. 237.

silica gel,[5,6] and vanadium pentoxide[3,7] used for the reaction between hydrocarbon and sulfur, were applied to the present reaction. However, the amount of hydrogen sulfide and carbon disulfide evolved did not change so markedly and sulfur dioxide was produced by the reaction between the oxygen in the catalysts and sulfur vapor. These catalysts are not suitable for the determination of the compound containing sulfonic- and nitro-groups since they were converted into sulfur dioxide.[1]

Effect of Stainless Steel Column. The reaction between hydrogen sulfide and stainless steel tube was examined. However, no reaction was confirmed under the conditions in the present procedure.[10]

Determination of Factors by Glycine. The factors for determination of each components were calculated by the equation $E/CO_2=F(A(E)/A(CO_2))$, where E: mole number of a particular element in glycine, CO_2: mole number of carbon dioxide in glycine, $A(E)$: peak area of the compound containing a particular element in glycine, $A(CO_2)$: peak area of carbon dioxide in glycine, F: factor.

Assuming the factor of carbon dioxide $F(CO_2)=1$, the factors for nitrogen, hydrogen, and carbon are $F(N_2)=1.56$, $F(H_2)=1.04$ and $F(C)=2.97$. The chemical composition of nitrogen, hydrogen, carbon and carboxyl group as carbon dioxide is easily determined by multiplying $A(E)/A(CO_2)$ by F.

Analysis of Aliphatic Carboxylic Acids. The monobasic acids which boil at lower temperature were used as their sodium salts. No carbon dioxide was captured by sodium salt. *n*-Caproic and *n*-caprylic acids were charged in a glass capillary and analyzed. Table 1 shows the results obtained.

Analysis of Amino Acids. Though L-cysteine and L-cystine contain sulfur as components, the sulfur content cannot be estimated by the present method, which is one disadvantage. However, the sulfur content in a sulfonic group is determined as sulfur dioxide. Both L-cysteine and L-lysine were subjected to analysis as their hydrochlorides, but no effect of hydrochloride was found (Table 2).

Analysis of Aromatic Carboxylic Acids. In the pyrolytic reaction of aromatic carboxylic acid at 800—850°C, the amount of carbon disulfide evolved was less than that in an aliphatic carboxylic acid. The same factors as for an aliphatic carboxylic acid could, however, be applied to the pyrolytic reaction of an aromatic carboxylic acid at 1000—1100°C (Table 3). This can be attributed to the fact that the carbon-carbon bond energy in a benzene ring is larger than that in an aliphatic compound. Pyridinecarboxylic acid alone did not give a satisfactory result, and no nitrogen being found in a gaseous product. It seems that the pyridine ring is still stable at the reaction temperature or converted into a nonvolatile substance, but this has not been confirmed. By this method we cannot estimate the absolute number of carboxylic group.

Table 3. Analytical results of aromatic carboxylic acids

Compound	Formula	
	Theroetical	Found

The Synergic Solvent Extraction of Rare Earths. II. The Absorption Spectra of Neodymium-, Holmium-, and Erbium-TTA-TOPO Complexes with ClO_4^-, CNS^-, NO_3^-, and Cl^- Ions

Tomitsugu TAKETATSU and Nobuyo OHKURA
College of General Education, Kyushu University, Fukuoka

(Received March 20, 1971)

The synergic solvent extraction behavior of neodymium, holmium, and erbium in Ln^{3+}/X^-/HTTA/TOPO systems ($X^- = ClO_4^-$, CNS^-, NO_3^-, and Cl^-) have been investigated. When the rare earths are completely extracted into an organic layer, the following equation is assumed:

$$Ln(TTA)_3(TOPO)_{2(o)} + 3TOPO_{(o)} + H^+_{(a)} + X^-_{(a)} \rightleftharpoons (Ln(TTA)_2(TOPO)_5)^+X^-_{(o)} + HTTA_{(o)}$$

for which the mixed equilibrium constant is defined by $k_3 = [(Ln(TTA)_2(TOPO)_5)^+X^-]_{(o)}[HTTA]_{(o)}/[Ln(TTA)_3(TOPO)_2]_{(o)}[TOPO]^3_{(o)}[H^+]_{(a)}[X^-]_{(a)}$. The log k_3 value for the holmium/ClO_4^-, /CNS^-, /NO_3^-, and /Cl^- systems are about 8.3, 6.5, 5.3, and 3.6 respectively. An obvious difference between Ln^{3+}/SO_4^{2-}/HTTA/TOPO and Ln^{3+}/ClO_4^-/HTTA/TOPO systems is observed in the order of the distribution ratio on the extraction of a series of rare earths with an increase in the atomic number.

In the previous paper,[1] when holmium and erbium were completely extracted from aqueous perchlorate solutions into various organic solutions containing 2-thenoyltrifluoracetone (TTA) and tri-*n*-octyl phosphine oxide (TOPO), it was shown that the following equation held:

$$Ln(TTA)_3(TOPO)_{2(o)} + 3TOPO_{(o)} + H^+_{(a)} + ClO^-_{4(a)} \rightleftharpoons (Ln(TTA)_2(TOPO)_5)^+ClO^-_{4(o)} + HTTA_{(o)}$$

for which the mixed equilibrium constant was defined by $k_3 = [(Ln(TTA)_2(TOPO)_5)^+ClO_4^-]_{(o)}[HTTA]_{(o)}/[Ln(TTA)_3(TOPO)_2]_{(o)}[TOPO]^3_{(o)}[H^+]_{(a)}[ClO_4^-]_{(a)}$ and in which the k_3 linearly increased with an increase in the dielectric constant of the organic solvent used.

In the present paper, we will describe a spectrophotometric study of neodymium-, holmium-, and erbium-TTA-TOPO complexes extracted from aqueous solutions containing perchlorate, thiocyanate, nitrate, chloride, sulfate or acetate ions, also, we will discuss the formation of these metal TTA-TOPO complexes associated with various anions.

Experimental

The preparation of the reagents and all the experimental procedures were the same as in the previous paper.

Results and Discussion

(i) Absorption Spectra in Nd^{3+}/HTTA/TOPO/ClO_4^- System. The absorption spectra of a cyclohexane solution containing neodymium-TTA-TOPO complexes extracted from an acetate solution and of a 1,2-dichloroethane solution containing the complexes extracted from the perchlorate solution by the extraction procedure are given in Fig. 1. The patterns of these spectra are defined as α- and β-types respectively. The pattern of the α-type is identical with that of the $Nd(TTA)_3(TOPO)_2$ complexes in the literature.[2,3]

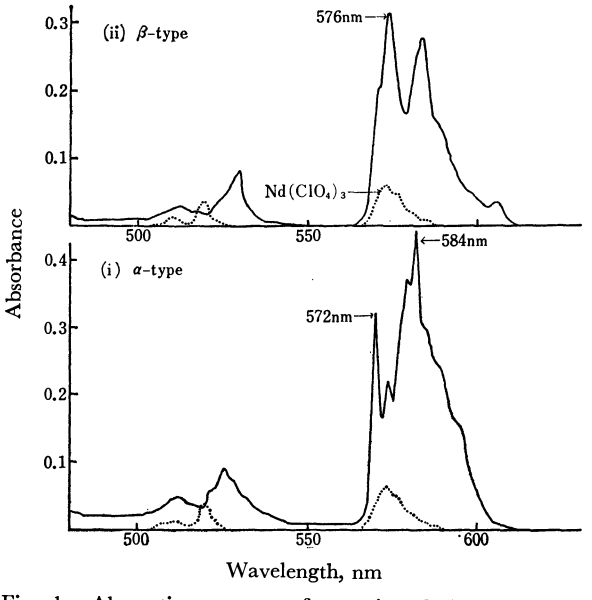

Fig. 1. Absorption spectra of organic solutions containing Nd-TTA-TOPO complexes.
(i) Aqueous layer: 0.00943M Nd^{3+}, 0.4M CH_3COO^-
Organic layer: 0.1M HTTA, 0.1M TOPO, cyclohexane
(ii) Aqueous layer: 0.00943M Nd^{3+}, 0.4M CH_3COO^-, 1.0M ClO_4^-
Organic layer: 0.1M HTTA, 0.1M TOPO, 1,2-dichloroethane

The absorption spectra of all the organic solutions containing the metal complexes extracted from the acetate solution gave an α-type spectrum. On the other hand, in the case of extraction from perchlorate solutions, the pattern of the spectra changed from the α- to the β-type with an increase in the dielectric constant of the organic solvent used, as was also observed in the cases of holmium and erbium.[1]

The variations in the absorption spectra of 1,2-dichloroethane solutions containing the neodymium-TTA-TOPO complex were studied as a function of the concentrations of perchlorate ions added to the acetate solution and of the hydrogen ions of the solutions containing a definite quantity of perchlorate ions.

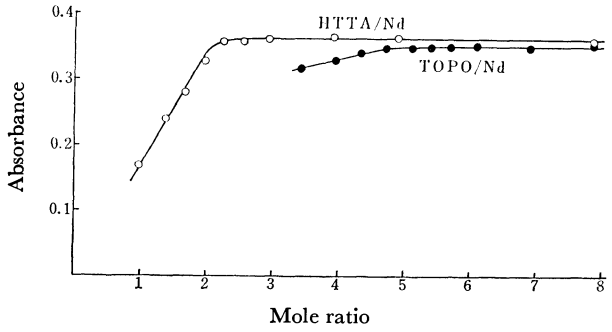

Fig. 2. Variation in absorbance with increasing of concentration of HTTA in the presence of excessive amount of TOPO and with that of TOPO in the presence of excessive amount of HTTA.
Aqueous layer: 0.0102M Nd^{3+}, 1.0M ClO_4^-, 0.5M CH_3COO^-.
Organic layer: varying HTTA, 0.1M TOPO or 0.1M HTTA, varying TOPO, 1,2-dichloroethane

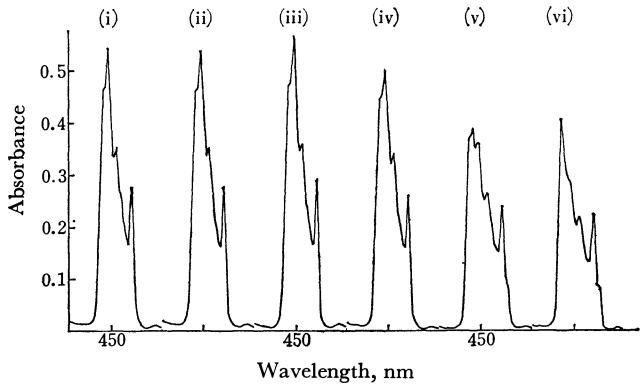

Fig. 3. Variation in absorption spectra with increasing of dielectric constant (ε) of organic solvents used in the Ho^{3+}/NO_3^-/HTTA/TOPO system.
Aqueous layer: 0.00541M Ho^{3+}, 1.20M NO_3^-.
Organic layer: (i) benzene (ε 2.28) (ii) trichloroethylene (ε 3.42) (iii) isopropyl ether (ε 3.88) (iv) chlorobenzene (ε 5.62) (v) dichloroethane (ε 9.08) (vi) 1,2-dichloroethane (ε 10.32), 0.2M HTTA, 0.2M TOPO.

The change in these absorption spectra from the α- to the β-type also progressed with an increase in the concentration of perchlorate or hydrogen ions.

The variations in the absorbance at 576 nm were studied as a function of the concentration of TTA *vs.* the neodymium added to the aqueous layer, using 1,2-dichloroethane solutions containing various amounts of TTA and a fixed, excessive amount of TOPO; we also studied them as a function of the concentration of TOPO *vs.* neodymium, using organic solutions containing a fixed, excessive amount of TTA and various amounts of TOPO. The results are given in Fig. 2. Breaks are observed at mole ratios of TTA: Nd=2:1 and TOPO: Nd=5:1 though the latter break is somewhat obscure.

It is supposed that the β-type complex has the chemical composition of $(Nd(TTA)_2(TOPO)_5)^+ClO_4^-$ for the

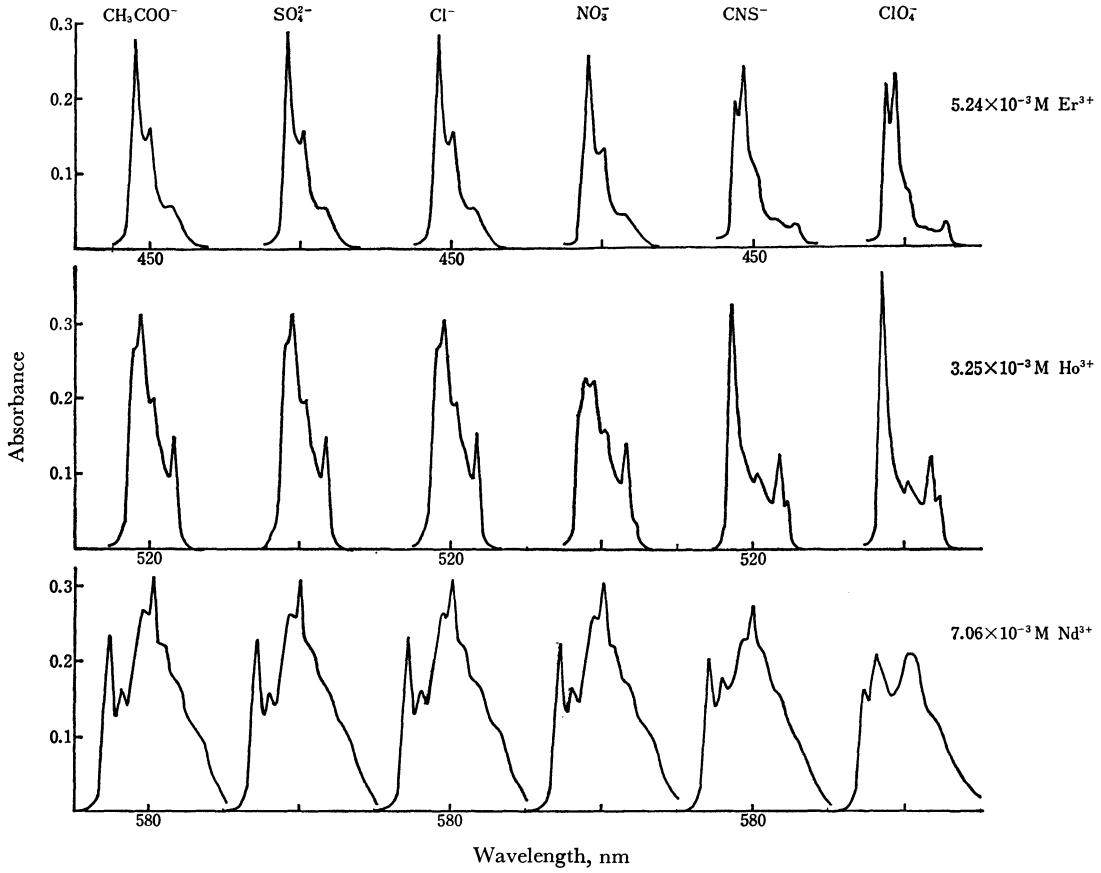

Fig. 4. Absorption spectra of 1,2-dichloroethane solutions in Er^{3+}, Ho^{3+}, and Nd^{3+}/CH_3COO^-/X^{n-}/HTTA/TOPO systems.
Aqueous layer: 0.1M SO_4^{2-}, Cl^-, NO_3^-, CNS^-, and ClO_4^-, 0.04M CH_3COO^-
Organic layer: 0.1M HTTA, 0.1M TOPO

electric conductivity of 1,2-dichloroethane solutions containing the neodymium complexes increases almost linearly with an increase in the absorbance at 576 nm, as was observed in the cases of holmium- and erbium-TTA-TOPO complexes.

Although the estimation of the k_3 value using the assumption described in the previous paper is not always accurate because the new band at 576 nm of the β-type spectrum appears in the middle of the bands at 572 and 584 nm of the α-type spectrum, it is assumed that the log k_3 value for neodymium using 1,2-dichloroethane is approximately 6 and that it is lower than that ($\log k_3 \fallingdotseq 8$) of holmium and erbium.

(ii) Absorption Spectra in Ln^{3+}/HTTA/TOPO/X^- Systems. The behavior of the absorption spectra of organic solutions containing rare earth-TTA-TOPO complexes extracted from an aqueous solution containing thiocyanate, nitrate, chloride, or sulfate ions in place of perchlorate ions was investigated. As an example, the absorption spectra of various organic solutions containing holmium extracted from acetate solutions containing a definite amount of nitrate ions are given in Fig. 3. It can be seen that the patterns of these spectra change from the α- to the β-type in accordance with an increase in the value of the dielectric constant, as was also observed in the case of the perchlorate ion. This phenomenon suggests that the nitrate ion associates with the TTA-TOPO complexes just as does the perchlorate ion.

The absorption spectra of 1,2-dichloroethane solutions containing neodymium, holmium, and erbium extracted from acetate solutions containing definite amounts of perchlorate, thiocyanate, nitrate, chloride, and sulfate ions are shown in Fig. 4. It can be seen that the extent of the change from the α- to the β-type is different according to the species of anions used and that the order of the effect is $ClO_4^- > CNS^- > NO_3^- > Cl^- > SO_4^{2-}$. It is considered that sulfate ions as well as acetate ions form scarcely any ion-associate complex because the α-type spectrum is not affected by the addition of a large amount of the ions.

From these results, it is assumed that the formula of the β-type complex can be represented as $(Ln(TTA)_2(TOPO)_5)^+X^-$: X^-=anions such as ClO_4^-, CNS^-, NO_3^-, and Cl^-. If the assumption for the Ln^{3+}/HTTA/TOPO/ClO_4^- system described in the previous paper can be generalized for the Ln^{3+}/HTTA/TOPO/X^- system, the following equation may be used:

$$Ln(TTA)_3(TOPO)_{2(0)} + 3TOPO_{(0)} + H^+_{(a)} + X^-_{(a)} \rightleftharpoons (Ln(TTA)_2(TOPO)_5)^+X^-_{(0)} + HTTA_{(0)}$$

for which:

$$k_3 = \frac{[(Ln(TTA)_2(TOPO)_5)^+X^-]_{(0)}[HTTA]_{(0)}}{[Ln(TTA)_3(TOPO)_2]_{(0)}[TOPO]^3_{(0)}[H^+]_{(a)}[X^-]_{(a)}}$$

Here, the k_3 value can be estimated spectrophotometrically from the degree of enhancement of a specific absorption band. The results for holmium-TTA-TOPO complexes using 1,2-dichloroethane solutions are given in Table 1. The average values of log k_3 for ClO_4^-, CNS^-, NO_3^-, and Cl^- systems are about 8.3, 6.5, 5.3, and 3.6 respectively.

In order to investigate the effect of the anion extracted into the organic layer on the equilibrium relation between α- and β-type complexes, the distribution ratio, D, of the X^- anion, $D=X^-_{(0)}/X^-_{(a)}$, where $X^-_{(0)}$ and $X^-_{(a)}$ are the total molar concentrations of the anion in a 1,2-dichloroethane soultion of 0.1M TOPO and an aqueous solution respectively, was measured using 0.05M sodium perchlorate, nitrate, and chloride solutions of about pH 3. The results obtained for ClO_4^-, NO_3^-, and Cl^- ions were 0.711, 0.082, and 0.011 respectively. In Fig. 5, it is shown that the plots of the log k_3 values for Ho^{+3}/HTTA/TOPO/ClO_4^-, /NO_3^-, and /Cl^- systems against the logarithm values of D for ClO_4^-, NO_3^- and Cl^- ions almost give a linearity.

Organic layer: 0.1M HTTA, 0.1M TOPO, 1,2-dichloroethane

Conocchioli, Tocher, and Diamond[4] reported that perchloric acid was extracted into a carbon tetrachloride solution of TOPO by the formation of the ion-associate complex $H_3O^+ \cdot n\text{TOPO} \cdot ClO_4^-$ ($n=1$ and 3). Therefore, it is assumed that the change from $Ln(TTA)_3(TOPO)_2$ to $(Ln(TTA)_2(TOPO)_5)^+X^-$ depends upon the molar concentration rather than on the kind of anion extracted with TOPO into the organic layer.

(iii) Extractability of Ln^{3+} in ClO_4^-/HTTA/TOPO and SO_4^{2-}/HTTA/TOPO Systems. An obvious discrepancy is observed in the order of extractability of a series of rare earths in relation to the formation of $Ln(TTA)_3(TOPO)_2$ and $(Ln(TTA)_2(TOPO)_5)^+ClO_4^-$ complexes. When the individual rare earth was extracted into a 1,2-dichloroethane solution containing TTA and TOPO from an aqueous acetate solution, the extractability of these elements was studied as a function of the pH value, which was adjusted with perchloric or sulfuric acid. The results are given in Fig. 6. For a perchloric acid system, the extractability of rare earths increases as the atomic number increases. On the other hand, for a sulfuric acid system, though the extractability of the lighter rare earth increases as the atomic number increases, that of heavier rare earths is the reverse with an increase in the atomic number.

The Chemical Behavior of Low Valence Sulfur Compounds. VII.[1] The Oxidation of Ammonium Sulfide and Ammonium Sulfite with Compressed Oxygen in Aqueous Ammonia Solution

Kunishige NAITO* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received March 20, 1971)

The oxidation of ammonium sulfide and ammonium sulfite with compressed oxygen in aqueous ammonia soultion was studied in order to confirm the formation of ammonium sulfamate. Ammonium sulfite is easily oxidized to ammonium thiosulfate through polysulfides with oxygen and further to ammonium sulfamate and ammonium sulfate. Suitable conditions for producing ammonium sulfamate were found to be: initial concentration of ammonium sulfide 2.0 mol/*l*, temperature 100°C, concentration of ammonia 12 mol/*l*, concentration of cupric ion 0.1 mol/*l* and oxygen pressure 50 kg/cm^2. Though ammonium sulfite is wholly oxidized to ammonium sulfate under the same conditions, it is partially oxidized to ammonium sulfamate besides sulfate in the presence of cupric ion under high concentration of ammonia. The mode of oxidation might differ from that of ammonium thiosulfate, ammonium sulfide and elemental sulfur because of no formation of polythionate as an intermediate.

In a previous study, the oxidation of ammonium thiosulfate was investigated for the purpose of production of ammonium sulfamate and it was found that the yield was improved by increasing the concentration of ammonia. Ammonium sulfide and ammonium sulfite can be easily obtained as industrial raw materials. If ammonium sulfamate could be produced by aqueous oxidation of these compounds, it would be of interest for industry. The aqueous oxidation of these compounds has been investigated and some results have been applied to the industrial production processes of ammonium sulfate.[2] However, no formation of ammonium sulfamate has been reported. We have studied the oxidation of ammonium sulfide and ammonium sulfite in concentrated aqueous ammonia solutions in order to obtain the suitable conditions for the industrial production of ammonium sulfamate.

Experimental

Apparatus and Procedure. The autoclave shown in a previous paper[3] was used.

An ammoniacal solution of ammonium sulfide was prepared from concentrated aqueous ammonia and hydrogen sulfide controlling the concentration of sulfide to be in the range 1.0—2.0 mol/*l*. A certain amount of cupric oxide as a catalyst, 400 m*l* of the above solution (or about 45 g of crystalline ammonium sulfite and 400 m*l* of concentrated aqueous ammonia) were put in the autoclave and kept in a heated glycerine bath. Temperature was regulated within 0.5°C. When the autoclave was heated to the desired temperature, oxygen was introduced, pressure being kept at a certain value. After the temperature and pressure became constant, about 15 m*l* of the reaction solution was withdrawn every few hours and was analyzed.

Analysis. Concentration of sulfide and free ammonia in the original solution were determined by iodometric and acidimetric titration.

Soluble sulfide, thiosulfate, sulfite, sulfamate, sulfate, and cupric ion were determined as follows.

Soluble Sulfide: Soluble sulfide appearing in the initial stage of the oxidation of ammonium sulfide was determined by iodometric differential titration.

Thiosulfate: In the presence of soluble sulfide, thiosulfate was determined by iodometry after removal of soluble sulfide as cadmium sulfide. In the presence of cupric ion, it was directly titrated with 0.05N standard solution of iodine after adding 0.01M EDTA solution for masking cupric ion, and adding 4N acetic acid until the sample solution became acidic with bromocresol purple.

Sulfite: After pouring the sample solution into 0.05N solution of iodine and then adding 0.01M EDTA solution as a masking reagent of cupric ion and 4N acetic acid, the excess iodine was titrated with 0.05N standard solution of sodium thiosulfate.

Sulfamate: In the oxidation of ammonium sulfide, sulfamate was determined by the same procedure described previously.[4] In the oxidation of ammonium sulfite, sulfamate was determined as follows: 0.1N potassium permanganate was added to the sample solution to oxidize sulfite to sulfate. After being kept standing for 10 min, the excess permanganate was decomposed by adding 2N solution of ammonium formate, and the precipitate formed was removed by filtration. Filtrate was acidified with 4N acetic acid and the barium sulfate precipitated was removed by filtration. After the filtrate was heated on a water bath and concentrated hydrochloric acid and 1M sodium nitrite were added, sulfamate was determined as barium sulfate by gravimetry.

Sulfate: In the oxidation of ammonium sulfide, sulfate was determined by the same procedure previously.[4] In the oxidation of ammonium sulfite, sulfate was determined as follows: After adding an aqueous solution formaldehyde into the sample solution and then acidifying it with 4N acetic acid, sulfate was precipitated as barium sulfate with the addition of 0.5M solution of barium chloride. Barium sulfate was determined by gravimetry.

Results and Discussion

Oxidation of Ammonium Sulfide with Compressed Oxygen in Aqueous Ammonia Solution. Ammonium sulfide is rapidly oxidized with oxygen to thiosulfate through polysulfides. At the maximum concentration of thiosulfate, cupric ion once predipitated begins to dissolve in the solution and accelerate the oxidation of thiosulfate to form sulfamate and sulfate. A general view of the oxidation of ammonium sulfide is shown in Fig. 1. A small amount of imidodisulfonate and nitrite were also detected in the final solution.

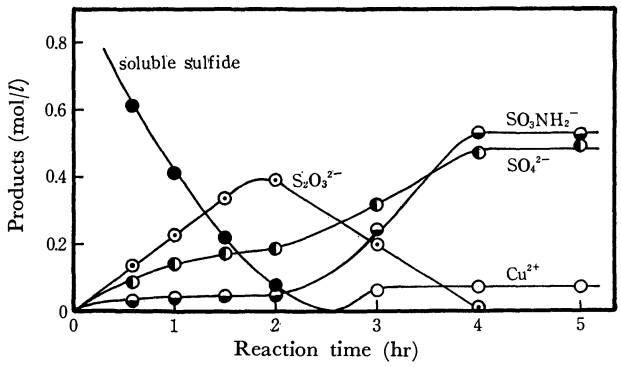

Fig. 1. General view of the whole reaction.
Temp.: 100°C, P_{O_2}: 25 kg/cm², NH_3 concn.: 12 mol/l, Cu^{2+} ion concn.: 0.05 mol/l, $(NH_4)_2S$ initial concn.: 1.0/mol/l

Effect of the Concentration of Cupric Ion: The effect of the concentration of cupric ion was examined in the range 0.05—0.3 mol/l. It was found that the proper concentration of cupric ion is 0.1 to 0.2 mol/l for the oxidation of ammonium thiosulfate.[4] The results are shown in Figs. 2, 3, and 4. The yield of sulfamate was not affected by the concentration of cupric ion.

Effect of Oxygen Pressure: The effect of oxygen pressure was examined in th range 25 to 75 kg/cm². Pressure is given in terms of total pressure, in which both the vapor pressure of water and ammonia are included in addition of that of oxygen. The yield of sulfamate decreases with the increase of oxygen pressure. It seems that there is an induction period at 25 kg/cm² due to the slow oxidation of thiosulfate under a low oxygen pressure.

SO_4^{2-}	—●—	—◐—	—○—
$SO_3NH_2^-$	--●--	--◐--	--○--

Effect of the Initial Concentration of Ammonium Sulfide: The yield of sulfamate is affected largely by the concentration of thiosulfate formed as an intermediate. The effect was examined by varying the initial concentration of ammonium sulfide from 1.0 to 2.0 mol/l. The results are shown in Fig. 5. It was found that the yield of sulfamate increases with the increase of initial concentration of ammonium sulfide, but the reaction time is hardly affected.

From the results, it seems that ammonium sulfide is oxidized to thiosulfate through polysulfides, and thiosulfate is further oxidized to sulfamate and sulfate.

Suitable conditions for the preparation of ammonium sulfamate in the highest yield are: initial concentration on ammonium sulfide 2.0 mol/l, reaction temperature 100°C, concentration of ammonia 12 mol/l, concentration of cupric ion 0.1 mol/l and oxygen pressure 50 kg/cm².

Oxidation of Ammonium Sulfite with Compressed Oxygen in Aqueous Ammonia Solution. The oxidation of ammonium sulfite, whose initial concentration was 1.0 mol/

l, was carried out in a concentrated aqueous solution of ammonia containing 0 to 0.2 mol/*l* of cupric ion at 60—120°C and under the pressure of 25 kg/cm². The results are shown in Figs. 6 and 7. The formation of ammonium sulfamate was observed in the oxidation of ammonium sulfite, and a small amount of dithionate was detected also in the final solution. Thiosulfate and polythionates which exist as intermediates in the oxidation of elemental sulfur, ammonium thiosulfate and ammonium sulfide were not detected during the course of oxidation. This suggests that the oxidation mechanism of ammonium sulfite differs from that of elemental sulfur, ammonium thiosulfate and ammonium sulfide.

The presence of cupric ion accelerates remarkably the oxidation, but makes the yield of sulfate decrease. The sulfite corresponding to the decrement of sulfate may be converted into dithionate, for a small amount of dithionate is detected in the final solution.

The elevation of temperature accelerates fairly the oxidation at temperature below 100°C, and improves the yield of sulfamate. This differs from that on the oxidation of ammonium thiosulfate and elemental sulfur. Though the formation of ammonium sulfamate has been achieved, its low yield makes the industrial application process still difficult.

Rearrangement and Decomposition of Phosphoranyl Peroxides Produced *in situ* from Alkylidenephosphoranes and *t*-Alkylperoxy Anions

Koh-ichi YAMADA, Kin-ya AKIBA, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
(Received November 13, 1970)

The reactions of alkylidenephosphoranes (I), produced *in situ* from the corresponding phosphonium salts and sodium ethoxide, with sodium salt of *t*-butyl hydroperoxide (II) were carried out in absolute ethanol. Carbanion (III) of phosphoranyl peroxide, formed by the reaction of I with II, underwent a rearrangement to produce *t*-butyl phenyl ether, alkyl *t*-butyl ether, and two kinds of phosphine oxides. Phosphoranyl peroxide (IV), formed by abstraction of proton from ethanol, decomposed in homolytic fashion to yield *t*-butyl alcohol and hydroxyphosphorane (V) as an intermediate, the decomposition of which gave benzene, hydrocarbon and corresponding phosphine oxides. Homolytic decomposition of IV was supported by the reaction of tetraphenylphosphonium bromide with II. The contribution of III was confirmed by the effect of base concentration on the amounts of rearrangement products. The reaction with cumylperoxy anion gave similar results. The mechanisms of these reactions were discussed.

There are a few reports on phosphorus peroxides such as diphenylphosphinyl peroxide[1] and *t*-butyl alkylperphosphonates,[2] but no report on the phosphoranyl peroxides.

We carried out the reactions of alkyltriphenylphosphonium bromides with sodium salt of *t*-butyl hydroperoxide in the presence of sodium ethoxide in ethanol in order to investigate the chemical behavior of *t*-butyl alkyltriphenylphosphoranyl peroxides.

Under the above conditions the following reactions would be expected to occur.

$$t\text{-BuOOH} + \text{EtO}^-\text{Na}^+ \rightleftarrows \underset{\text{II}}{t\text{-BuOO}^-\text{Na}^+} + \text{EtOH} \quad (1)$$

$$\text{Ph}_3\overset{+}{\text{P}}\text{CHRR}'\ \text{Br}^- \underset{\text{EtOH}}{\overset{\text{EtO}^-}{\rightleftarrows}} \text{Ph}_3\text{P=CRR}' \quad (2)$$

VIa: R=Ph, R′=H Ia: R=Ph, R′=H
VIb: R=R′=Ph Ib: R=R′=Ph
VIc: R=*n*-Pr, R′=H Ic: R=*n*-Pr, R′=H

$$\text{I} + \text{II} \longrightarrow \underset{\text{OO-}t\text{-Bu}}{\text{Ph}_3\text{P-}\overset{-}{\text{C}}\text{RR}'} \underset{\text{EtO}^-}{\overset{\text{EtOH}}{\rightleftarrows}} \underset{\text{III}}{}$$

$$\underset{\text{OO-}t\text{-Bu}}{\text{Ph}_3\text{P-CHRR}'} \longleftarrow \text{VI} + \text{II} \quad (3)$$

IV

This paper describes the difference in the decompositions of *t*-butyl alkyltriphenylphosphoranyl peroxides (IV) and the corresponding carbanions (III).

Results and Discussion

Sodium salt of *t*-butyl hydroperoxide (II) was produced *in situ* by addition of *t*-butyl hydroperoxide to absolute ethanol containing four times moles of sodium ethoxide. The position of the equilibrium (1) lies about 10^4 times to the side of II under the conditions given by Everett and Minkoff.[3]

To the solution was then added phosphonium bromide (VI) at room temperature under nitrogen to produce *in situ* alkylidenephosphorane (I), the formation of which was indicated by appearance of yellow color (in the case of Ia and Ic) or of reddish orange precipitate (in the case of Ib).

The reaction soon took place, the temperature of the mixture rose slightly, and the color of the solution gradually became pale. The reaction products were determined by vapor phase chromatography (vpc) and column chromatography. Peroxides (IV) could not be obtained under the reaction conditions.

Alkylphosphonium salts and alkylidenephosphoranes have been reported to react with sodium ethoxide in ethanol under reflux for several hours to give phosphine oxide and hydrocarbon:[4]

$$\text{Ph}_3\text{P=CRR}' \text{ or } \text{Ph}_3\overset{+}{\text{P}}\text{-CHRR}' \xrightarrow[\text{EtOH}]{\text{EtO}^-} \text{Ph}_3\text{P=O} + \text{RR}'\text{CH}_2 + \text{EtOEt} \quad (4)$$

This type of reaction occurred to a small extent in the case of Ia and appreciably in the case of Ib under the reaction conditions. The yields of products in Table 1 were roughly corrected for the contribution of the reaction (4), based on results of blank tests.

It is difficult to distinguish which of I and VI reacted with II, but we inferred that the reaction of I with II predominates in the present case, because the reaction rates was in the order Ib>Ia>Ic. This is also supported by the fact that II is a soft base whereas I is a softer acid than VI.[5]

The mechanisms for the formation of products are postulated as follows.

Carbanion (III) of pentacovalent phosphorus per-

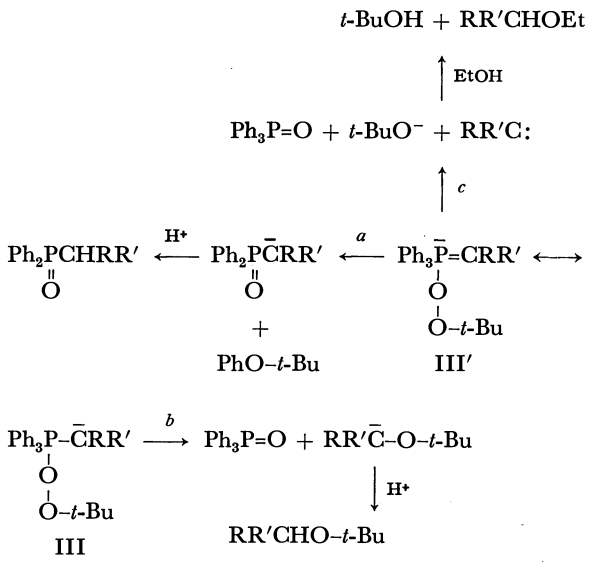
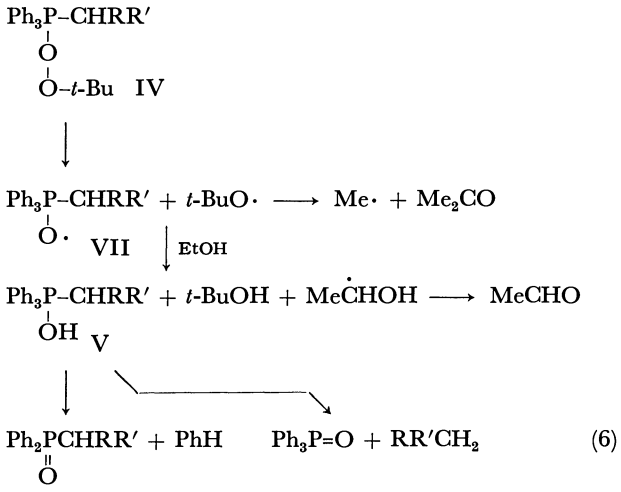
oxide, first formed by the reaction of II with I, is in the equilibrium (3) with the corresponding phosphoranyl peroxide (IV). Carbanion (III) undergoes a rearrangement of the phenyl or alkyl group to β-oxygen of the peroxide bond to yield *t*-butyl phenyl ether, alkyl *t*-butyl ether and corresponding phosphine oxides as shown in course *a* in the following scheme.



(5)

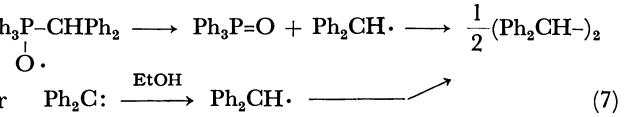
Rearrangement of the phenyl group may imply resonance contribution of III′, which may be supported by the existence of tris(biphenylene)phosphorane anion.[6] The diphenylmethyl group did not rearrange to the peroxide bond (course *b* in Scheme (5)) to form *t*-butyl ether, probably because of the steric hindrance or low nucleophilicity. The formation of alkyl ethyl ether may be ascribed to the intermediacy of carbene which reacts with solvent ethanol (course *c*).

On the other hand, it is considered that phosphoranyl peroxide (IV) undergoes a homolytic decomposition and the resulting radical (VII) abstracts hydrogen atom from ethanol to give hydroxyphosphorane (V), which decomposes to give benzene or hydrocarbons, and corresponding phosphine oxides:



(6)

From the product ratio of hydrocarbon to benzene, the mobility of phenyl and alkyl groups fell in the order $Ph_2CH{>}PhCH_2{>}Ph{>}n$-Bu. This is in good agreement with that in the reaction of phosphonium halides with hydroxide ion,[7] which proceeds through hydroxyphosphoranes of type V. Detection of small amounts of acetone and acetaldehyde by vpc indicates the intermediacy of *t*-butoxy and α-hydroxyethyl radicals, respectively. Furthermore, in the case of Ib, a trace amount of tetraphenylethane was isolated by column chromatography, indicating the presence of diphenylmethyl radicals:



(7)

In order to clarify whether *t*-butyl tetraphenylphosphoranyl peroxide gives *t*-butyl phenyl ether and triphenylphosphine oxide by migration of the phenyl group, tetraphenylphosphonium bromide (VIII) was allowed to react with II under similar conditions. Benzene, *t*-butyl alcohol and triphenylphosphine oxide

6) D. Hellwinkel, *Chem. Ber.*, **98**, 576 (1965).

7) G. W. Fenton and C. K. Ingold, *J. Chem. Soc.*, **1929**, 2342; H. Hoffmann, *Ann. Chem.*, **634**, 1 (1960); G. Aksness and J. Songstad, *Acta Chem. Scand.*, **16**, 1426 (1962).

were obtained as the sole reaction product (Table 1) and no *t*-butyl phenyl ether was detected by vpc. The result supports the view that ethers are produced from the carbanion (III) and hydrocarbons from the neutral peroxide (IV), because in this case no carbanion can participate in the reaction.

When VIII and silver hydroxide were allowed to react in ethanol, benzene and triphenylphosphine oxide were obtained in nearly quantitative yields. These products should be formed from tetraphenylhydroxyphosphorane (IX) as an intermediate:

$$\underset{\text{VIII}}{Ph_4\overset{+}{P}\ Br^-} + AgOH \longrightarrow AgBr + \underset{\text{IX}}{Ph_4P\text{-}OH}$$

$$\longrightarrow Ph_3P{=}O + PhH \quad (8)$$

Thus the intermediacy of hydroxyphosphorane (V) was supported.

From the above mechanistic consideration, we can evaluate the ratio of participation of carbanion (III), the amount of which is equal to the sum of the amounts of ethers, and that of the phosphoranyl peroxide (IV), the amount of which is equal to the sum of the amounts of benzene and hydrocarbon, in the course of reaction. The results are shown in Table 2. However, it is not possible to discriminate the homolytic decomposition of III, if it take place at all, from that of IV.

Table 2. Relative ratio of participation of III and IV as intermediates

	III[a]		IV[b]		III+IV (≡100)	
Ia	34.2	25.7	72.6	71.2	106.8	96.9

Ic	~2	~2	80.2	78.5	82.2	80.5
			97.1[c]	98.5[c]	99.1[c]	100.5[c]

a) [PhO-*t*-Bu]+[RR'CHO-*t*-Bu]+[RR'CHOEt].
b) [PhH]+[RR'CH$_2$].
c) The amount of butane was assumed to be the same as that of triphenylphosphine oxide according to Scheme (6).

In order to make the participation of carbanion (III) conclusive, the effect of the concentration of sodium ethoxide on the yields of the rearrangement products (*t*-butyl ethers) was examined in the case of benzylidenetriphenylphosphorane (Ia). The results are shown in Table 3. The yields of *t*-butyl phenyl ether and benzyl *t*-butyl ether increased gradually with the concentration of sodium ethoxide. This reveals the existence of equilibrium between III and IV, and the formation of *t*-butyl ethers from carbanion (III).

Table 3. Effect of concentration of sodium ethoxide on yields of *t*-butyl ethers in ethanol (mol %)

([$Ph_3\overset{+}{P}CH_2Ph\ Br^-$] : [*t*-BuOOH] : [EtONa] = 1 : 1 : *x*)

PhCH$_2$O-*t*-Bu	9.3	12.2	13.4	17.8	24.7
Total	17.5	22.5	23.5	27.9	40.0

Similarly the reaction of sodium salt of cumyl hydroperoxide with Ia was carried out in ethanol under similar conditions and similar results were obtained (Table 4), though the yield of benzyl cumyl ether decreased probably because of the steric hindrance in the cumylperoxy group.

Table 4. Yields of reaction products of Ia with sodium salt of cumyl hydroperoxide in ethanol

Experimental

Materials. Alkyltriphenylphosphonium bromides were prepared by the methods reported in literature: benzylthiphenylphosphonium bromide,[8] mp 271—274°C; *n*-butyltriphenylphosphonium bromide,[9] mp 232—234°C; benzhydryltriphenylphosphonium bromide,[10] mp 238—240°C; tetraphenylphosphonium bromide,[11] mp 281—284°C. Commercially available *t*-butyl and cumyl hydroperoxides were used after distillation under reduced pressure. *t*-Butyl phenyl ether was prepared from *t*-butyl peroxybenzoate and phenylmagnesium bromide,[12] bp 44—46°C/2 mmHg, n_D^{20} 1.4923. Benzyl *t*-butyl ether (bp 60—62°C/3.5 mmHg) and cumyl phenyl ether (mp 43—46°C) were prepared similarly. Benzyl ethyl ether (bp 183—185°C), benzhydryl ethyl ether (bp 158—161°C/18 mmHg), *n*-butyl ethyl ether (bp 90—91°C), benzhydryl *t*-butyl ether (mp 53—55°C), *n*-butyl *t*-butyl ether (bp 123—125°C) and benzyl cumyl ether which could not be distilled without decomposition but was confirmed to be almost pure by vpc, were prepared by the usual method. Benzyldiphenylphosphine oxide was prepared by the procedure of Hoffmann and Tesch,[13] mp 192—193°C. Benzhydryldiphenylphosphine oxide was prepared by the method described in literature,[14] mp 305—305.5°C.

Reactions of Alkylidenetriphenylphosphoranes with Sodium Salt of t-Butyl Hydroperoxide. Only typical examples are described.

a) Benzylidenetriphenylphosphorane (Ia): Sodium salt of *t*-butyl hydroperoxide (0.05 mol) was prepared in absolute ethanol by addition of *t*-butyl hydroperoxide (5.1 m*l*, 0.05 mol) in ethanol (300 m*l*) containing excess sodium ethoxide (0.20 mol) under nitrogen atmosphere. To this solution benzyltriphenylphosphonium bromide (21.6 g, 0.05 mol) was added with stirring in one portion, and yellow color appeared instantaneously showing the formation of benzylidenetriphenylphosphorane. The color of the solution faded to pale yellow after about 15 min and a white precipitate appeared. The mixture was stirred overnight at room temperature and the

amount of remaining peroxide was pursued by iodometry at appropriate intervals. Finally the solution was heated at 60°C for 2 hr. About 5% of the initial hydroperoxide remained unchanged.

The precipitate (NaBr, 2.2 g) was filtered and liquid products were determined by vpc after neutralization with hydrogen chloride in ethanol. From the filtrate ethanol was distilled off and the residue was chromatographed on alumina. Triphenylphosphine oxide (8.6 g, 0.031 mol, 62.1%), mp 155—156°C, was obtained and determined by mixed mp with an authentic sample and the IR spectrum. Benzyldiphenylphosphine oxide was not determined precisely but identified by vpc, and isolated in a small amount by column chromatography.

b) *Diphenylmethylenetriphenylphosphorane (Ib)*: The reaction was carried out under the same conditions and in the same scale as those for a), but in this case the corresponding phosphorane precipitated immediately as an orange-red solid and gradually disappeared during the reaction. The reaction was faster than that of benzylidenetriphenylphosphorane and the temperature of the mixture rose to 40—50°C after 2 hr. The products were determined by vpc. Diphenylmethane was also isolated by distillation under reduced pressure and triphenylphosphine oxide (11.3 g, 81.3%) was obtained by column chromatography on alumina. Elution with ether gave 10 mg of tetraphenylethane, mp 204—208°C. The structure was determined based on spectral data and by mixed melting point with an authentic sample.

c) n-*Butylidenetriphenylphosphorane* (*Ic*): The reaction was performed under the same conditions and in the same scale as those for a), except that a gas burrette was equipped to the system in order to measure the volume of *n*-butane, which is expected to be evolved. The reaction was slower than that of benzylidenetriphenylphosphorane. No gas evolution was observed in this system, *n*-butane evolved being probably completely soluble in ethanol. *n*-Butyl ethyl ether, triphenylphosphine oxide and diphenyl-*n*-butylphosphine oxide were determined by vpc. The two oxides were also obtained by column chromatography and the melting points were 155°C and 87—93°C (lit,[15] mp 95°C), respectively.

d) *Tetraphenylphosphonium bromide* (*VIII*): This reaction was carried out in the same manner and scale as those for a). Benzene and *t*-butyl alcohol were determined by vpc and triphenylphosphine oxide (7.7 g, 55.2%) was obtained by column chromatography on alumina.

Reaction of Benzylidenetriphenylphosphorane with Sodium Salt of Cumyl Hydroperoxide. To sodium ethoxide (0.08 mol) in ethanol (150 m*l*) was added cumyl hydroperoxide (2.8 m*l*, 0.02 mol) and then 8.7 g (0.02 mol) of benzyltriphenylphosphonium bromide was added. The reaction was carried out by the same procedure as mentioned above. The products were determined by vpc.

Reaction of Tetraphenylphosphonium Bromide with Silver Hydroxide. Silver hydroxide (2.5 g, 0.02 mol) freshly prepared, was added to tetraphenylphosphonium bromide (8.4 g, 0.02 mol) in ethanol (150 m*l*) with stirring. Pale brown precipitate was simultaneously formed and stirring was continued for one hour. The precipitate (AgBr, 3.5 g, 93%) was then filtered off. From the filtrate, benzene (85.5%) was determined by vpc. After removal of ethanol, the residue was recrystallized from benzene, yielding triphenylphosphine oxide (14.8 g, 86.2%), mp 149—156°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2440—2443 (1971)

The Preparation of Geometrical Isomers of β-Nitrostyrene and Their Addition Reactions with Ethanol

Kimiaki YAMAMURA, Setsuo WATARAI, and Toshio KINUGASA*

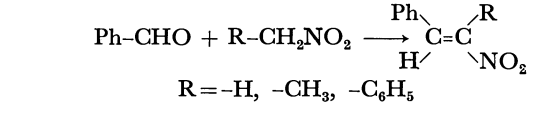
Institute of Chemistry, College of General Education, Kobe University, Tsurukabuto, Nada, Kobe

**Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe*

(Received December 1, 1970)

The preparation of the geometrical isomers of ethyl α-nitrocinnamate and α-nitrochalcone is described. Ethyl (*E*)-α-nitrocinnamate and (*Z*)-α-nitrochalcone were obtained by the thermal- or photoisomerization of the corresponding geometrical isomers, which were themselves produced predominantly through the Knoevenagel reaction. The facile addition of ethanol to the double bonds of β,β-dinitrostyrene, ethyl α-nitrocinnamates, and α-nitrochalcones without any catalyst at room temperature is also described.

The Knoevenagel condensation of benzaldehyde with primary nitroalkanes leads to the preferential formation of *trans*-β-nitrostyrenes, in which the nitro group and the phenyl group are on opposite sides of the carbon-carbon double bond.[1]



On the other hand, it is known that the base-catalyzed condensation reactions of benzaldehyde with ethyl phenylacetate and with desoxybenzoin afford predominantly ethyl (*E*)-α-phenylcinnamate with a *trans*-cinnamic ester moiety and (*E*)-α-phenylchalcone with a *trans*-chalcone moiety respectively.[2,3] Therefore, it seems to be worthwhile to examine the configurations of ethyl α-nitrocinnamate (β-carbethoxy-β-nitrostyrene) (I) and α-nitrochalcone (β-benzoyl-β-nitrostyrene) (II), obtained by the condensation of

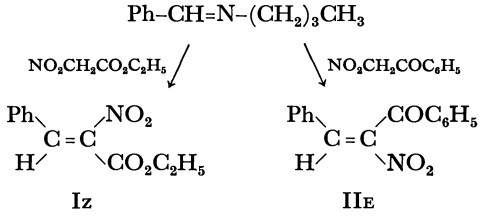
benzaldehyde with ethyl α-nitroacetate or ω-nitroacetophenone, since I and II can be regarded as β-nitrostyrene derivatives as well as α-nitrocinnamate and α-nitrochalcone respectively. The formation of a single geometrical isomer of I or II has been reported with no configurational assignment.[4]

The present paper will deal with the preparation of *cis*- and *trans*-isomers of I and II, and with the isomerization reaction of these compounds. The nucleophilic addition of ethanol to the carbon-carbon double bonds of these compounds under very mild conditions is also described.

The nitro valence vibrations and the ultraviolet spectra of these β-nitrostyrenes in correlation with their stereochemical configurations have been reported in a previous paper.[5]

Results and Discussion

Preparation. The condensations of *N*-benzal-*n*-butylamine with ethyl α-nitroacetate and with ω-nitroacetophenone according to the method reported by Dornow *et al.*[4] afforded ethyl α-nitrocinnamate (I) and α-nitrochalcone (II) in 88 and 82% yields respectively. The stereochemical configurations of the compounds were identified as ethyl (*Z*)-α-nitrocinnamate (Iz) with a *cis*-β-nitrostyrene moiety and (*E*)-α-nitrochalcone (IIE) with a *trans*-β-nitrostyrene moiety respectively, on the basis of their IR and UV spectroscopic behavior.[5] The formation of Iz is noteworthy,



because the formation of the *cis*-β-nitrostyrene derivative as a main product of the condensation of benzaldehyde with an aliphatic nitro compounds has never been reported in the literature. The only compounds having a well-established *cis*-β-nitrostyrene configuration are α-nitrostilbene[6] and its derivatives.[7]

The geometrical isomers of Iz and IIE were obtained by the thermal isomerization and/or by the photoisomerization of each compound. Ethyl (*Z*)-α-nitrocinnamate (Iz), on heating at 175°C for 8 hr, gave a mixture from which an oily yellow material has been isolated. The structure of the oily material was identified as ethyl (*E*)-α-nitrocinnamate (IE). Both isomers, IE and Iz, gave the same equilibrium mixture when treated for 8 hr at this temperature, and the ratio of IE/Iz was found to be *ca.* 1:1. This ratio seemed inconsistent with the finding that IE was not formed in the Knoevenagel reaction. Since, however, the gradual conversion of IE into Iz was observed at room temperature in the dark, Iz appears to be thermodynamically the more stable isomer.

(*E*)-α-Nitrochalcone (IIE) was recovered unchanged when subjected to the same thermal treatment, while under much more drastic conditions it gave tarry substances, along with a trace of benzoic acid. On the other hand, the (*Z*)-α-nitrochalcone (IIz) obtained by the photoisomerization of IIE could isomerize very readily to give IIE in a 90% yield when treated for 3 hr at 170°C, thus indicating the greater stability of IIe.

All the geometrical isomers of I and II easily isomerized to their counterparts when the benzene solution was irradiated with a high-pressure mercury lamp. Starting from both isomers of I, photoequilibrium was established for 8 hr, the ratio IE/Iz was found to be *ca.* 1:1. In the case of II, photoequilibrium was established more rapidly under the same conditions, and the ratio IIe/IIz at equilibrium was found to be 2:3 (as is shown in Fig. 1).

The Addition of Ethanol. It was observed that the intensity at the absorption maxima in the region of $\pi \rightarrow \pi^*$ of ethyl α-nitrocinnamates, IE and Iz, and α-nitrochalcones, IIE and IIz, decreased considerably

with the time when the ethanolic solutions were left standing at room temperature, even in the dark (Fig. 2). Also, β-bromo-β-nitrostyrene (III) showed a slight but evident decrease in the intensity at the absorption maximum under the present conditions. These results can be explained by assuming the addition of ethanol to the carbon-carbon double bonds of these compounds.

Actually, colorless needles were isolated from the ethanolic solutions of each geometrical isomer of II after keeping the solutions in the dark at room temperature for 24 hr, they were found to be identical with authentic 1-ethoxy-1-phenyl-2-nitro-2-benzoylethane (IV).[8] When the ethanolic solution of IIE or IIz was refluxed, ω-nitroacetophenone was produced together with IV. It might be thought that ω-nitroacetophenone was formed *via* IV, because ω-nitroacetophenone was also obtained by refluxing the ethanolic solution of IV. Similarly, 1-ethoxy-1-phenyl-2-nitro-2-carbethoxyethane (V), an ethanol adduct of I, was obtained from either of the geometrical isomers. β-Bromo-β-nitrostyrene (III) was less reactive toward ethanol than was either I or II, and its ethanol adduct, 1-ethoxy-1-phenyl-2-nitro-2-bromoethane (VI), could be obtained by refluxing the ethanolic solution of III for 120 hr or by treating III with equimolar sodium ethoxide in THF. Upon the treatment of VI with sodium ethoxide, ω-nitroacetophenone was formed. Recently, Hata *et al.* reported that ω-nitroacetophenone and its diethyl acetal were obtained from III upon treatment with excess sodium ethoxide.[9]

On the other hand, in the cases of (*E*)- and (*Z*)-α-nitrostilbenes (VIIE and VIIz), β-methyl-β-nitrostyrene and β-nitrostyrene, the addition of ethanol did not occure when their ethanolic solutions were allowed to reflux for an extended period. Additionally, α-benzoylchalcone, ethyl α-benzoylcinnamate, and diethyl benzalmalonate were recovered unchanged from their ethanolic solutions.

Although the reaction of nucleophilic reagents at the carbon-carbon double bond conjugated with the electron-withdrawing groups is well known,[10] it is noteworthy that the β-nitrostyrenes, which hold the nitro group and other strong electron-withdrawing groups at the same carbon atom, readily undergo the addition of ethanol without any catalyst at room temperature. In particular, β,β-dinitrostyrene (VIII) is very reactive to ethanol. The addition of ethanol seemed to come to completion instantaneously when VIII was dissolved in ethanol, since the solution had no maximum in the $\pi\rightarrow\pi^*$ region, but showed a lower intensity absorption near 370 mμ. Its UV spectrum was identical with that of 1-ethoxy-1-phenyl-2,2-dinitroethane (IX), which was otherwise obtained from the ethanolic solution of VIII after it had stood at room temperature. The UV spectrum of VIII in *n*-hexane did not vary even when the mixture stood for a long

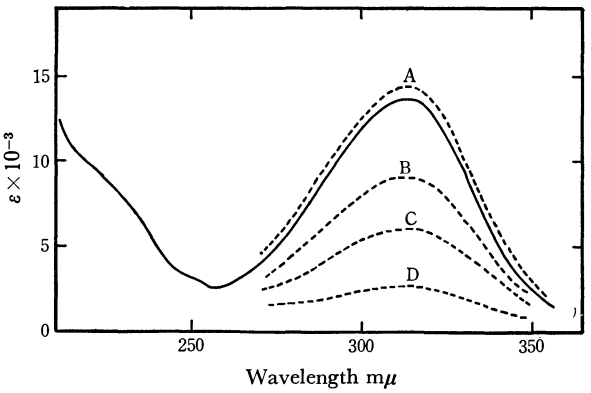

Fig. 3. UV spectra of β,β-dinitrostyrene (VIII).
—— in *n*-hexane
------ variations of UV spectra in ethanol-*n*-hexane (3:97) at 20°C; A: 0 hr, B: 0.5 hr, C: 1 hr, D: 2 hr

time, but in the *n*-hexane-ethanol mixture (97: 3) the absorption intensity at the maximum in the $\pi\rightarrow\pi^*$ region decreased very rapidly, as was expected (Fig. 3).

Thus, very significant differences in reactivities toward nucleophilic reagents, such as alcohol, were observed among various β-nitrostyrene derivatives, some rate coefficients (*k*), summarized in Table 1, for these ethanol-addition reactions were also measured.

TABLE 1. FIRST-ORDER RATE COEFFICIENTS AND ETHANOL ADDUCTS

$$C_6H_5\text{–}CH{=}C(X)(NO_2) + EtOH \longrightarrow C_6H_5\text{–}CH(OEt)\text{–}CH(X)(NO_2)$$

Substituent X	β-Nitrostyrenes	*k* × 10/hr (at 25°C)	Ethanol adducts: Compds. No.	Ethanol adducts: Mp (bp)°C
$CO\cdot OC_2H_5$	IE	1.05	V	39 — 40
	Iz	0.587		
$CO\cdot C_6H_5$	IIE	0.965	IV	118 —121
	IIz	3.41		
Br	III	0.07[a]	VI	(143/9 mmHg)
NO_2	VIII	very fast	IX	29 — 30
C_6H_5	VIIE & VIIz	—	b)	93.5— 94.0

a) Value at 30°C.
b) This compound was obtained by treating VIIE or VIIz with sodium ethoxide in the ethanolic solution.

Of the three pairs of *cis-trans* isomers of β-nitrostyrenes investigated, I, II, and VII, (*Z*)-α-nitrochalcone (IIz) gave the largest *k* value, six times the value of ethyl (*Z*)-α-nitrocinnamate (Iz). On the other hand, IIE, with a *cis*-chalcone moiety, showed almost the same degree of value as IE, with a *cis*-cinnamic ester moiety. These data indicate that the *trans*-chalcone conjugation, which is sterically little affected in IIz, contributes effectively to this addition reaction, although the extent of its contribution is far less than that of the *trans*-β-nitrostyrene conjugation in the case of VIII.

The *k* values of Iz and IIE, which were the major products of the Knoevenagel reaction, were evidently smaller than those of their counterparts, IE and IIz respectively.

Further studies of the difference in the *cis*- and *trans*-compounds of this series are in progress.

Experimental

All the melting points and boiling points are uncorrected. The UV spectra were obtained with a Hitachi model EPS-3 spectrophotometer; the data of some β-nitrostyrenes in *n*-hexane are presented in Table 2. The measurements of the IR spectra were made in chloroform on a Nihon-Bunko model DS-402G grating infrared spectrophotometer.

Teble 2. UV spectra of *cis*- and *trans*-β-nitrostyrenes in *n*-hexane[a] (C_6H_5–CH=C(X)–NO_2)

Substituent	Compds. No.	λ_{max} mμ	ε
CO·OC_2H_5	IE	285	14200
	Iz	282	17200
CO·C_6H_5	IIE	301	16300
	IIz	298	17100
C_6H_5	VIIE	307	13300
	VIIz	282	21500
NO_2	VIII	313	13500

a) Data in the ethanolic solutions were presented in the previous paper.[5]

Materials. β-Nitrostyrene,[11] β-methyl-β-nitrostyrene,[12] β-bromo-β-nitrostyrene (III),[13] (*E*)- and (*Z*)-α-nitrostilbenes (VIIE and VIIz),[6a] β,β-dinitrostyrene (VIII),[14] α-benzoylchalcone,[15] ethyl α-benzoylcinnamate,[16] and diethyl benzalmalonate[17] were prepared as has been described in the literature. Ethyl (*Z*)-α-nitrocinnamate (Iz, mp 72.5—73.5°C, yield 88%) and (*E*)-α-nitrochalcone (IIE, 91.5—92.5°C, yield 82%) were prepared essentialy according to the procedures reported by Dornow *et al.*,[4] but each compound was obtained in a far better yield than that described in the literature (lit,[4] yield: Iz, 45%; IIE, 48%).

Thermal Isomerizations of IE and Iz. Iz (30 g) was heated at 175°C for 8 hr under reduced pressure (3 mmHg). Cooling for 24 hr below −10°C, followed by filtration, gave the recovery of Iz (15 g). The filtrate was chromatographed over Wako-gel Q-22 using a mixture of benzene-petroleum ether(1:2.5) as an eluent. The first fraction contained Iz, while the subsequent fractions gave a yellow oil, which, when purified by chromatography until the refractive index indicated a constant value, gave 15.0 g of ethyl (*E*)-α-nitrocinnamate (IE); n_D^{20} 1.5780; yield 50%.

Found: C, 59.88; H, 5.28; N, 6.24%. Calcd for $C_{11}H_{11}O_4N$: C, 59.72; H, 5.01; N, 6.33%.

Starting from IE, Iz was obtained in about a 50% yield under similar conditions.

Thermal Isomerization of IIz. IIz, obtained by the photoisomerization of IIE, was isomerized in a manner similar to that described above to give (*E*)-α-nitrochalcone (IIE) in a 90% yield.

Photoisomerizations of α-Nitrochalcones (IIE and IIz). A solution of IIE (20 g) in 1650 m*l* of benzene was irradiated for 3 hr, and then the solvent was evaporated *in vacuo*. Fractional crystallization from benzene-petroleum ether gave colorless flakes of IIz; mp 103—104°C.

Found: C, 71.04; H, 4.77; N, 5.35%. Calcd for $C_{15}H_{11}O_3N$: C, 70.88; H, 4.79; N, 5.68%.

In a similar manner, IIE was obtained from IIz.

Photoisomerization of IE and Iz. Under conditions similar to those described above, *cis*- and *trans*-isomers of ethyl α-nitrocinnamate isomerized each other without any difficulty.

Preparation of IV. IIE (1 g) was dissolved in 60 m*l* of ethanol, and this solution was kept in the dark for 24 hr. The solvent was then evaporated *in vacuo*. Fractional crystallization from benzene gave 0.3 g of an ethanol adduct, IV, as colorless needles; mp 118—121°C.

Found: C, 68.16; H, 5.97; N, 4.72%. Calcd for $C_{17}H_{17}O_4N$: C, 68.21; H, 5.73; N, 4.68%.

Preparation of V. In a manner similar to that described above, Iz gave the ethanol adduct (V) as colorless plates; mp 39—40°C.

Found: C, 58.20; H, 6.48; N, 5.23%. Calcd for $C_{13}H_{17}O_5N$: C, 58.42; H, 6.41; N, 5.24%.

Preparation of VI. III (1 g) was dissolved in 80 m*l* of ethanol and was heated under reflux for 72 hr, and then the solvent was evaporated *in vacuo*. The ethanol adduct, VI, was thus obtained almost quantitatively. Yellow oil; bp 143°C/9 mmHg.

Found: C, 43.75; H, 4.64; N, 5.07%. Calcd for $C_{10}H_{12}NO_3Br$: C, 43.78; H, 4.36; N, 5.11%.

This compound was also prepared as follows. To a solution of III (2.3 g, 0.01 mol) in THF (60 m*l*), sodium ethoxide (0.7 g, 0.01 mol) was added at room temperature. The mixture was stirred for 1 hr and then poured into 200 m*l* of ice water. Then, CO_2 gas was bubbled through the mixture for 1 hr. The aqueous mixture was extracted with three 300 m*l*-portions of benzene. After the removal of the benzene, the ethanol adduct, VI, was obtained by distillation under reduced pressure.

Preparation of IX. VIII (1 g) was dissolved in 50 m*l* of ethanol, and the mixture was kept at 30°C for 24 hr. After the ethanol had then been evaporated *in vacuo*, the residual pale yellow liquid was chromatographed on Wako-gel Q-22, using *n*-hexane as the eluent. The first fraction gave 0.9 g of pale yellow crystals of IX; mp 29—30°C; yield, 72.8% (lit,[14] 29—31°C).

Equilibrium Ratios in the Isomerizations. The equilibrium ratios in the thermal- and photoisomerizations were determined by comparison with the known ratio of isomers and the characteristic absorption bands of the isomerization mixtures, at appropriate time intervals, as is shown in Fig. 1.

Kinetic Measurements. The ethanolic solutions of the β-nitrostyrenes (about 10^{-5}M concentrations) were thermostated, and the UV spectra, at appropriate time intervals, were measured. The logarithm of molar absorbance at the wavelength in the $\pi \rightarrow \pi^*$ region against the time was linear. The first-order rate coefficients (*k*) were calculated by the usual method.

The authors are indebted to Miss Masuko Nishinaka for her IR measurements and elemental analyses.

The Preparation of Amino-*s*-triazines with Amino- or Nitrophenyl Groups

Yasuo YUKI, Toshio KAKURAI,* and Tatsuya NOGUCHI*

Department of Fiber and Polymer, Nagoya Institute of Technology, Gokiso, Showa-ku, Nagoya

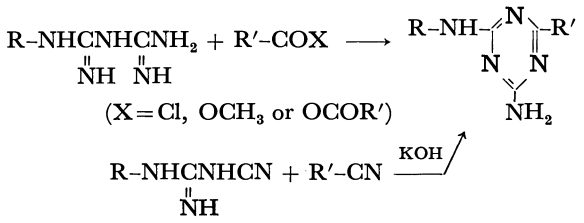
(Received December 1, 1970)

Amino-*s*-triazines with nitro groups were prepared by the reaction of biguanide derivatives with appropriate carboxylic acid derivatives (acyl chloride, anhydride, or ester) or by reaction between dicyanodiamide derivatives and nitrile. Amino-*s*-triazines with aminophenyl groups were prepared by the reduction of the corresponding nitro-compounds. Acylamino-*s*-triazines have been found to be formed when an excess of acyl chloride or anhydride is used.

The amino-*s*-triazines bearing extra amino groups attached to the side chain are interesting since these compounds can serve as possible intermediates for the synthesis of new triazine derivatives.

In this paper the preparation of amino-*s*-triazines bearing phenyl substituents with nitro or amino groups will be described.

In general,[1] amino-*s*-triazine derivatives have been prepared by the reaction of appropriate biguanide derivatives with acyl chloride, anhydride, or ester, or from appropriate dicyanodiamide derivatives with nitrile in the presence of strong alkali. These two methods were used in the present work.



Results and Discussion

The synthetic results are summed up in Table 1. The reaction of biguanide derivatives with methyl formate proceeded rapidly, but the corresponding reaction with methyl acetate was slow and gave poor yields of the desired materials.[2] With methyl benzoate, the reaction was found to proceed even more slowly than in the cases of methyl acetate and methyl formate. Therefore, acyl chloride or acid anhydride was used to obtain *s*-triazine from biguanide derivatives. In the present work, when an excess of acetic anhydride or benzoyl chloride was used as the acylation reagent, it was found that acylated amino-*s*-triazines were obtained as the by-products. On the other hand, when excesses of biguanide derivatives were used, it was found that no acylamino-*s*-triazines were obtained.

UV Spectra. The UV spectra of *s*-triazines have been reported by several investigators.[3-7] *s*-Triazines without phenyl or anilino groups attached directly to the triazine ring have ε values of around 10^3.[3]

The UV spectral data of *s*-triazines described in Table 1 are summed up in Table 2. These triazines have ε values of about 10^4. It can be seen from Table 2 that, while it has been known that 2,4-diamino-6-phenyl-*s*-triazine and 2-amino-4-anilino-6-phenyl-*s*-triazine have their absorption maxima at 245 mμ[8] ($\varepsilon = 22.2\times10^3$) and at 260 m$\mu$[8] ($\varepsilon = 43.4\times10^3$), *s*-triazines with *p*-nitroanilino substituents and those with *p*-aminophenyl substituents were found to reveal their absorption maxima at 344—352 mμ and at 315—320 mμ respectively. The comparisons of the absorption maxima of 4- or 6-substituted-*s*-triazines are described in Table 3. That is, the introduction of a nitro group into the *para* position of a 4-anilino-substituent, or that of an amino group into the *para* position of a 6-phenyl-substituent, of the 2-amino-*s*-triazine ring results in a large bathochromic shift, as expected. This is due to the resonance interaction involving contributions from the following structures:

a) Solvent: MCS, methyl cellosolve: Et, ethanol.
b) Shapiro has reported 255 mμ (ε, 39.7×10^3) in methanol (Ref. 5).
c) Reported previously (Y. Yuki, S. Sakurai, T. Kakurai, and T. Noguchi, This Bulletin, **43**, 2130 (1970)).
28: 2-amino-4-*p*-aminoanilino-6-*p*-aminophenyl-*s*-triazine,
29: 2-amino-4-*m*-aminoanilino-6-*p*-aminophenyl-*s*-triazine,
30: 2-amino-4-*m*-aminoanilino-6-*m*-aminophenyl-*s*-triazine.

TABLE 3. COMPARISONS OF THE ULTRAVIOLET ABSORPTION MAXIMA OF SUBSTITUTED *s*-TRIAZINES

4 or 6-Substituent	λ_{max}(mμ)	Compound
p-Nitroanilino	344—352	3,5,7,11, and 13
m-Nitroanilino	258—274	4,6,8,12, and 14
p-Nitrophenyl	275—290	1,9,11, and 12
m-Nitrophenyl	232—259	1,10,13, and 14
p-Aminoanilino	265—283	20,22, and 24
m-Aminoanilino	258—270	21,23, and 25
p-Aminophenyl	315—320	17,26,28, and 29
m-Aminophenyl	233—237 256—265	18,27, and 30

On the other hand, the introduction of a nitro or amino group into the *meta* position of a phenyl or anilino group attached to the 2-amino-*s*-triazine ring leads to little or no bathochromic effect, as is shown in Table 3.

Experimental

All the melting points were uncorrected, and mps above 250°C were measured by means of a Differential Scanning Calorimeter (DSC). MCS denotes methyl cellosolve.

*2-Amino-4-*m*-nitroanilino-*s*-triazine (4).* This product was predpared by the procedure detailed by Overberger and Shapiro.[9] When *m*-nitrophenylbiguanide (*m*-NPB) was treated with methyl formate in methanol, it gave **4** (43%). The removal of the solvent from the filtrate gave a residue which was then recrystallized from a methanol-ethanol mixture to afford formic acid salt of *m*-NPB, mp 186—187°C (decomp).

Found: C, 40.25; H, 4.31; N, 30.80%. Calcd for $C_9H_{12}N_6O_4$: C, 40.30; H, 4.51; N, 31.33%.

*2-Amino-4-*p*-nitroanilino-6-methyl-*s*-triazine (5).* Into a solution of 8.9 g (40 mmol) of *p*-nitrophenylbiguanide (*p*-NPB) in 100 m*l* of acetone, we slowly stirred 2.0 g (20 mmol) of acetic anhydride with ice-cooling. After 1 hr, the precipitate (8.73 g) was separated and washed with hot water to yield 3.0 g of the product, which was then treated with methanol-MCS mixture to give 0.2 g of insoluble, crude 2-acetamido-4-*p*-nitroanilino-6-methyl-*s*-triazine (**31**), mp 275°C. This was recrystallized from DMF, mp 286°C. The filtrates (acetone and methanol-MCS) were combined, and from this there were obtained 4.5 g (90%) of **5**, recrystallized from MCS, mp 269°C.

*2-Acetamido-4-*p*-nitroanilino-6-methyl-*s*-triazine (31).* To a solution of 1.23 g (5 mmol) of **5** suspended in 10 m*l* of dioxane, we added 3 m*l* of acetic anhydride, and then the solution was refluxed for 5 hr. We thus obtained 1.10 g (76%) of the product, which was subsequently recrystallized from DMF, mp 287°C.

Found: C, 50.03; H, 3.92; N, 28.84%. Calcd for $C_{12}H_{12}N_6O_3$: C, 50.00; H, 4.20; N, 29.15%. UV: λ_{max}^{MCS}mμ ($\varepsilon \times 10^{-4}$) 234(2.64) and 343(2.03).

*2-Amino-4-*m*-nitroanilino-6-methyl-*s*-triazine (6).* This compound was previously prepared by the reaction of *m*-NPB with methyl acetate.[2] In the present work the reaction of *m*-NPB with acetic anhydride was carried out as above. Acetic anhydride (1.02 g) and 4.44 g of *m*-NPB gave 1.34 g (55%) of **6**, mp 224—225°C, and 0.30 g of 2-acetamido-4-*m*-nitroanilino-6-methyl-*s*-triazine, recrystallized from DMF mp 259°C.

Found: C, 49.66; H, 4.04; N, 29.56%. Calcd for $C_{12}H_{12}N_6O_3$: C, 50.00; H, 4.20; N, 29.15%. UV: λ_{max}^{MCS}mμ ($\varepsilon \times 10^{-4}$), 231(2.13) and 271(3.00).

*2-Amino-4-*p*-nitroanilino-6-phenyl-*s*-triazine (7).* a) When *p*-NPB (6.66 g, 30 mmol) was treated with 4.20 g (30 mmol) of benzoyl chloride and 2.0 g (36 mmol) of sodium hydroxide, it gave 2.95 g (32%) of **7** and 1.45 g of 2-benzamido-4-*p*-nitroanilino-6-phenyl-*s*-triazine, which was recrystallized from DMF, mp 265°C.

Found: C, 63.20; H, 3.73; N, 20.64%. Calcd for $C_{22}H_{16}N_6O_3$: C, 64.07; H, 3.91; N, 20.38%. UV: λ_{max}^{MCS}mμ ($\varepsilon \times 10^{-4}$) 256(2.98) and 347(1.86).

b) *p*-NPB (4.70 g, 21 mmol) was treated with 1.40 g (10 mmol) of benzoyl chloride in acetone to give 2.30 g (75%) of the product, mp 228—229°C.

Found: C, 56.13; H, 3.94; N, 26.28%. Calcd for $C_{15}H_{12}N_6O_2 \cdot 1/2\ H_2O$: C, 56.78; H, 4.13; N, 26.49%.

c) *p*-Nitrophenyldicyanodiamide (*p*-NPD) (1.0 g, 5 mmol) was treated with 1 m*l* of benzonitrile and 0.1 g of sodium

9) C. G. Overberger and S. L. Shapiro, *J. Amer. Chem. Soc.*, **76**, 93 (1954).

hydroxide in MCS under reflux for 5 hr. There was thus obtained 0.89 g, (58%) of **7**, which was recrystallized from MCS-water, mp 230—231°C.

Found: C, 58.15; H, 3.63; N, 26.73%. Calcd for $C_{15}H_{12}N_6O_2$: C, 58.44; H, 3.92; N, 27.26%.

*2-Amino-4-*m*-nitroanilino-6-phenyl-*s*-triazine (8).* a) *m*-NPB (6.66 g, 30 mmol) was treated with 4.60 g (33 mmol) of benzoyl chloride and 2.0 g (36 mmol) of sodium hydroxide give to 5.02 g (54%) of **8** and 2.76 g of 2-benzamido-4-*m*-nitroanilino-6-phenyl-*s*-triazine, which was recrystallized from DMF, mp 266—267°C.

Found: C, 63.86; H, 3.66; N, 20.53%. Calcd for $C_{22}H_{16}N_6O_3$: C, 64.07; H, 3.91; N, 20.38%. UV: $\lambda_{max}^{MCS}m\mu$ ($\varepsilon\times10^{-4}$) 261(3.77).

b) Into 4.50 g (20.3 mmol) of *m*-NPB dissolved in 50 m*l* of acetone, we stirred, drop by drop, 1.27 g (9.1 mmol) of benzoyl chloride in 50 m*l* of acetone with ice-cooling over a half-hour period. As the precipitate, 2.03 g of hydrochloride of *m*-NPB were thus obtained. The filtrate was condensed and poured into water. A yellow product, 2.52 g (90%) of **8**, was obtained.

*2-Amino-4-anilino-6-*p*-nitrophenyl-*s*-triazine (9).* Phenylbiguanide (30 g, 0.17 mol) was treated with 25 g (0.13 mol) of *p*-nitrobenzoyl chloride. The precipitate was filtered to yield 27.5 g of the pure product.

Found: C, 57.72; H, 4.06; N, 27.09%. Calcd for $C_{15}H_{12}N_6O_2$: C, 58.44; H, 3.89; N, 27.27%.

From the filtrate we obtained 4.5 g of **9** and 4.0 g of *p*-nitrobenzoic acid. The total yield of the product was 32 g (77%), recrystallized from a water-MCS mixture, mp 223-224°C.

*2-Amino-4-*p*-nitroanilino-6-*m*-nitrophenyl-*s*-triazine (13).* a) *p*-NPB (15 g, 68 mmol) was treated with 9.3 g (50 mmol) of *m*-nitrobenzoyl chloride. We thus obtained 15.7 g (87%) of the product, mp 275°C.

b) The reaction of *p*-NPD (2.15 g 10.5 mmol) with *m*-nitrobenzonitrile (1.56 g, 11 mmol) was carried out using 0.2 g of potassium hydroxide in MCS under reflux for 5 hr; it gave 1.52 g (41%) of **13**, which was recrystallized from a DMF-MCS mixture, mp 278°C.

*2-Amino-4-*m*-aminoanilino-*s*-triazine (21).* Tin (0.6 g) and 0.55 g (2.36 mmol) of **4** were suspended in 10 m*l* of ethanol containing 3.0 m*l* of 12 N hydrochloric acid, after which the solution was refluxed for 1 hr. On cooling, the precipitate was filtered and dissolved in hot water. A further amount of sodium hydroxide was added. There was thus obtained 0.37 g of a product (78%) which was recrystallized from methanol, mp 215—216°C.

The authors wish to thank Mr. T. Saito of Tokyo Institute of Technology for his elementary analysis and Miss H. Asanuma for her help in the measurements of UV spectra.

Syntheses and Thermal Isomerizations of Bicyclo[3.2.2]-nona-2,6,8-triene and Its Benzo Analog[1,2]

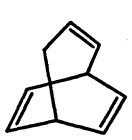
Teruji TSUJI, Hiroyuki ISHITOBI, and Hiroshi TANIDA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

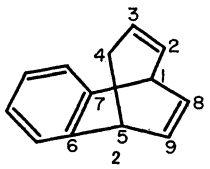
(Received December 31, 1970)

A convenient synthesis of bicyclo[3.2.2]nona-2,6,8-triene (**1**) was devised starting from the cycloheptatriene-maleic anhydride adduct. Benzo[*f*]bicyclo[3.2.2]nona-2,6,8-triene (**2**) was prepared starting from benzo[*f*] bicyclo[3.2.2]nona-3,6,8-trien-2-one. Heating **1** in *n*-hexane at 160—180°C gave almost quantitatively 3-vinyl-cycloheptatriene (**9**) besides a trace of 7-vinylcycloheptatriene (**10**). It was found however that **10** undergoes thermal isomerization into **9** under milder conditions. The result from **1** is thus rationalized by the existence of an equilibrium between **1** and **10** preceding the conversion of **10** into **9**. On the other hand, benzo analog **2** does not isomerize in a similar manner and instead, is transformed by heating at 270—290°C into benzobarbaralane (**14**) and hydrobenzindene (**15**). The contrast in behavior is discussed.

Despite the great interest involved, relatively little is known about bicyclo[3.2.2]nona-2,6,8-triene (**1**), a highly unsaturated polycyclic C_9H_{10} hydrocarbons, perhaps because of the difficulty in synthesizing it.[3]



1



2

Synthesis of **1** has been achieved independently by three groups,[3a-c] through multi-step processes and/or by ones involving troublesome purification procedures. During the course of studies on the cycloaddition reactions of cycloheptatriene,[4] we found a simple syntheses of **1**. This paper deals with the synthesis and

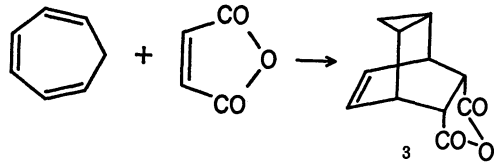
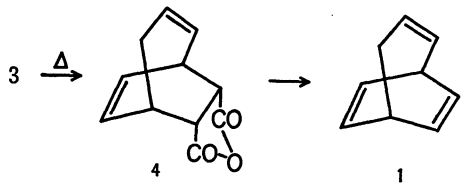
thermal rearrangement of **1** and a benzo variant, benzo[*f*]bicyclo[3.2.2]nona-2,6,8-triene (2). The thermal behavior of unsaturated polycyclic hydrocarbons is typically a unimolecular reaction, and as such can frequently give important data for testing the theories of such processes.[5] In this connection and because of our interest in such reactions,[6] thermolyses of the present [3.2.2]triene systems were investigated.

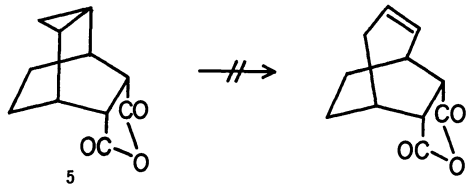
Results and Discussion

Synthesis. The cycloaddition of cycloheptatriene to maleic anhydride was reported by Alder and Jacobs[7] to produce a single adduct, tricyclo[3.2.2.$0^{2,4}$]-non-6-ene-8,9-dicarboxylic anhydride (**3**). The photosensitized addition with the same materials has also been found by Schenk *et al.* to form mainly the same adduct, together with two other minor compounds.[8,9] Conversion of **3** into bicyclo[3.2.2]nona-2,6-diene-8,

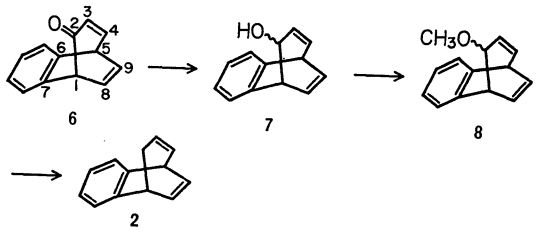




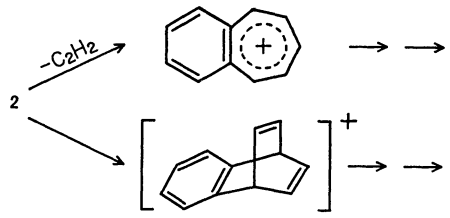
9-dicarboxylic anhydride (**4**) with opening of the cyclopropane ring was accomplished by heating **3** in chlorobenzene at 220°C. Such a relatively easy cleavage of cyclopropane was not observed with a similar treatment of the dihydro derivative of **3** (**5**).[10] Electrolytic bisdecarboxylation, principally by applying the reported procedure,[12] was carried out on **4** to obtain **1**, the physical properties of which were consistent in all respects with the reported data.[3a-c]



Essentially the same route reported for the preparation of bicyclo[3.2.1]octa-2,6-diene[13] and **1**[3c] was applied for the synthesis of **2**. Lithium aluminum hydride reduction of benzo[*f*]bicyclo[3.2.2]nona-3,6,8-trien-2-one (**6**) (prepared by the addition of benzyne to tropone)[14] gave a mixture of the *endo*- and *exo*-alcohols (**7**), which were methylated with dimethyl sulfate. *endo*- and *exo*-ethers (**8**) were treated with sodium-



potassium alloy in dimethoxyethane and then quenched with methanol to yield **2** as crystals from **6** in 43% yield. The UV, IR, NMR, and mass spectral data are consistent with the indicated structure for **2** (see Experimental). The NMR pattern of the aliphatic moiety is very similar to that of **1**[3c] and shows the C_3 vinyl proton at an unusually high field τ 5.71. Since all the peaks reported for 2-methylnaphthalene,[15a] and benzobicyclo[2.2.2]octatriene[15b,c] but no other peaks were observed in the mass spectrum of **2**, it is considered that the fragmentation of **2** begins with the formation of the benzotropyrilium ion and the benzobicyclo[2.2.2]octatriene ion (*m/e* 154).



Thermal Isomerization of Bicyclo[3.2.2]nonatriene (**1**). When a solution of **1** in *n*-hexane was heated in a degassed sealed ampoule in the temperature range 160—180°C, the reaction mixture initially showed an almost quantitative formation of 3-vinylcycloheptatriene (**9**)[3b] besides a trace of 7-vinylcycloheptatriene (**10**).[16] Further heating of the mixture resulted in a

8) G. O. Schenk, J. Kuhls, and C. H. Krauch, *Ann. Chem.*, **693**, 20 (1966).

9) Alder and Jacobs[7] originally assigned the *endo* configuration to the dicarboxylic anhydride group in **3**, while Schenk and his coworkers[8] suggested the *exo* configuration on the grounds that treatment of **3** with a basic iodine-potassium iodide solution did not cause iodolactonization. We re-examined the thermal cycloaddition reaction of cycloheptatriene with maleic anhydride and configuration of the adduct. From our preliminary results we prefer the *endo* configuration. Details of our re-examination will be reported soon.

10) A bond-breaking process in simple cyclopropanes requires an activation energy as high as ~63 kcal.[11] Therefore, the result from **5** would be more common.

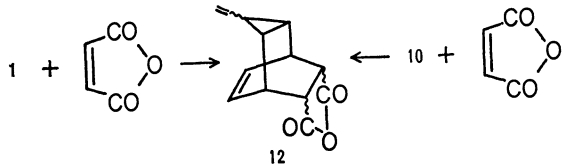
hydrogen shift transforming **9** into 1-vinylcycloheptatriene (**11**). The structure of **11** was determined principally by the NMR spectrum which shows a doublet at τ 7.46 (J=7.0 Hz) arising from two methylene protons at C_7.[17] The 7-vinyl isomer **10** was independently synthesized and subjected to thermal isomerization. It was observed that **10** isomerizes into a 1:9 mixture of **1** and **9** in the temperature range 120—140°C, and that the products are the same as those from the thermolysis of **1**, although the reaction proceeded at lower temperatures. No isomerization of **1** thus formed was confirmed under the present conditions. The results are therefore compatible with an equilibrium between **1** and **10** preceding the conversion of **10** into **9**. A further support of this view was

$$\mathbf{1} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{10} \xrightarrow{k_2} \mathbf{9}$$

provided by a trapping experiment. Thermolysis of **1** in the presence of maleic anhydride produced a tricyclic adduct bearing a vinylcyclopropane moiety (**12**), which was identical with the product obtained from the cycloaddition of **10** with maleic anhydride in boiling dioxane.

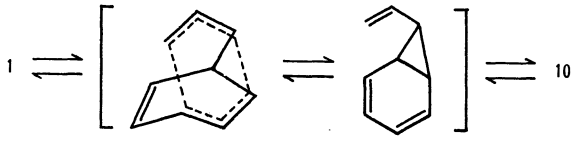


The rates of disappearance of **1** and **10** (k_t and k'_t, respectively) on thermolysis were determined by use of vpc. Good first-order kinetics was observed in all runs. The rate constants thus observed are listed in Table 1, with the kinetic parameters derived at 159.2°C. Since it was confirmed experimentally that the concentration of **10** did not exceed 1.4% of the total of reaction components through all the reaction period, it is not unreasonable to approximate a steady state on **10**. Thus we obtain

$$k_t = k_1k_2/(k_{-1}+k_2) \text{ and } k_t' = k_{-1} + k_2$$

where k_1 and k_{-1} are the interconversion rates between **1** and **10**, and k_2 is the rate of conversion of **10** into **9**. The constants, k_1, k_{-1}, and k_2, in Table 2 are thus calculated and the derived kinetic parameters produce a free energy diagram as shown in Fig. 1. The energy barrier $\Delta F^{\ddagger}$ for the interconversion between **1** and **10** at 159.2°C is 35.0 kcal/mol from **1** and 33.2 kcal/mol from **10**.

A mechanism which accommodates all the results is



17) Cycloheptatrienes having no substituent at C_1 and C_6 show a triplet due to the protons at C_7. Refer to R. Roth, *Angew. Chem. Int. Ed. Engl.*, **2**, 688 (1963); A. P. ter Borg and H. Kloosterziel, *Rec. Trav. Chem., Pays-Bas*, **82**, 741 (1963).

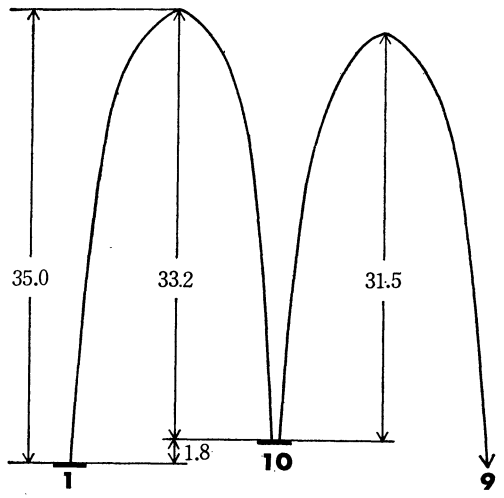

Fig. 1.

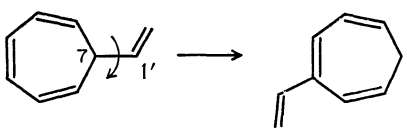
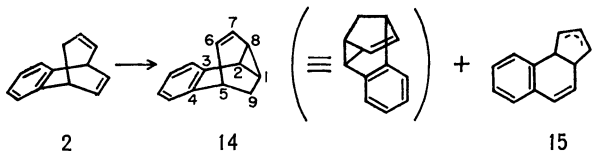
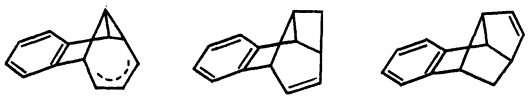
the Cope rearrangement (a [3,3]sigmatropic rearrangement) passing through *cis*-7-vinylnorcaradiene (**13**) as a transition state or an intermediate. The rearrangement of *cis*-6-vinylbicyclo[3.1.0]hex-2-ene to bicyclo[3.2.1]octa-2,6-diene[18] and the formation of bicyclo[3.2.2]nona-3,6,8-trien-2-one by treatment of cyclohepta-2,4,6-trienylacetyl chloride with triethylamine, presumably by a Cope rearrangement of the cyclohepta-2,4,6-trien-7-yl ketene intermediate,[19] are thought to be related precedents, although they are one-way reactions corresponding to the k_{-1} process and not interconversion as in the present case. The isomerization of **10** into **9** is an example of the familiar 1,5-hydrogen shift. It is noted that the kinetic parameters ($\Delta H^{\ddagger}=29.5$ kcal, $\Delta S^{\ddagger}=-4.5$ cal/deg at 159.2°C) are comparable with those reported for the thermal isomerization of 1,4-bis(7-cycloheptatrienyl)benzene into 1,4-bis(3-cycloheptatrienyl)benzene ($\Delta H^{\ddagger}=29.8$ kcal, $\Delta S^{\ddagger}=-3.9$ cal/deg at 140°C),[20] but not with those for the isomerization of 7-phenylcycloheptatriene into 3-phenylcycloheptatriene ($\Delta H^{\ddagger}=26.9$ kcal, $\Delta S^{\ddagger}=-11.7$ cal/deg: for which the specific temperature has not been reported).[21] The 7 substituents in these molecules have freedom of rotation around the C'_1–C_7 axis, but it is somewhat restricted after the hydrogen has shifted, because the π-electrons in the substituents now come to conjugation with the unsaturation in the ring. The observed entropy decrease is compatible with this decreasing freedom of motion in the molecules.



Thermolysis of Benzobicyclo[3.2.2]nonatriene (2). The thermal transformtion of **2** in *n*-hexane was monitored by vpc at two temperatures, 268.5°C and 289.8°C and found to give mainly benzo[3,4]barbaralane (**14**) and the hydrobenzindene (**15**) (in total, 95%), with a trace of an unidentified compound. The ratios of **14** and **15** were 2.5:1 at 268.5°C and 3.0:1 at 289.8°C.[22] Rates and kinetic parameters are summarized in Tables 1 and 2. The two major products, **14** and **15**, were isolated by vpc. The structure of **14** was assigned on the basis of spectral evidence. The presence of two vinyl protons and the absence of a double bond conjugated with benzene were indicated by NMR and UV, respectively. The 100 MHz NMR data obtained using double and triple resonance techniques are in line with the structure **14** (see Experimental). Also, the NMR demonstrated that **14** possess a fixed structure, and not a fluxional character like barbaralane.[23] Conceivable alternatives to structures **14**, **16**, **17**, and **18** were ruled out by NMR. The methylene protons appear as a triplet at a field higher than usually expected for allylic protons and show no coupling with the vinyl protons. These facts eliminate structure **16**. The





identical coupling constants ($J=7.6$ Hz) between H_1 and H_2, H_1 and H_8, and H_2 and H_8 support the existence of a three-membered ring, but not that of structure **17** or **18**. The UV maximum at 268 mμ (ε 8500) observed in product 15 indicates the presence of a double bond conjugated with a benzene ring. The NMR spectrum of **15** exhibits a doublet of doublets at τ 3.8 assignable to a vinyl proton adjacent to a benzene ring. Catalytic hydrogenation over palladium on carbon resulted in the uptake of 2 moles of hydrogen to yield the known 2,3,3aβ,4,5,9bβ-hexahydro-1*H*-benz[*e*]indene.[24] Consequently, the structure of **15** was determined to be either 3a,9b-dihydro-3*H*-benz[*e*]indene or its double-bond isomer, 3a,9b-dihydro-1*H*-benz[*e*]indene.

The formation of **14** can be explained by postulating an intramolecular ene reaction[25] through such a six-membered transition state as **19**, which involves one of the allylic hydrogens. Concerning the formation of

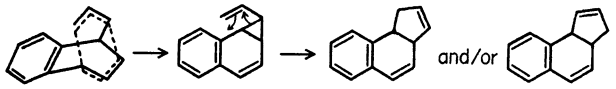
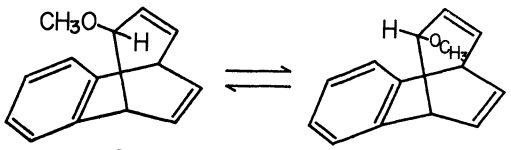
15, we have considered the Cope rearrangement leading to the *cis*-7-vinyl-2,3-benzonorcaradiene transition state or intermediate, followed by a vinylcyclopropane-



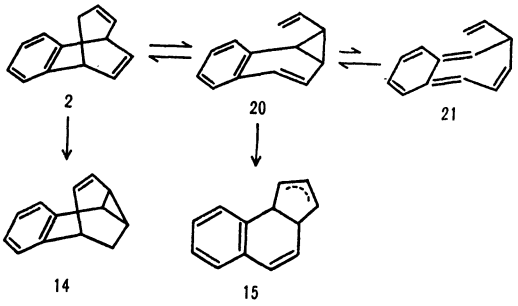
20

cyclopentene rearrangement. A pair of *exo*- and *endo*-2-methoxy derivatives of **2** (**8**) were prepared in order to get stereochemical information on the migrating C_4 site (inversion or retention). It was found however that epimerization of the methoxyl group takes place at a temperature (190°C) below that at which the thermo-



8

lysis occurs, and on thermolysis at ~230°C both epimers gave almost the same complex product mixtures. These findings can be understood by proposing an equilibrium between **2** and the norcaradiene intermediate (**20**)[26] preceding the product formation, which is analogous to the equilibrium between **1** and **10**. A rotation of the vinyl group in **20** followed by the return to **2** results in the epimerization. A resonable explanation for the present results is to assume the following reaction schema.



2 20 21 14 15

The question arises, why do the parent (**1**) and the benzo (**2**) compounds react differently? Transformation of **20** into the cycloheptatriene intermediate (**21**) must involve loss of aromaticity of the benzene ring which is thermodynamically unfavored. Such an unfavorable factor is not present in the reaction of **1**. As a result, the thermal isomerization of **2** must proceed by a different mechanism, requiring a temperature higher than that for **1**.

26) The vinyl-unsubstituted derivative of **20** has been found to be a stable compound. W. V. E. Doering and M. J. Goldstein, *Tetrahedron*, **5**, 53 (1959).

Experimental

All melting points were taken in sealed capillaries and are corrected. Infrared spectra were determined with a Nippon Bunko IR-S spectrometer, ultraviolet spectra with a Beckman DK-2A spectrometer, and NMR spectra with a Varian Associates A-60A and/or HA-100. Mass spectra were taken on a Hitachi RMU-6 mass spectrometer. Vpc analysis was carried out on a Hitachi-Perkin-Elmer gas chromatograph F-6D equipped with a hydrogen flame ionization detecter using one of the following columns: (A) 1 m×3mm, stainless steel column packed with 5% XE 60 on Chromosorb W; (B) 1 m×3 mm stainless steel column packed with 5% SE on the same support; (C) 2 m×3 mm stainless steel column packed with 5% diethylene glycol succinate polyester on the same support. Helium was used as a carrier gas. Preparative vpc was carried out with a Yanagimoto gas chromatograph GCG, equipped with 6 m×14 mm stainless steel column, packed with 20% Silicon 550 on the Chromosorb W.

Bicyclo[3.2.2]nona-2,6-dien-8,9-dicarboxylic Anhydride (4). A solution of 10 g of the cycloheptatriene-meleic anhydride adduct (**3**) in 70 m*l* of chlorobenzene was placed in a heavy-walled glass ampoule, cooled to −70°C and sealed. The ampoule was placed in a steel bomb and heated at 220°C for 17 hr. The reaction mixture was cooled, decolorized by treatment with charcoal, filtered, and concentrated under reduced pressure. The residue was extracted with warm carbon tetrachloride. The solution was decolorized again, filtered and cooled to separate 4.5 g crystalline **4**. Concentration of the mother liquor gave 1.0 g of **4** (in total, 55% yield), homogeneous on vpc. Recrystallizaton from carbon tetrachloride afforded a pure sample; mp 136—138°C (lit,[8] mp 138—139°C); IR (CCl_4): 3060 (C=C), 1868, 1780, and 1223 cm^{-1} (C=O); NMR ($CDCl_3$): τ 7.60 (m, 2H at C_4), 6.9 (broad m, 2H at C_1 and C_5), 6.52 (d-d, J=9.3 and 2Hz, 1H at C_8 or C_9), 6.23 (d-d, J=9,3 and 2 Hz, 1H at C_8 or C_9), 4.6 (d-t-d, J=10.2, 3.2, and 1 Hz, 1H at C_3), 4.1 (d-d-t, J=10.2, 8.0, and 2.3 Hz, 1H at C_2), 3.9 (d-d-d, J=8.8, 6.6 and 1.5 Hz, 1H at C_6), 3.57 (d-d-d, J=8.8, 6.7, and 1.5 Hz, 1H at C_7).

Found: C, 69.82; H, 5.27%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

Bicyclo[3.2.2]nona-2,6,8-triene (1). A solution of 3.0 g of **4** and 4 m*l* of triethylamine in 100 m*l* of 85% pyridine-water was placed under nitrogen atmosphere in an electrolysis apparatus equipped with two stationary electrodes made of platinum gauze, nitrogen inlet tube, and glass tube for cooling, and maintained below room temperature with strirring. Electrolysis was conducted for 300 min at 70 V. During the reaction, the current fell from 1.0 A to 0.20 A, and then remained constant. The dark reaction mixture was diluted with 300 m*l* of saturated sodium chloride solution and extracted three times with 200 m*l* of pentane. The combined pentane extract was washed twice with 20 m*l* of dilute hydrochloric acid, then 200 m*l* of water, and dried over sodium sulfate. Evaporation of the solvent and distillation of the residue at 61—62°C (45 mmHg) gave 367 mg of **1** (19.7%), which was homogeneous on vpc (column C) and had physical properties identical with the reported data.[3a-c]

Benzo[f]bicyclo[3.2.2]nona-2,6,8-triene (2). To a stirred suspention of 500 mg of lithium aluminum hydride in 50 ml of ether was added at −20°C a solution of 5.0 g of the ketone **6**[14] in 100 m*l* of ether. After the mixture had been stir-

red for 2.5 hr, the usual work-up gave 5.0 g of an alcohol mixture **7**. A solution of 5.0 g of **7** and 5.0 g of methyl iodide in 50 m*l* of dimethoxyethane was cooled to −15°C and stirred for 15 min during the additon of 750 mg of sodium hydride. The reaction proceeded with evolution of hydrogen gas. After further addition of 1.0 g of methyl iodide, the reaction mixture was warmed to room temperature, stirred for 3.0 hr, and then poured into water. After extraction with ether, evaporation of the solvent and distillation at 96—98°C (0.1 mmHg) gave 4.2 g of a crude ether. Further purification by elution chromatography over 100 g of Merck standard alumina using ether gave 3.6 g of **8**.

To a stirred solution of 3.6 g of **8** in 36 m*l* of dimethoxyethane, 3 m*l* of sodium-potassium alloy (1:5) was added at −10°C and the mixture was stirred for 4 hr. The reddish brown solution was poured into 50 m*l* of could methanol and diluted with water. After extraction with ether and washing with water, evaporation of the ether left 2.3 g of residue. Sublimation of the residue under reduced pressure afforded 2.0 g of **2**, mp 58—59°C. Total yield from **6** was 43%. IR (CS_2): 3026 and 1632 cm^{-1} (C=C); λ_{max}^{hexane} mμ (log ε): 265 (377) and 272 (397); NMR (CCl_4): τ 7.75 (m, 2H at C_4), 6.55 (m, 2H at C_1 and C_5), 5.1 (d-t-d, J=10.5, 3.8, and 1 Hz, 1H at C_3), 3.98 (d-d-t, J=10.5, 8, and 2 Hz, 1H at C_2), 3.77 (d-d-d, J=8,7, and 1.5 Hz, 1H at C_9), 3.37 (d-d-d, J=8,7 and 1.5 Hz, 1H at C_8), and 3.0 (aromatic 4H); mass spectrum (70 eV) *m/e* 168, 167, 165, 154, 153, 152, 141, 128, 115, 102, 89, 83, 76, 63, 51, 39.

Found: C, 92.80; H, 7.17%. Calcd for $C_{13}H_{12}$: C, 92.81; H, 7.19%.

Thermolysis of 1. A 0.1N solution of **1** in *n*-hexane was degassed, sealed in an ampoule and placed in a constant temperature bath controlled in the range 160—180°C. Analysis of the thermolysis products was carried out by vpc (column C at 50°C with a flow pressure of 1 kg/cm^2) and showed the formation of three products, whose retention times were 4 min, 8 min, and 8 min 30 sec, while that of **1** was 5 min 20 sec. The peak at 4 min was identical with that of independently synthesized **10**. The peak at 8 min was identified as **9**, which was obtained as the main product on thermolysis of **10** as reported by Daub and Schleyer.[3b] The peak at 8 min 30 sec did not appear at the initial stage of pyrolysis, but increased gradually as the reaction proceeded by further isomerization of the initially formed **9**. This isomerization product was assigned as 1-vinylcycloheptatriene (**11**) on the basis of its NMR spectra,[17] τ 7.46 (d, J=7.0 Hz, 2H at C_7).

Thermolysis was followed by vpc using dodecane as an interanl standard, and integration of the component peaks was carried out with a planimeter. After correction for the relative sensitivity of the detector, decreases in the concentration of **1** were determined by comparing the peak area of **1** with that of the standard. With this technique the yield of **9** was quantitative, at least for the half-life of the reaction. Vpc of the infinity ampoule (more than the 10 half-lives) showed complete disappearance of **1** and two peaks corresponding to **9** and **11** with areas of approximately 2:3. Thermolysis rates determined by following the decrease of **1** for two half-lives, were shown to be first-order.

Thermolysis of 10. The reaction was carried out at a temperature in the range 120—140°C and gave quantitatively a mixture of **1** and **9** in the ratio 1:9. Formation of **11** was not observed up to the three half-lives, and no rearrangement of **1** was observed under the present conditions. The rates of conversion of **10** into **1** and **9** were determined by the same technique employed for **1** and gave first-order constants.

3-Vinyltricyclo[3.2.2.0^{2,4}]nona-6-ene-8,9-dicarboxylic Anhydride (12). (a) A mixture of 100 mg of **1** and 100 mg of maleic anhydride in 10 m*l* of *n*-hexane was sealed in a degassed ampoule and heated at 160°C overnight. Vpc analysis of the reaction mixture on column A at 180°C with a flow pressure of 1.0 kg/cm^2 showed three peaks with retention times of 2 min 30 sec, 3 min 20 sec, and 3 min 40 sec with areas in the ratios 2:1:20. Evaporation of the solvent and recrystallization from ligroin gave 120 mg of **12**, mp 168—169°C, corresponding to the main peak with a retention time of 3 min 20 sec; IR ($CHCl_3$): 1865 and 1780 cm^{-1} (C=O), NMR ($CDCl_3$): τ 8.76 (m, 3H at C_2, C_3, and C_4), 6.76 (t, J=2 Hz, 2H at C_8 and C_9), 6.45 (m, 2H at C_1 and C_5), 4.2—5.2 (m, vinyl 3H), and 4.05 (d-d, J=5 and 3.5 Hz, 2H at C_6 and C_7).

Found: C, 71.99; H, 5.59%. Calcd for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

The minor peak, having a retention time of 3 min 20 sec, was identical with that of the product obtained from the reaction of **9** with maleic anhydride.

(b) A solution of 300 mg of **10** and 250 mg of maleic anhydride in 20 m*l* of dioxane was refluxed for 2 hr. After the usual work-up, recrystallization from carbon tetrachloride gave 450 mg of **12**, identical with the main product in procedure (a).

Thermolysis of 2. A solution of 900 mg of **2** in 40 m*l* of *n*-hexane was placed in an ampoule, cooled to −70°C, purged with nitrogen and sealed. The ampoule was heated at 230°C for 140 hr in the absence of light. After evaporation of the solvent, 900 mg of the residue was subjected to preparative vpc at a column temperature of 200°C with a flow rate of 300 m*l*/min of helium gas. The chromatogram showed three peaks with retention times of 50, 63, and 72 min with areas in the ratio 1:2:5. The fraction (63 mg) corresponding to the peak with a retention time of 50 min was identical with the starting material (**2**). Collection of the second peak, at 63 min, gave 130 mg of the hydrobenzindene (**15**): bp 80°C (0.3 mmHg), n_D^{25} 1.5987; λ_{max}^{hexane} mμ (ε): 260 (8080) and 268.5 (8500); NMR (CCl_4): τ 5.8—8.0 (complex signals due to aliphatic 4H), 4.3 (m, vinyl 3H), 3.8 (d-d, J=10 and 2 Hz, benzylic vinyl 1H) and 3.0 (m, aromatic 4H)].

Found: C, 92.80; H, 7.17%. Calcd for $C_{13}H_{12}$: C, 92.81; H, 7.19.

The third fraction, at 72 min, was collected to give 301 mg of benzobarbaralane (**14**), bp 76—78°C (0.25 mmHg), $n_D^{24.3}$ 1.6037; λ_{max}^{hexane} mμ (ε): 255 (692), 269.5 (550) and 276.5 (484); NMR ($CDCl_3$): τ 8.56 (t, J=2.3 Hz, 2H at C_9), 7.95 (t-d-d, J=7.6, 5.3, and 1.2 Hz, 1H at C_8), 7.82 (t-t, J=7.6 and 2.3 Hz, 1H at C_1), 7.45 (t, J=7.6 Hz, 1H at C_2), 6.78 (d-t-d, J=6.9, 2.3, and 1.4 Hz, 1H at C_5), 4.40 (d-d-d, J=9.6, 5.3, and 1.4 Hz, 1H at C_7), 4.20 (d-d-d, J=9.6, 6.9, and 1.2 Hz, 1H at C_6), and 3.0 (m, aromatic 4H); the mass spectrum was identical with that of **2**.

Found: C, 92.67; H, 7.24%. Calcd for $C_{13}H_{12}$: C, 92.81; H, 7.19%.

Kinetic measurements were carried out with a 0.1N solution of **2** in *n*-hexane using a vpc technique on column B at 100°C under a pressure of 1.0 kg/cm^2. Retention times of **2**, **15**, and **14** were 20, 34, and 41 min, respectively. Pentamethylbenzene, whose retention time was 8 min, was used as an internal standard. Extrapolation of the product compositions to zero time gave kinetically controlled ratios for **14** and **15**, of 2.5 at 268.5°C and 3.0 at 289.8°C, respectively. The decreasing rate of **2** was followed up to two half-lives and shown to be first-order.

2,3,3aβ,4,5,9bβ-Hexahydro-1H-benz[e]indene. A solution of 40 mg of **15** in 10 m*l* of methanol was hydrogenated at atmospheric pressure and room temperature over 5% palladium on carbon. Uptake ceased after absorption of 11 m*l*

of hydrogen. After the usual work-up, the hydrogenated product (37 mg), boiling at 80—82°C (1 mmHg), $n_D^{21.0}$ 1.5532, was found to be identical with the reported compound.[24]

Found: C, 90.40; H, 9.31%. Calcd for $C_{13}H_{16}$: C, 90.64; H, 9.36%.

Endo- *and* exo-*2-methoxybenzo*[f]*bicyclo*[*3.2.2*]*nona-3,6,8-triene.* A 7:3 mixture of the *endo*- and *exo*-2-methoxy compounds (**8**) was separated by preparative tlc using silica gel G (E. Merck Co.) as an adsorbent, and developing with ether-pentane (1:4). Collection and vacuum distillation of the more mobile fraction gave 580 mg of the *endo* compound, bp 115°C (0.25 mmHg), n_D^{25} 1.5758. Vpc (column C at 150°C with a flow pressure of 1 kg/cm^2) showed a single peak with a retention time of 8 min: IR (CCl_4): 1632 cm^{-1} (C=C) and 1100 cm^{-1} (C–O), NMR (CCl_4): τ 6.73 (s, 3H of CH_3O), 6.1—6.6 (m, 3H of C_1, C_2, and C_5), 5.1 (d–t, J= 10.2 and 2.5 Hz, 1H at C_3), 3.90 (d–d–d, J=10.2, 7.8, and 1 Hz, 1H at C_4), 3.70 (d–d–d, J=8.0, 6.4, and 1 Hz, 1H at C_8), 3.26 (d–d–d, J=8.0, 5.5, and 1 Hz, 1H at C_9) and 3.0 (m, aromatic 4H).

Found: C, 84.79; H, 7.05%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

The less mobile fraction gave 270 mg of the *exo* compound, bp 103°C (0.17 mmHg), n_D^{24} 1.5729. Vpc showed it to be homogeneous with a retention time of 6 min 30 sec: IR (CCl_4): 1631 (C=C) and 1100 cm^{-1} (C–O), NMR (CCl_4): τ 6.67 (s, 3H of CH_3O), 6.40 (m, 2H at C_1 and C_5), 6.10 (m, 1H at C_2), 5.03 (d–m, J=10.8 Hz, 1H at C_8), 3.86 (d–d–t, J=10.8, 5.0, and 1.0 Hz, 1H at C_4), 3.72 (d–d–d, J=9.0, 8.0, and 1.5 Hz, 1H at C_8), 3.30 (d–d–d, J=9.0, 6.0, and 1.5 Hz, 1H at C_9), and 3.0 (m, aromatic 4H).

Found: C, 84.43; H, 7.08%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

Thermolysis of 8. A 0.1N solution of the exo or endo methoxy compounds (two separate experiments) was degassed, sealed in an ampoule and heated at 190°C for 17 hr. Epimerization between the two alcohols was observed by vpc. Orientations of the methoxyl groups were determined by measurement of infrared hydroxyl bands in the corresponding saturated alcohols, which were obtained by hydrogenation of the two double bonds in **7**.

Benzo[*f*]bicyclo[3.2.2]nona-3,6,8-trien-2(*endo*)-ol had mp 91—91.5°C. Found: C, 84.65; H, 6.64%. Calcd for $C_{13}H_{12}O$: C, 84.75; H, 6.57%. The *exo* epimer had mp 109—109.5°C. Found: C, 84.91; H, 6.62%.

Benzo[*f*]bicyclo[3.2.2]non-6-en-2(*endo*)-ol had mp 52—53°C. Found: C, 83.09; H, 8.52%. Calcd for $C_{13}H_{16}O$: C, 82.93; H, 8.57%. IR (CCl_4): 3618 (free OH) and 3583 cm^{-1} (associated OH). The *exo* epimer had mp 95—96°C. Found: C, 82.90; H, 8.57%. IR (CCl_4): 3620 cm^{-1} (free OH).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2453—2455 (1971)

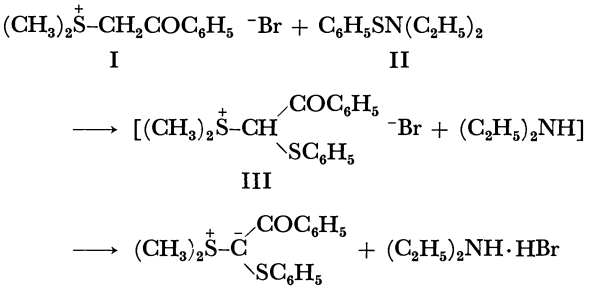
The Reactions of β-Ketosulfonium Salts with Sulfenamide Derivatives

Teruaki MUKAIYAMA, Kazuo HOSOI, Shun INOKUMA, and Takanobu KUMAMOTO
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received January 28, 1971)

2-Phenylthio-2-(dimethylsulfuranylidene)acetophenone was obtained in good yield by the reaction of dimethylphenacylsulfonium bromide with *N,N*-diethylbenzenesulfenamide. The reaction of dimethyl-α-methylphenacylsulfonium bromide with *N,N*-diethylbenzenesulfenamide gave α-phenylthioacrylophenone in good yield. The reactions of α-phenylthioacrylophenone thus obtained with various active methylene compounds were investigated.

Recently it was reported that sulfenamide derivatives reacted with active methylene compounds to give mono- or di-sulfenylated compounds in good yields. As an example, the reaction of *N,N*-diethylbenzenesulfenamide with acetylacetone in dichloromethane at room temperature gave 3-phenylthio-2,4-pentadione in 77% yield.[1)]

We studied the equimolar reactions of β-ketosulfonium salts with sulfenamide derivatives with the expectation that α-alkyl or arylthio-β-ketosulfonium salts and amines would be formed as a result of the introduction of sulfenyl group in place of the hydrogen atom attached to the α-carbon of the sulfonium salts. When *N,N*-diethylbenzenesulfenamide was treated with dimethylphenacylsulfonium bromide in dichloromethane at room temperature for an hour, 2-phenylthio-2-(dimethylsulfuranylidene)acetophenone and diethylammonium bromide were obtained in 70% and quantitative yields, respectively.

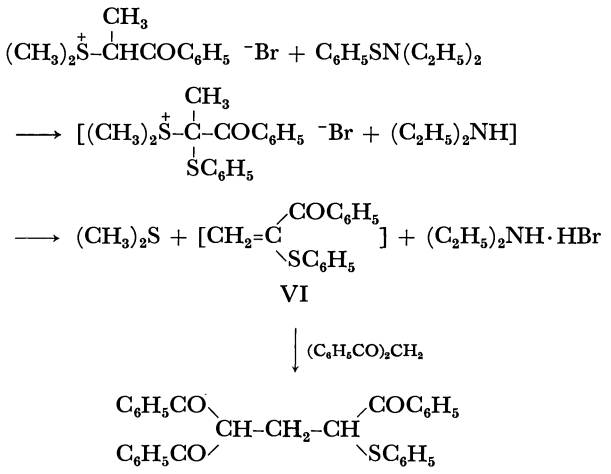


The result is explained as follows. Sulfonium salt (I) reacted with *N,N*-diethylbenzenesulfenamide (II) to form sulfenylated compound (III) and diethylamine as expected. The initially formed sulfonium salt was rapidly converted to 2-phenylthio-2-(dimethylsulfuranylidene)acetophenone by the influence of diethylamine.

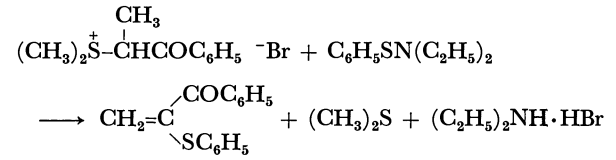
The reactions of dimethyl-α-methylphenacylsulfonium bromide with *N,N*-diethylbenzenesulfenamide and

1) T. Mukaiyama, S. Kobayashi, and T. Kumamoto, *Tetrahedron Lett.*, **1970**, 5115.

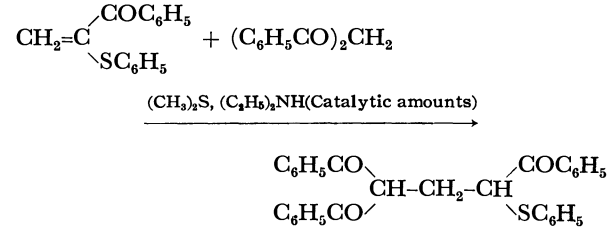
active methylene compounds were investigated with the expectation that initially formed dimethyl-α-methyl-α-phenylthiophenacylsulfonium bromide would further react with active methylene compounds to produce condensation products. However, the reaction of dimethyl-α-methylphenacylsulfonium bromide with *N*, *N*-diethylbenzenesulfenamide in dichloromethane at room temperature for 4 hr and the subsequent addition of dibenzoylmethane in refluxing dichloromethane for 4 hr afforded 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5-pentadione and diethylammonium bromide in 70% and quantitative yields, respectively. The unexpected formation of 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5-pentadione may be explained by considering an initial formation of sulfonium salt (V) and diethylamine from equimolar amounts of dimethyl-α-methylphenacylsulfonium bromide (IV) and *N*,*N*-diethylbenzenesulfenamide (II). Salt (V) rapidly reacts with diethylamine formed at the same time to give α-phenylthioacrylophenone (VI). The Michael addition of VI and dibenzoylmethane results in the formation of 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5-pentadione.



The presumed intermediate, α-phenylthioacrylophenone, was isolated in 98% yield by the reaction of dimethyl-α-methylphenacylsulfonium bromide with *N*, *N*-diethylbenzenesulfenamide, without the addition of dibenzoylmethane, in dichloromethane at room temperature for 4 hr.

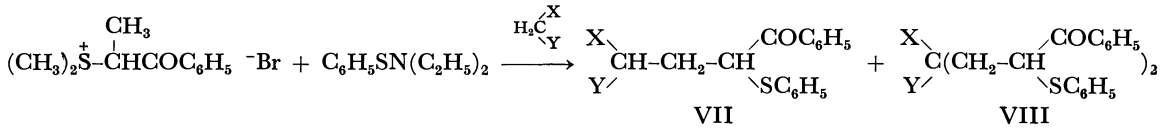


The α-phenylthioacrylophenone isolated by the above reaction did not react with dibenzoylmethane even when they were refluxed in dichloromethane for 4 hr. However, when the reaction was carried out in the presence of a catalytic amount of diethylamine and an equimolar amount of dimethyl sulfide, 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5-pentadione was obtained in 70% yield.



Similarly, it was established that reactions of dimethyl-α-methylphenacylsulfonium bromide with *N*,*N*-diethylbenzenesulfenamide and various active hydrogen compounds such as benzenethiol, ethanethiol, ethyl malonate, malononitrile, ethyl acetoacetate, without isolation of α-phenylthioacrylophenone, afforded 1:1 addition compounds or 1:2 addition compounds in good yields (Table 1).

TABLE 1. REACTIONS OF DIMETHYL-α-METHYLPHENACYLSULFONIUM BROMIDE WITH *N*,*N*-DIETHYLBENZENESULFENAMIDE AND ACTIVE HYDROGEN COMPOUNDS



CH_2(X)(Y)	VII	VIII	Mp (°C)	Analyses Found (Calcd) (%) C	H	N	S
HSC_6H_5	93%		oil	72.28 (71.99)	5.25 (5.18)		17.24 (17.46)

a) This was identified by transformation into sulfonium methyl sulfate.

Experimental

Materials. *N,N*-Diethylbenzenesulfenamide (II) was prepared according to the method of Lecher and Holschneider,[2] bp 96—97°C/8 mmHg (lit, 90°C/3.5 mmHg). Dimethylphenacylsulfonium bromide (I) was prepared from dimethyl sulfide and phenacyl bromide in dry acetone. Similarly, dimethyl-α-methylphenacylsulfonium bromide (IV) was prepared from dimethyl sulfide and α-bromopropiophenone.[3]

Reaction of Dimethylphenacylsulfonium Bromide with N,N-*Diethylbenzenesulfenamide.* A mixture of dimethylphenacylsulfonium bromide (2.61 g, 0.01 mol) and *N,N*-diethylbenzenesufenamide (1.81 g, 0.01 mol) was stirred in dichloromethane (50 m*l*) for an hour at room temperature. The reaction mixture was poured into water to remove diethylammonium bromide and the dichloromethane layer was collected. After the dichloromethane layer was dried with sodium sulfate, the solvent was removed under reduced pressure giving white crystals. The recrystallization from benzene gave 2-phenylthio-2-(dimethylsulfuranylidene)acetophenone,[4] mp 136—136.5°C, 2.00 g, (70%). (lit, 136°C).

Reaction of Dimethyl-α-methylphenacylsulfonium Bromide with N, N-*Diethylbenzenesulfenamide and Dibenzoylmethane.* A mixture of dimethyl-α-methylphenacylsulfonium bromide (1.43 g, 0.005 mol) and *N,N*-diethylbenzenesulfenamide (0.91 g, 0.005 mol) was stirred in dichloromethane (50 m*l*) at room temperature. Evolution of dimethyl sulfide was recognized by its characteristic odor accompanied by disappearance of the crystals of sulfonium salt. After stirring for 4 hr, dibenzoylmethane (1.12 g, 0.005 mol) was added to the reaction mixture and the mixture was refluxed for 4 hr. The solvent was removed under reduced pressure giving oily residue. Fifty milliliters of water was added into the residue and resulting oil was extracted with ether (50 m*l*). Removal of ether gave white crystals. Recrystallization from ethanol gave 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5-pentadione, 1.62 g (70%), mp 123—124°C.

Found: C, 77.81; H, 5.37; S, 6.64%. Calcd for $C_{30}H_{24}O_3S$: C, 77.57; H, 5.21; S, 6.89%. The NMR spectrum: τ= 1.7—2.8 (m, 20H), τ=4.43 (t, 1H), τ=5.12 (t, 1H), τ=7.27 (t, 2H).

Similarly, various addition products of active hydrogen compounds, such as benzenethiol, ethanethiol, ethyl malonate, malononitrile or ethyl acetoacetate, and α-phenylthioacrylophenone were obtained from dimethyl-α-methylphenacylsulfonium bromide, *N,N*-diethylbenzenesulfenamide and active hydrogen compounds. The results are listed in Table 1. The products were identified by elemental analyses, NMR spectra and IR spectra.

Reaction of Dimethyl-α-methylphenacylsulfonium Bromide with N, N-*Diethylbenzenesulfenamide.* A mixture of dimethyl-α-methylphenacylsulfonium bromide (1.43 g, 0.005 mol) and *N,N*-diethylbenzenesulfenamide (0.91 g, 0.005 mol) was stirred in dichloromethane (50 m*l*) for 4 hr at room temperature. The solvent was removed under reduced pressure giving a mixture of crystals and oil. Fifty milliliters of water was added into the mixture and resulting oil was extracted with ether (50 m*l*). After removal of the solvent, the oil was chromatographed on silica gel and elution with a mixture of petroleum ether (25—30°C) and benzene (1:1) gave α-phenylthioacrylophenone, 0.84 g (70%), mp 106—108°C.

Found: C, 74.82; H, 5.20; S, 13.21%. Calcd for $C_{15}H_{12}SO$: C, 74.99; H, 5.03; S, 13.32%. The NMR spectrum: τ= 1.8—2.8 (m, 10H), τ=7.55 (S, 1H), τ=7.65 (S, 1H).

Reaction of α-Phenylthioacrylophenone with Dibenzoylmethane. Into a solution of α-phenylthioacrylophenone (2.40 g, 0.01 mol) and dibenzoylmethane (2.24 g, 0.01 mol) in dichloromethane (50 m*l*), dimethyl sulfide (0.62 g, 0.01 mol) and a catalytic amount of diethylamine were added under stirring. The mixture was refluxed for 5 hr. After removal of the solvent, the residue was chromatographed on silica gel and elution with mixture of petroleum ether (25—35°C) and benzene (1:1) gave 2-benzoyl-1,5-diphenyl-4-phenylthio-1,5- pentadione, 3.00 g (70%), mp 123°C.

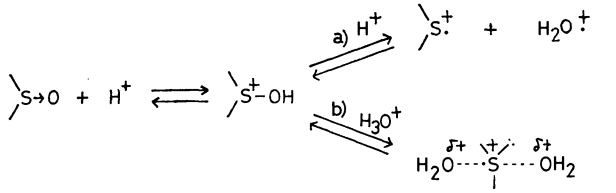
Effect of Ring Size on the Acid-Catalyzed Reduction of Cyclic Sulfoxides by Iodide Ion[1]

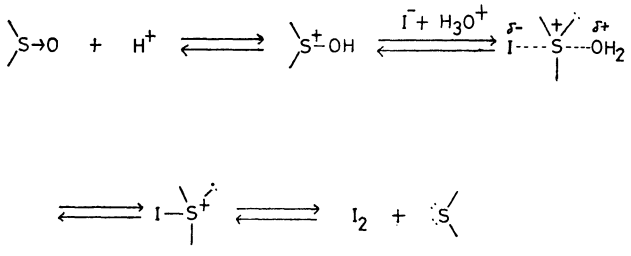
Seizo TAMAGAKI, Masao MIZUNO, Hiroshi YOSHIDA,
Hiroo HIROTA, and Shigeru OAE
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka
(Received February 1, 1971)

Acid-catalyzed reduction of various cyclic sulfoxides with iodide ion were kinetically investigated. The rates of reduction of thianthrene, phenoxathiin, dibenzothiophene oxides were found to be in a linear relation with their basicities, while those of alicyclic sulfoxides fall in the following sequence with a 700 fold range; 5-> 4->open>7->6- membered cyclic sulfoxides. This rate sequence seems to be correlated better by the steric effect than by basicity difference. For further information on the possible effect of steric hindrance, a few methyl alkyl sulfoxides were also subjected to the same reaction, but the results could not be explained by steric effect only.

The acid-catalyzed reduction of sulfoxide with iodide ion has been suggested to proceed by way of S_N2 type process on the sulfur atom.[2] Many similar S_N2 displacement reactions on the trivalent sulfur atom have been found. A distinct example[3] is oxygen exchange of diaryl sulfoxides with acetic anhydride or dilute sulfuric acid where the exchange leads to the inversion of configuration around the sulfur atom. Namely, the rate of oxygen exchange of diaryl sulfoxide is equal to that of racemization at a higher concentration (>80%) of sulfuric acid and the formation of radical cation intermediate was detected.[4] In the reactions at lower acid concentrations than 80% the mechanism changes from S_N1 (a) type to S_N2 (b) type displacement reaction shown below:



If the nucleophile in the above scheme, *i.e.*, H_2O, is replaced by such-reducing nucleophiles as iodide ion, the reaction does not lead to a reversible oxygen exchange but results in the predominant reduction illustrated below



By means of this reduction, we have investigated the nucleophilic displacement reaction on the trivalent sulfur atom of both aliphatic acyclic and cyclic sulfoxides. Although the structural effect on the reactivity of carbocyclic compounds has been examined by many workers and explanations have been given,[5] there is practically no investigation concerning the relation between the reactivity and the structure of heterocyclic compounds. We have therefore conducted a thorough kinetic study on the reduction of some simple alicyclic sulfoxides in order to disclose the effect of ring-size on the rates of the nucleophilic displacement reaction at the trivalent sulfur atom.

Experimental

Materials and kinetics: The boiling points or melting points of sulfoxides used are listed in Table 1.[6] The characterizations of reduction products of the acyclic sulfoxides were described[2] and the reduction of alicyclic sulfoxides such as five-, six- and seven- membered sulfoxides gave the corresponding sulfides in good yields of more than 80% under the kinetic conditions. However, in the case of the reduction of trimethylene sulfoxide, trimethylene sulfide was susceptible to decomposition to afford a polymer as white precipitates by the action of perchloric acid, although the sulfoxide itself was very stable to the same concentration of the acid. Special commercial grade 70%-perchloric acid was used for kinetics. Concentration of the acid was determined to be 11.83 mol/*l* with a standard solution of potassium hydroxide prepared by titrating with 0.200 mol/*l* potassium hydrogen phthalate. Water was distilled under nitrogen atmosphere and stored in a large nitrogen-flushed bottle. The aqueous solution of sodium iodide containing 0.50 mol/*l* was prepared and stored under nitrogen atmosphere. The reactor bottle was immersed in a thermostatted bath. Rate measurements were carried out by introducing a constant nitrogen stream into the reaction vessel in order to eliminate autoxidation of iodide ion to iodine which causes kinetic errors. The reaction was quenched by pouring the reaction mixture into a

Results and Discussion

Effect of Basicity on Rate. The acid-dependency of this reaction was studied and the rates were shown to be in linear relationships with the Hammett acidity-function (ho) in perchloric acid but the slope was found to vary from one sulfoxide to an other.[7] However, the effect of basicity on the overall rate of reduction of the sulfinyl group has not been examined. First we reexamined the basicities of several sulfoxides. Tamres and Seales[8] investigated the hydrogen-bonding ability of cyclic sulfoxides and concluded that the basicities of the cyclic sulfoxides fall in the following sequence assuming the parallelism[9] between the basicity and hydrogen-bonding ability with methanol.

6- $\geq$ 5- $>$ 4-membered ring sulfoxides

We measured the hydrogen-bonding abilities of sulfoxides with more acidic substrate, *i.e.*, phenol and found that the basicity sequence is not in complete agreement with that found in literature. The hydrogen-bonding abilities of several other acyclic and cyclic sulfoxides are listed in Table 2 and the plot of the rate constants against the differences of O–H stretching frequencies relative to the free phenol OH stretching frequency is shown in Fig. 1. Thus, the basicities newly determined fall in the following sequence:

5- $>$ Et–SO–Et $>$ 7- $>$ DMSO $>$ 6- $>$

(3.3.1) $>$ (2.2.1) $>$ 4-membered sulfoxides

The kinetic results of the reductions are also summarized

in Tables 3 and 4.

We see that the sequence of the hydrogen-bonding abilities is not always identical with that for the reduction, although the five-membered sulfoxide reacts remarkably fast as expected from its hydrogen-bonding ability. Thus, we may conclude that the overall rate of reduction may not entirely be controlled by the basicity of the sulfinyl groups.

Another illustration for the effect of basicity can be made with the dibenzo derivatives of a few heterocyclic sulfoxides (Table 3). The plot of the rate constants against the hydrogen bonding abilities is shown in Fig. 1, which indicates an approximate linearity between the rate constants and the hydrogen-bonding abilities. While diphenyl sulfoxide deviates far below the line, this phenomenon is easily accounted for by the steric hindrance caused by the four ortho hydrogens on the two phenyl rings. However, there is no further information as to what extent the protonation step influences the over-all rate of the reduction of these sulfoxides.

Activation Parameters. We see from Table 4 that the range of rates from the lowest one for the six-membered sulfoxide to that of the highest for the five-membered ring sulfoxide is 700 fold and the relative rates of the sulfoxides fall in the following decreasing order: 5-> 4->DMSO>7->6- membered cyclic sulfoxides. The nucleophilic substitution reaction of carbocyclic compounds[10] involving the rehybridization of reaction

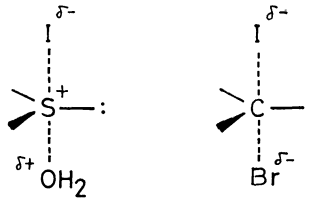
center from sp^3 to sp^2 shows a similar tendency, namely, 5- > open > 7- > 6- > 4- membered ring sulfoxides except the four-membered ring compound which is known to undergo solvolysis through a different course.

The apparent parallelism in reaction sequence between the two series of reactions undergoing displacement reaction on the two different atoms may be made clear by assuming both reactions to proceed through similar transition states. That is, in the case of sulfoxides the formation of trigonal bipyramidal structure such as (A) might be involved as in the S_N2 process on the carbon atom (B).

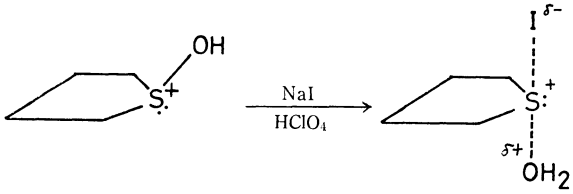


(A) (B)

Further evidence for the S_N2 like displacement at the sulfur atom may be the large negative activation entropy, −15 e.u., which is comparable to that of a typical S_N2 reaction on the carbon atom.

We have extended the study of this reduction to the series of methyl alkyl sulfoxides in order to re-examine the steric nature of this reaction. Strecker and Andersen[11] reported the importance of steric effect in a similar reduction of phenyl alkyl sulfoxides in which the rate constants decreased monotopically with increasing bulkiness of the alkyl group. However, there is a small rate acceleration by substitution of the ethyl group suggesting that in this series of methyl alkyl sulfoxides the ethyl group acts as an electron-donating group to facilitate the initial protonation step rather than as a steric hindrance group toward the incoming nucleophile at the second step. Likewise, the rate of reaction of diethyl sulfoxide is also about 30% faster than that of dimethyl sulfoxide. This seems to indicate that the steric inhibition is more important in the reaction of phenyl alkyl sulfoxides, perhaps due to the fact that the presence of a bulkier phenyl group makes the reaction center more sensitive to steric hindrance while in the series of methyl alkyl sulfoxides, the small methyl group can easily tolerate the steric inhibition of another primary alkyl group.

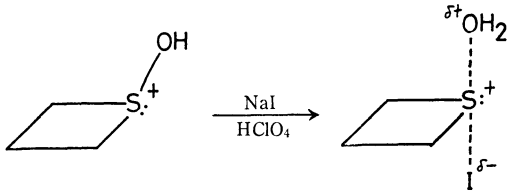
In view of thermodynamic parameters it is clear that the difference in reactivities of cyclic sulfoxides is mainly caused by the change in activation entropy. The activation entropy obviously decreases with increasing ring size and takes more negative value in the reaction of six- and seven- membered cyclic compounds and becomes less negative in reactions of four- and five-membered cyclic sulfoxides. The results can be best rationalized in terms of rigidity of the transition complex; namely, the less negative activation entropy for the five-membered cyclic sulfoxide indicates the transition state to have a similar rigidity to the ground state, and no reorganization of the molecular geometry along the reaction coordinate might be required. In other words, molecules which have already built-in ordered structure at the ground-state can reach the transition state without much loss of entropy to disturb the molecular motions. This gain of activation entropy would decrease the free energy of activation. For the enthalpy of activation, the five membered cyclic compound is so constrained already at the ground state that far less energy is required to reach the transition state, thus resulting in the lowest energy of activation among the aliphatic sulfoxides.



This is confirmed by an examination of the reaction of dibenzothiophene oxide which is very rigid due to the two benzo groups on both sides of thiophene molecule.

As anticipated, dibenzothiophene oxide has a less negative entropy of activation and a much lower enthalpy of activation, *i.e.*, $\Delta S^{\ddagger} = -10.4$ e.u. and $\Delta H^{\ddagger} = 18.5$ kcal/mol than $\Delta S^{\ddagger} = -15.1$ e.u. for tetramethylene sulfoxide and $\Delta H^{\ddagger} = 20.0$ kcal/mol for diphenyl sulfoxides.

Consideration of rigidity can be extended also to the four-membered sulfoxide system where the angle strain due to the smaller C–S–C angle and the molecular rigidity is evident. Thus, the four-membered cyclic sulfoxide is expected to have a large value of enthalpy and a less negative value of entropy of activation and hence to be highly reactive. This was the case for the highly strained four-membered cyclic sulfoxide. The observed large activation enthalpy amounting to 20 kcal/mol is in line with the relatively large energy required to overcome the accompanying unusual angle strain, while the less negative value of entropy of activation supports the view that the molecular shape is relatively unchanged in reaching the transition state.



However, in this case, from the consideration of less negative entropy of activation of −6.7 e.u., there is a possibility that the direct nucleophilic attack of iodide ion on the sulfur or carbon atom provides the ring-opening product instead of the corresponding normal reduction product, *i.e.*, trimethylene sulfide. Because of the instability of trimethylene sulfide which decomposed to form a polymer in the highly acidic condition we chose for the kinetic study, we can give no plausible mechanism.

When the ring size becomes larger than five, the sulfoxides should display entirely different patterns in

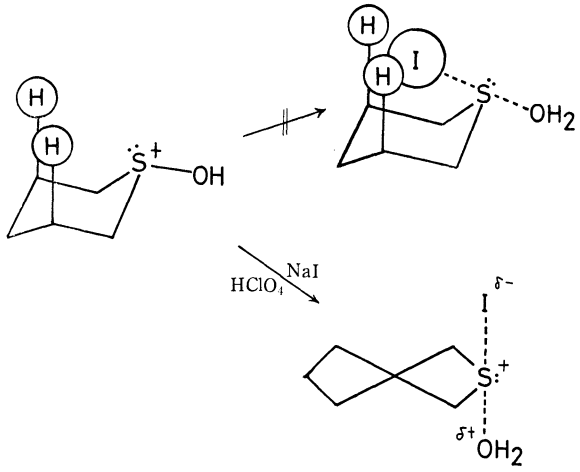
11) R. A. Strecker and K. K. Andersen, *J. Org. Chem.*, **33**, 2234 (1968).

the thermodynamic parameters from those of tetramethylene sulfoxide, since the molecules are no longer rigid.

Entropies of activation for the reduction of pentamethylene and hexamethylene sylfoxides are smaller by 6 e.u. than that of tetramethylene sulfoxide. Although these reactions may not be of a simple elementary process, a possible structure for the transition state may be obtained from a consideration of the activation parameters.

If the reaction proceeds keeping the molecular shape unchanged all through the process, the attack of iodide ion at the sulfur atom should be hindered by the presence of the axial hydrogens on β-carbon atoms of pentamethylene sulfoxide and the rate depressed. However, since the molecule is not rigid it can avoid such a steric strain by distorting or twisting the ring into a half-chair form.[12] This idea of half-chair form at the transition state does not violate the microscopic reversibility principle and both the entering and leaving groups have to occupy equivalent positions.

The same idea may be applied to the reaction of the seven-membered cyclic compound. The extremely slow rate of reduction of the bicyclic (3.3.1)-9-sulfoxide also may serve to support the above mentioned argument. Such a rigid compound which has built-in two chair forms should be in a much more unfavorable



situation in the process of the relief of steric strain as compared with the case of the six-membered sulfoxide. The molecule is so rigid that it cannot bend the bonds to assume the energetically favorable conformation to allow an attack of nucleophile to come close to the reaction center.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2460—2464 (1971)

The Bromination of 4-Acetyltropolone

Kahei TAKASE*, Kazuya SASAKI, Kohei SHIMIZU, and Tetsuo NOZOE
Department of Chemistry, Faculty of Science, Tohoku University, Katahira-2-chome, Sendai
(Received February 9, 1971)

The bromination of 4-acetyltropolone was examined, and two kinds of monobromo compounds, 4-acetyl-3-bromo- and 4-acetyl-7-bromotropolones, two kinds of dibromo compounds, 4-acetyl-3,7-dibromo- and 7-bromo-4-(ω-bromoacetyl)tropolones, a tribromo compound, 4-acetyl-3,5,7-tribromotropolone, and a tetrabromo compound, 3,5,7-tribromo-4-(ω-bromoacetyl)tropolone, were obtained. The third isomer of the monobromo compounds, 4-acetyl-5-bromotropolone, was synthesized from 4-acetyltropolone through 4-acetyl-5-aminotropolone. Moreover, an isomeric dibromo compound, 4-acetyl-5,7-dibromotropolone, was obtained by the debromination of the tribromo compound.

4-Acetyltropolone (I)[1] may be expected to be one of the most important materials for synthetical studies in troponoid chemistry, and in a previous paper[2] we reported on the properties of I and its methyl ethers in reaction to several oxidizing and reducing reagents. This paper will describe the results of our studies of bromination of I as one of a series of investigations of acetyltropolones.

The bromination of I is interesting in comparison with those of the other 4-substituted tropolones, such as 4-methyl-,[3] 4-ethyl-[4] and 4-isopropyltorpolones,[5] which

have been studied well. Moreover, it seems to be important to prepare ω-bromoacetyl derivatives of I from the point of view of synthetical studies.

Results and Discussion

The bromination of 4-acetyltropolone was examined under the various reaction conditions listed in Table 1. In each experiment, the product was usually a complex mixture of several bromo compounds, and the separation into components was rather difficult. The major products and some minor products were eventually isolated by means of fractional recrystallization. The bromo compounds thus obtained were two kinds of monobromo (II) and (III), two kinds of dibromo (IV) and (V), and a tribromo compound (VI); their data are summarized in Table 1. The further bromination of the bromo compounds obtained here was also examined; some of these results are also listed in Table 1.

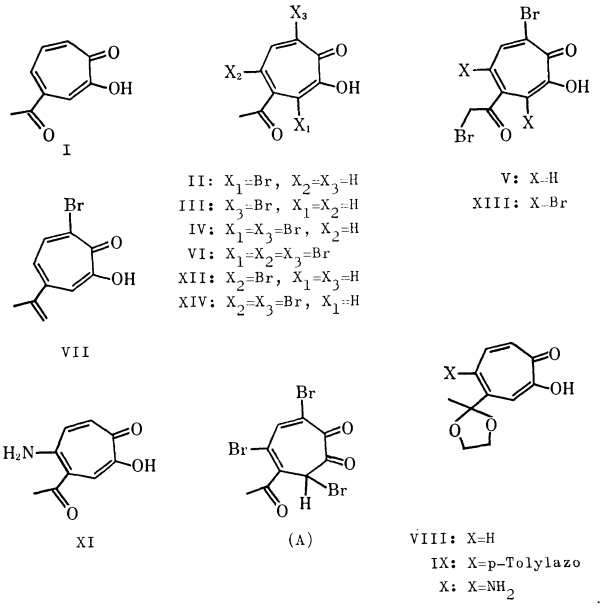
Table 2. The NMR spectra of the bromo derivatives of 4-acetyltropolone, δ ppm in $CDCl_3$ (intensity, signal pattern, coupling constant; Hz)

Compd.	Ring proton	Acetyl or bromoacetyl
II	6.70(1H, dd, J=7.8, 3.7) 7.38(1H, d, J=3.7) 7.42(1H, d, J=7.8)	2.59(3H, s)
III	7.47(1H, dd, J=10.4, 1.6) 7.92(1H, d, J=1.6) 8.37(1H, d, J=10.4)	2.68(3H, s)
V	7.47(1H, dd, J=10.3, 1.8) 7.89(1H, d, J=1.8) 8.41(1H, d, J=10.3)	4.43(2H, s)
VI	8.50(1H, s)	2.65(3H, s)
XII	6.97(1H, s) 7.10(1H, d, J=12.0) 7.77(1H, d, J=12.0)	2.57(3H, s)
XIII	8.52(1H, s)	4.49(2H, s)
XIV	6.99(1H, s) 7.25(1H, s)	2.58(3H, s)

a) s: singlet, d: doublet, dd: double doublet.

These bromo compounds showed the positive ferric chloride test characteristic of tropolones, and their ultraviolet absorption spectra indicated that all of them were tropolone derivatives. From the orientation in cationoid substitution at the tropolone nucleus[6] and from the reactivity of the acetyl group, it was expected that the bromo substituents of these bromo compounds should be present at the 3-, 5-, 7- and/or ω-positions. Moreover, it was assumed that the compound bearing the bromo substituents at the tropolone nucleus would be stable under a mild alkaline treatment, whereas ω-bromo compounds would be sensitive. On the basis of these considerations, as well as on that of the NMR data shown in Table 2 and the chemical evidence to be described below, the structures of the bromo compounds, II–VI, were determined as follows.



One of two monobromo compounds, II, was assigned the structure of 4-acetyl-3-bromotropolone on the basis of the NMR spectral data, which showed the presence of an acetyl group and three adjacent ring protons, as is shown in Table 2. The other monobromo compound, III, was identical to 4-acetyl-7-bromotropolone, which had been obtained from 7-bromo-4-isopropenyltropolone (VII)[7] by oxidation with hydrogen peroxide, followed by oxidation with metaperiodic acid, or by the Schmidt reaction. This structure was also revealed from the NMR spectral data shown in Table 2.

The dibromo compound, IV, was assigned the structure of 4-acetyl-3,7-dibromotropolone from the fact that IV was also obtained from both the monobromo compounds, II and III, on further bromination. The other dibromo compound, V, was assigned the structure of 7-bromo-4-(ω-bromoacetyl)tropolone, since it was also obtained from III by further bromination and gave

a resinous material when treated with dilute alkali. This structure was also supported by the NMR spectral data, which showed the presence of the bromoacetyl group and three adjacent ring protons, as is shown in Table 2. The tribromo compound, VI, was assumed to be 4-acetyl-3,5,7-tribromotropolone, since it was obtained on the bromination of IV and gave a stable sodium salt when treated with a sodium hydroxide solution. The NMR spectral data shown in Table 2 also supported this assumption.

As a result of the structural determination of the bromination products described above, it became clear that, on the bromination of 4-acetyltropolone (I), the positions at which bromination occurred predominantly were remarkably affected by the reaction conditions, such as the presence or absence of sodium acetate and the kind of solvent used. Thus, as is shown in Table 1, in the presence of acetate, bromination occurred only on the tropolone nucleus at the 3- and/or 7-position, whereas, in the absence of acetate, it occurred on the acetyl group as well as on the tropolone nucleus. This behavior of I is thought to be due to the dissociation of I, in the presence of sodium acetate, to its anion, in which the 3-, 5-, and 7-positions of the tropolone nucleus are more reactive toward the cationoid reagents. A similar tendency was also observed on the bromination of the monobromo compound, III.

It is interesting to find that, on the bromination of I in the presence of sodium acetate, the use of acetic acid as the solvent gave a 7-bromo compound, III, whereas the use of methanol gave a 3-bromo compound, II, predominantly. Moreover, it is noteworthy that the sterically-hindered 3-position was predominantly attacked with the reagents in the medium of methanol–sodium acetate, while no 3-bromo derivative is known to be obtained on the bromination of 4-alkyltropolones, except for the finding that the bromination of 4-isopropyltropolone in ethanol at −15°C afforded a small amount of the 3-bromo derivative, together with the other bromo derivatives.[5] The reason for the predominant formation of II is not yet apparent.

The third isomer of the monobromo derivative of I, that is, 4-acetyl-5-bromotropolone could not be obtained by the bromination of I, but it was derived from I as follows. Since the azo-coupling of I gave a cyclohepta[*c*]pyrazolone derivative,[8] the ethylene ketal (VIII)[9] of I was coupled with *p*-toluenediazonium chloride to give an azo compound (IX). The catalytic hydrogenation of IX in methanol over palladium on carbon gave an amino-ketal (X), which was then hydrolyzed to an amino-ketone (XI). The application of the Sandmeyer reaction to X or XI gave a bromo compound (XII). It is reasonable to assign the structure of 4-acetyl-5-bromotropolone to XII, since it has been known that the *p*-tolylazo group generally enters at the 5-position of the tropolone nucleus.[6] This structure was also supported by the finding that the bromination of XII gave VI in a good yield, as well as by its NMR spectral data, shown in Table 2.

The dibromo compound, IV, gave the tribromo compound, VI, when treated with bromine in the presence of sodium acetate. On the other hand, the similar treatment of the dibromo compound, V, gave a tetrabromo compound (XIII). The structure of XIII was identified as 4,5,7-tribromo-4-(ω-bromoacetyl) tropolone from the findings that it was derived from V and that its NMR spectrum showed two singlets at 4.49 (2H) and 8.52 ppm (1H).

Although the tribromo compound, VI, was stable under a mild alkaline treatment, giving only sodium salt, it gave a dibromo compound (XIV) when heated with sodium iodide in ethanol. This dibromo compound, different from IV, was assigned the structure of 4-acetyl-5,7-dibromotropolones on the basis of the finding that it gave the tribromo compound, VI, on bromination, as well as on the basis of its NMR spectral data, shown in Table 2. This debromination reaction is thought to take place through a diketone-type intermediate (A).

Experimental

All the melting points are uncorrected. The ultraviolet absorption spectra were measured on a Beckman DU spectrophotometer, while the infrared spectra were recorded on a Shimadzu IR-27 infracord apparatus. The NMR spectra were determined with a Varian A-60 spectrometer on samples dissolved in deuteriochloroform, containing tetramethylsilane as the internal standard.

Bromination of 4-Acetyltropolone (I). *a) Bromination in Methanol in the Presence of Sodium Acetate*: Into a suspension of I (3.20 g) and sodium acetate (2.40 g) in methanol (100 m*l*), a solution of bromine (3.50 g) in glacial acetic acid (6 m*l*) was stirred under cooling with ice water; the mixture was then stirred for 2 hr. After the addition of water (150 m*l*), the mixture was allowed to stand overnight in a refrigerator; the crystals thereby formed were collected by filtration. Yield, 4.35 g; mp 170—185°C. Recrystallization from methanol gave 4-acetyl-3-bromotropolone (II) (2.75 g) as pale yellow scales; mp 193—194°C.

Found: C, 44.67; H, 3.09%. Calcd for $C_9H_7O_3Br$: C, 44.47; H, 2.90%. UV (MeOH): λ_{max} nm (log ε); 260 (4.42), 340 (3.94), 385 (3.76), 410 (3.74). IR (KBr disk); $\nu_{C=O}$, 1712 cm^{-1}.

A similar treatment of I (320 mg) with two molar equivalents of bromine also gave II (220 mg); mp 193—194°C.

b) Bromination in Methanol in the Absence of Acetate: Into a suspension of I (960 mg) in methanol (15 m*l*), a solution of bromine (1.92 g) in the same solvent (5 m*l*) was stirred under cooling with ice water, after which the mixture was stirred for 2 hr. The solvent was then evaporated, and the residue was fractionally recrystallized from methanol. The less soluble part gave II (10 mg) as pale yellow scales; mp 193—194°C. The readily-soluble part gave 7-bromo-4-(ω-bromoacetyl)tropolone (V) (1.20 g) as yellow needles; mp 147—149°C. The melting point rose to 149—151°C upon further recrystallization from methanol.

Found: C, 33.58; H, 1.93%. Calcd for $C_9H_6O_3Br_2$: C, 33.57; H, 1.88%. UV (MeOH): λ_{max} nm (log ε); 260 (4.43), 335 (3.79), 385 (3.71). IR (KBr disk); $\nu_{C=O}$, 1702 cm^{-1}.

A similar treatment of I (320 mg) with an equimolar amount of bromine gave V (50 mg), mp 149—151°C, together with an oily material.

8) T. Nozoe, K. Takase, and K. Suzuki, to be published.
9) I. Murata, This Bulletin, **34**, 577 (1961).

c) Bromination in Acetic Acid in the Presence of Sodium Acetate: Into a solution of I (1.60 g) and sodium acetate (1.20 g) in glacial acetic acid (30 m*l*), a solution of bromine (1.80 g) in the same solvent (2 m*l*) was stirred under cooling with ice water. After being stirred for 3 hr, the mixture was diluted with water and the crystals thereby formed were collected by filtration. Yield, 2.30 g; mp 90—98°C. Repeated recrystallizations from methanol gave 4-acetyl-7-bromotropolone (III) (920 mg) as yellow needles; mp 132—133°C.

Found: C, 44.73; H, 2.58%. Calcd for $C_9H_7O_3Br$: C, 44.47; H, 2.90%. UV (MeOH): λ_{max} nm (log ε); 227 (4.38), 345 (3.97), 446 (3.92). IR (KBr disk); $\nu_{C=O}$, 1686 cm^{-1}.

All the filtrates of the recrystallization were combined, the solvent was evaporated, and the residue was fractionally recrystallized from methanol. The slightly-soluble part gave 4-acetyl-3,5,7-tribromotropolone (VI) (350 mg) as yellow needles; mp 158—159°C.

Found: C, 27.12; H, 1.27%. Calcd for $C_9H_5O_3Br_3$: C, 26.96; H, 1.26%. UV (MeOH): λ_{max} nm (log ε); 272 (4.47), 355 (4.14), 442 (4.13). IR (KBr disk); $\nu_{C=O}$, 1712 cm^{-1}.

The readily-soluble part gave further crops of III (110 mg); mp 132—133°C.

The first aqueous filtrate was extracted with chloroform; the subsequent evaporation of the solvent left an oily material, which was then solidified by the addition of methanol. Recrystallization from methanol gave 4-acetyl-3,7-dibromotropolone (IV) (70 mg) as pale yellow scales; mp 151—152°C.

Found: C, 34.16; H, 2.12%. Calcd for $C_9H_6O_3Br_2$: C, 33.57; H, 1.88%. UV (MeOH): λ_{max} nm (log ε); 268 (4.41), 345 (3.95), 425 (4.06). IR (KBr disk); $\nu_{C=O}$, 1703 cm^{-1}.

d) Bromination in Acetic Acid in the Absence of Acetate: To a solution of I (320 mg) in glacial acetic acid (6 m*l*), a solution of bromine (650 mg) in the same solvent (0.5 m*l*) was added; the mixture was then stirred for 2 hr under cooling with ice water. Water was added to this mixture, the product was extracted with chloroform, and the solvent was evaporated, leaving crystals. Recrystallization from methanol gave V (310 mg) as yellow needles; mp 149—151°C.

e) Bromination in Chloroform: To a solution of I (320 mg) in chloroform (5 m*l*), a solution of bromine (320 mg) in the same solvent (1 m*l*) was added under cooling with ice water, after which the mixture was stirred for 3 hr. The crystals thereby formed were collected by filtration and recrystallized from methanol, giving II (50 mg) as pale yellow scales; mp 193—194°C.

All the filtrates were combined in a chloroform solution and washed with water. The evaporation of the solvent left an oily material, which was then crystallized by the addition of methanol, giving yellow crystals (250 mg); mp 144—146°C. Recrystallization from methanol gave V (80 mg) as yellow needles; mp 149—151°C.

f) Bromination with N-*Bromosuccinimide*: To a solution of I (800 mg) in chloroform, *N*-bromosuccinimide (800 mg) was added, after which the mixture was stirred for 5 hr at room temperature. The solvent was then evaporated, and the residue was recrystallized from methanol, giving III (240 mg) as yellow needles; mp 132—133°C.

Bromination of 4-Acetyl-3-bromotropolone (II). *a) Bromination in Methanol*: To a suspension of II (240 mg) in methanol (5 m*l*), a solution of bromine (160 mg) in the same solvent (1 m*l*) was added, after which the mixture was stirred for 2 hr under cooling with ice water. The subsequent evaporation of the solvent left crystals, which were then fractionally recrystallized from methanol to give VI (60 mg) as pale yellow needles; mp 158—159°C; II (50 mg) was also recovered.

b) Bromination in Acetic Acid in the Presence of Sodium Acetate: To a solution of II (240 mg) and sodium acetate (130 mg) in glacial acetic acid (8 m*l*) a solution of bromine (160 mg) in the same solvent (1 m*l*) was added, after which the mixture was stirred for 2 hr under cooling with ice water. Water was added to this mixture, and the crystals thereby formed were collected and fractionally recrystallized from methanol, thus giving VI (90 mg) as yellow needles, mp 158—159°C, and IV (40 mg) as pale yellow scales, mp 151—152°C.

A similar treatment of II (240 mg) with two molar equivalents of bromine gave VI (240 mg); mp 158—159°C.

Bromination of 4-Acetyl-7-bromotropolone (III). *a) Bromination in Methanol in the Presence of Sodium Acetate*: To a suspension of III (720 mg) and sodium acetate (300 mg) in methanol (15 m*l*), a solution of bromine (480 mg) in the same solvent (1 m*l*) was added, after which the mixture was stirred for 3 hr under cooling with ice water. The reaction mixture was diluted with water, and the product was extracted with chloroform. The evaporation of the solvent left an oily material, which was solidified by the addition of methanol. Fractional recrystallization from methanol gave IV (420 mg) as pale yellow scales, mp 151—152°C, and VI (50 mg) as yellow needles, mp 158—159°C.

b) Bromination in Methanol in the Absence of Acetate: To a suspension of III (240 mg) in methanol (5 m*l*), a solution of bromine (160 mg) in the same solvent (1 m*l*) was added, after which the mixture was stirred for 3 hr under cooling with ice water. The solvent was then evaporated, and the residue was fractionally recrystallized from methanol to give V (90 mg) as yellow needles mp 149—151°C, and VI (50 mg) as yellow needles, mp 158—159°C.

c) Bromination in Acetic Acid: To a suspension of III (240 mg) and sodium acetate (100 mg) in glacial acetic acid (8 m*l*), a solution of bromine (160 mg) in the same solvent (1 m*l*) was added, after which the mixture was stirred for 2 hr under cooling with ice water. Water was then added to the mixture, and the crystals thereby formed were collected and fractionally recrystallized from methanol to give VI (80 mg) as yellow needles, mp 158—159°C, III (80 mg) was also recovered.

A similar treatment of III (120 mg) with two molar equivalents of bromine gave VI (160 mg); mp 158—159°C.

4-Acetyl-7-bromotropolone (III) from 7-Bromo-4-isopropenyltropolone (VII).[7] a) To a solution of VII (960 mg) in formic acid (7 m*l*), a 30% hydrogen peroxide solution (0.5 m*l*) was dropped in at 40—55°C; the mixture was then kept at this temperature for 3 hr. The solvent was evaporated, and the oily residue was dissolved in an N sodium hydroxide solution (10 m*l*). This solution was warmed at 50—60°C for 5 hr, and then acidified with 2N sulfuric acid and shaken with chloroform. To the aqueous layer potassium periodate (460 mg) was added, after which the mixture was stirred for an hour at room temperature. The crystals thereby formed were collected and recrystallized from methanol to give III (250 mg) as yellow needles; mp 132—133°C.

b) A solution of VII (480 mg) in chloroform (1 m*l*) was stirred to a mixture of sodium azide (400 mg), chloroform (2 m*l*), and concentrated sulfuric acid (2 m*l*) at about 20°C. After being stirred for 3 hr, the mixture was allowed to stand overnight; then it was poured into ice water and extracted with chloroform. The solvent was evaporated, and the residue was recrystallized from methanol to give III (150 mg) as yellow needles; mp 132—133°C.

4-(1,1-Ethylenedioxyethyl)tropolone (VIII). A mixture of I (2.20 g), ethyleneglycol (4.10 g), and benzene (15 m*l*) was refluxed for 5 hr in the presence of *p*-toluenesulfonic acid (10 mg). The benzene-soluble part was collected by decantation; the subsequent evaporation of the solvent gave VIII (2.68 g), mp 90—93°C. Recrystallization from petroleum ether af-

forded colorless needles; mp 98—99°C. The melting point previously reported[9] was 97—98°C.

Found: C, 63.95; H, 5.44%. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81%. UV (MeOH): λ_{max} nm (log ε); 238 (4.45), 320 (3.89), 350 (3.78).

4-(1,1-Ethylenedioxyethyl)-5-(p-tolylazo)tropolone (IX). Into a solution of VIII (600 mg) in pyridine (2 ml), we stirred a solution of *p*-toluenediazonium chloride which had been prepared by the diazotization of a solution of *p*-toluidine (330 mg) in 2N hydrochloric acid with a solution of sodium nitrite (240 mg) in water (1.5 ml); we did this under cooling with ice water. After additional stirring for 2 hr, water was added to this mixture and the crystals thereby formed were collected and recrystallized from benzene to give IX (470 mg) as red micro-prisms; mp 176—178°C.

Found: C, 65.95; H, 5.38; N, 8.42%. Calcd for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 9.58%. UV (MeOH): λ_{max} nm (log ε); 230 (4.39), 293 (4.00), 385 (4.35).

5-Amino-4-(1,1-ethylenedioxyethyl)tropolone (X). A suspension of IX (660 mg) in methanol (12 ml) was shaken under a hydrogen atmosphere in the presence of 5% palladium-carbon (80 mg); 100 ml of hydrogen gas was consumed during a period of 7 hr. After the subsequent removal of the catalyst, the solution was concentrated to a small volume and allowed to cool, thus giving X (270 mg); mp 164—166°C. Recrystallization from methanol afforded yellow plates; mp 166—167°C.

Found: C, 59.04; H, 5.65; N, 6.30%. Calcd for $C_{11}H_{13}O_4N$: C, 59.18; H, 5.87; N, 6.28%. UV (MeOH): λ_{max} nm (log ε); 238 (4.38), 360 (4.12), 387 (4.08).

4-Acetyl-5-aminotropolone (XI). A solution of X (200 mg) in methanol (5 ml) containing N hydrochloric acid (0.5 ml) was refluxed for an hour. The subsequent concentration of the solution gave XI (150 mg) as reddish-orange needles; mp 180—181°C.

Found: C, 60.39; H, 4.76; N, 7.47%. Calcd for $C_9H_9O_3N$: C, 60.33; H, 5.06; N, 7.82%. UV (MeOH): λ_{max} nm (log ε); 247 (4.47), 365 (4.12), 465 (3.93).

4-Acetyl-5-bromotropolone (XII). Into a solution of X (220 mg) in 50% aqueous dioxane (2.5 ml) containing 6N sulfuric acid (0.9 ml), a solution of sodium nitrite (75 mg) in water (0.2 ml) was added at 0—5°C. After stirring for an additional 30 min, this mixture was added to a solution of cuprous bromide (350 mg) in concentrated hydrobromic acid (1.9 ml), after which the mixture was stirred for 3 hr under cooling with ice water. The mixture was diluted with water, and the copper chelate compound thus precipitated was collected by filtration. Through a suspension of this copper chelate in chloroform, hydrogen sulfide gas was passed, after which the copper sulfide thereby formed was filtered off. The subsequent evaporation of the solvent from the filtrate left some crystals (170 mg); mp 105—125°C. Recrystallization from methanol gave XII (90 mg) as pale yellow needles; mp 142—143°C.

Found: C, 44.09; H, 2.80%. Calcd for $C_9H_7O_3Br$: C, 44.47; H, 2.90%. UV (MeOH): λ_{max} nm (log ε); 235 (4.29), 248 (4.30), 335 (4.04), 4.10 (3.54). IR (KBr disk); $\nu_{C=O}$, 1709 cm^{-1}.

A similar treatment of XI (70 mg) gave XII (30 mg); mp 142—143°C.

Bromination of 4-Acetyl-5-bromotropolone (XII). To a solution of XII (50 mg) and sodium acetate (40 mg) in glacial acetic acid (1 ml), a solution of bromine (65 mg) in the same solvent (0.5 ml) was added, after which the mixture was stirred for 2 hr under cooling with ice water. Water was then added to this mixture, and the crystals thereby formed were collected and recrystallized from methanol to give VI (70 mg) as yellow needles; mp 158—159°C.

Bromination of 4-Acetyl-3,7-dibromotropolone (IV). To a solution of IV (110 mg) and sodium acetate (30 mg) in glacial acetic acid (2 ml), a solution of bromine (60 mg) in the same solvent (0.5 ml) was added, after which the mixture was stirred for 2 hr. Water was then added to this mixture, and the crystals thereby formed were collected and recrystallized from methanol to give VI (110 mg) as yellow needles; mp 158—159°C.

3,5,7-Tribromo-4-(ω-bromoacetyl)tropolone (XIII). To a solution of V (640 mg) and sodium acetate (200 mg) in glacial acetic acid (20 ml), a solution of bromine (320 mg) in the same solvent (1 ml) was added, after which the mixture was stirred for 2 hr under cooling with ice water. Water was then added to this mixture, and the crystals thereby formed were collected and recrystallized from methanol to give XIII (490 mg); mp 161—162°C. Further recrystallization from the same solvent afforded yellow needles; mp 164—165°C.

Found: C, 22.23; H, 1.09%. Calcd for $C_9H_4O_3Br_4$: C, 22.53; H, 0.84%. UV (MeOH): λ_{max} nm (log ε); 273 (4.48), 360 (4.14), 450 (4.18). IR (KBr disk); $\nu_{C=O}$, 1730 cm^{-1}.

4-Acetyl-5,7-dibromotropolone (XIV). A solution of VI (400 mg) and sodium iodide (300 mg) in ethanol (10 ml) was refluxed for 3 hr. To this solution we then added water (30 ml) containing a small amount of sodium hydrogen sulfite, and the mixture was stirred for 30 min. The crystals thereby formed were collected and recrystallized from methanol to give XIV (90 mg) as yellow, silky needles; mp 191—192°C.

Found: C, 33.73; H, 1.94%. Calcd for $C_9H_6O_3Br_2$: C, 33.57; H, 1.88%. UV (MeOH): λ_{max} nm (log ε); 265 (4.40), 353 (4.15), 430 (4.00). IR (KBr disk); $\nu_{C=O}$, 1700 cm^{-1}.

Synthesis and Properties of Two Annelated Annulenes

Katsusuke ENDO,* Yoshiteru SAKATA, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received February 15, 1971)

Two annelated tridehydro[18]annulenes, trinaphtho[1,9,8,7-*abc*: 1′,9′,8′,7′-*ghi*:1″,9″,8″,7″-*mno*]- and tribenzo [*a,g,m*]-5,11,17-tridehydro[18]annulenes (VI and VII), were synthesized by the Castro reaction of cuprous salts of 1-ethynyl-7-iodonaphthalene (IX) and 4-[*o*-iodophenyl]-3-buten-1-yne (XIV), respectively. The UV spectra of these annelated annulenes revealed an extended delocalization of π-electrons around the inner eighteen membered ring. However, from the chemical shifts of the inner protons (H_A and H_B) it is concluded that both VI and VII are non-aromatic compounds.

The molecular orbital theory of cyclic conjugated systems by Hückel predicted that systems containing $(4n+2)$ π-electrons would display an aromatic character. This rule has been substantially confirmed by many investigations of various nonbenzenoid conjugated systems, particularly by elegant works on annulenes and dehydroannulenes.[1] Thus it was thought to be of interest to prepare annelated annulenes in order to realize the effect of annelation on aromaticity of annulene and dehydroannulene. Recently some planar and non-planar annelated annulenes (I—V)[2] were synthesized, but no direct evidence for the presence of the aromatic character was found in the compounds except for an anion of dibenzocyclononatetraene (IV)[2d] and derivatives (V)[2e] of [18]annulene containing heterocycles.

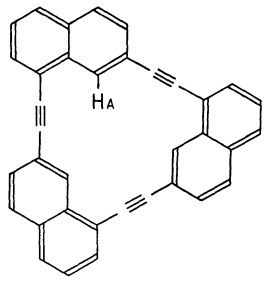
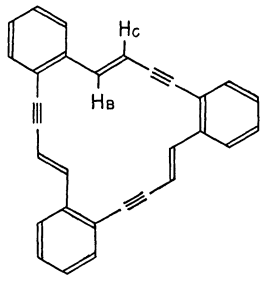
V, X=O,S

We have attempted to get better understanding of the effect of annelation on aromaticity. The present paper reports the results of a study of two planar annelated derivatives of aromatic 1,7,13-tridehydro[18]-annulene,[3] trinaphtho[1,9,8,7-*abc*: 1′,9′,8′,7′-*ghi*: 1″,9″, 8″,7″-*mno*]- and tribenzo[*a,g,m*]-5,11,17-tridehydro-[18]annulenes (VI and VII), to which Kekulé type structures of the inner eighteen membered ring systems can be assigned. The chemical shift of the inner protons (H_A and H_B) can provide significant information with regard to the diamagnetic ring current around the ring systems, *viz.*, the existence of aromatic character.



VI



VII

Results and Discussion

Synthesis 1-Acetyl-7-iodonaphthalene (VIII) was obtained by the acetylation of β-iodonaphthalene according to the Harnik method[4] in 18.5% yield. Ketone VIII was treated with phosphorus pentachloride in phosphorus oxychloride, followed by dehydrochlorination of the resulting chloride mixture with alcoholic potassium hydroxide to give 49% yield of 1-ethynyl-7-iodonaphthalene (IX). The Castro reaction[5] of dry cuprous salt of IX in pyridine afforded a cyclic acetylene compound in 8.0% yield. This compound was found to be fairly stable and can be kept without any change for a long time. The structure of VI was assigned to it based on the following. The lack of absorption due to the terminal ethynyl group in the IR- and NMR-

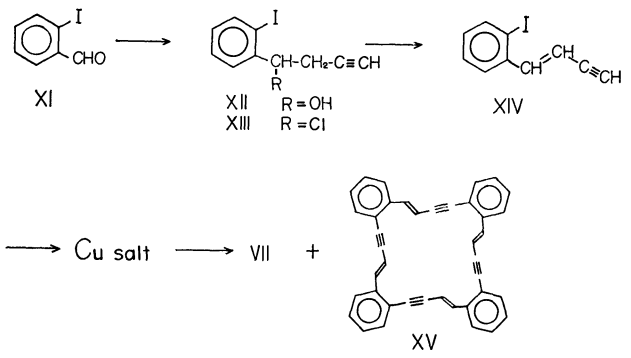
spectra suggests the cyclic structure of VI. Furthermore, the elemental analysis of VI and molecular weight determination of its hydrogenated product (X) which is satisfactorily soluble for vapour pressure osmometry established the formation of VI by trimolecular Castro reaction of IX.

An acetylenic alcohol (XII) was prepared by Reformatsky-type reaction of *o*-iodobenzaldehyde (XI)[6] with propargyl bromide using aluminum[7] in an excellent yield of around 80%. The normal Reformatsky reaction as well as the Grignard reaction afforded lower yields of XII. Chloride XIII, obtained by treatment of XII with phosphorus oxychloride, was dehydrochlorinated with methanolic potassium hydroxide. Chromatography of the reaction product on alumina gave *o*-iodophenylbutenyne (XIV) in an overall yield of 30% based on XII. The Castro reaction of cuprous salt of the butenyne XIV gave a cyclic trimer VII of fairly stable and bright yellow needles in 13.0% yield and a small amount of cyclic tetramer XV. Structures of trimer VII and tetramer XV were confirmed by elemental analysis, IR and NMR spectra and molecular weight determination.



Electronic Spectra The electronic spectra of VI and VII as well as those of diphenylbutenyne (XVI) and 1,7,13-tridehydro[18]annulene (XVII)[3] as reference substances are shown in Fig. 1. The spectrum of a cyclic trimer (I) of phenanthrene shows the maxima at the same wavelengths as those of biphenanthryl and

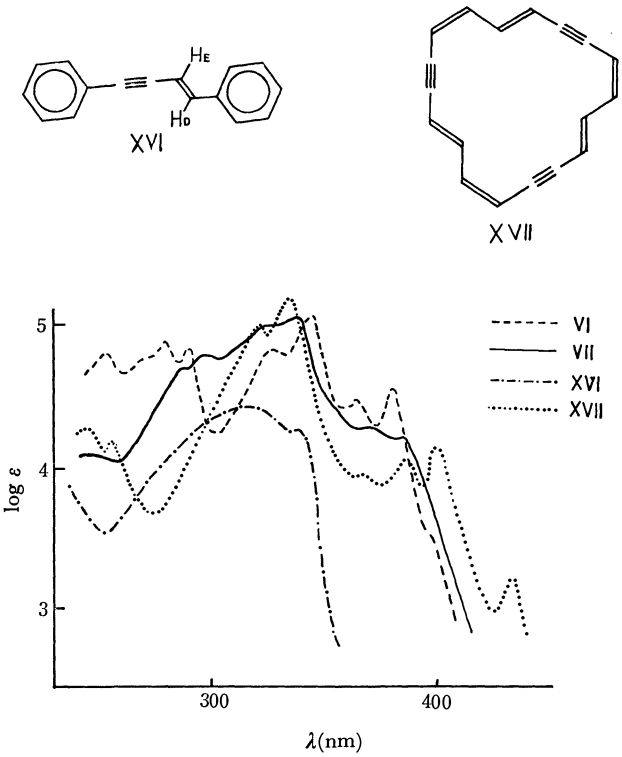


Fig. 1. The electronic spectra of VI, VII, XVI (in THF) and XVII (in isooctane).

terphenanthryl, whereas the maxima at the longest wavelength of VI and VII exhibit distinct red-shift as compared with those of tetramer XV and XVI. The absorption curve of VI is similar to that of XVII except for the lack of the maximum at near 430 nm, whereas VII shows broad and structureless absorption in contrast to VI and XVII. Thus, a comparison of these spectra suggests that both VI and VII are intermediates between I and XVII in respect of the delocalization of π-electrons. The fact that the by-product XV showed broad absorption curve and hypsochromic and hypochromic shifts of the maxima as compared with VII indicates a nonplanar structure of XV in agreement with a presumption from a skeletal molecular model.

Table 1. Chemical shifts (τ) and coupling constants (J) of inner protons of VI, VII, and XVII as well as those of olefinic protons of XV and XVI in $CDCl_3$

τ 1.51[a]	3.36	3.51	3.69	2.44	
	2.87	2.56	3.04	8.26	
J	16.2	16.2	16.2	15.6 Hz	

a) in $AsCl_3$ solution

NMR Spectra. The NMR spectra of VI, VII, and XVI are given in Table 1. The spectrum of VI shows two peaks, a singlet at τ 1.51 and a multiplet at τ 1.85—2.55, with an area ratio 1:5 and no other peak at a higher field. The peak at τ 1.51 is assigned to the proton H_A of naphthalene nuclei on account of its being singlet and of its area ratio to the other aromatic protons at τ 1.85—2.55. The position of the proton H_A is at a

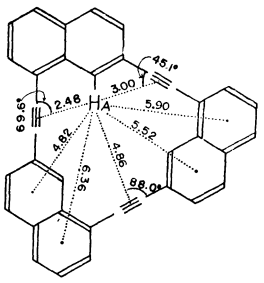
7) P. Läuger, M. Prost, and R. Charlier, *Helv. Chim. Acta*, **42**, 2379 (1959); K. Eiter and H. Oediger, *Ann. Chem.*, **682**, 62 (1965); F. Sondheimer, Y. Amiel, and Y. Gaoni, *J. Amer. Chem. Soc.*, **84**, 270 (1962).

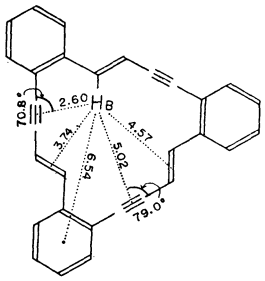
lower field than that of α-proton (τ 2.19)[8] of naphthalene.

Two plausible elucidations may be given. First, the effect of diamagnetically induced ring current around the inner eighteen membered ring system is considered. If the magnitude of the ring current were not large, it would be overcome by the magnetic anisotropy of the triple bonds and other two naphthalene nuclei. As a result, the proton H_A may be observed at a slightly lower field than α-proton of naphthalene. Secondly, such a small shift of the proton H_A to the lower field would be only caused by the magnetic anisotropy of the triple bonds and naphthalene nuclei. In order to solve this problem, the magnitude of the magnetic anisotropies should be estimated. An estimate of the extent to which the shift of the proton H_A of VI is affected by both π-electron systems was performed according to the following McConnell equation[9] by using the distances and angles shown in Fig. 2.

$$\Delta\sigma = \Delta\chi\sum_{i=1}^{n}\frac{1}{3R^3}(1-3\cos^2\theta) \qquad (1)$$



VI



VII

For three triple bonds ($\Delta\chi = -11.8\times10^{-6}$ cm^3/mol),[10] the total shielding effect was calculated to be −0.20 ppm from equation (1). The shielding effect of two naphthalene nuclei, in which the shielding contribution of each naphthalene was approximated as a sum of ring currents of two benzene rings according to theoretical predictions,[11] was calculated to be −0.71 ppm by use of Johnson–Bovey table.[12] A total value −0.91 ppm due to both shielding effects was consequently found to be in good agreement with the observed shift, −0.68 ppm, from α-proton of naphthalene.[8] Similarly, the shift of proton H_B of VII from proton H_D of XVI was calculated as in VI, and the whole effect, −0.50 ppm, of double bonds, triple bonds, and benzene nuclei was found to be reasonable as compared with the observed shift −0.17 ppm. Table 1 also shows the equal coupling constant of olefinic protons in VII, XV, and XVI.

Consequently, a considerable delocalization of π-electrons in VI and VII was revealed in the electronic absorption spectra as aforementioned. However, it can be concluded that the results obtained from NMR spectra support the second elucidation stated above and provide no positive evidence for the presence of diamagnetically induced ring current in the eighteen membered ring systems of both VI and VII, and that both the annelated annulenes are non-aromatic.

Experimental

All melting points are uncorrected. The electronic spectra were taken on a Hitachi EPS-3T, the infrared spectra on a Jasco DS-402G, the NMR spectra on a Hitachi R-20, the mass spectra on a Hitachi RMU-7 and the molecular weight on a Knauer vapour pressure osmometer.

1-Ethynyl-7-iodonaphthalene (IX). A mixture of 1-acetyl-7-iodonaphthalene[4] (10.0 g, 33.8 mmol) and phosphorus pentachloride (10.4 g, 50 mmol) in phosphorus oxychloride (100 m*l*) was refluxed with stirring for 1 hr. After the reaction was over, phosphorus oxychloride was evaporated under reduced pressure and the residue was dried in a desiccator over potassium hydroxide overnight. To the crude chloride thus obtained was added 40 g of powdered potassium hydroxide and ethanol (100 m*l*). The mixture was stirred under gentle reflux for 30 min. The residual solid obtained by evaporation of ethanol in vacuum was triturated with benzene. The benzene extract was washed with water and dried over sodium sulfate. After the solvent was removed *in vacuo*, the residue (14.02 g) was chromatographed on alumina (300 g) with benzene-petroleum ether (1:9) to give yellow oil of IX, 4.60 g (49.0% yield). NMR ($CDCl_3$): τ 1.34 (s, proton at C_8), 2.1—2.9 (m, other arom. protons), 6.60 (s, ≡CH).

Mercuric Salt of IX: A solution of potassium mercuri-iodide[13] was obtained by adding 10% aq. sodium hydroxide (0.6 m*l*) to a mixture of mercuric chloride (0.275 g, 1.05 mmol) and potassium iodide (0.695 g, 4.2 mmol) in water (0.7 m*l*). To this was added a solution of IX (0.292 g, 1.05 mmol) in 6 m*l* of ethanol with stirring to yield white precipitate of mercuric salt. After it had been filtered immediately and washed with 50% aq. ethanol, the precipitate was recrystallized from benzene to afford 0.266 g (67.0%) of mercuric salt, colorless fine needles, mp 263.5—264.7°C (decomp.).

Found: C, 38.20; H, 1.63%. Calcd for $C_{24}H_{12}I_2Hg$: C, 38.19; H, 1.60%.

Trinaphtho[1,9,8,7-abc: 1′,9′,8′,7′-ghi: 1″,9″,8″,7″-mno]-5,11,17-tridehydro[18]annulene (VI). To a solution of Ilosvay's reagent[14] was added a solution of iodonaphthylacetylene (IX) (4.60 g, 16.5 mmol) in 80 m*l* of ethanol to give immediately yellow precipitate of cuprous salt. The cuprous salt obtained by filtration was washed with water, ethanol, and ether, successively, and dried *in vacuo* at 40°C, 3.52 g (62.5%).

The cuprous salt (1.73 g, 5.08 mmol) in dry pyridine (50 m*l*) was heated with stirring at 120°C under nitrogen for 8 hr. After cooling, the reaction mixture was poured into water (150 m*l*) and extracted with ether. The extract was washed with dil. hydrochloric acid, 5% aq. sodium bicarbonate, and water, successively, and dried over magnesium sulfate. After the solvent had been evaporated, the residue was chro-

matographed on alumina with benzene. The residual solid (0.18 g) obtained from 4—6th fractions was recrystallized from benzene to afford 61 mg (8.0% yield) of VI, pale yellow needles, decomp. over 360°C.

Found: C, 95.72; H, 4.08%. Calcd for $C_{36}H_{18}$; C, 95.97; H, 4.03%. IR (KBr disk): 1610, 1585, 888, 831, 827 cm^{-1}. UV (in THF); λ_{max} (ε), 254 (59100), 266* (50200), 279 (78200), 290 (65600), 327 (69000), 342 (122000), 360 (25400), 365 (29000), 380 (33800), 396* nm (3410) (* inflection).

Reduction of VI. The acetylenic compound VI (40.3 mg, 9.0×10^{-2} mmol) and 10% palladium-on-charcoal (143 mg) in benzene (70 m*l*) were shaken with hydrogen at 50°C for 10 hr. After cease of hydrogen absorption, the catalyst was filtered and the solvent was evaporated under reduced pressure. The residue was recrystallized from petroleum ether to yield colorless needles of reduction product (X), mp 286—286.5°C, 38.8 mg (93.5%).

Found: C, 92.92; H, 6.54%. Calcd for $C_{36}H_{30}$: C, 93.46; H, 6.54%. Mol wt: Found; 477 (vapour pressure osmometry), 462 (mass spectrum). Calcd for $C_{36}H_{30}$; 462.6. IR (KBr disk): 830 (s), 748 (s) cm^{-1}. UV (in THF): λ_{max} (ε), 228 (193000), 278 (20600), 287 (22600), 316* (1580), 323 nm (1540) (* inflection).

o-Iodophenyl Propargyl Carbinol (XII). To aluminum metal plate (1.1 g, 40.7 mg atom), activated on heating with small pieces of mercuric chloride and iodine, was added a solution of propargyl bromide (7.2 g, 60 mmol) in dry tetrahydrofuran (10 m*l*) with stirring at room temperature. After consumption of aluminum metal, *o*-iodobenzaldehyde[5] (XI) (13.9 g, 60 mmol) in dry tetrahydrofuran (20 ml) was added dropwise to the solution at −60°C with stirring and the mixture was stirred at 0°C for 1 hr. After addition of saturated aqueous ammonium chloride (50 m*l*), the aqueous layer was separated and extracted twice with ether. The combined organic solution was washed, dried over magnesium sulfate and the solvent was removed under reduced pressure. A solution of the residue (15.64 g) in benzene-petroleum ether (1:1) was passed through a short column of alumina (30 g) and eluted with the same solvent. The effluent was concentrated to yield reddish brown oil of crude carbinol XII, 12.84 g (78.8%).

NMR ($CDCl_3$): τ 2.1—3.3 (m, 4H, arom.), 5.02 (quart., 1H, tert.), 6.96 (broad s, 1H, OH), 7.0—7.9 (m, 2H, $-CH_2-$), 7.95 (t, 1H, ≡CH).

4-[o-Iodophenyl]-3-buten-1-yne (XIV). To a cold solution of the carbinol XII (6.8 g, 25 mmol) in dry pyridine (30 m*l*) was added dropwise a mixture of dry pyridine (20 m*l*) and phosphorus oxychloride (20 m*l*) with stirring. The mixture was stirred below 5°C for 20 min, then carefully poured onto 300 g of ice and extracted with benzene. The extract was washed with water, dried and concentrated *in vacuo*. The oily residue was passed through a short column of alumina (15 g) with benzene-petroleum ether (1:1). The effluent was evaporated under reduced pressure to yield reddish brown oil of *o*-iodophenyl propargyl chloride (XIII), 3.26 g.

A mixture of the crude chloride XIII (3.26 g) and powdered potassium hydroxide (1.68 g, 30 mmol) in methanol (7 m*l*) was stirred at 50°C for 40 min. The reaction mixture was poured into 140 m*l* of water and extracted with benzene. The extract was washed with water, dried over magnesium sulfate and concentrated *in vacuo*. The residue (2.10 g) was dissolved in benzene-petroleum ether (3:17) and passed through a short column of alumina. The effluent was evaporated under reduced pressure to give unstable XIV as pale yellow oil, 1.77 g, 28.0% yield based on the carbinol XII (34.3% yield in the other run).

NMR ($CDCl_3$): τ 2.1—3.4 (m, 4H, arom.), 2.84 (d, 1H, olefin. H_1 at C_4), 4.10 (double d, 1H, olefin. H_2 at C_3), 6.94 (d, 1H, ≡CH), $J_{H_1,H_2}=15.6$ Hz.

Mercuric Salt of XIV: Mercuric salt of XIV was obtained according to the same method as IX and recrystallized from benzene, colorless needles, mp 227—232°C (decomp.).

Found: C, 34.06; H, 1.75%. Calcd for $C_{20}H_{12}I_2Hg$: C, 33.99; H, 1.71%.

Tribenzo[a,g,m]-5,11,17-tridehydro[18]annulene (VII). Well dried cuprous salt (10.0 g, 31.5 mmol) of XIV, obtained in a yield of 77% according to the same method as for IX, was heated in dry pyridine (350 m*l*) with stirring under nitrogen. The mixture was heated up to 120°C and the stirring at this temperature was continued for 8 hr. After cooling, the mixture was poured into 1.5 *l* of water and extracted with benzene. The extract was washed with dil. hydrochloric acid, 5% aq. sodium bicarbonate and water, successively, and dried over magnesium sulfate. The solvent was removed *in vacuo* to give 3.81 g of residue. The residue was chromatographed on alumina (250 g) with benzene-petroleum ether (1:1). The column was eluted with benzene-petroleum ether (the ratios 1:1 for 20 fractions and 7:3 for the successive 10 fractions of each 50 m*l*). The solid, obtained from 5—8th fractions, was recrystallized from benzene to give colorless prisms of the cyclic tetramer XV, 0.124 g (2.4% yield), decomp. over 260°C.

Found: C, 95.00; H, 4.93%. Calcd for $C_{40}H_{24}$: C, 95.21; H, 4.79%. Mol wt: Found; 509 (vapour pressure osmometry). Calcd for $C_{40}H_{24}$; 504.6. IR (KBr disk): 950 (s), 750 (s), 675 (s), 526 (m), 503 (m), 485 cm^{-1} (m). UV (in THF): λ_{max} (ε), 252 (36200), 292.5 (71700), 312.5 nm (70900).

The combined effluent of 14—30th fractions was evaporated *in vacuo* and the residue was recrystallized from benzene to afford yellow needles of the cyclic trimer VII, 0.527 g (13.0% yield), decomp. over 275°C.

Found: C, 95.37; H, 4.59%. Calcd for $C_{30}H_{18}$: C, 95.21; H, 4.79%. Mol wt: Found; 372 (vapour pressure osmometry). Calcd for $C_{30}H_{18}$; 378.5. IR (KBr disk): 950 (s), 750 (s), 745 (s), 515 (m), 498 cm^{-1} (m). UV in (THF): λ_{max} (ε), 241.5 (12300), 251* (12000), 287* (45500), 297.7 (58900), 325 (103000), 337 (114000), 366 (19800), 384 nm (15800) (* inflection).

1,4-Diphenylbutenyne (XVI). Butenyne XVI was prepared by the Castro reaction of the cuprous salt of 4-phenyl-3-buten-1-yne, obtained according to Eiter,[7] with iodobenzene, mp 96.7—97.8°C (lit,[15] mp 95°C).

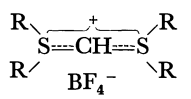
Di- and Trimethylenebis(ethylphenacyl)sulfonium Ylides

Shinzi KATO, Hideharu ISHIHARA, Masateru MIZUTA, and Yoshio HIRABAYASHI
Faculty of Engineering, Gifu University, Kakamihara, Gifu

(Received February 22, 1971)

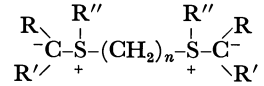
Bissulfonium phenacylides were obtained by the reactions of dimethylene and trimethylene bisethylphenacylsulfonium salts with sodium hydride. The chemical properties of these bis-ylides are similar to those of monosulfonium phenacylides. Biscarbamoylsulfonium phenacylides were obtained as stable crystals by the reactions of the above bis-ylides with phenyl isocyanate.

Recently, considerable information has accumlated concerning sulfur-stabilized ylides.[1-5] However, bissulfonium ylides have received little attention, except for the bissulfonium ylide of structure I.[6] In this paper, an attempt at the syntheses and reactions of bisylides of the II and III structures will be described.



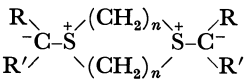
I

R: Methyl
Ethyl



II

R : H
R′ : Benzyl
R″: Ethyl



III

R′: Benzyl

By the use of open-chain sulfides (methylene, dimethylene, and trimethylene bisethylsulfide) and cyclic sulfides (1,3-dithiolane, 1,3-dithiane, 1,4-dithiane, and 1,3,5-trithiane) as the starting materials, an attempt has been made to synthesize phenacyl bissulfonium salts. Dimethylene and trimethylene sulfides among these sulfides gave bissulfonium salts by reactions with phenacylbromide. The subsequent treatment of these bissulfonium salts with sodium hydride gave bissulfonium phenacylide (Structure II). Several reactions of the above-mentioned bis-ylides were carried out (*cf.* Chart 1).

Results and Discussion

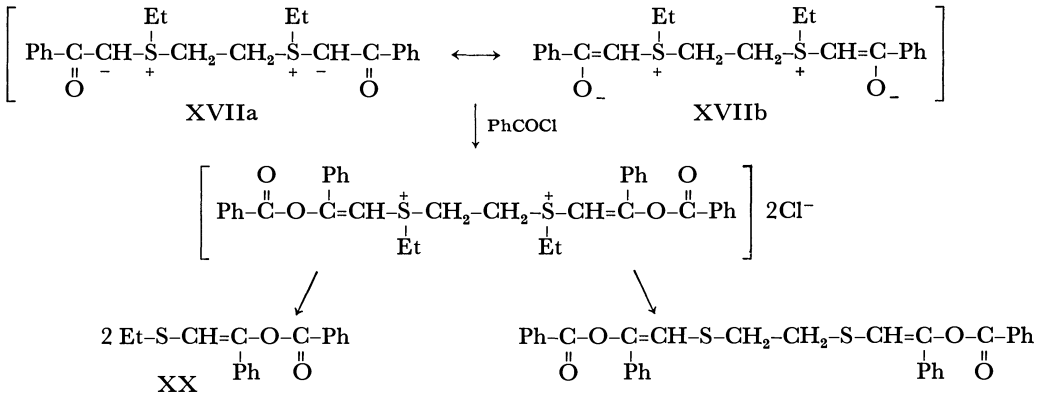
bromide (XII) was obtained as a white solid in a 40% yield by the reaction of dimethylene bisethylsulfide and phenacylbromide. The structure was confirmed by a study of its IR spectrum ($\nu_{C=O}$ 1662 cm^{-1}) and elemental analysis. A similar procedure for trimethylenebisethylsulfide gave trimethylene bisethylphenacylsulfonium bromide (XIII) as a white solid in a 55% yield. However, similar procedures for methylenebisethylsulfide and cyclic sulfides gave only monosulfonium salts in 30—90% yields, except for 1,3,5-trithiane.

The UV absorption curves of the bissulfonium salts (XII and XIII) do not obery Beer's law in cyclohexane solutions. Similar deviations from Beer's law by bissulfonium salts have been reported by Lillya[6] and Nicholson.[7]

Bissulfonium Phenacylides. The reaction of the bis-salt (XII) with sodium hydride in THF at 0——5°C gave a light yellow dimethylene bisethylsulfonium phenacylide (XVII). The structure of XVIII was confirmed by the results of elemental analysis and the spectroscopic data. This structure was further chemically confirmed by the formation of XII through the action of hydrogen bromide in an aqueous ethanol, and by the formation of XXI (as crystals in over a 50% yield) through the action of phenyl isocyanate in THF by an analogous treatment of XIII with sodium hydride, trimethylenebisethylsulfonium phenacylide (XVII) was obtained in a 72% yield (Table 1).

These bis-ylides (XVII and XVIII) were solids (although they could not be crystallized) and were fairly stable below 0°C. They decomposed on standing in the atmosphere or in a solution (ethanol and THF at room temperature), and the absorption due to ylide carbonyl in the 1520—1500 cm^{-1} range disappeared completely after two weeks. Furthermore, the addition of a few drops of water to XVII and XVIII accelerated their decomposition. They were also subject to thermal decomposition. The heating of the bis-ylide (XVII) in THF gave *trans*-1,2,3-tribenzoylpropane (XIX) in a 47% yield (based on the XVII used). The same products was obtained from XVII in 85% and 22% yields by treatment with phenacylbromide and by irradiation (UV) in THF at room temperature respectively.

It has been reported that the course of the acylation of the mono-ylides varied with the nature of the acylating agent and with the structure of the mono-ylides; dimethyl-oxy-sulfonium phenacylide[8] underwent a *C*-acylation with benzoylchloride, while methylphenylsulfonium phenacylide[9] and dimethylsulfonium phenacylide[10] underwent an *O*-acylation with benzoylchloride, but a *C*-acylation with benzoic anhydride.



Scheme 1

7) D. C. Nicholson, E. Rothstein, R. W. Saville, and R. Whitly, *J. Chem. Soc.*, **1953**, 4019.

8) H. König and H. Metzger, *Chem. Ber.*, **98**, 3733 (1965).

9) H. Nozaki, K. Kondo, and M. Takaku, *Tetrahedron*, **22**, 2145 (1966).

10) A. W. Johnson and R. T. Amel, *J. Org. Chem.*, **34**, 1240 (1969).

The acylation of XVII and XVIII with benzoylchloride resulted in an *O*-acylation, affording the enol benzoate (XX) of ethylmercaptoacetophenon in 78 and 71% yields respectively (Scheme 1)

The IR spectrum and the results of the elemental analysis of XX were consistent with those of an authentic sample prepared by the reaction of diethylsulfonium phenacylide (XXIII)[5] with benzoylchloride. The results suggest that the contribution of the enol form in the bis-ylides (XVII and XVIII) was stronger than that in dimethyl-oxy-sulfonium phenacylide.

The reaction of XVII and XVIII with benzoic anhydride did not give a product corresponding to *C*- or *O*-acylation; from the reaction products, benzoic acid in a 60% yield (based on the benzoic anhydride used), together with traces of the cyclopropane (XIX) and of a product with a melting point over 300°C, were obtained on a column chromatographic separation (alumina).

The treatment of the bis-ylides (XVII and XVIII) with phenyl isocyanate in THF at 0——5°C afforded other bis-ylides (XXI and XXII)[11] as colorless crystals in 53 and 87% yields respectively.

Johnson and Amel[10] reported that dimethylsulfonium phenacylide (XXIII) reacted with *p*-nitrobenzaldehyde to give a epoxide in a 10% yield, while Nozaki *et al.*[8] reported that the reactions of methylphenylsulfonium phenacylide with benzaldehyde or *p*-nitrobenzaldehyde did not afford epoxyketones. We have not been able to obtain mono- or bis-epoxyketone by the reactions of bis-ylides (XVII and XVIII) with *p*-nitrobenzaldehyde.

Nozaki[9] and Johnson[10] reported that the irradiation of monosulfonium phenacylide gave the cyclopropane (XIX). Ratt[12] and Johnson[10] reported the trapping of the carbene intermediate from monosulfonium phenacylide and *p*-nitrophenacylide by the use of triphenylphosphine and dimethylbenzylamine. We carried out the irradiation of the bis-ylides (XVII and XVIII) in THF with a high-pressure mercury lamp (300 W) and thus obtained the cyclopropane (XIX in a 20% yield), along with unidentified oily substances. We failed, however, to trap the benzoylcarbene with the above trapping reagents.

Experimental

General. All the melting points are uncorrected. The IR spectra were recorded on a JASCO grating infrared spectrophotometer IR-G. The UV spectra were measured on a Hitachi 124 spectrophotometer. The photochemical reactions were effected by the use of a Eikosha high-pressure mercury apparatus.

α,ω-alkanedithiols were prepared by the reactions of α,ω-dibromoalkanes with thiourea and by the subsequent hydrolysis of the salts: 1,2-ethanedithiol,[13] bp 61—63°C/45 mmHg; 1,3-propanedithiol, bp 72°C/25 mmHg.

Open-chain Sulfides and Cyclic Sulfides were prepared according to the directions in the literature and were purifided by distillation or recrystallization: methylenebisethylsulfide (IV),[14] bp 95—97°C/39—40 mmHg; dimethylenebisethylsulfide (V),[15] bp 209—213°C/760 mmHg; trimethylenebisethylsulfide (VI),[16] bp 86.0—87.5°C/8—9 mmHg; 1,3-dithiolane (VII),[17] bp 56—68°C/8—10 mmHg; 1,3-dithiane (VIII),[18] mp 52—53°C; 1,4-dithiane (IX),[19] mp 111.0—111.5°C; 1,3,5-trithiane (X),[20] mp 212—213°C.

The data of elemental analyses for mono- and bissulfonium bromides and phenacylides given below are summarized in Table 1.

Methylene Bisethylmonophenacylsulfonium Bromide (XI).[21] A solution of phenacylbromide (8.0 g, 0.04 mol) and IV (2.7 g, 0.02 mol) in methanol (150 m*l*) was refluxed for 6 hr. After the subsequent removal of the methanol, we added ether (200 m*l*) to the residue; further extraction of the insoluble parts with several portions of ether afforded 2.7 g (24.5%) of a clear, brownish residue (XI): IR (neat): $\nu_{C=O}$ 1670 cm^{-1}.

Dimethylenebisethylphenacylsulfonium Bromide (XII) and Trimethylenebisethylphenacylsulfonium Bromide (XIII). A mixture of phenacylbromide (8.0 g, 0.04 mol) and V (3.0 g, 0.02 mol) was warmed for 15 min at 50—60°C and then allowed to stand for two days at room temperature. To the reaction mixture (a light yellow solid), we then added several portions of acetone. The insoluble parts were recrystallized from hot acetone-ether to give IX (4.6 g, 41.8%) as colorless, microfine crystals: mp 128—130°C; IR (KBr): $\nu_{C=O}$ 1662 cm^{-1}. Similarly, a reaction mixture (a dark brown solid) of phenacylbromide (8.0 g, 0.04 mol) and VI (3.2 g, 0.02 mol) gave XIII (5.8 g, 57.2%) as colorless, microfine crystals on recrystallization from hot acetone - water: mp 136—138°C; IR (KBr): $\nu_{C=O}$ 1662 cm^{-1}.

1,3-Dithiolane-1-phenacylsulfonium Bromide (XIV) and 1,3-Dithianephenacylsulfonium Bromide (XV). A mixture of phenacylbromide (8.0 g, 0.04 mol) and VII (2.2 g, 0.02 mol) was warmed for 5 min at 50—60°C and then allowed to stand for two days below 15°C. To the reaction mixture (a dark red solid) we then added several portions of acetone. The insoluble part (a white solid) was recrystallized from methanol - acetone (3:1) to give XIV (4.2 g, 67.1%) as colorless, microfine crystals: mp 99—100°C; IR (KBr): $\nu_{C=O}$ 1662 cm^{-1}. Similarly, a reaction mixture of phenacylbromide (8.0 g, 0.04 mol) and VIII (2.4 g, 0.02 mol) gave XV (4.4 g, 69.2%) as colorless crystals after recrystallization from hot acetone - water: mp 110—111°C; IR (KBr): $\nu_{C=O}$ 1662 cm^{-1}.

1,4-Dithiane-1-phenacylsulfonium Bromide (XVI). 1,4-dithiane (2.4 g, 0.02 mol) was dissolved in phenacylbromide (8.0 g, 0.04 mol) at 80—90°C, and then the mixture was kept for 5 min at 90—100°C. To the reaction mixture (a light yellow solid) we then added several portions of hot methanol to give XVI (6.4 g, 93.7%) as colorless, microfine crystals; mp 130—131°C; IR (KBr): $\nu_{C=O}$ 1668 cm^{-1}.

Reaction of 1,3,5-Trithiane (X) with Phenacylbromide. A

11) The structures of XXI and XXII were comfirmed by their IR spectra and elemental analyses. The crystalline bis-ylides (XXI and XXII) were readily soluble in THF, chloroform, methanol, and water, and were fairly stable on standing in atmosphere at room temperature and on refluxing in THF.

20) R. W. Bost and E. W. Constable, "Organic Syntheses," Coll. Vol. II, p. 610.

21) In order to obtain methylenebisethylsulfonium salts, a mixture of IV and phenacylbromide in methylenechloride was treated with silvertetraflurorborate. The glistering colorless crystals (mp 153—154°C) was obtained, but this compound was unstable.

solution of X (1.4 g, 0.01 mol) and phenacylbromide (5.2 g, 0.03 mol) in benzene (200 m*l*) was refluxed for 10 days. After the removal of the benzene, methanol was added to the residue. By washing the insoluble part with several portions of methanol - acetone, trithiane (1.3 g) was then recovered.

Dimethylenebisethylsulfonium Phenacylide (XVII). To a suspension of XII (2.2 g, 0.04 mol) in 30 m*l* of anhydrous THF at 0——5°C, sodium hydride (0.008 mol) was added: the mixture was then vigorously stirred for 5 hr below 5°C. After the removal of the sodium bromide from the reaction mixture, the evaporation of the THF and treatment with petroleum-ether gave a pale yellow residue which solidified below 5°C, but which could not be crystallized. The chromatography of this residue on alumina gave XVII (62%) and a trace of *trans*-1,2,3-tribenzoylpropane (XIX); IR (neat): $\nu_{C=O}$ 1515 cm^{-1}; UV: λ_{max}^{EtOH} 229 mμ (ε 2.12×10^4), 308 mμ (ε 2.12×10^4). The IR spectrum of XIX was identical with that of an authentic sample prepared by the treatment of phenylmethylsulfonium phenacylide with phenacylbromide.

Trimethylenebisethylsulfonium Phenacylide (XVIII): Yield, 72%; IR (neat): $\nu_{C=O}$ 1510 cm^{-1}; UV: λ_{max}^{EtOH} 229 mμ (ε 2.61×10^4), 308 mμ (ε 2.50×10^4).

Acylation of the bis-ylides (XVIII). Enolbenzoate of Mercaptoacetophenone (XX): A solution of XVII (1.1 g, 0.0025 mol) and benzoylchloride (0.7 g, 0.005 mol) in anhydrous THF was stirred for 3 hr at room temperature. The white precipitates were then washed with THF - *n*-hexane (1:4) and dried over P_2O_5 to give XX (0.9 g, 64%): mp 107—108°C; IR (KBr): $\nu_{C=O}$ 1738 cm^{-1}; ν_{C-O-C} 1190 cm^{-1}, Found; C, 71.4; H, 5.6; S, 11.5%, (Calcd for $C_{17}H_{16}O_2S$: C, 71.83; H, 5.63; S, 11.27%). The melting point the results of elemental analysis, and the IR spectrum were identical with those of an authentic sample prepared by the reaction of diethylsulfonium phenacylide with benzoylchloride.

A similar treatment of XVIII (1.1 g, 0.0025 mol) with benzoylchloride (0.7 g, 0.0025 mol) gave XX (0.99 g, 71%).

Reaction of the bis-ylides (XVII and XVIII) with p-*Nitrobenzaldehyde.* A solution of XVII (1.1 g, 0.0025 mol) and *p*-nitrobenzaldehyde (0.75 g, 0.005 mol) in 30 m*l* of anhydrous THF was refluxed for 20 hr. After the subsequent evaporation of the THF, the chromatography of the residue on alumina gave *p*-nitrobenzylalcohol (0.8 g, 23%), together with a trace of the cyclopropane (XIX) and an intractable oil (1.0 g).

A similar treatment of XVIII (1.1 g, 0.0025 mol) with *p*-nitrobenzaldehyde gave *p*-nitrobenzylalcohol, the cyclopropane (XIX), and an intractable brown oil in a ratio analogous to that above.

*Reaction of the bis-ylide (XVII and XVIII) with Phenyl Isocyanate. Dimethylenebisethylsulfonium Benzoyl (*N-*phenylcarbamoyl) Methylide (XXI):* Phenyl isocyanate (0.6 g, 0.005 mol) and XVII (1.1 g, 0.0025 mol) were stirred in anhydrous THF (30 m*l*) for 5 hr at 0——5°C. After the subsequent evaporation of the THF, the recrystallization of the residue from AcOEt or chloroform - AcOEt gave XXI (0.85 g, 53%): mp 184—185°C; IR (KBr): $\nu_{C=O}$ 1640 and 1513 cm^{-1}; UV: λ_{max}^{EtOH} 243 mμ (ε 4.44×10^4), 284 mμ (ε 4.32×10^4).

Trimethylenebisethylsulfonium Benzoyl (N-*phenylcarbamoyl*) *Methylide (XXII):* A similar treatment of XVIII (1.1 g, 0.0025 mol) with phenyl isocyanate (0.6 g, 0.005 mol) gave XXII (1.0 g, 61%): mp 194—195°C; IR (KBr): $\nu_{C=O}$ 1635 cm^{-1}; UV: λ_{max}^{EtOH} 243 mμ (ε 4.28×10^4), 284 mμ (ε 4.11×10^4). trans-1,2,3-*Tribenzoylpropane (XIX). XVIII and Phenacylbromide:* An equimolar mixture of XVIII (1.1 g, 0.0025 mol) and phenacylbromide (0.5 g, 0.0025 mol) in THF was stirred at room temperature for 5 hr. The subsequent concentration of the solution and recrystallization of the residue from benzene gave the cyclopropane XIX (0.32 g, 48% based on the XVIII); mp 214—215°C.

Thermolysis of XVIII: A solution of XVIII (1.05 g, 0.0025 mol) in THF (20 m*l*) was heated under reflux for 24 hr. The subsequent evaporation of the solvent and the recrystallization of the residue from benzene gave a 47% yield (0.105 g, based on the XVII) of the XIX cyclopropane.

A similar treatment of XVIII (1.1 g, 0.0025 mol) gave a 40% yield (0.088 g, based on the XVIII) of the XIX cyclopropane.

Photolysis of XVIII: A solution of XVIII (1.1 g, 0.0025 mol) in THF (10 m*l*) was irradiated for 15 hr in a Pyrex tube. The subsequent concentration of the solution and recrystallization of the residue gave an 8% yield of XIX.

The Acid-catalyzed Reaction of Isocyanide with Oxetane

Takeo SAEGUSA, Naotake TAKA-ISHI, and Yoshihiko ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 23, 1971)

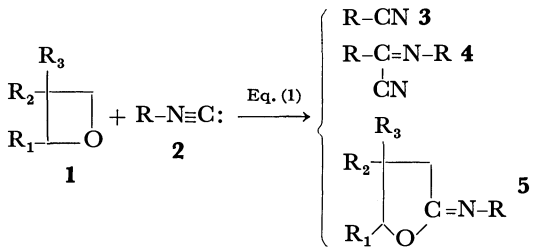
The reaction of isocyanide with oxetane in the presence of $BF_3 \cdot OEt_2$ was studied; in this reaction a 1:1 cyclic adduct, 2-iminotetrahydrofuran, was formed. From 2-methyloxetane, 2-imino-5-methyltetrahydrofuran was exclusively formed. These findings suggest an S_N2 mechanism for the cleavage of the oxetane ring. Oxetanes with electron-withdrawing substituents gave γ-alkoxybutyronitrile as the main product, along with 2-iminotetrahydrofuran. A reaction scheme involving an imidoyl cation was proposed to explain the formation of cyclic and linear products.

Several papers have been reported on the cycloaddition reaction of isocyanide.[1] We have reported the Lewis-acid-catalyzed cyclizations reaction of isocyanide with ketone, aldehyde, and a Schiff base.[2-4] In addition, we have presented a preliminary report[5] upon a new cycloaddition reaction of isocyanide with four-membered cyclic ethers (oxetanes) with a BF_3 catalyst, in which reaction 2-iminotetrahydrofuran was produced.

In this paper we wish to report on our further studies of the scope of the reaction of isocyanide with substituted oxetanes and some mechanistic studies.

Results and Discussion

In the reaction of oxetane (**1a**) with *t*-butyl isocyanide (**2a**) in the presence of $BF_3 \cdot OEt_2$ at room temperature, 2-*t*-butyliminotetrahydrofuran (**5a**) was produced, along with *t*-butyl cyanide (**3a**) and *N*-*t*-butylpivalimidoyl cyanide (**4a**). The two by-products, **3a** and **4a**, were found to be produced from **2a** with $BF_3 \cdot OEt_2$ in the absence of **1a** (Eq. (1)).



1a, $R_1=R_2=R_3=R_4=H$

2, 3, 4
- **a**, R = *t*-Bu-
- **b**, R = Me-C(Et)-
- **c**, R = *t*-Bu-CH_2-C(Et)(Me)-
- **d**, R = 
5a, $R_1=R_2=R_3=R_4=H$, R = *t*-Bu

Some results of the reaction of **1a** with **2a** are shown in Table 1. As the catalyst, an equimolar amount of $BF_3 \cdot Et_2O$ was required. A smaller amount of $BF_3 \cdot Et_2O$ gave a poorer result. The reaction proceeded rapidly at room temperature. At lower temperatures the conversion percent was low and the starting materials were recovered unchanged. As the reaction solvent, CH_2Cl_2 gave better results. Basic solvents like tetrahydrofuran and acetonitrile gave poor yields.

10	5	5	Et_2O	38

a) Reaction at room temperature for 2 hr.
b) Determined by glpc.
c) Reaction at 0°C.
d) Reaction at −78°C.

The structure of **5a** was established by elemental analysis and by a study of its IR and NMR spectra, as well as by the acid hydrolysis product. In the acid hydrolysis of **5a** with silicic acid, γ-butyrolactone (**6a**) was formed. The conversion of **5** to **6** has already been reported by Stirling.[6]

The same reaction was observed with other *t*-alkyl and phenyl isocyanides. The results are shown in Table 2. In the case of cyclohexyl isocyanide, the cationic polymerization of cyclohexyl isocyanide predominated and the iminotetrahydrofuran could not be isolated. However, the IR spectrum of the reaction mixture showed an absorption at 1715 cm^{-1} which was attributed to the cyclic imino group.

Then, the reaction of **2a** with various alkyl-substituted oxetanes was examined. The results are shown

1) B. Zeeh, *Synthesis*, **1969**, 65.

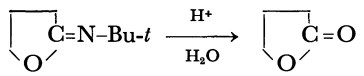
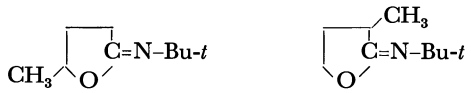
b) Identified by the comparison of the glpc retention time and IR spectrum with the authentic sample.[7)]



5a **6a**

in Table 3. 2-*t*-Butyliminotetrahydrofuran derivatives were obtained in relatively high yields. 2-Methyloxetane (**1e**), the unsymmetrical oxetane, gave 2-*t*-butylimino-5-methyltetrahydrofuran (**5e**) exclusively. The structure of **5e** was confirmed by its acid hydrolysis with silicic acid, where by γ-valerolactone was formed. The alternative possible product, 2-*t*-butylimino-3-methyltetrahydrofuran (**7**), could not be found in the reaction mixture.



5e **7**

In the cases of oxetanes with two electron-withdrawing substituents at the 3-position, the linear product, γ-alkoxybutyronitrile derivative (**8**), was produced along with the cyclic adduct, **5** (Eq. (2)). The results are summarized in Table 4.

(R: $ClCH_2$–, ICH_2–, $EtOCH_2$–)

Reaction Scheme

Considering the cationic isomerization of **2**, which takes place along with the formation of **5**, a reaction scheme involving the *t*-alkyl cation and the imidoyl cation as the key intermediates may be presented as follows:

$$RNC + BF_3 \cdot OEt_2 \rightleftarrows (RNC \rightarrow BF_3) + Et_2O$$
$$(RNC \rightarrow BF_3) \longrightarrow R^+[BF_3 \cdot CN]^- \qquad (3)$$

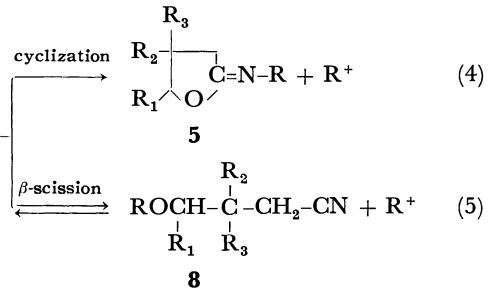
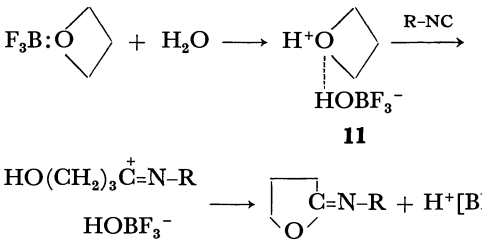
10

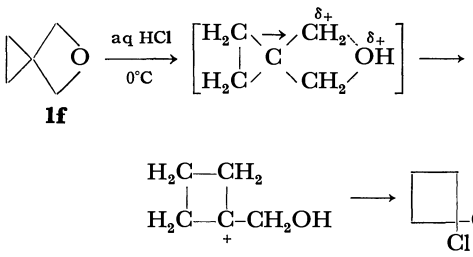


The initial generation of the *t*-butyl cation complex (Eq. (3)) has been shown in a previous paper.[8] As both 1-ethyl-1-methylpropyl isocyanide (**2b**) and 1,1,3,3-tetramethylbutyl isocyanide (**2c**) were isomerized by $BF_3 \cdot OEt_2$ to the corresponding nitriles, (**3b**) and (**3c**), the initiation reaction producing the *t*-alkyl carbonium ion is supported. The cyclic trialkyloxonium ion of oxetane (**9**) undergoes ring-cleavage as a result of the attack of isocyanide as a nucleophile.

An alternative scheme starting with the cyclic dialkyloxonium ion of oxetane (**11**) may also be assumed for the formation of the cyclic adduct (Eq. (6)). Especially, the second scheme of Eq. (6) can be taken to explain the reaction of *o*-tolyl isocyanide, where no isomerization of the isocyanide takes place. The water responsible for the protonic-acid complex may be ascribed to the incomplete dehydration of the reagents. The protonic-acid complex due to the water impurity has been assumed in the initiation of the BF_3-catalyzed polymerization of oxetane.[9,10]



In the reaction of **1e** with **2a**, the formation of **5e** *via* the cleavage of the ether linkage at the less substituted carbon suggests an S_N2 mechanism for the ring cleavage. The S_N2 mechanism is also supported by the reaction of oxetane-3-spirocyclopropane (**1f**). When a mixture of **1f** and **2a** was treated with $BF_3 \cdot OEt_2$ at room temperature, only the oxetane ring was cleaved to form 2-*t*-butyliminotetrahydrofuran-4-spirocyclopropane (**5f**). If the cleave of the oxetane ring of **1f** proceeded *via* S_N1 mechanism, the isomerization of the cyclopropyl ring would have occurred, *i.e.*, the treatment of **1f** with aqueous hydrochloric acid has been reported, and in it the cleavage of the ether linkage and the enlargement of the carbocyclic ring occurred.[11]



The re-cyclization of **10** to **5** (Eq. (4)) has been supported by a reference reaction in which 3,3-bis(chloromethyl)-4-*t*-butoxybutyronitrile (**8k**) was treated with triethyloxonium fluoroborate to give β,β-bis(chloromethyl)-γ-butyrolactone (**6k**) (Eq. (7)). The treatment of ω-benzyloxybutyronitrile (**13**) with triethyloxonium fluoroborate, followed by the hydrolysis of the reaction mixture, gave γ-butyrolactone in a yield of 31% (Eq. (8)).

The imidoyl cations, **12** and **14**, are considered as the reaction intermediates in these reference reactions. Similar cyclization reactions to 2-iminotetrahydrofuran have been reported in the reaction of ω-hydroxy nitrile[12] and unsaturated nitrile.[13]

12) E. M. Schultz, C. M. Robb, and J. M. Sprague, *J. Amer. Chem. Soc.*, **69**, 2454 (1947).

13) R. F. Raffauf, *ibid.*, **74**, 4460 (1952).

The cyclization of the imidoyl cation intermediate to 2-iminotetrahydrofuran seems to proceed rapidly. Any amide which might be derived from the imidoyl cation, if any was present, was not detected in the hydrolysis mixture of the reaction system.

It is of interest that **8** is formed only when oxetane is substituted by electron-withdrawing groups. This observation is explained by the low nucleophilicity of the ether oxygen of the imidoyl cation, **10**. The cyclization of **10** to **5** may be slow in these oxetanes; consequently, the formation of **8** by the β-scission of **10** may be predominant. In oxetanes substituted by chloromethyl and iodomethyl groups which have large σ_m values, the ratio of **8** to **5** in the product is high in comparison with that in 3,3-bis(ethoxymethyl)oxetane (**1m**). It has been known that substituent groups exert an influence on the basic strength of the ether oxygen of 3,3-disubstituted oxetanes.[14] Therefore, it is not unreasonable to assume that the nucleophilicity of the ether oxygen of **10** is influenced by substituent groups. Interference by the steric effect of the substituent for re-cyclization is less probable, because **8** was not formed in the cases of 3,3-diethyloxetane (**1i**) and oxetane-3-spirocyclohexane (**1j**), where substituent groups are as bulky as these of **1k** and **1l**. The formation of **8** by the β-scission of **10** is analogous to the β-scission of the imidoyl cation observed in the cationic isomerization and dimerization reaction of *t*-alkyl isocyanide.

Experimental

Reagents. *Oxetane*: Published procedures were utilized for the preparation of oxetane,[9] 2-methyloxetane,[15] oxetane-3-spirocyclopropane,[11] 3-methyloxetane,[15] 3,3-dimethyloxetane,[16] 3,3-diethyloxetane,[16] oxetane-3-spirocyclohexane,[17] 3,3-bis(iodomethyl)oxetane,[18] and 3,3-bis(ethoxymethyl)oxetane.[19] The 3,3-bis(chloromethyl)oxetane was a commercial sample which was purified by rectification under nitrogen prior to use. The 3,3-bis(*t*-butoxymethyl)oxetane was a new compound which was prepared, by a modification of Farthing's method,[19] in a yield of 12%; bp 94—95°C/7 mmHg. Found: C, 67.43; H, 11.98%. Calcd for $C_{13}H_{26}O_3$: C, 67.19; H, 12.15%. The structure was confirmed by a study of the NMR and IR spectra.

Isocyanide: Cyclohexyl isocyanide and *t*-butyl isocyanide were prepared according to Ugi's procedure.[20] 1-Ethyl-1-methylpropyl isocyanide was prepared according to Otsuka's method.[21] 1,1,3,3-Tetramethylbutyl isocyanide[21] was prepared by a modification of Ugi's method.[20] *o*-Tolyl isocyanide was prepared according to Ugi's procedure.[22] Triethyloxonium tetrafluoroborate ($Et_3O^+BF_4^-$) was prepared according to the method of Meerwein.[23] γ-Benzyloxybutyronitrile was prepared according to the method of Bennett *et al.*[24] $BF_3 \cdot Et_2O$ was a commercial reagent which was used without purification. The solvents were purified by the usual methods.

2-t-Butyliminotetrahydrofuran (5a). Into a solution of *t*-butyl isocyanide (**2a**) (0.83 g, 10 mmol) and oxetane (**1a**) (0.29 g, 5 mmol) in 5 m*l* of methylene chloride, $BF_3 \cdot Et_2O$ (0.71 g, 5 mmol) was added drop by drop with stirring at 0°C. After being allowed to stand at room temperature for 2 hr, the reaction mixture was poured into aqueous NaOH. The organic layer was then separated from the aqueous phase, and the aqueous phase was extracted twice with 5 m*l* portions of methylene chloride. The combined organic extracts were dried over magnesium sulfate and then subjected to distillation. From the volatile fraction, *t*-butyl cyanide (**3a**) and *N*-*t*-butylpivalimidoyl cyanide (**4a**) were obtained; they were identified by comparison with authentic samples. From the second fraction (bp 76°C/22 mmHg), **5a** was obtained in a yield of 70%. The IR spectrum of **5a** showed an absorption at 1712 cm^{-1} which was attributed to cyclic imidate. The NMR spectrum data are listed in Table 5. γ-Butyrolactone was obtained on the treatment of **5a** with silicic acid.

Found: C, 67.18; H, 10.57; N, 9.76%. Calcd for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92%.

2-Iminotetrahydrofurans Other than 5a. Into a solution of an isocyanide and an oxetane (mol ratio, 2:1) in methylene chloride, an equimolar amount of $BF_3 \cdot Et_2O$ was added drop by drop with stirring at 0°C. The mixture was warmed to room temperature and then allowed to stand for the prescribed length of time shown in Table 2 and Table 3. The procedure employed for the isolation of **5** was almost the same as that used for **5a**. The NMR spectra data of **5** are given in Table 5. Elemental analysis was carried out upon the corresponding lactones, **6**, which were obtained by the treatment of **5** with silicic acid. The analytical data of **6** are shown in Table 6.

Reaction of 1a with 1,1,3,3-Tetramethylbutyl Isocyanide (2c). This reaction was carried out under the conditions given in Table 2. According to a procedure similar to that used in the isolation of **5a**, the methylene chloride layer was subjected to distillation. From the volatile fraction, 2,2,4,4-tetramethylpentanenitrile (**3c**) was obtained; bp 75°C/23 mmHg. The IR spectrum of **3c** showed an absorption at 2225 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum of **3c** in $CDCl_3$ showed three singlets, at τ 8.47 (2H, $-CH_2-$), 8.60 (6H, $2CH_3$), and 8.90 (9H, *t*-Bu).

Found: C, 77.90; H, 12.12; N, 10.33%. Calcd for $C_9H_{17}N$: C, 77.63; H, 12.31; N, 10.06%. From the second fraction (bp 90°C/5 mmHg), 2-(1,1,3,3-tetramethylbutyl)iminotetrahydrofuran (**5c**) was obtained in a yield of 54%. The NMR spectrum data of **5c** are given in Table 5. **5c** was treated with silicic acid to give γ-butyrolactone.

Reaction of 3,3-Bis(chloromethyl)oxetane (1k) with 2a. Into a solution of **2a** (2.49 g, 30 mmol) and **1k** (4.65 g, 30 mmol) and 30 m*l* of methylene chloride, $BF_3 \cdot Et_2O$ (1.56 g, 11 mol) was added dropwise with stirring at 0°C. The reaction mixture was then left to stand at room temperature for 1 day. After the removal of needle crystals (mp 177—178°C), the reaction mixture was quenched with 10% aqueous NaOH. The methylene dichloride layer was distilled to give 3,3-bis(chloromethyl)-4-*t*-butoxybutyronitirle (**8k**), bp 100—120°C/5 mmHg, in a yield of 7%. The IR spectrum of **8k** showed an absorption at 2235 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum of **8k** in CCl_4 showed signals at τ 6.35 (4H, s, $2ClCH_2-$), 6.58 (2H, s, *t*-BuOCH_2-), 7.43 (2H, s, $-CH_2-CN$), and 8.75 (9H, s, *t*-Bu).

Found: C, 51.21; H, 7.45; N, 5.97%. Calcd for $C_{10}H_{17}NOCl_2$: C, 50.43; H, 7.20; N, 5.88%. The needle crystals were washed twice with ethyl ether and, by analysis, were found to be the catalyst complex of 2-*t*-butylimino-4,4-bis(chloromethyl)tetrahydrofuran (**5k**). The IR spectrum of this complex showed an absorption at 1708 cm^{-1} which was attributed to cyclic imidate. The NMR spectrum in d_6-DMSO showed signals at τ 5.19 (2H, s, $-CH_2O-$), 6.10 (4H, s, $2ClCH_2-$), 6.80 (2H, s, $-CH_2CN$), and 8.65 (9H, s, *t*-Bu–).

Found: C, 36.96; H, 5.69; N, 4.53%. Calcd for $C_{10}H_{17}NOCl_2-BF_3$: C, 39.26; H, 5.60; N, 4.58%. β,β-Bis(chloromethyl)-γ-butyrolactone (**6k**) was obtained by the treatment of the catalyst complex of **5k** with aqueous NaOH; bp 100—120°C (5 mmHg). The IR spectrum of **6k** showed an absorption at 1770 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum of **6k** in $CDCl_3$ showed signals at τ 5.75 (2H, s, $-CH_2O-$), 6.24 (4H, s, $2ClCH_2-$), and 7.33 (2H, s, $-CH_2-C=O$). The analytical data are shown in Table 6.

Reaction of 3,3-Bis(iodomethyl)oxetane (1l) with 2a. This reaction was carried out under the conditions shown in Table 5. According to a procedure similar to that used in the isolation of **5a**, the methylene chloride extract was concentrated and subjected to glpc analysis. 3,3-Bis(iodomethyl)-4-*t*-butoxybutyronitrile (**8l**) was isolated by preparative glpc in a yield of 24%. The IR spectrum of **8l** showed an absorption at 2240 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum of **8l** in CCl_4 showed signals at τ 6.57 (4H, s, $2ICH_2-$), 6.60 (2H, s, $-CH_2O-$), 7.39 (2H, s, $-CH_2CN$), and 8.72 (9H, s, *t*-Bu).

Reaction of 3,3-Bis(ethoxymethyl)oxetane (1m) with 2a. This

reaction was carried out under the conditions shown in Table 4. According to a procedure similar to that used in the isolation of **5a**, the fraction boiling at 100—110°C (4 mmHg) was collected and then subjected to glpc analysis. By preparative glpc, 2-*t*-butylimino-4,4-bis(ethoxymethyl)tetrahydrofuran (**5m**) and 3,3-bis(ethoxymethyl)-4-*t*-butoxybutyronitrile (**8m**) were isolated separately in yields of 69% and 6% respectively. The IR spectrum of **4m** showed an absorption at 1715 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum data of **5m** are given in Table 5. Elemental analysis was carried out upon the corresponding lactone (**6m**) (Table 6). The IR spectrum of **8m**, showed an absorption at 2235 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum of **8m** in CCl_4 showed signals at τ 6.51 (4H, q, $2CH_3CH_2O$–), 6.60 (4H, s, $2CH_3CH_2OCH_2$–), 6.65 (2H, s, *t*-$BuOCH_2$–), 7.58 (2H, s, $-CH_2-CN$), 8.75 (9H, s, *t*-Bu), and 8.78 (6H, t, $2CH_3CH_2O$–).

Found: C, 65.96; H, 10.81; N, 5.43%. Calcd for $C_{14}H_{27}NO_3$: C, 65.33; H, 10.57; N, 5.44%.

*Reaction of 3,3-Bis(t-butoxymethyl)oxetane (**1n**) with **2c**.* Into a solution of **1n** (1.15 g, 5 mmol) and **2c** (1.39 g, 10 mmol) in 20 m*l* of methylene chloride, $BF_3 \cdot OEt_2$ (0.78 g, 5 mmol) was added dropwise with stirring at 0°C. The reaction mixture was then allowed to stand at room temperature for 3 days. According to a procedure similar to that used in the isolation of **5a**, 2-(1,1,3,3-tetramethylbutyl)imino-4,4-bis(*t*-butoxymethyl)tetrahydrofuran (**5n**) was obtained in a yield of 38%; bp 110—120°C/2 mmHg. The IR spectrum of **5n** showed an absorption at 1715 cm^{-1} ($\nu_{C\equiv N}$). The NMR spectrum data of **5n** are given in Table 5. Elemental analysis was carried out upon the corresponding lactone (**6n**) (Table 6).

Reaction of 8k with $Et_3O^+BF_4^-$. A solution of **8k** (0.43 g, 1.8 mmol) and $Et_3O^+BF_4^-$ (0.68 g, 4 mmol) in 10 m*l* of methylene chloride was allowed to stand at room temperature for 5 days. Then the reaction mixture was poured into aqueous NaOH, and the methylene chloride layer was treated with silicic acid. **6k** was thus obtained in a yield of 31%, as determined by glpc analysis.

*Reaction of β-Benzyloxybutyronitrile (**13**) with $Et_3O^+BF_4^-$.* A solution of **13** (0.88 g, 5 mmol) and $Et_3O^+BF_4^-$ (0.85 g, 5 mmol) in 5.5 m*l* of methylene chloride was allowed to stand at room temperature for 6 days. According to procedures similar to the above, γ-butyrolactone was thus obtained in a yield of 31% as determined by glpc analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2479—2483 (1971)

Decomposition of *m*-Nitrobenzenesulfonyl Peroxide in Several Solvents[1]

Yasukazu YOKOYAMA, Hiroko WADA, Michio KOBAYASHI,[2] and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received March 8, 1971)

Rates of decomposition of *m*-nitrobenzenesulfonyl peroxide in chloroform, nitrobenzene, chlorobenzene, and benzene were determined, and activation parameters were calculated. Products of decomposition in nitrobenzene were *m*-nitrophenyl *m*-nitrobenzenesulfonate and *m*-nitrobenzenesulfonic acid, whereas those in chloroform were *m*-nitrobenzenesulfonic acid, hexachloroethane, and phosgene (when air is present). Activation parameters and reaction products indicate that the reaction in chloroform involves homolytic cleavage of the O–O bond, whereas that in nitrobenzene involves electrophilic attack of the peroxide on aromatic nuclei. When sulfonyl-^{18}O labeled *m*-nitrobenzenesulfonyl peroxide was decomposed in benzene, about 35—36% of the label was found in the phenolic oxygen of *m*-nitrophenyl *m*-nitrobenzenesulfonate. This finding could be accounted for by a mechanism which involves a loose π-complex prior to the formation of a σ-complex.

The published chemistry of the bis(arenesulfonyl) peroxides is still very limited. In 1966 and 1970 Dannley and his co-workers[3] reported that the thermal decomposition of *m*-nitrobenzenesulfonyl peroxide in benzene, chlorobenzene, or toluene produced *m*-nitrobenzenesulfonic acid and the corresponding aryl *m*-nitrobenzenesulfonate. On the basis of the relative yields and orientations of the esters obtained from mixtures of benzene or toluene with chlorobenzene, they calculated partial rate factors and concluded that these products arose from electrophilic attack of the peroxide on aromatic compounds.

So far no good ways for production of sulfonyloxy radicals have been reported yet, and it appeared of interest to investigate the possibility of the homolytic decomposition of arenesulfonyl peroxides to produce arenesulfonyloxy radicals. Therefore, the decomposition of *m*-nitrobenzenesulfonyl peroxide (NBSP) has been investigated in chloroform and nitrobenzene; these solvents were chosen because they appeared least likely to receive electrophilic attack of the peroxide. Then the rate of decomposition in nitrobenzene was compared with those in chlorobenzene, benzene, and toluene. The results will be described in this paper.

Results and Discussion

Decomposition of NBSP in chloroform was followed by iodometric titration. The rates were of first order, and the first-order rate constants were 1.25, 4.88, and 9.90×10^{-5} sec^{-1} at 25.0, 35.0, and 40.0°C, respectively. From these values, E_a and $\Delta S^{\neq}$ were calculated to be 24.5 kcal/mol and 4.6 e.u., respectively. The products of

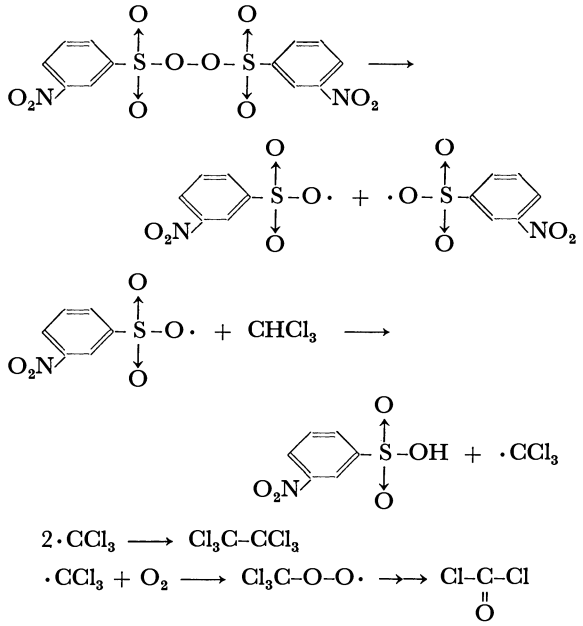
1) Organic Sulfur Compounds Part XXIV.
2) To whom correspondence should be addressed.
3) R. L. Dannley and G. E. Corbett, *J. Org. Chem.*, **31**, 153 (1966); R. L. Dannley, J. E. Gagen, and O. J. Stewart, *ibid.*, **35**, 3076 (1970).

decomposition in chloroform were analyzed, and the results are shown in Table 1.

Table 1. Products of decomposition of NBSP in chloroform

Product	mol/mol of NBSP	
	Absence of O_2	Presence of O_2
m-$O_2NC_6H_4SO_3H$	1.79	2.06
C_2Cl_6	0.03	—
$COCl_2$	—	1.58

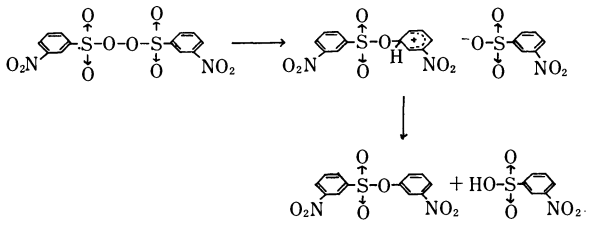
These results indicate that the decomposition of NBSP in chloroform involves homolytic cleavage of the O–O bond of NBSP, and the reaction steps are represented as follows.



$$2\cdot CCl_3 \longrightarrow Cl_3C\text{-}CCl_3$$

$$\cdot CCl_3 + O_2 \longrightarrow Cl_3C\text{-}O\text{-}O\cdot \longrightarrow\!\!\rightarrow Cl\text{-}\overset{\overset{O}{\|}}{C}\text{-}Cl$$

Then the decomposition of NBSP in nitrobenzene was investigated. The rates of decomposition in this solvent were also of first order in NBSP, and the rate constants were 1.40, 3.80, and 32.0×10^{-5} sec^{-1} at 20.0, 30.0, and 60.0°C, respectively. From these values E_a and $\Delta S^{\neq}$ were calculated to be 16.7 kcal/mol and −24 e.u., respectively. The products of decomposition in nitrobenzene are shown in Table 2. The products of decomposition and activation parameters indicate that the decomposition of NBSP in nitrobenzene is ionic, and the reaction probably proceeds as shown below.



Dannley and his co-workers did not determine the rate constants of decomposition of NBSP. Therefore it appeared of interest to determine the rate constants in various aromatic compounds. Kinetic studies were performed in chlorobenzene and benzene, and the results are shown in Table 3. Activation parameters and relative magnitude of rate constants are consistent with a mechanism which involves a nucleophilic attack of an aromatic compound on the peroxidic oxygen.

Table 2. Products of decomposition of NBSP in nitrobenzene

Product	mol/mol of NBSP

a) Calculated by extrapolation of log k *vs.* $1/T$ plots.
b) Ref. 3.

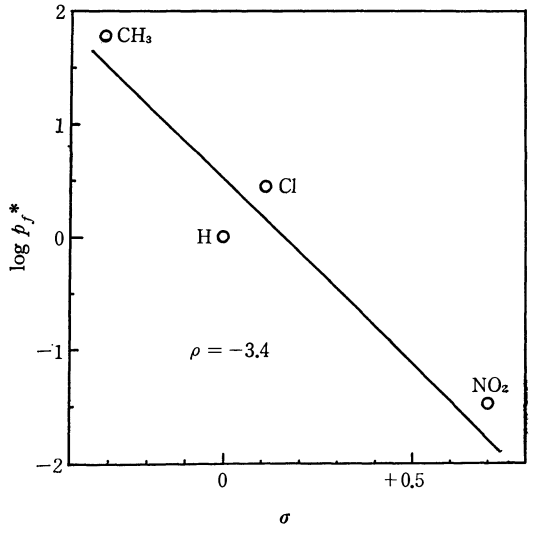

Fig. 1. Hammett plots for the decomposition of NBSP in aromatic solvents ($*f_f$=partial rate fatctor)

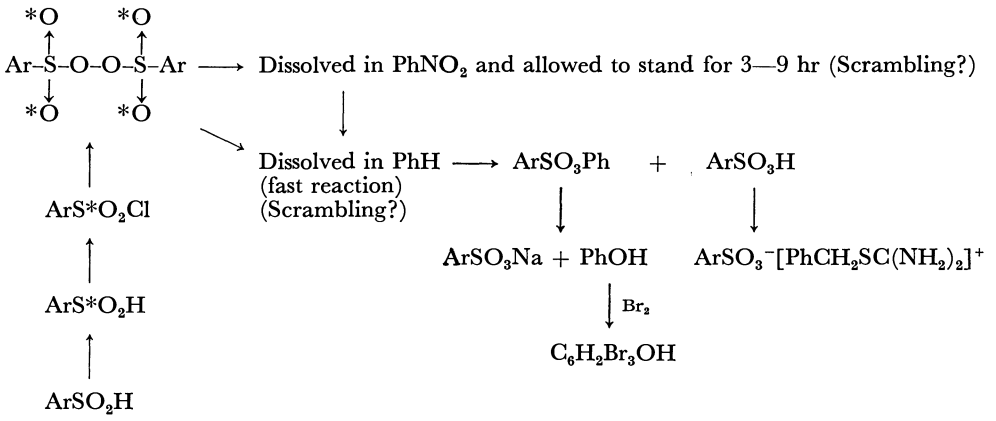
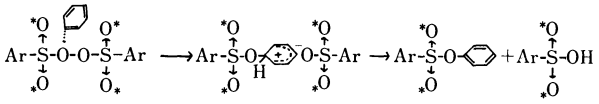


The rate constants at 10°C were compared and partial rate factors were calculated, which are shown in Table 4. Figure 1 is the Hammett plots of these partial rate factors against Hammett's σ values: ρ was found to be −3.4. The large negative ρ value indicates that the peroxidic oxygen is strongly electrophilic at the transition state, and the electron-releasing substituents on the aromatic solvents greatly facilitate the reaction.

In order to study the mechanism of the reaction between NBSP and aromatic compounds, sulfonyl-^{18}O labeled NBSP was prepared, and scrambling of the label was examined under various conditions. The experiments are summarized in the following scheme. The results are shown in Table 5.

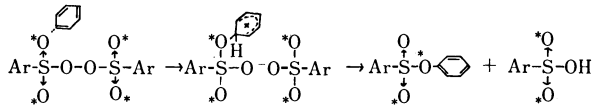
The following three cases are possible as the mechanisms of the reaction between NBSP and benzene.

A) Specific attack on peroxidic oxygen



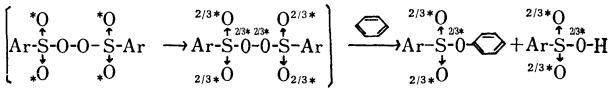
0% at phenolic oxygen

B) Specific attack on sulfonyl oxygen



100% at phenolic oxygen

C) Scrambling during preparation or standing, and then the reaction with benzene



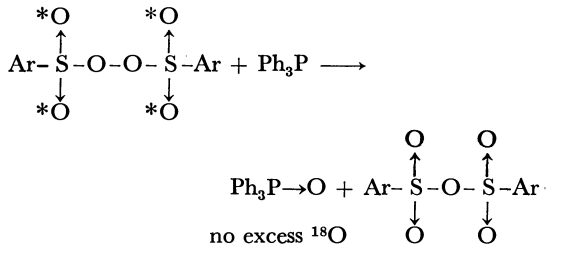
67% at phenolic oxygen

The possibility that the label was scrambled during the preparation of NBSP was excluded by use of the reaction of NBSP with triphenylphosphine. When the NBSP, prepared from *m*-nitrobenzenesulfonyl-^{18}O chloride with 1.08 excess ^{18}O atom %, was let to react with triphenylphosphine, the triphenylphosphine oxide produced was found to contain no excess oxygen-18.

Table 5. Excess oxygen-18 in the sulfonyl-labeled NBSP and the products of its reaction with benzene

Expt No.	NBSP used	Treatment	*m*-$O_2NC_6H_4SO_3C_6H_5$		*m*-$O_2NC_6H_4SO_3^-$ $[PhCH_2SC(NH_2)_2]^+$		C_6H_4BrOH	Y/X ×100
			Excess ^{18}O%	Excess ^{18}O% in SO_2	Excess ^{18}O%	Excess ^{18}O% in SO_2	Excess ^{18}O% (Y)	
1	A	$PhNO_2$ 6 hr; then PhH, 18°C	0.404	1.01	0.417	1.04	0.37	35
2	B	PhH, 16°C	0.415	1.04			0.40	36
3	B	$PhNO_2$ 3 hr; then PhH, 16°C	0.405	1.00			0.40	36
4	B	$PhNO_2$ 9 hr; then PhH, 16°C	0.408	1.01			0.39	36

NBSP No.	*m*-$O_2NC_6H_4S*O_2Cl$		(m-$O_2NC_6H_4S*O_2)_2O_2$	
	Excess ^{18}O%	Excess ^{18}O% in SO_2	Excess ^{18}O%	Excess ^{18}O% in SO_2 (X)
A	0.520	1.04	0.420	1.05
B	0.540	1.08	0.440	1.08



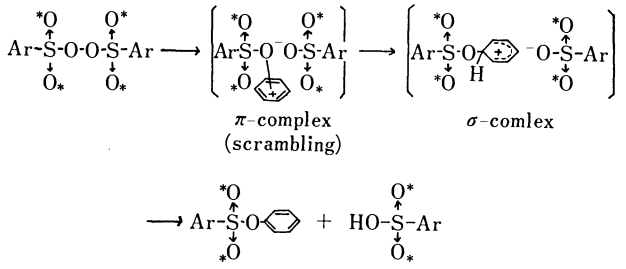
This finding establishes not only the non-occurrence of the scrambling of the label of NBSP during its synthesis but also the specific attack of triphenylphosphine upon the peroxidic oxygen of NBSP.

The data shown in Table 5 indicate that scrambling of the label does take place. When experiments 2, 3, and 4 are compared, it is clear that this scrambling does not take place during the long standing in nitrobenzene, but during the reaction with benzene. These findings indicate that Mechanism C) does not represent the reaction taking place.

The fact that the percentage of oxygen-18 excess found in the phenolic oxygen was neither 0% nor 100% shows that neither Mechanism A nor Mechanism B) alone can explain the reaction taking place. The figure 35—36% could be accounted for by an assumption that benzene molecules attack both peroxidic and sulfonyl oxygens. However, the possibility that the π-electrons of benzene nucleus attack negatively charged oxygen atoms of sulfonyl groups must be very small.

A more attractive mechanism for the reaction between NBSP and benzene is the following one.

D) Formation of a π-complex, and then a σ-complex.



Experimental

Materials. Nitrobenzene, chlorobenzene, benzene, toluene, and chloroform were purified by conventional procedures, and were distilled before use. Chloroform was used immediately after distillation in order to avoid contamination due to autooxidation.

m-Nitorobenzenesulfonyl peroxide was prepared from *m*-nitrobenzenesulfonyl chloride and hydrogen peroxide according to the method of Dannley and Corbett.[3] Yield, 12%, mp 112°C (dec.) (lit,[3] 112°C). The purity of the peroxide was determined by iodometric titration[4] to be 97.2%.

Determination of Rates of Reaction in Various Solvents. Into 100 m*l* of nitrobenzene in a flask placed in a bath of constant temperature, 0.625 g of NBSP (1.50 mmol) was added, and the flask was quickly shaken. At suitable intervals, certain amounts of the solution were withdrawn, and added to a flask containing crystals of potassium iodide. Then 10 m*l* of water was added, and the iodine liberated was titrated by a sodium thiosulfate solution.

Rates of reaction in other solvents were determined in a similar manner. Rates of reaction in chloroform were determined in sealed ampoules.

Products of Decomposition in Chloroform. *a) In a Degassed Chloroform*: A solution containing 0.941 g (2.33 mmol) of NBSP and 150 m*l* of chloroform was degassed, and placed in a bath of 40.0°C for 14 hr. The brown-colored solution was shaken with water. Evaporation of the aqueous extracts yielded 0.846 g (4.17 mmol) of *m*-nitrobenzenesulfonic acid, which was determined by converting it into *S*-benzylisothiuronium sulfonate. The chloroform solution was dried and evaporated. An oil obtained was analyzed by gas chromatography and it was found to contain 0.070 mmol of hexachloroethane.

b) In Chloroform Containing Air: A solution containing 0.260 mmol NBSP in 20 m*l* of chloroform was placed in a bath of 30.0°C for 29 hr in the presence of air. The solid *m*-nitrobenzenesulfonic acid which precipitated was decanted off, and aniline was added to the solution. Crystalline *N*, *N'*-diphenylurea formed weighed 0.0846 g (0.41 mmol); mp 233—234°C (decomp.). The same experiment was repeated for analysis of *m*-nitrobenzenesulfonic acid. After the decomposition the chloroform solution was washed with water. When the aqueous extracts were evaporated, 0.535 mmol of *m*-nitrobenzenesulfonic acid was obtained.

Products of Reaction in Nitrobenzene. In 20 m*l* of nitrobenzene 0.540 g (1.34 mmol) of NBSP was dissolved. A flask containing the solution was placed in a bath at 30.0°C for 2 days. Then the solution was washed with water several times. When the aqueous extracts were evaporated, *m*-nitrobenzenesulfonic acid was found, which was converted to its benzylisothiuronium salt (1.22 mmol).

When the nitrobenzene solution was evaporated, brownish solids remained, which was recrystallized in hexane and found to be *m*-nitrophenyl *m*-nitrobenzenesulfonate, mp 98—103°C. The ester was refluxed in 10 m*l* of 0.3N sodium hydroxide solution for 5 days, and the nitrophenol produced was methylated by use of dimethyl sulfate. When the nitroanisole obtained was analyzed by gas chromatography, only one peak was observed which corresponded to that of *m*-nitroanisole.

Preparation of Sulfonyl-^{18}O labeled m-*Nitrobenzenesulfonyl Peroxide.* In 41.5 m*l* of $H_2{}^{18}O$ (1.53 excess-^{18}O atom %) 23.5 g of *m*-nitrobenzenesulfinic acid was dissolved and the solution was heated at 90°C for 45 min after which the exchange of oxygen was almost complete. The sulfinic acid was converted to its sodium salt, which was treated with chlorine for 25 min and converted to *m*-nitrobenzenesulfonyl chloride. Crude crystals obtained (20 g) were recrystallized in hexane; yield, 10 g, mp 61—63°C. Its excess oxygen-18% was analyzed by mass spectrometry, and the results are shown in Table 5.

By using sulfonyl-^{18}O labeled *m*-nitrobenzenesulfonyl chloride and 30% hydrogen peroxide, sulfonyl-^{18}O labeled NBSP was prepared according to the method of Dannley and Corbett.[3]

Reaction of Sulfonyl-^{18}O labeled NBSP with Aromatic Solvents. As a representative case the experimental procedure used for Experiment 2 in Table 5 will be described. In 140 m*l* of purified nitrobenzene 2.002 g of sulfonyl-^{18}O labeled NBSP was dissolved, and the solution was stirred for 6 hr under a nitrogen atmosphere at 18°C. Then 300 m*l* of purified benzene was added, and the mixture was allowed to stand for 48 hr under a nitrogen atmosphere.

The reaction mixture was extracted with water. The *m*-nitrobenzenesulfonic acid in the aqueous extracts were con-

4) R. N. Haszeldine, R. B. Heslop, and J. W. Lethbridge, *J. Chem. Soc.*, **1964**, 4902.

verted to its *S*-benzylisothiuronium salt, which amounted to 1.405 g (76.5%). Crude crystals were recrystallized in ethanol-water, and the purified crystals (0.10 g) melting at 140.0—142.3°C were subjected to the mass-spectrometric analysis.

The aromatic hydrocarbon layer was dried over anhydrous magnesium sulfate, and the solvents were distilled under reduced pressure. The residue was chromatographed by a column containing 50 g of Florisil, and 1.008 g of phenyl *m*-nitrobenzenesulfonate was obtained from fractions eluted by hexane-benzene; yield, 72.4%. Crude crystals were recrystallized in methanol, and the purified crystals melting at 91—91.5°C were subjected to the mass-spectrometric analysis.

In order to separate the phenolic oxygen from the sulfonyl oxygen the ester was hydrolyzed. In 5 m*l* of a 0.3N sodium hydroxide solution in 70% dioxane-30% water, 0.252 g of phenyl *m*-nitrobenzenesulfonate was added, and the mixture was heated at 60°C in an ampoule for 7 days. After the solution was acidified by hydrochloric acid, a Br_2-KBr solution was added and white precipitates formed were washed with a sodium hydrogen sulfite solution and then with water. After drying, crude crystals of 2,4,6-tribromophenol weighed 0.335 g. They were purified by sublimation at 140°C under reduced pressure, and the purified crystals weighed 0.227 g (75.7%); mp 88.5—91.0°C.

The possibility that the oxygens of phenyl *m*-nitrobenzenesulfonate are scrambled during its hydrolysis can be excluded on the basis of the findings of Bunton and Frei, who studied the alkaline hydrolysis of phenyl *p*-toluenesulfonate in dioxane-water.[5] They showed that no C–O bonds were cleaved during hydrolysis and the S–O bond fission took place exclusively.

Reaction of Sulfonyl-^{18}O labeled NBSP with Triphenylphosphine. A solution of 2.0 g of triphenylphosphine in 20 m*l* of dichloromethane was slowly added to a stirred solution of 0.70 g of sulfonyl-^{18}O labeled NBSP in 50 m*l* of dichloromethane at room temperature. The reaction mixture was extracted with water, and the aqueous extracts were evaporated. Crystals of *m*-nitrobenzenesulfonic acid obtained were converted to its *S*-benzylisothiuronium salt, which amounted to 0.683 g. The dichloromethane solution was evaporated and the residue was washed with ether. The ether-insoluble solids were dissolved in benzene, and the solution was filtered in order to remove benzene-insoluble solids. When the benzene filtrate was evaporated, 0.480 g of white solids of triphenylphosphine oxide were obtained. They were recrystallized from ether, and purified crystals were subjected to the mass-spectrometric analysis.

Oxygen-18 Analysis. The oxygen-18 analyses were carried out according to the method of Rittenberg and Ponticorvo.[6] Each sample was pyrolyzed in the presence of mercuric chloride and mercuric cyanide at 400°C for 4 hr, and the oxygen-18 atom% of the carbon dioxide produced was determined by use of a Hitachi RMU-6D type mass spectrometer.

Grateful acknowledgement is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

A New Route to Polycondensed Aromatics: Photolytic Formation of Triphenylene and Dibenzo[*fg*, *op*]naphthacene Ring Systems[1]

Takeo SATO, Shigeru SHIMADA, and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received March 12, 1971)

Application of photo-aryl coupling reactions for the syntheses of triphenylene and dibenzo[*fg*,*op*]naphthacene was explored. Three types of reactions were developed: Photocyclodehydrogenation of polyphenyl compounds, photolytic reactions of iodoarenes, and photocyclodehydrohalogenation of halogenopolyaryls. The effects of solvent, oxidant, and wavelength on the photocyclization of *o*-terphenyl and 2,2′-diphenylbiphenyl to the triphenylene and naphthacene, respectively. were examined. The conversion was best achieved by the reaction carried out in an aromatic solvent in the presence of an equimolar amount of iodine using a quartz or a Vycor vessel. Versatility of the processes was shown by the formation of naphthacene starting from either 2,2′-diphenylbiphenyl (57% yield), 2,2′-bis(2-chlorophenyl)biphenyl (67%), 1,2,3-triphenylbenzene (21%), or 2,6-diiodobiphenyl.

Difficulties in obtaining pure samples of polycondensed aromatic compounds are largely overcome by utilizing the intramolecular photo-aryl coupling reaction.[2] Versatility of the process was examined by applying it to the synthesis of phenanthrene,[3] triphenylene,[4,5] pyrene,[6,7,8] and dibenzo[*fg*, *op*]naphthacene (I) ring systems.[1]

In this paper we wish to describe three types of photochemical processes, namely, a cyclodehydrogenation reaction of polyphenyls, a photolytic reaction of iodoarenes, and a cyclodehydrohalogenation reaction of halogenopolyphenyls, all aiming at the development of a synthetic means for triphenylene and dibenzonaphthacene I.

Results and Discussion

Photolytic Cyclodehydrogenation of Polyphenyls. Triphenylene was obtained in nearly quantitative yield by the irradiation of a dilute benzene solution of *o*-terphenyl (*ca.* 1.7×10^{-2}M) containing an equimolar amount of iodine (Scheme 1).[4] Similarly photocyclodehydrogenation of 2,2′-diphenylbiphenyl and 1,2,3-triphenylbenzene produced dibenzonaphthacene I in yields of 57% and 21%, respectively, as reported in a preliminary paper (Scheme 1)[1].

Representative examples for the preparation of triphenylene and I are shown in Tables 1 and 2, respectively. For comparison some of the previous data[4] are also included in Table 1.

The following generalization was deduced from a series of experiments: The reaction can be carried out under a stream of nitrogen but the presence of oxygen does not impede cyclization. Oxygen alone, however, is not effective as an oxidant. An equimolar amount of iodine is required to facilitate the reaction. As for solvent, aromatic solvents such as benzene or chlorobenzene are more suitable than cyclohexane. Use of a

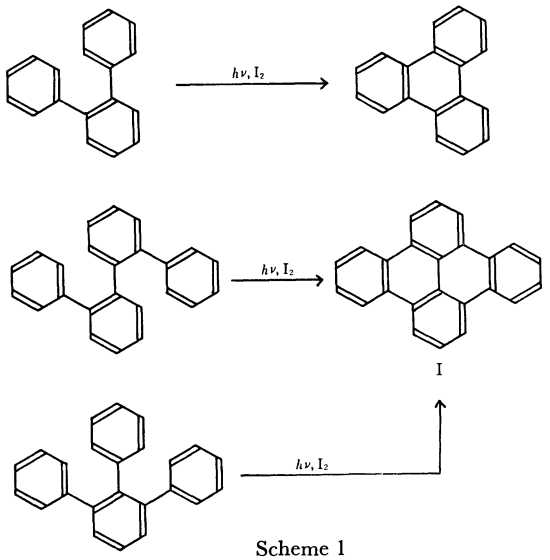
a) Irradiation was carried out for 72 hr under nitrogen.



I

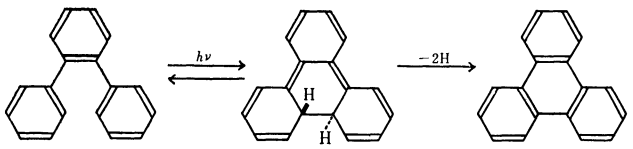
Scheme 1

benzene-cyclohexane mixture gave a medium result.

This is in a sharp contrast to the related photocyclization of *cis*-stilbene to phenanthrene, for which cyclohexane is a preferred solvent and both oxygen and iodine are equally effective.[9)] Only a catalytic amount of iodine is enough to effect cyclization.

Wavelength effects were studied by carrying out photolysis using various filters. Although the reaction proceeded satisfactorily either with a quartz or a Vycor filter, it was suppressed by a Pyrex filter. No reaction occurred when a glass filter was inserted.

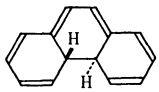
A possible pathway of the reaction is shown in the following equation for the case of *o*-terphenyl as an example. *o*-Terphenyl shows a UV maximum at 235 nm in ethanol. By photoexcitation, the molecules give dihydrotriphenylene II via a concerted process. Dehydrogenation of II generates triphenylene.



II

9) F. B. Mallory, C. S. Wood, and J. T. Gordon, *J. Amer. Chem. Soc.*, **86**, 3094 (1964); C. S. Wood and F. B. Mallory, *J. Org. Chem.*, **29**, 3373 (1964); F. R. Stermitz in O. L. Chapman ed. "Organic Photochemistry," Vol. 1, Marcel Dekker, New York (1967), p. 249; E. V. Blackburn and C. J. Timmons, *Quart. Revs.*, **23**, 482 (1969) and papers cited therein.

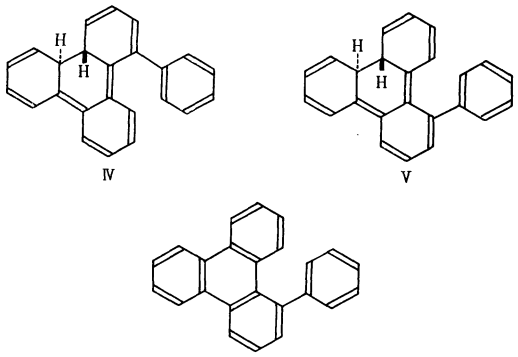
This sequence is formulated after the well-studied *cis*-stilbene - phenanthrene reaction,[9)] for which the structure of the intermediate, 4a,4b-dihydrophenanthrene (III), was determined beyond doubt either by chemical and spectroscopic methods[10)] or by direct trapping.[11)] A *trans* relationship of the tertiary hydrogens as shown in II and III is based on the conrotatory photocyclization of 1,3,5-hexatriene systems.[12)]



III

Spectral changes of a benzene solution of *o*-terphenyl during irradiation indicated the appearance of new bands at ~360, 375, and 400 nm, possibly due to II. Most peaks of triphenylene were masked by absorption due to the solvent. Detailed spectral and kinetic studies on the formation of II will be reported elsewhere.[13)]

With 2,2′-diphenylbiphenyl and 1,2,3-triphenylbenzene the structure of the intermediate can be written as IV and V. Although a stepwise cyclization *via* IV or V is favored to a simultaneous double cyclization



IV V

VI

reaction, no 1-phenyltriphenylene (VI) was isolated from the reaction mixture. Even when the conversion was incomplete, the rest of the material was found to be the starting compound. It is highly probable that VI, once formed, is rapidly cyclized to I since the molecular arrangement becomes favorable for further ring closure.[14)]

13) Upon irradiation benzene solutions of *o*-terphenyl exhibit spectral changes under both oxygen and deaerated conditions. On the other hand, no spectral changes occur in cyclohexane.

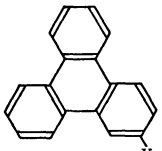
14) As a measure of photocyclization, the sum of the free valence numbers in the first excited state of atoms undergoing cyclization is calculated by the HMO method. The values found for 2,2′-diphenylbiphenyl, 1,2,3-triphenylbenzene, and 1-phenyltriphenylene VI are 0.962, 1.003, and 0.962, respectively. For details, see T. Sato and T. Morita, This Bulletin, in press.

Inability of oxygen to enter into a hydrogen abstraction step seems to reflect either an essential difference in the ability of hydrogen abstraction between oxygen and iodine or a factor concerning concentration. The latter possibility is indicated by experiments using a varying amount of iodine. Presumably tertiary hydrogens of II are less reactive than those of III, since rather higher concentration of II can be expected in the photoequilibrium when a favorable geometry for cyclization and extra conjugation extending over four rings are considered.

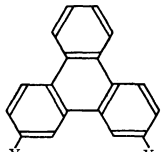
Incident light will be largely absorbed by solvent benzene. Enhancement of the reaction rate by the aromatic solvent indicates the possibility of sensitization. Action of iodine through complexation with the aromatic ring must also be considered.

The photocyclization of polyphenyl is proved to be an efficient synthetic method for certain polycondensed aromatics and may be further applied in various fields. Besides involving high yields and simple procedures the process has a simplified isolation technique. With triphenylene pure material was obtainable merely by concentrating the benzene solution after it was washed with sodium thiosulfate. It is more simple in the case of I, since the material separates out of the solution during the course of formation resulting from irradiation. Single recrystallization of the collected material from xylene gave pure I, mp 351—352°C.

Starting from substituted *o*-terpehnyls a number of triphenylene derivatives such as VII and VIII, were prepared.[5]



VII



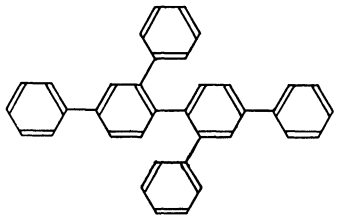
VIII

Substituents include CH_3, C_6H_5, Br, Cl, F, $COOC_2H_5$, and CN. The preparation of 2-cyanotriphenyelne, (VII/CN) and ethyl triphenylene-2-carboxylate (VII/$COOC_2H_5$) are described in Experimental. Most of the available synthetic methods known for triphenylene and its derivatives[15] can not be modified to allow introduction of such a variety of functional groups. Syntheses via trimerization are used to give some sym.-trisubstituted triphenylenes.[16] The electrophilic substitution reaction of triphenylene results in the formation of both 1- and 2-substituted compounds and it is difficult to control and direct the orientation.[17]

Only synthetic method reported for I is that of Sako,[18] who obtained I in 35—40% yield by decomposition of the bis-diazonium salt derived from 2,2′-diamino-6,6′-diphenylbiphenyl. There are several reports on the formation of I though not suitable for synthetic purposes.[19]

A possible alternative synthesis after Scheme 1 would be a thermal cyclodehydrogenation reaction over metal catalysts. The thermal conversion of *o*-terphenyl to triphenylene required high temperatures of 625°C with chromia-on-alumina (10% yield)[20] or 490°C with palladium-platinum-charcoal (63% yield).[21] Most substituents would not survive such severe reaction conditions. Attempted cyclodehydrogenation of 2,2′-diphenylbiphenyl using the metal catalyst produced a phenyl migration product, 2-phenyltriphenylene (VII/C_6H_5). Neither 1-phenyltriphenylene (VI) nor I was produced.

Concerning the limitations of the photocyclodehydrogenation reaction, no cyclization occurred with nitro-*o*-terphenyls.[5] Iodo-*o*-terphenyls underwent extensive C–I homolysis.[5] A similar limitation was also found for stilbenes, for which the effect of substituents on the quantum yields was studied.[22] No cyclization occurred with diphenylquaterphenyl (IX).



IX

Photolytic Reactions of Iodoarenes. Due to low bond dissociation energies (~55 kcal/mol) of the C–I bond, iodoarenes undergo a facile photolysis reaction to give aryl and iodo radicals.[23,24] Application to biaryl syntheses was described by Wolf *et al.*[25]

Polyphenylation is expected when polyiodoarenes are photolyzed in benzene. Several examples are shown in Table 3. Liberated iodine can effect photocyclization when an *o*-terphenyl structure is present. Such an example is illustrated in the accompanying equation.[5]

The photolysis reactions of polyiodoarenes are summarized in Table 4. The construction of highly con-

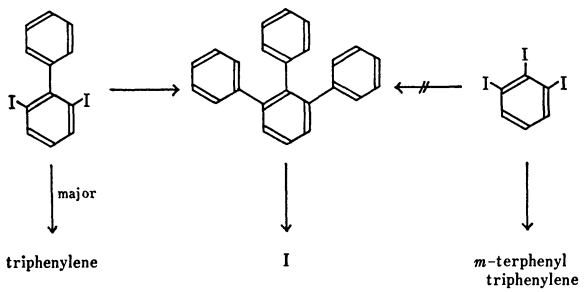
densed ring systems would become possible *via* polyphenylation-cyclization scheme.

The photolysis of *o*-diiodobenzene in benzene produced triphenylene in addition to 2-iodobiphenyl and *o*-terphenyl. Similar results have been reported[26)] and the formation of a benzyne intermediate was postulated.[26,27)] The yield of triphenylene was improved by starting from 2-iodobiphenyl.

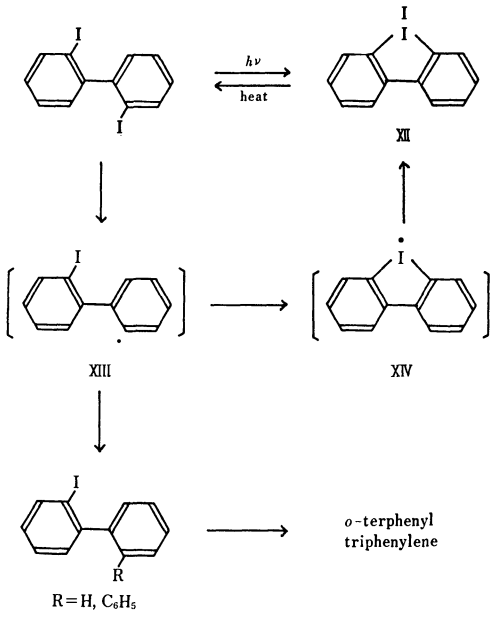
The photolysis of 1,2,3-triiodobenzene gave *m*-terphenyl and triphenylene but no 1,2,3-triphenylbenzene and/or its cyclization products. 2,6-Diiodobiphenyl produced I in a low yield, but again an alternative route leading to triphenylene was the major one (Scheme 2).



triphenylene I *m*-terphenyl triphenylene

Scheme 2

As a possible precursor to I, 2,2′-diiodobiphenyl was photolyzed in benzene. However, a solid material was produced which was identified as dibenziodolium iodide (XII), mp 213—214°C decomp.[28)] 2,2′-Diiodobiphenyl was regenerated from compound XII either by heating alone or by refluxing in xylene.[28)] Formation of XII is explained by assuming an intermediacy of iodobiphenylyl radical XIII. An intramolecular radical attack on iodine to give XIV is followed by a radical recombination step (Scheme 3). That an aryl



Scheme 3

radical has a very high affinity to iodine has been noticed earlier.[29)] Other products of the reaction include *o*-iodobiphenyl, *o*-terphenyl and triphenylene, the formation of which can also be explained by assuming XIII. *o*-Terphenyl radical XVII derived from 2-iodo-*o*-

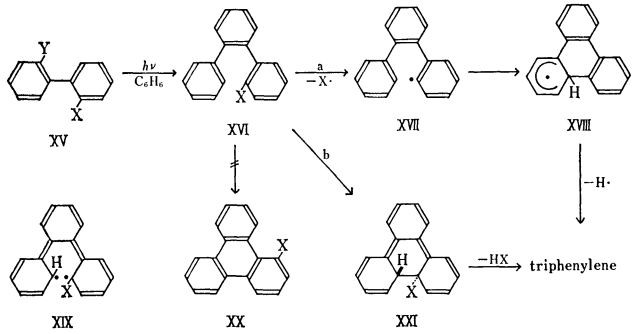
terphenyl undergoes an intramolecular arylation to give XVIII, from which triphenylene produced (Scheme 4, route a, X=Y=I).

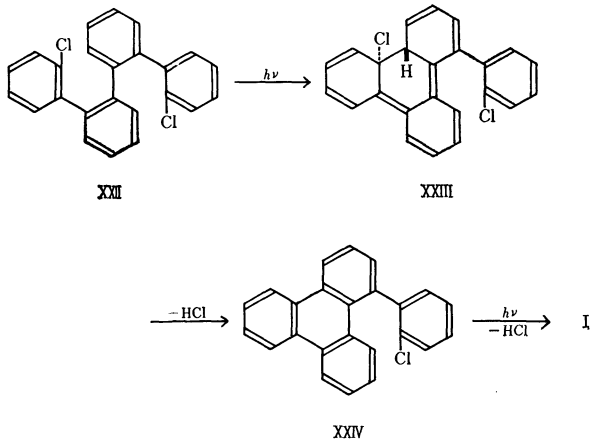
Photolytic Cyclodehydrohalogenation of o-Halogenopolyphenyl. Photolytic reactions of iodoarenes were further examined using 2,2′-dihalogenobiphenyls (XV). Irradiation of 2-chloro- and 2-bromo-2′-iodobiphenyls (XV: X=Cl, Br; Y=I) for 79 hr using a 1-kW high-pressure lamp gave triphenylene in 37 and 25% yields respectively. The course of the reaction is illustrated in Scheme 4, route b. 2-Halogeno-*o*-terphenyl (XVI)



Scheme 4

formed by photolytic phenylation of XV will cyclize to XXI, dehydrohalogenation of which affords triphenylene. A higher electron density at the carbon atom carrying a halogen by its conjugation effect (*e.g.* XIX) is assumed to promote reaction coupled with ready extrusion of hydrogen halide. 2,2′-Dibromobiphenyl (XV, X=Y=Br) was recovered unchanged on irradiation with a high-pressure lamp but was converted to triphenylene (20%) by using a 100-W low-pressure lamp.

An alternative way of cyclization to give 1-halogenotriphenylenes (XX) was not observed although oxidative cyclization leading to them was possible. At least with the chloride it is not likely that triphenylene is formed by the homolysis of C–X bonds after route a. The photolysis proceeds with increasing difficulties as the strength of the C–X bond increases.[24] Under the conditions studied no C–Cl cleavage occurred through C–Br bonds were partially photolyzed particularly when a low-pressure lamp was used.[5] Under conditions where extensive cleavage of the C–Br bond occurs triphenylene formation is possible by both routes a and b.



Scheme 5

In contrast to the oxidative cyclizations stated in the preceding sections, the cyclodehydrohalogenation reaction requires no added oxidant. When a benzene solution of 2,2′-bis(2-chlorophenyl)biphenyl (XXII) was irradiated for 20 hr under a stream of nitrogen I was obtained in 67% yield. The course of the reaction assuming an intermediacy of XXIII is shown in Scheme 5. No triphenylene derivative XXIV was detected. The reaction mechanism is in agreement with recent findings on the photolysis of certain *o*-halogenoarenes.[30]

Experimental

Starting Materials. Most compounds were purchased or prepared by the methods described in literature. Several new syntheses and modified procedures will be given below.

1,2,3- and 1,3,5-Triiodobenzene. By reductive deamination[31] of 3,4,5-triiodoaniline[31] 1,2,3- and 1,3,5-triiodobenzenes were produced, and then separated by column chromatography on alumina.

1,2,3-Triiodobenzene was recrystallized from ethanol as colorless plates, mp 110—113°C.[32]

Found: C, 16.07; H, 0.83%. Calcd for $C_6H_3I_3$: C, 15.81; H, 0.66%.

1,3,5-Triiodobenzene was recrystallized from ethanol as colorless needles, mp 177—179°C.[32] IR (KBr): 1735, 1700, 840 cm^{-1}.

Found: C, 16.02; H, 0.70%. Calcd for $C_6H_3I_3$: C, 15.81; H, 0.66%.

Dihalogenobiphenyls. They were prepared by the thermal decomposition of dibenziodolium halides[33] prepared from 2-iodosylbiphenyl by treatment with sulfuric acid followed by anion exchange.

Thermal reactions of dibenziodolium chloride, bromide, and iodide were carried out at 295, 290, and 210°C respectively.[34,35] From each reaction mixture the corresponding 2-halogeno-2′-iodobiphenyls were obtained as the major product. Each halide was purified by column chromatography on alumina: 2-chloro-2′-iodobiphenyl, mp 60—62°C; 2-bromo-2′-iodobiphenyl, mp 87.5—88°C; 2,2′-diiodobiphenyl, mp 108.5—110°C.

2,6-Diiodobiphenyl. 2,6-Diaminobiphenyl prepared by the reduction of 2,6-dinitrobiphenyl[36] was bis-diazotized and then decomposed with potassium iodide. After purification by column chromatography on alumina, it was recrystallized from *n*-hexane as prisms, mp 80—81°C. IR (KBr): 760, 720, 690, and 680 cm^{-1}.

Found: C, 35.62; H, 2.02%. Calcd for $C_{12}H_8I_2$: C, 35.49; H, 2.00%.

4′-Iodo-m-terphenyl. This was prepared from 4′-amino-*m*-terphenyl by diazotization followed by decomposition with potassium iodide, bp 183—187°C/0.2—0.3 mmHg. IR (KBr): 1000, 890, 820, 750, and 690 cm^{-1}.

Found: C, 60.72; H, 3.58%. Calcd for $C_{18}H_{13}I$: C, 60.70;

H, 3.68%.

4-Cyano-o-terphenyl. a) 4-Amino-*o*-terphenyl[5] was diazotized and treated with cuprous cyanide solution in the usual manner. Vacuum distillation at 158—160°C/1 mmHg produced colorless needles, mp 122.5—123.5°C, recrystallization from *n*-hexane. IR (KBr): 2220 cm^{-1}.

b) A mixture of 17 g (0.055 mol) of 4-bromo-*o*-terphenyl[5] 5.2 g (0.058 mol) of cuprous cyanide in 9 m*l* of pyridine was refluxed for 8 hr.[38] After washing with aqeous ammonia the mixture was extracted with benzene. Extraction with *n*-hexane gave 8.2 g of 4-cyano-*o*-terphenyl.

Found: C, 89.37; H, 5.20; N, 5.31%. Calcd for $C_{19}H_{13}N$: C, 89.38; H, 5.13; N, 5.49%.

Ethyl o-Terphenyl-4-carboxylate. A solution of 10 g (0.039 mol) of 4-cyano-*o*-terphenyl, 80 m*l* of ethanol and 28 m*l* of concentrated sulfuric acid was refluxed for 7 hr was obtained 3.8 g (32%) of the ethyl ester by chromatographical purification. IR (KBr): 1720 cm^{-1} as colorless needles, mp 81—81.5°C. IR (KBr): 1720 cm^{-1}.

Found: C, 83.69; H, 6.02%. Calcd for $C_{21}H_{18}O_2$: C, 83.42; H, 6.00%.

1,2,3-Triphenylbenzene. This was prepared by photolysis of 2,6-diiodobiphenyl in benzene in a 24% yield, mp 156—157°C. IR (KBr): 750, and 690 cm^{-1}.

Found: C, 93.75; H, 6.00%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

2,2'-Bis(2-chlorophenyl)biphenyl (XXII). This was prepared from 2-chloro-2'-iodobiphenyl by the Ullmann reaction carried out at 250—260°C for 20 min, colorless plates from *n*-hexane, mp 129.5—130.5°C. IR (KBr): 760 and 735 cm^{-1}.

Found: C, 76.26; H, 4.30%. Calcd for $C_{24}H_{16}Cl_2$: C, 76.81; H, 4.30%.

3',2''-Diphenyl-1,1':4',1'':4'',1'''-quaterphenyl (X). This was prepared by the Ullmann reaction of 4'-iodo-*m*-terphenyl at 280—300°C, mp>350°C. IR (KBr): 890, 830, 755, and 690 cm^{-1}.

Found: C, 93.71; H, 5.64%. Calcd for $C_{36}H_{26}$; C, 94.28; H, 5.72%.

Photochemical Reactions. Either a 1-kW high-pressure lamp (Wako HBC-1000) or a 100-W low-pressure lamp (Ushio UL2-1HQ) was used as a light source for the external irradiation of sample solutions. For experiments using the high-pressure lamp the set-up was immersed in a bucket kept cool with running water. The spiral-shaped low-pressure lamp was used in combination with a quartz cooling unit into which a reaction vessel made of Vycor was inserted.

Photolyses were carried out under a nitrogen current unless otherwise stated using sample solutions with concentration of *ca.* 1.7×10^{-2}M in appropriate solvents.

The analysis of the reaction mixture was performed by column chromatography on alumina by eluting with *n*-hexane or benzene, or a mixture of the two. Materials were characterized by comparing their physical properties and spectral data with those of the authentic compounds. For a qualitative study gas chromatographical analysis was also employed using a Hitachi K-53 machine in combination with XE-60 silicone gum rubber on chromosorb W column.

Representative results are summarized in Tables 1—4. The preparation of triphenylene and I by the photolytic cyclodehydrogenation reaction of polyphenyl compounds are compiled in Tables 1 and 2. Application of photolytic phenylation reaction is summarized in Tables 3 and 4. Typical examples are given.

1,1':4',1'':4'',1'''-Quaterphenyl. The irradiation of a benzene solution (60 m*l*) containing 403 mg (0.99 mmol) of 4,4'-diiodobiphenyl for 71 hr produced the quaterphenyl in 63% yield, recrystallized from benzene, mp 304—305°C.[39] IR (KBr): 820, 750, and 680 cm^{-1}. UV ($CHCl_3$): 298 nm (log ε 4.75).

Found: C, 94.37; H, 6.08%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

1,3,5-Triphenylbenzene. A solution of 481 mg (1.06 mmol) of 1,3,5-triiodobenzene in 60 m*l* of benzene was irradiated for 147 hr. 1,3,5-Triphenylbenzene was obtained in 79% yield, recrystallized from ethanol as colorless needles, mp 168—170°C.[32] IR (KBr): 870, 740, and 690 cm^{-1}.

Found: C, 93.91; H, 5.90%. Calcd for $C_{24}H_{18}$: C, 94.08, H, 5.92%.

Photolysis of 4'-Iodo-m-terphenyl. A benzene solution (60 m*l*) containing 362.7 mg (1.02 mmol) of 4'-iodo-*m*-terphenyl was irradiated for 48 hr. The product was separated by column chromatography on alumina to give *m*-terphenyl (29%), 2'-phenyl-*p*-terphenyl (5%) and 2-phenyl-triphenylene (28%), mp 180.5—181°C.[5] Recovery of the starting material was 25%.

2'-Phenyl-*p*-terphenyl was characterized by elemental analysis.

Found: C, 93.32; H, 5.88%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

Photolysis of 2,2'-Diiodobiphenyl. Irradiation of 2,2'-diiodobiphenyl resulted in the formation of an insoluble matter which began to separate immediately after the reaction. It was identified as dibenziodolium iodide, mp 210°C dec.,[28] and was obtained in 21% yield.

Gas chromatography analysis of the benzene solution identified 2-iodobiphenyl (1%), *o*-terphenyl (1%), starting material (23%), and triphenylene (3%) in the order of the retention times (Table 4).

Triphenylene. *a) From o-Terphenyl.* Triphenylene was obtained in an almost 90% yield by the photolysis of *o*-terphenyl and iodine in benzene (Table 1). The experimental procedures are essentially the same as before.[4]

b) From 2-Chloro- and -bromo-2'-iodobiphenyls: A solution of 287 mg (0.91 mmol) of 2-chloro-2'-iodobiphenyl in 60 m*l* of benzene was irradiated with the high-pressure lamp for 79 hr. Triphenylene (37%) and the starting material (14%) were isolated.

From 2-bromo-2'-iodobiphenyl 25% of triphenylene was produced, 16% of the starting material being recovered.

Upon irradiation with the low-pressure lamp for 65 hr 2,2'-dibromobiphenyl afforded 20% yield of triphenylene.

2-Cyanotriphenylene (VII, R=CN). A benzene solution (60 m*l*) of 256 mg (1.0 mmol) of 4-cyano-*o*-terphenyl and 258 mg (1.01 mmol) of iodine was irradiated in a quartz vessel using the high-pressure lamp for 96 hr. By repeated recrystallizations from ethanol and chromatography on Florisil 28 mg of colorless needles was obtained, mp 220—221°C. IR (KBr): 2220 cm^{-1}.

Found: C, 89.14; H, 4.39%. Calcd for $C_{19}H_{11}N$: C,90.09; H, 4.38%.

Ethyl Triphenylene-2-carboxylate (VII, R=$COOC_2H_5$). A benzene solution (60 m*l*) of 305 mg (1.01 mmol) of ethyl *o*-terphenyl-4-carboxylate and 256 mg (1.01 mmol) of iodine was irradiated as above. Colorless needles were obtained, mp 129.5—130.5°C, from ethanol. IR (KBr): 1700 cm^{-1}.

Found: C, 83.70; H, 5.34%. Calcd for $C_{21}H_{16}O_2$: C,

83.98; H, 5.37%.

Dibenzo[fg,op]*naphthacene (I).* *a) From 2,2′-Diphenylbiphenyl*: A solution of 310 mg (1.0 mmol) of 2,2′-diphenylbiphenyl, mp 116—117°C,[39] λ_{max} 228 nm (log ε 4.54), and 265 mg (1.0 mmol) of iodine in 60 m*l* of benzene was irradiated with a low-pressure lamp through a Vycor vessel. After 72 hr, a crystalline deposit was collected and was recrystallized from xylene, pale yellow prisms, mp 351—352°C,[18] yield 57%. UV (C_6H_6): 373 (log ε 2.36), 363 (2.76), 354 (2.85), 328.5 (4.21), 315 (4.26) and 288 nm (4.73).

Found: C, 95.66; H, 4.71%. Calcd for $C_{24}H_{14}$: C, 95.33; H, 4.67%.

b) From 1,3,5-Triphenylbenzene: Compound I was obtained in 21% yield (Table 2).

c) From 2,2′-Bis(2-chlorophenyl)biphenyl (XXII): A solution of 366 mg (0.98 mmol) of XXII in 60 m*l* of benzene was irradiated with the low-pressure lamp for 20 hr to give 67% of I.

d) From 2,6-Diiodobiphenyl: Among other products compound I was obtained in a low yield (Table 4).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2490—2495 (1971)

Aromatic Bromination by the Use of Organic and Inorganic Thallium Salts[1)]

Sakae UEMURA, Kazuhiro SOHMA, Masaya OKANO, and Katsuhiko ICHIKAWA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto*

(Received March 15, 1971)

Using organic and inorganic Tl salts, the following aromatic brominations were carried out in a CCl_4 or HOAc solvent and were found to occur very smoothly; (A) aromatic bromination with $TlBr_3 \cdot 4H_2O$, (B) aromatic bromination with Br_2 in the presence of Tl(III) and Tl(I) salts, and (C) the bromination of arylthallium(III) compounds. From a study of the relative rates and selectivities of benzene and toluene, it was deduced that an arylthallium(III) compound was not involved as an intermediate in the A and B reactions, that Tl(III) salts were more effective catalysts than Tl(I) salts for the B bromination, and that the A reaction was essentially identical with the B reaction with the $TlBr_3 \cdot 4H_2O$ catalyst. By considering the difference in the catalytic behavior of Tl(III) and Tl(I) salts in the B reaction, probable mechanisms are suggested.

Aromatic bromination with bromine in the presence of metallic iron or Lewis acid catalysts (*e.g.*, $FeCl_3$, $FeBr_3$, $AlCl_3$, $AlBr_3$, and $ZnCl_2$) is a well-known reaction.[2)] On the other hand, bromination with a certain metal halide itself, *e.g.*, $CuBr_2$, has also been reported.[3)] In view of the effectiveness of Tl(III) halides as Lewis-acid catalysts,[4-6)] it seems that it would be of interest to know their functions in the two types of bromination described above. Recently it was reported in a communication that, in the presence of Tl(III) acetate, bromine reacted with aromatics to give pure monobromocompounds.[7)] In addition, although it has been known that arylmercury(II) compounds react smoothly with bromine to give aryl bromide,[8)] there have been no reports about the analogous bromination of arylthallium(III) compounds. Hence, some characteristics of the following bromination reatcions were examined; (A) aromatic bromination with $TlBr_3 \cdot 4H_2O$, (B) aromatic bromination with bromine in the presence of Tl(III) and Tl(I) catalysts, and (C) the bromination of arylthallium(III) compounds with bromine. Some findings on the C reaction are of interest in connection with the problem of whether or not an arylthallium(III) compound is involved as an intermediate in the A and B reactions. Probable mechanisms for the Tl(III) and Tl(I) salt-catalyzed brominations were also considered on the basis of their selectivity data.

Results and Discussion

A. Aromatic Bromination with $TlBr_3 \cdot 4H_2O$. Aromatic compounds were added to a mixture of carbon tetrachloride (or acetic acid) and thallium(III) bromide tetrahydrate at the refluxing temperature. The reaction mixture was heterogeneous with molten Tl(III) salt in a CCl_4 solvent, while it was homogeneous in an acetic acid solvent. The red-brown color in the gas and liquid phases which was observed at the initial stage of the reaction because of the partial decomposition of $TlBr_3 \cdot 4H_2O$ [Eq.(1)] gradually disappeared as the reaction proceeded. Indeed, about a 9% conversion of $TlBr_3 \cdot 4H_2O$ to $TlBr \cdot TlBr_3$ in 1hr at 77°C was confirmed iodometrically by a blank experiment. Some

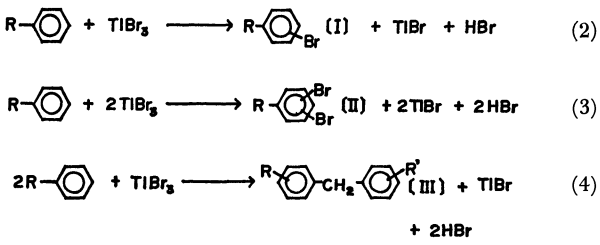
$$2TlBr_3 \cdot 4H_2O \longrightarrow Tl[TlBr_4] + Br_2 + 8H_2O \quad (1)$$

typical results are shown in Table 1. The products were monobromocompounds (major) and dibromocompounds (minor), and occasionally diarylmethanes were formed as by-products from alkylbenzenes. The yields of the products were calculated on the basis of the Tl(III) salt consumed according to Eqs. (2), (3), and (4). With less reactive aromatics, such as nitrobenzene,



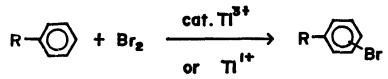
ethyl benzoate, and pyridine, no reaction occurred, even during a longer reaction time at the refluxing temperature. The reaction with benzene and toluene did not occur at 20°C, but with toluene it occurred slowly at 39°C, without any appreciable liberation of bromine. III, the yield of which changed greatly from run to run, could be formed *via* the corresponding benzyl bromides, which were formed by some route or other. A control experiment showed that benzyl bromide and toluene gave a 90% yield of phenyltolylmethane in the presence of $TlBr_3 \cdot 4H_2O$ (see Experimental section).

No evolution of hydrogen bromide was observed, probably because of the complexation with the $TlBr_3$ present [Eq.(5)] giving $HTlBr_4$ as with $HTlCl_4$.[9] This complex seems to suppress further bromination, because an elongation of the reaction time did not lead to an increase in the yields of bromocompounds. The same phenomenon had been observed in the $ZnCl_2$-catalyzed bromination of aromatics.[10]

$$TlBr_3 + HBr \longrightarrow H[TlBr_4] \quad (5)$$

As may be seen in the table, this bromination is rather slow and is apt to be accompanied by some side reactions, so the method is hopeless for preparative purposes.

B. Aromatic Bromination with Bromine in the Presence of Tl(III) and Tl(I) Catalysts. In the presence of small amounts of Tl(III) or Tl(I) salts, aromatics reacted with bromine smoothly in carbon tetrachloride at the refluxing temperature to give pure monobrominated compounds in good yields [Eq. (6)]. The mixtures were heterogeneous (under these experimental conditions only 29—33% of the Tl salts were dissolved in the solvent). In contrast to A reaction, the TlX_3-catalyzed reaction proceeded rather rapidly and a vigorous evolution of HBr gas was observed. Such a difference can be explained by assuming a stronger interaction of the Tl(III) salt with bromine than with



HBr. Some typical data are shown in Table 2. From toluene, a mixture of *o*- and *p*-bromotoluenes was rapidly obtained; in this mixture Tl(III) and Tl(I) catalysts favoured *o*-isomer formation and *p*-one formation respectively, while only traces of the *m*-isomer were

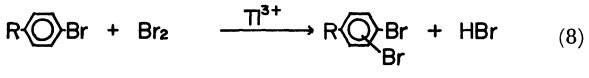
formed (detected by studying the NMR spectra). When enough water to dissolve the Tl(III) salt (more than 0.9 g in this case) was added to the reaction mixture, the major product from toluene became benzyl bromide rather than bromotoluenes. Under comparable reaction conditions without a Tl(III) or Tl(I) catalyst, benzene gave no brominated compounds, while toluene gave only benzyl bromide, even in the dark. In sharp contrast to Tl(III) acetate, mercury(II) and lead (IV) acetates, which have an isoelectronic structure with the Tl(III) salt and which exhibit similar behavior in many reactions,[11] showed no catalytic action in this bromination. Tl(III) salts are more effective than Tl(I) salts as catalysts; this is clearly reflected by the yields of bromobenzenes from benzene.

C. Bromination of Arylthallium(III) Compounds with Bromine. When bromine was added to a suspension of arylthallium(III) compounds (ArTlXY) in carbon tetrachloride at the refluxing temperature, the desired brominated products were readily obtained in good yields regardless of the kinds of X and Y [Eq.(7)]. However, the presence of excess bromine resulted in the formation of dibrominated compounds [Eq. (8)]. Some typical data are shown in Table 3.

(7)



(8)

(R=H, CH_3; X,Y=OAc, ClO_4; OAc, Br; C_6H_5, Br)

From a competitive reaction of the phenylthallium(III) compound and the p-tolyl compound (X=OAc, Y=ClO_4) the relative rate ratio, k_T/k_B, was determined; its value was nearly 1.5 (in CCl_4 at 77°C). In the case of X=OAc and Y=Br, a similar value was obtained. Hence, it seems reasonable to assume that the k_T/k_B ratios for the bromination of $ArTlBr_2$ or $ArTl(OAc)_2$ are nearly 1 or 2. This means that the bromination of the phenylthallium(III) compounds and the p-tolyl compound proceeds at similar rates. These estimated k_T/k_B values differ from those values (7 and 24 for $TlBr_3\cdot 4H_2O$ and $Tl(OAc)_3$ respectively) obtained in the Tl(III) salt-catalyzed reaction B, to be described below. In the B reaction, if rate-determining aromatic thallation is involved, this disagreement can be understood. However, the reported k_T/k_B value (2.6) for aromatic thallation[12] also disagrees with the values for the B reaction. In addition, the following experimental fact must be noted. Although arylthallium (III) compounds reacted easily with KI to give aryliodides,[6] when a mixture of 10 mmol of $TlBr_3\cdot 4H_2O$ and 40 m*l* of HOAc was treated with 50 mmol of KI (H_2O: HOAc=1:1 solution) and 50 mmol of benzene at 100°C, no traces of iodobenzene and phenylacetate (the acetolysis product of iodobenzene) were formed. Aromatic thallation is rather slow and can usually occur in polar solvents and under acidic conditions when reactive aromatics or strong electrophilic Tl(III) salts such as $Tl(OCOCF_3)_3$ are used as substrates.[6,13] Therefore, in a nonpolar CCl_4 solvent the possibility of aromatic thallation seems very rare.[7] From all these facts, it can be deduced that the Tl(III)-catalyzed bromination does not proceed *via* an arylthallium (III) compound.

D. Relative Reactivities of Benzene and Toluene in the A and B Brominations. In order to ascertain the nature of the transition states of bromination using

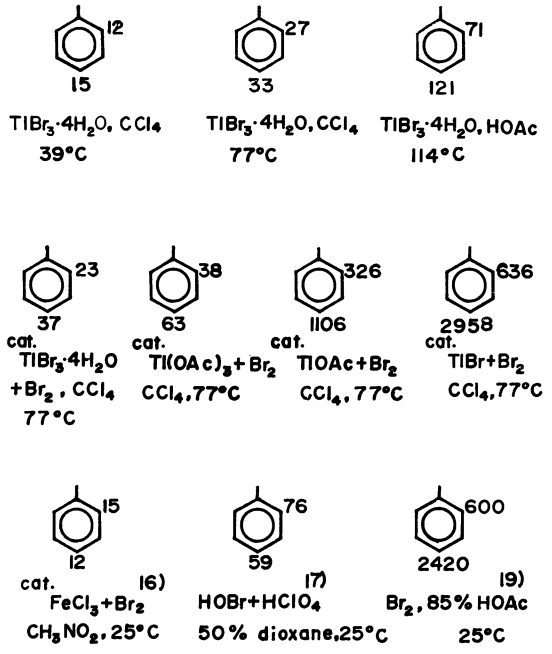
a) Benzene (100 mmol), toluene (100 mmol). b) No or trace amounts of *m*-bromotoluene were formed. c) Sum of bromotoluene and bromobenzene; unless otherwise noted no dibromocompounds were found. d) Traces of dibromocompounds were found. e) Benzene (200 mmol), toluene (100 mmol). f) Benzene (100 mmol), toluene (10 mmol).

Table 5. Partial rate factors for bromination of toluene



Tl salts, competitive reactions of benzene and toluene were carried out under various conditions. Some data on the relative rate ratio (k_T/k_B) and on the isomer ratio ($o/2p$) in the bromotoluenes formed are shown in Table 4. Neither the k_T/k_B ratio nor the $o/2p$ ratio changed significantly when the reaction time for a TlX_3-catalyzed reaction was varied from 5 to 60 min. On the basis of these data, partial rate factors were calculated; they are listed in Table 5, together with some previously reported values. Table 4 shows that the positional selectivity (reflected by the $o/2p$ ratio) increases with an increase in the substrate selectivity (k_T/k_B ratio). This is a general correlation which has been established in several electrophilic substitutions of aromatics.[14)] Our data on relative reactivities are rather limited and are not precise enough for us to undertake a detailed discussion; however, at least the following qualitative deductions are possible. First, there are no significant differences in either the k_T/k_B or $o/2p$ ratio for the two bromination reactions (A and B) using $TlBr_3 \cdot 4H_2O$. This suggests that the A and B brominations are essentially the same. Second, the remarkable differences in both the k_T/k_B ratio and the partial rate factor between TlX_3- and TlX-catalyzed brominations suggests two distinct attacking species for the two reactions. In the Tl(III)-catalyzed reaction, the observed k_T/k_B ratios were of the same order as those for the reaction with other metal chlorides catalysts (*e.g.*, 10—31 for $AlCl_3$ in $C_6H_5NO_2$ at 30°C, and 10—21 in CH_3NO_2,[15)] 3.6—32 for $FeCl_3$ in CH_3NO_2 at 25°C,[16)] and 148 for $ZnCl_2$ in HOAc at 25.4°C[10)]). The partial rate factors obtained were also comparable to those values for the $FeCl_3$-catalyzed bromination with bromine (in CH_3NO_2)[16)] and the perchloric acid-catalyzed bromination with hypobromous acid (in 50% dioxane).[17)] For the latter reaction, kinetic evidence for the attack of Br^+ or its hydrated form has also been given.[18)] On the other hand, in the Tl(I)-catalyzed reaction, both values (the k_T/k_B ratios and the partial rate factors) were quite large and were comparable to those for a bromination without a catalyst (in 85% HOAc),[19)] in which molecular bromine is considered to be the reactive species.[18)] Recently Olah[20)] cited a clear correlation between the electrophilicity of the reagent and the nature of the transition state. He reached the following conclusions. When the electrophilic species is sufficiently reactive, *i.e.*, in the case of a low k_T/k_B value and a high $o/2p$ ratio, the position of the transition state is represented by a much earlier state resembling the starting aromatics (oriented π-complex-like); on the other hand, in the reaction with a weak electrophile (a high k_T/k_B value and a low $o/2p$

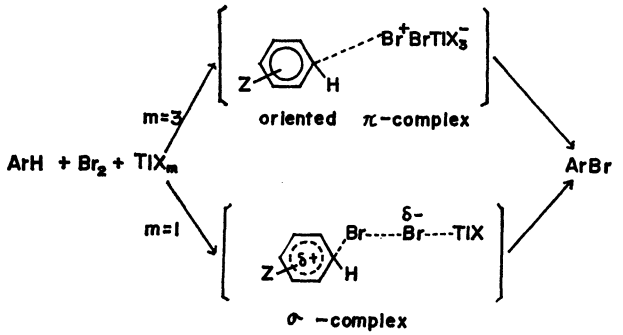
ratio), a late transition state resembling the intermediate (σ-complex-like) is involved. Taking account of this conclusion and the observed differences in selectivities, we propose the following reaction paths and transition states for these reactions. When the Tl (III) catalyst is used, the reaction may involve the initial formation of a polarized complex (probably an ion-pair containing Br^+) from Br_2 and TlX_3 and its subsequent attack on aromatics (oriented π-complex). The latter step would be rate-determining. In the case of the Tl (I) catalyst, the interaction between aromatics and Br_2 would be more important than that between Br_2 and TlX, for the Tl (I) salt is expected to be a rather weak Lewis acid because of two s-electrons in the outer shell. The transformation of the ArH·Br_2 (π-complex) to the ArH·Br^+ (σ-complex) would be essentially rate-determining, and Tl (I) salt may assist in breaking the Br-Br bond. The transition states for these reactions may be represented as follows:



Experimental

Materials. All the starting materials were used after distillation. The $TlBr_3 \cdot 4H_2O$ (mp 40—42°C, lit, 40°C;[21] the purity as determined by iodometry was greater than 97%), TlBr and TlOAc were commercial products. The $Tl(OAc)_3$ was prepared by dissolving Tl_2O_3 into acetic acid at 60°C for 20 hr, collecting white crystals after cooling, and drying over CaO (the purity was greater than 98%). The arylthallium (III) compound ($C_6H_5TlOAc \cdot ClO_4 \cdot H_2O$ and p-$CH_3C_6H_4TlOAc \cdot ClO_4 \cdot H_2O$) were prepared by the reaction of benzene or toluene with $Tl(OAc)_3$ in the HOAc-$HClO_4$ solvent. The synthetic method of these compounds was described in detail in a separate paper.[13] p-$CH_3C_6H_4TlOAcBr$ was prepared by the addition of an aqueous KBr solution to the aqueous p-$CH_3C_6H_4TlOAc \cdot ClO_4 \cdot H_2O$ solution at room temperature. The white precipitates which were formed instantly were recrystallized from benzene; mp>300°C (Found: C, 24.42; H, 2.22%. Calcd for $C_9H_{10}O_2TlBr$: C, 24.89; H, 2.32%). The phenyl analogues were prepared similarly. The diphenylthallium(III) bromide was prepared from phenylboric acid and $TlBr_3 \cdot 4H_2O$ in boiling water according to the reported method;[22] mp>300°C (Found: C, 32.86; H, 2.18%. Calcd for $C_{12}H_{10}TlBr$: C, 32.87; H, 2.30%).

Reaction of Aromatics with $TlBr_3 \cdot 4H_2O$. An aromatic compound (100 mmol) was added to a suspension of molten $TlBr_3 \cdot 4H_2O$ (24.2 mmol) in 80 m*l* of CCl_4 at the refluxing temperature (77°C). The reaction mixture was kept at that temperature for 1 hr, during which period the red-brown color of bromine which was observed at the initial stage gradually disappeared. Yellowish-white precipitates were filtered off, and the filtrate was washed with water and a sodium bicarbonate solution, dried over Na_2SO_4, and distilled. All the products were analyzed by g.l.c. and by a study of the IR and NMR spectra. The $o/2p$ ratio of isomeric bromotoluenes (bp 72°C/20 mmHg), bromoethylbenzenes (bp 71°C/10 mmHg), and bromoanisoles (bp 77°C/7 mmHg) were also determined by g.l.c. and by a study of the NMR spectra (for example, methyl protons of o- and p-bromotoluenes were observed at τ 7.62 and 7.73 respectively).

Bromination of Benzene with Bromine in the Presence of the $TlBr_3 \cdot 4H_2O$ Catalyst. Benzene (100 mmol) was added to a mixture of CCl_4 (80 m*l*), Br_2 (25 mmol) and $TlBr_3 \cdot 4H_2O$ (1.3 mmol) at the refluxing temperature (77°C). After 5 min, the red-brown color of the solution completely disappeared. The reaction mixture was then cooled rapidly and treated as has been described above to give 22.2 mmol of bromobenzene; bp 50°C/20 mmHg (yield, 89%).

Reaction of p-*Tolylthallium(III) Acetate Perchlorate Monohydrate with Bromine.* Carbon tetrachloride (42 m*l*) containing 25 mmol of bromine was added to a mixture of the p-tolylthallium(III) compound (4.72 g, 10 mmol) and CCl_4 (38 m*l*) at 77°C. The red-brown color of bromine gradually disappeared, while the evolution of HBr gas was observed. After 2 hr, the reaction mixture was cooled and worked up as usual. The only products obtained were isomeric dibromotoluenes; no isomeric bromotoluenes was detected by g.l.c. Distillation gave a mixture of dibromotoluenes, which were shown by their IR spectra to be 1-methyl-2,4-dibromotoluene and 1-methyl-3,4-dibromotoluene. Yield, 2.0 g (80%); bp 100—130°C/3.5 mmHg.

Reaction of p-*Tolylthallium(III) Acetate Bromide with Bromine.* A CCl_4 (2.6 m*l*) containing 1.6 mmol of bromine was added to a mixture of p-tolylthallium(III) acetate bromide (1.6 mmol) and CCl_4 (27.4 m*l*) at 77°C. Within 1 min, the bromine disappeared; after 20 min, the reaction mixture was cooled rapidly and treated as has been described above. G.l.c. analysis with bromobenzene as the internal standard showed that 1.06 mmol (yield, 66%) of p-bromotoluene and a trace of dibromotoluene were the only products.

Competitive Bromination of Benzene and Toluene in the Presence of $TlBr_3 \cdot 4H_2O$ Catalyst. A mixture of benzene (100 mmol) and toluene (100 mmol) was added to a stirred mixture of CCl_4 (80 m*l*), Br_2 (25 mmol) and $TlBr_3 \cdot 4H_2O$ (1 mmol) at 77°C. After 5 min, the reaction mixture was cooled rapidly and worked up as usual. The amounts of bromobenzene and isomeric bromotoluenes and the $o/2p$ ratio of the latter compounds were determined by g.l.c. analysis. The total yield of both bromocompounds was 76%, and the k_T/k_B value was 7.

Competitive Bromination of the Phenylthallium(III) Compound and the p-*Tolyl Compound.* A CCl_4 (40 m*l*) solution of bromine (10 mmol) was stirred into a suspension of equimolar (each 10 mmol) amounts of $C_6H_5TlOAc \cdot ClO_4 \cdot H_2O$ and p-$CH_3C_6H_4TlOAc \cdot ClO_4 \cdot H_2O$ in CCl_4 (40 m*l*) at 77°C. After 3 min, the reaction was stopped. G.l.c. analysis showed that bromobenzene (1.63 mmol), bromotoluenes (2.22 mmol), and dibromotoluenes (0.15 mmol) were thus formed.

Authentic Samples for G.l.c. Analysis. The bromobenzene, o-, m-, and p-bromotoluenes, o-, m-, and p-bromoanisoles, o- and p-dibromobenzenes, were commercial products. The bromoxylenes, bromomesitylene and bromoethylbenzenes were each isolated and determined by studying their NMR and IR spectra. The dibromoalkylbenzenes were prepared from bromine and the corresponding monobromoalkylbenzenes.

22) F. Challenger and B. Parker, *J. Chem. Soc.*, **1931**, 1462.

The isomeric phenyltolylmethanes (*o*- and *p*-) were prepared by heating benzyl bromide (20 mmol) and toluene (100 mmol) in the presence of the $TlBr_3 \cdot 4H_2O$ (25 mmol) catalyst at 77°C for 1 hr; yield, 3.1 g (18 mmol, 90%); *o*/*p*= 1.38; bp 100—102°C/2 mmHg. The *p*-tolyl-*p*-xylyl-methane was prepared from *p*-xylene, $Tl(OAc)_3$, and $HClO_4$ by a method reported in a separate paper.[13] Diarylmethanes from *o*-xylene and ethylbenzene could not be isolated in the pure form, but their NMR spectra revealed the presence of a methylene proton at τ 6.0—6.20.

Spectral Measurements. The NMR spectra were determined by a Varian A-60 spectrometer, using TMS as the internal standard in $CDCl_3$. The IR spectra were obtained by means of HITACHI EPI-2 and EPS-3T. G.l.c. analysis was carried out on a SHIMADZU 5APTF apparatus, using PEG 6000 (25%)-Chromosorb-W 3-m and Apz-L (30%)-Celite 3-m columns and on a HITACHI F-6 apparatus using Apz-L 1-m columns.

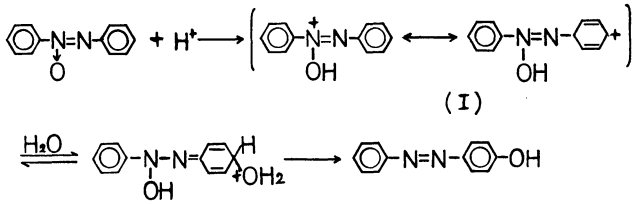
BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 2495—2501 (1971)

A New Rearrangement Reaction of Azoxybenzene with Arenesulfonyl Chloride

Shigeru OAE, Tetsuya MAEDA, Seizi KOZUKA, and Mamoru NAKAI
Department of Applied Chemistry, Osaka City University, Sugimoto-cho Sumiyoshi-ku, Osaka
(Received March 15, 1971)

Azoxybenzene was found to react with arenesulfonyl chloride to afford *o*- or *p*-arenesulfonyloxyazobenzene. This new rearrangement reaction is found in various substituted azoxybenzenes and arenesulfonyl chlorides. By the use of the ^{18}O tracer technique, the *ortho* rearrangement was found to proceed *via* an intramolecular path, while the rearrangement to the *para* position was intermolecular. The yields of the rearranged products were determined by the isotopic dilution technique, while the migratory aptitude was also determined by the use of azoxybenzene-1-^{14}C. It was found that the ratio of the sulfonyloxy migration to the phenyl ring attached to the azoxy side to that of the azo side is 1 to 2 for the *ortho* rearrangement. On the bases of these observations, the mechanism of this new rearrangement reaction is discussed.

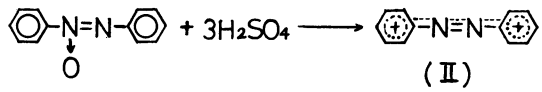
Azoxybenzene is known to undergo Wallach rearrangement in strong acidic media, such as sulfuric,[1] chlorosulfonic,[2] and fluorosulfonic acids,[3] to afford *p*-hydroxy azobenzene, and the reaction has been shown by an ^{18}O tracer experiment[4] to be an acid-catalyzed[5] intermolecular rearrangement. The following two mechanisms have been suggested:[6]



(I)

$+H_2O + H^+$ (I)

The former one is similar to that of the Bamberger reaction[7] and involves the initial formation of an intermediate (I), upon which subsequent nucleophilic attack by either water or a $-OSO_3H$ group takes place, while the other perhaps involves the symmetrical dication (II), in which both phenyl rings are liable to nucleophilic attack.



(II)

$+ H_3O^+ + 3HSO_4^-$ (2)

Meanwhile, the reactions of pyridine and isoquinoline *N*-oxides with arenesulfonyl chloride are known to give 3-pyridyl and 4-isoquinolyl arenesulfonates, apparently *via* the oxygen-bridged ion-pair path[8] (III):

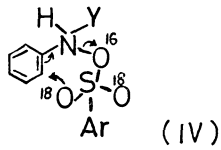
(III)

On the other hand, it has been suggested that the reaction of phenyl hydroxylamine with the same reagent to give *o*-hydroxy aniline proceeds through a concerted 6-membered cyclic process (IV).[9]



(IV)

In both cases, the initial step of the reaction is believed to be the sulfonylation of the *N*-oxide function. Therefore, it seemed that it would be interesting to use acylating agents, *e.g.*, acetic anhydride or arenesulfonyl chloride, for the study of the rearrangement of azoxybenzene, since, if the initial acylation proceeds successfully at the *N*-oxide function, then the subsequent rearrangement would proceed as in the similar rearrangement of a number of tertiary amine *N*-oxides with acylating agents. The Wallach reaction and the rearrangements of aromatic amine oxide with acylating agents have one common feature, *i.e.*, the generation of a cationic center in the course of the reaction. As in the Kuhara modification[10] of the Beckmann rearrangement of oximes the arenesulfonylation of the azoxy group may lead to an interesting modification of the Wallach rearrangement. Thus, we have investigated the title reaction and now wish to report a new rearrangement to afford *o*- and *p*-arenesulfonyloxyazobenzenes.

Results and Discussion

Unlike other aromatic and heteroaromatic oxides, the reaction of azoxybenzene with acetic anhydride[11] is sluggish and affords mainly reduced products, such as acetanilide and azobenzene. On the other hand, the reaction of azoxybenzene with arenesulfonyl chloride gave rearranged products, *i.e.*, *o*- and *p*-arenesulfonyloxyazobenzenes, along with arenesulfonic acid and hydrogen chloride. The reaction is also rather sluggish without a solvent, but proceeds smoothly in a polar solvent such as nitrobenzene. The results are summarized in Table 1. The yields of the products were determined by means of the isotopic dilution method using azoxybenzene-1-^{14}C.[12] The following five successive steps are conceivable for this rearrangement: (1) the sulfonylation of azoxy oxygen, (2) the nucleophilic attack of the chloride anion, (3) the

Table 1. The reaction of azoxybenzene-1-^{14}C with various sulfonyl chloride in nitrobenzene

Sulfonyl Chloride Reaction Conditions	Products Yield(%)	M.P. (°C)
O_2N-C$_6$H$_4$-SO_2Cl 110°C, 25hr	C$_6$H$_5$-N=N-C$_6$H$_4$-OSO_2-C$_6$H$_4$-NO_2 (59.7) C$_6$H$_5$-N=N-C$_6$H$_4$-OSO_2-C$_6$H$_4$-NO_2 (24.8)	144-6 170-1

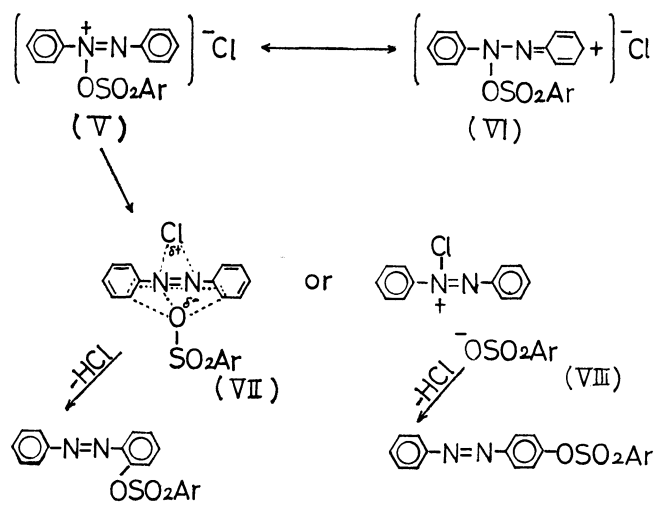
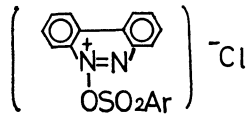
cleavage of the N–O bond, (4) the nucleophilic attack of the sulfonate group at either the *o*- or the *p*-position of either phenyl ring, and (5) the elimination of hydrogen chloride.



The formation of V is reasonable because, in the similar reaction of isoquinoline *N*-oxide with tosyl chloride, the formation of a similar *N*-tosyloxy salt was actually observed.[8] The nucleophilic attack of the chloride ion on the –N=N– group VII or VIII may be considered on the basis of the following evidence.

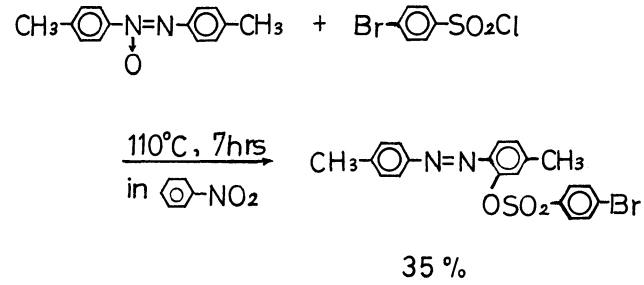


(IX)

i) In the reaction of sterically twisted benzocinnoline *N*-oxide with *p*-nitrobenzenesulfonyl chloride, no rearranged product was obtained because of the steric hindrance of the attack of the chloride ion on the azo group after the arenesulfonylation of the *N*-oxy function (IX).

ii) If chloride ion attacks the *para* position of azoxybenzene, which is considered to be the most active site for nucleophilic attack,[13] *p*-chloroazobenzene could be found in the reaction of azoxybenzene with *p*-nitrobenzenesulfonyl chloride as in the reaction of quinoline *N*-oxide with tosyl chloride to give 4-chloroquinoline.[14] However, the results of the isotopic dilution analysis showed no formation of *p*-chloroazobenzene.

iii) When both *para* positions are blocked by substituents, as in the case of *p,p'*-dimethylazoxybenzene, the rearrangement to the *ortho* position occurs as is shown below:



Therefore, the attack of the chloride anion on the *para* position of VI does not seem as a prerequisite step for this rearrangement. Apparently the rearrangement proceeds easily with a better leaving *p*-nitrobenzenesulfonyloxy group, as in many other rearrangements involving electron-deficient centers. The data in Table 1 show that the ratio of the *ortho* migration to the *para* migration changes with the change in the *para* substituent on benzenesulfonyl chloride. That is, the rearrangement to the *ortho* position is predominant when the substituent is the nitro group. On the other hand, the rearrangement occurs mainly to *para*, accompanied by only a minor *ortho* rearrangement, when an electron-releasing methyl group is substituted. When the chloride ion approaches the azo group of V, a better leaving group, such as *p*-nitrobenzenesulfonate, would cleave heterolytically and migrate to the *ortho* position intramolecularly *via* the formation of the transition complex VII. In the case of *p*-methylbenzenesulfonate, which is a poor leaving group in comparison with *p*-nitrobenzenesulfonate, the chloride ion is added before the cleavage and VIII is formed prior to the rearrangement to the *para* position, since the *para* position of II is a much more electron-deficient site than the *ortho* position from the calculation of the electron density using the ω technique.[13] Our usual ^{18}O tracer experiments were carried out with ^{18}O-labelled *p*-substituted arenesulfonyl chloride: the findings on the ^{18}O distributions of the sulfonates, hydrolyzed products, *etc.* are tabulated in Table 2.

An inspection of the data reveals that the whole pattern of migration is very similar to that of the Wallach rearrangement. That is, *o*-brosyloxyazobenzene retains the original oxygen atom of azoxybenzene, implying an intramolecular oxygen-bridged ion-pair process for the *ortho* migration. On the other hand, all the oxygen atoms of *p*-brosyloxyazobenzene are completely scrambled, suggesting a solvent-separated ion-pair process or an intermolecular nucleophilic process for the *para* migration.

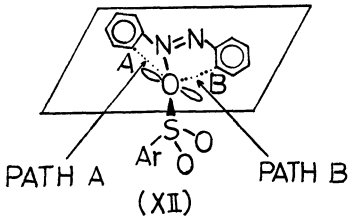
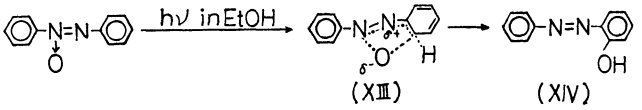
C$_6$H$_5$-NHCO-C$_6$H$_5$	3.84x10^4 "
C$_6$H$_5$-NH$_2$ (OH)	2.77x10^5 "

The small excess of ^{18}O found in the recovered azoxybenzene seems to suggest that there is a pre-equilibration of oxygen atoms between the azoxybenzene and arenesulfonyl groups prior to the rearrangement *via* either X or XI, though to a very minor extent; this is probably responsible for the small incorporation of ^{18}O in the *o*-hydroxyazobenzene obtained.



(XII)

Meanwhile, another interesting point of this rearrangement is that the sulfonyloxy group migrates to the two phenyl rings attached to the *N*-oxide group and the azo nitrogen, *i.e.*, in an intermediate XII for the *ortho* rearrangement. (Path A or Path B). The scheme involving the four-membered oxygen-bridged intermediate (Path A) resembles the intermediate of the isoquinoline rearrangement III. On the other hand, the photochemical rearrangement of azoxybenzene is known to proceed intramolecularly through a five-membered oxygen-bridged path, like Path B, as is be described below.



To shed further light on the mechanism, the reaction was carried out with azoxybenzene-1-^{14}C, and the location of the C-14 was determined by the reductive cleavage of *o*-hydroxyazobenzene XIV with sodium hydrosulfite to *o*-aminophenol and aniline. Aniline was converted to benzanilide, which was then subjected to the usual ^{14}C-activity measurements.

The data in Table 3 reveal that the photochemical rearrangement leads to no significant delocalization of the isotopic ^{14}C during the *ortho* rearrangement. However, there was a definite, though small, scrambling, and the ratio of Path A to Path B in an intermediate XII was found to be 13:87. This result shows that the main pathway for the photo rearrangement of azoxybenzene involves an intermediate XIII. Meanwhile, in the reaction of azoxybenzene-1-^{14}C with *p*-nitrobenzenesulfonyl chloride to afford *o*-(*p*-nitrobenzenesulfonyloxy)azobenzene, the ^{14}C distribution is somewhat different, as is shown in Table 4.

Incidentally, the synthesis of azoxybenzene-1-^{14}C and the degradation scheme are as is shown below:

TABLE 4. THE COUNTING DATA OF THE REACTION OF AZOXYBENZENE WITH *p*-NITROBENZENESULFONYL CHLORIDE FOR THE ORTHO REARRANGEMENT
