A standard alkali solution was prepared by dissolving pure KOH in water and standardised against $KH(IO_3)_2$ using phenolphthalein as indicator.

A standard dilute sulphuric acid solution was prepared by standardising against above alkali using phenolphthalein as indicator.

For preparing stock solution of $R_b^{\beta}H_2$, it was suspended in water and titrated with KOH solution to phenolphthalein end point and diluted so that the strength was about 3.5%.

Stock mercuric nitrate solution was prepared by dissolving pure HgO in nitric acid, free from nitrous fumes. This solution was standardised gravimetrically[5] as HgS and volumetrically with *N*-benzenesulphonyl glycine[1] along with free as-

sociated acid. Concentrations of Hg(II) and free acid were found to be 0.04435M and 0.05450N, respectively.

Spot Test for Hg(II). *Procedure*: The solution of Hg-(II) nitrate containing some other ions was treated with excess of $R_b{}^{\beta}H^-$ and slight excess of alkali using phenolphthalein (one drop of 1% ethanolic solution) till it became pink in colour. It was boiled for one minute, whereby other metals completely precipitated as oxide, just decolourised with dil H_2SO_4 solution and centrifuged. To one drop of the colourless test solution on a spot plate, one drop of 1% KI solution was added. A pink colour appeared due to liberation of alkali, confirming the presence of Hg(II). The limit of identification was found to be 0.5 μg of Hg(II) with a dilution limit of 1 : 100000.

Interferences: The spot test described above was highly selective and appeared to be specific under specificed conditions. Interferences were not found with Ag(I), Cu(II), Be(II), Mg-(II), Zn(II), Cd(II), Pb(II), Al(III), Cr(III), Bi(III), Ti(IV), Th(IV), Zr(IV), U(VI), phosphate, molybdate, and vanadate. Chloride in small concentration did not interfere. Bromide and iodide interfered. However by adding excess of $AgNO_3$, the interference due to chloride, bromide, and iodide for identification of Hg(II) may be eliminated. But there was a decrease in sensitivity particularly in presence of iodide.

Volumetric Determination of Hg(II). *Procedure*: A known volume of the standard Hg(II) solution was taken in a flask, treated with excess [about 3 to 4 times the amount of Hg(II) present] of the prepared reagent ($KR_b{}^{\beta}H$). The volume at this stage was kept about 50 m*l*. After adding two drops of 1% ethanolic solution of phenolphthalein, it was titrated with a standard alkali solution till a pink colour appeared. The amount of alkali consumed was equivalent to the sum of the free acid and twice the moles of Hg(II) present. To this solution excess of KI ($\approx$2 g) was added, when colour of the solution changed to deep pink due to liberation of alkali. This was titrated with a standard acid solution. The amounts of Hg(II) and free acid, taken and found by estimation, are shown in Table 1.

For determination of Hg(II) when associated with other metal ions the method was modified as follows: the solution was titrated with an alkali solution till a pink colour appeared and a slight excess was added. The volume at this stage was 50—60 m*l*. This mercury solution with the precipitated oxides of other metals was boiled for 2 min. The excess of alkali was then just neutralised, cooled and the volume was made upto 100 m*l*. The precipitates were then allowed to settle for about 1 hr. Fifty milliliters of the clear supernatant liquid was pipetted out and Hg(II) was estimated. The determination of Hg(II) at this stage was made to confirm that the extraction of Hg(II) as water soluble complex ion $Hg(R_b{}^{\beta})_2{}^{2-}$ was quantitative or not. In typical cases titrations, 5 m*l* of standard Hg(II) nitrate solution [containing 44.48 mg of Hg-(II)] was taken along with other metal salt solutions. Foreign ions with the amounts in the parentheses that were tolerated are stated in Table 2.

Table 2. Effect of foreign ions

Cations	Ag^+(37.6 mg), Cu^{2+}(35.52 mg), Pb^{2+}(64.0 mg) Be^{2+}(5.0 mg), Mg^{2+}(12.1 mg), Cd^{2+}(54.4 mg), Zn^{2+}(24.0 mg) Al^{3+}(7.2 mg), Fe^{3+}(10.4 mg), Cr^{3+}(10.5 mg), Bi^{3+}(64.0 mg) Zr^{4+}(10.6 mg), Th^{4+}(21.8 mg), $UO_2{}^{2+}$(45.6 mg)
Anions	Cl^-(25 mg), Cl^- with excess of $AgNO_3$(37.5 mg), $SO_4{}^{2-}$(560 mg) CH_3COO^-(780.0 mg), $HPO_4{}^{2-}$(43.04 mg), $MoO_4{}^{2-}$(41.5 mg), $VO_3{}^-$(46.2 mg)

Interferences: All cations which were precipitated as hydrous oxides gave low results when present in large amounts due to adsorption. Anions-acetate, sulphate, chloride in small concentration, phosphate, molybdate, and vanadate did not interfere, but chloride in large concentration, bromide and iodide interfered. However by adding excess of $AgNO_3$ to the original solution, the interferences due to chloride could be eliminated.

Transition-metal Complexes of Pyrrole Pigments. III. Copper(II) and Zinc(II) Complexes of 1,19-Dideoxy-8,12-dicarbethoxy-1,3,7,13,17,19-hexamethylbiladiene-ac[1]

Yukito MURAKAMI, Yoshihisa MATSUDA, and Yukiko KANAOKA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received June 22, 1970)

The copper(II) and zinc(II) complexes of 1,19-dideoxy-8,12-dicarbethoxy-1,3,7,13,17,19-hexamethylbiladiene-ac were synthesized and investigated by near-ultraviolet, visible, near-infrared, infrared, NMR, and ESR measurements as well as X-ray diffraction measurements of powdered samples. The ligand-field bands appeared at 701 and 752 mμ for the copper complex provided information on its geometry around the central metal atom. Namely, the copper atom is subjected to the square-planar ligand-field in the complex. Infrared bands characteristic of asymmetric stretching vibration of the carbethoxy groups at 8 and 12, and X-ray powder diffraction pattern gave another support to this structure by referring to the corresponding data for the nickel complex. ESR measurements also provided the spin Hamiltonian parameters consistent with the square-planar coordination. The most plausible structure for the zinc complex was concluded to be the binuclear form with tetrahedral coordination in conformity with that for the cobalt complex, which was revised in this work. Infrared bands in the 1100—1300 cm^{-1} range due to asymmetric vibration of the ester groups at 8 and 12, and X-ray powder pattern provided the evidence for this structure in reference to the corresponding data for the cobalt complex. The up-field shift of proton signals due to the methyl groups at 1, 7, 13, and 19, the 10-methylene group, and to the ethyl moiety of carbethoxy groups at 8 and 12 upon coordination are consistent with the tetrahedral coordination with dimeric structure. The molecular weight determination also confirmed the dimeric nature of the zinc complex.

Bilirubin and mesobilirubin are the typical biochemical compounds possessing a saturated methylene bridge at the center of a linear tetrapyrrolic structure, each of the four pyrrole rings of which are linked by a single carbon atom. These biladienes-ac are the members of so called bile pigments and have been extensively studied from biochemical point of view. Meanwhile, these biladienes (I) in general may behave as tetradentate ligands and produce various complex metal chelate compounds. In our previous work,[2] the cobalt and nickel complexes of 1,19-dideoxy-8,12-dicarbethoxy-1,3,7,13,17,19-hexamethylbiladiene-ac (II) were synthesized and investigated by means of various spectroscopic methods. As a result, a dimeric structure was assigned to the cobalt complex in which each cobalt atom attained approximately a tetrahedral configuration (III). On the other hand, the nickel atom was found to be subjected to the square-planar ligand-field in the complex of monomeric type (IV).

1) Contribution No. 196 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

2) Y. Murakami, Y. Kohno, and Y. Matsuda, *Inorg. Chem. Acta*, **3**, 671 (1969).

This paper reports the synthesis and the structural properties of copper(II) and zinc(II) complexes of the above biladiene pigment, as examined by visible, near-infrared, infrared, NMR, and ESR measurements as well as X-ray diffraction measurements of powdered samples. Since copper and zinc tend to assume square-planar and tetrahedral configurations, respectively, coordination configurations of the present metal complexes are to be discussed in reference to the corresponding nickel and cobalt complexes already reported.[2]

Experimental

Spectral Measurements. Visible and near-infrared spectra in chloroform (10^{-3}—10^{-5} M) were recorded on a Hitachi Model EPS-2 spectrophotometer at room temperature. Infrared and far-infrared spectra covering the range 4000—200 cm^{-1} were measured with a JASCO Model DS-403G grating spectrophotometer at room temperature, where both KBr disc and Nujol mull techniques were adopted. A Varian A-60 spectrometer was used to obtain NMR spectra in chloroform-d (3×10^{-2} M) at room temperature. Chemical shifts were reported in ppm from internal tetramethylsilane (TMS) and calibrated by the use of chloroform signal as the secondary reference. ESR spectra were taken on a JEOL JES-ME-3X X-band spectrometer using 100 kHz field modulation, where the copper-doped crystals (~1 wt%) of the isomorphous nickel complex and the xylene-benzene solution of the copper complex at room temperature as well as the frozen sample of the copper complex in xylene-benzene at 77°K were used as samples. X-Ray diffraction patterns of the powdered solid samples were measured with a Norelco X-ray diffractometer.

Zinc Complex. A 300 mg sample of zinc acetate dihydratein 10 m*l* of methanol was added to a suspension of 300 mg of 1,19-dideoxy-8,12-dicarbethoxy-1,3,7,13,17,19-hexamethylbiladiene-ac[2] (abbreviated as BLD hereafter) (free base) and 400 mg of sodium acetate trihydrate in 50 m*l* of methanol while heating on a water-bath. After refluxing for one hour, the mixture was allowed to cool down to room temperature. Reddish violet crystals were recovered and recrystallized from acetone: yield 250 mg (74.4%). Further recrystallization was performed from chloroform-methanol: 200 mg; mp>250°C(decomp.).

Found: C, 62.88; H, 5.93; N, 9.29%;[3] mol wt (osmometric method[4]), 1230. Calcd for $C_{62}H_{68}N_8O_8Zn_2$: C, 62.89; H, 5.79; N, 9.46%; mol wt, 1184.05.

Copper Compex. A 500 mg sample of copper acetate monohydrate in 30 m*l* of methanol was added to a mixture of 300 mg of the free base of BLD, 600 mg of sodium acetate trihydrate and 120 m*l* of methanol, and refluxed for 40 min. The dark crystalline precipitate was recovered and washed several times with methanol. The chloroform solution of this material was applied to the top of a chromatographic column of silica gel (60—80 mesh, Kanto Chemical Co., Inc.) and eluted with chloroform. The initial effluent was concentrated *in vacuo* and the product was recovered by reprecipitation with methanol: dark crystalline solid of metallic luster; yield 150 mg (44.3%). Further recrystallization was performed from chloroform-methanol: 120 mg; mp 214—217°C (decomp.).

Found: C, 62.76; H, 5.84; N, 9.35%; mol wt (osmometric method), 603. Calcd for $C_{31}H_{34}N_4O_4Cu$: C, 63.09; H, 5.81; N, 9.49%; mol wt, 590.18.

Results and Discussion

Electronic Spectra. The near-ultraviolet, visible, and near-infrared spectra for the BLD free base and the corresponding zinc and copper complexes in chloroform are shown in Fig. 1. The biladiene shows two intense absorption bands at 425 and 495 mμ, whose absorption coefficients are 27700 and 14800 respectively. These are attributed to the $\pi\rightarrow\pi^*$ transition.[5] Other broad bands located in the near-ultraviolet region may be due to the transitions to higher π energy levels.

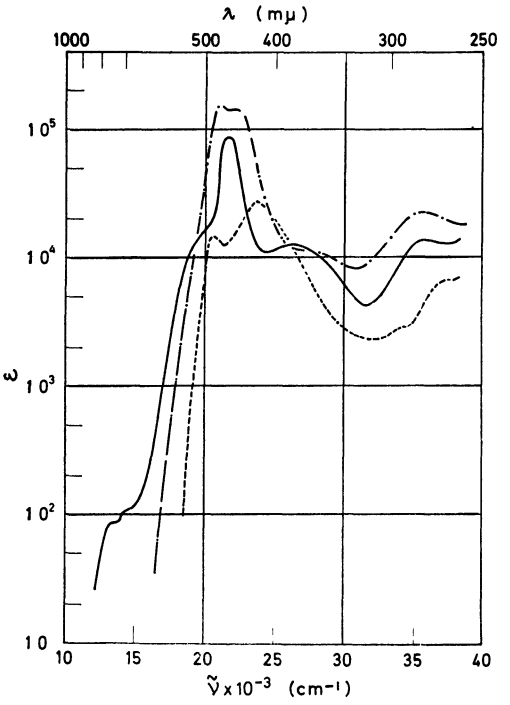

Fig. 1. Electronic absorption spectra in chloroform: ----, BLD free base; —·—·—, the zinc complex; ——, the copper complex.

The zinc complex shows four absorption bands in the 260—1000 mμ range. The bands in a higher energy region—282 mμ (ε=22800) and 356 mμ (ε=11400)—are considered to be due to the $\pi\rightarrow\pi^*$ transitions for which the ligand part is responsible. Both of the quite intense bands appearing at 454 mμ (ε=146000) and 475 mμ (ε=153000) are tentatively assigned to the metal to ligand charge transfer transitions, judging from their intensity and location. In the longer wavelength region beyond 620 mμ, there observed no significant absorption bands whose intensity is higher than 0.1.

The copper complex demonstrates six absorption bands in the 260—1000 mμ range, among which the

3) The elemental analyses were performed at the Microanalysis Center of Kyushu University.

4) A Hitachi Model 115 vapor pressure osmometer was used to measure the molecular weight of a sample dissolved in chloroform.

5) The spectrum of the BLD free base has been shown in our previous paper.[2] Its absorption intensity indicated in Fig. 1 of the previous paper is twice as large as the real value as a matter of fact. The correction has to be made for this mis-presentation of the spectrum.

higher energy bands observed at 280 mμ (ε=13700) and 380 mμ (ε=12700) are attributed to the $\pi \rightarrow \pi^*$ transitions of the ligand part. The most intense band appearing at 461 mμ (ε=97800) is assignable to the metal to ligand charge transfer transition, while the weaker bands at 701 mμ (ε=103) and 752 mμ (ε=85) in a lower energy region of the present study is due to the $d \rightarrow d$ transitions of the metal atom. When the copper atom is placed in the square-planar ligand-field, a $d \rightarrow d$ ($d_{z^2}, d_{xy}, d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$) absorption band has been known to appear in the 500—700 mμ range. In the case that the copper ion is subjected to a strong ligand-field perturbation produced by the four nitrogen donor atoms, such a $d \rightarrow d$ band can be found in general near the 500 mμ range.[6] The corresponding absorption intensity varies from several tens to a few hundreds, depending upon the structure of the ligand part.[7] When the copper complex assumes approximately a tetrahedral configuration around the central metal atom, no significant absorption bands originated from $d \rightarrow d$ transitions are seen in a shorter wavelength region lying below 1000 mμ.[8] If the coordination configuration is something between these two typical cases or the symmetry property of the ligand-field is lowered below D_{4h}, the multi-absorption bands tend to appear in the intermediate wavelength range with significant energy separation.[9,10] The above consideration leads to the conclusion that the copper atom in the BLD complex attains primarily the square-planar coordination without much distortion.

Vibrational Spectra. The infrared spectra in the 1000—1600 cm^{-1} range for the BLD free base and its zinc and copper complexes are shown along with those for the corresponding cobalt and nickel complexes in Fig. 2. The vibrational character of a family of tetrahedral complexes is found to be different from that of square-planar complexes particularly in the 1100—1300 cm^{-1} range in the present study. These characteristic bands are attributed to the asymmetric stretching modes of the ester group situated at positions 8 and 12 in the ligand part.[11]

The cobalt complex, where the metal atom has been shown to assume a tetrahedral coordination,[2] shows two absorption bands of equal intensity and a shoulder band in between in this range as shown in Fig. 2 by arrows. The present zinc complex demonstrates vibrational characteristics quite similar to those of the corresponding cobalt complex.

On the other hand, two strong bands of nearly equal intensity are located closely in the higher frequency part of the 1100—1300 cm^{-1} range and another band of medium intensity is found in the lower frequency part for the nickel complex which assumes a square planar configuration around the metal atom, as seen in Fig. 2. The present copper complex also shows vibrational bands of similar trend in the same frequency range. The infrared spectrum of the BLD free base appears to bear a resemblance to those of the cobalt and zinc complexes rather than those of the corresponding copper and nickel complexes. Outside this region some minor differences between these two types of complexes can be noticed around 1400 and 1550 cm^{-1}.

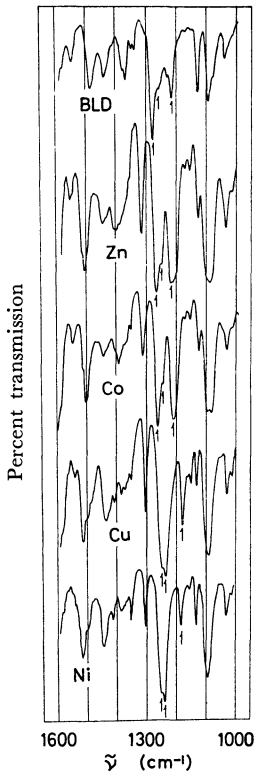

Fig. 2. Infrared spectra of the BLD complexes of bivalent metals (KBr disc method). Arrows refer to the characteristic bands due to asymmetric stretching vibration of the carbethoxy group (see text).

The above results indicate that the carbethoxy groups located at positions 8 and 12 of the ligand part in the cobalt and zinc complexes of tetrahedral configuration

are free from steric strain as expected in the ligand free base, a plausible structure for which is depicted in Fig. 3.

By inference from the far-infrared study on the dipyrromethene complexes,[12,13] absorption bands due to metal-nitrogen stretching modes are expected to appear in the 300—400 cm^{-1} range. Nevertheless, any reasonable assignments of empirical nature were not possible at present due to the complexity of these spectra caused by vibrational modes of the ligand part.

NMR Spectrum of the Zinc Complex. The NMR spectrum for the zinc complex is shown in Fig. 4 and the assignments are listed in Table 1 together with those for the BLD free base and the corresponding nickel complex. The proton signals due to the 3- and 17-methyl groups, the 2- and 18-protons, and the 5- and 15-methine groups shifted down-field upon coordination with zinc. All other proton signals, on the other hand, shifted up-field. The electron density around methine-carbon atoms at positions 5 and 15 seems to be decreased through delocalization caused by chelate ring formation, and the protons attached to these carbon atoms are deshielded as a result. This electronic effect for the zinc complex is smaller than that for the nickel complex. The similar explanation may be given to other proton signals which demonstrate down-field shift as mentioned above. The signal for protons of the 10-methylene group in the zinc complex is found in the highest field among the corresponding signals for the three compounds listed in Table 1. This is most likely due in part to the fact that the 10-methylene group is not involved in a chelate ring through coordination, while this group becomes a member of the chelate ring in the corresponding nickel complex of square-planar configuration. The similar trend was also observed for the proton signals due to the ethyl moiety of carbethoxy groups at positions 8 and 12, as well as for the signal due to the 7- and 13-methyl groups. Placement of these groups in the shielding zones of near-by pyrrole rings of another BLD molecule and the corresponding chelate rings in the same complex seems to result in such up-field shifts of the corresponding proton signals. This situation can be visualized by Fig. 5, where the zinc atoms are bound to pyrrolic nitrogens by assuming a tetrahedral configuration at a 2 : 2 molar ratio of ligand to metal. The ligand molecule attains a conformation entirely similar to that expected in the free base state

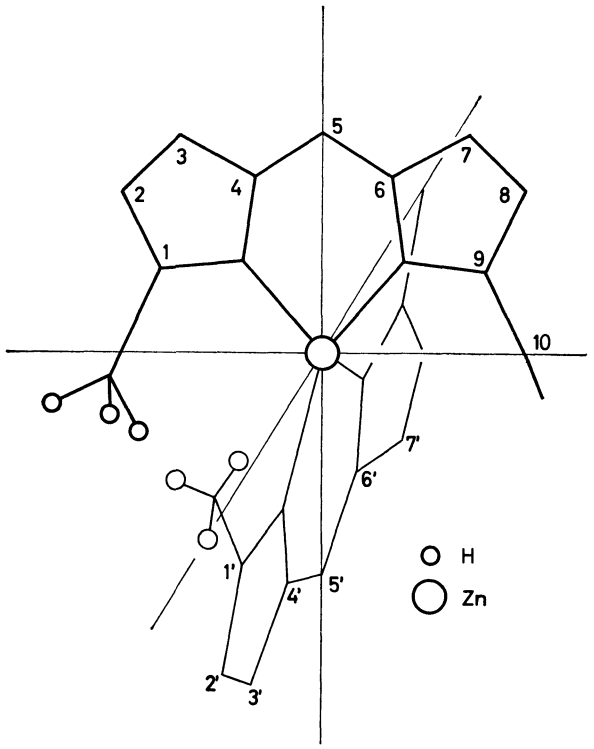

Fig. 7. Plausible geometrical configuration of the 1-methyl group in the Zn(II) complex of binuclear structure.

(Fig. 3) and the least steric interaction between the carbethoxy groups at positions 8 and 12 seems to be secured as a result. The state of affair around the 8- and 12-carbethoxy groups is shown in more understandable manner in Fig. 6. This is in agreement with the conclusion derived from the infrared data. A significant up-field shift of the proton signal due to the 1- and 19-methyl groups may also be caused by the shielding effect of pyrrole rings and metal chelate rings as shown in Fig. 7. The situation would be somewhat different in the nickel complex. A steric interaction between the 1- and 19-methyl groups in the monomeric nickel complex of square-planar coordination seems to result in a slight twist of these groups from the plane of each pyrrole ring. This effect would place these methyl groups in an edge of the shielding zone of each pyrrole ring.

ESR Spectra of the Copper Complex. The ESR spectra for the copper complex in xylene-benzene at room temperature and at 77°K as well as that doped in the isomorphous nickel complex at room temperature are shown in Fig. 8. The general feature of spectra B and C is consistent with the square-planar coordination. In these two spectra, the hyperfine lines due

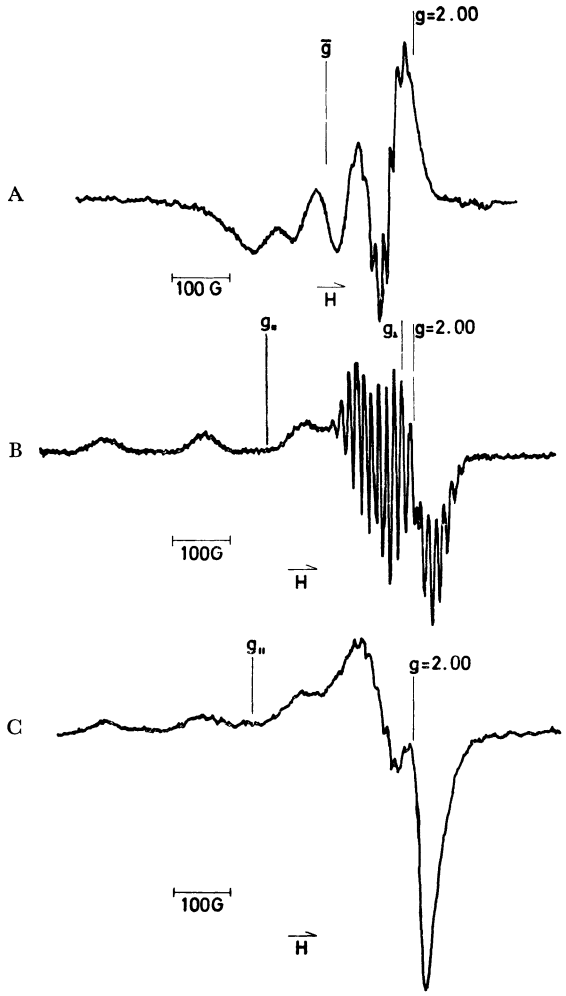

Fig. 8. ESR spectra of the Cu(II)-BLD complex: A, in xylene-benzene (6 : 4) at room temperature; B, in xylene-benzene (6 : 4) at 77°K; C, doped in the Ni(II)-BLD complex at room temperature.

to the copper nucleus can be observed on the $g_{\parallel}$ positions while such splittings are not obvious on the $g_{\perp}$ positions. Super-hyperfine lines due to the nitrogen nuclei, from which A_N values were evaluated, appear on the $g_{\perp}$ positions. The solution spectra (A) also shows four hyperfine lines due to the copper atom and additional splittings caused by the nitrogen nuclei in the upper field. The $g_{\perp}$ and $A_{\perp}$ values for the frozen sample were evaluated by the simulation method of hyperfine structure appeared in the upper field. The spin Hamiltonian parameters obtained in this work are almost comparable with the data for the phthalocyanine and porphyrin complexes taken from the literature, as shown in Table 2.

One of the σ-molecular orbitals for coordination in D_{4h} symmetry can be represested as follows:

$$\Psi_{B_{1g}} = \alpha d_{x^2-y^2} - 1/2\,\alpha' [-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_x^{(3)} - \sigma_y^{(4)}]$$

The sigma-bonding parameter α^2 can be calculated by the following equation given by Kivelson and Neiman:[14]

$$\alpha^2 = -(A_{\parallel}/P) + (g_{\parallel} - 2) + 3/7\,(g_{\perp} - 2) + 0.04$$

where 0.036 was given to P. Judging from α^2 values, the coordinate bond character seems to be comparable to those in the phthalocyanine and porphyrin complexes.

X-Ray Powder Diffraction Patterns. The X-ray powder diffraction patterns for the copper, zinc, nickel, and cobalt complexes of BLD are shown in Fig. 9. The general feature of the diffraction pattern for the copper complex has a close resemblance to that for the nickel complex although the careful comparison reveals some minor difference in their relative intensity. On the other hand, the powder pattern for the zinc complex is found to be almost identical with that for the corresponding cobalt complex. As a result, stacking manner of the copper complex in crystalline state is close to or almost identical to that of the nickel complex; so is the zinc complex to the cobalt complex.

These results provide another evidence for the structural properties of the present complexes: the copper complex involves the coordinate bonds of square-planar orientation in a monomeric form, while the zinc complex consists of tetrahedrally coordinated bonds in a binuclear form.

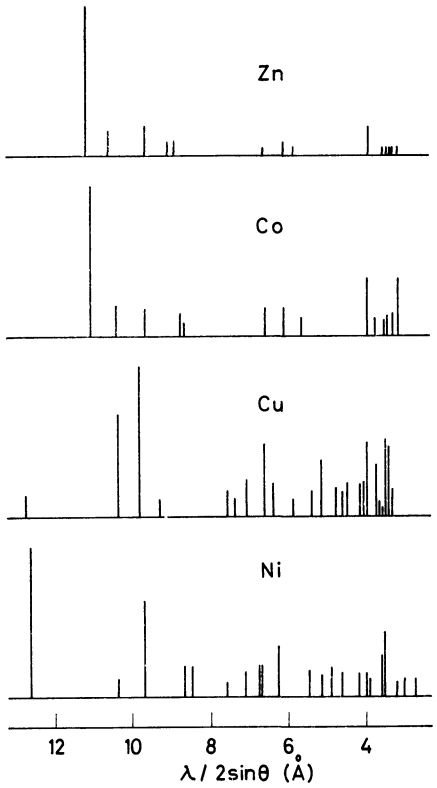

Fig. 9. X-Ray powder diffraction patterns of the BLD complexes of bivalent metals. The relative diffraction intensity at a Bragg angle θ is represented by the height of vertical lines.

Structure of the Metal Complexes. The elemental analysis of the copper complex is consistent with a ligand to metal ratio of 1 : 1 with no additional ions or species. The molecular weight determination by means of vapor pressure osmometer indicates this complex is monomeric. The infrared bands characteristic of asymmetric stretching vibration of the carbethoxy groups at positions 8 and 12 are different in their positions from those observed for the BLD free base and the corresponding zinc and cobalt com-

plexes, but in conformity with those for the nickel complex of square-planar coordination. The appearance of the ligand-field bands at 701 and 752 mμ also indicates that the copper atom is placed approximately in a square-planar ligand-field. The overall feature of the ESR spectrum and spin Hamiltonian parameters obtained therefrom ($g_{\parallel}$, $g_{\perp}$ and A values) are consistent with the square-planar coordination. Since the X-ray diffraction pattern of the powdered sample is closely related to that of the nickel complex, this data may give another support to the structure. In conclusion, these experimental facts as a whole are consistent with the square-planar coordination of the copper atom with the pyrrolic nitrogens of BLD in a monomeric manner (IV).

By referring to the elemental analysis and the molecular weight measurement of the zinc complex, the complex is binuclear with a ligand to metal ratio of 2 : 2. The infrared bands due to asymmetric stretching vibration of the ester groups provide an evidence that the carbethoxy groups at positions 8 and 12 are free from steric strain to an extent expected in the BLD free base and in the corresponding cobalt complex of tetrahedral coordination as explained in the previous section. The dimeric nature of the complex was also demonstrated by NMR spectroscopy. All the upfield shifts of proton signals through coordination can be predicted on the basis of binuclear complex formation. Although a dimeric form with tetrahedral coordination shown by structure III was put forward previously for the cobalt complex,[2] this turns out to be unsatisfactory for explaining the experimental data reported in this work and deserves an appropriate revision as depicted in Fig. 5. The X-ray powder diffraction pattern was indentical with that of the cobalt complex which assumes tetrahedral configuration around the central metal atom with dimeric structure. As a result, the most plausible structure for the zinc complex is the binuclear form with tetrahedral coordination of the metal atom, identical with the corresponding cobalt complex, as depicted in Fig. 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 415—417 (1971)

Chloropentakis(trichlorostannato)ruthenate(II)

Hisateru OKUNO, Tatsujiro ISHIMORI, Kunihiko MIZUMACHI, and Haruhiko IHOCHI*

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi Ikebukuro, Tokyo

(Received June 26, 1970)

The cesium and triethylammonium salts of chloropentakis(trichlorostannato)ruthenate(II), $Cs_4[RuCl(SnCl_3)_5]\cdot CsCl$ and $(Et_3NH)_4[RuCl(SnCl_3)_5]$, were prepared. Their IR absorption bands near 210 cm^{-1} are thought to be due to the Ru–Sn stretching vibration. The electronic spectra of dilute hydrochloric acid solutions of the complex salts were the same as the spectrum of a single crystal of the cesium salt. This suggests the presence of the complex ion, $[RuCl(SnCl_3)_5]^{4-}$, in acid solutions. A hydrolysis product of the complex ion contained ruthenium, tin and chlorine in the atom ratio of 1 : 5 : [$\alpha(<1)$], and the cesium salt was yielded from a dilute hydrochloric acid solution of the hydrolysis product. The observations show the presence of the Ru–Sn bonds in the complex ion.

. Complexes of platinum metals with the coordinating $(SnCl_3)^-$ groups have recently been studied.[1-7] As for the ruthenium complexes of this kind, $M^I_2[RuCl_2(SnCl_3)_2]$,[3] $[Ru_2Cl_3(SnCl_3)(CO)_2(PPh_3)_3(Me_2CO)_2]$, $[Ru_2Cl_3(SnCl_3)(CO)_2(PPh_3)_4]$ (PPh_3=triphenylphosphine)[6] and $[Me_4N][RuX_2(CO)_2(SnCl_3)_2]$ (X=Cl or Br)[6,7] have been reported. In the present work salts of chloropentakis(trichlorostannato)ruthenate(II), $[RuCl(SnCl_3)_5]^{4-}$ were prepared, and their chemical properties were investigated. A hydrolysis product of the complex ion was also isolated.

Experimental

Ruthenium(III and IV) in a hydrochloric acid solution was prepared from the distillate of ruthenium(VIII) tetroxide passed into an alcoholic hydrochloric acid solution. All the other reagents were of analytical grade. IR-spectra were measured in Nujol mull over the region of 700—200 cm^{-1} on JASCO IR-F.

Preparation of $[RuCl(SnCl_3)_5]^{4-}$ Complex Ion. Sufficient tin(II) chloride dihydrate (1.13 g) was added to 40 mg of ruthenium(III and IV) in 50 m*l* of 2—3 M hydrochloric acid solution, and the solution was digested in a boiling water bath for 45—60 min. The yellowish red solution obtained was passed through an anion-exchange column of Dowex 1, X-16 (20 m*l* of the chloride form), yielding a hydrochloric acid solution of the complex ion. This ion-exchange procedure is to remove tin(IV) and an excess of tin(II), and, if present, any small anionic ruthenium species

in the reaction mixture. However, no complex ion of a large size was adsorbed appreciably by the anion-exchanger with a high crosslinkage.

Preparation of $Cs_4[RuCl(SnCl_3)_5]\cdot CsCl$ and $[(C_2H_5)_3NH]_4[RuCl(SnCl_3)_5]$. Addition of acid cesium chloride solution to the complex ion in 2—3 M hydrochloric acid solution yielded a yellow salt, which was washed with a mixture of ethanol and hydrochloric acid (5 : 1). Crystals 0.5 to 1.5 mm in length were prepared by introducing 0.2 M cesium chloride solution slowly from a capillary into a 2—3 M hydrochloric acid solution of the complex ion; the solution was covered with ligroin during the addition of cesium chloride and the formation of the crystals.

Found: Ru, 5.0; Sn, 30.4; Cs, 33.8; Cl, 30.7%. Calcd for $Cs_5RuSn_5Cl_{17}$: Ru, 5.15; Sn, 30.25; Cs, 33.87; Cl, 30.72%.

Addition of a large excess of a concentrated acid triethylammonium chloride solution yielded an orange salt. The salt was washed with an acid triethylammonium chloride solution and then with the mixture of ethanol and hydrochloric acid (5 : 1). The triethylammonium salt was much more soluble in dilute hydrochloric acid than the cesium salt.

Found: Ru, 5.94; Sn, 35.2; Cl, 33.0; N, 3.46; C, 17.82%. Calcd for $[(C_2H_5)_3NH]_4[RuCl(SnCl_3)_5]$: Ru, 6.05; Sn, 35.52; Cl, 33.96; N, 3.35; C, 17.26%.

The tetramethylammonium salt was prepared in a similar way. It was less soluble in dilute hydrochloric acid than the triethylammonium salt.

Preparation of Hydrolysis Product of the Complex. When a 2—3 M hydrochloric acid solution of the complex ion was diluted 40-fold with water, a yellow hydrolysis product was obtained. This product was washed with water several times by centrifuging or by decantation; the chloride ion was gradually removed from the hydrolysis product by successive washings. The product turned brown when it was washed with ethanol and then ether or when it was dried over tetraphosphorus decaoxide. The brown product contained 10.6% Ru, 61.5% Sn and 0.4—3.1% Cl; the chloride content varied with the extent of the washing.

Results and Discussion

Complex Salts. The compositions of the cesium and triethylammonium salts were consistent with $Cs_5RuSn_5Cl_{17}$ and $(Et_3NH)_4RuSn_5Cl_{16}$, respectively. These compounds were diamagnetic. They are thought to be complex salts of ruthenium(II). Six-coordination is a very strong inherent tendency of ruthenium(II) complexes, and the only exceptions may be some complexes[6,8] with triphenylphosphine or triphenylstibine such as $RuCl_2(PPh_3)_3$. However, X-ray study on $RuCl_2(PPh_3)_3$[9] has shown that the complex is quasi-octahedral. From geometrical consideration, it is seen that covalent radii of ruthenium(II), tin(II), and Cl(-I) make an octahedral arrangement as $[RuCl(SnCl_3)_5]^{4-}$ possible for the complex ion presented here, and its complex salt can be represented as $Cs_4[RuCl(SnCl_3)_5]\cdot CsCl$ or $(Et_3NH)_4[RuCl(SnCl_3)_5]$. The equivalent conductivity, Λ_e, of the tetramethylammonium salt in nitromethane was 102.9, 104.1, and 106.1 $ohm^{-1}cm^2$ at 6.03×10^{-5}, 4.06×10^{-5}, and 2.05×10^{-5} eq/l, respectively, at 25°C. The data were compared with those of (3 : 1), (2 : 1) and (1 : 1) electrolytes by the method of Feltham and Hyter.[10] The value of $(\Lambda_0-\Lambda_e)/\sqrt{c}$, where Λ_0 is Λ_e at infinite dilution and c equivalent concentration, was 1.66×10^3, while the values for $Na[BPh_4]$, $[Ni(phenan)_3](ClO_4)_2$, and $[Co(bipy)_3](ClO_4)_3$ have been reported to be 216, 465, and 1020 respectively. The results of the comparison indicate that the tetramethylammonium salt is an electrolyte of the (4 : 1) type. The electronic absorption spectra of the tetramethylammonium and triethylammonium salts in nitromethane were the same as those of the salts in a dilute hydrochloric acid solution, which in turn are the same as the spectrum of the cesium salt single crystal. Thus, both cesium and triethylammoniun salts contain an identical complex anion, $[RuCl(SnCl_3)_5]^{4-}$.

The properties of the cesium salt were as follows: yellow for fine crystals and orange for crystals of length of the order of millimeters, insoluble in ethanol and ether; cubic system with the well developed (1, 1, 1) plane; lattice constant, $a=15.66\pm0.22$ Å; number of chemical units in an unit cell, $Z=4$; density=3.37 g/cm^3 at 25°C; refractive indices, $n_{700m\mu}=1.758\pm0.005$, $n_{589m\mu}=1.765\pm0.004$ at 23°C.

The electronic absorption spectrum of the crystal shown in Fig. 1 was measured by a photoelectric spectrometer equipped with a special microphotometric attachment.[11,12] Since the crystal used did not have completely planar surfaces, its thickness was not measured. A decrease in absorption was observed on irradiation with ultraviolet rays. This seems to be caused by a partial decomposition of the complex salt during the course of irradiation.

The infrared spectrum of the cesium salt has absorption bands at 324, 288(shoulder), 211, and 205 (shoulder) cm^{-1} as shown in Fig. 2. The spectrum of

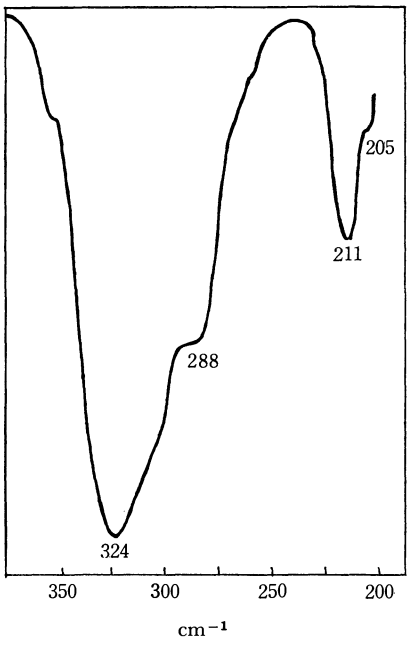

Fig. 2. Infrared spectrum of $Cs_4[RuCl(SnCl_3)_5]\cdot CsCl$ in Nujol mull.

the triethylammonium salt was the same as that of the cesium salt: the absorptions were at 318, 294(shoulder), 212, and 205(shoulder) cm^{-1}. The absorption bands in the region 350—275 cm^{-1}, including unresolved shoulders, are thought to be due to the stretching vibrations of Sn–Cl and Ru–Cl. Infrared absorptions[13] due to the platinum metal-tin bonds have been found near 200 cm^{-1} for $[Rh_2Cl_2(SnCl_3)_4]^{4-}$ and $[Pt(SnCl_3)_5]^{3-}$. The absorption bands at 210 cm^{-1} observed here can be assigned to the Ru–Sn stretching vibration.

Complex Ion in a Hydrochloric Acid Solution. The solution of the complex ion was prepared by use of an anion exchange column, and the Ru : Sn ratio in the solution was 1 : 5. When tin(II) chloride was added to this complex ion solution and the mixture again treated with the anion exchange column, the Ru : Sn ratio in the effluent was still 1 : 5. The results suggest that the complex ion in a dilute hydrochloric acid solution contains ruthenium and tin in the ratio of 1 : 5, and further that the coordinating $(SnCl_3)^-$ groups do not greatly dissociate and the rate of dissociation is not fast. The electronic absorption spectrum of the cesium salt in 0.5 M hydrochloric acid is shown in Fig. 1 ($\log \varepsilon = 3.34$, 4.58, and 4.83 at 22520, 32890, and 48540 cm^{-1} respectively). It is the same as that of the crystals of the cesium salt in the region 1.9×10^4—2.9×10^4 cm^{-1}. The spectrum of the complex ion prepared as a dilute hydrochloric acid solution was also identical with that of the cesium salt solution. Thus, the complex ion, $[RuCl(SnCl_3)_5]^{4-}$, is thought to be present in a dilute hydrochloric acid solution. However, the complex ion in an acid solution slowly fades.

Hydrolysis Product. The Ru : Sn : Cl ratio in the hydrolysis product was 1 : 5 : [$\alpha(<1)$]. The infrared absorption bands due to the Ru–Sn stretching vibrations were observed for the complex salts, but the corresponding bands were not found for the hydrolysis product. This is probably due to a polymer structure of the hydrolysis product. However, when the hydrolysis product was dissolved in 1 M hydrochloric acid, the electronic absorption spectrum of the solution was the same as that of the cesium salt in a hydrochloric acid solution ($\log \varepsilon = 3.0$ and 4.5 at 22520 and 34130 cm^{-1}). The slight differences in $\log \varepsilon$ and the wave numbers at the maximum absorptions are thought to be caused by the decomposition of a small part of the hydrolysis product. The cesium salt was prepared from a dilute hydrochloric acid solution of the hydrolysis product in a reasonable yield; decomposition products in the hydrolysis product, if any, were previously removed from the solution by the anion exchange technique. The cesium salt prepared was identified by means of electronic and infrared spectra. Thus, the skeleton of "$RuSn_5$" remains in the hydrolysis product, and the presence of direct metal-metal bonds in the complex ion is shown in terms of chemical reactions, the formation of the hydrolysis product from the complex ion and the reformation of the complex ion from the hydrolysis product. Incidentally, any hydrolysis product with metal-metal bonds other than that described above has not been reported yet.

Young *et al.*[3] have reported the preparation of $(Me_4N)_2[RuCl_2(SnCl_3)_2]$, and we tried to prepare this complex salt following their directions. However, the Ru : Sn ratio in the product was 1 : 5, not 1 : 2. The infrared spectrum was the same as that of $(Et_3NH)_4[RuCl(SnCl_3)_5]$.

The authors wish to express their appreciation to Professors Yukio Kondo and Masayoshi Nakahara of Rikkyo University for many helpful discussions, and to Miss Noriko Okazaki for her technical assistance. This work was made possible by the support of the Scientific Research Fund of the Ministry of Education.

The Formation of κ- and κ'-Al_2O_3 from the Dehydration of Tohdite $5Al_2O_3 \cdot H_2O$

Masataro Okumiya, Goro Yamaguchi, Osamu Yamada, and Shuichiro Ono*

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

** Government Chemical Industrial Research, Tokyo, Shinjuku-ku, Tokyo*

(Received August 3, 1970)

The dehydration of tohdite $5Al_2O_3 \cdot H_2O$ is well followed by means of the single-crystal electron-diffraction patterns, the X-ray powder patterns, differential thermal analysis, and the measurement of the density. Thermogravimetric measurements were also performed, both under a normal atmosphere and in a high vacuum. Just after the dehydration, an unstable intermediate phase was obtained; it was denoted as κ'-Al_2O_3 (from tohdite). The mechanism of the transformation series:

$$\text{tohdite} \rightarrow \kappa'\text{-}Al_2O_3 \rightarrow \kappa\text{-}Al_2O_3 \rightarrow \alpha\text{-}Al_2O_3$$

was discussed, and some basic data to serve as clues to elucidate the crystal structure of κ'- and κ-Al_2O_3 were obtained.

In 1966, Krischner reported an investigation into the thermal dehydration of tohdite $5Al_2O_3 \cdot H_2O$ (Al_2O_3-K1, according to his notation) by the electron-diffraction method.[1] In his work, fine-grained hexagonal plates of tohdite, with a particle size of about 1 micron, which had been obtained by the hydrothermal treatment of bayerite, were heated by means of an electron beam in an electron microscope, and electron-diffraction patterns were obtained at various reaction stages. Since the incident beam was parallel to the *c*-axis, all the patterns obtained in his work represent the reciprocal *a-b* plane. No experimental results to elucidate the atomic arrangement along the *c*-axis were obtained in his work. Therefore, it is difficult to determine the crystal structure of dehydration products of tohdite from his experimental results only.

Furthermore, Krischner's experimental results were insufficient to elucidate the transformation mechanism, because his experiment was limited to the method of comparing the electron-diffraction patterns of the materials heated by an electron beam at uncertain temperature.

The present study has aimed at elucidating the thermal dehydration and transformation mechanism in more detail, and at obtaining basic data to serve as clues to elucidate the atomic arrangement of dehydration products. For this purpose, differential thermal analysis, thermogravimetric measurements under both a normal atmosphere and in a high vacuum, an X-ray powder diffraction experiment, and density measurements were performed. A single-crystal electron-diffraction experiment was also performed for the needle-like crystals in order to obtain information on the atomic arrangement along the *c*-axis as well as for the hexagonal-plate crystals.

Experimental Procedure

Specimen Preparation. In previous paper,[2,3] detailed conditions for tohdite formation were discussed. It was established that the addition of certain mineralizers favers the formation of tohdite. The specimen of tohdite used in this experiment was prepared as follows.

(a) A sample of η-Al_2O_3 obtained from the dehydration of bayerite at 800°C in air was inverted to tohdite by heating it hydrothermally at 460°C, 300 atm, without any mineralizer. The tohdite thus obtained was in the form of hexagonal plates with a particle size of about 1 micron and will be denoted as "tohdite(η)."

(b) Gibbsite was heated hydrothermally at 480°C, 800 atm in the presence of aluminium fluoride. The tohdite thus obtained was in the form of hexagonal plates with a particle size of about 1 micron and will be denoted as "tohdite(F)." It contains about 0.3% fluorine ion in the crystal structure.

(c) Gibbsite was heated under hydrothermal conditions of 500°C, 1000 atm, by adding $Ti(SO_4)_2$ as a 3—4% aqueous solution. The tohdite thus obtained was in the form of needle-like crystals about 10 micron in size and will be denoted as "tohdite(Ti)."

Differential Thermal Analysis and Thermogravimetric Measurements. The differential thermal analysis and thermogravimetric measurements were performed simultaneously under a normal atmosphere and at a heating rate of 5°C/min using a simultaneous thermobalance analyser.

Thermogravimetric measurements in a high vacuum (10^{-4} mmHg) were also performed using a silica spring thermobalance (Fig. 1).

Electron-diffraction Procedure. Single-crystal electron-diffraction patterns were obtained by means of a Hitachi electron microscope, Type HU-11DS. All the specimens were dispersed with water on a folmbar film attached to the sample grid and were observed at a 100 kV accelerating potential.

X-Ray Powder Measurements. X-Ray powder diffraction patterns were obtained by means of a Rigaku-Denki diffractometer using Ni-filtered Cu$K\alpha$ radiation.

Density Measurements. The density of the dehydrated materials of tohdite was measured using the Archimedian principle. The buoyance of the materials (about 1 g) in toluene was measured with a highly-sensitive ($\pm$0.01 mg) microbalance, and the density was calculated. In order to increase the accuracy of measurement, the specific gravity of toluene (about 0.89) was checked at every measurement with a standard material of a piece of pure gold (99.99%).

Experimental Results

Differential Thermal Analysis and Thermogravimetric Data. The DTA and TGA curves at a normal atmosphere are shown in Fig. 2. A single endotherm was observed in the temperature range of 700—800°C, and there was a large weight loss. As can be seen in Fig. 2, the dehydration of tohdite is completed in a single step at this temperature range. After dehydration, no further change in DTA and TGA curves occurred until about 1000°C.

At about 1000°C an exotherm was observed ((a), (c) diffuse, (b) sharp). The X-ray powder diffraction patterns of the materials after exothermic reaction are the same as that of α-Al_2O_3.

The X-ray powder diffraction pattern of the material heated in the 700—1000°C temperature range, which corresponds to the temperature range between the endothermic and exothermic peaks, is very similar to the pattern of κ-Al_2O_3, which is one of the dehydration products of gibbsite. Therefore, this material will be denoted as "κ-Al_2O_3 (from tohdite)."

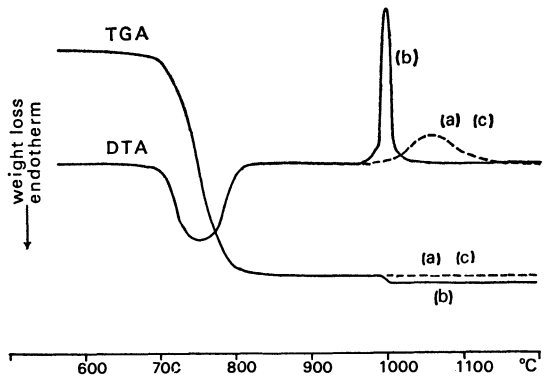

Fig. 2. DTA and TGA curves of tohdite.
(a) tohdite(η), (b) tohdite(F), (c) tohdite(Ti).

The dehydration of tohdite in a high vacuum also proceeded in a single step. Dehydration was observed at a lower temperature range (650—750°C) because of the rapid water loss in a high vacuum, the X-ray diffraction pattern of the dehydrated material is unlike the pattern of κ-Al_2O_3 (from tohdite) and this material will be denoted as "κ'-Al_2O_3 (from tohdite)." As κ'-Al_2O_3 (from tohdite) is an unstable intermediate phase, it can easily be transformed into κ-Al_2O_3 (from tohdite) by further heating both in a high vacuum and under a normal atmosphere. The stabilities of κ'-Al_2O_3 are, however, slightly different according to their starting materials, tohdite(η), tohdite(F), and tohdite(Ti). The κ'-Al_2O_3 obtained from tohdite(η) is more unstable than the κ'-Al_2O_3(from tohdite(F)) and the κ'-Al_2O_3 (from tohdite(Ti)); therefore, it is not easy to obtain κ'-Al_2O_3 (from tohdite(η)) crystal as as single phase without κ-Al_2O_3 crystals.

X-Ray Powder Data. The X-ray powder patterns of tohdite and its dehydration products κ'-Al_2O_3 (from tohdite) and κ-Al_2O_3 (from tohdite) are shown in Fig. 3. An important feature of the pattern of κ'-Al_2O_3 is that it resembles the pattern of tohdite itself, though it is rather more simple.

The tohdite reflections to which the oxygen atoms do not contribute decrease in intensity, while the reflections due mainly to the oxygen atoms remain to form the main part of the κ'-Al_2O_3 (from tohdite) pattern. The contribution of oxygen atoms to the intensity of the tohdite reflections was calculated; it is illustrated in Fig. 3, with sign + and −.

The reflections of κ'-Al_2O_3 (from tohdite) can be well indexed on the basis of the hexagonal unit cell of tohdite, which contains 5⅓ formulas of Al_2O_3. The propriety of employing this unit cell will be discussed later. The unit-cell dimensions of κ'-Al_2O_3 (from tohdite(F)) calculated from the X-ray data are shown in Table 1.

Table 1. Cell dimensions (in Å)

Tohdite(η)	$a=5.575$,	$c=8.761$
Tohdite(F)	$a=5.577$,	$c=8.774$
κ'-Al_2O_3 (from tohdite(F))	$a=5.544$,	$c=9.024$
κ-Al_2O_3 (from tohdite(F))	$a=9.599$,	$c=9.015$

The similarity between κ'- and κ-Al_2O_3 (from tohdite) was also seen (Fig. 3). The additional reflections of κ-Al_2O_3 (from tohdite) are probably caused by the distribution of aluminium atoms. The reflections are indexed on the basis of hexagonal unit cell with $a \approx \sqrt{3}a$ of tohdite, $c \approx c$ of tohdite. These cell dimensions were calculated from the X-ray data; they are also listed in Table 1.

Electron-diffraction Data. Electron-diffraction patterns were obtained for the following specimen series (the dehydration products have the same particle size and shape as the starting tohdite):

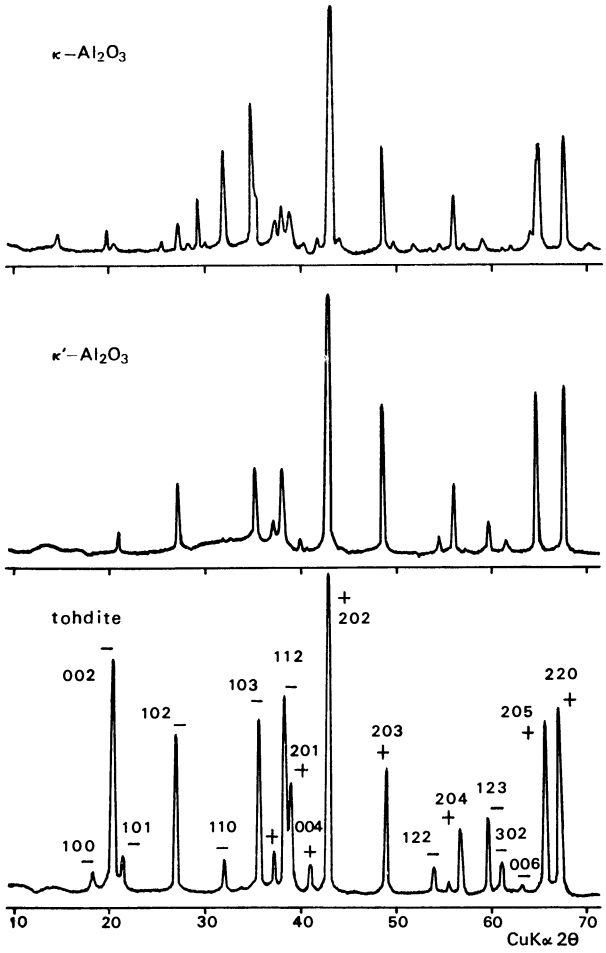

Fig. 3. X-Ray diffraction pattern of tohdite(F), κ'-Al_2O_3 (from tohdite(F)) and κ-Al_2O_3 (from tohdite(F)). The contribution of oxygen atoms on the intensity of tohdite is calculated.
+: reflection which is due mainly to the oxygen atoms
−: reflection for which oxygen atoms do not contribute

(a) tohdite(η) $\xrightarrow{900°C \text{ in air}}$ κ-Al_2O_3 (from tohdite(η))

These specimens correspond to the KI and KII of Krischner's study.

(b) tohdite (F) $\xrightarrow[(10^{-4} \text{ mmHg})]{750°C \text{ in vacuum}}$ κ'-Al_2O_3 (from tohdite(F))
$\xrightarrow{900°C \text{ in air}}$ κ-Al_2O_3 (from tohdite (F))

(c) tohdite (Ti) $\xrightarrow[(10^{-4} \text{ mmHg})]{750°C \text{ in vacuum}}$ κ'-Al_2O_3 (from tohdite(Ti))
$\xrightarrow{900°C \text{ in air}}$ κ-Al_2O_3 (from tohdite(Ti))

Patterns:

(a) The electron diffraction pattern of κ-Al_2O_3 (from tohdite(η)) agrees with that of KII described by Krischner. As has also been described by Krischner, this pattern agrees with the pattern, "(D)," of the dehydration product of gibbsite described by Brindley and Choe.[4]

(b) The electron-diffraction patterns of this series specimen are shown in Figs. 4, 5, and 6. The pattern of κ-Al_2O_3 (from tohdite(F)) is the same as that of κ-Al_2O_3 (from tohdite(η)).

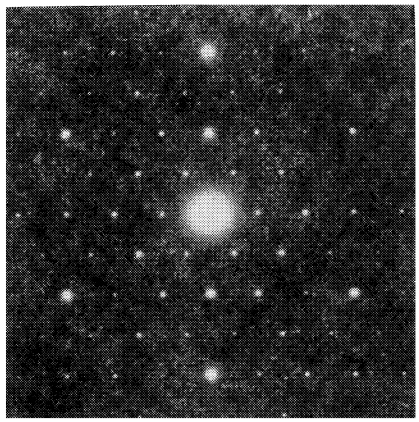

Fig. 4. Electron diffraction pattern of tohdite(F).

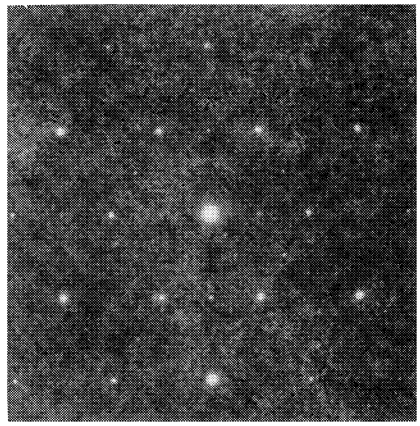

Fig. 5. Electron diffraction pattern of κ'-Al_2O_3 (from tohdite(F)).

Fig. 6. Electron diffraction pattern of κ-Al_2O_3 (from tohdite(F)).

The pattern of κ'-Al_2O_3 (from tohdite(F)) resembles that of tohdite, though the intensity distribution is different. Therefore, the reflections of this pattern are indexed on the basis of the unit cell of tohdite.

(c) The electron-diffraction patterns of needle-like crystals evaporated with aluminium metal were also obtained (Figs. 7—10). These patterns represent $(h, k, \overline{h+k}, l)$ reflections of the materials, where h and k are integers which should be determined from the

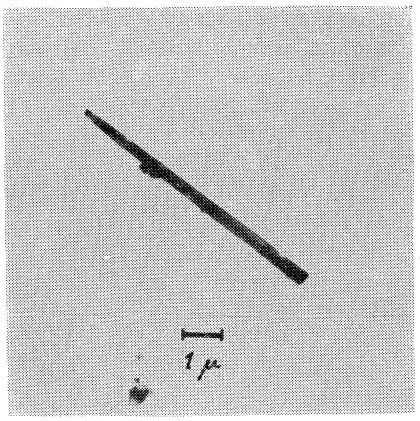
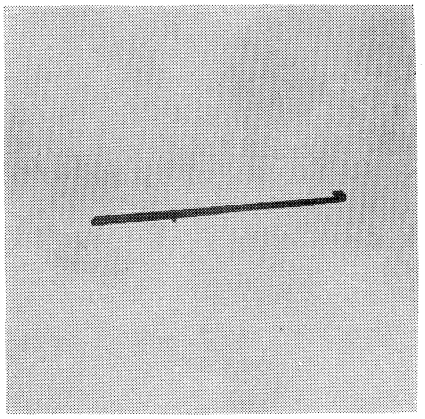
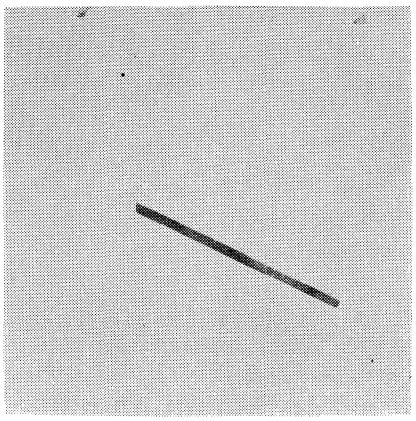
atomic netplane parallel to the electron beam. Whatever value h and k may have, a row of (000l) reflection spots can be found in the pattern. The interval between the (000l) spots of tohdite was calculated as 4.4 Å from the pattern. This agrees with the values of $c/2$=4.38 Å calculated from the X-ray data; the spots are indexed as (0002), (0004), *etc.* This indexing can also be expected from the crystal structure of tohdite,



(a)



(b)



(c)

Fig. 10. Needle like crystal. (a) tohdite(Ti), (b) κ'-Al_2O_3 and (c) κ-Al_2O_3 (from tohdite(Ti)).

which was determined from the X-ray powder data.[5,6] However, in some patterns of tohdite(Ti), the (000l) l=odd reflections were observed to have a very weak intensity, indicating a small deviation from the ideal structure of tohdite ($P6_3mc$). This deviation may be caused by the impurity titanium atoms contained in tohdite(Ti) (about 3%).

5) G. Yamaguchi, H. Yanagida, and S. Ono, *ibid.*, **37**, 752 (1964).
6) G. Yamaguchi, M. Okumiya, and S. Ono, *ibid.*, **42**, 2247 (1969).

By comparing the pattern of κ-Al_2O_3 (from tohdite (Ti)) with the pattern of tohdite(Ti), the following results are obtained. The row of (000l) spots is of the same type as that of tohdite(Ti), and the interval between the spots is 4.5 Å. From this value, the c-axis of κ-Al_2O_3 (from tohdite(Ti)) is calculated as 9.0 Å. In some patterns of κ-Al_2O_3 (from tohdite (Ti)), very weak (000l) l=odd reflections were also observed as in the case of tohdite(Ti), but no evidence was found that the c-axis of κ-Al_2O_3 (from tohdite (Ti)) was twice as large as that of tohdite(Ti).

The pattern of κ'-Al_2O_3 (from tohdite(Ti)) resembles that of κ-Al_2O_3 (from tohdite(Ti)). The cell dimension of c=9.0 Å which was calculated from the electron-diffraction patterns agrees with that of c= 9.015 Å calculated from the X-ray powder diffraction data.

Density Measurements. It is difficult to obtain the absolute value of the density of the fine-grained materials with a high accuracy. In the present work, it is important to compare the density of the dehydration products with that of the starting tohdite. For this purpose, the specimen series (b) was used, because the specimens of this series were easily obtained in a large amounts as a single phase. The average values of five measurements and their standard deviation are shown in Table 2. The measured valued of the density are as follows:

tohdite(F)<κ'-, κ-Al_2O_3 (from tohdite(F))<α-Al_2O_3

Table 2. Density of tohdite, κ'-, and κ-Al_2O_3 (from tohdite)

	Measured density with their standard deviations	Calculated density[a)]
Tohdite(F)	3.63 (0.006)	3.72
κ'-Al_2O_3 (from tohdite(F))	3.68 (0.002)	3.76
κ-Al_2O_3 (from tohdite(F))	3.67 (0.008)	3.77
α-Al_2O_3 (from tohdite(F))	3.96 (0.008)	4.00

a) These value are calculated from unit cell dimensions listed in Table 1 and formula unit per unit cell. The formula units are assumed as follows.
tohdite(F): $5Al_2O_3 \cdot H_2O$
κ'-Al_2O_3 (from tohdite(F)): $5\frac{1}{3}Al_2O_3$
κ-Al_2O_3 (from tohdite(F)): $16Al_2O_3$

Discussion

Krischner concluded, on the basis of their experimental results on electron diffraction, that the basic lattice of oxygen atoms is preserved during the transformation from tohdite to κ-Al_2O_3 (from tohdite), while the cations move to make the symmetry of κ-Al_2O_3 (from tohdite). However, their conclusion for the crystal structure of κ-Al_2O_3 (from tohdite) was that 30 formulas Al_2O_3 exist in a hexagonal unit cell with the cell dimensions of a=9.71 Å, and c=17.86 Å. This indicates a non-close-packed oxygen arrangement. He said that the measured density of 3.5 g/cm^3 agrees well with the value calculated from this unit cell and 30 formulas Al_2O_3. However the experimental results of the present work show that the measured density of κ-Al_2O_3 (from tohdite) (the value for κ-Al_2O_3 (from tohdite(F)), 3.67 g/cm^3), which has a close-packed oxygen arrangement in the crystal structure. Therefore, the present authors consider that the oxygen arrangement of κ-Al_2O_3 (from tohdite) is a close-packed one, as is that of κ'-Al_2O_3 (from tohdite) (the measured density for κ'-Al_2O_3 (from tohdite(F)) is 3.68 g/cm^3).

However, his experimental results on electron diffraction seem important in support the idea of the preservation of the oxygen lattice. This was confirmed by various methods in the present work. We will now consider the mechanism of the transformation and the crystal structure of the dehydration products on the basis of this idea.

Just after the 100% water loss, aluminium atoms are distributed at random in octahedral and tetrahedral positions between the oxygen layers, which are unchanged during the transformation. This atomic arrangement may give the X-ray and electron diffraction pattern of κ'-Al_2O_3 (from tohdite). The impurity atoms which are considered to distributed at random in the crystal structure of the starting tohdite stabilize the κ'-phase. As κ'-Al_2O_3 is an unstable intermediate phase, the κ'-Al_2O_3 (from tohdite) obtained by quenching has a "freezed" crystal structure.

The experimental results can be explained well by this consideration. Therefore, it is proper to employ a unit cell with cell dimensions of a=5.544 Å, and c= 9.024 Å, and which contains a non-integer unit formula of 5⅓ Al_2O_3 and an ABAC stacking sequence of oxygen layers for κ'-Al_2O_3 (from tohdite).

The electron-diffraction pattern of the material identified as "Bild 7" in the Krischner paper is very similar to that of κ'-Al_2O_3 (from tohdite) (Fig. 6). The cell dimensions calculated from "Bild 7" have been reported to include a=from 5.56 to 5.54 Å. This value agrees well with the cell dimension of κ'-Al_2O_3 (from tohdite), a=5.54 Å, calculated from the X-ray powder diffraction data. Therefore, the material, "Bild 7", which was obtained by heating tohdite quickly by an electron beam in an electron microscope may correspond to κ'-Al_2O_3 (from tohdite).

At higher temperatures aluminium atoms are allowed to move more freely and are distributed in a symmetry which gives the X-ray and electron-diffraction patterns of κ-Al_2O_3 (from tohdite). Though the oxygen position may deviate from the ideal position of tohdite, it is proper to assume that the oxygen arrangement of κ-Al_2O_3 (from tohdite) is an ABAC-type closed packing and that the unit cell dimensions are a=9.60 Å, and c=9.02 Å.

Over a temperature of 1000°C, a large-scale oxygen rearrangement takes place and the ABAC stacking sequence changes into the ABAB of α-Al_2O_3. The sharp exothermic peak for the specimen series (b) (Fig. 2) can be explained as follows. Since tohdite (F) is obtained by hydrothermal treatment with aluminium fluoride as a miniralizer, it is expected that this specimen will contain fluorine ions as impurities in

the crystal of tohdite. Furthermore, it can be assumed that fluorine ions, the ion radius of which is comparable to that of oxygen, exist in the oxygen sub-lattice of tohdite and remain in the oxygen sub-lattice of κ-Al_2O_3 (from tohdite(F)). The transformation reaction to α-Al_2O_3, which takes place through the rearrangement of oxygen stacking, is accelerated by the dissociation of the impurity fluourine ions from the oxygen sub-lattice, causing a sharp exotherm (Fig. 2). The dissociation of fluourine ions, which was observed as a slight weight loss (about 0.3%) in the thermogravimetric measurements (Fig. 2), was confirmed by the following analysis. The fluorine gas dissociated from the crystal was captured by a wet nitrogen flow which was introduced into a NaOH aqueous solution, and the photometric determination was performed with an alizarin complexon.

Conclusions

(1) The transformation series:

tohdite $\rightarrow$ κ'-Al_2O_3 (from tohdite)
$\rightarrow$ κ-Al_2O_3 (from tohdite) $\rightarrow$ α-Al_2O_3

was confirmed.

(2) Density measurements and electron-diffraction and X-ray diffraction experiments showed that the oxygen arrangements of both κ'- and κ-Al_2O_3 (from tohdite) are close-packed ones, with the oxygen sub-lattice kept unchanged. No evidence was found that the c-axis was twice as large as that of tohdite, in spite of Krischner's assumption. Therefore, it is proper to assume that the stacking sequence of oxygen layers is ABAC and a close-packed one.

(3) For κ'-Al_2O_3 (from tohdite), the hexagonal unit cell containing $5\frac{1}{3}$ Al_2O_3 non-integer unit formulas was employed. The cell dimensions were $a=5.544$ Å, and $c=9.015$ Å. The unit cell of κ-Al_2O_3 (from thodite) is hexagonal, with cell dimensions of $a=9.599$ Å, and $c=9.024$ Å.

On the basis of this conclusion, a crystal structure analysis of κ'- and κ-Al_2O_3 (from tohdite) is now being perfomed. The results will be published later.

The Effect of Consecutive Complex Formation on the Separation of Rare Earths by Electromigration

Emiko Ohyoshi

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received August 24, 1970)

The effect of a complexing agent with which rare earths consecutively form complexes on the separation of an adjacent pair of rare earths by electromigration was investigated. By assuming the complexes ML and ML_2 to be formed, the relation of the separation factor, the difference in the zone mobility of the two rare earths, to the ligand-ion concentration was derived and examined for the separation of the La-Ce and Ce-Pr pairs by using nitrilotriacetic acid (NTA), which is known to form the ML and ML_2 complexes with rare earths. It is found that the separation factor is affected not only by the difference in the first (k_1) or the second (k_2) consecutive formation constant of the two elements to be separated, but also by the value of the k_1/k_2 ratio.

In a previous paper,[1] it was reported that the separation of an adjacent pair of rare earths by using a complexing agent in electromigration is considerably influenced by the ligand-ion concentration and that when only one complex, ML, is assumed to be formed, the optimum ligand-ion concentration for their separation can be predicted from the values of the formation constants of the complexes. It was also suggested that, in the case where the consecutive formation of complexes, ML, ML_2,$\cdots$, ML_n, takes place, the range of ligand concentrations suitable for separation becomes wider compared with the case where only one complex is formed. However, the previous work was not extended beyond qualitative discussions. It appears to require further investigation for verification.

This paper will deal with the effect of a complexing agent with which rare earths consecutively form complexes on the separation of an adjacent pair of rare earths by electromigration. When two complexes, ML and ML_2, are assumed to be formed, the relation of the separation factor to the ligand-ion concentration has been derived and examined for the separation of the La-Ce and Ce-Pr pairs by using nitrilotriacetic acid (NTA), which is known to form the ML and ML_2 complexes with rare earths.

The Separation Factor for Two Kinds of Rare Earths. When the ML and ML_2 complexes are consecutively formed, the equilibria in solution can be expressed as follows:

$$M + L = ML \quad (1)$$

$$ML + L = ML_2 \quad (2)$$

where the charges are omitted for the sake of simplicity. The equilibrium constant of each process, *i.e.*, the first (k_1) and second (k_2) consecutive formation constants, are given by $k_1=[ML]/([M][L])$ and $k_2=[ML_2]/([ML][L])$. When the two species, M and ML, are equilibrated, the equation expressing the zone

1) E. Ohyoshi, This Bulletin, **43**, 1387 (1970).

mobility has previously been derived.[1,2] From a similar point of view, the following equations can be given for the system of the above equilibria, the attainment of which is rapid:

$$u([M] + [ML] + [ML_2]) = u_M[M] + u_{ML}[ML] + u_{ML_2}[ML_2] \quad (3)$$

$$u = \frac{u_M + u_{ML}k_1[L] + u_{ML_2}k_1k_2[L]^2}{1 + k_1[L] + k_1k_2[L]^2} \quad (4)$$

where u, u_M, u_{ML}, and u_{ML_2} are the mobilities of the zone, M, ML, and ML_2 respectively.

Since the charge of the complex tends to become more and more negative with the progress of the consecutive complex formation, the difference in the zone mobility of the two elements should be taken as the separation factor, S:

$$\begin{aligned} S &= u - u' \\ &= \{(u_M - u_{ML})(k_1' - k_1)(L) \\ &\quad + (u_M - u_{ML_2})(k_1'k_2' - k_1k_2)[L]^2 \\ &\quad + (u_{ML} - u_{ML_2})k_1k_1'(k_2' - k_2)[L]^3\}/ \\ &\quad \{(1 + k_1[L] + k_1k_1[L]^2)(1 + k_1'[L] + k_1'k_2'[L]^2)\} \end{aligned} \quad (5)$$

where it is assumed that $u_M = u'_M$, $u_{ML} = u_{ML}$, and $u_{ML_2} = u'_{ML_2}$. Equation (5) suggests that the greater the difference in the mobility of M, ML, and ML_2, or the greater the difference in the first or the second consecutive formation constants of the two elements, the larger the value of S.

When the values of k_1 and k_1' are much larger than those of k_2 and k_2', Eq. (5) can be simplified to Eq. (6) or (7) in a range of either low or high ligand concentrations.

$$S_{(1)} = \frac{(u_M - u_{ML})(k_1' - k_1)[L]}{(1 + k_1[L])(1 + k_1'[L])} \quad (6)$$

$$S_{(h)} = \frac{(u_{ML} - u_{ML_2})(k_2' - k_2)[L]}{(1 + k_2[L])(1 + k_2'[L])} \quad (7)$$

Equations (6) and (7) exhibit only two species, either M and ML or ML and ML_2, present in the respective range. As was shown by the relation of S to [L] expressed by Eq. (6) presented in the previous paper,[1] $S_{(1)}$ has its maximum at:

$$[L] = \{1/(k_1k_1')\}^{1/2} \quad (8)$$

An expression of Eq. (7) similar to that of Eq. (6) indicates that if $k_2' > k_2$, $S_{(h)}$ also has its maximum at:

$$[L] = \{1/(k_2k_2')\}^{1/2} \quad (9)$$

where $dS_{(h)}/d[L] = 0$. Hence, when $k_1 \gg k_2$ and $k_1' \gg k_2'$, S takes two maxima in a range of low or high ligand concentrations.

Experimental

The sample solution was prepared as has been described previously.[1] The concentration of La^{3+}, Ce^{3+}, or Pr^{3+} was 3×10^{-4} M. The electrolyte solutions were prepared as follows. Nitrilotriacetic acid (Dotite NTA), plus a small amount of NaOH, was dissolved in solutions of different pH's (1.86—4.80) to give concentrations from 10^{-3} to 10^{-2} M. Mixtures of 0.05 M HCl and 0.05 M NaCl (pH<2.1), biphthalate buffer solutions (pH 2.2—3.0), and acetate buffer solutions (3.5—4.8) were used to prepare solutions of various concentrations of the nitrilotriacetate ion, $[L^{3-}]$ ranging from 10^{-12} to 10^{-8} M. Considering the dissociation of NTA, the ionic strength of the solutions was finally adjusted so as to maintain them at 0.05. The chemicals used were of a G. R. grade.

The procedure for paper electromigration was essentially the same as that described previously.[1] In this experiment, the sample was spotted at the center of the paper strip, since the zone may migrate toward either the cathode or the anode, depending on the degree of complex formation. The migrating zone was detected by studying the color reaction with Arsenazo III.

Results and Discussion

The Concentration of NTA. For the rapid attainment on the paper strip of the equilibria expressed by Eqs. (1) and (2), an amount of a complexing agent sufficient to enable us to neglect the amount bound to the metal must be used. By using solutions of the same concentration of the ligand ion, obtained by adjusting the pH, the zone mobility was measured as a function of the total NTA concentration. From the results it was found that, at concentrations above 2.5×10^{-3} M, the mobility was almost constant, but it was lowered at 1.25×10^{-3} M. Hence, NTA concentrations ranging from 2.5×10^{-3} to 1.0×10^{-2} M were used.

Determination of u_M, u_{ML}, and u_{ML_2}. Since there is an appreciable difference between the first and the second consecutive formation constants of rare earth-NTA complexes (the value of k_1/k_2 is of the order of 10^3), Eqs. (6) and (7) can be applied in the ranges of both low and high ligand concentrations. The rearrangement of Eqs. (6) and (7) leads to these expressions:

$$u = \frac{1}{k_1[L] + 1}(u_M - u_{ML}) + u_{ML} \quad (6')$$

$$u = \frac{1}{k_2[L] + 1}(u_{ML} - u_{ML_2}) + u_{ML_2} \quad (7')$$

Hence, by plotting u *vs.* $1/(k_1[L]+1)$ or $1/(k_2[L]+1)$, the values of u_M, u_{ML}, and u_{ML_2} can be obtained from the intercept and slope. The plots of u *vs.* $1/(k_1[L^{3-}]+1)$ and $1/(k_2[L^{3-}]+1)$ for lanthanum, cerium, and praseodymium are shown in Figs. 1 and 2, where k_1 and k_2[3] are the first and second consecutive formation constants of the La(III)-, Ce(III)-, and Pr(III)-NTA complexes. The concentration of L^{3-} is calculated by dividing the total concentration of NTA by the α coefficient,[4] which is a function of the pH. The linear relationship obtained in both Figs. 1 and 2, proves that Eqs. (6) and (7) can be applied to these ranges of $[L^{3-}]$. From the intercept and slope of the lines, the values of u_M, u_{ML}, and u_{ML_2} are given as 0.014, 0, and -0.011 cm²/V min respectively. The value of 0 given for u_{ML} is consistent with the fact that the ML

complex is a neutral species.

Effect of the Ligand-ion Concentration on the Separation Factor. To verify Eq. (5), the separation of the La-Ce and the Ce-Pr pairs was carried out at various concentrations of the nitrilotriacetate ion, L^{3-}. In Fig. 3, the separation factor, S, the difference in the zone mobilities of lanthanum and cerium or of cerium and praseodymium observed (points) and calculated from Eq. (5) (the solid or dotted line) is given as a function of $[L^{3-}]$. From the fact that the points obtained experimentally are observed to be close to the lines, Eq. (5) is found to be verified. As has been described above, when $k_1 \gg k_2$ as in this case, the plots of S *vs.* $[L^{3-}]$ for both the La-Ce and the Ce-Pr pairs yield curved with two maxima at $[L^{3-}]=2.51\times10^{-11}$ and 2.72×10^{-8} M for the La-Ce pair, and at $[L^{3-}]=1.12\times10^{-11}$ and 8.92×10^{-9} M for the Ce-Pr pair, as calculated by Eqs. (8) and (9) (Fig. 3). These curves show that S varies with the degree of complex formation, that is, as M forms ML, S reaches the first peak and then decreases with a subsequent increase in the fraction of ML; after passing through the minimum where almost all of the metal exists in the form of ML, S again increases with the formation of ML_2, reaches a second peak, and then decreases with the completion of the formation of ML_2.

In seeking for the effect of the consecutive formation of complexes on the separation factor, we attempt to plot S *vs.* [L], assuming various conditions, in Fig. 4. Curve 1 is a plot of the relation given by Eq. (5) by assuming that $u_{ML}/u_M=0.2$, $u_{ML_2}/u_M=-0.5$, $k_1=10^3$, $k_1'=2k_1$, $k_2=10$, and $k_2'=1.5\,k_2$. Curves 2 and 3 plot the relations given by the simplified equations (6) and (7) by using the values assumed in curve 1. When we compare these curves, we find that in the range on the lower side of $[L]=\{1/(k_1k_1')\}^{1/2}$ and the higher side of $[L]=\{1/(k_2k_2')\}^{1/2}$ curve 1 agrees well with curves 2 and 3, indicating that only two species, M and ML or ML and ML_2 are present in such ranges. It is noted that, in the range between two maxima where three species M, ML, and ML_2, are coexisting, curve 1 always gives a higher value than those given by curves 2 and 3. This clearly indicates that the formation of both ML and ML_2 serves to enhance the separation factor. To make the three species, M, ML, and ML_2, all present, the value of k_1 must be close to that of k_2. Under the condition assumed in curve 1, if only the k_1/k_2 ratio is varied from 10^2 to 10, the plot

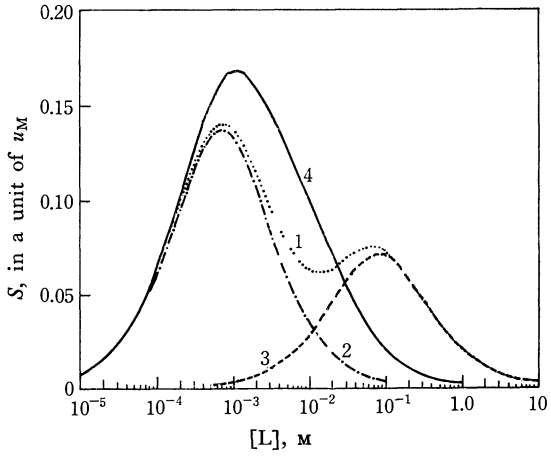

Fig. 4. Effect of the consecutive complex formation on the separation factor.
Curve 1, 4: Plots of S (in a unit of u_M) *vs.* [L] given by Eq. (5) assumed to be $u_{ML}/u_M=0.2$, $u_{ML_2}/u_M=-0.5$, $k_1=10^3$, $k_1'=2\,k_1$, $k_2'=1.5\,k_2$, and $k_2=10$ for curve 1 or $k_2=10^2$ for curve 4. Curve 2,3: A plot of $S_{(l)}$ (curve 2) or $S_{(h)}$ (curve 3) *vs.* [L] by using the same values as those in curve 1.

gives curve 4. When we compare curve 1 with curve 4, we find that even when the same difference in the k_1 or k_2 value of two elements is given, the S value is appreciably affected by the ratio of k_1 to k_2. With a reduction in the k_1/k_2 ratio, the two maxima become one, the value of which is considerably enhanced. This suggests that, when the further formation of ML_3, ML_4, $\cdots$, ML_n occurs and when their consecutive formation constants are not very different from each other, the high separation factor may be maintained over a wide range of ligand concentrations.

The above discussion was based on the assumption that $k_1' > k_1$, $k_2' > k_2, \cdots$, $k_n' > k_n$. Hence, when $k_1' > k_1$, $k_2' \simeq k_2, \cdots$, $k_n' \simeq k_n$, we can obtain only the same results as those in the cases when only one complex, ML, is formed.

Circular Dichroism of Mixed Biguanide Ethylenediamine Cobalt(III) Complexes

Kozo Igi, Takaji Yasui,* Jinsai Hidaka, and Yoichi Shimura
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received September 7, 1970)

Two kinds of mixed biguanide ethylenediamine complexes, $[Co(bgH)_2(en)]Cl_3 \cdot 3H_2O$ and $[Co(bgH)(en)_2]Cl_3 \cdot 2H_2O$, have been resolved into their optically active isomers. The circular dichroism spectra of a complete series of the mixed complexes, $(-)_{589}$-$[Co(bgH)_3]^{3+}$, $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$, $(+)_{589}$-$[Co(bgH)(en)_2]^{3+}$, and $(+)_{589}$-$[Co(en)_3]^{3+}$, have been investigated in neutral and alkaline aqueous solutions. In alkaline solutions, the circular dichroism and absorption curves of the biguanide complexes shift to longer wavelengths than those in neutral solutions; this may be caused by the change of the coordinated biguanide (bgH) to the uninegative ligand (bg^-) by deprotonation. A mixed guanylurea complex, $[Co(guH)(en)_2]Cl_3 \cdot 2H_2O$, has been newly prepared and optically resolved.

Biguanide, $NH\{C(NH_2)NH\}_2$=bgH,[1] combines with many kinds of transition metal salts to give a variety of coordination compounds with six-membered chelate rings,[2–4] of which cobalt(III) and chromium(III) complexes have recently been noted in terms of the circular dichroism (CD) spectra and absolute configuration.[5,6] Michelsen,[5] for example, suggested that $(-)_{589}$-$[Co(bgH)_3]^{3+}$ and $(-)_{589}$-$[Cr(bgH)_3]^{3+}$ have an absolute configuration Λ,[7] comparing the CD behavior of the complexes in the so-called first absorption band region with that of $\Lambda(+)_{589}$-$[Co(en)_3]^{3+}$, whose absolute configuration was unequivocally determined by an X-ray technique.[8] Recently, Brubaker and Webb[6] determined the absolute configuration of the $(-)_{589}$-$[Cr(bgH)_3]^{3+}$ to be Λ on the basis of X-ray analysis of the *d*-10-camphorsulfonate and suggested that the $(-)_{589}$-$[Co(bgH)_3]^{3+}$ should have Δ configuration, from the comparison of the ultraviolet CD spectra of the cobalt(III) and chromium(III) complexes. Thus, the conclusions from the CD of *d–d* absorption band region and of ultraviolet ligand absorption band region completely contradict each other for the tris-biguanide complex of cobalt(III).

In these circumstances, it is thought to be desirable to study more systematically the CD spectra of mixed complexes of ethylenediamine and biguanide, namely, $[Co(bgH)_3]^{3+}$, $[Co(bgH)_2(en)]^{3+}$, $[Co(bgH)(en)_2]^{3+}$, and $[Co(en)_3]^{3+}$. In the present paper, preparations and optical resolutions of such complexes and their absorption and CD spectra are reported. In the course of this study, a new guanylurea cobalt(III) complex, $[Co(guH)(en)_2]^{3+}$, happened to be obtained, where guH stands for a guanylurea molecule $NH(NH_2)CNHCO(NH_2)$.

Experimental

Preparation and Optical Resolution. *$[Co(bg)_3] \cdot 2H_2O$ and $[Co(bgH)_3]Cl_3$*: These complexes were prepared by the method of Ray and Dutt.[9]

by converting the known sulfate[11] with barium chloride. This complex was also prepared by the reaction of K[Co-$(CO_3)_2$(en)][12] and biguanide sulfate monohydrate. The complex is very soluble in water.

Found: C, 15.11; H, 5.97; N, 34.61%. Calcd for $C_6H_{22}N_{12}Cl_3Co\cdot 3H_2O$=[Co(bgH)$_2$(en)]$Cl_3\cdot 3H_2O$: C, 14.96; H, 5.87; N, 34.90%.

(−)$_{589}$- and (+)$_{589}$-[Co(bgH)$_2$(en)]$Cl_3\cdot H_2O$: To a solution containing 4.3 g of (±)-[Co(bgH)$_2$(en)]$Cl_3\cdot 3H_2O$ in 20 m*l* of hot water (70°C) was added with stirring a solution of 5.0 g of potassium di-μ-L-tartrato(4-)diantimonate-(III) trihydrate, $K_2[Sb_2(d\text{-}C_4H_2O_6)_2]\cdot 3H_2O$, in 30 m*l* of hot water (70°C). After the solution had been kept at room temperature for about an hour, the diastereomer deposited was filtered (the filtrate was used for the isolation of (+)$_{589}$ isomer) and washed with ice-water, ethanol and then ether. The diastereomer which was obtained in yellow crystals was recrystallized from hot water. $[\alpha]_{589}^{20}=+100°$.

To a suspension of 2.0 g of the diastereomer in 20 m*l* of water was added 3.5 g of powdered barium chloride dihydrate with vigorous stirring, and then 100 m*l* of ethanol was added to the resulted solution. After the solution had been kept in an ice-bath, the resulted precipitate was filtered off. The filtrate was evaporated to dryness in a vacuum evaporator at room temperature. The orange-colored residue was recrystallized from a small amount of water by adding ethanol-acetone (1 : 1) mixture and then acetone, and dried in air. $[\alpha]_{589}^{20}=-93°$, $[M]_{589}^{20}=-415°$.

(+)$_{589}$-[Co(bgH)$_2$(en)]$Cl_3\cdot H_2O$ was obtained from the filtrate described above.

Found: C, 16.33; H, 5.58; N, 37.43%. Calcd for $C_6H_{22}N_{12}Cl_3Co\cdot H_2O$=(+)$_{589}$-[Co(bgH)$_2$(en)]$Cl_3\cdot H_2O$: C, 16.17; H, 5.44; N, 37.72%. $[\alpha]_{589}^{20}=+93°$, $[M]_{589}^{20}=+415°$.

[Co(bgH)(en)$_2$]$Cl_3\cdot 2H_2O$: The preparation of this complex was carried out by a modified procedure of Dutta's method.[4] A solution containing 7.6 g of biguanide sulfate monohydrate in 200 m*l* of water was added to 150 m*l* aqueous solution of 11.1 g of barium hydroxide octahydrate. After the resulted barium sulfate had been filtered off, the filtrate was added to a solution containing 10 g of *trans*-[Co(Cl)$_2$-(en)$_2$]Cl in 100 m*l* of water. The solution was heated on a water bath for 8 hr at 55°C. The color of the solution changed from purple to orange red. When the solution was concentrated to about 80 m*l* with a vacuum evaporator at 33°C, the orange crystals, [Co(bgH)$_3$]Cl_3, began to appear. After the solution was kept in an ice-bath for about an hour, the crystals were removed by filtration. The filtrate was concentrated to 25 m*l* in a vacuum evaporator and allowed to stand at room temperature for several days. The crude orange red complex was filtered and washed with ethanol and then ether. Yield: 5.7 g. The crude product was recrystallized from hot water by adding ethanol-acetone (1 : 1) mixture.

Found: C, 17.01; H, 6.73; N, 29.89%. Calcd for $C_6H_{23}N_9Cl_3Co\cdot 2H_2O$=[Co(bgH)(en)$_2$]$Cl_3\cdot 2H_2O$: C, 17.05; H, 6.45; N, 29.83%.

(−)$_{589}$-[Co(bgH)(en)$_2$]$Cl_3\cdot 3H_2O$: The racemate, (±)-[Co(bgH)(en)$_2$]$Cl_3\cdot 2H_2O$, (2.0 g), was dissolved in 15 m*l* of hot water. To this solution was added a solution containing 2.37 g of potassium di-μ-L-tartrato(4-)diantimonate(III) trihydrate in 25 m*l* of hot water with stirring. The mixed solution was kept at room temperature for a few min to complete the crystallization. The less soluble diastereomer was obtained in light orange powder. $[\alpha]_{589}^{15}=-96°$.

One gram of the diastereomer, 3 g of barium chloride dihydrate and 10 m*l* of water was triturated in a mortar. The white precipitate resulted was filtered off. Fifty milliliters of ethanol was added to the filtrate and the white precipitate was filtered off again. After the filtrate had been concentrated to 4 m*l* in a vacuum evaporator at 28°C, 2 m*l* of ethanol-acetone (1 : 1) mixture was added to it. The white precipitate was filtered off once again. Then the filtrate was concentrated to 3 m*l* in the same way. After 12 m*l* of ethanol-acetone (1 : 1) mixture had been added to the solution, the orange red crystals desired were separated by filtration. Recrystallization of this complex was carried out from 2 m*l* of water by adding ethanol-acetone (1 : 1) mixture. The complex obtained was washed with ethanol and ether.

Found: C, 16.60; H, 6.45; N, 28.81%. Calcd for $C_6H_{23}N_9Cl_3Co\cdot 3H_2O$=(−)$_{589}$-[Co(bgH)(en)$_2$]$Cl_3\cdot 3H_2O$: C, 16.34; H, 6.64; N, 28.61%. $[\alpha]_{589}^{15}=-352°$, $[M]_{589}^{15}=-1551°$.

[Co(guH)(en)$_2$]Br_3 and [Co(guH)(en)$_2$]$Cl_3\cdot 2H_2O$: The suspension of 10 g of [Co(CO_3)(en)$_2$]ClO_4 and 6.5 g of biguanide sulfate monohydrate in 20 m*l* of water was heated on a water bath for about 30 min. To the hot solution was added 15 m*l* of perchloric acid (20%) with constant stirring and the solution was heated on a water bath for 2 hr. After cooling the resulted solution to room temperature, 16 g of powdered sodium bromide was dissolved into it. The orange crystals deposited were collected by filtration, and washed with water-ethanol (1 : 1) mixture, ethanol and then ether. The crude complex was recrystallized from hot water. As described in the Results and Discussion section, it was shown that during the reaction, the biguanide employed was hydrolyzed and changed into a guanylurea.

Found: C, 13.83; H, 4.31; N, 21.48%. Calcd for $C_6H_{22}N_8OBr_3Co$=[Co(guH)(en)$_2$]Br_3: C, 13.83; H, 4.26; N, 21.51%.

This bromide was converted to the chloride by treating it with silver chloride.

Found: C, 17.05; H, 6.38; N, 26.53%. Calcd for $C_6H_{22}N_8OCl_3Co\cdot 2H_2O$=[Co(guH)(en)$_2$]$Cl_3\cdot 2H_2O$: C, 17.01; H, 6.20; N, 26.45%.

(−)$_{589}$-[Co(guH)(en)$_2$]$(HO_3)_3$: Twenty and eight-tenths grams of (±)-[Co(guH)(en)$_2$]Br_3 was dissolved in 40 m*l* of warm water. To this solution was rapidly added a solution containing 20 g of potassium di-μ-L-tartrato(4-)diantimonate(III) trihydrate in 60 m*l* of hot water (70°C) with vigorous stirring. After the solution had been chilled in an ice-bath, the light orange needle crystals deposited were filtered, and washed with cold water, ethanol and then ether. Recrystallization was carried out from hot water. The diastereomer obtained was sparingly soluble in water. $[\alpha]_{589}^{20}=-142°$.

A mixture of the diastereomer (10 g), silver nitrate (10 g) and warm water (30 m*l*) was ground enough in a mortar. The resulted precipitate was filtered off and washed twice with a small amount of water. The combined washings and filtrate was evaporated to dryness with a vacuum evaporator at room temperature. The orange-colored residue was recrystallized from hot water. The orange needle crystals deposited were filtered, and washed with a little amount of ice-water, water-ethanol (1 : 1) mixture, absolute ethanol and then ether, and dried in air.

Found: C, 15.37; H, 4.81; N, 33.19%. Calcd for $C_6H_{22}N_{11}O_{10}Co$=(−)$_{589}$-[Co(guH)(en)$_2$]$(NO_3)_3$: C, 15.42; H, 4.75; N, 32.98%. $[\alpha]_{589}^{20}=-480°$, $[M]_{589}^{20}=-2243°$.

Measurements. The electronic absorption spectra were measured by Shimadzu spectrophotometer QR-50. The CD spectra were recorded with a Roussel-Jouan dichrograph

11) R. L. Dutta and S. Sarkar, *Sci. Cult.* (Calcutta), **30**, 549 (1964).

and the optical rotatory dispersions were checked with Yanagimoto Recording spectropolarimeter model-185. The CD measurements were made in aqueous and 0.10 N and 0.25 N NaOH aqueous solutions. In 0.25 N NaOH aqueous solutions, $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$ and $(-)_{589}$-$[Co(bgH)(en)_2]^{3+}$ were not racemized and the racemization of $(-)_{589}$-$[Co(bgH)_3]^{3+}$ in 0.10 N NaOH aqueous solution was negligible during the CD measurement. The CD curves and data for the $(-)_{589}$-$[Co(bgH)(en)_2]^{3+}$ and $(-)_{589}$-$[Co(guH)(en)_2]^{3+}$ and of their deprotonated species are presented in reverse signs in Results and Discussion Section, Table 2, and Figs. 1—4, for the convenience of comparison with those of the other complexes; therefore the CD curves and data are refered as those for the $(+)_{589}$ isomers.

Results and Discussion

1. The Absorption and CD Spectra of Ethylenediamine-Biguanide Cobalt(III) System. The first absorption bands of the biguanide complexes are shifted to the longer wavelength side and are more intense than that of $[Co(en)_3]^{3+}$ (Fig. 1 and Table 1). In this region, $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$ and $(-)_{589}$-$[Co(bgH)_3]^{3+}$ in water exhibit two CD bands, one negative and another positive listing from the longer wavelength side, whereas $(+)_{589}$-$[Co(bgH)(en)_2]^{3+}$ shows only a positive CD band which is more intense than the positive E_a CD component of $(+)_{589}$-$[Co(en)_3]^{3+}$ (Table 2). In the second absorption band region, all the biguanide complexes show negative CD bands in contrast to the $(+)_{589}$-tris(ethylenediamine) complex which shows a positive one. In the shorter wavelength region, the absorption spectra of the present complexes are similar to each other on the whole (Fig. 1 and Table 1). In the tris- and bis-biguanide complexes, it seems that the intense absorption bands which locate at the shorter wavelength than 250 mμ are due to π–π^* transitions of the coordinated biguanide ligand; the CD spectra in the corresponding region show two oppositely signed CD bands, and these are very intense only when two or three biguanide ligands coordinate to a cobalt(III)

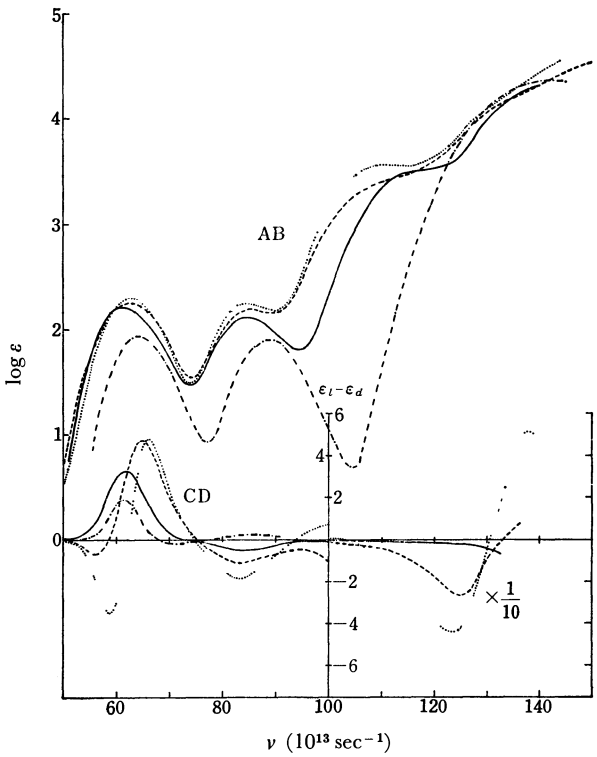

Fig. 1. Absorption (AB) and CD curves of $(-)_{589}$-$[Co(bgH)_3]^{3+}$ (……), $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$ (----), $(+)_{589}$-$[Co(bgH)(en)_2]^{3+}$ (——), and $(+)_{589}$-$[Co(en)_3]^{3+}$ (—·—·—).

ion (Figs. 2 and 3, and Table 2). Brubaker and Webb suggested that such CD band splitting in this region may be interpreted as the excition splitting, of which a theory has been recently developed mainly by Mason,[13] Bosnich,[14] and others,[15] and that the $(-)_{589}$-$[Co(bgH)_3]^{3+}$ complex which exhibits a negative CD component at lower energy has Δ configuration. This suggestion, however, seems to contradict with a conclusion from the behavior in the *d–d* absorption band region (see later section 3). The absorption bands

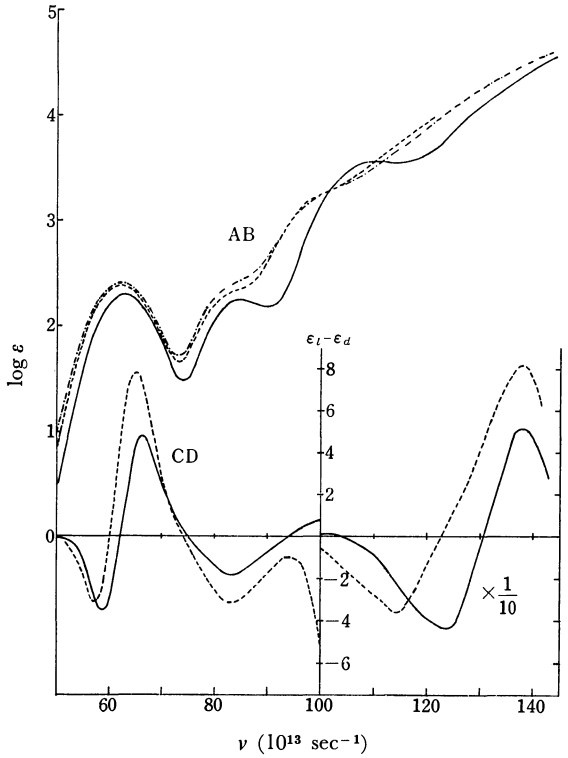

Fig. 2. Absorption (AB) and CD curves of (a) $(-)_{589}$-$[Co(bgH)_3]^{3+}$ and (b) $[Co(bg)_3]$: (a) in water (——), (a) in 0.10 N NaOH aq. soln. (----), and (b) in water (—·—·—).

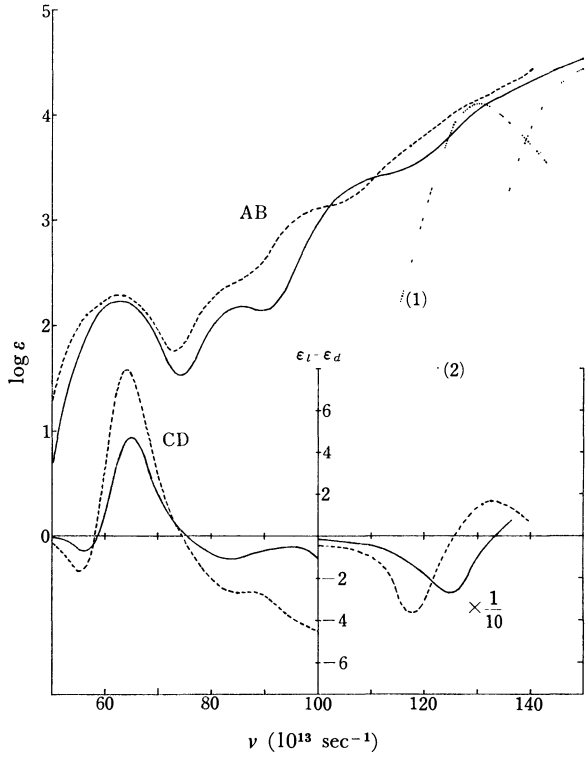

Fig. 3. Absorption (AB) and CD curves of $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$: in water (——) and in 0.25 N NaOH aq. soln. (----); and AB of biguanide sulfate monohydrate ($bgH \cdot H_2SO_4 \cdot H_2O$): in 0.10 N NaOH aq. soln. (1) (……) and in 0.10 N H_2SO_4 aq. soln. (2) (……).

which locate at about 270 mμ are not so contributed to CD that these bands may be considered to be charge transfer ones (or other kinds of inter ligand absorption bands).

The CD and absorption curves in NaOH aqueous solutions shift to the longer wavelength side on the whole than those in water, especially the bands which locate at the shorter wavelengths shift remarkably as seen in Figs. 2, 3, and 4. A similar red shift was also observed for the absorption curve of the free ligand biguanide (Fig. 3). The absorption curve of $(-)_{589}$-$[Co(bgH)_3]^{3+}$ in NaOH aqueous solution coincides well with that of $[Co(bg)_3]$ in water (Fig. 2). This fact points out that in 0.10 N NaOH aqueous solution, each of the three ligands of $(-)_{589}$-$[Co(bgH)_3]^{3+}$ is deprotonated and consequently $(-)_{589}$-$[Co(bgH)_3]^{3+}$ changes to optically active $[Co(bg)_3]$. It may be suggested that in the

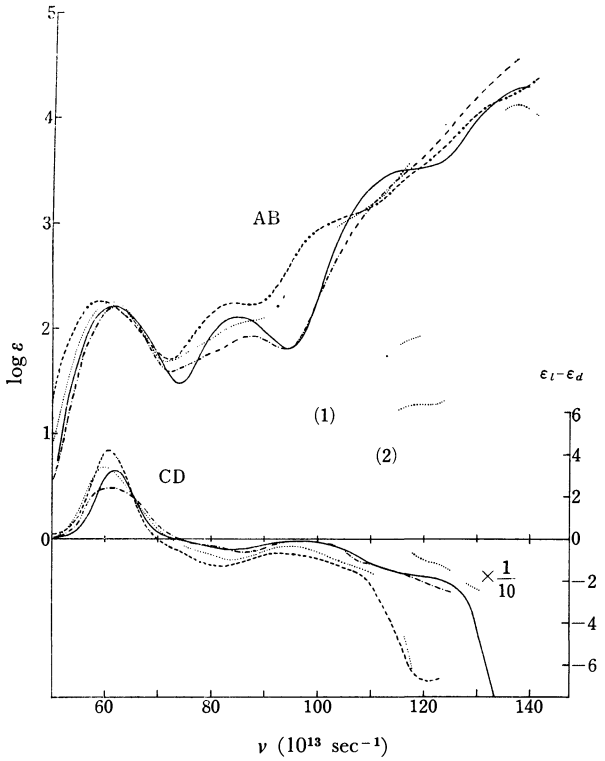

Fig. 4. Absorption (AB) and CD curves of (a) $(+)_{589}$-$[Co(bgH)(en)_2]^{3+}$ and (b) $(+)_{589}$-$[Co(guH)(en)_2]^{3+}$: (a) in water (——), (a) in 0.25 N NaOH aq. soln. (----), (b) in water (—·—·—), and (b) in 0.25 N NaOH aq. soln. (·····); and AB of guanylurea sulfate dihydrate ($(guH)_2\cdot H_2SO_4\cdot 2H_2O$): in 0.10 N NaOH aq. soln. (1) (·····) and in 0.10 N H_2SO_4 aq. soln. (2) (·····).

cases of $(+)_{589}$-$[Co(bgH)(en)_2]^{3+}$ and $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$ also the corresponding optically active bg^- complexes are formed in the alkaline solutions. Shift or intensification of the CD bands by such deprotonation occurred in the d-d absorption band region and these are also the case of the addition of sodium phosphate or selenite; then it was impossible to use the socalled "ion-paring criterion" proposed by Mason *et al.*,[16] for the component assignment of these biguanide complexes. Thus the assignment proposed by Brubaker and Webb[6] for the CD components of the first absorption band of $(-)_{589}$-$[Cr(bgH)_3]^{3+}$ from this criterion may be meaningless.

2. The Characterization of the Guanylurea Complex. As described in Experimental section, the analytical results suggest that the complex which was derived from $[Co(Cl)_2(en)_2]Cl$ and biguanide is $[Co(bgH)(en)_2]^{3+}$ and that the one from $[Co(CO_3)(en)_2]Cl$ and biguanide sulfate is $[Co(guH)(en)_2]^{3+}$. In the latter case, the biguanide is hydrolyzed into the guanylurea in the course of the reaction with $[Co(CO_3)(en)_2]Cl$.

The first absorption band of $[Co(guH)(en)_2]^{3+}$ is similar to that of $[Co(bgH)(en)_2]^{3+}$ as is shown in Fig. 4. Considering the fact that the effective symmetry of the former is much lower than that of the latter, it is expected that the first band of the former splits into two or more components. This consideration is realized in the CD spectra; namely, $[Co(guH)(en)_2]^{3+}$ exhibits an overlapped pattern of two positive CD bands, whereas $[Co(bgH)(en)_2]^{3+}$ shows only one positive (Fig. 4). Contrary to the first absorption band region, the second absorption band of $[Co(guH),(en)_2]^{3+}$ differs remarkably from that of $[Co(bgH)(en)_2]^{3+}$. The second band of the former splits into two components at 345 mμ and *ca.* 385 mμ, though the CD spectra of both the complexes are similar to one another in the corresponding region. It should be noted that the guanylurea complex is a rather rare example which shows the apparent splitting in the second absorption band. The CD and absorption curves shift to the longer wavelengths in alkaline solutions than those in water, especially in the region of the ultraviolet ligand absorption band; the absorption curve of the free ligand also shift to red in alkaline solution.

From the data presented in Table 1, it has been concluded that the spectrochemical series of the ligands concerned in this paper is

$$en > guH > bgH > gu^- > bg^-.$$

It is unknown which of the O and N atoms of the urea part in the guanylurea ligand is coordinated to the central cobalt(III) ion. This is also the case of a tris-guanylurea complex of cobalt(III).[2]

3. Absolute Configuration. Currently there have been encountered some difficulties in the attempt to make an inference of the absolute configuration of a tris-chelate type cobalt(III) or chromium(III) complex from the comparison of its CD signs in the region of the *d-d* or the ultraviolet ligand absorption bands to those of a reference complex, whose absolute configuration has been determined conclusively.

It is well known that MaCaffery and Mason[17] assigned a strong positive CD component at 61.5 (10^{13} sec^{-1}) of $(+)_{589}$-$[Co(en)_3]^{3+}$, whose absolute configuration was unequivocally determined by an X-ray technique by Saito *et al.*[8,18,19] to the transition $^1A_1$-^1E_a of the first absorption band from the CD measurement of a single crystal of $Na(+)_{589}$-$[Co(en)_3]_2Cl_7\cdot 6H_2O$; therefore another weak negative CD component at 70.6 (10^{13} sec^{-1}) of this complex should be assigned to a $^1A_1$-$^1A_2$ or to any other origin. Recently, Judkins and Royer[20] measured the single crystal CD spectra of $\Delta(+)_{589}$-$[Co(tn)_3]Cl_3\cdot 4H_2O$ containing trimethylenediamine (tn), whose absolute configuration was determined by Nomura *et al.*,[21] and reported that the relative positions of the A_2 and E_a components are reversed in this complex as compared with those found in $[Co(en)_3]^{3+}$; this means the E_a and the A_2 components of the Δ isomer of trimethylenediamine complex have positive and negative signs, respectively. Jud-

kins and Royer explained this contradiction between the ethylenediamine and trimethylenediamine complexes on the line of Piper's prediction[22,23] that stated, if the N–M–N angle in the chelate ring, α, is greater than 90°, the sign of the Cotton effects will reverse with respect to the complex with α less than 90°; the angle α of the $[Co(en)_3]^{3+}$ and $[Co(tn)_3]^{3+}$ have been reported to be 87.4°[19] and 94.5°,[21] respectively.

Unfortunately, Brubaker, and Webb reported that all three angles α of $[Cr(bgH)_3]^{3+}$ are 90° within experimental error, though this is for a chromium(III) and not for the cobalt(III) complex. In the meanwhile, the $\Lambda(-)_{589}$-$[Cr(bgH)_3]^{3+}$ has almost identical CD pattern in the *d–d* absorption band region to that of the $(-)_{589}$-$[Co(bgH)_3]^{3+}$. Accordingly, as far as we concern the *d–d* absorption band region, the $(-)_{589}$-$[Co(bgH)_3]^{3+}$ may be assigned to have the absolute configuration Λ, and the correspondency which is seen in Fig. 1 may suggest that all the isomers presented in Fig. 1 have the same absolute configuration Λ.

22) T. S. Piper and A. G. Karipides, *Mol. Phys.*, **5**, 475 (1962).
23) T. Bürer, *ibid.*, **6**, 541 (1963).

Nevertheless, a serious difficulty comes from the ultraviolet CD spectra as mentioned in Section 1 above; the criterion from the so-called exciton splitting shows reverse assignment, Δ, at least for the $(-)_{589}$-$[Co(bgH)_3]^{3+}$ and $(+)_{589}$-$[Co(bgH)_2(en)]^{3+}$ and their deprotonated species. A similar case has been found for $[Co(dip)_3]^{3+}$ (dip=2,2′-dipyridyl); the $(-)_{589}$ isomer has positive sign in the main CD component of the first absorption band and the negative and positive exciton splitting CD components, at longer and shorter wavelengths respectively, in the ultraviolet ligand absorption band region.[15] Clearly further studies are needed for these anomalies.

The overlapped positive CD components of the $(+)_{589}$-$[Co(guH)(en)_2]^{3+}$ in the first absorption band region suggest that this $(+)_{589}$ isomer has an absolute configuration Λ. It may be noticed that all the isomers containing biguanide or guanylurea, which were suggested to have absolute configuration Λ from the behavior in the first absorption band, have commonly negative CD bands in the second absorption band region.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 431—433 (1971)

The Characterization of $CdFe(CO)_4$ and $HgFe(CO)_4$ by Infrared and Mössbauer Spectroscopy and X-Ray Diffractometry

Tetsuo TAKANO and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 8, 1970)

Two compounds, $MFe(CO)_4$ (M=Cd or Hg), were investigated by the use of infrared and Mössbauer spectroscopy and X-ray diffractometry. The infrared data suggested that the M atoms link $Fe(CO)_4$ units to form infinite zig-zag chains; these metal atoms are attached to the iron atom at *cis*-positions and form an octahedron with four carbonyl groups. The Mössbauer spectra and infrared data indicate that the Cd–Fe and Hg–Fe bonds are not ionic but covalent, that they are as strong as C–Fe bonds in iron carbonyls. The isomorphism of the two compounds was confirmed by the X-ray diffractometry.

Among the compounds with metal-metal bonds, those with the simplest composition, $MFe(CO)_4$ (M= Cd, Hg), are interesting for their structures. They have been thought to have a polymeric structure formed by means of direct Cd–Fe or Hg–Fe bonds. Wells[1] proposed an endless structure of $HgFe(CO)_4$ in which the iron and mercury atoms are alternatively bonded to form a straight, linear chain. Adams *et al.*[2] and Beck and Noak[3] suggested that two cadmium or two mercury atoms and four carbonyl groups form an octahedral *cis*-configuration around the central iron atom of $CdFe(CO)_4$ or $HgFe(CO)_4$. However, so far no attempts have been made to provide precise structural information about these compounds. In this paper, their electronic states and structures will be discussed on the basis of infrared and Mössbauer spectroscopy and X-ray diffraction data.

Experimental

The sample of $HgFe(CO)_4$ was prepared by treating iron carbonyl with mercuric sulphate.[4] The corresponding cadmium compound was synthesized by the method of Feigl and Krumholtz,[5] yellow needle-like crystals of $CeFe(CO)_4$ being obtained after heating voluminous precipitates of $Cd(NH_3)_2Fe(CO)_4$ in an aqueous solution at 50°C for three days. The results of elemental analyses were satisfactory with regard to the above compositions. Thermal decomposition was carried out in a nitrogen stream over the temperature range of 15—300°C, using a Shimadzu Thermal Balance and a Rigaku Denki DTA apparatus. The infrared spectra were recorded with Nihon-Bunko DS402G (4000—700 cm^{-1}), Hitachi EPI-L02 (700—200 cm^{-1}), and Hitachi FIS-1 (300—60 cm^{-1}) spectrometers as Nujol mulls and as dispersion in fused polyethylene, at room temperature and at the temperature of

liquid nitrogen. The Mössbauer spectra were measured with a constant-velocity drive-type spectrometer with a source of ^{57}Co diffused onto a Pt-foil. The powder X-ray diffraction patterns were recorded with Rigaku-Denki and Norelco X-ray diffractometers. Filtered Cu$K\alpha$ and Fe$K\alpha$ radiations were used. Weissenberg cameras were used to obtain oscillation photographs of single crystals.

Results and Discussion

IR Spectra. The observed infrared absorption frequencies (measured as Nujol mulls at room temperature) are listed in Table 1a. The use of polyethylene as the dispersion media gave essestially the same results. In the far-infrared region, there appeared to be some discrepancies between our results and those of previous workers.[2,3] In the carbonyl region, four prominent stretching bands were observed for both compounds. This characteristic is just like that found for *cis*-$M(CO)_4L_2$ molecules of the C_{2v} symmetry with regard to the central metal atom, M. The four carbonyl stretching modes, assigned as is shown in Table 1a, and their force constants, calculated according to the Cotton-Kraihanzel model,[6] are listed in Table 1b, where K_1 is the stretching force constant of C–O *trans* to Hg or Cd, and where K_2 is the stretching force constant of C–O *cis* to Hg or Cd. The agreement between these values and the calculated frequencies of the A_1^1 mode support the present assignments. The fact that the frequency of each CO stretching band for $CdFe(CO)_4$ is lower than that of the corresponding band of $HgFe(CO)_4$ is consistent with the observations for $M[Co(CO)_4]_2$, where M refers to Cd or Hg.[7] In both cases, the order of frequencies may be associated with the difference in electronagativity and in atomic size between Cd and Hg.

Thus, it may be concluded that Cd is poorer π-electron acceptor than Hg in these molecules; in other words, the p orbitals of cadmium are less facile than those of mercury in forming $d\pi$–$p\pi$ bonds with the d-orbitals of iron.

The bands due to metal-metal vibrations are expected to appear in the region of the far-infrared spectra, where no band due to the M–CO group except those due to CMC bending vibrations is likely to appear.[8,9] Accordingly, the bands clearly observed at 217 cm^{-1} and 196 cm^{-1} can most reasonably be assigned to the Cd–Fe and Hg–Fe stretching modes; the other mode, A_1^1, could not be detected, presumably because this skeletal vibration frequency is lowered when molecules are polymeric,[10] as in the present cases. By assuming that a cadmium or mercury atom links $Fe(CO)_4$ groups to form a zig-zag chain, the force constants are calculated to be 2.1 and 1.9 md/Å for $HgFe(CO)_4$ and $CdFe(Co)_4$ respectively. These values, although rather rough, are still acceptable.[11] As for the above-mentioned cobalt carbonyl compounds, $M[Co(CO)_4]_2$ (M=Cd, Hg), the K(Cd–Co) and K(Hg–Co) values were reported to be 2.33 and 2.61 md/Å respectively by Stammreich, Kawai, and Sala.[7] These four bonds seem to be stronger than the Sn–Mn bonds in $Cl_3SnMn(CO)_5$ or $(CH_3)_3SnMn(CO)_5$, for which the values of 1.00 and 0.67 md/Å were obtained.[12]

The strength of the metal-metal bond in the compounds in question may be estimates to be comparable with those covalent metal-carbon bonds in neutral metal carbonyls. By comparing the K_1, K_2, and K_i values with those of iron carbonyl derivatives containing various ligands and Fe(0), the oxidation number of the iron atom in the present compounds was estimated to be nearly zero.

Mössbauer Spectra. The Mössbauer spectra data are given in Table 2 and in Fig. 1, along with those for the related compounds containing metal-metal bonds between different elements (these later values being taken from the literature).[13,14] In $HgFe(CO)_4$ the

Fig. 1. Mössbauer spectrum of $CdFe(CO)_4$ at 292°K.

Mössbauer effect could not be measured because of the large non-resonant absorption of mercury nuclides. The spectra of $Cd(NH_3)_2Fe(CO)_4$ which is the starting material for preparing $CdFe(CO)_4$ were too weak to be registered even at the temperature of liquid nitrogen. The large, negative isomer shift of $CdFe(CO)_4$ indicates that the charge on the iron atom is only slightly negative or is almost neutral.

The observed absorption, which is intense even at room temperature, suggests a rigid poymeric structure. Consequently, the polymeric structure containing the Cd(0)–Fe(0) covalent bond seems to be preferable to the ionic form, Cd^{2+}–$Fe(CO)_4^{2-}$, in the present complex.

It can be seen from the data that the compounds with the Sn–Fe–Sn bond, which also have a *cis*-configuration around the iron atoms,[14] closely resemble $CdFe(CO)_4$ in the valence state of the iron atom.

Two remarkable features of the Mössbauer spectra of $CdFe(CO)_4$ are the small value of the quadrupole splitting and its small temperature dependence. This fact may reflect a high-electric-field gradient symmetry around the iron atom, which can be interpreted in terms of the hybrid orbitals of the iron.

In six octahedral hybrid orbitals of these carbonyl compounds of iron in the low-valency state, the *d*-orbitals are so occupied as to complete the inert gas structure. The resulting electronic configuration reduces the angular dependency of the expanded *d*-electron clouds to some degree,[15] so that the field gradient at the iron nucleus becomes smaller, even in the present case, where a *cis*-configuration of the C_{2v} symmetry is suggested by the infrared data.

Considering the nature of the metal-metal bonds in terms of force constants, the results of our infrared and Mössbauer spectroscopy are compatible with regard to the electronic environment of the central iron atom.

Thermal Decomposition. On heating under nitrogen, $CdFe(CO)_4$ suddenly began to decompose at 245°C, while releasing just four CO per chemical unit. The residue burned violently on exposure to air. On its DTA curve, a sharp and huge endothermic-peak corresponding to the sudden decomposition appeared at 260°C. The stability of $CdFe(CO)_4$ against thermal decomposition up to 245°C seems unique among the metal carbonyl compounds of this type. On the other hand, $HgFe(CO)_4$ began to decompose gradually, releasing both carbon monoxide and mercury vapor.

Crystal Structure. The polarizing microscopic observations of the crystals of these compounds supported the idea that they belong to either a triclinic or a monoclinic system. The twenty-two diffraction lines observed for each compound were examined by Ito's method,[16] and it could be concluded that both compounds are triclinic and isomorphous, with the following lattice parameters:

$CdFe(CO)_4$ $a=11.8$, $b=9.4$, $c=9.3$ Å,
$\alpha=111.5$, $\beta=124.5$, $\gamma=106.0°$
Vol. $=748.2$ Å^3, $D_{calcd.}=2.48$ g/cm^3,

$HgFe(CO)_4$ $a=12.9$, $b=10.8$, $c=10.3$ Å,
$\alpha=108.5$, $\beta=121.5$, $\gamma=106.0°$
Vol. $=782.6$ Å^3, $D_{calcd.}=3.03$ g/cm^3.

Their densities, measured pycnometrically in benzene, gave the values of 2.5 and 3.1 g/cm^3, values which agreed with $Z=4$, for $CdFe(CO)_4$ and $HgFe(CO)_4$ respectively.

Although we have not been able to determine their precise structures from these results, there should be no significant differences in the crystal and molecular structures between the cadmium and mercury compounds. From the site symmetry about the iron atoms of C_{2v}, as estimated from the infrared data, one of the most probable structures is given in Fig. 2.

The weakness of the Mössbauer spectra of $Cd(NH_3)_2$-$Fe(CO)_4$ suggests that the metal-metal links are absent

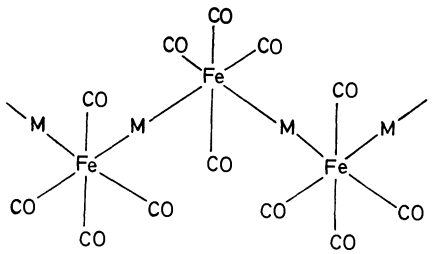

Fig. 2. Probable structure for $MFe(CO)_4$ (M=Cd, Hg).

in this compound and that they formed on the heat decomposition of this complex to yield $CdFe(CO)_4$.

The Syntheses and Properties of Some 2,4-Dimethyl-1,5-benzodiazepinium Halogenometalates

Akira Ouchi, Toshio Takeuchi, Mitsuhisa Nakatani, and Yoshiaki Takahashi

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September 21, 1970)

When 2,4-dimethyl-1,5-benzodiazepinium halide was reacted with a metal halide in ethanolic media, crystalline products, $M(C_{11}H_{13}N_2)_xX_y$ (where X=Br, Cl; M=Co(II), Mn(II), Zn(II), Cd(II), Sb(III) (chloride), Cu(II) (chloride), and Cu(I) (bromide)), were obtained. They are all new compounds. Their electronic and infrared spectra resemble those of the sarting chloride or bromide. The infrared band at about 1639 cm^{-1} of the chloride shifts to the lower-wave-number side when it is turned into a halogenometalate. On the other hand, the characteristic ν(M–X) bands were found in the far-infrared spectra of the halogenometalates, These compounds are likely to be ionic compounds consisting of the halogenometalato anion and the 2,4-dimethyl-1,5-benzodiazepinium cation.

Although tropolone and its derivatives were used as the ligands of the metal chelates, comparatively little investigation has been made of the metal compounds containing seven-membered ring components. Diazepines are relatively easily synthesized by the condensaion of diamine with diketones, as has been studied by Thiele[1] and Lloyd,[2-6] and these compounds have the seven-membered ring. From *o*-phenylenediamine and acetylacetone, for example, 2,4-dimethyl-3*H*-1,5-benzodiazepine is obtained. This compound forms a salt, deep violet in color, with hydrochloric acid. The salt is stable in the solid state, and it can be kept in the open air at room temperature without decomposition. There have been several discussions about the bonding structure of the salt,[4,7,8] but at any rate it is clear that the salt contains the 2,4-dimethyl-1,5-benzodiazepinium cation and that, therefore, the seven-membered ring was kept and not destroyed. When the salt was mixed with the anhydrous metal halides in an ethanolic medium, crystalline precipitates were obtained. These products are as deeply colored as the original dimethyl-benzodiazepinium salt. Repeated syntheses and elemental analyses gave reproducible results. Therefore, these products seem to be a new species containing the seven-membered ring.

Experimental

Instruments. The infrared spectra were obtained by the Nujol or hexachloro-1,3-butadiene mull procedure, using a 403G-type infrared spectrophotometer of Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with a Hitachi EPS-2-type automatic recording spectrophotometer. The magnetic moments were measured with a Gouy balance at room temperature.

The Syntheses of the Compounds: *The Synthesis of the 2,4-Dimethyl-1,5-benzodiazepinium Chloride Dihydrate*: This compound was synthesized from *o*-phenylenediamine and acetylacetone according to the Thiele or Lloyd method.[1,4]

The bromide was obtained by almost the same method, but using hydrobromic acid in place of hydrochloric acid. The bromide obtained was the dihydrate as the chloride.

The Synthesis of 2,4-Dimethyl-1,5-benzodiazepinium Tetrachlorocobaltate(II) Monohydrate: Five-tenths of a gram (2.1 mmol) of cobalt(II) chloride hexahydrate was heated, and the crystalline water was removed. A 99% ethanolic solution of the blue anhydrous salt (about 5 m*l*) and a 99% ethanolic solution of the 2,4-dimethyl-1,5-benzodiazepinium chloride dihydrate (0.5 g (2.0 mmol) in 5 m*l* of the solvent) were mixed and stirred. A crystalline precipitate appeared. The product was filtered off after it had stayed one night in a refrigerator. It was washed with 99% ethyl alcohol and then with ethyl ether. The recrystallization of the products has not yet been successful.

The other compounds were synthesized by almost the same method from the 2,4-dimethyl-1,5-benzodiazepinium chloride or bromide and the metal halides of the same halogen element.

In the case of the copper salt, the product from the chloride is paramagnetic and divalent, but the product from the bromide is diamagnetic and probably univalent. The analytical results support the results.

Some metal salts, nickel(II) halides, for example, do not give the precipitate by this method. Probably this is because of the instability of the halogeno complexes of these metals.

Results and Discussion

The elemental analyses, the chemical formula, and the magnetic moments of the compounds thus obtained are shown in Table 1. As the table shows, these compounds have the formula of ML_xX_y (where L^+ is the 2,4-dimethyl-1,5-benzodiazepinium ion and where X is Cl or Br). The oxidation number of the L is always+1. Although these compounds are all synthesized in the 99% ethanol medium, some of them contain crystalline water.

From the magnetic moments of cobalt complexes, it is possible to infer how the central cobalt ion is surrounded by ligands—either octahedrally or tetrahedrally. Due to the spin-orbit interaction, the magnetic moments of the cobalt complexes are higher than the spin-only value; if the magnetic moment is 4.7—

$L^+ = C_{11}H_{13}N_2^+$ (2,4-dimethyl-1,5-bezodiazepinium ion)

5.2 B.M., it is in the octahedral form, while if it is 4.4—4.8 B.M., it is in the tetrahedral form. The observed magnetic moments of the products are 4.77 B.M. and 4.98 B.M., as the table shows. The dithiolium halogenometalates which contain CoX_4^{2-} ions have magnetic moments of 4.6—4.8 B.M.,[9-11] this value is a little high, though it is expected, as in the tetrahedral configuration. Therefore, although the magnetic moments of these complexes are a little higher than that expected for the tetrahedral form, the central ion is probably surrounded tetrahedrally by four halogen atoms in these complexes. A deformed octahedral form, including additional coordination of the halogen atoms of other complex molecules or the halogen-bridging structure, is also probable. However, a strong coordination of the 2,4-dimethyl-1,5-benzodiazepinium cation to the central metal ion is less probable.

In the cases of copper compounds, only the Cu(I) compound was obtained from copper(II) bromide, while only the Cu(II) compound was obtained from copper(II) chloride. The stability of the copper(I)-compounds depends very strongly on the nature of the counter-anion or the ligand present, while the stabilities of Cu(I) halides are in the order of CuI > CuBr > CuCl; CuF is yet unknown. On the other hand, the dimethyl-benzodiazepinium salt seems to have a little reducing ability. Consequently, it reduced the copper(II) bromide to the stable copper(I) salt, while it is not a strong enough reagent as to produce the less stable copper(I) chloride.

The electronic absorption spectra of the ethanolic solution of these products were also examined. These metal compounds show spectra almost identical with those of the 2,4-dimethyl-1,5-benzodiazepinium halides. The main peaks (in kK) and their intensities (in $\log \varepsilon$ shown in parentheses) are as follows: 44.5 (4.1), 38.3 (4.4), 37.2 (4.4), ~30 (~3) 28.4 (3.0), 19.6 (2.9), 16.4 (2.5). As the absorption coefficients of the bands of the ion are too high, the peaks of the *d-d* bands of metals as well as the specific bands of the halogenometalates are not identified. Moreover, the halogenometalato ion may be decomposed into metal and halogen ions in such a dilute ethanolic solution.

The infrared spectra of these compounds were also examined. The general pattern of the spectra of the metal compounds resembles that of the 2,4-dimethyl-1,5-benzodiazepinium chloride in the finger-print region.

The exact assignments of the peaks are not easy, as the vibrations of the dimethylbenzodiazepinium ion

conjugate with each other and they can be separated into group vibrations only with difficulty. However, bands in the region of 1350—1650 cm^{-1} are likely to consist of ν(C=N), ν(C=C) or a mixture of them; at least, the contribution of these vibrations to these bands is probably important.

In the far-infrared region, there are some bands which are characteristic of the metal compounds and which are not observed in the spectra of the chloride of the ligand. Although no exact assignments were easily obtained, their ν(M–X) bands were tentatively assigned. The maxima of these bands are shown in Table 2.

The wave numbers of the ν(M–X) bands of these compounds are very similar to the values observed in the spectra of other halogenometallates.[12-14] The ν(M–X) bands of bromocuprate and bromocadmate compounds are not observed above 200 cm^{-1}. However, as the edge absorption appears near 200 cm^{-1}, they are expected to be found in the lower wave number region.

The band of the chloride at 1639 cm^{-1} shift to the lower wave number side, about 10—20 cm^{-1}, when the metal compounds are formed, as is shown in Table 2. This is probably caused by a slight change in the bonding states in the seven-membered-ring system of the cation—a prohibition of the tautomerism transition, for example. Thus, however, difficult as it is for a strong bond between the cation and metal ion to exist, some kind of interference between the cation and halogenometalato ion, such as was shown in the case of 3,5-dimethyl-1,2-dithiolium tetrachloroferrate(II), is to be expected in this case, too.[15]

Consequently, these metal compounds probably consist of the 2,4-dimethyl-1,5-benzodiazepinium cation and halogenometalato anion.

The authors wish to express their appreciation to Professors Yukichi Yoshino and Kunihiko Watanuki and their colleagues of this laboratory for their helpful discussions.

The Dehydration of *N*-Benzyloxy and *N*-Hydroxymaleamic Acid and the Isomerization of *N*-Benzyloxyisomaleimide

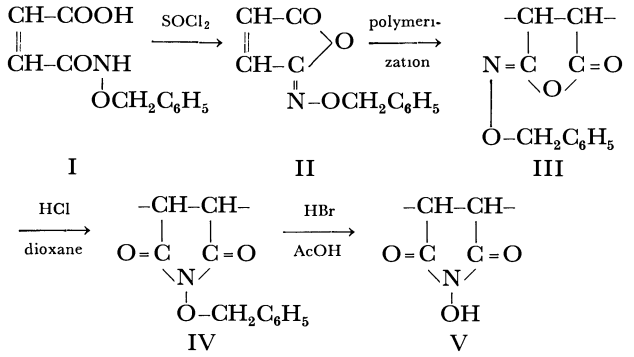
Mitsuaki NARITA, Masayasu AKIYAMA,* and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 17, 1969)

The dehydration of *N*-benzyloxy and *N*-hydroxymaleamic acids and the isomerization of *N*-benzyloxyisomaleimide were carried out under various conditions to obtain *N*-benzyloxyisomaleimide, *N*-hydroxyisomaleimide, and *N*-benzyloxymaleimide. *N*-substituents, such as benzyloxy, hydroxy, and acetoxy groups, depress the reactivity of nitrogen electronically and facilitate the formation of isomaleimides in the dehydration of *N*-substituted maleamic acids. The thermal isomerization of *N*-benzyloxyisomaleimide to the maleimide has been successful only in *N*,*N*-dimethylformamide. Further the conversion of isomaleimide to maleimide was performed *via* the addition of hydrogen bromide to isomaleimide followed by isomerization and dehydrobromination.

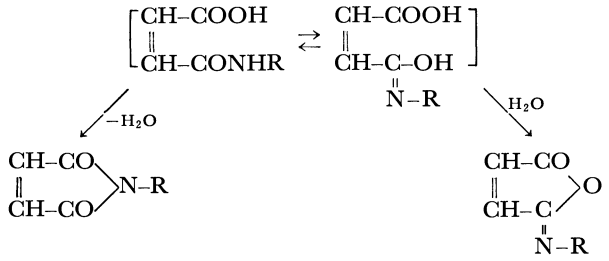
In peptide syntheses, *N*-hydroxysuccinimide has been frequently used as a convenient component for activation of carboxyl group of amino acids. In our early works, we reported the preparation of polymer (*e.g.* V) having the *N*-hydroxyimide structure in the chain and the activation of carboxylic acid group by use of such polymers.[1,2] During the course of these works, it was found[2] that the dehydrocyclization product of *N*-benzyloxymaleamic acid (I) with thionyl chloride was not the expected *N*-benzyloxymaleimide but *N*-benzyloxyisomaleimide (II), and that *N*-benzyloxy- (IV) or *N*-hydroxysuccinimide (V) structure was obtained by successive isomerization and hydrolysis of polymer (III). In this paper, we wish to report



the result of the further investigation on cyclization reactions of *N*-benzyloxy- and *N*-hydroxymaleamic acids with various dehydrating agents and also on the possibility of direct isomerization of *N*-benzyloxyisomaleimide to *N*-benzyloxymaleimide.

Results and Discussion

The Dehydration of N-*Benzyloxymaleamic Acid.* The dehydration of *N*-substituted amic acids, especially *N*-substituted maleamic and phthalamic acids, produces the corresponding imides[3–5] or isoimides[5–9] depending on the nature of amic acids and the reaction condition employed. One would postulate that *N*-substituted maleamic acid would be in equilibria with the tautomer of iminohydrine structure which is strongly stabilized by conjugation with the double bond and that the iminohydrine tautomer will produce the corresponding isoimide by treatment with dehydrating agents under certain condition as shown in Scheme 1.[8]



Scheme 1

Cotter[6] and Roderick[7] investigated on the reagents used for the dehydration of amic acids and classified the reagents which employed most commonly to effect the dehydration of amic acids to imides and isoimides. The effect of *N*-substituents in amic acids on the direction of the dehydration, however, has not been investigated systematically.

Ames reported[10] the formation of *N*-benzyloxymaleimide by treating *N*-benzyloxymaleamic acid (I) with thionyl chloride. We reported that the product obtained by Ames's procedure was *N*-benzyloxyisomaleimide (II).[2] In this paper, the action of phosphorus pentoxide, dicyclohexylcarbodiimide

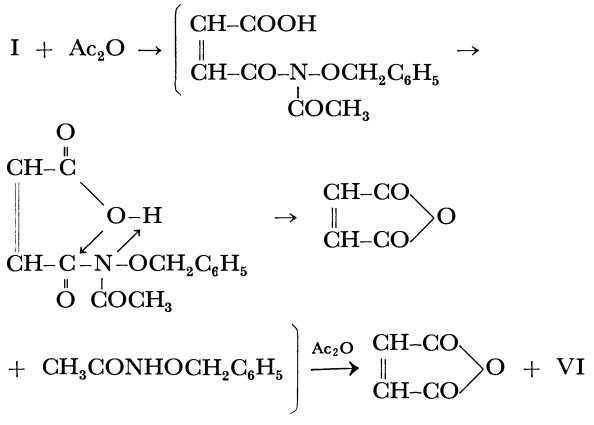
11	Dioxane	I_2 (0.1)	reflux	5	(75)
12	Dioxane	TsOH (0.2)	reflux	5	28[d]

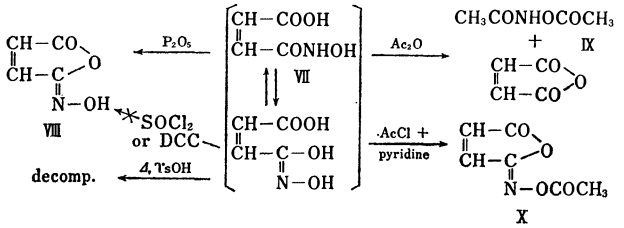
a) One gram of II was used for the reaction in every case. b) In the case of No. 5, 20 m*l* of the solvent was used. c) The product was α-bromo-*N*-benzyloxysuccimide(XV). d) The product was the mixture of II and XIII which was identified by IR spectrum. e) DMSO; dimethylsulfoxide. f) NB; nitrobenzene. g) DMF; *N*,*N*-dimethylformamide. h) AAn; acetic anhydride.

(DCC), acetic anhydride as well as thionyl chloride will be reported. Treatment of I with these dehydrating agents produced various compounds as shown in Scheme 2. The dehydration was carried out with thionyl chloride in benzene, phosphorus pentoxide in *N*,*N*-dimethylformamide(DMF) and DCC in DMF or dioxane. In every cases, the product was only the isoimide (II) in about 70% yield. The compound (I) decomposed at about 145°C and so the thermal dehydration failed to produce the imide. Treatment of I with acetic anhydride at room temperature gave maleic anhydride and *N*,*N*-diacetyl-*O*-benzylhydroxylamine (VI) probably due to the following way (Scheme 3).



Scheme 3

The Dehydration of N-*Hydroxymaleamic Acid.* We attempted the dehydration of *N*-hydroxymaleamic acid (VII) with phosphorus pentoxide, thionyl chloride, acetic anhydride, *p*-toluenesulfonic acid (TsOH), DCC and acetyl chloride-in-pyridine. These results are shown in Scheme 4. Ivanov *et al.*[4] reported that they obtained *N*-hydroxymaleimide by treatment of VII with phosphorus pentoxide. However, *N*-



Scheme 4

hydroxyisomaleimide(VIII) was obtained instead of the corresponding maleimide by the dehydration of VII with phosphorus pentoxide as shown in Scheme 4. Using thionyl chloride and DCC as dehydrating agents, neither *N*-hydroxymaleimide nor *N*-hydroxyisomaleimide was obtained. The compound(VII) decomposed at *ca.* 130°C and the thermal dehydration failed. The compound (VII) decomposed at 100°C by treatment with TsOH. The reaction of VII with acetic anhydride yielded *N*,*O*-diacetylhydroxyamine (IX) and maleic anhydride. With excess acetyl chloride

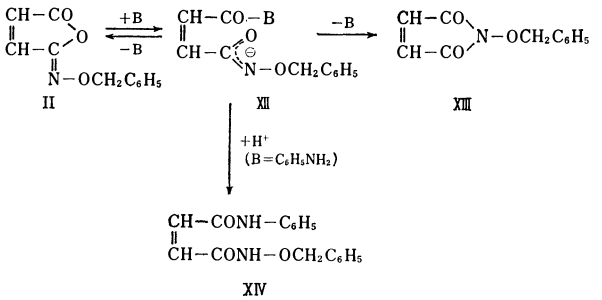
a) NMR spectra were measured in deuteriochloroform solution.
b) S=singlet, D=doublet, M=multiplet.
c) Carbon tetrachloride was used for the solvent.
d) H_a and H_b are indicated in XVII.

The Isomerization of N-*Benzyloxyisomaleimide (II) to the Corresponding Maleimide (XIII).* Isomerization of many cyclic isoimides to imides can be found in the literatures.[6-8,11-14] This reaction proceeds by basic or acidic catalyst and also thermally. For example, *N*-arylisomaleimide,[6,14] *N*-methoxyisophthalimide[11] and *N*-phenylisophthalimide[12] isomerize to the corresponding imides in the presence of sodium acetate in acetic anhydride, hydrogen bromide in nitromethane and thermally in chlorobenzene, respectively.

We carried out the attempted isomerization of *N*-benzyloxyisomaleimide (II) to *N*-benzyloxymaleimide (XIII) under certain conditions. The results are shown in Table 1. The thermal isomerization of II to XIII did not occur in dimethylsulfoxide (DMSO), nitrobenzene or by heating without solvent (Nos. 1—3). In DMF, however, II isomerized to XIII in a 40% yield when refluxed for ten hours (No. 4). In this case, basic impurities in DMF might act as an acyl group transfer agent by attacking the carbonyl group to give the intermediate (XII) as shown in Scheme 6. To confirm this, sodium acetate, pyridine, and quinoline were used as basic components, but the isomerization of II to XIII did not occur (Nos. 5—7). On the other hand, the isoimide (II) reacted with aniline in DMF at 100°C to give the ring opening product (XIV) in a 91% yield. In these reactions, it is most plausible



Scheme 6

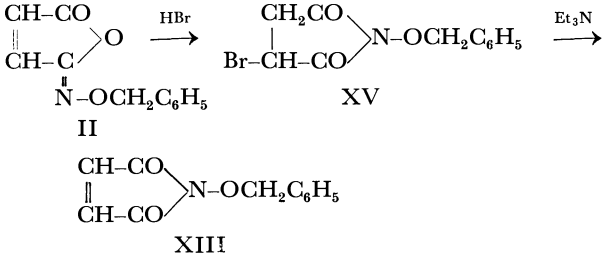
12) A. E. Kretov, N. E. Kyl'Chitskaya, and A. J. Mal'nev, *Zh. Obshch. Khim.*, **31**, 2415 (1961).
13) D. Y. Curtin and L. L. Miller, *J. Amer. Chem. Soc.*, **89**, 637 (1967).
14) C. K. Sauers, *J. Org. Chem.*, **34**, 2275 (1969).

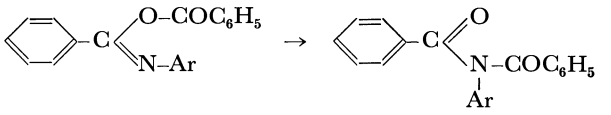
that the base attacks first the carbonyl group to form the intermediate (XII) from which the starting isomaleimide (II), maleimide (XIII) or the ring opening product (XIV) is produced according to the kinds of bases. Trifluoroacetic acid and boron trifluoride etherate were uneffective on the isomerization of II to XIII (Nos. 8 and 9).

On the other hand, *N*-substituted saturated amic acids are known to produce only the corresponding imides. Therefore the use of the compound which can add to double bond and easily leave to regenerate double bond is thought to be an alternate method to obtain intended compound (XIII). In order to verify this expectation, the reaction of II with hydrogen bromide was carried out in acetic acid at room temperature. As expected, the reaction yielded α-bromo-*N*-benzyloxysuccinimide (XV). (No. 10, Table 1) as shown in Scheme 7. The compound (XV) was easily dehydrobrominated with base to give XIII. Iodine and TsOH, which are known as effective catalysts for the isomerization of maleic acid derivatives, were not effective on the isomerization of II to XIII.



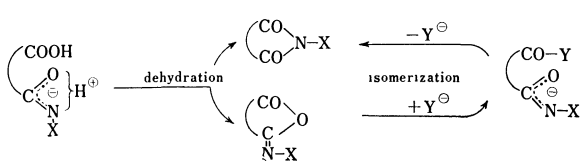
Scheme 7

Curtin and Miller[14] indicated that the electron-withdrawing substituents on Ar ring retarded the O→N migration of benzoyl group (*i.e.* ρ in Hammett rule was negative) in the following example. On



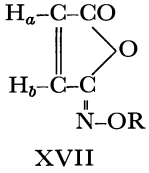
the other hand, Yamada *et al.*[5] examined the dehydrocyclization of *N*-β- or *N*-γ-hydroxypropylmaleamic acid with acetic acid and suggested the formation of maleimide or isomaleimide depended on the steric factor in the intermediates. These works and our results lead to the following conclusion.

The electron-withdrawing substituents such as hydroxy, acetoxy, and benzyloxy reduced the nucleophilic reactivity of nitrogen in *N*-substituted maleamic acids resulting the formation of isomaleimides in either the dehydration or the isomerization process shown below. Isomaleimide obtained by the dehydrocyclization of maleamic acid was isomerized to maleimide by heating in DMF, while the reason of effectiveness of DMF was not enough explained. Further, an indirect method was indicated to obtain maleimide in which the double bond of isomaleimide was saturated once with HBr to facilitate the isomerization.



Proof of Structure of N-*Substituted Isoimides and Imides.* Proof of the structures of II, VIII, X, and XIII were derived from the elemental analyses, IR and NMR spectra. Physical properties and spectral evidence were summarized in Tables 2 and 3. To compare with X, *N*-acetoxymaleimide (XVI)[16] was put in Table 3. Isomaleimides generally have two sharp bands in the infrared at *ca.* 1780 (strong) and 1670 (medium) cm^{-1}. These absorptions can be associated with the anhydride-like carbonyl and the >C=N–bonds present in the isomaleimide ring.[8] In contrast, maleimides have characteristic broad carbonyl bands in the infrared with maxima near 1720 cm^{-1}.[8] Infrared data of the compounds II, X, and XIII agree with these infrared data. The compound (VIII) have three bands of almost the same intensity at 1770, 1700, and 1630 cm^{-1}. We could not assign the band at 1700 cm^{-1}. In comparison with X, *N*-acetoxymaleimide have three bands at 1813 (strong, acetoxy carbonyl), 1780 (medium, imide), and 1741 (strong, imide) cm^{-1}.

The NMR spectra of isoimides show two doublets due to unsymmetrical nature of olefinic hydrogen. In contrast, maleimides have only one singlet due to symmetrical nature of olefinic hydrogen. The NMR data of the compounds II, VIII, and X show two doublets due to H_a and H_b which are shown in XVII. On the other hand, those of the compounds XIII and XVI show only one singlet due to symmetrical nature of olefinic hydrogen.



XVII

Experimental

All melting and boiling points are uncorrected. Infrared spectra were measured as potassium bromide disks or in liquid state using a Hitachi Infrared Photometer Model EPI-S2. NMR spectra were obtained with a Japan Electron Optics C-100 spectrometer in deuteriochloroform solution with tetramethylsilane as an internal standard. All solvents used for reactions were purified by usual methods.

Dehydration of N-*Benzyloxymaleamic Acid (I). Treatment of I with Thionyl Chloride*: According to Ames's procedure, the amic acid (I) was treated with thionyl chloride in benzene at refluxing temperature followed by working up of the reaction mixture to give the isoimide (II). Recrystallization from *n*-hexane gave colorless needles, mp 80—80.5°C (lit,[10] mp 80—81°C). Yield 72%.

Treatment of I with Phosphorus Pentoxide: Phosphorus pentoxide (1.7 g) was suspended in 10 m*l* of DMF. The amic acid (I), 2.2 g, was dissolved in 10 m*l* of DMF and the latter was combined with the suspension of P_2O_5 with cooling in

16) M. Narita, T. Teramoto, and M. Okawara, This Bulletin, **44** (1971), in press.

ice-cold water. After the exothermal reaction ended, the mixture was kept for 6 hr at room temperature and was poured into 100 m*l* of water. The precipitate was collected on filter and washed with water to give 1.4 g of the product (II), mp 73—76°C. Recrystallization from *n*-hexane gave colorless needles, mp 80—80.5°C.

Treatment of I with Dicyclohexylcarbodiimide: The amic acid (I), 1.0 g, was added to a solution of 1.1 g of dicyclohexylcarbodiimide in 10 m*l* of DMF. The reaction mixture was kept for 5 hr at room temperature. Dicyclohexylurea began to precipitate immediately. It was filtered off and the filtrate was poured into 100 m*l* of water to give precipitates which was collected by filtration and washed with water. The product was recrystallized from *n*-hexane, yield 0.73 g, mp 79—80.5°C. The same reaction was carried out in 10 m*l* of dioxane instead of DMF, yield 0.7 g, II, mp 79—80.5°C.

Treatment of I with Acetic Anhydride: The amic acid (I), 5.0 g, was suspended in 20 m*l* of acetic anhydride. It took 20 hr at room temperature till all the compounds dissolved in acetic anhydride. At the end of this time, acetic anhydride was distilled off under reduced pressure. The residue was dissolved in *n*-hexane and cooled. The product (VI) crystallized and was collected by filtration with suction, yield 0.23 g, mp 98—101°C. Repeated recrystallization of the product from *n*-hexane afforded needles of *N*,*N*-diacetyl-*O*-benzylhydroxylamine, mp 101—102°C (lit,[10] mp 101—102°C). The filtrate was distilled under reduced pressure to give three fractions. Fraction I, bp 63—65°C/3.5 mmHg (1.35 g), was maleic anhydride, fraction II, bp 120—5°C/0.4 mmHg (0.93 g), was the product (VI) and fraction III, bp 125—135°C/0.4 mmHg (1.96 g), was a mixture of VI and undefined product. These products were identified by IR spectra.

Dehydration of N-*Hydroxymaleamic Acid (VII). Treatment of VII with Phosphorus Pentoxide*: Phosphorus pentoxide, 6.0 g, was suspended in 7 m*l* of DMF and a solution of 2.6 g of the amic acid in 8 m*l* of DMF was mixed with it and the mixture was cooled in ice-cold water. When the heat ceased to evolve from the reaction mixture, it was kept for 5 hr at room temperature and poured into 80 m*l* of water. The solution was kept in a refrigerator for several days until the crystals appeared. Yield 0.24 g, mp 145°C (dec.). Further recrystallization from benzene-ethanol furnished pure *N*-hydroxyisomaleimide, mp 148°C (dec.).

Treatment of VII with Acetic Anhydride: The amic acid (VII), 5.0 g, was suspended in 20 m*l* of acetic anhydride. It took 20 hr at room temperature till all the compounds dissolved in acetic anhydride. At the end of this time, acetic anhydride was distilled off under reduced pressure. The residue was dissolved in 40 m*l* of hot benzene and cooled. The product, *N*,*O*-diacetylhydroxylamine (IX), crystallized and was collected by filtration with suction, yield 1.4 g, mp 86—90°C. Repeated recrystallisation of the product from benzene furnished colorless needles, mp 88.5—90°C (lit,[15] mp 91°C). IR (KBr disks): 3350, 3150 cm^{-1} (NH), 1795 cm^{-1} (–CO–O–N), 1655 cm^{-1} (–CO–NH–).

Found: C, 41.23; H, 6.14; N, 11.93%. Calcd for $C_4H_7NO_3$: C, 41.02; H, 6.03; N, 11.96%.

The filtrate (benzene solution) was distilled under reduced pressure to give maleic anhydride, bp 91—93°C/16 mmHg, (4.25 g). Maleic anhydride was identified by infrared spectrum. The pot residue was found to be *N*,*O*-diacetylhydroxylamine (0.65 g).

Treatment of VII with Acetyl Chloride and Pyridine: The amic acid (VII), 6.5 g, and 10 g of pyridine was dissolved in 50 m*l* of DMF. To this solution, a solution of 10 g of acetyl chloride in 50 m*l* of DMF was added with stirring under cooling with ice-cold water to maintain the temperature below 20°C. After the exothermal reaction ended, the mixture was kept for 6 hr at room temperature. DMF was distilled off under reduced pressure and the viscous residue was poured into 200 m*l* of water to give a precipitate, which was collected and washed with water, yield 2.9 g, mp 99—114°C. Recrystalization from carbon tetrachloride gave *N*-acetoxyisomaleimide, mp 115—116.5°C.

Isomerization of N-*Benzyloxyisomaleimide (II) to the Corresponding Imide (XIII).* Nos. 1—4 (see Table 1). The isoimide (II), 1.0 g, was dissolved in 10 m*l* of the solvent and the reaction was continued under the conditions described in Table 1. The solvent was distilled off under a reduced pressure and the residue was recrystallized from *n*-hexane. The respective products were characterized by mixed melting point with authentic sample and IR spectra. In the case of No. 4, the product was *N*-benzyloxymaleimide (XIII).

Nos. 5—9, No. 11, and No. 12 (see Table 1). The reaction was carried out under the condition shown in Table 1. After the reaction was over, the mixture was poured into 100 m*l* of water and the precipitate was collected and washed with water. The precipitates were recrystallized from *n*-hexane. The product was identified by mixed melting point with authentic sample and IR spectrum.

Reaction of N-*Benzyloxyisomaleimide (II) with Hydrogen Bromide and Dehydrobromination of the Product (XV).* No. 10 (see Table 1). The isoimide (II) was dissolved in 10 m*l* of 20% hydrogen bromide in acetic acid. The reaction mixture was kept for 5 hr at room temperature and then poured into 70 m*l* of water. The precipitate was collected and washed with ethanol, yield 1.2 g, mp 73—91°C. Repeated recrystallizations, from ethanol gave colorless needles, α-bromo-*N*-benzyloxysuccinimide (XV), mp 96—96.5°C. The product has characteristic bands at 3100—3050 cm^{-1}, 1500 cm^{-1} (–C_6H_5) and 1797 (weak), 1740 cm^{-1} (strong) (imide).

Found: C, 47.27; H, 3.43; N, 5.03; Br, 28.45%. Calcd for $C_{11}H_{10}NO_3Br$: C, 46.51; H, 3.55; N, 4.93; Br, 28.10%.

The imide (XV) (1.5 g) was suspended in 8 m*l* of triethylamine and allowed to stand for 3 hr at room temperature and poured into 80 m*l* of water. The precipitate was filtered off and washed with water to give 0.44 g of *N*-benzyloxymaleimide (XIII), yield 41%, mp 78—90°C. It was recrystallized from *n*-hexane to give light yellow crystals, mp 89.5—91°C.

Reaction of N-*Benzyloxyisomaleimide (II) with Aniline.* The isoimide (II), 1.02 g, was combined with 1.0 g of aniline in 10 m*l* of DMF and heated for 6 hr at 100°C. The mixture was cooled and poured into 50 m*l* of water to give precipitates, which were collected and washed with water to give 1.35 g of the product (XIV). The product was recrystallized from ethanol, mp 139.5—140.5°C. It has characteristic bands at 3320 cm^{-1} (NH), 1660, 1620 cm^{-1} (CO) and 1545 cm^{-1} (NH).

Found: C, 69.76; H, 5.72; N, 9.45%. Calcd for $C_{17}H_{16}N_2O_3$: C, 68.90; H, 5.44; N, 9.45%.

The Reaction of Azoxybenzene with Acetic Anhydride[1]

Shigeru OAE, Tetsuya MAEDA, and Seizi KOZUKA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

(Received December 7, 1970)

When azoxybenzene was allowed to react with equimolar amount of acetic anhydride, a mixture of azobenzene, acetanilide, and acetic acid was obtained along with such gaseous products as carbon dioxide, carbon monoxide and methane. In the reaction of azoxybenzene with an excess acetic anhydride, however, azobenzene was not isolated, and only acetanilide was obtained. Acetanilide and acetic acid were also obtained in the reaction of azobenzene with acetic anhydride. The results suggest the initial formation of azobenzene which is eventually converted to acetanilide in the subsequent reaction with an excess acetic anhydride. The formation of acetanilide was inhibited by the addition of such radical scavengers as iodine, hydroquinone, and nitrobenzene. A free radical mechanism is suggested for the reaction. Phenazine *N*-oxide also apparently undergoes similar reaction.

The reactions of tertiary amine *N*-oxides such as pyridine or picoline *N*-oxides with acetic anhydride have been investigated extensively by means of product analyses,[2] kinetics,[3] and tracer studies.[4] The first step of the reactions are considered to proceed throughout initial acylation of oxygen of the *N*-oxides.[5] Thus, the reactivity of *N*-oxide in the reaction with acetic anhydride depends primarily on the basicity of the *N*-oxide oxygen. Dimethylaniline *N*-oxide, a more basic *N*-oxide (pK_a=4.21[6]), reacts smoothly with acetic anhydride even below 0°C[7]), while the reaction of pyridine *N*-oxide, a less basic *N*-oxide (pK_a=0.56[8]), requires a few hours of refluxing for the completion of the reaction with the same reagent. Very little study has been made on the reaction of azoxybenzene with acetic anhydride,[9] presumably due to its poor reactivity. The reaction, however, did occur under prolonged heating at relatively high temperatures to give an unusual product, acetanilide, as the main product. This paper deals with the details of preliminary investigation of the reaction studied mainly by means of product analysis.

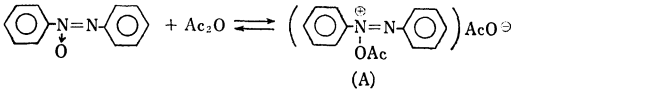
Results and Discussion

Reaction of Azoxybenzene with Acetic Anhydride. Since the basicity of azoxybenzene is very small (pK_a=6.45[10]), the reaction of azoxybenzene with acetic anhydride is considered to be sluggish. Thus, the reaction was carried out at 190°C in an autoclave under nitrogen atmosphere, and a mixture of azobenzene and acetanilide was obtained. The yield of acetanilide was less than 100% based on the amount of azoxybenzene used. That is, only a half of azoxybenzene used is apparently converted to acetanilide. Under the same conditions, azoxybenzene underwent no thermal deoxygenation. Gaseous components were analyzed by means of gas chromatography. Carbon dioxide, carbon monoxide, and methane were detected as the main gaseous products. When *N*-oxide was treated with an excess acetic anhydride, no detectable amount of azobenzene was found, whereas acetanilide was obtained along with acetic acid and gaseous products. The reaction conditions and the yield of the products are listed in Table 1.

Table 1. Reaction of azoxybenzene with acetic anhydride under N_2 atmosphere in autoclave

Reaction system	Reaction condition Molar ratio	Product (%)
PhN=NPh + Ac_2O ↓ O	190°C, 15 hr 1 : 1	PhN=NPh (60) $PhNHCOCH_3$(13) CH_3CO_2H(63) CO_2(95), CH_4(2) CO(14)
PhN=NPh + Ac_2O ↓ O	190°C, 15 hr 1 : 5	$PhNHCOCH_3$(78) CH_3CO_2H(70)
PhN=NPh + AcOH ↓ O	190°C, 15 hr 1 : 1	no reaction

The first step of the reaction is considered to be the formation of the *N*-acetoxyammonium salt (A) as in the



(A)

reactions of pyridine- and the related *N*-oxides with acylating agents.[5] No oxygen exchange reaction was found between the *N*-acyloxy compound of pyridine

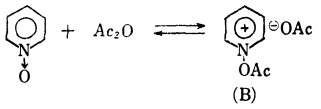
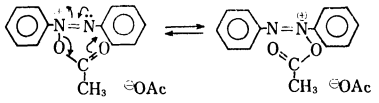
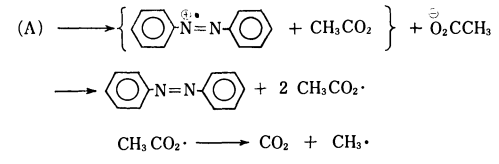
bases such as (B) in our earlier ^{18}O-tracer experiments,[11]



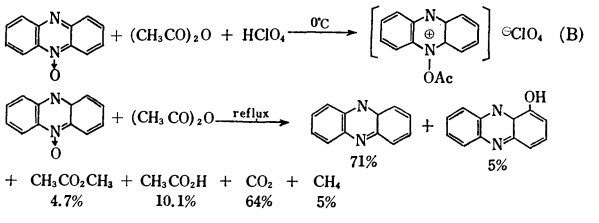
but a somewhat different oxygen exchange could be expected in this case through the following five membered cyclic migration. This supposition is based on



the observation with ^{15}N-labeled azoxybenzene by Shemyakin *et al.*[12] who showed that there is an intramolecular oxygen migration within the Wallach rearrangement. In order to examine the possible oxygen equilibration during the reaction, azoxybenzene was treated with equimolar amount of ^{18}O-labeled acetic anhydride and recovered when the reaction was about half completed . If the migration of the acetoxy group from one nitrogen atom to the other occurs during the reaction, a substantial incorporation of ^{18}O in the recovered *N*-oxide is expected. However, no noticeable amount of ^{18}O was found in the recovered *N*-oxide. Thus, the possibility of such a migration can be ruled out. For further insight into the nature of the reaction, the effect of atmosphere on the reaction was examined and the results are tabulated in Table 4. In view of the large amounts of carbon dioxide, carbon monoxide and methane, the mechanism of the reaction seems to involve the homolytic fission of the N–O bond of the *N*-acyloxy compound at the initial stage of the reaction. Acetanilide obtained in the reaction with an excess acetic anhydride is considered to be



formed *via* azobenzene. A similar reaction involving the formation of the salt (A) and subsequent homolytic fission of the N–O bond seems to take place with phenazine *N*-oxide which in the presence of acetic anhydride



gives salt (B) of perchloric acid, and generates large amounts of methane and carbon dioxide yielding mainly the reduced compound, phenazine, under refluxing with acetic anhydride.

Reaction of Azobenzene with Acetic Anhydride. Examination of the data shows that the reaction of an equimolar amount of azoxybenzene and acetic anhydride gives azobenzene along with a small amount of acetanilide while the reaction with excess acetic anhydride gave only acetanilide in a better yield. In order to examine the formation of the intermediate,

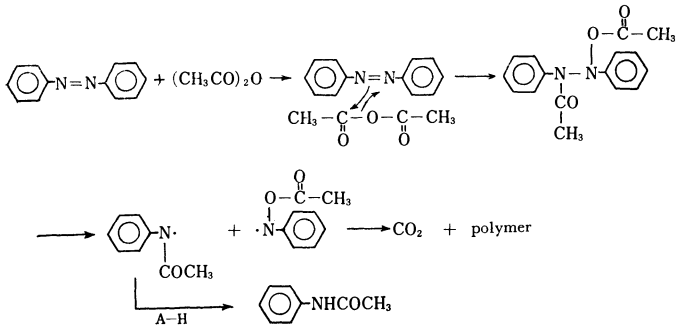
azobenzene, the reaction of azobenzene with acetic anhydride was studied. As was expected, acetanilide was obtained in good yield from the reaction mixture along with moderate amounts of acetic acid and gaseous products. Acetic acid was found to undergo no reaction with azobenzene. The effects of radical scavengers and atmosphere in an antoclave were also examined, the results of which are in Tables 2—4. The reaction with an unsymmetrical azobenzene, 4-methylazobenzene, gave nearly the same amount of both acetanilide and 4-methylacetanilide. No symmetrical azobenzene was found in the recovered reaction mixture in which only 4-methylazobenzene was found. The results clearly rule out the possibility of crossover and the return of the fragments to the original compound. The yield of acetanilide was apparently decreased not only by the presence of oxygen but also by the addition of radical scavengers such as hydroquinone, iodine and, nitrobenzene, suggesting a free radical mechanism for the reaction. The mechanism of the reaction of azobenzene with acetic anhydride to give acetanilide may be formulated as follows.



Experimental

Materials. Azoxybenzene was prepared by the reduction of nitrobenzene[13] (mp 35—36°C from methanol). Azobenzene was prepared by the usual method[14] (mp 66—67.5°C from ethanol). 4-Methylazobenzene was prepared by the process reported by Godger[15] (mp 71—72°C from ethanol). Preparation of ^{18}O-labeled acetic anhydride and the method of its isotope analysis were described previously.[16] Phenazine *N*-oxide was synthesized from aniline and nitrobenzene with sodium hydroxide.[17]

The reaction of Azoxybenzene with Acetic Anhydride. A mixture of azoxybenzene (7.0 g, 0.035 mol) and acetic anhydride (3.8 g 0.037 mol) was heated in an autoclave at 190°C for 15 hr under N_2 atmosphere. Distillation of the reaction mixture gave acetic acid (1.4 g). The residue was extracted first with *n*-hexane three times and then with benzene three times. From the hexane layer, azobenzene (3.8 g, 66—68°C) was obtained along with a small amount of acetanilide (0.04 g). Separation was performed by recrystallization from *n*-hexane. Acetanilide (0.6 g, mp 114—115°C) was obtained from the benzene layer. The residue which did not dissolve in these solvents, was chromatographed through an active alumina column with chloroform as an eluent. A small amount of acetanilide (0.05 g) was obtained. The gaseous components were directly transferred from the autoclave into a gas sampler and analyzed by gas chromatography (H_2 carrier, temp.: 60°C, active carbon 4 m); carbon dioxide, methane and carbon monoxide were detected. These compounds were identified by comparing their retention times with those of the corresponding authentic samples. Quantitative analysis of carbon dioxide was performed by the measurement of the amount of barium carbonate absorbed in saturated $Ba(OH)_2$ aq. solution. Carbon monoxide and methane were determined by comparing the peak areas with that of carbon dioxide, taking the relative intensities of the respective gaseous products into consideration hydrogen being used as a carrier gas.

Reaction of Azoxybenzene with ^{18}O-Labeled Acetic Anhydride. A mixture of azoxybenzene (2.0 g, 0.01 mol) and ^{18}O-labeled acetic anhydride (1.1 g, 0.01 mol, 0.89 atom% ^{18}O) was heated in an autoclave at 175°C for 10 hr under N_2 atmosphere. Distillation under reduced pressure gave crude azoxybenzene (1.2 g, bp 195—200°C/16 mmHg) along with small amounts of azobenzene (0.13 g) and acetanilide (trace). The recovered *N*-oxide was then purified by recrystallization from ethanol (mp 34—35°C). No incorporation of any excess ^{18}O was found in the recovered azoxybenzene (0.20 atom% ^{18}O).

Reaction of Phenazine N-Oxide with Acetic Anhydride. A mixture of phenazine *N*-oxide (5.0 g, 0.026 mol) and acetic anhydride (14.0 g, 0.14 mol) was refluxed for 5 hr. The low boiling point fractions trapped in acetone - dry ice bath and gaseous products were analyzed by gas chromatography. After any residual acetic anhydride was driven off, the residue was chromatographed on active alumina with methylene chloride as an eluent. The eluent was evaporated and the residue was hydrolyzed with 20% NaOH aq. solution. The precipitate was collected and recrystallized from ethanol (mp 171—172°C). This compound was identified as phenazine (3.3 g). The filtrate was acidified with HCl and the precipitate was recrystallized from isopropyl alcohol. Thus 1-hydroxy phenazine (0.25 g, mp 155—157°C) was obtained. All these compounds were determined by comparison with the authentic samples.

The isolation of N-Acetoxyphenazinium Perchlorate. The compounds was prepared by the process reported by Muth and Daolak[5] An ice cold solution of 0.7 g of 70% $HClO_4$ in 3 m*l* acetic anhydride was added dropwise to a stirred, ice-cold solution of 0.5 g of phenazine *N*-oxide in 5 m*l* of acetic acid and 10 cc of acetic anhydride. Orange colored crystals were separated by filtration. The crystals of *N*-acetoxyphenazinium perchlorate (mp 274—275°C, dec.) weighed 0.6 g. Found: C, 49.97; H, 3.38; N, 8.12%. Calcd for $C_{14}H_{11}ClN_2O_6$: C, 49.71; H, 3.26; N, 8.29%.

Reaction of Azobenzene with Acetic Anhydride. A mixture of azobenzene (6.4 g, 0.035 mol) and acetic anhydride (17.5 g, 0.175 mol) was heated at 190°C for 15 hr in an autoclave under N_2 atmosphere similarly and both acetanilide (3.88 g, 0.029 mol) and acetic acid (1.3 g) were isolated. Through gas-chromatographic analysis of the gaseous products, carbon dioxide and carbon monoxide were detected but not methane. The reaction 4-methylazobenzene (2.0 g, 0.013 mol) with acetic anhydride (1.1 g, 0.011 mol) was also carried out similarly and a mixture (0.41 g) of acetanilide and 4-methylacetanilide was obtained. The ratio of the mixture components was determined by integrating the NMR chemical shifts of methyl protons, *i.e.*, the 4-methyl signal of N-acetyl-*p*-toluidine *vs.* acetyl methyl protons of acetanilide. The results are given in Table 2. All the other experiments were carried out under corresponding conditions.

The Tracer Study of the Reaction of Diphenyl Sulfone-1-^{14}C with Elemental Sulfur Using a Convenient Degradative Method

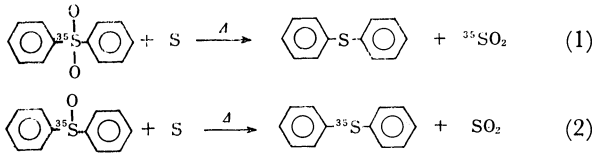
Shigeru OAE, Mamoru NAKAI,* Yoshiyuki TSUCHIDA, and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

(Received June 23, 1970)

The reaction of diphenyl sulfone with elemental sulfur to give diphenyl sulfide and sulfur dioxide at above 300°C was investigated using diphenyl sulfone-1-^{14}C. By the degradation of the product, diphenyl sulfide-*x*-^{14}C, it was found that no migration of sulfide group took place. *β*-Naphthyl phenyl sulfone was also subjected to the same reaction, and not only *β*-naphthyl phenyl sulfide but also di-*β*-naphthyl sulfide and diphenyl sulfide were found among the products. These observations appear to indicate the reaction to be a rather simple displacement reaction that involves the initial attack of polymeric sulfur radical chain at C-1 bearing sulfonyl function.

Krafft and Vorster[1] showed that diphenyl sulfone reacts with elemental sulfur to form diphenyl sulfide and sulfur dioxide at elevated temperature. The mechanism of this reaction was recently investigated using ^{35}S-labeled compounds.[2] It was shown to involve the initial S–C bond cleavage of the sulfone and the subsequent replacement of sulfone group by elemental sulfur as shown by Eq. (1). The reaction of diphenyl sulfoxide with elemental sulfur proceeds through a simple reduction involving the cleavage of S–O bond as shown by Eq. (2). The difference between the above two reactions seem to be due to the fact that the force constant of the S–O bond of the sulfoxide is appreciably lower than that of the sulfone.[3]



(1)

(2)

We have extended the reaction with elemental sulfur to dibenzyl[4] and dibutyl[5] sulfones or sulfoxides. We have also studied the reaction of diphenyl sulfone and sulfoxide with diphenyl disulfide,[6] and found that in each case the weakest bond of the respective compound is cleaved by elemental sulfur radical chain at the initial stage of the reaction. An important remaining question is if there is any cross-over of phenyl group between diphenyl sulfone or sulfide during the reaction. If there is any cross-over of the phenyl group, the possibility of migration of the sulfide group arises, since the attack of polymeric sulfur radical chain at *o*- or *p*-position of diphenyl sulfone could eventually give rise to the sulfide.

Thus, we have carried out a few critical experiments such as cross-over and ^{14}C tracer, by allowing *β*-naphthyl phenyl sulfone and diphenyl sulfone-1-^{14}C to react with elemental sulfur. We also examined the possibility of using the photolysis of diphenyl sulfone for a convenient method of degradation. This paper gives a detailed account and implications of these observations.

Results and Discussion

Reaction of β-Naphthyl Phenyl Sulfone with Sulfur. In order to examine the possibility of intermolecular cross-over of phenyl group in the reaction of diphenyl sulfone with sulfur, *β*-naphthyl phenyl sulfone was employed for the reaction. The reaction was carried out with equimolar amounts of the sulfone and elemental sulfur at a high temperature. The identification and analysis of the products were performed by means of gas chromatography.

If the reaction proceeded *via* an intermolecular process involving complete rupture of aryl-sulfur bonds, both diphenyl sulfide and *β*-dinaphthyl sulfide should be obtained among the products. If it proceeded without any cross-over of two aryl groups, *β*-naphthyl phenyl sulfide would be the sole product. (Eq. (3)).

Actually, from the product analysis, both diphenyl and di-*β*-naphthyl sulfides were obtained in 8% and 10% yields, respectively, along with *β*-naphthyl phenyl sulfide in 21% yield. Apparently the result indicates that there is some cross-over of aryl groups during the reaction, though the non-cross-over process is the predominant one.

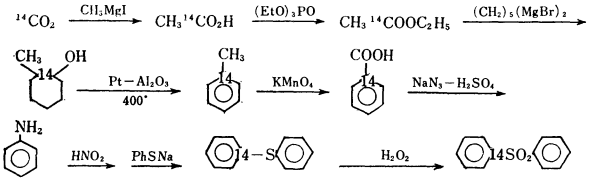
TABLE 2.

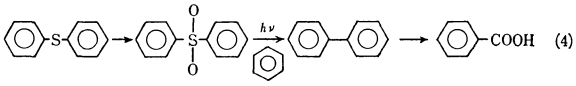
Activity of diphenyl sulfone	Condition	Yield of biphenyl	Activity of biphenyl	Activity of benzoic acid	% of rearrangement
4.62×10^5 dpm/mmol	15 hr, r.t. 0.3 g in 100 ml of benzene	27%	4.65×10^4 dpm/mmol	3.70×10^4 [a] dpm/mmol	0.6%

a) Employed diphenyl sulfone the activity of which was originally placed in 80.2% at 1-position.

Reaction of Diphenyl Sulfone-1-^{14}C with Sulfur. The synthesis of diphenyl sulfone-1-^{14}C is outlined below.

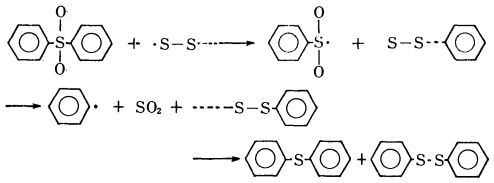


Diphenyl sulfone-1-^{14}C thus obtained was reacted with an equimolar amount of elemental sulfur at 310—320°C in nitrogen stream. Both the yield of diphenyl sulfide-*x*-^{14}C formed and diphenyl sulfone-*x*-^{14}C recovered were determined by the isotope dilution method. The degradation of diphenyl sulfide-*x*-^{14}C was carried out by the covenient process mentioned below (Eq. (4)). The results are shown in Table 1.



(4)

The result reveals that the amount of the ^{14}C rearrangement remains nearly the same in spite of the change of the reaction condition, though a slight difference is observed in the yield of diphenyl sulfide formed. Thus, the reaction of diphenyl sulfone with elemental sulfur appears to be a direct displacement reaction of the sulfone group by elemental sulfur, since the ratio of the rearrangement remains only about 5%. Besides diphenyl sulfide, a small amount of diphenyl disulfide and polymeric substance were formed in the reaction. Both the tracer experiments and previous results, suggest that the replacement of the sulfone group with sulfur atom involves the initial attack of sulfur biradical[7] on the carbon atom bearing sulfone group, followed by the cleavage of C–S bond of the sulfonyl radical and the subsequent attack on another sulfone by polymeric sulfur chain biradical, giving rise to diphenyl sulfide and diphenyl disulfide. Thus a rough sketch of the overall reaction may be illustrated as shown below. (Eq. (5)).



(5)

Previously, the degradation of ^{14}C-labeled diphenyl sulfone was carried out by means of a rather tedious way of the initial alkaline fusion of the sulfone,[8] followed by subsequent cleavage of phenol obtained.

Recently, it has been reported by Kharasch and Khodair that the photolysis of diphenyl sulfone in benzene at room temperature gave biphenyl in a good yield upon irradiation with 2537 Å light.[9]

In order to test the possibility of using this reaction for a simple convenient degradation, diphenyl sulfone-1-^{14}C was subjected to photolysis to see whether or not the original activity at ^{14}C remains at the same position. The result of the degradation reveals that all the activity remains at the carboxyl carbon of benzoic acid (corresponding to 1-position of diphenyl sulfone) as shown in Table 2. The low yield of biphenyl appears to be caused by the use of low efficient irradiation. Biphenyl formed by the photolysis was diluted with an aliquot of inactive biphenyl and then oxidized by CrO_3 in acetic acid. The activity of benzoic acid thus obtained was compared with that of biphenyl. The percentage rearrangement of the activity at 1-position of the sulfide or the sulfone was calculated by the following equation.

$$\left(1-\frac{\text{Activity of benzoic acid}}{\text{Activity of biphenyl}}\right)\times 100 \qquad (6)$$

Thus, the photolysis of diphenyl sulfone in benzene was found to proceed through the mechanistic route proposed earlier by Kharasch and Khodair[9] as shown by

7) It is known that elemental sulfur behaves as a biradical chain at high temperatures and diphenyl sulfide is obtained together with by-products such as diphenyl disulfide, when a mixture of benzene and sulfur is heated at 350°C. W. A. Pryor, "Mechanism of Sulfur Reactions," McGraw-Hill Book Co., Inc., New York (1962), p. 8; H. B. Glass and E. E. Reid, *J. Amer. Chem. Soc.*, **51**, 3428 (1929).

8) S. Oae and N. Furukawa, This Bulletin, **39**, 2260 (1966).
9) N. Kharasch and A. I. A. Khodair, *Chem. Commun.*, **1967**, 98.

Eq. (7).

$$RC_6H_4SO_2C_6H_4R \longrightarrow RC_6H_4\cdot + RC_6H_4SO_2\cdot$$

$$RC_6H_4\cdot + C_6H_6 \longrightarrow RC_6H_4(H)\text{-}C_6H_5 \quad (A)$$

$$(A) + RC_6H_4SO_2\cdot \longrightarrow RC_6H_4C_6H_5 + RC_6H_4SO_2H \quad (?)$$

(or $RC_6H_4\cdot$) (or RC_6H_5)

(where R=H or CH_3) (7)

According to this mechanism no rearrangement of the activity at 1-position should take place during photolysis of the sulfone. Therefore, the photolysis of diphenyl sulfone is a quite suitable and convenient method for the degradation.

Experimental

Preparation of Diphenyl Sulfone-1-^{14}C. Diphenyl sulfone-1-^{14}C was synthesized through 9 steps starting from barium carbonate-^{14}C. The synthetic method was described elsewhere.[10]

Reaction of Diphenyl Sulfone-1-^{14}C with Sulfur. The reaction was carried out in the same way as for the previous cases:[2] diphenyl sulfone-1-^{14}C, (0.005 mol), was thoroughly mixed with 0.005 g atom of elemental sulfur in a Claisen-flask, which was quickly placed in a pre-heated metal-bath, nitrogen gas being passed through the reaction flask. The reaction started at 310 or 320°C (metal-bath temperature) and sulfur dioxide evolved was trapped in several traps cooled with dry-ice - acetone. After the reaction mixture was kept at around 310 or 320°C for 1 hr, it was dissolved in benzene into which known amount of inactive diphenyl sulfide and the sulfone was added in order to determine their yields by means of the isotope dilution method. When a clear benzene solution was concentrated, crystals of the sulfone deposited and were recrystallized from *n*-hexane - benzene two or three times. Diphenyl sulfide obtained was also repeatedly distilled until it became transparent, then was converted into diphenyl sulfone for ^{14}C-counting.

Reaction of β-Naphthyl phenyl Sulfone with Sulfur. The reaction was carried out in the same way as in the reaction of diphenyl sulfone-1-^{14}C with sulfur. Identification of the products was performed by means of gas chromatography (High Vacuum Silicon at 250 or 300°C).

The Degradation of Diphenyl Sulfide-x-^{14}C. Photolysis of the sulfone in benzene was carried out in the same way as that by Kharasch and Khodair:[9] photolysis of the sulfone (0.3 g) was carried out in 100 m*l* of benzene at room temperature for 15 hr, and gave biphenyl in 27% yield together with tarry by-products. The reaction mixture was treated with carbon disulfide, and a part dissolved in it was diluted with 0.5 g of inactive biphenyl. An aliquot (about 0.1 g) of the crude biphenyl was purified by sublimation and the rest was dissolved in 5 m*l* of acetic acid. To this solution was added a solution of 5 g of anhydrous chromic acid in 2 m*l* of water and 5 m*l* of acetic acid dropwise with stirring at 70—75°C. Carbon dioxide evolved during the oxidation. After the addition was complete, the contents of the flask was stirred for 1/2 hr at 70—75°C. The reactant was then quenched into 40 m*l* of water and extracted with ether. The ether layer was washed with water three times to remove acetic acid and then re-extracted with 5% alkali solution. The crude benzoic acid thus obtained was purified by sublimation. The benzoic acid was obtained in about 20% yield. Both benzoic acid and biphenyl were employed for counting of ^{14}C activity.

Measurement of the Activities. All the compounds were counted by a liquid scintillation counter (TEN), in toluene solution using POPOP as a scintilator.

We wish to thank Dr. M. Hamada and Dr. T. Nakabayashi of the Radiation Center of Osaka Prefecture for their advice, and for affording facilities for the measurement of the activities.

The Mechanism of Silver Perchlorate Catalyzed Solvolysis Reaction of 2-Chlorocyclohexanone-1-^{14}C

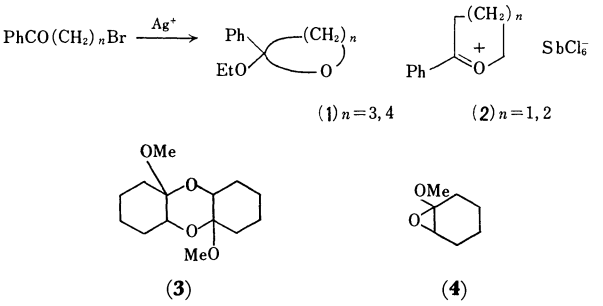
Taketoshi MASUIKE, Naomichi FURUKAWA, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

(Received July 2, 1970)

Silver perchlorate assisted solvolysis of 2-chlorocyclohexanone-1-^{14}C in ethanol-water solution gives 2-ethoxycyclohexanone-*x*-^{14}C. Successive degradation of the product reveals that the ^{14}C activity is distributed in both the carbonyl carbon and the α-carbon of ethoxyketone. The ^{14}C distribution pattern suggests that a part of the reaction proceeds *via* an epoxide intermediate which is formed by the initial attack of ethanol on the carbonyl carbon, followed by the migration of carbonyl oxygen to the α-carbon of 2-chlorocyclohexanone.

In the silver or mercury ion-catalyzed solvolytic reactions of haloketones, a carbonyl group, attached to either γ or δ position of the leaving group, is known to accelerate remarkably the rate of the reaction despite the fact that the carbonyl group is expected to retard it by its strong electron-withdrawing property. These results suggest that the carbonyl group participates in the solvolysis reaction. The rate enhancement and neighboring group participation of the carbonyl group were in fact confirmed by both kinetic study[1,2] and isolation of the products[2,3] such as **1** which undoubtedly results from the participation of carbonyl oxygen. Further, Ward and Sherman, Jr. recently isolated the intermediate **2** as a hexachloroantimonate.[4] More recently, Gassman and his coworkers demonstrated that the enol form of the ketone, which exists in a small amount in an equilibrium with the keto form, participates in the solvolysis reaction, by showing that the rate of solvolysis of anti-7-hydroxynorbornane-2-one-*p*-toluenesulfonate is 2×10^7 times larger than that of 7-hydroxynorbornane-*p*-toluenesulfonate.[5] Although participation of the carbonyl group in the solvolytic reaction has been well established in the case of halo-ketones, in which the carbonyl group is separated at least one methylene group away from the cationic center, evidence supporting the interaction of the carbonyl group with the adjacent cation center is also available. As an example of such interaction, Bergmann obtained the compound **3** from the methanolysis of 2-bromocyclohexanone.[6] The product **3** is probably formed by the dimerization of the epoxide **4**. Silver perchlorate-catalyzed solvolysis of 2-chlorocyclohexanone-1-^{14}C was carried out, to make this interaction clearer. This paper describes briefly the partial migration of carbonyl oxygen of 2-chlorocyclohexanone to the α-position of the product and the probable mechanism of the whole reaction.



(1) $n=3,4$ (2) $n=1,2$

(3) (4)

2-Chlorocyclohexanone-1-^{14}C was synthesized, and a series of successive degradations of the product was carried out as shown below (Fig. 1).

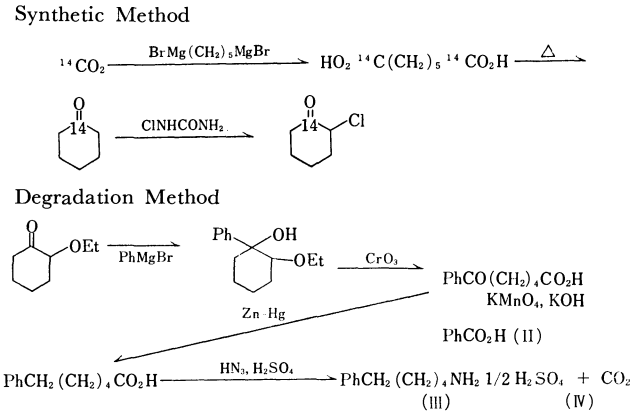


Fig. 1.

Experimental

Preparation of 2-Chlorocyclohexanone-1-^{14}C[7]. Pimeric acid-1,7-^{14}C was obtained by carbonation of the Grignard reagent prepared from 0.9 g of magnesium and 4.0 g of pentamethylene dibromide, with $^{14}CO_2$ generated from 7.0 g (5 mCi) of barium carbonate. The crude product was recrystallized from benzene: yield was 1.8 g (64.9%), mp 104°C.

A mixture of 1.8 g of pimeric acid-1,7-^{14}C and 0.1 g of barium carbonate was gradually heated in a metallic bath to about 320°C and the distillate was collected. The crude cyclohexanone-1-^{14}C (1.0 g), was diluted by adding 10 g of ordinary cyclohexanone and purified by distillation (bp 154—155.5°C). Four grams of the cyclohexanone-1-^{14}C was stirred gently overnight in a water bath at room temperature with 2 g of acetic acid and 20 m*l* of chlorourea solution, which was prepared by absorbing 35 g of chlorine in a stirred suspension of 50 g of calcium carbonate and 300 g of urea in 50 m*l* of water. The solution was then filtered with suction and the filtrate was finally diluted with water to 200 m*l*.

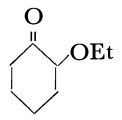
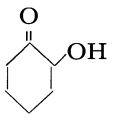
The reaction mixture was then extracted with benzene. The benzene solution was dried over anhydrous sodium sulfate. After removing the solvent, the residue was distilled to give 4 g of 2-chlorocyclohexanone-1-^{14}C, bp 159—159.5°C (74%).

Solvolysis of 2-Chlorocyclohexanone-1-^{14}C and Isolation of the Products. 2-Chlorocyclohexanone-1-^{14}C was solvolyzed in 12.5 m*l* of 80% aqueous ethanol containing 3.1 g of silver perchlorate at 70°C in a water bath for 18 hr. After completion of the reaction, the reaction mixture was neutralized with aqueous sodium carbonate solution. In order to determine the yield of the products by isotopic dilution method, the following non-radioactive compounds were added to the solution, *i.e.*, 1.113 g of 2-ethoxycyclohexanone, 1.086 g of 2-hydroxycyclohexanone, and 0.798 g of ethyl cyclopentanecarboxylate. After the precipitated silver chloride was filtered off, the filtrate was extracted with ether and then with methylene chloride. Both extracts were dried over sodium sulfate. The ether extract gave 2.7 g of yellow oily product (bp *ca.* 88°C/22.5 mmHg) from which 2-ethoxycyclohexanone (0.750 g) and ethyl cyclopentanecarboxylate (0.460 g) were identified and separated with gas liquid chromatography. 2-Hydroxycyclohexanone (0.340 g) was obtained from the methylene chloride extract by removing the solvent and keeping the residue in an ice-box for a few days, mp 110—113°C. The products thus obtained were identified by comparing their NMR, IR spectra and melting points with those of the authentic samples. The yield of the products is shown in Table 1.

Table 1. Yield of products[a)]



31%	23%	1%

a) The yields were determined by the isotopic dilution method.

Degradation of 2-ethoxycyclohexanone-x-^{14}C. 2-Ethoxycyclohexanone-*x*-^{14}C (0.75 g) was mixed with 2.00 g of ordinary 2-ethoxycyclohexanone and dissolved in 30 m*l* of dry ether. This etheral solution was added with stirring to the Grignard reagent prepared from 4.13 g of bromobenzene and 0.64 g of magnesium in 30 m*l* of dry ether. The solution was kept at room temperature overnight, and then acidified with dilute hydrochloric acid. The ether layer was separated and the aqueous layer was extracted with ether. The combined ether extract was washed with aqueous sodium bisulfite solution, neutralized with aqueous sodium carbonate solution, washed with water, and finally dried over sodium sulfate. After removal of ether, 3.8 g, of crude 1-phenyl-2-ethoxycyclohexanol was obtained in 70% yield (bp 114.5—116.0°C/1.5 mmHg). Found: C, 76.07; H, 9.03%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

A mixture of crude 1-phenyl-2-ethoxycyclohexanol-*x*-^{14}C (3.8 g) and chromic acid (1 g) was vigorously stirred. When the temperature reached 25°C, another 9 g of chromic acid was added during a period of one hour keeping the temperature at around 30°C. After the addition of chromic acid, the mixture was diluted with an equal amount of water and was extracted with ether several times. The ether extract was washed with water. The etheral solution was extracted with 300 m*l* of aqueous 5% sodium hydroxide solution. The alkali extract was warmed on a water bath to remove excess ether. After cooling, the solution was acidified with 100 m*l* of concentrated hydrochloric acid. The precipitates were filtered and recrystallized from benzene-*n*-hexane. Thus, 5-benzoylvaleric acid (1.01 g) was obtained in 31% yield; mp 75—76°C. A mixture of 0.35 g of 5-benzoylvaleric acid-*x*-^{14}C, 2.8 g of potassium permanganate, and 1.45 g of potassium hydroxide was dissolved in 50 m*l* of water and refluxed for 4 hr. After the reaction, the precipitates were filtered off and washed with *ca.* 100 m*l* of boiling water. The filtrate was bubbled with sulfur dioxide, acidified with dilute hydrochloric acid and then extracted with ether. The extract was dried over sodium sulfate. After removal of ether, benzoic acid was obtained in 71% yield, mp 120—121°C (recrystallized from *n*-hexane). 5-Benzoylvaleric acid-*x*-^{14}C (1.38 g) was reduced by Martin and Clemmensen's method.[8)] Thus, 6-phenylcaproic acid-*x*-^{14}C (0.81 g) was obtained in 62% yield, bp 150—151.5°C, mp 16—21°C. 6-Phenylcaproic acid-*x*-^{14}C (0.81 g), dissolved in 1.7 m*l* of concentrated sulfuric acid, was decarboxylated with 6.5 m*l* of 1.6 N hydrazoic acid in chloroform solution and the carbon dioxide generated was trapped with

0.25 N aqueous barium hydroxide solution. After completion of the reaction, chloroform and excess hydrazoic acid were removed *in vacuo*. The residue, to which a small amount of water was added, was filtered, washed with acetone-ether, and recrystallized from water. 5-Phenylamylamine-*x*-^{14}C 1/2 H_2SO_4 (0.673 g) was thus obtained in 75.2% yield, mp 325—330°C (decompd.).

Measurement of the Activities. The activities of the samples were measured both with a 2π-gas flow G.M. counter using Q gas and with a liquid scintillation counter using POP and POPOP as scintillators in toluene solution. 5-Benzoylvaleric acid-*x*-^{14}C was used as the standard sample of the total activity. The activity measurement with 2π-gas flow G.M. counter was described precisely in a previous paper.[9] An aliquot of each sample was thoroughly oxidized by the Van Slyke-Folch method, and all the carbon dioxide formed was converted to a barium carbonate tablet which was then subjected to measurement of its ^{14}C activity. The results are shown in Table 2.

Results and Discussion

The products were isolated and identified by the ordinary method and their yields were determined by isotope dilution technique. The result is shown in Table 1. The usual synthetic procedures were used for the ^{14}C compounds. Degradation of 2-ethoxy cyclohexanone was also carried out by a well-known procedure involving no skeltal rearrangement. 5-Benzoylvaleric acid was used as the standard sample of the total activity. The ^{14}C total activities and those of the respective degradative products were calculated from the specific activities of the corresponding samples. The result of the degradation is listed in Table 2. We see that 5-benzoylvaleric acid carries 75—80% of the total activity in carbonyl carbon and the rest is found in carboxylic carbon. This means that 75—80% of the total ^{14}C activity is in the carbonyl carbon atom and 20—25% is in the carbon atom bearing ethoxy group in 2-ethoxycyclohexanone. Namely, around 25% carbonyl oxygen migrates to the α-carbon attached to chlorine. The product analysis seems to rule out both the Wagner Meerwein type rearrangement mechanism, in which the carbon-carbon bond migrates to the cation center as in the case of the deamination of 2-amino cyclohexanone[10] and the Favorskii type mechanism[11] involving the initial formation of cyclopropanone *via* the participation of enolizable carbon-carbon double bond. If the reaction proceeds through one of these routes, cyclopentanecarboxylic acid derivatives would be the major products. Thus, both product analysis and ^{14}C tracer experiments suggest the following mechanism (Fig. 2). Namely, silver ion assists the abstraction of chlorine anion following the migration of carbonyl oxygen to the α carbon atom bearing chlorine atom.

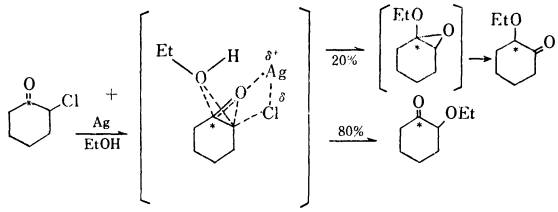

Fig. 2. Mechanism of the reaction.

The authors wish to express their appreciation to Dr. M. Hamada of the Radiation Center of Osaka Prefecture for the measurement of ^{14}C activities.

Tracer Study of the Reactions of Diphenyl Sulfone and Diphenyl Sulfoxide with Diphenyl Disulfide[1]

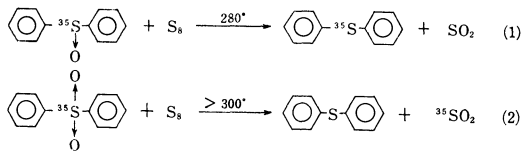
Shigeru OAE, Yoshiyuki TSUCHIDA, and Mamoru NAKAI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku, Osaka

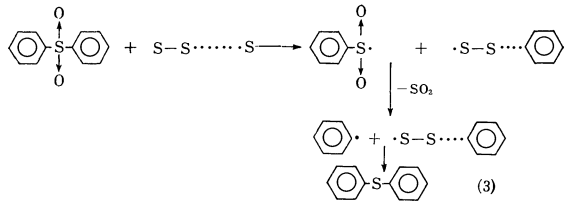
(Received August 22, 1970)

Diphenyl sulfoxide and diphenyl sulfone were found to react with diphenyl disulfide at elevated temperatures, forming in both reactions diphenyl sulfide and sulfur dioxide. On the basis of ^{35}S and ^{14}C tracer experiments, these reactions were found to proceed through quite different mechanistic routes, *viz.*, S–O bond fission in the case of sulfoxide and C–S bond fission in sulfone. The reactions apparently proceed through the attack of the thiyl radical on the sulfoxide and sulfone functions. Further mechanistic details of the reactions are discussed.

Diphenyl sulfoxide[2] and diphenyl sulfone[3] are known to react with elemental sulfur at elevated temperatures to yield diphenyl sulfide and sulfur dioxide.



We found through radio-active sulfur-35 tracer experiments that these two reactions, though yielding the same products, proceed through different mechanistic routes (Eqs. (1) and (2)).[2] In the case of sulfoxide the reaction is a straightforward reduction to give sulfide by the abstraction of labile oxygen atom with elemental sulfur. In the reaction of diphenyl sulfone, however, the sulfur atom of the sulfonyl group is replaced by that of elemental sulfur, apparently initiated by the attack of biradical chain of polymeric sulfur to cleave the C–S bond followed by the extrusion of sulfur dioxide and the formation of the sulfide (Eq. (3)).



These different reaction paths are ascribed to the weaker bond strength of the S–O bond of the sulfoxide than that of sulfone. However, further mechanistic details of these reactions are not well understood, mainly because of the complicated nature of elemental sulfur at elevated temperatures.

Diphenyl sulfone is known to react with diphenyl disulfide at elevated temperatures to form diphenyl sulfide and sulfur dioxide.[3] We found that diphenyl sulfoxide also reacts with disulfide similarly. The reactions appear to serve as simple model reactions for making detailed mechanistic study of the reactions with elemental sulfur.

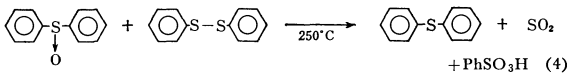
2) S. Oae and S. Kawamura, This Bulletin, **36**, 163 (1963).
3) F. Kraft and W. Vorster, *Ber.*, **26**, 2813 (1893).

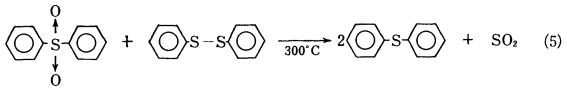
We have investigated the reactions of diphenyl sulfoxide and sulfone with diphenyl disulfide and present in this paper a detailed account of our investigation.

Results and Discussion

Diphenyl sulfoxide reacts nearly explosively with diphenyl disulfide at 250°C under nitrogen atmosphere giving diphenyl sulfide, sulfur dioxide, and a small amount of benzenesulfonic acid as shown in the following equation.



The reaction of diphenyl sulfone with diphenyl disulfide was shown by Kraft and Vorster to give diphenyl sulfide and sulfur dioxide in about 75% yield at about 300°C, a higher temperature than that for the reaction with sulfoxide.



^{35}S-Tracer Experiments. ^{35}S-tracer technique was very useful for showing that the reactions of sulfoxide and sulfone with elemental sulfur proceed through different mechanistic routes, and we have examined the reactions of sulfoxide and sulfone with diphenyl disulfide using sulfur-35 labeled diphenyl sulfoxide and diphenyl sulfone. The specific activities

Table 1. Tracer experiments

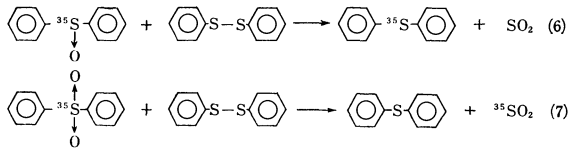
of the reactants and the products were then counted, and the results are tabulated in Table 1.

Inspection of the data reveals that replacement of sulfur atom does not take place in the reaction of the sulfoxide (Eq. (6)) and the reaction is a reduction proceeding through the S–O bond fission.

In the case of the sulfone, the activity of the sulfide formed was only 2.2% of that of the original sulfone. As will be shown later, 19.2% of the sulfide resulted from the sulfone and the rest from diphenyl disulfide under this reaction condition. Nevertheless, these results suggest that replacement of sulfur atom occurs during the reaction, and not the S–O bond but the C–S bond of the sulfone is cleaved in the main path.

The results from the two tracer experiments are similar to those obtained from the reactions with elemental sulfur.



These different modes of reaction can be interpreted in terms of the difference of the bond strengths of the S–O linkages of the respective compounds. It is known that the force constant of the S–O bond in the sulfone calculated from the infrared data, 9.5×10^5 dyne/cm,[4a] is appreciably higher than that of the sulfoxide (7.0×10^5 dyne/cm). Thus, unlike the sulfoxide group, the sulfur-oxygen bond in the sulfone group is not easily cleaved.[4b]

Mechanism of the Reaction of Diphenyl Sulfoxide with Diphenyl Disulfide. Two mechanisms are conceivable for the relatively facile S–O bond cleavage of sulfoxide as shown in Fig. 1, the homolytic reductive cleavage of the sulfoxide bond induced by the benzenethiyl radical formed by the thermal dissociation of the sulfur-sulfur bond of diphenyl disulfide (path A), and the nucleophilic reaction between the sulfoxide and the disulfide (path B). The fact that the reaction temperature (250°C) is high enough to dissociate diphenyl disulfide into the corresponding radical[5] and that the reaction proceeds nearly explosively suggests the free radical chain mechanism to be more favorable.

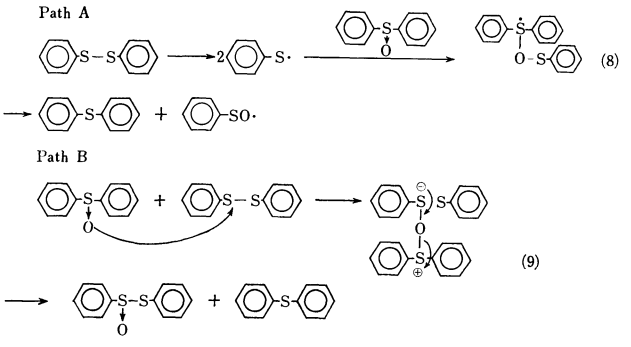


Fig. 1

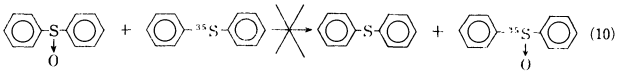
4) a) These values are of alkyl sulfoxides and sulfones, C. C. Price and S. Oae, "Sulfur Bonding," Ronald Press, Inc., New York (1962), p. 66. b) *ibid.*, p. 132.

Evidence to support path A may be found in the following observations. (1) Apparently, oxygen acts as an inhibitor. When nitrogen gas was not passed through the reaction system to sweep oxygen before heating, either a prolonged induction period was observed for this reaction or the reaction did not occur at all. (2) If the reaction proceeds through path B, it is reasonable to consider that an oxygen exchange reaction takes place between diphenyl sulfoxide and diphenyl sulfide as in the case with disulfide. However, by the ^{35}S tracer experiment no such exchange reaction was found to take place (Table 1). (3) A free radical



induced reductive cleavage of semi-polar *N*-oxide bond has been reported.[6]

In view of these observations, the cleavage of the sulfoxide seems to proceed through the former path (path A) involving the attack of the benzenethiyl radical on the sulfoxide oxygen.

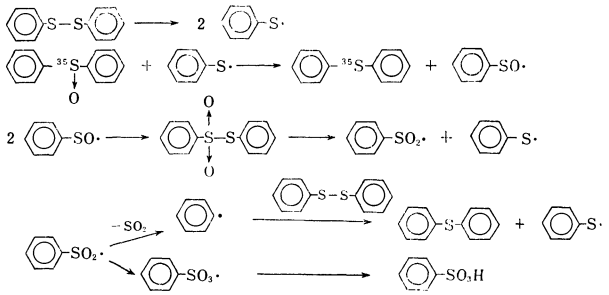


Fig. 2

The overall mechanism of the reaction is thus illustrated in Fig. 2. Phenylsulfinyl radical, PhSO·, has been considered to be rather long-lived[7] and known to undergo dimerization to give the corresponding thiolsulfonate.[7,8] However, thiolsulfonate thus formed would dissociate into $PhSO_2\cdot$ and PhS· radicals at these reaction temperatures. Desulfonylation[9] and disproportionation[10] of $PhSO_2\cdot$ radical have been known to occur readily. Desulfonylation of phenylsulfonyl radical leads to the formation of SO_2 and phenyl radical which would immediately be converted to diphenyl sulfide by the chain transfer reaction with diphenyl disulfide. By disproportionation both $PhSO_3\cdot$ and PhSO· radicals would result. Formation of a small amount of benzenesulfonic acid in the products may be rationalized on the basis of hydrogen abstraction with $PhSO_3\cdot$ radical.

According to this mechanism, the first step of the

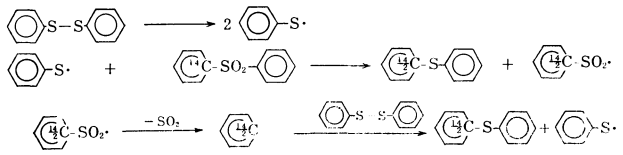
reaction in Fig. 2 will afford radioactive sulfide, and the subsequent desulfonylation of thiolsulfonate will afford the nonactive sulfide. Thus, the specific activity of diphenyl sulfide formed will be reduced substantially as compared to the activity of the original sulfoxide. This is consistent with our experimental result (Table 1).

Mechanism of the Reaction of Diphenyl Sulfone with Dephenyl Disulfide. It is known that at these temperatures for the reaction of sulfone (300°C) diphenyl disulfide dissociates into a pair of benzenethiyl radicals, which then attack the original diphenyl disulfide, eventually giving rise to diphenyl sulfide and elemental sulfur in several steps.[11]

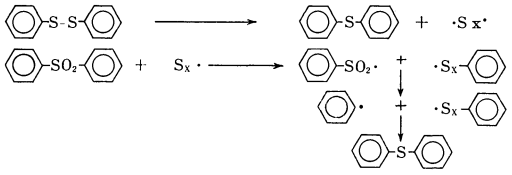
(11)

Since the reaction occurs nearly spontaneously at higher temperatures than that with diphenyl sulfoxide, the reaction of the sulfone with the disulfide is considered to proceed through a free radical process.[2] The following three paths involving the C–S bond fission are conceivable for the initial step of the reaction of diphenyl sulfone and diphenyl disulfide (Fig. 3), A) the attack of benzenethiyl radical formed from diphenyl disulfide at the sulfone function, B) the initial decomposition of diphenyl disulfide into the sulfide and polymeric sulfur, which in the subsequent step attacks the sulfone, C) both mechanisms occur concurrently.

Path A



Path B



Path C A and B in parallel

Fig. 3

In order to examine the possibility of the three conceivable mechanistic pathways, we first tried the reaction of diphenyl sulfone with bis(*p*-chlorophenyl)-disulfide, but this procedure was unsuccessful because of unexpected side reactions giving rise to many complicated products including chlorobenzene *etc.* Thus we adopted the reaction of carbon-14 labeled diphenyl sulfone with the disulfide. If the reaction proceeds through path A, the specific activity of the sulfide formed should be one half of that of the original sulfone at any time during the course of the reaction.

11) C. Graebe, *Ann. Chem.*, **174**, 189 (1874).

The result given in Table 1 reveals that the sulfide formed has an activity corresponding to 19.2% of the original sulfone. This indicates that the mechanism A can be excluded. Of the two mechanisms B and C, the latter seems to be adequate on the basis of the following observations.

$$\underset{1.0}{PhSSPh} \xrightarrow[21\ min]{302^\circ C} \underset{0.45}{PhSPh} + \cdot Sx\cdot \qquad (12)$$

$$\underset{1.0}{PhSO_2Ph} + \underset{1.0}{\cdot Sx\cdot} \longrightarrow \underset{0.10}{PhSPh} + SO_2 \qquad (13)$$

$$\underset{1.0}{PhSO_2Ph} + \underset{1.0}{PhSSPh} \longrightarrow \underset{0.68}{PhSPh} + \underset{(\times 10^{-3}\ mol)}{SO_2} \qquad (14)$$

Diphenyl disulfide, 1.0×10^{-3} mol, gave 0.45×10^{-3} mol of the sulfide and elemental sulfur at 302°C for 21 min, and equimolar (1.0×10^{-3} mol) amounts of the sulfone and elemental sulfur gave 0.10×10^{-3} mol of the sulfide under the same condition. If the reaction of the sulfone with the disulfide were to proceed through path B, the total amount of the sulfide formed should be less than $(0.45+0.1)\times10^{-3}=0.55\times10^{-3}$ mol, when equimolar (1.0×10^{-3} mol) amounts of the sulfone and the disulfide were reacted. However, 0.68×10^{-3} mol of the sulfide is actually formed.

The results cannot be explained on the assumption that the reaction proceeds through path B. Thus, it is reasonable to consider that both mechanisms A and B exist, namely, the attack of both benzenethiyl radical and the radical chain of elementary polymeric sulfur take place on the sulfone. Thus, the reaction of the sulfone proceeds through mechanism C.

Experimental

Diphenyl sulfide-^{35}S was prepared by Friedel-Crafts' reaction of benzene with radioactive sulfur in the presence of aluminium chloride according to the method[2] previously reported.

Diphenyl sulfoxide-^{35}S was prepared by the usual bromine oxidation of ^{35}S-labeled diphenyl sulfide.[12] From 4.6 g of the sulfide, the sulfoxide-^{35}S (mp 70.5°C) was obtained in 66% yield after repeated recrystallization from benzene-hexane.

Diphenyl sulfone-^{35}S was prepared by oxidizing diphenyl sulfide-^{35}S with potassium permanganate in glacial acetic acid. From 2.0 g of the sulfide, the sulfone-^{35}S (mp 123°C) was obtained in 80% yield.

Diphenylsulfone-1-^{14}C was prepared according to the procedure described elsewhere.[13]

Reaction of Diphenyl Sulfoxide with Diphenyl Disulfide. Diphenyl sulfoxide, 2.02 g, was thoroughly mixed with 1.09 g of diphenyl disulfide in a Claisen-flask and heated to about 100°C in order to melt the reactants. Dry nitrogen gas was bubbled through the liquid reaction mixture to remove any residual air. Then the flask was quickly put in a preheated silicon bath. In ten minutes the reaction took place nearly explosively and dark colored solution was formed with evolution of sulfur dioxide which was trapped in a few traps cooled with methanol - dry ice. The products were distilled *in vacuo*, and the distillate and the residue thus obtained were analyzed

12) S. Oae, Y. Ohnishi, S. Kozuka, and W. Tagaki, This Bulletin, **39**, 364 (1966).

13) S. Oae and N. Furukawa, *ibid.*, **39**, 2260 (1965).

by gas-liquid and column-elution chromatography, respectively. The distillate was found to be diphenyl sulfide alone. From the residue benzenesulfonic acid and a small amount of tarry substance were separated. Benzenesulfonic acid was identified as its thiouronium salt which has the same melting point and infrared spectrum as that of the authentic sample. The ^{35}S-tracer experiment was carried out similarly. The original sulfoxide having the specific activity of 8844 cpm/mg (converted to the sulfone) was treated with ordinary diphenyl disulfide. Diphenyl sulfide obtained was distilled repeatedly, usually two or three times, and then converted to diphenyl sulfone by the usual method (7677 cpm/mg).

Exchange Reaction of Diphenyl Sulfide-^{35}S and Diphenyl Sulfoxide. A mixture of diphenyl sulfide-^{35}S (5250 cpm/mg, converted to the sulfone), 1.03 g, and ordinary diphenyl sulfoxide, 1.12 g, was treated in the same way as in sulfoxide with disulfide. The reaction time was prolonged to 1 hr. After cooling the sulfide was distilled and the recovered sulfoxide was washed with *n*-hexane and recrystallized twice and the activity was counted (1.0 cpm/mg).

Reaction of Diphenyl Sulfone-^{35}S with Diphenyl Disulfide. Diphenyl sulfone-^{35}S (22100 cpm/mg), 1.09 g, was mixed with ordinary diphenyl disulfide, 1.09 g, in a Claisen flask and was put in a preheated air bath while nitrogen gas was passed through the reaction flask. After about 30 min, the flask was cooled down to room temperature and diphenyl sulfide formed was distilled *in vacuo* three times, and then converted to diphenyl sulfone by the usual method (481 cpm/mg).

Reaction of Diphenyl Sulfone-1-^{14}C with Diphenyl Disulfide. The reaction was carried out in the same way as in diphenyl sulfone-^{35}S. Diphenyl sulfone-1-^{14}C and diphenyl sulfide formed (converted into the sulfone) was found to have the activities of 2647 cpm/mg and 507 cpm/mg, respectively.

Estimation of the Conversions. The decomposition reaction of diphenyl disulfide was carried out at 302°C in degassed sealed tube in which 1.0×10^{-3} mol of the disulfide was placed with no solvent. A sealed tube was taken out from the silicon oil bath and cooled down to room temperature. The contents were then diluted with benzene to 10m*l* and the amount of diphenyl sulfide was determined by gas-liquid chromatography with biphenyl as an internal standard.

Conversion of the reactions of diphenyl disulfide (1.0×10^{-3} mol) and elemental sulfur (1.0×10^{-3} g atom) with diphenyl sulfone (1.0×10^{-3} mol) was determined similarly.

Counting of Radioactivities. The activities of all the compounds were counted by Packard Tri-Carb liquid scintillation counter, in toluene solution using POPOP as scintillator.

We are grateful to Dr. S. Kawamura of the Radiation Center of Osaka Prefecture, who kindly performed the counting of specific activities.

Study of Acidity Constants of 3-, 4-, 5-, and 6-Chloro-*o*-toluidinium Ions in Aqueous Solution and Related Thermodynamic Quantities. I

A. H. GANDHI and S. R. PATEL
Department of Chemistry, Sardar Patel University, Vallabh Vidyanagar, India
(Received April 13, 1970)

The acidity constants of anilinium, simple and 3-, 4-, 5-, and 6-chloro-*o*-toluidinium ions have been studied at seven different temperatures by pH metry in aqueous solution and correlated using the relation $\ln K=A+BT+CT^2$. The values of ΔG, ΔH, ΔS, and ΔC_p have been calculated at different temperatures. The possibility of the additivity in the thermodynamic quantities of these disubstituted anilinium ions has been examined. Hammett type equation has been developed to correlate the acidity constant of these ions at 25°C. Attempt has been made to explain the trends in the thermodynamic quantities of these ions in terms of polar, steric, and solvent effects.

Acidity constants of anilinium, *o*-, *m*-, and *p*-toluidinium and *o*-, *m*-, and *p*-chloroanilinium ions have been reported by Biggs at different temperatures.[1] The heats of ionization of the isomeric xylidinium and toluidinium ions have been determined by Laidler and co-workers by calorimetric method.[2] The present communication deals with the study of the acidity constants of 3-, 4-, 5-, and 6-chloro-*o*-toluidinium ions by pH metry at equally spaced seven temperatures ranging from 15 to 45°C. The acidity constant of each of these ions is correlated with temperature using a three constant equation, $\ln K=A+BT+CT^2$. This equation is used to calculate thermodynamic functions ΔG, ΔH, ΔS, and ΔC_p at all the seven temperatures. The thermodynamic quantities of the ionization of anilinium and *o*-toluidinium ions were required to check the possible additivity in the corresponding thermodynamic quantities of chlorotoluidinium ions. For examining such an additivity, it was desirable to study the acidity constants of these two ions at the corresponding temperatures under the conditions under which the acidity constants of the isomeric chloro-*o*-toluidinium ions were determined. Hence the acidity constants of these two ions were redetermined and the thermodynamic quantities were calculated by the application of the above mentioned equation. Modified Hammett relation is derived and applied to correlate the acidity constants of these *o*-substituted anilinium ions with Hammett σ and ρ constants. Attempt has also been made to interpret the values of the thermodynamic quantities ΔG, ΔH, and ΔS in terms of the polar, steric, and solvent effects.

Experimental

Reagents. Anilinium chlorides were prepared by the following method starting with laboratory grade chemicals. Each aniline derivative was distilled in an all-glass apparatus and the fraction boiling at constant boiling point was collected. The fraction was then redistilled over zinc dust. The liquid thus purified was dissolved in 10 times its weight of dry ether. Dry hydrogen chloride prepared from AR grade chemicals was passed through this solution and the white solid which separated was filtered and washed with ether. The white solid was crystallized from pure ethanol. The crystalline solid was dried over anhydrous calcium chloride in a vacuum desiccator. It was preserved in a dry coloured bottle kept in a vaccum desiccator. The boiling points of the aniline derivatives and the melting points of their anilinium chlorides were in accordance with those reported in literature.[3] The equivalents weights of the anilinium salts agreed within 0.2% of the calculated value.

Apparatus. The pH metric titrations were carried out using Metrohm pH meter E300 with an expanded scale on which pH could be conveniently read up to 0.005 pH units. A Metrohm dosigraph E364 micrometer syringe type burette capable of delivering volume of 0.001 m*l* was used. Metrohm glass electrode EA 100 X and calomel electrode with saturated potassium chloride solution were used. A 100 m*l* pyrex beaker was covered at the top with a special bakelite cork with four wholes, two of which were for the electrodes, one for thermometer and one for admitting the tip of the burette. The solution was stirred magnetically.

Temperature Control. The acidity constants were determined at equally spaced seven different temperatures from 15 to 45°C. The cell temperature was maintained by circulating water from a constant temperature bath into a jacket around the cell. The temperature of the cell was controlled within 0.1°C of the reported value.

Standardization of pH Meter. As pH of the reagent-solutions were found to lie in the range from 3 to 4, 0.05M aqueous solution of potassium hydrogen phthalate and saturated aqueous solution of potassium hydrogen tartarate were considered as suitable buffer solutions for the standardization of the pH meter. The pH values of NBS standard of these buffer solutions at various temperatures were followed while standardizing pH meter at the respective temperatures.[4]

Procedure. A stock solution, 0.01M with respect to the required anilinium chloride and 0.005M with respect to potassium chloride was prepared in distilled water. The three sets of solutions, 0.002, 0.003, and 0.004M, for the actual titration were prepared by diluting 10, 15, and 20 m*l* of the stock solution to 50.0 m*l* by adding ditilled water. The titrations were carried out at these three concentrations at each temperature. Standard potassium hydroxide solution, was prepared using carbonate free potassium hydroxide in triple distilled water. Its strength was adjusted to an exact value around 0.15M. The amount of titrant added each time was so adjusted that pH changes by about 0.05 to 0.10 units for each addition. The titration was carried out almost up to the point of neutrali-

zation.

As it was not possible to prepare a clear solution of 6-chloro-*o*-toluidinium ion in water, the procedure for titration of this ion was modified. Three solutions which were 0.002, 0.003, and 0.004M with respect to HCl and three other solutions which were 0.002, 0.003, and 0.004 both with respect to HCl and 6-chloro-*o*-toluidinium ion were prepared. They were titrated against the same standard alkali solution.

The pH meter readings for the titration of blank HCl solution and of solution containing both the reagent and HCl of the corresponding strength were plotted against the amount of alkali added on the same graph paper. The readings from the middle portion of graph were selected for calculation.

Results and Discussion

Calculations. At constant ionic strength, the thermodynamic acidity constant K_a^T for the reaction

$$BH^+ + H_2O \rightleftharpoons B + H_3O^+ \quad (1)$$

is given by the relation:

$$K_a^T = \frac{[B](H_3O^+)}{[BH^+]} \cdot \frac{1}{f_{BH^+}} = K_a^M \cdot \frac{1}{f_{BH^+}} \quad (2)$$

$$\therefore \quad pK_a^T = pK_a^M + \log f_{BH^+} \quad (3)$$

where K_a^M is called the mixed constant because out of the three terms in the equilibrium expression, [B] and [BH] are concentration terms and (H_3O^+) is an activity term.

Seven to eight titration readings were selected from the middle portion of the titration data in order to evaluate K_a^T. The activity term (H_3O^+) was calculated from the measured pH of the solution at a given stage in the titration. If $[K^+]$, [B], and $[BH^+]$ are the concentrations of the bracketed terms at the same stage in titration, and if $[BH_0^+]$ is the original concentration of the solution, it can be proved[5] that

$$[B] = [K^+] + [H_3O^+] \quad (4)$$

$$[BH^+] = [BH_0^+] - [B] \quad (5)$$

The concentration of OH^-, which is extremely low in acidic solution, is neglected. The activity coefficient f_{BH^+} was calculated using the Debye-Hückel limiting law,[6]

$$\log f_i = AZ_i^2\sqrt{I_m} \quad (6)$$

where $A = -1.823 \times 10^6/(DT)^{3/2}$, $Z_i = 1$ and I_m is the ionic strength at the stage of half neutralization. It has been recommended that for titration at low concentrations, the value of the ionic strength at the stage of half neutralization may be used in deriving the DHLL correction.[6] The DHLL corrections were not applied to 6-chloro-*o*-toluidinium ion as the observed scatter in the values of pK_a of this ion was of the order of the correction to be applied.

The method of calculation of acidity constant for ionization of 6-chloro-*o*-toluidinium chloride was slightly different. The concentration term [B], was obtained by subtracting the hydrogen ion concentration of blank HCl titration at a given stage of titration from the hydrogen ion concentration at the corresponding stage of titration of the solution of the anilinium chloride in HCl of the same strength. $[BH^+]$ is calculated using relation (5).

The values of pK_a^T for anilinium, *o*-toluidinium and 3-, 4-, 5-, and 6-chloro-*o*-toluidinium ions at all the seven temperatures are reported in Table 1. The values of pK_a^T agree within ± 0.01 pK units except for 6-chloro-*o*-toluidinium ion. For the latter ion the scatter is found to be about ± 0.02 pK unit.

Correlation of Acidity Constants and Temperature. Out of the many empirical equations proposed by various workers to correlate acidity constants with temperature,[7-11] the equation

$$\ln K = A + BT + CT^2 \quad (7)$$

is employed to correlate the experimental data reported in the present communication and to evaluate the thermodynamic quantities. This equation was empolyed by Ives and Pyror[10] to correlate successfully the variation of ionization constants of monohalogenoacetic acids with temperature. The selection of the equation is justified by the fact that the equation represents the experimental data within the limits of experimental error. The constants of the equations are evaluated by the application of the method of least squares.

From Eq. (7), the following equations are derived:

$$G = -RAT - RBT^2 - RCT^3 \quad (8)$$

$$H = RBT^2 + 2RCT^3 \quad (9)$$

$$S = 2RBT + 3RCT^2 + RA \quad (10)$$

$$C_p = 2RBT + 6RCT^2 \quad (11)$$

It has been reported that more than one equations may represent the same experimental data almost equally well and that there may be a fair agreement in the values of ΔH and ΔS calculated by the application of each of the equations. However, the values of ΔC_p are found to be different.[12] From this point of view, the values of ΔC_p evaulated by the appli-

cation of Eq. (8) have been reported at 25°C and no attempt has been made to attach any significance to the calculated value.

The calculated values of thermodynamic quantities for anilinium, *o*-toluidinium, 3-, 4-, and 5-chloro-*o*-toluidinium ions at all temperatures are given in Table 2. The thermodynamic quantities for the ionization of *o*-, *m*-, and *p*-chloroanilinium in aqueous solutions at 25°C were required for examining the possible additivity in the corresponding thermodynamic quantities of isomeric chloro-*o*-toluidinium ions. They were calculated by the application of Eq. (7) to the acidity constants of these ions reported by Biggs[1] at five different temperatures.

The scatter in evaluated acidity constants of 6-chloro-*o*-toluidinium ion was found to be of the order of DHLL correction. Hence it was throught improper to apply this correction to the calculated pK_a. For the same reason it was considered improper to apply Eq. (7) to the data for the purpose of correlating the values of acidity constants with temperature. The values are correlated using the following simplified equation[7b]

$$\log K = A - B/T \qquad (12)$$

The thermodynamic quantities of this ion at 25°C are reported in Table 2.

Additivity of Thermodynamic Quantities. According to Laidler the prediction of thermodynamic quantities for disubstituted anilinium ions from the changes produced when single substituents are introduced sepa-

rately in anilinium ion is referred to as additivity.[13] Laidler has analysed the role of polar, steric, and solvent effects in deciding the additivity of thermodynamic quantities. Laidler has also indicated that interpretation of the thermodynamic quantities has proved to be complicated because the above-mentioned effects do not operate independently.[13]

With a view to examining the additivity in the thermodynamic quantities of disubstituted anilinium ions, ionization of anilinium ion in aqueous solution is considered as a reference reaction. The increments in each of the thermodynamic quantities due to introduction of a single substituent is calculated by deducting the value of the particular thermodynamic quantity for the ionization of the mono-substituted anilinium ion (say $RC_6H_4NH_3^+$) from that of the corresponding quantity for the ionization of anilinium ion. The increments in the value of ΔG, ΔH, and ΔS thus calculated may be considered to be the corresponding thermodynamic quantities of the following reaction

$$ArNH_3^+ + PhNH_2 \rightleftharpoons ArNH_2 + PhNH_3^+ \qquad (13)$$

These values are shown in Table 3.

The increments in a particular thermodynamic quantity due to introduction of each of the substituents separately in the required position in anilinium ion are added up to calculate the increments due to the introduction of the two substituents in their respective positions in disubstituted anilinium ion.

Examination of the values shown in Table 3 indicates that additivity is observed in ΔG values of 4-, 5-, and 6-chloro-*o*-toluidinium ions. It is not observed in ΔG value of 3-chloro-*o*-toluidinium ion.

The additivity is not observed in ΔH and ΔS values of 3-, 4-, 5-, and 6-chloro-*o*-toluidinium ions. The predicted and the experimental values differ appreciably. However, the fact that the additivity is observed in ΔG values for the ionization of 4-, 5-, and 6-chloro-*o*-toluidinium ions, suggests that through the variations in ΔH and ΔS appear to be quite random, their variations have occurred in a compensating manner as suggested by Laidler.[13]

Linear Free Energy Relationships. The acidity constants of *m*- and *p*-substituted anilinium ions are correlated by the application of Hammett type equation.[14] The value of the reaction constant for the ionization of anilinium ions in aqueous solution at 25°C is reported by Jáffe to be 2.767.[15] The substituent constants for ortho substituents are not obtainable mainly because of the variable nature of steric and conjugation effects of such group in different reactions. According to Clark and Perrin,[14] apparent σ-ortho constants which are valid only for the given reaction conditions under which they are determined can be used satisfactorily in conjunction with the normal σ-meta and σ-para constants for prediction. The method suggested by Clark and Perrin[14] is used in arriving at the following equation on the basis of the values of acidity constants reported in Table 4 for *o*-substituted anilinium ions at 25°C.

$$pK_a = 4.615 - 2.85\sum\sigma \qquad (14)$$

b) *o*-Cl = +0.71, *m*-Cl = +0.37,[14] *p*-Cl = +0.23[14]

The apparent σ-ortho constants for methyl and chlorine are calculated for ionization of *o*-substituted anilinium ions in aqueous solution at 25°C. The normal Hammett equation was used for this purpose.

$$\log (K/K_0) = \rho \cdot \sigma \qquad (15)$$

The value of ρ was taken to be equal to 2.767.[15]

13) K. J. Laidler, *Trans. Faraday Soc.*, **55**, 1725 (1959).
14) J. Clark and D. D. Perrin, *Quart. Rev.*, **28**, (3) 295 (1954).

16) R. N. Beale, *J. Chem. Soc.*, **1954**, 4494.

The value of pK for anilinium ion was taken to be 4.615 (pK_o) at 25°C. The reported σ-meta and σ-para constants of methyl and chlorine groups were used.

A comparison of the experimental and estimated pK values indicates that except for 2:6-xylidinium and 3-chloro-*o*-toluidinium ion, there is a good agreement. As reported in the preceding section additivity is not observed in ΔG values of 3-chloro-*o*-toluidinium ions.

Interpretation of the Results

The fact that *o*-toluidinium ion is a stronger acid than anilinium ion is contrary to expectation on the basis of the inductive effect of methyl group ortho to NH_3^+ group. As compared to the ionization of anilinium ion, the ionization of *o*-toluidinium ion is less endothermic and less random. The contribution of the entropy effect to the ΔG values of *o*-toluidinium is very small. ($T\Delta S=0.036$ kcal·mol^{-1})

Molecular model for *o*-toluidinium ion constructed using Catalin Molecular Models showed that the CH_3 and NH_3^+ groups could be just accommodated in the ortho positions only in certain conformations. In such a situation, the interaction between the two groups through the π-electron system of benzene may not be completely restricted. However, the space around NH_3^+ is partly occupied in its immediate vicinity by the ortho methyl groups. Therefore, the extent of solvation will be reduced proportionately. The interaction between the electron releasing methyl group and the positive charge on the nitrogen atom of NH_3^+, will disperse this positive charge on the nitrogen atom. This will reduce the extent of solvation of the *o*-toluidinium ion and make the *o*-toluidinium ion more random. Hence, the process of ionization of *o*-toluidinium ion will proceed with a smaller entropy change. This explains why ΔS is smaller for ionization of this ion than that of anilinium ion.

The fact that ionization of *o*-toluidinium ion is less endothermic than that of anilinium ion suggests that the steric and solvent effects play a more important role than the polar effect. Such a view is also expressed by Brown and co-workers.[17]

The isomeric chloroanilinium ions are stronger acids than anilinium ion. This seems to be due to the presence of electron attracting chlorine atom which makes the release of protons easier. The entropy changes for the ionization of all the three chloroanilinium ions are very nearly the same as they do not differ much from that of the ionization of anilinium ion. Therefore the extent of solvation and hence stability induced by solvation will most probably be the same for all these ions. Hence the difference in ΔH values may possibly be due to the difference in the polar effects operating in bare chloroanilinium ions.

The trends in the thermodynamic quantities of the isomeric 3-, 4-, 5-, and 6-chloro-*o*-toluidinium ions are not explicable simply from the knowledge of the manner in which a particular property is affected by the introduction of a single substituent, methyl or chlorine, in the required position in anilinium ion. It is difficult and perhaps impossible to predict the nature of the possible interactions between the methyl and chlorine substituents in a chlorine substituted *o*-toluidinium ions.

It is also not reasonable to assume that each one of these groups will influence the reaction site independently. Hence no attempt is made to explain the trends in the thermodynamic quantities of these ions. The question of 3-chloro- and 6-chloro-*o*-toluidinium ions is considered because of their peculiar structures.

The molecular model for 3-chloro-*o*-toluidinium ion shows that it is possible to accommodate the three groups respectively in three consecutive positions on the benzene nucleus if NH_3^+ and CH_3 groups take up certain conformations. The methyl and chlorine substituents which are placed in ortho position with respect to each other have opposite polarities. It is quite possible that the methyl group may be pushed nearer to the chlorine atom and away from the NH_3^+ group. Due to this it will make the space around the NH_3^+ group roomier and its interaction with NH_3^+ group weaker. This may explain why ionization of 3-chloro-*o*-toluidinium ion is more random than that of *o*-toluidinium ion.

6-Chloro-*o*-toluidinium ion is the strongest acid of all the four isomeric chloro-*o*-toluidinium ions. The steric and solvent effects are likely to play a prominent role in the ionization of this ion. The space around the NH_3^+ group in this ion is occupied by the methyl and chlorine substituents placed in ortho position to NH_3^+ group. This will reduce the number of water molecules that can associate with NH_3^+ group and will increase the randomness of the ion. It is likely that under the given situation its randomness exceedes that of the hydronium ion. The ionization of 6-chloro-*o*-toluidinium ion may then proceed with decrease in randomness as has been observed. The decreased solvation of this ion will increase its enthalpy. Therefore, the ionization of this ion will be less endothermic than that of *o*-toluidinium or anilinium ion.

The authors thank Professor Dr. R. D. Patel and Dr. C. K. Patel for taking keen interest in the work and making helpful suggestions.

Studies of Phosphorylation. V.[1] The Synthesis of Inosine-5′-thiophosphates

Kazuko HAGA, Masatsune KAINOSHO, and Masaharu YOSHIKAWA
Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki
(Received April 20, 1970)

Two isomers of inosine-5′-thiophosphates, inosine-5′-phosphorothionate and 5′-deoxy-5′-thioinosine-5′-phosphorothioate, were synthesized by the direct phosphorylation of inosine with phosphorus thiochloride, and by the treatment of 5′-deoxy-5′-iodoinosine with trisodium phosphorothioate, respectively. The structure of the thiophosphate residues was identified by means of ^{31}P NMR. The flavoring activities of these thiophosphates were measured as the synergistic strength with monosodium glutamate; it was found that the strength of each compound was lower than that of inosine-5′-phosphate.

The nucleoside-5′-thiphosphates are of interest in connection with the relationship of the flavoring activity of the 5′-nucleotide to the structure of the phosphate residues. The present authors have attempted to prepare inosine-5′-thiophosphates and have obtained two isomers: inosine-5′-phosphorothionate (I) and 5′-deoxy-5′-thioinosine-5′-phosphorothioate (II). The other possible isomer, inosine-5′-phosphorothiolate (III), was not detected in the product. The synergistic flavoring strengths[2] of the nucleoside thiophosphates with monosodium glutamate were compared with that of inosine-5′-phosphate; the relative strengths of I and II were shown to be one-half and one-fortieth respectively. This paper will deal with the synthesis of the two isomers of inosine-5′-thiophosphates and with their structural identification by ^{31}P NMR.[3]

Results and Discussion

Synthesis of Inosine-5′-thiophosphates. The pyrimidine nucleoside phosphorothionates have been synthesized by the treatment of 3′-*O*-acetylthymidine and 2′,3′-*O*-dimethoxybenzylidene uridine with triimidazoyl-1-phosphinsulfide in only 25—30% yields.[4] In our previous report,[5] it has been shown that nucleosides were phosphorylated with phosphoryl chloride in trialkyl phosphate to give, selectively, the 5′-phosphates in good yields. This method was successfully applied to the phosphorylation of inosine with phosphorus thiochloride; inosine-5′-phosphorothionate (I) was obtained after the hydrolysis of the phosphorylation mixture. The product (I) was isolated by column chromatography and was identified by elemental analysis and by ^{31}P NMR spectroscopy, as will be

described later. The phosphorothionate was completely desulfurized to give inosine-5'-phosphate by being left for a few hours in an aqueous solution of pH 1—5, but it was stable in a neutral or mildly alkaline medium. When the phosphorothionate (I) was treated with active charcoal in order to purify it, the I was observed by paper chromatography to be entirely transformed into a different compound. The product was positive in sulfur analysis and was reduced quantitatively to I by the treatment of sodium in liquid ammonia. It can be concluded, from these results and from those of the ^{31}P NMR, that the oxidized compound was P^1,P^2-bis(inosine-5'-phosphoryl) disulfide (IV).

For the preparation of 5'-deoxy-5'-thioinosine-5'-phosphorothioate (II), we attempted to prepare 5'-deoxy-5'-thio-2',3'-*O*-isopropylideneinosine (VII) as an intermediate. The acetylthio derivative of inosine (VI) was prepared by heating 2',3'-*O*-isopropylidene-5'-*O*-(*p*-toluenesulfonyl)inosine (V) with sodium thioacetate using a modification of the method reported by Baddiley and Jamieson.[6] However, the treatment of the product with methanolic ammonia for deacetylation produced 5',5'-bis(5'-deoxy-2',3'-*O*-isopropylideneinosyl) disulfide (VIII), contrary to our expectations. The structure of disulfide was confirmed by its positive test with a Grote reagent[7] only after the treatment with potassium cyanate. The interesting result was observed, in the course of the preparative investigation of the acetylthio derivative, that two kinds of cyclonucleosides were produced by the self-exothermic degradation when the reaction has carried out without cooling. These products were isolated by alumina column chromatography. The PMR spectrum of one of the products has two peaks at 8.65 τ due to the isopropylidene group, a single peak at 6.19 τ due to the methyl ester, and a single peak at 3.91 τ due to the C_1'-proton, the latter of which is a typical signal of a cyclonucleoside group. The spectral results and the results of the elemental analysis prove that the product is 5-amino-4-methoxycarbonyl-N^5,5'-cyclo-1-β-D-(2',3'-*O*-isopropylideneribofuranosyl)imidazole (IX). The other product was confirmed to be 5-amino-4-carbamoyl-N^5,5'-cyclo-1-β-D-(2',3'-*O*-isopropylideneribofuranosyl)imidazole (X) by a comparison with an authentic sample.[8]

Some *S*-phosphoric esters have been synthesized by the treatment of halo-compounds with trisodium phosphorothioate.[9] When the 5'-deoxy-5'-iodoinosine was treated with trisodium phosphorothioate in water at room temperature, 5'-deoxy-5'-thioinosine-5'-phosphorothioate (II) was produced quantitatively; it was then isolated from the reaction mixture by means of cellulose-column chromatography. The phosphorothioate was extremely labile in acidic media and was completely hydrolyzed, in less than one minute, to produce 5'-deoxy-5'-thioinosine and orthophosphoric acid under the acidic conditions of pH 3 at 60°C. The compound, however, was relatively stable in neutral or alkaline media.

^{31}P NMR Spectra of Inosine-5'-thiophosphates. In order to clarify the ambiguities of inosine-5'-thiophosphates, the ^{31}P NMR spectra were determined at 40.5 MHz; the results are summarized in Table 1. The ^{31}P signal of I in aqueous ammonia appeared as a rather broad triplet (caused by the spin-coupling with the two protons at *C*-5') at 2812 Hz upfield from the locked P_4O_6. This chemical shift is approximately equal to that of −43.1 ppm downfield from 85%

TABLE 1. PARAMETERS OF THE ^{31}P NMR SPECTRA[a)]

Compound	Solvent	Chemical shifts[b)] (multiplicity; J[c)])
I	NH_4OH aq.	−43.1 (broad triplet; $J\simeq4.5$ Hz)
II	H_2O	−16.1 (triplet; $J\simeq10$ Hz)
IV	H_2O	−17.3 (broad singlet)
5'-IMP 2Na	H_2O	−3.9 (triplet; $J\simeq4.5$ Hz)
S=P(OEt)$_2$ | ONa (XI)	—	−56 −59
O=P(OEt)$_2$[d)] | SH (XII)	—	−24
O=P(OEt)$_2$ | ONa (XIII)	—	−3.8

a) All spectra were measured at room temperature (34°C).
b) Chemical shifts (ppm) are represented from 85% H_3PO_4 signal which is assumed to appear 4556 Hz upfield from P_4O_6.
c) Multiplicities and coupling constants are estimated based on the first order approximations.
d) "^{31}P Nuclear Magnetic Resonance," M. M. Crutchfield, C. H. Dungen, J. H. Letcher, V. Mark, and J. R. Van Wazer, Interscience Publishers, New York (1967).

H_3PO_4 which shows the phosphorothionate type (P=S), as is also supposed from the ^{31}P NMR spectrum of sodium diethyl phosphorothionate (XII). On the other hand, the ^{31}P NMR spectra of II and IV showed well-resolved triplets (J 10 Hz) at −16.1 and −17.3 ppm from 85% H_3PO_4 respectively. By comparing the chemical-shift data with those of the acyclic analogues, diethyl phosphorothiolate (XII), II and IV can be easily identified as thiophosphates which have a P–S single bond. The considerable differences encountered are attributable to the differences in the monoesters and diesters. Disodium inosine-5'-phosphate showed a triplet at −3.9 ppm downfield from 85% H_3PO_4, which is quite similar to that of sodium diethyl phosphate (XIII).[10)]

Experimental

Measurement of the ^{31}P NMR Spectra of Thiophosphates. The 100 MHz PMR spectra were recorded on a Varian HA-100 spectrometer by the frequency-sweep mode. The 40.5 MHz phosphorus-31 NMR spectra were also measured by the frequency-swept HA-mode, using a Varian HA-100 apparatus. A moltein P_4O_6 (supplied by Gallard-Schlesinger Co.) in a co-axial capillary held in the usual 5 mm sample tube offered a stable lock signal for the field/frequency control. A modulation frequency for the lock signal was generated by a Hewlett-Puckard 4204A audio-oscillator, and the chemical shifts from the lock signal were determined by a Hewlett-Puckard 5512A digital counter.

Paper Chromatographies of the Thio-compounds. The paper chromatographies were carried out by the ascending technique on Toyo Roshi No. 51 paper (40×40 cm), using the following solvent systems: Solv. A, *n*-propanol - concentrated ammonium hydroxide - water, 20 : 12 : 3; Solv. B, *n*-butanol - acetic acid - water, 4 : 1 : 1; Solv. C, isopropanol-saturated ammonium sulfate - water, 2 : 79 : 19. The R_f values of the thio-compounds are listed in Table 2.

TABLE 2. R_f VALUES OF THE THIO-COMPOUNDS

Compound	R_f Value		
	A	B	C
5'-Deoxy-5'-thionosine	0.43	0.38	0.30
5',5'-Bis(5'-deoxyinosyl)disulfide	0.39	0.08	0.01
5',5'-Bis(5'-deoxy-2',3'-*O*-isopropylideneinosyl)disulfide (VIII)	0.86	0.88	0.01
Inosine-5'-phosphorothionate (I)	0.30	0.02	0.54
5'-deoxy-5'-thioinosine-5'-phosphorothioate (II)	0.25	0.02	0.58
5'-acetylthio-5'-deoxy-2',3'-*O*-isopropylideneinosine (VI)	0.83	0.74	0.01
P',P^2-Bis(inosine-5'phosphoryl)-disulfide (IV)	0.32	0.02	0.29

Disodium Salt of Inosine 5'-Phosphorothionate (I). To a solution of phosphorus thiochloride (24 m*l*, 0.12 mol) in cold trimethyl phosphate (100 m*l*), inosine (10 g, 0.04 mol) was added, and then the solution was stirred for 8—9 hr at 0°C. The reaction mixture was poured into ice water, and the aqueous solution was adjusted to pH 3 with sodium hydroxide. The acidic solution was passed through a column of decolorizing resin (Resinous Adsorbent of Hokuetsu Tanso Kogyo Co.). The column was then washed well with water and eluted with a large volume of 0.5 N ammonium hydroxide. The eluate was concentrated and adjusted to pH 9—10 with concentrated ammonium hydroxide. The solution was then passed through a column of Dowex 1×2 ($HCOO^-$ form). After having been washed with water, the phosphorylated product was eluted with a large volume of 2—4 N formic acid. The eluate was evaporated to dryness *in vacuo*. Pure inosine 5'-phosphorothionate was obtained by means of cellulose (Toyo Roshi) column chromatography, which was developed in *n*-propanol-concentrated ammonium hydroxide-water (20 : 12 : 3). Ammonium salt of inosine 5'-phosphorothionate was converted to sodium salt and then recrystallized from water-methanol to give 9.5 g of the product, mp 205°C (dec.).

Found: C, 29.94; H, 3.56; N, 13.46%. Calcd for $C_{10}H_{11}N_4O_7SPNa_2$: C, 29.42; H, 2.72; N, 13.72%.

Disodium Salt of 5'-Deoxy-5'-thioinosine-5'-phosphorothioate (II). Trisodium phosphorothioate (7 g, 40 mmol) and 5'-deoxy-5'-iodoinosine (3.78 g, 10 mmol) were dissolved in water (100 m*l*), and then the solution was stirred for 7 hr at 40°C. The reaction mixture was evaporated *in vacuo* below 30°C, and the residual oil was dissolved in concentrated ammonium hydroxide (20 m*l*). After standing for 30 min, the precipitate was filtered off; the filtrate was then passed through a cellulose column (Toyo Roshi) which was developed in *n*-propanol-concentrated ammonium hydroxide-water (20 : 12 : 3). The fraction of II was evaporated to dryness *in vacuo* at 30°C, and the residue was dissolved in water. After filtration, ethanol was added to the filtrate and the resulting precipitate was recrystallized from water-ethanol to yield 3.5 g of the product, mp 208°C (dec).

Found: C, 27.22; H, 3.18; N, 12.68%. Calcd for $C_{10}H_{11}N_4O_7SPNa_2\cdot1.5\,H_2O$: C, 27.59; H, 3.24; N, 12.87%.

5'-Acetylthio-5'-deoxy-2',3'-O-isopropylideneinosine (VI). To a solution of sodium (2.9 g, 0.13 mol) in anhydrous methanol (75 m*l*), thioacetic acid (8.8 m*l*, 0.13 mol) was added with

10) Detailed accounts of the ^{31}P NMR spectra of nucleotides will be published elsewhere (M. Kainosho, A. Nakamura, and M. Tsuboi).

cooling on an ice bath; acetone (75 m*l*) and 2',3'-*O*-isopropylidene-5'-*O*-(*p*-toluenesulfonyl)inosine (V) (11.5 g, 0.025 mol) were then added. The reaction mixture was refluxed for 3 hr and evaporated to dryness at 40°C. The residue was dissolved in chloroform (150—200 m*l*), and the insoluble material was filtered off. The filtrate was evaporated to dryness, and the residue was dissolved in methanol (100 m*l*). After standing at room temperature for a few hours, the precipitate was separated and recrystallized from methanol to yield 8.5 g of the product, mp 241°C.

Found: C, 48.96; H, 4.69; N, 15.53%. Calcd for $C_{15}H_{18}N_4O_5S$: C, 49.17; H, 4.96; N, 15.29%.

5-Amino-4-methoxycarbonyl-N^5*,5'-cyclo-*1-*β*-D-*(2',3'-*O-isopropylideneribofuranosyl)imidazole (IX).* V was treated without cooling in the same manner as in the preceding paragraph. The reaction products soluble in chloroform were dissolved in a small amount of methanol and then passed through a column of alumina. The column was eluted with 5% methanolic-ether. The eluate was concentrated and ether was added to the residue to crystallize IX, mp 155°C.

Found: C, 52.37; H, 5.65; N, 13.98%. Calcd for $C_{13}H_{17}N_3O_5S$: C, 52.87; H, 5.80; N, 14.23%.

X was isolated by eluting the column with 50% methanolic ether.

*5',5'-Bis-(5'-deoxy-2',3'-*O*-isopropylideneinosyl)Disulfide (VIII).* 5'-Acetylthio-5'-deoxy-2',3'-*O*-isopropylideneinosine (VI) was dissolved in methanol, and the solution was saturated with anhydrous ammonia at 0°C. After standing overnight, the solution was concentrated and methanol was added to the residue. The resulting precipitate was recrystallized from water to give 5.5 g of the product, mp 235°C.

Found: C, 47.76; H, 5.04; N, 17.26; S, 9.89%. Calcd for $C_{26}H_{30}O_8N_8S_2$: C, 48.28; H, 4.67; N, 17.33; S, 9.92%.

The authors wish to thank Dr. Tetsuya Kato of Ajinomoto Co., Inc. for his valuable advice.

Thermal and Photolytic Decompositions of Azobis(2-phenylthio)-2-propane

Atsuyoshi OHNO, Noboru KITO, and Yutaka OHNISHI
Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received May 18, 1970)

Thermal and photolytic decompositions of azobis(2-phenylthio)-2-propane have been studied. The reaction mechanisms have been discussed on the basis of products. Almost all reactions of 2-phenylthioprop-2-yl radicals produced from the azo compound photolytically proceed with in-cage processes. The ratio, disproportionation/dimerization, predicts qualitatively that the radical center of the free radical is more electronegative than that of the corresponding oxygen analog.

In a study on the effect of a heteroatom on a radical center, we reported preliminary results on the rates of decomposition of azo compounds that have sulfur or oxygen atoms at α-positions.[1] We consider it worthwhile studying the reactions of free radicals produced from the azo compounds, since this will help to shed light on the nature of the interaction between a heteroatom and a radical center. The photolyses of azo compounds are often used as potential sources of free radicals, but their secondary reaction products have been scarcely studied.

The present study was carried out to see what information the product distribution would give on the mechanism of decomposition of azo compounds. In this paper, we wish to report thermal and photochemical reactions of 2-phenylthioprop-2-yl (**1**) and discuss the mechanism.

$$PhS\text{–}\dot{C}(CH_3)_2$$

1

Results

When a 0.25 M solution of azobis(2-phenylthio)-2-propane (**2**) in *p*-xylene was subjected to thermolysis, **2** decomposed completely over a period of 20 hr at 160°C. Products identified from the reaction mixture were 2-phenylthiopropane (**3**), 2-phenylthiopropene (**4**), 2,3-diphenylthio-2,3-dimethylbutane (**5**), diphenyl disulfide (**6**), 2-phenylthio-2-*p*-methylbenzylpropane (**7**), and 4,4′-dimethylbibenzyl (**8**) along with two minor unidentified compounds and polymeric material. On the other hand, the photolysis of the same solution in a pyrex flask at 25°C for 6 hr with the light from a 400 W high-pressure mercury lamp (principal wavelength, 3150 and 3660 Å) led to the complete decomposition of **2** and afforded 2,2-diphenylthiopropane (**9**), propylene (**10**), and 1,2-diphenylthiopropane (**11**) in addition to **3**, **4**, **5**, and polymeric material. Reaction conditions and yields are summarized in Table 1. The results of photolysis of azobis(2-benzyl)-2-propane, a methylene analog of **2**, in benzene are listed in Table 2 for comparison.

Yields were based on the free radical, two species of which had been produced from one molecule of the azo compound, and were determined by combination of vpc and NMR. As **5** and **14** could not be detected by vpc and their NMR spectra are quite similar to those of parent azo compounds, the yields of these compounds were determined by isolation from column chromatograms. For the analyses of gaseous products, mass spectroscopy and vpc were employed.

The free radical **1** can be generated by an alterna-

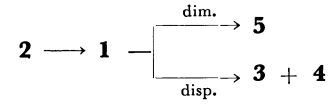
a) DTBP : **3** = 1 : 1 in mol ratio. Conversion = 11.6%
b) Qualitatively analyzed.

tive method. A mixture of **3** and di-*t*-butylperoxide (DTBP) (1 : 1 in mole ratio) was irradiated in the same way as described above, which resulted in no products expected from bimolecular reactions of **1** (except for trace of **4**) being found (see Table 3). Instead, a considerable amount of **6** and **10** with a small amount of phenyl *n*-propyl sulfide (**15**) were isolated.

Discussion

The products could be divided into several groups according to the reactions for their formation, *via*, disproportionation, dimerization and hydrogen abstraction of **1**. The former two proceed by either thermal or photolytic conditions, while hydrogen abstraction takes place only at elevated temperatures. All the reactions give important information and it will be convenient to discuss them separately.

Disproportionation and Dimerization. The presence of **3**, **4**, and **5** in the reaction mixture invokes unequivocally that both thermal and photolytic decompositions of **2** proceed with a radical mechanism.



Although yields of disproportionation products **3** and **4** are not counterbalanced, this is mainly due to their further decomposition or polymerization. As seen in Table 1, the longer the reaction time and the higher the temperature, the lower their yields, It is apparent that disproportionation is not the only route to **3** at least for thermolysis (*vide infra*). for This also seems true for photolysis, because the yields of **12** and **13** are unbalanced in spite of the fact that 100% of products have been identified. It is noteworthy that the ratio of yields, (**3**+**4**)/**5** or disproportionation/dimerization, is considerably smaller than the corresponding values with the methylene and oxygen analogs.[2] These ratios do not represent exactly the relative ratios of disproportionations and dimerizations. However, this tendecy indicates, at least qualitatively, that the electron density at the radical center decreases by a substituent at an α-position with the order $O \gg CH_2 \gtrsim S$.[3-5] This seems to imply that a canonical form **16** is more important for the oxygen analog than for the sulfur one.[1]

16

The photolytic decomposition of **2** produces almost all these compounds by "in-cage" reactions, since the reaction of **3** with DTBP does not afford them in a measurable amount. In the latter reaction, **1** is not paired by a partner and has difficulty in encountering one.

Another interesting phenomenon, seen in Table 2, is that the olefin formed by disproportionation was only **13** and no **17** was detected, contrary to expecta-

$$PhCH{=}C(CH_3)_2$$

17

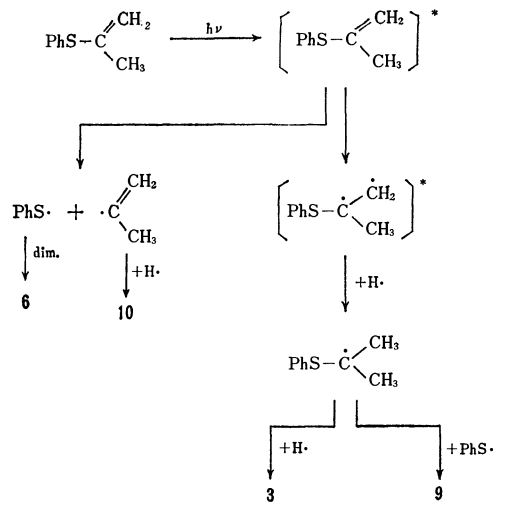
tion from the reactivities of hydrogen.[6] There are few such examples of high selectivity in radical reactions. Steric effects seem to play an important role for hydrogen abstraction.[7]

Hydrogen Abstraction from the Solvent. Since **7** and **8** are formed only at elevated temperatures, the

reaction might require a certain amount of activation energy. Taking into account the lifetime of **1**,[8] it is reasonable to attribute a "cage-wall" reaction for the formation of **7**.

Photochemical Reactions. Formation of **9** and **10** presents an interesting photochemistry. Since these compounds are not afforded by thermal reactions (runs 8 and 9 in Table 1) and since the experiment shown in run 7 in Table 1 confirms that they are not consumed by further reactions under the present thermal conditions, it is apparent that these compounds have been formed by a photochemical process.

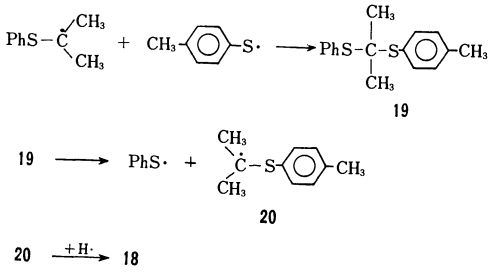
A control experiment revealed that they were formed from olefin, **4**, photochemically. The increase of the yield of **9** with prolonged irradiation (runs 1 to 3 in Table 1 and Experimental) can be attributed to this reaction. The mechanism may be as follows.



The olefin is known to undergo photocyclization yielding a benzothiophene derivative.[9] However, this mode of photodissociation has not been reported. It is interesting to note the formation of a vinyl radical.

Although **11** is formally afforded by the addition of thiophenol to **4**, there is an alternative pathway: the migration of **9** to **11**.[10,11] However, a control experiment showed that such a reaction does not take place under the present conditions both photochemically and thermally.

We claimed thermal carbene-formation from the fact that thermolysis of **2** in *p*-tolylmercaptan affords *p*-tolyl isopropyl sulfide (**18**).[1] However, we now believe that the mechanism of this reaction can be better ascribed to the addition-elimination process:



When a solution of **9** in *p*-tolylmercaptan was kept at 160°C for 20 hr, 2,2-(*p*-tolylthio)propane was isolated in good yield.

Experimental

Materials. Azobis(2-phenylthio)-2-propane (**2**) was prepared according to Benzing[12]; mp 90—90.5°C (lit, 90—90.5°C).

Azobis(2-benzyl)-2-propane was synthesized by the oxidation of 1,1-dimethyl-2-phenylethyl amine with IF_5;[13] 120 m*l* of CH_2Cl_2, 18 m*l* of pyridine, and more than 5 m*l* of IF_5 were placed in a 1*l* three-necked flask equipped with a mechanical stirrer, a dropping funnel, and a refluxing condenser, and cooled to about −10°C with a dry ice—CCl_4 bath. A solution of 1,1-dimethyl-2-phenylethyl amine (14 g)[14] in CH_2Cl_2 (10 m*l*) was then added slowly through dropping funnel. The whole mixture was stirred further for 1 hr at −10°C and 2 hr at 0°C. After excess IF_5 had been decomposed with water, the organic layer was washed with water, dilute aq-HCl, and 5% aq-$Na_2S_2O_3$, and dried over Drierite. Evaporation of the solvent under reduced pressure left a dark-brown oil, which was extracted with ether giving crystalline material. Recrystallization from methanol gave 2.5 g of the azo compound (mp 68—70°C).

Found: C, 81.70; H, 8.98; N, 9.61%. Calcd for $C_{20}H_{26}N_2$: C, 81.58; H, 8.90; N, 9.52%.

Authentic samples were prepared according to refer-

8) A. Ohno, N. Kito, and Y. Ohnishi, This Bulletin, **44**, 470 (1971). The ESR signal could not be obtained by photolysis of **2** at room temperature, though its oxygen and methylene analogs gave signals. This fact indicates that the lifetime of **1** is fairly short, which is also evidenced by the distribution of products from the reaction of **3** with DTBP.

ences.[15-19]

Photolysis. General Procedure: Unless otherwise indicated, all photolyses were carried out in pyrex tubes (15 mm o.d.) using a 400 W high-pressure mercury lamp (Riko-Kagaku Sangyo), which was placed in a water-cooled quartz immersion well.

All the solutions (0.25 M in purified *p*-xylene) were degassed under reduced pressure at 10^{-4} mmHg by the freeze-thaw method to exclude air and oxygen, and then were sealed in the usual manner. Sample tubes were placed 40 mm from the source of light.

Photolyses at elevated temperatures were performed by using a two-necked quartz tube; a sample tube was inserted from one side with the thermometer and hot air was introduced from the other. Temperatures were maintained within ±3°C.

Photolysis of **2**: Run 3 of Table 1 will be described in detail as a typical example. Photolysis of **2** (825 mg) was performed at 25°C for 40 hr. Compounds **3** and **4** were identified by retention time with those of authentic samples on vpc and by IR and NMR spectra. After elimination of excess solvent, **3**, and **4** under reduced pressure, the concentrated mixture was chromatographed on a column of silica gel (200 mesh) packed in petroleum ether. Elution of the column with a mixture of petroleum ether and benzene (90 : 10) yielded 98 mg (13%) of **5**, a trace of **6**, and an oil. Compound **5** was recrystallized from ethanol, mp 126—127°C, whose NMR spectrum had signals at (δ from TMS in CCl_4) 1.41 (s, 12H) and 7.02—7.35 (m, 10H).

Found: C, 71.27; H, 7.32; S, 21.07%. Calcd for $C_{18}H_{22}S_2$: C, 71.50; H, 7.33; S, 21.17%.

An oil was rechromatographed on a column of silica gel with petroleum ether - benzene (85 : 15) mixture as an eluent. Purified oil was identified to be **9** by comparing IR, NMR and mass spectra with those of the authentic sample as well as elemental analyses. Compound **11** was also obtained as an oil on column chromatographic separation on silica gel, IR, NMR, and mass spectra of which were identical with those of the authentic compound.

Formation of **10** was carefully examined by an independent photolysis of **2** in a breakable-sealed tube. Gas analyses on mass spectrometry and gas chromatography showed the presence of **10** in a considerable amount.

Thermolysis. General Procedure: Aliquots prepared as described above were placed in an oil bath of 160°C. Temperature was maintained within ±1°C.

Thermolysis of **2**: Run 9 of Table 1 will be described in detail as a typical example. Thermolysis of **2** (825 mg) was undertaken at 160°C for 20 hr. After the decomposition of **2** had been completed, **3**, **4**, and **6** were analyzed by VPC quantitatively. The reaction mixture was chromatographed on a column of silica gel packed in petroleum ether after the elimination of the solvent and **3** under reduced pressure. Elution of the column with a mixture of petroleum ether and benzene (90 : 10) gave white crystals and **6**. The crystals were identified to be **7** by the following evidence: NMR (δ from TMS in CCl_4) 1.15 (s, 6H), 2.28 (s, 3H), 2.76(s, 2H), 6.94(s, 4H), and 7.08—7.60 (m, 5H). Mass spectrum showed a parent peak at *m/e* 256 and a base peak at *m/e* 151 $(PhSCMe_2)^+$.

Found: C, 79.79; H, 7.87; S, 12.51%. Calcd for $C_{17}H_{20}S$: C, 79.65; H, 7.86; S, 12.48%.

Compound **8** was collected by vpc and was rechromatographed on a column of silica gel and its identity was confirmed with the authentic compound.

The presence of **10** in a mixture of thermolysis products was examined independently. There was no indication of the formation of this compound.

Thermolysis and Photolysis of **3**. Thermolysis (160°C) and photolysis (25°C) of **3** in *p*-xylene (0.25 M) were carried out in degassed tubes for 20 hr. It was found that no reaction had taken place.

Photolysis of **4**. A solution of **4** in *p*-xylene was irradiated as described above. Reaction conditions and results are summarized in Table 4.

Table 4. Products from photolysis of **4** in *p*-xylene at 25°C

Thermal and Photochemical Additions of Thiophenol to **4**. Equimolar mixtures of thiophenol and **4** in benzene (4.0 ml, 0.25 M) and in *p*-xylene (4.0 ml, 0.25 M) were subjected to photochemical (25°C) and thermal (160°C) reactions, respectively. No quantitative analysis on products was carried out. However, anti-Markownikoff addition product **11** was obtained, along with **6** and unreacted **4**, from both reactions.

Thermal and Photochemical Rearrangements of **9**. Thermolysis (160°C) and photolysis (25°C) of **9** in *p*-xylene (5.0 ml, 0.5 M) were performed in evacuated sealed tubes for 20 hr. Most of the starting material was recovered along with small amounts of **6**, **4**, and an unidentified material. It is apparent that the thermal and photochemical rearrangements from **9** to **11** did not occur. No formation of **10** took place.

Thermal Decomposition of **5**. Compound **5** (148 mg) was thermally decomposed in *p*-xylene (2.0 ml) at 160°C for 20 hr. Most of **5** was found to be recovered, but was detected the formation of 2,3-dimethylbutene-2 by vpc and mass spectrometry along with **6**.

Thermal and Photochemical Decompositions of **11**. Thermolysis (160°C, 40 hr) and photolysis (25°C, 40 hr) in *p*-xylene (5.0 ml, 0.25 M) were carried out in a degassed sealed tube. No definite change took place in both reactions. Original **11** was mostly recovered. Propylene **10** was detected by analyses of gaseous products.

The Reaction of **3** *with DTBP*. An equimolar mixture of **3** and DTBP was degassed thoroughly and sealed in a pyrex tube. Photoirradiation was carried out at 25°C for 20 hr. Product analysis was carried out as described before. Compound **12** was collected by vpc and was rechromatographed on a column of silica gel. Identity of its structure with that of the authentic compound was confirmed by

Thermal and Photolytic Decompositions of Azobis(2-phenoxy)-2-propane

Atsuyoshi OHNO, Noboru KITO, and Yutaka OHNISHI
Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received May 18, 1970)

Thermal and photolytic decompositions of azobis(2-phenoxy)-2-propane have been studied. More than half of the 2-phenoxyprop-2-yl radicals thus produced thermally cause the phenyl group to migrate from oxygen to the carbon, followed by elimination of the methyl group. Most of the remaining radicals abstract hydrogen from the solvent. When phenyl ether is employed as a solvent, homolytic aromatic substitution takes place yielding isopropylbenzene derivatives. It is shown by mechanistic consideration, although not completely decisively, that this is a new type of reaction in the sense that a part of the leaving group constitutes a part of the entering group.

In contrast to the ionic species, little has been studied on the effect of heteroatoms in free radicals. In a previous paper concerning kinetics of decompositions of azo compounds which have heteroatoms at α-positions, we reported that an α-oxygen atom exerts very minor, if any, effect on the stabilization of a carbon radical in comparison to an α-methylene group, while a sulfur atom stabilizes it extensively.[1] On the other hand, it is known from the study on ESR spectroscopy that a free radical which has an α-oxygen atom has much longer lifetime than its methylene or sulfur analog under the irradiation of light.[2] These facts indicate that the oxygen-containing radical is less reactive than others at least under the condition of photolysis. This prompted us to study the mechanism of thermal and photochemical decompositions of azobis(2-phenoxy)-2-propane (**1**) and of secondary reactions involving 2-phenoxyprop-2-yl (**2**).

$$PhO\text{–}\dot{C}(CH_3)_2$$

2

This paper deals with the analyses of final products of these reactions. The results are discussed in comparison to those obtained with sulfur and methylene analogs of **2**.[3]

Results

A 0.25 M solution of **1** in *p*-xylene was subjected to thermolysis at 160°C for 20 hr. Identified products were 2-phenoxypropane (**3**), 2-phenoxypropene (**4**), 2,3-diphenoxy-2,3-dimethylbutane (**5**), acetophenone (**6**), and methane (**7**) along with a considerable amount of *p*,*p*′-dimethylbibenzyl (**8**). Irradiation of light from a 400 W high-pressure mercury lamp to the same solution in a pyrex flask at 25°C for 6 hr (principal wavelength 3150 and 3660 Å) gave **3**, **4**, **5**, and phenol (**9**). Results are summarized in Table 1. Yields were based on the free radical **2**, two species of which had been produced from one molecule of the azo compound, and were determined by using vpc and NMR except for **5**. Since **5** has identical NMR signals to those of **1** and it decomposes in a column of vpc, the yield of this compound was obtained by isolation from a column chromatogram.

Irradiation of light to a mixture of **3** and di-*t*-butylperoxide (DTBP) also affords the same free radical, **2**. Products obtained were **4**, **5**, **9**, and a mixture of

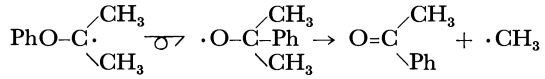
Discussion

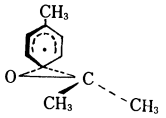
In view of the product distribution, marked difference can be seen between thermal and photolytic decompositions of **1**. Acetophenone is formed as a main product of thermolysis, while it is absolutely absent in the photolysis mixture. On the other hand, phenol is produced only by photolysis. Furthermore, as seen in the reaction of **3** with DTBP, homolytic aromatic substitution takes place when a reasonable amount of phenyl ether is present, which is not the case with phenyl sulfides or with aromatic hydrocarbons. These and other observations will be discussed respectively under separate titles.

Migration. The presence of acetophenone and methane suggests clearly that the reaction takes place



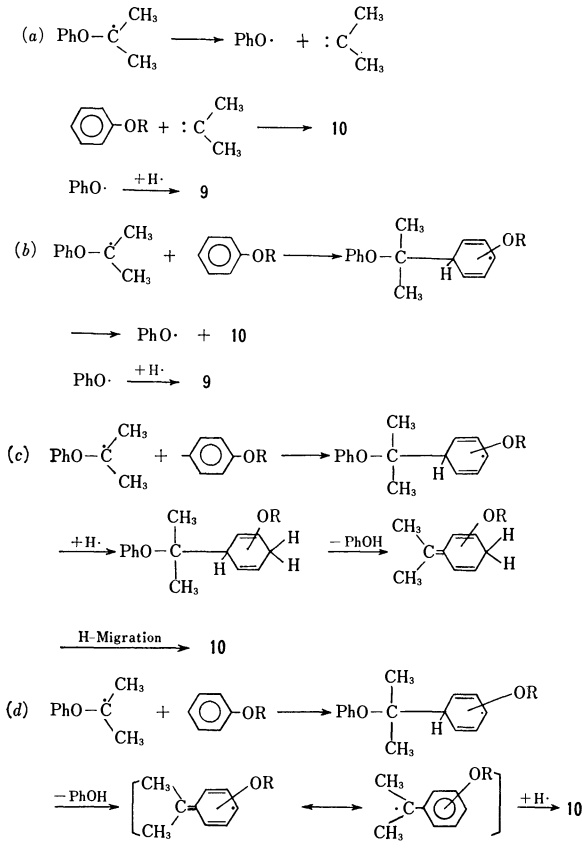
in the solution. Although this type of rearrangement is known in gas phase,[5-7] this is the first example of migration in a solution. The second step of the reaction takes place easily in solution and has been studied both kinetically[8-10] and spectroscopically.[11] Activation energy is estimated to be about 8 kcal/mol.[8] Cumyloxy radicals generated by the photolysis of dicumyl peroxide in benzene have too short a life for ESR detection at a room temperature.[11] However, 2-phenoxyprop-2-yl radicals generated by the photolysis of **1** in *p*-xylene have enough lifetime for detection after the irradiation of light has been stopped.[2] From the results, migration seems to require activation energy of more than 8 kcal/mol.

The fact that the same reaction with **11** affords *p*-methylacetophenone solely, seems to suggest that migration proceeds through a transition state expressed by **13**.



13

Homolytic Aromatic Substitution. When a mixture of **3** and DTBP is irradiated with light, a large amount of **9** and **10** is formed at the sacrifice of **4**.[12] The aromatic substitution of the same type also takes place when **1**, **11**, and **12** are decomposed in **3**. Several mechanisms are possible for this substitution:



4) R. Pummerer, H. Puttfarcken, and P. Scopflocker, *Ber.*, **58**, 1811 (1925).

where R stands for an isopropyl group and many other canonical forms are neglected for simplicity.

Mechanism *a* is highly implausible, since almost exclusive formation of the *o*-isomer cannot be explained by this mechanism.[13] In addition, there is no indication of carbene-formation during the reaction.[14] On the other hand, the predominancy of *o*-attack is well established in free-radical aromatic substitution.[15]

Although mechanism *b* seems reasonable, it involves free-radical 1,2-hydrogen shift. Despite much effort to find such a type of migration, nothing has been achieved.[16] This reduces the possibility of this mechanism greatly. Furthermore, it is important to consider the formation of phenol. If a phenoxy radical is a precursor of a phenol, we might expect coupling products at least in a detectable amount. However, no such compound was found. This implies that phenol results not from phenoxy radicals but from something which can eliminate it directly. Thus, mechanisms *c* and *d* remain as plausible pathways.

The difference between these mechanisms lies on the timing of hydrogen abstraction. The former mechanism involves abstraction of a hydrogen by a cyclohexadienyl radical before a phenol departs from it. This type of reaction is well known.[17-20] On the other hand, the latter mechanism consists of the elimination of a phenol followed by hydrogen abstraction at a benzyl position. Although it is impossible to decide which mechanism is correct without further information, we believe that mechanism *d* is more plausible than the others. In mechanism *d*, the driving force for the elimination of phenol could be attributed to the aromatization of a cyclohexadienyl radical. No such energy gain can be found in the step of phenol elimination in mechanism *c*.

It is noteworthy that this type of substitution is greatly reduced when **2** has a substituent at the *p*-position (Table 3) and that no reaction takes place when phenyl isopropyl sulfide is employed as a solvent. These facts suggest considerable contribution of electronic effect(s) for this reaction.[21] Even though mechanism *d* is plausible, some variations must be considered in this mechanism to elucidate giving *o*-isomer predominantly.

It should be noted anyhow that the reaction is of a new type of homolytic aromatic substitution in the sense that the entering group itself keeps a part of the leaving group.

Hydrogen Abstraction from the Solvent. The result of run 5 in Table 1 shows that about 40% of **2** thermally produced abstracts hydrogen from the solvent. At lower temperatures, discrepancies of yields of **3** and **4** are much smaller or almost comparable indicating disproportionation is much more important than hydrogen abstraction from the solvent. The corresponding value for the sulfur analog of **2** is at most 15%.[3] Uneyama and co-workers have reported that the relative reactivity of thioanisole and anisole toward hydrogen abstraction by *t*-butoxy radicals is only 1.5 : 1.0.[22] Although the present result is far from quantitative and cannot be compared to kinetic data precisely, longer life of **2** than its sulfur analog seems to play an important role for such a great facility of **2** in hydrogen abstraction. Thus, **2** has many chances to escape from a solvent-cage or from its counterpart and to react with the solvent in "out-of-cage" process. Since the sulfur analog of **2** is short-lived, the only chance for it to react with the solvent is a process of "cage-wall" reaction. According to this scheme, it is understandable why the sulfur analog of **2** affords 2-phenylthio-2-*p*-methylbenzylpropane and **2** does not afford the corresponding oxygen compound: when a *p*-methylbenzyl radical is formed at "cage-wall", as being the case of the sulfur compound, it is easily captured by a radical in "cage", while a *p*-methylbenzyl radical produced at out of "cage" has little chance to find such a counterpart.

Experimental

Materials. Azobis(2-phenoxy)-2-propane (**1**) was prepared after Benzing[23] from the corresponding chloride and phenol. For this reaction, however, ethanol was not a useful solvent and *N,N'*-dimethylformamide was employed (yield, 40%): mp 91—92°C.

Found: C, 72.80; H, 7.40; N, 9.43%. Calcd for $C_{18}H_{22}N_2O_2$: C, 72.45; H, 7.43; N, 9.39%.

Azobis(2-*p*-tolyloxy)-2-propane (**11**) was also prepared with 25% yield as described above: mp 76—78°C.

Found: C, 73.42; H, 8.11; N, 8.73%. Calcd for $C_{20}H_{26}N_2O_2$: C, 73.59; H, 8.03; N, 8.58%.

Azobis(2-*p*-chlorophenoxy)-2-propane (**12**) was prepared with the same procedure: mp 95—96°C.

Found: C, 58.88; H, 5.51; N, 7.82; Cl, 19.31%. Calcd or $C_{18}H_{20}Cl_2N_2O_2$: C, 58.87; H, 5.49; N, 7.63; Cl, 19.31%.

Photolysis and Thermolysis of Azo Compounds. A general procedure has been described previously.[3] All products except for **4** were identified by comparing their IR, NMR, and mass spectra and retention times of vpc with corresponding authentic compounds. Compound **4** was isolated from a column chromatogram of silica gel (200 mesh) and its structure was confirmed by the following data: mp 103—103.5°C. NMR (δ from TMS in CCl_4) 1.42 (s).

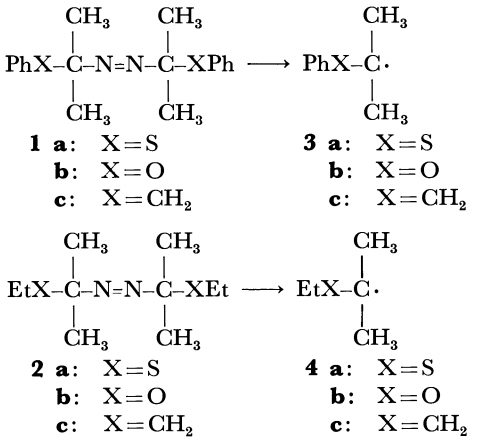
Studies on Electron Spin Resonance Spectra of 2-Substituted Prop-2-yl Radicals

Atsuyoshi Ohno, Noboru Kito, and Yutaka Ohnishi
Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received May 18, 1970)

Electron spin resonance spectra of 2-substituted prop-2-yl radicals have been obtained. The substituents reported herein are phenylthio, phonoxy, benzyl, ethylthio, ethoxy, and *n*-propyl groups. Spectra were not obtained for phenylthio- and ethoxy-substituted radicals. It has been elucidated that α-heteroatoms greatly delocalize the odd electron. The mechanism of heteroatom-participation is discussed. Time dependency of intensities of signals in ESR spectra has revealed a qualitative order of the lifetime of these free radicals.

Kinetic studies on decompositions of 2-substituted azobis-2-propane (**1** and **2**) have revealed that the stability of a free radical increases in the order $CH_2 \leq O < S$, and the results have been discussed in view of the effect of heteroatoms on the radical center.[1] The argument was based on enthalpies of activation of decompositions. Thus, in order to elucidate the absolute order of stabilities of these free radicals, we must know the quantitative order of ground-state stabilities of azo compounds. This involves difficulties, since we need data on heats of formations of solutions.



Another problem exists in the assumption that activation parameters of decompositions of azo compounds exemplify the effect of stabilities of free radicals being produced.[2]

It is well known that hyperfine splitting constants (a_H^i) in ESR spectra of free radicals are well correlated to spin densities of the unpaired π-electrons (ρ_c^i) on carbon atoms by means of McConnell's equation[3]

$$a_H^i = Q\rho_c^i \quad (1)$$

where Q is almost constant for similar radicals. Since the degree of delocalizations of π-electrons is a very important measure of stabilities of free radicals, a_H^i would present valuable information.

This paper deals with a discussion on the effect of heteroatoms on a carbon-radical center from the viewpoint of ESR spectroscopy. Qualitative discussion is given on lifetimes (or more precisely, reactivities) of free radicals under a certain condition.

Results

A 0.25 M solution of an azo compound in benzene was irradiated with light from a 100 W high-pressure mercury lamp (principal wavelength 3150 and 3660 Å) at room temperature in a cavity of ESR spectrometer. This technique is essentially suitable for generating free radicals. It produces free radicals in high concentration which makes it possible to detect them at elevated temperatures and free radicals of unequivocal and desired structure can be generated, which is an advantage over the technique of hydrogen abstraction. As an example, free radical **3c** cannot be generated predominantly by hydrogen abstraction reaction, because a benzylic hydrogen is more reactive than (or at least comparable to) the tertiary hydrogen.

The ESR spectrum of 2-phenoxyprop-2-yl (**3b**) was obtained with a good signal-to-noise ratio (Fig. 1) and showed a septet of intensity ratios 1 : 6 : 15 : 20 : 15 : 6 : 1. Other spectra so far obtained had signals attributable to structures **3** and **4**. However, none of them showed splittings due to aromatic protons or ethyl protons.[4]

2) W. Pryor, "Free Radicals," McGraw-Hill Book Co., New York, N. Y. (1966), p. 128.
3) H. M. McConnell and D. B. Chesnut, *J. Chem. Phys.*, **28**, 107 (1958).
4) Similar results have been reported: J. K. Kochi and P. J. Krusic, *J. Amer. Chem. Soc.*, **91**, 3940 (1969).

No signal from **3a** was obtained when a solution of **1a** was subjected to measurement. Neither a change of solvent nor the lowering of temperature ($\geqslant -100°C$) could achieve the detection of signals. This suggests that the fade of **3a** is much faster than that of **3b** under the condition. Similarly, we could not obtain signals from a solution of **2b** at room temperature, but ethyl radical was detected at $-196°C$.[5,6] The results are summarized in Table 1.

It has been demonstrated that a free radical **3b** is fairly long-lived. As seen in Fig. 2, the most intense signal from this radical remains detectable after the irradiation with light has stopped. Signals from **3c** and **4c** are detectable only during irradiation. In contrast, the intensities of signals from **4a** decreases in prolonged irradiation, indicating rapid fade of this radical (Fig. 3).

Table 1. Hyperfine splitting constants and *g*-values of 2-substituted prop-2-yl radicals

Radical	a, G		*g*-Value	No. of Signals	
	CH_3	CH_2		Found	Theoret.

Discussion

As seen in Table 1, there exists a good agreement between hyperfine splitting constants and g-values for **3c**, **4c**, and t-butyl radical (22.7 gauss)[7] as well as for **3b** and 2-hydroxyprop-2-yl radical (20.0 gauss).[8] This enables us to compare the effect of heteroatoms on radical centers by using hyperfine splitting constants due to β-hydrogens in the absence of data on **3a** and **4b**. However, this situation does not hold, at least with an α-hydrogens (Table 2).

Table 2. Hyperfine splitting constants of substituted methyl radicals

Radical	a_α, G	Ref.
$PhS\dot{C}H_2$	16.5	10
$PhO\dot{C}H_2$	17.7	10
$PhCH_2\dot{C}H_2$	22.0	4
$HS\dot{C}H_2$	19	9
$HO\dot{C}H_2$	17.2	8
$HCH_2\dot{C}H_2$	22.4	7

It has been also established that, as far as hyperfine splitting constants due to β-hydrogen are concerned, the value of Q in Eq. (1) is not affected by α-substituents.[11] Thus, we can use hyperfine splitting constants directly as a measure of spin delocalization, which increases in the order $S \gtrsim O > CH_2$ with the present series of free radicals. The corresponding g-values also support this order.[11,12]

The fact that, despite the large difference in spin-orbit coupling constants ($\zeta_s = -382$ cm^{-1}, $\zeta_o = -152$ cm^{-1}),[13] g-values of **3b** and **4a** do not differ a great deal suggests larger σ-character for the orbital containing an odd electron in **4a** than that in **3b**.[14] An alternative interpretation is, of course, possible: Smaller delocalization of an odd electron in **4a** than that in **3b**. However, the latter cannot explain results of kinetics[1] and others.[15]

It is interesting to compare the order of stabilities of radicals from the viewpoint of spin delocalization ($S > O \gtrsim CH_2$) with that obtained from activation parameters of decomposition of parent azo compounds ($S \gtrsim O > CH_2$). Although qualitative orders are the same for both cases, semi-quantitative orders are somewhat different with respect to positions of the oxygen-containing radical. We believe that this is attributable to larger electronegativity of oxygen than that of sulfur and methylene group. If the resonance effects of oxygen and sulfur were the same, the spin density on the carbon atom is expected to be smaller in the oxygen-containing radical than in its sulfur analog, because a larger inductive effect of oxygen than sulfur reduces more spin density on the former through a

σ-bond.[14] This in turn, predicts larger resonance effect for sulfur than for oxygen from the fact that these radicals have nearly equal hyperfine splitting constants. Since free radicals generated here are essentially neutral, the inductive effect of a heteroatom does not change significantly, from the starting azo compounds to the transition states of the decompositions. Thus, activation parameters hardly reflect inductive effects of heteroatoms. It has been reported that the substituent effect in decompositions of substituted azobiscumenes is correlated to the Hammett relationship with σ_R.[16] Consequently, kinetic order represents stabilization by resonance participation, while spectral order that by net electronic effect. The larger σ-character of the sulfur-containing radical than its oxygen analog does not contradict this conclusion, since potential *d-sp*^{3} overlapping is suggested for sulfur-carbon π-bonding.[17-19]

In addition, the time-dependency of signal intensities predicts qualitative order of life-times of free radical as

$$\mathbf{3b} > \mathbf{3c} \approx \mathbf{4c} > \mathbf{4a} (> \mathbf{3a})$$

Thus, we have found that reactivities of these radicals under photolytic conditions are quite different from their thermodynamic stabilities.

Experimental

Materials. Compounds **1a**, **1b**, **1c**, and **2a** were prepared as described previously.[15,20,21]

Azobis(2-ethoxy)-2-propane (**2b**): Into a 300 m*l* round-bottomed flask equipped with a condenser and a stirrer were placed 150 m*l* of anhydrous ethanol and 5.1 g (0.22 g-atom) of sodium metal. Azobis(2-chloro)-2-propane (18.2 g, 0.1 mol) was added slowly to sodium ethoxide at the temperature of ice-water. Exothermic reaction occurred gradually in 2 hr, and the reaction mixture then turned to milky white. The mixture was stirred for additional 2 hr to complete the reaction. Excess ethanol was evaporated under reduced pressure. After filtration, the filtrate was poured into ice-water, and organic material was then extracted with ether. Careful distillation under reduced pressure yielded 2.5 g (11% yield) of pure **2b**, bp 70.5—71.0°C/12 mmHg.

Found: C, 59.06; H, 10.73; N, 15.72%. Calcd for $C_{10}H_{22}N_2O_2$: C, 59.37; H, 10.96; N, 15.82%.

Azobis(2-propyl)-2-propane (**2c**): 2-Methylpentylamine (bp 100—104°C) was prepared from the corresponding alcohol according to Ritter and Kalish.[22] Sulfuryl chloride (13 g) in 10 m*l* of dry *n*-hexane was added dropwise to the amine (21 g) in *n*-hexane at the temperature of ice-water. After the addition had been completed, the organic layer was washed with water several times and dried over Drierite. Resulting crude sulfone amine (7.0 g) was used for the foregoing reaction without further purification. A mixture of the sulfone amine (7.0 g) in 50 m*l* of *n*-hexane and 150 m*l* of sodium hypochlorite (10% efficiency) was continuously stirred for 35 hr at room temperature. The organic layer was washed with water and dried over Drierite. Distillation under reduced pressure yielded 2 g (38% yield) of **2c**, bp 76—80°C/15 mmHg.

Found: C, 72.45; H, 13.40%. Calcd for $C_{12}H_{26}N_2$: C, 72.66; H, 13.21%.

Spectrometry. A 0.25 M solution of an azo compound in benzene was placed in 5 mm-o.d. quartz tube, which was thoroughly degassed by the thawing and freezing method. The sample tube was then sealed. The light from a 100 W high-pressure mercury lamp was focused on the sample in the cavity of the ESR spectrometer.

ESR spectra of generated radicals were measured at room temperature with a X-band, JES-3BX type spectrometer (Japan Electron Optics Laboratory Co., Ltd.) with 100 KHz field modulation. Magnetic-field-calibration markers were placed directly on the recorded spectrum by noting the occurrence of the proton resonance at a particular oscillator frequency which was then measured with a Hewlett-Packard frequency counter, Model 5245L.

2-Phenylthioprop-2-yl (**3a**): No signal was detected when a solution of **1a** in benzene, toluene, tetrahydrofuran or acetonitrile was subjected to measurement at various temperatures ($\geqslant -100$°C). An unidentified broad signal was observed at −196°C only when 2-methyltetrahydrofuran was used as a solvent. The signal is due to neither a benzenethiyl radical, nor a radical from the solvent, since the obtained *g*-value was 2.0026.

2-Phenoxyprop-2-yl (**3b**): After a few minutes irradiation with light, signals appeared on the first run of the spectrum. Signal intensities increased with prolonged irradiation period and a well-resolved spectrum was obtained within 2 hr. The spectrum showed a septet of relative intensity ratios 1.4 : 5.9 : 15.5 : 20.0 : 15.7 : 5.8 : 1.2, which were in good agreement with thoeretical values. The most intense signal from the radical remained detectable even after irradiation with light had been stopped. This kind of observation was obtained exclusively when 2-phenoxyprop-2-yl was applied in these studies.

2-Benzylprop-2-yl (**3c**): A spectrum resulting from the irradiation for 2 hr consisted of 17 lines of relative intensity ratios from the center of the spectrum to the wing; 20 : 9.3 : 9.7 : 14.3 : 3.6 : 7.5 : 5.7 :— : 3.6 : 1.8 : —. No resolvable hyperfine interaction was observed with the aromatic hydrogens in **3b** and **3c** with a modulation of 1 gauss.

2-Ethylthioprop-2-yl (**4a**): A spectrum obtained by irradiation for 2 hr exhibited a septet of relative intensity ratios close to the theoretical ones. Signal intensities decreased with a prolonged irradiation period. Splittings due to ethyl protons were not detected in the radical with a modulation of 0.5—1.0 gauss.

2-Ethoxyprop-2-yl (**4b**): When a solution of **2b** in *n*-pentane or isopentane was subjected to measurement, no signal was investigated at temperatures above −80°C. A well-resolved spectrum consisting of 12 lines (triplets of quartets) was obtained at −196°C, which was attributable to ethyl radical rather than **4b**. Observed hyperfine coupling constants ($a_\alpha = 22.4$ and $a_\beta = 26.7$) and *g*-value (2.0026) were in good agreement with those of previous studies.[4,7]

2-Methylpent-2-yl (**4c**): A similar type of spectrum with **3c** was obtained when **2c** was irradiated with light in benzene. No resolvable hyperfine interaction with 7-hydrogens was observed with a modulation of 0.5 gauss.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 474—477 (1971)

The Reaction of α-Oxo Acids with *N*-Phenyltriphenylphosphinimine[1)]

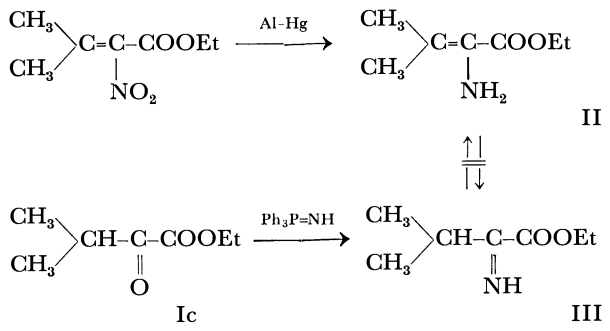
Chung-gi SHIN,* Hiroaki ANDO, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 25, 1970)

The reaction between ethyl α-oxocarboxylate and *N*-phenyltriphenylphosphinimine gave a mixture of ethyl α-phenyliminocarboxylate (IVa—f) and the tautomeric isomers (Va—f) in good yield. IVa and Va derived from ethyl pyruvate was converted gradually into 3-anilino-5-ethoxycarbonyl-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (VIIa) on standing at room temperature. The free acid of IVa and Va prepared by the same method could not be purified, but a small amount of 3-anilino-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (IX) was obtained from the reaction mixtures. In the reaction of aniline and pyruvic acid, α,γ-dianilino-γ-carboxy-α-methyl-γ-butyrolactone (XII) was obtained in the neutral reaction condition and 4-anilino-2-phenyliminopentanoic acid (XIV) in basic condition. The structure of the products was proved by NMR and IR spectrum, and the reaction courses were discussed.

In the previous paper, one of the authors reported the isolation of a primary enamine (ethyl α-amino-β-methylcrotonate (II)) by the reduction of the corresponding α,β-unsaturated α-nitrocarboxylic ester, and the tautomeric imine (ethyl 2-imino-3-methylbutanoate (III)) by the reaction of the corresponding α-oxocarboxylic ester (Ic) with triphenylphosphinimine (Scheme 1). The acylation of both II and III yielded the same enamine derivative,[2-4)] and the isomerization between II and III was not reached.



Scheme 1

On the other hand, Wieland *et al.*[5)] have reported that a treatment of pyruvic acid (Ia′) with aniline[6,7)] did not yield any amount of α-phenyliminopropionic acid (IVa′). However, it was expected from our previous result that the reaction of *N*-phenyltriphenylphosphinimine with α-oxocarboxylic acids would give the homologue of IVa′ and/or the tautomeric isomers.

In the present paper, the reactions of α-oxocarboxylic acid (Ia′) or α-oxocarboxylic esters (Ia—f) with *N*-phenyltriphenylphosphinimine or aniline were described.

Results and Discussion

Ethyl pyruvate (Ia) was treated with *N*-phenyltriphenylphosphinimine[8)] in anhydrous acetonitrile under reflux. Triphenylphosphine oxide precipitated quantitatively was removed by filtration and the filtrate was distilled under the reduced pressure to afford pale yellow oil in a 66% yield, which was a mixture of the corresponding imine (IVa) and enamine (Va) (Scheme 2). The infrared spectrum of the mixture of IVa and Va showed absorption bands at 3350 (NH), 1730—1720 (two COOEt), 1650 (C=N) and 1590 (C=C) cm^{-1}, while the NMR spectrum showed peaks at τ2.55—3.40 (m, two C_6H_5 and vinyl protons, *ca.* 10.9H), 5.62 (two q, $-CH_2-$, 4H), 7.58 (s, NH in Va, *ca.* 0.3H), 7.92 (s, $-\overset{\|}{C}-CH_3$ in IVa, *ca.* 2.2H), and 8.62 (two t, $-CH_3$ in IVa and Va, 6H). From the intensity of $-\overset{\|}{C}-CH_3$ proton signal of IVa and $-\overset{|}{C}=CH_2$ proton signal of Va, the yield was determined to be 47.4 and 18.6%, respectively. α-Oxocarboxylic esters (Ib—f), on being treated with *N*-phenyltriphenylphosphinimine, afforded similarly the corresponding mixtures (IVb—f and Vb—f). In other cases, these

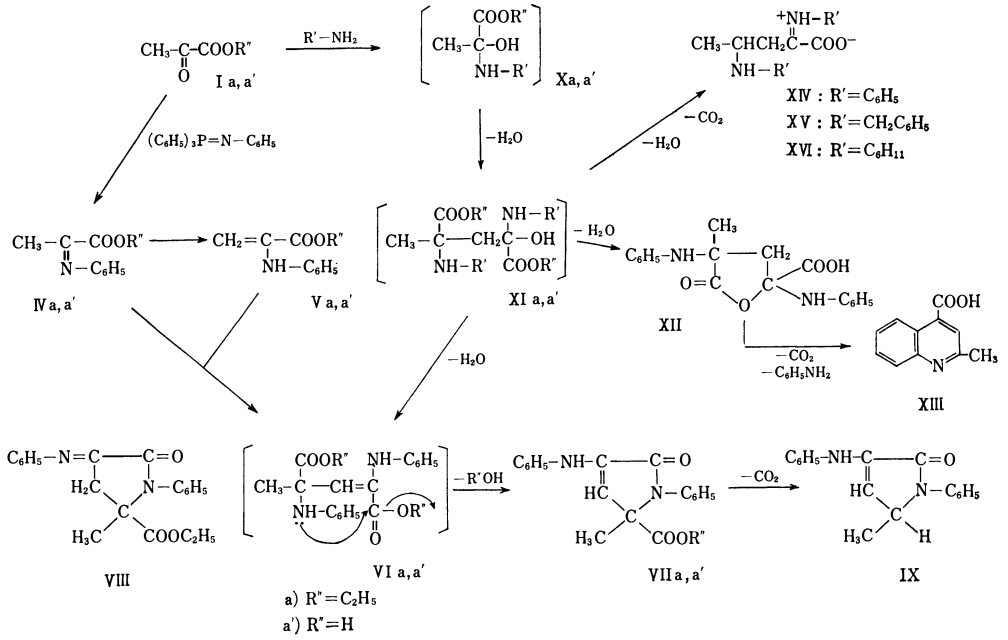
Scheme 2

ratios were evaluated from that of methylene and vinyl protons in the β-position of IV and V. The yields and some spectral data of the mixtures are summarized in Tables 1, 2 and 3.

On standing for a week at room temperature, the mixture (IVa and Va) became viscous and colored gradually, and then a part of the oil crystallized. This crystalline compound (VIIa) was identified as the same product obtained from Ia and aniline, and assigned as 5-ethoxycarbonyl-5-methyl-3-phenylimino-2-pyrrolidinone (VIII) by Simon.[9] However, VIIa showed the peaks at τ2.55—3.09 (m, tow C_6H_5 and NH, 11H), 4.03 (s, vinyl proton, 1H), 5.85 (q, $C\underline{H}_2$-CH_3, 2H), 8.36 (s, CH_3, 3H) and 8.80 (t, $CH_2C\underline{H}_3$), while the infrared spectrum showed the absorption bands of NH at 3270, of ester at 1720, of carbonyl at



Scheme 3.

1680, and of carbon-carbon double bond at 1640 cm^{-1}. The presence of one vinyl proton, and NH and C=C absorption in the above data indicates that VIIa is 3-anilino-5-ethoxycarbonyl-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one, the enamine form of VIII. In order to explore the intermediate step for the formation of VIIa, the conversion of viscous and colored oil into VIIa was followed spectrometrically. The appearance of two NH (τ6.15, s) and new vinyl proton signal (τ5.15, s) indicates that the reaction of IVa and Va proceeds through the formation of ethyl 2,4-dianilino-4-ethoxycarbonyl-2-pentenoate (VIa).

Simon has reported the treatment of Ia′ with aniline in ether gave a small amount of 4-anilino-2-phenyliminopentanoic acid (XIV) and α,γ-dianilino-γ-carboxy-α-methyl-γ-butyrolactone (XII),[9] which was converted into 4-carboxy-2-methylquinoline (XIII).[6] This reaction was reinvestigated in detail under various condition. The treatment of Ia′ with amines (aniline, benzylamine and cyclohexylamine) in the presence of triethylamine gave 4-(substituted-amino)-2-(substituted-imino)pentanoic acids (XIV—XVI), while in the absence of triethylamine the treatment of Ia′ with aniline afforded XII, which was qantitatively converted into XIII by heating in water, accompanying with the liberation of CO_2 and aniline. It was assumed that an intermediate (XIa′) formed *via* α-hydroxy-α-alkylaminopropionic acid (Xa′) was subjected to decarboxylation, β-elimination and isomerization in a basic media to give XIV—XVI, but in neutral condition XIa′ yielded XII by intramolecular dehydration. The infrared spectrum of XIV—XVI showed the absorption bands of NH (3250—3273), carbon-nitrogen double bond (1620—1625) and carboxylate group ($-COO^-$) (1520—1540 cm^{-1}), and the structures of XIV—XVI were assigned on the basis of these spectral data.

In order to obtain IVa′ and Va′, the mixture of IVa and Va was hydrolysed with 10% potassium hydroxide at room temperature, but pyruvic acid (Ia′) was obtained. Ia′ was treated with *N*-phenyltriphenylphosphinimine to give a viscous syrup (IVa′ and Va′) in a good yield and triphenylphosphine oxide in almost quantitative yield. Attempts to purify the resultant syrup were unsuccessful. The crude syrup was esterified, which, on being allowed to stand for few weeks at room temperature, gave a small amount of VIIa. This fact indicates that IVa′ and Va′ are certainly formed by reaction of Ia′ with *N*-phenyltriphenylphosphinimine. Moreover, the above assumption was supported by the fact that 3-anilino-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (IX) is gradually precipitated from the mixture of IVa′ and Va′ in 50% ethanol on standing for 2 days at room temperature.

Experimental

All boiling and melting points are uncorrected. The IR spectrum was recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectrum was measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 MHz.

Materials. *N*-Phenyltriphenylphosphinimine was prepared by the reaction of triphenylphosphine dibromide with aniline in the presence of triethylamine by the method reported.[10] Mp 126—128°C (lit, mp 128—130°C). The acetonitrile used was distilled from phosphorous pentoxide and dried over calcium hydride.

Reaction of Ethyl α-Oxocarboxylate with N-Phenyltriphenylphosphinimine. To a solution of ethyl α-oxocarboxylate (0.02 mol) in anhydrous acetonitrile (30 m*l*), *N*-phenyltriphenylphosphinimine (0.02 mol) was added and then the mixture was refluxed for 1 hr. On concentrating the resulting solution, a brown syrup remained, to which dry ether (30 m*l*)

was added, and then triphenylphosphine oxide precipitated was filtered off. The ethereal solution was concentrated to one third of its volume and then allowed to stand overnight in a refrigerator. The further triphenylphosphine oxide precipitated was filtered off. After concentrating the ethereal solution, dry petroleum ether (20 m*l*) was added to the residual syrup and the small amount of triphenylphosphine oxide was filtered off, and then finally the solvent was removed by evaporation. Distillation of the resulting syrup afforded a pale yellow oil. The results are summarized in Tables 1, 2 and 3.

Confirmation of Ethyl 2,4-Dianilino-4-ethoxycarbonyl-2-pentenoate (VIa) as Intermediate. When the mixture of IVa and Va, or the reaction mixture of ethyl pyruvate (Ia) with aniline, was allowed to stand for few days at room temperature, the oil became colored and viscous gradually. This syrup was subjected to the measurements of IR abosrption in NaCl and of NMR absorption in $CDCl_3$ using tetramethylsilane as an internal standard. The results are described in the former section.

3-Anilino-5-ethoxycarbonyl-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (VIIa). A) From Mixture of IVa and Va: When the above intermediate (VIa, 1 g) was allowed to stand for several days, the viscous syrup crystallized gradually. To the resulting product, a small quantity of dry ether was added, and then crystals precipitated were collected on a filter. Recrystallization from ethanol gave colorless prisms (0.5 g, 32%), mp 146—147°C.

Found: C, 71.62; H, 6.28; N, 8.29%. Calcd for $C_{20}H_{20}N_2O_3$: C, 71.41; H, 5.99; N, 8.33%.

B) From Ia and Aniline: A mixture of Ia (1.16 g) and aniline (0.93 g) was allowed to stand at room temperature for 3 days, during which water separated gradually in the reaction mixture, and crystalline product was obtained from the dark brown syrup. Recrystallization from petroleum ether (bp 70—120°C) gave colorless prismatic needles (0.62 g, 37%), mp 144—146°C. The melting point of this compound was not depressed on admixture with the compound obtained from procedure *A*.

Reaction of Pyruvic Acid and Amines (Aniline, Benzylamine, and Cyclohexylamine) in the Presence of Triethylamine. To a solution of pyruvic acid (0.025 mol) in dry ether (25 m*l*) with the presence of triethylamine (0.025 mol), amine (0.025 mol) was added drop by drop with stirring below 5°C. After standing for 2 hr in a refrigerator, the reaction mixture was kept overnight at room temperature. A red syrup in the bottom crystallized upon addition of water. Recrystallization from methanol or ethanol afforded colorless needles. results are summarized in Table 4.

Reaction of Pyruvic Acid and N-Phenyltriphenylphosphinimine. A) Esterification of the Reaction Product: To a solution of pyruvic acid (1.1 g) in dry acetonitrile (40 m*l*), *N*-phenyltriphenylphosphinimine (4.5 g) was added and then the mixture was refluxed for 1 hr. Triphenylphosphine oxide was removed out of the reaction mixture by the similar way to that for the reaction of ethyl α-oxocarboxylate. Thus obtained syrup was dissolved in ethanol (50 m*l*) and heated under reflux for 3 hr in the presence of *p*-toluenesulfonic acid (0.5 g) and concentrated sulfuric acid (0.5 m*l*). The solution was concentrated under a reduced pressure to give residual oil, which was extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate and then the solvent was evaporated. This oil, without further purification, was allowed to stand for few weeks at room temperature to yield a small amount of crystals. This compound was the same as VIIa. Yield 0.08 g.

B) 3-Anilino-5-methyl-1-phenyl-Δ^3-pyrrolin-2-one (IX). In the above procedure *A*), the final syrup (4.8 g) after removal of triphenylphosphine oxide was diluted with 50% ethanol (50 m*l*). On standing for 2 days at room temperature, crystals precipitated. Recrystallization from ethanol gave pale yellow needles (1.1 g), mp 175—178°C. IR (KBr): 3350 (νNH), 1680 (νC=O) and 1660 (νC=C) cm^{-1}. NMR ($CDCl_3$): 3.44 (broad s, NH, 1H), 3.95 (d, vinyl proton, 1H), 5.74 (double q, methine proton, 1H), and 8.74 (d, methyl protons, 3H)τ.

Found: C, 77.23; H, 6.27; N, 10.43%. Calcd for $C_{17}H_{16}N_2O$: C, 77.25; H, 6.10; N, 10.60%.

Studies on Seven-Membered Heterocyclic Compounds Containing Nitrogen. XI. The Schmidt Reaction of 1-Benzyl-1-azacycloheptan-4-one, Menthone, and 2-Methyl-4,5,6,7-tetrahydrobenzo[*b*]thiazol-7-one[1]

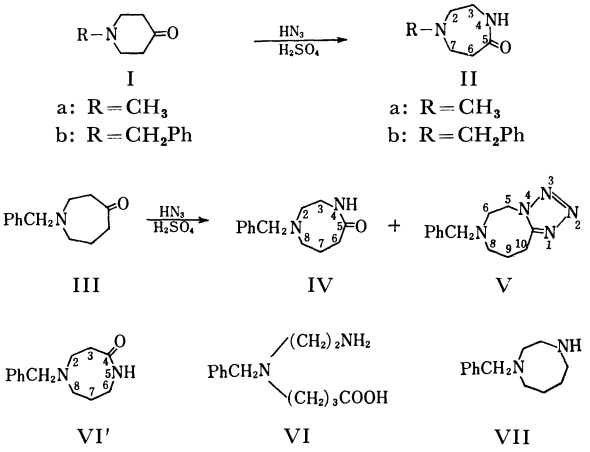
Yoshifumi SAKAKIDA,[2] Anthonius Sina KUMANIRENG,[3] Heizan KAWAMOTO, and Akira YOKOO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received June 17, 1970)

The Schmidt reaction of 1-benzyl-1-azacycloheptan-4-one afforded a mixture of 1-benzyl-1,4-diazacyclooctan-5-one (IV) and a tetrazole derivative (V). The treatment of menthone (VIII) was found to give a lactam (IX), plus a tetrazole derivative (X) as a minor product. 2-Methyl-4,5,6,7-tetrahydrobenzo[*b*]thiazol-7-one (XII) was subjected to the Schmidt reaction to give a lactam XIIIa; it did not afford a tetrazole derivative. The structures of these products were determined on the evidence of the NMR spectra.

As a part of our investigation of the syntheses and reactions of seven-membered nitrogen heterocycles leading to azepine compounds, we studied the Schmidt reaction of the compounds named in the title. Dickermann and his co-workers[4] have reported that the Schmidt reaction of 1-methyl- and 1-benzylpiperid-4-one (Ia and b) gave the corresponding 1,4-diazacycloheptan-5-ones (IIa and b respectively) in reasonable yields.



Scheme 1

The treatment of 1-benzyl-1-azacycloheptan-4-one[5] (III) was found to give a mixture of 1-benzyl-1,4-diazacyclooctan-5-one (IV) and a tetrazole derivative (V) on the evidence of the NMR spectra. The main product, IV, gave a single spot on a paper chromatogram and showed the presence of an amido group in the IR spectrum. The assignment of the NMR signals (Table 1) was made by comparing them with those of 2-pyrrolidone[6] and the diazacycloheptanone, IIb. Deuterium exchange in the spectrum of IV caused the disappearance of the multiplet at τ 2.4 and the simultaneous collapse of the multiplet at 6.8 to a broad triplet. On the irradiation of the deuterium-exchanged solution at τ 8.45, the multiplet at 7.7 and the triplet at 7.43 collapsed to broad singlets, while the broad triplet at 6.8 remained unchanged. This observation eliminated the possibility of an isomeric structure (IV') for IV, because if IV' were present, the broad triplet at τ 6.8 due to the methylene protons adjacent to the lactam nitrogen in the structure IV' would have collapsed to a singlet upon irradiation. The ring opening of the lactam IV with 5% sulfuric acid gave an amino acid (VI), and reduction with lithium aluminum hydride afforded 1-benzyl-1,4-diazacyclooctane (VII). The assignment of the NMR signals of the tetrazole derivative (V) is shown in Table 1. The lower chemical shift of the triplet at τ 5.50 indicated the presence of a methylene group adjacent to the tetrazole nitrogen. A reinvestigation of Dickermann's work gave no tetrazole derivative other than the lactam.

The Schmidt reaction of a carbocyclic six-membered ketone, menthone (VIII), afforded a lactam (IX), plus a tetrazole derivative (X) as a minor product. The NMR signals at τ 6.97 [CH(7) adjacent to the seven-membered ring nitrogen] for the lactam and at 5.65 for the tetrazole, and also the possible mode of formation, led to the assignment of the structure IX

and X for these products. The assignment of the signals is shown in Table 1. The treatment of IX with lithium aluminum hydride yielded the azacycloheptane (XI). The tetrazoles V and X were not formed from IV and IX under the same conditions as in the reaction of III or VIII. Therefore, the lactam can not be an intermediate of the tetrazole formation under these conditions.

2-Methyl-4,5,6,7-tetrahydrobenzo[*b*]thiazol-7-one (XII), which had been prepared according to the literature,[7] was subjected to the Schmidt reaction to give a lactam (XIIIa) in a 68% yield, but not a tetrazole derivative. It showed amido absorption in the IR spectrum. The assignment of the NMR signals is given in Table 1. On deuterium exchange, the multiplet at τ 2.35 disappeared and the broad quartet at 6.54 simultaneously became a more complex multiplet, while the other signals remained unchanged. This fact, as well as the lower chemical shift of the quartet at τ 6.54, indicated the presence of a methylene group adjacent to the lactam nitrogen, supporting the idea of the structure XIIIa for the reaction product. The alternative isomeric form (XIII') was eliminated on the grounds that such a compound would give the signal of CH_2(6) at about τ 7.7—7.8 (*cf.* the signals of 2-pyrrolidone, IV, and IX in Table 1) and that the deuterium exchange could not affect any signals of the compound. The complexity of the signal of CH_2(6) at τ 6.54 after deuterium exchange can be explained in terms of the unequivalency of the methylene hydrogens. The carbonyl group in XIIIa resisted reduction with lithium aluminum hydride even when refluxed for 15 hr in tetrahydrofuran. However, treatment with phosphorus pentasulfide gave the thio lactam, XIIIb, the structure of which was confirmed by a study of the NMR spectrum (for the assignment, see Table 1). The deuterium exchange caused the disappearance of the broad multiplet at τ 0.8, with a simultaneous change in the broad quartet at 6.45 to a more complicated multiplet, as in the case of XIIIa.

On the reaction of XIIIa with triethyloxonium fluoroborate,[8] the ethoxy compound XIV was obtained in a 78% yield.

Experimental

Elementary analyses were carried out using a Yanagimoto C.H.N. Corder, MT-1. The NMR spectra were recorded by means of a Hitachi High-resolution NMR Spectrometer, R-20A, and the IR spectra, by means of a Nihon-Bunko IR-S Spectrophotometer. Each analytical sample gave a single spot on a paper chromatogram (Toyo Roshi No. 51) developed with 3% aqueous ammonium chloride or 5 N acetic acid / 1-butanol (29 : 71 v/v) and examined under ultraviolet light at 365 and 254 mμ in turn.

1-Benzyl-1,4-diazacyclooctan-5-one (IV) and 7-Benzyl-5,6,7-8,9,10-hexahydrotetrazolo[4,5-d][1,4]diazocine (V). To a stirred solution of 9.6 g (0.04 mol) of III hydrochloride in 34 m*l* of concentrated sulfuric acid were added, in small portions, 4.2 g (0.065 mol) of sodium azide over a period of 6 hr at room temperature. After having been stirred for an additional 22 hr at the same temperature, for 9 hr at 30°C, and for 6 hr at 50—55°C, the reaction mixture was poured onto 50 g of ice and made alkaline with a saturated solution of sodium hydroxide under ice cooling. The sodium sulfate was filtered off, and the filtrate was extracted with ether and chloroform successively. The combined and dried (over anhydrous potassium carbonate) extract was evaporated, and the residue was distilled *in vacuo* to give two kinds of oily products. The first fraction (IV) amounted to 5.3 g (64%) (colorless; bp 155—156°C/0.14 mmHg, R_f=0.6).

Found: C, 71.64; H, 8.16; N, 13.20%. Calcd for $C_{13}H_{18}N_2O$: C, 71.52; H, 8.31; N, 12.84%.

The second fraction (V), 0.4 g (7%), was a viscous, light yellow oil, bp 177—180°C/0.1 mmHg, R_f=0.4.

Found: C, 63.96; H, 6.63; N, 28.41%. Calcd for $C_{13}H_{17}N_5$: C, 64.17; H, 7.04; N, 28.78%.

4-Methyl-7-isopropyl-1-azacycloheptan-2-one (IX) and 5-Isopropyl-8-methyl-5,6,7,8-tetrahydro-9H-tetrazolo[4,5-a]azepine (X). To a stirred, ice-cooled solution of 20 g (0.13 mol) of VIII in 50 m*l* of concentrated sulfuric acid were added 18 g (0.28 mol) of sodium azide over a period of 18 hr. The reaction mixture was stirred for an additional 50 hr at room temperature and then poured onto 100 g of ice and made alkaline

with a saturated solution of sodium hydroxide. The sodium sulfate thus formed was filtered off, and the filtrate was extracted with ether. The ether layer was dried over anhydrous potassium carbonate and evaporated to give a mixture of an oil and crystals. The mixture was dissolved in ethanol, and water was added. The solid was collected and recrystallized from dilute ethanol to give 10.6 g (70%) of IX as white needles, mp 118—119°C.

Found: C, 71.08; H, 11.00; N, 7.92%. Calcd for $C_{10}H_{19}NO$: C, 70.96; H, 11.31; N, 8.28%.

The original filtrate was concentrated, and the residue was distilled *in vacuo* to give 4.3 g (16%) of X as a colorless oil, bp 142—143°C/0.20 mmHg.

Found: C, 61.99; H, 9.28; N, 29.11%. Calcd for $C_{10}H_{18}N_4$: C, 61.82; H, 9.29; N, 28.84%.

N-Benzyl-N-(2-aminoethyl)-4-aminobutanoic Acid (VI). A solution of 3.0 g of IV in 60 m*l* of 5% sulfuric acid was refluxed for 10 hr. After cooling, the solution was adjusted to pH 7.0—7.2 with a 5% barium hydroxide solution. The excess barium hydroxide was removed by saturating the the solution with carbon dioxide, followed by filtration. The filtrate was evaporated to dryness under reduced pressure, and the residue was dissolved in a small amount of methanol (*ca.* 5 m*l*); ether was then added in small portions until precipitation began. The separation of the precipitate and two recrystallizations from methanol gave 1.3 g (58%) of VI as white prisms, mp 173°C (decomp.). The drying of an aliquot of the prisms at 70°C for 2 hr gave the analytical sample.

Found: C, 65.86; H, 8.52; N, 11.82%. Calcd for $C_{13}H_{20}N_2O_2$: C, 66.07; H, 8.53; N, 11.85%.

Picrate: VI combined with two molecules of picric acid to form yellow plates, mp 183°C (from ethanol). The analytical sample was dried at 70°C for 2 hr.

Found: C, 44.10; H, 4.17; N, 16.10%. Calcd for $C_{13}H_{20}N_2O_2 \cdot 2C_6H_3N_3O_7$: C, 43.83; H, 3.83; N, 16.36%.

2-Methyl-8-oxo-4,5,6,7-tetrahydro-8H-thiazolo[5,4-c]azepine (XIIIa). To a stirred solution of 3 g (0.018 mol) of XII in 15 m*l* of concentrated sulfuric acid, maintained at 0—5°C, were carefully added 2.5 g (0.038 mol) of sodium azide. After the mixture had been stirred for 10 hr, 100 m*l* of ice-cold water were added. The mixture was adjusted to pH 5 by adding a saturated solution of sodium hydroxide, and then it was repeatedly extracted with chloroform. The combined chloroform solution was dried over anhydrous magnesium sulfate and evaporated under reduced pressure. The residual solid was recrystallized from a mixture of acetone and chloroform to afford 2.1 g (67.5%) of XIIIa as colorless crystals, mp 174—175°C, which sublimed at 120°C/0.2 mmHg.

Found: C, 52.69; H, 5.54; N, 15.15%. Calcd for $C_8H_{10}N_2OS$: C, 52.72; H, 5.53; N, 15.37%.

2-Methyl-8-thioxo-4,5,6,7-tetrahydro-8H-thiazolo[5,4-c]azepine (XIIIb). A mixture of 1 g (0.0051 mol) of XIIIa, 1.4 g (0.0061 mol) of phosphorus pentasulfide, and 15 m*l* of pyridine was heated under reflux for 1 hr. The reaction mixture was treated with a small amount of water, evaporated to dryness under reduced pressure, and sublimed at 160°C/0.2 mmHg to give 0.9 g (83%) of XIIIb as light yellow crystals, mp 176—178°C.

Found: C, 48.34; H, 4.79; N, 14.20%. Calcd for $C_8H_{10}N_2S_2$: C, 48.45; H, 5.08; N, 14.13%.

2-Methyl-8-ethoxy-5,6-dihydro-4H-thiazolo[5,4-c]azepine (XIV). To a stirred solution of triethyloxonium fluoroborate[9] (freshly prepared from 5 m*l* of borontrifluoride etherate, 15 m*l* of dry ether, and 5 m*l* of epichlorohydrin), was added a solution of 1 g (0.0055 mol) of XIIIa in 20 m*l* of dichloromethane at room temperature. The mixture was stirred for 30 hr and then made alkaline by adding an aqueous solution of potassium carbonate. Extraction with dichloromethane, followed by the evaporation of the solvent and vacuum distillation, gave 0.9 g (78%) of XIV as a colorless oil, bp 94—95°C/0.22 mmHg.

Found: C, 57.88; H, 7.12; N, 12.17%. Calcd for $C_{10}H_{14}N_2OS$: C, 57.11; H, 6.71; N, 13.32%.

The *picrate* formed as yellow crystals, mp 149—150°C (from ethanol).

Found: C, 43.56; H, 3.76; N, 15.79%. Calcd for $C_{10}H_{14}N_2OS \cdot C_6H_3N_3O_7$: C, 43.73; H, 3.90; N, 15.94%.

The authors wish to thank Dr. S. Morosawa and Dr. H. Yamamoto for their valuable advice and encouragement.

Studies on Microbial Utilization of Petroleum. I. Separation and Characterization of Carotenoids Produced by a Species of *Brevibacterium* in Hydrocarbon Media

Hyoichiro SAKURAI, Kenji KATO, Toshio SAKAI, Yoshiro MASUDA, and Tohoru KURIYAMA

Central Research Laboratory, Mitsubishi Petrochemical Company Limited, Ami-machi, Inashiki-gun, Ibaraki

(Received June 22, 1970)

Ten pigment fractions were separated from a *Brevibacterium* sp. KY-4313 in hydrocarbon fermentation. The pigments were extracted from cell with a mixture of petroleum ether and acetone, and purified by column and thin-layer chromatography. The principal carotenoid of this organism was identified as canthaxanthin (4,4′-dioxo-β-carotene) by using visible, IR, NMR, and mass spectra of the pigment. Three other pigments were characterized as β-carotene, echinenone (4-oxo-β-carotene), and 15-*cis*-4,4′-dioxo-β-carotene. Three carboxylic carotenoids and three other carotenoids were also separated but their structures were left unidentified. Quantitation of the pigments showed that canthaxanthin represented 53% and its *cis*-isomer 20% of the pigments separated from extracts. β-Carotene derivatives comprise more than 80% of the pigments. Canthaxanthin and echinenone have not previously been reported as bacterial pigments in hydrocarbon fermentation.

Studies on carotenoid production by hydrocarbon fermentation have been reported regarding *Mycobacterium lacticola*,[1,2] *Nocardia lutea*,[3] *N. corallina*,[3] *Pseudomonas methanica*,[4] *Rhodotorula aurantiace*,[5] *R. glutinis*,[5] *Mycobacterium smegmatis*,[6] and *M. lacticolum*.[7]

Recently Iizuka and Nishimura[8] have reported that *Brevibacterium* strain No. 103 essentially produces astacin and astaxanthin when cultured on several *n*-alkanes.

Kato *et al.*[9] reported the cultural conditions for carotenoid production by a *Brevibacterium* sp. KY-4313 in *n*-alkane media and suggested that the bacterium seemed to produce xanthophylls extractive with petroelum ether.

The present authors reexamined the carotenoid pigments produced by *Brevibacterium* sp. KY-4313 cultivated on the different hydrocarbon medium, and established the presence of canthaxanthin among other carotenoids, as the main component.

Canthaxanthin has been isolated from mushroom *Cantharellus cinnabarinus*,[10] the feathers and the skin of the lesser flamingo *Phoeniconias minor*,[11] *Cyclops strenuus*,[12] and *Micrococcus roseus*[13] and *Corynebacterium michiganense*[14] in non hydrocarbon media.

Experimental

Measurements. Hitachi EPS-3, Perkin Elmer 225, Varian HA 100D, and Hitachi RMU-6 spectrometer were used for the measurements of visible, IR, NMR, and mass spectrum, respectively.

Reduction of Carbonyl Group. Carbonyl groups in carotenoids were reduced by sodium borohydride in 95% ethanol solution.

Detection Test for Carboxylic Group. Carboxylic groups were detected by the formation of ferric hydroxamates (brown).

Microorganism. The microorganism used was a *Brevibacterium* sp. KY-4313. The organism was maintained on a meat extract agar slant.

Media and Cultural Conditions. A meat extract agar slant was used as an inoculum. For sub-inoculum a portion of 100 m*l* conventional natural nutrient medium in a 500 m*l* Erlenmeyer flask was used. Mass cultures were grown for 7 days in fifty 500 m*l* Erlenmeyer flasks containing 200 m*l* of medium shown in Table 1 at 30°C on a rotary shaker running at 220 rpm describing a circle of 70 mm diameter.

Harvesting of Cells. The pale yellow culture was poured into a separatory funnel, allowed to stand for 1 hr, and the green aqueous layer was discarded. The yellow supernatant was centrifuged at 7000 rpm at 0°C for 10 min.

Extraction of Pigments from the Medium. Experiments

TABLE 2. CHROMATOGRAPHIC SEPARATION OF THE CAROTENOIDS AND THEIR CONTENTS

Column chromatog.[a]		Thin-layer chromatography				Per cent[b] content
Fraction	System of solvents	Layer	System of solvents	Fraction	R_f value	
1	PE-Ac (9.5+0.5, v/v)	Silica gel	PE-Bz (85+15)	1-1	0.67	6.2
				1-2	0.53	
				1-3	0.49	
				1-4	0	
2	(98+2)	$MgHPO_4$	CCl_4	2	0.57	7.4
3	(50+50)	Silica gel-$Ca(OH)_2$ (1+2)	Bz-Me (98+2)	3-1[c]	0.21	52.8
				3-2	0.12	20.2
4	Ac	Silica gel	PE-Ac (30+70)	4-1	0.71	7.0
				4-2	0.49	4.1
				4-3	0	2.3

a) Silica gel (200 mesh, 0.8×48 cm) was used for adsorbent.
b) The content was determined spectrophotometrically as β-carotene ($E^{1\%}_{1cm}$: 2580 in PE).
c) The main pigment was also isolated from Fr. 3 in PE at −20°C in the form of a fine deep red plate, which was found pure by thin-layer chromatography.
PE: petroleum ether, Ac: acetone, Bz: benzene, Me: methanol.

were carried out throughout under dim light and N_2 atmosphere. A portion of 2.5 *l* of petroleum ether and the same volume of acetone were added to about 200 g of orange yellow harvest. The hole mixture was washed with 5 *l* of distd. water. The procedure was repeated twice. The collected orange petroleum ether layer was evaporated to dryness in a vacuum and pigments were then dissolved in acetone. The carotenoid solution in acetone was allowed to stand at −20°C overnight, and the waxy substances separated were removed by filtration. The pigments were again transferred from the acetone solution into petroleum ether. The solution was passed through a silica gel column (0.8×48 cm, 200 mesh) to remove residual hydrocarbon, the column being washed with petroleum ether, and the adsorbed pigments were eluted with acetone.

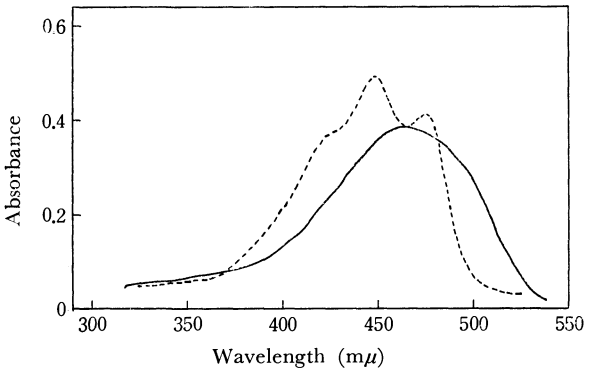

Fig. 1. The change of the absorption spectrum of Fr. 3-1 by $NaBH_4$ reduction.
Solvent: *n*-Hexane, (——): Fr. 3-1, (- - -): Reduced Fr. 3-1.

Saponification of the pigments was carried out in a 10% methanolic potassium hydroxide solution for 30 min at 40°C with continuous stirring in N_2 atmosphere, and the unsaponifiable matters were extracted with petroleum ether.

Separation of Pigments. Separation procedures are summarized in Table 2. Thin-layer chromatographic purification by different adsorbents was carried out.

Results and Discussion

The content of the pigments and their absorption maxima are shown in Tables 2 and 3, respectively.

The main carotenoid (Fr. 3-1, Fr. is used for fraction instead hereinafter) was identified with canthaxanthin. Three carotenoids were characterized as β-carotene, echinenone, and canthaxanthin *cis*-isomer. Hydroxy-carotenoid, a presumable precursor in oxocarotenoid biosynthesis, was not obtained.

From the fact that reduction of the pigment makes a 17 mμ hypsochromic shift in the visible spectra (Table 3, Fig. 1), the main pigment is considered to have two conjugated carbonyl groups on its ionone

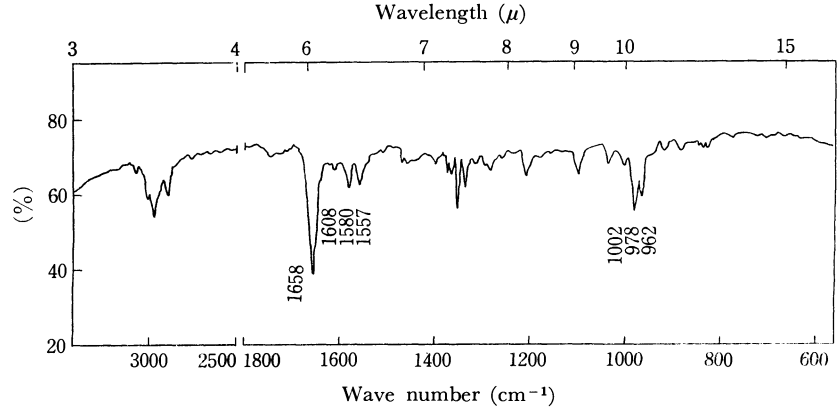

Fig. 2. IR spectrum of Fr. 3-1 (KBr: 0.3 g, Sample: 0.5 mg).

Table 3. Absorption maxima and identification of carotenoids

Carotenoid	Absorption maxima (mμ)	Solvent	R_f Value	Identification
Fr. 1-1	425 446 473	PE	0.67[g]	β-Carotene[a]
Fr. 1-3	439 466 496	PE		Unknown[b]
Fr. 2	458	*n*-Hexane	0.85[h]	Echinenone[c]
Reduced Fr. 2	426 450 478	*n*-Hexane	0.76[h]	
Fr. 3-1	466	*n*-Hexane	0.83[h]	Canthaxanthin[d]
Reduced Fr. 3-1	426 449 476	*n*-Hexane	0.51[h]	
Fr. 3-2	356 460	*n*-Hexane		*cis*-Isomer of canthaxanthin[e]
Reduced Fr. 3-2	332 422 445 472	*n*-Hexane		
Fr. 4-1	348 435 457 483	Chloroform		Carboxylic carotenoids[f]
Fr. 4-2	435 459 482	Chloroform		
Fr. 4-3	433 455 482	Chloroform		
β-Carotene[i]	425 447 475	PE	0.67[g]	
Echinenone[15]	458	PE		
Isocryptoxanthin[16]	426 451 479	*n*-Hexane		
Canthaxanthin[15]	467	*n*-Hexane		
Isozeaxanthin[15]	426 450 478	*n*-Hexane		

a) Identified with β-carotene from the R_f values and spectrum.
b) This pigment is neither carbonyl, hydroxy, nor carboxylic carotenoid from TLC behavior and result of $NaBH_4$-reduction.
c) Identified with echinenone from results of the maximum absorption shift and the change of R_f value on reduction, and by agrrement with the absorption maxima given in literature (Fig. 4).
d) The main pigment was identified with canthaxanthin from the results of visible absorption, IR, NMR and mass spectrum.
e) Identified with canthaxanthin *cis*-isomer (15-*cis*-) from the position of *cis*-peak[17] (Fig. 5).
f) Positive to the detection test of carboxylic group.
g) Layer: Silica gel, Solvent system: PE-Bz (85+15).
h) Layer; Silica gel, Solvent system: CH_2Cl_2-AcOEt (90+10).
i) β-Carotene (E. Merck, for biochemistry grade) used after being purified on TLC.

Table 4. IR absorption of Fr. 3-1 and canthaxanthin

Carotenoid	Frequencies in cm^{-1}						
	Conjug. C=O	Conjug. C=C			CH out-of-plane of conjug. *trans*-CH=CH		
Fr. 3-1	1658 vs	1608 w	1580 m	1557 m	1002 w	978 s	962 m
Canthaxanthin[18]	1658 vs	1608 w	1581 m	1555 s		998 m	966 s
Canthaxanthin[19]	1640 vs		broad (m)			*ca.* 960 s broad	

vs: very strong, s: strong, m: medium, w: weak. KBr discs were used.

Table 5. NMR absorption of Fr. 3-1 and canthaxanthin

Carotenoid	Solvent	*gem*-Me	Me on C adjacent to C=O	Me on polyene chain	*Vicinal* CH_2					
					α position to C=O			β position to C=O		
Fr. 3-1	C_6D_6-$CDCl_3$ (3+1)	8.99	7.98	8.12 8.14[a]	7.53	7.60	7.67	8.36	8.42	8.49[b]
Fr. 3-1	$CDCl_3$	8.79	8.12	7.99	7.42	7.48	7.55	8.08	8.15	8.22
Canthaxanthin[19]	CCl_4	8.81	8.21	7.89 7.99						
Relative intensity[c]		6	3	6		2			2	

a) The bands at 8.12 and 8.14 arise from 9,9'-Me and 13,13'-Me groups, respectively.
b) These two sets of triplet due to the vicinal CH_2 groups were confirmed by spin-spin decoupling technique.
c) The ratio was calculated from the spectrum measured in C_6D_6-$CDCl_3$.

rings. As shown in Table 4 and Fig. 2, the IR spectrum gives more information than the spectra reported heretofore, that is, we may conclude that the splitting of the region (960—1002 cm^{-1}) is due to the conjugation of ω,ω'-carbonyl groups through the trans polyene chain.

The NMR spectrum measured in a C_6D_6-$CDCl_3$ solution provides more useful information for complete assignment of bands than the ones measured in $CDCl_3$, or in CCl_4 (Table 5, Fig. 3). In the measurement in a C_6D_6-$CDCl_3$ solution, a band at 7.98 (τ value, Me on C adjacent to C=O) and a triplet at 8.42 (*vicinal* CH_2) can be completely separated by magnetic anisotropy effect of C_6D_6, while it is observed as an overlapping spectrum in $CDCl_3$.

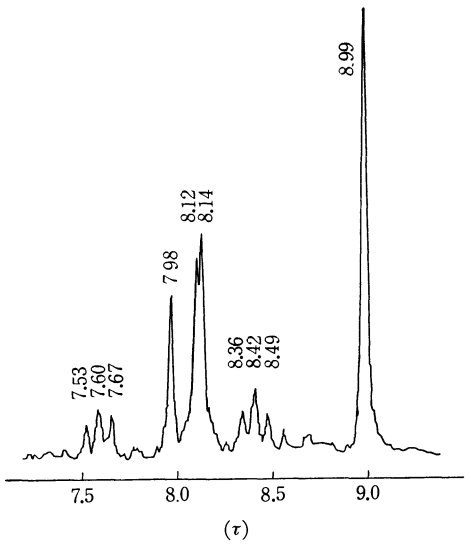

Fig. 3. NMR spectrum of Fr. 3-1. 0.5 mg/0.01 m*l* C_6D_6-$CDCl_3$ (3 : 1) at 100 MHz.

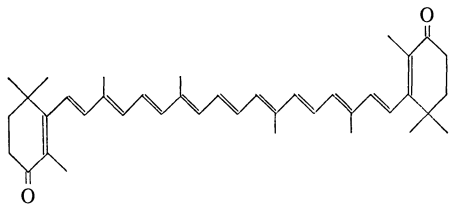
In the mass spectrum of Fr. 3-1, M^+ shows 564 mu (Calcd for $C_{40}H_{52}O_2$: mol wt, 564.4). The intensity ratio of M^+-92 to M^+-106 is 2.6, which agrees well with that of canthaxanthin (2.56) reported by Enzell *et al.*[21]

From the results, we identify Fr. 3-1 with canthaxanthin (4,4'-dioxo-β-carotene) (I).



(I) Canthaxanthin

Fr. 3–1 exposed to sunlight shows the same absorption spectrum as that of Fr. 3–2. Canthaxanthin is considered to have been converted to its *cis*-isomer during the cultivation of bacterium.

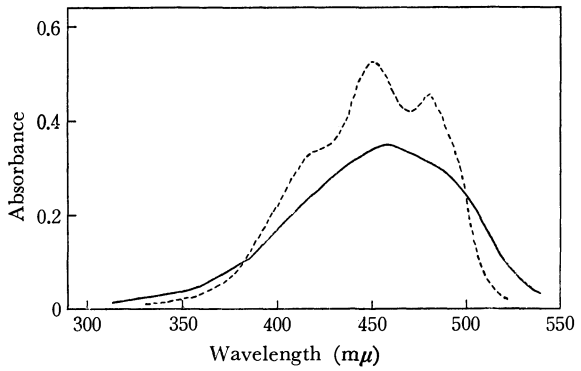


Fig. 4. The change of the absorption spectrum of Fr. 2 by $NaBH_4$ reduction. Solvent: *n*-Hexane. (——): Fr. 2, (- - -): Reduced Fr. 2.

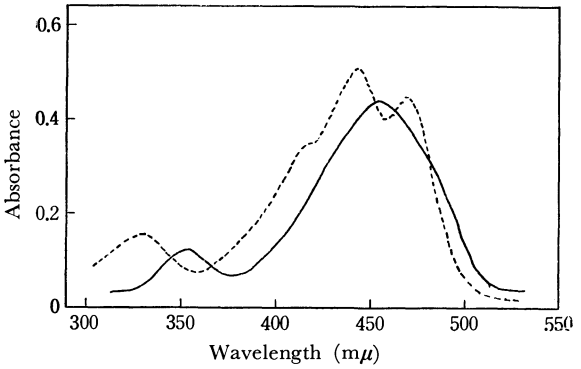

Fig. 5. The change of the absorption spectrum of Fr. 3-2 by $NaBH_4$ reduction. Solvent: Petroleum ether. (——): Reduced Fr. 3-2, (- - -): Reduced Fr. 3-2.

Brevibact. sp. KY-4313 and *B.* strain No. 103[8] differ in the carotenoid formation. While the former produces mainly mono- and dioxo-carotenoids, the latter gives dihydroxy-dioxo- and tetraoxo-carotenoids almost exclusively.

Mycobact. smegmatis[6] was reported to produce oxo- and hydroxy-oxo-carotenoids as main components in hydrocarbon media, but no hydroxy-carotenoid has been isolated so far.

In non-hydrocarbon medium *Micrococcus roseus*[13] has been found to produce a trace of isozeaxanthin as a precursor for canthaxanthin which is the main component.

From these facts, it seems that the organisms such as *Brevibact.* sp. KY-4313, *N.* strain No. 103, *Mycobact. smegmatis*, and *Micrococcus roseus* readily oxidize the hydroxyls of precursors to ketones.

We wish to thank Professor S. Fukui of Kyoto University for a gift of the specimen of *Brevibacterium* sp. KY-4313 and his helpful discussion, and also the technical assistants of our laboratory. We also wish to thank Mr. J. Fukuda, Director of Central Research Laboratory, Mitsubishi Petrochemical Co., Ltd., for permission to publish this paper.

Optical Rotatory Dispersion and Circular Dichroism of the Osmate Esters of Cyclic Mono-olefins[1,2]

Naokazu SAKOTA and Shunsaku TANAKA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama

(Received July 3, 1970)

The osmate esters (as the di-pyridine adducts) of optically active mono-, di- and tricyclic mono-unsaturated terpenes were prepared for measurements of optical rotatory dispersion (ORD) and circular dichroism (CD). All the osmate esters of the cyclic olefins examined exhibited a strong Cotton effect in 470 mμ regions and a weak Cotton effect near 600 mμ regions, which were similar to those of the osmate esters of the open chained olefins reported in our previous paper. The sign of CD maximum in 470 mμ regions was found to be correlated to the chirality of gauche structure of the chelate ring containing an osmium chromophore. Furthermore, their absolute configurations were deduced from the data of circular dichroism of two diastereoisomers of *cis*-α-pineneglycol.

An effective method has been reported by Bunnenberg and Djerassi[3] to introduce an appropriate chromophore to an ethylenic bond of optically active mono-unsaturated compound and to give rise to a Cotton effect in the relatively longer wavelength regions for the convenience of the measurement of ORD. They reported that the steroidal olefins reacted with osmium tetroxide to form the osmate esters, which exhibited a multiple Cotton effect in visible spectrum regions.

We have already mentioned that the sign of the Cotton effect of the osmate esters of optically active acryloyl esters,[4] α-olefins,[4] acryloyl-L-amino acids[5] and 1,2-glycols[6] can be associated with the configurations of these olefins. We measured ORD and CD curves of the osmate esters of optically active cyclic mono-unsaturated terpenes and tried to account for the correlation between the conformational structure of the osmate esters and the sign of CD maximum in 470 mμ regions.

Experimental

Menthene Isomers. (+)-*1-Menthene* [*1*]. The crude (+)-l-menthene supplied by Nippon Terpene Chem. Co., was subjected in batches to preparative gas chromatography (Silicone DC 550, 2.6 m×10 mmφ, 160°C), α^{17}_{589} +82.8° (neat).

(+)-trans-*2-Menthene* [*2*][7]. *l*-Menthyl toluene-*p*-sulphonate obtained by the reaction of *p*-toluenesulfonyl chloride with *l*-menthol was added to a solution of sodium in absolute ethanol. The mixture was refluxed for 6 hr in dry nitrogen. After ether extraction, the product was purified by preparative gas chromatography as above, α^{21}_{589}+109° (neat). The resulting product was found to contain (+)-*trans*-2-menthene (92%) and (+)-3-menthene (8%) by analytical gas chromatography (Dinonylphthalate, 3.7 m×3 mmφ, 145°C).

(−)-trans-*2-Menthene* [*3*]: The product obtained from α-menthyl tosylate by the method as above was found to contain (−)-*trans*-2-menthene (91%) and (−)-3-menthene (9%), α^{21}_{589} −108° (neat).

(+)-*3-Menthene* [*4*].[8] *l*-Menthol was added to metallic sodium in dry toluene and refluxed for 20 hr. To the reaction mixture was added ether solution of carbon disulfide and methyliodide. The yielded methyl (−)-menthyl xanthate was pyrolyzed to [*4*], which was purified by preparative gas chromatography. From the result of the analytical gas chromatography, it was found to contain (+)-*trans*-2-menthene (31%), α^{17}_{589} +83.2° (neat).

Dicyclic mono-terpenes.

The purity of the following compounds was determined by analytical gas chromatography (PEG 6000, 3 m×3 mmφ, 130°C).

(+)-α-*Pinene* [*5*][9]: $[\alpha]^{11}_{D}$ +21.5° (neat), purity 97%.
(−)-α-*Pinene* [*6*][9]: $[\alpha]^{11}_{D}$ −26.5° (neat), purity 97%.
(−)-β-*Pinene* [*7*][9]: $[\alpha]^{11}_{D}$ −19.9° (neat), purity 97%.
(−)-*Camphene* [*8*][9]: $[\alpha]^{21}_{D}$ −28.3° (*c* 8, ethanol), purity 92.5%.
(+)-*Bornylene* [*9*][9]: $[\alpha]^{21}_{D}$ +8.3° (*c* 6, benzene), purity 87%.

Patchoulene Isomers.

α- *and* γ-*Patchoulene* [*10*], [*12*].[10] Phosphorus oxychloride was added into a solution of patchouli alcohol ($[\alpha]^{22}_{D}$ −120°, *c* 5, chloroform) in pyridine. (−)-(*1R*:*2S*:*3R*:*5R*)-cis-α-*Pineneglycol* 〔*15*〕.[12] Pinocarbonoxide mixture prepared from (−)-α-pinene (optical purity 71%, kindly supplied by Mr. Katsuhara), was reduced by lithium aluminum hydride. The resulting mixture was separated as shown above into two *cis*-α-pineneglycols and a *trans*-α-pineneglycol. The *trans*-glycol and the *cis*-glycols were identified to be 〔*13*〕, 〔*14*〕, and 〔*15*〕 respectively by the R_f values of thin-layer chromatography.

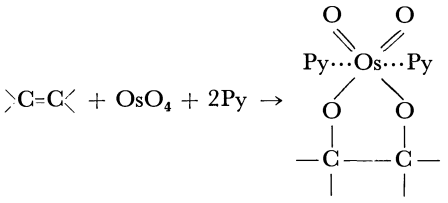
Measurements of ORD, CD and Visible Absorption Spectrum. Olefin (3—5 mg) was treated with two molar equivalents of pyridine dissolved in 1 m*l* of dichloromethane and one equivalent of osmium tetroxide. After standing for a certain time at room temperature, ORD, CD and visible absorption spectra were recorded on a Jasco Optical Rotatory Dispersion, Model UV-5 with an attached CD recorder using 1 mm and 2 mm cells. In the case of α-pineneglycol, 0.4% (v/v) pyridine - methanol was used as a solvent.

Results and Discussion

It has been reported[13] that the mono-unsaturated compounds react with one equivalent of osmium tetroxide and two equivalents of pyridine yielding the osmate esters (as di-pyridine adducts) as follows.



The ORD, CD and visible absorption spectra of the osmate esters of mono-unsaturated terpenes differ markedly from each other in amplitude, fine structure and position of the extrema according to their chemical structures. However, general features of these spectra resemble each other. As two examples, the spectra of the osmate esters of monocyclic terpene, (+)-1-menthene and dicyclic terpene, (−)-β-pinene are shown in Figs. 1 and 2, respectively. When these terpenes are treated with pyridine and OsO_4 in dichloromethane, the maximum absorption is always obtained only after standing for 1—2 days at room temperature, and the spectra at the maximum absorption are shown in these figures. As shown in Fig. 1, the osmate esters of (+)-1-menthene 〔*1*-Os〕 exhibit a strong negative CD maximum at about 465 mμ with the corresponding Cotton effect. Because of the strong absorption exhibited below 410 mμ, the visible absorption band corresponding to the CD maximum at 465

mμ regions reveals itself merely as a shoulder, which is shifted to the shorter wavelength. In Fig. 2, the osmate ester of (−)-β-pinene 〔*7*-Os〕 exhibits a similar CD curve of opposite sign.

The molar elipticities at maximum wavelength ($[\theta]_{max}$) of the osmate esters of mono-, di- and tricyclic mono-unsaturated terpenes are summarized in Fig. 3. The general features of the CD curves are similar to those of the osmate esters of the open chained mono-unsaturated compounds[4-6] and also to those of the osmate esters of steroidal olefins.[3] Notable results are obtained from Fig. 3 as follows. The osmate esters of monocyclic terpene, 1-, 2- and 3-menthene exhibit fairly large $[\theta]_{max}$ values compared to those of di- and tricyclic terpenes. Menthene reacts with osmium tetroxide, when a pair of diastereoisomers of the osmate esters are produced owing to the direction of the *cis*-addition. The ratio of the formation of these two stereoisomers might differ according to the stereoselectivity of the menthene to osmium tetroxide. As an example, the use of OsO_4 for (±)-*trans*- and (±)-*cis*-2-menthene is reported to take place in the

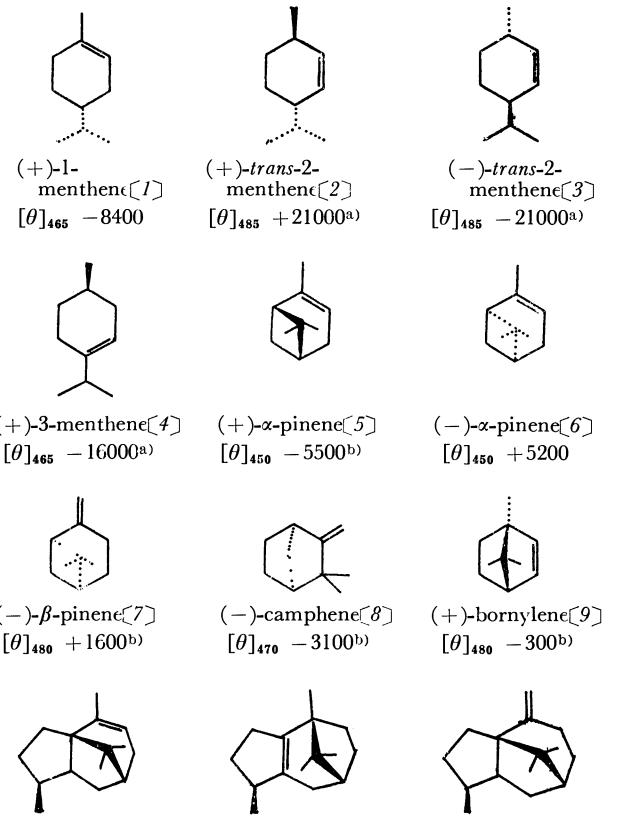

Fig. 3. The absolute configuration of cyclic terpenes and the $[\theta]_{max}$ in CD curves of their osmate esters.

a) $[\theta]_{max}$ values of *trans*-2-menthene and 3-menthene are calculated from $[\theta]_{max}$ values of the two mixtures having different proportions of 〔2〕 or 〔3〕 to 〔4〕.

b) These $[\theta]_{max}$ values show the corrected ones to the optical pure compounds. The specific rotations of optical pure terpenes are postulated as follows.
(+)-α-pinene $[\alpha]_D^{20}+51.8°$,[14]
(−)-α-pinene $[\alpha]_D-51.5°$,[14]
(−)-β-pinene $[\alpha]_D-22.1°$,[15]
(−)-camphene $[\alpha]_D^{20}-99.4°$,[16]
and
(+)-bornylene $[\alpha]_D^{17}+23.9°$.[17]

formation of a single epimer in each case.[18] In these cases, the stable conformation of the osmate esters must be the one in which cyclohexane ring takes one of the two possible chair forms.

The molecular model shows that the five membered ring containing an osmium chromophore is twisted and forms gauche structures, which seem to be more stable than the plain one with respect to the O–C–C–O angle. If the two gauche structures are defined as δ- and λ forms as shown in Fig. 4, it is reasonable to consider that the stable conformation of 〔3-Os〕 is the

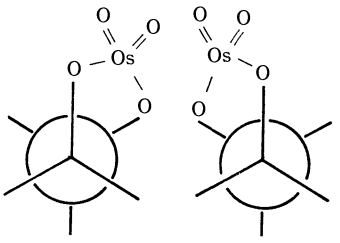

Fig. 4. The gauche structures of the osmium chromophore.

δ form and 〔2-Os〕 is the λ form. Experimental results show that the sign of CD maximum at 470 mμ is negative for 〔3-Os〕 and positive for 〔2-Os〕. This suggests that the sign of CD maximum at 470 mμ can be correlated to the gauche structure of the five membered ring. In contrast, the chiralities of 〔1-Os〕 and 〔4-Os〕 are so little effected by the stereoselectivity of 1- and 3-menthene to osmium tetroxide that the predominant twisted conformation is not easy to predict. However, if the above mentioned rule is applicable for 〔1-Os〕 and 〔4-Os〕, the negative sign of the Cotton effect of their osmate esters is ascribed to the predominance of δ form in the chirality of their five membered ring.

Bunnenberg and Djerassi[3] measured the ORD spectra of the osmate esters of four steroidal cholestenes which have a more rigid and twisted conformation than those of menthene isomers. Their results also show that λ- and δ structure of five membered ring exhibit the positive and negative Cotton effect near 470 mμ, respectively. In previous papers, it was suggested that the sign of the 460 mμ CD maximum in osmate esters of open chained (S)-1,2-glycols CH_2-(OH)CH(OH)R[6] and open chained (S)-α-olefins CH_2=CHR[4,5] was affected by the conformation of the five membered ring. It is well known that the metal complexes of ethylenediamine and propylenediamine have gauche structures.[19] Dwyer *et al.*[20] also showed that the stable conformation of the propylenediamine-cobalt complex is the gauche structure, in which the conformation of the methyl group is equatorial. The stable conformation of the osmate esters of (S)-open chained compounds is suggested to be δ structure in which R group is equatorial, and can explain the negative CD maxima.

Thus the chiral structure of five membered ring of the osmate esters can be correlated to the sign of the CD maximum near 470 mμ. A similar conclusion has been reported by Djerassi *et al.*,[21] who showed that the sign of the Cotton effect attributed to π–π* and n–π* transition of the steroidal trithiocarbonate depends upon the chirality of the trithiocarbonate chromophoric ring. In dibenzoate compounds, the

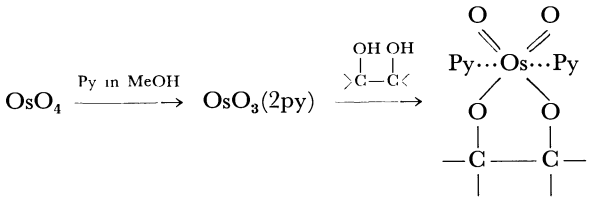
same consideration was reported by Harada and Nakanishi.[22] For the octahedral metal complexes, the possibility of a correlation between the octant sign and the sign of the Cotton effect for identified transitions within certain symmetry groups is mentioned.[23]

However, the molecular structure of the osmate esters of dicyclic monoterpenes, α-pinenes and bornylene, [5-Os], [6-Os] and [9-Os] are more rigid than those of the monocyclic terpenes, and their gauche structures of the chelate ring are less twisted. Thus, it is difficult to predict whether their stable chiral structure is to be λ or δ. In the case of the osmate esters of β-pinene [7-Os] and camphene [8-Os], not only the skeleton of the terpene moiety but also the whole molecular structure of the osmate ester should be taken into account for the evaluation of the stability of the five membered ring since the double bond is situated in exo position. Thus, for these osmate esters, the existence of a puckered conformation as mentioned above is difficult to predict. It is well established that in general the puckered chromophore contributes much more to the amplitude of the CD maximum than the plain chromophore. In Fig. 3, the molecular elipticities at CD maximum of the osmate esters of dicyclic terpenes are recognized to be smaller than those of monocyclic terpenes. This suggests the puckered conformation for the osmate esters of monocyclic terpenes. In the case of the osmate esters of patchoulene isomers, the situation seems to be more complicated.

Criegee *et al.*[13] has reported that glycols as well as α-olefins react with osmium tetroxide and pyridine to produce the osmate esters which resemble those from α-olefins:



In order to gain further insight into the osmate esters of (−)-α-pinene [6-Os], a *trans-* and two *cis*-α-pineneglycols, in which the configuration differs from each other only at C_2 and C_3 positions, were synthesized and the CD of these osmate esters was measured. Addition of osmium tetroxide to *trans*-α-pineneglycol [13] does not exhibit the CD maximum at 470 mμ, which denies the possibility of the trans addition of OsO_4 to olefins. The absolute configuration of *cis*-α-pineneglycol [14] obtained from (+)-2-hydroxypinocamphone was assigned to be [C] in Fig. 5 by Suga *et al.*,[11] but Schmidt[23] and Katsuhara[12] assigned [D] to it. Another *cis*-α-pineneglycol [15] having the opposite configuration at C_2 and C_3 was obtained from (−)-pinocarbonoxide. The CD curves of these two osmate

TABLE 1. THE $[\theta]_{max}$ IN CD CURVES OF THE OSMATE ESTERS OF α-PINENEGLYCOLS

Osmate ester	$[\theta]_{max}$[a]
[13-Os]	0
[14-Os]	+6400
[15-Os]	−12000
[6-Os]	+5200

a) These values are the corrected ones in relation to the optical pure compounds.

esters were measured, and the $[\theta]_{max}$ values were obtained as +6400 and −12000, respectively (Table 1). The osmate ester of (−)-α-pinene [6-Os] consists of two isomeric esters of *cis*-α-pineneglycols [C-Os], [D-Os]. The fraction of [D-Os] is considered to be larger than that of [C-Os], because the cis addition of osmium tetroxide to the double bond should be affected by the steric hinderance of the geminate dimethyl. The results in Table 1 show that [6-Os] mainly consists of [14-Os], and the absolute configurations of [14] and [15] should be assigned to [D] and [C], respectively. The trans glycol [13] obtained from (+)-2-hydroxypinocamphone should also be assigned to [B].

If we supposed that the sign of CD is dependent only upon the twisting of the five membered ring affected by the inherent α-pinene skeleton, both the CD maximum of [14-Os], and [15-Os] should have the same sign. However, the experimental results show different signs for them. This means that when osmium tetroxide reacts with (−)-α-piene from upper side or lower, the twisting of the chromophoric five membered ring might be reversed, *viz.*, the stable conformation of (−)-α-pinene skeleton is reversed. Accordingly, the chromophore in [14-Os] and [15-Os] should be a twisted five membered ring, whose conformation should be affected by the steric effects not only from the terpene moiety but also from the whole molecule.

We acknowledge the generosity of Mr. Katsuhara of Sun Star Research for providing the samples. We also wish to thank the Nippon Terpene Chem., Ltd. and the Yoneyama Chemical Industry Co., Ltd. for gifts of samples.

Studies of the Synthesis of Furan Compounds. XXII.[1] Synthesis and Antibacterial Activity of 5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole and Its Related Compounds[2]

Yasuhiko KATO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

(Received July 6, 1970)

In continuing our study of the relationship between structures and antibacterial activity, 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole and related derivatives have been synthesized. Their structures were confirmed by their chemical reactions and by their UV, IR, and NMR spectra. 1,3,4-Thiadiazole and its related derivatives show significant antibacterial activity.

In 1944 Dodd and Stillman[3] reported their finding that furan derivatives with a nitro group in the 5-position possess antibacterial activity; since then, extensive studies of the syntheses of 5-nitrofurans for an antibacterial substance have been undertaken. The substituents at the 2-position of the furan nucleus may be grouped into two types; one is –C=N–N–C=, as proposed by Dodd *et al.*,[4] and the other is –C=C, which has been investigated mainly by Japanese researchers.[5] In comparing the antibacterial activity of these two types, the latter is generally more effective than the former *in vitro*, but less effective *in vivo*. Therefore, the compounds which contain both these two atomic arrangements may be expected to retain a high activity both *in vitro* and *in vivo*. An example is the analog of 5-[2-(5-nitro-2-furyl)vinyl]-1,3,4-oxadiazole, in which the –C=C– system connects the furan nucleus with a heterocycle involving a –C=N–N=C– system; this has been studied in our laboratory.[6] The syntheses of two groups of such compounds, the 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazoles and -1,3,4-oxadiazoles, will be described in this paper.

Results and Discussion

1-[3-(5-Nitro-2-furyl)-2-(2-furyl)acryloyl]thiosemicarbazide(IIa) and hydrazide (III) were, respectively, prepared from thiosemicarbazide and hydrazine hydrate with chloride of acid (Ia)[7] (Chart 1). 5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole (IV) was obtained from IIa by the method described in a previous report.[8a] In a similar manner, when IIa was treated with phosphoryl chloride at 90—95°C, an isomer (V) of IV was obtained, along with a small amount of its 2-phosphoric amide compound (VI). Compound VI was easily converted to V by heating with water. The *cis-trans* conformations[9] of IV and V were confirmed on the basis of their UV, IR, and NMR spectra (Fig. 1—3) and the chemical reactions of their mother acid and esters.

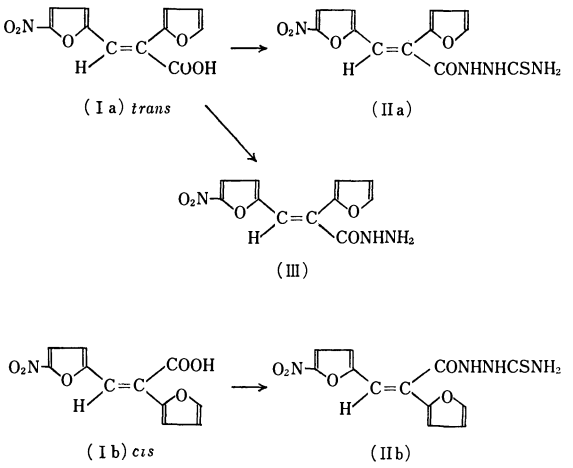

Chart 1

In our previous paper, an unknown isomer (VIIb) of methyl 3-(5-nitro-2-furyl)-2-(2-furyl)acrylate (VIIa) was isolated by the treatment of VIIa with hydrazine hydrate in methanol.[6d] It seems that the hydrazine serves as an isomerization catalyst much like the secondary amines. Thus, the isomerization reactions of the mother acid, Ia, and its esters with ahydrazine catalyst were attempted under several conditions (Table 1). The isomerization was involved in the conversion of the mother acid, Ia, and its benzyl ester (VIIIa) to their isomers (Ib[10] and VIIIb) in rather good yields,

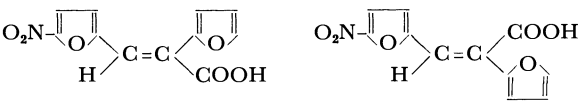
8) a) I. Hirao, *Nippon Kagaku Zasshi*, **89**, 713 (1968). b) *ibid.*, **88**, 574 (1967).

9) The *cis* and *trans* conformation were determined on the basis of the structures assigned[7] as follows.



trans acid (Ia) *cis* acid (Ib)

In this case, *trans* isomer (IV) means that 1,3,4-thiadiazole ring is on opposite side of 5-nitrofuran ring toward the ethylene double bond, and *cis* isomer (V) is both of the two rings being on a side.

10) This product did not agree with the compound already reported by Saikachi and Tanaka[7] dealing with the mp, UV, and IR spectrum.

a) The signal was overlapped with ring protons and disappeared by treating with deuterium oxide.
b) The spectra of Ia and Ib were recorded in methanol, and of VIIa and VIIb were in ethanol previously reported[6d] by the author *et al.*

except for the cases of the methyl (VIIa) and ethyl esters (IXa); the methyl ester, VIIa, was isomerized to its isomer (VIIb) in a lower yield but the ethyl ester (IXa)[7] was not. Furthermore, the author confirmed this reaction to be irreversible (Ib, VIIb, and VIIIb–⤫→Ia, VIIa, and VIIIa). The isomerization reaction of Ia also took place with sodium hydroxide, but those of the acids (Ia and Ib) and their esters (VIIa, b, VIIIa, b, and IXa) did not occur by means of an acid catalyst such as hydrochloric acid.

The structures of the acids (Ia and Ib) and their methyl esters (VIIa and VIIb) were determined by means of a study of their NMR spectra (Table 2); in the spectra, the chemical shift of the vinyl proton of Ia appeared at a lower magnetic field than that of Ib (Δ_{tc} 0.44 ppm), and also, in the case of the two methyl esters (VIIa and VIIb), the vinyl proton of VIIa revealed a signal lower than that of VIIb (Δ_{tc}

0.41 ppm). The conclusions may be reached from these results that both Ia and VIIa are *trans* and that the other two (Ib and VIIb) are *cis*. A similar conclusion may be reached as to the conformation of the other esters (VIIIa, b, and IXa). The structures of the *cis* esters were further confirmed by the treatment of chloride of the *cis* acid Ib with alcohols to afford the same *cis* esters. Thus, the *cis* isomer (IXb) of the ethyl ester, which could not be obtained by the isomerization of IXa, was prepared (Chart 2). Similarly, the 1,3,4-thiadiazole V was also produced from the *cis* acid Ib *via* its acyl thiosemicarbazide (IIb).

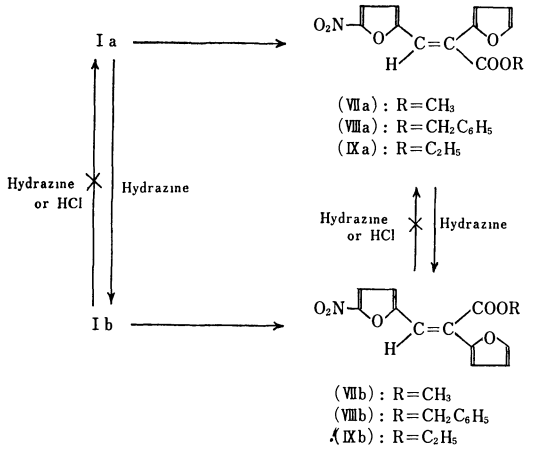

Chart 2

In conclusion, the conformation of V was determined to be *cis* and the compound, IV, which was derived from the *trans* acid, Ia, *via* its acyl thiosemicarbazide, IIa, was determined to be *trans*, since the posibility of the acid-catalytic isomerization of the starting acids (Ib and Ia) during the synthetic routes could be ruled out. The spectral data of these compounds (IV and V) also supported the above conclusion. In the UV spectra, the absorption maximum of V was observed at a slightly shorter wavelength and the extinction coefficient was larger than that of IV (Fig. 1). The IR spectrum of IV contained two medium NH_2 bands, at 3360 and 3300 cm^{-1}, and a medium C=N band at 1645 cm^{-1} due to the thiadiazole ring vibration. However, in the spectrum of V, a medium band (3400 cm^{-1}), a weak band (3300 cm^{-1}), and two medium C=N bands (1640 and 1615 cm^{-1}) were observed (Fig. 2). In comparison with the NMR spectra between IV and V (Fig. 3), the chemical shift of the NH_2 proton of IV was observed at a slightly lower magnetic field than that of V.

IV and V afforded the 2-acylamino (IVa—c and Va—c) and 2-hydroxymethylamino (IVd and Vd) derivatives respectively, when treated with acid anhydrides and 37% formaldehyde respectively in the usual way. 2-Methylamino (Xa), 2-ethylamino (Xb), and 2-anilino-5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-1,3,4-thiadiazole (Xc) were prepared by the treatment of the corresponding 4-substituted 1-[3-(5-nitro-2-furyl)-2-(2-furyl)acryloyl]thiosemicarbazides (IIIa—c)[1] with phosphoryl chloride.

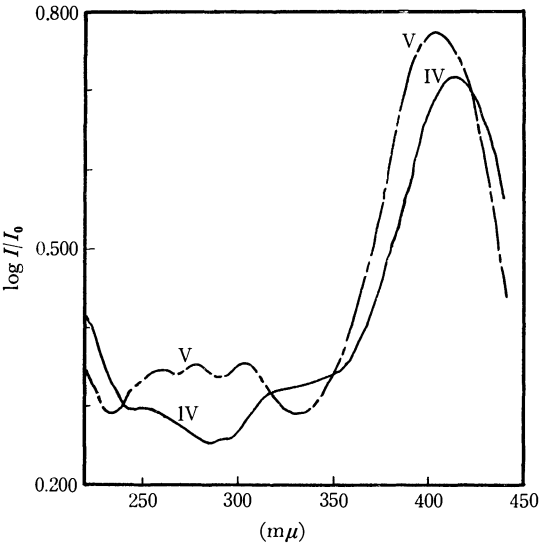

Fig. 1. UV spectra of IV and V (EtOH).

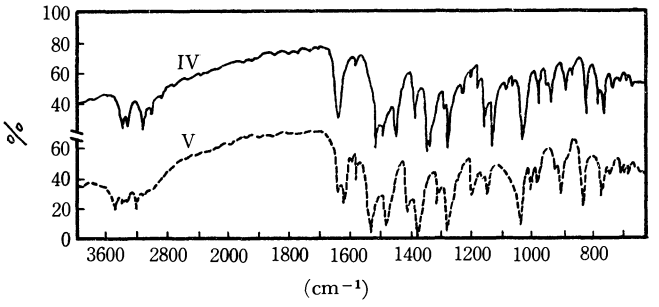

Fig. 2. IR spectra of IV and V (KBr).

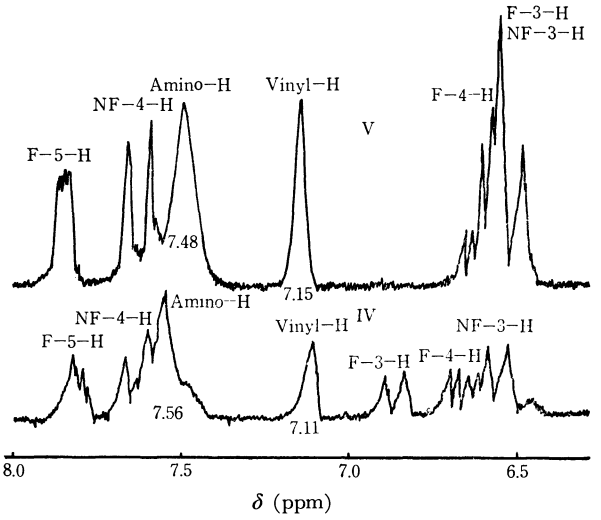

Fig. 3. NMR spectra of IV and V (DMSO-d_6).

F-5-H: C_5-H of furan ring

NF-4-H: C_4-H of 5-nitro-2-furan ring

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-oxadiazole (XI) was prepared according the method of a previous paper.[8b] Two monoacetyl derivatives, XIa and XIIa, were isolated on the treatment of XI with acetic anhydride in refluxing dioxane.

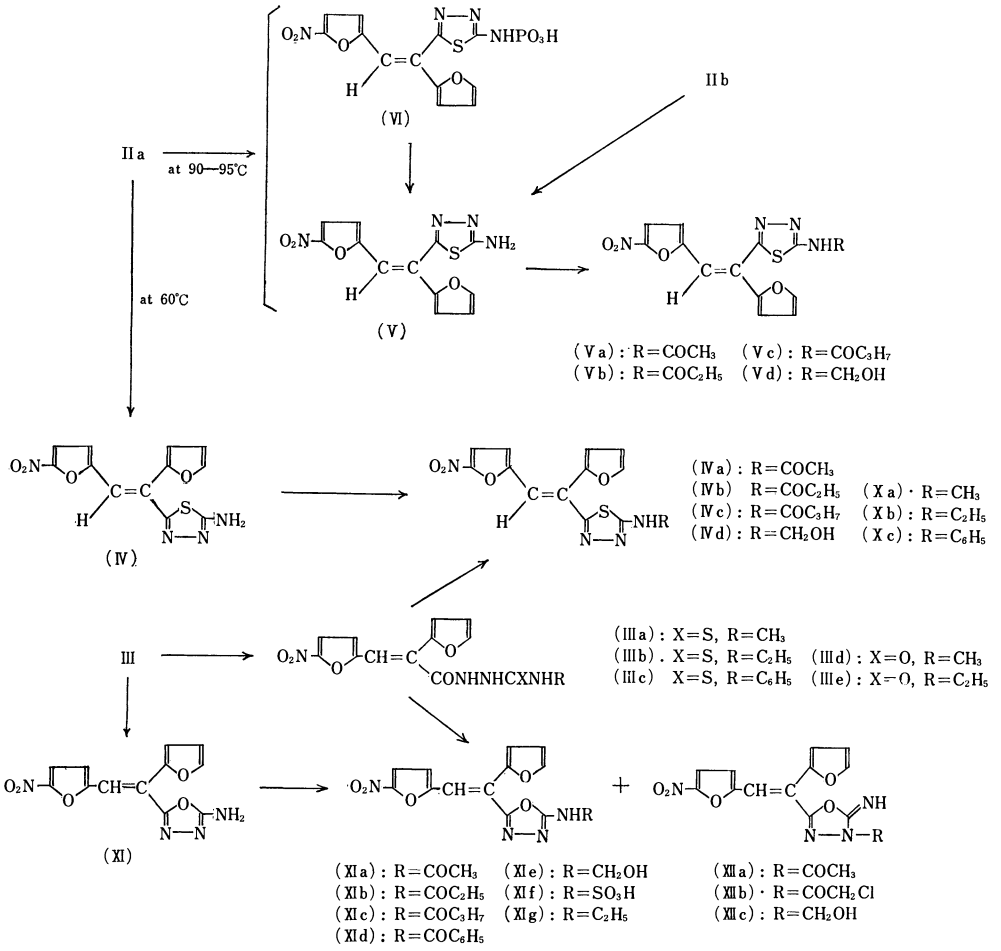

Chart 3

When XI was treated with boiling acetic anhydride without dioxane, XIIa was obtained as the main product. The compound XIa was a normal 2-acetylamino derivative, and the structure of XIIa was confirmed to be that of a ring acetyl compound, 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-3-acetyl-1,3,4-oxadiazol-2-imine, on the basis of the analytical and spectral data. In the IR spectra, both the C=O and C=N stretching frequencies of XIIa were moved, the former to higher frequencies, and the latter to lower, in the order of 20 cm^{-1} compared with those of XIa. A ring-acylated XIIa-type compound, 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-3-chloroacetyl-1,3,4-oxadiazol-2-imine (XIIb), was also produced by the reaction of XI with chloroacetic anhydride in a similar manner. By the reaction of XI with propionic and butyric anhydrides and benzoyl chloride, the corresponding 2-acylamino-type compounds, XIb, XIc, and XId respectively, were obtained. The hydroxymethylation of XI was carried out by treating it with 37% formaldehyde in *N*,*N*-dimethylformamide; this afforded two products, 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-2-hydroxymethylamino-1,3,4-oxadiazole (XIe) and 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-3-hydroxymethyl-1,3,4-oxadiazol-2-imine (XIIc).

When XI was treated with chlorosulfonic acid in refluxing ethyl acetate, 5-[2-(5-nitro-2-furyl)-1-(2-furyl)-vinyl]-2-hydrosulfoamino-1,3,4-oxadiazole (XIf) was obtained as its monohydrate. The IR spectrum had a strong absorption band at 1740 cm^{-1} due to the ring C=N stretching frequency, which was moved to abnormally higher frequencies by the interaction of a SO_3H group.

An attempt to prepare 2-substituted amino derivatives from the corresponding 4-substituted 1-[3-(5-nitro-2-furyl)-2-(2-furyl)acryloyl]semicarbazide (IIId, e) by the use of phosphoryl chloride was unsuccessful except for 2-ethylamino-5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-1,3,4-oxadiazole (XIg).

Microbiological Assays.[11] The antibacterial activities of the 5-nitrofuran compounds in response to ten microorganisms were examined (Table 3). The minimum amounts necessary for the complete inhibition of growth were determined by the dilution method, using the usual bouillon agar medium. As is shown in Table 3, *cis* and *trans* 5-[2-(5-nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole (V and IV) and -1,3,4-oxadiazole (XI) were found to exhibit strong antibacterial activity against most of the microorganisms employed. The antibacterial activity showed little difference between the *cis* and *trans* isomers of 1,3,4-thiadiazole and its 2-acylamino derivatives. 2-Hydroxymethylamino derivatives (Vd and

11) The author is indebted to Dr. R. Ueno and his staff of Ueno Pharmaceutical Company, Ltd., for the assay.

a) 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic amide was employed in the test.

XIe) still retain the high antibacterial activity of the mother compounds (V and XI). 3-Substituted 1,3,4-oxadiazol-2-imine-type compounds (XIIa and XIIc) slightly lowered the activity of XI. The substituted amino derivatives showed decreasing activity in the order: $R=CH_2OH \gg CH_3 \geq COCH_3 \approx C_2H_5 > COC_2H_5 > COC_3H_7$, SO_3H. This decreasing tendency of the activity is parallel with the increase in the carbon number of the substituent, R. These results suggest that the free amino group may be one of the dominant factors in antibacterial activity and that the long carbon chain blocks the reactivity of the amino group by steric hindrance.

Experimental

All the melting and decomposing points are uncorrected. Microanalyses were carried out with a Yanagimoto C. H. N. Corder, MT-2 type. The ultraviolet absorption spectra (UV) were recorded on a Shimadzu photoelectric spectrophotometer, Model QV-50. The infrared absorption spectra (IR) were obtained with a Shimadzu IR-27 S spectrophotometer. The nuclear magnetic resonance spectra (NMR) were determined by means of a Nihon-Denshi NMR spectrometer, JMN C-60HL (60 MHz). All the spectra were measured in dimethylsulfoxide, with tetramethylsilane as the internal standard; the peak positions were expressed in δ-values.

trans-*5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole (IV).* This product was prepared according to a procedure described before.[8a] Red needles (recrystallized from methanol); mp 169—170°C; decomposition. The yield was 55%. UV: λ_{max}^{EtOH} mμ(ε) 252sh(8652), 317sh (9284), 414(21104).

cis-*5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-thiadiazole (V) and Its 2-Phosphoric Amide Compound (VI). From 1-[3-(5-nitro-2-furyl)-2-(2-furyl)acryloyl]thiosemicarbazide (IIa):* A mixture of 16.1 g (50 mmol) of IIa[8a] and 50 ml of phosphoryl chloride was heated for 2 hr on a steam bath, cooled, and then poured onto ice with agitation. The solidified material was filtered off and washed with hot water. The crude product was purified by recrystallization from methanol to afford 5.75 g (37.8%) of yellow plates (V): mp 178—179°C dec. UV: λ_{max}^{EtOH} mμ(ε) 261(10126), 278(10617), 303(10757), 405(22750).

Found: C, 47.60; H, 2.90; N, 17.90%. Calcd for $C_{12}H_8N_4O_4S$: C, 47.36; H, 2.65; N, 18.41%.

A small amount of an oily substance was separated during the recrystallization of V; it solidified on standing and was crystallized from methanol to give 0.85 g (4.4%) of orange needles (VI), mp 160°C dec. Compound VI was easily converted to V by boiling it with water for several minutes. UV: λ_{max}^{EtOH} mμ(ε) 258(10754), 280(10934), 303(10756), 405(24272). IR: (KBr) cm^{-1} 3300(N–H), 1640(C=N). Qualitative analyses: Cl(−), S(+), and P(+).

Found: C, 37.16; H, 2.64; N, 14.19%. Calcd for $C_{12}H_8N_4O_7SP$: C, 37.50; H, 2.34; N, 14.60%.

From cis-*1-[3-(5-Nitro-2-furyl)-2-(2-furyl)acryloyl]thiosemicarbazide (IIb):* The method used here was virtually identical with that described for IV,[8a] but 9.8 g (30 mmol) of IIb were used instead of IIa; a 23% yield of V was obtained. Mp 178—179°C dec, undepressed upon admixture with a sample prepared by the above method.

Compound IIb was obtained by treating *cis* acid chloride

(mp 111—113°C dec) with thiosemicarbazide in dioxane according to a previously-established procedure;[8a] mp 179—180°C dec; yellow needles (methanol). The yield was 67.3%.

Found: C, 44.97; H, 3.61; N, 17.03%. Calcd for $C_{12}H_{10}N_4O_5S$: C, 44.72; H, 3.12; N, 17.39%.

trans-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-acetylamino-1,3,4-thiadiazole (IVa). Compound IV (0.9 g, 3 mmol) was covered with acetic anhydride (10 m*l*) and warmed on a steam bath for 1 hr. On cooling, the separated product was collected and washed with water, thus affording 1.0 g (99%) of orange-yellow needles; mp 231—234°C dec. Recrystallization from methanol raised the melting point to 239—239.5°C dec. IR: (KBr) cm^{-1} 1703(C=O).

Found: C, 48.65; H, 3.04; N, 16.20%. Calcd for $C_{14}H_{10}N_4O_5S$: C, 48.56; H, 2.91; N, 16.18%.

cis-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-acetylamino-1,3,4-thiadiazole (Va). A similar treatment of 0.9 g (3 mmol) of V instead of IV (0.9 g) afforded 0.93 g (94%) of Va; mp 241°C dec. Crystallization from methanol gave yellow needles; mp 243°C dec. IR: (KBr) cm^{-1} 1709(C=O).

Found: C, 48.48; H, 2.77; N, 15.92%. Calcd: same value as the IVa above.

trans-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-propionylamino-1,3,4-thiadiazole (IVb). This was prepared in the same way as was IVa, but using propionic anhydride (8 m*l*). In this way, 1.05 g (quantitative) of IVb were obtained; mp 244—245°C dec. Crystallization from 2-methoxyethanol gave orange needles; mp 248—249°C dec. IR: (KBr) cm^{-1} *ca.* 2920—2800(CH_3, CH_2), 1702(C=O).

Found: C, 50.13; H, 3.72; N, 15.57%. Calcd for $C_{15}H_{12}N_4O_5S$: C, 50.00; H, 3.53; N, 15.55%.

cis-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-propionylamino-1,3,4-thiadiazole (Vb). This was prepared by the method used for IVa, using 0.3 g (1 mmol) of V and 3 m*l* of propionic anhydride. Work-up as above afforded 0.29 g (84.2%) of Vb as orange needles; mp 230°C dec (from 2-methoxyethanol). IR: (KBr) cm^{-1} *ca.* 2900—2780(CH_3, CH_2), 1700(C=O).

Found: C, 49.87; H, 3.19; N, 15.14%. Calcd: same value as the IVb above.

trans-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-butyrylamino-1,3,4-thiadiazole (IVc). Yellow needles; mp 217.5—218°C dec (2-methoxyethanol). The yield was 91%. IR: (KBr) cm^{-1} *ca.* 2800(CH_3, CH_2), 1696(C=O).

Found: C, 51.56; H, 3.44; N, 14.66%. Calcd for $C_{16}H_{14}N_4O_5S$: C, 51.33; H, 3.77; N, 14.79%.

cis-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-butyrylamino-1,3,4-thiadiazole (Vc). Orange needles; mp 186°C dec (2-methoxyethanol). Yield: 72.5%. IR: (KBr) cm^{-1} *ca.* 2900(CH_3, CH_2), 1700(C=O).

Found: C, 51.24; H, 3.66; N, 15.35%. Calcd: same value as the IVc above.

trans-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-hydroxymethylamino-1,3,4-thiadiazole (IVd). A mixture of IV (0.3 g, 1 mmol) and 37% formaldehyde (3 m*l*) was warmed at 60°C for 1 hr. After cooling, 6 m*l* of water were added. The solidified product was collected and washed with water, ether, and ethanol successively. The product was obtained as an orange powder, mp 121°C dec., weighing 0.27 g (80.5 %). Recrystallization was unsuccessful because of the instability.

Found: C, 46.31; H, 2.57; N, 16.91%. Calcd for $C_{13}H_{10}N_4O_5S$: C, 46.70; H, 2.99; N, 16.80%.

cis-5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-hydroxymethylamino-1,3,4-thiadiazole (Vd). A similar treatment of V instead of IV afforded 0.23 g (72.1%) of an orange powder, Vd; mp 168°C dec.

Found: C, 46.49; H, 3.03; N, 16.77%. Calcd: same value as the IVd above.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-methylamino-1,3,4-thiadiazole (Xa). 4-Methyl-1-[3-(5-nitro-2-furyl)-2-(2-furyl)acryloyl]thiosemicarbazide (IIIa)[1] (1.8 g, 5.4 mmol) and phosphoryl chloride (10 m*l*) were heated together under reflux for 2 hr. After cooling, the mixture was poured onto crushed ice, and the precipitate was filtered, washed with water, and extracted with hot ether (*ca.* 4 *l*). On the concentration of the extracts, a red-colored residue was obtained; mp 120—155°C; 0.7 g. Recrystallization from benzene gave red prisms; mp 179—180°C dec. The yield was 0.31 g (18%).

Found: C, 49.41; H, 3.17; N, 17.92%. Calcd for $C_{13}H_{10}N_4O_4S$: C, 49.06; H, 3.14; N, 17.61%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-ethylamino-1,3,4-thiadiazole (Xb). This was prepared in a way similar to that used for Xa above, using IIIb ($R=C_2H_5$)[1] (2 g, 5.7 mmol) and phosphoryl chloride (5 m*l*). Red prisms; mp 171°C (benzene). Yield, 26%.

Found: C, 51.06; H, 3.57; N, 16.33%. Calcd for $C_{14}H_{12}N_4O_4S$: C, 50.60; H, 3.61; N, 16.87%.

5-[2-(Nitro-2-furyl)-1-(2-furyl)vinyl]-2-anilino-1,3,4-thiadiazole (Xc). A mixture of 1.5 g (20 mmol) of acetyl chloride and IIIc ($R=C_6H_5$) (2 g, 5 mmol) was heated at 45—55°C for 20 min, and then it was poured into water. Cooling gave a crude product; mp 168—178°C dec. Crystallization from benzene provided 0.45 g (23.7%) of red crystals; mp 209.5—211°C dec.

Found: C, 55.74; H, 3.17; N, 14.45%. Calcd for $C_{18}H_{12}N_4O_4S$: C, 55.68; H, 3.16; N, 14.74%.

Compound IIIc was obtained as follows: the hydrazide III[6d] (5.2 g, 20 mmol) and phenyl isothiocyanate (3.24 g, 24 mmol) were heated under reflux in 100 m*l* of methanol for 1.5 hr. Cooling provided 6.34 g (79.7%) of the product, IIIc; mp 163—164°C dec. Recrystallization from ethanol gave orange-yellow prisms; mp 166—167°C dec.

Found: C, 54.10; H, 3.69; N, 14.38%. Calcd for $C_{18}H_{14}N_4O_5S$: C, 54.27; H, 3.52; N, 14.07%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-amino-1,3,4-oxadiazole (XI). This was obtained according to a procedure previously described.[8b] Deep red needles; mp 224—225°C dec (dioxane). Yield, 90%. The product, XI, was shown to be the same by a study of its IR spectrum and by its failure to depress the melting point when mixed with an authentic sample. UV: λ_{max}^{EtOH} mμ(ε) 246(12733), 407(25933). IR: (KBr) cm^{-1} 3420 and 3280(NH_2), 1655(C=N).

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-acetylamino-1,3,4-oxadiazole (XIa) and 5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]3-acetyl-1,3,4-oxadiazol-2-imine (XIIa). A solution of 4.32 g (15 mmol) of XI and 2.04 g (20 mmol) of acetic anhydride in 200 m*l* of dioxane was heated under reflux for 5 hr. The solvents and the excess acid anhydride were then removed under reduced pressure. The residual crude product was purified by recrystallization from methanol to give a mixture (XIa and XIIa) as light orange-small needles, mp 218—219°C dec, weighing 4.9 g (almost quantitative). IR: (KBr) cm^{-1} 3240(N–H), 1735—1730(C=O), 1660 sh and 1640 (C=N).

Found: C, 51.37; H, 3.10; N, 17.00%. Calcd for $C_{14}H_{10}N_4O_6$(XIa and XIIa): C, 50.91; H, 3.03; N, 16.98%.

This mixture was extracted with 100 m*l* of hot benzene. On the cooling of the benzene extracts, the precipitates were filtered and then they were combined with the solid residue. Two recrystallizations from toluene afforded the pure material of XIa as light brown prisms, mp 189—190°C dec., weighing 0.3 g (6%). The benzene filtrate was taken to dryness under

reduced pressure. The residue and 200 ml of toluene were boiled, filtered, and then recrystallized from 2-methoxyethanol and then from dioxane to give XIIa as orange needles; mp 233—234°C dec. The yield was 0.54 g (11%). IR: (KBr) cm^{-1} XIa; 3240(N–H), 1720(C=O), 1660(C=N). XIIa; 3240(N–H), 1740(C=O), 1640(C=N).

Found: XIa; C, 51.14; H, 3.19; N, 17.11%. XIIa: C, 51.06; H, 2.94; N, 16.99%. Calcd for $C_{14}H_{10}N_4O_6$: C, 50.91; H, 3.03; N, 16.89%.

The 3-acetyl derivative, XIIa, was obtained by the following procedure. Compound XI (4.32 g, 15 mmol) was covered with acetic anhydride (6—10 ml) and heated under a reflux for 10 min. Cooling provided 2.92 g (59.1%) of the product; mp 221—223°C dec. Subsequent crystallization from dioxane gave orange needles; mp 233—234°C dec. The melting point of this product was not depressed by admixture with the sample of XIIa described above. From the mother filtrate small amounts of XIa and XIIa were obtained.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-3-chloroacetyl-1,3,4-oxadiazol-2-imine (XIIb). The procedure outlined above for XIa was followed using chloroacetic anhydride (3.4 g, 20 mmol). The product was obtained as fine yellow crystals; mp 213—214°C dec (dioxane). Yield: 4.74 g (86.8%). IR: (KBr) cm^{-1} 3240(N–H), 1749(C=O), 1640(C=N).

Found: C, 44.51; H, 2.38; N. 15.57%. Calcd for $C_{14}H_9N_4O_6Cl$: C, 44.26; H, 2.55; N, 15.89%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-propionylamino-1,3,4-oxadiazole (XIb). A mixture of 1.44 g (5 mmol) of XI and 30 ml of propionic anhydride was heated at 95—100°C for 2 hr. The excess acid anhydride was removed *in vacuo*, and the residue was washed with water to afford a yellow powder, mp 215—217°C dec, weighing 1.74 g (quantitative). Subsequent recrystallization from methanol gave yellow needles; 216—217°C dec. IR: (KBr) cm^{-1} 2900(CH_2), 1725(C=O), 1630(C=N).

Found: C, 52.33; H, 3.53; N, 16.45%. Calcd for $C_{15}H_{12}N_4O_6$: C, 52.33; H, 3.49; N, 16.28%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-butyrylamino-1,3,4-oxadiazole (XIc). The procedure described above for XIb was employed using butyric anhydride (0.87 g, 5.5 mmol) in 50 ml of dioxane. A work-up as above afforded 1.1 g (58.5%) of ochreous needles; mp 177—178°C dec (dichloroethane). IR: (KBr) cm^{-1} 2900(CH_2), 1725(C=O), 1630(C=N).

Found: C, 53.60; H, 4.09; N, 15.45%. Calcd for $C_{16}H_{14}N_4O_6$: C, 53.63; H, 3.93; N, 15.64%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-benzoylamino-1,3,4-oxadiazole (XId). The procedure outlined above for XIb was followed using benzoyl chloride (1.06 g, 7.5 mmol) in 50 ml of dioxane. Ochre-colored needles; mp 218—219°C dec (methanol). Yield: 1.1 g (69.4%).

Found: C, 57.86; H, 3.18; N, 14.16%. Calcd for $C_{19}H_{12}N_4O_6$: C, 58.16; H, 3.06; N, 14.29%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl]-2-hydroxymethylamino-1,3,4-oxadiazole (XIe) and 5-[2-(5-Nitro-2-furyl)-1-(2-furyl)-vinyl]-3-hydroxymethyl-1,3,4-oxadiazol-2-imine (XIIc). A mixture of XI (1.44 g, 5 mmol), 37% formaldehyde (0.75 g, 9.3 mmol), and 50 ml of *N,N*-dimethylformamide was heated at 60°C for 2 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with ether and methanol. Subsequent reprecipitation from methyl acetate-ether gave 0.21 g of a dark yellow powder XIIc; mp 148—152°C dec. Repeated similar treatment raised the melting point to 163—165°C dec. Yield: 0.12 g (7.6%). On the concentration of the mother methyl acetate - ether filtrate, the product was separated as a dark brown powder, mp 128—130°C, weighing 0.39 g (24.6%). Reprecipitation from methyl acetate - ether brought the melting point to 134—135°C; orange powder; XIe.

Found: XIe; C, 49.50; H, 3.00; N, 17.93%. XIIc; C, 49.36; H, 2.89; N, 17.72%. Calcd for $C_{13}H_{10}N_4O_6$: C, 49.06; H, 3.17; N, 17.61%.

5-[2-(5-Nitro-2-furyl)-1-(2-furylvinyl]-2-hydrosulfoamino-1,3,4-oxadiazole (XIf). To a stirred, ice-cooled suspension of XI (1.44 g, 5 mmol) in 50 ml of ethyl acetate, we added, drop by drop, a solution of chlorosulfonic acid (10 ml) in 50 ml of ethyl acetate. After the addition, the suspension was heated under reflux for 5 hr and cooled, and the product was collected by filtration; the product was then washed with cold ethyl acetate and crystallized from methanol to give 0.42 g (22.4%) of XIf as yellow needles; mp 190°C (darkened) (depressed to 160—163°C on admixture with the sulfate of XI of mp 174—175°C dec). IR: (KBr) cm^{-1} 1740(C=N), 1205 and 1042(SO_2), 640(S–O).

Found: C, 37.29; H, 2.68; N, 14.01%. Calcd for $C_{12}H_8N_4O_8S \cdot H_2O$: C, 37.31; H, 2.59; N, 14.51%.

5-[2-(5-Nitro-2-furyl)-1-(2-furyl)vinyl-2-ethylamino-1,3,4-oxadiazole (XIg).[1] A suspension of 4-ethyl-1-[3-(5-nitro-2-furyl)-2-(2-furyl)acryloyl]semicarbazide (IIIe) (0.67 g, 2 mmol) in phosphoryl chloride (30 ml) was heated gently at 70°C for 4 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was dissolved in 200 ml of ethanol. On cooling, orange needles precipitated; mp 194—195°C dec; weight, 0.53 g (84.1%).

Found: C, 53.11; H, 3.95; N, 17.70%. Calcd for $C_{14}H_{12}N_4O_5$: C, 53.16; H, 3.95; N, 17.72%.

Compounds IIIe and IIId were prepared as follows: the hydrazide III (2.63 g, 10 mmol) and ethyl (or methyl) isocyanate (10 mmol) were heated together at 60—65°C in 50 ml of ethanol (100 ml of methanol) for 2 hr. Cooling provided a crude product, and then recrystallization was carried out. IIIe; yellow needles (ethanol); mp 157—158°C dec. Yield: 2.4 g.

Found: C, 50.44; H, 4.08; N, 16.57%. Calcd for $C_{14}H_{14}N_4O_6$: C, 50.29; H, 4.19; N, 16.76%. IIId (R=CH_3); yellow needles (methanol); mp 161.5—162°C dec. Yield: 2.1g.

Found: C, 48.68; H, 3.59; N, 17.32%. Calcd for $C_{13}H_{12}N_4O_6$: C, 48.75; H, 3.75; N, 17.50%.

Isomerization of 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic Acid and Its Esters with Hydrazine Hydrate. A mixture of 10 mmol of *trans* acid (or esters) and 80% hydrazine hydrate in 100 ml of methanol was stirred under the reaction conditions indicated in Table 1. The resulting mixture was neutralized with concentrated hydrochloric acid and then taken to dryness *in vacuo*. The residue was washed with cold water to afford a crude reaction mixture. Fractional crystallization from methanol gave pure isomers; the yields are shown in Table 1.

cis *Acid (Ib)*: yellow needles (50% aqueous methanol); mp 183—184°C dec. Found: C, 52.98; H, 3.26; N, 5.44%. Calcd for $C_{11}H_7NO_6$: C, 53.01; H, 2.83; N, 5.62%.

cis *Benzyl Ester (VIIIb)*: yellow-ochre plates (aq. methanol), mp 109—110°C. Found: C, 64.05; H, 3.84; N, 4.02%. Calcd for $C_{18}H_{13}NO_6$: C, 63.72; H, 3.86; N, 4.13%.

The *cis* acid and its esters were not converted to *trans* isomers under the same reaction conditions.

Another isomerization reaction of each *trans* (or *cis*) acid and its esters was carried out in the presence of hydrochloric acid (1/20 fold mol) in refluxing methanol. No isomerization of these *trans* and *cis* isomers was observed.

Preparation of Esters of 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylic Acid. From Chloride: The esters were prepared in a way similar to that described by Saikachi and Tanaka[7] for

the preparation of the *trans* ethyl ester (IXa). Crystallization from aqueous methanol gave pure esters. Yield: 40—75%.

From Sodium Salt: To a warmed (45°C), stirred suspension of acid (10 mmol), alkyl halide (13 mmol) in 100 m*l* of ethanol, we added, drop by drop, a solution of sodium (10 mg atom) in ethanol (50 m*l*). Then the mixture was heated under reflux for 2 hr. On the concentration of the solution, the product separated along with an inorganic salt was washed with water and subsequently dried. Work-up as above afforded pure esters. Yield: 70—90%.

trans Benzyl ester (VIIIa); orange prisms (aq. methanol); mp 99—100°C. Found: C, 63.78; H, 4.01; N, 4.16%. Calcd for $C_{18}H_{13}NO_6$: C, 63.72; H, 3.86; N, 4.13%. *cis* Ethyl ester (IXb); orange-yellow plates (aq. methanol); mp 152—153°C. Found: C, 56.40; H, 4.01; N, 5.08%. Calcd for $C_{13}H_{11}NO_6$: C, 56.32; H, 3.97; N, 5.05%.

The author wishes to thank Dr. I. Hirao, Professor of Kyushu Institute of Technology, for his many helpful discussions and suggestions.

(Received July 8, 1970)

The resolutions of 6,6′-dihydroxy-3,3,5,3′,3′,5′-hexamethyl-bis-1,1′-spiroindane (IIIa), 3,3,3′,3′-tetramethyl-bis-1,1′-spiroindane-6,6′-dicarboxylic acid (IIIc), and 5,5′-dihydroxy-bis-1,1′-spiroindane (VIII) are reported. The circular dichroism and absorption spectra of these optically active compounds and their derivatives were measured. The spectra were analysed by means of a coupled oscillator model. The relative frequencies and signs of the rotational strengths associated with the *p*-band transition calculated for the (S)-configuration of 6,6′-disubstituted-bis-1,1′-spiroindanes agree with the positions and signs of the CD bands observed for the compounds derived from (−)-IIIc, establishing the absolute configuration of this series. The result was confirmed by the X-ray diffraction study of (−)-7,7′-dibromo-derivatives prepared from (+)-IIIa. It was found that these spiro compounds having the (S)-configuration showed a negative CD band in the longest wavelength region, except for the case in which the effect of the charge transfer between two aromatic chromophores overwhelmed that of the dipole-dipole interaction.

It is well known that, in the chiral molecules with the same two ligands at the tetragonal central atom, $X(A_2B_2)$, there are two types of structures, spiro types I and II[1] (Fig. 1). Several molecules of these types have already been resolved[2] and the absolute configuration of some of them has been determined by chemical methods.[3] It is interesting to study the relations between the structure and the CD spectrum of the molecule having C_2 symmetry like spiro type II bearing the aromatic chromophore at positions A or B, from the standpoint of the determination of the absolute configuration and the origin of the optical rotatory power.

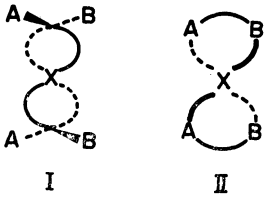

Fig. 1. Chiral molecules of the spiro type.

Curtis and his coworker[4] proved that Barnes's tetrahydroindenoindane derivatives, which were obtained from the reaction of 4-methyl-4-phenylpentane-2-one with acid,[5] had the structures of 3,3,3′,3′-tetramethyl-bis-1,1′-spiroindane. Later the mechanisms of the above reaction were proposed by others.[6] Other bis-1,1′-spiroindane derivatives have also been prepared by Baker and his coworkers and other group[7] by the reaction of phenols and acetone in the presence of acid.

These compounds have rigidly fixed conformation and it is interesting to investigate the spectrum arising from an interaction of the transition dipoles of the same two aromatic chromophores.

We wish to report the resolution and CD spectrum of this type of compound and the theoretical assignments of absolute configurations on some of them.

Resolution of 6,6'-dihydroxy-3,3,5,3',3',5'-hexamethyl-bis-1,1'-spiroindane, IIIa, which was prepared according to the direction of Baker and Besly,[7] was accomplished after a number of experiments[8] by using (+)-phenethylisocyanate.[9] The optically pure (−)-urethane, $[\alpha]_D$ −8.6° ($CHCl_3$), obtained by fractional recrystallization, was hydrolysed with KOH-EtOH (10%) to give (+)-IIIa, $[\alpha]_D$ +19.4° (dioxane), from which (−)-IIIb, $[\alpha]_D$ −108.9° (dioxane), was prepared by the action of bromine in chloroform.

Meanwhile, (−)-isomer of 6,6'-dicarboxylic acid derivative IIIc, $[\alpha]_D$ −93.7° (dioxane), was obtained by the decomposition of (−)-dibrucine salt, $[\alpha]_D$ −91.6° (MeOH), and also another antipode, (+)-IIIc, $[\alpha]_D$ +94.2° (dioxane), was prepared by the decomposition of (+)-monobrucine salt, $[\alpha]_D$ +76.1° (MeOH).

Optically active diamino derivative, (−)-IIIh, $[\alpha]_D$ −144.1° (MeOH), diacetoxy derivative, (−)-IIIj, $[\alpha]_{365}$ −301° (isooctane) and dihydroxy derivative, (−)-IIIk, $[\alpha]_{365}$ −254° (MeOH) were prepared from (−)-IIIc, and also non-substituted deriv-

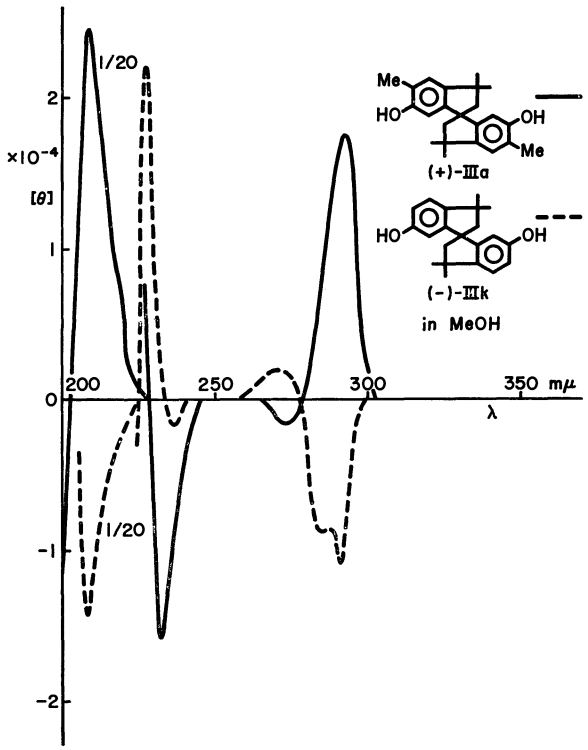

Fig. 2. CD spectra of (+)-IIIa and (−)-IIIk in methanol.

8) All attempts to resolve IIIa employing (+)-10-camphorsulfonic acid chloride, (−)-menthoxyacetic acid chloride and, (+)-α-phenchocomphorone-1-isocyanate failed.

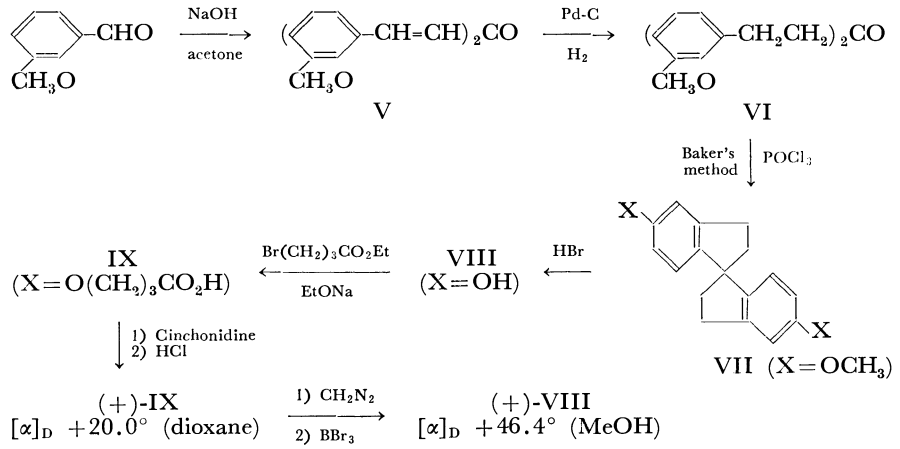

Chart 2

ative, (−)-IIIl, $[\alpha]_D$ −25.9° (dioxane) from (+)-IIIc, according to procedures similar to those used in the racemic ones described in literature.[4] We also obtained di-acid chloride, (−)-IIIf, $[\alpha]_D$ −174.7° (isooctane), and diazide, (−)-IIIg, $[\alpha]_D$ −246.3° (isooctane), stepwisely by applying the Curtius reaction to (−)-IIIc. Dicarbinol, (−)-IIIm, $[\alpha]_D$ −61.8° (MeOH), was prepared by the reduction with $LiAlH_4$ of diester, (−)-IIIe, $[\alpha]_D$ −124.2° (*n*-hexane), which was obtained by the esterification of (−)-IIIc with diazomethane. Configurational correlation among these compounds is shown in Chart 1. In connection with these 6,6′-disubstituted spiroindanes, optically active 5,5′-dihydroxy derivative IX was synthesized by the route described in Chart 2.

Comparing IIIa with IIIk, the aromatic chromophore can be regarded as the same from the viewpoint an electronic transition because the methyl group gives little perturbation effects to phenol chromophore. Thus, we considered that if optically active IIIa and IIIk had the same absolute configuration, these two derivatives would give almost the same Cotton effects. In fact, the CD spectrum of (+)-IIIa appears almost opposite to that of (−)-IIIk as shown in Fig. 2. An empirical rule can be obtained from Chart 1 and Table 1, that the compounds, (−)-IIIc—(−)-IIIm, including non-substituted spirane, (+)-IIIl, show negatively signed CD in the longest wave length [It should be noted that (−)-IIIl was derived from (+)-IIIc and hence (+)-IIIl must be correlated to the same configuration as (−)-IIIc. But even in this case, the above empirical rule was found to be valid.]. (+)-IIIa shows positively signed CD in the longest wave length. From the above observations, it was decided that the absolute configuration of (+)-IIIa and (−)-IIIb is opposite to that of the other derivatives, (−)-IIIc—(−)-IIIm, cited in Table 1.

The CD and UV spectra of these derivatives are shown in Table 1. Accessible CD spectra of these compounds consist of three bands which are termed α, p and β, from the longer wavelength according to the classification of Clar. From this Table it seems that the intensity and the polarization direction of the electronic transition or each aromatic chromophore

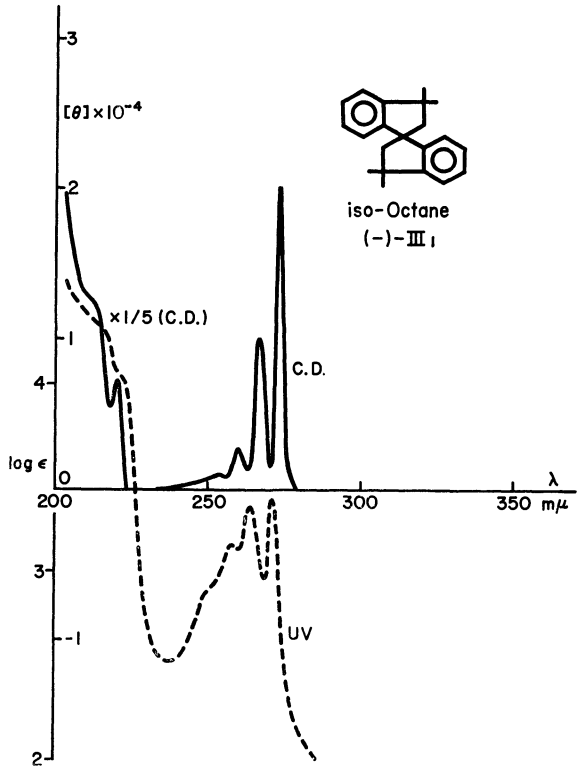

Fig. 3. CD and UV spectra of (−)-IIIl in isooctane.

have direct influence on CD spectra. For polysubstituted benzenes, a quantity called the spectroscopic monent has been assigned to each group by Platt.[10] Employing the spectroscopic moment, the absorption intensities and the transition moment directions may be calculated by the vector addition formula. The spectroscopic moment is considered to be useful for interpreting the CD of these derivatives. Following the value of the spectroscopic moment and the origin of the Cotton effect, we divided the derivatives into classes, I, II, III, and IV.

In class I, the substituent groups at the position 6

and 6′ of III influence the absorption spectrum of benzene to a lesser extent. (−)-IIIi, (−)-IIIl and (−)-IIIm belong to this class. They have very sharp Cotton effects in all transitions. In α-band, the Cotton effects attributable to the vibrational transition are all of negative sign, but in p-band, two oppositely signed Cotton effects are observed except for (−)-IIIl. In (−)-IIIl as shown in Fig. 3, the sign of all Cotton effects in the region accessible with the apparatus (205 mμ), is positive, but that of specific rotation at D-line is negative, from which it is deduced that there are very strong negatively signed Cotton effects in far-UV region.

In class II, the substituents have a comparatively large value in Platt's spectroscopic moment. In this class, (+)-IIIa, (−)-IIIc—g, and (−)-IIIj—k are included and the CD spectra seem to split into oppositely signed pair centered at each absorption region. That is, (−)-IIIk has the oppositely signed pair of Cotton effects centered at α- and p-bands, as shown in Fig. 2, although the rotational strengths are not the same. IIIa with the opposite absolute configuration gives negative and positive CD bands at longer and shorter wavelengths, respectively, in the region of the p-band.

A more typical example is observed in (−)-IIIc and (−)-IIIe (as shown in Fig. 4 on (−)-IIIc). Their Cotton effects in p-band are oppositely signed and almost similar in rotational strength, although in α-band they are not the same in magnitude.

(−)-IIIc was measured in a number of solvents but no remarkable solvent effect was observed. Moreover, the CD spectrum of (−)-IIId is similar to that of (−)-IIIc except for a small positively signed Cotton

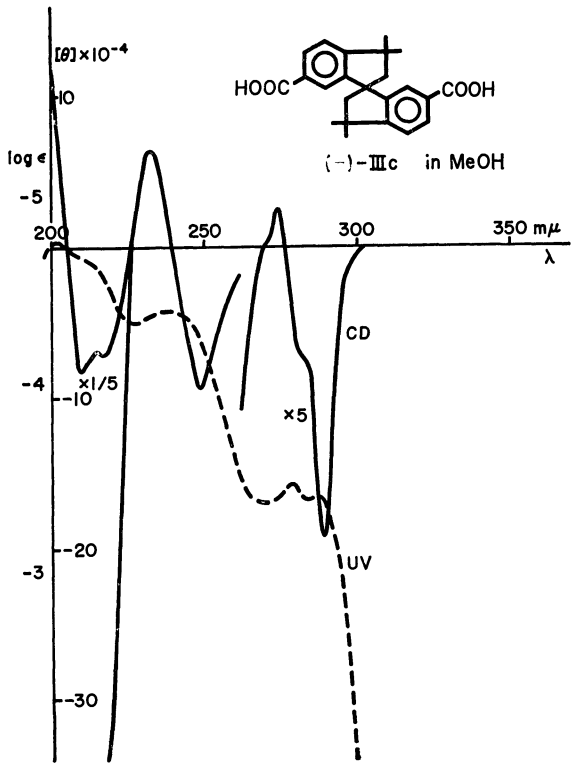

Fig. 4. CD and UV spectra of (−)-IIIc in methanol.

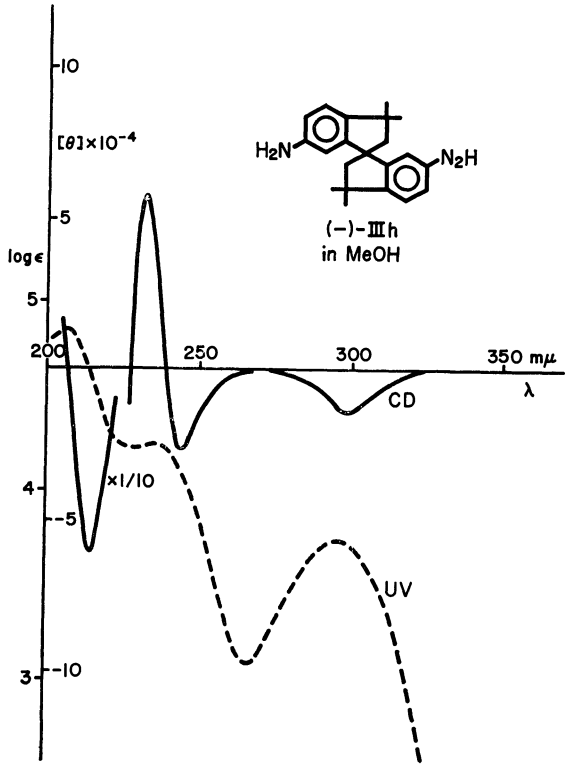

Fig. 5. CD and UV spectra of (−)-IIIh in methanol.

effect observed in α-band of (−)-IIIc.[11] (−)-IIIf and (−)-IIIg show the shift to a higher wavelength, but the curve is similar to that of (−)-IIId. From the similarlity in CD of the derivatives with COX group, it can be said that the polarization direction of the transition in the benzoyl chromophore is not affected so much, even if the group X is changed.

In class III, the substituent group interacts very strongly with the benzene ring. (−)-IIIh alone is contained in this class. Its spectrum (shown in Fig. 5) is also a typical example of splitting, as Mason and his coworkers[12] have pointed out in two-fold rotation axis molecules with aniline chromophore. But the α-band shows only negatively signed Cotton effect.

In class IV, the splitting of the CD band could not be observed, as shown in Fig. 6. (−)-IIIb is the only one example. In this molecule the bromo substituent of one aromatic chromophore is placed just over the other within the region where the exchange integral has a large value, as shown in X-ray crystallography.[13] Therefore one aromatic chromophore interacts with the other owing rather to the exchange force than the dipole-dipole interaction.

In these dissymmetrically situated dimers of aromatic chromophore, a given monomer excitation is doubly

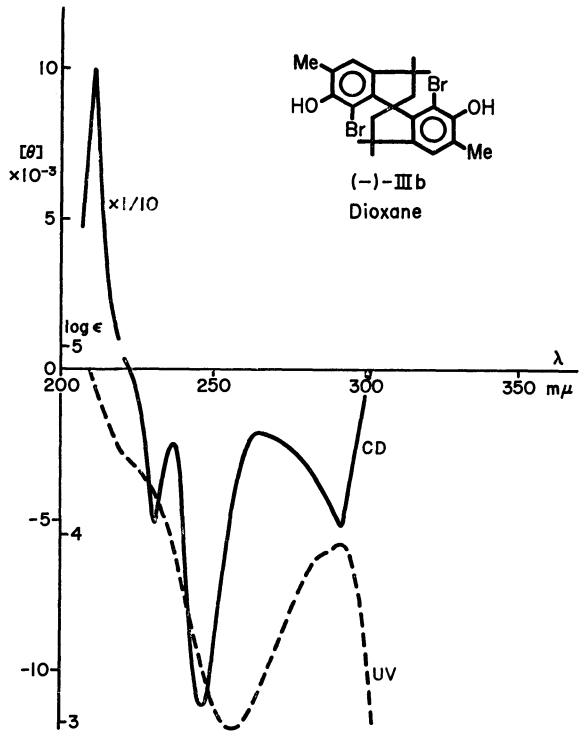

Fig. 6. CD and UV spectra of (−)-IIIb in dioxane.

degenerated to a zero-order, but dipole-dipole interaction between the two excitation monents splits the degeneracy and gives two optically active resultant transitions, one with A and the other with B symmetry in the point group C_2.[12,14]

11) We found that CD spectra of 11 (*endo*), 12 (*endo*)-dicarbomethoxy-9,10-dihydro-9,10-ethanoanthracene-1,5-dicarboxylic acid and its sodium salt show a remarkable difference at around 230 mμ. The details will be reported in the near future.

14) J. G. Kirkwood, *J. Chem. Phys.*, **5**, 479 (1937).

From the assumption that an excitation moment of the benzenoid chromophore is a point dipole located at the center of the benzene ring, the rotational strengths R of the two transitions are given by

$$R_A = -R_B = \pi\bar{\nu}d\rho^3 \cos v \cos t \quad (1)$$

and the separation $\Delta\bar{\nu}$ between the two resultant transition frequencies by

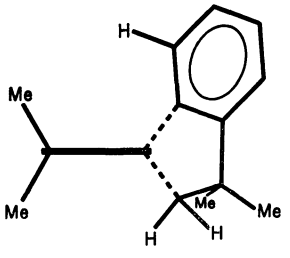
$$\Delta\bar{\nu} = \bar{\nu}_A - \bar{\nu}_B = 2\rho^2(\cos^2 v - \cos^2 t + 2\cos^2 r)/hcd^3 \quad (2)$$

In these expressions ρ is the transition dipole moment of the transition in the isolated chromophore which occurs at a wave number frequency of $\bar{\nu}$ and d is the distance between the centres of the two benzene rings. Each of the two excitation dipoles ρ have components directed parallel to the Cartesian axes of the dimeric system, and the magnitudes of the components are determined by the cosines of the vertical, tangential and radial angles, v, t, and r, respectively, between the excitation dipole and the local Cartesian axes, in which the x-axis is definied by the line joining the centres of the two benzene rings and z is the C_2 symmetry axis.

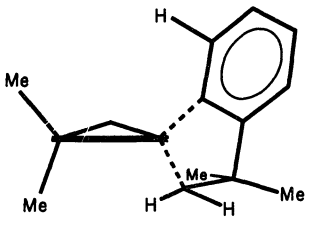
The stereochemical parameters d, v, t, and r necessary for the calculation of rotational strengths and the frequency intervals between the transitions depend upon the orientation of the excitation dipole within the benzenoid chromophore as well as the mutual stereochemical disposition of the two chromophores.

In the present case the values of the spectroscopic moments listed by Platt and an other[10] are applicable and the direction of the transition moment of each monomer is obtained by the vector addition of the spectroscopic moments induced by each substituent. The alkyl bridge which makes up the spiro skeleton is also regarded as a substituent and the value of t-butyl group was adopted. However, NH_2 group interacts so strongly with benzene that we neglected the effect of the alkyl bridge in (−)-IIIh and used the direction of the α- and p-bands of aniline. In other cases the following values were used for calculation: COOH(−28); OH(34); t-butyl(2); CH_2OH (−7); methyl(7).

Values of the parameters, d, v, t, and r are determined not only by the transition moment directions in the benzenoid chromophore but also by the spatial relations between the two chromophores. The stereochemical parameters have unique values in the rigid dimeric systems, but they have a range of values in the case of spiro indanes, owing to the conformational lability of the molecule. Models indicate that the extreme forms of the five membered ring in indanes are the planar (IVa) and the envelope conformation (IVb), in which the carbon atom at position 2 is moved out of the plane of the other four carbon atoms by 0.285 Å and the carbon atom at the position 2' is quasi-axial.



IVa



IVb

It has been reported[15] that the puckering of the cyclopentene ring having an atom out of the plane by an amount up to about 0.3 Å gave no change on the potential energy of the system. If we consider the 1,3-di-quasiaxial interactions between one of the gem-dimethyl group at position 3 and the methylene group at position 2', the planar conformation (IVa) would be probably more stable. In the cases of (−)-IIIh and (−)-IIIl (Table 2), the qualitative forms of the theoretical CD spectra depend only upon the configuration and are independent of the conformation. Therefore, the sets of stereochemical parameters, v, t, and r for the planar conformation of (S)-configuration are calculated from the coordinates provided by the X-ray diffraction study of 5,6-dibromoindane,[16] and are listed in Table 2. The theoretical and experimental results indicate that for (−)-IIIl and (+)-IIIm which belong to Class I, the absolute configurations can not be predicted. The following may be one of the main reaons. We approximated the alkyl bridge to the t-butyl group, but as the value of the spectroscopic moment of the substituent at positions 6 and 6' is small, the small change is value of position 1 should exert great influence on the direction of the excitation moment. Therefore the sign of rotational strength and/or the separation of frequencies might be changed.

An amino group interacts so strongly with the benzene ring that the contribution of other substituents can be neglected as compared to that of the amino group. Therefore, the direction of the transition dipole moment in the isolated chromophore of (−)-IIIh is independent of the change in the value of the spectroscopic moment of other substituents. In the case of (−)-IIIh, the calculated rotational strengths and separation indicate that the signs of the two CD bands associated with the p-band should be negative and then positive, from longer to shorter wavelength for (S)-configuration (Table 2). Although the CD in the α-band region shows only a negative sign, the observed CD bands in the region of the absorption maximum at 236 mμ lie clearly in the expected order (Fig. 5). Thus it is deduced that (−)-IIIh has (S)-configuration. The consistency between the calculated and experimental signs of the rotational strengths associated with the p-band for the derivatives in class II supports the assignment of (S)-configuration to the compounds derived from (−)-IIIc.

In class II and III the theoretical CD spectra for (S)-configuration lie in the order positive and then negative to lower wavelength in the region of the α-band, but the sequence of signs of the observed CD bands is opposite except in (−)-IIIh which shows only negative CD spectrum.

* Envelope conformation. E: enantiomer is measured.
Theoretical values were obtained from equations 1 and 2.

The ambiguity of the assignment of the absolute configuration due to the inconsistency between the theoretical and the experimental CD spectra in the α-band is avoided by the X-ray analysis of (−)-7,7′-dibromo-6,6′-dihydroxy-derivative, (−)-IIIb, which has the (R)-configuration. Thus, the inconsistency in α-band comes from the use of the point dipole approximation and the neglect of configurational interaction between transitions of the same symmetry. But even if the exciton theory cannot explain the CD in α-bands satisfactorily, it should be noted that all these spiro compounds having (S)-configuration except for class IV show the CD of negative sign in the longest wavelength. This means that the sign of the CD in the longest wavelength region is always determined by the configuration of spiro atom, *i.e.* the spatial arrangement of the two benzene rings.

In relation to the above consideration, it was observed that the CD of 5,5′-dihydroxyspiroindane, (+)-VIII, is similar to that of the corresponding 6,6′-derivatives, particularly in the region of α-band. The sign of the CD band was, from the longest wavelength to shorter, positive and negative in α-band, and negative in p-band (Fig. 7). From the feature of the CD curve (+)-VIII is considered to have (R)-configuration.

Applying the exciton theory to (R)-VIII, the calculated value of the CD should have the sign in the order negative and positive both in α-band and in p-band. This is contrary to the observed result. But the sign of the CD band in α-band may be reversed by a small change in the value of the parameters as in the case of spiroindane (−)-IIIl where the width of the splitting is small (−31 cm^{-1}).

The fact that the observed rotational strength in the p-band is greater than that calculated from exciton

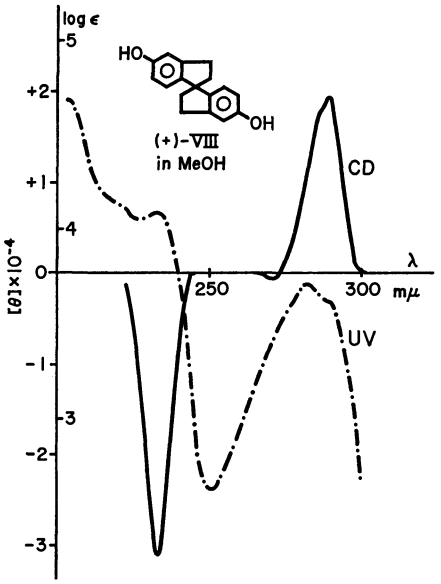

Fig. 7. CD and UV spectra of (+)-VIII in methanol.

theory may be considered to reflect the contribution from the mixing of other local transitions.

At any rate, exciton theory is not effective for deciding the absolute configuration of (+)-VIII, which should be confirmed by its correlation with other spiro compounds.

Experimental

All melting points were uncorrected. Optical rotations were measured on a Perkin Elmer polarimeter Model 141 using a 1-dm quartz cell. CD spectra were taken with a JASCO Model ORD/UV-6 and a Roussel-Jouan Dichrograph Type B. The UV spectra were run on a Hitachi Model EPS-3T spectrometer. The NMR spectra were taken at 60 Mc with a Varian A-60 spectrometer using TMS as internal standard. The IR spectra were measured on a JASCO Model DS 402G doublemonochromatic spectrophotometer in $CHCl_3$ solution. The mass spectra were measured on a Hitachi RMU-6 Single Focus Mass spectrometer.

Resolution of 6,6'-Dihydroxy-3,3,5,3',3',5-hexamethy-bis-1,1'-spiroindane (+)-IIIa. The mixture of (+)-IIIa (1.07 g), which was prepared according to the procedure of Baker and Besly,[7d] (+)-α-phenethylamine[9] (0.95 g), $[\alpha]_D$ +1.96° (*c* 1.890, benzene), and one drop of pyridine in dry toluene (10 m*l*) was heated under reflux for 25 hr. The solvent was distilled off and the residue was crystallized from toluene: *n*-hexane (405 mg). The (−)-diurethane was recrystallized from benzene three times to afford pure diastereomer (216 mg), mp 218—219°C. $[\alpha]_D$ −9.5° (*c* 0.200, $CHCl_3$). IR ν_{max} 3445, 1738 cm^{-1}.

Found: C, 78.22; H, 7.26; N, 4.17%. Calcd for $C_{41}H_{46}N_2O_4$: C, 78.06; H, 7.35; N, 4.44%.

(−)-Diurethane (216 mg) obtained above, and KOH-EtOH (10%, 5 m*l*) were heated under reflux for 6.5 hr. After cooling, the solution was acidified with 4 N HCl and crystalline product was collected, washed with H_2O and dried (100.6 mg). Recrystallization from benzene: *n*-hexane gave colorless leaflet (20.9 mg), mp 220—221°C. $[\alpha]$ +19.4° (*c* 0.194, dioxane). The IR spectrum in $CHCl_3$ was identical with that of racemic compound.

(−)-7,7'-Dibromo-6,6'-dihydroxy-3,3,5,3',3',5'-hexamethyl-bis-1,1'-spiroindane (−)-IIIb. Bromine (1.0 g) in $CHCl_3$ (20 m*l*) was dropped in to a solution of (+)-IIIa (150 mg) in $CHCl_3$ (5 m*l*) with stirring until the color did not fade any more. After further stirring for 20 min, EtOH was added. Crystals were filtered (138 mg), and then recrystallized from $CHCl_3$: EtOH to give prisms, mp 273—273.5°C. $[\alpha]_D$ −108.0°C (*c* 0.213, dioxane). NMR (in $CDCl_3$) τ: 8.69 (s, 6H), 8.63 (s, 6H), 7.82 (d, J=13.0 Hz, 2H), 7.69 (s, 6H), 7.50 (d, J=13.0 Hz, 2H), 4.47 (s, 2H), 3.14 (s, 2H). Mass spectrum: *m/e* 496, 492 (molecular ion). IR ν_{max} 3515 cm^{-1}.

Found: C, 55.92; H, 5.29; Br, 33.04%. Calcd for $C_{23}H_{26}Br_2O_2$: C, 55.89; H, 5.30; Br, 32.34%.

Resolution of 3,3,3',3'-Tetramethyl-bis-1,1'-spiroindane-6,6'-dicarboxylic Acid (−)-IIIc and (+)-IIIc. (±)-IIIc was prepared according to the procedure of Curtis.[7e] Mass spectrum: m/e 364 (parent peak).

Found: C, 76.40; H, 6.74%. Calcd for $C_{23}H_{24}O_4$: C, 75.80; H, 6.64%.

(±)-IIIc (12.0 g) and brucine·$2H_2O$ (28.4 g) in 99.5% EtOH (15 m*l*) were heated under reflux for 2 hr and then left to stand overnight at room temperature. The crystals were collected, washed with EtOH, dried *in vacuo* and then recrystallized from EtOH three times (6.3 g). $[\alpha]_D$ −91.6° (*c* 0.32, $CHCl_3$).

From the mother liquor of the reaction, EtOH was distilled off under reduced pressure. The residue was crystallized from acetone. The crude diastereomer was purified by recrystallization from MeOH: $CHCl_3$ five times (1.96 g). $[\alpha]_D$ +76.1° (*c* 0.551, $CHCl_3$).

(−)-Salt (6.3 g) was shaken with 6 N HCl (50 m*l*) at 50°C for 30 min. Crystals were filtered, washed with H_2O, dried *in vacuo*, and recrystallized from dioxane: acetone (1.57 g). $[\alpha]_D$ −93.7° (*c* 0.206, dioxane). (+)-Salt (1.25 g) was treated as above to give (+)-IIIc (476 mg). $[\alpha]_D$ +94.2° (*c* 0.243, dioxane).

(−)-Dimethyl-3,3,3',3'-tetramethyl-bis-1,1'-spiroindane-6,6'-dicarboxylate (−)-IIIe. A solution of diazomethane in ether was added to a solution of (−)-IIIc (200 mg) until the yellow color still remained. Ether was distilled off. The residue was chromatographed on Al_2O_3 (6.0 g, Woelm Co., Act. II) in benzene and then crystallized from *n*-hexane to give prisms (99.8 mg), mp 170.5—171°C. $[\alpha]_D$ −124.2° (*c* 0.233, *n*-heptane). Mass spectrum: *m/e* 392 (molecular ion). IR ν_{max} 1717 cm^{-1}.

Found: C, 76.79; H, 7.44%. Calcd for $C_{25}H_{28}O_4$: C, 76.50; H, 7.19%.

(−)-3,3,3',3'-Tetramethyl-bis-1,1'-spiroindane-6,6'-dicarboxylic Acid Chloride (−)-IIIf. (−)-IIIc (1.0 g) and thionylchloride (3.3 g) in abs. THF (5.0 m*l*) were heated under reflux for 1 hr. THF and excess thionylchloride were evporated under reduced pressure. The residue was crystallized from *n*-hexane and then recrystallized further two times (773 mg), mp 175—177°C. $[\alpha]_D$ −174.7°C (*c* 0.314, isooctane). IR ν_{max} 1755 cm^{-1}. Mass spectrum: *m/e* 400, 404 (molecular ion).

Found: C, 68.70; H, 5.63; Cl, 17.86%. Calcd for $C_{23}H_{22}O_2Cl_2$: C, 68.83; H, 5.53; Cl, 17.67%.

(−)-3,3,3',3'-Tetramethyl-bis-1,1'-spiroindane-6,6'-dicarboxylic Acid Azide (−)-IIIg. Sodium azide (230 mg) in H_2O was added in one portion to a solution of (−)-IIIf (718 mg) in acetone (5 m*l*) under cooling with vigorous stirring. After stirring for 15 min, oily precipitate was extracted with CH_2Cl_2 at 0°C. CH_2Cl_2 layer was washed with ice-water and dried with Na_2SO_4. CH_2Cl_2 was distilled under reduced pressure at room temperature. The residue was crystallized from *n*-hexane (271 mg), mp 92—93°C

(dec). $[\alpha]_D$ −246.3° (*c* 0.166, isooctane). IR ν_{max} 2143, 1691 cm^{-1}.

(−)-6,6'-Diamino-3,3,3',3'-tetramethyl-bis-1,1'-spiroindane (−)-IIIh. (1) (−)-IIIg (265 mg) in dry benzene (10 m*l*) was heated under reflux for 6 hr. Benzene was distilled off under diminished pressure. The IR spectrum showed N : C : O stretching absorption at 2270 cm^{-1}. This isocyanate was used for the next hydrolysis without further purification. The oily residue and 10% KOH-EtOH (10 m*l*) were heated under reflux for 2 hr. After cooling, H_2O (20 m*l*) was added and the mixture was extracted with benzene. The benzene solution was washed with H_2O and dried on Na_2SO_4. Benzene was distilled off. The residue was crystallized from benzene: *n*-hexane and then further sublimated at 170°C/2 mmHg (136 mg), mp 165—167°C. $[\alpha]_D$ −144.1° (*c* 0.270, MeOH). Mass spectrum: *m/e* 306 (molecular ion). IR ν_{max} 3380, 3458 cm^{-1}.

Found: C, 82.08; H, 8.56; N, 8.75%. Calcd for $C_{21}H_{26}N_2$: C, 82.30; H, 8.55; N, 9.14%.

(2) (−)-IIIc (370 mg) was treated according to the procedure of Curtis[7e] to give (−)-IIIh (236 mg), mp and the IR spectrum were identical with those of the above product.

(−)-6,6'-Diacetoxy-3,3,3',3'-tetramethyl-bis-1,1'-spiroindane, (−)-IIIj. This was prepared according to the procedure of Curtis,[7e] and recrystallized twice from *n*-hexane, mp 152—154°C. $[\alpha]_{365}$ −301 (*c* 0.00803, isooctane).

(−)-6,6'-Dihydroxy-3,3,3',3'-tetramethyl-bis-1,1'-spiroindane, (−)-IIIk. (−)-IIIj was hydrolyzed by the methods of Curtis,[7e] mp 96—98°C. $[\alpha]_{365}$ −254 (*c* 0.01284, MeOH). Mass spectrum: *m/e* 308 (parent peak). IR ν_{max} 3605 cm^{-1}.

Found: C, 79.07; H, 7.98%. Calcd for $C_{21}H_{24}O_2 \cdot 1/2H_2O$: C, 79.45; H, 7.94%.

(−)-3,3,3',3'-Tetramethyl-bis-1,1'-spiroindane (−)-IIIl. Decarboxylation of (+)-IIIc was performed by using copper chromite catalyst according to literature,[7e] mp 122.0—122.5°C. $[\alpha]_D$ −25.9° (*c* 0.315, dioxane). Mass spectrum *m/e* 276 (molecular ion). IR ν_{max} 1600 cm^{-1}.

Found: C, 91.26; H, 8.79%. Calcd for $C_{21}H_{24}$: C, 91.26; H, 8.79%.

(−)-6,6'-Dihydroxymethyl-3,3,3',3'-tetramethyl-bis-1,1'-spiroindane (−)-IIIm. $LiAlH_4$ (30 mg) in abs. ether (10 m*l*) was added to a solution of (−)-IIIe (86.2 mg) at room temperature. The reaction mixture was made to boil and then stirred for 1.5 hr. Excess $LiAlH_4$ was decomposed by dropping AcOEt and then HCl under cooling. The mixture was extracted with ether and ether layer was washed with $NaHCO_3$ - H_2O and H_2O and then dried on Na_2SO_4. Solvent was distilled off and the residue was crystallized from *n*-hexane (54.1 mg). $[\alpha]_D$ −61.8° (*c* 0.647, MeOH), mp 144—145°C. Mass spectrum: *m/e* 336 (molecular ion). IR ν_{max} 3600, 3440 cm^{-1}.

Found: C, 82.02; H, 8.45%. Calcd for $C_{23}H_{28}O_2$: C, 82.10; H, 8.39%.

Bis-(3-methoxybenzal)-acetone (V). A mixture of 50.0 g of *m*-methoxybenzaldehyde and 10.7 g of acetone in 25 m*l* of ethanol was added dropwise with stirring to the water-cooled alkaline solution (36.6 g of sodium hydroxide, 25 m*l* of ethanol and 370 m*l* of water). After stirring for 2 hr, the water layer was extracted with ether, the organic layers were combined and washed with water. Working up as usual furnished yellow oil, 60.1 g, which was chromatographed on a column of 90 g of Al_2O_3 (act. III). Benzene-petroleum ether and benzene eluate furnished 40.8 g oil, which solidified on standing. 2,4-Dinitrophenylhydrazone, mp 175.5—176.8°C.

Found: C, 62.90; H, 4.72; N, 11.77%. Calcd for $C_{25}H_{22}O_6N_4$: C, 63.28; H, 4.67; N, 11.81%.

Bis-(3-methoxybenzyl)-acetone (VI). 10 g of dienone (V) in 500 m*l* of acetone was hydrogenated on 1.0 g palladium-charcoal (10%). The uptake of hydrogen amounted to 110% of the theory in 90 min. After addition of a few drops of methanol, the catalyst was removed by filtration and the solvent was evaporated. The residual oil was taken in benzene and filtered on 20 g of Al_2O_3 (act. III).

Six runs from the total amount of 89.4 g of dienone in analogous procedure gave 85.3 g of crude oil, which was dissolved in 300 m*l* acetic acid and treated with a chromic acid solution (19.0 g of chromic trioxide, 18 m*l* of water and 150 m*l* of acetic acid). After the usual procedure the obtained oil, 72.2 g, was dissolved in benzene eluate ketone (VI) as yellow oil, 45.4 g (50%).

5,5'-Dimethoxy-bis-1,1'-spiroindane (VII). 5.2 g Bis-(3-methoxybenzyl)-acetone (VI) and 22 m*l* of freshly distilled phosphorus oxychloride dissolved in 57 m*l* of benzene were refluxed 4 hr. The reaction mixture was poured into ice-water and treated as usual. The obtained brown oil dissolved in petroleum ether was filtered on Al_2O_3 (act. III), and crystallized from petroleum ether, Yield 2.75 g (56.8%), mp 67—78°C. Recrystallisation raised the melting point to 83—85°C.

Found: C, 81.47; H, 6.61%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

5,5'-Dihydroxy-bis-1,1'-spiroindane (VIII). A mixture of 14.5 g of dimethoxy compound (VII), 120 m*l* of concentrated hydrobromic acid (d=1.48) and 120 m*l* of acetic acid was refluxed for 5 hr. After cooling, the reaction mixture was poured into 800 m*l* of water, extracted with ether and treated as usual. The obtained viscous oil was dissolved in benzene - acetone (6 : 1) and filtered on 20 g Al_2O_3 (act. III). Crystallisation from benzene yielded 7.4 g (57%) crystals, mp 175—178°C.

Found: C, 81.04; H, 6.29%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

Bis-1,1'-spiroindane-5,5'-dioxybutyric Acid (IX). 3.00 g of dihydroxyspiroindane (VIII) in 8.3 m*l* of absolute ethanol was added under reflux into a sodium ethoxide solution (1.1 g of sodium, 20 m*l* of abs. ethanol). To the mixture was added 18.0 g of ethyl - bromobutyrate. After refluxing for 90 min, a sodium ethoxide solution (0.54 g of sodium in 5.7 m*l* of absolute ethanol) and subsequently 6.07 g of bromo ester were added again. Refluxing was continued for 6 hr and the mixture was allowed to stand overnight. 40 m*l* of 30% aqueous sodium hydroxide was added and the mixture was boiled for 1 hr. Ethanol was evaporated under reduced pressure, water was added and the solution was acidified with hydrochloric acid. After working up as usual, the viscous oil was crystallized from aqueous methanol. Yield, 2.93 g (57%), mp 208—218°C. After drying at 140°C *in vacuo* the melting point was 213—216°C.

Found: C, 70.84; H, 6.63%. Calcd for $C_{25}H_{28}O_6$: C, 70.74; H, 6.65%.

Resolution of the Dicarboxylic Acid (IX). 500 mg of the carboxylic acid (IX) dissolves in 11 m*l* of methanol was mixed with 678.8 mg of cinchonidine in 22 m*l* of methanol and allowed to stand overnight. Evaporation of the solvent gave viscous oil, which was crystallized from 47 m*l* of methanol and 59 m*l* of water. Recrystallisation from aqueous methanol was repeated 4 times. Decomposition with 1 N hydrochloric acid and recrystallisation from aqueous methanol gave optically active dicarboxylic acid, 67.5 mg, $[\alpha]_D^{20}$ +23.2° (*c* 0.25, dioxane).

872 mg of the carboxylic acid (IX) treated with cinchonidine in acetone as above gave salt, mp 91—99°C.

Found: C, 71.67; H, 7.33; N, 5.21%. Calcd for $C_{63}H_{72}O_8N_4 \cdot 2H_2O$: C, 72.10; H, 7.32; N, 5.34.

Recrystallisation of the salt six times and decomposition with hydrochloric acid gave 39 mg of dicarboxylic acid, $[\alpha]_D^{20}$ +19.2° (*c* 0.13, dioxane).

Dealkylation of the Dicarboxylic Acid. 181.5 mg of the racemic dicarboxylic acid suspended in 76 m*l* of ether was treated with excess diazomethane in ether. The obtained homogeneous solution, after evaporating, gave 200 mg of ester, which was dissolved in 25 m*l* of toluene and treated with 0.18 m*l* of boron tribromide at −10°C. After 1 hr the reaction mixture was poured into water and treated as usual. The obtained amorphous product, 71 mg, was treated with charcoal in methanol, giving 60.5 mg of dihydroxy compound. The active dicarboxylic acid, 150 mg, treated analogously gave 15 mg of active acid, mp 164—172°C.

Found: C, 78.63; H, 6.71%. Calcd for $C_{17}H_{16}O_2 \cdot 1/2H_2O$: C, 78.13; H, 6.57%.

Studies of Compounds Related to Azines. VII.[1] The Pyrorlysis of 2-Acetylthiophene- and 2-Acetylfuranketazine

Otohiko TSUGE, Haruyuki WATANABE, and Kozo HOKAMA*

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

** Department of Chemistry, Faculty of Science and Engineering, Ryukyu University Naha, Okinawa*

(Received July 15, 1970)

As part of a study attempting to elucidate the relation between the chemical structure of an azine and its pyrolysate, the pyrolyses of 2-acetylthiophene- (I) and 2-acetylfuranketazine (II) have been investigated. The pyrolysis of I at 270°C afforded principally nitrogen, ammonia, and 7-methyl-5-(2-thienyl)-thieno[2,3-*c*]pyridine (III), plus lesser quantities of thiophenecarbonitrile and 2-acetylthiophene. The reductive desulfurization of III, followed by oxidation, afforded pyridine 2,4,6-tricarboxylic acid *via* 5-*n*-butyl-7-methyl-thieno-[2,3-*c*]pyridine and 2-*n*-butyl-4-ethyl-6-methylpyridine. On the other hand, II was pyrolyzed to give nitrogen, ammonia, and tars as the major products, together with furan, furancarbonitrile, 2-acetylfuran, 5-(2-furyl)-7-methyl-furo[2,3-*c*]pyridine, and 2,4,6-tri(2-furyl)pyridine.

In order to elucidate the relation between the chemical structure of an azine and its pyrolysate, pyrolyses of various azines have been investigated,[2–6] and it has been found that aromatic ketazines are decomposed by a free-radical process, giving the corresponding Piloty-Robinson's reaction product as the main product in many cases.[3–5]

In this paper we wish to report the formation of novel products from the pyrolyses of 2-acetylthiophene-(I) and 2-acetylfuranketazine (II).

When I was pyrolyzed at 270°C for 1 hr, nitrogen, ammonia, and colorless crystalline compound III, mp 103—104°C, were obtained as major products, accompanied by lesser quantities of thiophenecarbonitrile and 2-acetylthiophene.

Although the compound III was in agreement with the expected molecular formula, $C_{12}H_9NS_2$, which corresponded to that of the Piloty-Robinson's reaction product, 2,5-dithienylpyrrole, its IR spectrum did not show any bands ascribed to the NH group, while it did show the C=N band at 1570 cm^{-1}. The NMR spectrum had signals at τ 7.48 (3H, CH_3, *s*) and 2.3—3.2 (6H, aromatic protons, *m*), while the mass spectrum exhibited the parent ion peak (M^+) at *m/e* 231, together with major peaks at *m/e* 216 (M^+–Me), 205 (M^+–C_2H_2), 186 (M^+–CHS), 148 (186^+—C_3H_2), and 133 (148^+–Me). On the basis of these spectral data and the following chemical transformations, it seems reasonable to assume that III is a methyl-thienyl-substituted thienopyridine.

The relative desulfurization of III with Raney nickel catalyst was carried out. Treatment with Raney nickel catalyst (W-1 type) gave pale yellow oil IV and colorless oil V. On the further treatment of IV with Raney nickel catalyst (W-4 type), IV was transformed into V in a good yield.

The compound IV ($C_{12}H_{15}NS$) was assumed, by spectral studies as well as by elemental analysis, to be *n*-butyl-methyl-substituted thienopyridine, whose structure corresponded to that which will be derived from III under the reductive desulfurization of the thienyl group in III to the *n*-butyl group. The NMR spectrum exhibited signals at τ 9.1 (3H, $C\underline{H}_3$–$(CH_2)_3$–, *t*), 8.0—9.3 (4H, Me–$(C\underline{H}_2)_2$–CH_2–, *m*), 7.5 (3H, CH_3, *s*), 7.25 (2H, Me–$(CH_2)_2$–$C\underline{H}_2$–, *t*), 3.2 (1H, pyridine ring proton, *s*), 2.6 and 2.43 (each 1H, thieno ring proton, *dd*). In the mass spectrum, the parent ion peak (M^+) appeared at *m/e* 205, together with major peaks at *m/e* 190 (M^+–Me), 176 (M^+–Et), 163 (M^+–$MeCH{=}CH_2$), 148 (163^+–Me) and 122 (163^+–MeCN).

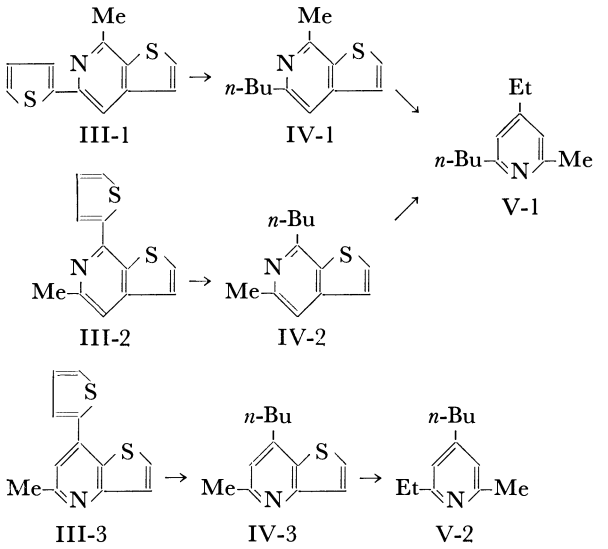
6) O. Tsuge, K. Hokama, and M. Koga, *ibid.*, **89**, 789 (1969).

On the other hand, the compound V ($C_{12}H_{19}N$) was presumed, by spectral studies and chemical transformation, to be 2,4,6-trialkyl (*n*-butyl, ethyl, and methyl)pyridine. The IR and UV spectra of V were very similar to those of 2,4,6-collidine, while the NMR spectrum had signals at τ 9.1 (3H, $C\underline{H}_3$–$(CH_2)_3$–, *t*), 8.8 (3H, $C\underline{H}_3$–CH_2–, *t*), 8.0—9.3 (4H, Me–$(C\underline{H}_2)_2$–CH_2–, *m*), 7.8 (3H, CH_3, *s*), 7.1—7.6 (4H, Me–$(CH_2)_2$–$C\underline{H}_2$– and Me–$C\underline{H}_2$–, *m*) and 3.4 (2H, pyridine ring protons, *s*). The mass spectrum showed the parent ion peak (M^+) at *m/e* 177, together with major peaks at *m/e* 162 (M^+–Me), 148 (M^+–Et), 135 (M^+–MeCH=CH_2), 120 (135^+–Me), and 107 (135^+–C_2H_4).

Furthermore, V was oxidized with selenium dioxide in pyridine to give pyridine 2,4,6-tricarboxylic acid, which was identical with an authentic specimen prepared by the oxidation of 2,4,6-collidine.

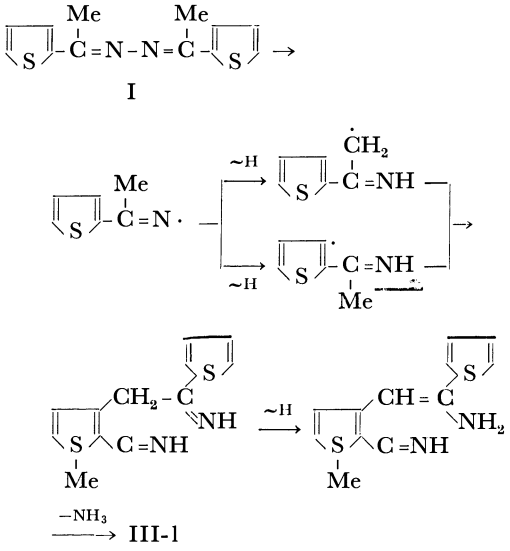


On the basis of the chemical shift of methyl protons in the respective NMR spectrum of III, IV, or V, it is evident that the methyl group is located at the α-position of the pyridine ring in the respective compound. Consequently, 2-*n*-butyl-4-ethyl-6-methyl- (V-1) and 4-*n*-butyl-2-ethyl-6-methylpyridine (V-2) are both possible structures for V.

It should be deduced that the compounds III and IV are 7-methyl-5-(2-thienyl)- (III-1) or 5-methyl-7-(2-thienyl)- (III-2) and 5-*n*-butyl-7-methyl- (IV-1) or 7-*n*-butyl-5-methylthieno[2,3-*c*]pyridine (IV-2) from the structure of V-1, and 5-methyl-7-(2-thienyl)- (III-3) and 7-*n*-butyl-5-methyl-thieno[2,3-*b*]pyridine (IV-3) from the structure of V-2. Unfortunately, it is very difficult to determine from spectral data which isomers would be more reasonable for III and IV.

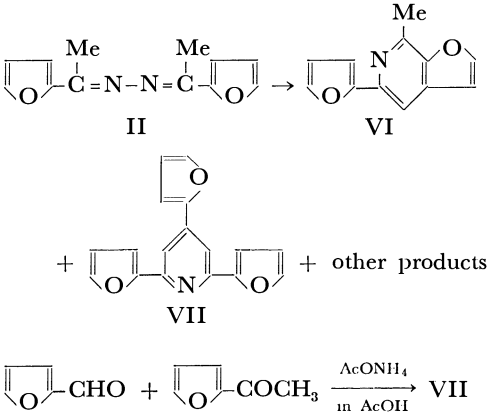
It has previously been found that the main pyrolytic pathway of aromatic ketazines is that through the homolysis of the N–N bond of ketazines.[3–5] For the formation of III-2 or III-3 from the ketazine I, anomalous homolyses of I and complicated reactions must take place.

In analogy with the pathway of the formation of 2,5-diphenylpyrrole from acetophenoneketazine,[4] however, the formation of III-1 from I can be illustrated by the homolytic dissociation of the N–N bond of I, followed by the rearrangement and recombination of the formed radicals and the subsequent elimination of ammonia.



On the basis of the spectral data and considerations of the pyrolytic pathway, it seems reasonable to conclude that III, IV, and V are 7-methyl-5-(2-thienyl)- (III-1), 5-*n*-butyl-7-methyl-thieno[2,3-*c*]pyridine (IV-1), and 2-*n*-butyl-4-ethyl-6-methylpyridine (V-1) respectively.

A similar pyrolysis of II gave 5-(2-furyl)-7-methyl-furo[2,3-*c*]pyridine (VI) and 2,4,6-tri(2-furyl)pyridine (VII) in low yields, accompanied by other products and intractable tars. The structure of VI was assumed on the basis of spectral studies as well as the elemental analysis. The UV spectrum of VI was similar to that of III, while the parent ion peak (M^+) appeared at *m/e* 199, together with major peaks at *m/e* 184 (M^+–Me), 170 (M^+–CHO), 142 (184^+–CH_2C=O) and 132 (170^+–C_3H_2) in the mass spectrum. On the other hand, the compound VII was identified by



comparing its IR spectrum with that of an authentic sample prepared by the reaction of furfural with 2-acetylfuran in the presence of ammonium acetate according to the improved Chichibabin pyridine synthetic method.[7]

Experimental[8]

Materials. The 2-Acetylthiophene- (I) and 2-acetylfuranketazine (II) were prepared by the reaction of the corresponding 2-acetyl compound with hydrazine hydrate in acetic acid; each was then recrystallized from ethanol. The yield was quantitative.

I: mp 95—96°C (lit,[9] 93°C).

II: mp 102—103°C. Found: C, 66.62; H, 5.52; N, 13.07%. Calcd for $C_{12}H_{12}O_2N_2$: C, 66.65; H, 5.59; N, 12.96%.

Procedure. After the pyrolysis had been carried out in an apparatus similar to one described previously,[3] the products were analyzed by the following methods. The products were divided into three fractions: gaseous material (nitrogen, ammonia), a lower-boiling fraction, and a residual fraction.

The analyses of nitrogen and ammonia were carried out by the reported method.[3] The lower-boiling fraction was analyzed by gas chromatography. The conditions for the gas chromatography were as follows: column, 30% high-vacuum silicon grease (HVSG) (3 m) and 20% PEG - 0.5% adipic acid (0.75 m); temperature, 200°C; carrier gas, hydrogen 30 ml/min. From the areas of the individual peaks, mol% figures were calculated for each product after determining the relative response data by the internal standard method using *o*-chloronitrobenzene. Individual peaks were identified by means of the retention times of pure samples.

After the residual fraction had been extracted with benzene, the benzene extract was chromatographed on alumina, giving pure crystalline compounds. The quantitative estimation of the compounds was carried out by the gas-chromatographic internal standard method using 1-benzylnaphthalene. The conditions for the gas chromatography were as follows: column, 30% HVSG (0.75 m); temperature, 300°C; carrier gas, hydrogen 147 ml/min.

Pyrolysis of I. Five grams of I were pyrolyzed at 270°C for 1 hr. The respective yields (mol%) of products obtained from the average values of three runs under the same conditions were as follows: nitrogen, 12.3; ammonia, 96.7; thiophenecarbonitrile, 2.6; 2-acetylthiophene, 3.1; 7-methyl-5-(2-thienyl)-thieno[2,3-*c*]pyridine (III), 50.5 mol%.

III: mp 103—104°C, colorless prisms. UV λ_{max}^{EtOH} mμ (log ε): 276 (4.3), 304 (4.0), 324 (4.0). Found: C, 62.15; H, 4.02; N, 5.91%. Calcd for $C_{12}H_9NS_2$: C, 62.34; H, 3.92; N, 6.06%.

Reductive Desulfurization of III with Raney Nickel Catalyst (W-1). A solution of III (10.0 g) in ethanol (800 ml) was stirred with a freshly-activated W-1 Raney nickel catalyst (100 g) under reflux for 60 hr. After the reaction mixture had then been filtered, the filtrate was concentrated, leaving a brown oil. The oil was divided by distillation into the fraction F_1 (bp 60—70°C/5 mmHg, colorless oil, yield 0.9 g), F_2 (bp 140—144°C/5 mmHg, pale yellow oil, yield 3.0 g), and a residue (yield 2.1 g). The fractions F_1 and F_2 were then both submitted to gas chromatography: from each fraction 2-*n*-butyl-4-ethyl-6-methylpyridine (V) and 5-*n*-butyl-7-methylthieno[2,3-*c*]pyridine (IV) were obtained in the pure state.

IV: UV λ_{max}^{EtOH} mμ (log ε): 231 (3.4), 273 (2.9), 298 (2.8). Found: C, 70.26; H, 7.26; N, 6.78%. Calcd for $C_{12}H_{15}NS$: C, 70.22; H, 7.37; N, 6.82%.

V: UV λ_{max}^{EtOH} mμ (log ε): 265 (3.7), 272 (3.7). Found C, 81.19; H, 10.82; N, 7.61%. Calcd for $C_{12}H_{19}N$: C, 81.30; H, 10.80; N, 7.90%.

A benzene solution of the residue was chromatographed on alumina, giving 1.2 g of III.

Reductive Desulfurization of IV with Raney Nickel Catalyst (W-4). A solution of IV (0.6 g) in ethanol (150 ml) was stirred with a freshly-activated W-4 Raney nickel catalyst (10 g) under reflux for 11 hr. After the reaction mixture had then been treated in a manner similar to that described above, a pale yellow oil (0.45 g) which was found to be composed of 70.6% of V by the gas-chromatographic estimation was obtained.

Oxidation of V. A solution of V (1.0 g) in pyridine (20 ml) was stirred with selenium dioxide (15.2 g) under reflux for 15 hr. The reaction mixture was filtered, and the filtrate was subjected to steam distillation. After active charcoal and chips of filter paper had then been added to the residue, the mixture was refluxed and then filtered. The filtrate was concentrated to about 20 ml and then allowed to stand overnight, giving pyridine 2,4,6-tricaraoxylic acid, mp 227°C (decomp.) (lit,[10] 227°C (decomp.)), as colorless crystals. Yield, 0.6 g (50%). This compound was identical the authentic sample prepared by the oxidation of 2,4,6-collidine.

Pyrolysis of II. Five grams of II were pyrolyzed under several conditions; the results are shown in Table 1.

5-Furyl-7-methyl-furo[2,3-*c*]pyridine (VI); mp 68—69°C, colorless prisms. NMR: τ 7.4 (3H, CH_3, *s*), 3.5 (1H, *m*), 3.0 (2H, *m*), 2.5 (2H, *m*), 2.2 (1H, *d*). UV λ_{max}^{EtOH} mμ (log ε): 241 (4.2), 268 (4.0), 277 (3.9), 320 (4.1). Found:

Table 1. Pyrolysis of II[a]

Conditions		Products, mol%							
Temp. (°C)	Time (min)	N_2	NH_3	F[b]	N[b]	A[b]	VI	VII	II

C, 72.61; H, 4.42; N. 6.95%. Calcd for $C_{12}H_9O_2N$: C, 72.37; H, 4.55; N, 7.07%.

2,4,6-Tri(2-furyl)pyridine (VII). A mixture of 2-2-acetylfuran (3.3 g), furfural (1.5 g), and ammonium acetate (15 g) in acetic acid (38 m*l*) was refluxed for 1 hr. After the reaction mixture had been extracted with benzene (100 m*l*), the benzene-extract was washed with water, dried over sodium sulfate, and then concentrated. A benzene solution of the residue was chromatographed over alumina, giving VII, mp 128—129°C, as colorless needles. Yield, 0.6 g (14 %).

Found: C, 73.73; H, 3.94; N, 5.00%. Calcd for $C_{17}H_{11}O_3N$: C, 73.64; H, 4.00; N, 5.05%.

This compound was identified by comparing its IR spectrum with that of the product melting at 128—129°C obtained in the pyrolysis of II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 508—513 (1971)

Stoichiometric Carbonylation of Aryl Halide with Nickel Tetracarbonyl in the Presence of Potassium Acetate

Mikitake NAKAYAMA and Tsutomu MIZOROKI

Gevernment Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received July 30, 1970)

In the stoichiometric reaction of aryl halide with $Ni(CO)_4$ in methanol to form the corresponding ester, it has been found that the carbonylation is effectively promoted by adding potassium acetate to the starting materials, and that four moles of the ester are obtained from one mole of $Ni(CO)_4$ without any appreciable side reactions. From the inhibition by gaseous carbon monoxide and the IR measurements during the carbonylation, it has been concluded that nickel tricarbonyl, $Ni(CO)_3$, is the initiator of the carbonylation and that its regeneration is the rate-determining step. The present results provide a basis on which the course of the carbonylation of aryl halide with carbon monoxide catalyzed by $Ni(CO)_4$ under high temperatures and pressures may be reasonable explained.

Nickel tetracarbonyl is highly reactive in the carbonylation of organic halide, especially for aryl[1,2] and allyl halide.[3] They give the corresponding esters in a methanol solution. The yield of the ester is highly increased by adding an acceptor of hydrohalogenic acid formed during the carbonylation, though the role of the acceptor is not yet understood well.

In our previous paper dealing with the carbonylation of aryl bromide catalyzed by nickel carbonyl under high temperatures and pressures, it was reported that the carbonylation is promoted by adding a sufficient amount of carboxylic salt; this yields a quantitative amount of the corresponding carboxylic acid[4] as follows:

$$C_6H_5Br + CO + H_2O + AcOK \xrightarrow{Ni(CO)_4} C_6H_5COOH + AcOH + KBr \quad (1)$$

The role of the added carboxylic salt has been considered to reduce the concentration of hydrobromic acid, which inhibits the regeneration of nickel carbonyl. A similar effect was also observed in the stoichiometric reaction of aryl iodide with $Ni(CO)_4$ in methanol at a low temperature. That is, the carbonylation rate is effectively increased by adding carboxylic salt. It is to be noticed in this reaction that about four moles of the carboxylic ester are obtained from one mole of $Ni(CO)_4$, without any appreciable side reaction; this novel result is similar to that claimed by Reppe in the stoichiometric carbonylation of acetylene with $Ni(CO)_4$,[5] $Ni(CO)_4 + 4CH{\equiv}CH + 4ROH + 2HX \rightarrow 4CH_2{=}CHCOOR + NiX_2 + H_2$ ($R = CH_3$, C_2H_5, *etc.*; $X = Cl$, Br, CH_3CO_2, *etc.*). During the course of this study, it was reported by Corey and Hegedus[6] that the treatment of organic halide, RX, with several equivalents of nickel carbonyl in an alcoholic medium (R'OH) containing 2—3 equivalents of the corresponding sodium or potassium alkoxide (strongly basic medium) also results in the formation of the RCOOR' ester, while the reaction path of the coordinated carbon monoxide is still obscure.

The present study has been undertaken in order to investigate the reaction path of coordinated carbon monoxide in the stoichiometric reactions of aryl iodides with nickel tetracarbonyl in a methanol solution. On the basis of the results of this study, the course of catalytic carbonylation with nickel carbonyl has been discussed.

Results

The results of the stoichiometric reaction of iodobenzene with nickel tetracarbonyl in methanol under a nitrogen atmosphere at 50°C are summarized in Table 1. Iodobenzene, which has been known to react with nickel tetracarbonyl in methanol at re-

flux to form methyl benzoate, was unchanged in the absence of potassium acetate under the conditions specified in Table 1, while it was vigorously changed by the addition of potassium acetate. It is highly soluble in methanol (more than 33 g/100 g methanol at 25°C). This is why potassium acetate and methanol were used preferably in this study. As soon as the temperature of the solution reached 50°C, its color changed from almost colorless to a reddish brown; this change was followed by the deposition of a black precipitate within half an hour. In the final stage, the solution turned green because of the Ni(II) ion.

In the absence of aryl halide, no reaction of nickel tetracarbonyl with potassium acetate was observed. The variations in the amounts of iodobenzene and methyl benzoate during the reaction were followed by gas chromatography; the results are shown in Fig. 1. The reaction was practically finished within 1 hr. The black precipitation did not show any absorption in the NaCl region of the IR spectrum, and it was easily dissolved in a dilute aqueous nitric acid solution, while some gas was evolved. The precipitate was found, by elementary analysis, to be metallic nickel, which has been partially oxidized by air during the separation. As is shown in Table 1, the mole ratio of the iodide ion to the total nickel[7] in the product ($[I^-]$/[Total Ni]), and that of methyl benzoate to the total nickel in the product ($[C_6H_5COOCH_3]$/[Total Ni]), are both approximately four. Practically no carbon monoxide was evolved during the carbonylation. From these results, we may conclude that all the carbon monoxide involved in nickel tetracarbonyl is consumed in the carbonylation of iodobenzene, as is represented by Eq. (2):

$$Ni(CO)_4 + 4C_6H_5I + 4CH_3OH + 4AcOK \longrightarrow Ni + 4C_6H_5COOCH_3 + 4AcOH + 4KI \quad (2)$$

That the $[C_6H_5COOCH_3]$/[Total Ni] ratio was smaller than 4 seems to be caused by the formation of smaller amounts of benzene and anisole. Neither free benzoic acid nor phenyl acetate could be detected.

Under a nitrogen atmosphere the carbonylation of iodobenzene took place smoothly, as has been described above; no carbonylation was, however, observed at all under a carbon monoxide atmosphere, and the solution remained colorless for at least 3 hr at 50°C, despite our expectation that the carbonylation might take place catalytically even under these mild conditions. This means that the reaction was completely inhibited by an atmospheric pressure of carbon monoxide. It was found that the carbonylation really started, even at room temperature (20°C), when a trace amount of carbon monoxide in the gas phase was removed by means of a nitrogen gas stream.

The IR absorption during the reaction with iodobenzene and with α-iodonaphthalene is shown in Figs. 2 and 3. As soon as the solution turned a reddish brown, four new bands are observed, at 1993, 1963,

7) "Total nickel" means the sum of the Ni^{2+} and the metallic nickl formed.

1845, and about 1720 cm^{-1}, in the range of the CO stretching vibration. The last one consisted of two absorptions due to the methyl esters formed and acetic acid; these absorptions were checked by authentic samples. Figure 3 shows that the intensities of the former three absorptions gradually decrease with the consumption of α-iodonaphthalene in the carbonylation, and that they disappear when the reaction is almost finished. In fact, α-iodonaphthalene is more reactive than iodobenzene, resulting in an almost quantitative formation of α-methyl naphthoate under the reaction conditions cited in Fig. 3. It should be noticed here that the absorptions at 1993 and 1845 cm^{-1} disappear more rapidly than that at 1963 cm^{-1}.

Aryl bromides, such as bromobenzene, α-bromonaphthalene or *p*-bromoanisole, did not undergo carbonylation under even more forced conditions than those cited in Table 1, while both α- and ω-bromostyrene were much more reactive than aryl iodides; in the cases of α- and ω-bromostyrene, methyl α-phenyl acrylate, and methyl cinnamate were selectively formed respectively.[8] Most of the carbon monoxide involved in nickel tetracarbonyl was found to be also consumed in their carbonylations. These carbonylations too rapidly, even at room temperature, and they were accompanied by the formation of much potassium bromide precipitation; this prevented the taking of the IR absorption spectrum during their reactions. Such alkyl halides as ethyl-, *t*-butyl-, *n*-amyl-, *t*-amyl, and cyclohexyl halides, including iodides, were treated with $Ni(CO)_4$ by the same procedure; however, no carbonylation was observed, only dehalogenation products as the corresponding alcohols and methyl ethers from ethyl-, *t*-butyl-, *n*-amyl-, or *t*-amyl halides and cyclohexene from cyclohexyl halide. On the other hand, allyl halide reacted vigorously with $Ni(CO)_4$ in methanol, even at 0°C, to form methyl 3-butenoate, plus considerable amounts of such by-products as 1,5-hexadiene, methyl allyl ether, and diallyl ether. The amount of methyl 3-butenoate was also increased by adding potassium acetate, whereas only half the amount of the carbon monoxide involved in $Ni(CO)_4$ could be used for the carbonylation of allyl halide, where no inhibition by gaseous carbon monoxide was observed. In this respect, the carbonylation of aryl halide was quite different from that of allyl halide, which has been studied in detail by Guerrieri and Chiusoli.[3]

8) α-Phenylacrylic acid and cinnamic acid, besides their esters, were isolated from the respective products.

Discussion

It is known that nickel tetracarbonyl forms unstable substitution products with such relatively weak bases as pyridine in a methanol solution and that they are

present in solution in equilibrium[9] with such polynuclear carbonyl anion as $[Ni_2(CO)_6]^{2-}$, $[Ni_3(CO)_8]^{2-}$, *etc.*[10,11] In a strong basic solution, as in potassium hydroxide solution, $[Ni_2(CO)_6]^{2-}$ or $[Ni_3(CO)_8]^{2-}$ is preferably formed. If these nickel carbonyl anions were reactive species in the carbonylation of aryl halide, a stronger basic solution would be more favorable for the carbonylation. However, carbonylation takes place more readily in a weak basic solution, as in the presence of potassium acetate, than in a strong basic solution, though no interaction between $Ni(CO)_4$ and potassium acetate is observed in the absence of aryl iodide.

From the following considerations, it has been concluded that nickel tricarbonyl is an active species in the carbonylation.

The Inhibition by Carbon Monoxide. The fact that iodobenzene does not undergo carbonylation at all under an atmospheric pressure of carbon monoxide, as has been described in the preceding section, can be understood on the basis of the following scheme:

$$Ni(CO)_4 \underset{k_2}{\overset{k_1}{\rightleftarrows}} Ni(CO)_3 + CO \quad (k_1 \ll k_2) \tag{3}$$

$$Ni(CO)_3 + C_6H_5I \xrightarrow{k_3} (C_6H_5I)Ni(CO)_3 \quad (k_3 \ll k_2) \tag{4}$$

It is well known that the exchange reaction between $Ni(CO)_4$ and ^{14}CO proceeds *via* S_N1 ($k_2 \gg k_1$) and that its rate is very large under a normal temperature and pressure (the half-value period of ^{14}CO radioactivity in the gas phase is less than 4 min in a toluene solution[9]). Accordingly, the coordination of iodobenzene to nickel tricarbonyl is in competition with the rapid recombination of carbon monoxide, where k_3 must be much smaller than k_2. The carbonylation starts practically when the former rate becomes larger than the latter. Accordingly, the lower the pressure of carbon monoxide, the more favorable for the coordination of iodobenzene to nickel tricarbonyl. It can be understood why no carbonylation is observed when $Ni(CO)_3(PPh_3)$ or $Ni(CO)_2(PPh_3)_2$ ($Ph = C_6H_5$) is used instead of $Ni(CO)_4$, since the dissociation rates of carbon monoxide from these carbonyls are extremely small.[12]

IR Absorption Spectrum During the Course of Reaction. Figures 2 and 3 show that the IR absorptions at 1845, 1963, and 1993 cm^{-1} during the carbonylation of iodobenzene are identical with those observed during the reaction of α-iodonaphthalene. These absorptions can not be regarded as due to some acyl complex such as $RCO\text{-}Ni(CO)_nI$, nor due to some σ-complex such as $R\text{-}Ni(CO)_nI$ ($R = C_6H_5$ or α-$C_{10}H_7$), because absorptions of acyl metal carbonyls are usually observed in the range between 1700—1750 cm^{-1}. If they correspond to aryl σ-complexes, the IR absorption of the phenyl σ-complex will probably be different from that of the naphthyl complex.

As was pointed out in the preceding section, the absorptions at 1993 and 1845 cm^{-1} disappear more quickly than that at 1963 cm^{-1}. This suggests that there are two kinds of intermediates present during the carbonylation. One has two absorptions, at 1993 and 1845 cm^{-1}, while the other has only one, at 1963 cm^{-1}. In the neutral binary carbonyls, the higher frequencies (2050—1900 cm^{-1}) are regarded as being due to terminal carbonyl groups, and the lower frequencies (1900—1800 cm^{-1}), as due to the bridging carbonyl groups, whose molar extinction coefficients are smaller than those of terminal carbonyls.[13] Accordingly, one of the intermediates can be ascribed to a binuclear nickel complex[14] with both bridging and terminal carbonyls, and the other, to a mononuclear nickel complex with only terminal carbonyls.

Reaction Path. From the considerations described above and the fact that all the carbon monoxide in $Ni(CO)_4$ are used for the carbonylation of aryl iodide, the reaction path can be represented as follows:

$$Ni(CO)_4 \rightleftarrows Ni(CO)_3 + CO \tag{3}$$

$$Ni(CO)_3 + RI \longrightarrow (RI)Ni(CO)_3 \tag{4}$$

$$(RI)Ni(CO)_3 + CH_3OH \longrightarrow (HI)Ni(CO)_2 + RCOOCH_3 \tag{5}$$

$$(HI)Ni(CO)_2 + AcOK \longrightarrow Ni(CO)_2 + AcOH + KI \tag{6}$$

$$Ni(CO)_2 + Ni(CO)_4 \rightleftarrows Ni_2(CO)_6 \tag{7}$$

$$3Ni(CO)_2 \rightleftarrows Ni + Ni_2(CO)_6 \tag{7'}$$

$$Ni_2(CO)_6 \longrightarrow 2Ni(CO)_3 \tag{8}$$

($R = C_6H_5$ or α-$C_{10}H_7$)

The reaction (5) proceeds rapidly, probably through steps analogous to those reported in the carbonylation using *cis*-$Rh(PPh_3)_2(CO)Cl$,[16] namely: $(C_6H_5I)Ni(CO)_3 \rightarrow C_6H_5\text{-}Ni(CO)_3I \rightarrow C_6H_5CO\text{-}Ni(CO)_2I \xrightarrow{+CH_3OH} (HI)Ni(CO)_2 + C_6H_5COOCH_3$. The reaction (6) means that the acetate anion effectively takes proton from $(HI)Ni(CO)_2$. In the absence of potassium acetate, $(HI)Ni(CO)_2$ will be rapidly decomposed and $Ni(CO)_3$ will not be supplied smoothly, with the result that practically no carbonylation is observed. The two intermediates expected from the IR absorptions observed during the carbonylation can be regarded as:  ($Ni_2(CO)_6$) and $Ni(CO)_2$.[17] These

9) Namely: $3Ni(CO)_3Py + 3Py \rightleftarrows [NiPy_6][Ni_2(CO)_6] + 3CO$
$3Ni(CO)_2Py_2 \rightleftarrows [NiPy_6][Ni_2(CO)_6]$
$[NiPy_6][Ni_2(CO)_6] + Ni(CO)_3Py \rightleftarrows [NiPy_6][Ni_3(CO)_8] + Py + CO$

14) The hexacarbonyldinickelate anion, $[Ni_2(CO)_6]^{2-}$, has four absorptions, at 1978, 1968, 1927, and 1870 cm^{-1}, in a potassium hydroxide methanol solution; these are all different from the absorptions observed during the carbonylation. This anion was prepared according to the method described in Ref. 15.

17) The solvent molecule or iodide ion probably coordinates to these intermediates.

intermediates can be accumulated sufficiently to be observed by IR absorption when the reaction (8) (the regeneration of $Ni(CO)_3$) is rate-determining. The formation of a considerable amount of metallic nickel[18] can also be explained by the reaction (7'). The stoichiometric equation (2), showing that all the carbon monoxide involved in $Ni(CO)_4$ is used for the carbonylation of aryl iodide, can be derived by combining the reaction path described above.

The catalytic carbonylation of aryl bromide under high temperatures and pressures can be reasonably explained by this reaction path, with Br and H_2O replacing I and CH_3OH respectively. The catalytic carbonylation of α-bromonaphthalene with carbon monoxide and water in the presence of $Ni(CO)_4$ is highly promoted by adding a sufficient amount of potassium acetate, resulting in the quantitative formation of α-naphthoic acid, as has been reported in the preceding paper.[19] That is, its rate increasing with an increase in the amount of $Ni(CO)_4$ and also with that of potassium acetate, while it depends on neither the amounts of α-bromonaphthalene and water, nor on the pressure of carbon monoxide under 60—150 kg/cm² at 200°C, though the rate decreases with an increase in the pressure to more than 200 kg/cm². Lower pressures should favor the equilibria of the reactions (3) and (4) inclining much toward the right, and the rate of the reaction (5) must be sufficiently large at this temperature. Accordingly, the rate of carbonylation will be determined by either the reaction (6) or the regeneration of nickel tricarbonyl. In this catalytic reaction, nickel tricarbonyl must be regenerated, preferably by the coordination of carbon monoxide to the $Ni(CO)_2$ formed by the reaction (6) instead of that formed by the reactions (7) and (8). Since the carbonylation rate of α-bromonaphthalene under lower pressures is independent of the pressure of carbon monoxide, the reaction (6) must be rate-determining.

On the other hand, a different kinetics has been observed for the carbonylation of bromobenzene under pressures of more than 150 kg/cm² at 250°C, where the rate is proportional to the amounts of $Ni(CO)_4$, bromobenzene, water, and the reciprocal of the pressure of carbon monoxide, and is independent of the amount of potassium acetate when its amount is more than that of the bromobenzene used, as has been reported in a previous paper.[4] In this case, bromobenzene is less reactive than α-bromonaphthalene and the catalyst must be present predominantly in the form of $Ni(CO)_4$ because of the high pressures of carbon monoxide. The carbonylation rate of bromobenzene can, accordingly, be explained by the same reaction path, assuming that the reactions (3) and (4) are in equilibrium and that (5) is rate-determining.

From the above discussion, it can be concluded that nickel tricarbonyl is the active species in the carbonylation of aryl halide with nickel tetracarbonyl in the presence of potassium acetate in methanol, and that the course of its catalytic reaction can reasonably be explained by the reaction path derived from the stoichiometric reaction.

Experimental

Materials. The iodobenzene and *trans*-ω-bromostyrene were commercial products. They were distilled before use. Iodobenzene especially was carefully purified by fractional distillation (Podbielniak 4500; glass concentric-tube column), because a trace amount of nitrobenzene strongly inhibited the carbonylation of iodobenzene. The *trans*-ω-bromostyrene might contain a small amount of *cis*-ω-bromostyrene, which was difficult to separate by distillation. The α-iodonaphthalene was freshly prepared by the iodination of naphthalene using $AgClO_4$, according to the method described in the literature.[20] The α-bromostyrene was prepared by drawing out hydrobromic acid with a potassium hydroxide ethanol solution from the α,ω-dibromoethylbenzene obtained by the bromination of styrene.[21] All these substances were purified by distillation under a vacuum. The nickel tetracarbonyl, potassium acetate, and other compounds employed in this study were obtained from commercial sources.

Carbonylation of Iodobenzene. A methanol solution of iodobenzene and potasssium acetate was placed in a two-necked flask (100 m*l* in vol.) equipped with a reflux condenser. A given amount of distilled nickel tetracarbonyl was condensed into the flask, which had been cooled by immersing it in solid carbon dioxide - methanol; then the flask was warmed up to 50°C while being vigorously stirred under an atmospheric pressure of nitrogen, with the temperature being kept constant. After 2 hr, the residual nickel tetracarbonyl was completely evacuated; then the solution was filtered to separate a black precipitate (metallic nickel). Sufficient amounts of ether and water were added to the filtrate to extract and separate organic compounds from the Ni^{2+} and I^- formed. The amounts of methyl benzoate and iodobenzene in the ether solution were determined by gas chromatography. The black precipitate was dissolved in aqueous nitric acid; its quantity was determined by the ordinary EDTA method. These results are summarized in Table 1.

Carbonylation of α-Iodonaphthalene. The reaction of α-iodonaphthalene (0.023 mol) with $Ni(CO)_4$ (0.0056 mol) was carried out at 30°C for 6 hr in methanol(2.0 mol) containing potassium acetate (0.023 mol) under an atmospheric pressure of nitrogen. By treating the product according to the same procedure described above, I^- (0.0177 mol) and total nickel (0.0049 mol; metallic nickel 0.0017 mol and Ni^{2+} 0.0032 mol) were separated from the organic compounds, where $[I^-]/[\text{Total Ni}]$ was 3.64. The amount of α-methylnaphthoate could be estimated from the amount of I^- formed, because no other organic compounds, such as naphthalene or ketones, were detected.

Carbonylation of Bromostyrene. Under the same reaction conditions and using the same procedure as those used for iodobenzene, ω-bromostyrene (0.046 mol) reacted with $Ni(CO)_4$ (0.012 mol) in methanol (2.0 mol) containing potassium acetate (0.046 mol) to give methyl cinnamate and cinnamic acid. In this case, the amounts of Br^- and Ni^{2+} were 0.046 mol and 0.0095 mol respectively. From an ethereal

18) The Ni^{2+} ion is presumably formed by the reaction of metallic nickel with the acetic acid formed, namely: $Ni + 2\,AcOH \rightarrow Ni(AcO)_2 + H_2\uparrow$.

19) M. Nakayama and T. Mizoroki, This Bulletin, **43**, 569 (1970).

20) L. Birckenbach and J. Goubeau, *Ber.*, **65**, 395 (1932).

21) F. Ashworth and G. N. Burkhardt, *J. Chem. Soc.*, **1928**, 1801.

solution, free cinnamic acid (0.0054 mol) beside its ester (0.0271 mol) were isolated, though no free carboxylic acid was isolated from the carbonylation product of iodobenzene or α-iodonaphthalene. α-Bromostyrene (0.046 mol) also gave methyl α-phenyl acrylate and α-phenylacrylic acid (atropic acid) (Found: C, 72.6; H, 5.4%. Calcd for $C_9H_8O_2$: C, 73.0; H, 5.4%. mp 108—9°C), and a small amount of styrene (0.0059 mol) was observed on their gas chromatograms. The total amount of α-phenylacrylic acid formed could be estimated from that of Br^- (0.0441 mol).

Analytical Procedure. Most of the organic compounds were quantitatively determined by gas chromatography. A 1.5-m stainless steel column (3 mmϕ) with silicone DC 11 was used at a temperature of 160 or 190°C, with a hydrogen carrier and a gas-flow rate of 40 ml/min. In this procedure, naphthalene was used as the internal standard for determining the amounts of iodobenzene and methyl benzoate, and α-bromonaphthalene was used for bromostyrene and their corresponding esters. Free carboxylic acids (cinnamic acid and α-phenylacrylic acid) were precipitated by adding an aqueous hydrochloric acid solution to their potassium salts, and their amounts were titrated with an aqueous potassium hydroxide solution. The compounds were identified by means of the IR absorption spectrum, the melting points, a comparison of their gas chromatograms with those of authentic samples, or the results of elementary analysis, if necessary. The halide ion (Br^- or I^-) and the nickel(II) ion were determined by the Volhard and EDTA methods respectively.

IR Absorption Spectra during the Carbonylation. To record the IR absorption spectrum during the course of the reaction with iodobenzene or α-iodonaphthalene, the carbon monoxide present in the gas phase had been excluded by a nitrogen-gas stream before the reaction was carried out at room temperature. A part of the solution was drawn out from the vessel about once an hour by means of a small cylinder and put into a KRS-5 cell under nitrogen in order to record the variation in the IR absorption spectra during the carbonylation.

The authors wish to acknowledge the enthusiastic assistance of Mr. Masao Ichinose in carrying out this work.

Polarography of Halides in Dimethylformamide. VI. The Formation of the Benzhydryl Radical from Benzhydryl Bromide and Its Subsequent Reduction at the Dropping Mercury Electrode

Yoshihisa MATSUI, Takashi SOGA, and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu-cho, Matsue

(Received August 6, 1970)

The polarographic behavior of benzhydryl bromide at the dropping mercury electrode was investigated in dimethylformamide at 25°C. It gives three waves, with half-wave potentials at about +0.19, −0.15, and −1.00 V *vs.* SCE. The first wave is anodic, while the others are cathodic. It was concluded that benzhydryl bromide, prior to being electrolytically reduced, rapidly reacts with the mercury of the cathode according to the following equation:

$$3(C_6H_5)_2CHBr + Hg \longrightarrow 2(C_6H_5)_2CH\cdot + (C_6H_5)_2CH^+ + HgBr_3^-$$

The first wave given by the bromide was ascribed to the oxidation of $HgBr_3^-$ to $HgBr_2$; the second, to the reduction of $HgBr_3^-$ to Hg and Br^-, and the third, to the reduction of $(C_6H_5)_2CH\cdot$ to $(C_6H_5)_2CH^-$. The cation, $(C_6H_5)_2CH^+$, was found to give no wave. Such behavior of benzhydryl bromide was discussed in comparison with that of the corresponding chloride, which gives a single wave with a usual two-electron transfer.

Organic halides are not always electrolyzed in a usual two-electron reduction, followed by the uptake of the hydrogen ions to yield the corresponding hydrocarbons. For example, when an organic halide reacts rapidly with the mercury used as the indicator electrode, the electrode process can differ from those of usual halides which are reduced in two-electron steps. Thus, Keller *et al.*[1] have polarographically shown that the mercury may remove two chlorine atoms from 1,1-di-*p*-chlorophenyl-1,2,2,2-tetrachloroethane before the electron transfer occurs and thus form 1,1-di-*p*-chlorophenyl-2,2-dichloroethylene, which in turn is electrolytically reduced. Wawzonek *et al.*[2] have shown that benzyl iodide in acetonitrile, prior to being electrolytically reduced, reacts with the mercury of the indicator electrode to yield benzylmercuric iodide, which is then reduced to toluene, mercury, and the iodide ion. Similar examples can also be seen in benzotrichloride,[3] diphenyldichloromethane,[3] and triphenylmethyl chloride.[4] These indicate that polarography with the dropping mercury electrode is a useful means of elucidating the mechanisms of the reactions between mercury and the organic species which are reactive to mercury.

In the present paper, we will examine the polarographic behavior of benzhydryl bromide in dimethylformamide (DMF). The bromide was found to give unusual polarographic waves as a result of its reaction with mercury preceding the electrolytic reduction. The mechanism of the chemical and electrochemical reactions of the bromide at the dropping mercury

electrode will be discussed in detail on the basis of the results of DC polarography and large-scale electrolysis at a controlled potential.

Results and Discussion

Polarographic Behavior of Benzhydryl Bromide. The polarographic behavior of benzhydryl bromide at the dropping mercury electrode was investigated in DMF containing 0.10 M tetraethylammonium perchlorate at 25°C. The bromide gives three waves; the first wave is anodic,[5] while the others are cathodic (Fig. 1). The ratio of the heights of these waves is approximately 1 : 2 : 2. However, the height of the third wave decreases with the time, while those of the first and second waves remain constant (Table 1). The decrease in the height of the third wave can be accelerated by stirring the cell solution, but it is appreciably

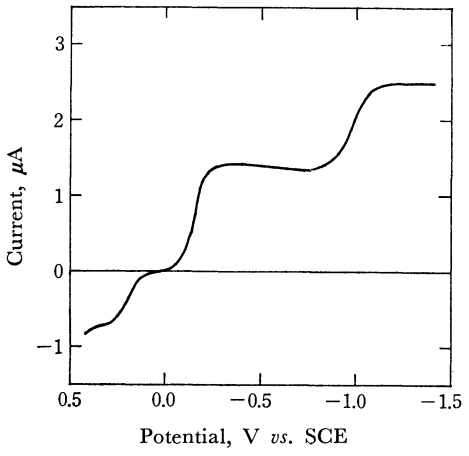

Fig. 1. Polarogram of 0.75 mM $(C_6H_5)_2CHBr$ in DMF containing 0.1 M Et_4NClO_4 at 25°C.

Table 1. Change of the heights of the waves given by benzhydryl bromide[a] with the time (25°C)

Time[b] (min)	i_d (μA)		
	1st wave	2nd wave	3rd wave
2	1.20	2.38	2.11
120	1.18	2.39	1.87
180	1.22	2.47	1.30
260	1.17	2.13	1.00

a) 1.0 mM.
b) The time was measured after the addition of mercury to the test solution.

5) When the solution of the bromide in DMF was fresh enough, the first wave was cathodic in part; it then turned anodic in time. The change did not stop until the first wave became completely anodic. It seems that this change is closely related to the simultaneously-occurring increase in the specific conductance of the bromide solution, as will be shown in Fig. 5. Thus, it is evident that the bromide undergoes ionization in DMF to form the ion-pair intermediate, and that the polarographic behavior of the resulting ionic species is different from that of the bromide in a covalently-bonded initial state. In the present study, the bromide was always allowed to stand in DMF for at least 3 hr before being used. Accordingly, most of the bromide might have been ionized by the time it was examined.

suppressed by using the platinum foil as the anode instead of the mercury pool. So far as the test solution is allowed to stand without contact with mercury, the height of the third wave does not decrease. These facts indicate that benzhydryl bromide reacts with mercury to form at least two electroactive species, one of which must be labile. Accordingly, the measurement of the polarogram of this depolarizer was always started as soon as possible after the test solution had come into contact with the mercury.

The polarographic characteristics of the bromide at various concentrations are given in Table 2. The height of each wave is practically proportional to the concentration of the depolarizer and to the square root of the height of the mercury reservoir; these facts indicate that each wave is diffusion-controlled. The diffusion coefficient of the bromide, calculated from the Ilkovic equation on the assumption that the third wave is due to a one-electron reduction, is equal to 3.3×10^{-6} cm²/sec; this value is too small to be regarded as the true value. We will discuss this question again later. It was also found that the half-wave potential of the third wave is practically independent of the concentration of the depolarizer, whereas that of the second wave shifts to the more negative potentials with an increase in the concentration. Because of the considerable irregularity of the plots given, no trends were obtained as to the change in the half-wave potential of the first wave with the concentration.

Comparison of the Polarographic Behavior of Benzhydryl Bromide with That of the Corresponding Chloride. The polarogram of benzhydryl chloride is in clear contrast to that of the corresponding bromide. The former gives only a single reduction wave (Fig. 2), although a maximum appears at depolarizer concentrations higher than 0.8 mM. The polarographic characteristics of the chloride at various concentrations are shown in Table 3. The height of the wave is virtually proportional to the concentration of the depolarizer; this indicates that the wave is diffusion-controlled. The diffusion coefficient of the chloride, calculated from the Ilkovic equation on the assumption that the wave is due to a two-electron step, is equal to 11.3×10^{-6} cm²/sec; this value is fairly appropriate for this molecule. The marked difference in the polaro-

graphic behavior between the chloride and the bromide may be related to the difference in their reactivities with mercury. As has been described above, benzhydryl bromide in DMF reacts rapidly with mercury. It seems that the rate of the reaction is determined by the diffusion of the bromide. On the other hand, benzhydryl chloride in DMF reacts very slowly with mercury. When a solution of the chloride in DMF was stirred with mercury at 25°C, the height of the polarographic wave resulting from the reduction of the chloride decreased very slowly with the time (Fig. 3). At the same time, two new waves appeared in the less negative potential region, and they increased with the time. The new waves were closely similar in characteristics to the first and second waves of benzhydryl bromide; the first was anodic, the second was cathodic, and the ratio of the wave heights was about 1 : 2.

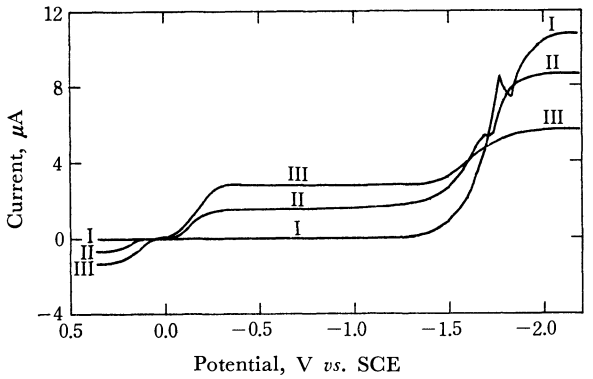

Fig. 3. Change of the polarogram of $(C_6H_5)_2CHCl$ (1.68 mM) in DMF at 25°C with the time.
I, 0 min; II, 2.0 days; III, 10.0 days after the addition of mercury to the test solution

The First and the Second Waves of Benzhydryl Bromide. It was noticed that the first and the second polarographic waves of benzhydryl bromide, as well as those of the reaction mixture of benzhydryl chloride with mercury, are very similar to the waves of the trihalogenomercurate ion. As has been shown in previous papers,[6,7] the trihalogenomercurate ion gives two waves, at about +0.2 and −0.15 V *vs.* SCE; the first is anodic, the second is cathodic, and the ratio between the heights of the waves is approximately equal to 1 : 2. This suggests that benzhydryl bromide and chloride react with mercury to form the tribromo- and trichloromercurate ions respectively. The reaction of benzhydryl bromide with mercury may be so rapid that it precedes the electrolytic reduction. Hence, the bromide gives the waves due to the electrolysis of the tribromomercurate ion instead of those due to the electrolysis of benzhydryl bromide itself.

This conclusion was substantiated by the analysis of the waves given by benzhydryl bromide. The electrode reactions of the tribromomercurate ion at the dropping mercury electrode can be expressed in terms of the following equations:[6]

$$\text{1st wave: } 2\,HgBr_3^- + Hg \rightleftarrows 3\,HgBr_2 + 2\,e \quad (1)$$

$$\text{2nd wave: } 2\,HgBr_3^- + 4\,e \rightleftarrows 2\,Hg + 6\,Br^- \quad (2)$$

If the first and the second waves of benzhydryl bromide are due to the depolarization by the tribromomercurate ion, the following relations between current and potential, which have shown to hold for the waves of the latter,[6] should hold for those of the former:

$$\text{1st wave: } E = C_1 + (RT/2F)\ln i^3/(i_d - i)^2 \quad (3)$$

$$\text{2nd wave: } E = C_2 - (RT/2F)\ln i^3/(i_d - i) \quad (4)$$

The results of the analyses of these waves, as well as that of the third wave, are given in Fig. 4. A nearly linear relation was obtained for each of these waves; this means that the presumption presented above is valid. From Eqs. (3) and (4) we can easily derive the relation between the half-wave potential and the concentration of the depolarizer,[6] which shows that the half-wave potential of the first wave should shift to more positive potentials, and that of the second wave, to more negative potentials, with an increase in the depolarizer concentration. The results in Table 2 show that this speculation is also valid, although the data for the first wave show considerable scatter.

The Third Wave of Benzhydryl Bromide. It was found that the height of each of the waves given by 1.0 mM of the tribromomercurate ion (I_d's=1.95 and

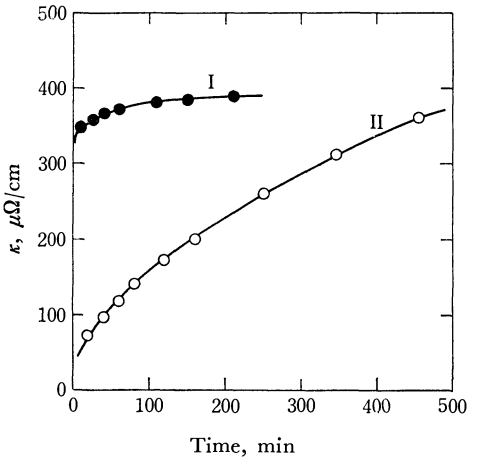

Fig. 5. Plots of the conductance *vs.* the time.
I: $(C_6H_5)_2CHBr$ (44.4 mM) + $HgBr_2$ (44.4 mM) in DMF
II: $(C_6H_5)_2CHBr$ (83.4 mM) in DMF

3.54 for the first and the second waves respectively[6]) is about three times that of the corresponding waves given by 1.0 mM of benzhydryl bromide; this indicates that three moles of benzhydryl bromide react with one gram-atom of mercury to yield one mole of the tribromomercurate ion. Hence, the following stoichiometric equation seems the most probable:

$$3\,(C_6H_5)_2CHBr + Hg \longrightarrow 2\,(C_6H_5)_2CH\cdot + (C_6H_5)_2CH^+ + HgBr_3^- \qquad (5)$$

Provided that the reaction expressed by Eq. (5) precedes the electrolytic reduction of benzhydryl bromide itself, the third wave of the bromide may be ascribed either to the reduction of the benzhydryl radical or to that of the benzhydryl cation. In order to make this point clear, we examined the polarographic behavior of an equimolar solution of benzhydryl bromide and mercuric bromide in DMF. The reaction between them is fairly rapid, as is shown by the rapid increase in the conductance of the solution (Fig. 5), while the conductance of the DMF solution containing only benzhydryl bromide shows a slower increase with the time. The polarogram of the equimolar solution is shown in Fig. 6. Although the two waves corresponding to the electrolyses of the tribromomercurate ion appeared, no wave arose in the potential region where the third wave of benzhydryl bromide appeared. This shows that benzhydryl bromide reacts with mercuric bromide and yields the tribromomercurate ion, together with the benzhydryl cation; the latter, however, gives no polarographic wave. The cation thus formed may be so labile that it may rapidly react either with the solvent or with the moisture in the solution to form electrolytically-inert species, such as the strongly solvated benzhydryl cation or benzhydrol. Accordingly, the third wave of benzhydryl bromide can be ascribed to the reduction of the benzhydryl radical (Eq. (6)). This is substantiated by the identification of the reaction products, to be described later.

$$\text{3rd wave: } (C_6H_5)_2CH\cdot + e \rightleftarrows (C_6H_5)_2CH^- \qquad (6)$$

It is evident that we can explain, in terms of the

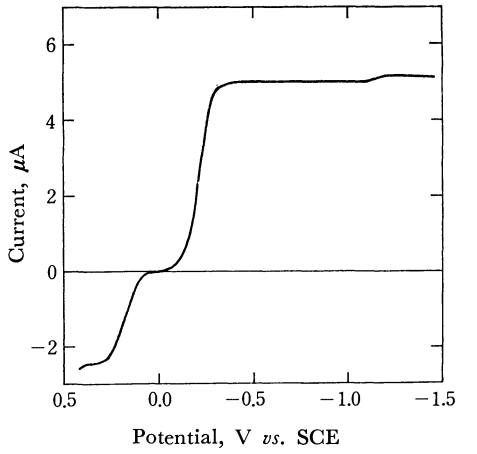

Fig. 6. Polarogram of the equimolar solution (0.83 mM) of $(C_6H_5)_2CHBr$ and $HgBr_2$ in DMF at 25°C.

chemical reaction expressed by Eq. (5) and the subsequent electrochemical reactions expressed by Eqs. (1), (2), and (6), the fact that the ratio among the three waves of the bromide is approximately 1 : 2 : 2. Moreover, the diffusion coefficient of the bromide calculated on the basis of this mechanism equals 7.4×10^{-6} cm²/sec; this value seems appropriate for the depolarizer. The decrease in the height of the third wave of benzhydryl bromide with the time can also be explained in terms of the above mechanism. During repeated measurements of the polarograms, benzhydryl bromide reacts with mercury, mainly that of the mercury pool. The resulting benzhydryl radical is so unstable that it dimerizes to form *sym*-tetraphenylethane, which is electrolytically inert. Since the decrease in the concentration of benzhydryl bromide in the cell solution is accompanied by no increase in the concentration of the benzhydryl radical, the height of the third wave decreases with the time. On the other hand, the decrease in the concentration of benzhydryl bromide is accompanied by an increase in the concentration of the tribromomercurate ion. Therefore, the heights of the first and the second waves scarcely change at all with the time.

The logarithmic plot of the third wave is shown in Fig. 4. A nearly linear relation was obtained between the potential and $\log i/(i_d-i)$ with the reciprocal slope of 0.098 V, indicating that the electrode reaction is irreversible.

It is noteworthy that the half-wave potential of the labile benzhydryl radical is less negative by 0.67 V than that of benzhydryl chloride. The polarographic reduction of organic halide is usually expressed in terms of the following reactions:[8]

$$RX + e \rightleftarrows R\cdot + X^- \quad (7)$$

$$R\cdot + e \longrightarrow R^- \quad (8)$$

$$R^- + \text{solvent} \longrightarrow RH \quad (9)$$

Among these reactions, the one expressed by Eq. (7) is considered to be the potential-determining step, for the radical, R·, may be more reducible than the starting halide. Thus, once the halide is electrolytically reduced to the corresponding radical, the latter may immediately be reduced to the corresponding carbanion at the same potential. However, the half-wave potential of such an unstable organic radical had never actually been measured until, in the present experiment, it was shown that the half-wave potential of the benzhydryl radical is less negative than that of the corresponding chloride.

Identification of Reaction Products. Benzhydryl bromide in DMF containing 0.10 M tetraethylammonium perchlorate was reacted with mercury in an atmosphere of nitrogen. From the reaction mixture, *sym*-tetraphenylethane, benzophenone, and benzhydrol were isolated by chromatography in 46, 6, and 34% yields respectively, based on the starting bromide (see the Experimental section). It seems that the *sym*-tetraphenylethane is formed by the dimerization of the benzhydryl radical. It might be considered that the benzophenone is an impurity contained in the starting bromide. However, it is known[9] that the radicals with α-hydrogens, such as the benzhydryl radical, react with oxygen and form the corresponding ketones, together with the corresponding alcohols, according to the following reactions (see also the subsequent paragraph):

$$R_2CH\cdot + O_2 \longrightarrow R_2CHOO\cdot \quad (10)$$

$$2\ R_2CHOO\cdot \longrightarrow R_2CO + R_2CHOH + O_2 \quad (11)$$

Thus, it seems that at least a part of the benzophenone, as well as a part of the benzhydrol, may be formed by the reaction of the benzhydryl radical with the small amount of oxygen contained in the nitrogen. The main part of the benzhydrol may be formed by the hydrolysis of the solvated benzhydryl cation. Thus, the reaction products can be classified into two groups, *i.e.*, the products obtained *via* the benzhydryl radical and those obtained *via* the benzhydryl cation; it is evident that the number of the moles of the former is approximately twice that of the latter. Furthermore, it was found that in this reaction *ca.* 1.0 g-atom of mercury is consumed per three moles of the benzhydryl bromide. These results indicate that Eq. (5) is valid.

When benzhydryl bromide was allowed to react with mercury in a stream of dry air, the yield of *sym*-tetraphenylethane based on the starting bromide decreased to 18%, whereas those of benzophenone and benzhydrol increased significantly, to 24 and 45% respectively. Dibenzhydryl ether, which may be produced by the reaction of the benzhydryl cation with benzhydrol, was also obtained in an 8% yield. These results agree well with those to be expected from Eqs. (10) and (11).

In order to examine the effect of the solvent on the present reaction, benzhydryl bromide was allowed to react with mercury in benzene. It was found that *sym*-tetraphenylethane is formed quantitatively, while benzophenone and benzhydrol are scarcely formed at all. It was also found that mercurous bromide is quantitatively formed at the same time. These results indicate that the solvent plays an important role in the present reaction. It is known[6] that the tribromomercurate ion, as well as mercuric bromide, is extremely stable in DMF, while mercurous bromide is insoluble in DMF and decomposes in part to form mercury and mercuric bromide. Hence, benzhydryl bromide in DMF reacts with mercury to yield the most stable species of the brominated mercurys, *i.e.*, the tribromomercurate ion, together with the benzhydryl radical and the benzhydryl cation. On the other hand, in benzene mercurous bromide may be more stable than either mercuric bromide or the tribromomercurate ion. Thus, the benzhydryl bromide in benzene reacts with mercury to form mercurous bromide and the benzhydryl radical, but the benzhydryl cation may not be formed in this case.

When benzhydryl bromide in DMF was electrolyzed with the Hg cathode at the controlled potential of −0.60 V *vs.* SCE, where the limiting current corresponding to the second polarographic wave of the bromide flows, an almost quantitative yield (89%) of *sym*-tetraphenylethane was obtained. The quantity of electricity (n) required for the reduction of one mole of the depolarizer was found to be 1.10 Faradays. These results can be explained in terms of the following mechanism:

$$3\ (C_6H_5)_2CHBr + Hg \longrightarrow 2\ (C_6H_5)_2CH\cdot + (C_6H_5)_2CH^+ + HgBr_3^-$$

$$HgBr_3^- + 2\ e \rightleftarrows Hg + 3\ Br^-$$

$$(C_6H_5)_2CH^+ + Br^- \longrightarrow (C_6H_5)_2CHBr \quad (12)$$

$$2\ (C_6H_5)_2CH\cdot \longrightarrow (C_6H_5)_2CHCH(C_6H_5)_2 \quad (13)$$

The bromide ion, formed by the reduction of the tribromomercurate ion at −0.60 V *vs.* SCE, may react with the solvated benzhydryl cation, thus regenerating the original benzhydryl bromide. Thus, none of the products expected to be formed *via* the benzhydryl cation are obtained. Furthermore, it can also be explained in terms of the above mechanism that the value of n is virtually equal to 1.0 Faraday rather than to the 0.67 Faraday which is to be expected from the results of the DC polarography.

9) C. Walling, "Free Radicals in Solution," John Wiley & Sons, New York, N. Y. (1957), p. 423.

The electrolytic reduction of benzhydryl bromide with the Hg cathode at the controlled potential of −1.40 V *vs.* SCE, where the limiting current of the third polarographic wave of the bromide flows, resulted in the formation of 38% of diphenylmethane and 51% of *sym*-tetraphenylethane, based on the original bromide. The value of n was measured to be 1.13 Faradays. These results can be explained by the following mechanism:

$$3\,(C_6H_5)_2CHBr + Hg \longrightarrow$$
$$2\,(C_6H_5)_2CH\cdot + (C_6H_5)_2CH^+ + HgBr_3^-$$
$$HgBr_3^- + 2\,e \rightleftarrows Hg + 3\,Br^-$$
$$2\,(C_6H_5)_2CH\cdot + 2\,e \rightleftarrows 2\,(C_6H_5)_2CH^-$$
$$(C_6H_5)_2CH^- + \text{solvent} \longrightarrow (C_6H_5)_2CH_2 \quad (14)$$
$$(C_6H_5)_2CH^- + (C_6H_5)CH^+ \longrightarrow (C_6H_5)_2CHCH(C_6H_5)_2 \quad (15)$$

Since diphenylmethane has never been obtained until the present run, it is obvious that the substance is formed *via* the benzhydryl anion. About a half of the benzhydryl anion generated may react with the solvated benzhydryl cation to form *sym*-tetraphenylethane. According to the above mechanism, the value of n should equal 1.33 Faradays; this value agrees roughly with that observed.

The electrolytic reduction of benzhydryl chloride at the controlled potential of −2.13 V *vs.* SCE, where the limiting current corresponding to the single polarographic wave of the chloride flows, resulted in the formation of 46% of diphenylmethane and 6% of *sym*-tetraphenylethane. *It is remarkable that the yield* of diphenylmethane is much higher than that of *sym*-tetraphenylethane, unlike the case of benzhydryl bromide. This indicates that the benzhydryl anion has reacted with the solvent to form diphenylmethane before it reacts with the benzhydryl chloride diffusing toward the electrode to form *sym*-tetraphenylethane. On the other hand, when benzhydryl bromide is the depolarizer, the formation of the benzhydryl cation by the chemical process, together with that of the benzhydryl anion by the electrochemical process, occurs on the electrode surface. Hence, the yield of the product due to the combination of the anion with the cation, *i.e.*, the yield of *sym*-tetraphenylethane, increases significantly.

Experimental

Materials. The DMF used as a solvent was purified as has been described previously.[10] The tetraethylammonium perchlorate used as a supporting electrolyte was prepared according to the directions of Fujinaga *et al.*[11] The benzhydryl bromide was prepared by the reaction of bromine with diphenylmethane[12] (bp 148—150°C/5 mmHg). The benzhydryl chloride was prepared by the reaction of thionyl chloride with benzhydrol[13] (bp 131—133.5°C/7 mmHg). Mercuric bromide obtained commercially was purified by recrystallizing it from ethanol.

Procedure. DC polarography, large-scale electrolysis at a controlled potential, and conductivity measurements were carried out as has been described previously.[6] All the potential measurements were done with reference to an aqueous saturated calomel electrode connected with the cell solution by a DMF-agar salt bridge.[14] The dropping mercury electrode used had the following characteristics in a 0.10 M solution of tetraethylammonium perchlorate in DMF (open circuit): $m=1.540$ mg/sec and $t=6.4$ sec for $h=66$ cm. Benzhydryl bromide was always allowed to stand in DMF for at least 3 hr before being used. The oxygen dissolved in the solution was expelled by passing a stream of dry nitrogen through the cell solution for about 20 min prior to each electrolysis.

The Reaction of Benzhydryl Bromide with Mercury in a Degassed DMF Solution. A 0.10 M solution (50 ml) of tetraethylammonium perchlorate in DMF was degassed for 1 hr with nitrogen. To the solution, mercury (68.73 g, 342.6 mg-atom) and benzhydryl bromide (1.30 g, 5.26 mmol) were then added; the mixture was subsequently held at 25°C under a nitrogen atmosphere for 22.5 hr. The mercury was then separated from the reaction mixture, washed with water, dried *in vacuo*, and found to weigh 68.40 g (341.0 mg-atom). Hence, 1.6 mg-atom of mercury was consumed for its reaction with 5.26 mmol of the bromide. The DMF solution was concentrated by vacuum distillation, and the residue was taken up with benzene. The resulting solution was washed with water, dried with calcium chloride, and evaporated. The residue was recrystallized from *n*-hexane - benzene (4 : 1 by volume) to afford 0.366 g of *sym*-tetraphenylethane (mp 207—210°C; lit,[15] mp 211°C), the infrared spectrum of which was identical with that of an authentic sample. The mother liquor from the recrystallization was evaporated *in vacuo*, and the residue was chromatographed on alumina. Elution with *n*-hexane - benzene (9 : 1 by volume) afforded 0.033 g of additional *sym*-tetraphenylethane, mp 205—207°C (its identity was established by the infrared spectrum). The benzene fractions gave 0.062 g of benzophenone (mp 46—48°C; lit,[16] mp 49°C), which was identified by comparing its infrared spectrum with that of an authentic sample. The ether fractions afforded 0.326 g of benzhydrol (mp 65—67°C; lit,[16] mp 69°C), the infrared spectrum of which was identical with that of an authentic sample. From these results, the yields of *sym*-tetraphenylethane, benzophenone, and benzhydrol were estimated to be 46, 6, and 34% respectively.

The Reaction of Benzhydryl Bromide with Mercury in a DMF Solution Saturated by Oxygen. Dry air was bubbled into a mixture of 3.00 g (12.1 mmol) of benzhydryl bromide, 93.50 g of DMF, and 80.60 g of mercury for 280 min at room temperature. A white precipitate appeared. The reaction mixture was then filtered, and the filtrate was concentrated by vacuum distillation. When benzene was added to the residue, *ca.* 1 ml of insoluble liquid appeared; this was then separated. The benzene solution was washed with water, dried with magnesium sulfate, and evaporated *in vacuo*. By the recrystallization of the residue from methanol, 0.34 g

of *sym*-tetraphenylethane was obtained (mp 206—208°C). The combined filtrates were evaporated *in vacuo* to give 1.97 g of an oily material, of which 0.96 g was chromatographed on alumina. *n*-Hexane fractions gave 0.10 g of crystals, which were fractionally recrystallized from ethanol to give 0.009 g of *sym*-tetraphenylethane (mp 195—201°C) and 0.079 g of dibenzhydryl ether (mp 101—105°C; lit,[17] mp 110°C; its identity was established by a study of the infrared spectrum). The benzene fractions gave 0.235 g of benzophenone (mp 44—48°C). The ether fractions gave 0.492 g of benzhydrol (mp 66—68°C). From these results, the yields of *sym*-tetraphenylethane, dibenzhydryl ether, benzophenone, and benzhydrol were estimated to be 18, 8, 24, and 45% respectively.

The Reaction of Benzhydryl Bromide with Mercury in a Benzene Solution. To a solution of 1.505 g (6.09 mmol) of benzhydryl bromide in 50 m*l* of benzene, 5 m*l* of mercury was added, and the resultant mixture was boiled under reflux for 9 hr. Gray solids precipitated. After the separation of the mercury, the reaction mixture was filtered. The residue was washed several times with hot benzene, and the combined benzene solution was evaporated *in vacuo* to give a viscous oil containing some white crystals; these crystals were recrystallized from benzene to give 0.659 g of *sym*-tetraphenylethane (mp 202—207°C). The mother liquor was evaporated *in vacuo*, and the residue was chromatographed on alumina. Elution with *n*-hexane gave 0.287 g of *sym*-tetraphenylethane (mp 205—207°C; total yield, 93%). The benzene fractions gave 0.001 g (0.1% yield) of benzophenone, and the ether fraction gave a trace of benzhydrol. Each of these products was identified by means of its infrared spectrum.

The gray solids precipitated from the reaction mixture were practically insoluble in DMF, too. However, when they were added to the solution of 2.56 g (12.2 mmol) of tetraethylammonium bromide in 100 m*l* DMF, they dissolved and the mercury was separated. The polarographic measurement of the resulting solution indicated that it contained 2.70 mmol of the tribromomercurate ion. This behavior of the gray solids is identical with that of mercurous bromide, which has been studied in the previous paper.[6] Hence, the yield of mercurous bromide was estimated to be 89%, based on the original bromide.

The Controlled Potential Electrolysis of Benzhydryl Bromide in DMF at −0.60 V vs. SCE. In a 1-*l* electrolytic cell, 300 m*l* of DMF, 6.87 g of tetraethylammonium perchlorate, and 50 m*l* of mercury were placed; the mixture was cooled to 2—4°C and degassed with nitrogen. Immediately after 0.366 g (1.48 mmol) of benzhydryl bromide had been added to the mixture, controlled potential electrolysis was started at −0.60 V *vs.* SCE. The quantity of electricity required for the complete electrolysis was estimated graphically from the current-time curve to be 0.00163 Faraday. The polarogram of the resulting catholyte agreed virtually completely with that of the bromide ion. The catholyte was concentrated by vacuum distillation and the residue was taken up in benzene. The benzene solution was washed with water, dried with calcium chloride, and evaporated. From the residue, 0.221 g (89% yield) of *sym*-tetraphenylethane (mp 205—206.5°C) and 0.029 g (8% yield) of benzophenone were isolated by fractional recrystallization and chromatography on alumina. Identity was established by a study of the infrared spectrum.

The Controlled Potential Electrolysis of Benzhydryl Bromide in DMF at −1.40 V vs. SCE. In a 1-*l* electrolytic cell, 300 m*l* of DMF, 6.87 g of tetraethylammonium perchlorate, and 50 m*l* of mercury were placed; the mixture was cooled to 2—4°C and degassed by a stream of nitrogen for 2 hr. Immediately after 0.344 g (1.39 mmol) of benzhydryl bromide had been added to the mixture, the resulting solution was electrolyzed at −1.40 V *vs.* SCE for 130 min. The quantity of electricity required for the complete electrolysis was estimated to be 0.00157 Faraday. The polarogram of the resulting catholyte agreed closely with that of the bromide ion. The catholyte was worked up exactly as in the previous experiment; 0.119 g (51% yield) of *sym*-tetraphenylethane (mp 210—212°C), 0.088 g (38% yield) of diphenylmethane (mp 25—26°C; lit,[16] mp 27°C) (identity established by a study of the infrared spectrum), and 0.012 g (5% yield) of benzophenone were thus obtained.

The Controlled Potential Electrolysis of Benzhydryl Chrolide in DMF at −2.13 V vs. SCE. A solution of 300 m*l* of DMF, 6.89 g of tetraethylammonium perchlorate, and 5.70 g (28.1 mmol) of benzhydryl chloride was degassed for 2 hr with pure nitrogen, and then electrolyzed at a controlled potential of −2.13 V *vs.* SCE. The current started at 7.5 A and fell to 0.026 A after 42.5 hr. The resulting catholyte was worked up exactly as in the previous experiment; 2.182 g (46% yield) of diphenylmethane (mp 25—26°C), 0.270 g (6% yield) of *sym*-tetraphenylethane (mp 206.5—207.5°C), 0.164 g (3% yield) of benzophenone, and 0.308 g (6% yield) of benzhydrol were thus obtained. Identity was established by a study of the infrared spectrum.

The Mechanism of the Reaction of Quinolines with Organolithium Compounds[1]

Yoshio Otsuji, Kiyohiko Yutani, and Eiji Imoto

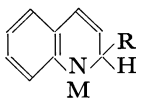
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received August 12, 1970)

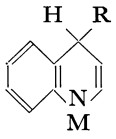
The treatment of lepidine (IV) with phenyllithium in ether afforded 2-phenyl-4-methylquinoline (V) along with small amounts of 2-phenylquinoline (VI) and 2-methyl-4-phenylquinoline (VII). The similar treatment of IV with phenyllithium and then with ethyl chloroformate gave 1-ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa). The alkaline hydrolysis of VIIIa produced a mixture of V, VI, and VII. Similar experiments were carried out on the reactions between IV and *n*-butyllithium and between quinoline and phenyllithium. On the basis of these results and other observations, a new mechanism involving an addition-rearrangement-elimination was proposed for the reaction of quinolines with organolithium compounds.

Many investigations have already been made into the mechanism of the reactions of quinolines with organometallic compounds.[2] However, the mechanism still seems not to be well established. For example, quinoline reacts with phenyllithium,[3] butyllithium,[4] and phenylmagnesium bromide[5] to give mainly the 2-substituted products, *i.e.*, 2-phenyl- or 2-butylquinoline, along with only a small amount of the corresponding 4-substituted product. On the other hand, the treatment of quinoline with the methylsulfinyl carbanion in DMSO undergoes the substitution reaction exclusively at the 4-position of quinoline to produce lepidine in a quantitative yield.[6,7]

Throughout a whole series of these reactions between quinolines and organometallic reagents, it has always been assumed that the reactions proceed *via* the intermediate I or II. However, no conclusive evidence



I



II

for the existence of these intermediates has yet been appeared in the literature.[8] Furthermore, the factors which cause the difference in the orientation of the reactions (1,2- or 1,4-additions) remain unexplained.

In this paper we wish to report our findings on the isolation and characterization of the intermediates in the reactions of quinolines with organolithium compounds. We will also propose a new mechanism of the reactions based on the chemical properties of these intermediates.

Results and Discussion

Products of the Reaction of Lepidine with Phenyllithium. The treatment of lepidine (IV) with phenyllithium in ether at −70°C for 30 min produced a yellow precipitate. After the hydrolysis of the precipitate with water, the mixture was analyzed by the vpc. The analysis revealed that the mixture contained 2-phenyl-4-methylquinoline (V), 2-phenylquinoline (VI) and 2-methyl-4-phenylquinoline (VII) in a ratio of 96.5 : 3.0 : 0.5 respectively.

Isolation and Characterization of the Intermediates in the Reactions of Quinolines with Organolithium Compounds. When an ethereal solution of ethyl chloroformate was added to the suspension of the yellow precipitate in ether which had been produced by the reaction of lepidine with phenyllithium, the precipitate disappeared and a homogeneous solution was obtained. From this solution, 1-ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa) was isolated as white crystals in a 51% yield, along with small amounts of V and VII. The similar treatment of lepidine with *n*-butyllithium and then with ethyl chloroformate gave 1-ethoxycarbonyl-4-*n*-butyl-4-methyl-1,4-dihydroquinoline (VIIIb) as a pale yellow liquid in a 45% yield.

Commun.*, **1969**, 142), in studying the reaction of pyridine with phenyllithium, have characterized the intermediate of the type III on the basis of the NMR data.

III

The structures of VIIIa and VIIIb were established by a study of the results of their elemental analyses and spectral data, which are summarized in Table 1. The absorptions due to the C=C double bond in the IR spectra partly support the assigned structures; the comparison of the IR spectra of 1,4-dihydroquinolines and those of 1,2-dihydroquinolines suggests that the C=C double bond of the former absorbs at higher wave numbers than that of the latter compounds, which appears at $<1630\ cm^{-1}$, probably because the C=C bond in the latter is in conjugation with the benzene ring.[9] However, the final confirmation of the structures was attained from the NMR spectra, shown in Figs. 1 and 2. The spectra for the protons of the hetero-ring were readily analyzed as of the AB and AX types.

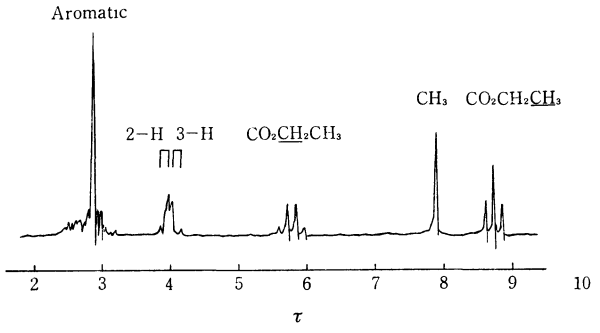

Fig. 1. NMR spectrum of 1-ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa) in CCl_4.

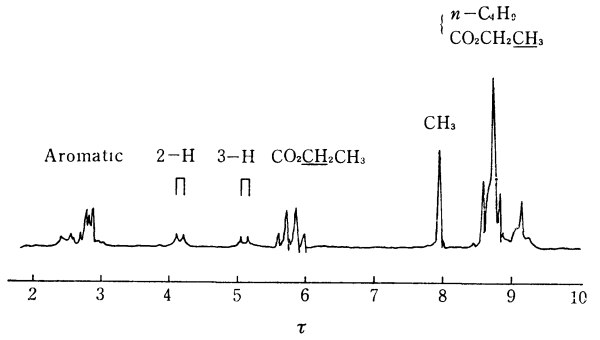

Fig. 2. NMR spectrum of 1-ethoxycarbonyl-4-*n*-butyl-4-methyl-1,4-dihydroquinoline (VIIIb) in CCl_4.

The chemical shifts for 2-H and 3-H, and the coupling constants, $J_{2,3}$ listed in Table 1, clearly indicate that they are of the olefinic protons in the hetero-ring; therefore, the structures identified as VIIIa and VIIIb are correct. It is now worthwhile to point out that the $J_{2,3}$ values obtained in this investigation are very close to those found by Bramley and Johnson[10] for the majority of 1,4-dihydroquinolines.

When quinoline was treated in ether with phenyllithium and then with ethyl chloroformate in a manner similar to that described above, a pale yellow liquid was obtained in a 59% yield. The structure of this liquid was supposed to be 1-ethoxycarbonyl-4-phenyl-1,4-dihydroquinoline (VIIIc). Though the IR spectrum supported the assigned structure, showing absorptions at 1695 and 1650 cm^{-1} (shoulder) due, respectively, to the C=O and C=C double bonds, the NMR spectra in CCl_4 exhibited a complex pattern which could not be readily analyzed; τ 2.5—3.2 (9H, multiplet, aromatic), 3.25—3.98 (3H, multiplet, 2-H, 3-H, 4-H), 5.78 (2H, quartet, $J=7.0$ Hz, $CO_2\mathbf{CH_2}$-CH_3), 8.72 (3H, triplet, $J=7.0$ Hz, $CO_2CH_2\mathbf{CH_3}$). However, further suport for the structure was secured by the experiments to be described below.

Hydrolysis of 1-Ethoxycarbonyl-1,4-dihydroquinolines. Surprisingly, VIIIa, VIIIb, and VIIIc were all unable to hydrolyze with hydrochloric acid or sodium hydroxide in an aqueous ethanol even when the mixtures were refluxed for 2 hr; all were recovered in quantitative yields. The hydrolysis of these compounds was satisfactorily performed with sodium hydroxide in DMSO-water (5 : 1) by heating on a water bath. The vpc analysis of the reaction mixtures after almost complete hydrolysis gave the following products in the molar ratios shown in the parentheses:

VIIIa → V(87.5%) + VI(7.5%) + VII(5%)

VIIIb → 2-*n*-butyl-4-methylquinoline(IX)(100%)

VIIIc → VI(74.5%) + VII(25.5%)

The hydrolysis of VIIIc yielded an unexpected product, VII. The reason for this result was, however, soon clarified. The treatment of VIIIc with the dimethylsulfinyl carbanion in DMSO, followed

Table 1. Spectral data

Compd.	NMR			Others[a,b]	IR, cm^{-1}		UV, mμ
	2-H[a]	3-H[a]	$J_{2,3}$[b]		C=O	C=C	$\lambda_{max}^{n\text{-hexane}}$
VIIIa	3.85	4.00	7.5	Aromatic: 2.41—2.98(m) $CO_2CH_2CH_3$: 5.76 (q, $J=7.5$) $CO_2CH_2CH_3$: 8.72 (t, $J=7.5$) CH_3: 7.85(s)	1686[c]	1660[c]	267 ($\varepsilon=5\times10^3$) 307 ($\varepsilon=2\times10^3$)
VIIIb	4.14	5.12	6.5	Aromatic: 2.41—3.10(m) $CO_2CH_2CH_3$: 5.78 (q, $J=7.5$) $CO_2CH_2CH_3$, n-C_4H_9: 8.62—9.17(m) CH_3: 7.95(s)	1695[d]	1660[d]	270 ($\varepsilon=2\times10^3$) 305 ($\varepsilon=2\times10^3$)

a) Chemical shifts are represented as τ-values. b) Coupling constants are represented in the Hz unit. c) in KBr. d) in liquid film. The absorption at 1660 cm^{-1} appeared as a shoulder.

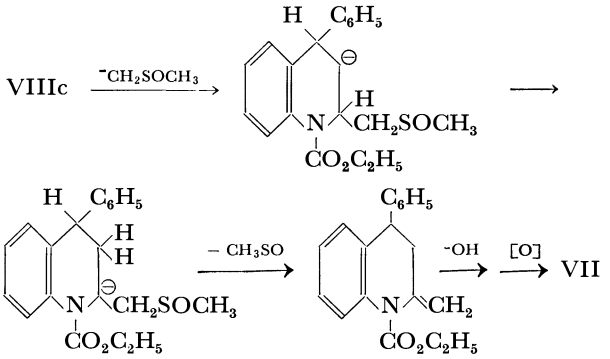
by the hydrolysis, resulted in an increase in the yield of VII to 38.4%. A plausible explanation of these results is that VII is produced by the attack of the carbanion on the 2-position of VIIIc. Thus, the above results support the structure VIIIc.



Rate of the Hydrolysis of 1-Ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa). The hydrolysis of VIIIa was carried out with sodium hydroxide in DMSO-ethanol-water (60 : 15 : 15) at 72°C. The rate of the reaction was followed by analyzing the amounts of the products by means of vapor-phase chromatography. The results are depicted in Fig. 3. The amount of V produced reached a maximum after about 3 hr and then gradually decreased. On the other hand, the amount of VI increased with the decrease in the amount of V.

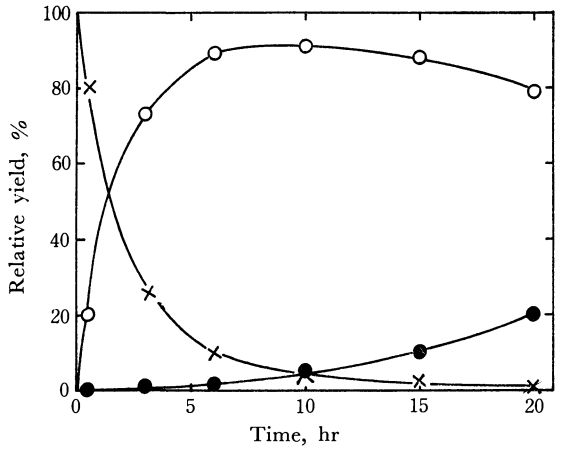


Fig. 3. Rate of the hydrolysis of 1-ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa) in DMSO-H_2O-C_2H_5OH (60 : 15 : 15) at 72±1°C.
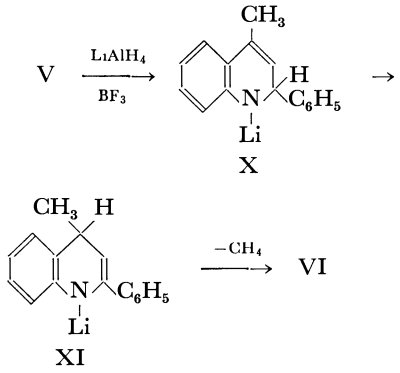
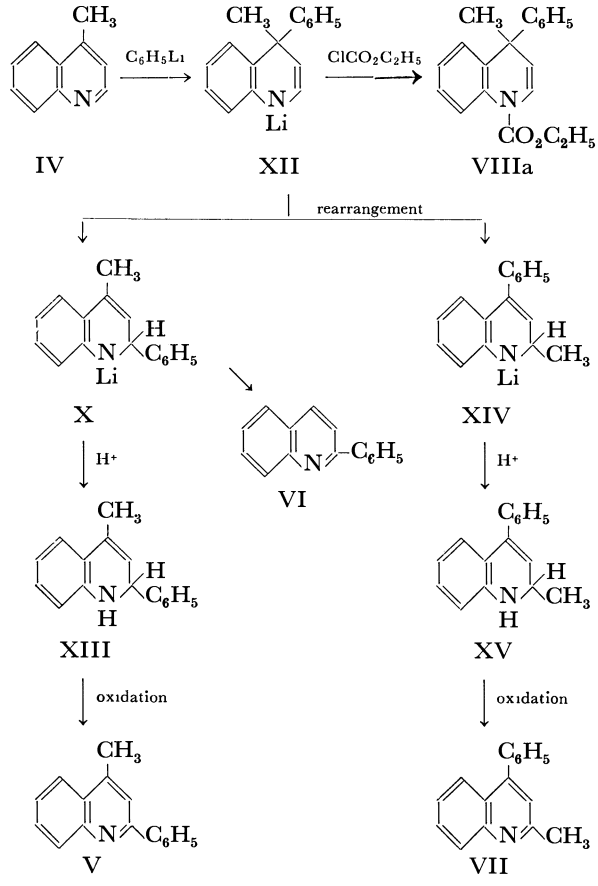
—×—, VIIIa; —○—, 2-phenyl-4-methylquinoline (V); —●—, 2-Phenylquinoline (VI)

Reaction of 2-Phenyl-4-methyl-1,2-dihydroquinoline (X). Since the rate profile of the hydrolysis of VIIIa described in the preceding paragraph suggested that VI is produced from X which is a precursor of V, the chemistry of X was studied; V itself was stable under the reaction conditions used for the hydrolysis of VIIIa.

It is well known that quinolines can be reduced to 1,2-dihydroquinolines by the action of $LiAlH_4$, though with some difficulty.[11] Hence, V was treated with $LiAlH_4$ in boiling ether. However, no reaction took place, and the starting material was recovered unchanged. This is probably because of a steric hindrance due to the phenyl group at the 2-position. The methiodides of quinolines are, however, readily reduced to the corresponding 1,2-dihydro derivatives with $LiAlH_4$.[12] In view of these facts, V was treated in ether with BF_3-etherate and then with $LiAlH_4$. After hydrolysis, the vpc analysis of the reaction mixture revealed that the mixture consisted of 31% of V and 69% of VI. This result suggests that VI is produced from X. A probable mechanism of this reaction is as follows:



Mechanism. On the basis of the observations presented earlier, we propose a new mechanism, involving addition-rearrangement-elimination(or-oxidation), for the reaction of quinolines with organolithium



Scheme 1

11) K. W. Rosenmund, *Chem. Ber.*, **87**, 1229 (1954).

12) R. C. Elderfield and B. H. Wark, *J. Org. Chem.*, **27**, 543 (1962).

compounds. The mechanism is represented Scheme 1, taking as an example the reaction of lepidine with phenyllithium. A similar mechanism would operate for the other reactions.

The possibility of the rearrangement of XII to X and XIV can be explained by the Woodward-Hoffmann rule for the sigmatropic reactions.[13] In this rearrangement, the transition state could be envisaged as being made up by the combination of the orbital of the phenyl or methyl radical with those of the quinoline radical anion, which contains eleven π electrons. The highest occupied orbital of the radical anion possesses the symmetry shown in Fig. 4.[14] Since the migrating group, the phenyl or methyl radical, can possess an accessible π orbital, the appreciable positive overlap between the framework orbital and that of the migrating group can be maintained in the transition state (Fig. 5). Hence, the rearrangement is possible. Furthermore, the overlap of the above sort would be larger between C_4 and C_2 than between C_4 and C_3, since the coefficients of the component π AO's on the highest occupied MO are larger at C_2 than at C_3. The migration can, therefore, be expected to take place from C_4 to C_2 rather than from C_4 to C_3. The migratory aptitudes of the migrating groups would be proportional to the availability of the π orbital on the groups in the transition state of the rearrangement. Thus, the phenyl migration is favored over the methyl migration in the rearrangement of XII to X and XIV.

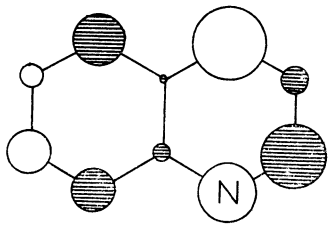


Fig. 4. HO MO of the quinoline radical anion. The phase of π AO's on the one side of the molecular plane are depicted: the shaded circle represents the positive phase and the unshaded one the negative phase.

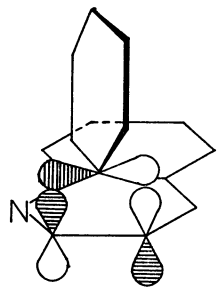

Fig. 5. Transition state of the phenyl migration.

The existence of the dihydro species, XIII and XV, although their structures were not unambiguously confirmed, was inferred from the facts that the NH absorption appeared in the IR spectra of the initially-isolated products and that this absorption disappeared upon the oxidation of the products with air or nitrobenzene.

Experimental

The melting points are uncorrected. The IR spectra were recorded on a Hitachi EPI-S_2 infrared spectrophotometer. The UV spectra were determined on a Hitachi EPU-2U recording spectrophotometer. The NMR spectra were obtained on a Hitachi H-60 high-resolution NMR spectrometer, with TMS as the internal standard. The elemental analyses were performed with a Yanagimoto MT-1 CHN Corder. The vpc analyses were carried out with a Yanagimoto GCG 5DH chromatograph, employing a stainless steel column (2 m×6 mm o.d.) packed with 25% PEG-20 M or 25% Apiezon N on chromosorb (80 mesh). The column temperature was generally maintained at 300°C with a helium flow rate of 30 m*l*/min. For quantitative analyses, the respective authentic samples were used as the internal standards.

Materials. Lepidine (IV) was prepared from methyl vinyl ketone and aniline hydrochloride by the method of Campbell and Schaffner,[15] bp 86—88°C/1 mmHg. 2-Phenyl-4-methylquinoline (V) was prepared from benzylideneacetone and aniline hydrochloride by the method of John and Noziczka,[16] mp 58—59°C. 2-Phenylquinoline (VI) was prepared from quinoline and phenyllithium by the method of Ziegler,[17] mp 81—82°C. 2-Methyl-4-phenylquinoline was prepared, starting with paraldehyde, acetophenone, and aniline, by the method of Knövenagel and Goos,[18] mp 98—99°C. The other chemicals were of commercial origin and were used after purification by distillation or recrystallization.

Reaction of Lepidine and Phenyllithium. A solution of 5.3 g (0.034 mol) of bromobenzene in 25 m*l* of ether was stirred, drop by drop and over a period of 30 min, into a suspension of 0.47 g (0.067 mol) of small pieces of lithium foil in 100 m*l* of ether under nitrogen and at room temperature. Stirring was continued for 30 min to complete the reaction, during which time the reaction mixture was refluxed. During this period the lithium dissolved completely and lithium bromide was precipitated. The mixture was cooled in a dryice - acetone bath, and a solution of 4.0 g (0.0167 mol) of lepidine in 25 m*l* of ether was stirred, drop by drop, into this mixture under a nitrogen atmosphere. A yellow solid soon started to precipitate. After stirring for 30 min, the reaction mixture was hydrolyzed by adding 25 m*l* of water under cooling in a dry ice - acetone bath. The yellow precipitate disappeared, and a homogeneous mixture was obtained. The ether layer was separated, and the aqueous layer was extracted with ether. The combined ether solution was washed with water, dried over sodium sulfate, and then evaporated to produce 6.1 g (almost quantitative) of a yellow oil. The oil was directly subjected to the vpc analysis, which revealed that the oil consisted of a mixture of V, VI, and VII.

13) R. B. Woodward and R. Hoffmann, "The Conservation of Orbital Symmetry," Verlag Chemie, GmbH, Weinheim/Bergstr. (1970), Chapter 7.

14) The highest occupied MO of the quinoline radical anion was calculated by the Hückel method, using as parameters $\alpha_N=\alpha+\beta$ and $\beta_{CN}=\beta$. The coeffcients of the component π AO's were: N=−0.39354, C_2=0.42401, C_3=0.20559, C_4=−0.51515, C_5=0.36108, C_6=−0.18282, C_7=−0.28004, C_8=0.30696, C_9=0.14397, and C_{10}=0.02276. The size of each π AO in Fig. 4 is so dipicted as to reflect the above coefficients.

The oil was distilled under reduced pressure to give again a pale yellow oil; bp 175—179°C/2 mmHg. The IR spectrum (liquid film) of this oil showed absorptions at 3400 and 1650 cm^{-1} due, respectively, to the NH and C=C bonds. These results indicate that the species initially produced by the reaction are the dihydro derivatives of V, VI, and VII (see Mechanism) and that they are oxidized to V, VI, and VII themselves in a column during the vapor-phase chromatography.

To isolate 2-phenyl-4-methylquinoline (V), 10.0 g (0.07 mol) of lepidine were treated with phenyllithium in ether, which had been prepared from 1.4 g (0.2 mol) of lithium and 15.7 g (0.1 mol) of bromobenzene, in a manner similar to that described above. The yellow oil obtained after the evaporation of the ether was refluxed in 60 m*l* of nitrobenzene for 3 hr. A 6 N sulfuric acid was added to the reaction mixture to yield a solid (sulfate of the bases), which was then filtered and washed with three 10-m*l* portions of ether. The filtrate was extracted with ether, and the organic layer was separated. The aqueous layer and the solid were combined, made alkaline with aqueous sodium hydroxide and sodium carbonate solutions, and then extracted with ether. The ether solution was washed with water, dried over sodium sulfate, and evaporated to yield 14 g (82%) of a crude V. Recrystallization from water-ethanol gave pure V as white needles; mp 58—59°C.

The IR spectrum (KBr) of the V thus obtained showed an absorption at 1600 cm^{-1} and was identical with that of the authentic sample, lacking absorptions due to the NH and C=C bonds.

The hydrochloride, mp 212—213°C, and the picrate, mp 208—209°C, were all identical with those of the authentic sample in every respect and gave satisfactory elemental analyses.

Isolation of 1-Ethoxycarbonyl-4-methyl-4-phenyl-1,4-dihydroquinoline (VIIIa). A suspension of phenyllithium in 170 m*l* of ether was prepared from 1.4 g (0.02 mol) of lithium and 15.7 g (0.1 mol) of bromobenzene as described above. Into this suspension we stirred, drop by drop, a solution of 14.3 g (0.1 mol) of lepidine in 20 m*l* of ether at room temperature under nitrogen. The mixture soon turned green and then started to precipitate a yellow solid. After stirring for 1 hr, a solution of 10.9 g (0.1 mol) of ethyl chloroformate in 50 m*l* of ether was added, drop by drop, to the above mixture. The yellow solid gradually dissolved with the evolution of heat. When stirring was continued for 1 hr, the yellow solid disappeared completely. The mixture was cooled in an ice bath, and then 50 m*l* of water was added. The ether layer was separated, and the aqueous layer was extracted with ether. The combined ether solution was washed with water, dried over sodium sulfate, and evaporated to yield 26.3 g of a yellow oil. The recrystalliation of the oil from water-ethanol gave 14.9 g (51%) of VIIIa as white needles; mp 74—75°C. No picrate was formed.

Found: C, 77.67; H, 6.34; N, 4.87%. Calcd for $C_{19}H_{19}O_2N$: C, 77.79; H, 6.53; N, 4.77%.

Isolation of 1-Ethoxycarbonyl-4-methyl-4-butyl-1,4-dihydroquinoline (VIIIb). A suspension of 0.1 mol of *n*-butyllithium in 170 m*l* of ether was prepared by the reaction between a suspension of 1.4 g (0.2 mol) of lithium in 150 m*l* of ether and a solution of 13.8 g (0.1 mol) of *n*-butyl bromide in 20 m*l* of ether in a manner similar to that described for the preparation of phenyllithium. Into this suspension we then stirred a solution of 14.3 g (0.1 mol) of lepidine in 40 m*l* of ether at room temperature. A yellow solid soon started to precipitate. Stirring was continued for 30 min at room temperature, and then a solution of 10.9 g (0.1 mol) of ethyl chloroformate in 50 m*l* of ether was added to the reaction mixture. By the time the mixture has been stirred for 1 hr, the yellow solid had completely disappeared. The mixture was cooled in an ice bath, and then a 50-m*l* portion of water was added. The ether layer was separated, dried over sodium sulfate, and evaporated to yield 23.8 g of a pale yellow oil. Two distillations gave 12.3 g (45%) of VIIIb; bp 125—128°C/0.2 mmHg. No picrate was formed.

Found: C, 74.34; H, 8.59; N, 4.96%. Calcd for $C_{17}H_{23}O_2N$: C, 74.69; H, 8.47; N, 5.12%.

Isolation of 1-Ethoxycarbonyl-4-phenyl-1,4-dihydroquinoline (VIIIc). A suspension of 0.1 mol of phenyllithium in 170 m*l* of ether was prepared as has been described above. Into this suspension we then stirred a solution of 13 g (0.1 mol) of quinoline in 25 m*l* of ether at room temperature. A yellow solid precipitated. Stirring was continued for 1 hr at room temperature, and then a solution of 10.9 g of ethyl chloroformate in 50 m*l* of ether was added. The yellow solid disappeared, and the reaction mixture was worked up in a manner similar to that described above. The evaporation of the ether yielded 23.4 g of an oil. The distillation of this oil gave 12.6 g (59%) of VIIIc; bp 172—174°C/1 mmHg. No picrate was formed.

Found: C, 77.57; H, 5.87; N, 5.19%. Calcd for $C_{18}H_{17}O_2N$: C, 77.39; H, 6.13; N, 5.01%.

Hydrolysis of VIIIa. *A. Acid hydrolysis*: A mixture of 4.40 g (0.015 mol) of VIIIa in 20 m*l* of 95% ethanol and 30 m*l* of 2 N hydrochloric acid was heated on a boiling-water bath for 5 hr. The mixture was made alkaline with an aqueous sodium carbonate solution and then extracted with ether. The ether solution was washed with water, dried over sodium sulfate, and then evaporated to give 4.3 g of the starting material.

The heating of VIIIa in a mixture of acetic acid and concentrated hydrochloric acid(1 : 1) on a boiling-water bath for 5 hr resulted in the recovery of the starting material in a quantitative yield.

B. Alkaline Hydrolysis in an Aqueous Ethanol: A mixture of 1.7 g (0.0058 mol) of VIIIa in 30 m*l* of ethanol and 1.0 g (0.018 mol) of sodium hydroxide in 5 m*l* of water was refluxed for 2 hr. The work-up of the mixture resulted in the recovery of the starting material in an almost quantitative yield.

C. Alkaline Hydrolysis in an Aqueous DMSO: A mixture of 2.5 g (0.0085 mol) of VIIIa in 25 m*l* of DMSO and 1.5 g (0.027 mol) of sodium hydroxide in 5 m*l* of water was warmed at 72°C for 27 hr and then extracted with ether. The ether layer was washed thoroughly with water, dried over sodium sulfate, and evaporated to yield 2.0 g of an oil. When the oil thus obtained was subjected to the vpc analysis, the oil was found to be a mixture of V, VI, and VII.

The picrate formed from this oil was recrystallized from methanol; it melted at 208—209°C and was identical in every respect with that of the authentic sample of V.

Hydrolysis of VIIIb. *A*: The acid hydrolysis of VIIIb with a mixture of acetic acid and concentrated hydrochloric acid, and alkaline hydrolysis with an aqueous sodium hydroxide solution, were carried out under conditions similar to those described for VIIIa. In each case, the starting material was recovered in an almost quantitative yield.

B: A mixture of 1.0 g (0.0037 mol) of VIIIb in 25 m*l* of DMSO and 0.6 g (0.01 mol) of sodium hydroxide in 5 m*l* of water was heated on a boiling-water bath for 3 hr and then extracted with ether. The ether layer was washed thoroughly with water, dried over sodium sulfate, and evaporated to give an oil. The vpc analysis of the oil revealed that the oil consisted of only one compound. The distillation of the oil

gave 0.5 g (68%) of 2-*n*-butyl-4-methylquinoline (IX); bp 115—117°C/mmHg.

Found: C, 84.01; H, 8.72; N, 7.25%. Calcd for $C_{14}H_{17}N$: C, 84.37; H, 8.60; N, 7.03%.

IR($CHCl_3$): 1605, 1563, 1510, 1452 cm^{-1}. NMR(CCl_4): τ 1.98—3.00 (5H, *m*, aromatic), 7.12(2H, *t*, J=7.0 Hz, $\mathbf{CH_2}CH_2CH_2CH_3$), 7.39(3H, s, CH_3), 7.95—9.04(7H, *m*, $CH_2\mathbf{CH_2CH_2CH_3}$).

This compound did not form the picrate, probably due to bulky butyl substituent at the 2-position. The spectral data and the above result support the structure IX.

Hydrolysis of VIIIc. A mixture of 4.4 g (0.016 mol) of VIIIc in 30 m*l* of DMSO and 2.5 g (0.045 mol) of sodium hydroxide in 6 m*l* of water was heated on a boiling-water bath for 3 hr, and then the reaction mixture was worked up as has been described above. The evaporation of the ether extract produced 3.0 g of a yellow oil which was then analyzed by vapor-phase chromatography. The oil contained 2-phenylquinoline (VI) as the main product, along with a small amount of VII. The oil formed a pictrate which melted at 187—188°C after recrystallization from methanol and which was identical in every respect with that of the authentic sample of VI.

Reaction of VIIIc with the Dimethylsulfinyl Carbanion. The dimethylsulfinyl carbanion in DMSO was prepared from 0.02 mol of sodium hydride and 80 m*l* of DMSO by the method of Corey and Chaykovsky.[19] Into this solution we stirred, drop by drop, a solution of 2.7 g (0.01 mol) of VIIIc in 50 m*l* of DMSO over a period of 30 min at room temperature under nitrogen. The mixture, which soon turned red and then deep blue, was stirred for a further 3 hr at 50°C under nitrogen. A 20-m*l* portion of water was added, after which the reaction mixture was heated on a boiling-water bath for 2 hr while a white solid precipitated. The mixture was poured onto 200 m*l* of water and extracted with ether. The ether layer was washed thoroughly with water, dried over sodium sulfate, and then evaporated to give 2.2 g of an oil. The vpc analysis of this oil revealed that the oil consisted of 61.6% of VI and 38.4% of VII.

Rate of Hydrolysis of VIIIa. A homogeneous mixture was prepared by mixing a solution of 1.0 g (0.0034 mol) of VIIIa, 0.80 g (0.014 mol) of sodium hydroxide in 15 m*l* of water, and 15 m*l* of 95% ethanol (the ethanol was necessary to obtain a homogeneous mixture). Fourteen-m*l* portions of the mixture were pipetted into six 30-m*l* test tubes. The test tubes were then sealed and immersed into a constant-temperature bath at 72±1°C. The six tubes was withdrawn after 0.5-, 3-, 6-, 10-, 15-, and 20-hr intervals, respectively, and the contents were extracted with 50 m*l* of ether. The ether solution was washed twice with 20-m*l* portions of water, dried over sodium sulfate, and then concentrated. The residue was directly subjected to the vpc analysis. The proportion of the components in the mixture was calculated from the corresponding peak areas on the chromatogram; the peak areas for the components had been calibrated with the corresponding authentic samples.

Reaction of 2-Phenyl-4-methylquinoline (V) with $LiAlH_4$-BF_3. Into a solution of 1.0 g (0.0056 mol) of V in 50 m of ether we stirred 6.5 g of BF_3-etherate (47%) at room temperature under nitrogen. A pale yellow solid soon precipitated, after which the mixture was stirred for an additional 30 min. To this mixture 1.0 g (0.026 mol) of powdered $LiAlH_4$ was added in portions. Stirring was continued for 24 hr at room temperature, and then 10 m*l* of ice water were added, drop by drop, to the reaction mixture, which had been cooled in an ice bath. The mixture was filtered, and the filtrate was extracted with ether (when the filtrate was diluted with ethanol, the BF_3-salt of V precipitated as white needles). The evaporation of the ether yielded 0.5 g of an oil. The vpc analysis of the oil revealed that the oil was 69% 2-phenylquinoline (VI) and 31% V.

Rotatory Dispersion and Stereochemistry of Organic Compounds. XVI.[1] Carbonylphenyl Glucosides

Yojiro TSUZUKI, Shintaro KATAOKA, Minako FUNAYAMA, and Koko SATSUMABAYASHI*

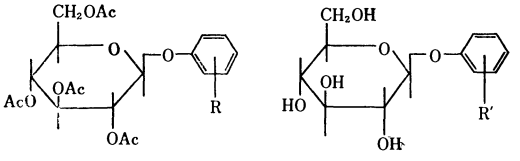
Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received August 17, 1970)

Rotatory dispersion, circular dichroism and ultraviolet absorption of six kinds of carbonylphenyl tetraacetyl glucoside (carbonyl=*o*- and *p*-CHO, *o*- and *p*-$COCH_3$, *o*- and *p*-COC_2H_5) and their deacetylation products were measured, and the optical rotatory contributions of carbonyl groups were investigated, especially with respect to the effect of the bulk and position of the substituent. This led to the conclusion that all the absorption bands due to the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions are optically active. Anomaly was also observed in the *o*-substitution products, thus making the general effect of electrophilic substituents on optical rotation definite, *viz.*, that all the Cotton effects of the longer wavelength (due to the $n\rightarrow\pi^*$ transition) are negative in *p*-carbonylphenyl β-glucosides, and in good accordance with the optical contribution of C_1-configuration, but optical anomaly was invariably observed with the *o*-isomers which displayed positive Cotton effects. This rule in rotatory dispersion holds with the deacetylated compounds, in contrast to the deacetylated *o*-nitrophenyl glucosides (in this sense *o*-nitro group is anomalous). Some regularities were found with the Cotton effects due to the $\pi\rightarrow\pi^*$ transition and the effect of the bulk of the carbonyl groups was discussed.

The anomalous specific rotation of *o*-nitrophenyl glycosides was elucidated by studying the rotatory dispersion of various nitrophenyl glycosides, and it was found that the sign of the Cotton effects became inverted by deacetylation of acetyl-*o*-nitrophenyl glycosides, which is contrary to the corresponding *p*-substituted derivatives.[1]

The present paper deals with a similar study on phenyl glucosides containing three types of carbonyl group situated at the ortho and para positions, in order to investigate whether the anomaly[1,2] is characteristic of the nitro group. For this purpose the twelve compounds shown in Fig. 1 were studied. They are all β-glucosides with aglycones, such as *o*- and *p*-formylphenyl, *o*- and *p*-acetylphenyl as well as *o*- and *p*-propionyl phenyl (compounds Ib—VIb) and their acetyl derivatives (compounds Ia—VIa).



(Ac=$COCH_3$)

Compound	R	Compound	R'
Ia	*o*-CHO	Ib	*o*-CHO
IIa	*p*-CHO	IIb	*p*-CHO
IIIa	*o*-$COCH_3$	IIIb	*o*-$COCH_3$
IVa	*p*-$COCH_3$	IVb	*p*-$COCH_3$
Va	*o*-COC_2H_5	Vb	*o*-COC_2H_5
VIa	*p*-COC_2H_5	VIb	*p*-COC_2H_5

Fig. 1. Twelve β-phenylglucosides studied.

Measurements were made with these compounds on their rotatory dispersion (RD), circular dichroism (CD), ultraviolet absorption (UV) and NMR spectra. Some considerations will be given on the effect of the bulk of the substituents affecting the optical rotation.

Results and Discussion

The RD, CD, and UV curves of *o*-formylphenyl tetraacetyl-β-D-glucoside (Ia) are shown in Fig. 2. The RD curve exhibits complex Cotton effects. The CD curve shows a positive peak at 340 mμ, a negative CD_{max} at 300 mμ and a positive CD_{max} below 260 mμ, from which the signs of the Cotton effects are clearly determined. That the RD and CD curves have fine structures near the absorption regions is evidenced by the UV curve, which shows a slight anomaly near 350 mμ and two absorption maxima at 304 mμ and 250 mμ. Hence, the positive Cotton effects (CD_{max} at 340 mμ) show that the $n\rightarrow\pi^*$ transition due to the *n*-electron resonance between the phenyl group and the carbonyl group is optically active, although it is not clearly seen from the UV curve. It became evident that the absorption bands around 304 mμ and 250 mμ are also optically active, and are attributed to the $\pi\rightarrow\pi^*$ transition brought about by the resonance

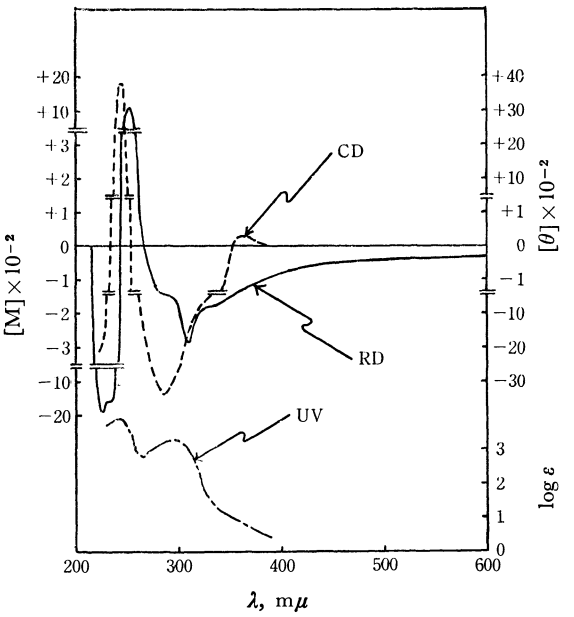

Fig. 4. RD, CD, and UV of compound IIIa.

electron of the phenyl-carbonyl group. This is evident in the UV curve.

In the NMR spectrum of *o*-formylphenyl glucoside (Ia) is observed the proton of an aromatic aldehyde as a singlet, which is in agreement with the signal of the proton of aromatic *o*-aldehydes.

In the RD, CD, and UV spectra of *p*-formylphenyl tetraacetyl-*β*-D-glucoside (IIa), given in Fig. 3, the RD curve exhibits a negative Cotton effect evidenced by the CD curve, which shows a CD_{max} near 330 mμ, and a positive Cotton effect can be expected to appear below 290 mμ from the CD curve. The UV spectrum has an absorption maximum at 264 mμ and a shoulder around 310—330 mμ. Like compound Ia this indistinct absorption due to the $n\rightarrow\pi^*$ transition is optically active, and the positive Cotton effect expected to appear on the shorter wavelength region from the CD curve may be attributed to the $\pi\rightarrow\pi^*$ transition around 264 mμ.

By comparing the RD of Ia and IIa, it is apparent that the Cotton effect near 330—340 mμ is positive in the ortho-aldehyde of the glucoside and negative in the para isomer, thus exhibiting a distinct difference in the two compounds. The NMR spectrum of IIa exhibits a singlet near $\delta=10$ ppm as a signal of the proton of *p*-aldehydes.

The RD, CD, and UV spectra of *o*-acetylphenyl tetraacetyl-*β*-D-glucoside (IIIa) and those of *o*-propionyl tetraacetyl-*β*-D-glucoside (Va) are shown in Figs. 4 and 5, respectively. They exhibit similar curves of complex Cotton effects, both RD curves exhibiting no clear Cotton effect in the longer wavelength region, where a small positive CD_{max} appears. Compound IIIa shows a more or less red- shifted CD_{max} of positive sign, due to the $n\rightarrow\pi^*$ transition, as compared with compound Va, but the CD_{max} and the Cotton effects due to the $\pi\rightarrow\pi^*$ transition in these two compounds are both negative at 285 mμ and positive at 240 mμ and again negative below 220 mμ, the values being

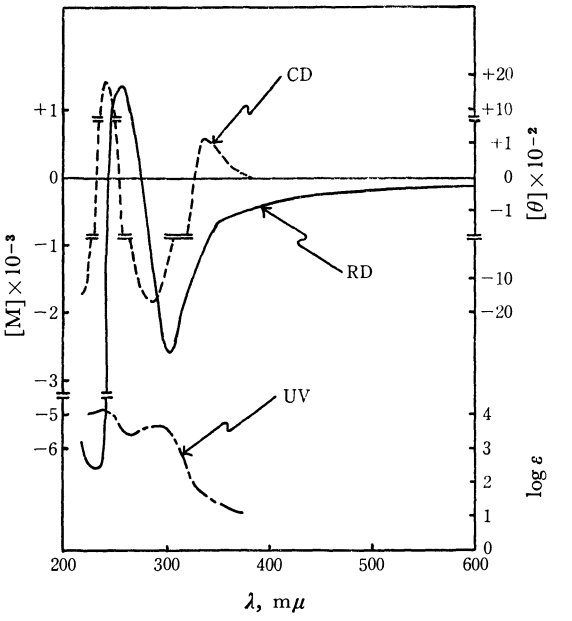

Fig. 5. RD, CD, and UV of compound Va.

also of the magnitude of the same order. In the UV curves of IIIa and Va, both absorption maxima appear at 290 mμ and 240 mμ[3] but no absorption bands corresponding to the CD_{max} at 335 mμ (Va) and 360 mμ (IIIa).

The RD, CD, and UV curves of *p*-acetylphenyl tetraacetyl-*β*-D-glucoside (IVa) are shown in Fig. 6. The RD curve exhibits complex Cotton effects, which can be evidenced, however, by the CD curve with maxima at 320 mμ and 265 mμ. The RD curve is similar in pattern to that of compound IIa which con-

3) These absorption bands are red-shifted by 3—4 mμ in polar solvents, which can be explained by presuming that $\pi\rightarrow\pi^*$ transition is subjected to the conjugation effect between the carbonyl group and the benzene ring. See S. Nagakura and K. Kuboyama, *J. Amer. Chem. Soc.*, **76**, 1003 (1954).

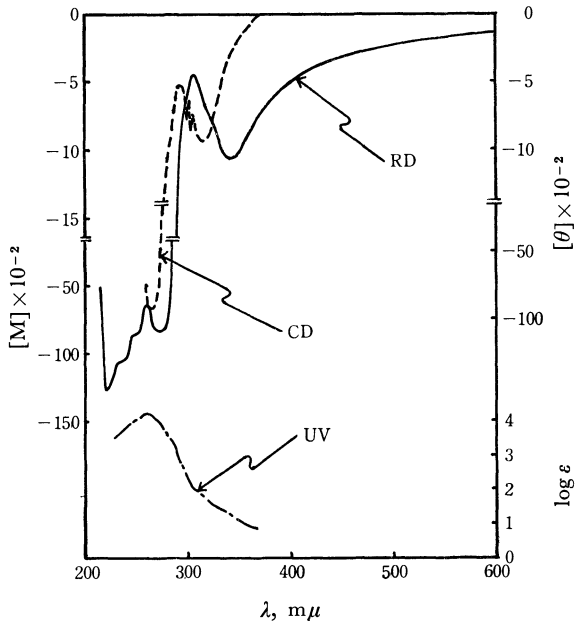

Fig. 6. RD, CD, and UV of compound IVa.

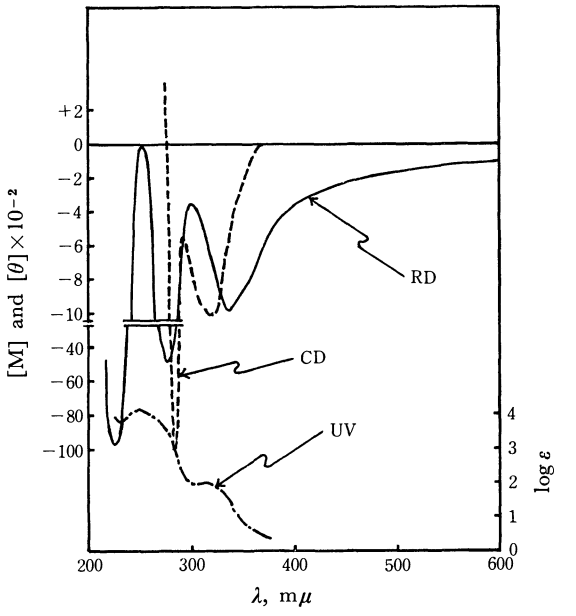

Fig. 7. RD, CD, and UV of compound VIa.

tains an aldehyde group at the *p*-position, but a difference can be seen, *viz.*, the CD_{max} of IVa at 265 mμ is negative while the CD_{max} expected from the CD curve of IIa is positive.

The RD curve of *p*-propionylphenyl tetraacetyl-β-D-glucoside (VIa) shown in Fig. 7 together with CD and UV spectra is also similar in pattern to those of *p*-compounds IIa and IVa. The CD curve of VIa has a negative maximum at 320 mμ like IIa and is expected to have a large positive maximum below 280 mμ. The UV curve of VIa exhibits absorption bands due to the $\pi \rightarrow \pi^*$ transition around 312 mμ and 252 mμ, and the absorption band attributed to the $n \rightarrow \pi^*$ transition is optically active, though it is not apparent in the curve. Thus the *p*-substituted phenyl glucosides exhibit no singularity due to the carbonyl group, having curves similar to those of *p*-NO_2 derivatives.[1] These facts suggest that the compounds with electrophilic substituents have common properties in rotatory contribution.

The RD, CD, and UV curves of the deacetylated products of the above mentioned acetylated phenyl glucosides are shown in Figs. 8—13.

Figure 8 gives the RD, CD, and UV spectra of *o*-formylphenyl β-D-glucoside (Ib). The spectra are complex, the CD_{max} at 340 mμ being positive, those at 306 mμ and 250 mμ both negative, and that below 220 mμ expected to be negative. The UV spectrum shows absorption bands around 310 mμ and 256 mμ. These bands as well as the Cotton effects evidenced by the CD_{max} can be interpreted in a similar way as in the case of the corresponding acetylated compound

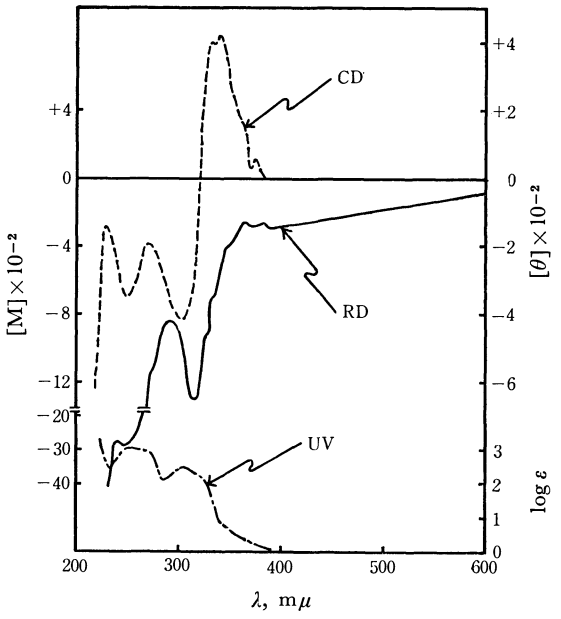

Fig. 8. RD, CD, and UV of compound Ib.

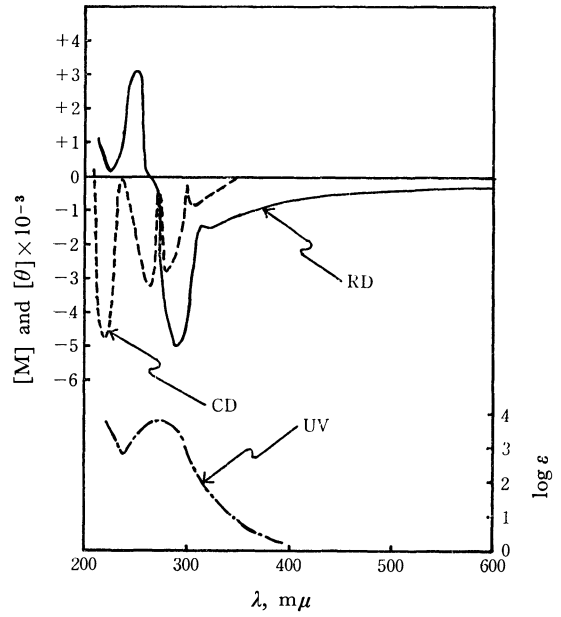

Fig. 9. RD, CD, and UV of compound IIb.

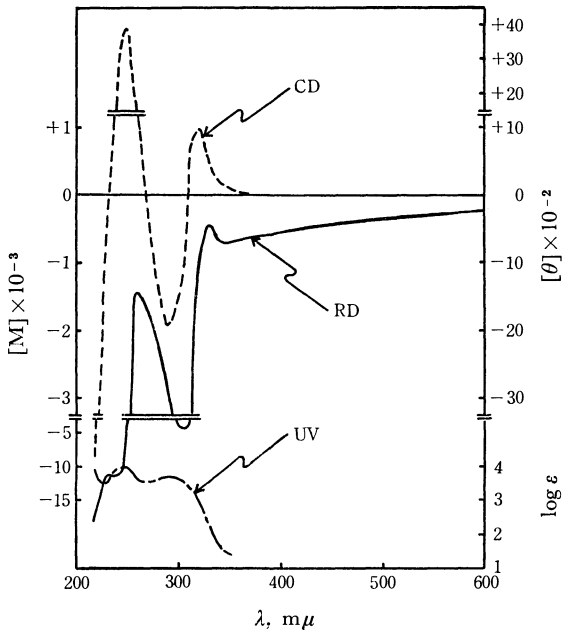

Fig. 10. RD, CD, and UV of compound IIIb.

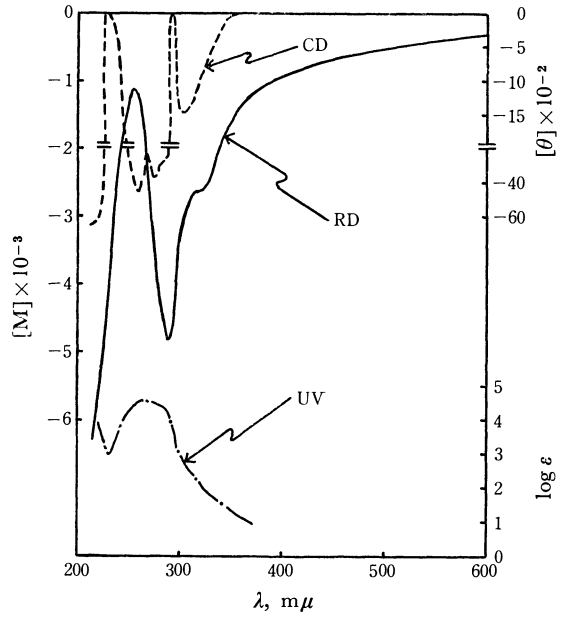

Fig. 11. RD, CD, and UV of compound IVb.

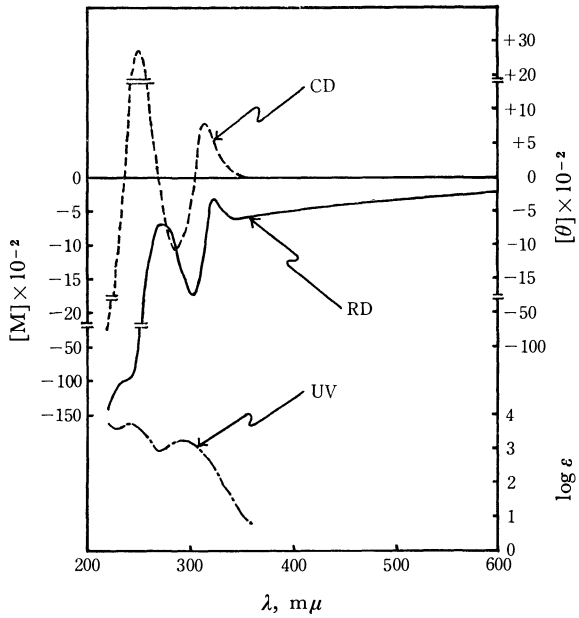

Fig. 12. RD, CD, and UV of compound Vb.

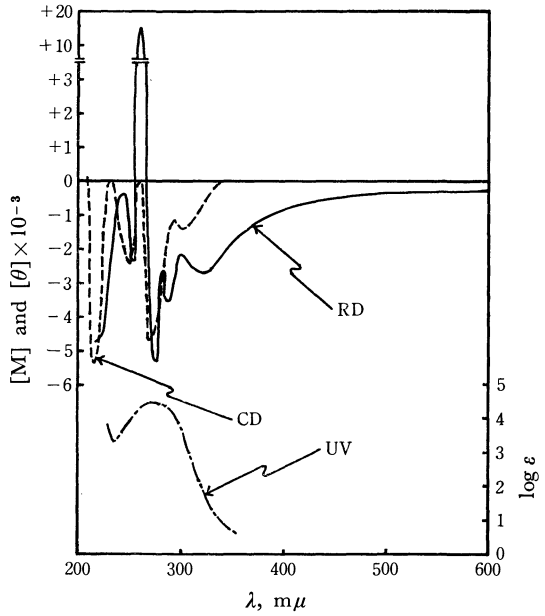

Fig. 13. RD, CD, and UV of compound VIb.

Ia (Fig. 2). However, it should be noted that the Cotton effect centered at 250 mμ due to the $\pi\rightarrow\pi^*$ transition is inverted in sign, that is, a positive Cotton effect is expected in Ia, whereas a negative Cotton effect appears in Ib. This is the greatest difference between the acetylated and deacetylated products.

Figure 9 shows the RD, CD, and UV curves of *p*-formylphenyl β-D-glucoside (IIb). The RD curve has a shoulder around 310—320 mμ, suggesting a weak Cotton effect which was confirmed to be negative by the CD_{max} at 303 mμ. The CD_{max} due to the $\pi\rightarrow\pi^*$ transition which appears at 264—280 mμ is split, but the UV spectrum is observed to have a single absorption band centered at 270 mμ. It should be noted however, that a negative CD_{max} was observed at 219 mμ.

Figure 10 shows the RD, CD, and UV curves of *o*-acetylphenyl β-D-glucoside (IIIb). The Cotton effects appearing at 320 mμ and 290 mμ in the RD curve can be decided by the RD curve to be positive and negative, respectively, and those around 250 mμ and below 220 mμ respectively positive and negative. The CD curve is similar to that of the corresponding, acetylated compound IIIa (Fig. 4), and attribution to the absorption bands may be made in a similar fashion excepting that the CD_{max} attributable to the $n\rightarrow\pi^*$ transition is of $[\theta]_{320}=965°$ in IIIb, and $[\theta]_{360}=28.2°$ in IIIa, indicating that the position as well as the intensity of the Cotton effect is affected by acetylation.

Figure 11 shows the RD, CD and UV curves of *p*-acetylphenyl β-D-glucoside (IVb). The RD curve exhibits no distinct Cotton effect above 300 mμ, indicating a shoulder around 310—220 mμ. This is sup-

ported by the negative CD_{max} appearing at 300 mμ, suggesting that the Cotton effect must be negative in contrast to the positive Cotton effect of the *o*-substituted product (IIIb), and although the UV curve shows no distinct absorption bands except at 268 mμ, the absorption due to the $n\rightarrow\pi^*$ transition must be hidden as in the case of IVa (Fig. 6), but is proved to be optically active. By comparing the RD curves of *p*-acetyl substitution product (IVb) and *p*-formyl derivative (IIb) it is seen that the signs of the Cotton effects are the same and their position nearly the same, although the optical rotation of IIb below 260 mμ appears in the positive region. This is due to the difference of the substituents, but the fact that the CD curves of IVb and IIb are almost the same can be attributed to similar absorptions.

The RD, CD, and UV curves of *o*-propionylphenyl β-D-glucoside (Vb) are given in Fig. 12. The CD curve exhibits a positive peak at 315 mμ, a negative maximum at 285 mμ, again a positive peak at 250 mμ and a negative maximum below 220 mμ. These curves are almost the same as those of the acetylated product of substituted phenyl glucoside (IIIb), indicating that the acetyl and propionyl groups at the ortho position in these glucosides hardly influence the RD at all either sterically or electronically.

The RD, CD and UV curves of *p*-propionylphenyl β-D-glucoside (VIb) in Fig. 13 show a slight, but distinct negative Cotton effect due to the $n\rightarrow\pi^*$ transition in the RD curve unlike IIb (Fig. 9) and IVb (Fig. 11). The UV curve only shows an absorption band at 277 mμ, but the absorption due to the $\pi\rightarrow\pi^*$ transition is not apparent. It should be noted, however, that two negative Cotton effects corresponding to the split CD_{max} due to the K-band were observed around 245—283 mμ in VIb. As stated above, deacetylated *p*-substituted products show no distinct Cotton effects above 300 mμ in the RD curves.

It has thus been found that the $n\rightarrow\pi^*$ transition as well as the $\pi\rightarrow\pi^*$ transition become optically active in carbonylphenyl glucosides.

It is concluded by the wavelength of the absorption band that the $n\rightarrow\pi^*$ transition is caused by the *n*-electron as the result of resonance between the carbonyl and phenyl groups, and becomes optically active irrespective of the sort and the substitution position of the carbonyl groups. However, the optical rotatory contributions are different, that is, the Cotton effect is positive with *o*-substituted products, and negative with *p*-isomers. This experimental rule holds irrespective of the presence of acetyl groups, which shows that the inversion of the sign of Cotton effect due to the $n\rightarrow\pi^*$ transition on deacetylation on acetyl *o*-nitrophenyl glycosides is an anomaly observable only with the nitro group.[1]

The question arises as to the reason for the difference in sign of Cotton effect between the *o*- and *p*-substituted products. With *o*-carbonylphenyl glucosides a certain steric effect of the carbonyl group on the sugar moiety causes one of the possible rotational isomers (due to the rotation of the aglycone) to be stable or fixed making the rotatory contribution positive in sign.[1] On the other hand the optical activity of the *p*-compound is mainly determined by the configuration of C_1 to be laevorotatory in accordance with the β-configuration of the glucoside, since the *p*-substituent is free from steric hindrance.

We shall next consider the $\pi\rightarrow\pi^*$ transition due to the resonance between the phenyl and carbonyl groups. *o*-Carbonylphenyl glucosides show two peaks in the UV spectra and *p*-compounds only one high peak. These peaks are all closely related to the optically active chromophores corresponding to the maxima of the CD curves.

According to the studies of Burawoy *et al.*,[4] and Plott,[5] the UV absorption due to the $\pi\rightarrow\pi^*$ transition observed with *o*-substituted products gives two peaks (B- and K-bands), while with *p*-substituted products a larger K-band (of a shorter wavelength) covers the B-band (of a longer wavelength) and thus a wide UV maximum appears. When this assignment is applied to the carbonylphenyl glucosides, we have the results given in Table 1, which shows the signs of the Cotton effects due to the bands. As can be seen from Table 1, the R-band (due to the $n\rightarrow\pi^*$ transition) signs are all positive in the *o*-substituted products and negative in the *p*-substituted products. Furthermore, all the B-bands contribute to negative Cotton effects, while the K-bands appear complicated. The solvent effect on the $n\rightarrow\pi^*$ transition should be mentioned. The blue-shift by polar solvents can be observed in the RD as well as CD curve of IVb (in ethanol) in contrast to that of IVa (in 1,2-dichloroethane), where the role of conjugation effect is clearly displayed.[3] In addition, strong negative optical rotations may be expected by some CD curves below 220 mμ, which should, however, be attributed to the CT bands.[6]

Table 1. Cotton effects due to UV absorption band

Glucoside	Carbonyl group	K-band	B-band	R-band
Ia	*o*-CHO (acetylated)	+	−	+
Ib	*o*-CHO	−	−	+
IIIa	*o*-$COCH_3$ (acetylated)	+	−	+
IIIb	*o*-$COCH_3$	+	−	+
Va	*o*-COC_2H_5 (acetylated)	+	−	+

6) K. Kimura, H. Tsubonuma, and S. Nagakura, This Bulletin, **37**, 1336 (1964).

We will next consider the effects of the bulk of the carbonyl group and of the acetyl group on the optical rotation.

The CD_{max} values due to the R-band in the *o*-carbonylphenyl glucoside are shown in Table 2. The

Table 2. [θ]-Values of CD_{max} due to R-band

Carbonyl group	Acetylated glucoside		Deacetylated glucoside	
CHO	Ia	5090°	Ib	433°
$COCH_3$	IIIa	28.2°	IIIb	965°
COC_2H_5	Va	114°	Vb	815°

acetylated derivative Ia with an aldehyde group solely exhibits an incomparably higher value, since the aldehyde group being small in bulk may exert only a slight steric hindrance as compared with that of larger carbonyl groups (IIIa and Va) and thus the resonance between the carbonyl and the phenyl group may be unhindered to such a degree that it may influence mainly the C_1-atom of the glucoside. The difference in bulk between the acetyl group (IIIa) and the propionyl group (Va) is regarded to have little effect on C_1-atom, so that they are nearly equal in rotatory contribution. This effect is more evident in the deacetylated glucosides (IIIb and Vb). As is shown in Table 2, the rotatory contribution of C_1 is increased ([θ]-value is enhanced) because of resonance effect between the phenyl group and the acetyl group (IIIb), or the propionyl group (Vb) being increased by removal of the steric hindrance between the carbonyl group and the acetyl groups of the glucose moiety. A weak bond between the free OH group and the more bulky carbonyl group is possible in view of the increase of the [θ]-value and accordingly fixation of the flexible conformation is conceivable. On the other hand it is seen that the [θ] value falls by deacetylation, due to the small bulk of the formyl group (Ib). With the *p*-substituted-carbonylphenyl glucosides such a steric hindrance is inconceivable, and the Cotton effect due to the $n\rightarrow\pi^*$ transition is not affected much by the kind of substituents and by the presence of the acetyl groups on the side of the sugar moiety.

Experimental

The rotatory dispersion and circular dichroism were measured in 1,2-dichloroethane, water, and ethanol at 25°C in the wavelength region from 210 to 600 mμ with a JASCO optical rotatory dispersion recorder of the ORD/UV-5 type. The ultraviolet absorption was measured in 1,2-dichloroethane, ethanol, and water with a self-recording spectrophotometer of Hitachi EPS-3T type. The NMR spectra were measured with a Varian A-60 spectrometer.

o-*Formylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (Ia)*.[7,8] A solution of salicyl aldehyde (0.03 mol), anhydrous potassium carbonate (5 g) and tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.025 mol) in anhydrous acetone (100 m*l*) was refluxed for 3 hr. The product was precipitated by adding water and cooling to 0°C. Recrystallization from ethanol gave needles; mp 142°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.990). $[\alpha]_{600}$ −25.0°, $[\alpha]_{589}$ −25.0°, $[\alpha]_{500}$ −33.0°, $[\alpha]_{400}$ +22.0°, $[\alpha]_{360}$ +197° (peak), $[\alpha]_{316}$ −2270° (trough), $[\alpha]_{280}$ +707° (peak), $[\alpha]_{220}$ −1210°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 0.990). $[\theta]_{370}$ +138°, $[\theta]_{340}$ +5090° (peak), $[\theta]_{310}$ −2750° (trough), $[\theta]_{250}$ +3160°. The UV spectrum was measured at 25°C 1,2-dichloroethane. ε_{304} 3420 (max), ε_{250} 11500 (max).

p-*Formylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (IIa)*.[9] The compound was prepared according to the method of Ia. Colorless needles; mp 143.5—144°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 1.000). $[\alpha]_{400}$ −88.0°, $[\alpha]_{346}$ −188° (trough), $[\alpha]_{312}$ −108° (peak), $[\alpha]_{300}$ −162°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 1.018). $[\theta]_{360}$ −205°, $[\theta]_{330}$ −586° (trough), $[\theta]_{280}$ +1320°. The UV spectrum was measured at 25°C in 1,2-dichloroethane. ε_{264} 18100 (max).

o-*Acetylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (IIIa)*.[10] The compound was prepared by cooling and triturating a mixture of tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.025 mol), *o*-hydroxyacetophenone (0.03 mol), silver oxide (0.025 mol), and quinoline (0.08 mol), standing for half an hour on anhydrous calcium chloride with stirring every ten min. The mixture was extracted with glacial acetic acid (40 m*l*). The product was precipitated by pouring the extract into water (450 m*l*) at 0°C and recrystallized from ethanol to give yellowish needles; mp 151°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.512). $[\alpha]_{600}$ −52.7°, $[\alpha]_{589}$ −55.7°, $[\alpha]_{309}$ −615° (trough), $[\alpha]_{252}$ +2440° (peak), $[\alpha]_{226}$ −19100° (trough), $[\alpha]_{215}$ 0°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 0.980). $[\theta]_{380}$ +6.28°, $[\theta]_{360}$ +28.2° (peak), $[\theta]_{285}$ −3390° (trough), $[\theta]_{243}$ +3770° (peak), $[\theta]_{225}$ −1880°. The UV spectrum was measured at 25°C in 1,2-dichloroethane. ε_{293} 2220(max), ε_{241} 8940(max).

p-*Acetylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (IVa)*. The compound was prepared according to the method for IIIa. Yellowish needles; mp 168—169°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.530). $[\alpha]_{600}$ −32.7°, $[\alpha]_{589}$ −34.6°, $[\alpha]_{342}$ −237°(trough), $[\alpha]_{307}$ −100° (peak), $[\alpha]_{270}$ −1830°(trough), $[\alpha]_{260}$ −1440°(peak), $[\alpha]_{220}$ −2790°(trough), $[\alpha]_{214}$ −4940°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 0.520). $[\theta]_{360}$ −65.0°, $[\theta]_{323}$ −945°(trough), $[\theta]_{265}$ −9450°(trough), $[\theta]_{260}$ −8860°. The UV was measured at 25°C in 1,2-dichloroethane. ε_{250} 15800(max).

o-*Propionylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (Va)*.[9] The compound was prepared according to the method for IIIa. Colorless plates; mp 162°—162.5°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.440). $[\alpha]_{600}$ −30.0°, $[\alpha]_{589}$ −31.0°, $[\alpha]_{302}$ −545°(trough), $[\alpha]_{258}$ +273° (peak), $[\alpha]_{230}$ −1360°(trough), $[\alpha]_{220}$ −1250°. The CD was measured at 25°C in 1,2-dichloroethane (*c*, 0.530). $[\theta]_{370}$ +18.0°, $[\theta]_{338}$ +114°(peak), $[\theta]_{285}$ −2690°(trough), $[\theta]_{240}$ +1790°(peak), $[\theta]_{220}$ −2540°. The UV was measured at 25°C in 1,2-dichloroethane. ε_{290} 4200(max), ε_{240} 14000 (max).

p-*Propionylphenyl Tetra*-O-*acetyl*-β-D-*glucopyranoside (VIa)*.[9] The compound prepared according to the method for IIIa. Colorless needles; mp 158°—159.5°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.450). $[\alpha]_{600}$ −20.0°, $[\alpha]_{589}$ −21.5°, $[\alpha]_{336}$ −203°(trough), $[\alpha]_{304}$ −74.0°(peak), $[\alpha]_{224}$ −2230°(trough), $[\alpha]_{220}$ −1340°, The CD was measured at 25°C in 1,2-dichloroethane (*c* 1.000). $[\theta]_{350}$ −28.3°,

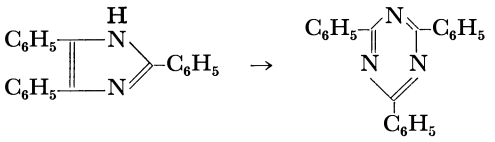
(Received August 19, 1970)

2,4,6-Triphenyl-*s*-triazine (II) is formed either in the chemiluminescence reaction of 2,4,5-triphenylimidazole (I) in the presence of oxygen and a strong base or in the photolysis of I in alcohol in the presence of ammonia and oxygen. II is also formed in the sensitized photo-oxygenation of I in alcohol containing ammonia. It was found that II was produced by the reaction between the lophyl hydroperoxide (V), which was prepared from I and was known to be one of the intermediates in chemiluminescence reaction of I, and ammonia. Chemical and spectroscopic evidence that II is produced from V and not *via* the dioxetane-type peroxide (VI) nor *N,N'*-dibenzoylbenzamidine (IV), is given. II and several other 2,4,6-triaryl-*s*-triazines were found to be easily prepared from the corresponding triarylimidazoles by the sensitized photo-oxygenation in methanol in the presence of ammonium acetate and this provides a new method for the synthesis of triaryl-*s*-triazine.

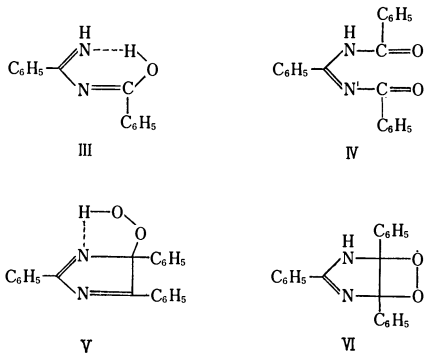
We found[2)] that after the chemiluminescence of 2,4,5-triphenylimidazole (I) was exhibited by oxygen for about 1 day in 1 N ethanolic solution of potassium hydroxide at room temperature, a small amount (lower than 5%) of 2,4,6-triphenyl-*s*-triazine (II) was isolated as alkali-insoluble fine crystals, besides the major products, benzoic acid and ammonia.[3)] Formation of II was also found to occur in a photolysis of I in alcohols in the presence of oxygen and ammonia at room temperature (16% yield) and in a sensitized photo-oxygenation of I in the presence of ammonia at about 0°C (22% yield). In this paper we will report the results of the study on the species involved in the transformation of I into II which led to a new synthetic method of triaryl-*s*-triazine.



I II

Results and Discussion

Compound II obtained in the chemiluminescence reaction of I was considered to be formed by the ring expansion of I by insertion of one nitrogen atom between C-4 and C-5 of the imidazole ring. The yield of II decreases with rise of the reaction temperature and increases slightly by addition of ammonia to the solution. These facts suggested that the inserted nitrogen atom is supplied by ammonia which is one of the major products of the chemiluminescence reaction of I. Therefore, the photolysis of I in the presence of ammonia was investigated in some detail. When a methanolic solution of I containing ammonia was irradiated by a high-pressure mercury lamp under bubbling of oxygen, II separated from the solution in 16% yield, and from the filtrate 4,5-(9',10'-phenanthryl)-imidazole (9%), benzamide (25%) and *N*-benzoylbenzamidine (III) (45%) were isolated. When the photo-oxygenation of I was carried out in a methanolic solution of ammonia containing methylene blue as sensitizer at about 0°C by an incandescent lamp, a considerable change in UV absorption of the solution was observed and after the irradiation was shut off II gradually separated from the solution in 22% yield. From the filtrate, III (33%) and benzamide (12%) were obtained. 4,5-(9',10'-Phenanthryl)imidazole could not be detected in this case. White and Harding[4)] isolated III and IV from the reaction products of the chemiluminescence reaction of I and found that the observed luminescence is the fluorescence emission of IV which was suggested to be formed from the anion of lophyl hydroperoxide (V) through the anion of the dioxetane-type peroxide (VI). In view of their work and our present results, we assumed that IV, V or VI and ammonia were involved in the formation of triphenyl-*s*-triazine.



III IV V VI

In order to clarify the mechanism involved in the ring expansion, reactions of IV and V with ammonia were investigated. When V which was prepared[5)] by the photo-oxygenation of I was dissolved in a metha-

nolic solution of ammonia at room temperature, II separated from the solution within about 15 min (20% yield based on V) and from the filtrate I (13%), a small amount of III, and benzamide (65%) were isolated. II was also obtained by dissolving V in solutions of ammonia in ethanol, 2-propanol or dimethyl sulfoxide when the yield of II was lower than that obtained in alcoholic solutions. When V was dissolved in ether, acetone or benzene containing ammonia, II was not isolated. On the other hand, when IV was dissolved in a methanolic solution of ammonia at room temperature, II was not obtained, but III and benzamide were isolated. These facts showed that the ring expansion proceeds through V (probably its anion) and IV is not involved in the reaction. In order to elucidate whether VI is involved in the ring expansion or not, the following experiments were carried out. When V (0.026 g) was dissolved in a methanolic solution of potassium hydroxide (1 N, 20 m*l*), the solution exhibited chemiluminescence and showed an absorption band (λ_{max} 245 nm) coinciding with that of IV. The band disappeared within about 20 min with appearance of absorption bands (λ_{max} 247, 279 nm) which coincided with those of III and gradually changed to that of benzamide (λ_{max} 225 nm). On the other hand, when V (0.026 g) was dissolved in a methanolic solution of ammonia (0.45 g in 20 m*l*), the solution did not exhibit chemiluminescence and an absorption spectrum gradually changed to that of III without appearance of the absorption

band of IV, and then gradually changed to that of benzamide. Considering these facts together with the conclusion of White and Harding[4] it seems that in a methanolic solution of ammonia, II is formed directly from V and ammonia and VI is not involved in the ring expansion.

When ammonium salts (acetate, chloride, and carbamate) were used in place of ammonia, it was found that II was obtained from V in yields higher than those in the case of ammonia. When V was dissolved in a methanolic solution of ammonium acetate at room temperature, II precipitated in 35% yield after a few minutes. From the filtrate, a large amount of I (64%) was recovered, but III, IV, and benzamide were not obtained.

2-*p*-Chlorophenyl-4,6-diphenyl-*s*-triazine was obtained by the reaction of hydroperoxide of the corresponding imidazole with ammonia or ammonium acetate in methanol at room temperature. 2-*m*-Nitrophenyl-4,5-diphenylimidazole which did not give a hydroperoxide by the sensitized photo-oxygenation did not produce the corresponding *s*-triazine in the presence of oxygen and ammonia. The results are compatible with our finding that lophyl hydroperoxide is an immediate precursor in the ring expansion.

II was also obtained in relatively high yield (35%) by a sensitized photo-oxygenation of I in a methanolic solution of ammonium salts. Other substituted triphenyl-*s*-triazines shown in Table 1, were obtained from the corresponding substituted triphenylimidazole by the similar method. This is a new synthetic method of triaryl-*s*-triazine. This method has an advantage over other procedures since the triazines are obtained in an almost pure state even without recrystallization.

Experimental

Materials. Triarylimidazoles shown in Table 2 were prepared according either to the method of Davidson, Weiss, and Jelling[10] or that of Cook and Jones.[11]

Hydroperoxides of triarylimidazole were prepared according to the method of Sonnenberg and White.[5] A chloroform solution of triarylimidazole (0.20 g and 100 m*l*) containing methylene blue (0.015 g) as sensitizer was irradiated by an incandescent lamp (300 W) for 20 min under cooling with ice-water until an absorption spectrum of the hydroperoxide was observed. After methanol was removed under reduced pressure at room temperature, the residue was dissolved in ether to remove methylene blue. After removal of ether under reduced ressure, the hydroperoxide was obtained as an oily product which was crystallized from methanol.

2,4,5-Triphenyl-4-hydroxy-4*H*-isoimidazole (V) decomposed at 235—245°C, producing I. λ_{max}^{EtOH}: 225 nm (ε: 1.5×10^4), 280 nm (ε: 1.6×10^4). IR (KBr and $CHCl_3$): 2820, 1620, and 850 cm^{-1}. NMR ($CDCl_3$): Signals were observed at 7—9 ppm, but no signal was observed at 10—15

N,N'-Dibenzoylbenzamidine (IV) was prepared according to the method of Dufraisse and Martel,[15] mp 141.5—142.5°C. Satisfactory C, H, and N analyses were obtained for $C_{21}H_{16}N_2O_2$.

Photolysis of I in Methanol in the Presence of Oxygen and Ammonia. A methanolic solution of I (0.5 g in 500 m*l*) containing ammonia (0.5 g) was irradiated at room temperature by a 100 W high-pressure mercury lamp under bubbling of oxygen, until a crystalline precipitate of II began to separate after about 2 hr. Absorption spectrum and thin-layer chromatogram of the solution showed the absence of I and suggested the presence of 4,5-(9',10'-phenanthryl)imidazole, III, and benzamide in the solution. II (mp 238—239°C) was collected by filtration (0.083 g 16%) which was proved to be identical with an authentic sample. The filtrate was evaporated to leave a yellow oil which deposited a white crystalline precipitate upon standing overnight. A small amount of benzene was added and the crystalline precipitate (about 0.15 g) was filtered. The precipitate (A) was shown to consist of benzamide and III by thin-layer chromatography and UV spectrum. An oily residue obtained by evaporation of the solvent from the yellow filtrate was dissolved in methanol and a small amount of water was added to produce a crystalline precipitate, The precipitate collected was identified to be 4,5-(9',10'-phenanthryl)imidazole (0.050 g, 9%) by mixed-melting with an authentic sample. After removal of the solvent, the oily residue was shown to contain III and benzamide by thin-layer chromatography and UV spectrum. The oily residue and the precipitate (A) were dissolved in benzene-acetone (4 : 1) and chromatographed on a column of alumina (20 g), using the same solvent system for elution. The early fractions collected were evaporated and the oily residue obtained was crystallized from *n*-hexane to give colorless crystals of III (0.181 g, 45%) which was proved to be identical with an authentic sample. From the later fractions collected benzamide (mp 124—125°C, 0.190 g, 25%) was obtained by evaporation of the solvent.

Sensitized Photo-oxygenation of I in Methanol in the Presence of Ammonia. A methanolic solution of I (0.10 g in 100 m*l*) containing ammonia (0.1 g) and methylene blue (0.015 g) was irradiated by a 300 W incandescent lamp for 15 min under bubbling of oxygen at about 0°C. Thin-layer chromatogram and UV spectrum of the resultant solution showed the absence of I and formation of lophyl hydroperoxide (V). When the solution was allowed to stand at room temperature for about 1 hr, a crystalline precipitate of II separated from the solution. II (mp 238—239°C) was collected by filtration (0.023 g, 22%). The filtrate was evaporated to dryness, and the residue was dissolved in ether to remove methylene blue. The yellow filtrate was evaporated to obtain a yellow residue (about 0.05 g) showing the presence of III and benzamide by UV spectrum and thin-layer chromatography. A benzene-acetone (4 : 1) solution of the residue was chromatographed on a column of alumina (5 g) using the same solvent system for elution. III (0.024 g, 33%) and benzamide (0.010 g, 12%) were obtained from the early and later fractions, respectively.

Reaction of V with Ammonium Acetate in Methanol. When V (0.20 g) was dissolved in a methanolic solution of ammonium acetate (1.0 g in 10 m*l*) at room temperature, a crystalline precipitate appeared within about 5 min. It was proved to be identical with an authentic sample of II. After the solution was allowed to stand overnight at room temperature, the precipitate of II (mp 238—239°C) was collected by filtration (0.066 g, 35%). The filtrate was shown by thin-layer chromatography and UV spectrum to consist largely of I. After the filtrate was concentrated to about one-half, water was added to yield a precipitate of I. The precipitate of I collected was washed with water and recrystallized from ethanol (mp 272—273°C, 0.107 g, 64%).

Preparation of II by Sensitized Photo-oxygenation of I in a Methanolic Solution of Ammonium Acetate. A methanolic solution of I (0.20 g in 100 m*l*) containing ammonium acetate (5.0 g) and methylene blue (0.015 g) was irradiated by a 300 W incandescent lamp at about 0°C under bubbling of oxygen. On irradiation for 10—20 min, the absorption spectrum of I changed to that of V and only a spot of V on a thin-layer chromatogram was obtained. After shutting off the irradiation the solution was heated (about 50°C) until the absorption band of II appeared with diminishing of that of V (about 3 hr). When the solution was allowed to stand at room temperature, II gradually separated from the solution. II (mp 238—239°C) was collected by filtration (0.073 g, 35%). The filtrate was shown to consist largely of I by thin-layer chromatography and UV spectrum. The filtrate was concentrated by evaporation and water was added to the residue to give a precipitate of I and to remove methylene blue. The precipitate of I collected was washed with water and recrystallized from ethanol (mp 272—273°C, 0.10 g, 50%). The yield of II did not increase when the solution was allowed to stand at room temperature or lower after shutting off the irradiation.

The authors wish to express their gratitude to Professor Ikuzo Tanaka of Tokyo Institute of Technology and Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research for their kind help. This research was supported in part by a Grant for Co-operative Research from the Ministry of Education.

The Cationic Polymerization of Methallyl Vinyl Ether

Heimei YUKI, Koichi HATADA, Tomoyuki EMURA, and Kazuhiko NAGATA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received August 25, 1970)

The polymerization of methallyl vinyl ether was carried out in toluene by means of $BF_3 \cdot OEt_2$. The reaction proceeded through the vinyl double bond, giving a polymer containing one methallyl double bond per monomeric unit. The polymer obtained below −78°C was a white powder and had an isotactic configuration. The molecular weight of the polymer decreased with an increase in the polymerization temperature, and the polymer obtained at 0°C was a viscous liquid. In *n*-heptane, the yields of the polymer decreased and a part of the polymer obtained was insoluble in usual organic solvents, probably because of the cross-linking which occurred during the polymerization reaction. In *n*-heptane - toluene mixtures, the yields were much higher than those in toluene or *n*-heptane alone. The NMR spectra of the polymer were measured in CCl_4, benzene, pyridine, and quinoline at various temperatures in order to investigate the polymer-solvent interaction; the π-complex formation between the monomeric unit of the polymer and the aromatic solvent molecule was suggested.

A number of papers have been published on the stereospecific polymerization of vinyl ethers.[1-6] However, there have been only a few reports[7-9] on the cationic polymerization of vinyl ether with an unsaturated substituent. In a previous work,[9] we studied the polymerization of allyl vinyl ether by $BF_3 \cdot OEt_2$. In the present work we investigated the polymerization of methallyl vinyl ether (MAVE) by $BF_3 \cdot OEt_2$; the polymerization was found to proceed through the vinyl double bond, giving a polymer containing one methallyl double bond per monomeric unit. At low polymerization temperatures, the polymer produced was a white powder with a predominantly isotactic configuration.

Experimental

Reagents. MAVE was prepared from methyl vinyl ether and methallyl alcohol by the vinyl transetherification catalyzed by mercuric acetate in the presence of molecular sieves.[10] The monomer obtained was refluxed over lithium aluminum hydride under a nitrogen atmosphere and was then fractionally distilled. Bp 90.0°C. The purified MAVE was sealed in ampoules under dry nitrogen and was stored at −20°C.

The toluene and *n*-heptane were purified in the usual manner, dried, and stored over calcium hydride. They were then dried further with a small amount of *n*-butyllithium and distilled under a high vacuum just before use.

Methylene chloride, nitroethane, and diethyl ether were purified as usual, dried with calcium hydride, and distilled under a high vacuum just before use.

$BF_3 \cdot OEt_2$ was purified by distillation under a reduced nitrogen pressure and was used as a toluene solution.

Nitrogen gas was purified by being passed through a column packed with molecular sieves 4A cooled at −78°C in a dry ice - acetone bath.

Polymerization. A vessel equipped with a three-way stop-cock was flushed with dry nitrogen. The monomer and a solvent were added with hypodermic syringes, and cooled at a given temperature. The polymerization was initiated by introducing the catalyst drop by drop with a syringe, and was stopped by adding a small amount of ammoniac methanol which had been cooled to the same temperature as the reaction mixture. The mixture was then poured into a large amount of methanol containing a small amount of phenyl-β-naphthylamine. The precipitated polymer was collected by filtration, washed throughly with methanol, and dried *in vacuo* at room temperature for three days. The filtrate was concentrated to dryness under a high vacuum. The resultant methanol-soluble fraction was redissolved in benzene to free it from inorganic materials and then dried by the freeze-drying technique. The polymer was stored under reduced nitrogen pressure at −20°C in order to avoid the formation of a cross-linked insoluble polymer.

Measurements of NMR Spectra. The NMR spectra were obtained with a JEOL JNM-4H-100 spectrometer at 100 MHz by using a 10 w/v% solution containing a small amount of tetramethylsilane as an internal standard. The spectra of the polymer and MAVE were measured in carbon tetrachloride at 60°C and in chloroform at 22.5°C respectively. The spectra using a spin-decoupling technique were measured in pyridine at 100°C.

The temperature dependence of the spectrum of the polymer was investigated in several solvents, using hexamethyldisilane as an external standard, in precision coaxial tubing (Wilmad Glass Co.). A correction of the chemical shift involving the difference between the bulk diamagnetic susceptibilities of the reference compound and the sample solution was applied. The volume magnetic susceptibilities, χ_v, were taken from the literature.[11,12] The χ_v value of the neat solvent was used instead of that of the sample solution.

Viscosity Measurements. The solution viscosity of the polymer was measured on its toluene solution (0.7—1.0 g/dl) at 30.0±0.03°C using Ostwald's viscometer.

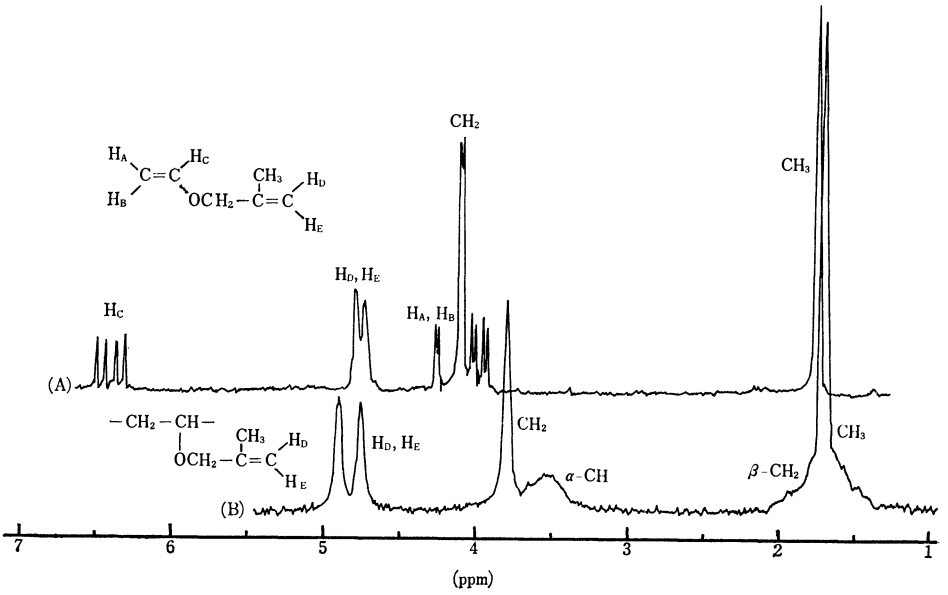

Fig. 1. NMR spectra of methallyl vinyl ether (A) and poly(methallyl vinyl ether) (B) obtained in toluene at −78°C by $BF_3 \cdot OEt_2$

Measurements of Molecular Weight. The molecular weight of the polymer was measured on its benzene solution (10 g/*l*) at 37°C using a Mechrolab 301 A Vapor Pressure Osmometer.

Results and Discussion

Structure and Tacticity of PMAVE. Figure 1 shows the NMR spectrum of PMAVE obtained at −78°C in toluene by $BF_3 \cdot OEt_2$, together with the spectrum of MAVE. The spectrum of the polymer consisted of four groups of peaks, which correspond to the methyl-proton signal overlapping with that of the β-methylene protons, α-methine proton signal, methallyl methylene proton signal, and the terminal methylene proton signals with decreasing magnetic field. The intensity ratio of these groups of peaks was 5.3 : 1.1 : 2.0 : 2.0. There were no resonances due to the protons of the vinyl group, which were observed at about 3.9—4.3 and 6.4 ppm in the spectrum of the MAVE. These facts show that MAVE polymerized exclusively through the vinyl double bond, leaving the methallyl double bond unaffected by the polymerization.

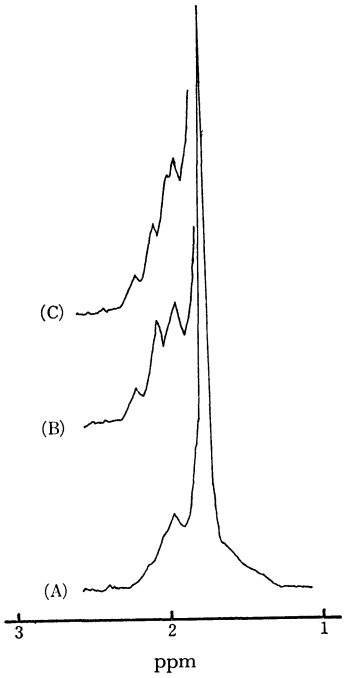

Fig. 2. β-Methylene and methyl protons resonances of PMAVE obtained in toluene at −78°C (20 w/v% pyridine solution, 100°C).
A: Undecoupled.
B: Decoupled from α-methine proton.
C: PMAVE obtained in toluene at 0°C. Decoupled from α-methine proton.

In the CCl_4 solution the β-methylene-proton resonance of PMAVE overlapped with methyl-proton resonance, but in the pyridine solution it was partially separated from it as is shown in Fig. 2 (A). The β-methylene-proton resonance decoupled from the α-methine proton split into three peaks, at 1.96, 2.08, and 2.21 ppm (B in Fig. 2). These splittings are considered to be three of the four peaks of a typical AB quartet, which originated from the meso methylene protons of an isotactic polymer. The fourth peak at the highest field, must overlap with the methyl signal. These results suggest that the polymer obtained at −78°C was highly isotactic. On the other hand, the decoupled β-methylene resonances of the polymer obtained at 0°C in toluene (C in Fig. 2) was somewhat different, showing that the polymer was less isotactic and that the singlet due to the syndiotactic methylene protons overlaps with the peak at 1.96 ppm, one of the signals of the meso methylene quartet. However, no quantitative determination of the tacticity could be made because of the poor resolution of the decoupled spectrum.

NMR Spectra of PMAVE in Various Solvents. The NMR spectra of PMAVE obtained at −78°C in toluene were taken at 22.5°C on a 10 w/v% solution in various solvents. The results are shown in Table 1. All the signals shifted to a higher field on going from a CCl_4

Table 1. NMR spectra of PMAVE in various solvents at 22.5°C

Solvent	Chemical shift (ppm)					
	$-CH_2-\underset{\underset{O}{|}}{C}-$	$-\underset{\underset{O}{|}}{C}-CH-$	$\overset{O}{\overset{|}{CH_2}}\overset{|}{C}$	$\overset{|}{C}-CH_3$	$\overset{|}{C}-$	$\overset{\|}{CH_2}$
Carbon tetrachloride	2.12	3.98	4.30	2.24	5.29	5.42
Benzene	1.54	3.56	3.67	1.49	4.64	4.91
Pyridine	1.56	3.54	3.66	1.43	4.57	4.82
Quinoline	1.96	3.87	3.95	1.69	4.86	5.16

solution to the solutions in aromatic solvents. The extent of the shift is almost the same in the benzene and pyridine solutions. The quinoline solution showed a smaller shift than the above two solutions did. While pyridine and quinoline have nearly the same dielectric constant and dipole moment, those of benzene are considerably smaller. The above results clearly indicate that the shifts are not caused by the different dielectric constants and dipole moments of the solvents, but by the interaction of the polymer with the solvents. The interaction may be the π-complex formation between the monomeric unit in PMAVE and the solvent molecule, as was reported in connection with the benzene solution of poly(methyl methacrylate).[13]

The temperature dependences of the chemical shifts were investigated in CCl_4 and quinoline solutions. In the CCl_4 solution the chemical shifts of all the protons were scarcely dependent at all upon the temperature. On the other hand, in the quinoline solution all the signals shifted to a low field with an increase in the temperature (Fig. 3). In the benzene and pyridine solutions, nearly the same changes in the chemical shifts were observed. These results may support the idea of the formation of a π-complex in these aromatic solvents.

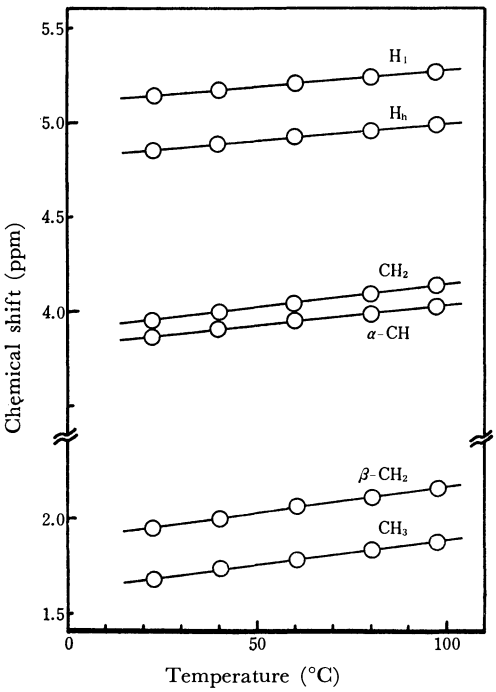

Fig. 3. Temperature dependences of the chemical shifts of all protons in PMAVE obtained in toluene at −78°C. ——Quinoline solution—— H_l and H_h denote the protons of vinyl methylene ones which give the signals at the lower and the higher field, respectively.

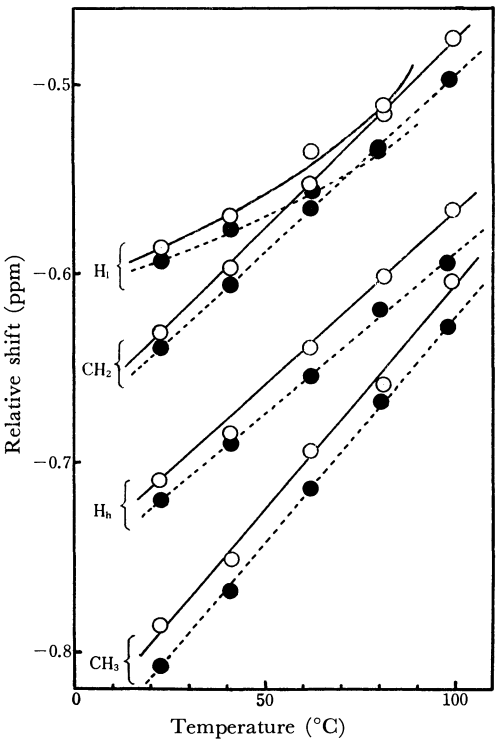

Fig. 4. Relative shifts of the protons in PMAVEs obtained in toluene at 0°C (○) and at −78°C (●) ——Pyridine solution——.

In Figs. 4 and 5 the relative shifts of the protons of the PMAVEs obtained at −78°C and 0°C in toluene are plotted against the temperature, where the relative shift is defined as the difference between the chemical shifts of each particular group in an aromatic solvent and in CCl_4. In both the pyridine (Fig. 4) and quinoline (Fig. 5) solutions, the relative shifts became smaller with an increase in the temperature. Small but significant differences were observed between the relative shifts of the PMAVE obtained at −78°C and those of the PMAVE obtained at 0°C in both the solutions. Liu[14] has revealed, by NMR spectroscopy, that

the tacticity variation affects the polymer-solvent interaction in a benzene solution of poly(methyl methacrylate). Therefore, the results presented above indicate that the tacticity of PMAVE obtained at −78°C in toluene is different from that of PMAVE obtained at 0°C, as has been suggested above.

Effect of the Polymerization Temperature. The polymerizations were carried out in toluene at various temperatures. The results are shown in Fig. 6. The yield of the methanol-soluble polymer was constant below −20°C and increased remarkably at 0°C. However, the molecular weight was almost constant, regardless of the polymerization temperature.

The yield of the methanol-insoluble polymer had its minimum at −40°C. The solution viscosity and the molecular weight of the methanol-insoluble polymer decreased slightly with the elevation of the polymerization temperature. The polymer obtained below −78°C was a white powder which had an isotactic configuration, as has been mentioned above. The polymer obtained at 0°C was a viscous liquid which had a molecular weight of 12000. The rate of the termination or chain-transfer reaction in the polymerization may increase, and a polymer with a lower molecular weight may be obtained with an increase in the polymerization temperature.

Polymerization in Various Solvents. The polymerizations were carried out in various solvents at −78°C. The results are listed in Table 2. The yield of the polymer was lowered in polar solvents, and no methanol-insoluble polymer was obtained.

In *n*-heptane-toluene mixtures, the yields of the methanol-insoluble polymer were much higher than in toluene or *n*-heptane alone. In *n*-heptane, the yield of the polymer decreased and a part of the polymer obtained was insoluble not only in methanol but also in usual organic solvents, probably because of cross-linking during the polymerization reaction.

The authors wish to express their thanks to Mr. Y. Terawaki for the NMR experiments and to Mrs. F. Yano for her clerical assistance in preparing the manuscript.

Condensation Reactions of Sulfonylcarbanion

Yasusi YAMAMOTO, Tetuya NISIMURA, and Hitosi NOZAKI

Department of Industiral Chemistry, Kyoto University, Yoshida, Kyoto

(Received September 5, 1970)

Phenylsulfonylcarbanion $PhSO_2CH_2^-$ reacts with anthracene and acridine in HMPA to afford methylated products much as does methylsulfinylcarbanion $MeSOCH_2^-$ in DMSO. The reaction mechanism is examined by following the change in the D-content during the reaction of 9-deuterioanthracene. The transformation of the negatively-charged σ-complex into the methylated product involves the concerted occurrence of a hydride shift and the elimination of the sulfinate anion. Meanwhile, the reaction of this carbanion with anthracene at a higher temperature yields the ethylated products of 9-ethyl-10-methyl- and 9,10-diethylanthracene besides 9,10-dimethylanthracene. Other condensation reactions of the carbanion investigated are those with (a) $Ph_2C{=}CH_2$, (b) $PhC{\equiv}CPh$, (c) Ph_2CO, (d) PhCOCOPh, and (e) 2-aminobenzophenone, the main products being (a) $Ph_2CHCH_2\text{-}CH\text{-}CPh_2$ (cyclopropane ring), (b) $Ph_2C{=}C(Ph)Me$, (c) $Ph_2C(OH)CH_2CH_2SO_2Ph$ and $Ph_2C{=}CHCH_2SO_2Ph$, (d) $PhCOCH_2SO_2Ph$ and PhCOOH, and (e) 3-phenylindole respectively.

Synthetic reactions by means of methylsulfinylcarbanion were explored by Corey,[1] Russell,[2] and their co-workers.[3] Previously, we recorded the attainment of the nucleophilic methylation of condensed aromatic rings with this carbanion,[4,5] this reaction was reported independently by several other groups at almost the same time. The condensation reactions of sulfonylcarbanions were documented equally well[6] and our previous communication[7] was concerned with aromatic methylation involving the carbanion produced from methyl phenyl sulfone and sodium hydride in HMPA. The present paper will present (a) a summary of our investigations of the aromatic methylation and (b) a comparison of the behavior of sulfinyl- and sulfonylcarbanions in relation to aryl-conjugated olefinic and acetylenic bonds as well as compounds containing a benzoyl group.

Table 1 summarizes the methylation of anthracene and acridine with sulfonylcarbanions. The reaction can be effected by means of the carbanion derived from *N,N*-dimethyl(methylsulfonamide) equally well, and the solvent HMPA can be replaced with DMF. Phenanthrene, quinoline, and isoquinoline failed to be methylated with sulfonylcarbanions, whereas the reaction of these substrates with methylsulfinylcarbanion proceeded smoothly. The mechanism of the methylation with sulfinylcarbanion was outlined in the previous communication.[5a] Analogous investigations have now been extended to the methylation of anthracene with sulfonylcarbanions. Scheme 1 shows two possible reaction paths, A and B. The path A implies that a concerted hydride shift and the elimination of the sulfinate anion are involved in the transformation of the negatively-charged σ-complex (IIa or IIb) into the methylated product. The other path, B,[5a] assumes proton abstraction by IIa or IIb, followed by the elimination of sulfinic acid and, finally aro-

4) Ordinarily a paper such as this should contain experimental details on the nucleophilic aromatic methylation with methylsulfinylcarbanion reported in our previous communication (Ref. 5a), but this will not be done. The reason is that independent reports by Russell, Argabright, and their co-workers have made such a description meaningless. Though the reaction of D-labelled aromatics was recorded only in Ref. 5a, the experimental procedure was almost the same as the methylation reaction with phenylsulfonylcarbanion in HMPA described in the "Experimental" section.

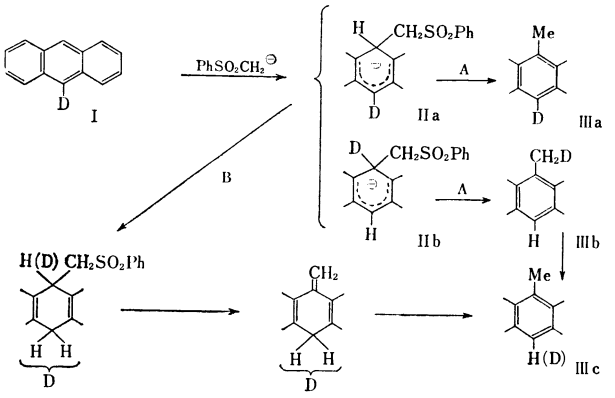
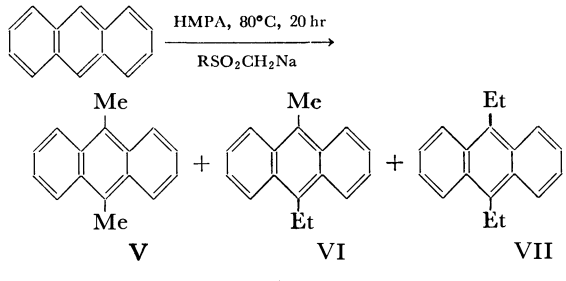
TABLE 1. METHYLATION OF ANTHRACENE AND ACRIDINE BY MEANS OF RSO_2CH_2Na

Aromatics	R	Solvent[a]	(Aromatic/Base) Mole ratio	Reaction Temp. (°C)	Reaction Time (hr)	Products (Yield %)[b]
Anthracene	Ph	HMPA	3	60	15	9-Methylanthracene (55) 9,10-Dimethylanthracene (10)
Anthracene	NMe_2	HMPA	2.1	30	20	9-Methylanthracene (35)[c]
Acridine	Ph	HMPA	1.5	25	4	9-Methylacridine (60)
Acridine	Ph	HMPA	2	80	4	9-Methylacridine (33) 9-Methylacridane (4)
Acridine	Ph	DMF	3	30	4	9-Methylacridine (67)
Acridine	NMe_2	HMPA	3	22	4	9-Methylacridine (40)

a) HMPA stands for hexamethylphosphoric triamide and DMF for *N,N*-dimethylformamide.
b) All reaction products were identified with authentic samples.
c) Yields are based on the substrates initially added, as the recoveries of unchanged materials have not determined accurately.



Scheme 1



Scheme 2[8]

matization. A choice between the two is made by examining the change in the D-content in the reaction of 9-deuterioanthracene (I). As the CH_2D group (IIIb) attached to the aromatic ring is rapidly changed into the CH_3 group (IIIc) under the reaction conditions, the path A gives a 50% retention, and the path B, a 25% retention, in the absence of a primary isotope effect. Mass spectrometric analyses have indicated that the original D-content (82%) is unchanged in the recovered I. In contrast, the 9-methylanthracene produced retains 45% of its D-content; therefore, nearly 50% of the deuterium is lost by methylation.

The path A is also supported by another experimental fact, the fact that the reaction of acridine with ethyl phenyl sulfone gives 9-(α-phenylsulfonylethyl)-acridane (IV). This indicates that the hydride shift in the σ-complex is slower than the protonation in this case, possibly because of the presence of a methyl substituent in the S_N center.

A remarkable feature of aromatic substitution by means of sulfonylcarbanion is the formation of ethylated by-products, as is shown in Scheme 2. *A priori*, we can not exclude the possibility of the initial formation of ethyl phenyl sulfone. However, all attempts either to detect ethyl phenyl sulfone among the recovered sulfone or to confirm the formation of monoethylated anthracene were unsuccessful. In contrast, the treatment of V under the conditions of Scheme 2 gave a 53% yield of VI and a 24% yield of VII, besides a 46% recovery of V. The ethylation would thus conceivably involve the preliminary formation of arylcarbanion by proton-abstraction from the C-methyl group.

Other condensation reactions of sulfinylcarbanion with 1,1-diphenylethylene (VIII),[9,10] tolan (XV),[11] benzophenone (XVII),[9,10] and with benzil (XXI)[12] in DMSO were recorded previously. We have examined the condensation of phenylsulfonylcarbanion with these substrates in HMPA in order to observe closely the several remarkable points of difference.

8) As the three products could not be sharply separated, the yields were calculated as follows. On the basis of a comparison of the products with authentic samples by GLC (Apiezon L 30%), we could detect the presence of 9,10-dimethyl-, 9-ethyl-10-methyl-, and 9,10-diethylanthracene (not isolated). 9-Methylanthracene was absent. The NMR spectra indicated that the substituents of anthracene were either methyl- or ethyl-groups and that the substitution had occurred at C-9 and C-10 exclusively (This is the AA′BB′-pattern of aromatic protons). Accordingly, we calculated the yields of 9,10-dimethylanthracene and 9-ethyl-10-methylanthracene from the integral ratio of the NMR signals of the mixture, while a small amount of diethylanthracene was detected by observing the parent peak in the mass spectra.

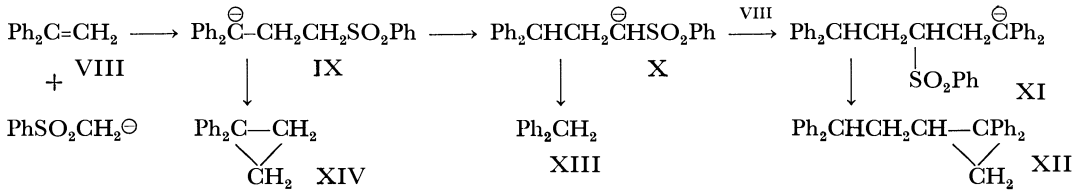
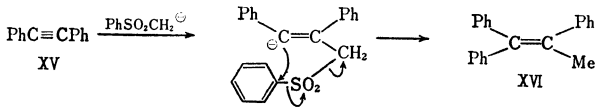


Scheme 3

The reaction of phenylsulfonylcarbanion (15 mmol) with VIII (10 mmol) yielded mainly XII (60%), besides XIII (34%) and XIV (1%) (Scheme 3); these results are in contrast with those of methylsulfinylcarbanion, which afforded XIII (64%) and XIV (36%) only. The present reaction is, therefore, characterized by the facile isomerization of the carbanion IX into the sulfonylcarbanion X.

The reaction of XV with methylsulfinylcarbanion is known to produce 2,3-diphenyl-1,3-butadiene.[11] Meanwhile, the reaction with phenylsulfonylcarbanion proceeded according to Scheme 4 to give 1,1,2-triphenylpropene (XVI) (21%), possibly *via* Truce-Smiles rearrangement.[13]



Scheme 4

Scheme 5 shows the reactions of XVII with phenylsulfonylcarbanion, affording XIX (21%) and XX (22%). The condensation of XVII with methylsulfinylcarbanion[9,10] gives mainly VIII (47%), in addition to such by-products as XIII (30%), XIV (3%), and diphenylacetaldehyde (20%). The aldehyde may be ascribed to intermediary 2,2-diphenyloxirane (XVIII) (not isolated). In contrast, the reaction of phenylsulfonylcarbanion with XVIII gave XIX (44%), whose dehydration with trifluoroacetic acid afforded XX.

The reaction of phenylsulfonylcarbanion with benzil (XXI) afforded mainly phenacyl phenyl sulfone (XXII) (22%) and benzoic acid (XXIII) (26%), besides desoxybenzoin (XXIV) (17%) and the Kostanecki compound (XXV) [14] (11%). This is in contrast to that of methylsulfinylcarbanion, which has been recorded to produce 2,4,5-triphenyl-3-benzoylfuran and XXIII.[12] The condensation of phenylsulfonylcarbanion with 2-aminobenzophenone (XXVI) yielded 3-phenylindole (XXVII) (59%), while that with salicylaldehyde (XXVIII) gave not benzofuran, but *o*-hydroxystyryl phenyl sulfone (XXIX) (73%).

On the basis of these observations, we may summarize the points of difference between sulfinyl- and sulfonylcarbanions as follows: the sulfinylcarbanion has a higher reactivity than the sulfonylcarbnion, as is evident from the comparison of the methylation reaction of condensed aromatics and from the reaction temperature required for the condensation with olefinic and acetylenic compounds. It is also to be noticed that higher temperatures are generally required for the reaction of sulfonylcarbanion and that products retaining the sulfonylgroup are obtained more frequently, although it has often been demonstrated that sulfinic acid is a better leaving group than the sulfenic acid.[16] The reason for this remains to be clarified.

Experimental

All the mps are uncorrected. The microanalyses were performed at the Elemental Analyses Center of Kyoto University and by Mrs. K. Fujimoto at Prof. K. Sisido's Laboratory. The NMR spectra were obtained in $CDCl_3$, CCl_4, or D_3CSOCD_3 on a 60 MHz instrument (JEOL C-60H spectrometer). The mass spectra were obtained on a Hitachi RMU-6E or RMU-6D spectrometer, lent by the Sagami Chemical Research Center and the Toray Co. respectively.

Reaction of Phenylsulfonylcarbanion with Anthracene. A solution of sodium phenylsulfonylcarbanion was prepared under N_2 from sodium hydride (0.41 g, 16.8 mmol) and methyl phenyl sulfone (5.3 g, 33.6 mmol) in HMPA (30 m*l*). Into this solution, at room temperature, anthracene (1.0 g, 5.6 mmol) in HMPA (30 m*l*) was stirred over a period of

2 min. The dark-brown reaction mixture was then stirred at 65°C for 15 hr. The products were isolated and confirmed by chromatography on a silica-gel column and GLC (Apiezon L 30%). 9-Methylanthracene was obtained in a 55% yield as prisms; mp and mixed mp 81°C (EtOH) (lit,[17] 81°C). The recovery of anthracene was 4%.[18] GLC of the mother liquor indicated the presence of 9,10-dimethylanthracene (*ca.* 10%).

An equimolar mixture of 9-deuterioanthracene (I) (D-content 82%, obtained by the treatment of the Grignard reagent of 9-bromoanthracene with D_2O), and phenylsulfonylcarbanion in HMPA was allowed to react at 65°C for 15 hr. The reaction mixture was separated by preparative GLC (Apiezon L 30%). The D-contents of the recovered anthracene and 9-methylanthracene were estimated to be 82% and 45% respectively, on the basis of the molecular peaks in the mass spectra.

Meanwhile, the reaction of anthracene (1.0 g, 5.6 mmol) in HMPA (30 m*l*) with the phenylsulfonylcarbanion obtained from sodium hydride (0.4 g, 17 mmol) and methyl phenyl sulfone (5.25 g, 34 mmol) in HMPA (40 m*l*) yielded 0.59 g of a mixture of 9,10-dimethylanthracene (13%) and 9-ethyl-10-methylanthracene (43%) as yellow needles; mp 145—146°C upon chromatography on a silica-gel column. The yields were calculated by the method described in the footnote.

The Reaction of Phenylsulfonylcarbanion with 9,10-Dimethylanthracene. 9,10-Dimethylanthracene (0.52 g, 2.5 mmol), dissolved in HMPA (30 m*l*), was added to a solution of carbanion prepared from sodium hydride (0.24 g, 10 mmol) and methyl phenyl sulfone (1.56 g, 10 mmol) in HMPA (30 m*l*); the mixture was then allowed to react at 85°C for 24 hr. A subsequent work-up gave 53% of 9-ethyl-10-methylanthracene and 24% of 9,10-diethylanthracene, besides 46% of the recovered 9,10-dimethylanthracene.

The Reaction of Phenylsulfonylcarbanion with Acridine. Acridine (2.0 g, 11 mmol), dissolved in HMPA (10 m*l*), was added to a solution of carbanion prepared from sodium hydride (0.40 g, 17 mmol) and methyl phenyl sulfone (2.6 g, 17 mmol) in HMPA (30 m*l*); the mixture was then allowed to react at 25°C for 4 hr. A subsequent work-up and isolation by chromatography on a silica-gel column gave 9-methylacridine (1.3 g, 60%); mp 118—119°C (lit,[19] 117—118°C) (EtOH).

The heating of a solution of the same components (2 : 2 : 1 ratio) at 80°C for 4 hr gave 9-methylacridine (33%) and 9-methylacridane (4%); mp 123—125°C (lit,[19] 124—125.5°C). IR (Nujol): 3400 cm^{-1} (NH). NMR (CCl_4): δ 1.34 (d, 3H, Me), 4.02 (q, 1H, -CH-), 5.83 (s (broad), 1H, NH) and 6.43—7.25 (m, 8H, aromatic protons).

9-(α-Phenylsulfonylethyl)acridane (IV). Acridine (2.0 g, 11 mmol), dissolved in HMPA (10 m*l*), was treated with a solution of carbanion obtained from ethyl phenyl sulfone (3.0 g, 18 mmol) and sodium hydride (0.41 g, 17 mmol) in HMPA (40 m*l*) under N_2 at 50°C for 4 hr. A subsequent work-up gave IV (2.11 g, 54%). The analytical sample crystallized from benzene as colorless prisms; mp 209—212°C (dec.). IR (Nujol): 3300 cm^{-1} (NH), 1300, 1140 cm^{-1} (SO_2). NMR (CD_3SOCD_3 at 72°C using hexamethyldisilane as an internal standard): δ 0.82 (d, 3H, Me, J=8 Hz), 3.16 (d of q, 1H, -C*H*(Me)SO_2-, J=2 and 8 Hz), 4.94 (d, 1H, -C*H*-CH(Me)SO_2-, J=2 Hz), 6.7—8.0 (m, 13H, aromatic protons) and 8.60 (s (broad), 1H, NH).

Found: C, 72.1; H, 5.2%. Calcd for $C_{21}H_{19}NO_2S$: C, 72.2; H, 5.5%.

The Reaction of Phenylsulfonylcarbanion with 1,1-Diphenylethylene (VIII). A solution of phenylsulfonylcarbanion was prepared under N_2 with sodium hydride (0.36 g, 15 mmol) and methyl phenyl sulfone (2.3 g, 15 mmol) in HMPA (40 m*l*). A solution of VIII (1.6 g, 9 mmol) in HMPA (10 m*l*) was stirred into this carbanion solution at room temperature over a period of 5 min. After subsequent stirring at 85°C for 20 hr, the mixture was separated from the recovered sulfone by chromatography on an alumina column and was distilled at 70—90°C/2.5 mmHg. The distillate was isolated by GLC (Apiezon L 30%) and was identified as being composed of diphenylmethane (XIII) and 1,1-diphenylcyclopropane (XIV). The yields were 34% and 1% respectively. A work-up of the mother liquor gave 1.01 g (60%) of 1,1-diphenyl-2-(β,β-diphenylethyl)cyclopropane (XII) as white prisms; mp 109—110°C. IR (Nujol): 1030 cm^{-1} (cyclopropane). NMR ($CDCl_3$): δ 1.00—2.35 (m, 5H, cyclopropane hydrogens and those of ring-attached methylene), 3.95 (t, 1H, Ph_2CH-) and 6.99, 7.06, 7.12 and 7.28 (four s, total 20 H, aromatic protons). Mass *m/e* (rel intensity): 374 (M^+), 296 (trace), 270 (7), 207 (17), 194 (33), 180 (26), 167 (15) and 91 (100).

Found: C, 92.9; H, 6.9%. Calcd for $C_{29}H_{26}$: C, 93.0; H, 7.0%.

The Reaction of Phenylsulfonylcarbanion with Tolan (XV). A solution of XV (0.90 g, 5 mmol) in HMPA (20 m*l*) was stirred into a carbanion solution prepared from sodium hydride (0.35 g, 15 mmol) and methyl phenyl sulfone (1.95 g, 13 mmol) in HMPA (30 m*l*). After stirring at 95°C for 18 hr, the reaction mixture was treated as above. 1,1,2-Triphenylpropene (XVI) (0.28 g, 21%) was thus obtained as white crystals; mp 85—86°C (lit,[20] 86—89°C). NMR ($CDCl_3$): δ 2.12 (s, 3H, Me), 6.95, 7.12, 7.28 (three s, 15H, aromatic protons). Mass *m/e*: 275 (M^+).

Found: C, 93.0; H, 6.7%. Calcd for $C_{21}H_{18}$: C, 93.3; H, 6.7%.

The Reaction of Phenylsulfonylcarbanion with Benzophenone (XVII). The treatment of benzophenone (1.82 g, 10 mmol) with a solution of carbanion prepared from sodium hydride (0.36 g, 15 mmol) and methyl phenyl sulfone (2.34 g, 15 mmol) in HMPA (20 m*l*) at 60°C for 20 hr gave a mixture of 3,3-diphenyl-3-hydroxypropyl phenyl sulfone (XIX) and 3,3-diphenyl-2-propenyl phenyl sulfone (XX). XIX (0.73 g, 21%), mp 200—201°C, was isolated as a product which did not resolve in benzene. IR (Nujol): 3500 cm^{-1} (OH), 1300, 1150 cm^{-1} (SO_2).

Found: C, 71.9; H, 5.8%. Calcd for $C_{21}H_{20}O_3S$: C, 71.6; H, 5.7%.

XX (0.73 g, 22%), isolated from the mother liquor by chromatography on a silica-gel column (benzene), showed a mp of 109—110°C. IR (Nujol): 1300, 1140 cm^{-1} (SO_2). NMR ($CDCl_3$): δ 3.90 (d, 2H, -CH_2-), 6.14 (t, 1H, =CH-) and 6.53—7.80 (m, 15H, aromatic protons).

Found: C, 75.3; H, 5.6%. Calcd for $C_{21}H_{18}O_2S$: C, 75.5; H, 5.4%.

The Reaction of Phenylsulfonylcarbanion with 2,2-Diphenyloxirane (XVIII). The treatment of XVIII (2.76 g, 15 mmol) with a solution of carbanion prepared from sodium hydride (0.72 g, 30 mmol) and methyl phenyl sulfone (4.64 g, 30 mmol) in HMPA (20 m*l*) at 60°C for 20 hr gave XIX (2.32 g, 44%).

20) J. Bornstein and F. Nunes, *J. Org. Chem.*, **30**, 3324 (1965).

The Reaction of Phenylsulfonylcarbanion with Benzil (XXI). To a solution of carbanion prepared from sodium hydride (0.72 g, 30 mmol) and methyl phenyl sulfone (4.7 g, 30 mmol) in HMPA (30 m*l*), we added XXI (3.15 g, 15 mmol) in HMPA (10 m*l*) at room temperature; the mixture was then allowed to react at 85°C for 20 hr. The reaction mixture was treated with water and extracted with benzene. A subsequent work-up of the benzene solution gave the Kostanecki compound (XXV) (11%) and desoxybenzoin (XXIV) (17%) upon chromatography on a silica-gel column. The water solution was neutralized with acetic acid and extracted with benzene. Phenacyl phenyl sulfone (XXII) (22%) and benzoic acid (XXIII) (26%) was obtained upon chromatography on a silica-gel column. Sulfone XXII showed a mp of 92—93.5°C (lit,[21] 93—94°C). IR (Nujol): 1670 cm^{-1} (CO), 1300, 1150 cm^{-1} (SO_2). NMR ($CDCl_3$): δ 4.30 (s, 2H, $-CH_2-$) and 7.20—8.15 (m, 10 H, aromatic protons). The Kostanecki compound, XXV, showed a mp of 122—123°C (lit,[15] 120°C) and was identical with the authentic sample.

The Reaction of Phenylsulfonylcarbanion with 2-Aminobenzophenone (XXVI). The reaction of carbanion, prepared from sodium hydride (0.96 g, 40 mmol), and the sulfone (6.2 g, 40 mmol) in HMPA (30 m*l*) with XXVI (2.23 g, 11 mmol) in HMPA (10 m*l*) was carried out at 110°C for 48 hr. Chromatography on a silica-gel column (hexane) gave 3-phenylindole (XXVII) (1.25 g, 59%); mp 88—89°C (lit,[22] 88—89°C).

Found: C, 87.0; H, 5.7; N, 7.1%. Calcd for $C_{14}H_{11}N$: C, 87.0; H, 5.7; N, 7.3%.

The Reaction of Phenylsulfonylcarbanion with Salicylaldehyde (XXVIII). The reaction of carbanion, prepared from sodium hydride (0.72 g, 30 mmol), and the sulfone (4.68 g, 30 mmol) in HMPA (25 m*l*) with salicylaldehyde (2.64 g, 22 mmol) in HMPA (10 m*l*) gave *o*-hydroxystyryl phenyl sulfone (XXIX) (4.17 g, 73%); mp 171—172°C. IR (Nujol): 3350 cm^{-1} (OH), 1280, 1130 cm^{-1} (SO_2) and 965 cm^{-1} (-CH=CH-). NMR (CD_3SOCD_3 using sodium 3-(trimethylsilyl)propylsulfonate as the internal standard): 6.70—8.31 (m, 11H, aromatic and olefinic protons) and 10.65 (s (broad), 1H, OH).

Found: C, 64.6; H, 4.7%. Calcd for $C_{14}H_{12}O_3S$: C, 64.6; H, 4.7%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 545—550 (1971)

Reaction of Aromatics with Thallic Salts——Preparation of Arylthallic Compounds[1]

Katsuhiko Ichikawa, Sakae Uemura,* Takeshi Nakano, and Eizo Uegaki

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

**Institute for Chemical Research, Kyoto University, Uji, Kyoto*

(Received September 8, 1970)

Arylthallic acetate perchlorate monohydrates, Ar-Tl(OAc)(ClO_4)·H_2O, were obtained as the major products of the reaction between thallic acetate and aromatics in acetic acid containing perchloric acid. As the minor products, various types of oxidation products including oxidative coupling were obtained. Reactivity order of the aromatics and the isomer distributions in the products were the same as those in the usual electrophilic aromatic substitution. With thallic nitrate, sulfate, and chloride, no arylthallic compounds could be obtained.

Aromatic mercuration has been well known as one of the family of electrophilic aromatic substitution.[2,3] Davidson and Triggs reported the possibilities of aromatic substitution with heavy metals such as thallation, plumbation, auration, palladation, and platination.[4] Since aromatic heavy metal compounds are not always stable, isolation of the compounds from direct substitution products was successful only in the case of thallation.[4] We have also studied the aromatic thallation under the similar conditions independently and wish to present our results, since our experiments were to develope a synthetic method of preparation of arylthallic compounds and different from those by Davidson and Triggs which were rather for mechanistic study.

So far, several methods of preparation of aromatic thallium compounds (using no metal exchange reaction) have been reported, for example, the reaction of thallic chloride with dibenzofuran[5] and the reaction of thallic isobutyrate with benzene and alkoxybenzenes.[6,7] Very recently, McKillop *et al.* found that thallic trifluoroacetate reacts with various aromatics to give arylthallic di-trifluoroacetates in good yields at room temperature.[8]

Results and Discussion

Aromatic compounds were added to acetic acid solutions of various thallic salts such as acetate, sulfate, nitrate, and chloride at various temperatures. The mixtures were homogeneous except in the case of thallic sulfate. As the reaction proceeded, formation of insoluble thallous salts was observed. Product distribution depends on the several factors such as the structure of aromatics, the kind of thallic salt used, the addition of mineral strong acid, and the conditions. Structures of the identified products are shown in Chart 1.

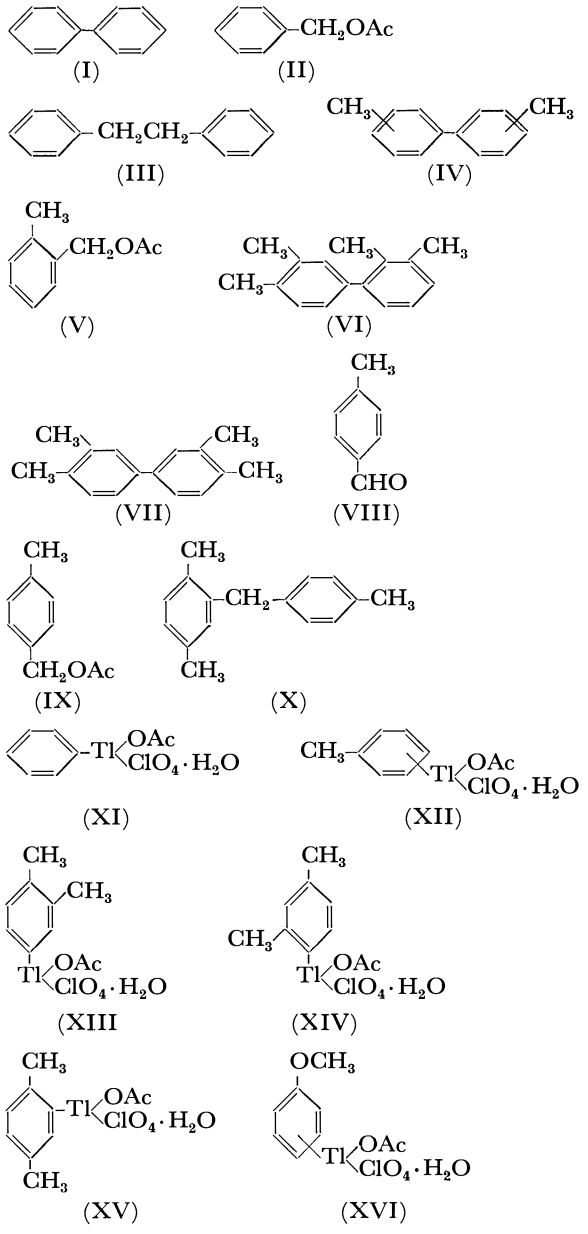

Chart 1. Structures of products.

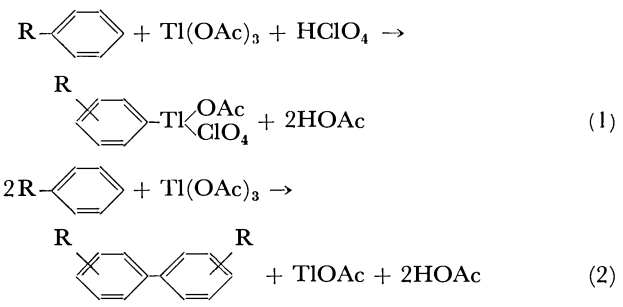
Reaction with Thallic Acetate. In Table 1, the experimental results are summarized. Sluggish reactions between aromatics and thallic acetate were accelerated remarkably by the addition of perchloric acid to the reaction mixtures. Sulfuric acid, nitric acid and boron trifluoride showed the same effect, but were not so effective. The main products were arylthallic acetate perchlorate monohydrate, $ArTl(OAc)(ClO_4)\cdot H_2O$. Oxidative coupling products were also obtained along with small amounts of oxidation products of side chain. The yields were calculated according to the following equations on the basis of thallic acetate used.



Material balance of oxidation-reduction by Eq. (2) was very poor, probably because acetic acid was oxidized with thallic acetate, particularly in the presence of perchloric acid. In fact, 97% of thallic acetate (0.35 M) dissolved in acetic acid containing perchloric acid (0.6 M) were reduced to thallous salt after refluxing for 7 hr. It has been reported also that the yield of thallic acetate was poor when thallic oxide was dissolved in refluxing acetic acid.[9]

Fairly good yields of arylthallic compounds have been obtained by the reaction of benzene, toluene, xylenes, and anisole. Prolonged reactions at higher temperature resulted in the decrease in the yields of arylthallic compounds and in the increase of the oxidation products. No quantitative relationship, however, appears to exist between the two types of the reaction. It was also noted that some of the arylthallic salts oxidize acetic acid as solvent at refluxing temperature gradually and form thallous salt without giving oxidative coupling products.

Anisole reacted readily even at lower temperature to give anisylthallic derivative. At refluxing temperature, however, no organothallium and only a trace of oxidation products could be obtained even after short reaction time, despite that thallic salt was reduced to thallous state completely. With mesitylene the same phenomenon was observed. Aromatic compounds with electron withdrawing group such as nitro and chloro did not react at all. Therefore, the reactivity order of aromatics appears to be similar to that in the usual electrophilic aromatic substitution.

The structures of arylthallic compounds were identified to be arylthallic acetate perchlorate monohydrate by the results of elemental analyses and IR and NMR spectra measurements. IR spectra (KBr disc) showed strong absorption at 1570—1530 and 1420—1380 cm^{-1} due to carboxylate group and at 1150—1080 cm^{-1} due to perchlorate anion. As a typical example, in Figs. 1 and 2, are shown the spectra of XI together with that of thallic acetate for a con-

a) Calculated on the basis of used thallic acetate

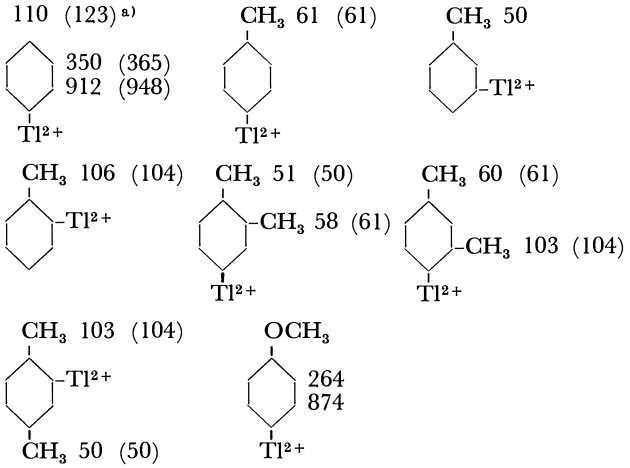

Chart 2. $J_{Tl^{205}-H}$ and $J_{Tl^{205}-CH_3}$ of arylthallic compounds.

a) The values reported by Maher and Evans are in parenthesis.

venience of comparison. Absorptions at about 3500 cm^{-1} due to water were observed in all of XI—XVI. Elemental analyses show that they are monohydrated. NMR spectra (in D_2O) shows the presence of aromatic protons and acetyl protons. From the comparison of the intensities of the two types of protons, it is concluded that ratio of aromatic nucleus and acetyl group is 1 : 1. In Figs. 3 and 4, the NMR spectra of *p*-isomers of, XII and XVI are given as typical examples. $J_{Tl^{205}-H}$ and $J_{Tl^{205}-CH_3}$ values (Chart 2), which agreed well with those reported by Maher and Evans,[10] were useful for determining the substituted position of thallium and rough isomer distribution. For example, crude tolylthallic compound from toluene was found to be mixture of *o*-/*m*-/*p*-isomers of 12/6/82 in one run and 16/6/78 in the other run.

The arylthallic compounds are stable in air, soluble in water, acetone, methanol, ethanol, pyridine, DMF, and DMSO, insoluble in ether, ligroin, and benzene, and can be recrystallized from acetic acid to give white crystalline products. All of them reacted with bromine in carbon tetrachloride to give corresponding bromobenzenes.[11] XI gave diphenylthallic chloride (mp >300°C) upon treating with excess of aqueous sodium chloride and phenylthallic acetate bromide with one mole of aqueous potassium bromide.

Concerning the oxidation products according to Eq. (2), the following remarks should be added to the data shown in Table 1. Throughout the experiments no acetoxylated products of aromatic nucleus could be detected. NMR data showed that IV from toluene

10) J. P. Maher and D. F. Evans, *J. Chem. Soc.*, **1965**, 637.
11) S. Uemura, K. Sohma, M. Okano, and K. Ichikawa, Presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April 1970.

contained unidentified Ar–CH_2–Ar′ type product other than those in Table 1 (NMR τ 6.15, methylene protons). In the case of *p*-xylene, fairly good yield of X was obtained. This type of oxidative coupling of *p*-xylene has been reported by Kovacic and Wu[12] as a side reaction in the preparation of *p*-tolyl-di-*p*-xylylmethane by the reaction of *p*-xylene with ferric chloride.

Reaction of Other Thallic Salts than Acetate with Aromatics. Several attempts to obtain arylthallic compounds by the reaction of aromatics with other thallic salt than acetate were unsuccessful. Under the conditions similar to those with thallic acetate in Table 1, the yields of organic products containing no thallium were also low.

With 50 mmol of thallic nitrate (at 105—115°C, 12 hr) the following products were isolated: From benzene (0.1 mol); nitrobenzene (1.6 mmol) and I (trace). From toluene (0.1 mol); benzaldehyde (trace), II (4.7 mmol), IV (trace), *o*-nitrotoluene (7.0 mmol). and *p*-nitrotoluene (5.9 mmol). From *p*-xylene (0.1 mol); VIII (7.5 mmol), IX (10.6 mmol), *p*-toluic acid (16.2 mmol), and nitro-*p*-xylene (6.1 mmol). All amounts of thallic salt were reduced to thallous salt.

With thallic sulfate (at 110—114°C, 1 hr) the following products were obtained: From benzene; I (trace). From toluene; IV (6.4%, calculated on the basis of thallic salt used). From *p*-xylene; X (9.3%). The amount of reduced thallic salt was 70—80%.

With thallic chloride, the reaction was very slow and only 22—27% of thallic salt was reduced at refluxing temperature in 14 hr. The following products were obtained: From benzene; nothing. From toluene; III (2.0%) and IV (0.3%). From *p*-xylene; VIII (1.8%) and X (1.6%). Addition of perchloric acid gave little effect on the reaction.

Experimental

Materials. All starting organic materials were used after distillation. Thallic acetate was prepared by dissolving thallic oxide into acetic acid at 60°C in 20 hr, collecting white crystals after cooling and drying over P_2O_5 (purity by iodometry was more than 98%). Thallic chloride and nitrate were commercial products. Thallic sulfate was prepared by dissolving the oxide into hot aqueous sulfuric acid.

Reaction of Alkylbenzene with $Tl(OAc)_3$: Formation of Organothallium Compounds. The following example shows a typical experimental procedure. Toluene (200 mmol) was added to a solution of thallic acetate (45.5 mmol) in 80 m*l* of acetic acid containing 8 g of 70% perchloric acid (*ca.* 0.5 M) at refluxing temperature (115°C). The reaction mixture was kept at 110°C under stirring. The color of the mixture turned from pale yellow to purple red. After 3 hr's duration the hot mixture was filtered off from white precipitates formed (4.78 g). When the filtrate was allowed to stand at room temperature, the same precipitates(0.60 g) were obtained again. These precipitates (5.38 g, 17.7 mmol) were identified as thallous perchlorate ($TlClO_4$) by the IR spectrum. Distillation of most part of acetic acid from the filtrate under reduced pressure gave 7.40 g of pale yellow crystals which were identified as XII (decomposed at 126°C 15.7 mmol, 34.6%). The residue from which XII was filtered off was diluted with water and extracted with benzene. The benzene extract was washed with saturated aqueous $NaHCO_3$ and dried over Na_2SO_4. Upon removal of benzene, there was obtained 0.66 g of residue, which was found to be consisted of benzene, toluene, benzaldehyde (trace), II (5%), III (68%), and IV (14%, mainly *p,p′*-isomer) by gas chromatographic analysis. The yields of II, III, and IV were calculated to be 0.2 mmol (0.4%), 2.5 mmol (5.4%), and 0.5 mmol (1.1%), respectively. Recrystallization of XII three times from acetic acid gave white crystals which were pure *p*-isomer. XII was stable in air, soluble in water, methanol, ethanol, acetone, pyridine, DMF, DMSO, and hot acetic acid, and insoluble in ether, ligroin, benzene, and chloroform. IR spectrum of XII is very similar to that of XI (Fig. 1). NMR spectrum of XII (*p*-isomer) in D_2O is shown in Fig. 3.

XI, XIII, XIV, and XV were obtained similarly by the method described above. They all decomposed without melting and showed almost the same solubility as those of XII. The IR spectra were similar to that of XI, showing the strong absorption bands due to carboxylate group and perchlorate ion. Coupling constants of Tl^{205}–H in NMR determination (D_2O solvent) are summarized in Chart 2. Analytical data are as follows:

	Dec. p. (°C)	Calcd for $ArTl(OAc)ClO_4 \cdot H_2O$		Found	
		C	H	C	H
XI	174	20.98	2.20	21.06	2.25
XII	145	22.88	2.56	22.79	2.40
XIII	165	24.71	2.90	24.72	2.91
XIV	175	24.71	2.90	24.52	2.47
XV	176	24.71	2.90	24.40	2.87

Reaction of Anisole with $Tl(OAc)_3$: Formation of XVI. Anisole (50 mmol) was added to a solution of thallic acetate (12 mmol) in 50 m*l* of acetic acid containing 4 g of 70% perchloric acid (*ca.* 0.5 M) at 35°C. The reaction mixture was kept at 35°C for 1 hr under stirring. The color of the mixture changed from white to red brown. White precipitates thus formed (0.30 g, 1 mmol) were filtered off and acetic acid was evaporated from the filtrate to give brownish crystals of XVI (2.60 g, 5.33 mmol, 44.0%). NMR spectra showed that main constituent of XVI was para-isomer. Recrystallization from acetic acid gave 2.20 g of pure *p*-isomer of XVI which decomposed slightly at 157°C and completely at 177°C. (Found: C, 22.15; H, 2.48%. Calcd for $C_9H_{12}O_8TlCl$: C, 21.89; H, 2.42%.)

Reaction of Benzene with $Tl(OAc)_3$: Formation of I. Benzene (100 mmol) was added to a solution of thallic acetate (50 mmol) in 100 m*l* of acetic acid containing 8 g of 70% perchloric acid (*ca.* 0.5 M) at 117°C. The reaction mixture was kept at 105°C (refluxing temp.) for 10 hr under stirring. After cooling to room temperature white precipitates thus formed ($TlClO_4$, 13.0 g, 42.9 mmol) were filtered off. The fitrate was diluted with water and extracted with benzene. The extract was washed with saturated aq. $NaHCO_3$ and dried over Na_2SO_4. After removing benzene white crystals of I (1.0 g, 13%) were obtained as residue. Recrystallization from ethanol gave pure I, mp 69—70°C.

Reaction of p-*Xylene with $Tl(OAc)_3$: Formation of X.*

12) P. Kovacic and C. Wu, *J. Org. Chem.*, **26**, 762 (1961).

Reaction between *p*-xylene (100 mmol) and thallic acetate (34 mmol) was carried out in 100 m*l* of acetic acid at 117°C for 13 hr. Yellowish white precipitates thus formed ($TlClO_4$, 9.0 g, 29.7 mmol) were filtered off from the resulting black solution. The filtrate was treated as mentioned above. There was obtained a mixture which was analyzed to contain *p*-xylene, VIII (0.23 g, 5.8%), and X (1.47 g, 20.7%). Distillation of the mixture gave pure X (bp 128—131°C/2.5 mmHg, $n_D^{20}=1.5678$). NMR ($CDCl_3$) τ 3.0—3.20 (m.) 7H, 6.17 (s.) 2H, 7.75 (s.) 6H, and 7.85 (s.) 3H. (Found: C, 91.62; H, 8.93%; Calcd for $C_{16}H_{18}$: C, 91.37; H, 8.63%.)

Reaction of XV with p-*Xylene in Acetic Acid.* A mixture of XV (2.14 mmol) and *p*-xylene (10 mmol) dissolved in 40 m*l* of acetic acid containing 70% perchloric acid (2.3 g, *ca.* 0.4 M) was stirred at 110°C for 2 hr. The color of the reaction mixture turned from clear pale yellow to purple red and white precipitates were formed. After removing the precipitates ($TlClO_4$, 0.50 g, 76%) the filtrate was treated as described above. Gas chromatographic analysis showed that the products were VIII (4.3%), X (1.6%), and unidentified material (3.5 times as large as X in peak area). Any amount of xylenyl acetate could not be detected.

Reaction of Toluene with $Tl_2(SO_4)_3 \cdot 7H_2O$: Formation of IV. Toluene (100 mmol) was added to a milky suspension of thallic sulate (22 mmol) in 100 m*l* of acetic acid at 114°C under stirring. After 10 hr the black reaction mixture was cooled to room temperature and white precipitates were filtered off. The precipitates were found to be consisted of 33.4 mmol of thallous salt and 13.7 mmol of thallic salt. The filtrate was treated as mentioned above and 0.51 g (2.8 mmol, 15.2%) of IV (mainly *p,p'*-isomer) was obtained. Distillation gave almost pure *p,p'*-isomer of ditolyl, bp 100—115°C/3mmHg, mp 110—115°C. Recrystallization from ether gave pure *p,p'*-isomer of IV, mp 120°C.

Authentic Samples for Gas Chromatography. I, II, III, V, VIII, nitrobenzene, *o*- and *p*-nitrotoluenes, and benzaldehyde were commercial products. VI and VII were prepared by the reaction of palladium chloride and sodium acetate with *o*-xylene.[13] Nitro-*p*-xylene was prepared by the method reported in the literature,[14] bp 109°C/9 mmHg. IX (bp 104—108°C/13 mmHg) was prepared by acetylation of *p*-methylbenzyl alcohol (mp 58°C) with acetic anhydride at 50°C for 1 hr in the presence of zinc chloride catalyst.

Spectral Measurements. IR spectra were obtained by Hitachi EPI-2 and EPS-3T. NMR spectra were determined by JEOL-3H-60 and Varian A-60 using TMS as internal standard in $CDCl_3$ in the case of organic products and in D_2O (without internal standard) in the case of organothallium compounds. Gas chromatographic analyses were carried out on Hitachi K-53 using Apiezon-L 1 m and PEG 20 M 1 m columns and Shimadzu 4APT using the similar 3 m colunns.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 550—553 (1971)

4-Acetylierung der 5-Hydroxy-indol-Derivate

Tadashi SUEHIRO und Machiko NIITSU
Chemisches Institut der Gakushuin Universität, Mejiro, Tokio

(Eingegangen am 16, September, 1970)

5-Hydroxy-4-acetyl-2-äthoxycarbonyl-indol und 5-Hydroxy-2-methyl-4-acetyl-indol wurden durch die Friedel-Crafts-Acetylierung oder durch die Fries-Umlagerung in Gegenwart von Lewis-Säure bzw. unter Belichtung hergestellt. Die Acetylierung wird stark von dem sterischen Faktor des 3-Subtituenten beeinflusst und bei 5-Hydroxy-2-methyl-3-äthoxycarbonyl-indol läuft die 6-Acetylierung ab. Wenn kein 3-Substituent vorhanden ist, wird es eher an der 4-Stellung als an der 6-Stellung acyliert. Der Strukturbeweis wurde aus den NMR-Spektren geführt. 5-Hydroxy-4-acetyl-2-äthoxycarbonyl-indol lässt sich in Dimethylformamid durch Natriumhydrid und Alkylhalogenid an den *O*- und *N*-Stellungen alkylieren.

Aus synthetischen Interessen haben wir die 4-Acylierung von 5-Hydroxy-indol-Derivaten unternommen. Die Friedel-Crafts-Acetylierung von 5-Hydroxy-2-methyl-3-äthoxycarbonyl-indol (Ia) in Nitrobenzol bei 50°C führt zu einer Acetyl-Verbindung vom Schmp. 229—235°C (II) in 19% Ausbeute. Dieselbe Verbindung erhält man bei der Fries-Umlagerung von 5-Acetoxy-2-methyl-3-äthoxycarbonyl-indol (Ib) bei 70°C in Gegenwart von zweifachen Mengen Aluminiumchlorid in 6% Ausbeute. NMR-Spektrum von II mit zwei Singuletts bei τ 2.04 (H^7) und 2.30 (H^4) in Trifluoressigsäure hatte zur Folge, dass die Acetyl-Gruppe in die 6-Stellung eingeführt wurde. Die Belichtung einer äthanolischen Lösung von Ib mit Hoch- bzw. Niederdruckbrenner ergab wieder II in 7% Ausbeute.

Es war also nicht gelungen, bei I durch die Friedel-Crafts-Reaktion oder durch die Fries-Umlagerung, selbst unter photolytischen Bedingungen, die Acetyl-Gruppe in die 4-Stellung einzuführen. Dass die 3-Äthoxycarbonyl-Gruppe so sehr gegen die Aufnahme des Acetyl-Restes an die 4-Stellung wirkt, ist bemerkenswert, wenn man die leichte 4-Benzylierung[1,2] und 4-Allylierung[1,2] von Ia berücksichtigt.

5-Hydroxy-2-äthoxycarbonyl-indol (IIIa) lässt sich in Nitrobenzol bei 50°C in 42% Ausbeute an der 4-Stellung acetylieren, und 5-Hydroxy-4-acetyl-2-äthoxycarbonyl-indol (IVa) vom Schmp. 235—239°C (Zers) wird erhalten. Die 4-Acetyl-Struktur von IVa wird durch die NMR-Signale von zwei Dubletts bei τ 2.17 (H^7) und 2.87 (H^6) jede mit J=9 Hz unterstützt.

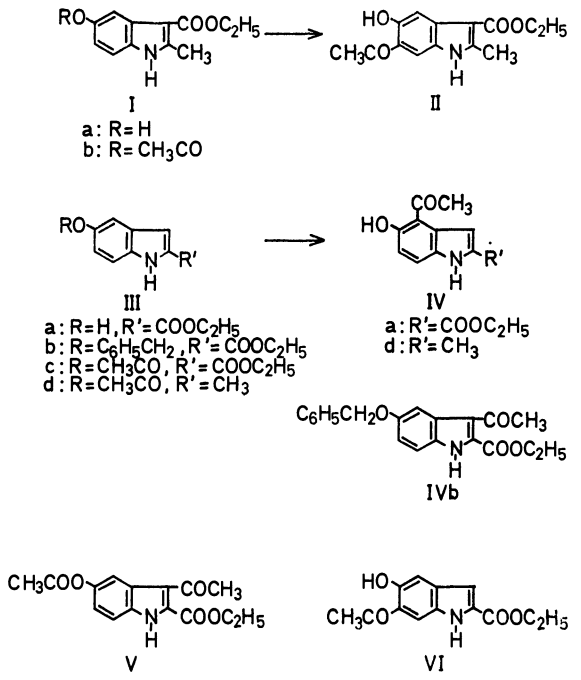
Aus der Nitrobenzol-Lösung der Friedel-Crafts-

1) T. Suehiro, *Chem. Ber.*, **100**, 905 (1967).
2) T. Suehiro und S. Sugimori, Dieses Bulletin, **40**, 2925 (1967).

Reaktion isoliert man nebenbei eine Verbindung vom Schmp. 123—124°C (V) in 11% Ausbeute, dessen Struktur aufgrund der Mikroanalyse und NMR-Spektren zu der *O*,3-Diacetyl-Verbindung von IIIa kommt; es zeigt sich hier, dass die 5-Acetoxy-indol-Verbindung an die 3-Stellung acetyliert werden kann, wie es in der Mannich-Base Darstellung der Fall ist.

IVa lässt sich auch in Kohlendisulfid durch Acetylieren von 5-Benzyloxy-2-äthoxycarbonyl-indol (IIIb) in kleiner Ausbeute (1.4%) erhalten, dabei entsteht ein Acetyl-Derivat, 5-Benzyloxy-3-acetyl-Verbindung vom Schmp. 177—180°C (IVb) (0.7%).

Die 4-Acetylierung von IIIa und IIIb durch die Friedel-Crafts-Reaktion läuft in Nitrobenzol in mässiger Ausbeute ab, nebenbei entstehen aber manche andere Acetyl-Derivate. In diesem Sinne verläuft die Fries-Umlagerung einfach: Der Acetyl-Rest von 5-Acetoxy-2-äthoxycarbonyl-indol (IIIc) wandert in die 4-Stellung beim 67 Stunden Belichten einer äthanolischen Lösung von IIIc, und das Produkt IVa wird in 11% Ausbeute isoliert. Die Umlagerung des Acetyl-Restes in die 6-Stellung verlief in kleinerem Masse (0.4%), diese Isomere konnte man leicht abtrennen.

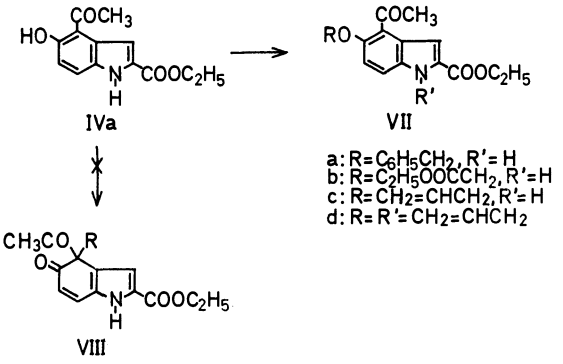


Formelschema 1.

Die Zuordnung der Substituenten an die 4- bzw. 6-Stellung lässt sich durch die Deutung der Proton-Signale von IIIc erleichtern. Die Spektren von IIIc in Deuteroaceton bei Ab- und Anwesenheit von Deuteriumoxyd sind in Abbild. 1 wiedergegeben. Durch H-D-Austausch an N-H gehen die doppelten Dubletts von H^3 [3] (2.3 Hz und 0.9 Hz) bei 431 Hz in ein Dublett mit J=0.9 Hz über, und die doppelte Tripletts bei 445 Hz gehen in die doppelte Dubletts mit J=0.7 Hz und 2.3 Hz über. Die doppelte Dubletts bei 422 Hz mit J=9.0 Hz und 2.3 Hz und die doppelte Tripletts bei 452 Hz mit J=9.0 Hz und 0.8 Hz bleiben beim H-D-Austausch unverändert. Die beiden Signale sollten von H^6 und H^7 stammen aufgrund der Grösse von J=9.0 Hz. Die Signale bei 445 Hz mit J=0.7 Hz und 2.3 Hz gehören dann zu dem H^4-Atom ($J_{4,7}$= 0.7 Hz und $J_{4,6}$=2.3 Hz). Weiter folgt die Zuordnung der Signale bei 452 Hz mit J=9.0 Hz und 0.8 Hz dem H^7. Das Wasserstoffatom H^7 koppelt ferner noch mit H^3 mit J=*ca.* 0.8 Hz. Hier ist zu bemerken, dass H^7 nicht mit N-H koppelt und H^4 nicht mit H^3 koppelt. Diese Reihenfolge von H^6 und H^7 ist umgekehrt der von Thomas und anderen[4] gedeuteten.

Die Fries-Umlagerung von 5-Acetoxy-2-methyl-indol (IIId) läuft in Gegenwart von Lewis-Säure nicht glatt, aber beim Belichten doch in mässiger Ausbeute (26%) ab, und 5-Hydroxy-2-methyl-4-acetyl-indol (IVd) vom Schmp. 188—189°C wird gebildet. Die Beweisführung der 4-Acetyl-Struktur von IVd erfolgte aus dem Spektrum, in dem zwei Dubletts bei τ 2.65 und 3.30 jede mit J=9 Hz auftreten.

IVa lässt sich sehr schwer unter alkalischen Bedingungen alkylieren, weil die Verbindung wie 1-Acetyl-2-naphthol im alkalischen Medium sehrunbeständig ist.[5] Doch gelingt die Alkylierung in einer Ausbeute von 10% in Tetrahydrofuran bei 50°C mittels Natriumhydrid und Benzyljodid bzw. Bromessigester. Besser, d.h. in 16% Ausbeute, verläuft die Allylierung in Dimethylformamid bei Raumtemperatur mittels Natriumhydrid und Allylbromid, wobei auch *N*,*O*-Diallylierung zu VIId in 4% Ausbeute mitlief. Jedenfalls findet die Alkylierung nur an der *O*- oder *N*-Stellung statt, und keine C^4-Alkylierung unter Bildung von 5-Oxo-4,4-dialkyl-4,5-dihydro-indol-Derivat VIII wie bei der Benzylierung von Ia[1] war zu finden.



Formelschema 2.

Beschreibung der Versuche[6]

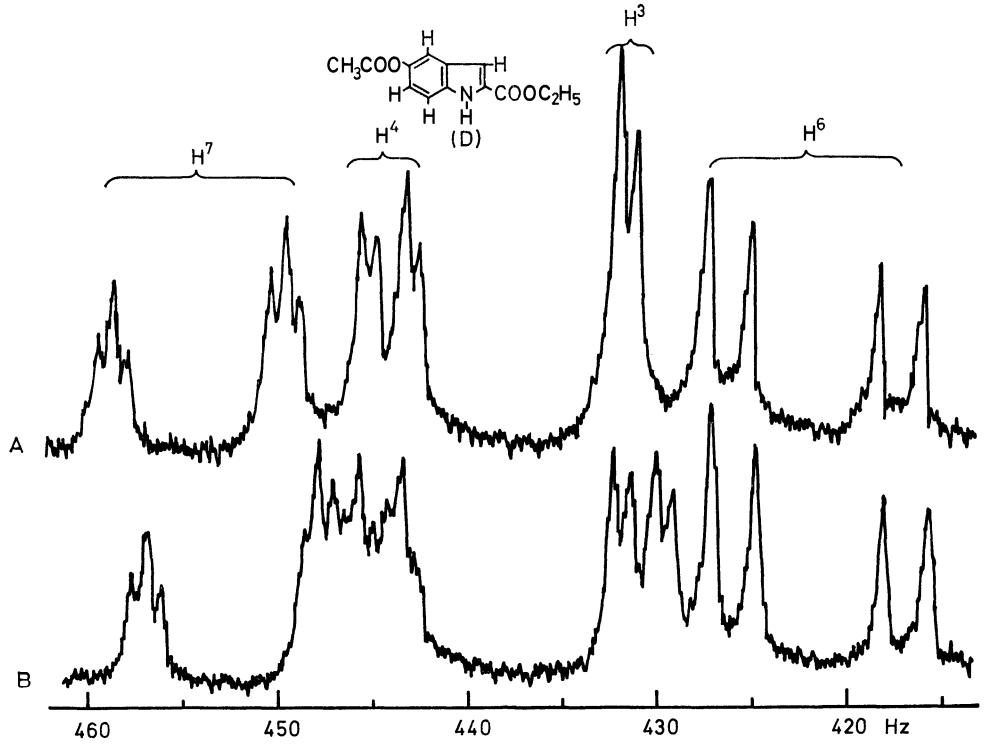
5-Hydroxy-2-methyl-3-äthoxycarbonyl-indol (II). a) Friedel-Crafts-Reaktion: Zu einer Suspension von 5 g (22.8 mMol)

3) Die Signale können nicht von H^6 oder H^7 sondern von H^3 oder H^4 herkommen, weil die Koppelung klein ist. Wenn es H^4 ist, so muss es nach H-D Austausch noch mit H^6 und H^7 Koppelung und doppelte Dubletts zeigen.

4) D. W. Thomas, H. Achenbach, und K. Biemann, *J. Amer. Chem. Soc.*, **88**, 1537 (1966).

5) O. N. Witt und O. Braun, *Ber.*, **47**, 3230 (1915).

6) Die Schmelzpunkte sind nicht korrigiert. Die Aufnahme der NMR-Spektren erfolgte mit eimem Gerät von Varian A60 Spektrometer. Der innere Standard war Tetramethylsilan.



Abbild. 1. NMR-Spektren von 5-Acetoxy-2-äthoxycarbonyl-indol (IIIc) in Deuteroaceton in (A) An- und (B) Abwesenheit von Deuteriumoxyd (Hz aus Tetramethylsilan als innerem Standard)

5-Hydroxy-2-methyl-3-äthoxycarbonyl-indol (Ia) in 200 m*l* Nitrobenzol fügt man 9.23 g (68.4 mMol) Aluminiumchlorid ein, wobei die Suspension in die Lösung geht. Dazu gibt man 2.7 g (34.2 mMol) Acetylchlorid unter Eiskühlung und erwärmt die Mischung 3 Stunden bei 50°C. Nach dem Zersetzen der Reaktionmischung durch verd. Salzsäure destilliert man das Nitrobenzol mit Wasserdampf ab, kristallisiert den Rückstand aus Äthanol um und erhält 1.11 g (19%) feine gelbe Nadeln vom Schmp. 229—233°C. Diese Verbindung stimmt im Schmp. und im IR-Spektrum mit denen vom Produkt nach der Fries-Umlagerung überein.

b) Fries-Umlagerung: Man löst 1.00 g (3.85 mMol) 5-Acetoxy-2-methyl-3-äthoxycarbonyl-indol (Ib) vom Schmp. 150—151.5°C[1] in 15 m*l* Nitrobenzol und versetzt mit 1.00 g (6 mMol) Aluminiumchlorid und lässt die Mischung 48 Stunden bei Raumtemperatur stehen. Nach Aufarbeitung wie üblich erhält man 60 mg (6%) feine gelbe Nadeln vom Schmp. 227—232°C (zers.). IR-Bande (KBr) bei 3450 1665, 1645, 1625/cm. NMR-Spektrum (Trifluoressigsäure) bei τ 0.37 (NH), 2.04 s (H^7), 2.30 breites s (H^4), 5.41 quartett, 7.15 s, 8.40 t.

Gef.: C, 64.44; H, 5.36; N, 5.57%. Ber. für $C_{14}H_{15}O_4N$: C, 64.36; H, 5.79; N, 5.36%.

c) Photolytische Fries-Umlagerung: Man belichtet 96 Stunden eine Lösung von 6.53 g (25 mMol) Ib in 850 m*l* Äthanol bei Raumtemperatur unter Stickstoffatmosphäre mit Niederdruckbrenner. Beim Einengen der Lösung bis zu *ca.* 100 m*l* kommen hellbraune Blättchen aus. Umkristallisieren aus wässr. Äthanol gibt 0.47 g (7.2%) IIa vom Schmp. 234—237°C.

Gef., C, 64.64; H, 5.57; N, 5.29%.

5-Hydroxy-4-acetyl-2-äthoxycarbonyl-indol (IVa). a) Friedel-Crafts-Reaktion.: Man versetzt eine Suspension von 2.00 g 5-Hydroxy-2-äthoxycarbonyl-indol (IIIa)[7] vom Schmp. 151—152°C in 50 m*l* Nitrobenzol mit einer Lösung von 4.00 g (30 mMol) Aluminiumchlorid in 50 m*l* Nitrobenzol und erwärmt die Mischung nach Zugabe von 1.26 g (15 mMol) Acetylchlorid 3 Stunden bei 50°C. Beim Zersetzen mit verd. Salzsäure fällt ein hellgelber Niederschlag aus, welcher nach Umkristallisieren aus Essigester 1.03 g (42%) gelbe Nadeln vom Schmp 235—239°C, (Zers.) gibt. Der Schmelz punkt und das IR-Spektrum stimmen mit denen von nach b) hergestelltem Produkt IVa überein.

Man treibt Nitrobenzol mit Wasserdampf ab, und den Rückstand kristallisiert man mehrmals aus verd. Äthanol bzw. Benzol um, und man isoliert 0.27 g (11%) hellbraune Kristalle vom Schmp 123—124°C. IR-Bande (KBr) bei 3250, 1755, 1715, 1545/cm. NMR-Spektrum (Deuterochloroform) bei τ 0.16 breites s (NH), 2.22d (2 Hz, H^4), 2.78d (9 Hz, H^7), 3.08 doppelte d (9 Hz, 2 Hz, H^6), 5.58q (OCH_2CH_3), 7.32s (CH_3CO), 7.68s (CH_3CO), 8.63t (OCH_2-CH_3).

Gef.: C, 62.63; H, 5.18; N, 4.82%. Ber. für $C_{15}H_{15}O_5N$ 5-Acetoxy-3-acetyl-2-äthoxycarbonyl-indol (V): C, 62.28; H, 5.23; N, 4.84%.

Man acetyliert 3.00 g (10 mMol) 5-Benzyloxy-2-äthoxycarbonyl-indol[8] (IIIb) in Suspension in einer Mischung von 60 m*l* Kohlendisulfid und 60 m*l* Benzol 3 Stunden bei 50°C mittels 1.2 g (15 mMol) Acetylchlorid in Gegenwart von Aluminiumchlorid. Nach dem Zersetzen mit verd. Salzsäure trennt man die unlöslichen Kristalle ab (0.33 g), kristallisiert aus verd. Äthanol um und erhält 31 mg IVa vom Schmp. 220—230°C. Das IR-Spektrum stimmt mit dem vom Produkt nach b) überein.

Aus der Kohlendisulfid-Benzol-Lösung isoliert man 26 mg (0.7%) farblose Nadeln vom Schmp. 177—180°C. IR-Bande (KBr) bei 3370, 1760, 1700/cm. NMR-Spektrum (Trifluoressigsäure) bei τ 2.55 breites s (H^4), 2.80s (C_6H_5), 2.95d (9 Hz, H^6), 2.60d (teilweise überlagert von H^4, 9 Hz,

b) Fries-Umlagerung: *5-Acetoxy-2-äthoxycarbonyl-indol (IIIc)*: Man acetyliert IIIa in Pyridin mit Acetanhydrid. Farblose Nadeln vom Schmp. 148—150°C. Die NMR-Spektren (Deuteroaceton) von Ring-Protonen sind in Abbild. 1 gezeigt.

Gef.: C, 63.65; H, 5.20; N, 5.65%. Ber. für $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%.

Man äelichtet 11.3 g (48 mMol) IIIc in 1 *l* Äthanol 67 Stunden unter Stickstoffatmosphäre bei Raumtemperatur mit Niederdruckbrenner. Beim Einengen bis zu 100 m*l* fallen 1.27 g (11%) gelbe Nadeln vom Schmp. 230—237°C (zers), aus. IR-Bande (KBr) bei 3350, 1695, 1610, 1520, 1260, 1240, 1020/cm. NMR-Spektrum (Trifluoressigsäure) bei τ 2.17d (9 Hz, H^7), 2.42 breites s (H^3), 2.87d (9 Hz, H^6).

Gef.: C, 63.42; H, 5.29; N, 5.47%. Ber. für $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30; N, 5.67%.

Die Mutterlauge dampft man ab, und den Rückstand chromatographiert man an Aluminiumoxyd mit Essigester, wobei man 39 mg gelbe Nadeln vom Schmp. 193—196°C aus 66% Äthanol erhält. IR-Bande (KBr) bei 3330, 1710, 1640, 1610/cm. NMR-Spektrum (Trifluoressigsäure) bei τ 1.77 breites s (H^4), 2.65s (H^7), 2.70 breites s (H^3).

Gef.: C, 62.97; H, 5.21; N, 5.47%. Ber. für $C_{13}H_{13}O_4N$ 5-hydroxy-6-acetyl-2-äthoxycarbonyl-indol (IV): C, 63.15; H, 5.30; N, 5.67%.

5-Acetoxy-2-methyl-indol (IIId): Man kocht 2.0 g (9.1 mMol) Ia mit 20%iger Salzsäure 2 Stunden unter Stickstoffatmosphäre. Nach Neutralisieren bis zu Kongo-Rot sauer zieht man mit Essigester aus. Man dampft die Lösung ab, kristallisiert den Rückstand aus *n*-Hexan - Methylenchlorid um und erhält 5-Hydroxy-2-methyl-indol vom Schmp. 131—134°C in 52% Ausbeute. Man acetyliert 2.0 g von dem Indol in Pyridin mit Acetanhydrid. Farblose Nadeln vom Schmp. 129—131°C aus Äthanol. Ausbeute 1.5 g (58%). IR-Bande (KBr) bei 3430, 1730, 1240/cm.

Gef.: C, 69.32; H, 5.33; N, 7.22%. Ber. für $C_{11}H_{11}O_2N$: C, 69.82; H, 5.86; N, 7.40%.

5-Hydroxy-2-methyl-4-acetyl-indol (IVd). a) Man lässt 1.00 g (5.3 mMol) IIId in 15 m*l* Nitrobenzol 24 Stunden bei Raumtemperatur mit 1.4 g (11 mMol) Aluminiumchlorid stehen. Man erhält nur die Ausgangssubstanz zurück. Wenn man die Mischung von IIId und Zinkchlorid 5 Stunden auf 150—160°C erhitzt, so isoliert man 6 mg in Benzol unlösliche gelbe Kristalle vom Schmp. 165—172°C, deren IR-Spektrum mit dem vom Produkt nach b) übereinstimmt.

b) Man belichtet eine Lösung von 2.00 g (11 mMol) IIId in 100 m*l* Äthanol 48 Stunden unter Stickstoffatmosphäre mit Hochdruckbrenner. Beim Einengen fällt ein gelblich braunes Produkt aus. Umkristallisieren aus wässr. Äthanol gibt 0.51 g (26%) gelbe Nadeln vom Schmp. 188—189°C. IR-Bande (KBr) bei 3350, 1610, 1235/cm. NMR-Spektrum (Deuterochloroform) bei τ 2.65d (9 Hz, H^7), 3.30d (9 Hz, H^6), 3.66 breites s (H^3), 7.24s, 7.54s.

Gef.: C, 70.22; H, 5.91; N, 7.45%. Ber. für $C_{11}H_{11}O_2N$: C, 69.82; H, 5.86: N, 7.40%.

5-Benzyloxy-4-acetyl-2-äthoxycarbonyl-indol (VIIa). Man versetzt unter Stickstoffatmosphäre 0.52 g (2.2 mMol) IVa in 50 m*l* Tetrahydrofuran - Benzol bei Raumtemperatur mit 0.105 g (2.2 mMol) 50% Natriumhydrid, wobei ein rotes Natriumsalz ausfällt. Man gibt dazu 0.477 g (2.2 mMol) Benzyljodid in 10 m*l* Tetrahydrofuran und erwärmt 3 Stunden bei 50°C. Man filtriert 0.33 g Niederschlag ab, und gewinnt daraus 0.20 g Ausgangssubstanz zurück. Man dampft die Tetrahydrofuran-Lösung ab, chromatographiert den Rückstand an Aluminiumoxyd mit Essigester und erhält 65 mg (9%) farblose Nadeln (aus Äthanol) vom Schmp. 152—153°C. IR-Bande (KBr) bei 3370, 1680, 1650, 1520/cm. NMR-Spektrum (Deuterochloroform) bei τ 2.29 doppelte d (2 Hz, H^3), 1.3 breites s (NH), 2.45d (9 Hz, teils überlagert von C_6H_5, H^7), 2.85d (9 Hz, H^6), 2.55s (C_6H_5), 4.79s ($PhCH_2$), 5.55q, 7.31s, 8.58t.

Gef.: C, 71.35; H, 5.29; N, 4.00%. Ber. für $C_{20}H_{19}O_4N$: C, 71.20; H, 5.68; N, 4.15%.

5-Äthoxycarbonylmethoxy-4-acetyl-2-äthoxycarbonyl-indol (VIIIb). Wie bei VIIa versetzt man 0.52 g (2.2 mMol) IVa mit 0.105 g (2.2 mMol) Natriumhydrid in Tetrahydrofuran und dann mit 0.365 g (2.2 mMol) Bromessigester bei 50°C. Man isoliert durch Chromatographie an Aluminiumoxyd-Essigester 0.27 g rohes Produkt, welches beim Umkristallisieren aus Tetrachlorkohlenstoff 55 mg (10%) farblose Nadeln vom Schmp. 157—158.5°C gibt. UV (Äthanol) λ_{max} (nm) (ε) bei 252 (10100), 265 (Schulter), 332 (14300). IR-Bande (KBr) bei 3450, 1750, 1710, 1650, 1530/cm. NMR-Spektrum (Deuterochloroform) bei τ 2.36 doppelte d (2 Hz, 1 Hz, H^3), 2.51 doppelte d (9 Hz, 1 Hz, H^7), 3.06d (9 Hz, H^6), 5.27s (OCH_2COO), 5.66 (zwei Quartetts machen ein Quintett, OCH_2CH_3), 7.22s, 8.65 (zwei Tripletts machen ein Quartett, OCH_2CH_3).

Gef.: C, 61.20; H, 5.52; N, 4.08%, Ber. für $C_{17}H_{19}O_6N$: C, 61.25; H, 5.75; N, 4.20%.

5-Allyloxy-4-acetyl-2-äthoxycarbonyl-indol (VIIc). In 60 m*l* Dimethylformamid versetzt man 2.1 g (8.9 mMol) IVa mit 0.43 g (10 mMol) 50% Natriumhydrid unter Stickstoffatmosphäre und Eiskühlung. Nach 2 Stunden Umrühren gibt man 2.58 g (17.8 mMol) Allylbromid dazu und lässt 20 Stunden bei Raumtemperatur und zum Schluss 2 Stunden bei 50°C reagieren. Nach dem Eindampfen nimmt man den Rückstand in Essigester auf und chromatographiert an Aluminiumoxyd-Essigester, wobei man 0.40 g (16%) farblose Kristalle vom Schmp. 145—147°C erhält. IR-Bande (KBr) bei 3350, 1680, 1640/cm. NMR-Spektrum (Deuterochloroform) bei τ 2.30 doppelte d (2 Hz, 1 Hz, H^3), 2.48 doppelte d (9 Hz, 1 Hz, H^7), 2.98d (9 Hz, H^6), 7.23s (CH_3CO).

Gef.: C, 66.51; H, 5.90; N, 4.77%. Ber. für $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88%.

Aus der Mutterlauge der Umkristallisierung isoliert man unreines *N,O*-Diallyl-4-acetyl-2-äthoxycarbonyl-indol (VIId) vom Schmp. 87—90°C in 4% Ausbeute.

Gef.: C, 69.06; H, 6.17; N, 4.40%. Ber. für $C_{19}H_{21}O_4N$: C, 69.70; H, 6.47; N, 4.28%.

Spectrophotometric Determination of Iodide Ions by Solvent Extraction with Neutral Red[1)]

Masahiro TSUBOUCHI
Faculty of Education, Tottori University, Tottori
(Received April 27, 1970)

Many investigations have been made on the spectrophotometric determination of iodide ions. Although the catalytic method[2)] and diphenylcarbazone-mercury(II) method[3)] are sensitive, they are influenced by the changes in temperature or the presence of bromide ions.

This paper deals with a new spectrophotometric method for iodide ions, which is based on a solvent extraction of the ion-pair formed between the colored neutral red cation and colorless iodide ion. The method has a greater sensitivity than that in which methylthymol blue - mercury(II),[4)] diethyldithiocarbamate-silver(I)[5)] or 1,10-phenanthroline-iron(II)[6)] complex, are employed.

Experimental

Apparatus and Reagents. Absorbance measurements were made with a Shimadzu Beckman Model QR-50 spectrophotometer with matched 1 cm quartz cells. An Iwaki Model KM shaker was used for extraction.

Potassium iodide of guaranteed grade was dissolved in deionized water; it was then standardized according to Volhard's method. The working standard solutions were obtained by diluting this solution. The neutral red (NR) solution of 2×10^{-3}M was prepared by dissolving NR (guaranteed grade) in 0.01N sulfuric acid. The citrate buffer solution of 0.2M was made from sodium citrate and dilute sulfuric acid.

Procedure. 2—10 m*l* of sample solutions containing less than 5×10^{-5}M of iodide ions were placed in separatory funnels. 5 m*l* of the buffer solution (pH 3) and 5 m*l* of the NR solution were then added. The solution was diluted to 25 m*l* with water. After adding 10 m*l* of nitrobenzene, the contents were mixed thoroughly by means of a shaker for about 2 min. The nitrobenzene layer were drawn off into glass tube equipped with a glass stopper containing about 1 g of anhydrous sodium sulfate, and shaken to remove droplets of water. The absorbance of the extract was measured at 552 mμ against a reagent blank.

Results

Figure 1 shows the obtained visible absorption spectra of extracts. The absorbance maximum of the extracts was at 552 mμ. From pH 7 to 11 the red color was not formed in the nitrobenzene layer. The optimum pH was 2—4. Of the solvents such as chloroform, isoamyl alcohol, nitrobenzene, methyl isobutyl ketone *n*-hexane, ethyl acetate, benzene, and ether, only nitrobenzene can extract the ion-pair consisting of NR and iodide ion. 0.01—0.08M citrate used as a buffer had no influence on the absorbance of the extract. Maximum

color development in the nitrobenzene layer required about a 10-fold molar excess of NR to iodide ion. Variation of room temperature 14—24°C had no measurable effect. Full color development took about 1 min shaking. The red color of the extract remained stable for 2 hr.

In order to investigate the structure of the extracted species the method of continuous variations was employed. As shown in Fig. 2, the resulting curves have a maximum at 0.5 mol fraction of NR, indicating a 1 to 1 NR - iodide ion ratio.

Calibration and Foreign Ions. The system followed Beer's law over the range of 4×10^{-6}—2×10^{-5}M of iodide ions, with molar absorptivity of 3.25×10^{4} $mol^{-1}\cdot cm^{-1}$ liter in the aqueous solution. Experiments with ten identical samples, each with a final iodide concentration of 1.6×10^{-5}M, gave the mean absorbance 0.520, with a standard deviation of 0.005 absorbance unit.

The effect of foreign anions was studied by adding solutions of their sodium or potassium salts. Tolerance for a foreign ion was taken as the largest amount that could be present and give an absorbance differing by no more than 0.025 from that produced by iodide alone. Tolerances are shown in Table 1. Halogens and cyanide did not interfere.

Table 1. Effect of foreign ions

Ion	Tolerance(M)	Ion	Tolerance(M)
Br^-	5×10^{-3}	HCO_3^-	5×10^{-3}
BrO_3^-	1×10^{-3}	$H_2PO_4^-$	5×10^{-3}
Cl^-	5×10^{-3}	IO_3^-	1×10^{-6}
ClO_3^-	1×10^{-6}	NO_2^-	5×10^{-5}
ClO_4^-	1×10^{-7}	NO_3^-	2×10^{-5}
CN^-	5×10^{-3}	SCN^-	2×10^{-7}
CH_3COO^-	5×10^{-3}	SO_4^{2-}	5×10^{-3}
F^-	5×10^{-3}	$S_2O_3^{2-}$	1×10^{-4}

Iodide ion: 1×10^{-5}M

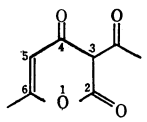
The Photoreaction of Dehydroacetic Acid

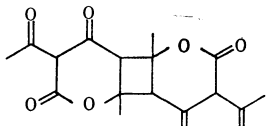
Noboru SUGIYAMA, Toshiaki SATO, Hiroshi KATAOKA and Choji KASHIMA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received May 14, 1970)

Since dehydroacetic acid (DHA)[1] shows strong antifungal and antibacterial activity, it has been widely used as a fungicide and bactericide in food. The present authors are interested in the photoreaction of DHA in the solid state from the points of view of photochemistry and biochemistry.



1



2

DHA (**1**) was irradiated for a week in the solid state in thin layers by means of a high-pressure mercury lamp. After removing the cold, acetone-soluble fraction from the irradiated material, the residue was recrystallized from acetone to give colorless needles (**2**) in a yield of 4%. The elemental analysis, the thermal decomposition to a monomer at the melting point, and the mass spectrum fragment (*m/e* 239 M^+-COCH_3 and *m/e* 168, which is equivalent to a monomer) all show a dimeric structure. The UV,[2] IR,[2] and NMR spectra supported the idea of the presence of the $(2+2)\pi$ dimer at the 5 and 6-positions. The NMR spectrum, which showed a singlet signal at τ 6.60, indicated a cyclobutane methine proton instead of a vinyl proton in a monomer. The head-to-tail form was suggested by the following reactions. The hydrolysis of the dimer **2** with aqueous sodium hydroxide gave 2-acetyl-3,5-xylenol (**5**) and 2,6-diacetyl-3,5-xylenol (**6**) in a yields of 46 and 42% respectively. The formation of **5** and **6** may be explained by assuming the intermediates **3** and **4**, which have been postulated by Yates[3] in the hydrolytic formation of 2-acetyl-1,8-dihydroxy-3,6-dimethylnaphthalene from the 2,6-dimethyl-4-pyrone cage dimer. In the case of the hydrolysis of **2**, the reaction conditions are stronger than these of the cage dimer of Yates, so two deacetyl-

1) Physical data are listed in E. E. Royals and J. C. Leffingwell, *J. Org. Chem.*, **30**, 1255 (1965).

2) Methyl 2-acetylacetoacetate has a closely similar structure. IR: 1711(s), 1559(braod), 1441(s) 1240, 1086(s), 918 cm^{-1}. UV: 277 nm (log ε, 4.08). T. Motoda and Y. Yoshida, *Kogyo Kagaku Zasshi*, **68**, 1669 (1965).

3) P. Yates and M. J. Jorgenson, *J. Amer. Chem. Soc.*, **85**, 2956 (1963).

ated compounds, **5** and **6**, might be produced. The compound **5** was identical with the authentic specimen of 2-acetyl-3,5-xylenol,[4] while **6** was identical with the authentic specimen of 2,6-diacetyl-3,5-xylenol prepared by the Fries rearrangement of the acetate **5** (**7**).

Although whether the structure of **2** is of a syn or anti form is at present uncertain, the formation of this head-to-tail, four-membered dimer is the first such example in any photodimer of 4-pyrones[3,5] and 2-pyrones[6,7] except for the case of 2,6-diphenyl-4*H*-thiopyran-4-one.[8]

Experimental

Photoreaction of Dehydroacetic Acid (**1**). The inner surface of the wall of the irradiation vessel (cylindrical, 10×25 cm) was covered with solid DHA film by rotating and warming the vessel. In the vessel we placed a concentrated acetone solution of 1 g of DHA. The DHA film thus formed was irradiated with a 125-W, high-pressure mercury lamp at room temperature for a week. After irradiation, the solid was triturated with acetone to dissolve the unchanged starting material. The sparingly-soluble, colorless solid was collected and washed with cold acetone. This material, the crude photodimer (**2**), was obtained in a yield of about 4%. Recrystallization from acetone gave colorless needles; mp 214.5—215.5°C.

Found: C, 57.39; H, 4.90%. Calcd for $C_{16}H_{16}O_8$: C, 57.14; H, 4.80%. Mass: *m/e* 293(4%), 169(82%, base), 153(base), 125(33%), 85(62%), 69 (33%), 43(118%). UV: λ_{max}^{EtOH} nm (ε) 279 (27800). IR (KBr): 1706(s), 1555 (broad), 1445(s), 1240, 1080(s), 910 cm^{-1}. NMR (in $CDCl_3$): τ 8.46 (s, 6H), 7.31(s, 6H), 6.60(s, 2H), −7.91(s, 2H).

The irradiation of 1-g protions of DHA solutions in 5 m*l* of acetone, 6 m*l* of benzene, or 20 m*l* of methanol in a Pyrex tube under a nitrogen atmosphere with a high-pressure mercury lamp for 5 days showed no change.

Hydrolysis of the Dimer **2** *to 2-Acetyl-3,5-xylenol* (**5**) *and 2,6-Diacetyl-3,5-xylenol* (**6**). A mixture of 40 mg of **2**, 12.5 m*l* of saturated aqueous sodium bicarbonate, and 2.5 m*l* of aqueous 5% sodium hydroxide was heated under reflux for 4.5 hr. After cooling, the reaction mixture was extracted with chloroform. The aqueous layer was acidified with dilute sulfuric acid and then again extracted with chloroform. Treating both chloroform extracts separately in the usual manner gave **5** (9 mg; 46%) and **6** (10 mg; 42%) respectively; they were purified by silica-gel-column chromatography using benzene. No change was observed upon the same treatment of DHA.

Preparation of 2-Acetyl-3,5-xylenol (**5**) *and 2,6-Diacetyl-3,5-xylenol* (**6**). Compound **5** was prepared by Smith's method[4]; mp 56—58°C (lit, 57—58.5°C). To a pyridine solution of 290 mg of **5** we added an excess of acetic anhydride. After the reaction mixture had stood overnight, it was poured into cold water and extracted with chloroform. Treating the chloroform extract in the usual manner gave 2-acetoxy-4,6-dimethylacetophenone (**7**) (370 mg; 100%); bp 164—167°C /13 mmHg.

Found: C, 69.81; H, 6.95%. Calcd for $C_{12}H_{14}O_3$; C, 69.88; H, 6.95%. UV: λ_{max}^{EtOH} nm(ε) 246(20600), 285(3000) sh. IR (KBr): 1770, 1695 cm^{-1}. NMR(in $CDCl_3$): τ 7.77, 7.74, 7.70, 7.58 (all s, 3H each), 3.23 (s, 1H), 3.12 (s, 1H).

A mixture of 370 mg of **7** and 720 mg of anhydrous aluminum chloride was heated on a steam bath for 2.5 hr, and then it was mixed with *ca.* 5 m*l* of water. The mixture was extracted with chloroform. The chloroform extract was treated in the usual manner, the chloroform was evaporated, and the residue was chromatographed on silica gel. The fraction which was eluted with benzene gave **5** (96 mg; 33%) and **6** (175 mg; 42%), mp 108—109.5°C.

Found: C, 69.87; H, 6.97%. Calcd for $C_{12}H_{14}O_3$; C, 69.88; H, 6.84%. UV: λ_{max}^{EtOH} nm 243 (12900), 267 (9500) sh. IR (KBr): 1687, 1615 cm^{-1}. NMR (in $CDCl_3$): τ 7.60(s, 6H), 7.41(s, 6H), 3.42(s, 1H), −2.10(s, 1H).

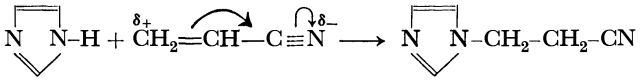
Kinetics of the Reaction of Imidazole with Acrylonitrile by Using NMR

Fukiko YAMADA and Yasuyoshi FUJIMOTO

Department of Applied Chemistry, Faculty of Engineering, Kansai Universtiy, Senriyama, Osaka

(Received June 6, 1970)

Imoto and his co-workers[1] recently reported that acrylonitrile (AN) polymerized in the system of imidazole (Im) and carbon tetrachloride (CCl_4) and that the polymerization proceeded through the radical mechanism. On the other hand, Sawa and Okamura[2] confirmed that, in the presence of the catalyst, potassium hydroxide, the Im derivatives reacted with AN at 100°C to give the corresponding 1-(β-cyanoethyl)-imidazoles. In the latter case, the cyanoethylation appears to proceed through the following ionic mechanism:



The work reported here was carried out in order to study the kinetics of the ionic reaction and to ascertain how the polymerization can be initiated when CCl_4 is present in the reaction system.

Experimental

Measurements. The NMR spectra were obtained at 60 MHz with a Japan Electron Optics Model JNM 3H-60 spectrometer. The chemical shifts are reported in ppm downfield from the internal TMS (δ). A constant-temperature water bath was employed; it was equipped with an immersion heating element that afforded a temperature control of ± 0.1°C.

Materials. The AN, Im, and CCl_4 were purified by the reported methods.[1,3] All the reagents used were of an analytical grade.

The Reactions. (*1*) *Cyanoethylation*: The reaction between Im and AN with or without CCl_4 was carried out in sealed tubes. The rate of the disappearance of Im was followed by the NMR method. After the reaction had been completed, the evaporation of the remaining AN at room temperature afforded an oily product that was then purified by means of column chromatography on silica-gel, using methylene chloride as the eluent; this yielded pure 1-(β-cyanoethyl)imidazole (CEIm). NMR, δ, (in CH_2Cl_2): 7.6 (singlet, 1H), 7.0 (doublet, 2H), 4.2 (triplet, 2H), and 2.8 (triplet, 2H). IR absorption (C≡N) at 2258 cm^{-1}. Mol wt (by mass spectrometry), 121. Picrate, mp 121°C (lit,[2] mp 120—121°C), Found N, 23.76%; Calcd for $C_{12}H_{10}N_6O_7$: N, 24.00%.

(2) *Polymerization*: The polymerization of AN in the system of Im and CCl_4 was carried out in sealed tubes in the dark. Definite amounts of AN, Im, and CCl_4 were charged in separate test tubes, cooled in a bath of dry ice and methanol, and sealed in a vacuum. The sealed tubes were then shaken at 25°C for a given time. The rate of the disappearance of Im was followed by the NMR method. After the polymerization had been initiated, the polymer produced was precipitated in the system. Each ingredient was then freed from the precipitate, and the filtrate was examined by the NMR method. The precipitate was washed with methanol. The molecular weight of the polymer obtained for 29 hr at 25°C was found to be 7.20×10^7 by the viscometric method in the dimethylformamide solution.[3]

Results and Discussion

Cyanoethylation. In the reaction between Im and AN with CCl_4, the changes in the NMR spectra with the reaction time are shown in Fig. 1. The one-proton

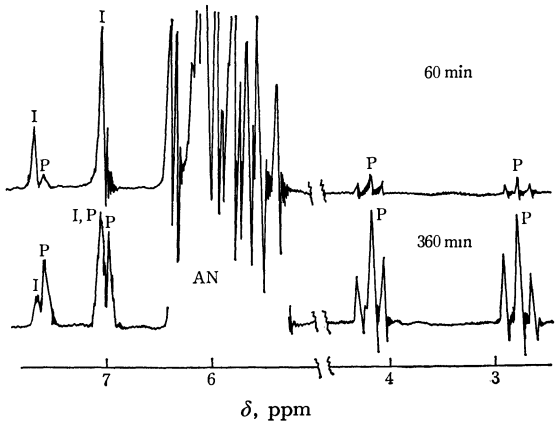


Fig. 1. Changes of the NMR spectra with reaction time at 25°C. Peaks marked AN, I, and P belong to acrylonitrile, imidazole, and the product, respectively.

and two-proton singlets due to the ring protons of Im appear at 7.7 and 7.1 ppm respectively. In the earlier period of the reaction, the new methylene signals due to the reaction product, CEIm, began to appear at 4.2 and 2.8 ppm respectively, and their intensities increased with the reaction time. The proton numbers of the methylene signals can be evaluated by comparing the data of the integrated signals with those of the signals due to the Im ring protons, which were unchanged by the reaction. The conversion of the cyanoethylation based on the initial concentration of Im can, therefore, be obtained by means of the integrated data of these signals. The time-conversion curve is shown in Fig. 2. From these data, the reactions between Im and AN with or without CCl_4 were found to follow a second-order rate equation:

$$dx/dt = k(a-x)(b-x)$$

giving;

$$\log_{10} b(a-x)/a(b-x) = kt(a-b)/2.303$$

a=the initial concentration of AN
and b=the initial concentration of Im

The values of the second-order rate constants, k, were obtained graphically by plotting $\log_{10}b(a-x)/a(b-x)$ against t, the slope of the line being $k(a-b)/2.303$. The points obtained fell on good straight lines. The rate constants for the reactions between Im and AN with or without CCl_4 at 25°C are presented in Table 1.

Table 2 shows the rate constants for the reaction at different temperatures, along with the values of the activation energy as evaluated from the slope of the Arrhenius plots.

Table 1. Second-order rate constants for the reaction of Im with AN at 25°C

Run	(AN/Im), mol ratio	CCl_4, mol/l	$k\times10^4$, l/mol·min
1	6.8	0.88	3.7
2	8.2	2.00	3.7
3	9.2	2.01	3.7
4	6.0	3.65	3.6
5	5.7	4.12	3.7
6	3.4	——	5.2
7	6.9	——	4.6, 4.9, 5.0
8	9.8	——	4.9
9	13.4	——	4.6

Table 2. Reaction rates and the energy of activation for the reaction of Im with AN in CCl_4

Temperature °C	10	20	25	30	40
$k\times10^4$, l/mol·min	1.2	2.8	3.6	4.6	9.0
E, kcal/mol			12.0		

As is shown in Table 1, in the absence of CCl_4 the rates were slightly increased over those of the reactions in CCl_4. In runs 1 and 5, the mol ratios of Im : AN : CCl_4 are 1 : 7 : 0.5 and 1 : 6 : 3. When the CCl_4 content in the system exceeds the latter ratio, they do not blend with each other. Under the conditions shown in Table 1, the rate is unaffected by the concentration of CCl_4.

Polymerization of AN. As can be seen in Fig. 2, the polymerization of AN was carried out at 25°C in the system of Im and CCl_4. The cyanoethylation of

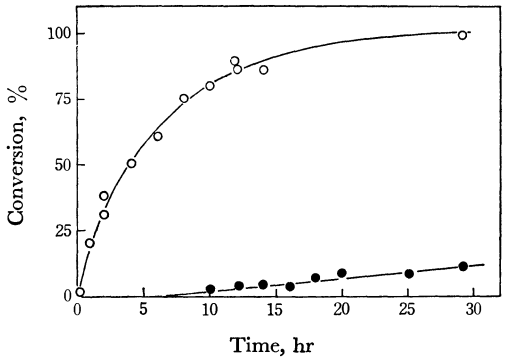

Fig. 2. Time-conversion curves in the system of Im-AN-CCl_4 (mol ratio, 1:6:2.5) at 25°C.
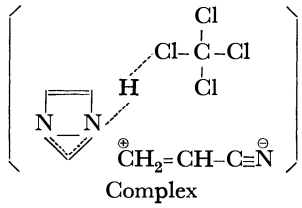
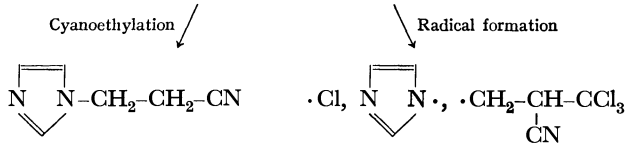
○: Conversion of cyanoethylation is based on the initial concentration of Im.
●: Conversion of polymerization is based on the initial concentration of AN.

Im had also occurred in the reaction system before the radical polymerization, and the rate constant of the cyanoethylation was found to be 3.7×10^{-4} l/mol·min, which was the same as that of the reaction without polymerization in the presence of air.

Possible Formation Mechanism. On the basis of the results mentioned above and other considerations,[1-3] a possible reaction mechanism for the polymerization and the cyanoethylation can be described as follows:



Complex



The above complex may be expected to be formed by the participation of Im, AN, and CCl_4 in the initial step of the reaction.

We wish to thank the Toho Rayon Co. Ltd., for the supply of imidazole.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 559—560 (1971)

Simple Relationship between Entropy Change upon Fusion or Sublimation at Melting Point, Electronic Polarizability and the Interatomic Distance for Alkali Halides

Hitoshi KANNO

Department of Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo

(Received June 24, 1970)

It has been previously reported[1] that in alkali halides there is almost a linear relation between $\Delta S(m)/\alpha^{1/3}$ and r^+/r^- for a sequence LiX, NaX, KX, and RbX (X=F, Cl, Br, and I). Here $\Delta S(m)$, α, and r^+/r^- are the entropy change upon fusion, electronic polarizability of the salt, and the ionic radius ratio of cation to anion, respectively. Thus the entropy change upon melting can be given by

$$\Delta S(m) = \alpha^{1/3}\left(\frac{A}{r^-}+B\right) \qquad (1)$$

where A and B are the constants for the system.

The present author would like to point out that a similar relation also exists between the entropy change upon sublimation at melting point $\Delta S(s)$, α, and, r^+/r^-. As shown in Fig. 1, a good linear relationship between $\Delta S(s)/\alpha^{1/3}$ and r^+/r^- is obtained for the sequence LiX, NaX, KX, RbX, and CsX with exceptions of KF, RbF, and CsF.

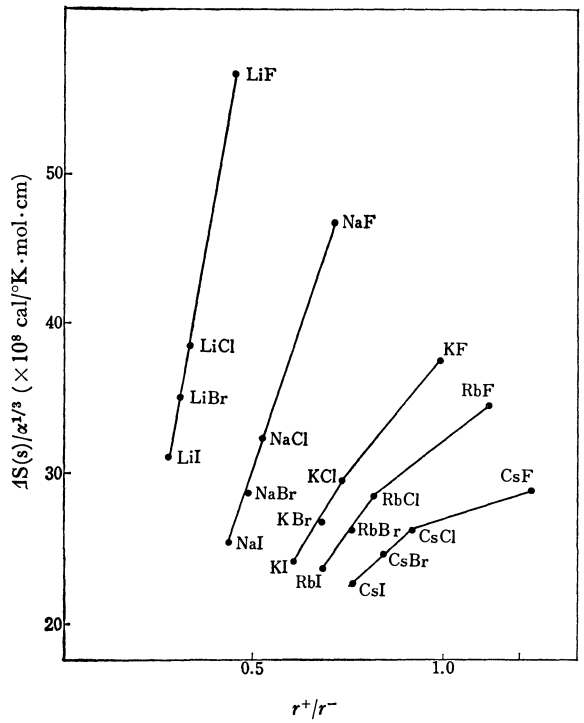


Fig. 1. Linear relationship of $\Delta S(s)/\alpha^{1/3}$ against r^+/r^- for alkali halides.
Sources of data: Heat of sublimation; S. H. Bauer and R. F. Porter, "Molten Salt Chemistry," ed. by M. Blander, Interscience Publishers, New York, N. Y. (1964), p. 627, Melting point: L. Brewer and E. Brackett, *Chem. Rev.*, **61**, 425 (1961), Electronic polarizability; J. R. Tessman, A. H. Kahn and W. Schockley, *Phys. Rev.*, **92**, 890 (1953), Ionic Radius: L. Pauling, "The Nature of the Chemical Bond," third ed., Cornell Univ. Press, Ithaca, N. Y., (1960), p. 527.

1) H. Kanno, *Nature*, **218**, 765 (1968).

Irregular variances of KF, RbF, and CsF are also observed in the case of fusion. A posssible explanation may be found in the data obtained by Pistorius,[2] in which he found that the change of volume upon fusion is considerably smaller for the fluorides of potassium and rubidium than for other halides of potassium and rubidium. He also stated that while chloride, bromide, and iodide of both potassium and rubidium have remarkably similar melting curves, the fluorides of potassium and rubidium behave differently from the other halides. It is of interest to note that the point of CsCl falls on the extrapolated line connecting the points of CsCl and CsI. In the case of fusion, the $\Delta S(m)/\alpha^{1/3}$ value of CsCl is much lower than that expected from the extrapolation of the straight line of CsBr and CsI (Fig. 2). This may be ascribed to the fact that solid CsCl

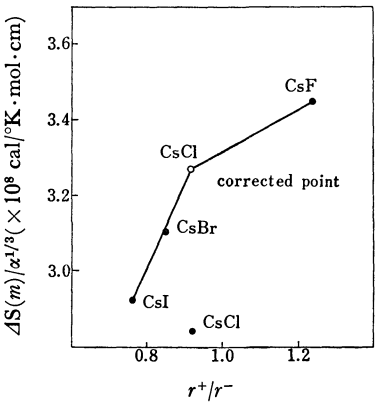

Fig. 2. Regular variation of the corrected $\Delta S(m)/\alpha^{1/3}$ of CsCl

shows phase transformation from the P_m3_m (CsCl) structure to F_m3_m (NaCl) structure at 446°C with an entropy change of 0.807 cal/deg mol.[3] As shown in Fig. 2, the point corrected by including the entropy of phase transformation into the entropy change upon melting nearly falls on the extrapolated line of CsBr and CsI. On the other hand, it is considered that in the case of sublimation a small change of entropy gives little effect upon regularity.

Another interesting aspect in Fig. 1 is the linear relation of $\Delta S(s)/\alpha^{1/3}$ with r^+/r^- for the halides having same anion except for lithium halides which behave

differently. It has been experimentally shown that many thermodynamic properties of simple ionic salts, such as alkali halides and alkaline earth oxides, vary in regular fashion with change in interatomic distance.[4,5] Concurrently, much effort has been made to understand these thermodynamic properties on the basis of models.[6,7] Of the many suggested models, the most simple one is the reduced equation of state for ionic salt obtained by Reiss, Mayer, and Katz.[6] They noted that the potential function for the system can be characterized by a single distance scale factor, namely $r^+ + r^-$ $(=r)$. They postulated that the melting point of alkali halides is represented by

$$T_m = \frac{10^5}{3.19 \cdot r} \text{ °K} \tag{2}$$

In this connection, some improvements can be made by replacing r^+/r^- with $1/r$ in Eq. (1):

$$\Delta S = \alpha^{1/3}\left(\frac{A'}{r} + B'\right) \tag{3}$$

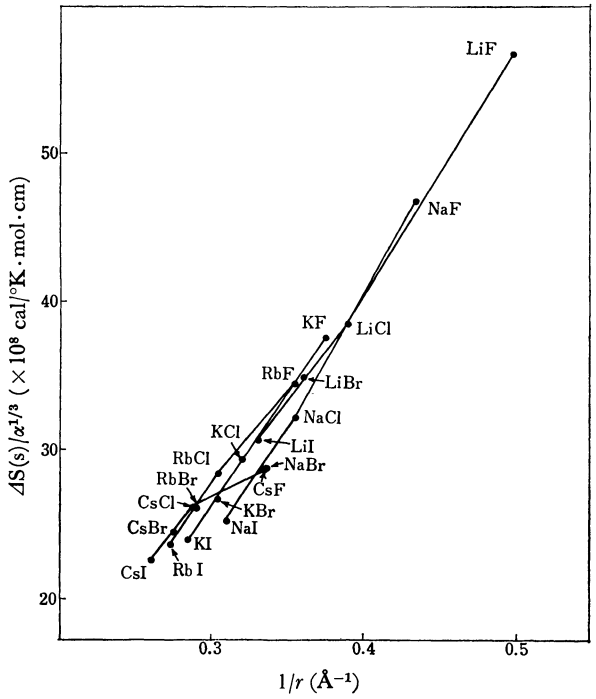

Fig. 3. Relationship of $\Delta S(s)/\alpha^{1/3}$ against $1/r$ for alkali halides. Interatomic distance; L. Pauling, "The Natune of the Chemical Bond", third ed., Cornell Univ. Press, Ithaca, N. Y., (1960), p. 527.

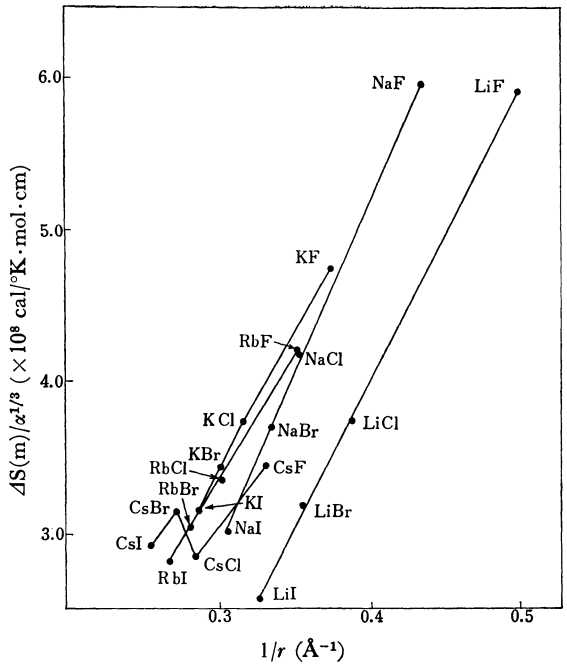

Fig. 4. Relationship of $\Delta S(m)/\alpha^{1/3}$ against $1/r$ for alkali halides. Heat of fusion; A. S. Dworkin and M. A. Bredig, *J. Phys. Chem.*, **64**, 269 (1960).

Substituting Eq. (2) into Eq. (3), we have

$$\Delta S = \alpha^{1/3}(A'' T_m + B'') \tag{4}$$

where A', B', A'', and B'' are the constants for the system.

The relationship between $\Delta S(s)/\alpha^{1/3}$ or $\Delta S(m)/\alpha^{1/3}$ and $1/r$ is shown in Figs. 3 and 4.

We see that all points of alkali halides are approximately represented by a linear function of the reciprocal of the interatomic distance. A significant feature of Fig. 3 is that nearly the same value of $\Delta S(s)/\alpha^{1/3}$ is given for the salts having the same value of $1/r$. Thus it is concluded that the interatomic distance is the better correlating parameter than the ionic radius ratio.

Let $\Delta S(v)$ represent the entropy change of vaporization for alkali halides at a specified temperature and we obtain the following relation at the melting point

$$\Delta S(s) = \Delta S(v) + \Delta S(m) \tag{5}$$

Thus it is expected that the linear relation also holds between $\Delta S(v)/\alpha^{1/3}$ and $1/r$.

In conclusion, we might say that the entropy change upon phase transformation is well characterized by the interatomic distance and the electronic polarizability of the salt.

Conductometric Studies of the Reaction of Pyridine and 3-Picoline with Iodine in Methanol

J. P. SAXENA, B. K. JOSHI, and G. D. MENGHANI
Chemical Laboratories, University of Jodhpur, Jodhpur, India

(Received July 17, 1970)

Saxena and Gelra[1] investigated the reaction of some heterocyclic tertiary bases (pyridine, 3-picoline, quinoline, *etc.*) with acetone in methanolic medium; an extension of King's keto-alkylation reaction[2] to aliphatic ketones. They reported the formation of *N*-acetonylpyridinium and *N*-acetonyl-3-picolinium iodides in good yields. An immediate formation of the di-iodide[3] of the heterocyclic tertiary bases was first observed on mixing the base with iodine and acetone in methanol. The crystals of the di-iodide gradually disappeared on keeping for 2—3 days and crystals of the quaternary β-ketoalkyl iodide appeared. This prompted us to investigate the mechanism of formation of the di-iodides of the heterocyclic tertiary bases (pyridine and 3-picoline) and their subsequent reaction with methyl ketones resulting in the formation of quaternary β-ketoalkyl iodides. In the present investigation only the first part of the reaction, *i. e.* the reaction of pyridine and 3-picoline with iodine in methanol, has been studied through conductivity measurements. The latter part of the reaction with the methyl ketones will be reported elsewhere.

Experimental

Reagents Used. Analytical grade reagents were used. They were purified before use by standard methods. Every care was taken to use reagents in the reaction in the complete absence of moisture.

Procedure. A stock solution of iodine in absolute methanol was prepared. No change in conductivity values of this solution was observed the solution was preserved in a flask tightly stopped with ground glass. Fresh slutions of pyridine or 3-picoline in methanol containing 5—15% of the desired tertiary base were made in different flasks. This particular range was selected because in concentration of the base below 5%, the reaction was found to be very slow and the conductivity keeps on changing for more than 24 hr, whereas in concentrated solutions (base above 15%), the reaction becomes extremely fast and the conductivity changes are negligible after 15 min. Selected volumes of the solutions of iodine and the desired base were mixed in a tightly stoppered conductance cell, with the platinum electrodes immeresed in the reaction mixture. The cell was thermostated and the conductance values were recorded at temperatures 25, 30, 35, and 45°C. As the time of measurement was nearly 2 hr, no appreciable effect of the platinum electrodes on the resistance values was observed. Philips conductivity bridge was used for conductivity measurements.

The results are summarized in Tables 1—4.

Discussion

Neglecting the change of equivalent conductance with ionic strength, the reciprocal of resistance (R) was assumed to be proportional to the ionic concentration,[4] and a plot of $1/R$ against time gave a straight line. This linear relationship showed a zero-order of reaction with respect to iodine. The change in con-

centration of the base resulted in a corresponding change in the slope, thereby showing that the reaction is first order with respect to the base.

Saxena and Gelra[5] studied the reaction of pyridine with iodine in methanol and proposed the following mechanism:

$$MeOH \cdot I_2 + Py \overset{K_1}{\rightleftharpoons} Py \cdot I_2 + MeOH \quad \text{(fast)} \qquad (1)$$

$$Py \cdot I_2 \overset{K_2}{\rightleftharpoons} [Py \cdot I]^+ + I^- \quad \text{(slow)} \qquad (2)$$

We have studied the reactions of both pyridine and 3-picoline with iodine in methanol at different temperatures and have found that the general behavior of both the reactions is identical, and in the case of 3-picoline also the dissociation of 3-Pic$\cdot I_2$ is the rate determining step, as suggested in the case of pyridine.

$$3\text{-Pic} \cdot I_2 \overset{K_3}{\rightleftharpoons} [3\text{-Pic} \cdot I]^+ + I^- \quad \text{(slow)} \qquad (3)$$

The thermodynamic data also confirm the identity of the behavior of the di-iodides of the two bases. From the specific rate constants obtained in the case of pyridine-iodine system, the activation energy was calculated to be 14.97 kcal/mol and the entropy change was evaluated as −8.69 e.u. In the case of 3-picoline-iodine system the activation energy was found to be 11.67 kcal/mol and the entropy change was evaluated as −10.4 e.u. This negative value of entropy change lends additional support to the proposed rate determining step, because as expected the dissociation would lower the entropy change appreciably in both cases. In the case of 3-picoline the hyperconjugative effect of the 3-CH_3 group is operative, due to which the dissociation of I^- ions from 3-Pic$\cdot I_2$ takes place with greater ease and gives rise to the decrease in the entropy change (ΔS^* −10.4) as compared with pyridine (ΔS^* −8.69). With the existence of $[Py \cdot I]^+$ as $[Py_2 \cdot I]^+$ apparently through solvation,[6] and of I^- ions as I_3^- ions, a negative entropy change is anticipated. This also holds true in the case of 3-picoline, and subscribes to the mechanistic step (3).

We are thankful to Professor R. C. Kapoor for providing facilities for work.

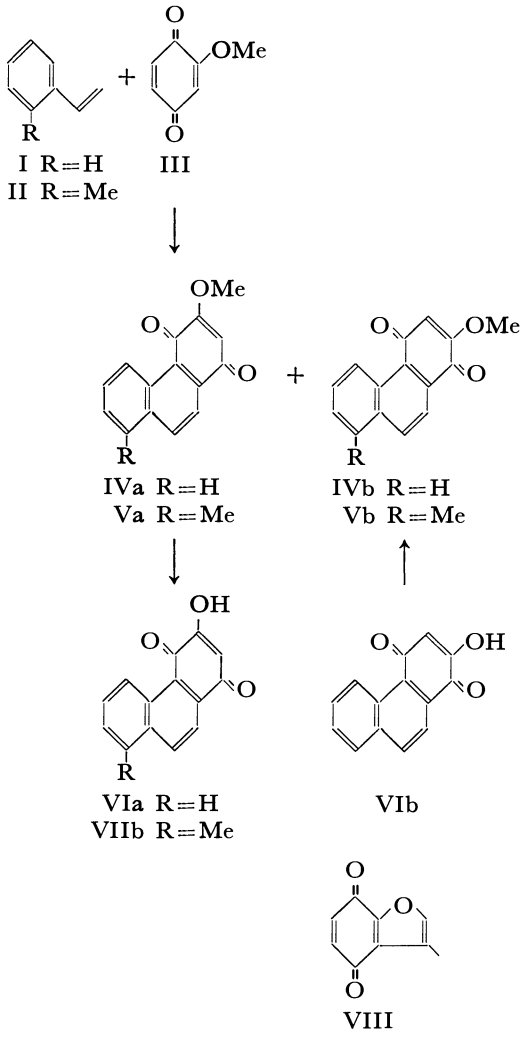
Diels-Alder Reactions of Benzoquinone. I. Reactions of Methoxybenzoquinone with Styrene and *o*-Methylstyrene[1]

Yoshinobu INOUYE and Hiroshi KAKISAWA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received July 9, 1970)

The Diels-Alder reactions of substituted benzoquinones with vinyl aromatics were mainly examined by Lora-Tamayo.[2] The characteristic features of substituted benzoquinones when compared with those of aliphatic dienes[3,4] are as follows: i) the addition occurs only at the non-substituted ethylene linkage of benzoquinone, and no addition occurs if subtituents are present on both ethylene linkages such as in *p*-xyloquinone and 4-methoxytoluquinone[5]; ii) the reaction generally accompanies tetradehydrogenation[2] to give a phenanthrenequinone derivative. The orientation of the quinone is not clarified except the reaction between styrene (I) and methoxybenzoquinone (III) to afford 2-methoxyphenanthrene-1,4-quinone (IVb) exclusive ly.[2]



During the course of our studies on the Diels-Alder reaction of 3-methylbenzofuran-4,7-quinone (VIII),[4] we found that the orientation (namely of the oxygen function) of VIII to the aliphatic diene was identical with that of methoxybenzoquinone (III), and that the reaction of VIII with *o*-methylstyrene (II) gave 3,7-dimethylphenanthro[3,2-*b*]furan-4,11-quinone as a main product.

These results throw doubt upon Lora-Tamayo's experiments.[2] Firstly we examined the Diels-Alder reaction between *o*-methylstyrene (II) and methoxybenzoquinone (III) to clarify the difference between III and VIII in the behavior to vinyl aromatics.

The mixture of II and III was heated at 100—110°C for 10 hr and the phenanthrenequinone parts were isolated through silicic acid column in 42% yield. Recrystallization from benzene afforded a pure quinone Va (or Vb), $C_{16}H_{12}O_3$, mp 243—245°C (dec), although the melting point was slightly lower than that of the reported, mp 253°C (dec).[2] The quinone Va (or Vb) was hydrolyzed with ethanolic potassium hydroxide to the corresponding hydroxyquinone VIIa (or VIIb), $C_{15}H_{10}O_3$, mp 219—224°C (dec), which was identified as 3-hydroxy-8-methylphenanthrene-1,4-quinone (VIIa) by mixed melting point and by comparison of IR spectra with the authentic sample.[6]

As Lora-Tamayo has not clarified the position of the methoxyl group, the difference in melting points seemed to be due to the positional isomer. However, the isomer VIIb could never be characterized in the present work.

Determination of the methoxyl position in the reaction of *o*-methylstyrene (II) prompted us to reinvestigate the reaction of styrene (I) itself. The reaction between I and III was carried out under the same condition as before. The phenanthrenequinone fractions were obtained in 26% yield, from which pure 3-methoxyphenanthrene-1,4-quinone (IVa),[7] mp 168—169°C was isolated by recrystallization from methanol. Melting point of IVa was similar to but IR spectrum was quite different from that of the authentic isomer IVb[8] (see

8) L. F. Fieser, *ibid.*, **51**, 1896 (1929).

experimental). By careful chromatographic separation, IVb was isolated in low yield. The ratio of IVa to IVb was 12.

Lora-Tamayo's confidence to 2-methoxyl structure has been based on comparison of the physical properties and the products formed on alkaline hydrolysis with those of the authentic samples,[7,8] although details were not reported. Alkaline hydrolysis of IVa gave 3-hydroxyphenanthrene-1,4-quinone (VIa), $C_{14}H_8O_3$, mp 194—196°C (dec), to which Fieser[7] reported the melting point to be 230°C (dec).

In conclusion, the position of methoxyl group in the main product in the Diels-Alder reaction of methoxybenzoquinone and vinyl aromatics is not at C_2, but at C_3 in contrast to Lora-Tamayo's assignment.[2]

Finally, the influence of the molar ratio of methoxybenzoquinone (III) to styrene (I) on the yield of adducts was investigated and the results are summarized in Table 1. Apparently, the yield depends on the molar ratio when it is below 3, but does not when it is above 3. This might correspond to the fact that two moles of the quinone act as the acceptor of hydrogen from the adduct.

Table 1. Reactions between sytrene (I) and methoxybenzoquinone (III)

Run	Styrene (I) mg	Quinone (III) mg	Molar ratio of III/I	Solvent ml	Reaction time hr	Yield[a] mg	Yield[a] %
1	65	85	1	—	10	20	13.4

8	27	180	5	0.2	40	20	32

a) mixtures of IVa and IVb
b) 100% recovery of the quinone (III)

Experimental

Diels-Alder Reaction between o-*Methylstyrene (II) and Methoxybenzoquinone (III).* a) A mixture of 53 mg of *o*-methylstyrene (II) and 124 mg (two equivalents to the diene) of methoxybenzoquinone (III) in a sealed tube was heated at 100—110°C for 10 hr.[2] The resulting dark red oil was chromatographed on silicic acid (10 g) and phenanthrenequinone fractions (47 mg, 42%) were collected from chloroform eluates. Repeated recrystallization from benzene afforded 3-methoxy-8-methylphenanthrene-1,4-quinone (Va), mp 243—245°C(dec).[9] IR(KBr): 1668, 1643, 1620 cm^{-1}. UV(EtOH): 227(logε=4.62), 287.5(4.36), 320 (3.70), 376 mμ(3.54).

Found: C, 76.06; H, 4.93%. Calcd for $C_{16}H_{12}O_3$; C, 76.18; H, 4.80%.

b) A suspension of 55 mg of II and 129 mg of III in 0.2 m*l* of benzene was heated at 100—110°C in a sealed tube for 40 hr. Working up as in a) afforded 50 mg (42%) of phenanthrenequinones.

Hydrolysis of 3-Methoxy-8-methylphenanthrene-1,4-quinone (Va). To a suspension of 30 mg of Va in 3 m*l* of ethanol was added *ca.* 200 mg of powdered potassium hydroxide. After standing overnight, water was added and the solution was acidified with 6 N hydrochloric acid. Precipitates were collected and purified through silicic acid column. Recrystallization from benzene gave 3-hydroxy-8-methylphenanthrene-1,4-quinone (VIIa), mp 219—224°C (dec). IR (KBr): 3320, 1653, 1632, 1587 cm^{-1}. UV (EtOH): 225, 290, 331, 380 mμ. Mass: *m/e* 238 (M^+), 210 (M^+-CO). Found: C, 75.25; H, 4.12%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

The IR spectrum of VIIa was identical with that of Thomson's[6] and mixed melting point was 217—220°C (dec) although the original Thomson's sample had somewhat different melting point (~213°C (dec)).

2-Hydroxyphenanthrene-1,4-quinone (VIb). Following the known procedure,[6,10] 2-hydroxyphenanthrene[11] was converted into 2-hydroxyphenanthrene-1,4-quinone *via* 1,2-phenanthrenequinone. Pure VIb, mp 184—185°C (dec) (from benzene). (Lit,[8] mp 190°C (dec)). IR (KBr): 3370, 1660sh, 1647, 1640sh cm^{-1}.

2-Methoxyphenanthrene-1,4-quinone (IVb). To a solution of 25 mg of 2-hydroxyphenanthrene-1,4-quinone (VIb) in 3 m*l* of ether was added 10 m*l* of ethereal diazomethane (prepared from 300 mg of nitrosomethylurea) and the mixture was left for 30 min. The ether solution was washed with dilute alkali, dried through anhydrous sodium sulfate layer and was evaporated to give solid (25 mg). Recrystallization from methanol afforded pure 2-methoxyphenanthrene-1,4-quinone (IVb), mp 168—169°C. (Lit,[8] mp 172.5°C). IR (KBr): 1675, 1640, 1620 cm^{-1}. UV (EtOH): 223 (4.59), 282 (4.38), 374 mμ (3.31).

Found: C, 75.28; H, 4.17%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

Diels-Alder Reaction between Styrene (I) and Methoxybenzoquinone (III). a) The reaction was carried out with or without benzene as in the case of *o*-methylstyrene and the phenanthrenequinone was obtained in 26% yield in both reactions. Recrystallization from methanol gave 3-methoxyphenanthrene-1,4-quinone (IVa), mp 168—169°C. (Lit,[7] mp 170°C). IR (KBr): 1670, 1648, 1623 cm^{-1}. UV (EtOH): 226 (4.58), 282.5 (4.33), 316 (3.82), 371 mμ (3.51). Mass: *m/e* 238 (M^+), 223.

Found: C, 75.14;H, 4.12%. Calcd for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%.

The crude mixture (69 mg) was recrystallized from methanol to give 48 mg of IVa and the residue was chromatographed on silicic acid (10 g) to afford further 10 mg of IVa and 5 mg IVb. The latter, purified by recrystallization from methanol, melted at 169°C and showed identical IR spectrum with that of the authentic sample.

b) A mixture of styrene and methoxybenzoquinone in a different molar ratio was heated at 100—110°C in a sealed tube. The results are summarized in Table 1.

Hydrolysis of 3-Methoxyphenanthrene-1,4-quinone (IVa). As in the case of Va, IVa was hydrolyzed in ethanolic potassium hydroxide to afford 3-hydroxyphenanthrene-1,4-quinone (VIa) in 93% yield. Recrystallization from benzene gave the pure sample, mp 194—196°C (dec). (Lit,[7] mp 230°C (dec)). IR(KBr): 3200, 1650, 1627 cm^{-1}.

Found: C, 74.90; H, 3.60%. Calcd for $C_{14}H_8O_3$: C, 74.99; H, 3.60%.

We are deeply indebted to Professor Thomson for a gift of 3-hydroxy-8-methylphenanthrene-1,4-quinone.

9) Lora-Tamayo[2] reported the melting point of the adduct to be 253°C (dec), though the position of methoxyl group has not been clarified.

The Dipole Moment of Halogenobenzotropones

Takashi SHIMOZAWA, Shigekazu KUMAKURA, Masamatsu HOSHINO, and Seiji EBINE

Department of Chemistry, Saitama University, Shimo-Okubo, Urawa

(Received July 17, 1970)

The dipole moments of three bromobenzotropones and a chlorobenzotropone were measured in benzene solutions, and the positions of halogen atoms on the tropone ring were determined by comparing the observed and calculated values of their dipole moments. The bond moments of C=O and C–X (X=halogen) bonds were examined through an analysis of their dipole moments. The dipole moment of 4,5-benzotropone was also measured, and the derived bond moment of the corbonyl group suggested that the carbonyl group is affected by the conjugation of the benzene ring through the double bonds of the tropone ring.

Experimental and Results

a) Samples. The synthesis of the samples has been described elsewhere.[1] The samples were used for the observations without any further purification.

b) Dipole Moment Measurements. The dipole moment (μ) was observed by the solution method using benzene as a solvent. The dielectric constant (ε) was measured by the heterodyne beat method, and the density (d) was obtained using a pycnometer. The details of the measurements of the dipole moments were the same as in a previous report of one of the authors (T.S).[2]

The observed values of the total polarization (P), the summation of the electronic and the atomic polarization and the dipole moments are listed in Table 1. The electronic polarizations (P_E) are computed from the table of atomic refraction; and the atomic polarization (P_A) was taken as 5% of the electronic polarization. Each value of the observed dipole moment includes an inaccuracy of $\pm$ 0.01 D.

TABLE 1. OBSERVED VALUES OF DIPOLE MOMENTS

Compound	P	P_E+P_A	μ(D)
5-Bromobenzotropone (I)	215.52cc	56.70cc	2.79
5-Chlorobenzotropone (II)	200.91	53.66	2.68
4,7-Dibromobenzotropone (III)	263.04	64.85	3.08
5,7-Dibromobenzotropone (IV)	326.67	64.85	3.53
4,5-Benzotropone (V)	535.44	48.54	4.88

Calculation of Dipole Moments

a) Bond Angles. The bond angles of these compounds were assumed to be such as would result if the tropone ring and the benzene ring are connected with each other holding their skeletal angles. Figure 1 shows the bond angles of the benzotropone ring.

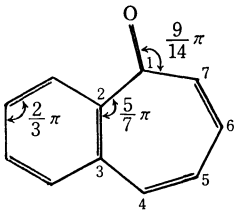

Fig. 1. The bond angle of benzotropone.

b) Bond Moments. The bond moments of C=O and C–X (C–Cl and C–Br), were assumed to be 4.0 and 1.4 D, respectively, which are the values of halogenotropones.[3,4]

c) Monosubstituted Compounds (Compounds I and II). The calculated values of dipole moments for monohalogenobenzotropones are listed in Table 2, where the bond moments of C=O and C–X assumed in (b) are used.

TABLE 2. CALCULATED VALUES OF DIPOLE MOMENTS FOR MONOSUBSTITUTED BENZOTROPONES

Position of halogen atom	4	5	6	7
μ calcd (D)	2.80	2.80	3.93	4.99

d) Disubstituted Compounds (Compounds III and IV). The disubstituted compounds have six possible structures, as listed in Table 3, in which the corresponding values of dipole moments calculated using the bond moments assumed in (b) are shown.

TABLE 3. CALCULATED VALUES OF DIPOLE MOMENTS FOR DISUBSTITUTED BENZOTROPONES

Position of halogen atoms	(4,5)	(4,6)	(4,7)	(5,6)	(5,7)	(6,7)
μ calcd (D)	1.48	2.54	3.64	3.13	3.99	5.18

Discussion

1) Monosubstituted Benzotropones. Compounds I and II (Table 1) have dipole moments of 2.7—2.8 D; therefore, the position of the halogen atom in each of these compounds could be chosen from either the 4 or 5 position by a comparison of the observed (Table 1) and calculated (Table 2) values of their dipole moments. However, the position of the halogen substituent in compound I has been determined to be 5, by NMR study of this compound and its Diels-Alder adduct with maleic anhydride.[5,6] Thus the possibility of substitution

2) T. Shimozawa, *ibid.*, **38**, 1046 (1965).
3) Y. Kurita and M. Kubo, *ibid.*, **27**, 364 (1954).
4) D. J. Bertelli and T. G. Andrews, Jr., *J. Amer. Chem. Soc.*, **91**, 5280 (1969).
5) S. Ebine, to be published.
6) W. E. Parham, D. A. Bolon, and E. E. Sweizer, *J. Amer. Chem. Soc.*, **83**, 603 (1961).

at the 4-position is eliminated.

For compound II, two kinds of substitution reactions can be considered, namely, 5 or 7.[6] The dipole moment measurements excluded the possibility of 7-bromobenzotropone for this compound II. Thus, compound II is determined to be 5-chlorobenzotropone by the dipole moment measurement.

2) Disubstituted Compounds (III and IV). The calculated values of dipole moment in Table 3 are thought to be accurate within the range of ± 0.7 D, so the comparison of the observed and the calculated values results in three possibilities for compound III: (4,6), (4,7), or (5,6). However, it is not possible that compound III has a halogen atom at the 6-position, considering the chemistry of III.[1] Therefore, compound III is determined to be 4,7-dibromobenzotropone which has no halogen atom at the 6-position.

The possible structures of compound IV are (4,7), (5,6), or (5,7), for which the calculated values of dipole moments are in agreement with the observed within ± 0.7 D. It has also been reported that in the case of compound IV, the halogen atom could not be at the 6-position.[1] Therefore, there remain two possibilities, (4,7) or (5,7) for compound IV through a consideration of the dipole moment.

Fortunately, compound III is uniquely determined as the 4,7-disubstituted compound. Since compound III is different from compound IV, the latter should be 5,7-dibromobenzotropone. Although the calculated values for monosubstituted compounds are in agreement with those observed, there are substantial differences between the calculated and observed values of the disubstituted series. These discrepancies can be explained using the so-called ortho effect. Both of these compounds have a halogen atom at the 7-position which is an ortho position to the carbonyl group, and because of negative groups adjacent to each other, the values of the bond moments of both C=O and C–X bonds should decrease.

By bringing the calculated and the observed values of compounds III and IV into agreement through repeated calculations, the bond moments for C=O and C_7–X were finally obtained as 3.6 and 1.2 D, respectively. The decreases in the C=O bond moment of 0.4 D and that in the C–X of 0.2 D are thought to be reasonable, on considering the ortho effect of compounds such as *o*-dichlorobenzene, where 10—20% decreases in C–Cl bond moment from that of chlorobenzene are known.[7]

3) 4,5-Benzotropone (V). The observed value of compound V, 4.88 D, is larger than that of tropone which was used for the estimation of the C=O bond moment (4.0 D) of the benzotropone series. The difference of 0.8 D in those bond moments might be the induction moment resulting from the conjugation between the carbonyl bond and the benzene ring (Fig. 2), provided that the intrinsic bond moment of the C=O group has the same magnitude in both 4,5-benzotropone and 2,3-benzotopone.

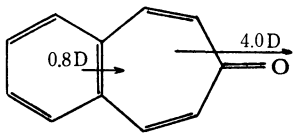

Fig. 2. Dipole moment of 4,5-benzotropone μ(C=O) and μ(induction)

Summary

The dipole moments of 5-bromo-, 5-chloro-, 4,7-dibromo-, and 5,7-dibromobenzotropones and 4,5-benzotropone were reported; and the positions of the substituents were determined and the bond moments of the carbon-halogen bonds and the carbonyl bonds were estimated.

The authors wish to express their gratutide for a Scientific Research Grant provided by the Ministry of Education.

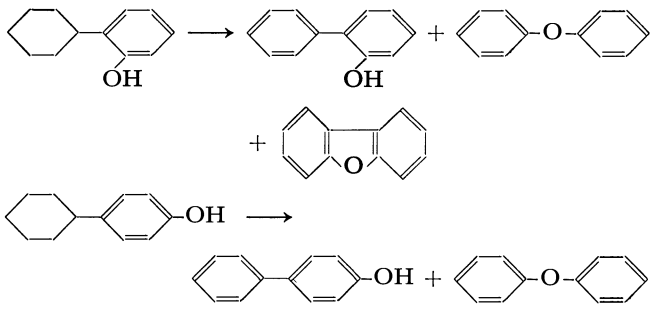
Rearrangements in the Palladium-Catalyzed Dehydrogenation of Cyclohexylphenols to Phenylphenols

Hisashi MATSUMURA, Kimiaki IMAFUKU, Izumi TAKANO,[1] and Senjiro MATSUURA
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto
(Received August 10, 1970)

Although allyl phenyl ether is well known to rearrange to *o*-allylphenol upon heating to a high temperature,[2] diphenyl ether does not rearrange to phenylphenols. Photochemically, however, diphenyl ether rearranges not only to *o*- and *p*-phenylphenols[3,4] but also to dibenzofuran.[5]

In the dehydrogeation of cyclohexylphenols to phenylphenols, we found the formation of diphenyl ether as a rearrangement product and dibenzofuran as a cyclization product.



Experimental

Materials. *Cyclohexylphenols*: *o*- and *p*-Cyclohexylphenols were prepared by Friedel-Crafts type condensation of phenol with cyclohexyl chloride in the presence of ferric chloride hexahydrate,[6] and were purified by fractional recrystallization. The purity of each cyclohexylphenol was checked by gas-chromatography.

Palladium Catalyst: Five per cent palladium-charcoal catalyst, manufactured by Kawaken Fine Chemical Co. Ltd., Tokyo, was used without purification.

Dehydrogenation of Cyclohexylphenols. A mixture of 1 g of *o*- or *p*-cyclohexylphenol and 200 mg of palladium catalyst was heated at 300°C (bath temperature) for 4 hr under nitrogen atmosphere. The reaction mixture was dissolved in benzene, and the catalyst was filtered off. The filtrate was analyzed gas-chromatographically for the determination of reaction products.

Identification and Determination of the Products. Identification and quantitative determination of each product were performed gas-chromatographically on a Shimadzu Model GC-1C (column packing: XE-60) with authentic materials.

Results and Discussion

Gas-chromatographical analysis of the dehydrogenation products gave results given in Table 1.

TABLE 1. DEHYDROGENATION PRODUCTS FROM CYCLOHEXYLPHENOLS (in %)

Starting material	Phenylphenol	Diphenyl ether	Dibenzofuran
o-Cyclohexylphenol	72	23	3
p-Cyclohexylphenol	79	17	—

Although the main products are *o*- and *p*-phenylphenols, respectively, a considerable amount of diphenyl ether is found in both cases. Formation of diphenyl ether on dehydrogenation of cyclohexylphenols involves a novel rearrangement, containing C–C bond fission between the two benzene nuclei and the new C–O bond formation. It is not clear, however, whether the formation of diphenyl ether results by intramolecular or intermolecular rearrangement.

Cyclization to dibenzofuran also occurred in the dehydrogenation of *o*-cyclohexylphenol. Under the same condition, *o*-phenylphenol also cyclizes to give dibenzofuran (5%) and diphenyl ether (trace), but *p*-phenylphenol and diphenyl ether do not give dibenzofuran. Changes in the yields of dibenzofuran from *o*-cyclohexylphenol and *o*-phenylphenol with the reaction time were very similar to those shown in Fig. 1.

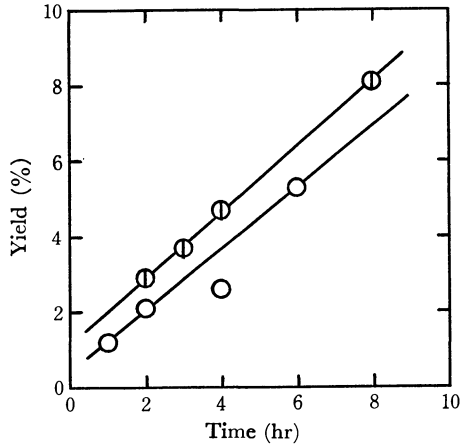

Fig. 1. Dibenzofuran from *o*-cyclohexylphenol(○) and *o*-phenylphenol (ⓘ).

From these results, it is concluded that diphenyl ether is directly formed in the dehydrogenation of the *o*- and *p*-cyclohexylphenols, and dibenzofuran is produced *via* *o*-phenylphenol.

Abstraction of Methyl Hydrogen of Organosilicon Compounds by *t*-Butoxy Radicals

Hideki SAKURAI,[1] Akira HOSOMI, and Makoto KUMADA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 11, 1970)

It has been known that in photochlorination of organosilicon compounds with chlorine in the liquid phase a large amount of dichloromethyl derivatives is produced as a by-product, along with the chloromethyl compounds.[2] On the other hand, although 1,2-phenyl migration readily takes place in the system of $Ph_3CCH_2\cdot$,[3] the similar migration does not occur for $Ph_3SiCH_2\cdot$,[4] instead triphenylmethylsilane being formed. Such differences in the chemical behavior of silicon- and carbon-substituted radicals may be attributed to the former being larger in size than the latter, the electronegativity being lower for silicon as compared with carbon, and the availability of empty *d*-orbitals in silicon, which are absent in carbon.

In this connection, it seemed interesting to investigate the relative reactivity of organosilicon compounds towards free radicals in solution. Studies of the radical chemistry of organosilicon compounds are not ample and most of the reported investigations are related to synthesis.[5] Recently, a kinetic information in the gas phase has been reported in this field.[6] Nagai *et al.* also reported the relative reactivities of some alkylsilanes in the liquid phase photochlorination.[7] The reactions described here were concerned with reactivities of *t*-butoxy radicals in hydrogen abstraction of methylsilicon compounds.

TABLE 1. RELATIVE REACTIVITIES OF ONE METHYL HYDROGEN OF ORGANOSILICON COMPOUNDS TOWARDS *t*-BUTOXY RADICALS AT 45.0°C IN 1,1,2-TRICHLOROTRIFLUOROETHANE

Substrate	k_a/k_d	Substrate	k_a/k_d
$Si(CH_3)_4$	0.29	$C_6H_5C(CH_3)_3$	0.21
$C_6H_5Si(CH_3)_3$	0.27	$(C_6H_5)_3CCH_3$	0.52
$(C_6H_5)_2Si(CH_3)_2$	0.33	$C_6H_5OCH_3$	1.99
$(C_6H_5)_3SiCH_3$	0.54	$C_6H_5SCH_3$	8.66
p-$ClC_6H_4Si(CH_3)_3$	0.29	$C_6H_5N(CH_3)_2$	very large
m-$ClC_6H_4Si(CH_3)_3$	0.33	$C_6H_5CH_3$	2.19
$(CH_3)_3SiSi(CH_3)_3$	0.60		
$Ph(CH_3)_2SiSi(CH_3)_2Ph$	0.52		

By the application of the quantitative method described in the previous papers,[8,9] the reactivities of one methyl hydrogen atom of methylsilanes towards the abstraction by *t*-butoxy radicals have been investigated in 1,1,2-trichlorotrifluoroethane (Freon 113) at 45.0°C. Di-*t*-butyl peroxyoxalate[10] was used as a source of *t*-butoxy redicals. The results are given in Table 1 along with the reactivities of compounds of the type of C_6H_5-$M(CH_3)_n$, in which M stands for a carbon atom or a heteroatom, O, N, and S. It is apparent that, for the attack by the *t*-butoxy radicals, the relative reactivities (k_a/k_d), which show the ratio of rate constant of hydrogen abstraction to that of decomposition of *t*-butoxy radicals to acetone and methyl radicals, are identical within an experimental error, for the substituted phenyltrimethylsilanes.

$$(Me_3COOC)_2 \longrightarrow 2Me_3CO\cdot + 2CO_2$$

$$Me_3CO\cdot \xrightarrow{k_d} Me\cdot + Me_2CO$$

$$Me_3CO\cdot + R\text{-}CH_3 \xrightarrow{k_a} Me_3COH + R\text{-}CH_2\cdot$$

The reactivities of methyl hydrogen in organosilicon compounds are little larger than those of the corresponding carbon analogs. Since the transition state of hydrogen abstraction, especially by electrophilic radicals such as *t*-butoxy radicals, resembles the initial state of the reaction, the polar effect is exerted mainly on the reactivities of abstraction, unless overthrowing strong conjugation effect is present. Therefore, the fact that the reactivities of organosilicon compounds do not differ considerably from those of the corresponding carbon analogs shows that the free redical formed by hydrogen abstraction is little stabilized by vacant 3*d*-orbitals of silicon, but the reactivities depend on the electron density of the C–H bond. It may be concluded also that pentamethyldisilanyl group is more electron-releasing than trimethylsilyl group.[11]

It might be considered that the reactivities of the compounds containing one of the other hetero-atoms such as O, S, and N are very large, since these atoms have the electron-releasing effect due to lone pair electrons.

In conclusion, the α-silyl radicals formed by hy-

drogen abstraction is little stabilized by a conjugation between 3*d*-orbitals on silicon and an odd electron on carbon.

Experimental

Materials. Di-*t*-butyl peroxyoxalate was prepared by the method of Bartlett *et al.*[10] Freon-113 was commercially available and used after distillation. *t*-Butylbenzene, anisole, thioanisole, dimethylaniline, and toluene were commercial samples and were used after purification by the usual way. All of the organosilicon compounds and 1,1,1-triphenylethane were prepared by the Grignard reaction.

Procedure for Kinetic Runs. The procedure for kinetics was carried out in a similar way to that described previously[8,9] at 45.0°C in Freon-113. *t*-Butyl alcohol/acetone ratios were determined by glc on a column packed with polyethylene glycol 1500 using helium as a carrier gas at 90.0°C. The ratios of *t*-butyl alcohol/acetone *vs.* concentration of the substrates were calculated by the method of least squares.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 569—570 (1971)

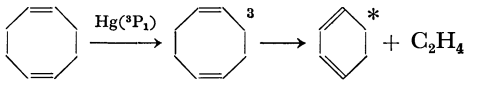
The Photolysis of 1,3-Cyclootadiene Vapor. Vibrationally Excited Molecules Produced by the Photoelimination of Ethylene

Setsuo TAKAMUKU and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received August 25, 1970)

Photochemical initiation has often been used as a method of studying vibrationally-excited molecules.[1] The primary step in many systems is followed by a sequence of steps, which may include conventional unimolecular processes of species with excess energy. In a previous paper of this series,[2] it has been observed that a vibrationally-excited molecule (**1**) was produced by the elimination of ethylene in the mercury-photosensitized decomposition of 1,5-cyclooctadiene (1,5-COD) vapor:



(**1**)

The vibrationally-excited molecule (**1**) may decompose to benzene and hydrogen, may be collisionally stabilized to 1,3-cyclohexadiene(CHD), or may isomerize to 1,3,5-hexatriene(HT). In the present study, it has been observed that the mercury-photosensitized decomposition of 1,3-cyclooctadiene (1,3-COD) also causes an elimination of ethylene, leading to the formation of a vibrationally-excited 1,3,5-hexatriene molecule which gives final products similar to those from 1,5-COD.

Experimental

The experimental procedures were essentially the same as those reported previously in the photolysis of 1,5-COD.[2] The vapor of 1,3-COD, which had been obtained commercially and which had been shown to be 99.8% pure by gas-chromatographic analysis, was irradiated in a quartz reaction vessel (5-cm in diameter and 5 cm long) with light from a low-pressure mercury resonance lamp in the presence of a small amount of mercury vapor. Most of the runs were at temperatures between 20 and 22°C.

The product gases volatile at −196°C were collected by means of a Toepler pump in a gas buret in a greaseless vacuum system, and then subjected to a Pd thimble heated at 300°C for hydrogen measurements. The other products were analyzed mainly gas chromatographically. A 3-m silica gel column at 100°C was used for the gases volatile at −120°C (C_2 fraction), and a 7.5-m squalane column at 80°C was used for the liquid components. Quantitative determinations were based on the calibrations of peak areas using measured amounts of certain hydrocarbon standards (propane and benzene respectively).

The quantum yields were determined by comparison with those of the mercury-photosensitized decomposition of propane at 300 mmHg, in which the hydrogen yield was assumed to be unity at a low conversion (0.06%).[3]

Results and Discussion

In the mercury-photosensitized reaction of 1,3-COD vapor, ethylene and *cis*-and *trans*-1,3,5-hexatriene were

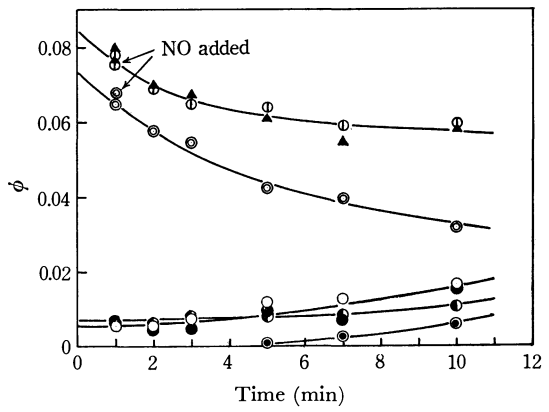


Fig. 1. Quantum yields *vs.* exposure time in the mercury-photosensitized decomposition of 1,3-COD (pressure 3 mmHg); ○, H_2; ⊙, C_2H_2; ⓘ, C_2H_4; ●, benzene; ◐, 1,3-cyclohexadiene; ◎, 1,3,5-hexatriene; ▲, total C_6 (benzene+1,3-CHD+1,3,5-HT).

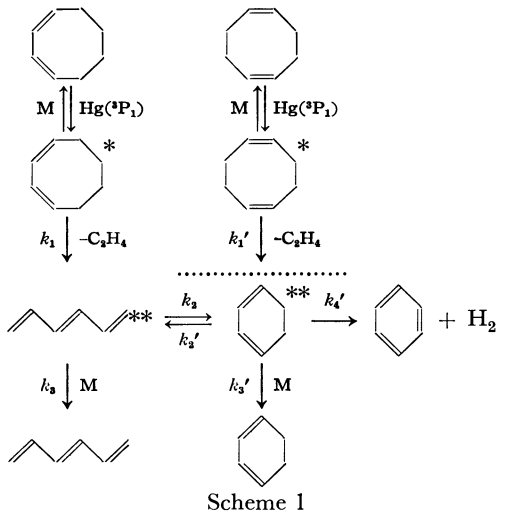
2) S. Takamuku and H. Sakurai, *J. Phys. Chem.*, **73**, 1171 (1969); S. Takamuku, M. Utsunomiya, and H. Sakurai, *Chem. Commun.*, **1969**, 173.

3) R. A. Back, *Can. J. Chem.*, **37**, 1834 (1959); K. Yang, *J. Amer. Chem. Soc.*, **86**, 3941 (1964).

found to be the major initial products, together with small amounts of hydrogen, benzene, and 1,3-cyclohexadiene. Figure 1 gives the dependence of the quantum yields on the exposure time at relatively low conversions (less than 5%). The yields of these main products decreased with an increase in the irradiation time, while the minor products increased gradually. The plot also clearly shows that acetylene is newly produced by prolonged irradiation. These observations may be explained satisfactorily on the basis of the further photolysis of the main products (ethylene and 1,3,5-hexatriene), which forms hydrogen, acetylene, and 1,3-cyclohexadiene, as has been pointed out in discussing the photolyses of ethylene[4] and hexatriene[5] respectively. Thus, acetylene was not assumed to be a primary product.

The yields of the main products were unaffected by the addition of 15 mole% nitric oxide, as is shown in Figure 1, and the minor products were also essentially unaffected. These results strongly suggest an intramolecular mechanism, to the exclusion of a free radical path, for the formation of these products.

The mercury-photosensitized decomposition of 1,3-COD was studied as a function of the pressure (0.4—4.3 mmHg) in order to obtain some information on the active intermediates of this reaction. When the 1,3-COD pressure was increased, the yields of the main products increased; they showed a maximum at a pressure about 2 mmHg and then gradually decreased, probably because of the collisional deactivation of a triplet 1,3-COD molecule, while the yields of hydrogen and benzene homogeneously decreased with the pressure. Further, the pressure dependence of a path producing hydrogen and benzene seemed to be different from those of paths forming 1,3,5-hexatriene or 1,3-cyclohexadiene (the kinetic plots are shown in Fig. 2), suggesting the competing processes shown in the following scheme:



Scheme 1

An excited 1,3-COD molecule with a relatively long lifetime, probably a triplet state, may produce a vibrationally-excited 1,3,5-hexatriene by the simultaneous ruptures of two allylic C–C bonds in the molecule, *i. e.*, the molecular elimination of ethylene. It has been observed by Lossing[6] and by Cvetanovic[7] that, in the mercury-photosensitized decomposition of olefin, an initial rupture of the weak allylic bond occurs. The vibrationally-excited 1,3,5-hexatriene thus formed isomerizes to vibrationally-excited 1,3-cyclohexadiene, which is then subjected to collisional deactivation or dissociates to benzene and hydrogen. The pathway for the photolysis of 1,5-COD, which was proposed previously,[2,8] is also presented in the scheme (above the dotted line). It can be seen that very similar photolysis products were observed in 1,3- and in 1,5-COD.

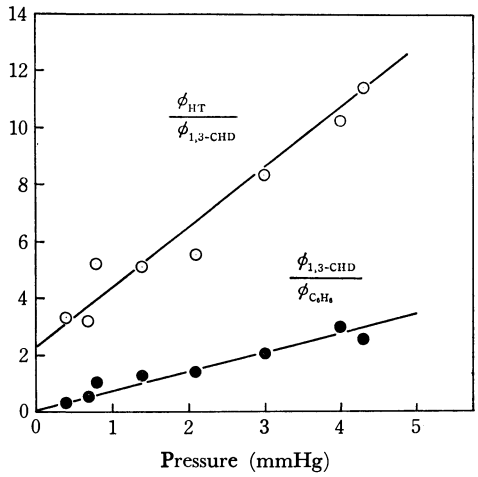


Fig 2. Kinetic plots of $\phi_{HT}/\phi_{1,3\text{-CHD}}$ and $\phi_{1,3\text{-CHD}}/\phi_{C_6H_6}$ *vs.* pressure of 1,3-COD (irradiated for 1 min); $\phi_{HT}/\phi_{1,3\text{-CHD}}$, intercept=2.4, slope=2.0 $mmHg^{-1}$; $\phi_{1,3\text{-CHD}}/\phi_{C_6H_6}$, slope=0.71 $mmHg^{-1}$.

The satisfactory material balances shown in Eqs. (1) and (2) were observed to hold under a wide variety of conditions (Fig. 1):

$$\phi_{C_2H_4} = \phi_{HT} + \phi_{1,3\text{-CHD}} + \phi_{C_6H_6} \quad (1)$$

$$\phi_{C_6H_6} = \phi_{H_2} \quad (2)$$

A steady-state treatment of the reaction scheme for 1,3-COD gives:

$$\frac{\phi_{HT}}{\phi_{1,3\text{-CHD}}} = \frac{k_3}{k_2}\left(\frac{k_4'+k_2'}{k_3'}+M\right) \quad (3)$$

$$\frac{\phi_{1,3\text{-CHD}}}{\phi_{C_6H_6}} = \frac{k_3'}{k_4'}\cdot M \quad (4)$$

Although there is some scatter in the data shown in Figure 2, satisfactory trends are apparent. The kinetic parameter deducible from such a treatment may permit a precise discussion of the excess energy if it is compared with that obtained from the 1,5-COD system, in which a similar reaction mechanism has been observed. In addition, such a photoelimination process of ethylene has also been found in the mercury-photosensitized decomposition of cyclooctene;[9] it seems to be characteristic of cyclic olefins.

The Reaction of Bis(methoxycarbonyl)carbene with Allyl Chloride. "Solvent Effect"

Wataru Ando, Shuji Kondo, and Toshihiko Migita
Department of Chemistry, Gunma University, Kiryu, Gunma

(Received August 31, 1970)

We have recently reported that the bis(methoxycarbonyl)carbene generated by the photochemical decomposition of dimethyl diazomalonate reacts with allyl halides to give addition products to the carbon-carbon double bond, cyclopropane derivatives (I) and the carbon–halogen insertion product, allylhalogenomalonate (II).[1] We have also indicated that only singlet bis(methoxycarbonyl)carbene is capable of affording the insertion product through an allylic rearrangement of the halonium ylide intermediate, and that the triplet carbene produced by a benzophenone-photosensitized decomposition is added to olefin rather than interacts with the halogen atom.[2]

A carbene in a singlet excited state has been reported to be transformed into the triplet state by collision with inert solvents,[3,4] particularly with those possessing heavy atoms.[5] The effect of such a collisional transformation may be expected to affect the ratio of the insertion and the addition products if the reactions of bis(methoxycarbonyl)carbene with allyl halides are carried out in such solvents. In this paper, we wish to repot on the ratio of the insertion and the addition products in the photochemical reactions of dimethyl diazomalonate with allyl chloride in methylene halides and cyclohexane as the solvents, these data will give some evidence of transformation into the deactivated bis(methoxycarbonyl)carbene produced by the collision of singlet bis(methoxycarbonyl)carbene with solvent molecules. The results are compiled in Table 1.

We can immediately see that the ratio of the insertion and addition products (II/I) decreases with dilution with methylene halides, and it tends toward the value obtained in the benzophenone-sensitized reaction. We take this to indicate that the reacting carbene species are partly triplet in these solvents and that almost they are exclusively triplet in the system highly diluted with CH_2Br_2. Furthermore, in 10% methylene halides, the ratio of the insertion and addition products is highest in CH_2Cl_2 and lowest in CH_2I_2. These tendencies are in agreement with the findings that the singlet-triplet interconversion is more effective when the reaction solvents possess heavier halogen atoms.[6] The overall yields (I+II) decreased as the concentration of methylene halides increased. This is probably because of the reaction of the singlet carbene with the solvent to give halogenomalonate as well as the insertion product into the carbon–halogen bond of the solvent.[7]

$$N_2C(CO_2CH_3)_2 + CH_2X_2 \xrightarrow{h\nu} CH_2XCX(CO_2CH_3)_2 + CHX(CO_2CH_3)_2$$

7) T. Migita, W. Ando, S. Kondo, H. Matuyama, and M. Kosugi, *Nippon Kaguku Zasshi*, **91**, 374 (1970).

Therefore, an alternative explanation might be advanced: perhaps the singlet carbene is trapped preferentially by the solvent, thus giving a higher proportion of the triplet in the solution and leading to more of the addition product. Unfortunately, the reaction mechanism of the carbene with methylene halides is not yet clear.

The addition of cyclohexane to the irradiation mixture results in initially increased yields of the insertion products. This can presumably be explained in terms of the deactivation of a part of the excited singlet carbenes formed by photolysis to the lowest singlet state in which it can react more selectively. A similar dilution effect has previously been reported, that is, dilution with hexafluorobenzene increased the stereospecificity of the addition of bis(methoxycarbonyl)carbene to a olefin.[8]

On the basis of the data presented here, we may conclude that the singlet carbene formed by the photolysis of dimethyl diazomalonate can be readily deactivated, through collisions with methylene halides, to the triplet carbene, which is incapable of ylide formation with allyl chlorides.

Experimental

General. Samples of dimethyl diazomalonate were placed in clean 10×100 mm Pyrex tubes. The tubes were then corked(nondegassed) and placed in a water-cooled bath in order to irradiate them. The light source was a Rikosha 400-W high-pressure mercury lamp with maximum out-put at 3650—3660Å. Photolyses were carried out until the diazo band in the infrared spectra disappeared. The solutions were analyzed on an Ohkura gas-liquid partition chromatography with a calibrated 2 m×4 mm stainless steel column of 10% DC-710 and 10% Carbowax 20M on C-22 Firebrick.

Preparation of Dimethyl Diazomalonate. A solution of dimethyl diazomalonate(26.4 g) and tosyl azide (39.4 g) in diethyl ether (200 m*l*) was treated at 0°C with dry diethylamine (20 m*l*). The mixture was stirred for 1 hr at 0°C, and then for a further hour at room temperature. When a solid has been deposited, the mixture was treated with petroleum ether (bp below 60°C) and the solid was filtered off. The removal of solvent from the filtrate and the distillation of the residue gave dimethyl diazomalonate; bp 60—61°C/2mmHg (50% yield), (lit,[9] 63°C/1 mmHg).

Reaction of Dimethyl Diazomalonate in Allyl Choride. In a typical run, 0.218 g (0.0013 mol) of diazomalonate in 1 m*l* of allyl chloride was irraidated in a Pyrex tube for 5 hrs. Dimethyl allylchloromalonate and bis(methoxycarbonyl)cyclopropane were observed as the major products in yields of 53 and 23% respectively. Dimethyl allylchloromalonate showed infrared bands at 1752, 1645, and 950 cm^{-1}, and its NMR spectrum showed at 1.92 (doublet, 2-H), 3.78 (singlet, 6-H), and 5.24 ppm(multiplet, 3-H). Found: C, 46.71; H, 5.49%. Calcd for $C_8H_{11}O_4Cl$: C, 46.48; H, 5.32%.

The cyclopropane showed an infrared band at 1725 cm^{-1}, and its NMR spectrum showed bands at 1.43 (doublet, 1-H), 1.55 (singlet, 1-H), 2.12 (multiplet, 1-H), 3.50 (doublet, 2-H), 3.71 (singlet, 3-H), and 3.75 ppm (singlet, 3-H). Found: C, 46.49; H, 5.43%. Calcd for $C_8H_{11}O_4Cl$: C, 46.48; H, 5.32%.

Photosensitized Decomposition of Dimethyl Diazomalonate in Allyl Chloride. A solution of 0.325 g of diazomalonate and 1.74 g of benzophenone was irradiated in 2 m*l* of allyl chloride. The usual work-up yielded 88% of bis(methoxycarbonyl)-cyclopropane and 5% of the insertion product, dimethyl allylchloromalonate.

The Syntheses of 5,5′-, 6,6′-, and 5,6′-Diformyl-2,2′,3,3′-tetramethoxybiphenyls

Yoshimori Omote, Yoshimori Fujinuma, and Noboru Sugiyama
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received September 2, 1970)

Very recently Chapman and Swan[1] have reported the syntheses of biphenyls and related compounds, which are possible intermediates in the melanogenesis of 3,4-dihydroxyphenylalanine (DOPA). They have synthesized three DOPA dimers, one of which had already been reported by us.[2] In relation to the DOPA dimers, three kinds of veratrumaldehyde dimers, 5,5′-, 6,6′-, and 5,6′-diformyl-2,2′,3,3′-tetramethoxybiphenyl (I, II, and III), are of interest.

Among these, I and II are known. The dimer I was obtained by the oxidative coupling of vanillin with ferric chloride,[3] or by that of sodium persulfate catalyzed by ferrous sulfate,[4] followed by methylation. The dimer II was obtained by an Ullmann reaction on 2-iodo-3,4-dimethoxybenzaldehyde.[5] Chapman and Swan,[1] however, found it more convenient to use the 2-bromo-compound, which is easier to prepare. They prepared I and II, but did not give any spectral data.

Now we wish to report on the synthesis of the unknown head-to-tail dimer (III), and present the spectra of I, II, and III. The dimer III was obtained by the Ullmann reaction of 2- and 5-iodo-veratraldehyde. The molecular models of these dimers suggest that two benzene rings

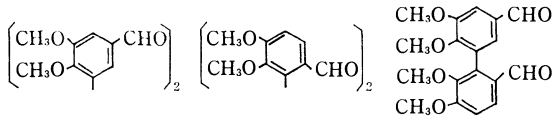
of each dimer are perpendicular to each other. The UV data support this suggestion, because the spectra of the dimers roughly coincide with that of veratraldehyde.



I II III

Experimental

Attempted Synthesis of the Dimer I by an Ullmann Reaction. It was examined if 5-bromoacetylvanillin gives its dimer by an Ullmann reaction.[6] Reactions at fusion or in various solvents, such as nitrobenzene, dimethylformamide, or methyl benzoate, were tested. In spite of many attempts under various conditions, the dimer was not obtained.

Attempted Synthesis of II by an Oxidative Coupling. The dimerization of isovanillin in the presence of sodium persulfate or ferric chloride was examined, but the formation only of black, intractable materials was observed. This result is consistent with the consideration that isovanillin can behave as a bifunctional compound to give polymeric pigments.

2-Iodo-and 5-Iodo-veratraldehyde. The former was prepared from vanillin by the route of acetylation, nitration, reduction, halogenation, and methylation,[7] while the latter was prepared by the same route except for acetylation. We found that 2-nitrovanillin was reduced smoothly to 2-aminovanillin with ferrous sulfate, but not with stannous chloride,[8] while 5-nitrovanillin was reduced only with stannous chloride.[7]

5,5′-Diformyl-2,2′,3,3′-tetramethoxybiphenyl (I). By the oxidative coupling of vanillin with sodium persulfate, followed by methylation with dimethyl sulfate, I was obtained nearly quantitatively. Colorless needles; mp 136°C, IR (KBr) cm^{-1} 2930(CH), 2840(CH), 1685(CHO), 1575(aromatic), 1450 (CH), 1388(CH), 1265(COC), and 1135(COC); UV λ_{max}^{EtOH} nm (ε) 228(34900), 275(18600), and 313(12000); NMR($CDCl_3$) δ 9.92(2H, s, CHO), 7.51(2H, d, J=2.5Hz, 6,6′-H), 7.32 (2H, d, J=2.5 Hz, 4,4′-H), 4.00(6H, s, 3,3′-OCH_3), and 3.80 (6H, s, 2,2′-OCH_3).

6,6-Diformyl-2,2′,3,3′-tetramethyoxybiphenyl (II). A mixture of 1 g of 2-iodo-3,4-dimethoxybenzaldehyde and 7 g of copper powder was heated in a pressure tube at 180—190°C for 1 hr. The reaction mixture was then extracted with chloroform. After the removal of the solvent, the residue was extracted with ether. The extract was evaporated to dryness and recrystallized from ethanol to afford 0.25 g (37.6%) of II as colorless prisms; mp 134—135°C; sublimed at 130—140°C/10^{-3}—10^{-4} Torr. When the reaction period was extended to 4 hr, the yield was 9.4%; when it was shortened to 30 min at 170—185°C, the yield was 63.4%. IR(KBr) cm^{-1} 2930, 2840, 1675, 1585, 1450, 1386, 1250, and 1135; UV λ_{max}^{EtOH} nm(ε) 232(28200) and 287(21500); NMR($CDCl_3$) δ 9.56 (2H, s, CHO), 7.82(2H, d, J=8.4Hz, 5,5′-H), 7.11(2H, d, J= 8.4Hz, 4,4′-H), 4.00(6H, s, 3,3′-OCH_3 and 3.61(6H, s, 2,2′-OCH_3).

5,6-Diformyl-2,2′,3,3′-tetramethoxybiphenyl (III). From a solution of 5 g of 2-iodo-3,4-dimethoxybenzaldehyde and 5 g of 5-iodo-3,4-dimethoxybenzaldehyde in benzene, the solvent was evaporated. The residual mixture was heated with 50 g of copper powder in a pressure tube at 180—187°C for 30 min. The reaction mixture was then worked up as has been described above to give 4.5 g of the product, which was chromatographed on silica gel with benzene-ethyl acetate (20:1 v/v). Each dimer, I, II, and III, was eluted, in that order. The yields of the dimers in a pure form were 27.8, 20.4, and 18.6% respectively. We attempted to improve the yield of III by changing the ratio of the 2-iodo- and 5-iodo-compounds. When a mixture of 2 g of coper powder was heated under the above conditions, the yields of I, II, and III, were 15.3, 37.1, and 13.5% respectively. The dimer III; colorless prisms from ethanol; mp 126—127°C. (Found: C, 65.22; H, 5.67%. Calcd for $C_{18}H_{18}O_6$; C, 65.44; H, 5.49%.; IR (KBr) cm^{-1} 2930, 2840, 1685, 1580, 1455, 1385, 1250, and 1135; UV λ_{max}^{EtOH} nm(ε) 229(31800) and 280(19100); NMR($CDCl_3$) δ 9.92(1H, s, 5-CHO), 9.61 (1H, s, 6′-CHO), 7.82(1H, d, J=8.4Hz, 5′-H), 7.55(1H, d, J=2.5Hz, 6-H), 7.35(1H, d, J=2.5Hz, 4-H), 7.11(1H, d, J=8.4Hz, 4′-H), 4.01(6H, s, 3,3′-OCH_3), 3.76(3H, s, 2-OCH_3), and 3.66(3H, s, 2′-OCH_3).

The γ-Radiolysis and Mercury-Photosensitized Decomposition of Ethylbenzene Vapor

Yukio YAMAMOTO, Setsuo TAKAMUKU, and Hiroshi SAKURAI

The Radiation Laboratory, The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received September 10, 1970)

Previously we reported that, in the gas-phase radiolyses of toluene, ethylbenzene, and *m*-xylene, the benzylations of the aromatic nuclei of the parent alkylbenzene molecules were commonly observed as the main processes of the product formations.[1] These reactions have been attributed to the electrophilic substitutions by $C_7H_7^+$ ions,[2] which are well known to be the most abundant ions in the mass spectra of these alkylbenzenes.[3] Furthermore, in a preceding paper on the gas-phase radiolysis of toluene the overall product formation was studied and compared with that of the mercury-photosensitized decomposition.[4] In order to investigate the specific mode of the gas-phase radiolyses of alkylbenzenes, where ionic species and various excited molecules play important roles, we felt it was of some significance to compare those results with those of photolytic studies. In the present paper we wish to call attention to the radiolysis and mercury-photosensitized decomposition of ethylbenzene vapor at room temperature.

Experimental

The radiolysis was carried out in Pyrex cylinders approximately 120 m*l* in volume with γ-rays from a 5000 Ci cobalt-60 source. The dose rate to ethylbenzene was 4.3×10^{15} eV/hr·μmol, and the total dose, 3.1×10^{17} eV/μmol.

The photolysis of ethylbenzene containing a small amount of mercury vapor at 2537 Å was studied using cylindrical quartz cells (5 cm in diameter and 5 cm long) and a low-pressure mercury lamp.[5] The relative yields of the products were not appreciably affected by the use of a filter, Toshiba UV-25, which does not transmit below about 2000 Å; therefore, the contribution of 1849 Å light from the low-pressure mercury lamp may be neglected. The analysis of the products was the same as that described previously.[4]

Results and Discussion

Mercury-Photosensitized Decomposition. A few papers have been published on the mercury-photosensitized decomposition of ethylbenzene vapor at 2537 Å,[6,7] though these have dealt exclusively with the gaseous products. The products reported by Takase *et al.*[7] are ethane and relatively small yields of hydrogen and methane. They concluded that the major bond scission in the primary process occurs at the C–C bond β to the ring as follows:

$$\text{EB(Ethylbenzene)} \xrightarrow[\text{Hg}]{h\nu} \text{EB}^* \quad (1)$$

$$\text{EB}^* \longrightarrow C_6H_5CH_2\cdot + CH_3\cdot \quad (2)$$

and that ethane is formed almost exclusively by the combination of methyl radicals, judging from the results of the photolysis of ethylbenzene-β-d_1 vapor.

Table 1. The product yields of the Hg-sensitized photolysis and γ-radiolysis of ethylbenzene vapor at room temperature

Product	Photolysis, μmol	Radiolysis, *G* value		
	Pressure, mmHg

a) Data of Wiltzbach and Kaplan (Ref. 9). The *G* values of the other products such as xylenes and ethyltoluenes are also determined.
b) The mol% of NO was 10.
c) Not determined owing to the interference with added NO.
d) Not detectable.
e) Isopropylbenzene.
f) Diphenylpropane.
g) Ethyldiphenylmethane.

The product yields of our study are presented in Table 1, together with the results of the radiolysis. The formation of large yields of the products, such as ethane and bibenzyl, which is attributable to the reactions of the radicals formed by the β C–C bond scission, the reaction (2), was also observed in our study. As is shown in Table 1, small amounts of benzene and propane,

1) Y. Yamamoto, S. Takamuku, and H. Sakurai, *J. Amer. Chem. Soc.*, **91**, 7192 (1969).
2) The question of whether the $C_7H_7^+$ ions, which attack aromatic rings, are tropylium ions, as has been suggested in the mass-spectrometric studies (see Ref. 3), or benzyl ions still remains.
3) H. M. Grubb and S. Meyerson, "Mass Spectrometry of Organic Ions," ed. by F. W. McLafferty, Academic Press, New York (1963), p. 453.
4) Y. Yamamoto, S. Takamuku, and H. Sakurai, *J. Phys. Chem.*, **74**, 3325 (1970).
5) The direct photolysis may also occur to some extent, since ethylbenzene absorbs light in the 2537 Å region.
6) R. R. Hentz and M. Burton, *J. Amer. Chem. Soc.*, **73**, 532 (1951).
7) A. Takase, M. Murano, H. Mikuni, and M. Takahashi, International Conference on Photochemistry, Tokyo (1965).

the latter of which is thought to be formed by the combination of methyl and ethyl radicals, were formed in almost equivalent yields; it is indicated that the scission of the α C–C bond occurs in the primary process, though to a relatively small extent.

$$EB^* \longrightarrow C_6H_5\cdot + C_2H_5\cdot \quad (3)$$

In previous studies,[6,7] the possibility of the formation of styrene has been pointed out. However, in our study styrene was not found to be produced in a detectable yield; the only primary process leading to the formation of hydrogen suggested by our results is as follows:[8]

$$EB^* \longrightarrow C_6H_5\dot{C}HCH_3 + H \quad (4)$$

In our experiment at room temperature, the predominant reactions of the radicals formed by the primary processes, (2), (3), and (4), are considered to be combinations and α hydrogen abstractions from ethylbenzene with relatively small activation energies. Thus, we can write the processes of the formation of the observed products as follows:

$$R\cdot + EB \longrightarrow RH + C_6H_5\dot{C}HCH_3 \quad (5)$$

$$R\cdot + R\cdot \longrightarrow R\text{–}R \quad (6)$$

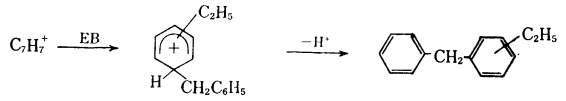
where R· represents any radical produced in the primary processes or by the hydrogen abstractions from ethylbenzene.

Neglecting the combinations of the radicals and hydrogen atoms, the yield of the $C_6H_5\dot{C}HCH_3$ radicals formed by the hydrogen abstractions (5) may be approximately represented by the sum of the yields of hydrogen, methane, benzene, and toluene. Such a yield, 0.39 μmol, was smaller than the sum of the yields of the products from $C_6H_5\dot{C}HCH_3$ radicals, isopropylbenzene (*i*-PB) and 1,2-diphenylpropane (1,2-DPP), 0.46 μmol, supporting the view that $C_6H_5\dot{C}HCH_3$ radicals are formed by the process (4) as well as by the hydrogen abstractions (5).

Radiolysis. The *G* values of the products of the gas-phase radiolysis of ethylbenzene were obtained in the presence and in the absence of a radical scavenger, nitric oxide; they are presented in Table 1, together with the results of the previous study.[9] As new products which were not detected in the photolysis, acetylene, ethylene, and three isomers of ethyldiphenylmethane (EDPM) were formed in the radiolysis.

When 10 mol% NO was added, ethane, propane, *i*-PB, bibenzyl, and 1,2-DPP disappeared; it may be that these products are formed through radicals as are some benzene and toluene substances, whose yields were partially reduced by the addition of 10 mol% NO (to be discussed below). The appreciable yields of ethane and propane indicate that methyl radicals are largely formed in the primary process of the radiolysis; this is analogous with the photolysis.

The remarkable difference between the radiolysis and the photolysis was observed in the formation of dimeric products; that is, the main dimeric products in the radiolysis were EDPM's, whose yields were not appreciably affected by the addition of 10 mol% NO, while the main products in the photolysis were bibenzyl and 1,2-DPP. As has been previously reported,[1] the formation of EDPM's may be attributed to the ion-molecule reaction of the $C_7H_7^+$ ions with ethylbenzene, as is shown by the following scheme:[10]



On the basis of these results, it may be concluded that the major bond scission in the primary process of the gas-phase radiolysis of ethylbenzene occurs at the β C–C bond *via* ionization, resulting in the formation of a methyl radical and the $C_7H_7^+$ ion as follows:

$$EB \rightsquigarrow EB^{+*} \quad (7)$$

$$EB^{+*} \longrightarrow C_7H_7^+ + CH_3\cdot \quad (8)$$

The formation of the $C_7H_7^+$ ions is the most important process observed in the mass spectrometry of ethylbenzene as well as in those of toluene and xylenes.[3]

When 10 mol% of NO was added, ethylene and acetylene were not appreciably affected, indicating that these products are formed through intermediates unscavengeable with NO. In our study of the gas-phase radiolysis of toluene,[4] the yield of ethylene was negligible over the pressure range studied (2 to 19 mmHg); the fact that the *G* value of ethylene from ethylbenzene is much larger than that from toluene seems to indicate that a great portion of ethylene is formed from the side chain, the ethyl group, of ethylbenzene, probably through an excited ethyl radical.[11] On the other hand, the *G* value of acetylene from ethylbenzene was of the almost same order as that from toluene; the processes of the acetylene formation suggested in the gas-phase radiolysis of toluene,[4] that is, the fragmentations of the $C_7H_7^+$ ions and aromatic rings, is probable for the ethylbenzene radiolysis.

The dependence of the yields of benzene and toluene on the NO concentration was studied. These yields were partially reduced by the addition of 10 mol% NO (Table 1); it was also observed that both were almost constant above about 6 mol% NO, indicating the presence of the unscavengeable benzene and toluene. The mechanism of the formation of these unscavengeable products is uncertain, though the possible mechanisms might be thought to involve the reactions of $C_6H_5^+$ ions[12] and $C_7H_7^+$ ions.

8) The dissociation of this bond might also occur by means of the reaction of the excited mercury atoms and ethylbenzene molecules.

9) K.E. Wiltzbach and L. Kaplan, *Advances in Chemistry Series*, No. 82, American Chemical Society, Washington, D. C., (1968), p. 134.

10) In a previous paper (Ref. 1), the isomer distribution of EDPM's has been accounted for by the isomerization of the intermediate complexes, $C_{15}H_{17}^+$ ions; the precise mechanism of such an electrophilic substitution of aromatic rings by $C_7H_7^+$ ions has also been discussed in a previous paper on the gas-phase radiolysis of toluene (Ref. 4).

11) The formation of ethylene by the decomposition of the excited ethyl radicals has been proposed in the vacuum ultraviolet photolysis of saturated hydrocarbons [J. R. McNesby and H. Okabe, "Advances in Photochemistry," Vol. 3, ed. by W. A. Noyes, Jr., G. S. Hammond, and J. N. Pitts, Jr., Interscience Publishers, New York, N. Y. (1964), p. 204].

12) The $C_6H_5^+$ ions are the product ions in the mass spectra of toluene and ethylbenzene (see Ref. 3); the formation of unscavengeable benzene was also observed in the gas-phase radiolysis of toluene (see Ref. 4).

The most interesting result obtained in these experiments was that the β bond scissions are the major primary process in both the γ-radiolysis and the mercury-photosensitized decomposition of ethylbenzene vapor. However, in the former, the $C_7H_7^+$ ions result, while the latter results in benzyl radicals. A similar result was also obtained in the study of toluene vapor, as has previously been reported.[4]

Application of Proton NMR Shift Reagents to the Stereochemical Analysis of Nicotine

Mamoru OHASHI, Isao MORISHIMA, and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 10, 1970)

Recently the proton NMR contact shift has received considerable attention.[1-4] In previous papers[5,6] we have discussed the proton paramagnetic shifts of piperidines using nickel and cobalt diacetylacetonate (Ni(AA)$_2$ and Co(AA)$_2$), as well as their application to the stereochemical analysis of some tropane alkaloids. This communication will deal with the application of these paramagnetic shifts to the 220 MHz-NMR-spectrum analysis of nicotine and to the determination of its conformation.

In contrast to the case of the 60 MHz NMR spectrum,[7] this high-frequency NMR technique demonstrated the presence of two triplet signals at δ 3.27 (J=8Hz) and 3.11 (J=8Hz) ppm and a quartet peak at δ 2.34 (J=8Hz) ppm (Fig. 1). These signals can unquestionably be assigned to the methine and methylene protons positioned alpha to the nitrogen in the pyrrolidine ring. In order to assign these signals to particular hydrogens, the contact and pseudocontact shifts of these signals with Co(AA)$_2$, Ni(AA)$_2$, and tris(benzoylacetonato)europium Eu(BA)$_3$ were used effectively. Since the proton magnetic resonance of a particular proton was found to shift from its normal value in proportion to the concentration of the added

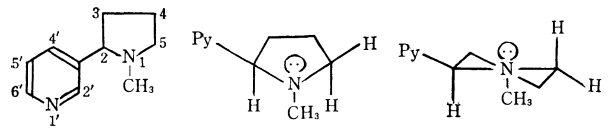
Table 1. Chemical shifts and relative contact shifts[a] for nicotine coordinated with the metal chelates

(+ and − mean up- and downfield shifts respectively, in CDCl, internal standard TMS at 220 MHz)

	2′	4′	5′	6′	2	5ax	5eq	3	NCH_3
δ ppm	8.53	7.70	8.47	3.11	3.11	2.34	3.27	−1.8[b]	2.16
$Ni(AA)_2$	−[c]	−10.0	−[c]	−[c]	−5.4	0	0	0	0
$Co(AA)_2$	−10.0	+ 3.5	−1.5	−10.0	+1.8	+0.8	+0.7	+2.6	+1.5
$Eu(BA)_3$	−10.0	− 3.1	−3.1	− 9.1	−1.9	−0.5	−0.5	−1.6	−1.3

a) The observed shifts are normalized to give a value of 10.0 for the largest proton shift.
b) Signals are overlapped one another and the exact chemical shift can not be determined.
c) Line broadening is so great that the exact position is not obvious.



(1) (2) (3)

Scheme. 1

metal chelates,[5,8] we are interested only in the relative shifts for various protons. The results are summarized in Table 1.

From these data the following conclusions were drawn: i) Since the 2, 5′ and 6′-hydrogens were shifted dramatically, the nitrogen lone-pair of pyridine, not that of pyrrolidine, is the binding site of the metal chelates. ii) On the addition of $Ni(AA)_2$ or $Co(AA)_2$, the triplet signal at δ 3.11 ppm shifted downfield or upfield respectively. This behavior is similar to that of the methyl in the β-picoline spectrum;[8] the signal was, consequently, assigned to 2-hydrogen. iii) On the basis of the coupling features, a triplet signal at δ 3.27 ppm and a quartet at δ 2.34 ppm were analyzed to be quasi-equatorial and -axial protons respectively at C_5 position. iv) As far as energy is concerned, two conformers, an envelope form (**2**) and a half-chair form (**3**), are conceivable for the pyrrolidine ring.[9] In **2**, the quasi-equatorial and -axial protons are in *cis* and *trans* relationships to the pyridyl group respectively, while in **3** the relationships are the reverse. It is well known that the observed paramagnetic shift using $Co(AA)_2$ is the sum of the isotropic contact shift and the anisotropic pseudocontact shift, which is proportional to the geometric factor, $f=(3\cos^2\theta-1)/r^3$, where r is the distance between the resonating proton and the Co atom and where θ is the angle between the Co–N axis and the r vector.[10] Since the contact shift with $Ni(AA)_2$ was not observed on the protons attached to the pyrrolidine ring, and since the ratios of the spin densities at the various protons would be the same for the Co(II) and Ni(II) systems,[5] the upfield shifts of *N*-methyl, C_3, and C_5-protons must be due only to the anisotropic pseudocontact shift caused by the cobalt t_{2g} orbital.[8] It is also known that, in the case of the rare earth chelates of Eu(III), the observed downfield shifts are probably caused by the predominant pseudocontact term and that, therefore, they depend upon the geometric factor.[10,11] Assuming the nitrogen-metal length to be 2 Å,[5] the molecular model of nicotine indicates that the amount of the geometric factor is qualitatively in the order of: the C_3-quasi-axial proton > *N*-methyl protons > C_5-quasi-axial ≈ -equatorial protons in the case of **2**, while it is: the C_3-quasi-axial proton > *N*-methyl ≈ C_5-quasi-axial protons > the C_5-quasi-equatorial proton in the case of **3**. The fact that the observed relative amount of the paramagnetic shift of each proton is in accord with the case of **2** and not of **3** indicates that the conformation of the pyrrolidine ring is in an envelope form.

It is well established that the chemical shift of a proton positioned at the *cis* configuration to the nitrogen lone-pair is in a lower field than that of *trans*.[12] The fact that the chemical shift of the quasi-equatorial proton (δ 3.27 ppm) is in a lower field than that of the quasi-axial proton (δ 2.34 ppm) is consistent with the case of **2** and supports the aforementioned conclusion.

The above discussion is an example of the usefulness of contact and pseudocontact shifts with $Ni(AA)_2$, $Co(AA)_2$ and $Eu(BA)_3$ in analyzing complex spectra and in solving stereochemical problems. Further applications of these phenomena to alkaloids as well as to natural-product chemistry are now in progress.

Experimental

All the materials used in this study except $Eu(BA)_3$ were commercially available ones. The $Ni(AA)_2$ and $Co(AA)_2$ were dried at 60°C *in vacuo* overnight before use. The $Eu(BA)_3$ was supplied by Dr. T. Suzuki of this department.[13]

The spectra were observed with a Varian HR-220 spectrometer for $CDCl_3$ solutions containing varying amounts of nicotine and $Co(AA)_2$, Ni(AA), or $Eu(BA)_2$. The proton-resonance shifts were measured relative to the internal TMS. The spectra were recorded after each of the successive additions of a few milligrams of the metal chelates.

Aromatic Substitution of Olefins XV. The Steric Course of the Reaction

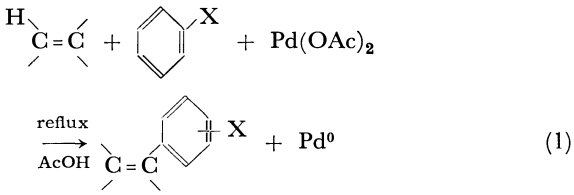
Ichiro MORITANI,* Sadao DANNO,** Yuzo FUJIWARA,* and Shiichiro TERANISHI*

* *Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka*

** *Polymer Research Laboratory, Ube Industries Ltd., Goi, Chiba*

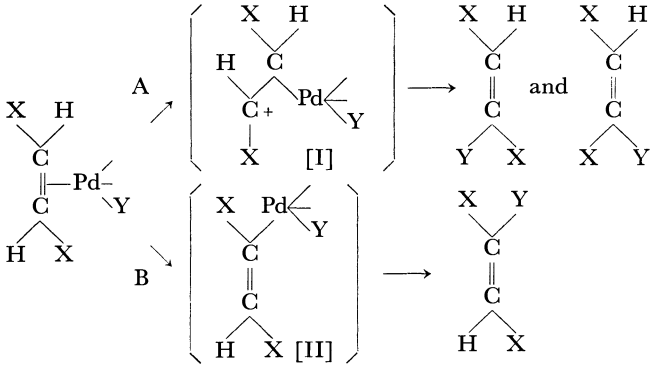
(Received September 25, 1970)

In previous papers, we have reported that aromatic compounds react smoothly with olefins in the presence of palladium acetate to produce aryl-substituted olefins (Eq. (1))[1] and that the reaction proceeds through a different mechanism from that of the Wacker process,[2] for no hydride shift occurs in the course of the aromatic substitution reaction of olefins.



(1)

It has been reported that, in the Wacker process,[3] a σ-complex (I) may be formed after the nucleophilic attack of an anion on the olefin-Pd π-complex, followed by the π-electron transfer:



In the aromatic substitution of olefins, we have proposed a mechanism in which an olefin-palladium σ-complex (II) is formed through hydrogen abstraction from the olefin.[4]

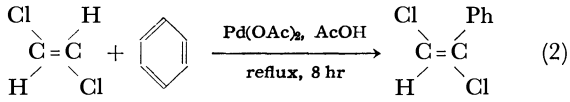
If the aromatic substitution reaction proceeds *via* an intermediate (I) according to the path A, a free rotation about the C–C axis becomes possible, for the electronic configuration changes from sp^2 to sp^3 hybridization, and the products will be a mixture of *cis*- and *trans*-isomer.

Contrary to this, in the case of the path B, olefinic carbon atoms will remain in the intermediate (II), so the reaction will proceed with a retention of the configuration.

Thus, it is possible to determine the reaction path if the olefins which do not isomerize under the reaction conditions are allowed to react with benzene, and the stereochemistry of the product can be investigated.

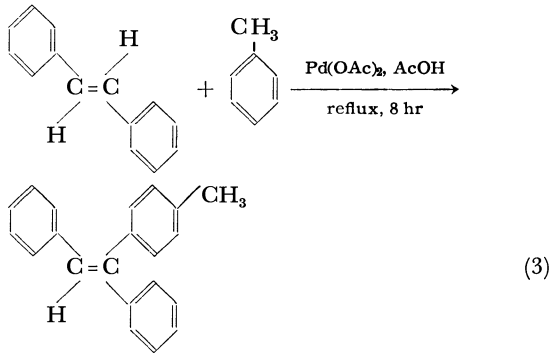
Therefore, *trans*-stilbene, *cis*- and *trans*-dichloroethylenes were selected as olefins, for they do not isomerize in the course of the reaction.

The reaction of *trans*-dichloroethylene with benzene proceeded in acetic acid in the presence of palladium acetate. Phenyl-*trans*-dichloroethylene was obtained in a 42% yield (based on pallaium), but no phenyl-*cis*-dichloroethylene was detected (Eq. (2)). Similary, *cis*-dichloroethylene reacted with benzene and produced phenyl-*cis*-dichloroethylene.



(2)

Moreover, the *trans*-stilbene was reacted with benzene to produce *p*-tolyl-*trans*-stilbene. The reaction of *cis*-stilbene with toluene was not the same, however, because it is isomerized to the *trans*-isomer when treated under the same conditions for two hours.



(3)

These results strongly demonstrate that the substitution reaction proceeds with a retention of the configuration of the olefins, and the path B is favored for the aromatic substitution reaction of olefins. Moreover, it is reasonable to assume the existence of an olefin-palladium σ-bonded intermediate in the reaction.

Experimental

All the boiling points are uncorrected. The infrared spectra recorded by means of a Hitachi EPI-S2 IR spectrophotometer, while the ultraviolet spectra were obtained on a Hitachi-EPS-2U spectrophotometer. The NMR spectra were obtained by the use of a Japan Electron Optics JNM-4H-100 or JNM-C-60HL spectrometer, using tetramethylsilane as the internal standard. Chemical shifts are given on the τ-scale, together

with the splitting patterns and the relative integrated area.

General Procedure for the Reaction. A mixture of the palladium acetate, an equivalent amount of the olefin, acetic acid, and the aromatic compound was stirred for 8 hr at reflux. The reactions were carried out with an excess of the aromatic compound, which behaved as both a reactant and a solvent. The resulting mixture was filtered to remove the palladium metal, and then the filtrate was poured into water and the organic layer was separated. The organic layer was treated with an aqueous sodium bicarbonate solution, washed with water to free it from acetic acid, and then dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the products were isolated by gas chromatography. Analyses of the products were carried out by the use of a Yanagimoto GCG-3 gas chromatograph, using an Apiezon L, Carbowax 20M, or SE-30 column. Identities with the products formed were proved by IR, UV, or NMR comparison with authentic samples.

Reaction of trans-*Stilbene with Toluene.* In a solution of dry toluene (300 m*l*) and dry acetic acid (100 m*l*), we dissolved palladium acetate (28.8 mmol, 6.47 g) and *trans*-stilbene (28.8 mmol, 5.25 g). The mixture was then refluxed for 8 hr. The resulting mixture was filtered to remove the reduced palladium metal and the filtrate was poured into water. The organic layer was treated with an aqueous sodium bicarbonate solution, washed with water, and then dried over $MgSO_4$. After the evaporation of the solvent, the products were separated by vpc to give 1.79 g of *p*-tolyl-*trans*-stilbene; UV spectrum: $\lambda_{max}^{EtOH}=312$ mμ (ε: 2.08×10^4); NMR spectrum (in CCl_4): 2.8(m,14H), 3.17(s,1H), and 7.65τ (s, 3H).

Preparation and Separation of p-*Tolyl*-cis *and* trans-*Stilbenes.* *p*-Methylbenzophenone (10 g) dissolved in absolute ether (30 m*l*) was added, drop by drop, to the Grignard reagent prepared from freshly distilled benzyl chloride (8.3 g) and magnesium shoot (1.6 g). After having been refluxed for 1.5 hr, the reaction mixture was hydrolysed with cold water. The residual oil was refluxed for 2 hr with 20% sulfiic acid (70 m*l*) to dehydrate the alcohol thus produced. *p*-Tolylstilbene, (175—182°C/2.5 mmHg[5]) was obtained in a 94% yield. Found: C, 93.10; H, 6.82%. Calcd for $C_{21}H_{18}$: C, 93.29; H, 6.71%.

The *p*-tolyl-*cis* and *trans*-stilbenes prepared by the above described method were separated by VPC (10% SE-30 on Celite 545, 2 m$\times$6 mm, 260°C, 30 m*l* He/min). *p*-Tolyl-*cis*-stilbene; UV spectrum: $\lambda_{max}^{EtOH}=314$mμ(ε: 4.45×10^4); NMR spectrum (in CCl_4): 2.9(m, 14H), 3.19(s, 1H), and 7.62 τ (s, 3H). *p*-Tolyl-*trans*-stilbene; the UV and NMR spectra have been described above.

Preparation of cis-*Dichlorostyrene.* This compound was prepared by the methods described by Dycherhoff.[6] A mixture of ω-chloroacetophenone (8 g) and phosphorus pentachloride (10.8 g) were heated at 135°C for 2 hr, and the product was distilled in a boiling range of 225—234°C. The distillate was dried over $MgSO_4$ and then redistilled (bp 221—224°C). This product was separated and purified by VPC. NMR Spectrum (in CCl_4): 3.0 (m, 5H) and 3.16τ (s, 1H). Also, *trans*-dichlorostyrene was prepared by the method of Koenig and Wolf.[7] Bp 90—93°C/10 mmHg; IR spectrum (direct): 695, 760 (monosub. benzene), and 1660 cm^{-1}; NMR spectrum in CCl_4): 2.58 (m, 5H) and 3.33 τ (s, 1H).

SHORT COMMUNICATIONS

The Effect of the Krypton Moderator on the Isomeric Transition-induced Reactions of ^{80}Br with CH_4

Masuo YAGI, Kenjiro KONDO, and Takaaki KOBAYASHI*1

Laboratory of Nuclear Science, Tohoku University, Sendai

(Received October 22, 1970)

In a previous paper[1] we studied the reactions of isomeric transition-activated ^{80}Br in the CH_4-$^{80m}BrBr$ system and found that the $CH_3{}^{80}Br$ yields were much higher than the $CH_2{}^{80}BrBr$ yields over the whole range of mole fractions of the $^{80m}BrBr$ additive. In this paper, we will report on our investigation of the effect of the Kr moderator in the same system in order to elucidate further the chemical behavior of the isomeric transition-activated ^{80}Br.

Nicholas and Rack[2] studied the effects of rare gas moderators on the total organic yields in the CH_4-$^{82m}BrBr$ system and suggested that one-half of the organic products are formed *via* the excess kinetic-energy processes, while the others are formed *via* the thermal ionic (kinetic-energy-independent) processes. Tachikawa[3] and his co-workers[4,5] also studied the influence of the moderator gases, such as He, Ar, and Xe, on the individual product yields in the CH_4-$^{80m}BrBr$ and the CH_4-$^{82m}BrBr$ systems, they concluded that the radioactive $CH_3{}^*Br$ is formed *via* both the excess kinetic-energy and the thermal ionic processes, while the radioactive $CH_2{}^*BrBr$ is formed *via* only the thermal ionic processes.

Since the Br_2 additive is an efficient moderator of the bromine hot atoms, it is necessary to use the smallest pressure of Br_2. Therefore, in our experiments, the mole fraction of the $^{80m}BrBr$ additive to CH_4 was kept constant at 0.029 and the individual product yields were determined in the presence of pressures of Kr gas sufficient to remove the excess kinetic-energy of the ^{80}Br atoms. The experimental methods may be found elsewhere.[1]

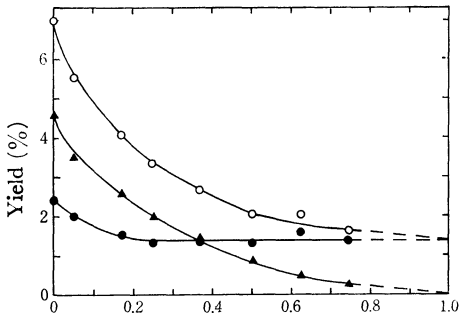

Fig. 1. Effect of the Kr moderator on the product distribution in the reaction of (I.T.)-activated ^{80}Br with CH_4. ($^{80m}BrBr/CH_4=0.029$, total pressure: 400—700 mmHg)
○: ^{80}Br as organic, ▲: $CH_3{}^{80}Br$, ●: $CH_2{}^{80}BrBr$

The effects of the Kr moderator on the total organic and the individual product yields are shown in Fig. 1. Extrapolations of the presented values to the zero mole fraction of the Kr moderator gave the limiting $CH_3{}^{80}Br$ yield of $4.6\pm0.2\%$ and the $CH_2{}^{80}BrBr$ yield of $2.4\pm0.1\%$ respectively. On the other hand, at one mole fraction of the Kr moderator, the data are $0.0\pm0.1\%$ for the $CH_3{}^{80}Br$ and $1.4\pm0.1\%$ for the $CH_2{}^{80}$ BrBr respectively. Our value of 1.4% for the total organic yield at one mole fraction of the Kr moderator was agreed very well with that of 1.6% reported by Tachikawa[3] and his co-workers[4,5] for the ^{80}Br and ^{82}Br systems. However, it was significantly lower than that of 3.7% reported by Nicholas and Rack[2] for the ^{82}Br. It is not immediately obvious why our value is lower than their value.

Under our experimental conditions, $CH_3{}^{80}Br$ may be seen to be formed *via* only the excess kinetic-energy processes. On the contrary, it is clear that the $CH_2{}^{80}BrBr$ yield of 2.4% minus 1.4% is derived from the excess kinetic-energy processes and that of 1.4% is derived from the thermal ionic processes. These facts indicate that about 80% of the organic products are formed principally *via* the excess kinetic-energy processes, while the rest are formed principally *via* the thermal ionic processes under the present conditions.

Arylation of Olefin with Aryl Iodide Catalyzed by Palladium

Tsutomu Mizoroki, Kunio Mori, and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received October 20, 1970)

The arylation of olefin with aromatic hydrocarbon[1] or arylmercuric compound[2] by the reaction with palladium(II) compound has been reported, where the reaction consumes almost stoichiometric amount of the palladium(II) compound, forming metallic palladium. In this communication we wish to report that the arylation of olefin with iodobenzene in the presence of a catalytic amount of palladium(II) dichloride takes place smoothly when potassium acetate is added as an acceptor of hydrogen iodide formed. A characteristic feature of this reaction is that the arylation of olefin is effectively catalyzed by palladium or palladium(II) compounds without accompanying polymerization of the corresponding styrene derivatives formed, as long as the amount of potassium acetate added is greater than that of iodobenzene used. The reaction can be represented as follows:

$$C_6H_5I + CH_2{=}CHX + CH_3COOK \longrightarrow C_6H_5CH{=}CHX + CH_3COOH + KI$$
(X=H, C_6H_5, CH_3, and $COOCH_3$)

This can be compared with the carbonylation of aryl halide with carbon monoxide catalyzed by nickel carbonyl in the presence of sufficient amount of potassium acetate in methanol ($C_6H_5X + CO + CH_3OH + CH_3COOK \longrightarrow C_6H_5COOCH_3 + CH_3COOH + KX$, X=I, Br).[3]

The catalyst in the present case was initially palladium dichloride, but most of the palladium was found to be reduced to metal in the course of the reaction. As shown in Table 1, metallic palladium has also high catalytic activity for the arylation of olefin (No. 5). This differs considerably from the stoichiometric arylation of olefin with palladium(II) compounds. Pyridine, triethylamine, or potassium benzoate was also used as the acceptor of hydrogen iodide formed, potassium acetate being the most effective. Ethylene, propylene, styrene, and methyl acrylate were used as olefin. The corresponding styrene derivatives (styrene, α- or β-methylstyrene, *trans*-stilbene and methyl cinnamate, respectively) were produced in high yields. The results are summarized in Table 1.

The experimental procedure is illustrated by the arylation of ethylene with iodobenzene. Iodobenzene (50 mmol), potassium acetate (60 mmol), palladium dichloride (0.5 mmol), and methanol (1.0 mol) were placed in a titanium-alloy autoclave (100 m*l*) equipped with a magnetic stirrer. The gas phase in the autoclave was displaced by nitrogen stream, and ethylene from commercial sources was then introduced up to 8 kg/cm² at room temperature. The autoclave was heated up to 120—125°C within 1 hr and kept at this temperature for 3 hr. The decrease in pressure was observed during the first 1 hr (from 16 to 9 kg/cm²). After the reaction, all materials were taken out from the autoclave by using methanol and acetone and the products were quantitatively determined by gas chromatography.

Table 1. Arylation of olefin with iodobenzene

$PdCl_2$ 0.50 mmol, CH_3OH 0.8—1.0 mol, Temp. 120°C

No.	C_6H_5I (mmol)	CH_3COOK (mmol)	Olefin introduced	React. time (hr)	Arylation product (mmol) (%)[c]	
1	50	0	C_2H_4, 8 kg/cm² [b]	3	$C_6H_5CH{=}CH_2$	trace(0)
2	50	15	C_2H_4, 8 kg/cm²	3	$C_6H_5CH{=}CH_2$	13 (26)
3	50	30	C_2H_4, 8 kg/cm²	3	$C_6H_5CH{=}CH_2$	24 (48)
4	50	60	C_2H_4, 8 kg/cm²	3	$C_6H_5CH{=}CH_2$	37 (74)[d]
5[a]	50	60	C_2H_4, 8 kg/cm²	3	$C_6H_5CH{=}CH_2$	36 (72)[d]
6	50	60	$C_6H_5CH{=}CH_2$ 100 mmol	2	*trans*-Stilbene 1,1-Diphenylethylene	45 (90) 6.0 (12)
7	30	48	C_3H_6, 3.5 kg/cm² [b]	2	α-Methylstyrene β-Methylstyrene	8.1 (27) 22 (73)
8	30	48	$CH_2{=}CHCOOCH_3$ 60 mmol	2	Methyl cinnamate	29 (97)[e]

a) Palladium black (54 mg) obtained by reducing $PdCl_2$ was used as a catalyst.
b) The methanol solution was saturated with the olefin at room temperature.
c) Based on the amount of iodobenzene used.
d) *trans*-Stilbene and 1,1-diphenylethylene were detected in the product.
e) No methyl atropate was detected.

Diiodo-π-cyclopentadienyliridium and Its Derivatives

Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received October 28, 1970)

Recently formation of dihalo-π-(pentamethylcyclopentadienyl)iridium from the reaction of iridium chloride hydrate with hexamethyl (Dewar benzene) was reported.[1] However, simple dihalo-π-cyclopentadienyliridium is not known as yet in spite of its ability to prepare complexes having a π-cyclopentadienyliridium group. We wish to report the preparation of diiodo-π-cyclopentadienyliridium and some derivatives thereof.

Cyclooctatetraene-π-cyclopentadienyliridium[2] [mp 114—116°C. IR(KBr): $\nu_{C=C}$ 1635 cm^{-1}. NMR(*p*-xylene): 4.27τ (singlet, –CH=CH–), 5.21τ (singlet, C_5H_5), 5.77τ (singlet, coordinated –CH=CH–).] was treated with equimolar amount of iodine in methylene chloride at room temperature to give insoluble brown crystals of diiodo-π-cyclopentadienyliridium (I) in almost quantitative yield. The infrared spectrum of I is very similar to that of the rhodium analogue.[4] A similar treatment of 1,5-cyclooctadiene-π-cyclopentadienyliridium did not give I but insoluble brown crystals having a combined composition of the reactant, $C_{13}H_{17}I_2Ir$, which was deduced on the basis of elemental analysis.

Similar to the rhodium analogue,[5] I reacted with triphenylphosphine in methylene chloride giving air-stable orange red crystals of diiodo-triphenylphosphine-π-cyclopentadienyliridium (II) [Yield 90%. Mp ~310°C (decomp). NMR($CDCl_3$): 2.2—2.7τ (C_6H_5), 4.57τ (doublet, J_{PH} 1.5 Hz, C_5H_5).]. Methyldiphenylphosphine and carbon monoxide also gave diiodo-methyldiphenylphosphine-π-cyclopentadienyliridium [Orange red crystals. Yield 82%. Mp 209—211°C. NMR($CDCl_3$): 2.1—2.7τ (C_6H_5), 4.57τ (doublet, J_{PH} 1.5 Hz, C_5H_5), 7.26τ (doublet, J_{PH} 11 Hz, CH_3).] and diiodo-carbonyl-π-cyclopentadienyliridium [Red crystals. Yield 93%. Mp>180°C (decompn without melting). IR(KBr): ν_{CO} 2040 cm^{-1} (with a shoulder at 2020 cm^{-1}). NMR($CDCl_3$): 3.99τ (singlet, C_5H_5).] respectively.

The reaction of II with methylmagnesium iodide in tetrahydrofuran-benzene mixture gave air-stable orange red crystals of iodo-triphenylphosphine-π-cyclopentadienylmethyliridium [Yield 80%. Mp 233—236°C (decomp). NMR($CDCl_3$): 2.4—2.7τ (C_6H_5), 4.89τ (doublet, J_{PH} 1.5 Hz, C_5H_5), 8.37τ (doublet, J_{PH} 7 Hz, CH_3).]. The reaction of II with isopropylmagnesium bromide in the presence of carbon monoxide afforded triphenylphosphine-carbonyl-π-cyclopentadienyliridium[6] [Yellow crystals. Yield 18%. Mp 180—183°C. IR(Nujol): ν_{CO} 1925 cm^{-1}. NMR($CDCl_3$): 1.9—3.1τ (C_6H_5), 5.03τ (singlet, C_5H_5).] and in the presence of triphenylphosphine, ionic hydridoiridium complex of the formula, $[C_5H_5Ir(PPh_3)_2H]^+I^-$ [Colorless crystals. Yield 47%. Mp 194—198°C (decomp). IR(KBr): ν_{IrH} 2150 cm^{-1}. NMR($CDCl_3$): 2.4—3.0τ (C_6H_5), 4.60τ (singlet, C_5H_5), 24.4τ (triplet, J_{PH} 26 Hz, Ir–H).]. The last reaction differs from the cases of cobalt and rhodium analogues which gave bis(triphenylphosphine)-π-cyclopentadienyl-cobalt and -rhodium.[7]

Asymmetric Hydrogenation Catalyzed by Bis(dimethylglyoximato)cobalt(II)-Optically Active Amine Complex

Yoshiaki OHGO, Seiji TAKEUCHI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Meguro-ku, Tokyo

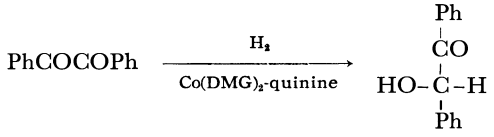
(Received November 11, 1970)

We reported that cyanocobalt - optically active amine complexes catalyze asymmetric hydrogenation.[1] It has been concluded that rigid conformational fixation and proximity of asymmetric grouping to the reaction center result in higher optical yield, but at the same time there is the drawback that the close and rigid grouping prevents coordination of substrate.

In order to overcome this, we sought a system in which a polyfunctional asymmetric substance bound to ligand could draw the substrate into the reaction center with a weakly attractive force.

On the other hand, it has previously been reported that bis(dimethylglyoximato)cobalt(II) complex, Co(DMG)$_2$, catalyzes hydrogenation of activated olefins, nitro-, azoxy-, and azo-benzenes, α-diketones, and α-keto carboxylic esters.[2,3] This complex has polar groups around the metal which are suitable for the binding of asymmetric substances. Thus we used this complex with quinine (polyfunctional, optically active substance) in the hydrogenation of benzil.

Catalytic hydrogenation was carried out at room temperature under atmospheric pressure of hydrogen. The reaction mixture was poured into water and extracted with benzene or ether. The organic layer was successively washed with water, hydrochloric acid, sodium hydroxide solution and water. The organic layer was concentrated *in vacuo* to give crystals which were characterized as benzoin by IR and NMR spectra. It was shown by gas-liquid chromatography and thin layer chromatography that the crystals contained no substantial contaminant. Optical yield was calculated from the specific rotation of the product and that of the optically pure benzoin. The results are shown in Table 1. In every case S(+)-benzoin was predominant.



From the Table 1 it can be seen that increase in the molar ratio of substrate to cobalt or base causes no decrease in optical yield. The benzoin recovered after the treatment of racemic benzoin under the same conditions as in run 6 was found to be optically inactive. This indicates that the asymmetric synthesis is not due to a quinine-catalyzed isomerization(favored in S(+)-isomer) of racemic benzoin, but to the asymmetric induction at the stage of catalytic hydrogenation. Stereoselectivity of the asymmetric hydrogenation was sensitive to the polarity of the solvent. The reaction in benzene afforded maximum optical yield(61.5%). So far, this optical yield is the highest for homogeneous metal complex-catalyzed asymmetric syntheses.[4] However, the asymmetric induction seems to occur through a mechanism different from our initial idea, *i. e.*, one equivalent of optically active amine is enough to bring about maximum asymmetric yield, and alkylcobalt complexes produced by the reaction of olefins with Co(DMG)$_2$-Base and hydrogen have trans structure.[2] Provided that the reduction of benzil proceeds through the same reaction mechanism as that of olefins, the reaction must take place at the trans site which can not interact directly with asymmetry of the base. This asymmetric reaction would be considered to be due to an induced asymmetry on the bis-dimethylglyoxime ring.

TABLE 1. ASYMMETRIC HYDROGENATION OF BENZIL CATALYZED BY Co(DMG)$_2$-QUININE[a]

Run	S/Co[b]	B/Co[c]	Solvent (ratio)[d]	Yield (%)	$[\alpha]_D$[e]	Optical Yield (%)
1	5	3	M	98.5	+10.3	8.7

Hydrolysis of *p*-Nitrophenyl(deoxyguanylyldeoxyguanosine Succinate) by Deoxyguanylyldeoxyguanosine *N*-Acetylhistidate on Polycytidylic Acid

Takeo SHIMIDZU* and Robert L. LETSINGER**

*Faculty of Engineering, Kyoto University, Kyoto

**Department of Chemistry, Northwestern University, Evanston, Illinois, U.S.A.

(Received December 4, 1970)

For a study of a chemical reaction on a macromolecule, it is important to make clear a shape of the interaction of a reactant onto the macromolecule. The interaction between polyribonucleotide and oligodeoxyribonucleotide is specific and selective, although the magnitude of the interaction varies with its condition. In the present study, the shape of the interaction was investigated through the hydrolysis of *p*-nitrophenyl (deoxyguanylyldeoxyguanosine succinate) (I) by deoxyguanylyldeoxyguanosine *N*-acetylhistidate (II) on polycytidylic acid, Poly C, (III).

I and II were synthetized from di-*p*-methoxytrityldeoxyguanosine dimer.[1] I contained 1.2 *p*-nitrophenyl group per molecule and II contained 0.9 imidazolyl group per molecule.

Figure 2 shows the hydrolyses of I by II with poly C and without poly C. The hydrolysis rate, R, was

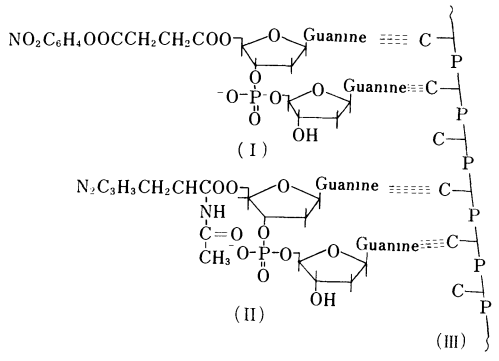

Fig. 1. Schematic diagram showing the hydrolysis of I by II on III.

1) T. Shimidzu and R. L. Letsinger, *J. Org. Chem.*, **33**, 708 (1968).

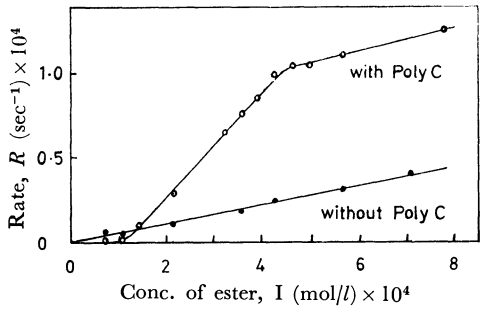

Fig. 2. Hydrolysis rates of I by II with and without Poly C.
○: presence of Poly C; 0.35×10^{-3} mol/l
●: absence of Poly C
0.01 M $MgCl_2$, 0.0001 M $Mg(OAc)_2$ pH=7.9; 5°C;
EtOH : H_2O = 1 : 100
I and II are the same concentrations.

defined as the increase of the hydrolyzed *p*-nitrophenol residue concentration per unit concentration of histidyl group, at the initial stage of the hydrolysis; R= [*p*-nitrophenol]/[*N*-acetylhistidine in II]·t.

The hydrolysis does not occur when the ratio of I and II to poly C is less than 0.2, but it increases linearly with the ratio exceeding 0.3. When the ratio is over 1.3, the rate increasing with I in the presence of poly C is parallel to that in the absence of poly C.

It can be concluded that the interaction between the dinucleotide derivatives and poly C is statistically homogeneous at lower concentrations, so that the distance of two dinucleotide derivatives widens and no reaction takes place, and also that the shape of the interaction becomes heterogeneous with increase of the concentration of the dinucleotide derivatives so that the reaction takes place because of a successive lining up.

Photochemical Reactions of Phenanthraquinone with Hydrogen Donors. An Investigation of the Reaction by CIDNP Method

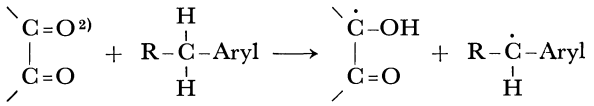
Kazuhiro MARUYAMA, Heisaburo SHINDO,* and Tetsuo MARUYAMA*

Department of Chemistry, College of Liberal Arts and Science, Kyoto University, Kyoto

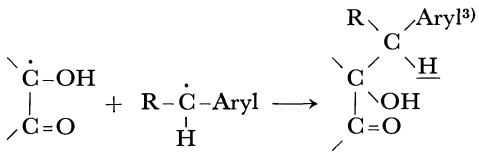
**Japan Electron Optics Laboratory, Akishima, Tokyo*

(Received December 5, 1970)

The rate of hydrogen abstraction by α-dicarbonyl compounds in triplet state is usually too fast for the observation of intermediate radicals by means of ESR technique. In order to make direct confirmation of the contribution of radicals in the photochemical reaction between phenanthraquinone and hydrogen donors, CIDNP (chemically induced dynamic nuclear polarization) technique[1] was applied. During the course of irradiation a strongly enhanced proton NMR absorption signal was observed at the methylene group region of photo-adduct. This is due to the secondary recombination process of two different intermediate radicals resulting from the primary hydrogen abstraction reaction by photo-excited phenanthraquinone triplet state as shown in the following:



(primary hydrogen abstraction process)



(secondary recombination process)

Phenomena of such an enhanced NMR absorption signal were observed during the course of irradiation in the following systems: phenanthraquinone and toluene (enhanced signal at τ: 7.10), phenanthraquinone and ethylbenzene (enhanced signal at τ: 7.10), and phenanthraquinone and diphenylmethane (enhanced signal at τ: 5.92). When irradiation was stopped, the enhanced signal disappeared immediately. Thus, the contribution of radical species in the hydrogen abstraction reaction of photo-excited α-dicarbonyl compounds was directly confirmed.

General procedures: Phenanthraquinone, dissolved into a hydrogen donor as solvent, was irradiated in a rotating NMR sample tube fitted with a light guide with a 500 W high pressure Hg lamp from above. Light was collected by a quartz lens before irradiation, and focused at the light guide. The light guide is a simple quartz tube coated on the in ner side with an aluminum metal. Oxygen dissolved into a sample was expelled by passing nitrogen. Assignment of a signal observed to the photo-adduct was carried out by comparison with that of the authentic sample, prepared by photochemical reaction of phenanthraquinone with a hydrogen donor on a larger scale. 60 MHz NMR spectrometer manufactured by JEOL was used.

The Crystal Structure of *cis*-Dichlorobis(2,2′-dipyridyl)cobalt(III) Tetrachlorocobaltate(II), *cis*-[Co Cl_2 dip_2]$_2$[Co Cl_4]

Masayuki HINAMOTO, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received December 10, 1970)

In 1936 Jaeger prepared a green-colored cobalt(III) complex,[1] [Co Cl_2 dip_2]Cl, whose cation has been believed to have a structure analogous to that of *trans*-[Co Cl_2 en_2]$^+$,[2] the two dipyridyl molecules being coplanar. A coplanar disposition of dipyridyl molecules, however, has never yet been found, not even for any of the bis-dipyridyl copper(II) complexes,[3-6] in which the dipyridyl molecules are most likely to be on a plane. This is attributable to the steric interference between the two dipyridyl molecules in this arrangement. Therefore, the structure of Jaeger's green cobalt complex is of much interest with respect to the disposition of the chelating ligands.

The crystals obtained by Jaeger's method[1] were too thin for X-ray work. Vlček found another way of preparing this compound.[7] The crystals of a suitable size were obtained following the latter method. However, none of the definite formulae, such as [Co Cl_2-dip_2]Cl, were compatible with the values of elemental analyses (C, 43.31; N, 10.00; H, 3.19%).

The crystal data were as follows: monoclinic, $a=21.22$, $b=14.11$, $c=7.36$ Å, and $\beta=98.3°$; the space group was $P2/n$. Z was assumed to be four. Multiple-film equi-inclination Weissenberg photographs, $hk0$-$hk5$, were taken with Ni$K\alpha$ radiation. The intensities of 1684 reflections were estimated visually, and the usual corrections were applied. The crystal structure was determined by the conventional Patterson and Fourier techniques and refined to an R factor of 0.136 by block-diagonal least-squares method, using isotropic thermal parameters.

It was established that the green crystal does not contain the *trans*-[Co Cl_2 dip_2]$^+$, but is composed of *cis*-[Co Cl_2 dip_2]$^+$ and [Co Cl_4]$^{2-}$ in a ratio of 2:1. The results of elemental analyses are consistent with the formula of *cis*-[Co Cl_2 dip_2]$_2$[Co Cl_4].[8] The crystal structure is shown in the figure. The geometry around the Co(III) atom is similar to that in *cis*-[Co Cl_2 en_2]$^+$[9] and in *cis*-[Co Cl_2 $phen_2$]$^+$.[10]

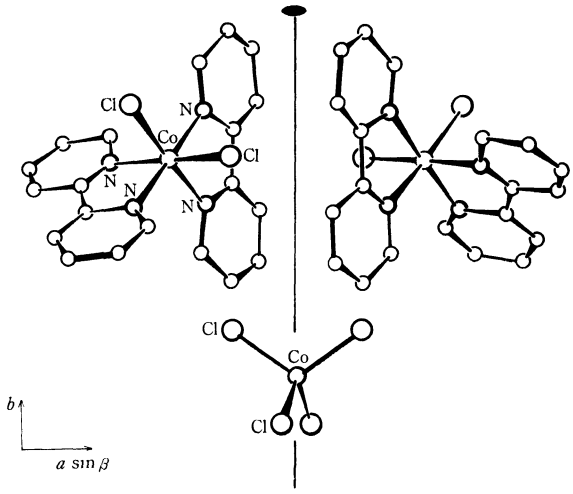

Figure. The crystal structure viewed along the c-axis.

The corresponding bond lengths and angles agree well with one another within the limits of experimental error; the values used below are averages. The Co(III)–Cl bond, 2.23 Å, compares well with those in the above complexes. In the chelate ring, ∠N–Co–N and ∠Co–N–C are 81.3° and 122.7° respectively. Both of the dipyridyl molecules are almost planar, the two pyridine rings twisting slightly to each other (~5°).

[Co Cl_4]$^{2-}$ is almost tetrahedral. Co(II)–Cl is 2.28 Å, which is consistent with that found in [$N(CH_3)_4$]$_2$[Co-Cl_4] (2.280 Å).[11]

The X-Ray Emission Spectra of the Compounds of Third-period Elements. I. The *K* Spectra of Chlorine in Compounds

Yoshihito TAKAHASHI

Government Industrial Development Laboratory, Hokkaido, Higashi-Tsukisamu, Sapporo

(Received March 15, 1970)

On chlorine gas and several oxysalts of chlorine, the values of the wavelength shift of Cl$K\alpha_{1,2}$ lines and the spectra of Cl$K\beta$ lines were measured. We thus verified our assumption that the $K\beta'$ line results from the bias of valence electrons from the atom of the third-period element to the oxygen atom in the oxyanion; this can be explained in terms of the relationship between the chemical structure and the Cl$K\beta$ spectrum of the hypochlorite ion. The relationship between the relative intensity of the $K\beta'$ line and the wavelength shift of the $K\alpha_{1,2}$ lines was linear, just as in the cases of oxygen-sulfur compounds.

In previous papers, we reported our studies of the wavelength shifts of S$K\alpha_{1,2}$ lines and the shapes of the S$K\beta$ band spectra in many sulfur compounds.[1-3] It was found that a linear relation exists between the relative intensity of the S$K\beta'$ satellite line and the wavelength shift of the S$K\alpha_{1,2}$ lines in the spectra of oxygen-sulfur compounds. We think that this relationship offers a key for the assignment of the $K\beta'$ satellite line, which we have not yet been able to decide clearly. Therefore, in order to ascertain the generality of this relationship, we intend to extend our investigation to other elements of the third-period. In this paper, we will report on the $K\beta$ spectra of several chlorine compounds, particularly on the character of the $K\beta'$ line.

Recently, Best investigated the Cl$K\beta$ spectra of some oxysalts of chlorine.[4] Schnell measured the Cl$K\beta$ spectra on several chlorine compounds.[5] LaVilla and Deslattes measured the $K\beta$ spectra on some gaseous chlorine compounds.[6] On hypochlorite and chlorine gas, though, the *K* spectra have not yet been examined.

Experimental

The apparatus was the same as that described in previous papers.[1,3] A Machlett Wolfram target X-ray tube OEG-50 was operated at 40 kV, 40 mA. A flat, germanium analyzing crystal (2d: 6.53272 Å) was used. The helium path was maintained using a flow of 1.5 *l*/min at ordinary pressure. For the measurement of the spectrum of chlorine gas, a gas-sample cell was used.[7]

The wavelengths of the $K\alpha_{1,2}$ lines were measured as follows: the X-ray intensities were counted for a minute at intervals of $1'(2\theta)$; then, after drawing the spectral curve, the position of the line was decided as the maximum intensity position (the average of triplicates). In actual measurement, the wavelength shifts from the Cl$K\alpha_{1,2}$ lines of sodium chloride were measured. The absolute wavelength value of the Cl$K\alpha_{1,2}$ lines of sodium chloride was decided by comparison with the third-order line (4.62150 Å) for Cu$K\alpha_1$. The spectrum of the $K\beta$ lines was obtained as follows: the X-ray intensities were measured of a minute at intervals of $3'(2\theta)$, and then, after the substraction of the background (X-ray intensity at 4.54 Å), these intensities were plotted against the wavelength. Each spectrum was made on the same scale at the maximum intensity.

The separation of the $K\beta$ spectrum into several peaks was done as follows: 1) assuming that the $K\beta$ spectrum of sodium chloride can be taken as the standard shape of the C peak in Fig. 1, 2) to separate the C peak from each spectrum, this curve was superposed on the highest peak of each spectrum; 3) the A and D peaks were separated by the subtraction of C peak from the original spectrum. By the way, Best had reported in his paper the presence of a $K\beta_x$ satellite line at the short-wavelength side of the $K\beta_1$ line in the spectrum of sodium chloride,[4] but we could not separate them. Therefore, the present method might have a chance of mistakes in the separation of the D peak from the spectrum, but for the A peak ($K\beta'$ line) there can be no mistake.

A solution sample of sodium hypochlorite was prepared as follows: 1) to eliminate impurities (mainly chloride), a mixture of some higher bleaching powder and a small amount of cooled water was slowly stirred for ten or more minutes, and subsequently filtered. 2) The precipitate was dispersed into water and then, after about 30 min, filtered. 3) The filtrate was converted into a solution of sodium salt. The sample prepared by this method contained 0.80M hypochlorite and 0.09N chloride (impurity). After X-ray irradiation for two hours, the sample lost 5 percent of the hypochlorite and the equivalent amount of chloride was increased.

Results

In Fig. 1a—f, we show the Cl$K\beta$ spectra of the element and five compounds. The shapes of the spectra are similar to those of sulfur compounds which show a corresponding chemical structure, *i. e.*, chloride to inorganic sulfide, chlorate to sulfite, and perchlorate to sulfate, respectively. The characteristic values of the Cl$K\alpha_{1,2}$ lines and Cl$K\beta$ lines of the element and five compounds are listed in Table 1. In order to compare these data with the data of sulfur compounds, the directly-measured values of the energy shift in the $K\alpha_{1,2}$ lines of sodium chloride were converted to those of the element (Cl_2 gas). The intensity ratio of the $K\beta'$ line is defined as the ratio of the area of the $K\beta'$ line (the A peak in Fig. 1) to the total area of the $K\beta$ lines in the spectrum. A linear relationship exists between the

intensity ratio of the $K\beta'$ line and the energy shift of the $K\alpha_{1,2}$ lines,[8] as is shown in Fig. 2.

Discussion

On the intensity ratio of the Cl$K\beta'$ line of the perchlorate, our value (sodium salt) is 0.37, but Best's (potassium salt) is 0.225,[4] in terms of the present definition. Under X-ray irradiation, potassium per-

chlorate was decomposed to chloride,[12] and so its $K\beta'$ ratio was rapidly lowered, as is shown in Fig. 3. Moreover, his sample was placed in a vacuum; this might have caused the more rapid decomposition in his measurements. We adopted only the value of sodium salt.

In the previous paper,[3] we reported that the relative intensity of the $K\beta'$ line increased as the number of the valence electrons of the sulfur atom decreased. Therefore, we now presume that the $K\beta'$ line occurs as a result of the bias of valence electrons from the atom of the third-period element to the oxygen atom in the oxyanion. In the Cl$K\beta$ spectrum of a hypochlorite solution, the $K\beta'$ line is little observed; nevertheless, the oxygen atom is present in its molecule (see Fig. 1d). This result is explainable on the basis of the chemical structure of the hypochlorite ion ($Cl-O^-$) and our presumption relating to the occurrence of the $K\beta'$ line. That is, in this oxyanion, 1) the chlorine atom is combined with a oxygen atom by a single bond. The electron-inductive effect of the oxygen atom in a single bond is less than that of the oxygen atom in a double bond, and 2) the difference in the electronegativity between the oxygen atom (3.5) and the chlorine atom (3.0) is small. Moreover, the force of the electron attraction of the oxygen atom becomes weakened as a result of the acceptance of electrons from the sodium atom to the oxygen atom. Therefore, the valence electrons of the chlorine atom will be little attracted by the oxygen atom (indeed, the energy shift of Cl$K\alpha_{1,2}$ lines of this sample was small, if present at all). Consequently, from the above presumption, it may be concluded that the $K\beta'$ line occurs to only a small extent in the spectrum of hypochlorite. The above explanation serves to verify the assumption relating to the occurrence of the $K\beta'$ line.

For further discussion, we show the relationship between the relative intensity of the $K\beta'$ line and the energy shift of the $K\alpha_{1,2}$ lines for chlorine compounds in Fig. 2, and that for sulfur compounds,[3] in Fig. 4. To our surprise, the two relationships are expressed by the same straight line. From the fact that the straight line runs near the point of origin, there might be no other dominant factor which contributes to the occurrence of the $K\beta'$ line other than the energy shift of the $K\alpha_{1,2}$ lines, namely, the effective charges of the atom. From the equality of the gradient of the two lines, we cannot but think that the gradient of the line is determined by neither the sulfur atom nor the chlorine atom, but only by the oxygen atom, in oxygen-compounds. Nefedow claimed in his paper that, on the compound of the third-period element having second-period elements, the $K\beta'$ line was related to the electron transition from the molecular orbital to the $1s$ state of the third-period element, that this molecular orbital could virtually be regarded as the $2s$ orbital of the second-period element.[13] Our results seem to be consistent with his deduction.

The Chemisorption of Nitric Oxide and Nitrogen on Rhenium

Teijiro TAMURA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received May 16, 1970)

The chemisorption of nitric oxide and nitrogen on a polycrystalline rhenium filament was studied using flash-desorption mass spectroscopy. For the chemisorption of nitric oxide, the initial sticking probability was found to be close to unity, with a saturation coverage of 5.2×10^{14} molecules/cm^2 at room temperature. Nitric oxide adsorbs nondissociatively, and dissociation occurs at an elevated temperature. The rate of the desorption of nitrogen from the nitric oxide layer is roughly proportional to θ^2. The majority of the oxygen in the nitric oxide layer was presumed to be liberated as rhenium oxide. The nitrogen adsorption was investigated in order to compare it with the nitric oxide adsorption. The saturation coverage and the initial sticking probability were 1.08×10^{14} molecules/cm^2 and 0.003 respectively.

Studies of the chemisorption of gases on metal surfaces are useful in deducing the mechanism of chemical reactions between gas and metal. Many studies in this field have been reported, and, recently, more useful information has been provided by such modern techniques as the method of flash filament, isotopic mixing, F.E.M., F.I.M., and L.E.E.D.[1-3]

Extensive studies of the chemisorption of gases on tungsten have been made,[4-19] but there have been only a few studies of rhenium.[20-26]

Although there is a general similarity between the physical properties of tungsten and rhenium, particularly in their very high melting points, there are some marked differences in their chemical properties;[27] for example, tungsten can form stable carbides and nitrides, while rhenium can not.

It is of interest to determine whether or not chemisorbed nitric oxide molecules are dissociated to form adsorbed atomic species, and what changes occur by flash desorption.

In the present investigations, the chemisorption of nitric oxide on rhenium has been studied using flash desorption mass spectroscopy. The saturation coverage of nitric oxide on rhenium was about one-third of that on tungsten, but the initial sticking probability was very high compared with that of other gases (its value was close to unity). The desorption of nitric oxide as molecules was negligibly small; the majority of the nitric oxide was decomposed and evaporated as nitrogen, oxygen, and rhenium oxide molecules when the rhenium temperature was raised.

Apparatus

The apparatus is shown schematically in Fig. 1. The reaction system, including the omegatron mass spectrometer, the Bayard-Alpert ionization gauge (B–A gauge), and the Pirani gauge, was all made of glass. The reaction vessel with a volume of $V=0.8\ l$ contained a rhenium filament with a geometrical area of $A=0.6$ cm^2. The rhenium filament was analyzed spectroscopically. (Found; Si:0.02%, Fe:0.008%, Mg: 0.005%.) The system was pumped through a greaseless valve with an ion pump. After a rigorous outgassing of all parts of the system, the ultimate pressure, as read with the B–A gauge, was 3×10^{-10} Torr. The omegatron mass spectrometer was operated in a magnetic field of 3600G with a variable r. f. generator driven by a synchronous motor. The ion currents were measured with a high-sensitivity electrometer (TAKEDA RIKEN TR-81). The mass spectrum was recorded on a chart recorder with a 0.8 sec full-scale response. Under the conditions employed, the 28—30 masses were completely resolved, the sensitivities were taken to be 12 Torr^{-1} for N_2 (mass 28) and 11.8 Torr^{-1} for NO (mass 30). The omegatron was also used to measure the partial pressure as a function of the time in slow-flash experiments. This was done by recording the

time variation of the ion current at a constant r.f. corresponding to a particular mass peak.

The Pirani gauge was used to measure the total pressure; it has a sensitivity of 7.2×10^{-8} Torr/μV for N_2 and NO. The B–A gauge was used only to measure the ultimate pressure; it was not operated during the actual experiments.

The rhenium filament could be flashed rapidly (within 1 sec) to 2200°K for rapid desorption experiments or slowly to 2000°K, with an approximately linear sweep rate of 20°/sec, for slow desorption experiments, by means of a controllable DC power supply. The temperature of the filament was determined from the resistance using the published values of the resistance-temperature relationship for rhenium,[28] above 1000°K, its temperature was also measured with a micro optical pyrometer.

The nitric oxide was prepared by dropping sulfuric acid into a mixed solution of potassium nitrate and potassium iodide. The gas thus evolved was passed through a concentrated caustic potash solution and a dry ice trap, was purified by liquid nitrogen trap-to-trap distillations, and was finally stored in a 1 *l* gas reservoir.

The nitrogen was prepared by the thermal decomposition of barium azide, labeled extra pure, and was introduced into a gas reservoir through the liquid nitrogen trap and stored there without further purification. No impurities up to mass 200 were detected by means of the omegatron mass spectrometer.

Procedure

Amount of Adsorption. In order to burn off any possible carbonaceous surface contamination prior to the adsorption experiments, the rhenium filament was heated to about 2000°K in oxygen of 1×10^{-6} Torr for several hours. When the rhenium filament is heated at high temperature in a nitric oxide atmosphere, rhenium oxide is formed on the surface. Therefore, the conventional flash-filament method[1,2,5,10] can not be used. To avoid this difficulty, the rhenium filament was flashed in a vacuum to clean it and then allowed to cool to room temperature. The leak-valve was opened to give a suitable exposure of the nitric oxide, and the pressure was recorded, by means of the omegatron or Pirani gauge, as a function of the exposure time. The number of nitric oxide molecules that strike the filament during the exposure can be calculated from the pressure-*vs.*-time curve. After the leak-valve was closed, the system was evacuated until the nitric oxide pressure dropped to 5×10^{-9} Torr. The system was then separated from the evacuating system by means of the greaseless valve, and the rhenium filament was flashed at 2200°K in the closed system. The amount of molecules desorbed can be calculated from the pressure and the volume of the system. In the case of the adsorption of nitric oxide, the number of molecules adsorbed is twice the number of molecules desorbed, because the desorbed gas is nitrogen.

Desorption Spectra. Nitric oxide or nitrogen, at a desired pressure, was streamed over the rhenium filament by adjusting the leak-valve. After the desired exposure time had passed, the leak-valve was closed and the system was evacuated. When the pressure dropped to 5×10^{-9} Torr, the slow desorption runs were initiated by using a controllable DC power supply. At that time, ion currents of the omegatron mass spectrometer for each mass were recorded on the chart recorder as a function of the time. The desorption spectra were obtained for each chemical species; they are shown in Fig. 6.

Results and Discussion

Sticking Probability and Amount of Adsorption. The number of molecules of nitric oxide that strike

28) C. T. Sims, C. M. Craighead, R. I. Jaffee, D. N. Gideon, E. N. Wyler, F. C. Todd, D. M. Rosenbaum, E. M. Sherwood, and I. E. Campbell, "Investigations of Rhenium," Battle Memorial Institute, Wright Air Development Center Technical Report 54—371, June (1954), p. 47.

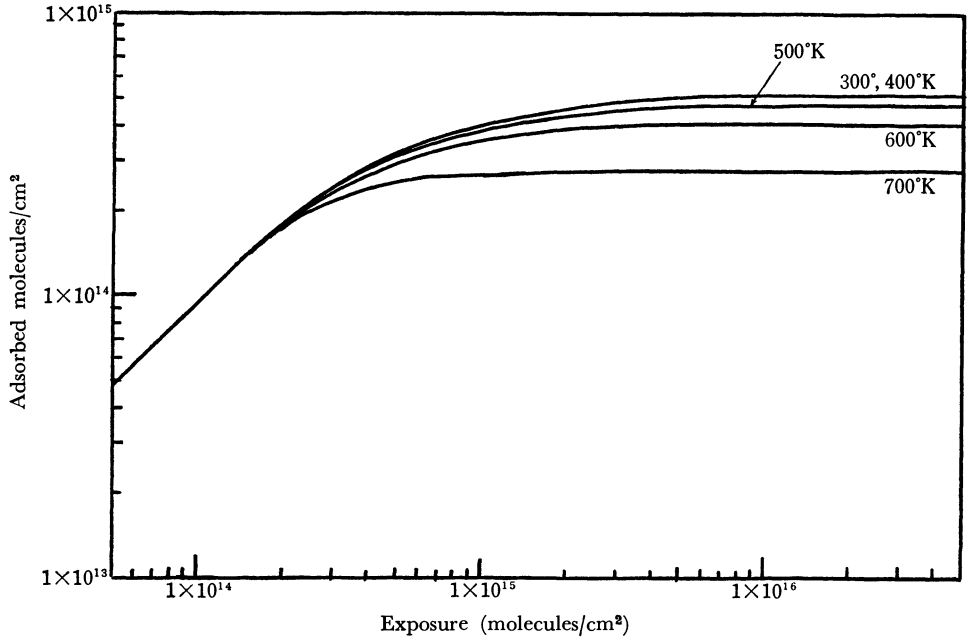

Fig. 2. Surface coverage as a function of exposure.

the filament during the adsorption process, $N_{(e)}$, is calculated from the recorder trace of the omegatron, while the number of molecules adsorbed, N, is obtained by rapid flashing into the closed system, as has been described above. The relation between the number of molecules colliding with the filament at various temperatures and those adsorbed is shown in Fig. 2. The saturation coverage (θ=1) of nitric oxide was 5.2×10^{14} molecules/cm² at 300°K, about one-third of that on tungsten (1.4×10^{15} molecules/cm²).[17] When the rhenium temperature was increased, the saturation coverage of nitric oxide decreased, as Fig. 2 shows. Assuming that the number of metal surface atoms is 1.5×10^{15} atoms/cm², these are equivalent to a Re: NO ratio of about 3:1 and to a W:NO ratio about 1:1. It seems that a considerable number of bare sites exist on rhenium, even for the full coverage of the nitric oxide adsorption.

From the curve in Fig. 2, the sticking probability, s, can be calculated by means of the following equation:

$$s = \mathrm{d}N/\mathrm{d}N_{(e)}.$$

The dependence of the sticking probability on the coverage at various temperatures is shown in Fig. 3. The initial sticking probability is close to unity. Such a high value has not been seen for other gases.[20-22,25,26] Therefore, the Re-N_2 system was studied by the same method for the sake of comparison. The saturation coverage of nitrogen on rhenium was 1.08×10^{14} molecules/cm², this value agreed well with the previously-reported values, 1.5×10^{14} molecules/cm² at 291°K,[21] 7×10^{13} molecules/cm² at 300°K,[20] and 8.9×10^{13} molecules/cm² at 300°K.[26] The initial sticking probability was 0.003; this also agreed well with the previously-reported values of 0.0024[21] and 0.0022,[26] but it differed from that of 0.009.[20] This difference can be accounted for by differences in the polycrystalline wires used.

The results obtained by the usual method, using the flash desorption at a constant flow rate,[10] also agreed well with those of the present method.

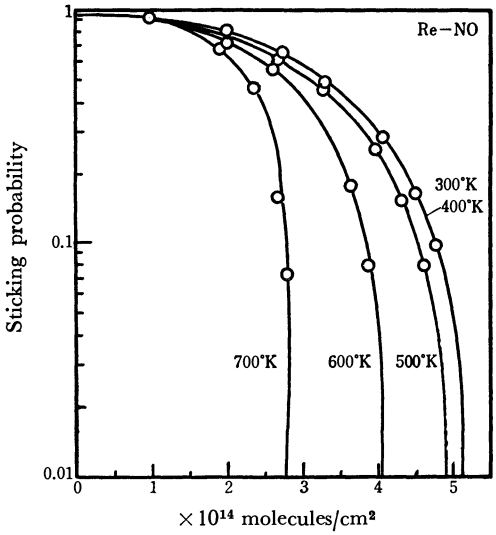

Fig. 3. Sticking probability as a function of surface coverage.

The saturation coverage of nitric oxide is 4.8 times as much as that of nitrogen on the same rhenium. This ratio agrees well with that on tungsten.[17] However, the saturation coverage on rhenium is smaller than that on tungsten.

The initial sticking probability of the nitric oxide adsorption is very high compared with the nitrogen adsorption on rhenium. We consider that one of the reasons for such a high value is probably that the electron in the nitric oxide molecule transfers easily to the vacant *d*-orbital in rhenium, because the ionization potential of nitric oxide (9.5 eV) is lower than that of nitrogen (~16 eV).[29]

29) R. B. Heslop and P. L. Robinson "Inorganic Chemistry," Elsevier Pub., Co., New York (1960), p. 319.

Rates of Adsorption and Desorption. At various combinations of the pressure of nitric oxide and the exposure time needed to obtain the same exposure, it was found that the amounts of adsorptions were always the same. These results show that the rate of adsorption depends on the first-power of the pressure. The rate of adsorption at a constant pressure and temperature may, then, be expressed as:

$$dN/dt = K \cdot P(1-\theta)^n,$$

where K and n are constants and where P is the nitric oxide pressure.

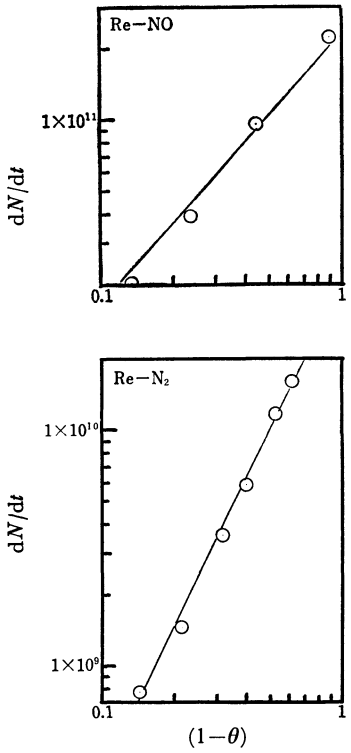

Fig. 4. The relation between the rate of adsorption and $(1-\theta)$.

For the nitric oxide and the nitrogen adsorption at a constant pressure and 300°K, the dependence of the rate of adsorption on the vacant site, $(1-\theta)$, is shown in Fig. 4. On the nitric oxide adsorption, it was found that the rate of adsorption was proportional to $(1-\theta)$ for surface coverages between 0.1 and 0.8. This indicates that the nitric oxide molecules are adsorbed non-dissociatively on rhenium. On the nitrogen adsorption, it is shown that the adsorbed nitrogen exists dissociatively, because the rate of adsorption was proportional to $(1-\theta)^2$.

When the adsorbed nitric oxide or nitrogen is desorbed at a definite temperature in the closed system, the rate of desorption may be simply written as:

$$-dN/dt = K'\theta^{n'},$$

where K' is a rate constant of the $K'=\nu\exp(-E/\boldsymbol{R}T)$ form and where n' is the order of the desorption. In the Re-NO system, the nitric oxide is decomposed with a rise in the rhenium temperature and is desorbed as nitrogen. The relation between the rate of desorption and the surface coverage is shown in Fig. 5. As

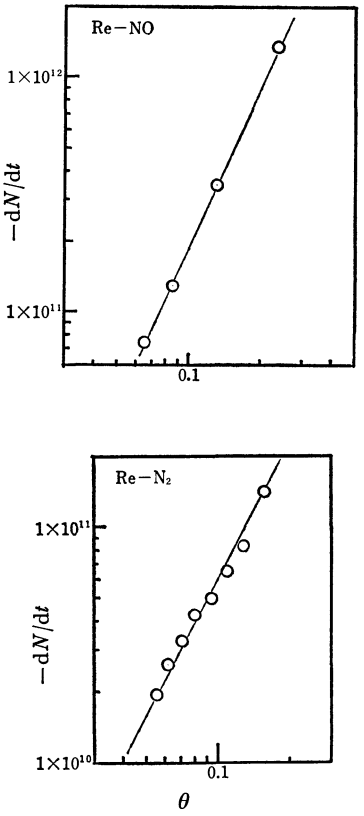

Fig. 5. The relation between the rate of nitrogen desorption and θ.

can be seen, the rate of the desorption of nitrogen from both nitric oxide and nitrogen layers is roughly proportional to θ^2. At such high temperatures, the re-adsorption can be neglected.

Desorption Spectra. *1) Desorption from a Nitric-oxide Monolayer on Rhenium*: For the saturation coverage of nitric oxide, the desorption spectra are shown in Fig. 6. The evolution of nitric oxide (mass 30) begins at about 350°K. The temperature of the desorption-peak maximum was about 450°K, and above 900°K no further desorption of nitric oxide was observed. The amount of nitric oxide desorbed corresponds to about 0.5% of the total amount of nitric oxide at saturation coverage.

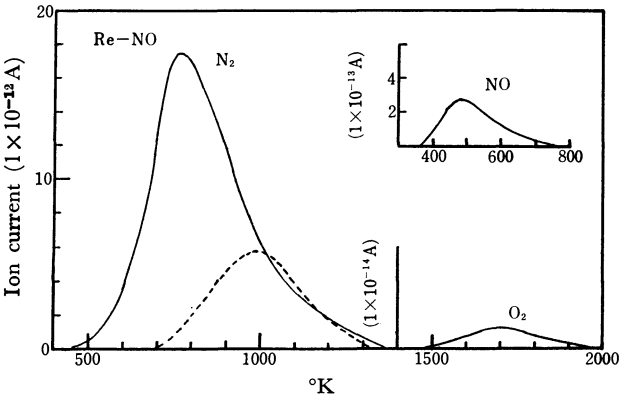

Fig. 6. The desorption spectra from a nitric oxide monolayer on rhenium.
Dashed curve denotes nitrogen from nitrogen monolayer.

For the desorption of nitrogen from a nitric oxide monolayer, the temperature at which the desorption rate was at its maximum, T_p, was 775°K, and the greater part of the nitrogen was desorbed before the temperature reached to 1300°K. The T_p of nitrogen desorption from a nitric oxide monolayer is lower than that from a nitrogen monolayer by about 200°K.

The oxygen desorption was seen at a considerably high temperature, and the T_p of oxygen was about 1700°K. The amount of oxygen desorbed was relatively small. From these results, it seems that the majority of the oxygen from nitric oxide evaporates as rhenium oxide.

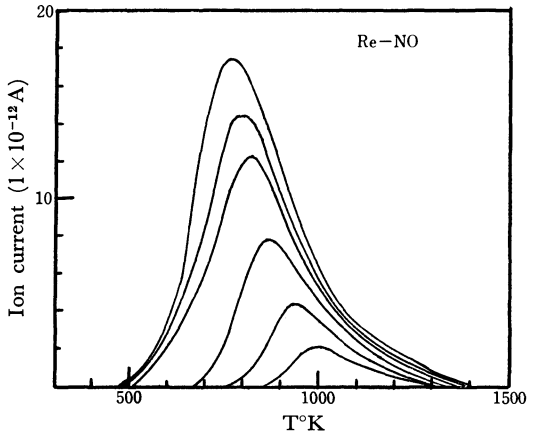

Fig. 7. The desorption spectra from various initial coverages of nitric oxide.

2) Desorption of Nitrogen from a Partial Coverage of Nitric Oxide on Rhenium: The nitrogen desorption spectra for various initial coverages of nitric oxide ($\theta\simeq0.1$—1.0) at 300°K are shown in Fig. 7. The T_p of the nitrogen desorption monotonously shifts to higher temperatures with a decrease in the coverage. On the chemisorption of nitric oxide on tungsten, a retrograde behavior of T_p above $\theta=0.8$ was observed in the nitrogen desorption spectra, and two ω mode peaks (ω_1, ω_2) were observed in the desorption spectrum.[17] However, no such behavior was observed for the nitric oxide adsorption on rhenium. Yates *et al.*[17] state that vacant sites are necessary for the decomposition of nitric oxide on tungsten. If this assumption is true, the fact that a retrograde T_p behavior was not found on rhenium at a high coverage can be understood from the fact that the vacant sites already existed on the rhenium surface, as has been mentioned above.

The desorption spectra from the very low coverages of nitric oxide on rhenium resemble those from the very low coverages of nitrogen. This behavior is reasonable, since the dissociation of nitric oxide at a very low coverage and at an elevated temperature would produce a dilute layer of adsorbed nitrogen and oxygen; the desorption of nitrogen should, under these conditions, be uninfluenced by the small oxygen coverage. Therefore, the processes of adsorption, dissociation, and desorption may be simply expressed as follows:

$$NO_{(g)} \longrightarrow NO_{(a)} \quad (1)$$

$$NO_{(a)} \longrightarrow N_{(a)} + O_{(a)} \quad (2)$$

$$2N_{(a)} \longrightarrow N_{2(g)} \quad (3)$$

Equations (2) and (3) show the reactions during the heating process. We consider that the rate of the process (2) is faster than that of the process (3), since the rate of nitrogen desorption is roughly proportional to θ^2.

3) Desorption of Nitrogen from a Nitrogen Layer on Rhenium: Although studies of the nitrogen adsorption of rhenium had previously been made,[20,21,26] the present experiments were carried out to compare it with the nitric oxide adsorption. An α state was not found in the nitrogen desorption spectra from the nitrogen layer. This result agreed with that of Yates *et al.*[26] Although the β state from nitrogen layer on tungsten was separated into two states, β_1 and β_2,[11,13,15,16] the β state from the nitrogen layer on rhenium was only one state (corresponding to β_2); this finding agreed with those of other papers.[20,21,26] Since the desorption energy of nitrogen on rhenium is lower than that on tungsten, the binding force with rhenium may be said to be weaker than that with tungsten.[26] Therefore, it seems that the β_1 (weaker than β_2) adsorption may not occur; the lack of a β_1 state may be a reason why many vacant sites remain on rhenium for the nitric oxide adsorption compared with those on tungsten.

Summary

1) The saturation coverage of nitric oxide on rhenium is 5.2×10^{14} molecules/cm^2, and the sticking probability is close to unity in the initial stage of adsorpion at room temperature.

2) Nitric oxide adsorbs nondissociatively on rhenium at room temperature. The rate of adsorption is proportional to $(1-\theta)$.

3) As the rhenium temperature is increased, the saturation coverage of nitric oxide decreases.

4) The evolution of nitric oxide (mass 30) begins at about 350°K, and the amount of nitric oxide corresponds to about 0.5% of the saturation coverage.

5) The rate of the desorption of nitrogen from a nitric oxide layer is proportional to θ^2.

6) The T_p of nitrogen desorption from a nitric oxide monolayer is lower than that from a nitrogen monolayer by about 200° as a result of the interactional effect in the adsorbed layer of oxygen.

7) A small fraction of the oxygen from the nitric oxide layer desorbs above 1500°K as molecules; it seems that the rest of the oxygen evaporates as rhenium oxide.

8) At a high coverage of nitric oxide, the retrograde behavior of T_p for nitrogen desorption is not observed.

9) At a very low nitric oxide coverage, the desorption spectra resemble those from a very low coverage of nitrogen.

10) The saturation coverage of nitrogen on rhenium is 1.08×10^{14} molecules/cm^2, and the initial sticking probability is 0.003 at room temperature.

11) Nitrogen adsorbs dissociatively at room temperature. The rate of adsorption is proportional to $(1-\theta)^2$.

12) For nitrogen adsorption at room temperature, an α state is not found, and the β state is only one state.

The author wishes to express his deep thanks to Professor Takuya Hamamura of this Institute, to Professor Kumasaburo Kodera and Dr. Masaru Onchi of Kyoto University for their kind discussion and encouragement, and to Dr. Minoru Ozasa of the Matsushita Electronics Corporation, who made the spectroscopic analysis of rhenium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 595—599 (1971)

Inter and Intramolecular Charge and Excitation Transfer Observed in Irradiated Polyvinyl Chloride Particles with Surface-coated Additives

Hisashi UEDA and Dairokuro YASHIRO

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received May 27, 1970)

Particles of polyvinyl chloride were coated with small amounts of various aromatic compounds from benzene solutions and were then irradiated in a vaccum. The ESR spectra of the specimen thus obtained were recorded. Though the amount of the coated additives, in the ratio of 1 molecule for 100 monomer units of PVC, was small, strong effects on the ESR spectra were observed. The additives coated on the surface affect the ESR spectra in two ways. They cause a decrease in the total ESR absorption intensity; this was observed with all the additives studied. They also often transform the ESR spectrum; this was observed with several additive compounds, such as *p*-benzoquinone, tetramethylphenylenediamine-2·HCl, chrysene, hydroquinone, nitrosonaphthol, perylene, and diphenylpicrylhydrazine. Only the conduction of the excitations, holes and electrons formed in the bulk particles, to the surface of the particle can explain these results. On the surface of the particle, the excitation or the electric charge is transferred to the additive by means of an intermolecular interaction with it. The possibilities for the mechanism of the conduction of the excitation and the electric charges, and the ionization processes are discussed.

Ueda and his co-workers studied the ESR spectra of γ-irradiated polyvinyl chloride (to be abbreviated as PVC) and their trans-formations in the presence of various gases.[1-5] Some of the anomalies observed in these transformations were ascribed to free radical transformations. In the past decade, much evidence for ionic processes has been found for the systems including alkyl halide-aromatic hydrocarbon solutions in both the solid and liquid phases.[6-10] It seems quite obvious, however, that free radical interpretations do not wholly account for the observed phenomena.[5] Therefore, it is necessary to reinvestigate the ESR of irradiated PVC from a different point of view.

The results of the kinetic studies of the pulse radiolysis of the alkyl halide-aromatic hydrocarbon solutions showed that only the "conduction theory" of the ions and possibly their precursors explains the kinetic data obtained. Therefore, it seems desirable to test further the possibilities of the conduction of the radiation-induced activated species across a particle of PVC.

The transient species generated in radiation-chemical systems are observed either by a quick-detection method or by trapping them in some stable forms. Many experiments have been done by trapping them in frozen rigid glass.[9,10] It has also been possible to trap them on porous solid surfaces. For this reason, we expected to find some stable ionic species on the surface of PVC which are trapped and stabilized at room temperature.

Experimental

The PVC powder used in this study was Vinychlon 4000L of the Mitsui Toatsu Chemical Co.; it contained no additives. The particle were all below 50 mesh in size. 0.500 g of PVC (8 mmol of $-CH_2CHCl-$ equivalent) and 0.08 mmol of additive were mixed, and then 2.0 m*l*, or more if needed, of benzene was poured onto it in order to dissolve the additive completely. The mixture thus prepared was kept in the air at room temperature under a dust cover to evaporate the solvent. The sample thus obtained, *i. e.*, the PVC particles coated with an additive, was placed in a spectrosil ESR sample tube; the tube was evacuated to 10^{-4} mmHg and then sealed off. Irradiation was made with 1.5 kCi ^{60}Co source to the dose of 6.65×10^4 rad (referred as D_1) and 7.315×10^5 rad (referred as D_2) at 20°C.

In this work, the number of unpaired electrons trapped in the specimen must be determined, together with their physical states. For this reason, the quantitative measurements were carried out as follows. A microwave output of 9V54 was attenuated to exactly 1/10, thus maintaining the same incident powder. The crystal current of the detector, 1N23C, was always adjusted to the same value, 0.08 mA, by adjusting the dielectric rod in one of the arms of the magic

tee. 100 kHz phase-sensitive amplifier was allowed to stand for at least three hours prior to use. The overall signal intensity was checked and calibrated by using standard specimens, such as dispersed charcoal in alumina powder sealed in a vacuum, and Mn^{2+} ions diluted with MgO.

Results

The intensities of the ESR absorption for D_1 are listed in Table 1. The paramagnetic species, which is observed in the PVC without any additive and which shows the ESR spectrum of Fig. 1a when irradiated to D_1 in a vacuum, is written as S·. The S· has been described as a free radical in the early literature,[1,2] but its true nature has not been known exactly. Its observed amount is written as r_0. The amount of S· obtained with the PVC with an additive at the same dose is written as r. The r/r_0 ratio is shown in Table 1. The amount of the species which is obtained at the dose of D_1, and which shows the ESR spectra shown in Figs. 1b and 1c, is written as r_+. The r_+/r_0 ratio is also shown in Table 1. The same values for D_2 are listed in Table 2. In Table 2, the spin concentration (divided by r_0) due to the species, which was unaffected by bleaching the sample in air, A^+-left, is also shown. In Figs. 1—3, the ESR spectra obtained from the PVC-perylene, PVC-hydroquinone, PVC-*p*-benzoquinone, PVC-α-nitroso-β-naphthol, and PVC-β-nitroso-α-naphthol specimens are shown. Figure 1b′ indicates that there are eight almost equivalent protons which interact with the unpaired electron. Figure 1c indicates that at the dose of D_2, the spectrum resembles Fig. 1a more than Fig. 1b (see Tables 1 and 2) with respect to r_+/r_0. The same tendencies may be found in Fig. 2. In Fig. 3b, the hyperfine splitting is better resolved than in Fig. 3a because the absorption due to S· had been bleached by

air before this spectrum was taken. Figures 3a and 3c indicate that, in these two isomers of nitrosonaphthol, the isotropic hyperfine splittings are somehow different.

Discussion

The primary radiation-chemical process in PVC is undoubtedly either an ionization or the formation of an excited state. Until now, the thermal-molecular and the thermal-segmental motions have generally been

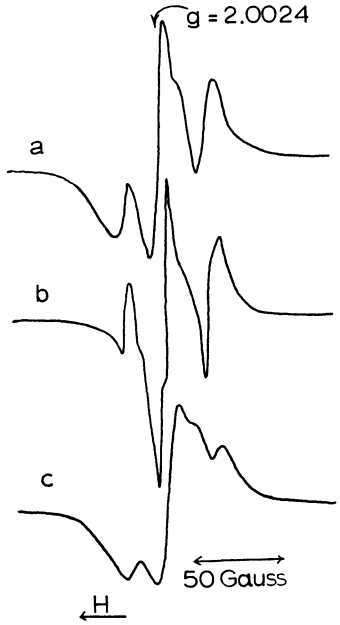

Fig. 3. a; PVC with α-nitroso-β-naphthol irradiated to D_1.

used to interpret the transporation of the excitation and the ionization in condensed phases as well as in the gas phase, and the kinetics governed by them. If, in some cases, the molecular motion-transportation theory was unsuccessful in explaining the kinetic data obtained, some inhomogeneous distribution of the primary, activated species, *e. g.*, a spur-like distribution, or some unknown impurities were assumed in order to solve such difficulties. In the present work it was found that the ESR of PVC can be totally converted to something else, or some 90% of it does not appear at all, if the PVC particles are coated with an aromatic additive. Benzene, used as the solvent for the additive, is not a solvent of PVC, and so it is very unlikely that additive molecules as large as 3-methylcholanthrene (5 rings with a methyl side chain) can uniformly penetrate into the segments of PVC. The additives are adsorbed only on the surface of polymer particles, probably by van der Waals adsorption. Therefore, it is definitely impossible to interpret the results obtained in this work if we limit the mechanism of the charge and excitation transporations to the molecular and the segmental motions.

The radiation-chemical studies of alkyl halides and the systems in which an alkyl halide is the matrix or the solvent have almost established that an aromatic compound is converted to its cation, not to its anion, when it is supported in the alkyl halide matrix and irradiated by ionizing radiation.[6-10] In the present work, therefore, the most likely species for explaining the ESR spectra in Figs. 1, 2, and 3 are the cations of the additive molecules which coated the surface of PVC particles. Free radicals can be ruled out from the possible species for interpreting the spectra. If PVC $\rightsquigarrow$ PVC'$\cdot$+H$\cdot$ (or Cl$\cdot$), which is a bond scission, occurs and if the atomic species formed jumps out of the PVC particle and adds to the aromatic hydrocarbon on the surface

of the particle, A, to form AH·, both PVC'· (which should be identical with S·) and AH· will be observed in most of the cases studied. The hyperfine structure of the perylene-PVC spectrum in Fig. 1 also leads us to reject the idea of the existence of AH·. Since AH· has 13 hydrogen atoms, two of which are in the $>CH_2$ form, there cannot be any set of eight nearly-equivalent pairs of protons interacting with the unpaired electron.

Two effects of the additives adsorbed on the surface have been observed. One is the transformation of S· to the additive cation, and the other is the quenching of the precursors of S·, which otherwise generates S·. In the cases of diphenylpicrylhydrazine and *p*-benzoquinone, at the dose of D_1 most of the unpaired electrons were observed in the form of the additive cation. In the cases of fluorene, 2,3-benzophenanthrene, and 3-methylcholanthrene, the number of unpaired electrons observed was reduced to some 10% of the value obtained without an additive.

These results indicate that the activated species (ionic or excited) can conduct through a PVC particle. On the surface, this activation is transferred to the additive molecule by intermolecular interaction. After the transfer, the activated additive molecule can either be ionized or lose its energy by a radiative or a nonradiative deactivation to its ground state.

If the primary activated state of PVC described above is an excited state, to be written as P**, it moves to the surface to become a surface excited species, P_s**;

$$P^{**} \longrightarrow P_s^{**},\ P_s^{**} + A \longrightarrow P_s + A^* \qquad (1)$$

which then may react with the adsorbed additive, A, to be deactivated to P_s. The P_s** may also produce S·, whose nature is not yet known exactly. The excited additive, A*, thus formed will be deactivated or ionized to A^+ and e^-, depending on the nature of the additive molecule:

$$A^* \longrightarrow A^+ + e^- \qquad (2)$$

$$A^* \longrightarrow A + (h\nu) \qquad (3)$$

Along with (2), the electron capture by PVC, P, takes place: $e^- + P \rightarrow P^-$. The amounts of S· and A^+ are shown in Table 1 and Table 2. The amount of (3) is equal to $(1-r_+/r_0-r/r_0)$ in the tables. $(1-r/r_0)$ in the tables indicates, then, the sum of the amounts of (2) and (3). In other words, $1-r/r_0$ in Table 1 indicates the total amount of energy going out of a PVC particle to the surface additives. $1-r/r_0-r_+/r_0$ in both tables indicates the total amount of energy which is dissipated by A* by a radiative (with $h\nu$ in (3)) or by a non-radiative relaxation to the ground state. An alternate scheme, postulated by Ueda,[7] is also possible; in it (1) and (2) are replaced by the equation: $P_s^{**} + A \rightarrow P_s^- + A^+$.

A hole-conduction may also explain the phenomena. By irradiation, an excited ion, P+*, may be formed. The P+*, an energy-rich hole, may then move to the surface to form P_s^{+*}, which may then be transferred to the additive molecule:

$$P \rightsquigarrow P^{+*} + e^-$$

$$P^{+*} \longrightarrow P_s^{+*},\ P_s^{+*} + A \longrightarrow P_s + A^+ \qquad (1')$$

P_s^{+*} may also form S·;

$$P_s^{+*} \longrightarrow S\cdot \qquad (2')$$

The electron, which conducts more slowly than P+* in this system,[6] will gradually come to the surface of the particle to recombine with A^+, which will create an excited state of A, which may then go to the ground state; on the other hand, if the electron affinity of A^+ is not larger than P, A^+ will stay stable on the surface. According to this scheme;

$$A^+ + e^- \longrightarrow A^* \longrightarrow A + (h\nu) \qquad (3')$$

$1-r/r_0$ in the tables is equal to the amount of (1'). So far as the present paper is concerned, there is no way to judge which is true, (1) or (1'), or whether or not both are true.

As is shown in Table 2, oxygen does not much affect the unpaired electrons found in additive molecules (see (A^+-left) in Table 2). This is good evidence that these species are cations and not anions, because an anion is very vulnerable to O_2. The unpaired electron left in pure (meaning without an additive) PVC after irradiation has been believed to be in the form of a free radical. However, the electric conductivity studies of irradiated PVC by Barnes *et al.*[11] have indicated that the unpaired electrons formed in irradiated PVC can be squeezed out if an electrostatic field and some thermal gradient is applied. Therefore, it is proper to say that no definite structure has been established for the paramagnetic species formed in irradiated PVC at room temperature.

Though the carbon atom has $2s2p^3$ sigma bonds, there can be $3s3p^3$ sigma orbitals and so on. Normally these additional "sigma orbitals" are not occupied by any electrons. However, if the 1*s* electron of a carbon atom is knocked off by a γ-photon, it may occupy the $3s3p^3$-sigma orbital, which is extended throughout the molecule. This excited state, P**, $1s^1(2s2p^3)^{8/2}(3s3p^3)^{1/n}$, where 8/2 signifies the shared covalent bond and where $1/n$ signifies a bond extended to *n*-carbon atoms, would move quite quickly throughout the molecule or the polymer particles. Also, the P+*, $1s^1(2s2p^3)^{8/2}$ hole can be expected to conduct. Though the 1*s* orbital radius of carbon atom is considerably smaller than the $2s2p^3$ sigma-bond radius, which decides the adjacent C–C bond distance in PVC, some overlap of adjacent 1*s* orbitals is possible if one of them includes only one electron. Therefore, the 1*s* unpaired spin (hole) may be exchanged between two adjacent carbon atoms.

It may be concluded that the cation or the excitation of PVC formed inside a particle penetrates through the particle toward the surface to form P_s^{+*} or P_s^{**}. Otherwise, 90% of the quenching of the unpaired electrons on the surface is impossible. Inside a particle, the molecular orbital or the unpaired electron will show some repulsive interactions with the normal sigma orbitals of other polymer segments or other molecules. On the surface, no such interaction exists; the ionized species can thus be said to be more stable than inside the particle.

In the present experiments, it seemed that the surfaces of PVC particles were saturated with the additive molecules. The overall efficiency of an additive, therefore, may be determined by the following four conditions:

11) J. E. Barnes, F. E. Hoeker, and L. Kevan, *Rad. Res.*, **40**, 235 (1969).

(a) the concentration of the additive on the surface (which is almost saturated with the additive) of the PVC particle; (b) the overlap integral between the wave functions of the additive orbitals and that of the surface of a PVC particle in the excited or the ionized state; (c) the energies required for the ionization or the excitation of the additive molecule, and (d) the relaxation rate constants of the excited states of the additive molecule on the surface of PVC. The values of (a) and (b) are not yet known, while those of (c) and (d) have been partly tabulated in several books.[12,13] There is an experimental method for ascertaining the values of (a), but the values of (b) will not easily be found. For this reason, at the present stage of our research, it is not possible to interpret the data in Table 1 and Table 2 in terms of the physical properties of each of the 38 additive compounds listed. It is hoped that the data presented in the tables nevertheless open a new possibility for the study, both in experiment and in theory, of the conduction and stabilization processes of the radiation-induced active centers in the condensed phases.

The authors wish to express their thanks to Dr. Sachiyuki Tominaga of the Mitsui Toatsu Chemical Co. for his kind suggestions in connection with this work.

The Electrodeposition of Aluminum from a Solution of Aluminum Bromide in *N,N*-Dimethyl Aniline

Takeo HISANO, Toshio TERAZAWA, Ichiro Takeuchi, Shinzo INOHARA, and Hiroshi IKEDA

Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minami-Josanjima-cho, Tokushima

(Received June 4, 1970)

This paper will describe that metallic aluminum was deposited electrolytically from a solution of aluminum bromide in dimethyl aniline with a current efficiency of 95% or more under optimum conditions. The superposition of a sinusoidal alternating current (AC) on the electrolysis direct current (DC) affected the properties of coatings and the throwing power of solutions to a great extent. A smooth, white-bright, ductile, and adherent coating was obtained under such appropriate conditions as that the frequency of AC was 60 Hz, the AC to DC ratio of 2 to 3. Aluminum dissolved anodically, and it was deposited at the cathode. The freezing temperature-composition diagram indicated the occurrence of two stoichiometric molecular complexes, $AlBr_3 \cdot C_6H_5N(CH_3)_2$ and $AlBr_3 \cdot 2C_6H_5N(CH_3)_2$, and the former was isolated.

Aluminum has not been deposited electrolytically from any aqueous solutions, probably because of the preferential discharge of hydrogen ions. For that reason, the electrodeposition of the metal from organic solutions containing no hydrogen ion has attracted considerable attention during the last about 20 years. The history has been well reviewed in the papers of Brenner[1-3] and other authors.[4] Several baths for the electroplating have been proposed by various investigators, but most of the baths are easily deteriorated by moisture and/or are difficult to operate. Of these, the lithium-aluminum-hydride-type bath, which was developed by Brenner and his co-workers,[5] would probably be the most excellent one for commercial use at present. The bath, however, seems not to be entirely perfect, because the solvent, diethyl ether, is inflammable and the aluminum dissolved at the anode does not deposit at the cathode. In order to improve this type of bath, Ishibashi and his co-workers[6] have proposed the use of tetrahydrofuran instead of ether as the solvent.

A variety of organic solvents has been examined by various authors in the studies of the electrodeposition of aluminum as well as of other metals, but *N,N*-dimethyl aniline (DMA) seems never to have been referred to. The present paper will describe that metallic aluminum was electroplated from the solution of aluminum bromide in DMA with a current efficiency of 95% or more under optimum conditions. When an alternating current (AC) was superimposed on the direct current (DC) in the electrolysis, a bright, ductile, and adherent coating was obtained.

Though preliminary experiments showed that aluminum chloride could be used as an alternative to the bromide, the latter was here chosen simply because its anhydride can be more easily prepared.

In an electrochemical sense, DMA seems to be a moderately active solvent, having in the molecule a nitrogen atom capable of coordinating with a solute. On account of this property, DMA and its related compounds are worthy of study as non-aqueous solvents in the electrodeposition of metals, particularly of metals that have never been electrodeposited from aqueous solutions.

Experimental

Aluminum Bromide. Its preparation and subsequent purification were carried out in an all-glass apparatus capable of evacuation. The bromide was synthesized by heating alminum turnings (99.5% pure) in a current of purified bromine vapor. The bromide thus formed, without being exposed to the air, was purified by successive sublimation through a series of vessels, and finally sealed off in glass ampules, each of which was fitted with a breakable joint for subsequent use *in vacuo*. Colorless and anhydrous aluminum bromide was thus obtained.

N,N-*Dimethyl Aniline.* Care was taken to remove aniline, monomethylaniline, and water from a commercial DMA. When mixed with a suitable amount of acetic anhydride, it was submitted to fractional distillation. After the removal of the remaining acetic anhydride by washing with water, and the removal of the water by standing over potassium hydroxide, the distillate was further distilled fractionally under reduced pressure of nitrogen in the presence of metallic sodium.

Electrolysis Cells, Ancillary Apparatus, and Procedures. The cells and the procedures used here for the electrolyses were virtually identical with those of Menzies and others.[4,7] In brief, care was taken so as to prevent the contamination of the solution with atmospheric oxygen and moisture during both the mixing of the constituents and the electrolysis. About 40 m*l* of the solution was used in each run. The quantity of electricity (60—200 coulombs usually) passed through an electrolysis cell was measured with a water coulometer when an DC only was applied. The superposition of a sinusoidal AC on the DC was carried out by the usual method. The currents over a frequency range of 20—2,000 Hz were supplied from an audio-frequency generator. The net quantity of electricity participating in the cathodic process at the cathode was calculated from the area of a wave in an oscillogram of the resultant electrolysis current. In the expression for the ratio between the amount of superimposed AC and that of DC, the former was described by a root mean-square value.

Preparation of Electrodes. An aluminum spiral ribbon was generally used as the anode; at its center a cathode was placed. The aluminum was 99.5% pure, containing Fe, Cu, and Si as the main impurities. When the anodic dissolution of aluminum was studied, an aluminum wire anode (99.999% pure) was used. They were cleaned before use with a sodium hydroxide solution, dil hydrochloric acid, water, and finally with methanol. As the cathode a copper plate or a platinum wire was mainly used; its widest surface area was about 2 cm^2. They were cleaned in a mixture of hydrochloric, nitric, and sulfuric acids, as recommended by Graham.[8]

The aluminum deposited at a cathode was determined in two ways. One was a volumetric method, while the other was the measurement of the volume of the hydrogen generated by the addition of 8N hydrochloric acid. These two methods always gave concordant results, within the limits of experimental errors, which was a support for the idea of the deposit being completely metallic.

Adherence of Coating to Base Metal. This was estimated simply on the basis of the number of times at which a specimen was bent at right angles with pincers until the coating showed signs of flaking.

Freezing Temperature-Composition Diagram for the Solution System. The freezing points were determined on the basis of the cooling curves. The successive dilution of a solution with DMA was carried out in the presence of dry nitrogen (1 atmospheric pressure) in a vessel equipped with a magnetic stirrer.

Preparation of 1 : 1 Molecular Complex. After the dissolution of aluminum bromide in excess amounts of DMA with the aid of gentle heating, the excess DMA was permitted to distill off. The residue was then distilled at a higher temperature and collected in ampules. All the operations were carried out under a reduced pressure of nitrogen.

Results and Discussion

Appearance of Solutions. *In vacuo* or in an atmosphere of dry nitrogen free from oxygen, a newly-prepared solution of aluminum bromide in DMA was colorless at any temperature lower than about 100°C and at any concentration. At an elevated temperature above 100°C, the solutions gradually developed a color between light yellow and reddish orange *in vacuo* or in nitrogen, except for a solution with an equimolar composition, which was colorless irrespective of the temperature. In the air, the solutions containing less than 50 mol% of bromide turned blue. Even in the absence of oxygen, sunlight or ultraviolet rays also turned the solution blue. Sato[9] has shown that the reaction of DMA with aluminum chloride *in vacuo* gives a blue solution, the electronic spectrum of which displays an absorption maximum at 600—610 mμ, and that the maximum is the same as crystal violet in the same solvent gives. In the present case of an aluminum bromide-DMA solution that was colored by virtue of oxygen or

ultraviolet rays, a maximum was also found at about 605 mμ. In the air, the solutions containing the bromide more than 50 mol% turned light brown; this was perhaps an alkaline color of crystal violet.

When electrolyzed, these solutions exhibited various colors, from blue to reddish violet, according to the experimental conditions. The coloring during electrolysis was partly attributed to unknown reactions at the anode.

Cathode Current Efficiency. The first run of electrolyses of freshly-prepared solutions occasionally yielded an unusually low current efficiency and a poorly adherent deposit. This is perhaps due to the trace amounts of water remaining in the solvent. The experimental datum of every first run was, therefore, discarded, or solutions were preliminarily electrolyzed for a while.

Figure 1 shows some examples of the effects of current density (CD) on the cathode current efficiency. At any concentration of aluminum bromide, the efficiency varied remarkably within a range of relatively low CDs; then it remained almost constant over a wide range of higher CDs. Again, the rise of the temperature decreased the efficiency rather slightly for concentrated solutions (curves A and A'), while it affected the efficiency for dilute solutions in the other direction (B and B').

The variation in the efficiency with the concentration of aluminum bromide is illustrated in Fig. 2, which shows the case when the CD was 50 mA/cm² at 120°C. The efficiency varied unusually with the concentration,

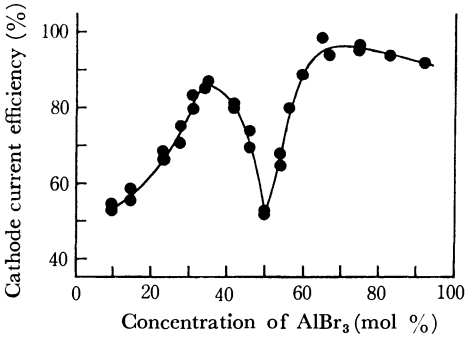

Fig. 2. Variation of cathode current efficiency with bath composition (120°C, 50 mA/cm²).

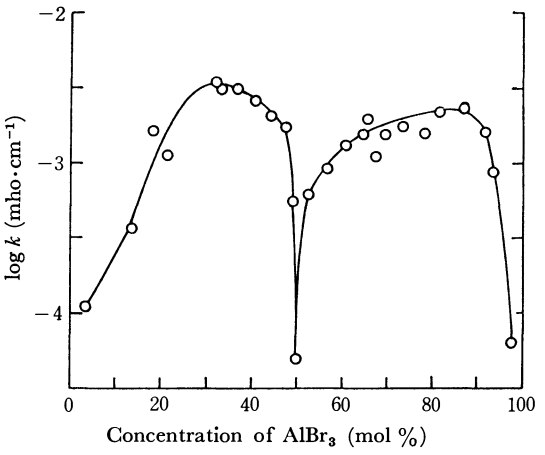

Fig. 3. Variation of specific conductivity (k) with composition at 110°C.

exhibiting maximum values of about 85 and 95% at concentrations around 35 and 65 mol% respectively. For the solution with an equimolar composition, the efficiency dropped unexpectedly, irrespective of the CD, to a value of about 50—60%. As is illustrated in Fig. 3, the curve for specific conductivity plotted against the composition of the solution also passed through a minimum at the equimolar composition, regardless of the temperature. It is of interest to note that the curve of Fig. 2 is, to some extent, similar in shape to that of Fig. 3; it is difficult at present to explain this.

Improvement of the Properties of Coating by Superimposing AC. The deposits were metallic aluminum with no organic contaminants. They were, however, generally grey or sometimes black. Moreover, a nodular or dendritic growth of the deposit was often observed, particularly when the concentration of aluminum bromide was less than about 50 mol%. At higher concentrations these irregular growths diminished considerably, but were favored by high CDs. The adhesion of the coating to the substrate (copper or steel) was not very good, so pealing or blistering of the coating occasionally occurred, even when it was bent only once.

In order to improve the properties of the coating,

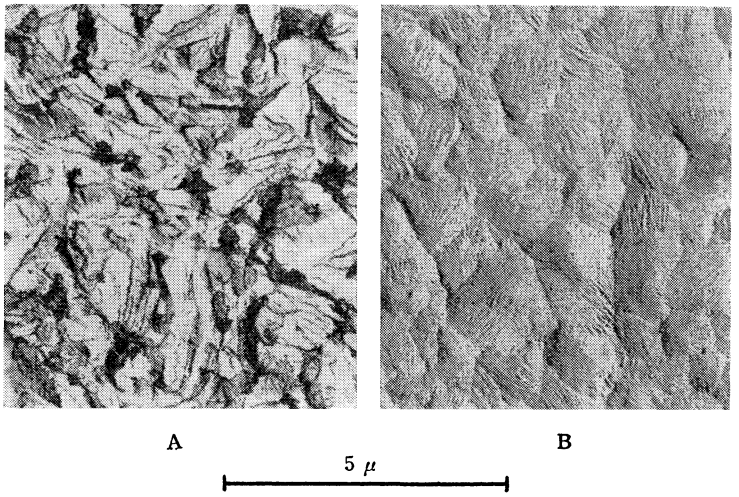

Fig. 4. Electron microphotograph (carbon replica) of surface of Al deposited (100 mA/cm², 58.5 mol%, 160°C).
A: DC only B: AC was superimposed (AC/DC = 3)

each of the following substances was added to the bath in various amounts of 10 to 1,500 mg/*l*. The attempt, however, was unsuccessful. The appearance and the adhesion were more inferior than ever. The tested substances were polyvinyl chloride, thiourea, sulfamic acid, benzoic acid, and sodium 2,7-dinaphthalen sulfonate. For the same purpose, a sinusoidal AC was superimposed on the DC for the electroplating. It affected the properties of coating to a great extent. The superposition, when the conditions were appropriate, yielded a smooth, white-bright, ductile and adherent coating, improving the throwing power of the bath, though the estimation of its extent was qualitative. Figure 4 (electron microphotographs) may be sufficient to illustrate that the superposition effectively smoothed the surface of the coating. Clean, white-bright electroplates as thick as 0.05 mm, which was not the maximum value possible, were easily obtained.

The frequency of a superimposed AC had appreciable effects on the properties of the coating and the throwing power of the bath. Generally, the favorable effects were observed at frequencies from roughly 60 to 200 Hz. At frequencies of 300 and 20 Hz, the coatings obtained were of a dull appearance and the throwing power was very poor. At frequencies above 300 Hz, grey coatings were obtained. At above 1,000 Hz, the coatings were black and less adherent than ever. The ratio of the amount of AC to that of DC was also one of the influential factors. The irregular growth was prevented when the ratio was more than 2. The current with an AC–DC ratio more than 4, however, generally yielded a poor cathode throw and a rough surface was deposited, particularly when the CD was high. The current efficiency decreased with an increase in the ratio. Some examples are shown in Fig. 5.

Anodic Behavior of Aluminum in the Solution. An aluminum anode dissolved electrolytically into the solution. Figure 6 shows the variation in the anodic current efficiency with anode CD. These efficiencies were computed for the formation of trivalent ions. At higher concentrations (above 55 mol%) of aluminum bromide, the efficiency was practically constant and was 100% over the whole range of CD observed; moreover, its change with the temperature was very small. Figure 7 shows the variation in the efficiency with the composition of the solution at 120°C and at a CD of 90—100 mA/cm². The efficiency decreased markedly as the concentration decreased below 50 mol%, and the solution adjacent to the anode turned blue or violet, seemingly because of the deposition of bromine.

Conner and Brenner[5] have reported that the aluminum dissolved at the anode did not deposit at the cathode in their Li-Al-hydride-type bath, probably because of the formation of a new ionic species. On the contrary, the following experimental facts suggested that the aluminum dissolved anodically could deposit at the cathode in the present bath. A solution of 6 m*l*, initially containing 68.5 mg of aluminum, was electrolyzed with an DC of 5 mA/cm² of CD for 72 hr; 198 mg of aluminum were thus deposited on the cathode. Similar results were obtained when an AC was superimposed.

Molecular Complexes between Aluminum Bromide and DMA. Figure 8 shows the freezing diagram of the system. An open circle represents the freezing point that was observed by cooling a solution from a temperature 10—20°C higher than the point. There were some cases in which the freezing point shifted slightly after the same solution had once been heated to about 150°C. The closed circles in the figure represent such cases. The curve connecting the open circles passes through one maximum and two minima; the latter are the freezing points of eutectic mixtures. The maximum at the equimolar composition suggests the occurrence of a molecular complex, the simplest formula of which is expected to be $AlBr_3 \cdot C_6H_5N(CH_3)_2$. Koblukow and

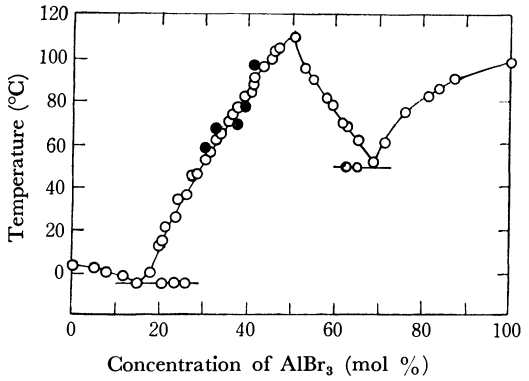

Fig. 8. Freezing temperature-composition diagram for $AlBr_3$-DMA system.

Ssachanow[10] have already reported a complex as being a dimeric molecule $Al_2Br_6 \cdot 2C_6H_5N(CH_3)_2$ on the basis of their thermometric data. Its melting point (mp) was 95°C. On the other hand, the compound isolated by the present authors had a mp of 108—110°C. It seems likely, however, that these two compounds are the same. The difference in mp may be ascribable to the difference in purity between the two. The compound obtained here was colorless, crystalline, and somewhat hygroscopic; it was decomposed by water, but not so easily as aluminum bromide. It was colored blue by sunlight, but not by dry air. Found: Al, 6.92; Br, 61.4; C, 24.61; H, 3.52; N, 3.60%. Calcd for $AlBr_3 \cdot C_6H_5N(CH_3)_2$: Al, 6.96; Br, 61.80; C, 24.77; H, 2.86; N, 3.61%. The apparent molecular weight of the complex in benzene was 402, while the calculated value for the monomeric molecule was 388.

The curve connecting the closed circles exhibits a discernible shoulder at the composition of about 33 mol%. This seems to indicate the presence of another complex, possibly $AlBr_3 \cdot 2C_6H_5N(CH_3)_2$, though attempts at its isolation have not yet succeeded. Considering that the cathode-current efficiency exhibited a maximum around this composition, as may be seen in Fig. 2, this anticipated complex appears to be closely related to the behavior in electrolysis and to the conductivity of the solutions. An example is seen in Fig. 1. The curve B′ represents the current efficiency for a 35 mol% solution at 80°C; the solution had never been heated above this temperature. On the other hand, the point B′-a is for the same conditions except that the solution was once heated to 120°C. The difference in efficiency is remarkable. Again, the specific conductivity of any solution with a concentration of lower than 50 mol% was essentially changed and never returned to its initial value, after the solution had been submitted to a certain higher temperature. For example, the conductivity of the 33% solution was initially $10^{-3.7}$ $(ohm.cm)^{-1}$ at 80°C; it finally became $10^{-2.6}$ at the same temperature after the solution had once been heated to 150°C.

The results described above are, of course, insufficient to establish the mechanism of the cathode reaction. The solution system displayed very intricate changes in conductivity as functions of the composition, the temperature, and the time of heating; the details will be reported at a later date. Throughout this study, the efficiencies were calculated for convenience on the basis of the reaction $Al^{3+} \rightarrow Al$. Considering the complicated change in the conductivity, together with that of the cathode-current efficiency, however, one can doubt whether the number of electrons, or the ionic species, participating in the cathode process would be the same throughout the whole range of aluminum-bromide concentrations. Further work, therefore, such as electrode-potential and transport-number measurements, will be required.

Electronic Structure of Lone Pairs. II.[1] Disulfides and Acyl Thiol

Hiroko YAMABE, Hiroshi KATO,[2] and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 4, 1970)

The electronic structure and the electronic transition of three cyclic disulfides, $(CH_2)_3S_2$, $(CH_2)_4S_2$, and $(CH_3)_2S_2$, are calculated by the semi-empirical ASMO SCF method in order to study the interaction of the neighbouring lone pairs of the S–S bond in connection with the ability of reductive scission. It is concluded that the absorption at 2500—3000 Å is the transition of n—σ^* and that the variation in the maximum for the various cyclic disulfides and the chain disulfide are induced by the change in the dihedral angle that a molecule can take. The electronic structure and the reactivity of $(CH_3)_2S_2$, CH_3SSH, and CH_3SCOCH_3 are then discussed on the basis of an extended Hückel calculation. It is suggested that there is the possibility of an interaction between two molecules, R_2S_2, through the S–S bond of each molecule, in the HO of one molecule and in the LV of another.

The compounds containing sulfur atoms have some characteristic properties in organic and biological reactions. The S–S bond between two divalent sulfur atoms has a particular role in retaining the tertiary structure of polypeptide as a weak chemical bond. Also, 6,8-thioctic acid is a coenzyme for the decarboxylation of pyruvate to active groups, which through CoA feed carbon atoms into the Krebs cycle; a reductive scission of the S–S linkage of 6,8-thioctic acid to form a dithiol is also involved in the mechanism.[3] Acetyl CoA, $CoASCOCH_3$, is an important biological acetylating reagent, and its C–S bond is a so-called high-energy bond. Though many experimental investigations have been made, there have been only a few discussions of their electronic structures.[4]

Previously we calculated the electronic structure and the electronic interaction of the lone pairs of some azine compounds and quinones.[5] In this connection, in the earlier part of the present paper the electronic structures and electronic transitions of several disulfides, trimethylene-disulfide $(CH_2)_3S_2$ (a model compound of 6,8-thioctic acid), tetramethylene-disulfide $(CH_2)_4S_2$, and dimethyl disulfide $(CH_3)_2S_2$ were investigated by the semi-empirical ASMO SCF method[6] for valence electron systems in order to study the interaction of the neighbouring lone pairs of S–S linkage in connection with the ease of reductive scission. In the later part, the electronic structures of $(CH_3)_2S_2$, CH_3SSH, and CH_3SCOCH_3 (a model compound of $CoASCOCH_3$) are calculated by the extended Hückel method[7] in order to establish the properties of these molecules, based upon the MO theory, and to discuss the reactivity in relation to the lone pair.

I. Dimethyl Disulfide and Cyclic Disulfides

The normal value for the dihedral angle for the S–S bonds of such compounds as S_8, S_2Cl_2,[8] and $(CH_3)_2S_3$[9] is known to be approximately equal to 100° from the X-ray analysis, the measurement of the dipole moment, the IR spectrum, and so on. The dihedral angle of $(CH_3)_2S_2$,[9,10] too, is approximately 90°. On the other

hand, only a few investigations[9,11] have been performed on the electronic structures and configurations of these compounds in relation to the electronic spectrum. Calvin *et al.*[12] observed the UV spectrum of some cyclic disulfides and *n*-propyl disulfides out of their biological interest in 6,8-thioctic acid (see Table 1). They discussed the variation in the absorption spectra in the 2500—3000Å range of these compounds qualitatively in relation to the ring strain, which may come from the interaction of the two lone pairs of the sulfurs and the shift of the dihedral angle from its stable value of about 90°. Later, Bergson[11] made an attempt to interpret the above observation in terms of a simple molecular orbital theory. That is, he explained it by considering only the interaction between two lone pairs constructed by the $3p$ electrons of the neighbouring sulfur atoms.

Including all the valence electrons, and also taking into account the conformations of these molecules, our calculation in this paper was carried out by the semi-empirical ASMO SCF method for valence electron systems previously proposed by the present authors.[6]

Calculations. By estimating on the base of the molecular model, the dihedral angles of the above cyclic disulfides seem to be in the neighbourhood of 0°, 40°, and 90° for the five-, six-, and seven-membered rings respectively. In order to establish the relation between the dihedral angle and the absorption maximum, shown in Table 1, the electronic structures of dimethyl disulfide with the dihedral angles of 0°, 45°, and 90°

are calculated. It is the purpose of these calculations not only to reveal the ϕ dependency (see Fig. 1) of the absorption spectra, but also to carry out a simplified model calculation for the cyclic disulfides. The validity of this simplification is confirmed by the calculation of tri- and tetra-methylene disulfide for the assumed structure of Fig. 1. The bond lengths and bond angles of dimethyl disulfide and the five-membered ring are referred to the compilation by Sutton.[13] They are shown in Table 2. The structure of the six-membered ring is assumed by taking the S–S, S–C, and C–C bond lengths as 2.10Å, 1.78Å, and 1.54Å respectively and the hybridization for all carbon atoms as sp^3. However, the resulting dihedral angle becomes approximately 10°, which is considerably smaller than the expected value.[14] The numberings of the atoms of the five- and six- membered rings are shown in Fig. 1, in which the S_1, S_2, C_3, and C_4 atoms and the S_1, S_2, and C_6 atoms are assumed to be on the same x–y planes. The calculation was carried out by the semi-empirical ASMO SCF method for valence electron systems,[6] in this method the approximation of the zero differential overlap is adopted, and the contribution of $3d$ and $4s$ orbitals of the sulfur atom is neglected.

13) L. E. Sutton, "Interatomic Distances of Molecules and Ions," The Chemical Society, London (1958).
14) The dihedral angle of the six-membered ring is considered to be about 40°, assuming a molecular model with somewhat deformed angles of the carbon atom from the sp^3 hybridization. This value (~40°) seems to be reasonable in view of the UV spectrum (see Table 1). when the sp^3 hybridization is assumed, for convenience in the calculation of the molecular conformation, the dihedral angle becomes about 10°.

Dimethyl Disulfide. The calculated results for the dimethyl disulfide, $(CH_3)_2S_2$, are given in Table 3. The minimum value of the total energy[15] of $(CH_3)_2S_2$ is obtained for the dihedral angle of 90°; this is in accordance with the observation.[10] The calculated transition energies are in good agreement with the experimental values (Table 1). The oscillator strengths increase with the increase in the dihedral angle from 0° to 90°, and run parallel with the experimental values.[12] The lowest vacant orbital (LV) becomes an antibonding orbital of the S–S $p\sigma$ bond. The partial bond orders of the S–S $p\sigma$ bond, p_{sr}^{LV},[6] in the lowest vacant orbital are negative and large, and their absolute values increase in the order of 0°, 45°, and 90°. This means that the ring-opening reaction by the means of the nucleophilic reagent occurs more easilly in this order; the five-, six-, and seven-membered rings, this order may be parallel to that of the ring strain of these compounds.[12,16,17] In fact, the ring-opening reaction to form linear polymers is known to take place in this order.[16] It has been reported[18] that 5- and 4- thioctic acids have, respectively, 0.3% and 0.1% pyruvate oxidation activity relative to 6-thioctic acid.

The atomic orbital (AO) charge densities[6] of the sulfur atom are given in Table 4. For 0°, the electron densities of the p_z AO of the sulfur atom are almost all 2.0; this indicates a lone-pair orbital of the p type. For 90°, the p_z orbital of the S_1 atom (S_1z) and the p_y orbital of the S_2 atom (S_2y) become lone-pair orbitals. That is, the direction of the interacting lone-pair orbitals varies, but almost without changing the absolute value of the population, following the change in the dihedral angle, ϕ. More exactly, one can see in Table 4 that the AO density of the lone pair (S_1z) has a minimum value at 90°, that is, the delocalization of the lone pair is at a maximum. As the dihedral angle increases, the total electron density of the S_1 atom increases and those of the C_3 atom and the CH_3 group, which is a summation of the atomic-charge[6] of the atoms C_3, H_4, H_5, and H_6, decrease. Also, the AO-charge density of S_1y increases and that of C_3y decreases. That is, the electron may migrate from the p_y orbital of the C_3 atom to that of the S_1 atom.[19] The bond orders, s–x and s–y, of the sulfur atom are nearly equal, and that of the s–z is zero for 0°, as is shown in Table 4. The direction of the atomic dipole becomes approximately that of an sp^2-type lone pair. That is, other sp^2-type lone pairs, which result from the delocalization of 3s electrons, are observed. These sp^2-type lone pairs, too, rotate according to the change in the dihedral angle, ϕ.

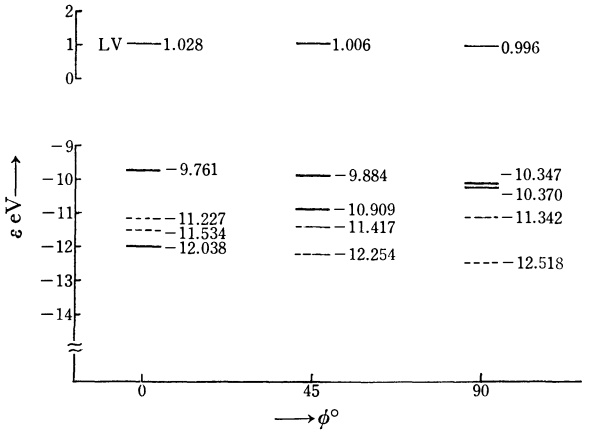

Fig. 2. Lone pair levels and the lowest vacant level of dimethyldisulfide *vs.* dihedral angle ϕ. The heavy lines and the dashed designate the levels of the p-type lone-pair and sp^2-type lone pair, respectively.

The lone-pair levels and the lowest vacant levels of $(CH_3)_2S_2$ for the various ϕ's are illustrated in Fig. 2. The fine line designates the lowest vacant level, while the heavy line and the dashed line designate the lone-pair level of the p type and that of the sp^2 type respectively. It is observed that the splitting of the lone-pair levels of the p type becomes larger in the order of 90°, 45°, and 0°. This may mean that the lone pairs of the p type aligned parallel, as in 0°, have more mutual

19) The same tendency has been observed by Morokuma *et al.* in (Ref. 20) their *ab-initio* calculation of H_2O_2; it may also be seen in the report by Pitzer *et al.* (Ref. 21).

20) L. Pedersen and K. Morokuma, *J. Chem. Phys.*, **46**, 3941 (1967).

interaction than those in an orthogonal form, as in 90°.

Trimethylene Disulfide and Tetramethylene Disulfide. The calculated results for trymethylene disulfide, $(CH_2)_3S_2$, tetramethylene disulfide, $(CH_2)_4S_2$, are given in Table 3. The transition energies of the n–σ^* of $(CH_2)_3S_2$ show a better agreement with the observed value than in the preceding, simplified calculation, in which the dimethyl disulfide of the dihedral angle 0° corresponds to the observed value of $(CH_2)_3S_2$. The first n–σ^* transition of $(CH_2)_4S_2$ is 4.01 eV; it is the transition from the next highest occupied lone-pair level of a p type to the lowest unoccupied level.[22] As has been mentioned previously, the dihedral angle of the assumed structure is smaller than the expected angle[14] (See Table 1). Therefore, the obtained transition energy should become smaller than the experimental value. The calculated oscillator strength of $(CH_2)_3S_2$ is larger than $(CH_2)_4S_2$, showing a parallelism with the experimental value. Judging from the value of p_{rs}^{LV}, LV is an antibonding orbital of the S–S $p\sigma$ bond. This is compatible with the fact that the scission of the S–S bond of 6,8-thioctic acid is induced by light. The atomic-charge density,[6] the AO charge density,[6] and the partial bond orders of the s–x, s–y, and s–z of the sulfur atom are shown in Table 5. For $(CH_2)_3S_2$, two lone pairs of the p type in the z direction are parallel, and the lone pairs of the sp^2 type lie in a nearly orthogonal form; those of the sp^2 type, too, are approximately orthogonal.

Table 5. Atomic-charge density, AO-charge density and bond order, p_{s,p_i}, of the S_1 atom of $(CH_2)_3S_2$ and $(CH_2)_4S_2$

		$(CH_2)_3S_2$	$(CH_2)_4S_2$
Atomic-charge density		6.148	6.181
AO-charge density	s	1.716	1.679
	x	1.308	1.405
	y	1.126	1.101
	z	1.999	1.996
p_{s,p_i}	S–x	−0.294	−0.330
	S–y	−0.286	−0.238
	S–z	−0.000	0.003

From the results of our calculation, it may be concluded that the absorption of 2500—3000Å is an n–σ^* transition and that the variation in the absorption maximum for various cyclic disulfides and a chain disulfide are induced by the change in the dihedral angle, ϕ, of the molecule.

22) The orbital sequence of the 1 one-pair MO's of $(CH_2)_4S$ is slightly different from that of $(CH_3)_2S_2$, $\phi=45°$, shown in Fig. 2. The highest occupied level (—9.131 eV) of $(CH_2)_3S_2$ is the one connected with the sp^2-type lone pair, which is anomalously high compared to the highest occupied level of $(CH_2)_3S_2$ in various dihedral angles and $(CH_2)_3S_2$. The next highest occupied level (—9.905 eV) becomes the one connected with the p-type lone pair. The transition energies and the oscillator strengths, Osc., of these n(p type)-σ^* and n(sp^2 type)-σ^* transitions of $(DH_2)_4S_2$ are obtained as follows:
n(p type)-σ^* ; 4.01 eV, Osc.=0.034 (See Table 2)
n(sp^2 type)-σ^* ; 4.78 eV, Osc.=0.224

II. Chemical Reactivity of $(CH_3)_2S_2$, CH_3SSH, and CH_3SCOCH_3

It has been noted that the E–H method[17] is a tolerable approximation in some cases for discussing the reactivity.[23] Sometimes, the E–H method gives more reasonable results for use in the interpretation of the reactivity, compared to the semiempirical ASMO SCF method, particularly in the calculation of the interaction of two molecules.[24] Therefore, we employed the E–H method in discussing the chemical reactivity of $(CH_3)_2S_2$, CH_3SSH, CH_3SCOCH_3, and the proton affinity of the S–S bond. It will be established later that a discussion similar to those given by the E–H calculation regarding the reactivity of $(CH_3)_2S_2$ and the cyclic interaction of two $(CH_3)_2S_2$ molecules is also possible on the basis of SCF calculations.

In the E–H calculation,[7] the resonance integral, H_{rs}, is evaluated by $H_{rs}=1/2\ KS_{rs}(H_{rr}+H_{ss})$, putting $K=1.75$, where S_{rs} is the overlap integral between two AO's, X_r and X_s. The Coulomb integrals, H_{rr}'s are given in Table 6.

Table 6. H_{rr}'s in the extended Hückel calculation (eV)

	$1s$	$2s$	$2p$	$3s$	$3p$
H	−13.60	—	—	—	—
C	—	−21.43	−11.42	—	—
O	—	−35.30	−15.45	—	—
S	—	—	—	−20.08	−13.32

$(CH_3)_2S_2$; First we will report the results for $(CH_3)_2S_2$, although the molecular orbital interpretation of the reactivity is carried out analogously to that for H_2O_2, previously reported by the present authors.[23] The highest occupied orbital (HO) and the next highest occupied orbital (NHO) are almost degenerate lone-pair MO's. The AO populations[26] of S_2y and S_1z

in HO, which are almost equal to those of S_1z and S_2y in NHO respectively, have large values, as is shown in Table 7. This means that a cation attack takes place in the lone-pair direction. LV is an antibonding orbital of the S–S $p\sigma$ bond, and AO populations of S_1x and S_2x are large. This means that the anion attack should takes place at the S atom of the S_2 atom from the outside of the S–S bond[27] and that the S–S $p\sigma$ bond is ready for scission. Then, in the absence of steric hindrance, the molecule having the S–S bond will be able to receive the nucleophilic and the electrophilic interaction from two directions at the same time in a mutually perpendicular way.[26] This property causes the S–S bond to be susceptible to ionic scission.[28] A similar discussion can also be made in the case of the SCF calculation of $(CH_3)_2S_2$, presented in the preceding section.

Possibility of a Cyclic Interaction of two Disulfides. The existence of a O_4 molecule has been known;[30] it seems to be an associated form of two O_2 molecules, in which two O_2 molecules are held together by bonds much weaker than an ordinary covalent bond. In our calculation of $(CH_3)_2S_2$, we notice the possibility of a cyclic interaction between two molecules, R_2S_2, through the S–S bond of each molecule, employing the HO of one molecule and the LV of another.[31] Figures 3(A) and (B) show two kinds of the interaction of $(CH_3)_2S_2$ molecules (I, II); only the atoms S and C are illustrated. Figure 3(A) shows the interaction between the HO of the molecule I and the LV of the molecule II,[32] while Fig. 3(B) shows the interaction between the LV of the molecule I and the HO of the molecule II, which is the reverse of that of Fig. 3(A). The relevant MO coefficients of the p_y orbitals[32] are also shown.[33] The S_1–S_2 and the S_1–C_4 bonds of the I and II molecule are placed in the same plane, and the S_2–C_3 bond is directed upwards from the x–y plane. As has been pointed out by Fukui *et al.*,[31] the most favorable conditions for a cyclic interaction include the same symmetry in the corresponding orbitals of the two molecules. This condition is satisfied in the above case.[34,35]

If a II molecule has a conformation which is a mirror image[36] of that of the I molecule, other forms of the interaction may be constructed.

Furthermore, not only the interactions in the completely-square forms, such as in Figs. 3(A),3(B),3′(A),[34] and 3″(A),[34] but also those in the oblique forms are possible.[37] An example, which is an oblique form of Fig. 3′(A),[34] is shown in Figs. 4(A) and 4(B), where the interaction is denoted by the dotted line. In Fig. 4(A), interaction is assumed between the p_y AO (lone-pair AO) in the HO of one molecule and the p_y AO in the LV of another molecule. At the same time, the inverse interaction, as in Fig. 4(B), is also possible, in which the HO and LV in Fig. 4(A) are replaced by the LV and HO respectively. By the superposition of these two interactions, the interaction between disulfides will become stronger. An interaction of this type may be expected in a crystal of disulfides.[37]

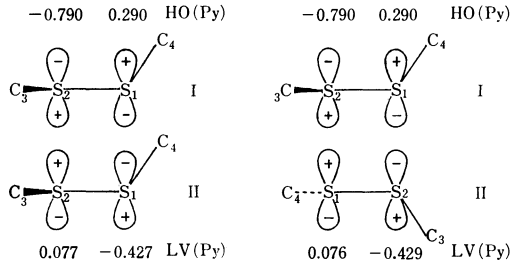

Fig. 3′(A)

Fig. 3″(A)

27) Because, in the inner part of the S–S bond, the mutual signs of the S_1x and S_2x are antagonistic, the AO's largely cancel out and the MO develops to the outside of the S–S bond, as has been pointed out by Fukui *et al.* in their work on H_2O_2 (Ref. 23).

28) In the ionic scission of the S–S bond, the approach of a nucleophile or an electrophile, for the capture of positive or negative scission products, becomes easy (Ref. 29).

31) K. Fukui and H. Fujimoto, This Bulletin, **39**, 498 (1966).

32) The p_y orbital of the S_2 atom in HO is a lone-pair orbital. The numbering of the atoms and the coordinate axes for each $(CH_3)_2S_2$ molecule are the same as those of Fig. 1.

33) In the preceding section it has been shown that a disulfide such as $(CH_3)_2S_2$, is most stable at the dihedral angle of 90°. It has been pointed out by Fukui (in a private communication) that this stabilization at 90° partially due to the intramolecular interaction between the S_2y AO(lone-pair AO) in the HO and the S_2y AO in the LV.

34) From the point of view of orbital symmetry, another type of cyclic interaction may be expected, as in Fig. 3′(A), as may its inverse form (not shown) constructed in a way similar to that of Fig. 3(B). However, in this case, as the lone pairs of the S_2 atoms of the molecules I and II lie in a line on the same plane, this cyclic form is less probable. The other form of the interaction between the p_y AO(Ref. 33) in the HO of the molecule I and the p_z AO in the LV of the molecule II is also possible, as in Fig. 3″(A) and as in its inverse form. That is, the molecule II of Fig. 3(A) is rotated about its S–S axis. Then, in Fig. 3″(A), the S_1–C_4 bond of the molecule I and the S_2–C_3 bond of the molecule II are placed on the same plane. The S_2–C_3 bond of the molecule I is directed upwards from the plane of the paper, and the S_1–C_4 bond of the molecule II, downward from the plane. However, this type of its interaction is also not very probable, because the lone pairs of the S_1 atoms of the molecules I and II lie on a line.

35) In the case of the SCF calculation, too, there is a possibility of a cyclic interaction when the s orbitals (their NO coefficients are 0.309 and —0.307) are used instead of the p_y AO in the LV of the molecule II of Fig. 3(A) and the molecule I of Fig. 3(B). In this calculation, as a form of cyclic interaction, some rotation about its S–S axis is permited for each molecule, I and II, because the s orbital is spherically symmetric.

36) B. M. Oughton and P. M. Harrison, This Bulletin, **2**, 396 (1959); *ibid.*, **10**, 497 (1957).

37) Yakel *et al.* describe, in their report about the X-ray analysis of *N,N′*-diglycyl-L-cystine dihydrate, that the van der Waals contacts (or the distances) between molecules related by the b-axis repeat are significantly lower than the normal value (Ref. 29). It is to be expected from the discussion in this section that not only the hydrogen bond (Ref. 29), but also the interaction between the S–S bonds may induce the smaller distance of the repeat. Oughton *et al.*, in their study of the structure of hexagonal L-cystine, also pointed out the close van der Waals contacts between each sulfur atom and its non-bonded neighbouring atoms (Ref. 36). Takagi *et al.* have reported that the CD spectrum of L-cystine hydrochloride indicates interaction between the neighbouring S–S bonds (Ref. 38).

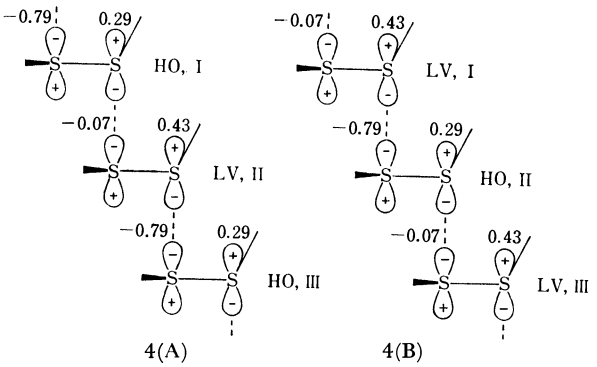

Fig. 4. Interactions in the oblique form.

Proton Affinity of the S–S Bond. Hughes described, in his review,[29] that the outstanding reactive characteristic reactivity of the S–S bond is its ability to undergo ionic (heterolytic) scission in reactions with nucleophilic reagents, and that ionic scission takes place also upon the attack of such electrophilic reagents such as sulfide-forming metal cations and proton. The S–S bond also acts as a chemical bond, are which undergoes ionic scission easily, holding a tertiary structure of polypeptide through a CyS–CyS linkage. Disulfide and dithiol interconversion is a conspicuous property of a S–S bond. In contrast with this, hardly no ionic scission of a C–C bond takes place. These properties of the S–S bond may be due partly to the lone pair of the sulfur and partly to the 3*d* orbitals of the sulfur. In this paper, only the contribution of the lone pair will be discussed.

Table 8. Proton affinity of a S–S bond

	direction of a proton approach	atomic population of proton	Δq[a]	ΔE(eV)[b]
$(CH_3)_2S_2$	case I	0.999	0.966	−4.75
	case II	0.776	0.383	−2.90
C_2H_6	case III	0.525	0.315	−1.72
	case IV	0.526	0.301	−1.85

a) The difference of atomic population, q, between two atoms of Fig. 4.
$\Delta q = q(S_1) - q(S_2)$ for $(CH_3)_2S_2$
$\Delta q = q(S_1) - q(C_2)$ for C_2H_6

b) ΔE is a difference of total energies of two forms, as $\Delta E = E$(protonated form) $- E$(neutral form)

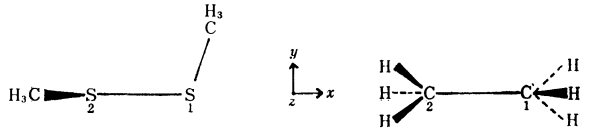

Fig. 5. Conformations and the numbering of the atoms of $(CH_3)_2S_2$ and C_2H_6.

In a case of a proton attack, the following two points must be considered. First, a proton will approach more easily to the S–S bond in a lone-pair direction than to a bond with no lone pairs such as a C–C bond. Second, when a proton approaches one of the lone pairs of the sulfurs, change transfers from the lone pair to the proton and the polarization of the S–S bond will be induced. This polarization may become one step to a heterolytic scission. The protonated form of $(CH_3)_2S_2$ is calculated in Table 8. The calculated results for protonated C_2H_6, in which hardly any ionic scission takes place, are cited in the same table for comparison. In the calculation, the proton is placed 2Å from the S–S bond, first in the lone-pair direction (case I) and then in the z direction to the center of the S–S bond (case II). As for C_2H_6, a proton is placed 2Å from the C–C bond, first in the z direction to the C_1 atom of the C–C bond in Fig. 5 (case III), and then to the center of the C–C bond (case IV). When a proton approaches from a lone-pair direction, the atomic population[26] of the proton is the largest (0.999) and the stabilization energy, ΔE, of the protonated form is the largest (−4.75 eV). The difference in the atomic population[26] between the S_1 atom and the S_2 atom (0.996) is considerably larger than that between the C_1 atom and the C_2 atom (0.315). That is, when a proton approaches the S–S bond, a larger inclination of the charge distribution is induced that in an approach to the C–C bond. The energy of the LV of $(CH_3)_2S_2$ (−0.53 eV) is lower than that of C_2H_6 (3.21 eV), such as in the case of H_2O_2.[23] This means that $(CH_3)_2S_2$ is more apt to accept a nucleophilic attack than C_2H_6, as described before.

Reaction of Aralkyl Hydrodisulfide. Tsurugi *et al.* have given a series of reports[39] about the reaction of

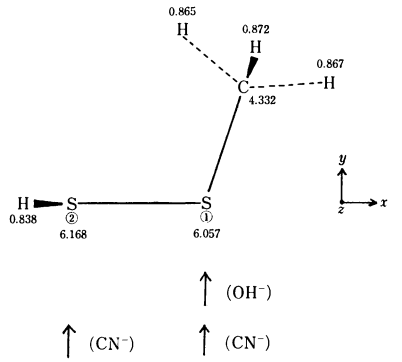

Fig. 6. Conformations and the numbering of the atoms of CH_3SSH are shown together with its atom populations. Arrows show the usual position of an anion attack.

	S_2x	0.531
P_{rs}^{LV}	S_1x-S_2x	0.450

aralkyl hydrodisulfide, RSSH, with various anions. They concluded in one of their papers that, in the absence of steric hindrance, the weaker nucleophiles, such as hydroxide and sulfite ions, attack exclusively the sulfenyl sulfur of benzyl hydrodisulfide. Stronger nucleophiles,[39] such as cyanide and thiolate ions, attack both sulfenyl and sulfhydryl sulfur atoms. We calculated the electronic structure of CH_3SSH, as a model compound. The adopted conformation of the compound is shown in Fig. 6, together with the obtained atomic population. The S_1, S_2, and C_3 atoms are placed on the x–y plane, and the H_7 atom, on the x–z plane, while the dihedral angle is assumed to be 90°. The bond lengths and bond angles are given in Table 2. The AO populations of S_1z and S_2y are 1.996 and 1.989 respectively; they should be lone-pair AO's. The AO populations of S_1x and S_2x in LV are large, as is shown in Table 9, they become antibonding orbitals of the S–S $p\sigma$ bond. That is, an anion attack occurs along the S–S bond from the outside. Furthermore, in LV, the AO population of the S_1x is larger than that of the S_2x, though the difference between them is small. Therefore, the S_1 atom is more susceptible to the anion attack than the S_2 atom. This accounts for the experimental facts that weak nucleophiles attack the S_1 atom, while strong nucleophiles attack both the S_1 and S_2 atoms.

Reactions of Acyl Thiol. There have been several reviews[40,41] about various reactions of acyl thiol and the thiol ester, with particular attention payed to their role in biochemistry. As has been described before, CoAS-$COCH_3$ is an acetylating intermediate and its C–S bond is a high energy bond.[3] We calculated the electronic structure of CH_3COSCH_3, as a model compound. The assumed conformation of the compound is shown in Fig. 7, together with the atomic population. The S_1, C_2, O_3, C_4, and C_5 atoms are all assumed to be on the same x–y plane. The bond lengths and bond angles are given in Table 2. The AO populations are shown in Table 10, while those of the main p orbitals in HO and LV are shown in Table 11. HO(−12.69 eV) is a π-type lone-pair MO, largely localized at the S_1z AO, which is a lone-pair AO of the sulfur atom. This lone-pair level localized at the sulfur atom become higher than that localized at the oxygen atom. Therefore, a cation attack must take place at S_1z AO, this is in agreement with the experimental results The LV is an antibonding π-type MO largely localized at the C_2z AO. The partial AO bond populations of C_2z–O_3z and C_2z–S_1z in LV are −0.352 and −0.276 respectively. Therefore, an anion attack must take place at the C_2z AO in LV. This accounts for the several reactions[42] reviewed by Bruice,[39] in which an inter- or intra-molecular nucleophilic attack on the carbon atom of acyl thiol or the acyl thiol ester by a lone pair of a nitrogen atom or a sulfur atom is often essential. The energy of LV (−8.47 eV)is remarkably lower than those of CH_3SSH (−0.79 eV) and $(CH_3)_2S_2$ (−0.53 eV). This shows that CH_3SCOCH_3 is very apt to accept an anion attack.

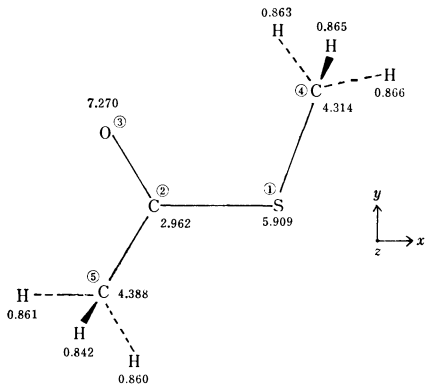

Fig. 7. Conformation and the numbering of the atoms of CH_3SCOCH_3 are shown together with its atom populations.

Electronic Structure of Lone Pairs. IV.[1] The Transannular Interaction of Several Meso-cycles

Hiroko YAMABE, Hiroshi KATO,[2] and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 30, 1970)

The MO calculation of the transannular interaction of eight-membered model systems, containing S,O,N, or C atoms in the position opposed to the C atom of the C=O group, are made by the extended Hückel method and the semi-empirical ASMO SCF method. The relation between the bond order (P_{rs} value or E_{AB} value) and the infrared absorption frequency, $\nu_{C=O}$, is discussed. The electronic absorption maxima in the 221 mμ—235 mμ region are assigned to π–π^* type transitions of intramolecular charge transfer from the interacting atom, X, to the C=O group. The absorptions in the region from 217 mμ to about 190 mμ are n–σ^* type transitions. In the model calculation of the NH_3 and HCHO system, it is shown that the interaction is large, the lone pair being directed to the C atom.

The transannular interaction of diametrically-opposed nitrogen and carbonyl groups in meso-cycles was noticed formerly by Kermack and Robinson[3] in their work on alkaloid. Cromwell *et al.* reported[4] that the presence of an amino group (either substituted or unsubstituted) on the beta carbon atom of an α,β-unsaturated ketone lowers the carbonyl-streching band by 20—80 cm^{-1}. Many subsequent investigations have been performed by Leonard *et al.*[5-8] for the transannular nitrogen-carbonyl interaction in cyclic aminoketones and amino-acyloines of a medium ring size, such as compounds I,[5,6] II,[5,6] and III[5,9] in Fig. 1. They have shown that the

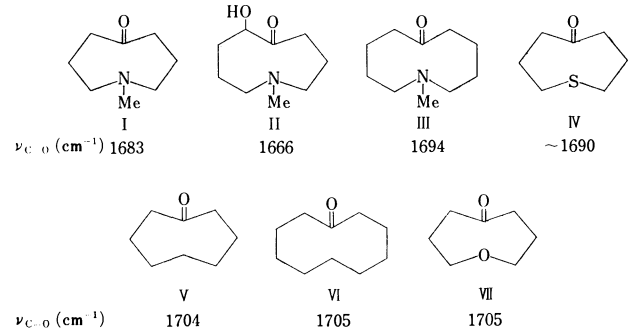

Fig. 1.

occurrence of transannular interaction, $R-\overset{|}{\underset{|}{N}}^{\delta+}: \quad \overset{|}{\underset{|}{C}}=O^{\delta-}$, depends upon the ring size,[6,8,9] the strain,[7,9] and the environmental factors.[5,10] Further, they also established the transannular effects between sulfur or sulfoxide and ketone functions in an eight-membered model systems[11,12] (as IV[5,11] in Fig. 1). Namely, the lone pairs of nitrogen or sulfur atom have a through-space interaction with the carbon atom of the >C=O group (denoted by C_{CO}), which is polarized as $>^{+\delta}C=O^{-\delta}$. The frequencies of the infrared absorption maxima of the C=O stretching, $\nu_{C=O}$, of the compounds (such as I, II, III, and IV in Fig. 1) are abnormally lower than those of the corresponding alkanones[5,11,12] (as V, VI, and VII in Fig. 1). This is probably due to a transannular interaction and may reflect the different bond orders, P_{CO}, of the C=O group in the various compounds in Fig. 1. Note that VII does not show a transannular interaction, in spite of the existence of the lone pair of the oxygen atom.

The UV spectra of these compounds observed by Leonard *et al.*[13] are reproduced in Tables 1A and 1B. In Table 1A, the maxima appear in the ~217 mμ region and ~264 mμ region for the compounds in which no appreciable transannular interaction is expected. On the other hand, the absorption maxima of the molecules in which the transannular interaction is expected appear in the region from 225 mμ to 231 mμ.[14] Similar relations[15] may be seen for the compounds listed in Table 1B. However, the assignments of these transitions have not yet been made.

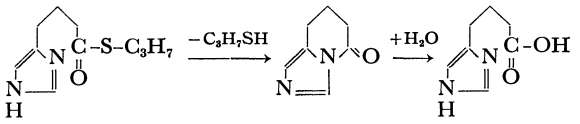
Furthermore, there have been several reports about biochemical interactions; it has reported that a lone pair of a nitrogen or a sulfur atom has a kind of a catalytic action through these transannular interactions[16,17] The important factor in these interactions is a favorable mutual situation of the interacting lone pair and the C=O group, and the maintenance of its situation in time and space, which will be done by the surrounding atoms and groups.[16,17]

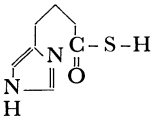
The purposes of the present study are three-fold: (i) to ascertain whether the transannular interaction of the molecules can also be seen in the molecular orbital calculation; (ii) to ascertain the role of the lone pair in this interaction, and (iii) to determine the assignment of the main absorption maxima. Fig. 2 shows the electronic structures of some model compounds[20,21] which we investigated in Fig. 2. As a first trial method, the extended Hückel method[22] (abbreviated as E–H) is employed, because the system to be examined is large. Next, in order to ascertain the results by means of E–H calculation and to study the electronic transitions, semi-empirical ASMO SCF calculations[23] (abbreviated as SCF) for the valence electron systems are carried out, neglecting the contribution of the *d* orbitals.

When the molecule has a situation in which the direction of the lone pair to the C_{CO} atom is a ppropriate and the distance between them is one at which their potential energy is about at its minimum, a large transannular interaction may be expected. To show the existence of these critical values, we will make a model calculation of the electronic structure of the NH_3 and HCHO system, varying the mutual angle and distance between the NH_3 molecule and the HCHO molecule. At the same time, the variation in the atomic population,[24] the bond order of the C=O bond, P_{CO}, and the bond order between the C atom and the N atom, P_{CN}, are also studied.

16) There is a report that, with the intramolecular assistance of the imidazole group, the following thiol-ester undergoes solvolysis at 10^6—10^7 times as fast as a normal thiol-ester. Its mechanism may be shown as follows (Refs. 18 and 19):



In our E–H calculation of a model compound,



the obtained bond order between the N atom and the opposed C_{CO} atom of the C=O group becomes positive and shows a transannular interaction.

17) An example of the transannular interaction, in the extended sense (through space interaction), is seen in the enzymatic action shown in the following scheme (Ref. 18):

Method of Calculations

Figure 3 shows the conformations used for the MO calculations. The coordinate axes for the conformation of Fig. 3A[25] and the numbering of the atoms are given in Fig. 3C. As no definite conformation of these molecules has been reported, the calculation is carried out for the assumed structure, consulting the literature.[11] The bond lengths[26] and bond angles[26] employed are given in Table 2. With these lengths and angles, the $C_1\cdots X_3$ distance (in Fig. 3A and Fig. 3C) becomes approximately 2.5Å. The y axis is chosen as the line connecting the interacting C_1 atom (C_{CO} atom) and the X_3 atom. The opposed triangle planes, $C_4X_3C_9$ and $C_6C_1C_7$, are parallel to each other, as in Fig. 3C. Namely, the dihedral angle, θ, between these two planes is set as zero.[27]

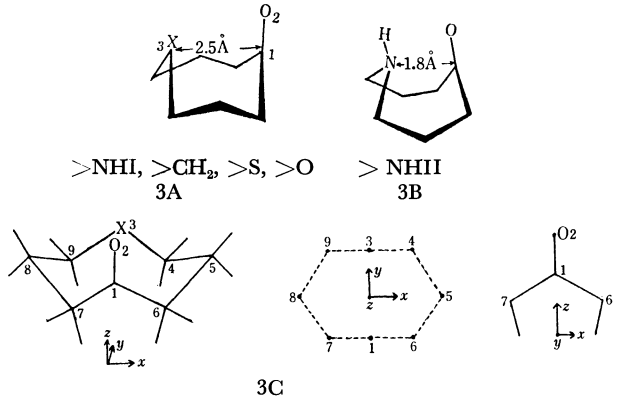

Fig. 3. 3A and 3B show two conformations for the calculation. X denotes the N atom (of NH group), the C atom (of CH_2 group), the S atom or the O atom of each compound (Ref. 26. *cf* Fig. 2).
The coordinate axes for the conformation of 3A, and the numbering of the atoms are given in 3C.

Table 2. bond lengths (in Å) and bond angles

C–H	1.09	∠C (sp^2)	120°
C–C	1.54	∠C (sp^3)	109°28′
C=O	1.22	∠COC	112°
C–O (in C–O–C)	1.44	∠CSC	98°
C–S (in C–S–C)	1.82	∠CNC	107°
C–N (in C–N–C)	1.47		
N–H	1.01		

In this zero conformation the lone pair of the S atom will be approximately directed perpendicularly to the C=O bond.[28] However, the lone pair of the N atom is not directed in the way perpendicular to the C atom, but is directed slightly upwards. Then, for the compound containing the NH group, another limiting conformation, as in Fig. 3B, is calculated. This conformation is referered to as NHII, and the previous one, in Fig. 3A, as >NHI. In >NHII (Fig. 3B), the $C_1\cdots N$ distance becomes shorter, 1.8 Å, and the derection of the lone pair of the N atom is more perpendicular to the plane including the C=O bond than in the case of >NHI.

Results and Discussion

Interaction of NH_3 and HCHO (A Model Calculation). In order to ascertain the interaction of the lone pair and the C=O group more explicitly, we calculated the electronic structure of the system of NH_3 and HCHO. HCHO is assumed to be planar, and the molecular plane is placed on the y–z plane, and the C=O bond, on the z axis, as in Fig. 4. The C···N distance is put

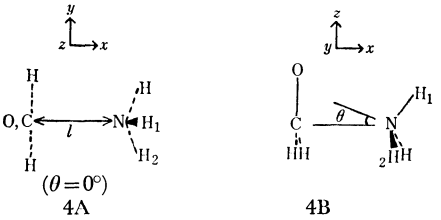

Fig. 4. HCHO and NH_3 system.

as l along the x axis, and the angle between the direction of the sp^2 type lone pair of the N atom and the x axis is put as θ. The angle θ is changed by the rotation of NH_3 on the x–r plane. The calculation of system as a function of θ (from $-10°$ to 30°) and l(from 0.5Å to 3.5Å) is carried out by the E–H method in order to ascertain values of θ and l in which the total energy of the system is at a minimum. The θ dependency of the atomic population[24] is shown in Table 3. The total energy and the bond order of the C–O bond, P_{CO}, and that between the C atom and N atom, P_{CN}, are shown in Table 4. The energy minimum is obtained at $\theta=0°$. The positive P_{CN} value indicates a bonding property between the C atom and the N atom. As θ approaches zero, the charge is transferred from NH_3 to HCHO, the polarization of the C–O bond and the P_{CN} value become large, and the P_{CO} value becomes smaller. Namely, the (transannular) interactions of the two molecules are the largest when the lone pair is directed to the C atom ($\theta=0°$).

As for the l dependency, the energy is decreased monotonically toward a larger l value and the expected energy minimum cannot be obtained by either method. This may be due to a defect in the approximation of the calculation.[29]

Population Analysis. The atomic orbital (AO) population[24] of the X_3 atom calculated by the E–H method and the AO-charge density[23] calculated by the SCF method are shown in Table 5. The AO population

25) In Fig. 3A, X denotes the N atom of the NH group, the C atom of the CH_2 group, and the S atom or the O atom of the NHI, >NHII, $>CH_2$, >S, or >O compounds, respectively. In Fig. 3A, the H atom of the groups and CH_2NH are not shown, for the sake of simplicity.

26) "Tables of Interatomic Distances and Configuration in Molecules and Ions," ed. by L. E. Sutton, The Chem. Soc., London (1956) and (1965).

27) Leonard *et al.* estimated $\theta=21°$ for >O and $\theta=68°$ for >S from the dipole moment (Ref. 11).

28) Actually, as the van der Waals radii of the sulfur atom are large, the molecule may have a larger dihedral angle than zero (Ref 27).

29) In the SCF calculation, the atomic-charge density and the E_{AB} values (E_{CO} and E_{CN}) do not change smoothly with the variation in θ and l.

and the AO-charge density of the p_y AO of the N,S, and O atoms are large. These values of the p_y AO of the C atom are also larger than the p_x AO and the p_z AO. In the extreme case of >NHII, which is revealed to be too extreme, the electron of the p_y orbital flows to the p_y AO of the C_{CO} atom[30] and to the p_y AO of the O atom,[30] compared to the case of >NHI. This trend was also seen in the NH_3 and HCHO system, with a larger transannular interaction.

In the SCF calculation, according to a previous paper,[23] the total electronic energy, E_{AB},[23] of the AB bond is used instead of this bond order:

$$E_{AB} = \sum_{r}^{\text{on A}} \sum_{s}^{\text{on B}} P_{rs}(H_{rs}+F_{rs})$$

where H_{rs} is the core resonance integral,[23] where F_{rs} is the Fock's operator, and where $\sum_{r}^{\text{on A}}$ denotes the summation over all the valence AO's belonging to the A atom. The E_{AB} values obtained by the SCF calculation are listed in Table 6, together with the observed infrared absorption maximum of C=O stretching.[6,8]

TABLE 6. P_{rs} AND E_{AB} VALUES (eV) OF THE C=O BOND AND THE C_{CO}----X INTERACTION OBTAINED BY THE E–H AND THE SCF CALCULATIONS, AND THE OBSERVED CARBONYL FREQUENCY $\nu_{C=O}(cm^{-1})$

The bond orders, P_{CX}'s, between the C_1 atom (or C_{CO} atom) and the X_3 atom (Fig. 3) become positive. This shows the bonding property (the transannular interaction) between the C_{CO} atom and the X atom. In Table 6, a correlation between P_{CO}, P_{CX}, E_{CX}, and $\nu_{C=O}$ may be expected. For the larger transannular interaction and the smaller $\nu_{C=O}$, the P_{CX} value becomes larger, the E_{CX} value becomes more negative, and the P_{CO} value becomes smaller. In the conformation with

30) The AO population of the p_yAO of the C_{CO} and O atoms of >NHI and >NHII are obtained as follows by the E–H calculations:

	>NH I	NH II

the dihedral angle larger than zero,[27,28] the P_{CX} value of >S becomes smaller and the parallelism with $\nu_{C=O}$ becomes better. When the NHII conformation is adopted (rather than >NHI), the parallelism becomes better. However, the total energy of >NHII is higher than>NHI, and the P_{CX}, E_{CX}, P_{CO}, and E_{CO} values of >NHII deviate too much[31] compared to the values of the other examples (see Table 6). That is, the>NHII conformation is too extreme. It is possible that an actual molecule may have an intermediate conformation[32] between the two, >NHI and >NHII (denoted hereafter by >NHIII), in which the total energy is at a minimum and the parallelism between the P_{rs}, E_{AB}, and $\nu_{C=O}$ values become better. However, since the two methods we employed cannot give an energy minimum for the variation in the distance between the C_{CO} atom and the X atom, it is difficult to determine the actual conformation of >NHIII in these approximations.

Electronic Transitions. The transition energy and the transition moment are calculated by the SCF method. The calculated results are listed in Table 7 and there compared with the observed UV absorpations. As for the π–π^* transition of the oxygen meso-cycles (2→1* and 3→1* of Table 7) the configuration interaction (CI) is carried out. The results are shown in the bottom raws of Table 7. The energy levels concerning these transitions, and the main orbital coefficients of the C_1 or C_{CO}, O_2 and X_3 atoms, are shown in Table 8. The numbering of the levels is made from the highest-occupied level to the lower levels, and from the lowest unoccupied level (denoted by *) to the higher levels.

Though the agreement between the observed and the calculated transition energies is not very good, we tried to obtain some information about the nature of these transitions. The calculated transition with the higher energy is a sort of n–σ^* (A'') transition, the energy of which is equal for $>CH_2$ and >NHI, and does not vary very much for >S and >O. In the n MO, the MO coefficient of the lone pair AO of the O atom of the C=O group is large, and in the σ^* MO the MO coefficient of the s orbital of the C_1 atom is large. That is, it is noted that the n–σ^* transition is not affected very much by the transannular interaction. Therefore, these n–σ^* transitions correspond to the absorption is the 217 mμ region, which shows a comparatively small deviation among the compounds in Table 1A, or to the absorption about the 190 mμ region of the compounds in Table 1B.

The absorption maximum in the 230 mμ region (Tables 1A and 1B) may be a π–π^* (A')-type transition, in which π and π^* MO's are much more affected by the transannular interaction. That is, the π MO (see Table 8) is mainly constituted by the interacting lone pair AO and the π orbital of the C=O group. The π^* MO is considerably localized to the π^* antibonding orbital of the C=O group; the MO coefficient of the C_1 atom is especially large. Thus, these π–π^* transitions are essentially the intramolecular charge transfer from the interacting atom, X, to the C=O group.

In our calcultion, the transition with the third intense transition moment becomes an $n(\bar{\pi})$–π^* type (A′). The orbital, denoted by $n(\bar{\pi})$, has a comparatively large MO coefficient of the lone-pair AO of the O atom of the C=O group. In Table 7, the $n(\bar{\pi})$–π^* transition energy of NHI is smaller than the π–π^*. Possibly, the weak absorption with no detectable maximum in the longer-wavelength (carbonyl) region (shown by d in Table 1A)[13] is due to this $n(\bar{\pi})$–π^*-type transition.

From preceding calculations and discussions, it is found that the P_{CX} value is positive and the E_{CX} value is negative; this indicates the transannular interaction of the bonding type. Because of the larger transannular interaction, the P_{CO} value becomes large. The approximate parallelism between the P_{CO} value and $\nu_{C=O}$ is seen. Furthermore, the πMO, which is mainly constituted by the interacting lone-pair AO and the π orbital of the C=O group, and the π–π^* transition are affected by the transannular interaction.

One of the authors(H.Y) wishes to thank Mr. Hiroshi Nakatsuji for reading the manuscript and for his helpful suggestions.

The calculation was carried out on a HITAC 5020 Computer at the computation center of the University of Tokyo.

31) The P_{CO}, P_{CX}, E_{CO}, and E_{CX} values are sensitively change depending on the interatomic distance between the C_{CO} atom and the X atom.

32) The >NH III contormation has an intermediate $C_{CO}\cdot\cdot X$ distance between the two.

The Optical Activity of Bis-1,1′-spiroindanes. The Direct Calculation of Optical Rotational Strengths

Sanji HAGISHITA and Kaoru KURIYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Sagisu, Fukushima-ku, Osaka

(Received July 8, 1970)

A calculation based on Longuet-Higgins and Murrell's method using the MO's of aniline and phenol obtained by the SCF-MO-CI calculation is carried out for the π-electron structures of (−)-6,6′-diamino-(I) and (−)-6,6′-dihydroxy-bis-1,1′-spiroindane (II). These wave functions are then used to calculate the rotation strengths of these compounds. The circular dichroism curves calculated from the results, assuming a Gaussian curve, are compared with the observed spectra; a quantitative agreement with the experimental value is found. The nature of the transitions and the origin of the optical activity are also discussed.

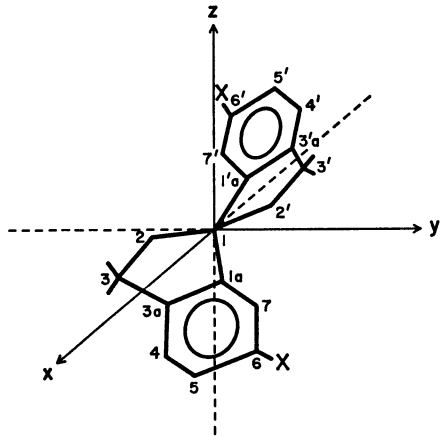
In a previous paper[1] we reported the resolution, the CD spectra, and, from an analysis of the CD spectra, the determination of the absolute configuration of C_2-symmetrical bis-1,1′-spiroindane derivatives. The previous analysis was based on simple dipole-coupling mechanisms. This treatment has been widely used for the determination of the absolute configuration of the chiral molecules considered to be constructed from two or three groups with electric-dipole-allowed transitions.[2] The determination of the absolute configuration of spiroindanes belonging to the classes II and III[3] was based on the quantitative agreement between the observed and calculated rotational strengths associated with the *p*-band. However, the signs of the Cotton effects associated with the α-band are not in agreement with each other; moreover, there are some derivatives in which only one Cotton effect is associated with the α-band. Therefore, in order to satisfy all the electronic absorption regions, the application of simple dipole-coupling mechanisms seems not to be useful; this may be attributed partly to the fact that the value of the spectroscopic moment and the assumption of a point dipole located on the center of the benzene ring are not suitable.

There are also other shortcomings. The transitions correlated with the α- and the *p*-bands are orthogonal to each other and do not mix; also, it is necessary to adopt the configuration interaction among other transitions of the same symmetry and also, in these spiroindanes, to consider the mixing of the transitions through the repulsion force produced from the interaction between the transitions of one isolated chromophore and that of another chromophore. When two π systems are held in perpendicular planes by a common atom of a tetrahedral geometry, the overlap between the *p* orbitals on atoms bound directly to the insulating atom is considerable. Consequently, exchange interactions may become significant and may also produce charge-transfer transitions and a mixing of the local excitations.

In the present paper, we will report on the analysis of the CD spectra of the 6,6′-diamino-(I) and 6,6′-dihydroxy-bis-1,1′-spiroindane (II) by improved theoretical methods.

Method of Calculation

The σ electron, especially at the C-1 position, will influence the π electron framework;[4] in this calculation, however, only π electrons are considered. Therefore, (−)-I and (−)-II can be approximated to the dimers of two anilines and two phenols respectively, set at the spiro position. The five-membered rings of these spiroindanes may not have the envelope form because of the described in the previous paper.[1] Therefore, we have approximated the planar conformation in which the two systems are held in a perpendicular plane by a carbon atom of a tetrahedral geometry, with the S-configuration depicted in Fig. 1, for we believe that the small difference in geometry will not greatly influence the results of the calculated CD spectra.



(−)-I : X=NH$_2$ (−)-II : X=OH

Fig. 1. The coordinate system employed. The bond lengths are chosen as follows: the aromatic C–C bond, 1.40 Å; the C–C single bond between C_1 and C_{7a} (and also C_1 and $C_{7a'}$), 1.52 Å, the C–O bond, 1.36 Å; the C–N bond, 1.41 Å. A perfect tetrahedral geometry is taken for C_1.

3) The spiroindane derivatives were separated into three classes according to the origin of the optical power. In the classes II and III, the contribution of the dispersion force between the two aromatic chromophores is greater than the other effects, and the substituents at the benzene ring have large values in Platt's spectroscopic moment.

4) H. E. Simmons and T. Fukunaga, *J. Amer. Chem. Soc.*, **89**, 5208 (1967).

In this geometry, the resonance integrals between the AO's of the carbon atoms of the two aromatic chromophores must be considered. Assuming appropriate values for the overlap integrals, the wave functions can be obtained for the (−)-I and (−)-II molecules by the SCF–MO treatment. In this calculation, however, the Longuet-Higgins-Murrell formalism[5] is utilized. This method is particularly suitable for the investigation of the nature and origin of the coupling between chromophores and to take account of the configuration interaction effects. Moreover, a fairly well established approximation, such as the SCF-MO-CI method, can be used.

First, it is necessary to obtain the exact wave functions of the local chromophores. Nishimoto and Foster[6] have obtained the wave functions of mono-substituted benzenes by the SCF-CI formalism of the Pariser-Parr-Pople method[7] with variable β approximation. Their results showed that the calculated singlet transition energies and the oscillator strengths of aniline and phenol were in good agreement with the experimental values. Therefore, we adopted these wave functions as the local chromophores (see Appendix 1).

From these wave functions, we took account of only four locally-excited states, from the lowest to the fourth energy level for each chromophore. The resonance integrals between the AO's of the carbon atoms of the two chromophores cannot be neglected, and the energies of the highest occupied and the lowest vacant π MO are very similar to those of the second occupied and the second vacant π MO respectively. Therefore, we took into account an additional eight kinds of charge-transfer configurations, in which an electron is transferred from one aromatic chromophore to another, and *vice versa*. Thus, we considered a total of sixteen configurations for each of the molecules, (−)-I and (−)-II.

Taking the energy of the ground configuration as the standard, the energy values of locally-excited configurations can be directly determined from the results of Nishimoto and Foster.[6]

Neglecting the penetration integrals[8] and assuming a zero differential overlap,[7] the energy for the charge-transfer configuration can be evaluated by the following equation:

$$E_{CT} = I_\mu - A_\nu - \sum_r \sum_s C_r^\mu C_r^\mu C_s^\nu C_s^\nu (rr|ss) \quad (1)$$

where I_μ and A_ν are the ionization potential of μth and the electron affinity of the νth level of the MO of the aromatic chromophore respectively, and where C_r^μ is the coefficient of the rth AO's of the μth level of the MO. Two-center repulsion integrals of the $(rr|ss)$ type are computed from the Ohno approximation:[9]

$$(rr|ss) = \frac{1}{2}\left(1\sqrt{R_{rs}^2 + 1/(rr|rr)^2} + 1\sqrt{R_{rs}^2 + 1/(ss|ss)^2}\right) \quad (2)$$

where the one-center repulsion integrals $(rr|rr)$ are computed from the valence-state ionization potentials, I_r, and the electron affinities, A_r, for carbon, nitrogen, and oxygen by means of Eq. (3):

$$(rr|rr) = I_r - A_r \quad (3)$$

I_r and A_r are taken from Hinze and Jaffé's table.[10]

As the diagonal matrix elements have been evaluated, it is necessary to consider the off-diagonal matrix elements of the total electric Hamiltonian, each of which represents the magnitude of the interaction between two different configurations. The evaluation of the off-diagonal elements is carried out by the formulations by Pople[11] and Longuet-Higgins and Murrell.[5] In these calculations, the values of the two-center core integrals, β_{CX} (X=C, N, or O), at 1.40 Å for a C–C bond, at 1.38 Å for a C–N bond, and at 1.36 Å for a C–O bond are taken as standard from the literature,[6] while the β_{rs} values are evaluated by means of the following equation:

$$\beta_{rs} = (S_{rs}/S_{CX})\beta_{CX} \quad (4)$$

Here, S_{rs}/S_{CX} is the ratio of the overlap integrals at each distance. The two-center repulsion integrals are also calculated by the Ohno approximation.

Solving the secular equations constructed for each molecule by the use of the matrix elements evaluated above, the energy levels and wave functions shown in Table 1 are obtained.

In this calculation, using the Longuet-Higgins-Murrell formalism, the resonance energy between two aromatic chromophores is very small. The mixing of the locally-excited configurations and charge-transfer configurations by this spiro-conjugation contributes only a little. Therefore, in the other methods, the charge-transfer configurations are neglected and the repulsion among the locally-excited configurations is considered only by the formulation by Pople.[11] Moreover, we have taken twenty and sixteen local configurations for the compounds (−)-I and (−)-II respectively. We name this calculation "Method II"; the results are shown in Table 2.

The CD is governed by the rotational strength, R_i, to which Rosenfeld[12] first applied a quantum mechanical theory. The rotational strength is defined as the imaginary part of the scalar product of the molecular electric dipole moment, $\langle\psi_0|\vec{\varepsilon}|\psi_i\rangle$, with the magnetic dipole moment of $\langle\psi_i|\vec{m}|\psi_0\rangle$ for the electric transition under consideration:

$$R_i = Im\langle\psi_0|\vec{\varepsilon}|\psi_i\rangle\langle\psi_i|\vec{m}|\psi_0\rangle \quad (5)$$

where

$$\vec{\varepsilon} = e\sum_k \boldsymbol{r}_k \text{ and } \vec{m} = \frac{eh}{4\pi imc}\sum_k \boldsymbol{r}_k \times \nabla_k$$

The values of the electric and magnetic moments are not formulated on an equal footing; the rotational strength so calculated is origin-dependent. The evaluation of the electric and magnetic dipole moments is

The symbol G and L_i are used in the same manner as in Table 1.

achieved in the following way:[13]

$$\langle\psi_0|r|\psi_i\rangle = \frac{h}{4\pi^2 m\nu_{i0}}\langle\psi_0|\nabla|\psi_i\rangle \quad (6)$$

where

$$h\nu_{i0} = E_i - E_0$$

The wave functions obtained above can be written in the form:

$$\psi_i^{D} = \sum_i C_i^i\psi_i^{M} + \sum_k C_k^i\psi_k^{CT} \quad (7)$$

where ψ_i^{M} and ψ_k^{CT} represent the ith wave function of the monomer chromophore and the kth wave function of the charge-transfer transition respectively. The monomer wave functions can be rewritten as a linear combination of configurations:

$$\psi_i^{M} = \sum_l\sum_m C^i_{lm}(\psi_l^{-1}\psi_m) \quad (8)$$

Then, the electric dipole moments of the monomer may be approximated as follows:

$$\langle\psi_0^{M}|\nabla|\psi_i^{M}\rangle \doteqdot \sqrt{2}\,C^0_{00}\sum_l\sum_m C^i_{lm}\langle\psi_l|\nabla|\psi_m\rangle \quad (9)$$

Similarly, the magnetic moments are approximated as follows:

$$\langle\psi_i^{M}|\vec{m}|\psi_0^{M}\rangle = \frac{eh}{4\pi imc}\cdot\sqrt{2}\,C^0_{00}\sum_m\sum_l C^i_{ml}\langle\psi_m|r\times\nabla|\psi_l\rangle \quad (10)$$

where $\boldsymbol{r}$ is the radius vector to the electron under consideration. The MO's, ψ_l and ψ_m, are written as linear combinations of AO's (X):

$$\psi_l = \sum_\alpha C_\alpha{}^l\chi_\alpha \quad (11)$$

Therefore,

$$\langle\psi_l|\nabla|\psi_m\rangle = \sum_{\text{all bond}} C^{lm}_{\alpha\beta}\langle\chi_\alpha|\nabla|\chi_\beta\rangle \quad (12)$$

$$\langle\psi_l|r\times\nabla|\psi_m\rangle = \sum_{\text{all bond}} C^{lm}_{\alpha\beta}r_{\alpha\beta}\times\langle\chi_\alpha|\nabla|\chi_\beta\rangle \quad (13)$$

where $C^{lm}_{\alpha\beta}$ is the transitional bond order ($C^{lm}_{\alpha\beta}=C_\alpha{}^lC_\beta{}^m - C_\beta{}^lC_\alpha{}^m$) and where $\vec{r}_{\alpha\beta}$ is the radius vector to the mid-point of the bond. We also made similar calculations on the charge transfer, but the electric and magnetic dipole moments are very small. Therefore, these quantities for the charge-transfer configuration are neglected. By these procedures, we found the rotational strengths which are origin-independent. Using the MO's, the rotational strengths can be calculated on the basis of these formulations.

On the other hand, the rotational strength can be calculated by using Eqs. (5) and (11') for the wave-function of method II:

$$\langle\psi_i|\vec{m}|\psi_0\rangle = \frac{\pi\nu_{i0}}{C}i\sum_k \boldsymbol{R}_k\times\langle\psi_i|e\boldsymbol{r}_k|\psi_0\rangle \quad (11')$$

where $\boldsymbol{R}_k$ is the radius vector to the center of gravity of π-electrons in the ground state of the aromatic chromophore. By this procedure (named method III), we could also find the rotational strengths which are origin-independent.

Results and Discussion

From the results of the compounds (—)-I and (—)-II given in Table 1, the contribution of the configurations to the excited states can be estimated, and we can see the nature of the transitions. By method I, the first and the second excited states can be said to be mainly composed of the ψ_1^M configuration (α-band) of the monomer and to have A and B symmetries respectively. In the third and fourth excited states, although the main configuration is the ψ_2^M (p-band) of the monomer, the charge-transfer configuration contributes to these states only to some extent. On the contrary, the main configuration of the fifth and sixth excited states is the charge-transfer configuration. This means that these transitions involve a large amount of electron transfer between the aromatic chromophores.

When the intramolecular charge-transfer configurations are neglected, the results given in Table 2 also show the mixing of the locally-excited configurations and the A and B symmetry of the transitions respectively. The first and the second excited states have mainly the ψ_1^M configuration, while the third and the fourth excited states have again the ψ_2^M configurations; in higher excited states, a mixing of the configurations is clearly observed.

When the excitation energies obtained by the two methods are compared with those of the experiments, the experimental results show still lower energies. This may be explained by the fact that the local excitation energies are adopted from aniline and phenol directly instead of from 6-amino- and 6-hydroxy-indane.

When the observed and the calculated CD spectra are compared, it is important to consider any mutual cancellation or addition of bands in areas where they overlap. The rotational strength, R, of an isolated, optically-active transition can be defined in the terms of directly observable properties, such as the ellipticity, $[\theta]_\lambda$[14]:

$$R = \frac{hc}{48\pi^2 N}\int [\theta]_\lambda \mathrm{d} \ln \lambda \text{ (integration taken through the bond)} \tag{15}$$

If the ellipticity has a Gaussian dependence on the wavelength,

$$[\theta]_\lambda = [\theta]_{max} \exp\left[-\left(\frac{\lambda-\lambda_i}{\Delta_i}\right)^2\right] \tag{16}$$

where $[\theta]_{max}$ is the maximum value of the ellipticity, Δ_i is the half-width, and λ_i is the wavelength corresponding to the maximum ellipticity. Furthermore, one obtains a direct relation between the ellipticity, $[\theta]_\lambda$, and the rotational strengths, R_i:

$$[\theta]_\lambda = \frac{1}{1.233\times 10^{-42}} \sum_i R_i \frac{\lambda_i}{\Delta_i} \exp\left[-\left(\frac{\lambda-\lambda_i}{\Delta_i}\right)^2\right] \tag{17}$$

In this calculation, the values of the half-widths, Δ_i, are different in every transition, but we approximate the λ_i/Δ_i value to a constant. Using this equation and this assumption, we plot the theoretical CD curves in Figs. 2 and 3.

14) W. Moffitt and A. Moscowitz, *J. Chem. Phys.*, **30**, 648 (1959).

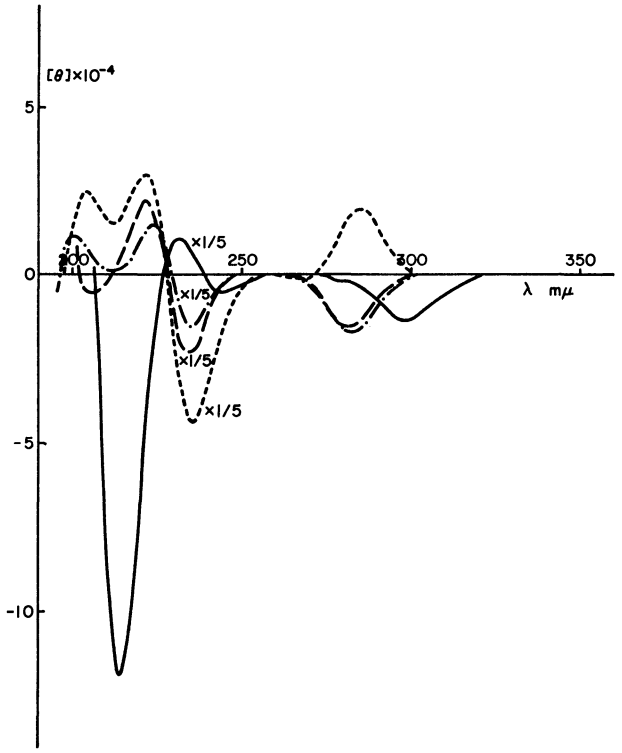

Fig. 2. CD spectra of (—)-3,3,3′,3′-tetramethyl-6,6′-diamino-bis-1,1′-spiroindane. Found (——), method I (----), method II (-·-·-), and method III (·····).

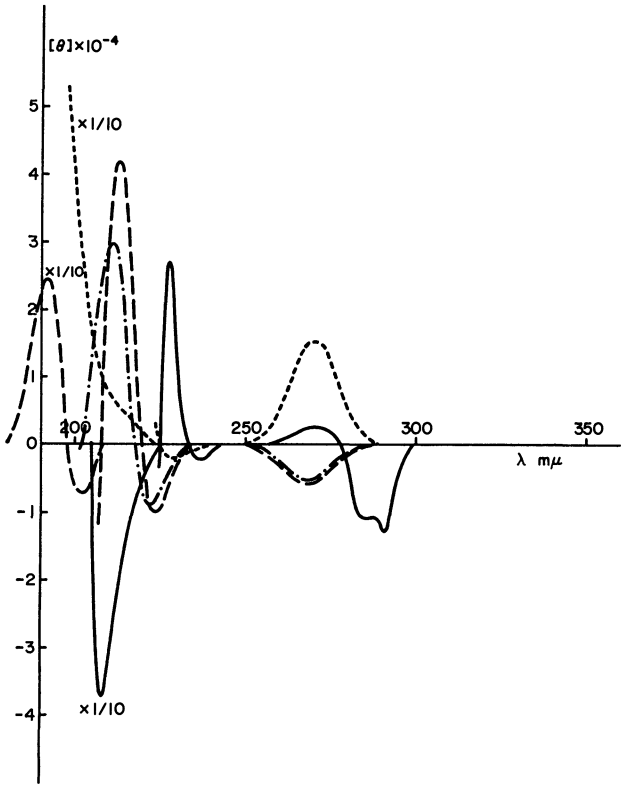

Fig. 3. CD spectra of (—)-3,3,3′,3′,-tetramethyl-6,6′-dihydroxy-bis-1,1′-spiroindane. Found (——), method I (----), method II (-·-·-), and method III (·····).

As has been mentioned above, the calculated excitation energies are higher than the observed ones. By comparing the observed and calculated CD spectra cited in Fig. 2, the calculated Cotton effect centered at

ca. 280 mμ can be considered to be correlated with the observed Cotton effects at *ca.* 300 mμ. Although the simple dipole-coupling mechanisms and method III could not predict the correct signs and magnitudes of the Cotton effect in this region, the results of methods I and II predict almost quantitatively the sign and the magnitude of the Cotton effect.

In (−)-II, we can see two oppositely-signed Cotton effects at 291.5 and 270 mμ, but the CD spectra calculated by methods I and II in Fig. 3 show only the negatively-signed Cotton effect, while that calculated by method III shows only a positively-signed one at *ca.* 269 mμ. Although these methods, I and II, cannot predict the small Cotton effect of a positive sign, the large, negatively-signed Cotton effect corresponds to the results of the calculation. The results are, therefore, not so unsatisfactory, while method III gives an unsatisfactory result from the same point of view.

In the shorter-wavelength regions, the observed rotational strengths at 244 and 233 mμ of (−)-I are correlated with the four calculated strengths at 231.3, 230.6, 226.1, and 224.8 mμ by method I or with the two at 230.0 and 228.9 mμ by the method II, and the calculated magnitudes are much larger than those observed. However, it is considered that many bands overlap with each other in this region, giving rise to a mutual cancellation or addition of band areas; the validity can be judged by means of the calculated CD curves.

From the CD curves depicted in Fig. 2, the observed Cotton effects centered at 244 and 233 mμ of (−)-I can be correlated with those calculated at *ca.* 235 and 225 mμ respectively. Similarly, in Fig. 3 the observed Cotton effects at 236 and 228 mμ of (−)-II can be correlated with those calculated at *ca.* 225 and *ca.* 210 mμ respectively.

In the method I, the charge-transfer configurations are mixed to some extent in the third and fourth excited states; also, the fifth and sixth excited states have the character of a charge-transfer overlap in these band areas, the results calculated by methods I and II, however, show almost the same CD spectra. From these result, the contribution of the charge-transfer transition can be considered to be small. It cannot, however, be denied that the bands in these regions have the character of a mixture of a number of configurations. The signs and the magnitudes of the observed Cotton effects and those calculated by these three methods agree almost quantitatively.

In the even-shorter-wavelength regions, the CD bands could not be predicted from these calculations. This may be due to the neglect of the higher energy states in method I and of the π–σ^* transitions, which may contribute to the CD spectra in these regions.

From the quantitative agreement between the experimental and the calculated results obtained by the methods, I and II, these methods can be considered to be suitable for the determination of the absolute configuration and for the estimation of the order of the rotational strengths of compounds with two or more chromophores composed of π-electrons. It must be noted that, for the same good wave-functions, methods II and III give different rotational strengths; method III especially shows incorrect signed Cotton effects in the α-band region. The difference in these results may be caused by the choice of the center of the transition dipole in method III, but the true reason for the failure of method III and for the success of method II does not appear to be understood at present. From our present studies, however, it could be concluded, for π-electron systems, that the rotational strengths calculated by method II are more likely to give a good agreement with the experimental data.

On the Effects of Doubly Excited Configurations in Semi-Empirical Molecular Orbital Calculations on Non-Alternant Hydrocarbons

Hiroshi KASHIWAGI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 17, 1970)

Effects of inclusion of doubly excited configurations in semi-empirical SCF-CI calculations are studied for the π-electrons of the four non-alternant hydrocarbons, fulvene, heptafulvene, vinylfulvene, and fulvalene. Transition energies to lower excited states are little affected by inclusion of doubly excited configurations. However, oscillator strengths change substantially and a good agreement with experiment is obtained. Dipole moments of ground states are affected by about 20%.

The importance of configuration interaction (CI) is well known in semi-empirical molecular orbital calculations of π-electron systems. However, often only singly excited configurations are taken into account. Recently, effects of inclusion of doubly or higher excited configurations on calculated molecular properties have been discussed by several authors. Allinger and his coworkers[1-3] treated many unsaturated hydrocarbons by a modified Pariser-Parr-Pople type self-consistent field (SCF)-CI calculation including both singly and doubly excited configurations. They concluded that inclusion of doubly excited configurations has very little effect on transition energies in about 90% of the molecules studied, but it has a substantial effect in certain cases such as *trans*-butadiene. They also found that calculated extinction coefficients become smaller by taking doubly excited configurations into account, but the calculated results are still about 50% too large when compared with the observed values.[2] Eveleth[4,5] and Hirota and Nagakura[6] treated some unsaturated organic hetero-compounds by a similar method. They both found some remarkable changes of transition energies. In some cases, even the order of levels are changed. They also found a large decrease in oscillator strength.

We have studied the effects of doubly excited configurations in semi-empirical SCF-CI calculations. Excitation energies, transition probabilities, and π-electron distributions in a molecule were investigated for four non-alternant hydrocarbons. From our calculations, we hope to find answers to the following questions:

1) Does inclusion of doubly excited configurations lead to a better agreement with experiment. In non-empirical calculations, we believe that bigger CI calculation will yield better wave functions. But this is open to question in semi-empirical calculations.

2) What kind of molecular properties are sensitive to the inclusion of doubly excited configurations?

3) If CI is important, how many configurations should be included to obtain reasonable agreement with experiment?

Fulvene, heptafulvene, vinylfulvene, and fulvalene were chosen because a) only a small number of semi-empirical parameters are necessary, b) π-electron densities on carbon atoms might differ from unity and their values may be sensitive to a small change of wave functions, and c) as many as nine absorptions of singlet π–π transitions are observed for these molecules.

For each molecule, several CI calculations with different dimensions including both singly and doubly excited configurations were carried out. Only basis functions whose energies are below a certain cut-off energy were included in CI. Transition energies, oscillator strengths, π-electron densities, and weights of doubly excited basis functions of excited states were calculated. We investigated the changes of these physical quantities with the cut-off energy. The details of the calculation method is given in the second section. Main features of the results are shown in Figs. 2—9 in the third section.

Method of Calculation

A more or less standard Pariser-Parr-Pople method[7] is followed. Basis wave functions for CI are constructed from SCF molecular orbitals (MO's). For each symmetry type of singlet states, CI matrix elements are calculated and an eigenvalue problem is solved. A FORTRAN program was written. In this program, the number of basic atomic orbitals is not more than 50, and the number of basis wave functions in CI is at most 50 for each symmetry type.

Semi-empirical parameters for carbon $2p\pi$ atomic orbitals are determined as follows: The valence state ionization potential and the one center Coulomb integral are 11.22 eV and 10.60 eV, respectively.[8] Two center Coulomb integrals are evaluated by the quadratic interpolation formula proposed by Pariser and Parr.[7] The effective nuclear charge of the Slater type carbon $2p\pi$ atomic orbital is 3.25. Core resonance integrals between non-nearest neighbors are neglected. For nearest neighbors, core resonance integrals are determined by

$$\beta = -10.59S, \qquad (1)$$

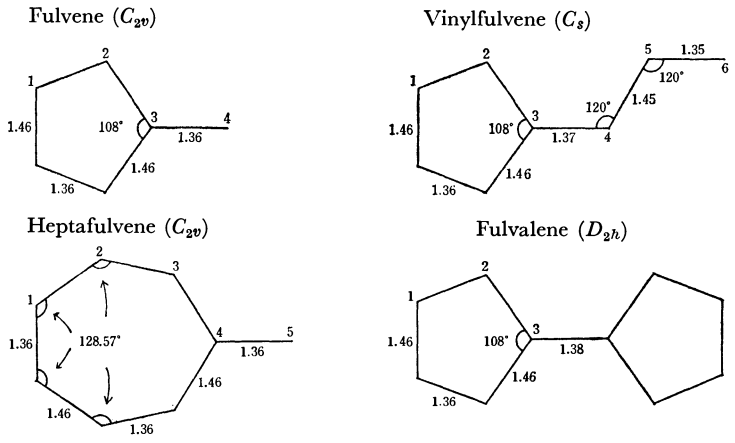

Fig. 1. Molecular geometries. (interatomic distances in Å)

where S is the overlap integral, which is theoretically evaluated from the Slater atomic orbitals. The numerical coefficient in the above formula is fixed by fitting the calculated transition energy $^1A_{1g}-{}^1B_{2u}$ of benzene to the observed value, 4.90 eV. The C–C bond length of benzene is 1.397 Å and the resulting resonance integral is −2.60 eV. It should be noted that the numerical coefficient in Eq. (1) is the only parameter which has been newly determined in this work.

The geometry of the compounds is determined by the following method. The molecular symmetry is assumed as shown in Fig. 1. As for vinylfulvene, it is assumed that the five-membered-ring is symmetric with respect to the axis through the atoms, C_3 and C_4. The values of the marked angles are fixed as shown in Fig. 1. In determining bond lengths and the remaining angles, the following procedure is employed. First bond lengths are assumed, and π-electron wave functions are calculated. From the resulting bond order P, a bond length R is calculated by the formula

$$R = 1.517 - 0.18P. \qquad (2)$$

If there is a difference of more than 0.01 Å between input and output bond lengths, we repeat all the calculation until self-consistency is obtained. The final bond lengths are shown in Fig. 1. All unassumed angles are automatically determined by this procedure.

Results and Discussion

Several calculations with CI are made for each molecule in order to investigate the variation of physical quantities against the number of included configurations. First, only singly excited basis functions are included. We call it S-CI. Other kinds of CI are carried out including both singly and doubly excited basis functions with energies up to certain values, such as 9, 11, 13, 15, and 17 eV. We call these values cut-off energies. The last kind of CI includes the largest number of both singly and doubly excited basis functions for each symmetry type. The largest numbers are 31 ($^1A_1$) and 24 ($^1B_1$) for fulvene. It is 50 for each symmetry type of the other molecules. The CI with the largest number of basis functions is called M-CI.

First Excited States. Transitions to the first excited states of the four molecules are observed at about 3 eV. Their strengths are weak and observed oscillator strengths are about 0.01.

In Fig. 2, transition energies, oscillator strengths, π-electron densities, and weight of doubly excited basis functions are plotted against cut-off energies. The number of doubly excited basis functions and the total number of basis functions included in calculations are also given. The dotted lines show observed values. The calculated transition energies scarcely change

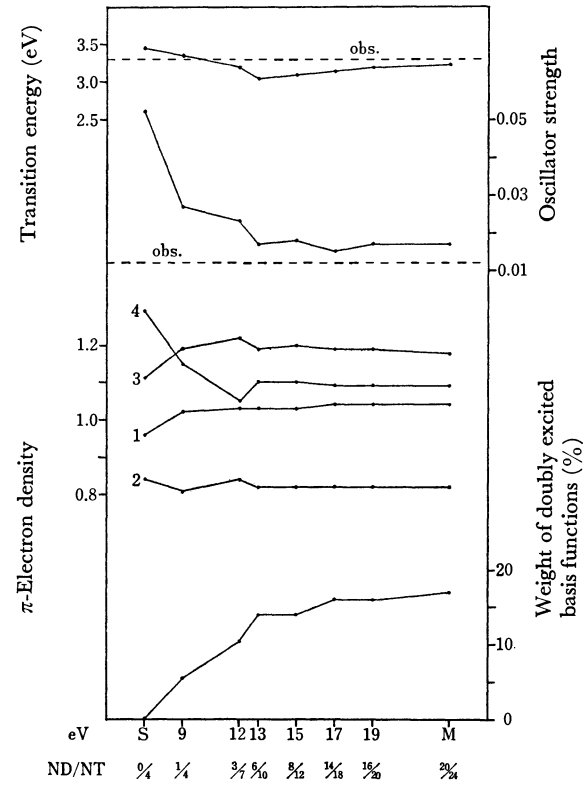

Fig. 2. The first excited state of fulvene ($^1B_1$). Calculated values are plotted against cut-off energies. S and M are abbreviations of CI including only singly excited configurations and CI with the largest number of basis fuctions including both singly and doubly excited functions, respectively. ND is the number of doubly excited basis functions included in CI, and NT is the total number of basis functions included in CI. The numbers of the π-electron density curves correspond to the atomic positions in Fig. 1.

from S-CI to M-CI. This means that S-CI is good enough to predict the energy of this level. On the other hand, the calculated oscillator strength decreases

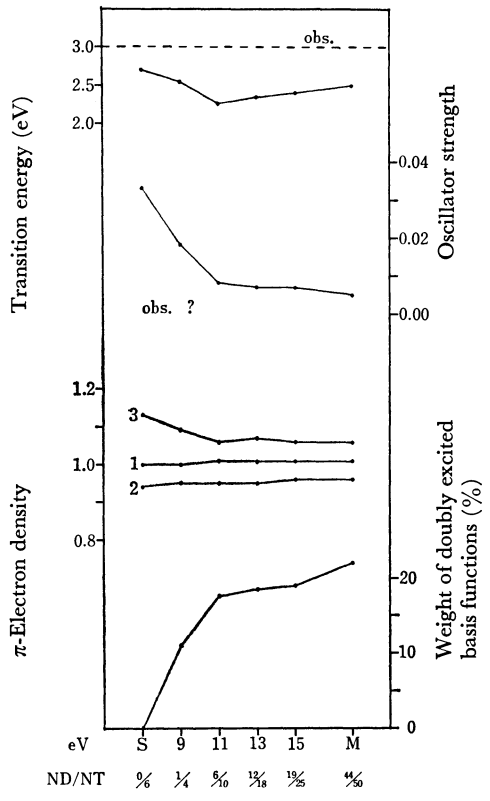

Fig. 5. The first excited state of fulvalene ($^1B_{3u}$). See legend for Fig. 2.

radically from 0.051 of S-CI to 0.017 of a CI with a cut-off energy, 13 eV, where the number of added doubly excited basis function is only six. It then becomes almost a constant, which is close to the observed value. The π-electron densities on the carbon atoms change considerably until the cut-off energy becomes 13 eV, and then none of them markedly change any more. The weight of doubly excited functions also increases until the cut-off energy of 13 eV. On the other hand, in the ground state of fulvene, π-electron densities on the carbon atoms fluctuate by only 0.03 at most, and the weight of the original single determinant is 94.3%. In the case of the other three compounds (Figs. 3—5), almost the same behaviors are obtained. From these four examples, we may conclude that, at a critical point of the cut-off energy, we get an approximate wave function which is good enough to predict not only transition energy but also oscillator strength and probably π-electron distribution as well. The critical value of the cut-off energy is 11—13 eV for the first excited states of the four compounds studied in this paper.

Second Excited States. Second absorptions of the four compounds are observed at about 5 eV. The observed oscillator strengths are 0.2—0.6. In the case of fulvene and heptafulvene (Figs. 6 and 7), the main features of calculated quantities *versus* the cut-off energy are similar to those of the first excited states. Transition energies calculated by S-CI approximately coincide with observed values. They scarcely change by the addition of doubly excited basis functions. But oscillator strengths are greatly improved by inclusion of doubly excited

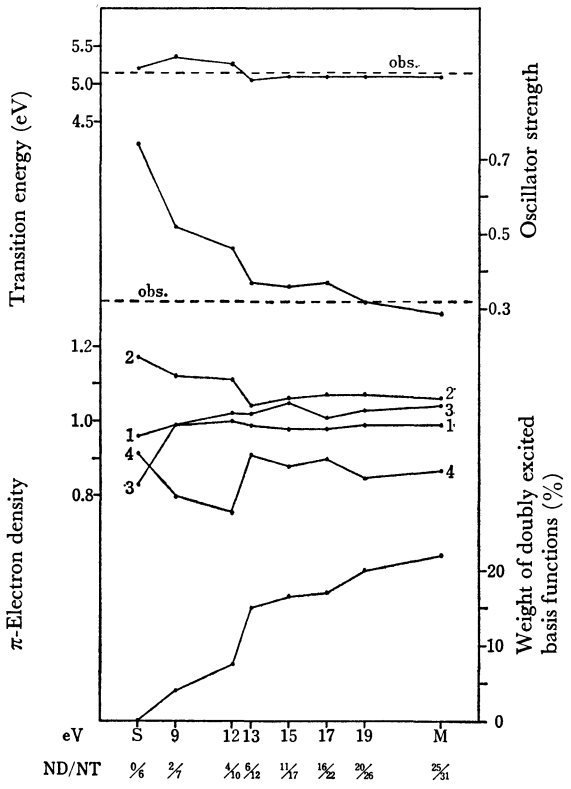

Fig. 6. The second excited state of fulvene ($^1A_1$). See legend for Fig. 2.

configurations. Their final values are close to the observed values. The curves of π-electron densities on the carbon atoms become flat to some extent when the cut-off energies reach certain values. The critical values are at about 13 eV.

As for the second excited states of vinylfulvene and fulvalene (Figs. 8 and 9), the calculated oscillator strengths of M-CI are closer to the observed values than those of S-CI. But the agreement between the calculated and the observed values is not so good. The weight of doubly excited basis functions is only 5.4% or 8.0% even by M-CI. They are much lower than the weights in the second excited states of fulvene and heptafulvene, which are about 20%. It seems that one must add more basis functions of higher energy or triply excited functions in order to get better results for the second excited states of vinylfulvene and fulvalene.

Higher Excited States. Calculated transition energies and oscillator strengths to excited states, whose transition energies are lower than 7 eV, are listed in Table 1 with experimental data. Most higher excited states appear in the vacuum ultra-violet region, where there is no experimental data. Below this region there are several higher excited states, but many of them have small oscillator strength values. The only exceptions are the two states of heptafulvene, whose energies are 5.48 and 5.99 eV by the M-CI calculation. The observed third peak of heptafulvene corresponds probably to one or both of the two transitions. The calculated oscillator strengths for the two transitions are nearly equal, and are of the same order as the observed value. For all of the four compounds, new π–π absorptions in the vacuum ultra-violet region can be found.

TABLE 1. TRANSITION ENERGIES (IN eV) AND OSCILLATOR STRENGTHS (IN PARENTHESES)

S-CI	M-CI	Obsd

TABLE 2. CALCULATED QUANTITIES OF GROUND STATES

Molecule	CI	π-electron total-energy (eV)	π-electron dipole-moment (Debye)	Weight of the original single determinant (%)
Fulvene	S–CI	−158.10	1.40	100.0
	M–CI	−158.75	1.11	94.3
Heptafulvene	S–CI	−240.13	0.89	100.0
	M–CI	−240.81	0.80	93.6
Vinylfulvene	S–CI	−235.57	2.04	100.0
	M–CI	−235.96	1.72	96.1
Fulvalene	S–CI	−337.06	0.00	100.0
	M–CI	−337.82	0.00	92.2

S–CI, M–CI: See footnote to Table 1.

Ground States. For the ground states of the four compounds, π-electron total energies, π-electron dipole moments, and weights of the original single determinants are listed in Table 2. The π-electron total energies decrease 0.4—0.6 eV by inclusion of doubly excited configurations. Dipole moments decrease about 20%. As can be seen in the changes of the weights of the original single determinants, the improvement of ground state wave function is smaller than that of excited state wave functions. This is understandable because the calculations are based on SCF MO for the ground state. The improvement of π-electron dipole moments will play non-negligible role in the estimate of the total dipole moments.

Conclusion

The three questions concerning the importance of CI are answered as follows.

1) From the results of the four molecules, we conclude that inclusion of doubly excited configurations leads to a better agreement with experiment for oscillator strengths. For transition energies to lower excited states, the improvement is not so significant.

2) Oscillator strengths and π-electron densities of excited states are sensitive. Transition energies to lower excited states are rather insensitive, but those to higher excited states are sensitive. The properties of ground states are also not so sensitive.

Table 3. The number of basis functions included in CI at the critical points of the cut-off energies (in eV)

Molecule	E (obs.)	CE	ND	NT
Fulvene	3.32	13.0	6	10
	5.13	13.0	6	12
Heptafulvene	2.91	11.0	4	11
	4.42	13.0	12	21
Vinylfulvene	3.12	13.0	20	37
	4.27	—	—	—
Fulvalene	2.98	11.0	6	10
	3.95	—	—	—

The following abbreviations are used in the table:
E(obs.): observed transition energies.
CE: cut-off energies at critical points.
ND: the number of doubly excited basis functions included in CI.
NT: the total number of basis functions included in CI.

3) The number of doubly excited basis functions and the total number of basis functions included in CI at the critical points of the cut-off energies for each state are shown in Table 3. These numbers for vinylfulvene are larger than those for the other molecules, since the CI matrix cannot be separated into two parts because of its lower symmetry. From the table, we see that, in the lower excited states of small molecules, the inclusion of a rather small number of doubly excited basis functions is quite effective in getting better agreement with experiment by the semi-empirical CI calculation.

The author wishes to thank Professor K. Ohno and Dr. F. Hirota, Shizuoka University, for helpful suggestions and discussions. The calculations reported in this paper were carried out on the HITAC 5020E computer in the Computer Center, the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 629—637 (1971)

Electronic States of Diphenylamine and Its Related Compounds

Tadao HINOHARA,* Seikichi CHO, and Toshifumi MORITA

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu

(Received July 27, 1970)

For the analysis of the characteristic nature of the first absorption band of diphenylamine (DPA), calculations of the electronic states of DPA and its analogous compounds, diphenylether (DPE) and diphenylmethane (DPM), were carried out and the solvent effects on the fluorescence spectra of these compounds were investigated. The calculated results show that the first excited states of these three compounds are mainly benzene B_{2u}. However, in DPA, the ionic state (CTs^-) is located very closely to the B_{2u} state. It seems reasonable to say, therefore, that, in solution, the ionic state lowers its energy down to the position of the B_{2u} state and that the first absorption band observed in the solution is a superposed band of two transitions, $G \rightarrow B_{2u}$ and $G \rightarrow CTs^-$. To confirm this assumption, the value of $\Delta\mu$, which is the dipole-moment change between the ground and excited states, is estimated from the solvent effect on the fluorescence spectrum. The observed value of $\Delta\mu$ for DPA is intermediate between the theoretical values for the lowest (B_{2u}) and the second excited state (CTs^-); from this fact it may be inferred that the mixing of CTs^- to the lowest excited state (B_{2u}) is increased in the excited equilibrium state.

The electronic absorption spectra of molecules containing two benzene rings joined by one atom having a lone pair electron (C_6H_5-X-C_6H_5) are expected to differ from that of the corresponding monophenyl compounds (C_6H_5-XH). The observed first absorption bands of diphenylether and diphenylmethane are, however, essentially the same as those of the corresponding monophenyl compounds, phenol and toluene respectively. On the other hand, the first absorption band of diphenylamine is considerably different from that of aniline (see Fig. 1).

The first absorption bands of aniline, phenol, and toluene have been assigned to the B_{2u} band of benzene perturbed by substitution.[1] Therefore, it is probable that the first excited states of diphenylether and diphenylmethane are of a B_{2u} character. On the other hand, the nature of the first excited state of diphenylamine should be different from pure B_{2u}, because the intensity of the first band is too high to attribute it to the B_{2u}-band. In this connection, the chemical reaction in the excited state (photochemical reaction) of diphenylamine has been found to be different from those of diphenylether and diphenylmethane.[2] From these points of view, it seemed that it would be very interesting to clarify the electronic structure of diphenylamine; this is the objective of the present investigation. In this paper, the first absorption band of diphenylamine was mainly treated, because its photochemical reaction is concerned with the first excited state.

Investigations of the electronic absorption spectra of the same type of molecules as are treated in the present investigation have already been published by several authors.[3-8] According to Matsen[6] and Bugai,[7] the

first absorption band of diphenylamine is to be attributed to the benzene B_{2u}-band.

In order to clarify the nature of the first excited state, we have measured the solvent effect on the fluorescence spectra of these molecules. We have also made calculations of the energy levels of these molecules in order to obtain more reliable knowledge about the nature of the first excited state.

Experimental

Materials. Commercially-obtained GR-grade diphenylamine and diphenylether were carefully purified by recrystallization from ethanol. GR-grade diphenylmethane was used without further purification. Cyclohexane was purified by passing it through a silica-gel column and by subsequent distillation. The other solvents were purified by the ordinary procedures.

Spectroscopy. The ultraviolet-absorption spectra were measured with a Hitachi EPS 3T and 125 model spectrophotometer. The absorption spectrum in the vapor phase was taken by the flow method, using nitrogen gas as the carrier gas. The temperature of the carrier gas was held at about 80°C.

Experimental Results

Electronic Spectra of C_6H_5-X-C_6H_5 and C_6H_5-XH. To compare the spectra of C_6H_5-X-C_6H_5 and C_6H_5-XH-type molecules, it is desirable to remeasure the absorption spectra under the same conditions, so all the absorption spectra were remeasured in cyclohexane. The observed spectra are shown in Fig. 1. The fluorescence spectra of diphenylamine, diphenylether, and diphenylmethane are also shown in Fig. 1; here, mirror-image relationships are observed. In Fig. 1, it may be seen that the band at about 280 mμ of diphenylamine observed in the solution splits into two bands, the peaks of which are at about 265 and 285 mμ, when the experimental condition is changed from a solution to a vapor.

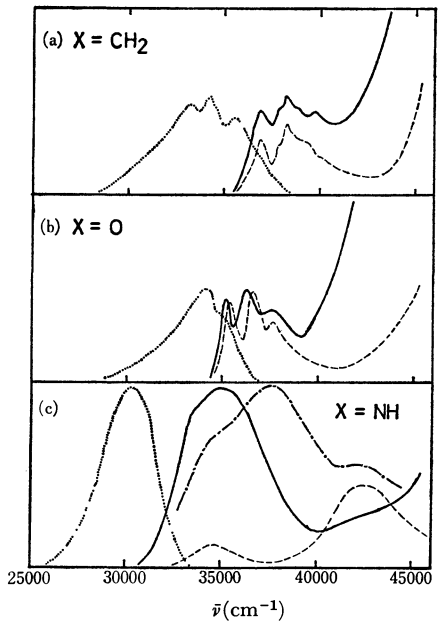

Fig. 1. Absorption and fluorescence spectra of C_6H_5-X-C_6H_5 and C_6H_5-XH. —— absorption in cyclohexane, -·-·- absorption in vapor, ····· fluorescence of C_6H_5-X-C_6H_5, ---- absorption of C_6H_5-XH in cyclohexane. Fluorescence curves are corrected.

Solvent Effects on Fluorescence Spectra. According to Mataga *et al.*[9] and Lippert,[10] the difference between the absorption maximum (σ_a) and the fluorescence maximum (σ_f) is given by the following equation:

$$\sigma_a - \sigma_f = \frac{2\Delta f}{hca^3}(\mu_e - \mu_g)^2 + \text{const.} + \text{smaller terms} \quad (1)$$

where $\Delta f = (D-1)/(2D+1) - (n^2-1)/(2n^2+1)$,
D: dielectric constant of the solvent,
n: refractive index of the solvent,
a: Onsager's cavity radius,
μ_e: dipole moment of the solute in its excited state,
μ_g: dipole moment of the solute in its ground state,
h: Planck's constant, and
c: light velocity.

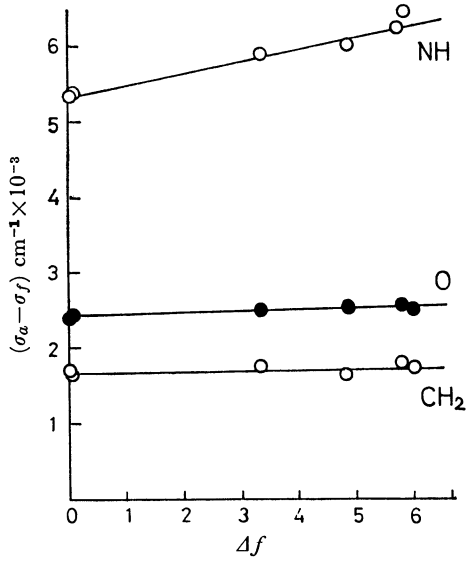

Fig. 2. Difference between absorption and fluorescence maxima, $(\sigma_a-\sigma_f)$, plotted against Δf values.

If the smaller terms in the equation are small enough, the difference, $\sigma_a-\sigma_f$, measured in various solvents should be linear with respect to Δf. The experimental results are shown in Table 1 and Fig. 2. A linear relation between $\sigma_a-\sigma_f$ and Δf is observed in Fig. 2, and from the slopes of these lines, $(\mu_e-\mu_g)^2/a^3$ can be obtained. Assuming that $a=4$ Å[12], and using the value of μ_g given in the literature,[11] the dipole moment in the excited state can be calculated. The results are summarized in Table 2.

Theoretical

Method. The present method of calculating the electronic structure of C_6H_5-X-C_6H_5-type molecules is essentially based on that presented by Longuet-Higgins and Murrell.[13] In the present case, the interaction between three fragments, consisting of two benzene rings and the central atom, X, are taken into account by configuration interaction among the ground, charge-transfer, and locally-excited configurations. In the present calculation, the doubly-excited configurations were ignored.

The Configuration of C_6H_5-X-C_6H_5. Because of the steric hindrance of two hydrogen atoms at the *o*- and *o'*-positions of two benzene rings, the molecule cannot take the planar configuration. Although several considerations of the configurations of two benzene rings in C_6H_5-X-C_6H_5 molecules have been presented,[14-17] no detailed structural data of these molecule have yet been reported. We assume the nonplanar configuration shown in Fig. 3, where the two rings are twisted around the bond axes, NC_1 and NC'_1, at the angles of φ_1 and φ_2 respectively. When the two benzene rings are twisted in the same direction, the molecule may belong to the point group C_2, and when they are twisted in opposite directions, to C_{1h}. The distance between two hydrogen atoms, H and H', must be equal to or larger than 2.4 Å, because the van der Waals radius of the hydrogen atom is 1.2 Å. Therefore, the twisting angle for diphenylamine, satisfying the above restriction, is as follows:

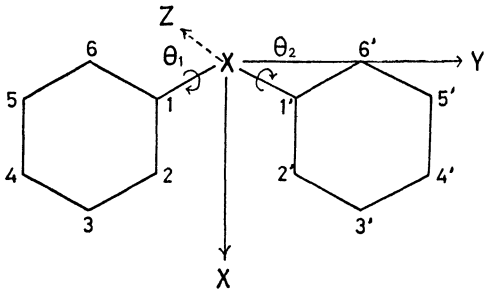

Fig. 3. Configuration of C_6H_5-X-C_6H_5 molecule.

$$\varphi_1 = \varphi_2 = 35° \text{ for } C_2$$
$$\varphi_1 = -\varphi_2 = 88° \text{ for } C_{1h}$$

These values are obtained on the assumptions that the central atom (N) is in the sp^2 hybrid valence state, that the bond length, NC_1, is 1.407 Å,[18] that CC in the benzene ring is 1.397 Å,[10] and that CH is 1.09 Å.[20] Diphenylether and diphenylmethane are assumed to be in the same configuration as diphenylamine.

In the case of the C_{1h} symmetry, the lone-pair orbital of the central atom is almost perpendicular to the pi-electron orbitals of two benzene rings, and the resonance intraction between the central atom and the benzene rings is neglegibly small. The resonance integral, β, can be correlated with the twisting angle, φ, as follows:

$$\beta = \beta_0 \cos\varphi \qquad (2)$$

where β_0 is the resonance integral when the twisting angle is zero.

Local-excitation in a Benzene Ring and the Effect of Excitation Delocalization. Additional effects due to the phenylation of C_6H_5-XH to C_6H_5-X-C_6H_5 may be considerably more complex. Therefore, in the present investigation, our considerations are restricted to the effect necessary for the explanation of the spectral change due to the phenylation, as is shown in Fig. 1.

When the molecules are in a C_{1h} symmetry, the resonance interaction between the central atom and two benzene rings may be ignored, as has been described above, and only the effect of the excitation delocaliza-

tion may be taken into account. The singly-excited states of two benzene rings can be written as follows:

$$\begin{aligned}
\Psi(B_{2u}) &= 2^{-1/2}(\phi_3^{-1}\phi_5-\phi_2^{-1}\phi_4),\\
\Psi(B'_{2u}) &= 2^{-1/2}(\phi'_3{}^{-1}\phi'_5-\phi'_2{}^{-1}\phi'_4)\\
\Psi(E_{1u'}) &= 2^{-1/2}(\phi_3^{-1}\phi_5+\phi_2^{-1}\phi_4),\\
\Psi(E'_{1u'}) &= 2^{-1/2}(\phi'_3{}^{-1}\phi'_5+\phi'_2{}^{-1}\phi'_4)\\
\Psi(B_{1u}) &= 2^{-1/2}(\phi_3^{-1}\phi_4+\phi_2^{-1}\phi_5),\\
\Psi(B'_{1u}) &= 2^{-1/2}(\phi'_3{}^{-1}\phi'_4+\phi'_2{}^{-1}\phi'_5)\\
\Psi(E_{1u}) &= 2^{-1/2}(\phi_3^{-1}\phi_4-\phi_2^{-1}\phi_5),\\
\Psi(E'_{1u}) &= 2^{-1/2}(\phi'_3{}^{-1}\phi'_4-\phi'_2{}^{-1}\phi'_5) \qquad (3)
\end{aligned}$$

where the self consistent orbitals, ϕ_t and ϕ'_t, are the same as those used by Pople.[21] The excitation of an electron within a benzene ring will give rise to two singlet states. For instance, if we take the excitation to the B_{2u} state, two singlet states, B_{2u} and B'_{2u}, are possible, and these two will interact with each other in the manner of the exciton interaction.[22] Such interaction produces one set of exciton states, B_{2u}^+ and B_{2u}^-. The wave functions and energy formulae are:

$$\begin{aligned}
&\Psi(B_{2u}^+) = 2^{-1/2}(B_{2u}+B'_{2u}),\ E(B_{2u}^+) = E(B_{2u})+\langle B_{2u}|H|B'_{2u}\rangle\\
&\Psi(B_{2u}^-) = 2^{-1/2}(B_{2u}-B'_{2u}),\ E(B_{2u}^-) = E(B_{2u})-\langle B_{2u}|H|B'_{2u}\rangle
\end{aligned} \qquad (4)$$

where the interaction matrix element is given by:

$$\begin{aligned}
\langle B_{2u}|H|B'_{2u}\rangle &= 2^{-1}\{\langle\phi_3^{-1}\phi_5|H|\phi'_3{}^{-1}\phi'_5\rangle\\
&\quad+\langle\phi_2^{-1}\phi_4|H|\phi'_2{}^{-1}\phi'_4\rangle\}\\
&\quad-\langle\phi_3^{-1}\phi_5|H|\phi'_2{}^{-1}\phi'_4\rangle\\
&= (\phi_3\phi_5|\phi'_3\phi'_5)+(\phi_2\phi_4|\phi'_2\phi'_4)\\
&\quad-2(\phi_3\phi_5|\phi'_2\phi'_4) \qquad (5)
\end{aligned}$$

The two electron integrals were evaluated under the zero-differential overlap approximation, and the two center atomic integrals of the (rr/ss)-type were equated to e^2/R_{rs}. The observed value was used for the local excitation energy in a benzene ring, $E(B_{2u})$. With regard to other local excitations within a benzene ring, E_{1u}, B_{1u}, and E_{1u}, the same type of equations can be derived. The splitting of locally excited states (degenerated) due to exciton delocalization are shown in Fig. 4. The interaction matrix element between B_{2u} and B'_{2u} is zero, and the exciton states, B_{2u}^+ and B_{2u}^-, are degenerated.

Effect of Interaction among the Exciton States. The exciton states can interact with each other. The elements of the matrix for calculating the interaction between the four exciton states are as follows:

For the plus state:

$$\begin{array}{c} \\ B_{2u}^+ \\ E_{1u'}^+ \\ B_{1u}^+ \\ E_{1u}^+ \end{array}\begin{pmatrix} E(B_{2u}^+) & 0 & 0 & 0\\ 0 & E(E_{1u'}^+) & H_{E_{1u'},B_{1u}} & H_{E_{1u'},E_{1u}}\\ 0 & H_{B_{1u},E_{1u'}} & E(B_{1u}^+) & H_{B_{1u},E_{1u}}\\ 0 & H_{E_{1u},E_{1u'}} & H_{E_{1u},B_{1u}} & E(E_{1u}^+) \end{pmatrix}$$

and for the minus state:

$$\begin{array}{c} \\ B_{2u}^- \\ E_{1u'}^- \\ B_{1u}^- \\ E_{1u}^- \end{array}\begin{pmatrix} E(B_{2u}^-) & 0 & 0 & 0\\ 0 & E(E_{1u'}^-) & -H_{E_{1u'},B_{1u}} & -H_{E_{1u'},E_{1u}}\\ 0 & -H_{B_{1u},E_{1u'}} & E(B_{1u}^-) & -H_{B_{1u},E_{1u}}\\ 0 & -H_{E_{1u},E_{1u'}} & -H_{E_{1u},B_{1u}} & E(E_{1u}^-) \end{pmatrix}$$

Diagonal elements are given by Eq. (4) and so on. The off-diagonal elements were evaluated under the same approximation as those used in calculating Eq. (5).

Since all the matrix elements involving $B_{2u}^{\pm}$ are zero, the degeneracy of $B_{2u}^{\pm}$ exciton states is not removed; moreover, $B_{2u}^{\pm}$ does not mix with any of the other exciton states. These results indicate that the B_{2u}-band in the absorption spectrum of C_6H_5-XH will not be essentially changed by the phenylation. This is the case for diphenylether and diphenylmethane, as is shown in Fig. 1 (b) and Fig. 1 (c) respectively. The ground state can not interact with any of the exciton states. The calculated results are shown in Fig. 4 and Table 3.

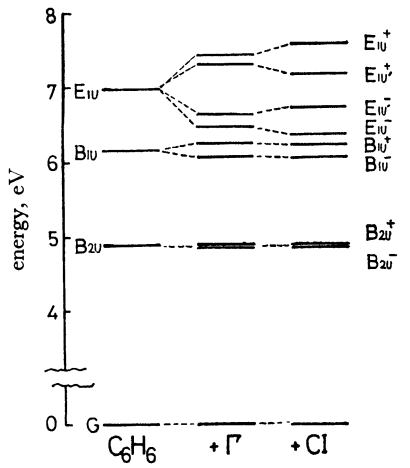

Fig. 4. Change of energy levels due to the exciton interaction (Γ) and configuration interaction (CI).

W_5=6.29,	$\Psi_5=0.963B_{1u}^-$	$+0.232E_{1u}^-$	$+0.139E_{1u'}^-$
W_6=6.82,	$\Psi_6=-0.012B_{1u}^+$	$-0.552E_{1u}^+$	$+0.834E_{1u'}^+$
W_7=7.17,	$\Psi_7=0.011B_{1u}^-$	$-0.550E_{1u}^-$	$+0.835E_{1u'}^-$
W_8=8.07,	$\Psi_8=-0.057B_{1u}^+$	$+0.833E_{1u}^+$	$+0.550E_{1u'}^+$

Effect of Charge-resonance Interaction. Effect of resonance interaction between the central atom and the two benzene rings must be taken into account if the molecule is in C_2 symmetry, for, in this case, the resonance interaction can not be ignored.

Unlike the benzene excited state, eight ionic states do not interact with each other. However, we can take, for convenience, these ionic configurations in the sym-

21) J. A. Pople, *Proc. Phys. Soc.*, **68A**, 81 (1955).

metry combination:[23]

$$(CTs^{\pm}) = 2^{-1/2}(\theta^{-1}\phi_5 \pm \theta^{-1}\phi'_5)$$
$$(CTa^{\pm}) = 2^{-1/2}(\theta^{-1}\phi_4 \pm \theta^{-1}\phi'_5)$$
$$(CT_{ij}^{\pm}) = 2^{-1/2}(\phi_i^{-1}\phi'_j \pm \phi'_i{}^{-1}\phi_j) \quad (6)$$

As for CT_{ij}, we take the following four configurations into account: CT_{24}, CT_{25}, CT_{34}, and CT_{35}. The corresponding energies are given by the following equations:

$$E(CTs^{\pm}) = E(\theta^{-1}\phi_5) = (I-A) - Q_s,\ Q_s = (\theta\theta|\phi_5\phi_5)$$
$$E(CTa^{\pm}) = E(\theta^{-1}\phi_4) = (I-A) - Q_a,\ Q_a = (\theta\theta|\phi_4\phi_4)$$
$$E(CT_{ij}^{\pm}) = E(\phi_i^{-1}\phi_j) = (I'-A) - Q_{ij},\ Q_{ij} = (\phi_i\phi_i|\phi_j\phi_j)$$

where A is the electron affinity of benzene and where I and I' the ionization potentials of the central atom, X, and benzene respectively. The $(\phi_i\phi_i/\phi_j\phi_j)$-type integrals were evaluated using the approximation of zero differential overlap and the point charge. Q_s and Q_a may be expanded as follows:

$$Q_s = 3^{-1}\{(C_1C_1|\theta\theta) + 1/2(C_2C_2|\theta\theta) + 1/2(C_3C_3|\theta\theta) + (C_4C_4|\theta\theta)\}$$
$$Q_a = 2^{-1}\{(C_2C_2|\theta\theta) + (C_3C_3|\theta\theta)\} \quad (8)$$

The two center integrals, $(C_jC_j/\theta\theta)$, where C_j indicates the j'th carbon atom of the benzene ring, were calculated by the use of quadratic equations with an interatomic distance of r_{CX}.[24]

The off-diagonal elements of the matrix for calculating the interaction between the exciton states and the electron transfer states are evaluated by the method of Pople[21] and Murrell[13] as follows:

$$H_{G,CTs^{\pm}} = -2/\sqrt{6}(\beta-\beta'),\quad H_{CTs^{\pm},CT_{24}^{\pm}} = \mp 1/\sqrt{3}\beta$$
$$H_{CTs^{\pm},B_{1u}^{\pm}} = -1/\sqrt{6}(\beta+\beta'),\quad H_{CTa^{\pm},CT_{25}^{\pm}} = \mp 1/\sqrt{3}\beta$$
$$H_{CTs^{\pm},E_{1u}^{\pm}} = 1/\sqrt{6}(\beta+\beta') \qquad H_{CT_{ij}^{\pm},CT_{lm}^{\pm}} = -(\phi_i\phi_i|\phi'_j\phi'_m)$$
$$H_{CTa^{\pm},B_{2u}^{\pm}} = 1/\sqrt{6}(\beta+\beta'),$$
$$H_{CTa^{\pm},E_{1u}^{\pm}} = 1/\sqrt{6}(\beta+\beta') \quad (9)$$

where β is the resonance integral between two atomic orbitals belonging to the central atom and adjacent carbon atoms, and where β' is that belonging to the central atom and ortho carbon atoms. β' was originally taken into consideration by Kimura *et al.*[25] in the calculation of the electronic structure of aniline and its related compounds. According to them, β' is correlated with β as follows:

$$\beta' = S'/S \times \beta = 0.116\beta \quad (10)$$

where S and S' are the overlap integrals corresponding to β and β'. In the present investigation, the transition energies and wave functions were calculated by assuming β_0 and I-A as the parameters. The transition energies, ΔW, evaluated by the use of -1.8 eV for β_0 and 35° for φ are plotted against the $(I$-$A)$ values in Fig. 5. In those calculations, the CT_{34} and CT_{35} configurations were ignored, for these configurations were found to be unimportant in interpreting the nautre of the lower energy levels, as is shown in Table 4.

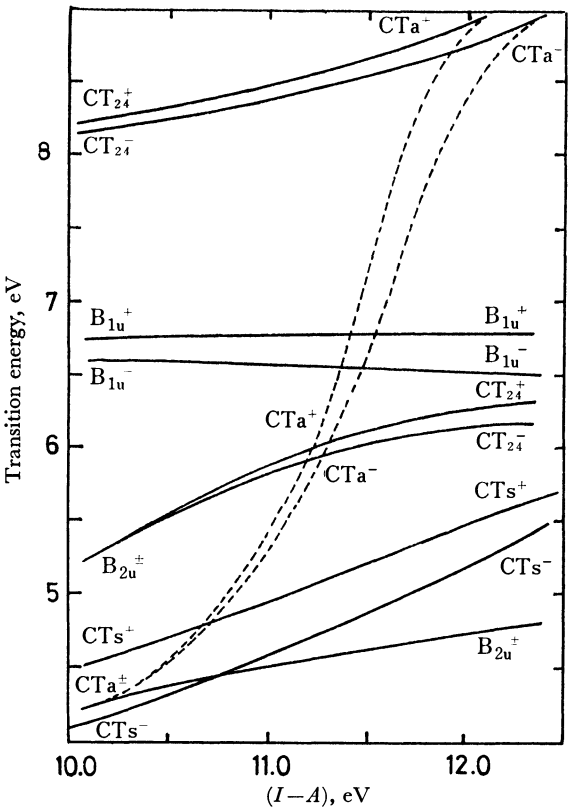

Fig. 5. The calculated transition energies plotted against $(I-A)$ values. ($\beta_0 = -1.8$ eV, $\theta = 35°$)

The results calculated using different β_0 values were essentially the same as those shown in Fig. 5. Therefore, the qualitative nature of the lower excited states of C_6H_5-X-C_6H_5 molecules may be understood from Fig. 5, in which the values of $(I$-$A)$ is assumed to be about 11.0 eV for diphenylamine (X=NH), about 12.0 eV for diphenylether, (X=O), and about 14.0 eV for diphenylmethane ($X=CH_2$). A more detailed comparison of diphenylamine and diphenylether is shown in Fig. 6, in which the relation between the electron configurations used in the present calculation and the energy levels finally obtained is shown.

Table 4 gives the energy levels and wave functions calculated using the following values for $(I$-$A)$ and β_0:

$(I-A) = 11.0$ eV and $\beta_0 = -1.8$ eV for diphenylamine,[26]

$(I-A) = 12.2$ eV and $\beta_0 = -1.64$ eV for diphenylether,[26]

$(I-A) = 14.6$ eV and $\beta_0 = -1.52$ eV for diphenylmethane.[27]

The correlation between the energy levels of diphenylamine and those of aniline is illustrated in Fig. 7 in comparison with the observed spectrum. The oscillator strength was calculated using the following equation:

$$f = 0.0875 \times E\sum_i Q_i^2 \quad (11)$$

23) θ is the nonbonding orbital of the central atom, X.

24) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).

25) K. Kimura, H. Tsubomura, and S. Nagakura, This Bulletin, **37**, 1336 (1064).

26) Values of $(I$-$A)$ and β_0 used here are taken from the following literature; S. Nagakura and K. Kimura, *Nippon Kagaku Zasshi*, **86**, 1 (1965) and Ref. 23.

27) Ionization potential of CH_3 group and the resonance integral between the central carbon atom and the adjacent carbon atoms are taken as 13.25 and -1.52 eV respectively. (H. Hanazaki, H. Hosoya, and S. Nagakura, This Bulletin, **36**, 1673 (1963)).

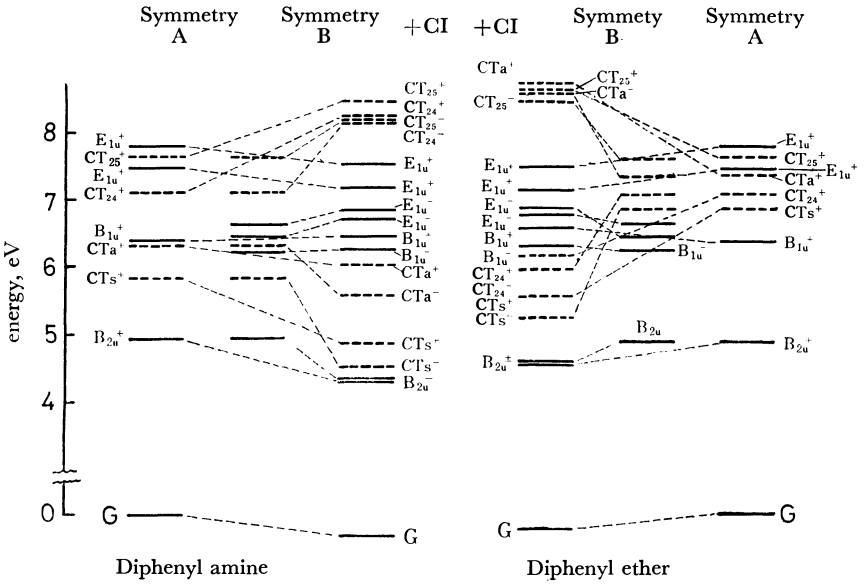

Fig. 6. Energy levels of diphenylamine and diphenylether before and after configuration interaction. (—— locally excited state of benzene; ----- charge transfer state)

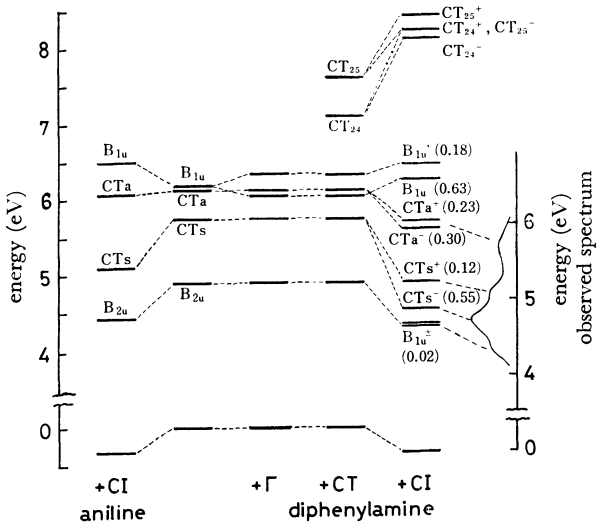

Fig. 7. Correlation among the energy levels of diphenylamine, those of aniline and the observed spectrum. Numbers in parentheses indicate the oscillater strength. The energy levels before and after introduction of excition interaction (Γ), electron transfer interaction (CT) between two benzene rings and configuration interaction (CI) are shown.

where E and Q_i are the transition energy in electron volts and the transition moment in Å respectively.

Theoretical Calculation of $\Delta\mu$ Values. The theoretical expression for $\Delta\mu$ in terms of the state function, Ψ, is given by:

$$\Delta\mu = \langle\Psi_e/M/\Psi_e\rangle - \langle\Psi_g/M/\Psi_g\rangle \qquad (12)$$

where $M = \sum e_t r_t$ and where e_t and r_t are the charge and the position vector of the t'th particle respectively. In the present calculation, Ψ_e for the lowest excited state and Ψ_g are approximated as follows:

$$\Psi_g = \chi_g$$

$$\Psi_e = aB_{2u}^- + bE_{1u'}^- + cCTa^-, \text{ for B symmetry}$$

$$\Psi_e = a'B_{2u}^+ + b'E_{1u'}^+ + c'CTa^+, \text{ for A symmetry}$$

where χ_g is the ground-state configuration. The necessary formulae for the expansion of Eq. (12) have been presented by Pariser[28] and also by Mataga.[29] The Eq. (12) is thereby reduced to the following:

$$\Delta\mu = c^2(M_{44} + M_{4'4'})/2 \text{ for B symmetry}$$

$$\Delta\mu = c'^2(M_{55} + M_{5'5'})/2 \text{ for A symmetry}$$

where $M_{ii} = \langle\phi_i/M/\phi_i\rangle = \sum c_{ij}^2 R_j$. R_j is the position vector of the j'th particle. The calculated values of $\Delta\mu$ for the lowest excited states of diphenylamine, diphenylether, and diphenylmethane are tabulated in Table 2.

Discussion

One of the characteristic features of the calculated results shown in Fig. 5, Fig. 6, and Table 4 is that the lowest excited state of each of the compounds treated here is of a B_{2u} character. Moreover, the exciton states, B_{2u}^+ and B_{2u}^-, are degenerated, and these two states do not interact with any of the other exciton states. These facts indicate that the first absorption band of diphenyl compound, C_6H_5-X-C_6H_5, are essentially the same as that of the monophenyl compound, C_6H_5-XH, in the case of the C_2 symmetry or that of benzene in the case of the C_{1h} symmetry. As may be seen in Fig. 1, the first absorption bands of diphenylether and diphenylmethane are not identical with that of benzene, but they are identical with those of the corresponding monophenyl compounds, phenol and toluene respectively. This clearly indicates that the configurations of the two benzene rings belong to the C_2 symmetry. On the other hand, the first absorption band of diphenylamine can not be attributed solely to the B_{2u} of benzene, for its intensity is too high.

The distinctive feature of diphenylamine observed in Fig. 6 is that the CTs^- state is located very close to the B_{2u}^- states. On the contrary, the finaly CTs^- state of

28) R. Pariser, *J. Chem. Phys.*, **24**, 250 (1956).
29) N. Mataga, This Bulletin, **36**, 654 (1963).

diphenylether obtained after the configuration interaction is located at higher energy and has little effect on the lower-lying energy levels.

Unlike the benzene-excited configurations, the two charge-transfer configurations, $\theta^{-1}\phi_4$ and $\theta^{-1}\phi_4'$, do not interact with each other, and the energy of the charge-resonance state is equal to that of aniline. The origin of the distinction between the observed spectrum of diphenylamine and that of aniline must be attributed to the existence of an interaction between the two benzene rings. Two types of interaction, exciton interaction (Γ) and electron-transfer interaction (CT) between two benzene rings, were considered to explain the distinctive nature of the absorption spectrum of diphenylamine. The effect of the exciton (Γ) and electron-transfer (CT) interactions on the lower energy levels of diphenylamine are illustrated graphically in Fig. 7 and Fig. 8. The energy levels of CTs of aniline split into two levels, CTs^- and CTs^+, upon the introduction of the Γ or CT interaction, while the B_{2u} level is not affected so strongly. The final CTs^- state of diphenylamine obtained after configuration interaction is located at a lower energy than the CTs level of aniline, and the energy gap between CTs^- and B_{2u}^- in diphenylamine is considerably smaller than that in aniline, as may be seen in Fig. 7. This distinction of the calculated energy levels between diphenylamine and aniline can be correlated with that of the observed spectrum between diphenylamine and aniline.

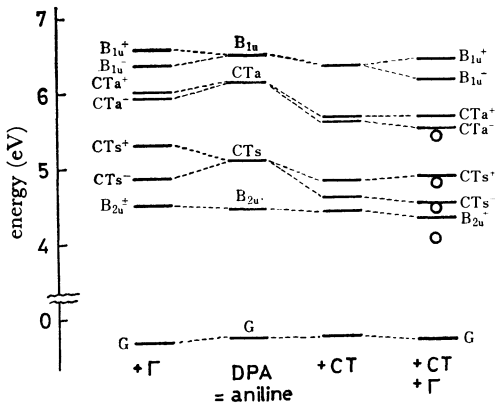

Fig. 8. Comparison of effect of exciton (Γ) and electron transfer (CT) interaction between two benzene rings on stabilizing the CTs^- level of diphenylamine. ○ indicate the observed energy levels.

The mechanism of the stabilization of the CTs^- level due to the introduction of Γ and CT interaction may be illustrated as follows. Firstly, in diphenylamine, the B_{1u} state of benzene, which is located just above the CTs state, splits through the exciton interaction, giving two exciton states, B_{1u}^+ and B_{1u}^-, as may be seen in Fig. 7. The minus state is lower in energy than the plus state, and the energy gap between the CTs^- and B_{1u}^- states is smaller than that between the CTs and B_{1u} states in aniline. Therefore, the configuration interaction will cause more stabilization of the CTs^- level of diphenylamine than the CTs level of aniline. Secondly, the introduction of another benzene ring into aniline at the N-position produces new electron configurations arising from electron transfer between the two benzene rings. One of these configurations, CT_{25}^-, which is located above the CTs^- state, interacts with the CTs^- state; moreover, the interaction matrix element between these two configurations is considerably larger than that between B_{1u}^- and CTs^-. It may be seen in Fig. 8 that the "CT" interaction has a greater effect than the "Γ" interaction in stabilizing the CTs^- level. This result indicates that the electron-transfer interaction between the two benzene rings is important in interpreting the nature of the absorption spectrum of diphenylamine.

The correspondence of the calculated energy levels to the observed absorption spectrum is shown in Fig. 7. The observed band at 260 mμ (4.74 eV) of diphenylamine is reasonably attributed to the Ψ_0—Ψ_3 transition (5.25 eV, f=0.50), and the broad shoulder at 275 mμ (4.49 eV) may be thought to consist of two transitions Ψ_0—Ψ_1 and Ψ_0—Ψ_2 (4.92 eV, degenerated, f=0.016). The nature of the former transition is that of an intramolecular charge transfer, while the later is of a B_{2u} character.

Since the band shift due to the solute-solvent interaction in a solution may be larger in the charge-transfer band than in B_{2u} band,[30] it may be assumed that in solution, these two bands are superposed upon each other, giving one broad intense band. If this assumption is valid, the solvent effects on the wave-number difference between the first absorption and fluorescence bands, $\sigma_a-\sigma_f$, may be expected to be larger than that of diphenylether or diphenylmethane. In Fig. 2, it may be seen that the slope of the straight line for diphenylamine is considerably larger than that of diphenylether or diphenylmethane. As may be seen in Table 2, the values of $\Delta\mu$ obtained from the slope of the straight lines for diphenylether and diphenylmethane are in good agreement with the theoretically-calculated values of $\Delta\mu$. Therefore, it may be said that the lowest excited states (fluorescent state) of diphenylether and diphenylmethane are mainly benzene B_{2u}. In the case of diphenylamine, the situation is somewhat more complicate. As has already been described, the first absorption band of diphenylamine does not consist of one transition, but of two transitions, G→B_{2u} and G→CTs^-. The absorption due to the G→B_{2u} transition appears as a shoulder on the lower-frequency side of the absorption band attributable to the G→CTs^- transition, as may be seen in Fig. 1 (c). Therefore, the effect of the solvent on the shift of the absorption peak should concern the G→CTs^- transition.

It has been known, in general, that the fluorescent state is the lowest excited singlet state. In diphenylamine, the CTs^- state is located very close to the lowest excited singlet state (B_{2u}). However, the possibility that the second excited state (CTs^-) is the emissive state may be eliminated on the basis of the following facts. First, the absorption and fluorescence bands are not in a good mirror-image relation, as may be seen in Fig. 1 (c); the absorption band is broad, while the fluorescence is sharp. Secondly, the energy gap between the first and second excited states is about 1000 cm^{-1}, and the population of the second excited state,

30) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).

as the emissive state, can not be taken into account because of the presence of a rapid internal conversion process and the Boltzman distribution law. Therefore, the observed solvent effect on the fluorescence should be related to the G←B_{2u} transition. However, the observed shift of the fluorescence band due to the change in the solvent polarity is larger than that to be expected from the degree of the CT contribution to the lowest excited state, as may be seen in Table 1 and Table 4. One reasonable explanation for this is the resonance (or mixing) of the first and second excited states. This mixing may arise from the change in the molecular configuration in the excited equilibrium state. The interference effect of two closely-spaced excited states have been discussed by Jano[31] and Bixon.[32] In the present case, also, the fluorescent state may be a mixed state of B_{2u} and CTs^- states. The observed value for $\Delta\mu$ (the dipole-moment change between the ground and excited states) of diphenylamine listed in Table 1 may be explained well as the basis of the above conception.

Summary

As for the configuration of the molecule of the C_6H_5-X-C_6H_5 type, two possibilities may be considered. One belongs to the point group C_2, and the other, to C_{1u}. The first excited states of diphenylether and diphenylmethane, calculated theoretically, are B_{2u}, and theoretical considerations suggest that the first absorption bands of diphenylether and diphenylmethane are identical with that of benzene (in the case of C_{1h}) or those of the corresponding monophenyl compounds, phenol and toluene respectively. The observed spectra clearly indicate that these molecules belong to the C_2 symmetry.

The first absorption band of diphenylamine is quite distinctive compared with those of diphenylether and diphenylmethane. The theoretical analysis of this point indicates that the characteristic feature of the first absorption band of diphenylamine is to be ascribed to its low-lying charge-transfer configuration and to the existence of exciton and electron-exchange interaction between the two benzene rings. The first absorption band of diphenylamine in solution is illustrated by the assumption that the lowest excited state is not pure B_{2u}, but a superposed state of B_{2u} and CTs^-. This assumption is verified experimentally by the solvent effects on the absorption and emission spectra.

The authors wish to express their thanks to Professor Ikuzo Tanaka of the Tokyo Institute of Technology for his valuable suggestions and encouragement during this work.

Studies on Salt Solution Aerosols. IV.[1] Droplet Size Determination of Aqueous Sodium Chloride Solution Aerosols by Chemical Spot Method

Yasuo UENO and Isamu SANO

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 11, 1970)

Droplets of aqueous NaCl solution aerosols generated by atomization were collected on an $AgNO_3$ containing film, by measuring microscopically the sizes of the AgCl spots formed on the film, the diameters of the droplets were determined with the aid of the calibration curve between the spot and droplet diameters. It was found that the calibration curve can be expressed by a relation $D_d^3 = Kd_s^2$, where D_d is the volume average diameter of the droplets, d_s the surface average diameter of the spots and K a constant. The meaning of K was considered.

For aerosol investigation it is essential to measure the particle size distribution. This is one of the main tasks of aerosol studies, but it is very difficult to size and count the droplets of volatile aqueous solution that evaporate appreciably during sampling and measurement.

The oil method,[2] in which the collected droplets are suspended in an oil film on a glass slide and observed under a microscope is most frequently used.

There are other methods such as ultramicroscopical measurement of the sedimentation rate of droplets or of their mobility in electric field. Recently photoelectric counters have been available for use, but these are not always applicable for aerosols of volatile droplets as complete elimination of evaporation is very difficult.

As one technique for measuring droplet size with an optical microscope we deal with their spots impressed on a support. Soot-[3] or magnesium oxide-[4] coated glass slides have been utilized widely, though they cannot register spots less than 10 μ in diameter owing to their poor impressions. Because of fragile soot or oxide coating, use of films containing a dye or special reagents

in gelatine, polyvinyl alcohol, ethyl hydroxycellulose and so on has been introduced.[5] However, these is little information for physicochemical studies both of the spots of aqueous salt solution droplets on these films and of the application to the droplet size measurement, except a few reports on the solid particles of sodium chloride.[6]

Employing an Hg_2SiF_6 or $HgNO_3$ containing gelatine film, Sano *et al.*[7] measured the particle size of NaCl aerosols having an average diameter less than 0.5 μ (prepared by condensation method) and one less than 8 μ (prepared by dispersion method). They assumed the spot of HgCl formed to be hemispherical and found a good agreement between the calculated and observed sizes. Farlow[8] developed a technique making use of an $Ag_2Cr_2O_7$ containing gelatine film. The NaCl particles collected on the film, and dissolved by keeping the film in moist air, reacted with the dichromate to produce the spots of AgCl, which were apparently clear. Assuming that they are cylindrical, he found that the relation $w=0.54\ d^{2/3}$ ($w>20\ \mu$) holds, where w is the particle size represented by the width of one crystal face of a cubic NaCl particle and d the diameter of the spot on the film. This paper will present information on the droplet size determination of aqueous NaCl aerosols.

Experimental

Materials. C_2H_5OH, HNO_3, and $AgNO_3$ used were of the extra pure grade. Polyvinyl alcohol obtained from the Kurashiki Rayon Co. was 1700 in polymerization degree and 85% in saponification.

Preparation of the Reagent Film. An aqueous solution containing 4% by weight of PVA was made by stirring the dry powder into distilled water with strong agitation at room temperature. To 100 g of the solution, 200 m*l* of C_2H_5OH and 1.5 m*l* of 1N HNO_3 were mixed and further, (a) 2 m*l*, (b) 3 m*l*, (c) 5 m*l*, or (d) 7 m*l* of an aqueous 40% $AgNO_3$ solution was added to obtain four NaCl-detecting reagents of different concentrations. The $AgNO_3$ containing PVA solutions so prepared retained their properties for an extended time at room teperature in the dark.

By dropping 10 μl of the $AgNO_3$ containing PVA solution upon a diameter of around 2.1 cm is obtained and the solvent alcohol and water, rapidly evaporate off. The film formed is photosensitive and must be stored in a closed container in the dark.

The glass side used as PVA film carrier was first immersed in chromic acid mixture to remove greasy material and then, thoroughly washed in running water and finally in distilled water. The slides were kept in a desiccator, hanging in a vertical position.

Generation of the Droplets and the Measurement of their Size Distribution. Droplets were generated by using an atomizer filled with an aqueous 5% NaCl solution and introduced into a chamber, where they were dispersed homogeneously and subjected to aging with constant stirring. The chamber is a cylindrical plastic vessel of about 0.23 m^3, the inside of which had been saturated, previous to introduction of the droplets, with water vapor by putting an aqueous 5% NaCl solution on the bottom.

The film carrying glass slides were inserted horizontally, at chamber, the droplets collected on them impressing the spots. In order to know the size of the droplets corresponding to the spots impressed, the oil film technique was applied at the same time, employing glass slides coated on one slide with silicone or the like. Their microphotographs were enlarged and the size reading of both the spots and droplets were made with care, the droplets examined being in the size range of a few tenths of a micron and greater in diameter.

Results

Spots on the Reagent Film. Typical spots impressed on the film are shown in Fig. 1. Influence of the concentration of reagent as well as the exposure to ultraviolet light upon the spot formation is shown in Fig. 2. We see that the smaller spots exhibit more distinct and clear-cut outlines after a 30 min exposure at 10 cm distance from a mercury lamp, the mechanism possibly being that, by photochemical reduction of precipitated AgCl to colloidal silver, spots are given sharp contrast in color, the spots not subjected to the exposure being of somewhat ambiguous image so that they could be observed only when they were of the size above 1 μ in diameter, under a phase-contrast microscope. Figure 3 indicates the microphotographs of the droplets in the oil film.

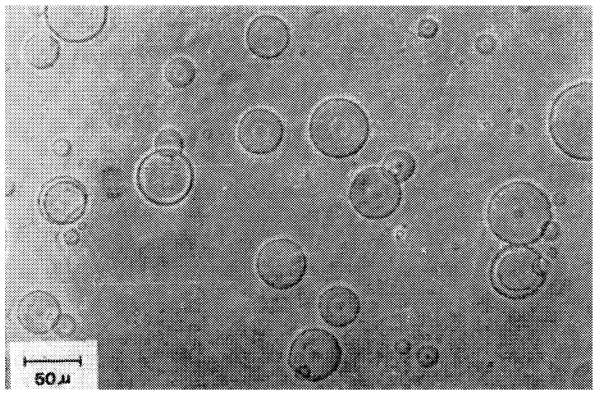

Fig. 1. Spots of 5% NaCl solution droplets (viewed under phase-contrast microscope) on a 5 m*l* $AgNO_3$ solution film.

Construction of the Calibration Curve. The droplets suspending in the oil film and their spots impressed on the reagent film have both their own size distributions, and therefore, taking the volume average diameter (D_d) for the former and the surface average diameter (d_s) for the latter, the calibration curve was drawn for each of the four films, (a), (b), (c), and (d) having different concentrations with respect to the reagent, $AgNO_3$ (Fig. 4). From the figure, it is evident that the spot diameter increases more rapidly than the droplet diameter and that it gets smaller as the reagent concentration in film increases.

Discussion

It has been referred to above that the circular film

(a) on a 2 m*l* $AgNO_3$ solution film (b) on a 3 m*l* $AgNO_3$ solution film
(c) on a 5 m*l* $AgNO_3$ solution film (d) on a 7 m*l* $AgNO_3$ solution film

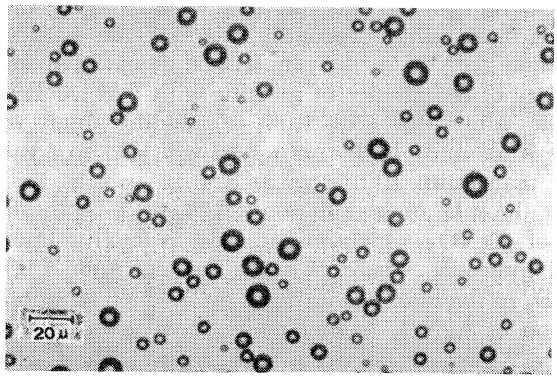

Fig. 3. 5% NaCl solution droplets in oil (viewed under microscope).

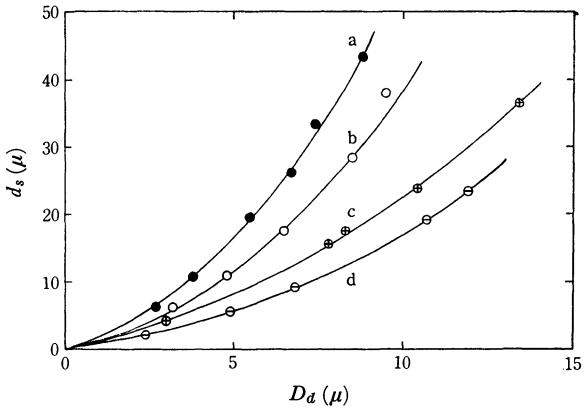

Fig. 4. Plot of the spot diameter (d_s) against the droplet diameter (D_d).
(a): 2 m*l* $AgNO_3$ (b): 3 m*l* $AgNO_3$
(c): 5 m*l* $AgNO_3$ (d): 7 m*l* $AgNO_3$

of PVA–$AgNO_3$ mixture formed on a glass slide is of a constant diameter (2.1 cm) within experimental error, regardless of the reagent concentration in the film. Let us assume as follows:

1) The circular film has a uniform thickness and consists of solid PVA and $AgNO_3$, with a density corresponding to the mixing ratio, 2) the reagent, $AgNO_3$, is distributed homogeneously throughout the film, 3) all the chloride ions in a droplet collected on the film react with silver ions in the film to yield silver chloride, 4) the spots are cylinders which are microscopically viewed and whose heights are equal to the film thickness.

On the basis of these assumptions we obtain the expression

$$D_d^3 = 3/2\rho[\text{Film}]C[AgNO_3]M[\text{NaCl}]/\rho[\text{NaCl}]C[\text{NaCl}]M[AgNO_3]Hd_s^2 \quad (1)$$

ρ[Film]: density of film
ρ[NaCl]: density of aqueous NaCl solution
C[NaCl]: concentration of aqueous NaCl solution (wt%)
C[$AgNO_3$]: concentration of $AgNO_3$ in film (wt%)
M[NaCl]: molecular weight of NaCl
M[$AgNO_3$]: molecular weight of $AgNO_3$
H: thickness of film

Since the concentration of the NaCl solution used is constant throughout the whole range of distribution, we get, in place of Eq. (1),

$$D_d^3 = Kd_s^2 \quad (2)$$

K being a constant which is given by $K=10.0\ \rho[\text{Film}]HC[AgNO_3]$.[9] According to Eq. (2), a plot of log D_d

9) For the values of ρ_{Film}, H and C_{AgNO_3}, *cf.* Table 1. The concentration of the dispersing solution is 5% by weight of NaCl. The term corresponding to $3/2\cdot M_{NaCl}/(\rho_{\text{Film}}\cdot C_{AgNO_3}\cdot M_{AgNO_3})$ is then.

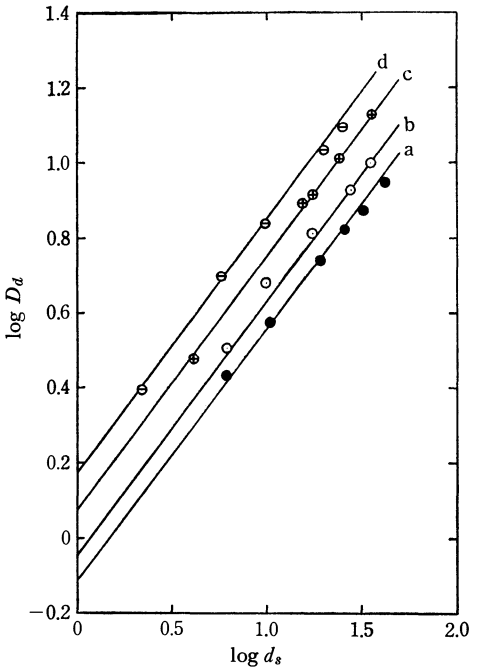

Fig. 5. Plot of log D_d (droplet diameter) against log d_s (spot diameter).
(a): 2 m*l* $AgNO_3$ (b): 3 m*l* $AgNO_3$
(c): 5 m*l* $AgNO_3$ (d): 7 m*l* $AgNO_3$

against log d_s should be linear, and this is found to be actually the case, as is shown in Fig. 5, where the experimental values depicted in Fig. 4 are reproduced as the relation between log D_d and log d_s; these plots are all straight lines parallel with one another and have a slope of 2/3 that might be expected of Eq. (2).

From Eq. (2), we write as follows.

$$D_d{}^3{}_{\text{theor.}} = K_{\text{theor.}} d_s{}^2{}_{\text{theor.}} \quad (3)$$

$$D_d{}^3{}_{\text{exptl.}} = K_{\text{exptl.}} d_s{}^2{}_{\text{exptl.}} \quad (4)$$

It follows from Eqs. (3) and (4), on equating $D_{d\text{exptl.}} = D_{d\text{theor.}}$ that

$$d_{s\ \text{theor.}}/d_{s\ \text{exptl.}} = (K_{\text{exptl.}}/K_{\text{theor.}})^{1/2} = \varepsilon \quad (5)$$

It is to be noted that K's of Eq. (5) can be evaluated either theoretically from Eq. (2) with the known values of ρ[Film], H, and $C[AgNO_3]$ or experimentally as the intercept on the log D_d axis in Fig. 5. Denote the square root of their ratio by ε. It will give us a measure of a theoretical size of a spot relative to a experimental one. The value of ε thus found is represented in Table 1 and it might be considered from the table that ε increases with the increase in the reagent concentration.

If the above assumptions be valid, we should obtain a value of unity for ε. However, this is not the case actually. First, if the concentration of the reagent is small as in the films (a) and (b), a greater part might have been protected by PVA for it to be of lower reactivity, and consequently, the droplets collected would spread to yield larger spots, giving ε values less than unity. In these cases, we have portion of the reagent remaining unreacted in the spot, and in line with this, we have occasionally found a smaller forming on a larger one with the cases of the droplets collected on the film (c) and (d) which contain $AgNO_3$ thickly. On the other hand, if the concentration of the reagent is large as in the films (c) and (d), a greater part would possess reactivity and we will obtain ε values close to unity; for the films of highest concentrations of reagent, it might be very likely that the precipitate of AgCl is formed densely, preventing the NaCl molecules in the droplet from diffusing to react upon $AgNO_3$ molecules outside the spot; in this case, we would have ε values higher than unity. Secondly, there is the possibility that some $AgNO_3$ in the film will be deprived owing to location, of the chance of meeting with NaCl collected on the film; this will vary, depending upon what shape is assumed by the spot, and will lead to ε values other than unity.

Table 1. The estimated values of ρ_{Film}, H, and C_{AgNO_3} and the experimental value of ε

Film	ρ_{Film} (g/cc)[a)]	H (μ)[b)]	C_{AgNO} (%)[c)]	ε
(a)	1.56	0.32	22.7	0.60_6
(b)	1.67	0.33	30.6	0.56_9
(c)	1.86	0.35	42.4	0.80_6
(d)	2.03	0.37	50.7	0.93_0

a), b), c) The values of ρ_{Film}, H, and C_{AgNO_3} are obtained, by the relations:

$$\rho_{\text{Film}} = (W_{\text{PVA}}/\rho_{\text{PVA}} + W_{AgNO_3}/\rho_{AgNO_3})/(W_{\text{PVA}} + W_{AgNO_3})$$
$$H = 4(W_{\text{PVA}}/\rho_{\text{PVA}} + W_{AgNO_3}/\rho_{AgNO_3})/\pi D^2$$
$$C_{AgNO_3} = 100\, W_{AgNO_3}/(W_{\text{PVA}} + W_{AgNO_3})$$

where W and ρ are the weight and density of solid PVA or $AgNO_3$, and D the diameter of the film (2.1 cm). For example, in the case of the reagent concentration of (a),

$$\rho_{\text{Film}} = (1.32\times10^{-4}/1.31 + 3.88\times10^{-5}/4.35)/(1.32\times10^{-4} + 3.88\times10^{-5}) = 1.56$$
$$H = 4(1.32\times10^{-4}/1.31 + 3.88\times10^{-5}/4.35)/3.14\times2.1^2 = 0.32\times10^{-4}$$
$$C_{AgNO_3} = 100\times3.88\times10^{-5}/(1.32\times10^{-4} + 3.88\times10^{-5}) = 22.7$$

For the sake of formulation, let $1-f(C)$ be the fraction of $AgNO_3$ which might hold reactivity upon a NaCl molecule, where C is the concentration (%) of $AgNO_3$ in the film. Concerning $f(C)$ which signifies the fraction of $AgNO_3$ having no reactivity, we have

$$f(C+\mathrm{d}C) = f(C)\cdot(1-\beta \mathrm{d}C)$$

where βdC is the reactivity of an $AgNO_3$ molecule in the range of concentration of dC. It follows that

$$\mathrm{d}f(C) = -f(C)\cdot\beta \mathrm{d}C$$

which, on integrating under the assumption of β being independent of concentration, gives

Table 2. Applicability of Eq. (7), $\varepsilon = K(1-\alpha\, e^{-\beta C})$

C	$\varepsilon_{\text{obsd}}$[a)]	$\varepsilon_{\text{calcd}}$ $K=2.0$[b)]	$K=5.0$[c)]	$K=10.0$[d)]
0.0	—	0.094	0.18	0.19
22.7	0.61	0.52	0.53	0.54
30.6	0.57	0.65	0.64	0.65
42.4	0.81	0.82	0.81	0.83
50.7	0.93	0.92	0.93	0.94
100.0	—	1.38	1.54	1.62

a) *cf.* Table 1.
b) $\alpha = 0.95_3$, $\beta = 0.011_2$
c) $\alpha = 0.96_4$, $\beta = 0.0033_2$
d) $\alpha = 0.98_1$, $\beta = 0.0015_7$

$$f(C) = \alpha e^{-\beta C} \quad (6)$$

where α is a constant determinable by the condition that, $f(C)$ has at $C=100\%$, a value γ, differing from zero since it is probable for some $AgNO_3$ to remain unreacted, so that $\alpha=\gamma\, e^{100\cdot\beta}$. Supposing that the quantity $1/\varepsilon$, which represents the ratio of d_{exptl} to d_{theor} is inversely proportional to the reactivity $1-f(C)$, and is affected by diffusivity composed of lateral (surface) and longitudinal (bulk) components, we obtain

$$\varepsilon = d_{\text{theor}}/d_{\text{exptl}} = k(1-\alpha e^{-\beta C}) \quad (7)$$

where k is a constant relating to diffusivity.

Table 2 indicates the applicability of Eq. (7). We could not carry out experiments for concentrations lower than 20%, because of the difficulty in finding the spots with sharp impression, or for those higher than 60% owing to production of a film with coarse $AgNO_3$ particles deposited, probably due to its decreasing solubility in drying PVA solution.

For a number of years we have been conducting the research on salt solution aerosol droplets and have here reported the size measurement of chloride containing droplets.[10] Extending the technique, we are now making experiments[11] on sulfate containing droplets whose details will be given in near future.

Photosensitive Ionomer. I. Preparation of Mercurous Acrylate and Photosensitive Plates

Shin SUZUKI and Kazuyuki SUGITA

Department of Graphic Engineering, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received August 14, 1970)

Photographic plates were prepared by coating an emulsion consisting of mercurous acrylate, polyvinyl alcohol and water on glass plates. They were found to be sensitive to light ranging from 250 nm to 340 nm. A dark brown image with density *ca.* 0.6 above the fog was formed by a printing-out process. The latent image could be amplified with the reducing developers such as hydroquinone or metol. Image formation was ascribed to metallic mercury which was isolated by photoreduction and/or reduction of mercurous ion.

On exposure to light, mercurous acetate disproportionates to mercuric acetate and metallic mercury[1] to give dark brown materials as illustrated in Eq. (1). Photoreduction of mercurous ion into metallic mercury is similar to that of silver ion, and mercury is available for photographic image formation.

$$2CH_3COOHg \longrightarrow (CH_3COO)_2Hg + Hg \qquad (1)$$

The ionomer, ionically crosslinked polymer, is well known since 1964. The ionic crosslinkages are $-COO^-\cdots M^+\cdots O^-CO-$ or $-COO^-\cdots M^{2+}\cdots O^-CO-$ formed by adding mono- or divalent metallic ion, respectively, to linear polymer with side chains of carboxyl groups. Though the ionomer has been studied chiefly for the purpose of improving mechanical properties of plastics, no attempt was made for application to photosensitive plastics. As the strength of the ionic crosslinking depends on the valence of metallic ion, the ionomer crosslinked by a metallic ion of variable valence on exposure may become a new type of photosensitive polymer.

Thus, mercuric ion which is produced by photooxidation of mercurous ion, will form crosslinkages, if some linear polymer has side chains of mercurous carboxylate groups. Polymeric mercurous compound is then expected to be a new photosensitive polymer which undergoes hardening by ionic crosslinking, and can be used for lithographic image formation.

We have prepared an emulsion consisting of mercurous acrylate and polyvinyl alcohol which can be regarded as a model emulsion of linear polymer with side chains of mercurous carboxylate and hydroxyl groups, and have studied some photographic properties of the acrylate plate.

Experimental

Materials. Acrylic acid was purified by distillation of a commercial reagent. Polyvinyl alcohol was supplied by Yotsuwa Sangyo K.K. (PVA GL-05, 95% saponified, $\bar{M}n=$ 22000). The other reagents used were chemicals of extra pure grade.

Apparatus. Titration was performed by using a Yokokawa pH Meter KPH-51B. Wedge spectrogram was obtained with a Ushio Xenon Arc Lamp UXL-500D and a Narumi Monochrometer RM-23. Ultraviolet and visible spectra were taken by measuring the reflection of mercurous acrylate plates with a Shimadzu Spectrophotometer QV-50. Photographic plates, which were irradiated by a Ushio Low-pressure Mercury Lamp ULI-309 (chemical lamp) from a distance of 15 cm, were measured for the photographic reflection density by a Macbeth Densitometer RD-100.

1) G. Brauer, "Handbook of Preparative Inorganic Chemistry," Academic Press Inc., London (1965), p. 1120.

Preparation of Mercurous Acrylate. A 10% aqueous solution of sodium hydroxide was exactly neutralized by acrylic acid, and the concentration of sodium acrylate was determined by titration with 0.5N hydrochloric acid. 14 g of mercurous nitrate was dissolved in 80 m*l* of about 6% nitric acid, and concentrations of mercurous ion and nitrate ion were titrated with 0.1N potassium hydroxide. When the mercurous nitrate solution was added to 8 m*l* of the sodium acrylate solution under vigorous stirring in the dark, mercurous acrylate was precipitated as white flakes. In order to prepare white, stable mercurous acrylate, nitrate ion should be equivalent to sodium ion in the sodium acrylate solution. The white flakes were filtered and washed with water. After drying *in vacuo*, mercurous acrylate weighed 1.64 g (yield 87.2%). This compound gradually decomposes above 150°C without fusing.

Preparation of the Photosensitive Plate. White flakes of mercurous acrylate without drying, were uniformly dispersed in 30 m*l* of 20% aqueous solution of polyvinyl alcohol. The emulsion was spread over glass plates and left to dry.

Results and Discussion

Spectral Sensitivity of the Acrylate Plate. The wedge spectrogram (Fig. 1) shows that the mercurous acrylate was sensitive to light 250—340 nm, when the grayish white plate turned dark brown.

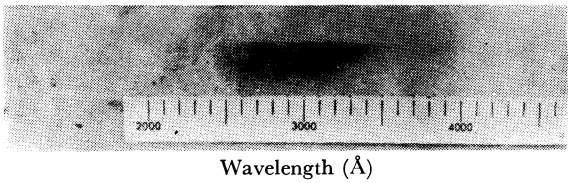

Fig. 1. Wedge spectrogram of a mercurous acrylate plate.

Ultraviolet and Visible Spectra. Reflection spectra were measured for mercurous acrylate plates before and after exposure to ultraviolet light. The results are given in Fig. 2. An absorption below 350 nm, which was found in the ultraviolet spectrum of an unexposed plate, seemed to be closely related with the photosensitivity of the acrylate plate.

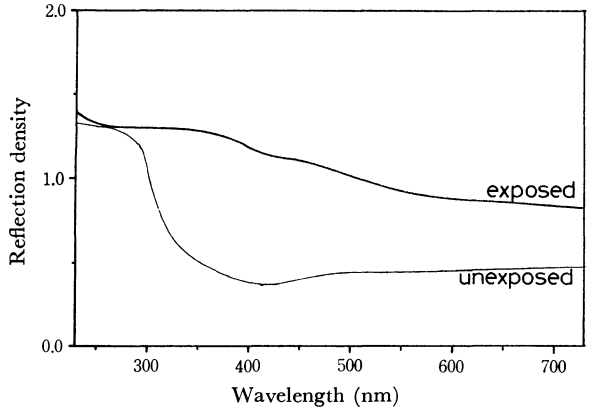

Fig. 2. Reflection UV and visible spectra of mercurous acrylate plates.

Characteristic Curve of the Plate. The plates were placed in a dark box and irradiated by a low-pressure mercury lamp for a certain time and their reflection density was measured. Density was plotted against exposing time. The curve is S-shaped. The maximum density was *ca.* 0.6 above the fog (Fig. 3).

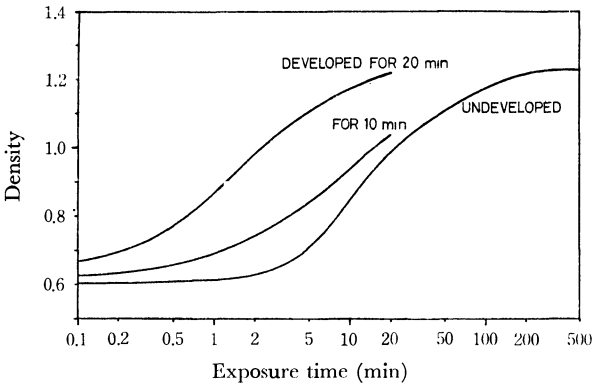

Fig. 3. Characteristic curves of mercurous acrylate plates.

Development of Latent Image. One half of the acrylate plate was irradiated by a low-pressure mercury lamp for two minutes. However, the exposed part was still grayish white and could not be distinguished from the unexposed one. The exposed plate was immersed in an aqueous alcohol solution (water : alcohol=1 : 4, by volume) of hydroquinone. In a few minutes, the exposed part blackened and a distinct difference in color appeared between the exposed and unexposed parts. Fogging was observed on the unexposed part after development for longer than 20 min. Characteristic curves of the acrylate plates, developed in 10 and 20 min respectively, are demonstrated in Fig. 3.

When an aqueous solution of metol or hydroquinone was used for developing, development was completed in 5 min and further development resulted in fogging of the unexposed part. However, the polyvinyl alcohol binder for the mercurous acrylate swelled and the image became detached from the plate when taken out of the developing solution.

Studies on the Preparative Method of the Photosensitive Plate. In the preparation of mercurous acrylate, exact neutralization of sodium hydroxide with acrylic acid was indispensable for excellent photosensitivity of the plate. Otherwise, the plate turned gray while the emulsion was left to dry. Though the density increase smaller because of high fog density, latent images on the gray plate could be developed in the same way as those on a white plate, while no blackening took place in the unexposed part. This may indicate that the gray color was not due to any compounds formed by the disproportionation of mercurous acrylate during the course of drying.

When alkaline solutions such as sodium hydroxide, potassium hydroxide, ammonium hydroxide or hexamethylenetetramine, were used instead of the developing solution, immediate blackening took place on both the unexposed and the exposed parts of the acrylate plate. Blackening caused by alkali may be ascribed to the formation of mercurous hydroxide or mercurous oxide. If the developing solution contains sulfur compounds such as thiourea, sodium thiosulfate, or sodium sulfite, fogging was observed on the unexposed part of the plate. Utilization of gelatin as a binder of the mercurous acrylate gave rise to the fogging of the plate.

The fogging may be due to some dark colored materials formed by the reaction between mercurous ion and the sulfur compounds or basic compounds in gelatin.

Fading and Bleaching of the Image. The black image formed by the developing method as well as the dark brown image formed by the printing-out method were stable and never faded during storage for three months or more.

Treatment of the exposed plate with hydrogen peroxide or nitric acid caused bleaching of the blackened image until no difference in color between the exposed and unexposed parts was observed. Developing by the reducing agent and bleaching by the oxidizing agent suggest that photoreduction of mercurous ion to form metallic mercury, $Hg^{+} \rightarrow Hg$, contributes to the photosensitivity of mercurous acrylate and the formation of image.

The authors wish to thank Professor Takahiro Tsunoda of this University for use of the monochrometer.

The Crystal Structure and Nonstoichiometry of Rare Earth Oxyfluoride

Koichi NIIHARA and Seishi YAJIMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received August 27, 1970)

Oxyfluoride phases for the rare earth Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, and Y have been prepared by heating a mixture of lanthanon fluorides, LnF_3, and lanthanon oxides, Ln_2O_3. Three phases were identified. The rhombohedral phases, LnOF, have a stoichiometric composition, and the tetragonal phases, $Ln_4O_3F_6$, have a comparatively large nonstoichiometric composition range. The third cubic phase, with a fluorite-type structure, was observed in the SmOF-$Sm_4O_3F_6$ region after quenching from a high temperature. This establishes that both the rhombohedral SmOF and the tetragonal $Sm_4O_3F_6$ transform to the cubic phase and form a complete solid solution in the high-temperature range. It is postulated that the rhombohedral and tetragonal phases are pseudo-cubic from the fact that the diffraction patterns of these two phases are closely similar to that of the fluorite type.

Relatively few data on the chemical properties of the rare earth oxyfluorides exist in the literature; there is an adequate reason for this. Similar in size to the fluoride ion, the oxide ion may be substituted through a wide concentration range in these heavy metal fluorides. Therefore, the compositional variability of the rare earth oxyfluorides with respect to the anionic ligands is very extensive. Accurate property data are, consequently, very limited. Research problems connected with those materials require mainly information concerning the extent of the oxide-fluoride miscibility before other data may be obtained. If the generally indiscrete composition of the solid phases can be well understood, attempts to obtain other accurate data will be stimulated.

Oxyfluorides of lanthanum, cerium, praseodymium, neodymium, samarium, europium, gadolinium, terbium, dysprosium, holmium, erbium, and yttrium have been prepared using several techniques.[1-6] Zachariasen[1] prepared two types of crystal structures of LaOF and YOF by the hydrolysis of LaF_3 and YF_3 at 900°C and 500°C respectively, one being rhombohedral and the other tetragonal. The rhombohedral phases were observed to have stoichiometric compositions, LaOF and YOF. The tetragonal phases appeared with an increase in the fluorine in the LaO_xF_{3-2x} system ($0.7<x<1$). Zachariasen related all the structures to the fluorite-type structure. He postulated that the rhombohedral and tetragonal forms result from a complete ordering of the oxygen and fluorine atoms into distinct sites of the unit cell.

Hund[2] prepared tetragonal and cubic YOF by heating a mixture of Y_2O_3 and YF_3 in a high vacuum at 900°C for several hr.

Popov[3] and other Russian workers[4] prepared rare earth oxyfluorides (La through Er) by heating their metal fluorides in a muffle furnace in dry air or in a stream of moist air. All the compounds except CeOF, which was cubic, were found to exhibit rhombohedral symmetry.

Thus, there are various structures which have been reported for the rare earth oxyfluorides. The main purpose of this study is to elucidate the relation between the crystal structure and the nonstoichiometric composition of the rare earth oxyfluorides, and to give precise lattice parameters.

Experimental

The anhydrous lanthanon trifluorides, SmF_3, EuF_3, GdF_3, DyF_3, HoF_3, ErF_3, TmF_3, and YbF_3 were prepared by converting the 99.9% pure Ln_2O_3 to fluoride according to the following chemical reaction:

$$Ln_2O_3 + 6NH_4 \cdot HF_2 = 2LnF_3 + 6NH_4 \cdot F + 3H_2O.$$

A mixture containing excess $NH_4 \cdot HF_2$ was heated at 350°C

for 10 hr in a platinum boat, which was placed in an Inconel tube situated in an electric furnace. The resulting water, HF, and NH_4F were evacuated by an aspirator during the reaction. The trifluoride sample thus obtained was degassed in another furnace by careful heating in a high vaccum, *i. e.*, by raising the temperature to 600°C at a rate of 5°C/min and by then maintaining the temperature these for 5 hr.

The lanthanon trifluoride was mixed with lanthanon sesquioxide in various ratios. The fully homogenized mixtures were compacted into pellets, about 10 mm in diameter and 10—30 mm thick. These pellets were reacted in a high vacuum or in an inert gas atmosphere at 1000—1200°C for 5—10 hr, and then quenched or slowly cooled to room temperature. This method of preparing the oxyfluoride is very convenient in studying the nonstoichiometry if enough attention is paid to the weight loss during the reaction and to the anhydrolysis of the rare earth oxides and fluorides.

The nonstoichiometric compositions of the lanthanon oxyfluorides can be expressed as follows:

$$a\mathrm{LnF_3} + b\mathrm{Ln_2O_3} = (a+2b)\mathrm{LnO}_x\mathrm{F}_{3-2x} \quad (x=3b/a+2b)$$

If the amount of either LnF_3 or Ln_2O_3 exceeds the nonstoichiometric composition given by this formula, the excess amount of either LnF_3 or Ln_2O_3 can be determined by X-ray. The pellets thus obtained were pulverized after heat treatment and were examined by X-ray powder diffraction using copper $K\alpha$ radiation and a 114.6 mm-diameter Debye-Scherrer powder camera. Chemical analysis was performed by direct ignition to the oxide.

Experimental Results

The oxyfluorides of samarium, europium, gadolinium, dysprosium, holmium, erbium, thulium, and ytterbium were prepared by the above-described method. The results of the identification of the reaction products cooled slowly in the furnace are shown in Fig. 1; they indicate that there are two oxyfluoride phases. According to the interpretation of the X-ray diffraction patterns, one phase is tetragonal, and the other, rhombohedral. Only in the SmF_3-Sm_2O_3 system, were phases of the fluorite type observed upon quenching from 1200°C. However, in the other system, LnF_3-Ln_2O_3, efforts to obtain a phase of the fluorite type by quenching were unsuccessful.

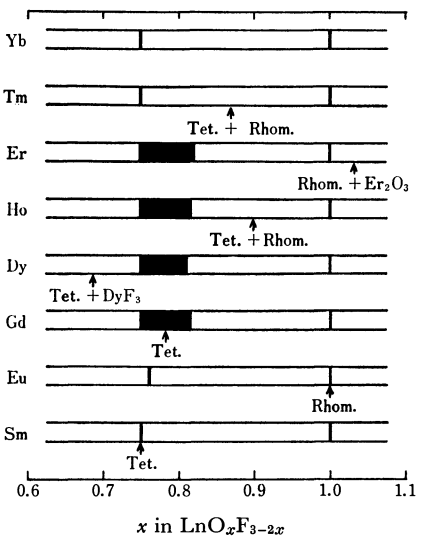

Fig. 1. Phase regions of rhombohedral and tetragonal oxyfluorides.

Rhombohedral-phase LnOF. In all cases, the rhombohedral phases were found to be a single phase only when $x=1$. In the regions of $x>1$ and $x<1$, the diffraction lines of both Ln_2O_3 and the tetragonal oxyfluoride occurred, as well as the rhombohedral phase. No variation in the unit-cell dimensions of this rhombohedral phase was observed. Therefore, it may be concluded that the chemical composition of the rhombohedral phase is sharply defined and corresponds exactly to LnOF. The diffraction data of SmOF and ErOF are shown in Table 1. The diffraction data of EuOF, GdOF, DyOF, HoOF, TmOF, and YbOF are good similar to those of SmOF and ErOF.

Zachariasen[1] found, for LaOF, the space group $R\bar{3}m$ with two molecules in the unit cell; he reported atomic positions which were satisfactory for YOF as well. The data for SmOF, EuOF, GdOF, DyOF, ErOF, TmOF, and YbOF obtained in the present research

can be interpreted in a similar way, as the X-ray diffraction data agree well with those observed by Zachariasen for LaOF and YOF. The structure is a superlattice based upon a slightly distorted CaF_2-type structure. For the undistorted structure, α is 33.56°. The relation between the rhombohedral cell and the fluorite cell is shown in Fig. 2-a. The lattice constants, unit cell volume, and X-ray density obtained are listed in Table 2, where they are also compared with the previous

data.[1,7-9] The change in the molecular volume against the atomic number of rare earth elements plotted in Fig. 3 is characteristic of the well-known lanthanide contraction.

Tetragonal-phase $Ln_4O_3F_6$ ($Ln_2O_3 \cdot 2LnF_3$). The tetragonal phases were observed as mono-phases in the fluorine-rich region. Generally, the chemical composition of the phase throughout its homogeneity range can be expressed by the LnO_xF_{3-2x} formula. As is shown in Fig. 1, the tetragonal phases of Sm, Eu, Gd, Dy, Ho, Er, Tm, and Yb exist as stable mono-phases in the regions of $x=0.75$, $x=0.77$, $0.75<x<0.83$, $0.75<x<0.82$, $0.75<x<0.83$, $0.75<x<0.84$, $x=0.75$, and $x=0.75$ respectively. In the regions of $x<0.75$ and about $x>0.83$, the LnF_3 fluoride and the LnOF rhombohedral oxyfluoride respectively appear as second phases. Therefore, it is resonable to assume that the tetragonal phases have the ideal chemical composition, $LnO_{0.75}F_{1.5}$, that is, $Ln_4O_3F_6(Ln_2O_3 \cdot 2LnF_3)$. The results of the chemical analysis of each $Ln_4O_3F_6$ are summarized in Table 3. The X-ray diffraction data of $Sm_4O_3F_6$ and $Er_4O_3F_6$ are shown in Table 4. The second column lists the indices postulated by Zachariasen. The unit cell of the tetragonal oxyfluoride is illustrated in Fig. 2-b in comparison with the unit cell of Zachariasen. The diffraction data of the tetragonal $Ln_4O_3F_6$ are compara-

tively similar to the data of Zachariasen[1] for the tetragonal YOF and LaOF with respect to the intensities and line structure, compared after the axis transformation. However, the (110) and (103) planes can not be explained by the unit cell of Zachariasen, as is shown in Table 4. On the other hand, all the diffraction planes can be explained by the unit cell used in this research. According to our results, $Ln_4O_3F_6$ is a tetragonal structure containing 4 molecules in the unit cell with $c/a=1$. Thus, our results differ from those of Zachariasen, who assumed 2 molecules in the unit cell with $c/a=\sqrt{2}$. The lattice parameters and X-ray density are given in Table 5. The lattice parameter of the tetragonal $Gd_4O_3F_6$, $Dy_4O_3F_6$, $Ho_4O_3F_6$, and $Er_4O_3F_6$, all of which have a nonstoichiometric composition range, are plotted

as a function of the parameter, x, in Fig. 4 and Fig. 5. The variation in the lattice parameters is plotted in Fig. 6 against the atomic number of the rare earth element. The lattice parameters of the tetragonal $Gd_4O_3F_6$, $Dy_4O_3F_6$, $Ho_4O_3F_6$, and $Er_4O_3F_6$ in the homogeneity range vary in such a way that c increases and a decreases. As is shown in Fig. 6, the tetragonal phases show the well-known lanthanide contraction as a function of the atomic number of the rare earth element.

Cubic Phase (Fluorite-type Structure). In the SmF_3-Sm_2O_3 system, the rhombohedral phase and the tetragonal phase were observed, as is shown in Fig. 1. Some of these specimens were reheated to 1200°C and then quenched to room temperature. The crystal structure of these samples was examined by X-ray analysis; it was thus clarified that lines due to a face-

centered structure exist, and the relative intensities suggested a fluorite-type structure. In specimens containing only the rhombohedral phase ($x=1$), or only the tetragonal phase ($x=0.75$), or both the rhombohedral and tetragonal phases ($0.75<x<1$), only the fluorite-type phase was obtained by quenching. If two-phase specimens contained the rhombohedral oxyfluoride and Sm_2O_3, or the tetragonal oxyfluoride and SmF_3, quenching produced the fluorite-type phase and left the Sm_2O_3 or SmF_3 respectively unchanged. Consequently, it can be considered that a transformation from the rhombohedral and tetragonal phases to the fluorite-type phase may occur. The correlation between the lattice parameter of the fluorite-type SmO_xF_{3-2x} and the parameter, x, is shown in Fig. 7. This curve

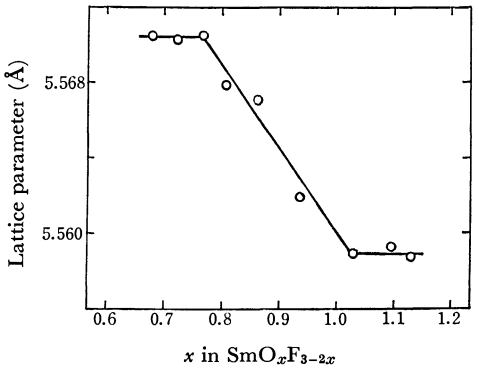

Fig. 7. Variation of the lattice parameter of SmO_xF_{3-2x} with the fluorite type structure.

shows that the lattice parameter decreases linearly with x, *i. e.*, with a decrease in the fluorine content. In all the other systems except SmF_3-Sm_2O_3, the fluorite-type phase was not obtained by quenching. In the $x>1$ region of the SmF_3-Sm_2O_3 system, a strange phenomenon was observed. The Sm_2O_3 used as the starting material had a B-type structure (Sm_2O_3-type, monoclinic), but the Sm_2O_3 found in the quenched products showed a C-type structure (La_2O_3-type, cubic). This means that a transformation of the Sm_2O_3 structure from the B-type to the C-type occurred. According to a previous study,[10] the C-type Sm_2O_3 is stable up to about 950°C and the transition process from the C-type to the B-type is completed within several days at 950°C and within about 1 hr at 1100°C. The transformation had also been found to be irreversible. Therefore, it is conceivable that the C-type Sm_2O_3 obtained in this experiment is stabilized by the presence of small amounts of fluorine.

Discussion

The rare earth oxyfluorides with the rhombohedral-, tetragonal-, and fluorite-type structures were observed in the system of Ln_2O_3-LnF_3. The chemical composition of the rhombohedral structure corresponds to the exact stoichiometric composition, LnOF, and no nonstoichiometric composition range exists in any of the systems. However, two kinds of tetragonal structures could be identified. One is the tetragonal phase, $Ln_4O_3F_6$, with out a nonstoichiometric composition range such as those with Sm, Eu, and Tb. The other type is the tetragonal phase, $Ln_4O_3F_6$ with a comparatively large nonstoichiometric composition range, such as those with Gd, Dy, Ho, and Er. It is very interesting that, in the former type, the rare earth ion is comparatively easy to convert into the divalent ion, but in the latter one this seems to be very difficult.

In the SmF_3-Sm_2O_3 system, the rhombohedral phase, SmOF, was observed at a ratio of 1 : 1, while the tetragonal phase, $Sm_4O_3F_6$, appeared at a ratio of 2 : 1. The fluorite-type phase was observed in the region of SmOF-$Sm_4O_3F_6$ after quenching from a high tempera-

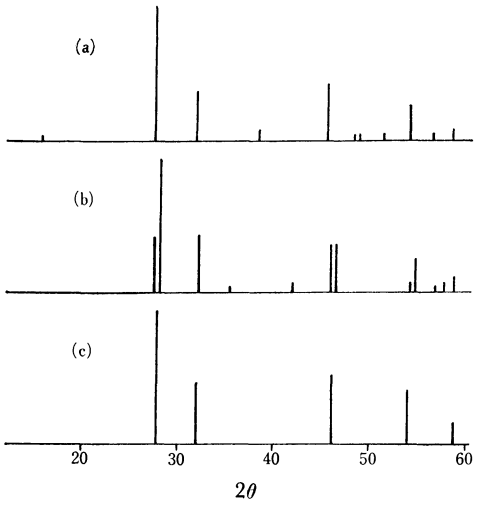

Fig. 8. Typical difraction patterns of samarium oxyfluoride.
(a) Tetragonal, (b) Rhombohedral, (c) Fluorite type

ture. This indicates that both the rhombohedral SmOF and the tetragonal $Sm_4O_3F_6$ are transformed to the cubic phase and form a complete solid solution in the high-temperature range.

Three typical X-ray patterns of the samarium oxyfluorides are illustrated in Fig. 8. The diffraction patterns of the rhombohedral- and tetragonal-type structures are very similar to that of the fluorite type. In view of those results, it is conceivable that the rhombohedral and tetragonal phases are pseudo-cubic.

Zachariasen[1] postulated that both the rhombohedral and tetragonal forms have the LaOF composition and result from a complete ordering of the oxygen and fluorine atoms into distinct sites of the unit cell. He also described the tetragonal unit cell as having the axial ratio of $c/a=\sqrt{2}$ and containing two metal atoms. The present results concerning the rhombohedral phase are in agreement with those of Zachariasen. However, it is concluded that the tetragonal phase has the ideal chemical composition, $Ln_4O_3F_6$, and that the unit cell has the axial ratio of $c/a\fallingdotseq 1$ and contains four metal atoms. Zachariasen also mentions that the tetragonal phase has a wide homogeneity range, LaO_xF_{3-2x} $(0.7<x<1.0)$, but that this phase is unstable relative to the rhombohedral phase at $x=1.0$. Therefore, in the system of LaF_3-La_2O_3 examined by Zachariasen, it is considered that the tetragonal phase, $La_4O_3F_6$, has a large homogeneity range reaching up to LaOF $(x=1)$ by chance.

The relation between the rare earth oxyfluorides, LaOF and $Ln_4O_3F_6$, is similar to that between $NaF\cdot YF_3$ and $5NaF\cdot 9YF_3$[11] in the system of NaF-YF_3, and to that between the uranium oxides, UO_2 and U_4O_9,[12] taking into consideration the fact the fluoride ion is as large as the oxide ion. In the case of the NaF-YF_3 system, two intermediate compounds, $NaF\cdot YF_3$ and $5NaF\cdot 9YF_3$, crystallize from the melt as fluorite-like cubic crystals near the middle of the system, form a continuous series of solid solutions up to the melting temperatre, and are converted to other forms at a low temperature. The $5NaF\cdot 9YF_3$ compound also forms on an ordered phase below 700°C.

As has previously been stated, the fluorite type was observed after quenching only in the SmF_3-Sm_2O_3 system, not in the other Ln_2O_3-LnF_3 systems. However, if more rapid cooling were employed, the fluorite-type structure might appear in all systems.

Intermolecular Forces and Rotational Phase Transition in the C_2H_2 Crystal

Masao HASHIMOTO, Michiko HASHIMOTO, and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received September 16, 1970)

The potential energy of the acetylene crystal was calculated as a function of the rotational molecular orientations. The potential energy of this crystal has two kinds of minima, not a double minima; one arises from the quadrupole-quadrupole interaction, to which the high-temperature is due, while the other arises from the overlap repulsion interaction with which the low temperature structure is coincident. It was suggested that the mechanism of the phase transition in this crystal is a rotational transition between the two molecular orientations.

Acetylene is known to undergo a phase transition at 133°K. The crystal structure has been determined to be T_h^6-$Pa3$ at 156°K.[1] Below 133°K however, the information given by the X-ray analysis is ambiguous.

From the observed multiplet structure of the infrared-active fundamental vibrations[2,3] of the low-temperature phase, the acetylene molecules were determined to be located at the sites of the C_{2h} symmetry.

Recently, Ito *et al.*[4] have suggested, on the basis of the Laser Raman spectrum, that the low-temperature form has a layer-type orthorhombic structure belonging to the space group D_{2h}^{18}.

In the present article we calculated the intermolecular potential energy of crystalline acetylene in the expectation that the phase transition in this crystal would correspond to the rotational transition between two molecular orientations. The results indicate that there are two stable molecular orientations in this crystal; one of them corresponds to the high-temperature structure, while the other is coincident with the low-temperature structure.

Theoretical

The theoretical foundations for the calculation of the potential energy in the case where intermolecular separations are small enough for the overlap of the molecular wavefunction to be disregarded[5-9] are due mainly to Banerjee and Salem.[10] We will list the main points briefly and apply them to the case of acetylene.

(1) The molecular wavefunction, Ψ, of an acetylene molecule is expressible as an antisymmetrized sum of the products of the one-electron molecular orbitals:

$$\Psi = |\varphi_{C-H}\bar{\varphi}_{C-H}\varphi'_{C-H}\bar{\varphi}'_{C-H}\varphi^{\sigma}_{C-C}\bar{\varphi}^{\sigma}_{C-C}\psi^{\pi 1}_{C-C}\psi^{\pi 1}_{C-C}\psi^{\pi 2}_{C-C}\psi^{\pi 2}_{C-C}|$$

with:

$$\psi_{C-H} = (di_C + 1s_H)/(2+2S_{CH})^{1/2},$$

$$S_{CH} = \int di_C 1s_H d\tau,$$

$$\psi^{\sigma}_{C-C} = (di_C + di_C)/(2+2S)^{1/2},$$

$$S = \int di_C di_C d\tau$$

$$\psi^{\pi}_{C-C} = (\pi_C + \pi_C)/(2+2S_{\pi})^{1/2},$$

and

$$S_{\pi} = \int \pi_C \pi_C d\tau,$$

where di_C and $1s_H$ are the diagonal hybrid and the $1s$ orbital centered on the carbon and hydrogen atoms, respectively. π_C is the $2p\pi$ orbital centered on the carbon atom.

(2) The ionization potential, I and I', appear in terms of the conventional van der Waals energy:

$$W_{disp} = -(3/2)R^{-6}\alpha\alpha' II'/(I+I'), \quad (2)$$

are replaced by quantum mechanically-calculable averages. The results are:

$$W_{disp} = [(A-2B+C)\{\sin\theta\sin\theta'\cos(\phi-\phi') - 2\cos\theta\cos\theta'\}^2 + 3(B-C)\{\cos^2\theta+\cos^2\theta'\} + (2B+4C)]/R^6 \quad (3)$$

with:

$$A = e^2\alpha_{\parallel}\langle(\sum_i q_{\parallel},i)^2\rangle/4,$$

$$B = e^2\alpha_{\parallel}\alpha_{\perp}\langle(\sum_i q_{\parallel},i)^2\rangle\langle(\sum_i q_{\perp},i)^2\rangle/ 2\{\alpha_{\parallel}\langle(\sum_i q_{\perp},i)^2\rangle + \alpha_{\perp}\langle(\sum_i q_{\parallel},i)^2\rangle\},$$

and

$$C = e^2\alpha_{\perp}\langle(\sum_i q_{\perp},i)^2\rangle,$$

where $\langle(\sum_i q,i)^2\rangle$ are called the quantum mechanical averages and where

$$\langle(\sum_i q,i)^2\rangle = \langle\Psi|(\sum_i q,i)^2|\Psi\rangle.$$

$q_{\parallel},i$ and $q_{\perp},i$ are the coordinates of the ith electron along the directions respectively parallel to and perpendicular to the molecular symmetry axis (C–C bond). $\alpha_{\parallel}$ and $\alpha_{\perp}$ are the corresponding components of the polarizability. θ and θ' are the angles which the two molecules, separated by the distance R, make with a line joining their center of gravity. φ and φ' are their azimuthal angles.

(3) The repulsive energy can be expressed as the sum of the interaction energies between individual atoms of the two molecules:

$$W_{\text{repl}} = \sum_{i>j}\{V(H_i \cdots H_j) + V(H_i \cdots C_j)\} \quad (4)$$

with $V(H_i \cdots H_j)=21.3\times S^2/R$ and $V(H_i \cdots C_j)=49.0\times S^2/R$[11] where $V(H_i \cdots H_j)$ and $V(H_i \cdots C_j)$ are the intermolecular hydrogen-hydrogen and hydrogen-carbon repulsion energies respectively.[11] S is the overlap integral of $1s$ hydrogen atoms separated by the distance R. The C···C repulsion energy may be ignored, as usual.

(4) The pair potential energy between the molecules in the acetylene crystal is made up of Eqs. (3) and (4):

$$W = W_{\text{disp}} + W_{\text{repl}} \quad (5)$$

The potential energy of the crystal is, then, obtained by summing (5) over all the molecules in the crystal.

In this paper, besides the above interactions, we will also consider the following interaction energy and will examine the validity of the pair additivity assumption in the case of the acetylene crystal.

The acetylene molecule has a quadrupole moment of 3.00×10^{-26} c.g.s.e.s.u.;[16] therefore, at least the quadrupole-quadrupole interaction must be considered. This interaction can be expressed as:

$$\begin{aligned}\mathcal{Q}_{ab} = {} & 3qq'[1-5\cos^2\theta-5\cos^2\theta'+17\cos^2\theta\cos^2\theta' \\ & + 2\sin^2\theta\sin^2\theta'\cos(\varphi-\varphi') \\ & + 16\sin\theta\sin\theta'\cos\theta\cos\theta'\cos(\varphi-\varphi')]/4R^5, \quad (7)\end{aligned}$$

where the q's are the observed quadrupole moments of the acetylene molecule and where the θ's and φ's are as defined in Eq. (3).

If the molecules of the polarizabilities, α_a, α_b, and α_c, make an abc triangle, the three-body non-additive force may be expressed as follows:[17,18]

$$E_3 = (9/16)\times I\times\alpha^3\times(3\cos\gamma_a\cos\gamma_b\cos\gamma_c+1)/(R_{ab}{}^3R_{bc}{}^3R_{ca}{}^3), \quad (8)$$

where the γ's are the inner angles of the triangle, the R's are the distances among the three molecules, α is the average polarizability, and I is the mean excitation energy, which can be considered as the ionization potential of the molecules. In the acetylene molecule, $I=11.40$ eV and $\alpha=33.3\times10^{-25}$ cm^3;[19] therefore, for the nearest molecules in the crystal, E_3 is of the order of 10^{-5} kcal/mol; this can be ignored in comparison with the other interaction energies.

Numerical Calculations

If the phase transition of the acetylene crystal corresponds to the transition between the two molecular orientations, the calculated potential energies for various orientations and displacements of the molecules in the crystal should have minima of more than two.

For the displacements of the molecules, no consideration will be made now because there is no drastic structural change which causes a large elongation or

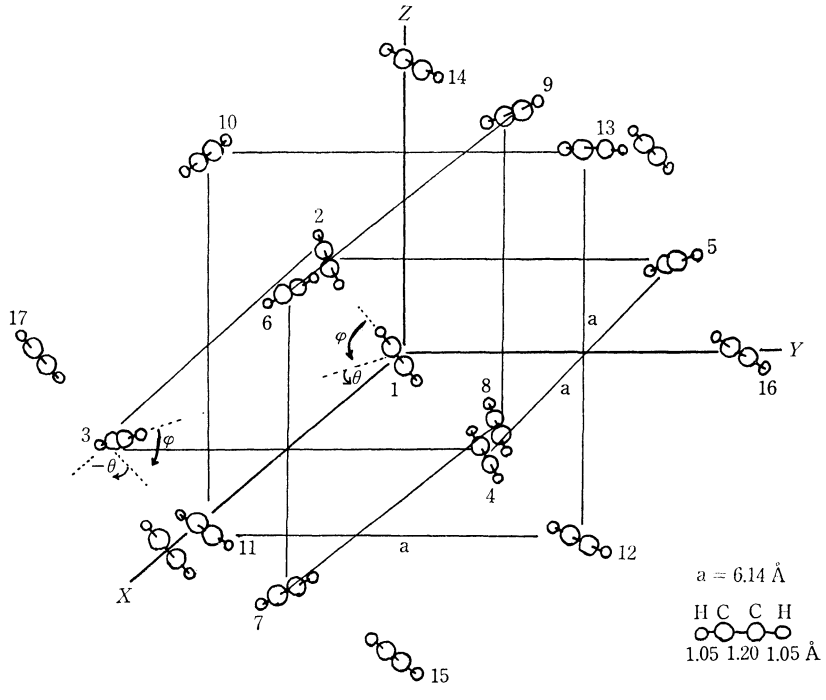

Fig. 1. Face centered position of cubic lattice of C_2H_2 crystal.

11) The coefficient of 21.3 was determined by Banerjee and Salem,[10] so $V(H\cdots H)=k\times S^2/R$ reproduces the H···H potential obtained from the scattering experiments of Amdur *et al.*[12-14] The coefficient of 49.0 was obtained by using the empirical relation due to Adrian,[15] connecting $V(H\cdots H)$ to $V(H\cdots C)$: $V(H\cdots H)=k'\times V(H\cdots C)$.

contraction of the lattice during the phase transition.[20] The displacements of the molecules will be discussed in detail in future works of this series.

In the present investigation we have made the calculations on the basis of Eqs. (3), (6), and (7) for various rotational orientations of the molecule.

We start from the structure in which the centers of gravity of the molecules are located on the face-centered position of the cubic lattice, with the unit-cell dimension of $a=6.14$ Å (see Fig. 1).

With respect to the central molecule, 1, at the origin of the coordinate, there are 18 first-neighbour molecules. We calculated the dispersion and quardrupole-quadrupole interaction energies for the molecules from the 1st to 5th nearest neighbours, but the repulsion energy for the 1st neighbours only. The 5th-nearest neighbours are separated from the point of origin by 30 Å.

Two kinds of molecular rotation are considered. One is the rotation measured by the deflection of the molecular axis from the (100) plane, and the other is the rotation measured by the deflection from the (011) plane. The angle of the former is indicated by φ, and the latter, by θ.

The integrals appearing in the quantum-mechanical averages and the overlap integrals are calculated using Simpson's formula.[21] All the computational work in this paper was done at the Computer Center of Tohoku University using the NEAC 2200-500-model Computer System.

Results and Discussion

Figures 2 and 5 indicate the variation in the dispersion energy with φ and θ. In Fig. 2 the values

when θ is zero are indicated. The curves in which θ is different from zero are all more or less similar to the curve in Fig. 2 whenever θ is smaller than ± 10 degrees.

Figure 5 shows that the depth of the potential minimum decreases as φ becomes smaller.

The overlap repulsion energies are indicated in Fig. 4 and in Fig. 7. As we defined the dispersion attraction energy as negative, the repulsive energies are expressed in positive terms. When θ is zero, the curve indicating the variation with the φ has a minimum point at φ= 45°. When φ is constant, the variation with the θ has a minimum when θ is zero, as may be seen from Fig. 7.

The quadrupole interaction energy curves are indicated in Figs. 3 and 6. As in the case of the dispersion energy, the depth of the potential minimum seen in Fig. 6 decreases as the φ becomes smaller and disappears at φ=0.

No one of the above three interaction energies has double potential minimum, contrary to our expectations. However, the potential curves against φ may be worthy of note. In overlap repulsion energy curves the interaction energy has a minimum point at φ=45°, while in quadrupole-quadrupole interaction it has a minimum point at φ=0°. In short, the potential energy of crystalline acetylene has no double minima, but it has two kinds of minima. One arises from the overlap repulsion, and the other, from the quadrupole-quadrupole interaction.

Let us consider which of these two is the more stable. It may be seen from the curves in Figs. 5, 6, and 7 that when φ=0° the quadrupole-quadrupole and dispersion interaction energies reach a maximum at θ=0°, where the repulsion energy for H···H is at a minimum. On the contrary, when φ=45°, not only the repulsion but also the quadrupole-quadrupole and dispersion interaction energies have minima at θ=0°. Therefore, the orientation corresponding to φ=45° is more stable than the molecular orientation corresponding to φ=0°. We have assumed, therefore, that the former molecular orientation will be realized in low-temperature regions. The crystal structure proposed by Ito *et al.* for the low-temperature phase coincides with the structure of φ= 45°.

On the other hand, the molecular orientation corresponding to φ=0° coincides with the structure determined by X-ray analysis by Sugawara *et al.* for the high-temperature form.

The calculated lattice energy of the high-temperature form is 5.1 kcal/mol, while the experimental one[22] is 5.5 kcal/mol. Their coincidence is also quite good.

In conclusion, the potential energy of crystalline acetylene has two kinds of minima, not double minima; one arises from the quadrupole-quadrupole interaction, to which the high-temperature structure is due, and the other, from the overlap repulsion interaction, to which the low-temperature structure corresponds.

(Received October 9, 1970)

The crystal structure of π-cyclooctenyl-π-cycloocta-1,5-dienecobalt, $Co(C_8H_{13})(C_8H_{12})$, has been established by successive Fourier analyses. The atomic parameters were refined by least-squares techniques using three-dimensional X-ray data to an R factor of 0.125. The complex molecule crystallizes in the space group $P2_1/c$ with four molecules in the unit cell of dimensions: $a=10.78$, $b=7.30$, $c=17.81$ Å, $\beta=104.2°$. The four cobalt atoms lie nearly on the face-centered positions in the unit cell and are sandwiched between the two ligands, cyclooctenyl C_8H_{13} and cyclooctadiene C_8H_{12}. The seven nearest Co···C distances range from 2.02 Å to 2.09 Å. Atoms Co, C(1), C(3) and the respective centers of the two double bonds, C(9)–C(16) and C(12)–C(13), in C_8H_{12} ring are coplanar to within 0.08 Å. The conformation of C_8H_{13} is of the tub form and C_8H_{12} of the boat form. The two lengths of the double bonds in C_8H_{12} are 1.41 Å and 1.39 Å, while those in the allyl part in C_8H_{13} are 1.35 Å and 1.46 Å, respectively. The average distance of the remaining twelve C–C bonds is 1.54 Å.

π-Cyclooctenyl-π-cycloocta-1,5-dienecobalt was prepared by Otsuka and Rossi.[1] They reported the formation of $CoH(dp)_2$ [dp=1,2-bis(diphenylphosphino)-ethane] when this complex was treated with an excess of dp and the release of cyclooctene upon thermal decomposition. The latter is in contrast to the thermal decomposition of bis(cycloocta-1,5-diene)nickel, $Ni(C_8H_{12})_2$ which yields only cyclooctadiene and metallic nickel. On the basis of a NMR and IR study, they proposed two possible molecular structures in each of which two hydrogen atoms on the octenyl ligand are found at exceptionally short distances from the cobalt atom. Thus the reactivity of this complex was attributed to the proximity of the two hydrogen atoms to the cobalt atom. In order to clarify the postulated structures, particular emphasis being laid on the role of the hydrogen atoms, we have undertaken a three-dimensional X-ray crystal analysis of $Co(C_8H_{13})(C_8H_{12})$. A preliminary account of this work has already been reported.[2]

Experimental

Crystals of π-cyclooctenyl-π-cycloocta-1,5-dienecobalt were kindly provided by Professor S. Otsuka. They were recrystallized as brilliant black plates from *n*-hexane solutions. Specimens used in this investigation were sealed in thin-walled glass capillaries and were held below 0°C during experiments to prevent oxidative and thermal decompositions. Oscillation and Weissenberg photographs taken with Fe$K\alpha$ radiation exhibited a monoclinic symmetry with space group $P2_1/c$. The lattice parameters were obtained from ($0kl$) and ($h0l$) Weissenberg photographs superimposed by silicon powder patterns and were refined by a least-squares method. In order to collect the three-dimensional intensity data, equi-inclination integrating Weissenberg photographs were taken with Mn-filtered Fe$K\alpha$ radiation from $0kl$ to $6kl$ and from $h0l$ to $h4l$, using a multiple-film technique. The intensities were visually estimated using a calibrated scale. Thus, 1043 independent non-zero reflections were observed. These relative intensities were corrected for Lorentz and polarization factors and were placed on an absolute scale by Wilson's methods. No absorption correction was applied since $\mu R \simeq 1$. The crystal data are summarized in Table 1.

Structure Determination

A three-dimensional sharpened Patterson function showed three large peaks at (1/2, 0, 1/2), (1/2, 1/2, 0), and (0, 1/2, 1/2). This vector set implies that the arrangement of the cobalt atoms is of the face-centered type so that these atoms lie either on the two sets of special positions (centers of symmetry) or on the general positions with $x \fallingdotseq 1/4$, $y \fallingdotseq 0$, $z \fallingdotseq 1/4$. The latter case was chosen because the complex molecule was expected to be noncentro-symmetric. The symbolic addition procedure was applied, but this attempt was not successful owing to a pseudo-symmetry arising from the arrangement of the cobalt atoms.

The positions of the cobalt atom were refined by a diagonal-matrix least-squares method, and a Fourier synthesis phased on the metal atom alone was carried out. All of the sixteen carbon atoms were satisfactorily located by successive Fourier analyses. After several cycles of refinement with isotropic temperature factors for all the atoms, the discrepancy factor R, $R=\sum||F_o|-|F_c||/\sum|F_o|$, dropped to 0.16. The positional and anisotropic thermal parameters were further refined by a block-diagonal-matrix least-squares method to the R value of 0.125. The final atomic coordinates and

anisotropic temperature factors of the form: $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{23}kl+B_{31}lh)\}$ together with their estimated standard deviations are given in Table 2(a) and (b). The observed and calculated structure factors are listed in Table 3. The scattering factors of Co^{+1} and C were taken from International Tables for X-ray Crystallography (1962). The oxidation state of the cobalt atom will be discussed later. All the numerical calculations were carried out on a FACOM 270-20 computer of this University using the programs written in our laboratory.

Results and Discussion

Figure 1 shows the view of the molecule along the *b*-axis, where the hydrogen atoms are given in positions postulated on the assumption of the conventional bond distances and angles. The numbering scheme for the carbon and hydrogen atoms are also shown. Interatomic bond distances and angles and their estimated standard deviations are summarized in Table 4 (a) and (b).

As is shown in Fig. 1, the cobalt atom is sandwiched between the two ligands, cyclooctenyl C_8H_{13}, and cyclooctadiene C_8H_{12}. Interatomic distances from the metal atom to the seven nearest carbon atoms, C(1), C(2), C(3), C(9), C(12), C(13), and C(16), fall in the range from 2.02 Å to 2.09 Å. Atoms Co, C(1), C(3), and the respective centers of the two double bonds, C(9)–C(16) and C(12)–C(13), in C_8H_{12} ring are coplanar to within 0.08 Å. We shall designate the plane thus described as the Co-plane. The equation of the plane and the deviations of the respective atoms from the plane are listed in Table 5. Figures 2 and 3 represent the geometry around the cobalt atom which are the projections along the directions parallel and normal

C(13)	0.02
C(16)	−0.02

In the above equations, X, Y, and Z are the rectangular coordinates in Å unit, where $X=x+z\cos\beta$, $Y=y$, $Z=z\sin\beta$.

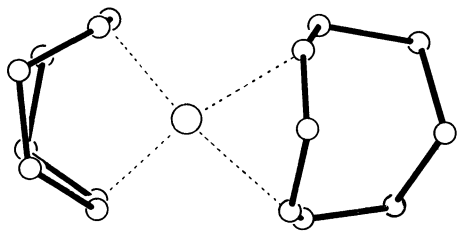

Fig. 3. The molecule viewed along the direction normal to the Co-plane.

to the Co-plane respectively. The planar configuration of the cobalt atom with the allyl part of the cyclooctenyl ligand (C(1)-C(2)-C(3)) and the two double bond centers of the cycloocta-1,5-diene ligand is clearly shown in Figs. 2 and 3. The formal oxidation state of the cobalt atom is suggested to be +1 by the reaction absorbing carbon monoxide to give a carbonyl complex, $Co(CO)(C_8H_{13})(C_8H_{12})$, from which hydridocarbonylphosphine complexes, $CoH(CO)L_3$ ($L=PPh_3$ or $PMePh_2$), are derived.[3] Thus the cobalt atom attains an outer configuration of sixteen electrons by forming the complex with the two ligands. In this case, the allyl part in the octenyl ligand acts as a four-electron bidentate donor.

The two carbon-carbon bond lengths in the allyl part differ somewhat; C(1)-C(2)=1.46 Å and C(2)-C(3)=1.35 Å. On the other hand, the three interatomic distances between the cobalt and the three carbon atoms, C(1), C(2), and C(3), are 2.08 Å, 2.03 Å, and 2.06 Å, respectively. Taking the standard deviations into con-

3) S. Otsuka and M. Rossi, *J. Chem. Soc.*, *A*, **1969**, 497.

sideration, the bonding of the allyl group to the cobalt atom is probably symmetrical. In the NMR spectrum of this complex too, signals of the symmetrical π-allyl group have been found.[1]

The average bond length of the two double bonds, C(9)–C(16) and C(12)–C(13), is 1.40 Å, giving the bond order of 1.5.[4] The remaining twelve C–C interatomic distances in the two ligands are found to be in the range 1.47 Å to 1.59 Å. These are comparable to the reported values of the single bond length in several complexes of this type.[5,6] Some of the bond angles are found definitely larger either than 109.5° for sp^3 or than 120° for sp^2 (Table 4 (a) and (b)).

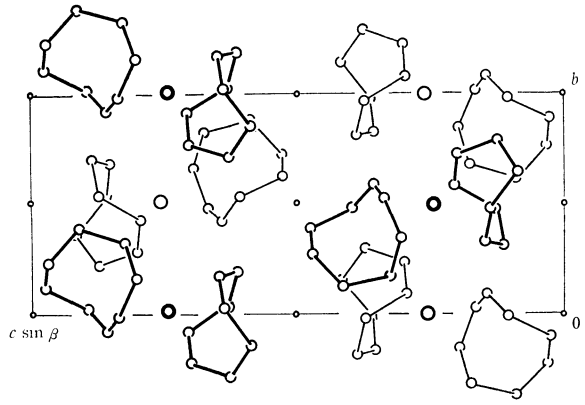

Fig. 4. The crystal structure viewed along the *a* axis.

Atoms C(9), C(12), C(13), and C(16) deviate by only 0.02 Å from a least-squares plane, and atoms C(1), C(3), C(4), and C(8) also approach planarity. The dihedral angles between the Co-plane and plane C(9)–C(12)–C(13)–C(16), plane C(1)–C(3)–C(4)–C(8) and plane C(1)–C(2)–C(3) are 93°, 100°, and 108°, respectively. The equations of these planes and deviations of the respective carbon atoms from the planes are summarized in Table 5.

The cyclooctenyl ring is of the tub form. The two parts of the ligand, C(8)–C(1)–C(2)–C(3) and C(1)–C(2)–C(3)–C(4), deviate from the planar *cis*-conformation. The angles of twist around the two bonds, C(1)–C(2) and C(2)–C(3), are 32° and 38°, respectively. The cycloocta-1,5-diene ring is of the boat form. The conformation of C(9)–C(10)–C(11)–C(12) is incompletely eclipsed; the C(11)–C(12) and C(9)–C(10) groups are skewed around the C(11)–C(12) bond, the dihedral angle between the C(9)–C(10)–C(11) and C(10)–C(11)–C(12) planes being 22°. This twisting probably arises from the repulsion between hydrogen atoms attached to the carbon atoms concerned. The conformation of C(13)–C(14)–C(15)–C(16) is similar to that of C(9)–C(10)–C(11)–C(12). Here, the dihedral angle is 27°.

Positions of the hydrogen atoms attached to all the sixteen carbon atoms were calculated based upon a C–H distance of 1.08 Å and H–C–H bond angles of 120° for sp^2 and 109.5° for sp^3. No abnormally short interatomic distances between Co and H have been found. However, there are two short interatomic distances between hydrogen atoms: H(3)···H(12) and H(4)···H(8) are 1.73 Å and 1.87 Å, respectively, which are comparable to those reported for $Ni(C_8H_{12})_2$.[5]

The arrangement of molecules in the crystal viewed along the *a* and *b* axes is shown in Figs. 4 and 5. The crystal contains discrete molecular units of π-cyclooctenyl-π-cycloocta-1,5-dienecobalt, separated by normal van der Waals distances. The shortest C···C intermolecular distances are 3.84 Å for sp^3–sp^3 and 3.66 Å for sp^2–sp^3.

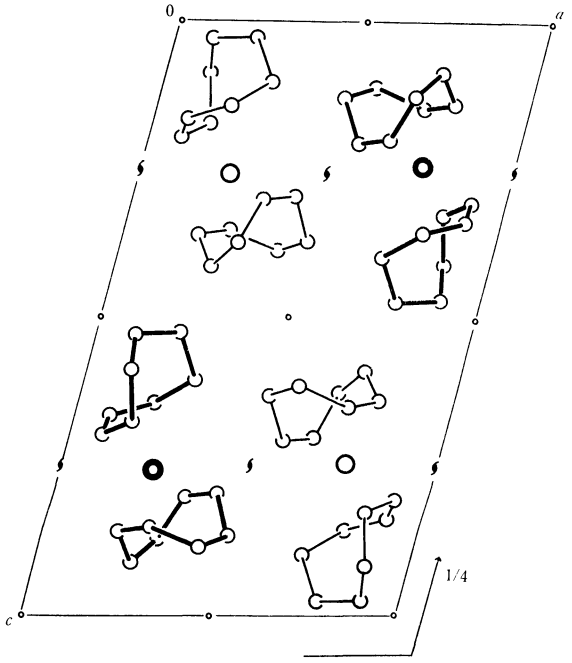

Fig. 5. The crystal structure viewed along the *b* axis.

The authors wish to express their gratitude to Professor S. Otsuka, Faculty of Engineering Science, Osaka University, for providing them with the specimens for this investigation.

Emission Spectra Obtained by Low Energy Electron Bombardment of Methane and Chlorinated Methanes

Teiichiro OGAWA,[1] Iwao FUJITA, Motoyoshi HATADA,* and Kozo HIROTA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

**Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, Mii, Neyagawa, Osaka*

(Received September 4, 1970)

Spectroscopic studies of a molecular beam bombarded by a low energy electron beam were carried out for several simple organic molecules. The collision chamber resembled the ionization chamber of a mass spectrometer, and the electrons were accelerated at about 270 V. The spectrum of methane showed lines of excited hydrogen atoms and bands of excited CH radicals. The spectra of chlorinated methanes showed lines of excited chlorine atoms and bands of excited hydrogen chloride positive ions (HCl^{+}*) in addition. Even the spectrum of a mixture of methane and carbon tetrachloride revealed bands of HCl^{+}*. Dependence of emission intensities on target currents and gas pressures indicated the origin of the excited hydrogen atoms and CH radicals to come from direct fragmentation and the excited HCl^{+} ions from a bimolecular process.

Mass spectrometric studies have provided information on the ionization and fragmentation of electron-bombarded molecules, but it is limited to the ionized species. Though, there are a few studies[2] on the neutral species, little is known on the excitation of molecules and their fragments in the ionization chamber. Thus, spectroscopic studies on the excited species in the ionization chamber would be of use.

The electric discharge method has been used to produce unstable species in combination with their spectroscopic detection in the discharge chamber and on the cathode. Though this method is very effective for analysis, the complicated character of the discharge is a major obstacle for detailed analysis of the mechanism of fragmentation and excitation of the species concerned. Horie, Nagura and Otsuka[3] investigated collisions between molecules and electrons with known velocities and observed an unusual distribution of the rotational energy of the fragment species OH, which was produced by the electron impact of H_2O or H_2O_2. An interpretation by a statistical model was reported.[4] Emission spectra of such simple molecules as N_2, CO, and CO_2 produced by electron bombardment were reported[5] and lifetimes of their excited species were measured by a similar method,[6] though only a few organic molecules were studied.

According to the quasi-equilibrium theory, fragmentation schemes of molecules in a mass spectrometer were interpreted,[7] while by use of a molecular orbital treatment, predictions as to the initial fragmentation were made by Hirota and his co-workers.[8] To clarify the mechanism of bond scissions and to justify the theoretical interpretation, knowledge of possible excited species and their behavior is of vital importance. Thus, we carried out spectroscopic studies of a molecular beam of some simple organic molecules bombarded by electrons.

Experimental

A molecular beam was crossed perpendicularly to collide with an electron beam in a chamber as shown in Fig. 1. A rhenium filament (e) was heated by a regulated DC power supply at about 6V and 3A. Two grids (c, d) were used to push the electron into a collision chamber (a). The collision chamber was kept at 220—270 V above the filament and had a slit of 20×2 mm, through which the electron beam was introduced. A target (b) was kept at 21 V above the chamber to collect the electrons. The sample gas was introduced from the bottom through several pin holes. In order to keep the filament and its surroundings in a high vacuum, a differential pumping system was used. Typical target and chamber currents used were 300 μA and 5 mA, respectively. The rate of molecular beam was estimated to be about 10^{19} molecules/min.

The light emitted perpendicularly both to the molecular beam and to the electron beam through a quartz window (g), 11 mm in diameter, was measured with a Shimadzu GE

100 grating spectrograph, equipped with a 1200 grooves/mm grating blazed for 5000 Å and with a 1000 mm collimator system. Photographic measurements were carried out with a Kodak Tri-X Pan Film in the 2500—7000 Å region for determination of wavelength and finer details of emission lines. An EMI 6256 B photomultiplier was used for photometric measurements, when the intensities were to be determined in the 2000—6600 Å region.

The wavelength was calibrated by a low pressure mercury lamp. The intensity was calibrated by a Toshiba standard tungsten lamp (1500°C). No features of water or of organic substances were observed in the spectra of nitrogen and of carbon monoxide, which were utilized to see the performance of the instrument. The mass spectrum was recorded on a Hitachi RMU-5 mass spectrometer. Methane used was a Research Grade product from Takachiho Trading Co., and other compounds were of the best grade available from Wako Pure Chemical Ind., except for CH_2Cl_2 which was from Nakarai Chemicals. All the samples were used after repeated degassing in a high vacuum.

260 V impact at 300—400μA.

Results and Discussion

A typical spectrum of methane is shown in Fig. 2. The very intense lines are the hydrogen Balmer series, which are denoted by H_α, H_β,···. Six lines were clearly observed and their relative intensities were close to those in literature,[9] though the intensity of H_α line could not be determined accurately because of the poor sensitivity of the photomultiplier used at 6500 Å. The complicated features in the 3800—4500 Å region were assigned to CH (A→X) and CH (B→X) emission.[10] The detailed spectrum in 4200—4400 Å region is shown in Fig. 3. The assignments of vibrational and rotational bands were carried out with reference to literature.[11] A few very weak lines assignable to nitrogen were found, but no bands of CO.

Dependence of emission intensity on target current is shown in Figs. 4 and 5 for H_β (4861 Å) and for CH (4312 Å), respectively. The linear relationship was found in the region of 10—600 μÅ in both cases. The

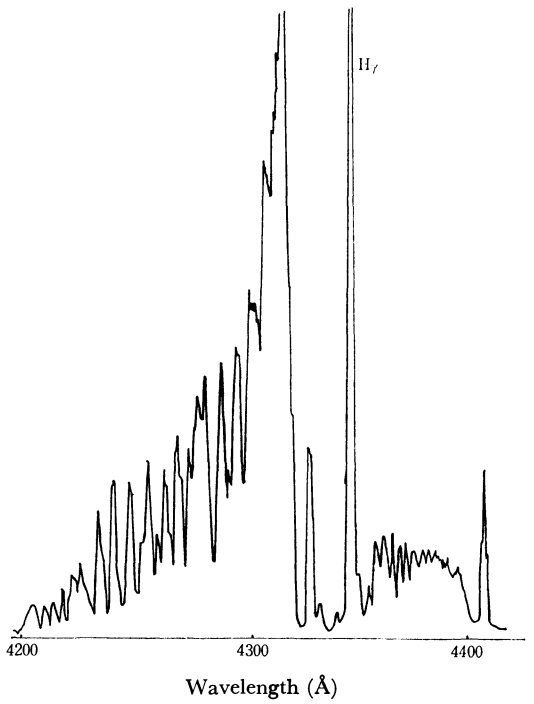

Fig. 3. Emission spectrum of methane in 4200—4400 Å region.

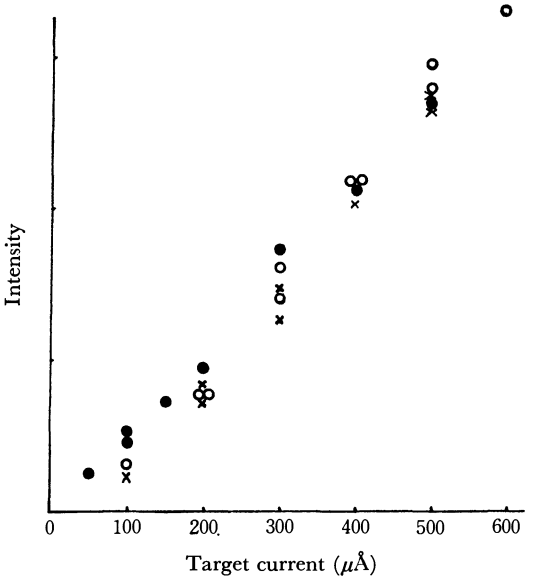

Fig. 4. Emission intensity *vs.* target current. H_β from methane at 4861 Å. For the sake of clarity, ten data were omitted below 50 μA, all of which lay on the same straight line. × 13.5 mm Hg, ● 15 mm Hg and ○ 18.5 mm Hg in the gas reservoir.

production of excited H atoms and excited CH radicals was, therefore, concluded to be a first-order reaction to the incident electrons, if it was assumed to be proportional to the target current. Dependence of emission intensities on gas pressures is shown in Fig. 6 for both H_β (4861 Å) and CH (4312 Å). The gas pressure was measured in the gas reservoir, where the pressure was assumed to be proportional to that in the collision chamber. The intensity of emission lines was in linear relation to pressure at lower pressures but the curves

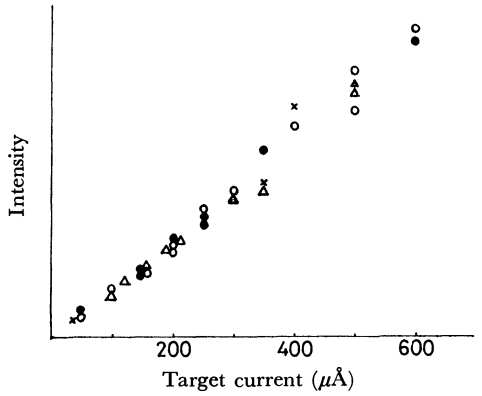

Fig. 5. Emission intensity *vs.* target current. CH* from methane at 4321 Å. For the sake of clarity, eight data were omitted below 60 μA, all of which lay on the same straight line. × 12.5 mmHg, ● 13.5 mmHg, ○ 17 mmHg and △ 21 mmHg in the gas reservoir.

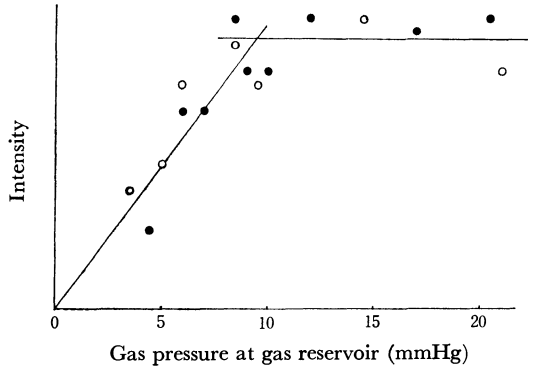

Fig. 6. Emission intensity *vs.* gas pressure. Target current was 10 μA. ○ H_β and ● CH*. Gas pressure indicated was measured not in the collision chamber but in the gas reservoir.

leveled off at a certain pressure, which was common to both H_β and CH and shifted to a lower value when the target current was increased. These results imply that collisional deactivation among excited species plays a dominant role, since the collisional deactivation between excited species and parent molecules should cause a shift to a higher value.

The linear relations lead to the conclusion that the excited hydrogen atoms and the excited CH radicals were produced by a mechanism of direct excitation and fragmentation as follows:

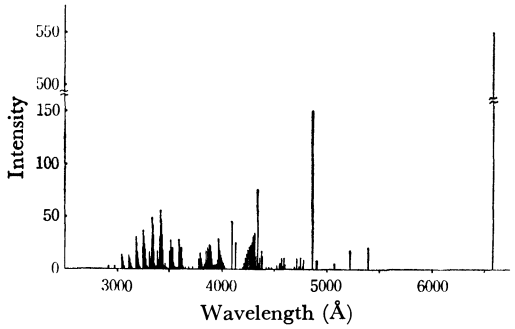

Fig. 7. Emission spectrum of methylene chloride bombarded by an electron beam. 260 V impact at 400—600 μA.

$$CH_4 + e \longrightarrow CH_4^* \longrightarrow H^*, CH^* \cdots$$

The emission spectra of chlorine derivatives of methane bombarded by an electron beam showed some additional features. The spectra of methyl chloride, methylene chloride and chloroform looked alike. A typical spectrum of methylene chloride is shown in Fig. 7. The strongest lines are assigned also to the hydrogen Balmer series, but the relative intensity of H_β to H_α in this case was found to be larger than that of methane. Emission bands of CH radicals (A→X and B→X) were also observed and are similar to those of methane.

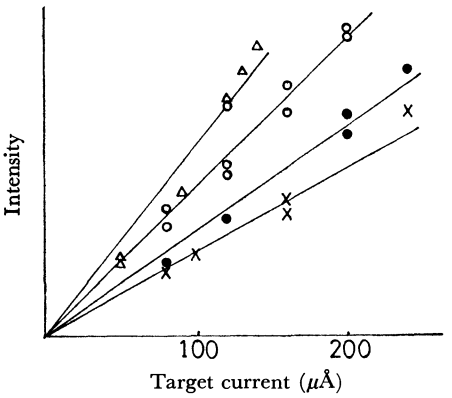

Fig. 8. Emission intensity *vs.* target current. H_β from methylene chloride at 4861 Å. × 5.5 mmHg, ● 10.5 mmHg, ○ 14.5 mmHg and △ 20 mmHg in the reservoir.

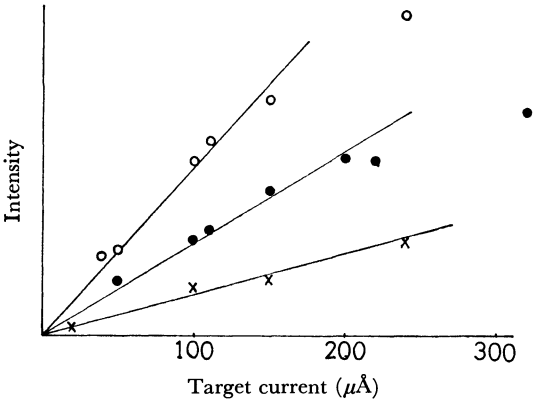

Fig. 9. Emission intensity *vs.* target current. CH* from methylene chloride at 4312 Å. × 6 mmHg, ● 9.5 mmHg and ○ 17.5 mmHg in the gas reservoir.

Dependence of emission intensities on target current is shown in Figs. 8 and 9 for H_β (4861 Å) and for CH (4312 Å), respectively. Since the intensities were in linear relation to target current, the production of excited H atoms and excited CH radicals can be concluded to be of the first order to the incident electrons. The identical argument as for methane could be applied further to the production of H* and CH* from chlorinated methanes, since the behavior of emission intensities was similar.

The most remarkable characteristic in this spectrum is shown by the bands which appear in the 2900—4000 Å region. Doublet splitting of vibrational structures is clearly observed. A detailed spectrum is shown in Fig. 10. The bands, together with vibrational and rotational structures, were assigned to HCl^+ (A→X)

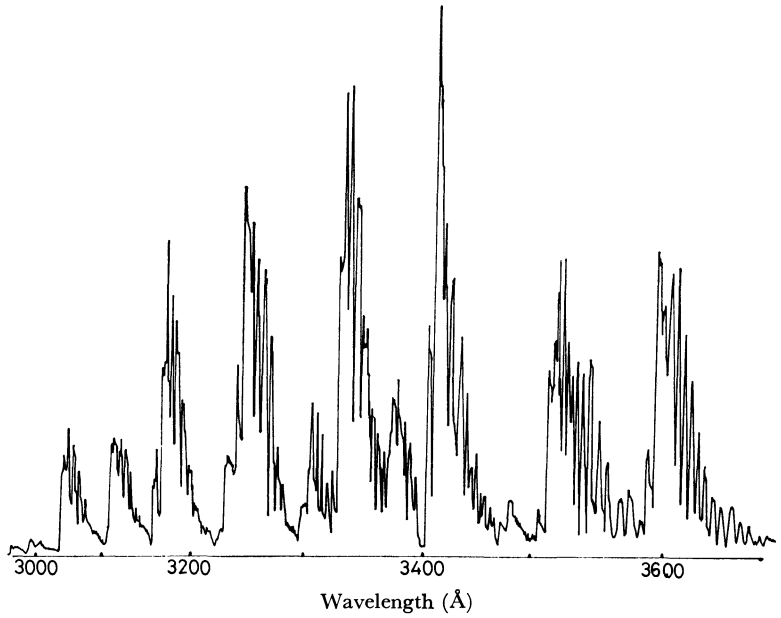

Fig. 10. Emission spectrum of methylene chloride in 3000—3700 Å region. 260 V impact at 400—600 μA.

according to the results by Brice and Jenkins,[12] and Norling.[13] The bands observed were in order of intensity: (1,0) at 3334 Å and 3410 Å, (2,0) at 3180 Å and 3245 Å, (0,0) at 3515 Å and 3595 Å, and (0,1) at 3863 Å and 3965 Å and also the (3,1) and (3,0) bands. The (1,1) (2,1) (2,2) and (4,0) bands could be pointed out. In comparison with the electrical discharge of HCl,[12] HCl^+ was found to be vibrationally excited.

The linear relations between the intensities and the amount of incident electrons as observed in the case of H and CH were not observed for HCl^+. It seems unlikely that H and CH and HCl^+ were produced by a similar mechanism. No strong peak was observed at $m/e=36$ (HCl^+) in the mass spectrum of methylene chloride; the intensity of HCl^+ was 3.5% of that of the strongest CH_2Cl^+. Since the pressure is much lower in the mass spectrometer, this suggests that HCl^{+*} would not be produced by direct fragmentation of methylene chloride, and HCl^{+*} observed in the present study would come from a bimolecular process.

The emission spectra of 1,1,1-trichloroethane and of a one-to-one mixture of methane and carbon tetrachloride were observed by the photographic method. In both cases, the bands of HCl^+ were clearly observed and looked identical to those of CH_2Cl_2. Similarity of the fine structure of HCl^+ suggests that the origins of HCl^+ were common for all parent species. From this and the result of mass spectroscopy on methylene chloride, it can be concluded that the excited hydrogen chloride positive ions were produced by a bimolecular process. Cashion and Polanyi[14] investigated the reaction,

$$H + Cl_2 \longrightarrow HCl + Cl$$

They observed that the product HCl was in vibrationally excited states. In the present study, the vibrationally excited HCl^+ might be produced by a related mechanism.

The authors would like to express their grateful acknowledgement to Professors Shigero Ikeda and Yu Yokoyama for use of their Shimadzu GE 100 monochromator and various accessories. The authors also thank Professors Tadao Horie and Tsuruji Iwai and Dr. Seiji Tsurubuchi for their advice in constructing the collision chamber and calibrating the spectrometer.

The Cation Radical Salts of Phenothiazine and Related Compounds[1]

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 10, 1970)

The cation radical salts of phenothiazine bromide, phenothiazine bisulfate monohydrate, and phenothiazine picrate were prepared. The absorption spectra in a dilute hydrochloric acid solution and the solid-state spectra of the salts were examined. The solid-state spectra showed a strong charge-transfer band and blue-shifts of the high-energy bands, unlike the absorption spectra in solution. The magnetic susceptibilities of these salts were measured at room temperature. They were found to be diamagnetic, with values almost corresponding to those of the diamagnetic contribution of the salts, except for that of the picrate. These spectroscopic and magnetic properties were discussed on the basis of the charge-transfer interaction between the phenothiazine cation radicals. The properties of the usual phenothiazine-picric acid charge-transfer complex and the holoquinoid phenothiazine perchlorate were investigated in association with those of the cation radical salts.

In 1913 the cation radical salts of phenothiazine were first prepared by Pummerer and Gassner, and then in 1915 they were prepared again by Kehrmann and Diserens.[2,3] In their articles, however, these cation radical salts were described as "semiquinoid phenazathionium salts," because the concept of "the cation radical salts" had not yet been established.

Much attention has been paid to the cation radical salts of phenothiazine and its derivatives, since (1) the tranquilizer drug, chloropromazine, is a substituted phenothiazine and (2) many dyestuffs, such as methylene blue, are oxidation products of substituted phenothiazines. Although many papers have been written on the ESR of the radical cations of phenothiazine and its derivatives in solution,[4] few attempts have been made to investigate the solid-state properties of the phenothiazine cation radical salts.[5]

In general, solid ion-radical salts have been a matter of great interest, because the ion-radical molecules form, in themselves, a plane-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals.[6] Much knowledge regarding the mutual charge-transfer interaction has been accumulated by measuring the solid-state spectra and the magnetic susceptibilities.[7-10] Hence, the purpose of the present paper is to apply these physical methods to the solid phenothiazine cation radical salts. We shall examine how the charge-transfer interaction contributes to the solid-state properties of these cation radical salts.

On the other hand, the phenothiazine-picric acid charge-transfer complex and the holoquinoid phenothiazine perchlorate were also prepared, since the properties of these compounds are interesting in comparison with those of the phenothiazine cation radical salts.

Experimental

Materials. The cation radical salts of phenothiazine bromide, phenothiazine bisulfate monohydrate,[11] and phenothiazine picrate were prepared according to the methods of Pummerer and Gassner[2] and of Kehrmann and Diserens.[3] Although Pummerer and Gassner reported two polymorphic forms for the picrate,[2] no such polymorphism was found in the present preparation.

The phenothiazine-picric acid charge-transfer complex was precipitated from a benzene solution containing nearly equivalent amounts of phenothiazine and picric acid. The holoquinoid phenothiazine perchlorate was prepared from phenothiazine *S*-oxide, which had been made through the oxidation of phenothiazine with hydrogen peroxide.[3]

The synthetic schemes of these compounds are illustrated in Fig. 1.

Measurements. The absorption spectra of the cation radical salts were measured in a 4.2% aqueous hydrochloric acid solution, while that of the holoquinoid phenothiazine perchlorate was measured in an acetonitrile solution. All the measurements of the absorption spectra were made at room temperature by means of a Beckman DK-2A spectrophotometer.

The diffuse reflection spectra were recorded on a Beckman DK-2A spectroreflectometer in the range from 4.0 to 30.8 kK at room temperature. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance. The experimental details were the same as those in previous papers.[8-10]

The magnetic susceptibility measurements were made by the Gouy method at room temperature. Water was used in calibrating the cell constant.

The Absorption Spectra in Solution

In order to characterize the solid-state spectra of the phenothiazine cation radical salts, it is necessary to compare them with the absorption spectra of the salts in solution; therefore, we will examine the spectra in this section.

All of the cation radical salts exhibit a golden yellow color in solution and are quite stable in an acidic solution, such as an acetic acid or a dilute hydrochloric acid solution. In other solvents, however, they rapidly decompose to show a green color, the molecular species of which has not yet been ascertained.

Some of the absorption spectra of these cation radical salts in a 4.2% hydrochloric acid solution are reproduced in Fig. 2. In these measurements, the salts seem to be completely dissociated, because the concentrations are as dilute as of $1-2\times10^{-4}$ mol/l. When the counter anions are Br^- and $HSO_4^-\cdot H_2O$, since they have no absorptions in the energy region now under consideration, the absorption spectra of the salts appear to be solely due to the phenothiazine cation radical monomer. The absorption spectrum of the salt of the picrate has extra shoulders around 24.5 kK and 28 kK; these shoulders are assigned to the bands due to the picrate anion.

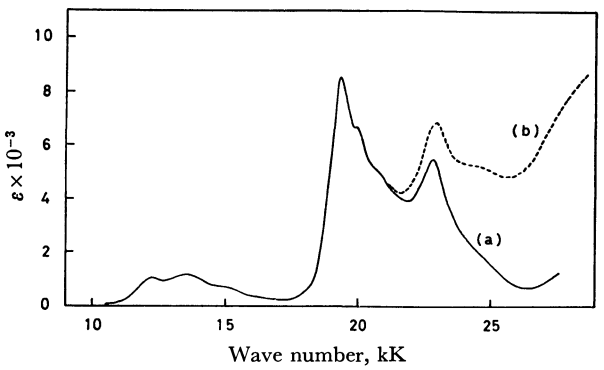

Fig. 2. The absorption spectra of the cation radical salts of (a) phenothiazine bisulfate monohydrate and (b) phenothiazine picrate, in 4.2% aqueous hydrochloric acid solution.

The monomer spectrum of the phenothiazine cation radical has a weak band around 13.5 kK composed of several vibrational structures at 15.0 kK, 13.5 kK, and 12.2 kK, a strong band at 19.3 kK with a shoulder at 19.9 kK, and a band at 22.8 kK. These features are well in accordance with those of the cation radical reported by Shine and Mach,[12] who dissolved phenothiazine in a sulfuric acid solution and then examined the absorption spectrum. Unfortunately, however, no attempt has been made to account for the electronic transitions by means of molecular orbital calculations.

On the other hand, Kagiya *et al.* reported on the temperature variation of the absorption spectrum of the phenothiazine bromide in an ethanol-ether-sulfuric acid solution.[13] They found that, at low temperatures, the monomer absorptions were diminished, while new bands

13) T. Kagiya, K. Nakai, S. Nakayama, and K. Suzuki, Paper presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

appeared at 23.9 kK, 21.3 kK, and 14.5 kK. These bands were assigned to the dimer of the cation radicals on the basis of the concentration dependence on their optical densities. The high-energy bands at 21.3 kK and 23.9 kK seem to be shifted bands of the monomer bands at 19.3 kK and 22.8 kK respectively. On the other hand, the band at 14.5 kK is located in the low-energy region, and it is broad without any vibrational structures. It can not be assigned to the shifted band of the cation radical monomer, since it takes place only when the dimer is formed between the cation radicals. Therefore, the low-energy band at 14.5 kK seems to be attributable to charge-transfer absorption in the dimer.[14]

The Solid-State Spectra

Phenothiazine Bisulfate Monohydrate (Fig. 3, Curve a). The solid-state spectrum of this salt shows a strong low-energy band at 12.0 kK, high-energy bands at 21.1 kK and 23.3 kK, and a shoulder around 28 kK. These spectroscopic features are different from those of the cation radical monomer in solution, but they are similar to those of the cation radical dimer. The high-energy bands at 21.1 kK and 23.3 kK in the solid-state spectrum are coincident with those at 21.3 kK and 23.9 kK respectively in the dimer spectrum. These bands arise mostly from the monomer bands at 19.3 kK and 22.8 kK respectively. This means that in both the solid state and the dimer, when the cation radicals come close enough together for the π orbitals to overlap, the π–π transitions due to the monomer are blue-shifted by the field of the other cation radicals. In accordance with this view, the low-energy band at 12.0 kK of the solid-state spectrum is as much intensified as the charge-transfer band at 14.5 kK of the dimer spectrum.[13] Although the former value is a little bit lower than the latter, the band at 12.0 kK can be assigned to the charge-transfer transition between the phenothiazine cation radicals in the solid state. However, we must keep in mind the fact that the weak absorption due to the monomer spectrum around 13.5 kK should overlap with this charge-transfer band.

Phenothiazine Picrate (Fig. 3, Curve b). The solid-state spectrum of this salt is composed of the charge-transfer band at 12.8 kK and the high-energy bands at 20.7 kK and 23.3 kK. The increased intensity of the absorption at 23.3 kK, compared to that of the bisulfate monohydrate, may arise from the overlap with the band due to the picrate anion. Except for this difference, the situation of the solid state of this salt appears to be very analogous to that of the bisulfate monohydrate.

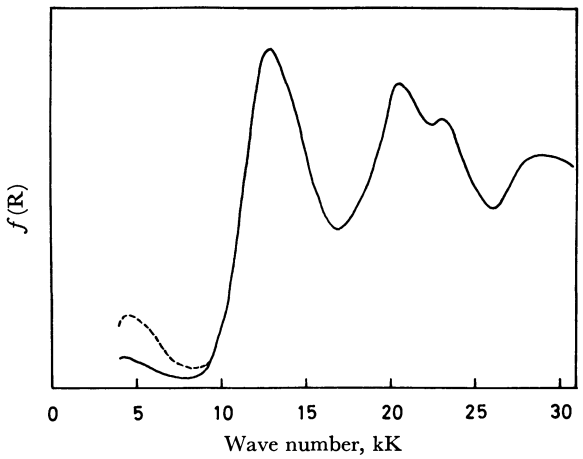

Fig. 4. The solid-state spectrum of the cation radical salt of phenothiazine bromide. The broken line indicates the spectrum of the sample taken from a different batch, as the salt was synthesized repeatedly.

Phenothiazine Bromide (Fig. 4). The solid-state spectrum of this salt shows a weak low-energy band at 4.2 kK, a strong charge-transfer band at 12.9 kK and high-energy bands at 20.5 kK, 23.0 kK, and 28.6 kK. Except for the band at 4.2 kK, these spectroscopic features are quite identical with those for the bisulfate monohydrate. As for the band at 4.2 kK, the intensity, although weak, was found to be not reproducible when the preparation of the salt was repeated. Matsunaga and Shono found that the intensity of this band was very much increased when some iodine was added to this salt.[15] They suggested that the formation of a complex cation radical salt, (Phenothiazine)$^+$ (Phenothiazine)^0 Br_2I^-, might be responsible for the appearance of this band. Therefore, the phenothiazine bromide, which exhibits its band at 4.2 kK, may be contaminated with a small amount of a complex cation radical salt of (Phenothiazine)$^+$ (Phenothiazine)^0 Br_3^-.

Magnetic Susceptibilities

It has been well established that the charge-transfer interaction between the ion radicals leads to a marked decrease in the paramagnetic susceptibilities of ion radical salts.[7–10] The charge-transfer interaction is known to stabilize the antiferromagnetic state where the spins associated with the ion radicals are antiparallel. This is also true of the present phenothiazine cation radical salts. Table 1 shows the observed values of the magnetic susceptibilities at room temperature, together with the estimated diamagnetic contribution.

Solid phenothiazine bromide was found to be diamagnetic at room temperature (-147×10^{-6} emu/mol). After correction had been made for the diamagnetism, the paramagnetic contribution of the salt was found to be as small as 13×10^{-6} emu/mol. It is not clear whether this paramagnetic contribution is due to the intrinsic paramagnetism or to an impurity paramagnetism. However, even if it is attributed to the intrinsic paramag-

14) According to the Hausser and Murrell theory, the ion-radicals in a dimer may be stacked face-to-face, and the spin exchange interaction leads to a singlet ground state and an excited triplet state. Therefore, we must take into consideration the fact that intermolecular charge-transfer may make a significant contribution to stabilizing the ground singlet state of the dimer. The low-energy charge-transfer absorption characteristic of the dimer arises mostly from a transition from the thus-stabilized ground state to an excited singlet state expressed by a combination of the wave functions for charge-transfer structures, R–R^{2+}. See K. H. Hausser and J. N. Murrell, *J. Chem. Phys.*, **27**, 500 (1957).

The experimentally determined value of diamagnetic susceptibility for a neutral phenothiazine was used in place of the cation radical. See Ref. 5.

netism for the bromide, the antiferromagnetic spin exchange interaction between the cation radicals seems to be greater than 0.1 eV. The situation in the bisulfate monohydrate appears to be almost the same as that in the bromide.

In the phenothiazine picrate, the observed value of the magnetic susceptibility was found to increase progressively as the measurements were repeated. This is shown by the multiple values of the susceptibilities listed in Table 1. In this case, the antiferromagnetic spin exchange interaction may be gradually eliminated by the fine pulverization of the sample in the course of the measurements. The population of the free spins may increase accordingly. However, a question still remains of why only the salt of the picrate, as it was ground to a fine powder, shows such a magnetic behavior.

Compounds Related to the Cation Radical Salts

Phenothiazine-Picric Acid Charge-Transfer Complex. The difference in chemical composition between the phenothiazine-picric acid charge-transfer complex and the cation radical salt of the picrate is slight; that is, the former includes the picric acid, while the latter includes the picrate anion. However, there is a marked difference in electronic structure between the two substances. In the cation radical salt, as has been mentioned above, the charge-transfer interaction takes place between the cation radicals, whereas in the charge-transfer complex it takes place between phenothiazine and picric acid. As is shown in the solid-state spectrum (Fig. 5, Curve a), the charge-transfer band in the latter case was found to be located at 18.2 kK.

The magnetic susceptibility for the charge-transfer complex was found to be -197×10^{-6} emu/mol; this value corresponds well to the -205×10^{-6} emu/mol value for the sum of the diamagnetic contribution of the component molecules, and it should be compared with that for the cation radical salt of the picrate.

Holoquinoid Phenothiazine Perchlorate. The phenothiazine cation radical is known to undergo both one-

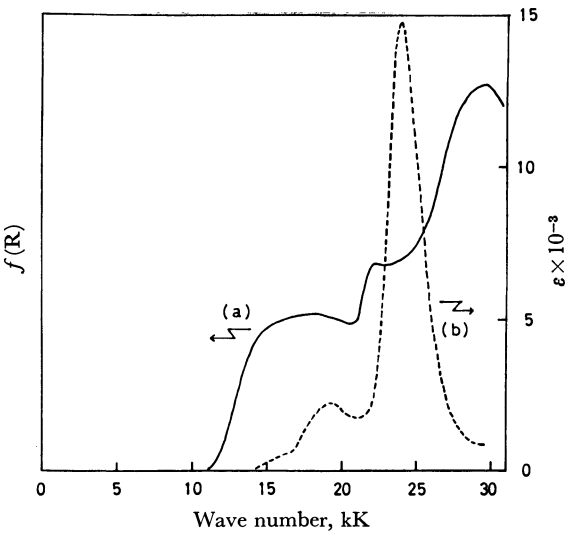

Fig. 5. The solid-state spectrum of the phenothiazine-picric acid charge-transfer complex (a), and the absorption spectrum of the holoquinoid phenothiazine perchlorate in acetonitrile solution (b).

electron oxidation and deprotonation to form the holoquinoid cation;[3] this cation has, therefore, a closed electronic shell and is a univalent cation (see Fig. 1). The holoquinoid cation appears yellow in solution and is stable at room temperature. As is shown by Curve b of Fig. 5, the absorption spectrum of the holoquinoid salt of the perchlorate in an acetonitrile solution[16] consists of a weak band at 19.3 kK and a strong absorption at 23.9 kK. This spectrum seems to be solely due to the holoquinoid cation monomer.

Discussion

The above-mentioned results on the solid-state properties of all the phenothiazine cation radical salts clearly indicate the large values both in an antiferromagnetic spin-exchange interaction and in the intensity of the charge-transfer band. This means that a strong charge-transfer interaction takes place between the phenothiazine cation radicals. Therefore, the cation radical molecules may be expected to be stacked in a face-to-face manner and to form, in themselves, linear chain columns; this feature of the crystal structure has been found in a number of other ion radical

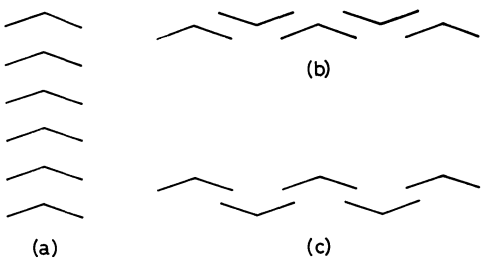

Fig. 6. Three kinds of possible stackings of the phenothiazine cation radical molecules to form linear chain columns in the solid state. A folded figure denotes a phenothiazine cation radical molecule viewed along the direction connecting the nitrogen and sulfur atoms.

16) The concentration of the solution was 8.05×10^{-5} mol/l.

salts.[6] In this case, the charge-transfer absorption may be expressed as a transition of the $\{\cdots P^{+}P^{+}\text{-}P^{+}P^{+}\cdots\} \rightarrow \{\cdots P^{+}P^{2+}P^{0}P^{+}\cdots\}$ type, where P denotes a phenothiazine molecule. As for the spin system, these cation radical salts may be considered to be a linear-chain antiferromagnet.

On the other hand, the molecular structure of neutral phenothiazine is known to be non-planar, but to be of a folded form.[17] It appears that the structure of its cation radical, although it has not yet been ascertained, is also of a folded form. Therefore, unlike planar ion-radical molecules, the stacking manner of the phenothiazine cation radicals seems to be complicated, for the linear chain columns of the cation radicals can be built up not only by the arrangement of (a) but also by that of (b) or (c), as is illustrated in Fig. 6. In this respect, further study of the X-ray diffraction is required to determine by which arrangement the phenothiazine cation radicals are stacked in the present solid salts.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 667—671 (1971)

The Primary Process of the Photochemical Dimerization of Carbostyril

Tetsu YAMAMURO, Ikuzo TANAKA, and Norisuke HATA*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

* *Deparment of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo*

(Received September 10, 1970)

Carbostyril dimerizes photochemically in ethanol to yield its dimer. In order to clarify the primary process of this photochemical dimerization, studies by means of steady-light irradiation and flash spectroscopy and measurements of the absorption spectrum of the intermediate and of the phosphorescence spectrum at 77°K were carried out under various conditions. The transient absorption was observed around 430 mμ, it was identified as being due to a T–T transition of carbostyril. Experiments on both the decay kinetics of the triplet species and the quantum yield of the carbostyril disappearance under various conditions revealed that the photochemical dimerization of carbostyril proceeded through a bimolecular interaction between the triplet and the unexcited molecules.

Recently, a number of interesting photochemical reactions of heterocyclic *N*-oxides have been reported by several workers.[1,2] In the course of our studies of the primary photochemical process of quinoline *N*-oxide and its derivatives, it was necessary to identify the excited state responsible for the photochemical dimerization of carbostyril, for the carbostyril produced photochemically from the quinoline *N*-oxide in ethanol further absorbs ultraviolet light to yield its dimer. Therefore, in order to clarify the primary process of the photochemical dimerization of carbostyril, the present authors carried out investigations by means of steady-light irradiation and flash spectroscopy and measured the absorption spectrum of the intermediate and also the phosphorescence spectrum at 77°K.

Experimental

Materials. The carbostyril used in this experiment was prepared by ultraviolet irradiation for the quinoline *N*-oxide in ethanol, the product was purified by recrystallization several times.[3] Reagent-grade ethanol and dichloromethane were used without further purification. Reagent-grade piperylene was purified by distillation, while isopentane and liquid paraffin were purified by column chromatography (silica gel). Spectro-grade glycerol and methylcyclohexane were also used.

Steady-light Experiment. The light source employed was a Toshiba high-pressure mercury lamp (H-400P), while for 3130 Å irradiation a filter combination of a nickel sulfate solution with a UV-31 Toshiba filter was used. Two kinds of cylindrical quartz reaction cells were used; one was 5 cm in diameter and 1 cm thick, while the other was 5 cm in diameter and 4 cm thick. In order to determine the quantum yield of the carbostyril disappearance, the light intensity was measured with a potassium ferrioxalate actinometer. The absorption spectra were taken with a Hitachi recording spectrophotometer, EPS-3T.

Flash Spectroscopic Experiment. The absorption spectra of the transient species were taken with a flash-photolysis apparatus described in a previous paper.[4] In the case of the decay kinetic studies of the transient species, a xenon flash lamp used for excitation was operated by discharging a bank of condensers of 2 μF charged to 11 kV, 120 joules of energy being dissipated; the half-width of the discharge time was about 10 μsec.

Results and Discussion

Buchardt[3,5] has reported that the carbostyril (I)

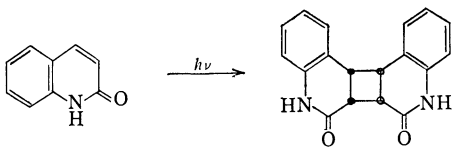
5) O. Buchardt, *Acta Chem. Scand.*, **18**, 1389 (1964).

dimerizes, under irradiation by a 3130 Å light in ethanol under bubbling nitrogen to give the carbostyril dimer (II), which is only slightly soluble in the ethanol used as a solvent.



I II

This photochemical dimerization also proceeded in other solvents, such as water, cyclohexane, and dichloromethane, but it was inhibited by the addition of piperylene or the bubbling in of oxygen. As an example of these experiments, Table 1 shows how the photochemical conversion from carbostyril to its dimer in dichloromethane was influenced by the addition of various amounts of piperylene. It is evident from these results that both oxygen and piperylene act as quenchers for the photochemical dimerization of carbostyril.

TABLE 1. EFFECT OF PIPERYLENE ON THE PHOTOCHEMICAL CONVERSION FROM CARBOSTYRIL TO ITS DIMER[a)]

Piperylene (M)	0	0.5×10^{-4}	1.0×10^{-4}	1.8×10^{-4}	7.0×10^{-4}	3.5×10^{-3}
Conversion (%)[b)]	47	38	32	30	25	11

a) Solvent: dichloromethane (under bubbling nitrogen) Concentration of carbostyril: 3.52×10^{-3} M (60 cc) Irradition time: 75 min.
b) Conversion refers to the percentage of carbostyril converted to its dimer.

Figure 1 shows the progressive spectral change of carbostyril on 3130 Å irradiation in ethanol, where it was observed that the absorption of carbostyril decreased progressively with the irradiation time and that a new absorption band appeared around 255 mμ as the irradiation time increased, with isosbestic points at 265 mμ, 283 mμ, and 298 mμ. On the basis of a comparison with the absorption spectrum of the carbostyril dimer in ethanol (Fig. 2), the new absorption band which appeared around 255 mμ on 3130 Å irradiation is considered to be due to a carbostyril dimer.

The phosphorescence spectrum from EPA, ethanol, or methylcyclohexane glass containing approximately 1.0×10^{-4}M carbostyril was measured at 77°K; the spectrum thus obtained is shown in Fig. 3. It was estimated, from the first maximum of the phosphorescence spectrum (434 mμ), that the lowest triplet state of carbostyril has an excitation energy of about 66 kcal·mol^{-1}. Consequently, the addition of piperylene (E_T=57 kcal·mol^{-1}) to the carbostyril in amounts much greater than the molar equivalence led to the complete disappearance of the phosphorescence (Fig. 3). From this result, the radius of the active sphere with the piperylene molecule at its center, where triplet carbostyril molecules outside this sphere were assumed not to be quenched, was estimated to be about 15 Å. The phosphorescence lifetime (τ_p) of carbostyril in EPA at 77°K was also determined to be 0.88 sec (Fig. 9).

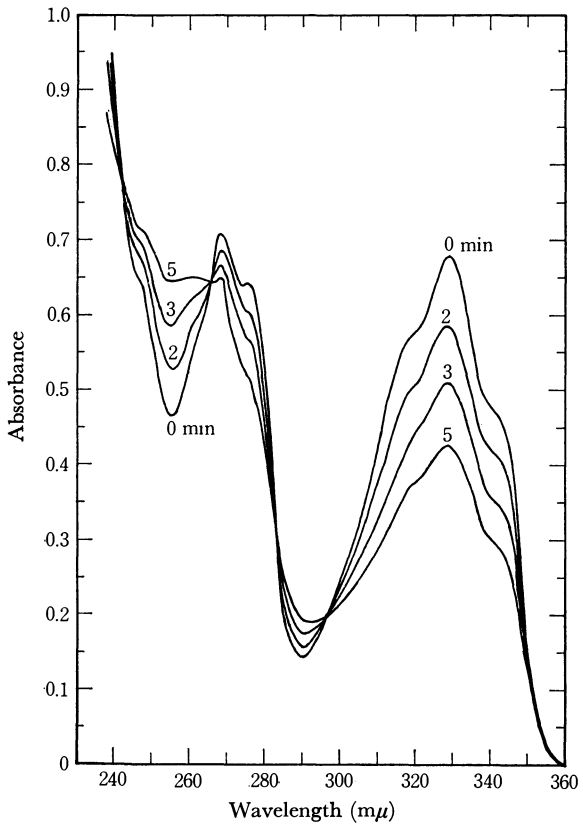


Fig. 1. Spectral change of carbostyril on 3130 Å irradiation in deaerated ethanol (initial concentration of carbostyril: 1.05×10^{-4}M).

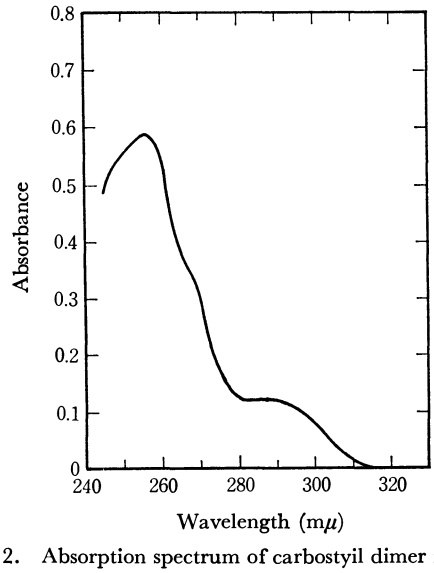

Fig. 2. Absorption spectrum of carbostyil dimer in ethanol.

The quantum yields of the carbostyril disappearance in deaerated ethanol were measured under various conditions. Figure 4 shows the effect of the light intensity on the quantum yield of the carbostyril disappearance, the results indicate that the quantum yield was independent of the light intensity. The quantum yield of the carbostyril disappearance as a function of the concentration was also determined; the results are shown in Fig. 5. As may be seen from Fig. 5, the quantum yield increased with an increase in the con-

(c) [Piperylene]: 2.0×10^{-1}M

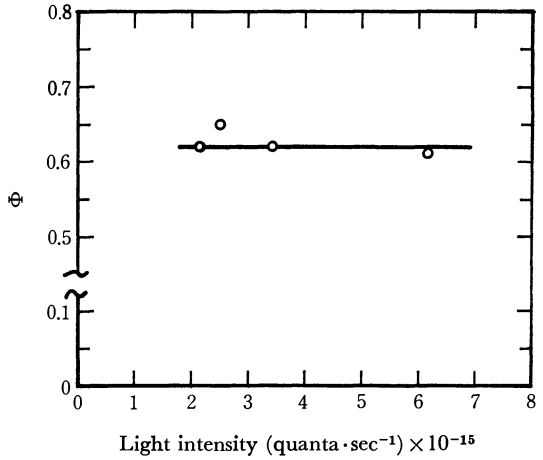

Fig. 4. Quantum yield of carbostyril disappearance *vs.* light intensity in deaerated ethanol at room temperature (concentration of carbostyril: 1.30×10^{-4}M).

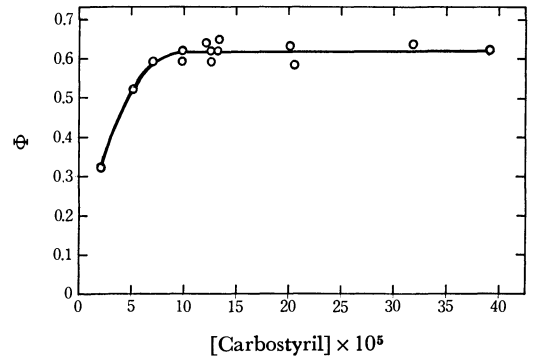

Fig. 5. Quantum yiled of carbostyril disappearance *vs.* concentration in deaerated ethanol at room temperature.

centration, approaching a constant value at concentrations of more than 1.0×10^{-4}M.

Next, in order to characterize the excited state responsible for the photochemical dimerization, the effect of piperylene on the quantum yield of the carbostyril disappearance was investigated, with the piperylene being chosen as the triplet quencher. Figure 6 shows plots of Φ/Φ_Q against the concentration of piperylene

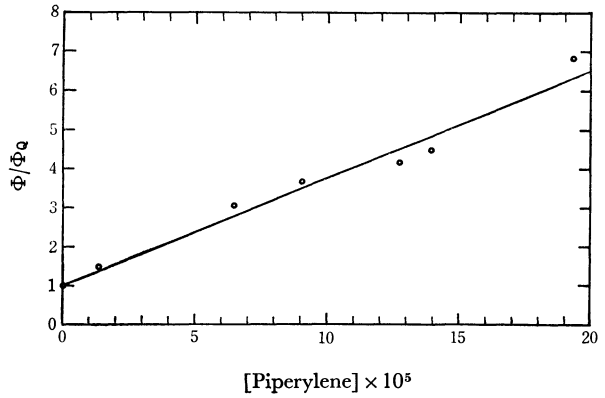

Fig. 6. Stern-Volmer plot for carbostyril dissapearance by piperylene in deaerated ethanol at 20°C (concentration of carbostyril: 1.20×10^{-4}M).

([Q]), where Φ and Φ_Q represent the quantum yield of the carbostyril disappearance in the absence and in the presence of piperylene respectively. It is apparent from Fig. 6 that the simple Stern-Volmer relationship (1):

$$\Phi/\Phi_Q = 1 + K_Q[Q] \tag{1}$$

is followed in this reaction. The quenching constant, K_Q, at $[S_0]=1.20\times10^{-4}$M, $[S_0]$ being the initial concentration of carbostyril, was estimated, from the slope of the curve in Fig. 6, to be $2.76\times10^{4}\ l\cdot\text{mole}^{-1}$. The quenching constant in this photochemical dimerization is represented by Eq. (2):

$$K_Q = \frac{k_8}{k_2 + k_3 + (k_4+k_5)[S_0]} \tag{2}$$

from a consideration of the following reaction scheme, (i)—(viii), to be given below. The observed value of K_Q will be compared with that estimated from a flash-spectroscopic experiment later.

The dependence of the quantum yield on the concentration of carbostyril and the quenching experiment seem to be explained by the following mechanism:

$S_0 + h\nu \longrightarrow S_1 \longrightarrow T_1$	$I_a\phi_{isc}$	(i)
$T_1 \longrightarrow S_0$	k_2	(ii)
$T_1 \longrightarrow$ Decomposition	k_3	(iii)
$T_1 + S_0 \longrightarrow S_0 + S_0$	$k_4[S_0]$	(iv)
$T_1 + S_0 \longrightarrow (T_1S_0)$	$k_5[S_0]$	(v)
$(T_1S_0) \longrightarrow$ Dimer	k_6	(vi)
$(T_1S_0) \longrightarrow S_0 + S_0$	k_7	(vii)
$T_1 + Q \longrightarrow S_0 + Q$	$k_8[Q]$	(viii)

Assuming the photostationary state conditions, the quantum yield of the carbostyril disappearance in the absence of a quencher could be given by the following equation:

$$\Phi = A\left(1-\frac{C}{1+B[S_0]}\right) \tag{3}$$

where:

$$A = \frac{k_5k_6\phi_{isc}}{(k_4+k_5)(k_6+k_7)}$$

$$B = \frac{k_4+k_5}{k_2+k_3}$$

$$C = 1 - \frac{(1+k_4/k_5)(1+k_7/k_6)}{(1+k_2/k_3)}$$

and where ϕ_{isc} represents the efficiency of the S_1—T_1 intersystem crossing. Equation (3) accounts qualitatively for the concentration dependency of the quantum yield.

As has been described above, the photochemical dimerization of carbostyril is considered to proceed through a bimolecular interaction between the triplet and the unexcited molecules. However, another mechanism is also considered to be possible for this reaction. That is, the dimerization might occur from an interaction of the unexcited molecule (S_0) with the intermediate (M) which may be produced from the triplet state of carbostyril as follows:

$$T_1 \longrightarrow M \qquad \text{(ix)}$$

$$M + S_0 \longrightarrow (MS_0) \qquad \text{(x)}$$

$$(MS_0) \longrightarrow \text{Dimer} \qquad \text{(xi)}$$

Therefore, it is necessary to determine which mechanism is most reasonable in accounting for this reaction. If the dimerization proceeds through the processes (v) and (vi), the T–T absorption of carbostyril can possibly be observed. On the other hand, if the processes (ix)—(xi) are involved in the dimerization, the absorption spectrum of the intermediate (M) or, simultaneously, a T–T absorption of carbostyril will probably be obtained. That is, the detection and identification of triplet species and the examination of their kinetic behavior could be important in determining the mechanism of the photochemical dimerization of carbostyril.

Figure 7 shows the absorption spectrum of the transient species produced by a flash excitation of the carbostyril in such solvents as glycerol (room temperature), liquid paraffin (268°K), and EPA (77°K).[6] In each case, the transient absorption was observed in the region between 380 mμ and 500 mμ.

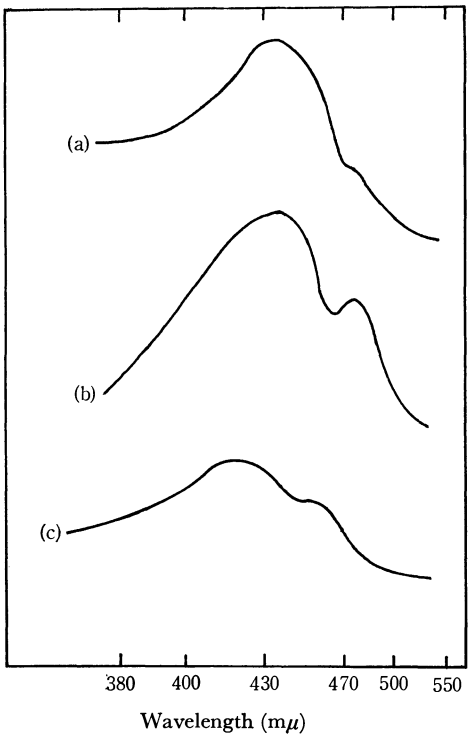

Fig. 7. Transient absorption of carbostyril.
(a) in glycerol (room temperature)
(b) in liquid paraffin (268°K)
(c) in EPA (77°K)

The decay constant of the transient absorption (k_T) was determined at several wavelengths in deaerated ethanol (room temperature), liquid paraffin (268°K), glycerol (room temperature), and EPA (77°K); the results are shown in Figs. 8 and 9. As may be seen from Figs. 8 and 9, the decay obeyed the first-order law and the decay constant was independent of the wavelength. The decay lifetime ($\tau_T = 1/k_T$) in EPA at 77°K was 0.96 sec, very close to the phosphorescence lifetime (τ_p = 0.88 sec) described before. These results suggest that

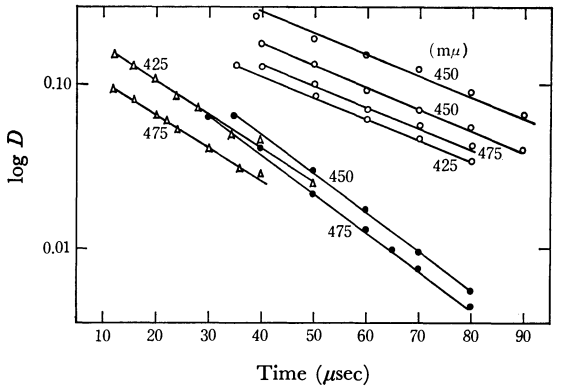

Fig. 8. Decay analysis for the transient species at several wavelengths in various solvents at room temperature.
○ in glycerol ● in liquid paraffin △ in ethanol

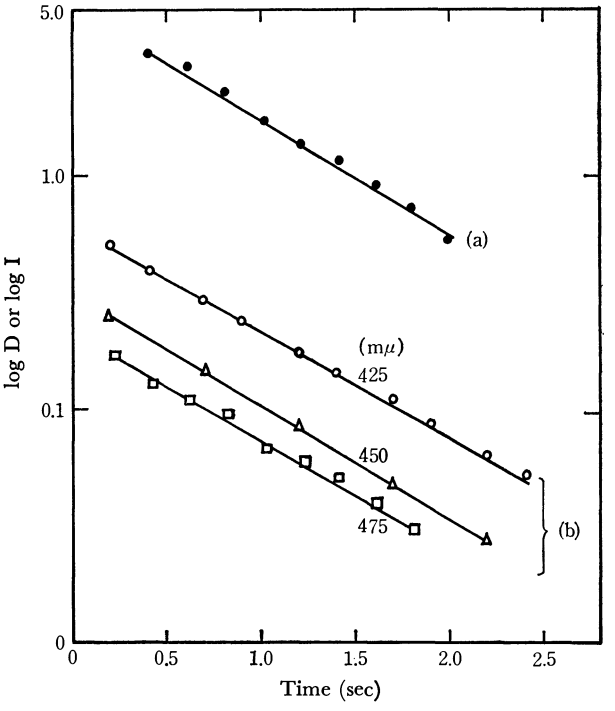

Fig. 9. Decay analysis for the phosphorescence (a) and for the transient species (b) at several wavelength in EPA (1:1:3) at 77°K (concentration of carbostyril: 1.0×10^{-4}M).

6) The absorption spectrum of the transient species in EPA at 77°K was taken by means of a steady-light crossed illumination.

the transient absorption around 430 mμ is due to a T–T transition of carbostyril.

The next problem is to clarify whether or not the triplet species observed is responsible for the photochemical dimerization of carbostyril. If the dimerization proceeds through a bimolecular interaction of the unexcited molecule with the triplet molecule, the decay rate of the triplet species may be given by the following equation:

$$k_T = k_2 + k_3 + (k_4+k_5)[S_0] \quad (4)$$

That is, the decay rate may be expected to vary linearly with the initial concentration of carbostyril. When the piperylene is added to a solution of carbostyril, the decay rate is probably given by the following equation:

$$k_T = k_2 + k_3 + (k_4+k_5)[S_0] + k_8[Q] \quad (5)$$

That is, when $[S_0]$=constant, the rate is considered to increase in proportion to the concentration of the quencher. Therefore, the effects of both the concentration of carbostyril and that of piperylene on the decay rate were examined in deaerated ethanol at room temperature. As is shown in Fig. 10, it was seen that the decay rate of the triplet species was directly proportional to the initial concentration of carbostyril; this was consistent with Eq. (4). k_4+k_5 was evaluated from the slope of the curve, while k_2+k_3 was estimated by extrapolating the concentration of carbostyril to zero. In this manner, the following values were obtained:

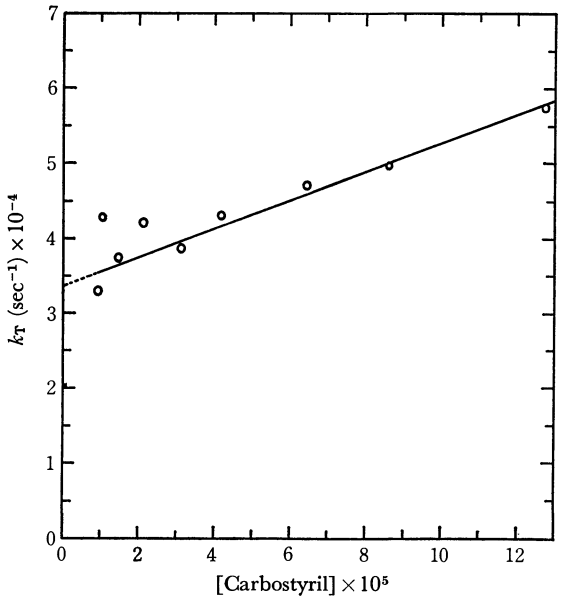

Fig. 10. Decay constant of the triplet species *vs.* concentration in deaerated ethanol at 34°C.

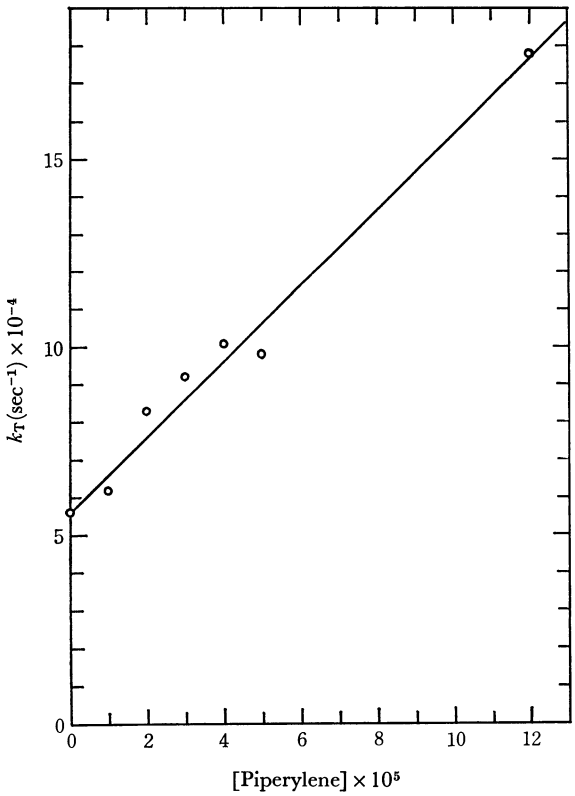

Fig. 11. Quenching of the triplet species by various amounts of piperylene in deaerated ethanol at 35°C (concentration of carbostyril: 1.16×10^{-4}M).

$k_2+k_3=3.36\times10^4$ sec^{-1} and $k_4+k_5=1.92\times10^8$ $l\cdot$mol$^{-1}\cdot$sec^{-1}

The effect of the concentration of the quencher on the decay rate of the triplet species at $[S_0]=1.16\times10^{-4}$M is shown in Fig. 11. As was expected from Eq. (5), a linear relationship between k_T and [Q] was found and the k_8 obtained from the slope was 1.01×10^9 mol^{-1} l sec^{-1}. By substituting the observed values of k_8, k_2+k_3, and k_4+k_5 and $[S_0]=1.20\times10^{-4}$M into Eq. (2), K_Q was obtained as 1.78×10^4 $l\cdot$mol^{-1}; this value agreed closely with that obtained by the steady-light experiment. These facts support the idea that the photochemical dimerization of carbostyril proceeds through a bimolecular interaction between the triplet and the unexcited molecules.

The authors wish to express their hearty thanks to Professor Y. Mori of the Tokyo Institute of Technology for his kind discussions and to Professor S. Matsumoto of Aoyama Gakuin University for his permission to use the flash-photolysis apparatus.

Absorption Spectra of Crystals of Cytosine and Its Derivatives

Masashi TANAKA and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya
(Received October 16, 1970)

The electronic spectra of cytosine, one of DNA bases, have been studied. The absorption spectra of single crystals of cytosine and its derivatives are presented, and the direction of the transition moment of the first $\pi\rightarrow\pi^*$ band is determined to be inclined at about $+100°$ from the N_1–C_4 line toward the C_5 atom. The second $\pi\rightarrow\pi^*$ band is shown to have polarization direction at $+30°$ inclined to the reference axis.

Cytosine is one of the important base components of DNA and RNA. The electronic structures and spectra of these molecules are significant in studying the conformation and optical properties of polynucleotides since the hypochromism and circular dichroism are mainly governed by the nature of the electronic transitions and the interaction of excited states of these base pairs. The directions of the electronic transition moments are particularly important in considering the exciton type interactions. The polarization measurements of absorptions on the single crystals are most helpful in order to find these directions. Although many investigations[1] have been presented on the spectra of DNA bases in solution, a few works have been connected with the polarization of the excited state. In the subsequent paper[2] we have presented the absorption spectra of the single crystals of thymine and uracil derivatives and discussed on the directions of the transition moments of two lowest $\pi\rightarrow\pi^*$ bands. In the present paper we are presenting the results of the crystal absorption spectra on cytosine and its derivatives with the probable direction of transition moments.

Experimental

Materials. Cytosine and cytidine sulfate were obtained from Wako Pure Chemical Industries, cytidine was purchases from Biochemica Co. Ltd. and 1-methyl cytosine was obtained from Sigma Chemical Company.

Apparatus. The crystal spectra were recorded at room temperature on a specially designed microspectrophotometer consisting of (i) an Olympus polarizing microscope with Zeiss ultrafluar objectives and a quartz Rochon polarizer, (ii) a Zeiss M4Q III monochrometer with tungsten and hydrogen sources and (iii) a 1P28 photomultiplier tube with the standard Zeiss detection system.

Results

1-Methyl Cytosine. The absorption spectrum of the single crystal of 1-methyl cytosine is shown in Fig. 1. The crystals obtained on the quartz plate from the ethanol solution were employed for measurement of the polarized spectra. The developed plane of the crystal is assigned to the (100) plane judging from the paper by Mathews and Rich.[3] In this crystal, the

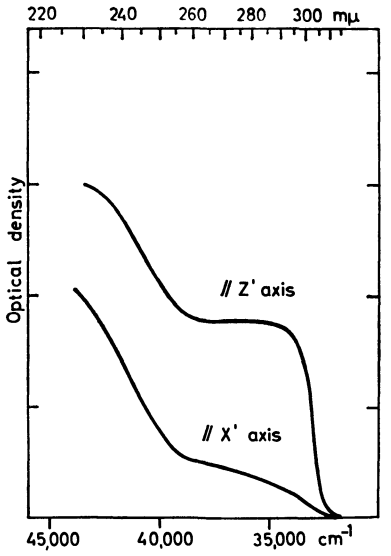

Fig. 1. The polarized absorption spectrum of the single crystal of 1-methyl cytosine.

first $\pi\rightarrow\pi^*$ band is observed in the vicinity of 285 mμ and is shifted to the longer wavelength as compared to the solution and other crystalline spectra. The second band has a peak below 230 mμ for the two perpendicularly polarized light and its position is not firmly ascertained. The direction of the transition moments of these two bands can not be discussed with the crystal since the coordinates of atoms are not reported.[3]

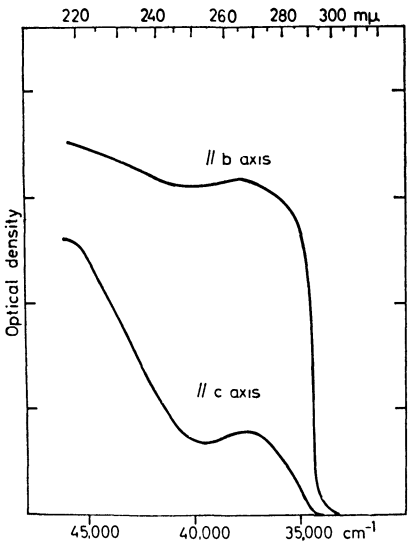

Fig. 2. The polarized absorption spectrum on the plane (100) of the single crystal of cytosine monohydrate.

Cytosine. The absorption spectrum of the single crystal of cytosine monohydrate has been measured and is shown in Fig. 2. The crystal structure analysis has been carried out by Jeffrey and Kinoshita[4] and it has been shown that the crystal belongs to the space group of $P2_1/c$ and four molecules are included in a unit cell. The unit cell dimensions are $a=7.80$, $b=9.84$, $c=7.68$ Å, and $\beta=99°42'$. Single crystals of cytosine monohydrate were obtained by slow evaporation from dilute aqueous solution as monoclinic plates tabularly on the (100) plane. The projection of molecules onto this developed plane (100) is pictured in Fig. 3. According to this figure,

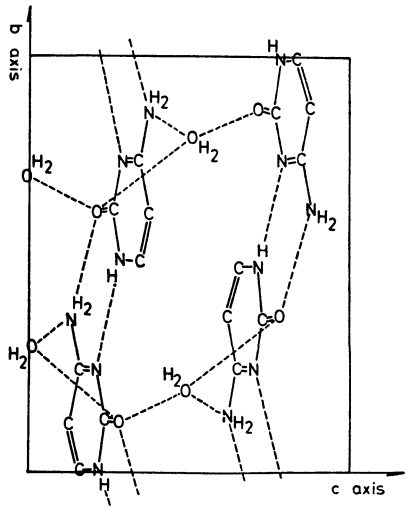

Fig. 3. The projection of cytosine molecules onto the developed plane (100).

the cytosine molecules are hydrogen-bonded into parallel ribbons extending in the *b* axis direction. Adjacent ribbons are related by the *c* glide symmetry and the perpendicular separation of the planes of the ribbons is 3.2 Å. The crystalline absorption spectrum has been measured on the *bc* plane. As shown in Fig. 2, cytosine is a weakly coupled system in this crystal and no large frequency shifts and splitting are observed for the bands in the crystal relative to their positions in the solution spectrum. The first $\pi\rightarrow\pi^*$ band has a peak at 265 mμ in both the *b* and *c* axes spectra. In the second $\pi\rightarrow\pi^*$ bands, only a tail of the band was measured but a peak may be located in the vicinity of 220 mμ in both the *b* and *c* axes spectra. The observed dichloric ratio for the $\pi\rightarrow\pi^*$ band at 265 mμ is determined from the areas under the two perpendicularly polarized absorption curves and (I_b/I_c) may be seen to be equal to $\cot^2\theta$. Here θ is the angle between the transition moment and the *c* axis. From the crystal structure data we may now determine the relation of the molecular frame to the *b* axis and finally the relation of the transition moment to the molecular frame. According to the above method, the transition moment of this band is determined to lie at either $+25°$ or $+100°$ inclined to the reference axis which designates the line joining the nitrogen (N_1) and its para partner (C_4) (clockwise rotation denoted as positive). The dichroic ratio of the second $\pi\rightarrow\pi^*$ band is about 1.5 : 1 (I_b/I_c) judging from the observed

4) G.A. Jeffrey and Y. Kinoshita, *Acta Crystallogr.*, **16**, 20 (1963).

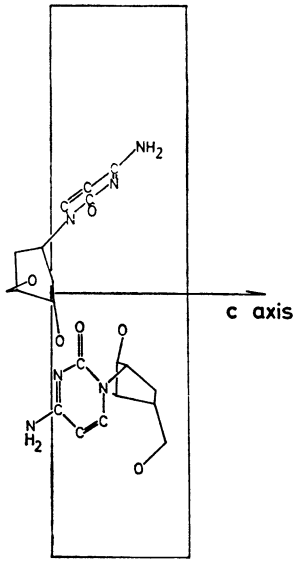

Fig. 4. The projection of cytidine molecules onto the developed plane (110).

region. The angle between the transition moment and the reference axis is determined by the dichroic ratio to be either $+45°$ or $+80°$.

Cytidine. Furberg, Petersen, and Rϕmming[5] analyzed the crystal structure of cytidine and showed that the crystal belongs to the space group of $P2_12_12_1$ and there are four molecules in the unit cell. The unit cell dimensions are $a=13.99$, $b=14.79$, and $c=5.12$ Å. The crystal is obtained by evaporating slowly a solution of cytidine in an alcohol-water mixture and has the shape of prism elongated along the *c* axis. The projection of molecules onto the developed plane (110) is pictured in Fig. 4. Two cytosine rings in the unit cell are nearly parallel to this developed plane and other two cytosine rings are located perpendicularly. The crystalline absorption spectrum has been measured along the directions parallel or perpendicular to the *c* axis on the

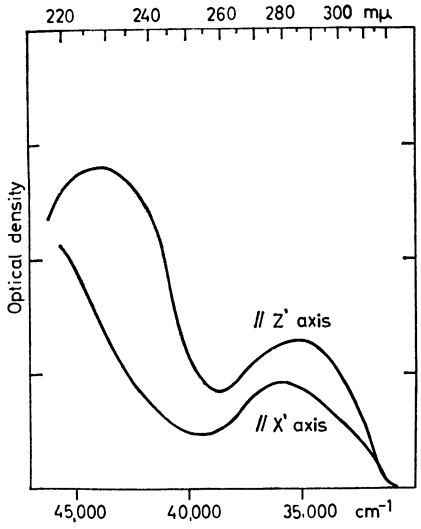

Fig. 5. The polarized absorption spectrum on the plane (110) of the single crystal of cytidine.

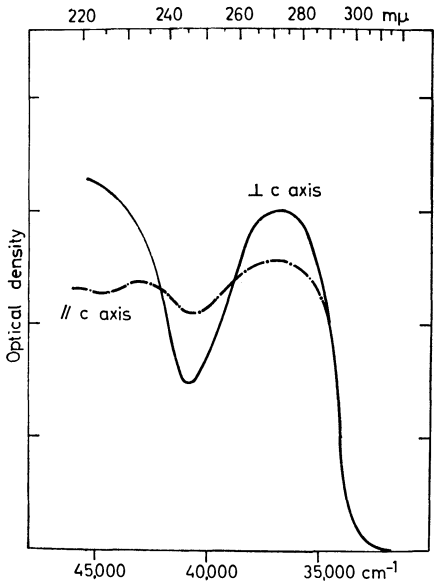

Fig. 6. The polarized absorption spectrum of the single crystal of cytidine sulfate.

plane (110) as shown in Fig. 5. The peak of the first $\pi\rightarrow\pi^*$ band exists at 272 mμ and the observed dichroic ratio is about 1.1 : 1 ($I_{\perp c}/I_c$) and the direction of the transition moment is deduced to be either +15° or +105° to the N_1—C_4 reference axis. The second $\pi\rightarrow\pi^*$ band exists in the 230 mμ region and its dichroic ratio is 1.4 : 1 ($I_{\perp c} : I_c$). By this ratio its transition moment is determined to lie at either +20° or +90° inclined to the reference axis.

Cytidine Sulfate. The absorption spectrum of the single crystal of cytidine sulfate is shown in Fig. 6. In this crystal, Davydov splittings are observed. The first band has a peak at 288 mμ for the light polarized parallel to the *c* axis and at 280 mμ for the light polarized perpendicular to the *c* axis and Davydov splitting is about 1000 cm^{-1}. The second band has a peak at 228 and 220 mμ for the light polarized parallel and perpendicular to the *c* axis, respectively. Davydov splitting of this second band is about 1600 cm^{-1}. Unfortunately the direction of the transition moment can not be discussed with this crystal because the crystal structure has not been analyzed so far.

Discussion

The absorption spectra of single crystals of cytosine and its derivatives show two absorption $\pi\rightarrow\pi^*$ bands corresponding to the 220 and 260 mμ bands in solution in the measured region. The observed dichroic ratios of the 220 and 260 mμ bands of these crystals are summarized in Table 1. There are in general two in-plane directions consistent with a dichroic ratio measured on a single crystal and data from a single crystal face will not in general be sufficient for a unique assignment of polarization directions. Therefore, the spectra of a few of cytosine derivatives were measured in order to determine the directions of the transition moments of

Table 1. Observed dichroic ratios and directions of the transition moments

		First band		Second band	
Cytosine monohydrate	I_b/I_c	7	+ 25° or+100°	1.5	+45° or+80°
Cytidine	$I_{\perp c}/I_c$	1.1	+ 15° or+105°	1.6	+20° or+90°

two $\pi\rightarrow\pi^*$ bands but these directions could not be uniquely assigned from the observed ratios. As shown in Table 1, the transition moment of the first 260 mμ band is determined to be inclined at +20° or +100° from the N_1—C_4 line toward the C_5 atom and that of the second 220 mμ band at +30° or +85°. On the other hand, Nagata *et al.*,[6] Berthod, Giessner, and Pullman[7], and Morita and Nagakura[8] calculated the electronic states of cytosine molecule by the P-P-P method and discussed the directions of the transition moments. Particularly, Berthod, Giessner, and Pullman[7] decided the transition moments of two $\pi\rightarrow\pi^*$ bands to be inclined at +95° and +47° with respects to the N_1–C_4 axis. Accordingly, it is reasonable that the transition moments of the first and second bands are uniquely speculated to be inclined at +100° and +30° from the N_1–C_4 line toward the C_5 atom as shown in Fig. 7.

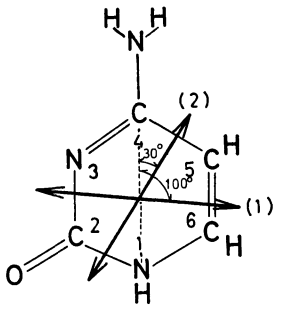

Fig. 7. The directions of the transition moments of the first (1) and second (2) $\pi\rightarrow\pi^*$ bands.

In the polarized absorption spectra of the crystal of thymine and uracil derivatives,[2] an usual absorption band appears at about 285 mμ in addition to the usual $\pi\rightarrow\pi^*$ transition when the crystal has the C=O···H–N hydrogen bond. The direction of the transition moment of this band is along the direction of the hydrogen bond between a pair of C=O···H–N groups. In the crystal of cytosine monohydrate, the cytosine molecules are hydrogen-bonded through N–H···N and C=O···H–N into parallel ribbons extending in the *b* axis direction but no hump was observed in the vicinity of 280 mμ.

The Effect of Pressure on the Electronic Absorption Spectra of Alkali Metal Cation-Chloranil and -Bromanil Anion Radical Salts, and the Dimerization of the Chloranil Anion Radical in Solution

Nobuko SAKAI, Ichimin SHIROTANI, and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received October 20, 1970)

The pressure dependence, up to 7 kbar, of the electronic absorption spectra of ion-radical salts composed of the alkali metal cation and the chloranil or bromanil anion radical in the crystalline state at room temperature, and the temperature dependence, down to 134°K, of the dimerization of chloranil anions in an ethanol solution at 1 bar have been studied. The absorption band in the visible region shows a blue shift with an increase in the pressure for Li^+ and Na^+ salts, while for K^+ and Rb^+ salts the spectra are insensitive to the pressure. The anion radicals seem to be in the dimeric electronic state for the former and to be in the monomeric state for the latter, in the crystalline state.

The magnetic and electronic properties of the ion-radical salts, such as Würster's blue perchlorate (WBP) and tetracyanoquinodimethane (TCNQ) salts, have attracted interest in connection with the behavior of the unpaired electrons and the characteristic intermolecular interactions in the crystalline state, and their properties under high pressure have been studied in order to get useful information on the electronic structure of ion-radical salts in the crystalline state.[1-6]

The electronic absorption spectra of ion-radical salts have been studied extensively in solution and solid states since Hausser and Murrell[7] pointed out that the new lowest-energy absorption band of the dimer in WBP, which exists in solution at low temperatures, is the charge-transfer band between the half occupied orbitals of component radicals. For example, in the case of Würster's salts, the electronic structures in the crystalline state have been discussed on the basis of the following data; the polarized reflectance spectra of WBP at temperatures above and below the phase transition point,[8] the polarized absorption spectra of some Würster's salts at room temperature,[9,10] and a comparison between the temperature dependence of the charge-transfer band intensity and that of the magnetic susceptibility.[11] On the other hand, Pott and Kommandeur[12] suggested a disproportionation of charges in a crystal which differed from dimerization.

In this paper, the effect of pressure on the electronic absorption spectra of ion-radical salts composed of an alkali metal cation and a chloranil or bromanil anion radical ($M^+(CA)^-$, M:Li, Na, K, and Rb, CA:chloranil, $M^+(BA)^-$, M:Na and K, BA: bromanil) will be investigated in order to determine the influence of the counter ions upon the electronic structures of chloranil or bromanil anion radicals in the crystalline state; also, the dimerization of chloranil anions in an ethanol solution at low temperatures and at 1 bar will be reported.

Experimental

Commercially-available *p*-chloranil and *p*-bromanil synthesized by the method of Torrey and Hunter[13] were purified by recrystallization from benzene and then by sublimation *in vacuo*. Their alkali metal salts were synthesized according to the method of Torrey and Hunter;[13] lithium and rubidium salts were synthesized by a method similar to that used for potassium salt. The ethanol was purified by distillation.

The optical measurements were carried out with a Cary recording spectrophotometer, Model 14M, or with a Shimadzu SV-50A spectrophotometer. The electronic absorption spectra of crystalline powder were measured on samples rubbed on glass plates, because the methods using the KBr disk and liquid paraffin mull, which are usually used for powder samples, were unsuitable for the measurements of the electronic absorption spectra of some ion radical salts because of the influence of the applied force at the time of the disk formation upon their electronic states, and for the measurements of the pressure dependence on the spectra, respectively. The spectra at low temperature were measured by using a Pyrex Dewar vessel and using liquid nitrogen as a refrigerant, the temperature being measured by means of a copper-constantan thermocouple. The spectra under high pressure at room temperature were measured by using a high-pressure optical cell which had two sapphire windows. A hydrostatic pressure up to 7 kbar was applied by means of a pressure-transmitting medium, white gasoline, through a pressure-intensifier. The pressure was determined by a Harwood manganine resistance gauge and a Heise Bourdon tube gauge.

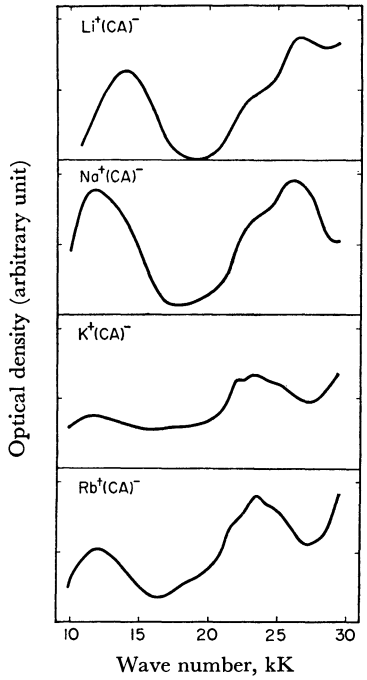

Fig. 1. Electronic absorption spectra of four alkali metal cation-chloranil anion radical salts.

powder samples rubbed on glass plates are shown in Fig. 1.[14] The spectra of $Na^+(CA)^-$ and $K^+(CA)^-$ almost coincide with the recent work of André and Weill.[15] The absorption spectra of $Li^+(CA)^-$ and $Na^+(CA)^-$ show considerable differences from those of $K^+(CA)^-$ and $Rb^+(CA)^-$: that is, in the visible region, the former shows the absorption band around 26 kK, with a shoulder around 23 kK, while the latter shows the band with structures around 22.0, 23.3, and 24.5 kK, and the ratio of the absorption-band intensity in the near-infrared region to that in the visible region is larger for the former than for the latter.[16] The absorption band in the near-infrared region of $Li^+(CA)^-$ is around 14 kK; this energy is 2 kK higher than those of the other salts.

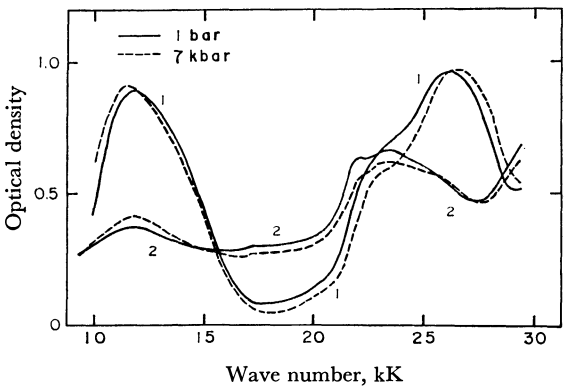

Fig. 2. Pressure dependence of the absorption spectra of crystalline $Na^+(CA)^-$ and $K^+(CA)^-$, curve 1: $Na^+(CA)^-$, curve 2: $K^+(CA)^-$.

The effect of pressures up to 7 kbar on the electronic absorption spectra of these salts was measured at room temperature. The absorption spectra of $Na^+(CA)^-$ and $K^+(CA)^-$ at 1 bar and 7 kbar are shown in Fig. 2. $Li^+(CA)^-$ and $Na^+(CA)^-$ exhibit a blue shift for the visible absorption band and a red shift for the near-infrared band, with an increase in the pressure. The rates of the frequency shift with the pressure are +62 and −58 cm^{-1}/kbar for the 26.2 and 11.8 kK peaks of $Na^+(CA)^-$ respectively, as is shown in Fig. 3 and as has previously been reported briefly[5]; those of $Li^+(CA)^-$ are almost the same. On the other hand, in the cases of $K^+(CA)^-$ and $Rb^+(CA)^-$, the absorption spectra are insensitive to the pressure: that is, no effect of the pressure is observed, at least up to 7 kbar, except for a slight change in the band intensity of $K^+(CA)^-$ (Fig. 2).

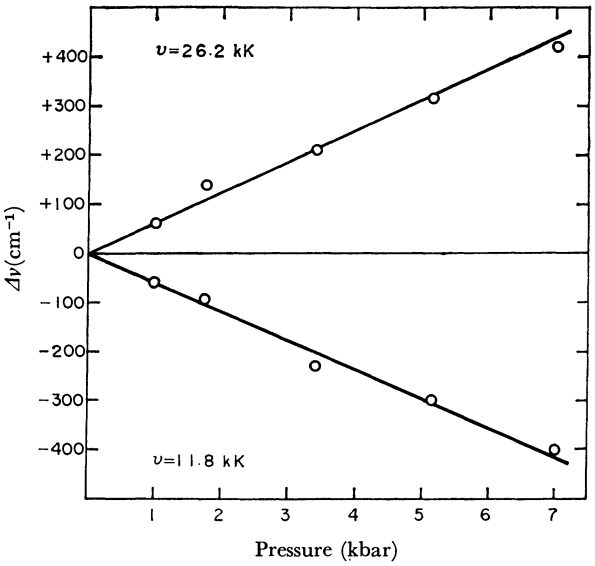

Fig. 3. Frequency shift with pressure for 26.2 and 11.8 kK peaks of $Na^+(CA)^-$.

These pressure effects, in particular, a large pressure-induced blue shift of the band in the visible region, suggest that chloranil anions associate bimolecularly in the crystalline state in $Li^+(CA)^-$ and $Na^+(CA)^-$. This is analogous to the situation with alkali metal cation-TCNQ anion radical salts in the crystalline state, where the absorption spectra are similar to those of the radical dimer $(TCNQ^-)_2$ in an aqueous solution, and where, in the visible region, there is a large blue shift with an increase in the pressure. This shift has been discussed in connection with the stabilization of the electronic-ground state from the characteristic crystalline structure (stacked face-to-face) of TCNQ anions and the crystal-field effect of the metal cations surrounding the TCNQ anions.[6] Therefore, we investigated whether or not the dimerization of the chloranil anion occurs in solutions,

14) As a test of the reliability of this method, the absorption spectra of single crystals of K^+ $(CA)^-$ in the visible region were measured by using a microspectrophotometer. The spectra measured by the present method agree well with those measured on single crystals.

15) J. J. André and G. Weill, *C. R. Acad. Sci., Paris, Ser. B*, **269**, 499 (1969).

16) The spectra of Rb^+ $(CA)^-$ obtained by the method of the KBr disk are similar to those of Na^+ $(CA)^-$ in the visible region; therefore, when the method of the KBr disk is used, some attention should be taken.

as has been observed in a solution of Würster's cation,[17] the *p*-benzosemiquinone anion,[18] and the TCNQ anion;[19] consequently, a monomer-dimer equilibrium for $(CA)^-$ is confirmed in an ethanol solution at low temperatures (see the next section, B).

The absorption spectra of crystalline $Li^+(CA)^-$ and $Na^+(CA)^-$ are similar to those of the dimer in solution, while the spectra of $K^+(CA)^-$ and $Rb^+(CA)^-$ are similar to those of the monomer in solution except for the weak near-infrared absorption band in the crystalline state. Although the dimerization of the chloranil anion in solution is observed in all four alkali metal cation-chloranil anion radical salts, $K^+(CA)^-$ and $Rb^+(CA)^-$ show an electronic structure with the nature of the monomer in the crystalline state.

The X-ray diffraction powder patterns of $Na^+(CA)^-$ and $K^+(CA)^-$ at room temperature, in which slight differences are observed from sample to sample, show a remarkable difference in the crystalline nature between the two salts, as is shown in Fig. 4.

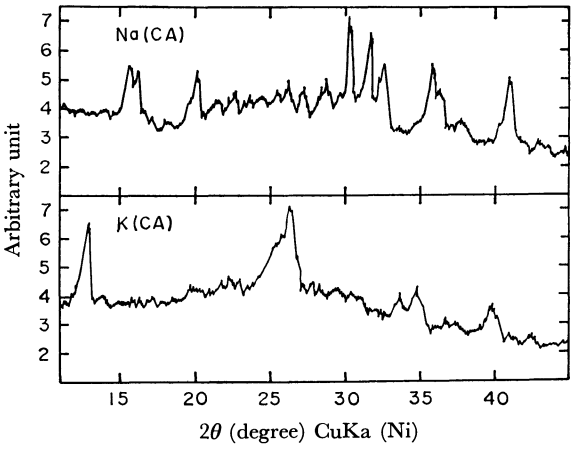

Fig. 4. X-ray diffraction powder patterns of $Na^+(CA)^-$ and $K^+(CA)^-$ at room temperature.

The ionic radii of Li^+, Na^+, K^+, and Rb^+ are 0.78, 0.98, 1.33, and 1.49 Å, respectively, where the increase from Na^+ to K^+ is marked.[20] The polarizing powers, which are equal to Ze/r^2 (Z: number of charge, e: elementary charge, r: ionic radius), are 1.64, 1.04, 0.57, and 0.45 (arbitrary unit) for Li^+, Na^+, K^+, and Rb^+ respectively, where the values for Li^+ and Na^+ are much larger than those for K^+ and Rb^+.[20] That is, Li^+ and Na^+ have a stronger power to distort the opponent electron cloud than K^+ and Rb^+, and the effect of this power cannot be ignored for a molecule with π-electrons. Although alkali metal cation-TCNQ anion radical salts show little difference in the electronic structure of TCNQ anions in the crystalline state, in the case of alkali metal cation-chloranil anion radical salts, the packing and the electronic structure of the chloranil anions in the crystalline state may be considerably affected by the size and the polarizing power of the counter ion; consequently, chloranil anions seem to be dimeric in $Li^+(CA)^-$ and $Na^+(CA)^-$, the alkali metal cations of which have small ionic radii and large polarizing powers.[21] On the other hand, chloranil anions seem to be monomeric, with a weak interaction between anion radicals in $K^+(CA)^-$ and $Rb^+(CA)^-$[21]; it also seems that their absorption spectra are insensitive to the pressure because of the weak inter-radical interaction and seem to be less compressible because of the large ionic radii.

In the case of bromanil salts, the absorption spectra of crystalline $K^+(BA)^-$ are similar to those of crystalline $K^+(CA)^-$, and the effect of pressure on the absorption spectra was not observed, at least up to 7 kbar; the absorption spectra of crystalline $Na^+(BA)^-$ are diffused and are not clear, but they seem to be characteristic of both of the monomer and the dimer of BA^-. The spectra of $Na^+(BA)^-$ obtained by the method of the KBr disk are, however, similar to those of $Na^+(CA)^-$ and behave the same as $Na^+(CA)^-$ under high pressures. The dimerization of the bromanil anion was not observed in an ethanol solution down to the temperature of liquid nitrogen. The X-ray diffraction powder patterns of $Na^+(BA)^-$ and $K^+(BA)^-$ at room temperature resemble each other.

The phase transition accompanying a change in the electronic structure, as has been observed in WBP,[8,11,12,22] should be expected to occur in these chloranil and bromanil anion radical salts in which the intermolecular interaction between anion radicals differs from radical to radical.

21) From the temperature dependence of the intensities of the ESR spectra, it has been observed that, in the temperature range from 290°K to 370°K, the singlet-triplet model was approximately followed, with $\delta=0.16$ eV (the singlet-triplet energy separation) for $Na^+(CA)^-$, whereas the Curie-Weiss law was followed for $K^+(CA)^-$. These results would appear to be coincident with the electronic structure of chloranil-anion radical salts assumed from the electronic absorption spectra

22) H. Chihara, M. Nakamura, and S. Seki, This Bulletin, **38**, 1776 (1965).

When an ethanol solution of alkali metal cation-chloranil anion radical salts, a solution which is yellow at room temperature, is cooled to about 145°K, it turns green and new absorption bands appear in the electronic absorption spectra. The temperature dependence of the absorption spectra of $Na^+(CA)^-$ in ethanol is show nin Fig. 5. The absorption band around 22 kK may be attributed to the lowest energy π–π^* transition in the chloranil anion monomer.[23,24] From the concentration dependence (between 10^{-3} and 10^{-4} mol/l) of the absorption intensity of $Na^+(CA)^-$ in ethanol, the monomer and dimer of the chloranil anion radical can be said to be in equilibrium in solution. The thermodynamic quantities of dimerization are obtained by the following procedure.

An equilibrium of the degree of association of n for the anion radical is assumed:

$$n(CA)^- \rightleftarrows (CA^-)_n \qquad (1)$$

The equilibrium constant, K, is given by:

$$K = (1-\alpha)/(nc^{n-1}\alpha^n) \qquad (2)$$

where c is the stoichiometric concentration[25] of $Na^+(CA)^-$ and where α is the fraction of the stoichiometric concentration existing as a monomer. The apparent molar extinction coefficient at a certain wavelength is related to the molar extinction coefficients of the monomer and n-polymer as:

$$\varepsilon = \alpha\varepsilon_m + (1-\alpha)\varepsilon_n \qquad (3)$$

where ε is the apparent molar extinction coefficient, as calculated from the measured optical density and the concentration, where ε_m is the molar extinction coefficient of the monomer, and where ε_n is the molar extinction coefficient of one molecule in the n-polymer. The values of ε_m at several peaks are determined from the optical density measured at higher temperatures (190—170°K), where it seems that no association of the radicals occurred.[26] From the relation of Eqs. (2) and (3), the following equation is obtained:

$$\log\{c(1-\varepsilon/\varepsilon_m)\} = \log(BK) + n\log c(\varepsilon-\varepsilon_n)/\varepsilon_m\} \qquad (4)$$

where:

$$B = n(1-\varepsilon_n/\varepsilon_m)^{1-n}$$

Therefore, assuming $\varepsilon \gg \varepsilon_n$, Eq. (4) leads to:

$$\log\{c(1-\varepsilon/\varepsilon_m)\} = \log(BK) + n\log(c\varepsilon/\varepsilon_m) \qquad (5)$$

When $\log\{c(1-\varepsilon/\varepsilon_m)\}$ is plotted against $\log(c\varepsilon/\varepsilon_m)$ for the monomer band (λ_{max}=427 mμ) at 134°K, the slope of the straight line, n, is about 2. This means that the concentration dependence of the absorption spectra of $Na^+(CA)^-$ in ethanol at low temperatures can be explained by the equilibrium between the monomer and the dimer. The value of ε_d[27] is chosen to give a straight line with a slope of 2 when $\log\{c(1-\varepsilon/\varepsilon_m)\}$ is plotted against $\log\{c(\varepsilon-\varepsilon_d)/\varepsilon_m\}$, as is shown in Fig. 6: using this value of ε_d, the value of K is evaluated from Eq. (4). The ε_d values at other peaks are evaluated using Eq. (3) from the measured ε, ε_m, and α values, calculated from ε, ε_m, and ε_d at 427 mμ using Eq. (3). The molar extinction coefficients at several peaks are shown in Table 1.

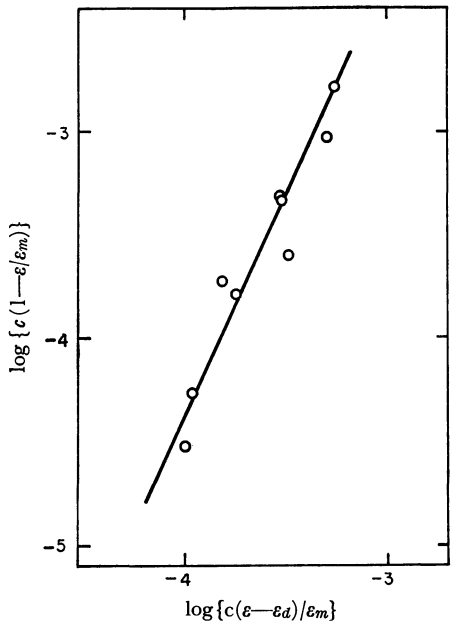

Fig. 6. Plots of $\log\{c(1-\varepsilon/\varepsilon_m)\}$ against $\log\{c(\varepsilon-\varepsilon_d)/\varepsilon_m\}$ for the monomer band (λ_{max}=427 mμ) at 134°K.

Table 1. Molar extinction coefficients of $Na^+(CA)^-$ in ethanol

25) Volume changes in solution with the temperature were taken into account.
26) The solution is stable at low temperatures, but it is slowly discolored at room temperature.
27) Here the ε_n in Eq. (4) is rewritten as ε_d.

Table 2. Thermodynamics of dimerization of CA^- at 134°K

K (l/mol)	ΔF (kcal/mol)	ΔH (kcal/mol)	ΔS (cal/mol·deg)
2.0×10^3	−2.0	−4.5	−18.7

A series of spectra at various temperatures on one solution is measured, and the equilibrium constant, K, at each temperature is calculated from α, obtained from the data at 427 mμ, using Eq. (2): in Fig. 7 $\log K$ is plotted against $1/T$. The thermodynamic quantities are shown in Table 2.

The dimerization in ethanol at low temperatures is observed for $Li^+(CA)^-$, $K^+(CA)^-$, and $Rb^+(CA)^-$, too. The thermodynamic quantities for other salts are of interest with regard to the influence of the counter ion upon the dimerization of CA^-.

The dimerization of CA^- is observed in an aqueous solution at room temperature, but it is very unstable in air.[28]

Spreadability of Ovalbumin Monolayers at Air-water Interface. Effects of Additives to Spreading Solutions

Toshio Ishii* and Mitsuo Muramatsu

Department of Chemistry, Tokyo Metropolitan University, Setagayaku, Tokyo

(Received October 26, 1970)

The effect of additives (urea, potassium chloride, butanol, and thioglycol) to spreading solutions upon spreadability of ovalbumin monolayers has been studied in terms of the rate constants and the limiting areas for intermediate (fast) and final (slow) processes of uncoiling of the protein molecule. It has been found that the addition results in the disappearance of the first (fast) process, which appeared upon spreading without additives. In the second (slow) process, the rate constant is found to be the same as that for the case without additives regardless of the type of the additives. Sodium dodecyl sulfate (SDS) added to the spreading solution is showed a peculiar behavior, which is explained in relation to the interaction between the protein and SDS molecules.

It has been reported that the monolayers of proteins[1-5] and synthetic polypeptides[6-8] are markedly affected by their addition to subphase of various salts, surface-active agents, or other substances which influence the net-work formation involving hydrogen bonding. The increase or decrease thereby observed was interpreted by the interaction between protein and the additive molecules. Most of the interpretations were based on the tacit assumption that the systems were always in the equilibrated states. It has been pointed out in the preceding paper[9] that the properties of protein monolayers should preferably be analysed as a reflection of kinetic processes rather than the equilibrated state. Thus, the isoelectric point was characterized by acidity, when the spreading was achieved instantaneously to give the highest rate of uncoiling of the polypeptide chain. A similar type of instantaneous spreading has also been observed[10,11] when adequate additives are contained in aqueous subphases or in spreading solutions. The present paper deals with the effect of additives to the aqueous solution of ovalbumin on its spreadability at air-water interface, in order to make clear how the mixed solutions of the protein and the additives reveal themselves in the monolayer properties to be studied from the kinetic aspects.

Experimental

Apparatus used was the same as that in the previous work.[9] The surface pressure (F) was determined by means of a Whilhelmy plate balance of ± 0.05 dyn/cm sensitivity. A glass tray contained subphase water, on which ovalbumin monolayers were spread from aqueous solutions of various additives, such as urea, potassium chloride, butanol, thioglycol, and sodium dodecyl sulfate. The aqueous surface prior to the spreading was clean enough to observe $F<5$

dyn/cm, when it had been compressed to 1/20 area ratio after having been kept standing for 24 hr.

The sample of ovalbumin was the same as that in the previous work.[9] The additives were purified thoroughly by appropriate procedures; recrystallization and/or distillation, followed by ethereal elimination of possible impurities in a Soxhlet extractor. They were all clean enough to recognize appreciable increment in the surface pressure for the protein-free surface, to which their solutions were applied for blank test. All experiments were carried out on subphase of initial pH 5.3±0.1 adjusted with a small amount of hydrochloric acid at 25.0±0.5°C.

Results and Discussion

The surface denaturation processes can quantitatively be expressed as[9]

$$(A_\infty^0 - A^0) = (A_\infty^0 - A_2^0)\exp(-k_2 t) + (A_2^0 - A_1^0)\exp(-k_1 t) \quad (1)$$

where A^0 is the limiting area at a given time, t, elapsed from the spreading, A_∞^0 the area at $t=\infty$, A_1^0 the area for the first process starting at $t=0$, A_2^0 that for the second, and k_1 and k_2 are the rate constants for the two processes, in which the whole denaturation processes are comprised. This is the case of protein monolayer spread from aqueous solution without any additives, appearing as the dotted and dashed lines in Fig. 1. The additives to the spreading solution caused the disappearance of the second term in Eq. (1), as seen in Fig. 1, where the six straight lines for four additives

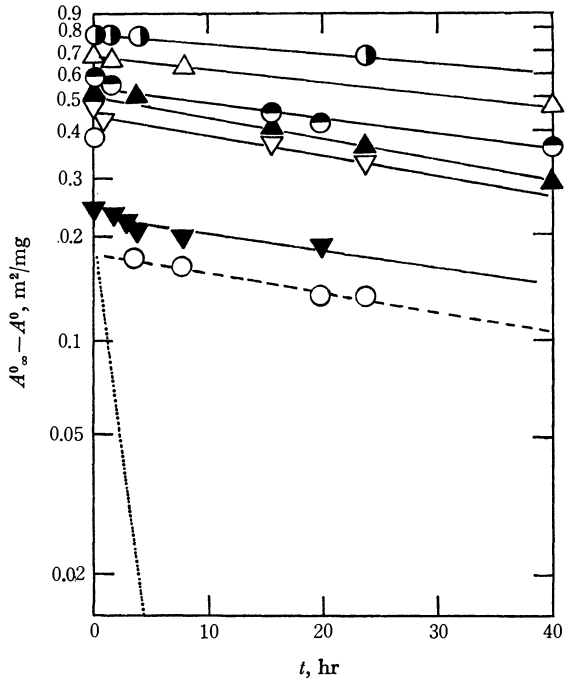

Fig. 1. Time dependences of $(A^0_\infty - A^0)$ for the monolayers of ovalbumin spread from its solutions containing urea (1M, ◑), KCl (1M, △▲), butanol (0.1%, ◓), and thioglycol (0.1%, ▽▼), or without any additives (○). The dashed and dotted lines express the first and second terms, respectively, in Eq. (1) for the case without additives. In the case of KCl and thioglycol, experiments were carried out twice independently and the results are shown as upward and downward triangles, respectively.

run almost in parallel with the dashed line. This means that the k_2 values are not changed by the addition of any of the four additives to the solution, with the $(A_\infty^0 - A_2^0)$ values characteristic of their effect. Such an effect of the additives has been reported for potassium chloride added to the spreading solution of myosin[10] and bovine serum albumin,[11] for which the instantaneous spreading could be understood either as $A_\infty^0 = A_2^0 = A_1^0$ or as $k_1 = k_2 = \infty$.

Differentiation of Eq. (1) gives

$$dA^0/dt = k_2(A_\infty^0 - A_2^0)\exp(-k_2 t) + k_1(A_2^0 - A_1^0)\exp(-k_1 t). \quad (2)$$

For the region,

$$t > \frac{1}{k_1 - k_2}\ln\left(\frac{k_1}{k_2}\cdot\frac{A_2^0 - A_1^0}{A^0 - A_2^0}\right), \quad (3)$$

or for

$$(A_2^0 - A_1^0) = 0, \quad (4)$$

Eq. (1) is simplified as

$$dA^0/dt = k_2(A_\infty^0 - A^0). \quad (5)$$

Eq. (3) is the case of the tailing period of the dashed line, while Eq. (4) corresponds to the disappearance of the dotted line. This means that the addition results in the verified applicability of Eq. (5) to any of the four additives. Taking into account of the conditions, dA^0/dt is plotted in Fig. 2 against A^0. It can be seen from the

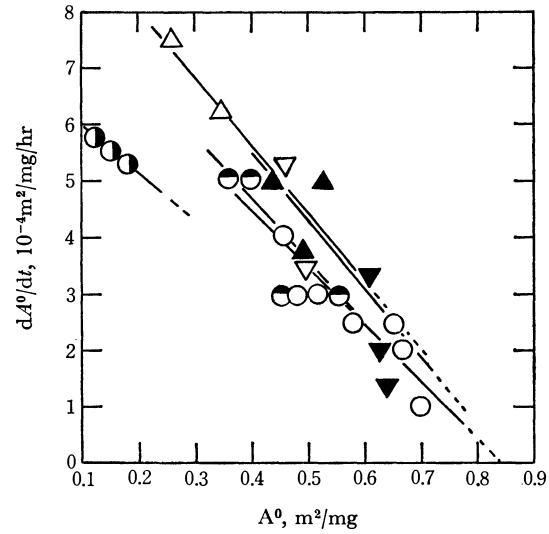

Fig. 2. Relationship of dA^0/dt and A^0 for ovalbumin monolayers spread from aqueous solutions containing urea (1M, ◑), KCl (1M, △▲), butanol (0.1%, ◓), and thioglycol (0.1%, ▽▼), or without any additives (○).

figure that all of the five lines give more or less the same values in their slant and intercept at the abscissa, suggesting the same k_2 and A_∞^0 values in Eq. (5). Thus, the difference in the intercept at the ordinate in Fig. 1 is an indication of the difference in A_2^0 values for individual additives. The additives seem to affect the spreading processes in such a manner as to eliminate one of the two steps involving A_1^0 and to keep the other, starting with individual A_2^0 values and ending at the same A_∞^0 value, which is 0.83 m²/mg or 16.4 Å²/residue, as in the previous report.[9]

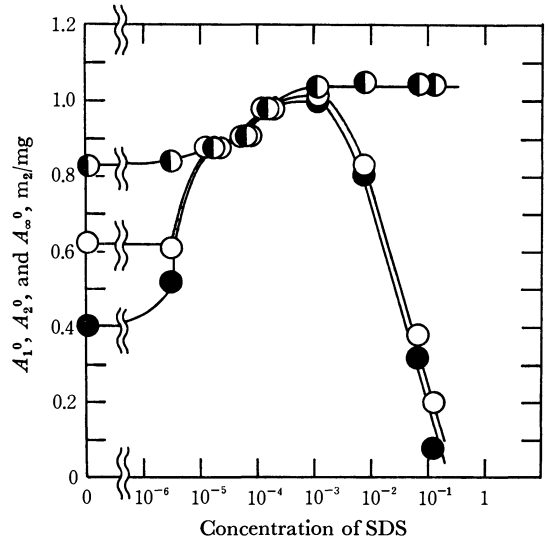

Fig. 3. Effects of SDS concentration in spreading solution on limiting areas, A_1^0 (●), A_2^0 (○), and A_∞^0 (◐) of ovalbumin monolayers.

Similar treatments were applied to the system involving SDS added to the spreading solution. Results are shown in Fig. 3, in which A_i^0's ($i=1$, 2, and ∞) are plotted against SDS concentration in the spreading solution containing protein for monolayer. It can be seen that the addition of SDS to the spreading solution affects in two different stages. For concentrations lower than *ca.* 3×10^{-4}M, it causes increments in A_i^0's with the coincident value of 0.83—1.04 m^2/mg, which is higher than the A_∞^0 value (0.83 m^2/mg) obtained for the protein monolayers without SDS.[9] For concentrations beyond this the addition of SDS results in the constant A_∞^0 value and the marked lowerings in A_1^0 and A_2^0.

These two stages seem to reflect the different fashions in interacting SDS molecules with protein. It should be noted for the first stage that the rate constants, k_1 and k_2, are almost the same as those for the protein without SDS. These phenomena can be interpreted by the attachment of SDS molecules to protein, which causes the increase of limiting area in such a manner as not to influence the easiness of its uncoiling processes.

At the concentration of around 3×10^{-4}M, uncoiling is completed instantaneously. This means that the interaction reaches a critical point, so that the association is made between SDS and protein molecules. A similar association has been proposed for explaining the shifting of optical absorption spectra of a mixed solution of *p*-aminoazobenzene and SDS when bovine serum albumin is added to it.[12] Electrophoretical studies[13] on the mixed solution of SDS and ovalbumin have also shown the appearance of a shift due to the formation of SDS-protein complex at around 10^{-5}M, which is in accord with the threshold value of the coincident region in Fig. 3.

The second stage is characterized by k_2 values 1.4—3.3 times larger than those for the first, with the constant A_∞^0 and the lowering A_1^0 and A_2^0 values. The increment beyond the saturation concentration seems to contribute to the interaction in such a manner as to decrease the A_1^0 and A_2^0 values but not to affect the saturated A_∞^0, which does not much differ from that obtained in the first stage. Probably, the attached SDS is increased by a small amount throughout the second stage. The role of these SDS molecules in the second stage should be different from that in the first. Blei[12] has proposed a solubilizing complex comprised in SDS molecules located to hydropohbic residue of the molecules of bovine serum albumin. A similar structure may be taken into account for elucidating the uncoiling processes of ovalbumin in the second stage of SDS concentration.

Electronic Structures, Electronic Spectra, and Aromatic Characteristics of Peri-Condensed Tetracyclic Nonbenzenoid Aromatic Hydrocarbons Containing a Naphthalene Nucleus

Hiroyuki YAMAGUCHI and Takeshi NAKAJIMA

Department of Chemistry, Tohoku University, Katahira-cho, Sendai

(Received October 28, 1970)

The ground-state electronic properties and electronic spectra of pyracylene (I), acepleiadylene (II), and dipleiadiene (III) have been studied by using the semi-empirical SCF LCAO-π-MO method, which allows for bond order-bond length correlation at each iteration. It is shown that the I and III molecules do not belong to, respectively, the pentalenoid and heptalenoid systems, as was expected from the HMO energy diagram. The predicted chemical reactivities, diamagnetic anisotropies, and electronic spectra for I and II are in good agreement with the available experimental data. The calculated C–C bond lengths indicate that the I, II, and III molecules are all both aromatic and polyolefinic. The upfield shift of the NMR spectrum and the unusually low value of the first half-wave potential for I can be well explained in terms of, respectively, the diamagnetic anisotropy and the energy of the lowest vacant SCF MO, calculated by using the predicted equilibrium configuration that corresponds to the aromatic model (Ia).

The electronic structures and aromatic characteristics of tetracyclic nonbenzenoid aromatic hydrocarbons containing a naphthalene nucleus have been of theoretical interest since Boekelheide and Vick[1] synthesized acepleiadylene (II) in 1956.

Trost and Bright[2] have recently reported the successful synthesis of pyracylene (I). Theoretical interest in whether I or not is a pentalenoid system was then stimulated. These authors proposed two possible structures, a naphthalene core with two vinyl bridges (Ia) and a cyclododecahexene with a vinyl cross-link (Ib). They concluded, from the upfield shift of the NMR spectrum and the unusually low value of the first half-wave potential, that the peripheral model (Ib) is a better representation for I. Lo and Whitehead[3] have calculated the ground-state electronic properties of I using the LCAO MO SCF PPP ($\pi+\sigma$) method and have concluded that the most stable configuration corresponds to the aromatic model (Ia).

Pullman *et al.*[4] have studied the electronic structures and spectra of II using the Hückel MO method. From the calculated delocalization energy, they have found that II should be aromatic. Koutecký *et al.*[5] have applied the SCF MO method based on the Pariser-Parr-Pople approximation to II and have calculated its transition energies and intensities, but they have not mentioned its aromaticity.

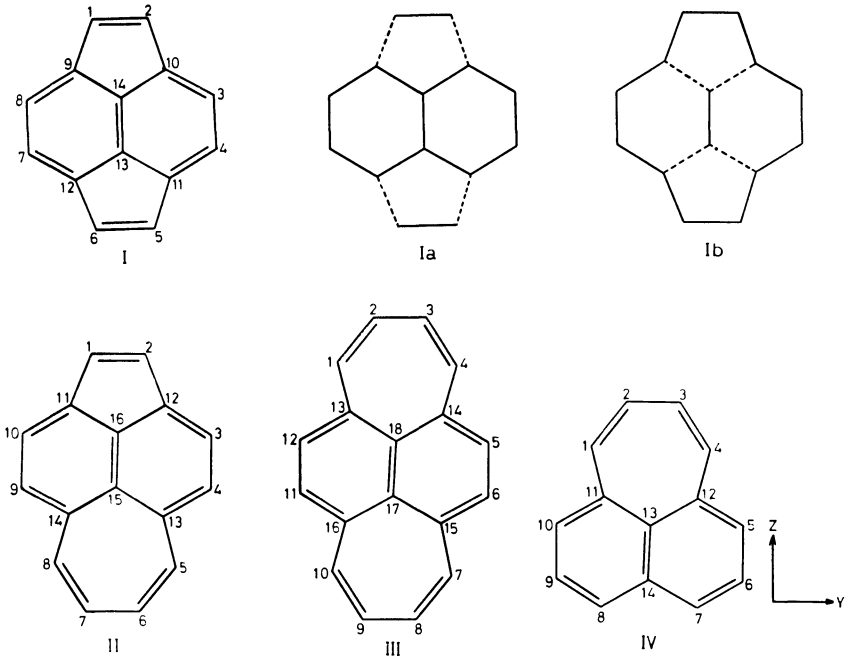

Fig. 1. Co-ordinate system and numbering of atoms.

5) J. Koutecký, P. Hochman, and J. Michl, *J. Chem. Phys.*, **40**, 2439 (1964).

Using the HMO method, Zahradnik *et al.*[6] have investigated the electronic structures, electronic spectra, and stability of I, II, and dipleiadiene (III), the last of which is yet unknown. On the basis of a new definition of stability, they have concluded that I and III are unstable, while II is stable. Recently, using the Molecules in Molecules method, Favini *et al.*[7] have calculated the transition energies and intensities for I, II, and III, but they have not considered anything with regard to the stable configurations and aromaticity of these molecules.

It is the purpose of this paper to determine the equilibrium configurations of I, II, and III by using the variable bond-length SCF LCAO-π-MO CI technique and to examine theoretically their ground-state electronic properties and electronic spectra. It should be possible to use the results of such calculations to deepen our understanding of the aromatic characteristics of I, II, and III.

Method of Calculation

The electronic structures and spectra are calculated by using the variable bond-length SCF LCAO-π-MO method, in which the C–C bond lengths and, consequently, the resonance and two-center repulsion integrals are allowed to vary with the bond order at each iteration until self-consistency is reached. The C–C bond lengths, r, are correlated with the bond orders, p, by the following relationship:

$$r(\text{Å}) = 1.520 - 0.186p \quad (1)$$

The two-center repulsion integrals are calculated using the Mataga-Nishimoto formula.[8] The resonance integrals are evaluated using Method 2 of Ref. 9, in which the dependence of the resonance integral on the bond length is assumed to be exponential; the value of the exponent was determined by trying to reproduce as many properties of the ground and excited states as possible in a series of reference molecules. In order to discuss the properties of excited states, a configuration mixing of all the singly-excited states is included.

The diamagnetic susceptibilities are calculated by using the London[10]-Hoarau[11] method in the framework of the Wheland-Mann-type SCF MO approximation.[12] The resonance integral is assumed to be again of the exponential form, the value of the exponent in this case being 4.4 Å^{-1}. This value was determined so as to reproduce the bond lengths, electron densities, and dipole moments, which were obtained from the variable bond-length SCF LCAO-π-MO technique, for butadiene, pentafulvene, heptafulvene, and naphthalene. This method has been applied to a number of benzenoid and nonbenzenoid aromatic hydrocarbons and has been found to produce theoretical values which are in good agreement with the experimental results.[13]

Results and Discussion

Ground-state Symmetries. The HMO energy levels show that, in the I molecule, the lowest unoccupied MO is non-bonding as in pentalene, while in the III molecule the highest occupied MO is non-bonding as in heptalene. In this sense, it has been said that the I molecule belongs to the pentalenoid system, and the III molecule, to the heptalenoid system.[6,14] The energy differences between the highest occupied MO and the lowest unoccupied MO for I and III are almost the same as those of, respectively, the pentalene and heptalene molecules, both of which are pseudo-Jahn-

Teller molecules.[15] Therefore, it may be expected that the I and III molecules will suffer a pseudo-Jahn-Teller effect, which may result in a symmetry reduction from the fully symmetrical configuration.

We thus examined the ground-state symmetries of the I and III molecules, using a method of predicting the energetically most favourable equilibrium configuration of a conjugated hydrocarbon.[16] It turned out that, in both the molecules, the starting bond distortions belonging to irreducible representations, a_g, b_{3g}, b_{1u}, and b_{2u}, of the full symmetry group, D_{2h}, all converge into the unique self-consistent set of bond lengths corresponding to that symmetry group.

Thus, we may conclude that I and III molecules are not pentalenoid and heptalenoid respectively and that neither molecule is a so-called pseudo-Jahn-Teller molecule.

Ground-state π-Electronic Properties. The calculated charge densities, free valence numbers, and bond lengths are summarized in Table 1. The greatest nucleophilic reactivity is predicted to be exhibited by the 3, 4, 7, and 8 atoms in I, by the 3 and 10 atoms in II, and by the 17 and 18 atoms in III. The greatest electrophilic reactivity is expected at the 13 and 14 positions in I, the 16 position in II, and the 5, 6, 11, and 12 positions in III. The results for II do not agree with those of the simple HMO method,[4] which indicate that the highest reactivity for nucleophilic and electrophilic reactions is to be expected at the 5 and 8 positions and at the 1 and 2 positions, respectively. It is hoped that eventually this point can be established experimentally. From the viewpoint of chemical reactivity, it is noteworthy that the free valence values of atoms belonging to the 5- and 7-membered rings of all the molecules examined are significantly larger than those in classical aromatic hydrocarbons. This perhaps provides evidence for the fact that the attempts to isolate the I molecule produce only amorphous yellow polymers.[2]

Next, let us discuss the reactivity for the addition reactions of I, II, and III. It has been known that, in the presence of cyclopentadiene, the 1, 2-dibromo derivative of I gives an addition product[17] at the 5 and 6 positions and that II does not react with maleic anhydride under the same conditions under which maleic anhydride gives Diels-Alder adducts with pleiadiene IV.[1] These facts can be explained by comparing the sum of the free valences for the two positions concerned; $F_5+F_6=1.040$ in I and $F_1+F_4=1.028$ in IV are larger than $F_1+F_2=0.968$ and $F_5+F_8=0.990$ in II. Furthermore, it is expected that III will suffer addition reactions at the 1 and 4 positions, because the sum of the free valences at these positions ($F_1+F_4=1.034$) is comparable to F_1+F_2 for I and F_1+F_4 for IV

As for the bond lengths, it is of interest to note that the bond lengths of the naphthalene core of I, II, and III are almost the same as those of the free naphthalene molecule. There is a marked double-bond fixation in the remainder of the periphery. The I and III molecules show a double-bond fixation in their peripheries to a greater extent than II. In fact, the presence of two isolated vinyl bridges in the periphery of I is confirmed by the experimental fact that hydrogenation occurs only at the 1, 2- and 5, 6-positions to give pyracene.[2] The reason why the equilibrium configurations of I and III show such a double-bond fixation in the periphery may be explained by using a simple perturbational treatment. The I and III molecules have a 4n perimeter which has degenerate nonbonding orbitals, Φ_A and Φ_S, which are antisymmetric and symmetric respectively with respect to the y axis, as is shown in Fig. 2. The antibonding orbital of the vinyl segment located at the center of I interacts with the Φ_A state of the 12-monocyclic system and stabilizes it, as is also shown in Fig. 2. On the other hand, the bonding orbital of the vinyl segment

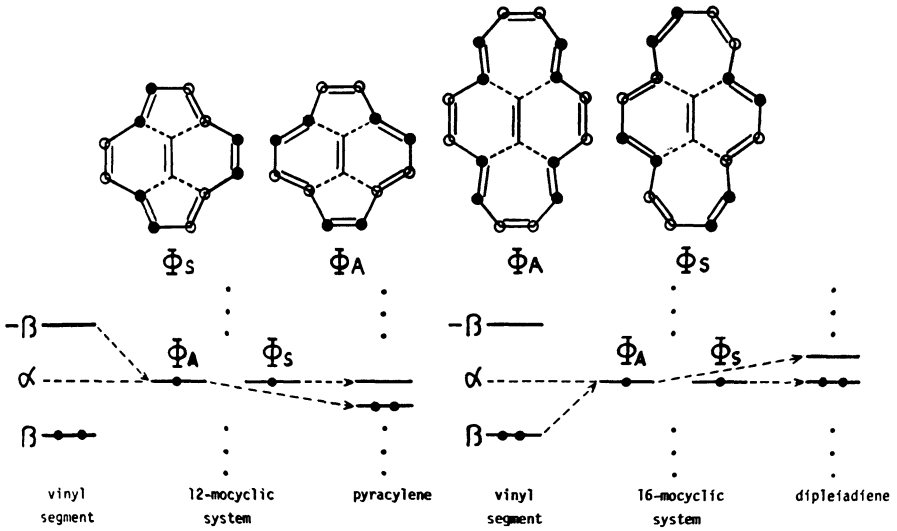

Fig. 2. Wave functions of nonbonding orbitals, Φ_A and Φ_S of 4n monocyclic systems and interaction scheme between vinyl segments and 4n monocyclic systems. The open and dark circles represent plus and minus signs of the LCAO coefficients, respectively.

located at the center of III interacts with the Φ_A state of the 16-monocyclic system and makes it unstable.

Magnetic Properties. The diamagnetic susceptibility of a ring π-electron system is one of the important indications of π-electron delocalization. The calculated molar magnetic anisotropies, ΔK, for I, II, and III are -0.40, 3.92 and -0.34 respectively, in units of $\Delta K_{\text{benzene}}$. The predicted value for II is in good agreement with the experimental exaltation ($\Lambda/\Lambda_{\text{benzene}}=3.87$).[18] It turned out that the magnetically-induced ring currents in I and III are very much impeded. A part of the evidence for this fact is given by the NMR spectrum of I, which consists of two singlets of equal intensity at 3.48 and 3.99τ,[2] which are close to that observed for the olefinic protons of linear conjugated polyenes. The periphery of I and III may give a paramagnetic ring current characteristic of the 4n perimeter.[19] On the other hand, the naphthalene core in I and III may exhibit a diamagnetic ring current to the same extent as that of a free naphthalene molecule. Therefore, it may be expected that the paramagnetic ring current and the diamagnetic ring current cancel out each other to give a small magnetic susceptibility in I and III.

Half-wave Reduction Potentials. It has been shown that there is an excellent correlation between the energy of the first unoccupied molecular orbital and the half-wave reduction potential. Polarographic half-wave reduction potentials for a number of hydrocarbons in aqueous dioxane are summarized in Ref. 20. A plot of these aqueous-dioxane data against m, the energy (in units of eV) of the lowest vacant SCF MO, gives a good linear correlation (see Fig. 3). The least-square correlation line is:

$$-\varepsilon_{1/2}(\text{aq. diox.}) = -0.919(-m) + 4.240 \qquad (2)$$

The half-wave potentials, $\varepsilon_{1/2}$, predicted using Eq. (2) for I, II, and III are -1.083, -1.716, and -1.935 V *vs.* SCE respectively. The predicted $\varepsilon_{1/2}$ value for I is in good agreement with the experimental value, -1.056 V *vs.* SCE.[2]

Electronic Spectra. The calculated singlet transi-

Tavle 3. Bond lengths of first singlet excited states of I and III

Molecule	Bond	Bond length(Å)
I	1—2	1.390
	1—9	1.430
	3—4	1.394
	8—9	1.411
	12—13	1.439
	13—14	1.399
III	1—2	1.383
	1—13	1.435
	2—3	1.428
	5—6	1.396
	12—13	1.407
	16—17	1.435
	17—18	1.403

tion energies and intensities are summarized and compared with the experimental data in Table 2. The predicted transition energies for I and II are in good agreement with the observed absorption peaks. The spectral results calculated for I, II, and III by Favini *et al.*,[7] who used the aromatic model, are in fairly good agreement with the present results.

The calculated bond lengths of the first singlet excited states for I and III are listed in Table 3. It can be seen that, in both the molecules, the double-bond fixation in the first singlet excited state is considerably more relaxed than that in the ground states. This may be one of the reasons for the appearence of a long tail, extending to 600mμ, on the long-wavelength side of the first absorption band in I.[2]

Aromatic Characteristics. The predicted C–C bond lengths for I, II, and III indicate that, in these molecules, the C–C skeleton is composed of two distinguishable parts: one in which bond lengths are smoothed out and another in which a strong double bond fixation exists. Thus, there are two regions, one aromatic in the sense that π-electrons are highly delocalized and the other polyolefinic, in the peripheries of the I, II, and III molecules. Nevertheless, the II molecule is more aromatic than the I and III molecules.

No definition of aromaticity which is correlated with the global π-electronic properties of a conjugated molecule, such as the delocalization energy and the diamagnetic susceptibility, is sufficient for these molecules, which are essentially both aromatic and polyolefinic.

One of the present authors (T. N.) especially wishes to thank Dr. B. M. Trost for providing him with copies of the ultraviolet absorption spectra of pyracylene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 686—688 (1971)

Studies of the Formation Mechanism of Sodium Tripolyphosphate from Orthophosphates by the Use of Radioisotopes

Takaya IIDA, Nobuharu TAKAI, and Takeo YAMABE

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received March 28, 1970)

The reaction process of an equimolar mixture of mono- and disodium orthophosphates was examined to serve as a reference for the considerations of the mechanism of the formation of sodium tripolyphosphate. Differential thermoanalysis, thermogravimetric analysis, X-ray diffraction analysis and thin-layer chromatographic analysis were done. Particularly, the reaction mechanisms (the formation of liquid $Na_3HP_2O_7$, *etc.*) were also examined by the use of the "^{32}P" radioisotope. The reaction process is as follows:

$$\left.\begin{array}{l} NaH_2PO_4 \longrightarrow Na_2H_2P_2O_7 \\ Na_2HPO_4 \longrightarrow Na_4P_2O_7 \end{array}\right\} \rightleftarrows Na_3HP_2O_7\,(liq.) \longrightarrow \left\{\begin{array}{l} Na_2H_2P_2O_7 \\ Na_5P_3O_{10}\,(I) \end{array}\right.$$

$$\longrightarrow Na_5P_3O_{10}\,(I) + Na_5P_3O_{10}\,(II) + NaPO_3\,(II)$$

A feedback phenomenon of $Na_2H_2P_2O_7$ was observed.

Condensed phosphates have interested many investigators as inorganic poly-substances. Among them, sodium tripolyphosphate is industrially most important, because it is used in large quantities as *e. g.*, a builder of synthetic detergents.

In general, sodium tripolyphosphate is prepared from a mixture of orthophosphates with a Na_2O/P_2O_5 mole ratio of 5/3 by thermal dehydration:

$$2Na_2HPO_4 + NaH_2PO_4 \longrightarrow Na_5P_3O_{10} + 2H_2O \quad (1)$$

In the intermediate step, tetrasodium pyrophosphate and sodium acid pyrophosphate are formed at first.[1] T. Seiyama *et al.* proposed that the reaction process of the formation of sodium tripolyphosphate from pyrophosphates mixture was as follows:[2,3]

$$Na_4P_2O_7 + Na_2H_2P_2O_7 \longrightarrow 2Na_3HP_2O_7\,(liq.) \quad (2)$$

$$2Na_3HP_2O_7 \longrightarrow Na_5P_3O_{10}\,(I) + 1/2Na_2H_2P_2O_7 + 1/2H_2O \quad (3)$$

$$1/2Na_2H_2P_2O_7 \longrightarrow 1/4Na_4H_2P_4O_{13} + 1/4H_2O \quad (4)$$

$$1/4Na_4H_2P_4O_{13} + Na_4P_2O_7 \longrightarrow Na_5P_3O_{10}\,(II) + 1/4H_2O \quad (5)$$

In the thermal decomposition of $Na_3HP_2O_7$, reaction (3) takes place at first; then the following reaction occurs:[4]

$$Na_2H_2P_2O_7 \longrightarrow 2NaPO_3\,(II) + H_2O \quad (6)$$

Studies of the thermal reaction of equimolar mixtures of mono- and disodium orthophosphates did not concern the detailed reaction process.[5]

1) J. W. Edwards and A. H. Herzog, *J. Amer. Chem. Soc.*, **79**, 3647 (1957).
2) T. Seiyama, A. Ichikawa, and T. Inoue, *Kogyo Kagaku Zasshi*, **66**, 573 (1963).
3) T. Seiyama, A. Kato, T. Ikeda, and H. Miyazaki, *ibid.*, **68**, 449 (1965).

5) F. E. Hubbard, *Ind. Eng. Chem.*, **41**, 2908 (1949).

Studies of the thermal reaction of equimolar mixtures of mono- and disodium orthophosphates were also performed; particularly, the reaction mechanisms (the formation of liquid $Na_3HP_2O_7$ from a pyrophosphates mixture, etc.) were investigated by the use of the "^{32}P" radioisotope.

Experimental

Reagents. The Na_2HPO_4 was a commercially available substance (Analytical grade; Wako Pure Chemical Industries, Ltd.); it was dried at 110°C. The NaH_2PO_4 was prepared from commercial $NaH_2PO_4 \cdot 2H_2O$ (Analytical grade; Wako) by thermal dehydration at 110°C.

Differential Thermal Analysis (DTA) and Thermogravimetric Analysis (TGA). DTA and TGA were done simultaneously by the use of a Thermoflex (DG-C1H, Rigaku-Denki Co., Ltd.). Heating rates were 2.5°C/min and 5°C/min, respectively.

As to quenched samples, X-ray diffraction analysis and chromatographic analysis were done. The quenched samples were prepared as follows;

Equimolar mixtures of mono- and disodium orthophosphates were heated to the appointed temperature at the heating rate of 2.5°C/min by the use of the Thermoflex, and then the heated mixtures were rapidly quenched. (Sample No. 1: 223°C, Sample No. 2: 303°C, Sample No. 3: 380°C).

X-Ray Diffraction Analysis. The X-ray diffraction work was done by the use of a Geigerflex (D-9C, Rigaku-Denki Co., Ltd.). The X-ray diffraction analysis was made by the use of the diffraction angles[6] shown in Table 1. Cu$K\alpha$ radiation was used.

Table 1. X-ray diffraction angles used in X-ray diffraction analysis

Phosphates	2θ (°)
$Na_5P_3O_{10}$ (I)	21.8, 29.1
$Na_5P_3O_{10}$ (II)	24.8
$Na_4P_2O_7$	26.4
$Na_3P_3O_9$	26.2
$NaPO_3$ (II)	30.9
$Na_2H_2P_2O_7$	30.5, 25.9

Chromatographic Analysis. The thin-layer chromatographic analysis was done using acidic and basic developing solvents.

Acidic Solvents.[7] Isopropanol-60 m*l*; water-40 m*l*; trichloroacetic acid-4 g; ammonia water(28%)-0.25 m*l*; and acetic acid-1.5 m*l*.

Basic Solvents.[9] Isopropanol-40 m*l*; isobutanol-20 m*l*; ammonia water(28%)-1 m*l* and water-39 m*l*.

The Na_2HPO_4 and NaH_2PO_4 were weighed accurately to make them easy to mix, and then they were enclosed in polyethylene tubes and neutron bombardment was made using JRR-2 ($\phi_n = 8 \times 10^{13}$ n/cm^2·sec; 5 min; reactor temperature) at the Japan Atomic Energy Research Institute, Tokai, Ibaraki.

The formation of phosphorus oxyacids and of polyphosphates other than phosphates is thought to be fairly slight under these conditions,[10] so we did not consider them.

One mole of Na_2HPO_4 was mixed with one mole of neutron applied NaH_2PO_4 (Sample A), and one mole of NaH_2PO_4, with one mole of neutron applied Na_2HPO_4 (Sample B). The two samples were simultaneously heated from room temperature up to the temperature of 380°C at the heating rate of about 3°C/min in quartz tubes in an electric furnace.

Radioactivity Measurements. Sample A and Sample B were dissolved in water, and the undissolved substances were separated by the use of a glass filter. The radioactivity of the undissolved substances was measured using a G.M. counter (SA-30, Ten Kogyo).

Results and Discussion

The DTA and TGA curves of an equimolar mixture of Na_2HPO_4 and NaH_2PO_4 are shown in Fig. 1.

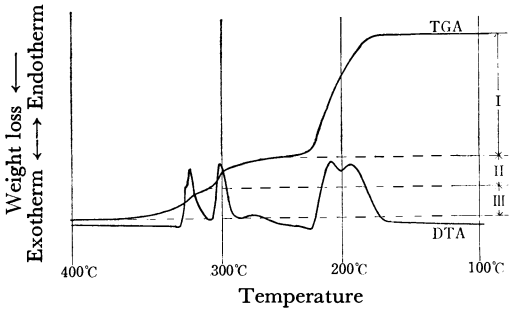

Fig. 1. DTA and TGA curves of equimolar mixture of Na_2HPO_4 and NaH_2PO_4.
Heating rate: 2.5°C/min Sample weight: 389 mg
I: obsd −25.9 mg, calcd −26.7 mg
II: obsd −6.6 mg, calcd −6.7 mg
III: obsd −6.6 mg, calcd −6.7 mg

According to X-ray diffraction analysis and chromatographic analysis, the main substances existing in the quenched samples are as follows:

Sample No. 1: $Na_2H_2P_2O_7$ and $Na_4P_2O_7$

Sample No. 2: $Na_5P_3O_{10}$ (I), and $Na_2H_2P_2O_7$

Sample No. 3: $Na_5P_3O_{10}$ (I), $Na_5P_3O_{10}$ (II), and $NaPO_3$ (II)

We could not separate the endothermic reactions with peaks at 193°C and 210°C. DTA was done on mixtures of orthophosphates in different proportions ($Na_2HPO_4 : NaH_2PO_4 = 2 : 1$, $1 : 1$, and $1 : 2$ (mole ratio)). The results are shown in Fig. 2. It is thought that the endothermic reaction with a peak at 193°C corresponds to the reaction (7), and that the one at 210°C corresponds to the reaction (8):

$$2NaH_2PO_4 \longrightarrow Na_2H_2P_2O_7 + H_2O \quad (7)$$

$$2Na_2HPO_4 \longrightarrow Na_4P_2O_7 + H_2O \quad (8)$$

The endothermic reaction with the peak at 301°C is considered to correspond to this reaction:

$$\left.\begin{matrix} Na_2H_2P_2O_7 \\ Na_4P_2O_7 \end{matrix}\right\} \longrightarrow Na_5P_3O_{10}\,(I) + 1/2Na_2H_2P_2O_7 + 1/2H_2O \quad (9)$$

7) A solvent slightly modified from the solvent in Ref. 8 was used.

8) E. Thilo and W. Feldmann, *Z. Anorg. Allg. Chem.*, **298**, 316 (1959).

9) E. Karl-Kroupa, *Anal. Chem.*, **28**, 1091 (1956).

10) S. Ohashi *et al.*, "KURRI-TR-52 (Kyoto University Reactor Research Institute Technical Reports)," (1968), p. 23.

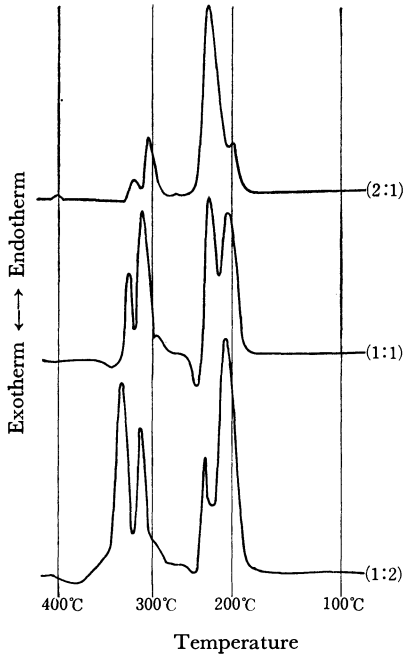

Fig. 2. DTA curves of mixtures of orthophosphates in different proportion (Na_2HPO_4: NaH_2PO_4= 2:1, 1:1, and 1:2 (mole ratio)).
Heating rate: 5°C/min

Further, the endothermic reaction with the peak at 321°C is considered to correspond to this reaction:

$$1/2Na_2H_2P_2O_7 \longrightarrow NaPO_3\,(II) + 1/2H_2O \qquad (10)$$

The final products were sodium tripolyphosphate and sodium metaphosphate (type II). The former is soluble in water, while the latter is insoluble in water. Therefore, these two substances can be separated when the final products are dissolved in water and filtered.

Table 2. Results of radioactivity measurements

Sample	before filtration ($Na_5P_3O_{10}$+$NaPO_3$ (II))	after filtration ($NaPO_3$(II))
A	12150±100 cpm	3374±194 cpm
B	6909±240 cpm	1383± 27 cpm

The results of the radioactivity measurements are shown in Table 2. As for sample A, the ratio of the radioactivity after filtration ($NaPO_3$(II)) to that before filtration ($Na_5P_3O_{10}$+$NaPO_3$(II)) was about 1 : 3.6. As for Sample B, the ratio was about 1 : 5.0.

If all of the $Na_2H_2P_2O_7$ and $Na_4P_2O_7$ react to liquid $Na_3HP_2O_7$ and are then converted to $Na_5P_3O_{10}$(I) and $Na_2H_2P_2O_7$, the ratio should be 1 : 4 (Scheme 1). However, the results do not agree with this value. It is, therefore, better to think of some different processes in this case. Two processes can be considered.

First, it is thought that the decomposition of liquid $Na_2HP_2O_7$ to $Na_2H_2P_2O_7$ and $Na_4P_2O_7$ occurs,[4] but that the ratio should be 1 : 4 if there is no feedback phenomenon of $Na_2H_2P_2O_7$ (this will be discussed below).

Second, it is thought that the formation of liquid $Na_3HP_2O_7$ from $Na_2H_2P_2O_7$ and $Na_4P_2O_7$ is slow, that the conversion to $Na_5P_3O_{10}$(I) and $Na_2H_2P_2O_7$ is fast, and that the feedback phenomenon of $Na_2H_2P_2O_7$ occurs. If only one feedback of $Na_2H_2P_2O_7$ is assumed, it is calculated that about 6.5% of the $Na_2H_2P_2O_7$ is fed back. (For Sample A, the ratio is about 1 : 3.4, and for Sample B, the ratio is about 1 : 4.8 (Scheme 2).)

The $Na_5P_3O_{10}$(II) in Sample No. 3 is thought to be formed by the conversion of the $Na_5P_3O_{10}$(I) in Sample No. 2.[1] The reaction precess is shown in Scheme 3.

Study of Hydration and Association of Ions in Solution. I. Chromatographic and Electrophoretic Behaviors of Hexamminetype Cobalt(III) Complexes in Aqueous Solutions of Various Electrolytes

Hayami YONEDA, Masayuki MUTO, Tetsuo BABA,[1] and Takao MIURA
Department of Chemistry, Wakayama University, Masagocho, Wakayama
(Received March 30, 1970)

The dissolved state of ions in solution was investigated through the study of separation mechanism of a series of tervalent hexammine-type cobalt(III) complexes in thin-layer chromatography and in electrophoresis. The results obtained are summarized as follows. In the case of strongly hydrated complexes, a strongly hydrated anion has a greater tendency towards association than a weakly hydrated anion. On the contrary, in the weakly hydrated complexes, a weakly hydrated anion is associated more easily than a strongly hydrated anion. From these findings, ionic association was presumed to occur through direct contact of a complex cation and an anion.

We have been studying the dissolved state of ions by use of inert metal complexes. The reasons for our using inert metal complexes instead of simple salts are as follows: 1) In the case of simple cations, *i. e.*, Mg^{2+}, Fe^{2+}, Ni^{2+}, *etc.*, both direct and solvent-separated associations of anions take place simultaneously around a cation, so that a migrating cationic species changes its structure even at the first coordination sphere. In contrast to this, when inert complex salts are used, only the outer sphere association of anions around a complex cation has to be considered, because the first coordination sphere remains unchanged. Thus, the analysis of the phenomenon is expected to be much simpler. 2) In the case of complex salts, there are a series of related compounds which differ from each other in certain properties, *i. e.*, ionic charge, ionic size, number of N–H bonds, *etc.*, so that the use of such related compounds enables us to find out the effect of the property upon the phenomenon concerned.

In this paper we would like to report the results of experiments with thin-layer chromatography and paper electrophoresis in which a series of tervalent hexammine-type cobalt(III) complexes were used as samples and to discuss the relation between hydration and association of ions in solution.

Results and Discussion

Thin-layer Chromatography on Alumina. The hexammine-type cobalt(III) complexes used in chromatography are $[Co(NH_3)_6]Cl_3$, $[Co(NH_3)_4en]Cl_3$, $[Co(NH_3)_4pn]Cl_3$, $[Co(NH_3)_2en_2]Cl_3$, $[Co\ en_3]Cl_3$, $[Co\ tn_3]Cl_3$, $[Co\ pn_3]Cl_3$, $[Co\ dip_3]Cl_3$, and $[Co\ phen_3]Cl_3$. When these complexes were developed with distilled water, they all remained at the starting point. This is not surprising when we remember that alumina has negatively charged sites on its surface and adsorbs complex cations. However, when aqueous soultions of 0.2M NaCl and $NaClO_4$ were used as a developer, these complexes began to move and showed a regular increase of R_f values in the decreasing order of the number of N–H bonds within the complex. Further, the results from chromatograms developed in 0.2M Na_2SO_4 aqueous solution are worthy of note.

While the spots of the complexes having many N–H bonds show nearly the same R_f values both in NaCl and in Na_2SO_4 developers, the R_f values of $[Co\ dip_3]^{3+}$ and $[Co\ phen_3]^{3+}$ developed with Na_2SO_4 solution are definitely smaller than those developed with the NaCl solution (See Fig. 1).

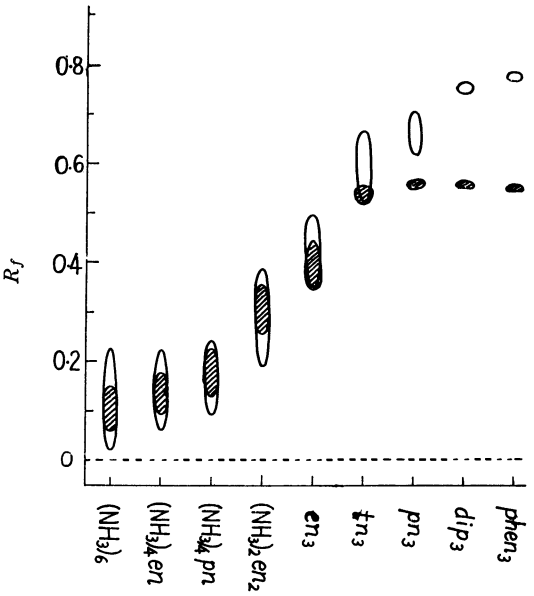

Fig. 1. Chromatogram of hexammine-type cobalt(III) complexes.
○: developed with 2M NaCl
●: developed with 2M Na_2SO_4
adsorbent: alumina

This can be interpreted in terms of ionic association. Through such ionic association, the complex cation reduces its apparent positive charge, which results in the decreased adsorption on alumina and in the increased R_f value. Since hydration of the complex cation is presumed to take place not only by ion-dipole attraction but also through hydrogen bonds between the N–H bonds and solvent water molecules, the degree of hydration is expected to decrease with the decreasing number of N–H bonds within the complex. Thus, the present results are summarized as follows. 1) Ionic association proceeds more easily when the complex has a lower

1) On leave from the Minoshima High School, Arita-shi, Wakayama.
2) T. Baba, M. Muto, and H. Yoneda, This Bulletin, **42**, 2697 (1969).

number of N–H bonds within itself, that is, when the complex is less hydrated.

2) As far as weakly hydrated complexes such as [Co-dip$_3$]$^{3+}$ or [Co phen$_3$]$^{3+}$ are concerned, a univalent anion like Cl^- or ClO_4^- forms an ion-pair more easily than bivalent anion like SO_4^{2-} does.[3] In other words, the more weakly an anion is hydrated, the more easily it forms an ion-pair with a weakly hydrated complex.

Electrophoresis. Although information concerning hydration and association of ions in solution can be obtained through chromatography by use of a simple device, the analysis of the result is not always simple, because adsorption plays an essential role in the process of development. In fact, the above mentioned chromatographic behavior of the complexes can be explained in terms of adsorption also. If we assume that adsorption on alumina is caused not only by the mere electrostatic attraction but also through the Al–O··· H–N–Co type hydrogen bonds to a large extent, it is easily understood that the complex having more N–H bonds is adsorbed more firmly and shows a smaller R_f value than the complex having less N–H bonds. Thus, it may be reasonable to assume that both mechanisms, association and adsorption, work together in the actual development process. In this respect, electrophoresis has an advantage of facilitating the analysis of the result, because adsorption can be eliminated by selecting suitable conditions.

The electrophoresis of tervalent hexammine-type cobalt(III) complexes were studied by Mazzei and Lederer.[4] They measured the mobilities of [Co-(NH$_3$)$_6$]$^{3+}$, [Co en$_3$]$^{3+}$, [Co dip$_3$]$^{3+}$ and [Co phen$_3$]$^{3+}$ in several kinds of salt solutions and showed a marked effect of ionic association upon the mobility of the complex. However, they did not give a detailed discussion of the mechanism of association. We have carried out a similar measurement using a wide variety of background electrolytes in order to find the mechanism of association.

Figure 2 shows a part of the results. Hexammine-type cobalt(III) complexes are represented with their ligands NH_3, en, tn, dip, and phen and arranged in the decreasing order of hydration from left to right. Anions shown at the sides of the curves represent the background electrolytes which were used in electrophoresis. Sodium salts were used in all cases. The ordinate corresponds to the mobility of the complex. (Here the mobility is defined as the relative migrating distance of a complex, when the migrating distance of [Co en$_3$]$^{3+}$ in 0.1 M NaCl is taken to unity.)

Let us consider the behavior of the [Co(NH$_3$)$_6$]$^{3+}$ complex. This complex is presumed to be most highly hydrated through many hydrogen bonds between the coordinating NH_3 and solvent water. In this case, it should be noted that the mobility of the complex is definitely larger in solutions containing univalent anions

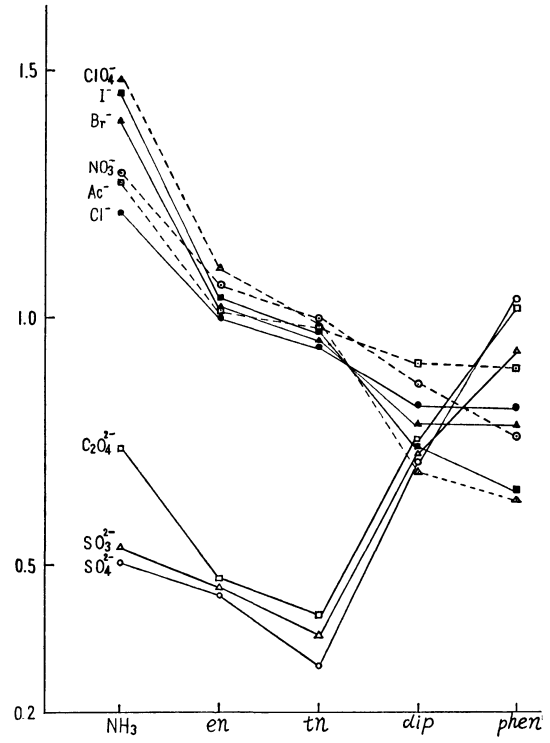

Fig. 2. Electrophoretic migration of hexammine-type cobalt (III) complexes in various background solutions.
potential gradient 500 V/34 cm
time about 1 hour
temperature 25°C
concentration of a background electrolyte 0.1 M

than in solutions containing bivalent anions. In other words, migration of the complex cation is retarded to a greater extent by bivalent anions than by univalent ones. Such difference in mobility is observed also in the cases of [Co en$_3$]$^{3+}$ and [Co tn$_3$]$^{3+}$, though less markedly. However, in the case of [Co dip$_3$]$^{3+}$ and particularly of [Co phen$_3$]$^{3+}$, the situation is the reverse. The complex cation migrates more easily in a solution containing bivalent anions than in a solution containing univalent ones.

Let us next consider the trend of mobilities of the complexes in a certain salt solution from the highly hydrated [Co(NH$_3$)$_6$]$^{3+}$ complex to the poorly hydrated [Co phen$_3$]$^{3+}$ complex. In the case of a salt solution containing univalent anions, the mobility of the complex decreases in the decreasing order of hydration of the complex. On the other hand, a reversed trend is observed in the case of a solution containing bivalent anions, the mobility increasing with the decrease of hydration.

Such a variation of mobility can be attributed to various degrees of the electrostatic withdrawing effect of anions. However, it is more effective to consider the phenomenon in terms of ionic association

$$\text{Complex cation} + \text{anion} \rightleftarrows \text{ion-pair}$$

Through such association, the complex cation reduces its apparent positive charge. This results in the decrease of mobility. Thus, it can be concluded that the more the mobility is decreased, the more the equilibrium can be considered to be shifted towards ion-pair forma-

3) The hydration number of ions can be estimated by various methods. As an example, Padova estimated the hydration number of Cl^-, ClO_4^- and SO_4^{2-} to be 1.1 and 4, respectively, from the amount of Volume decrease of an ionic solution due to hydration (J. Padova, *J. Chem. Phys.*, **39**, 1552 (1963)).

4) M. Mazzei and M. Lederer, *J. Chromatog.*, **31**, 1965 (1967).

tion. The present results can be summarized as follows. In the highly hydrated complex such as $[Co(NH_3)_6]^{3+}$, the bivalent anion is associated with it more easily than the univalent anion is. However, in the weakly hydrated complex such as $[Co\ phen_3]^{3+}$, the situation is reverse. The univalent anion can form an ion-pair more easily than the bivalent anion. In certain salt solution containing univalent anions, the association takes place more easily in a less hydrated complex, and in a certain salt solution containing bivalent anions, association takes place more easily in the more hydrated complex.

The results are in good agreement with the interpretation of the chromatographic behavior of the complexes. As to the hydration of anions, it is reasonably assumed that the bivalent anion is more strongly hydrated than the univalent anion. Thus, we can state as follows. In a strongly hydrated complex, association with a strongly hydrated anion takes place more easily than that with a weakly hydrated anion, and in a weakly hydrated complex, association occurs with a weakly hydrated anion more easily than with a strongly hydrated anion. In either case, ionic association is presumed to take place not in a solvent-separated state but rather by the direct contact of an anion and a complex cation. The strength of hydration is considered to correspond to the tendency towards hydrogen bonding. Thus, a strongly hydrated anion is expected also to form a strong hydrogen bond with the N–H bond of a strongly hydrated complex. This is regarded as the main cause of ionic association in a strongly hydrated complex. In fact, the strength of the hydrogen bonds between the N–H bonds and the outer-sphere anions is estimated from the shift of the N–H stretching frequency of the $[Co(NH_3)_6]^{3+}$ and $[Co\ en_3]^{3+}$ complexes (hydrogen bonding is expected to weaken N–H bond and shift the N–H stretching band to a lower frequency). The infrared data[5] indicate that the strength of the hydrogen bonds is in the order $Cl^->Br^->I^-$. This is in good agreement with the present results.

A weakly hydrated complex has no tendency towards hydrogen bonding. Thus, a strongly hydrated anion has little tendency towards association, because the removal of the solvating water molecules from the anion is not compensated for by the hydrogen bonding with the complex. Thus, a weakly hydrated univalent anion has an advantage for association because the energy required for the removal of the solvating water molecules in less as compared with the case of the more strongly hydrated bivalent anion.[6] This trend is observed not only between the uni- and bivalent anions, but also among univalent anions. Thus, the mobility data indicate that ionic association takes place in the order $I^->Br^->Cl^-$ in the case of a weakly hydrated complex such as $[Co\ dip_3]^{3+}$ and $[Co\ phen_3]^{2+}$. This is just the reverse order of the hydration energies of these halide ions.

Table 1. Mobilities of complex cations in a series of electrolyte solutions

The mobility of the $[Co\ en_3]^{3+}$ complex in 0.1M NaCl solution is taken as standard.

Anion	$[Co(NH_3)_6]^{3+}$	$[Co\ en_3]^{3+}$	$[Co\ tn_3]^{3+}$	$[Co\ dip]^{3+}$	$[Co\ phen_3]^{3+}$
1) In 0.1M electrolyte solutions					
Cl^-	1.21	1.00	0.94	0.82	0.84
Br^-	1.40	1.02	0.95	0.78	0.80
I^-	1.46	1.03	0.96	0.73	0.64
Ac^-	1.29	1.01	0.96	0.90	0.90
ClO_4^-	1.49	1.10	0.98	0.68	0.63
NO_3^-	1.29	1.04	0.99	0.86	0.76
$C_2O_4^{3-}$	0.73	0.45	0.39	0.78	1.03
SO_3^{2-}	0.53	0.43	0.35	0.76	0.93
SO_4^{2-}	0.50	0.43	0.29	0.74	1.03
2) In 0.5M electrolyte solutions					
Cl^-	1.00	0.65	0.64	0.61	0.60
Br^-	1.03	0.72	0.65	0.53	0.52
I^-	1.16	0.75	0.67	0.40	0.34
Ac^-	0.98	0.68	0.67	0.66	0.57
ClO_4^-	1.05	0.73	0.72	0.30	0.27
NO_3^-	0.97	0.77	0.75	0.50	0.48
$C_2O_4^{2-}$	0.55	0.53	0.36	0.62	0.69
SO_3^{2-}	0.35	0.26	0.25	0.55	0.58
SO_4^{2-}	0.33	0.24	0.23	0.61	0.64

The above discussion is based on the mobility data of the complexes in 0.1M electrolyte solutions. The same conclusion can be drawn when 0.5M electrolyte solutions are used as a background, as can be seen in Table 1. However, comparison of the two sets of data obtained in 0.1M and 0.5M solutions revealed that the mobility order of a complex in a series of background solutions in the both cases showed a slight difference from each other. Thus, the mobility of the $[Co(NH_3)_6]^{3+}$ complex in 0.5M solutions decreases in the order

$$I^- > ClO_4^- > Br^- > Cl^- > Ac^- > NO_3^-$$

while the mobility of the same complex in 0.1M solutions decreases in the order

$$ClO_4^- > I^- > Br^- > NO_3^- > Ac^- > Cl^-$$

Therefore, the association tendency in 0.5M solutions is presumed to increase in the order

$$I^- < ClO_4^- < Br^- < Cl^- < Ac^- < NO_3^-$$

while the association tendency in 0.1M solutions is presumed to increase in order

$$ClO_4^- < I^- < Br^- < NO_3^- < Ac^- < Cl^-$$

Thus, the order of association tendency concerning the $[Co(NH_3)_6]^{3+}$ complex in a certain series of electrolyte solutions various with the concentration of an electrolyte solution. This can be explained in the following way. With the increases of the concentration of a solution, the number of the solvating water molecules per one complex cation is presumed to decrease, and the complex is presumed to become poorly hydrated. Owing to such sort of dehydration, the highly hydrated $[Co(NH_3)_6]^{3+}$ in 0.1M background electrolyte solution be-

5) J. Fujita, K. Nakamoto, and M. Kobayashi, *J. Amer. Chem. Soc.*, **78**, 3295 (1956).

6) Among univalent anions, the acetate ion is considered to be strongly hydrated. Thus, the mobility of the $[Co\ dip_3]^{3+}$ and $[Co\ phen_3]^{3+}$ in the acetate solution is fairly large, compared with that in the halide solution.

comes poorly hydrated in the more concentrated background solution, and the hydrated state of the $[Co(NH_3)_6]^{3+}$ becomes similar to that of the less hydrated species like $[Co\ en_3]^{3+}$ and $[Co\ tn_3]^{3+}$ or even to that of the least hydrated $[Co\ dip_3]^{3+}$ and $[Co\ phen_3]^{3+}$ in 0.1M solution. The change in the order of the association tendency with variation of the background electrolyte concentration can thus be understood.

The association constants of the $[Co(NH_3)_6]^{3+}$ and $[Co\ en_3]^{3+}$ with the halide ions are in the order $I^-<Br^-<Cl^-$.[7-9] On the other hand, the solubility of $[Co(NH_3)_6]X_3$ and of $[Co\ en_3]X_3$ (X=Cl, Br, and I) is in the order $I^-<Br^-<Cl^-$. These two trends contradict each other. If we regard the undissolved complex salt which is in equilibrium with the saturated solution, as the final product of ionic association, it is expected from the data of the association constant that the solubility should increase in the order $Cl^-<Br^-<I^-$. However, this is not the case. This apparent discrepancy can be understood by the above consideration. In other words, the hydrated state of $[Co(NH_3)_6]^{3+}$ and $[Co\ en_3]^{3+}$ in the saturated solution is presumed to be similar to that of $[Co\ dip_3]^{3+}$ and $[Co\ phen_3]^{3+}$ in solution, for example in a 0.1M background electrolyte solution. In the latter case, the association constant is presumed to increase in the order $Cl^-<Br^-<I^-$, which is just the same order of decreasing solubility of $[Co(NH_3)_6]X_3$ and $[Co\ en_3]X_3$ (X=Cl, Br, and I).

Concerning the behavior of the perchlorate ion, it is believed that the perchlorate ion has little tendency toward complex formation with a metal ion and also has little associating ability with a complex cation. Consequently, sodium perchlorate is often used to keep the ionic strength of a series of solutions constant in the determination of the formation constant and of the association constant. However, although the tendency of the perchlorate ion toward association with $[Co(NH_3)_6]^{3+}$ and $[Co\ en_3]^{3+}$ is least among univalent anions, it is almost the same as that of the iodide ion as can be seen in Fig. 2. Furthermore, the order of the associating ability of the perchlorate and iodide is reversed in the case of 0.5M background solution. In addition, the association tendency of the perchlorate ion with the hydrophobic complex cations like $[Co\text{-}dip_3]^{3+}$ and $[Co\ phen_3]^{3+}$, is the largest among univalent anions studied. Thus, we must re-examine the validity of the use of the perchlorate for adjustment of ionic strength in the study of an association equilibrium.

Addition of the perchlorate ion to the equilibrium system, *i. e.*,

$$[Co(NH_3)_6]^{3+} + \text{anion } X^- \rightleftarrows \text{ion-pair}$$

gives vise to a new equilibrium

$$[Co(NH_3)_6]^{3+} + ClO_4 \rightleftarrows \text{ion-pair}$$

which causes a big change in the first equilibrium, if the associating ability of the perchlorate ion is comparable to or larger than that of the anion X^-.

The association constants of the $[Co(NH_3)_6]^{3+}$ and $[Co\ en_3]^{3+}$ complexes with the halide and sulfate ions were determined by various methods. For instance Evans and Nancollas[7] determined spectrophotometrically the association constants of the $[Co(NH_3)_6]^{3+}$ with the halide ions, whereas King *et al.*[8] obtained the different values of the association constants of the same ion-pair. Tanaka *et al.*[9] redetermined the association constants of these two complexes with the halide and sulfate ions by the spectrophotometric method under the same ionic strength as by Evans and Nancollas. However, they got quite different values. They attributed this to the inaccurate measurement of optical density by Evans and Nancollas. However, this does not seem to give an explanation. If we assume the big influence of the perchlorate ion upon the equilibrium, the difference can be explained. Although both groups of workers used the same ionic strength, the conditions under which they worked were quite different. Evans and Nancollas worked with very low concentrations and Tanaka *et al.* much higher concentrations of the halide ions as compared with the complex ion. This makes the equilibrium quite different. Thus, it becomes clear that the association constant is of little value unless the disturbing effect of the perclorate ion is taken into consideration.

Experimental

Thin-layer Chromatography on Alumina. As an adsorbent, Merck's aluminum oxide H prepared for thin-layer chromatography was used without further purification. This was spread in 250 μ thickness over a glass plate of 20 cm length. Solutions were applied at a starting point 5 cm above the lower edge of the plate and development was carried out to a distance of 14 cm above the starting point. A sodium sulfate solution was sprayed for visualization of the spot.

Paper Electrophoresis. A migration apparatus with multi-compartment cells was used, so that ten samples could be run at the same time. A paper strip was dipped uniformly in the background electrolyte solution and then the excess of the solution was removed by hanging the strip. After that, about 5 μl of a sample solution was placed on the paper strip (Toyoroshi No. 51 A, 2×40 cm). Samples were run for about one hour under a potential gradient 500 V/34 cm, keeping the temperature of the migrating box at 25°C. The spot of the sample was detected in the same way as in thin-layer chromatography.

The authors wish to express their thanks to Dr. Y. Kiso, Kyoto University, for his kind advice in the electrophoresis experiment.

Rapid Extraction of Antimony with Tributyl Phosphate. Direct Photometric Determination with Brilliant Green

A. A. YADAV and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay-76, India

(Received April 17, 1970)

A new method is developed for the rapid extraction and direct photometric determination of antimony. With 20% TBP-toluene 3 to 15 μg of antimony is extracted from 2M hydrochloric acid containing 1M magnesium chloride. From the organic phase, antimony is directly determined photometrically at 640 nm as its complex with brilliant green. Antimony can be selectively extracted in the presence of a large number of cations and anions. The total operation requires only 20 min.

The methods for the solvent extraction of antimony are best summarised by De, Khopkar[1] in their recent monograph. Tri-dodecylamine,[2] diethyl ether,[3] diisopropyl ether,[4] ethyl acetate,[5] isoamyl acetate,[6] and diisobutyl carbinol[7] were used for the solvent extraction of antimony from mineral acids. The iodocomplex of antimony[8–11] was extracted in benzene from 3—5M sulphuric acid. The complexes of antimony with dyes such as rhodamine B,[12–13] crystal violet;[12–15] methyl violet,[16] pyridylazo compounds[17] malachite green[18] and brilliant green [19–20] were extracted with organic solvents. Bis(2-ethylhexyl) phosphoric acid[21] in heptane was similarly used. However, these methods have certain limitations. They are time consuming, tedious and are neither selective nor applicable at microgram concentrations of antimony.

The method proposed in this paper is rapid, simple and permits clean-cut separation of antimony. 20% TBP-toluene quantitatively extracts antimony from 2M hydrochloric acid with 1M magnesium chloride as the salting-out agent. Antimony from the organic phase is then directly determined photometrically as its complex with brilliant green at 640 nm.

Experimental

Apparatus and Reagents. Type ϕ3KH-57 photoelectric photometer; Type C ϕ8-recording spectrophotometer with matched 10 mm glass cuvettes; Wrist action flask shaker: Cambridge pH indicator.

A stock solution of antimony was prepared by dissolving about 0.27 g of potassium antimonyl tartrate hemihydrate in 10 m*l* of 6N hydrochloric acid.[22] The solution was then made to one liter with water. On standardisation volumetrically with[23] Chloramine-T, it was found to contain 100 μg/m*l* of antimony. The dilute solution was prepared by ten-fold dilution. Tributyl phosphate (B.D.H), bp 143°C.

Brilliant green (B.D.H. Anal R): 0.05% aqueous solution.

General Procedure. An aliquot of solution containing about 10 μg of antimony was taken. In a total volume of 10 m*l*, hydrochloric acid and magnesium chloride were added so that each had a concentration of 2 and 1M respectively. The solution was then transferred to a separatory funnel. Ten milliliters of 20% TBP in toluene (0.73M) was then added. The mixture was vigorously shaken for about three minutes. The two phases were allowed to settle and separate. After withdrawing the aqueous phase, the organic phase was once

again shaken with 2 ml of 0.05% solution of brilliant green for about three minutes. After separating the two phases, the green colored complex[20] of antimony in the organic phase was measured photometrically against a reagent blank at 640 nm.

Results and Discussion

Absorption Spectra. The absorption spectrum of the solution of antimony(III)-brilliant green complex in tributyl phosphate-toluene ($Sb=8.22\times10^{-6}$M) is shown in Fig. 1. The colored complex shows strong absorbance at 640 nm. The reagent blank at this wavelength also shows some absorbance. The difference in absorbance of reagent blank and complex is maximum at 640 nm; hence all absorbance measurements were carried out at this wavelength. The molecular extinction coefficient at 640 nm is 7.3×10^4.

Effect of Acidity and TBP Concentration. The hydrochloric acid concentration was varied from 0.5—5M in the presence of 1M magnesium chloride. The concentration of TBP was varied from 10—100% (0.37—3.66M) with toluene as a diluent. It was observed (Table 1) that quantitative extraction of antimony is possible from 2M hydrochloric acid with 20% TBP-toluene in the presence of 1M magnesium chloride as a salting-out agent. The distribution ratios (D) were

at 3M hydrochloric acid concentration. With further increase in acidity there is no change in the absorbance. Since these extractions were carried out in the absence of salting-out agent the extraction was quantitative at 3M hydrochloric acid. However, if 1M magnesium chloride is used as the salting-out agent the extraction is complete even at 2M hydrochloric acid.

Beer's Law. Different amounts of antimony were extracted at 2M hydrochloric acid in the presence of 1M magnesium chloride with 20% TBP-toluene (Table 3). They were measured at 640 nm as their complexes with brilliant green. The system conforms to Beer's law over the concentration range of 0.15—15 μg/m*l* of antimony at 640 nm. Sandell's sensitivity was found to be 0.0017 μg/cm^2 of antimony.

Effect of Salting-out Agent. Ammonium, lithium, magnesium, and aluminium chlorides (0.5—2M) were used as the salting-out agents when hydrochloric acid concentration used was 0.5—2M. The results show (Table 4) that ammonium chloride is not a good salting-out agent. 1M lithium, magnesium, or aluminium chloride are effective salting-out agents, at 2M hydrochloric acid concentration. On account of the ease of availability of 1M magnesium chloride, it was preferred as the salting-out agent.

Table 5. Effect of brilliant green concentration
Sb(III)=10 μg; 20% TBP toluene; 2M HCl+1M $MgCl_2$

Reagent concn.	Volume in m*l*	Absorbance at 640 nm
0.001	2	0.010
0.005	2	0.100
0.010	2	0.300
0.02	2	0.450
0.04	2	0.600
0.05	2	0.600
0.05	4	0.600
0.05	5	0.600

Effect of Brilliant Green Concentration. With all other factors kept constant the concentration of brilliant green was varied from 0.001 to 0.05 per cent (Table 5) in the aqueous solution. It was observed that 2 m*l* of 0.05 per cent aqueous solution of brilliant green was quite adequate for color development in 20% TBP toluene media.

Period of Shaking. The period of equilibration during extraction with TBP and during color development with brilliant green was varied from 30 sec to 20 min. In both cases the optimum period of extraction is three minutes.

Table 6. Stability of color of the complex

Time, hr	Absorbance at 640 nm
0.5	0.600
1	0.600
2	0.600
4	0.600
8	0.600
12	0.600
18	0.600
24	0.560
48	0.480

Stability of the Color. The absorbance of the colored complex was measured at lapsed intervals of time (Table 6). The complex decomposes after 18 hr. Therefore, it is recommended to measure the absorbance within the first 12 hr after extraction.

Effect of Diverse Ions. Various ions were studied to observe their effect on the process of extraction (Table 7). The tolerance limit was calculated as the amount to cause $\pm$2% error in antimony recovery. Lead, copper, zinc, cobalt, nickel, zirconium, beryllium, alkali and alkaline earths, thorium, cerium, uranium, selenite, tellurite, phosphate, acetate, and fluoride are tolerated in larger ratios (>1 : 500). Ions like silver, cadmium, bismuth, iron, organic complexing acids, thiocyanate, thiosulphate are tolerated in the ratio of 1 : 100. However, platinum metals, mercury, tin, titanium are tolerated in smaller amounts. Thallium, gold, chromate, bromide, and chlorate interfere. Some interferences can be eliminated by masking ions with EDTA, pyrophosphate, tartaric acid, and sodium fluoride (Table 7).

a) 2500 μg of EDTA was used for masking.
b) 5000 μg of alkali pyrophosphate was used for masking.
c) 2500 μg of Tartaric acid was used for masking.
d) 5000 μg of sodium fluoride was used for masking.

From ten runs with 10 μg of antimony using the general procedure the average recovery is 99.2±0.8%, the relative standard deviation being 1.3%. Each determination took a total of 20 min.

A Polarographic Study of the Complex Formation Equilibria of the Lead(II) Ion with Aspartic and Iminodiacetic Acids

Mutsuo KODAMA and Sozo TAKAHASHI*

Department of Chemistry, Ibaraki University, Bunkyo, Mito, Ibaraki

(Received May 8, 1970)

In this experiment, we studied the complex formation equilibria of the lead(II) ion with aspartic acid and iminodiacetic acid by using the polarographic method. In acetate buffer solutions ($5.80>pH>3.70$), the lead(II) ion forms one normal complex, PbX^0, and two mixed ligand complexes involving the acetate ion, $PbX(Ac)^-$ and $PbX(Ac)_2^{2-}$, with aspartic acid. On the other hand, with iminodiacetic acid, it forms a normal complex, PbX^0, and only one mixed ligand complex, $PbX(Ac)^-$. By observing the effects of the concentrations of the hydrogen ion, the acetate ion, and aspartic acid or iminodiacetic acid on the half-wave potential of the lead(II) ion, their formation constants were determined to be as follows:

$$(K^{Ac}_{PbX})_{Asp} = \frac{[PbX(Ac)^-]}{[PbX^0]\cdot[Ac^-]} = 7.0\times 10, \quad (K^{Ac}_{PbX(Ac)})_{Asp} = \frac{[PbX(Ac)_2^{2-}]}{[PbX(Ac)^-]\cdot[Ac^-]} = 1.3_4,$$

$$(K^{Ac}_{PbX})_{IDA} = \frac{[PbX(Ac)^-]}{[PbX^0]\cdot[Ac^-]} = 3.0, \quad (K_{PbX})_{Asp} = \frac{[PbX^0]}{[Pb^{2+}]\cdot[X^{2-}]} = 1.0_6\times 10^6,$$

$$(K_{PbX})_{IDA} = \frac{[PbX^0]}{[Pb^{2+}]\cdot[X^{2-}]} = 5.7_0\times 10^7, \quad (K^{X}_{PbX})_{Asp} = \frac{[PbX_2^{2-}]}{[PbX^0]\cdot[X^{2-}]} = 1.4_2\times 10^2,$$

$$(K^{X}_{PbX})_{IDA} = \frac{[PbX_2^{2-}]}{[PbX^0]\cdot[X^{2-}]} = 6.0_6\times 10^3$$

In a previous paper,[1] we systematically studied the polarographic behavior of the cadmium(II) ion in an aspartate solution and reported that the cadmium(II) ion can form 1-to-2 as well as 1-to-1 complexes with aspartic acid (Asp). The lead(II) ion can also be expected to form stable complexes with aspartic acid and iminodiacetic acid (IDA). However, few equilibrium studies of the complex formation reaction of the lead(II) ion with these ligand have been conducted. In this connection, it seemed that it would be worthwhile to determine the equilibria between the lead(II) ion and Asp or IDA. In this paper, we will try to determine the solution equilibria between the lead(II) ion and Asp or IDA.

Experimental

Reagents. A standard lead(II) nitrate solution was prepared by dissolving a known amount of pure lead(II) nitrate in redistilled water. Aspartic acid and iminodiacetic acid were recrystallized twice from their aqueous solutions by adding a suitable amount of pure ethanol. The other reagents were of an analytical-reagent grade and were used without further purification. The ionic strength of the sample solution was adjusted by adding an appropriate amount of sodium perchlorate.

Apparatus and Experimental Procedures. All the polarographic studies were conducted in solutions with an ionic strength of 0.30 at 25°C. The DC current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane;[2] they were corrected for the residual current and the ohmic drop of the cell circuit. In the pH range from 3.70 to 5.80, an acetate buffer was used to keep the solution's pH constant. In an alkaline medium ($8.30<pH<10.40$), however, no buffer reagent was used, because the sample solution always contains an excess amount of uncomplexed Asp or IDA over the lead(II) ion, hence, it is considered to have a buffer capacity sufficient to keep the solution's pH constant.

Results and Discussion

The lead(II) ion in both Asp and IDA solutions invariably gave a single well-defined wave. As is illustrated by the straight lines in Fig. 1, the plot of $\log(i/(i_l-i))$ against the DC potential, E, gave a straight line with a slope falling in the range from -30 to -32 mV, a line corresponding to the two-electron reversible reduction. Here, i_l and i are the limiting current and the current at E respectively. The limiting current was exactly proportional to the bulk concentration of the lead(II) ion and to the square root of the effective pressure on the dropping mercury electrode (these results are not shown here). Therefore, the electrode reaction is reversible in the usual polarographic sense; hence, the half-wave potentials obtained can be analyzed with the aid of the theoretical relation derived thermodynamically.

In an acid solution, when the other experimental conditions are kept constant, the half-wave potential was shifted to more negative potentials by increasing the concentration of Asp or IDA. It was also shifted to the negative potentials by increasing the acetate-ion concentration. From the thermodynamic point of view, the above findings can be interpreted as resulting from the formation of lead(II) complexes of the acetate ion and Asp or the IDA anion. In a usual complex formation reaction, the coordination number of the lead(II) ion is four or six, and IDA and Asp act as tridentate

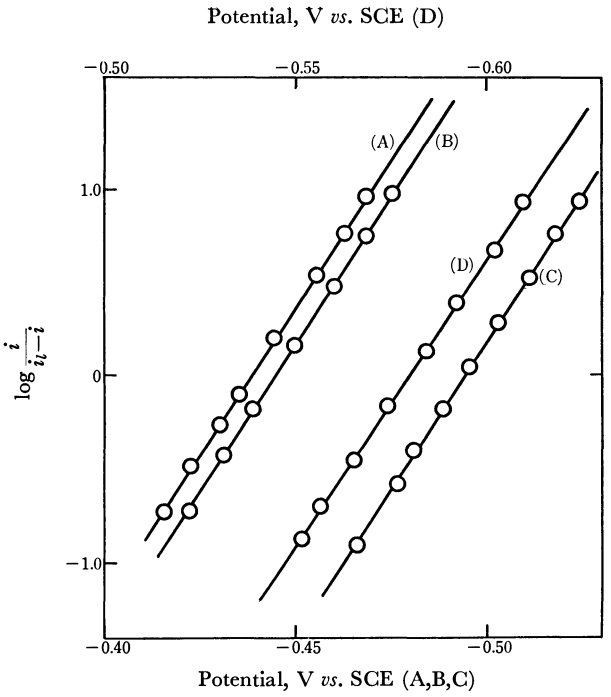

Fig. 1. The plot of log $(i/i_l - i)$ against the *d.c.* potential.
A: Concentration of acetate ion=0.20M
Concentration of lead(II) ion=0.50mM, μ=0.30
Concentration of Asp=70.0 mM, pH=5.62
B: Concentration of acetate ion=0.10M
Concentration of lead(II) ion=0.50mM, μ=0.30
Concentration of IDA=40.0 mM, pH=5.62
C: Concentration of lead(II) ion=0.50 mM
Concentration of Asp=70.0mM, pH=9.33, μ=0.30
D: Concentration of lead(II) ion=0.50 mM
Concentration of IDA=60.0mM, pH=9.50, μ=0.30

ligands. Therefore, as was discussed in connection with the polarography of the copper(II)-GEDTA complex,[3] we can assume the following electrode reaction mechanism for the lead(II) ion in acetate buffer solutions containing Asp or IDA:

$$\begin{array}{ccc} Pb(Ac)_2^0 & \rightleftarrows & Pb(Ac)^+ \\ \uparrow\downarrow & & \uparrow\downarrow \\ PbX(Ac)_2^{2-} & & Pb^{2+} + 2e^- + Hg \rightleftarrows Pb(Hg) \\ \uparrow\downarrow & & \uparrow\downarrow \\ PbX(Ac)^- & \rightleftarrows & PbX^0 \end{array} \quad (1)$$

with the shift of the half-wave potential corresponding to:

$$\Delta E_{1/2} = 0.0296\left[\log\left(1+\frac{K_{PbAc}\cdot[Ac]_f}{(\alpha_H)_{Ac}}+\frac{K_{PbAc}\cdot K^{Ac}_{PbAc}\cdot[Ac]_f^2}{(\alpha_H)^2_{Ac}} + \frac{K_{PbX}[X]_f}{(\alpha_H)_X}+\frac{K_{PbX}K^{Ac}_{PbX}[X]_f\cdot[Ac]_f}{(\alpha_H)_X(\alpha_H)_{Ac}} + \frac{K_{PbX}K^{Ac}_{PbX}K^{Ac}_{PbX(Ac)}\cdot[X]_f[Ac]_f^2}{(\alpha_H)_X(\alpha_H)^2_{Ac}}\right) + \log\frac{k_{PbX}}{k_{Pb^{2+}}}\right] \quad (2)$$

where Ac^- denotes an acetate ion, where X^{2-} denotes Asp or an IDA bivalent anion, where the k's mean the diffusion current constants, and where $[X]_f$ and $[Ac]_f$ are the concentrations of uncomplexed Asp or IDA and of acetic acid respectively. The symbols in Eq. (2) have the following meanings:

$$K_{PbAc} = \frac{[PbAc^+]}{[Pb^{2+}]\cdot[Ac^-]},\quad K^{Ac}_{PbAc} = \frac{[Pb(Ac)_2^0]}{[PbAc^+]\cdot[Ac^-]},$$

$$K_{PbX} = \frac{[PbX^0]}{[Pb^{2+}]\cdot[X^{2-}]},\quad K^{Ac}_{PbX} = \frac{[PbX(Ac)^-]}{[PbX^0]\cdot[Ac^-]},$$

$$K^{Ac}_{PbX(Ac)} = \frac{[PbX(Ac)_2^{2-}]}{[PbX(Ac)^-]\cdot[Ac^-]},$$

$(\alpha_H)_{Ac} = 1 + [H^+]/K_a$ (acetic acid),

$(\alpha_H)_X = 1 + [H^+]/K_2 + [H^+]^2/K_1\cdot K_2$ (Asp or IDA).

Since all the polarographic measurements were conducted in solutions containing large excesses of acetic acid and Asp or IDA over the lead(II) ion, the $[X]_f$ and $[Ac]_f$ in Eq. (2) can be equated with the total concentrations of acetic acid and Asp or IDA respectively. When the acetate-ion concentration and the solution's pH are kept constant, the plot of the antilog-$(\Delta E_{1/2}/0.0296+\log(k_{Pb^{2+}}/k_{PbX}))$ value against $[X]_f$ invariably gives a linear relation (Fig. 2). This clearly

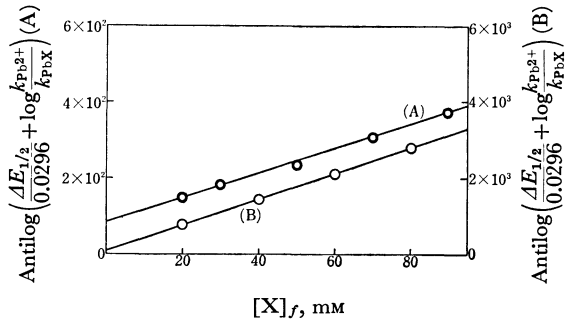

Fig. 2. The plot of antilog$(\Delta E_{1/2}/0.0296 + \log(k_{Pb^{2+}}/k_{PbX}))$ against the concentration of uncomplexed Asp or IDA.

TABLE 1. EQUILIBRIUM CONSTANTS (μ=0.30, 25°C)

$$K_{PbAc}=\frac{[PbAc^+]}{[Pb^{2+}]\cdot[Ac^-]}=2.1_8\times10^2$$

$$K^{Ac}_{PbAc}=\frac{[Pb(Ac)_2{}^0]}{[PbAc^+]\cdot[Ac^-]}=9.7_0$$

$$(K_{PbX})_{Asp}=\frac{[PbX^0]}{[Pb^{2+}]\cdot[X^{2-}]}=1.0_6\times10^6$$

$$(K_{PbX})_{IDA}=\frac{[PbX^0]}{[Pb^{2+}]\cdot[X^{2-}]}=5.7_0\times10^7$$

$$(K^{X}_{PbX})_{Asp}=\frac{[PbX_2{}^{2-}]}{[PbX^0]\cdot[X^{2-}]}=1.4_2\times10^2$$

$$(K^{X}_{PbX})_{IDA}=\frac{[PbX_2{}^{2-}]}{[PbX^0]\cdot[X^{2-}]}=6.0_6\times10^3$$

$$(K^{Ac}_{PbX})_{Asp}=\frac{[PbX(Ac)^-]}{[PbX^0]\cdot[Ac^-]}=7.0\times10$$

$$(K^{Ac}_{PbX})_{IDA}=\frac{[PbX(Ac)^-]}{[PdX^0]\cdot[Ac^-]}=3.0_9$$

$$(K^{Ac}_{PbX(Ac)})_{Asp}=\frac{[PbX(Ac)_2{}^{2-}]}{[PbX(Ac)^-]\cdot[Ac^-]}=1.3_4$$

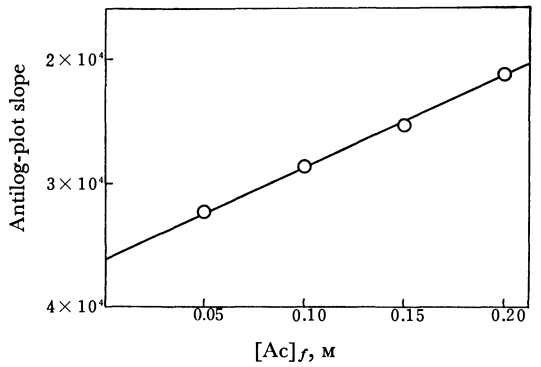

Fig. 4. The plot of antilog-plot slope against the concentration of acetate ion.
IDA system:
Concentration of lead(II) ion=0.50mM, μ=0.30, pH=5.62

indicates that the concentration of the 1-to-2 complex of Asp or IDA is negligible under the present experimental conditions. In the cases of both Asp and IDA systems, the plot of the antilog-plot −1 divided by $[Ac]_f$ *versus* $[Ac]_f$ gives a straight line (Fig. 3). On the basis of Eq. (2), it is very clear that the intercept and the slope of the straight line in Fig. 3 correspond to $K_{PbAc}/(\alpha_H)_{Ac}$ and $K_{PbAc}\cdot K^{Ac}_{PbAc}/(\alpha_H)^2_{Ac}$ respectively. The K_{PbAc} and K^{Ac}_{PbAc} determined from the intercept and the slope of the linear relation in Fig. 3 are given in Table 1. In the case of the IDA system, the plot of the antilog-plot slope *vs.* $[Ac]_f$ gave a linear relation (Fig. 4). This indicates that, with the IDA anion, the lead(II) ion forms a mixed ligand complex, $PbX(Ac)^-$, as well as a normal complex, PbX^0. From the slope and intercept of the above linear relation, the $(K_{PbX})_{IDA}$ and $(K^{Ac}_{PbX})_{IDA}$ values were determined; they are listed in Table 1. On the other hand, in the case of the Asp system, only the plot of the ratio of antilog-plot minus $(K_{PbX})_{Asp}/(\alpha_H)_X$ to $[Ac]_f$ *vs.* $[Ac]_f$ gave a straight line (Fig. 5). This suggests that, in the case of the Asp system, two mixed ligand complexes, $PbX(Ac)^-$ and $PbX(Ac)^{2-}_2$, as well as a normal complex are formed. The K^{Ac}_{PbX} and $K^{Ac}_{PbX(Ac)}$ values determined from the

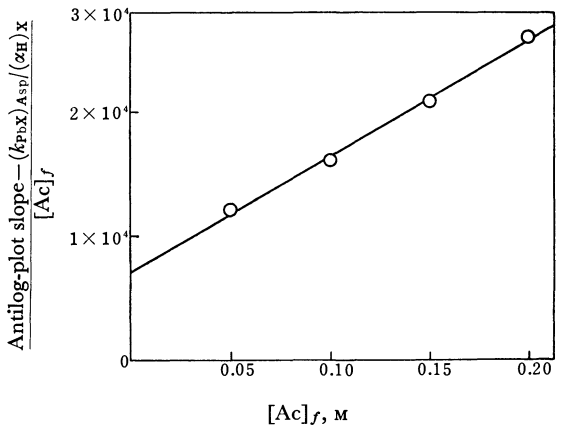

Fig. 5. The plot of (antilog-plot slope $-(k_{PbX})_{Asp}/(\alpha_H)_X$)/$[Ac]_f$ against the concentration of acetate ion.
Asp system:
Concentration of lead(II) ion=0.50mM, μ=0.30, pH=5.62

slope and intercept of the straight line in Fig. 5 are also listed in Table 1. If the above conclusion is correct, the change in the half-wave potential, $\Delta E_{1/2}$, with the change in the hydrogen-ion concentration should be calculable with the aid of Eq. (2). In the case of the IDA system, we used the relation in which the $K_{PbX}\cdot K^{Ac}_{PbX}\cdot K^{Ac}_{PbX(Ac)}\cdot[Ac]^2_f[X]_f/(\alpha_H)^2_{Ac}\cdot(\alpha_H)_X$ in Eq. (2) is not involved. In Table 2, the $\Delta E_{1/2}$ values calculated

TABLE 2. THE RELATION BETWEEN THE HALF-WAVE POTENTIAL AND THE CONCENTRATION OF HYDROGEN ION

Concentration of lead(II) ion=0.5 mM, μ=0.30, 25°C

(A) Asp system
Concentration of Asp=90.0 mM
Concentration of acetate ion=0.05 M

$E_{1/2}$, V *vs.* SCE	pH	$\Delta E_{1/2}$, mV	
		Calcd	Obsd
−0.4015	3.71	0	0
−0.4030	4.60	− 1.9	− 1.9
−0.4112	5.50	−13.0	−12.7

(B) IDA system
Concentration of IDA=40.0 mM
Concentration of acetate ion=0.10 M

$E_{1/2}$, V *vs.* SCE	pH	$\Delta E_{1/2}$, mV	
		Calcd	Obsd
−0.4208	4.50	0	0
−0.4225	4.70	− 4.4	− 4.7
−0.4323	5.01	−11.9	−11.5
−0.4387	5.31	−20.0	−18.0
−0.4443	5.50	−25.2	−23.5

by using the equilibrium constants determined in this study are given, together with those obtained experimentally. The agreement of the calculated $\Delta E_{1/2}$ values with those determined experimentally can be regarded as satisfactory.

In an alkaline medium, in the cases of both Asp and IDA systems, the plot of the antilog $(\Delta E_{1/2}/0.0296+\log(k_{Pb^{2+}}/k_{PbX}))$ value divided by $[X]_f$ *vs.* $[X]_f$ gave

a straight line with an intercept of a definite value. As was discussed in connection with the polarography of the cadmium(II)-EDTP complex,[4] this fact indicates that the lead(II) ions exist in the forms of PbX^0 and PbX_2^{2-}, and that the electrode reactions can be assumed to be:

$$PbX^0 + 2e^- + nH^+ + Hg \rightleftarrows Pb(Hg) + H_nX^{2-n} \quad (3)$$
$$\Updownarrow$$
$$PbX_2^{2-}$$

with the shift of the half-wave potential corresponding to:

$$\Delta E_{1/2} = 0.0296\left[\log\left(\frac{K_{PbX}\cdot[X]_f}{(\alpha_H)_X} + \frac{K_{PbX}\cdot K^X_{PbX}\cdot[X]_f^2}{(\alpha_H)_X^2}\right) + \log\frac{k_{PbX}}{k_{Pb^{2+}}}\right] \quad (4)$$

where H_nX^{2-n} means incompletely-deprotonated Asp or IDA, where PbX_2^{2-} means a 1 : 2 lead(II)-Asp or -IDA complex, and where K^X_{PbX} is the second successive formation constant of the lead(II)-Asp or -IDA complex. From the slopes and intercepts of the straight lines in Fig. 6, the K_{PbX} and K^X_{PbX} values were determined (Table 1). The K_{PbX} values thus determined agreed well with those estimated in an acid solution. If the electrode reaction in an alkaline medium is given by Eq. (3), the K_{PbX} and K^X_{PbX} thus determined should explain satisfactorily the change in the half-wave potential with the change in the hydrogen-ion concentration. The $\Delta E_{1/2}$ values calculated with the aid of Eq. (4) by using the K values in Table 1 and those determined experimentally are listed in Table 3. A good agreement between them could be observed.

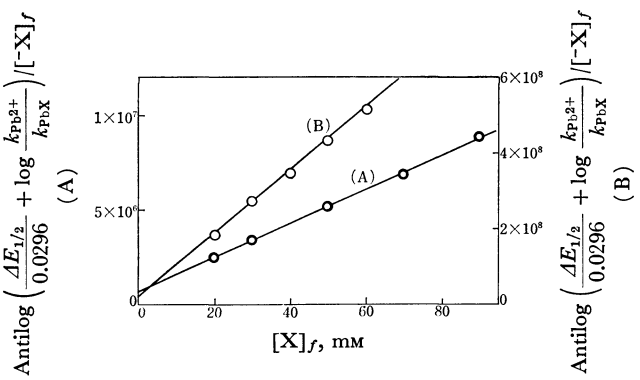

Fig. 6. The plot of antilog $(\Delta E_{1/2}/0.0296 + \log(k_{Pb^{2+}}/k_{PbX}))/[X]_f$ against the concentration of uncomplexed Asp or IDA.
Concentration of lead (II) ion=0.50mM, μ=0.30, 25°C
A : Asp system, pH=9.70
B : IDA system, pH=9.50

The K_{PbAc} and K^{Ac}_{PbAc} values determined in the IDA solution agreed well with those obtained in the Asp solution. They also agree well with those reported by Tanaka and Kato.[5] Here, we can mention that the K^{Ac}_{PbX} and $K^{Ac}_{PbX(Ac)}$ values are all smaller than K_{PbAc} and K^{Ac}_{PbAc}. This is not unreasonable, because the steric and electrostatic effects of coordinated Asp and IDA will reduce the stability of the mixed ligand complexes. The formation constants of the lead(II)-IDA complexes are fairly much larger than those of the Asp complexes. This may be ascribable to the rigid and stable five-membered ring of the IDA complex. It should also be mentioned that, although the Asp anion can from two mixed ligand complexes, the IDA anion can form only one mixed ligand complex, $PbX(Ac)^-$. This fact can be explained well by assuming that the Asp anion acts as a bidentate ligand while the IDA anion acts as a tridentate ligand. As was discussed in the polarographic study of the complex formation reaction of EDTP with the cadmium(II) ion,[4] the assumption that the Asp anion which has a propionate group acts as a bidentate ligand is not unreasonable. Even if the Asp anion acts as a tridentate ligand, from the electronic point of view it can be expected that the lead(II)-Asp complex with a less rigid six-membered ring can be interact with an acetate ion and give a mixed ligand complex more easily than can a rigid IDA complex. In order to describe the properties of the Asp anion as a ligand in detail, further systematic investigations should be conducted.

Derivatographic Studies on Transition Metal Complexes. IV.[1] Deaquation-Olation of Hydroxoaquo Cobalt(III) Complexes with Aminotricarboxylic Acids.[2]

Ryokichi Tsuchiya, Akira Uehara, and Eishin Kyuno
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa
(Received May 13, 1970)

Thermochemical functions of the deaquation-olation on $K[Co(OH)L_4(H_2O)]$ type complexes in the solid phase were determined by means of derivatography and UV spectral measurements and the mechanisms were discussed on the basis of the results. In the above formula, L_4, denotes nitrilotriacetate (nta), nitriloisopropionicdiacetate (nipda), *d,l*-α-amino-*n*-butyric-*N,N*-diacetate (α-abda), *l*-leucine-*N,N*-diacetate (*l*da), *l*-valine-*N,N*-diacetate (vda), *d*-α-phenylglycine-*N,N*-diacetate (pgda), or *d,l*-α-phenylalanine-*N,N*-diacetate (pada) ions. These complexes were found to liberate one mole of coordinating water upon heating and to turn into the olated compound bridged with two OH groups at the same time. From an estimation of enthalpy change and activation energy for the reaction, it was found that the reaction is apt to take place more easily as the structural complexities of chelating agents increase and that the reaction always proceeds in the first order. We might conclude that the evolution of coordinating water is the rate-determining step in the reaction.

In 1907, Werner found that when $[Co(OH)(H_2O)(NH_3)_4]X_2$ type complexes were heated at *ca.* 100°C, the following olation took place.[3]

$$2[Co(OH)(H_2O)(NH_3)_4]X_2 \longrightarrow [(NH_3)_4Co(OH)_2Co(NH_3)_4]X_4 + 2H_2O$$

Wendlandt and Fisher estimated the heats of olation in several complexes of the above type in which only the counter anions are different from each other.[4]

Pfeiffer observed that when the red $[Cr(OH)(H_2O)en_2]Cl_2$ is heated at 120°C, a bluish violet salt is formed.[5] He also suggested that the resulting salt has two bridged OH groups between two metal atoms and the reaction is expressed as follows:[6]

$$2[Cr(OH)(H_2O)en_2]Cl_2 \longrightarrow [en_2Cr(OH)_2Cr\,en_2]Cl_4 + 2H_2O$$

From the fact that the reaction of this type could occur readily, the red salt is considered to have the *cis* configuration with respect to the position of OH and H_2O.

In general, if the quadridentate ligands such as NTA or its analogues reside in the octahedral environment together with OH and H_2O, the latter two are situated at the *cis* position with each other. Therefore, this kind of complex is expected to bring about the olation expressed by

$$2K[M(OH)L_4(H_2O)] \longrightarrow K_2[L_4M(OH)_2ML_4] + 2H_2O.$$

It might be named "Deaquation-olation," because it involves both deaquation of the coordinating water and formation of the olated compound simultaneously. A few examples of such reactions have already been found on the cobalt(III) complexes with the aminotricarboxylic acids.[7–10] However, little thermochemical or kinetic functions of the reaction were reported and no mechanism discussed. Therefore, the present study was undertaken (1) to trace the thermal reaction by means of derivatography, (2) to estimate the enthalpy change (ΔH) and activation energy (E^*) of the respective thermal reactions, and (3) to deduce the mechanisms of the reaction.

Experimental

Preparation of Starting Complexes. Table 1 gives the rational formulas of the ligands and the chemical formulas of the complexes containing the ligands in the present work. All the ligands are analogues of NTA, and they can form the complexes including the 5,5,5-membered chelate rings when they act as a quadridentate ligand. The complexes were prepared by the methods described in respective references.[7-10]

Derivatographic Measurement. The derivatograms for these complexes were obtained with a Metrimpex Derivatograph Typ-OD-102. All the measurements were carried out in a constant nitrogen stream under the heating rate of 1°C min^{-1}. Five-hundred milligrams of the sample was used in each run. Analysis of derivatograms for each reaction process was carried out in a similar way to that described in part I of this series.[11]

Measurement of Electronic Spectra. The electronic spectra of the complexes were measured with a Hitachi EPU-2A Spectrophotometer in solid state by means of a diffuse-reflection method.

Results and Discussion

Observation on the Thermal Reaction Process by Derivatography. Figure 1 contains the derivatograms for nta- (I), nipda- (II) and *l*da-compleses (V) as the representatives. As seen in this figure, complex II liberates successively two moles and one mole of water at about 100 and 195°C, respectively. The former step is endothermic and the latter exothermic. The color of the sample changed to pink from bluish violet at the latter step. The latter step seems to involve the deaquation of coordinating water and the simultaneous formation of diol complex.

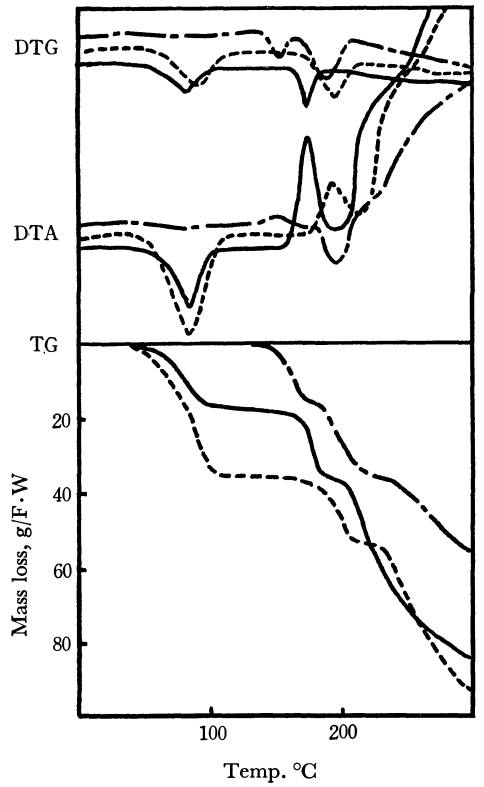

Fig. 1. Derivatograms for nta (·—·—·), nipda (·····) and *l*da (——) complexes.

In complex V, the mass losses corresponding to one mole of crystalline water in an endothermic reaction and then to one mole of coordinating water in an exothermic reaction were found at 100°C and at 180°C, respectively. The color of the sample changed to pink from bluish violet at the latter step as in the case of complex II. Such a change could be observed with all complexes except for complex I.

In complex I, although the two steps of mass losses corresponding to each one mole of water were separately observed at 160°C and 180°C, the color change and the exothermic DTA peak were found only at the former step. The former step is, hence, thought to correspond to the deaquation-olation and the latter, to the liberation of crystalline water alone.

In order to compare the thermal stability of all the complexes with each other, the exothermic DTA peaks alone are sketched in Fig. 2.

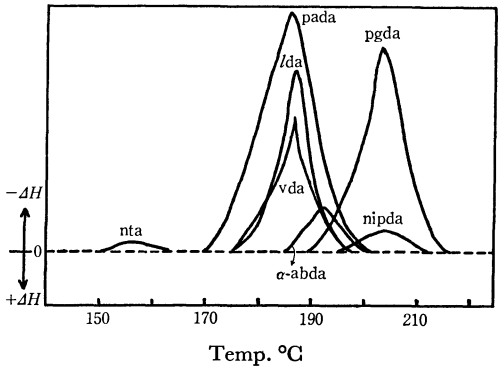

Fig. 2. DTA curves for deaquation-olation of the complexes.

The abscissa shows temperature and the ordinate an arbitrary scale of DTA curves. The dotted line gives the base of DTA curve, and $-\Delta H$ and $+\Delta H$ shows the scales for the exothermic and the endothermic reactions, respectively. As seen from the figure, although the reaction temperature differ with the kinds of the complexes, the peak area becomes larger in the order: nta- < nipda- < α-abda- < vda- < *l*da- < pgda- < pada-complexes.

Electronic Spectra. As an example, the electronic spectra of hydroxoaquo-pada-cobalt(III) complex (VII), of the complex after heating at 190°C and of diol-pada complex prepared in another method[10] are given in Fig. 3. The spectrum for complex VII after heating at 190°C, where the deaquation-olation seems to have taken place, closely resemble that of the diol complex, and the second band (due to *d–d* transition) does not appear distinctly. Similar results are also obtained in all the remaining complexes. They are in line with

the electronic spectra for the ol-ammine-cobalt(III)[12] and the diol-nta cobalt(III) complexes.[7]

Enthalpy Change and Activation Energy. The enthalpy changes, ΔH, for each step of the thermal reactions in these complexes were estimated from DTA curves in the same way as described.[11] It was also confirmed by the analyses of DTA curves[13] that both the evolution of the crystalline water and the deaquation-olation proceed in the first order. The Arrhenius plots, log-k *vs.* $1/T$, for both reactions showed a good linearity. Only those for the latter reaction are given in Fig. 4. The activation energies, E^*, of the reactions were

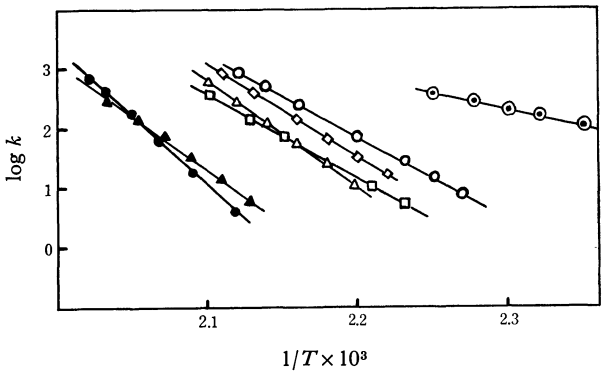

Fig. 4. Arrhenius plots for deaquation-olation of nta-(⊙-⊙), nipda-(▲-▲), α-abda-(△-△), vda-(○-○), *l*da- (□-□), pgda-(●-●), and pada-(○-○) complexes.

calculated from the slope of the respective Arrhenius plots. The values of ΔH and E^* estimated in all the complexes are summarized in Table 2.

The values of ΔH and E^* for the liberation of crystalline water from complexes II, III, IV, and V are close to the values for the reaction $CuSO_4\cdot 5H_2O \rightarrow CuSO_4\cdot 3H_2O + 2H_2O$ ($\Delta H \approx 13.1$ kcal/mol, $E^* \approx 21.3$ kcal/mol). The five moles of crystalline water of complex VII were liberated step by step: first four moles and then one mole. The one mole was more difficult to be liberated than the four. It was found that only in the case of complex I the activation energy for the liberation of crystalline water (38.8 kcal/mol) is greater than that for the deaquation-olation (29.7 kcal/mol). It is thus considered that coordinating water can be more easily lost than crystalline water. This is in good agreement with the fact that the deaquation-olation precedes the evolution of crystalline water as shown by the lower starting temperature in the former process than that in the latter (Table 2).

In the deaquation-olation, the values of ΔH for all the complexes show an increasing trend with the structural complexities of the chelating agents. On the contrary, the inverse trend was found in the values of E^* except complexes I and VI. It is not clear why complexes I and VI show a much lower and higher activation energy respectively. The numerical data in Table 2 indicate that the deaquation-olation takes place in the order: nta-$<$nipda-$<$α-abda-$<$vda-$<$ *l*da-$<$pgda-$<$pada-complexes.

Proposed Thermal Reaction Mechanism. The thermal reaction mechanisms of these complexes will be discussed on the basis of the above results. Figure 5 shows the proposed thermal reaction scheme for complex I and Fig. 6 that for complexes II through VII.

It is reasonable to conclude that for complex I the crystalline water is evolved after deaquation-olation took place. On the other hand, complexes II through VII are considered first to lose the crystalline water, and then to show the deaquation-olation as in Fig. 6.

If the activated complex in the above two figures were assumed to be an intermediate in the deaquation-olation, two mechanisms are possible, *viz.*, the formation of activated complex from the corresponding hydroxoaquo complex is slow or the liberation of coordinating water from the activated complex is slow. However,

Table 2. Thermochemical functions for evolution of crystalline water and deaquation-olation

Complex	Evolution step of crystalline waters			Deaquation-olation step		
	Starting temp (°C)	ΔH(kcal/mol)	E^*(kcal/mol)	Starting temp (°C)	ΔH (kcal/mol)	E^*(kcal/mol)
I	175	8.2	38.8	150	−1.2	29.7
II	40	13.6	19.9	195	−4.8	85.8
III	50	13.5	21.0	185	−6.3	75.4

the idea that the liberation of coordinating water is slow (the rate-determining step) might be reasonable in the present deaquation-olation. It would be supported by satisfactory linearity in the Arrhenius plots which were plotted from the view point that the reaction proceeds in the first order.

The authors wish to express their appreciation to the Ministry of Education for the financial support granted for this research.

Derivatographic Studies on Transition Metal Complexes. V.[1] Thermal *cis*, *trans*-to-*trans*, *cis* Isomerization of $[CoCl_2(NH_3)_2en]ClO_4$ in Solid Phase[2]

Ryokichi TSUCHIYA, Yasuo NAKATA,[3] and Eishin KYUNO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received June 27, 1970)

The complex, *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4$, regardless whether its state is monohydrate or anhydride, was isomerized to *trans,cis*-form by heating in a solid phase. In the kinetic study on perchlorate in a closed system, it was found that the isomerization of the hydrated compound proceeded through a second order reaction with respect to the remaining fraction of the starting compound with the activation energy, $E^*=29.5$ kcal mol^{-1}, while that of the anhydrous one proceeded through a first order reaction with $E^*=51.4$ kcal mol^{-1}. On the other hand, derivatographic analyses showed that the enthalpy change in the dehydration partly including isomerization was $\Delta H=13.9$ kcal mol^{-1} for the monohydrated perchlorate and the activation energy was $E^*=39.9$ kcal mol^{-1}, whereas the enthalpy change of isomerization of the anhydrous perchlorate was $\Delta H=-2.1$ kcal mol^{-1}. From the results, it is believed that the "Aquation-anation" mechanism on the crystal surface is predominant in the isomerization for the hydrate, but it proceeds through some intramolecular reactions for the anhydride.

The isomerization which takes place after complete dehydration has only recently been detected and reported for *trans*-$[CoCl_2(NH_3)_4]IO_3\cdot 2H_2O$.[4,5] Typical examples as the above, where two steps of dehydration and *trans*-to-*cis* isomerization are obviously separated in a solid phase are relatively less in the field of thermochemistry of transition metal complexes. The thermal isomerization of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ to the corresponding *cis*-isomer[6,7] simultaneously gives rise to the loss of one molecule of hydrogen chloride and two molecules of crystalline water. The ammine complex, *trans*-$[CoCl_2(NH_3)_4]Cl$, undergoes partial isomerization accompanied by much decomposition at somewhat higher temperature.[5] In the case of the ethylenediamine complex, *trans*-$[CoCl_2en_2](H_5O_2)Cl_2$,[6] the corresponding isomerization was not detected.

Examples of *cis*-to-*trans* isomerization are much more rare.[8] It is expected in the complexes, *cis,trans*-$[CoCl_2(NH_3)_2en]X$, that, when the two adjacent chloride ions change their coordination sites to the *trans*-position upon heating, the color changes from blue to green.

Three geometrical isomers can be postulated for the above complexes as shown in Fig. 1. Distinct thermochromism from blue to green in a solid phase was observed in our preliminary experiments on the complex *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4$. A similar phenomenon was also observed for the anhydrous perchlorate. This is considered to correspond to the transformation from *cis,trans*- (a) to *trans,cis*- form (b) as shown in Fig. 1. The present study deals with the thermal isomerization of *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$ and its anhydride to *trans,cis*-form complex.

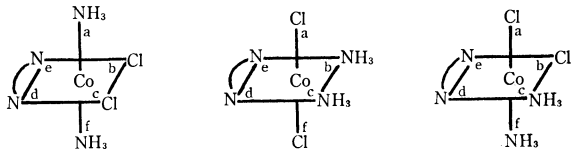

Fig. 1. Three geometrical isomers of $[CoCl_2(NH_3)_2en]X$.

(b) *trans*(dichloro), *cis*(diammine)-form (*trans, cis*-form)
(c) *cis*(dichloro), *cis*(diammine)-form (*cis,cis*-form)

Experimental

Syntheses of Complexes. The complexes *trans,cis*- and *cis,trans*-$[CoCl_2(NH_3)_2en]Cl\cdot nH_2O$ were prepared by the known method.[9] The corresponding perchlorate were obtained from the respective chlorides by saturating their solutions with 60% perchloric acid at room temperature and by putting them to stand in a refrigerator for a while. The blue crystals corresponding to *cis,trans*-form complexes or the green crystals corresponding to *trans,cis*-form complexes deposited out were filtered and washed with a small amount of ethanol-water (2 : 1) and then ethanol-ether (1 : 1) mixtures, and dried over silica-gel in a desiccator for a while.

Found: C, 7.07; H, 4.70; N, 16.51%. Calcd for *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$: C, 7.03; H, 4.72; N, 16.41%.

Found: C, 7.52; H, 4.40; N, 17.25%. Calcd for *trans,cis*-$[CoCl_2(NH_3)_2en]ClO_4$: C, 7.43; H, 4.36; N, 17.32%.

The corresponding anhydrous *cis,trans*-compound was prepared by standing the monohydrate obtained above over silica-gel in a vacuum desiccator at room temperature for 10 days. The content of the crystalline water in the hydrate was sometimes determined with a thermobalance. In general, complete dehydration of the compound was achieved in a week at room temperature under similar conditions. Complete dehydration was also achieved even at 90°C in a few hours without any detectable isomerization. This was verified by the UV and IR spectral measurements.

Found: C, 7.62; H, 4.40; N, 17.25%. Calcd for $[CoCl_2(NH_3)_2en]ClO_4$: C, 7.43; H, 4.36; N, 17.32%.

Derivatographic Measurement. The derivatograms of these compounds were obtained with a MOM Derivatograph Typ-OD-102.[10] Samples in each run were 0.4 g, finely powdered, 100—200 mesh inch^{-1}. The measurements were carried out under a constant flow of nitrogen stream with the heating rate of 1°C min^{-1} unless otherwise stated. The enthalpy changes, ΔH, and the activation energies, $E^{\neq}$, in the thermal changes concerned were calculated by DTA curve analysis in the derivatograms.[11-13]

Spectral Measurements. Visible and UV absorption spectra of the complexes in solution were measured with a Hitachi R-3 Spectrophotometer. The IR spectral measurements of the complexes were carried out with a JASCO Model IR-E and IR-G Spectrophotometers in a Nujol mull.

Isothermal Measurements. The isothermal rate determination on dehydration was carried out with a Shimadzu TM-1A Thermobalance as a complement to derivatographic determinations. Measurements were carried out at several desired constant temperatures in a static air with the same samples as those used in the derivatographic study.

The rate of isomerization of the complexes was measured by using an Abderhalden apparatus keeping a small sample vessel under constant temperatures in a closed system. The products were taken out from the sample vessel at certain time intervals and the absorption spectra were measured to determine the mole ratio of *cis,trans/trans,cis* in the products.

The complex species, *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$ and the corresponding *trans,cis*-form anhydride, are fairly soluble in dimethylformamide (DMF) in the original stable form, and the solution is found not to undergo further chemical change at least during the measurement. The absorption obeys Lambert-Beer's law within the concentration range for the determination. The pure complexes as shown in the spectra in Fig. 2, have the following absorption coefficients at 594 and 625 nm in DMF solution:

	ε_{594nm}	ε_{625nm}
cis,trans-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$ and its anhydride	128.8	118.8
trans,cis-$[CoCl_2(NH_3)_2en]ClO_4$	33.8	43.8

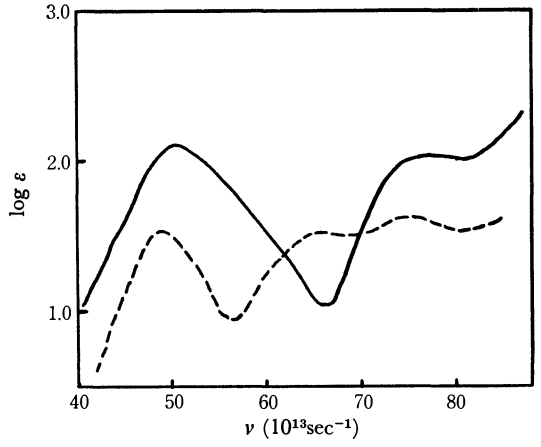

Fig. 2. Electronic spectra of $[CoCl_2(NH_3)_2en]ClO_4$ in DMF.
——, *cis,trans*-isomer; ----, *trans, cis*-isomer

From the results, the mixed mole ratio of two isomers in each product can be calculated spectrophotometrically by means of the equations

$$33.8X + 128.8Y = D_{594}$$
$$43.8X + 118.8Y = D_{625},$$

where X and Y are the concentrations in mol l^{-1} of *trans, cis*-complex and that of *cis,trans*-complex, respectively, and D_{594} and D_{625} the observed absorbancies at 594 nm and at 625 nm, respectively, with a 1.0 cm cell.

Results and Discussion

Dehydration of *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$ proceeds through one step in TG and DTG curves, but the DTA gives a complicated pattern in the derivatogram as shown in Fig. 3. It is likely that the DTA curve in the derivatogram contains the overlapped heats of the two reactions, dehydration and isomerization. The DTA curve on the corresponding anhydrous complex, however, shows a small exothermic peak at about 160°C, probably due to isomerization, without any detectable mass loss as shown in Fig. 4.

The enthalpy change of the dehydration, including a partial isomerization, and that of the pure isomerization were derivatographically found to be ΔH=13.9 kcal mol^{-1} and −2.1 kcal mol^{-1}, from Fig. 3 and Fig. 4, respectively. Thus, the heat of pure dehydration for the perchlorate is presumed to be about 16 kcal mol^{-1}.

Dehydration containing a partial isomerization of *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$ is considered to proceed through first order reaction, and the Arrhenius plots obtained on the basis of the above presumption are given in Fig. 5, from which the activation energy is calculated to be 36.6 kcal mol^{-1}.

When the complex, *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4\cdot H_2O$, was heated in static air by a thermobalance under

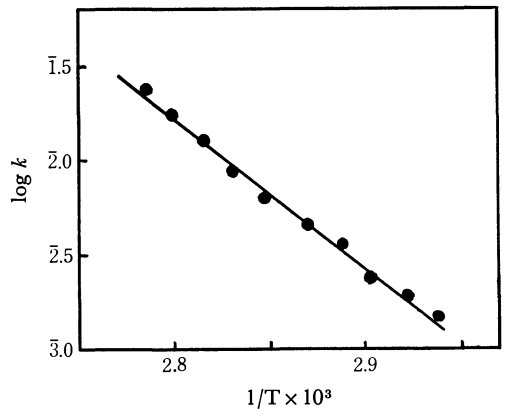

Fig. 5. Arrhenius plots for dehydration containing partial isomerization (derivatography).

the heating rate of 0.5°C min^{-1}, dehydration began at 85°C, and isomerization started at 120°C after complete dehydration. When it was heated at 150°C, the product consisted of about 40% of the *trans,cis*-isomer and the remaining *cis,trans*-isomer. Isomerization was finally completed at 175°C. The IR spectrum for the product obtained at 175°C is shown in Fig. 6, together with those for monohydrated *cis,trans*-isomer and for anhydrous *trans,cis*-isomer directly prepared. The figure verifies that the final heating product is *trans,cis*-$[CoCl_2(NH_3)_2en]ClO_4$. A similar type isomerization was observed in the corresponding anhydrous perchlorate complex.

The rate constants of isomerization for the hydrated and anhydrous *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4$ in the closed system as well as those of dehydration in the static air were determined in an isothermal condition. The kinetic data are summarized in Table 1.

It is of interest that, in the closed system, isomerization for the hydrated complex was found to proceed in a second order reaction with respect to the remaining complex, and that for the anhydrous complex in first order. The presence of crystalline water might play some important role in the difference described above, but a reasonable explanation could not be obtained.

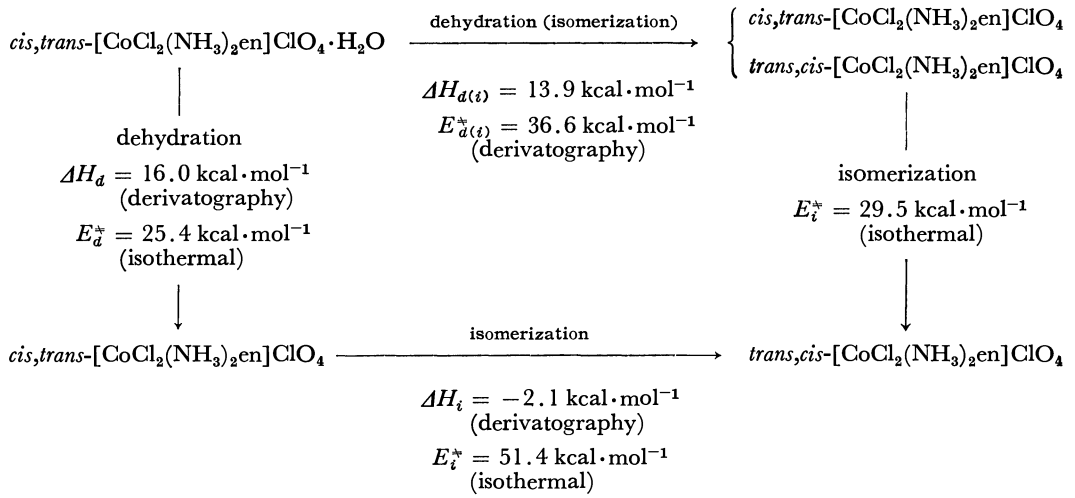
	$[CoCl_2(NH_3)_2en]ClO_4 \cdot H_2O$				$[CoCl_2(NH_3)_2en]ClO_4$	
°C	K_d, sec^{-1}	E_d^*, kcal mol^{-1}	K_i, sec^{-1}	E_i^*, kcal mol^{-1}	K_i, sec^{-1}	E_i, kcal mol^{-1}
70	$(7.9\pm0.3)\times10^{-4}$					
80	$(2.8\pm0.2)\times10^{-3}$					
90	$(5.0\pm0.2)\times10^{-3}$	25.4				
100	$(1.2\pm0.2)\times10^{-2}$					
138			$(2.0+0.2)\times10^{-3}$		$(7.5\pm0.2)\times10^{-6}$	
153			$(2.8\pm0.2)\times10^{-2}$		$(5.2\pm0.2)\times10^{-5}$	
158			$(4.1\pm0.2)\times10^{-2}$	29.5	$(1.2\pm0.2)\times10^{-4}$	51.4
178			$(2.0\pm0.2)\times10^{-1}$		$(1.2\pm0.2)\times10^{-3}$	

k_d and k_i are the rate constants of isomerization and those of dehydration.
E_d^* and E_i^* are the corresponding activation energies.



ΔH_d, ΔH_i and $\Delta H_{d(i)}$ represent to enthalphy changes of dehydration, isomerization, and dehydration containing partial isomerization.
$E^*_{d(i)}$ denotes the activation energy of dehydration containing partial isomerization.

Fig. 8. Schematic diagram for thermal reactions on *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4 \cdot H_2O$.

The Arrhenius plots concerned are shown in Fig. 7, from which the activation energies for isomerization were calculated to be 29.5 kcal mol^{-1} and 51.4 kcal mol^{-1} for the monohydrate and anhydride, respectively.

The thermal reaction pathways concerning *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4 \cdot H_2O$ and the thermal functions corresponding to the respective steps obtained are summarized schematically in Fig. 8.

The value of activation energy for the isomerization of *cis,trans*-$[CoCl_2(NH_3)_2en]ClO_4 \cdot H_2O$ was found to be of a similar order to that of the *trans*-to-*cis* isomerization of $[CoCl_2pn_2](H_5O_2)Cl_2$ under similar conditions.[7] Thus, the mechanism for the isomerization of the former hydrated complex seems to be explained by that of "aquation-anation" in closed system, as presumed in the latter complex.

Since remarkably higher activation energy is necessitated for the reaction in first order, isomerization of the anhydrous complex suggests an intramolecular reaction mechanism, *e. g.*, "twist" or "chelate ring opening-closing," because a similar mechanism has been also postulated for the isomerization of *trans*-to-*cis* reaction of $[CoCl_2pn_2]Cl$.[7] The difference between the activation energy from the derivatograms and that from the results obtained in a closed system may be due to the fact that the former contains both the data of isomerization and a part of dehydration and the latter that of isomerization only.

Derivatographic Studies on Transition Metal Complexes. VI.[1] Thermal, *cis*, *trans*-to-*cis*, *cis* Exchange-Isomerization[2] of $[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ in Solid Phase[3]

Ryokichi Tsuchiya, Masatatsu Suzuki, and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 27, 1970)

The exchange-isomerization of the complex, *cis*(dichloro), *trans*(diammine)-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ to *cis*-(chloro isothiocyanato), *cis*(diammine)-$[CoCl(NCS)(NH_3)_2en]Cl$, was investigated by means of both derivatographic and isothermal methods. The reaction took place immediately after the liberation of crystalline water. The thermochemical functions were obtained to be $\Delta H = (5.5 \pm 1.0)$ kcal/mol and $E^* = (22.8 \pm 2.0)$ kcal/mol for the dehydration, while those for the exchange-isomerization were $\Delta H = (4.8 \pm 1.0)$ kcal/mol and $E^* = (62.3 \pm 3.0)$ kcal/mol, respectively. As a probable reaction mechanism for the exchange-isomerization, a certain seven coordinated intermediate in the reaction pathway was introduced.

Recently, several examples of thermal, *cis*-to-*trans*[1,4] and *trans*-to-*cis*[5–7] isomerization on transition metal complexes in solid phase have been reported. The different mechanisms were proposed between the thermal isomerization including dehydration in the hydrated solid phase and that in anhydrous phase; *i. e.*, "aquation-anation" mechanism was well fitted for the former isomerization and "twisting"[8] or "chelate ring opening-closing" mechanism[9] were mainly applied to the latter.

Although the exchange-isomerization in solid phase on transition metal complexes containing the simultaneous occurrence of the isomerization and exchange reaction between the ligand coordinated and the counter ion in the outer sphere is very rare, it is known that a similar reaction sometimes takes place in the case of using matrix-method[10] for the preparation of the complexes.

When the compound, *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$, was heated in solid phase, the following reactions occurred successively:

$$\textit{cis,trans}\text{-}[CoCl_2(NH_3)_2en]SCN \cdot H_2O \longrightarrow \textit{cis,trans}\text{-}[CoCl_2(NH_3)_2en]SCN + H_2O \quad \text{(Dehydration)} \qquad (1)$$

$$\textit{cis,trans}\text{-}[CoCl_2(NH_3)_2en]SCN \longrightarrow \textit{cis,cis}\text{-}[CoCl(NCS)(NH_3)_2en]Cl \quad \text{(Exchange-isomerization)} \qquad (2)$$

The distinct color change, from blue to violet, was found in the reaction (2) at the temperature near 135°C. The present paper is concerned with the dehydration (1) and the exchange-isomerization (2) described above.

Experimental

Preparation of the Complex. The complex, *cis,trans*-$[CoCl_2(NH_3)_2en]Cl$, was prepared by the known method.[11] The corresponding thiocyanate was obtained by saturating the solution of the pure chloride with potassium thiocyanate. The row product was recrystallized in a dilute potassium thiocyanate solution. The blue crystals collected by filtration were washed with small amounts of cold water, ethanol and ether in turn and air-dried.

Found: C, 12.01; H, 5.17; N, 22.97%. Calcd for *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$: C, 12.00; H, 5.38; N, 23.48%.

Derivatographic Measurement. The apparatus and techniques used in this work were the same as described in an earlier paper.[6]

Isothermal Measurement by using a Thermobalance. The measurement and analytical method for the experiments were also the same in an earlier paper.[12] Determination of the mixed ratio of two compounds, the starting *cis,trans*-form complex and *cis,cis*-form produced, was made spectrophotometrically.

Results and Discussion

Structural Determination of Reaction Product from the Spectra. The complex, $[CoClX(NH_3)_2en]^+$ is expected to exist in either of the four geometrical isomers as given in Fig. 1.

The infrared absorption spectra of $[CoCl(NCS)(NH_3)_2en]Cl$ produced and of the related compounds the structure of which is clear are shown in Fig. 2. It has been well known that, in general, the cobalt(III) complexes which have the two ammine groups in *cis*-

position give two peaks assigned to the symmetric deformation, δ_{NH_2}, in the region of 1400—1200 cm^{-1} in the IR spectra, while *trans*-diammine ones have only one peak in this region: *e. g.*, the *cis*-diammine complexes involving organic amine like the ethylenediamine or propylenediamine, *trans,cis*-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$[13,14] and *trans,cis*-$[CoCl_2(NH_3)_2pn]Cl\cdot H_2O$,[15] show two peaks at 1310 and 1280 cm^{-1}, respectively, while the *trans*-diammine complexes, *cis,trans*-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$, *cis,trans*-$[CoCl_2(NH_3)_2pn]Cl\cdot H_2O$[16] and *cis,trans*-$NH_4[Co(SO_3)_2(NH_3)_2en]\cdot 2H_2O$,[11] have also two neighboring peaks at 1310 and 1330 cm^{-1} in rather higher wave number region than that given by the *cis*-diammine complexes. It has been understood by the fact that the bands assigned to the symmetric deformation, δ_{NH_2}, of ammonia and of organic amine are overlapped in this region.

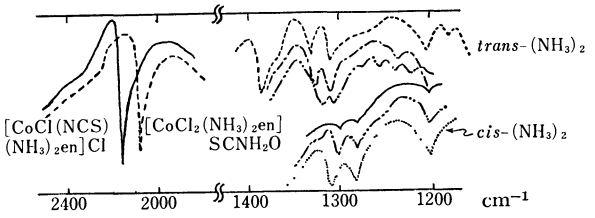

Fig. 2. IR spectra for the complexes.
cis, trans-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$ (------)
cis, trans-$[CoCl_2(NH_3)_2pn]Cl\cdot H_2O$ (-·-·-·-)
cis, trans-$NH_4[Co(SO_3)_2(NH_3)_2en]\cdot 3H_2O$ (-·-·-)
cis, cis-[CoCl (NCS) $(NH_3)_2en]Cl$ (——)
trans, cis-$[CoCl_2(NH_3)_2pn]Cl\cdot H_2O$ (-·-·-·-)
trans, cis-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$(·····)

When the complex *cis,trans*-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$ was heated, the color changed from blue to violet and the two peaks at 1310 and 1330 cm^{-1} of the starting material were shifted to lower wave number side at 1280 and 1310 cm^{-1} in their IR spectra as shown in Fig. 2.

From the above results, it is clearly recognizable that the structural change, from *trans*-diammine to *cis*-diammine, may be involved in the thermal reaction. It has also been found that the band of the starting complex assigned to the stretching vibration, $\nu_{C=N'}$,[17,18] was shifted from 2080 cm^{-1} to 2160 cm^{-1} upon heating it. This shift should include the exchange between chloride coordinated to central metal ion and thiocyanate in counter-ion sphere.

In addition, an interesting information derived from the change in the frequency of the $\nu_{C=N}$ band comes whether or not the linkage isomerism by the coordination of -SCN or -NCS occurs in the exchange reaction. The evidence is not very much clear, but it seems that the ligand coordinates as -NCS toward the central metal atom in this case based on the analysis of IR spectrum.[18]

It has been well known that one of the most available method in determining the geometrical structure of the transition metal complexes is the use of the analysis of electronic spectra. Since a very large difference on the electronic spectra[19] between the complexes involving two negative ligands in the *cis* position and the corresponding ones in the *trans* position has been found clearly, it will be possible to decide whether *cis* or *trans* position is occupied by these ligands coordinated in the unknown geometrical structure. The electronic spectra of $[CoCl(NCS)(NH_3)_2en]Cl$ and of the related complexes are shown in Fig. 3.

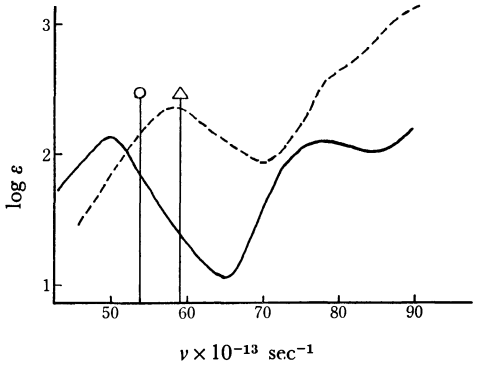

Fig. 3. Electronic spectra for *cis,trans*-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$(——) and *cis,cis*-$[CoCl(NCS)(NH_3)_2en]Cl$ (·····) (○ and △ indicate the frequencies of absorption maxima for *trans*-$[CoCl(NCS)en_2]Cl$ and *cis*-$[CoCl(NCS)en_2]Cl$, respectively.).

Aside from the appearance of the band splitting tendency[19] when such negative ligands are involved in the *cis* position as in the case of *cis,cis*-$[CoCl(NCS)(NH_3)_2en]Cl$[14] and *cis*-$[CoCl(NCS)en_2]Cl$,[20] the band exists in the rather higher frequency region than that of the corresponding *trans* one, *trans*-$[CoCl(NCS)en_2]Cl$.[14] The first absorption band of bis(ethylenedi-

amine) complexes, in general, appears in slightly higher frequency region than that of diammine-ethylenediamine one, being obeyed on "Spectrochemical Series".[21] The utility of the empirical rule in this case suggests that the product, $[CoCl(NCS)(NH_3)_2en]Cl$ from *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ by the thermal reaction is still held the *cis* structure with respect to two negative ligands coordinated in spite of exchange of one of the ligands.

Kinetic Studies. The derivatogram for *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ is given in Fig. 4. When the complex was heated at the heating rate 1° min^{-1} by using Derivatograph, the loss of crystalline water began at about 75°. The TG curve indicates that the dehydration is completed up to 120° and no further mass loss was detected until about 170°. The DTA curve exhibits two endothermic peaks corresponding to dehydration and the genuine decomposition of the complex, respectively. And one more small exothermic peak appears at about 135° without the change of both TG and DTG curves in the derivatogram, where the color change from blue to violet was, however, found, which is corresponding to the exchange-isomerization, *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \longrightarrow$ *cis,cis*-$[CoCl(NCS)(NH_3)_2en]Cl$. From the situation, it is possible to conclude that the exchange-isomerization proceeds after the dehydration process.

The experimental thermochemical functions calculated from the derivatogram were $\Delta H = (5.5 \pm 1.0)$ kcal/mol and $E^* = (22.8 \pm 2.0)$ kcal/mol for the dehydration, and $\Delta H = (4.8 \pm 1.0)$ kcal/mol and $E^* = (62.3 \pm 3.0)$ kcal/mol for the exchange-isomerization, and the Arrhenius plots for the calculation of the activation energy are shown in Fig. 5.

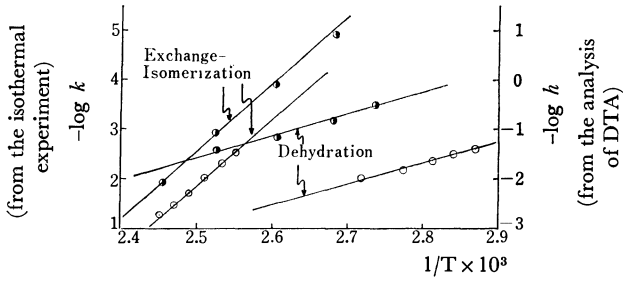

Fig. 5. The Arrhenius plots for *cis, trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ from isothermal (◑) and from DTA analysis(○).

The thermal exchange-isomerization of *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ was also studied by means of isothermal method. At a certain constant temperature, the mole ratio of the *cis,trans*-form complex against the *cis,cis*-form complex produced was estimated every after several different times. Since pure *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ and *cis,cis*-$[CoCl(NCS)(NH_3)_2en]Cl$ show the absorption coefficients, 168 and 58.3 at 518 nm, and 65.3 and 121.5 at 598 nm in DMF, respectively, the *cis,trans*/*cis,cis*-ratio in the product in each step can be determined spectrophotometrically by means of the following equations:

$$168X + 58.3Y = D_{518}$$
$$65.3X + 121.5Y = D_{598},$$

where X and Y are the concentrations (in mol l^{-1}) of *cis,trans*- and *cis,cis*-complexes, and D_{518} and D_{598} are the absorbancies at 518 and 598 nm with 1.0 cm cell, respectively. Thus, *cis,trans*/*cis,cis*-ratios are given by X/Y.

From the mole ratio obtained above, the rate constants of dehydration, k_d, and of exchange-isomerization, k_i, were calculated, which are summarized in Table 1.

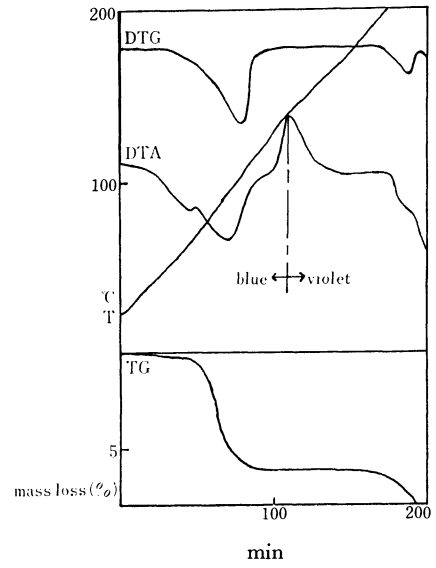

Fig. 4. Derivatogram for *cis,trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$.

Table 1. The rate constants of dehydration, k_d and of exchange-isomerization, k_i, in isothermal measurements

Temp. (°C)	k_d (sec^{-1})	k_i (sec^{-1})
90	$(1.6 \pm 0.4) \times 10^{-4}$	
100	$(4.9 \pm 0.4) \times 10^{-4}$	$(8.5 \pm 0.3) \times 10^{-6}$
110.8	$(9.2 \pm 0.4) \times 10^{-4}$	$(7.1 \pm 0.3) \times 10^{-5}$
121.1	$(1.5 \pm 0.2) \times 10^{-3}$	$(6.7 \pm 0.3) \times 10^{-4}$
138.3		$(8.0 \pm 0.2) \times 10^{-3}$

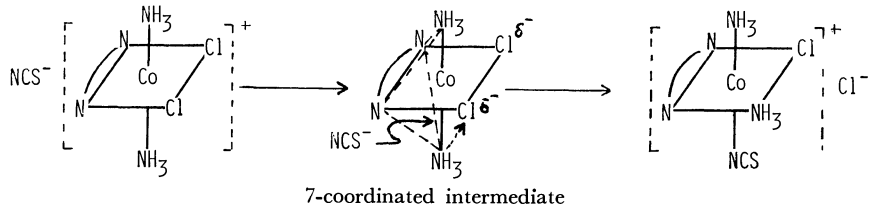

Fig. 6. The possible mechanism for exchange-isomerization of *cis, trans*-$[CoCl_2(NH_3)_2en]SCN \cdot H_2O$ to *cis, cis*-$[CoCl(NCS)(NH_3)_2en]Cl$.

21) Y. Shimura and R. Tsuchida, This Bulltein, **29**, 311 (1956).

The Arrhenius plots are given in Fig. 5, together with those obtained from derivatography. The thermochemical functions calculated from the isothermal measurement were $E^*=(20.1\pm2)$ kcal/mol and (62.3 ± 3.0) kcal/mol for the dehydration and exchange-isomerization, respectively, which are in good agreement with the corresponding data from the derivatography.

The possible reaction mechanism for the exchange-isomerization of *cis,trans*-$[CoCl_2(NH_3)_2en]SCN\cdot H_2O$ to *cis,cis*-$[CoCl(NCS)(NH_3)_2en]Cl$ in the solid phase may be proposed as shown in Fig. 6. It is likely that a a certain intramolecular thermal reaction proceeds through seven coordinated intermediate by the action with SCN^- as the counter ion in the second coordination-sphere. The product by this mechanism should have *cis,cis*-b structure as shown in Fig. 1, if the incoming SCN^- group attacks the *trans* side to the negative coordinated chloride ligand, and as the result, one of Cl^- may be removed from the seven coordinated intermediate by push-effect of NCS ligand.

When the SCN ligand approaches to the central cobalt ion, the linkage: M–NCS will prefer to that of M–SCN. However, there is still no evidence whether the final product is *cis,cis*-a or -b.

The Chemical Structures of Glasses of the $NaPO_3$-Sb_2O_3-Na_2O System

Makoto WATANABE, Kazuo TANABE, Tomoyoshi TAKAHARA, and Tamotsu YAMADA*

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi

* *Department of Industrial Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya*

(Received May 15, 1970)

Glassy and crystalline substances of the $NaPO_3$-Sb_2O_3-Na_2O system with P/Sb ratios in the range from 1.0 to 300 were prepared by heating $NaPO_3$, Sb_2O_3, and Na_2CO_3 at 1000°C and by then quenching the melts of the mixtures. Samples with P/Sb ratios smaller than 5.0 were obtained as crystalline substances containing amorphous substances. The chemical compositions of these crystalline substances were estimated from the data obtained by X-ray diffractometry and paper chromatography. Samples with P/Sb ratios larger than 7.0 were obtained as glassy substances. Condensed phosphates were separated by paper-chromatographic analysis, and the average degree of the polymerization of the phosphates was measured by the pH-titration method. It has been found that the crystalline substances in the samples with P/Sb ratios in the range from 1.0 to 5.0 were Sb_2O_5, $NaSbO_3$, and an unknown crystalline substance. Assuming that the glasses have the P-O-P, P-O^-, P-O-Sb, and Sb-O^- linkages, a theoretical treatment of the degree of polymerization of condensed phosphates has been made and compared with the experimental data. It has been concluded that the glasses with P/Sb ratios larger than 7.0 have P-O-P, P-O^-, and P-O-Sb linkages.

Several attempts to prepare condensed phosphates containing oxoacid anions of some elements other than phosphorus have been made. For instance, Thilo and his co-workers investigated arsenate-phosphates,[1] and Ohashi and his co-workers investigated phosphate-silicates,[2] vanadate-phosphates,[3] and borate-phosphates.[4] It has been reported that the condensed compounds of this type have P-O-As, P-O-Si, P-O-V, and P-O-B linkages respectively. All of these oxoacid anions have a tendency to polymerize at a high temperature.

In the present work, glassy and crystalline substances of sodium phosphate-antimonates with various P/Sb ratios have been prepared in order to obtain some information on the chemical compositions and structures of the system. The compositions of the condensed phosphates have been determined by paper-chromatographic analysis of their aqueous solutions, while the structures of the crystals have been estimated by means of a study of their X-ray diffraction patterns. The theoretical treatment of the degree of polymerization of the condensed phosphates has been made and compared with the experimental data. The results reveal that the glasses also have P-O-Sb linkages.

Experimental

Materials. Sodium metaphosphate was prepared by heating monosodium dihydrogen orthophosphate dihydrate in a platinum crucible at 1000°C for 3 hr and by then quenching the melt by pressing it between two stainless steel plates. The average chain length of the glass thus obtained was about 100. The antimony trioxide and sodium carbonate were commercial reagents.

Glassy Substances. After the weight of the glass had been measured, calculated amounts of antimony trioxide and of sodium carbonate were taken on the glass and then mixed in an alumina mortar. The number of moles of sodium carbonate was equal to that of antimony trioxide. The mixture of these three materials was melted at 1000°C for 2 hr and then quenched by the method used in the preparation of sodium metaphosphate. By this procedure, glassy substances of the $NaPO_3$-Sb_2O_3-Na_2O system with P/Sb ratios in the range from 7.0—300 were prepared. All the glasses thus obtained were transparent and colourless.

Crystalline Substances. A mixture of sodium metaphosphate, antimony trioxide, and sodium carbonate (with P/Sb ratios of 1.0, 2.0, and 5.0) was heated in a platinum crucible at 1000°C for 2 hr, and then the melts were quenched by placing the crucible in ice water. The crystalline substances with P/Sb ratios of 1.0 and 2.0 were opaque and a weak yellow, and the substances with a P/Sb ratio of 5.0 were transparent and colourless.

Paper Chromatography. The glassy substances were dissolved in water, and the phosphate species in the solution were separated by paper chromatography and then determined colorimetrically. Acidic and basic solvents were used for the paper chromatography. The acidic solvent was made by mixing 70 m*l* of ethyl alcohol, 5 g of trichloroacetic acid, 0.3 m*l* of concentrated aqueous ammonia, and 30 m*l* of water, it was used for the separation of ortho-, di-, tri-, tetra-, and long-chain phosphates. The basic solvent was made by mixing 40 m*l* of isopropyl alcohol, 20 m*l* of isobutyl alcohol, 1 m*l* of concentrated aqueous ammonia, and 39 m*l* of water, it was used for the separation of trimeta- and tetrametaphosphates. A sample solution was made by dissolving 1—2 g of the crystalline or the glassy substance in 150 m*l* of water. About 5 μl of the sample solution was placed on a filter paper of Toyo No. 53 of 2 by 40 cm and developed at room temperature for 20 hr. After the paper had been dried at 75°C for more than 30 min, it was sprayed a perchloric acid-molybdate solution so as to convert the phosphates into molybdophosphates. After it had then been dried again, the paper was exposed to ultraviolet light in order to reduce the molybdophosphates to blue complexes. Each band of the phosphates on the filter paper was identified by the same treatment of the reference solution of known phosphates.

The separated phosphates on the paper chromatograms were determined as follows, the filter paper containing each separated phosphates was cut at the demarcation line, and then immersed in 10 m*l* of a 0.1N aqueous solution of ammonia in a 50-m*l* Erlenmeyer flask. After 1 hr or more, this solution was transferred into a 25-m*l* volumetric flask, and then 10 m*l* of water and 2 m*l* of Lucena-Conde and Prat's reagent[5] were added. The flask was placed in a boiling-water bath for 1 hr, then cooled rapidly by placing it in a bath of cold water, and diluted to the mark with water. The absorbance of the solution was measured with a Shimadzu photoelectric photometer, Spectonic-20, at 800 mμ. The distribution of the phosphate species was calculated from the absorbance data.

The Measurement of the Average Chain Length of Polyphosphates. The average chain length of polyphosphates was measured by the pH-titration method proposed by Van Wazer, Griffith, and McCulough.[6,7] About 2 g of the glassy substance was dissolved in about 100 m*l* of water in a 250-m*l* Erlenmeyer flask. Most of the antimonate in the sample was precipitated and then filtered off. A twenty-five milliliters aliquot of the filtrate was diluted to about 100 m*l* and acidified with 1N hydrochloric acid to about pH 3 and then titrated with 0.1N sodium hydroxide. The volume of the 0.1N sodium hydroxide solution consumed between two inflection points, located at approximately pH 4.5 and 9.5, was measured. Twenty-five milliliters of another aliquot of the filtrate was transferred into a 250-m*l* Erlenmeyer flask, the mixture was diluted to about 80 m*l* with water, and then 10 m*l* of concentrated hydrochloric acid and 1 g of potassium chloride were added. The solution was boiled to dryness in order to hydrolyze completely all the condensed phosphates, the residue was dissolved with 50 m*l* of water and adjusted the pH to about 3 with a 6N carbonate-free sodium hydroxide solution. The solution was titrated by the same method mentioned above. If the volume of the 0.1N sodium hydroxide solution for the first titration is A, and if the volume for the second one is A_h, the average chain length, $\bar{n}$, is given by the $\bar{n}=2A_h/A$ equation, assuming that the only phosphates present in the glass are polyphosphates.

X-Ray Diffractometry. The samples were ground with an agate mortar until they could pass through a 150-mesh screen. Their X-ray diffraction patterns were taken by means of a powder method, using a Toshiba X-ray diffractometer.

Results and Discussion

The ignition loss of the mixture of these three materials was equal to the weight of the CO_2 gas which evolved upon the decomposition of Na_2CO_3. After heating, therefore, the crystalline and the glassy substances formed the $NaPO_3$-Sb_2O_3-Na_2O system. According to the observation of these samples under a polarizing microscope, the samples with the P/Sb ratios of 1.0, 2.0, and 5.0 were composed of an opaque and a transparent portion, and the amounts of the opaque portion decreased when the P/Sb ratio increased. The glasses with P/Sb ratios larger than 5.0 were almost entirely composed of the transparent portion, and the crystalline substances were negligibly small. The crystalline substances in the samples with P/Sb ratios of 1.0, 2.0, and 5.0 can be estimated from the data obtained by X-ray diffractometry. The data for the $NaPO_3$-Sb_2O_3-Na_2O system, with P/Sb ratios of 1.0, 2.0, and 5.0, are given in Table 1. By means of the X-ray diffraction patterns

Table 1. Chemical compositions of substances of the $NaPO_3$-Sb_2O_3-Na_2O system with P/Sb ratios of 1.0—5.0

	X-Ray diffractometry			Paper chromatography Phosphate(P%)				
P/Sb	Sb_2O_5	$NaSbO_3$	Unknown	Ortho	Pyro	Tri	Tri-meta	High poly
1.0	###	###	+	46.5	32.1	1.3		20.1
2.0	##	##	###	41.9	24.2	1.8		32.1
5.0	—	—	+	6.1	34.7	18.2	7.7	33.3

of the samples with P/Sb ratios of 1.0, 2.0, and 5.0, it has been found that there are unknown peaks of a strong intensity at spacings of 7.40 Å and of a medium intensity at spacings of 6.21 Å. Other crystalline substances of the samples with P/Sb ratios of 1.0 and 2.0 are antimony pentoxide and sodium metaantimonate. The antimony pentoxide and sodium metaantimonate were identified by comparing the X-ray patterns of the samples with those of "A. S. T. M. Diffraction Data File." The X-ray diffraction patterns of no phosphate species appear. The antimony pentoxide and sodium metaantimonate contents in these samples decrease with the increase in the P/Sb ratio, while that of the unknown crystalline substance increases with the increase in the P/Sb ratio

from 1.0 to 2.0. The crystalline substance of the sample with the P/Sb ratio of 5.0 consists only of the unknown substance, and the contents of the unknown substance are small. From the results of the paper-chromatographic analysis of the samples with P/Sb ratios of 1.0, 2.0, and 5.0, it is found that the quantities of ortho- and pyrophosphate in the samples with the P/Sb ratios of 1.0 and 2.0 are very large, but those of the orthophosphate in the samples decrease rapidly with the increase in the P/Sb ratio from 2.0 to 5.0. When the samples are treated with water, white crystalline substances are deposited. In the X-ray diffraction patterns of the white deposits, there are also unknown peaks of a strong intensity at spacings of 7.40 Å and of a medium intensity at spacings of 6.41 Å, and the peaks of antimony trioxide, antimony pentoxide, and sodium metaantimonate. From these results, it may be concluded that the unknown crystalline substance is not dissolved in water and that all the sodium phosphate species contained in the samples compose an amorphous phase.

TABLE 2. DISTRIBUTION AND AVERAGE CHAIN LENGTH OF PHOSPHATES OF THE $NaPO_3$-Sb_2O_3-Na_2O SYSTEM WITH P/Sb RATIOS OF 7.0—300

	Phosphate (P%)						
P/Sb	Ortho	Pyro	Tri	Tri-meta	Tetra-meta	Higher	$\bar{n}$
7.0	2.7	28.8	21.6	5.4	8.5	33.1	3.6
10	2.0	15.8	7.2	5.6	7.9	61.5	4.7
15	2.0	8.5	7.4	5.6	6.4	70.1	7.0
20	1.9	5.2	5.2	5.0	5.4	77.2	8.4
30	1.8	4.4	4.2	4.3	4.3	80.9	11
50	1.5	4.0	3.9	3.8	4.4	82.3	21
80	1.1	3.3	3.5	3.3	4.1	84.7	29
100	0.8	2.4	3.0	2.6	3.7	87.5	37
150	0.6	1.3	2.5	2.0	3.3	90.3	49
200	0.4	0.9	1.0	1.5	3.4	92.8	52
300	0.4	0.7	0.8	0.8	2.9	94.4	65

When the samples of the glassy substances with the P/Sb ratios larger than 7.0 are treated with water, antimony trioxides are deposited. The compositions of the phosphate species in the sample solutions were determined by paper chromatography. The results for the samples are given in Table 2. When the P/Sb ratio increases, the contents of ortho- and pyrophosphate decrease, and that of high polyphosphate increases. The contents of tripolyphosphate increase with the increase in the P/Sb ratio from 1.0 to 7.0 and decrease with the decrease in the P/Sb ratio from 7.0 to 300. The trimetaphosphate contents indicate the largest value when the P/Sb ratio is 5.0, and decrease with the increase in the P/Sb ratio. The tetrametaphosphate contents decrease with the increase in the P/Sb ratio from 7.0 to 300.

The average chain lengths of the polyphosphates given in Table 2 were measured by the pH titration method, assuming that the phosphates were composed of polyphosphates and did not contain ortho- and ring phosphates. By the results of the paper-chromatographic analysis of the glasses, it is shown that the quantities of orthophosphate and of ring phosphates are less than several per cent. Therefore, the effect of their presence on the calculation of the average chain length of polyphosphates is disregarded in the following discussion.

Between the Na/P ratio and the average chain length, $\bar{n}$, of sodium polyphosphate, there is this relation:

$$\mathrm{Na/P} = (\bar{n}+2)/\bar{n} \qquad (1)$$

where Na/P is the atomic ratio of these two elements. If antimony trioxide does not react with phosphate glass to form P-O-Sb linkages in the melted state, the Na/P ratio is equal to $(x+1)/x$, where x is the P/Sb ratio. By using these relations, Eq. (2) is obtained:

$$\bar{n} = 2x \qquad (2)$$

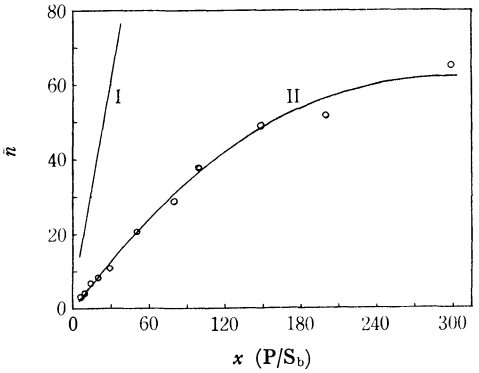

Fig. 1. Variation of average chain length of polyphosphates.
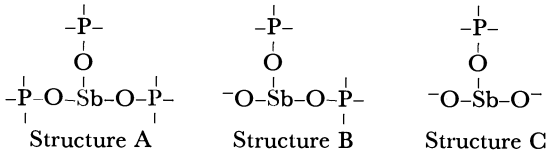
I: Values calculated by Eq. (2)
II: Experimental values

The straight line, I, in Fig. 1 indicates this relation. Curve II in Fig. 1 indicates the relation between the measured average chain length of polyphosphates and the P/Sb ratio, x. The great discrepancy between the straight line, I, and the curve, II, means that the above assumption is not correct. Therefore, the sodium phosphate glass seems to react with antimony trioxide at a high temperature to form P-O-Sb linkages. There are three possible structures containing P-O-Sb and Sb-O$^-$ linkages. Assuming that the hydrolytic scission



of P–O–Sb linkage occurs rapidly in water, the average chain length, $\bar{n}$, of the polyphosphates in the glass of the $NaPO_3$–Sb_2O_3–Na_2O system is given by Eq. (3):

$$(\bar{n}+2)/\bar{n} = (x+y+1-z)/x \qquad (3)$$

where x, y, and z are the numbers of phosphorus atoms, P-O-Sb linkages, and Sb-O$^-$ linkages per atom of antimony. If the glasses are composed only of Structure A, y is 3 and z is 0, and x is the P/Sb ratio of the glass. The average chain length of the polyphosphate can be calculated by inserting these values into Eq. (3). The calculated values of $\bar{n}$ are given in Table 3. The

Table 3. Average chain length of polyphosphates

x (P/Sb)	$\bar{n}$ Found	Column I $\bar{n}$ calcd by Eq. (3) Structure A (y=3, z=0)	Structure B (y=2, z=1)	Structure C (y=1, z=2)	Column II $\bar{n}$ calcd by Eq. (4) (f=0.02) Structure A (y=3, z=0)	Structure B (y=2, z=1)	Structure C (y=1, z=2)
7.0	3.6	3.5	7.0	∞	3.4	6.5	100
10	4.7	5.0	10	∞	4.8	9.1	100
15	7.0	7.5	15	∞	7.0	13	100
20	8.4	10	20	∞	9.1	17	100
30	11	15	30	∞	13	23	100
50	21	25	50	∞	20	33	100
80	29	40	80	∞	29	44	100
100	37	50	100	∞	33	50	100
150	49	75	150	∞	43	60	100
200	52	100	200	∞	50	67	100
300	65	150	300	∞	60	75	100

underlined values are the average chain length nearest to the measured one. As the column I of Table 3 shows, even the calculated values of the average chain length based on Structure A are considerably larger than the measured values when x is larger than 20.0. The presence of a branching point and impurities in the phosphate-antimonate glasses shortens the chain length of polyphosphates. Representing all these factors by factor f, Eq. (3) is modified into Eq. (4):

$$(\bar{n}+2)/\bar{n} = (x+y+1-z+fx)/x \qquad (4)$$

where f is given with respect to an atom of phosphorus. If f is arbitrarily set at 0.02, the calculated average chain lengths of the glasses shown in column II of Table 3 are given by Eq. (4). If the factor, f, is zero, Eq. (4) is reduced to Eq. (3). As column II of Table 3 shows, the values calculated on the basis of Structure A are close to the experimental values through out the range of P/Sb ratios from 7.0 to 300. According to above discussion, it seems reasonable to conclude that the structural framework of the glasses of condensed phosphate-antimonates is composed of Structure A, and that Structure B and C are not involved in the structural framework.

Summary

Crystalline and glassy substances of phosphate-antimonate systems with P/Sb ratios in the range from 1.0 to 300 were prepared by heating a mixture of sodium metaphosphate, antimony trioxide, and sodium carbonate at 1000°C for 2 hr. The samples with P/Sb ratios in the range from 1.0 to 5.0 were obtained as crystalline substances containing amorphous substances, while those with P/Sb ratios in the range from 7.0 to 300 were obtained as glassy substances. By paper chromatography and X-ray diffractometry, the samples containing crystalline and amorphous substances were found to be composed of Sb_2O_5, $NaSbO_3$, an unknown crystalline substance, and various condensed phosphates. From the results of paper chromatography and the measurement of the average chain length of the phosphates by the pH titration method, it was revealed that the higher the P/Sb ratio, the longer were the chains of the polyphosphates produced; it was concluded that the $NaPO_3$-Sb_2O_3-Na_2O glasses with the P/Sb ratios in the range from 7.0 to 300 had P-O-Sb linkages.

Coexistence States of Iron in Synthesized Iron-bearing Allophane (Al_2O_3-SiO_2-Fe_2O_3-H_2O System)

Joyo OSSAKA,* Shin-ichi IWAI,** Mitsuhiro KASAI,***
Toshiaki SHIRAI,*** and Shuichi HAMADA***

*** *Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo*

(Received June, 29, 1970)

A sharp exothermic peak at 980°C, which is found characteristic of allophane in its differential thermal analysis, shifted to the lower-temperature side and broadened as the iron content in the iron-coprecipitated samples increased. In the case of the iron-mixed samples, however, this exothermic peak did not shift, and a new broad exothermic peak, which was ascribed to hydrated ferric oxide, appeared. The crystallization processes in the heat-treated samples were found to depend on the coexistence state and the quantity of the iron. The dimensions of a unit cell of the mullite, crystallized at 1200°C from the iron-coprecipitated samples, varied with the iron content. The iron-mixed samples, however, showed little change in their cell dimensions. It is concluded that there are two states of the coexistence of iron in the allophanes. In one of them, iron ions form solid solutions of the allophane, *i.e.*, as an iron-allophane. In the other, iron is in the mixture as the hydrated ferric oxide. The maximum amount of iron in the solid solution was estimated to be 5 wt% in the iron-allophane.

An allophane is an amorphous or low-crystalline mineral, and its main components are silica, alumina, and water. Its chemical formula may be generally expressed as $1\text{-}2SiO_2 \cdot Al_2O_3 \cdot 5H_2O$. The allophane is considered not to be a simple mixture of a hydrated aluminum oxide gel and a silicic-acid gel.[1,2] The natural allophanes usually contain iron. The natural iron-bearing allophane dose not always show the same properties. It has, therefore, been suggested that there are two states of the coexistence of iron in the soil-allophane.[3]

In this work, the coexistence states of iron in the synthesized iron-bearing allophanes were studied by means of differential thermal analysis and X-ray powder diffractometry on heat-treated samples.

Experimental

Materials. The iron-coprecipitated samples were prepared in the following manner:[4] a mixed solution of aluminum sulfate, sodium silicate,[5] and ferric sulfate was boiled at a specified acidity of pH 5.4—6.0 obtained by adding hexamethylenetetramine. The gel thus coprecipitated was washed by decantation and then air-dried for three weeks. The iron-mixed samples were also prepared by mixing the synthesized allophane, free from iron, and the hydrated ferric-oxide gel in order to compare the properties of the iron-coprecipitated samples. The colors of the iron-coprecipitated and the iron-mixed samples were yellow and light-purplish red respectively.

Procedure. The X-ray powder diffractograms of the samples were taken with a Geigerflex, Model D-3F, Rigaku Denki Company, while the differential thermal analysis was carried out with equipment designed in our laboratory.

The sample, in a quartz tube, was heated for five hrs in an electric furnace at 800, 900, 1000, 1100, and 1200°C respectively. The firing-products were identified and their relative amounts were estimated by using the diffraction peaks at (210) and (120) of the mullite, those at (104) and (110) of the hematite, that at (440) of the silico-alumina spinel, and that at (101) of the cristobalite. The unit-cell dimensions of the mullite, one of the firing products, was calculated by using the diffraction peaks at (230), (121), and (201) of the mullite.

TABLE 1. CHEMICAL COMPOSITIONS OF COPRECIPITATED AND MIXED SAMPLES

Results

The chemical compositions of the samples are given in Table 1.

The silica/alumina ratios in the samples did not agree with the original ratios of the components in the solutions. The former were almost always smaller than the latter.[6]

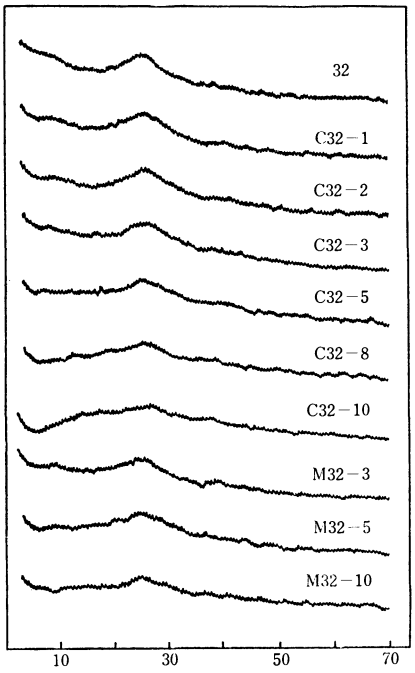

Fig. 1. X-Ray powder diffraction patterns.

The X-Ray Powder Diffractometry and the Differential Thermal Analysis of the Samples. Figure 1 shows the X-ray powder diffraction patterns. All the samples were identified as amorphous or lower crystalline materials, since there were few sharp peaks. However, a very broad peak was observed at approximately 25° (2θ; CuKα) in the iron-coprecipitated samples with a smaller amount of iron.

The DTA curves are shown in Fig. 2. All the samples showed the broad endothermic peak in the range from 100°C to 200°C and the exothermic peak at approximately 900°C, a position which was characteristic of the allophane. The exothermic peak observed in the iron-coprecipitated samples shifted from 980°C to 860°C and broadened as the iron content increased. On the contrary, the exothermic peak observed in the iron-mixed samples did not shift and did not broaden in spite of the change in the iron content, while the very broad exothermic pattern, which was assigned to the hydrated ferric oxide, was observed in the range from 300°C to 500°C. Although the iron-coprecipitated samples containing less than 5 wt% of iron showed only allophane-characteristic DTA curves, the broad exothermic peak due to the hydrated ferric oxide was observed when the iron content was above 5 wt%.

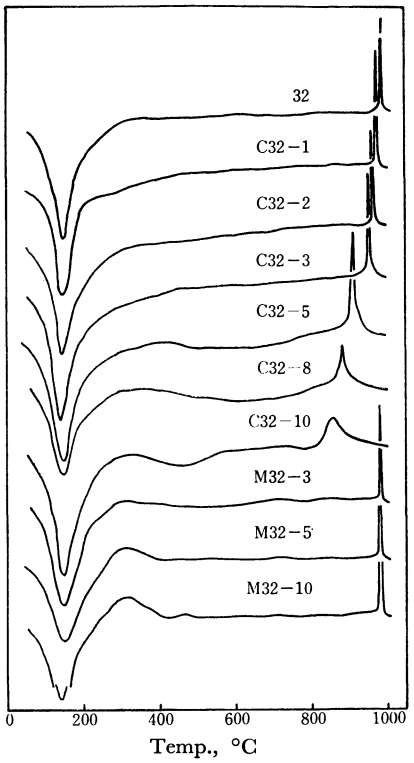

Fig. 2. DTA curves.

The Variation in Firing-products in the Samples during the Heat-treatment. The crystalline phases formed in the heat-treated samples at 800, 900, 1000, 1100, and 1200°C respectively were examined by means of the X-ray powder diffractometer. Although the final product of the heat treatment was the mullite, the crystallization process was found to vary, depending on the condition of the original samples (Fig. 3). The crystal-

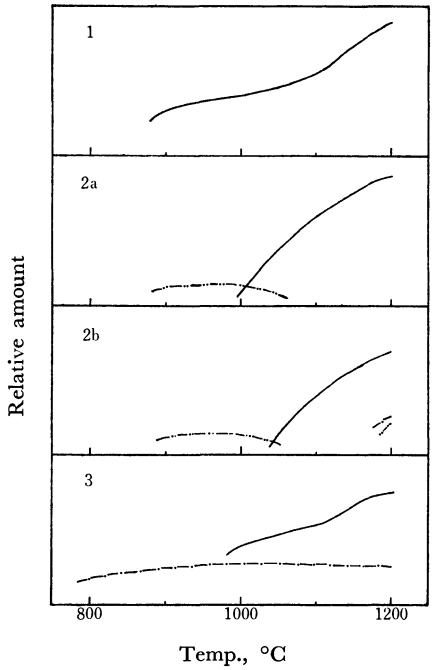

Fig. 3. Types of crystallization processes.
——— Mullite —·—·—·— Silico-alumina spinel
–·–·–·– Hematite ····· Cristobalite

lization processes may be classified into three types, as is shown in Fig. 3. It can be seen from Fig. 3 that the crystallization processes depend on the content and the coexistence state of the iron, while the silica/alumina ratio did not affect the crystallization process. The crystallization of all the iron-mixed samples belonged to the 3-type process, even if the iron content was only 3 wt%. The crystallization process of the iron-coprecipitated samples was found to be of the 1 or 2 type. The crystallization process of the iron-coprecipitated samples with less than 3 wt% iron was the same as that of the iron-free allophane, while those above 3 wt% were transformed into the mullite through the silico-alumina spinel phase. However, the hematite and the cristobalite phases were observed at 1200°C when the samples contained more than 8 wt% of iron. A clear difference between the crystallization processes of the iron-coprecipitated and the iron-mixed samples was also found in the DTA analysis.

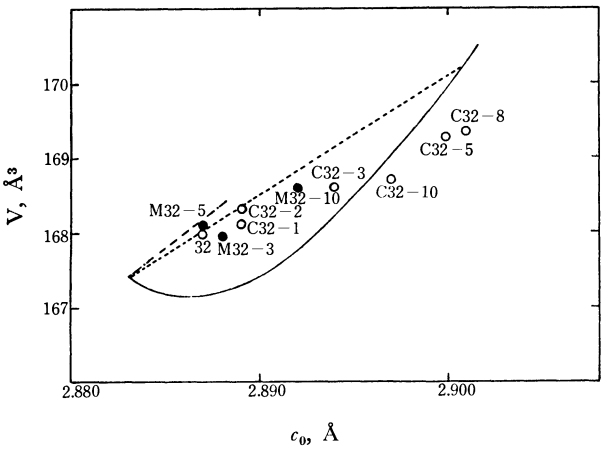

Fig. 4. Relationship between c_0 and V of crystallized mullite at 1200°C.
-·-·-·- iron free mullites[6]
– – – – iron and titanium-bearing mullites.
····· iron bearing mullite[11]

The Unit-cell Dimensions of the Mullite Formed in the Samples. The values of c_0 and the unit-cell volume, V, of the mullite which was formed in the heat-treated samples at 1200°C for five hrs were estimated from the X-ray powder diffractograms. The relationship between c_0 and V is shown in Fig. 4. The c_0 and V values of iron-free mullite varied with the silica/alumina ratios.[7] Therefore, the variation in the cell dimensions in the mullite with the quantity of iron was examined by comparing samples with the same original ratio of silica/alumina. The c_0 and V values of the mullite crystallized from the iron-coprecipitated samples increased with an increase in the iron content, while the c_0 and V values for the iron-mixed samples were nearly equal to those for the iron-free allophane except for the M32-10 sample. A clear difference in the cell dimensions was observed between the two types of samples.

Discussion

The exothermic peak at approximately 900°C in the differential thermal analysis on silica-alumina gel was explained as originating from the formation of γ-alumina[8] or mullite.[9,10] However, the X-ray analysis favored the conclusion that the formation of the mullite was mainly responsible for this peak in the present experiment.

It was found, in the case of the iron-coprecipitated samples with more than 3 wt% of iron, that the transformation to the mullite occurred through the intermediate stage of the formation of the silico-alumina spinel, while the iron-coprecipitated samples with less than 3 wt% of iron were transformed directly into the mullite, as with the iron-free allophane. The existence of the silico-alumina spinel as a metastable phase in the mullite was found in the course of the crystallization of heat-treated kaolinite by Brindley and Nakahira.[11]

The iron-mixed samples were converted into hematite with little change in their cell dimensions. Therefore, it can be said that the silica-alumina gel reacted in some degree with the hydrated ferric oxide, but formed a solid solution only with difficulty. Agrell and Smith,[7] and Murthy and Hummel[12] pointed out that the cell dimensions increased considerably with an increase in the iron content in the solid solution of the mullite, while the silica/alumina ratio in the mullite hardly influenced the cell dimensions. The large change in the cell dimensions of the mullite which was found when the iron content of the sample was varied indicates the formation of a solid solution of the mullite with iron. Agrell and Smith[7] also reported that there was 2 wt% of iron in a solid solution of the mullite, while the hematite was found, besides the solid solution of the mullite, when 5 wt% of iron was present in the sample. In the present study, it can be concluded, as in Fig. 4, that the solid solution of the mullite with iron is formed when the iron content is less than 5 wt%.

These facts support the idea that iron is contained as a solid solution of the allophane, *i.e.*, that it is the iron-allophane, when the amount of iron in the coprecipitated samples, is less than 5 wt%, while a part of the iron takes the form of the hydrated ferric oxide when its quantity is larger than 5 wt%.

Synthesis of Iron-Titanium Oxides under Hydrothermal Conditions

Kiyoshi MATSUOKA

Faculty of Literature and Science, Kôchi University, Kôchi

(Received August 5, 1970)

The solid solutions in the system FeO-Fe_2O_3-TiO_2 were synthesized under hydrothermal conditions up to 700°C and 2.5 kb (P_{H_2O}). The results of X-ray diffraction, chemical and thermomagnetic analyses indicated that the products always consisted of magnetite-ulvöspinel or hematite-ilmenite solid solutions and, in some cases, rutile was also formed. The presence of the solid solutions of magnetite and ulvöspinel indicates a reducing atmosphere during the treatment. When P_{H_2O} increased from 1 kb to 2.5 kb, the FeO contents in the products decreased.

Minerals belonging to the system FeO–Fe_2O_3–TiO_2 are abundant in the earth's crust. Magnetite (Fe_3O_4), a representative mineral, is known to have a spinel structure and to be ferrimagnetic.[1] Ulvöspinel (Fe_2TiO_4) also has a spinel structure but is not ferrimagnetic at room temperature. These two minerals form a continuous solid solution.[2] Hematite (α-Fe_2O_3) has a rhombohedral structure which makes this substance parasitic ferromagnetic.[3] The crystallographic structure of ilmenite ($FeTiO_3$) is analogous to that of hematite, with some differences in magnetic properties.[4] Hematite and ilmenite are the final components of solid solutions, and the relations between chemical composition and cell dimensions have been investigated in detail.[5] Another series of solid solutions is found in the system $FeTi_2O_5$-pseudobrookite (Fe_2TiO_5). These solid solutions have orthorhombic structures and exhibit paramagnetism.[6] Of the three polymorphic forms of TiO_2 (rutile, brookite, and anatase), rutile is the most commonly occurring phase and found to be stable in a wide region of temperature and pressure.[7]

Most investigators have studied the synthesis and stability concerning the FeO–Fe_2O_3–TiO_2 system at atmospheric pressure or below (Ref. 8). In the present investigation, a synthesis of minerals belonging to the above system was attempted in relation to the determination of stable phases under hydrothermal conditions. If this attempt is successful, the results are expected to be useful for explaining the occurrence of these minerals in nature.

Experimental

Starting Materials. A series of solutions containing titanium (IV) chloride and iron (III) chloride in various ratios were mixed with ammonia. The resulting precipitate was washed with ammonia, air-dried, and ground to powder. The powder was confirmed to be amorphous by X-ray diffraction. After ignition, the content of Fe_2O_3 in the powder was determined by the Reinhardt method. The molar ratio of TiO_2 and Fe_2O_3 in the powder was then calculated. The powder was used as the starting material. The chemical compositions of the starting materials are shown in Table 1.

TABLE 1. COMPOSITION (MOL%) OF STARTING MATERIALS

Starting material	TiO_2	Fe_2O_3
A	70.0	30.0
B	59.2	40.9
C	50.9	49.1
D	29.2	70.8
E	15.0	85.0

Apparatus and Procedure of Synthesis. Each starting material was sealed in a gold capsule together with a nearly constant amount of water, and was treated in a test-tube type reactor[9] under various conditions of temperature and pressure from 400° to 700°C and at 1 kb or 2.5 kb (P_{H_2O}). After being kept for 48 to 454 hours, the reactor was quenched to room temperature within three minutes.

Examination of Specimens. *Chemical Analysis*: The FeO content in the quenched specimen was determined by permanganate titration. The molar ratio of TiO_2, Fe_2O_3, and FeO was then calculated.

X-Ray Diffraction: X-Ray powder patterns, obtained with iron-filtered Co-$K\alpha$ radiation, were used for identification of phases and determination of the chemical composition of the solid solutions.

The values of a and c were calculated for the hematite-ilmenite solid solution. The value of c, which is sensitive to variation of the chemical composition, was compared with Lindsley's result[10] to determine the chemical composition. In the case of the magnetite-ulvöspinel solid solution, the chemical composition was also determined by referring to the relation obtained by Lindsley.[10]

Thermomagnetic Analysis: A magnetic balance similar to the apparatus reported by Shimada *et al.*[11] was used for the thermomagnetic analysis at room temperature and above.

R*: $FeO/(2Fe_2O_3+FeO)$ calculated from composition.

the products are summarized in Table 2. Since no Fe (II) ion was contained in any of the starting materials, the ratio $FeO/(2Fe_2O_3+FeO)$ shows the extent of reduction which occurred during the treatment. Figs. 1 (a) and (b) give ternary diagrams in which the composition of the starting materials and the products are plotted. A comparison of these results with those in Table 2 reveals the following. (1) The extent of reduction increases under conditions of temperature and pressure above 600°C and 1 kb. (2) The extent decreases at 600°C, when P_{H_2O} increases from 1 kb to 2.5 kb.

In the range from 400 to 500°C, hematite-like and

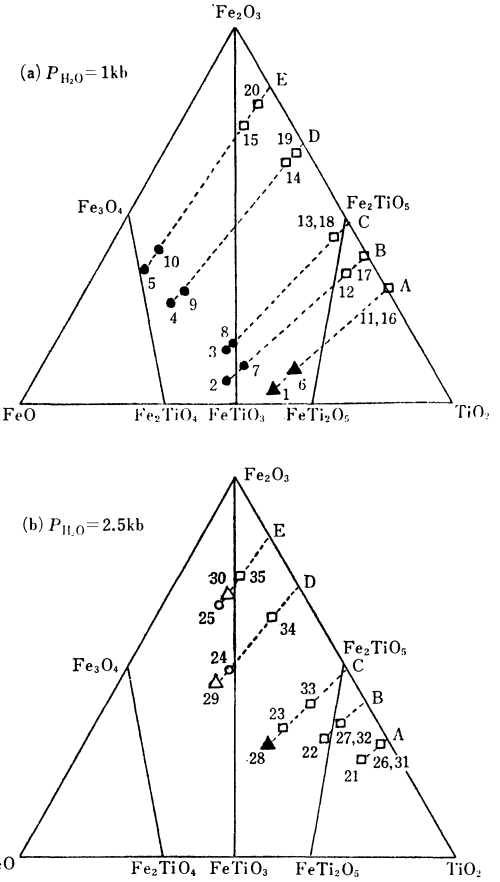

Fig. 1. Ternary diagrams in the system FeO-Fe_2O_3-TiO_2 on which the chemical composition of the starting materials and those of the hydrothermal products are plotted. The letters A, B, *etc.* in the diagrams correspond to those in Table 1. The numbers also correspond to those in Table 2.
●: coexistence of ilmenite-like crystal with magnetite.
○: hematite-like crystal.
□: coexistence of hematite-like crystal with rutile.
△: coexistence of hematite-like crystal with magnetite.
▲: coexistence of ilmenite-like crystal with rutile.

rutile-like crystals are formed regardless of the starting materials. When temperature increases, the composition of the hematite-like crystals approaches that of ilmenite.

X-Ray Diffraction and Composition of Products. The results of X-ray powder diffraction and the composition determined from the cell dimensions are summarized in Table 3. The products consist of one or two phases and each phase corresponds to rutile, hematite, ilmenite or magnetite, although the *d*-spacings of each phase differ from ideal values. The differences are caused by the fact that these phases are not the final components of solid solution series in the FeO–Fe_2O_3–TiO_2 system but those of an intermediate composition.

Figures 2 (a) and (b) show the variation of d_{104} of the hematite-ilmenite solid solutions with the change in reaction conditions. The values of d_{104} of the hematite-ilmenite solid solutions are plotted against the chemical composition in Fig. 3.

Thermomagnetic Analysis. The results of thermomagnetic analysis indicate that the products have the

a) Mole percentage of ilmenite in ilmenite-hematite solid solution.
b) Mole percentage of magnetite in magnetite-ulvöspinel solid solution.
R_1 and R_2 were determined using the cell dimensions and Lindsley's results. When diffraction was weak and the calculation of the cell dimensions was difficult, the composition was estimated by the value of d_{104} with reference to Fig. 3.

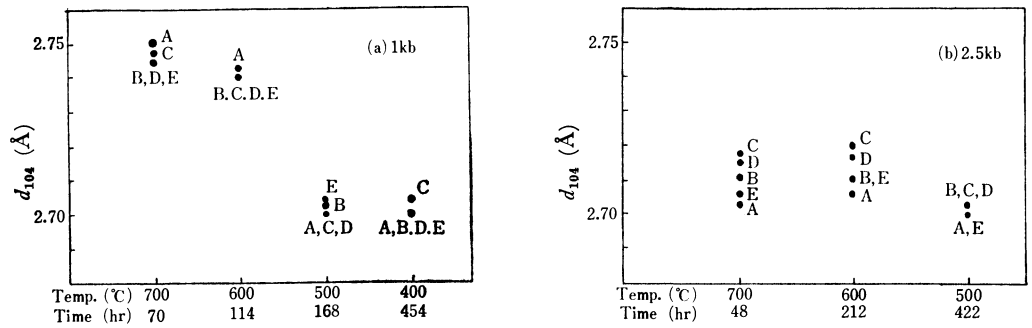

Fig. 2. Variation of d_{104} of hematite-ilmenite solid solutions with change in the reaction conditions. The letters A, B, *etc.* correspond to those in Fig. 1.

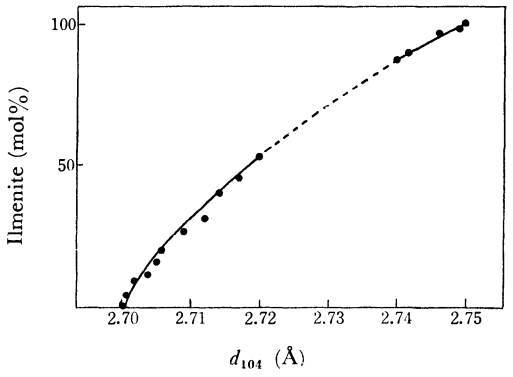

Fig. 3. Relation between the chemical composition and d_{104} in hematite-ilmenite solid solutions.

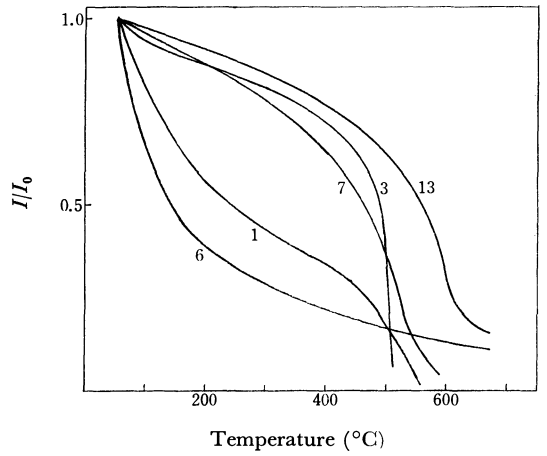

Fig. 4. Magnetization of the products as a function of temperature. The numbers on each curve correspond to those in Table 2. I_0 : Magnetic moment at 50°C.

intermediate composition of solid solution series in the FeO–Fe_2O_3–TiO_2 system. This is in line with the results obtained by X-ray diffraction. In Fig. 4 the curves (3) and (7) show a similar temperature dependency to magnetite. In these cases, the magnetite-ulvöspinel solid solutions are found by X-ray diffraction.

From the curve (13), the presence of a hematite-like crystal is expected which agrees with the result of X-ray diffraction.

It is thought that the decreasing P_{O_2} at elevated temperatures is established either by the dissociation of water or by the reaction of water and the metal wall of the reactor.[12] This has not been clarified in the present experiments.

From the results, the following conclusions are obtained.

(i) All the crystals that belong to the system FeO–Fe_2O_3–TiO_2 and remain stable under hydrothermal conditions up to 700°C and 2.5 kb are classified into rutile, magnetite-ulvöspinel solid solutions and hematite-ilmenite solid solutions.

(ii) Synthesis of a new mineral is unsuccessful under the conditions of the present investigation, when the starting materials belonging to the system Fe_2O_3–TiO_2 are used.

(iii) Atmosphere surrounding the samples under the hydrothermal conditions was reducing to a certain extent. The cause of this reduction is not clearly shown at this stage of investigation, but P_{O_2} acting on the samples at 700°C and 1 kb corresponds to the value of the order of 10^{-8} atm at 1300°C proposed by Taylor.[13]

(iv) The common occurrence of magnetite-ulvöspinel or hematite-ilmenite solid solutions in nature is explained if these minerals remain stable even under hydrothermal conditions as was proved by the present experiments.

The author wishes to thank Professor Mitsue Koizumi and Professor Shoichi Kume of Osaka University for their kind guidance and help. Thanks are also due to Professor Jumei Yamasaki of Kôchi University for his encouragement throughout this work.

A Proton Magnetic Resonance Study of Cobalt(III) Complexes Containing 1,10-Phenanthroline and Ethylenediamine

Haruko Ito, Junnosuke Fujita, and Tasuku Ito*

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

* *Department of Chemistry, Faculty of Education, Fukushima University, Fukushima*

(Received August 17, 1970)

The proton magnetic resonance (PMR) spectra of the phenanthroline ligand in $[Co(phen)_3]Cl_3$, $[Co(phen)_2(en)]Cl_3$ (new complex) and $[Co(phen)(en)_2]Cl_3$ were measured in deuterium oxide and analyzed as ABX systems. Significant up-field shifts of signals were observed only for the protons 2 and 9 of $[Co(phen)_3]^{3+}$ and the proton 2 of $[Co(phen)_2(en)]^{3+}$, not for the proton 9 of $[Co(phen)_2(en)]^{3+}$ nor the protons 2 and 9 of $[Co(phen)(en)_2]^{3+}$. The up-field shift was considered to be due to the effect of the ring current of the other phenanthroline ligands, since the protons 2 and 9 of $[Co(phen)_3]^{3+}$ and the proton 2 of $[Co(phen)_2(en)]^{3+}$ lies very close and to above the neighboring aromatic ligand.

The PMR spectra of 1,10-phenanthroline and its diamagnetic tris-complexes of iron(II), ruthenium(II), osmium(II), zinc(II), and cobalt(III) have been well examined.[1,2] Their spectra were analyzed as an ABX system, for the two halves of the ligand are chemically and magnetically equivalent, and no coupling was observed between neighboring protons on different aromatic rings (*e. g.*, H_4 and H_5 in Fig. 1). On the other hand, the spectra of *cis*-$[CoX_2(phen)_2]^{n+}$ were considered to consist of two independent ABX systems (H_2, H_3 and H_4, and H_9, H_8 and H_7) and an AB system (H_5 and H_6).[3] The significant up-field shift of signals corresponding to H_2 and H_9 in $[M(phen)_3]^{n+}$ and to H_2 in $[CoX_2(phen)_2]^{n+}$ was interpreted in terms of a metal-nonbonded hydrogen interaction,[1,2] or the effect of the ring current of the other aromatic ligand.[4,5] In order to clarify the origin of this kind of up-field shift, we have analyzed the PMR spectra of a series of complexes, $[Co(phen)_3]Cl_3$, $[Co(phen)_2(en)]Cl_3$, and $[Co(phen)(en)_2]Cl_3$. These three complexes are ter-positive ions surrounded by six nitrogen atoms in pseudo-octahedral positions. Thus, the effect of solvation on the spectra will not be significantly different among these complexes.

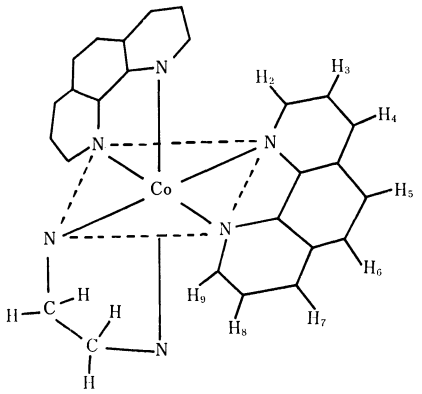

Fig. 1. Numbering of the protons on the phenanthroline ligand.

Experimental

Materials. *Bis(phenanthroline)ethylenediaminecobalt(III) perchlorate,* $[Co(phen)_2(en)](ClO_4)_3$: A mixture of 0.54 g of *trans*-(Cl–Cl)-$[CoCl_2(NH_3)_2(en)]Cl \cdot 0.5H_2O$[6] and 0.78 g of phenanthroline monohydrate in 50 m*l* of water was refluxed at 80°C for about 6 hr. The orange solution was then evaporated on a water bath to about 20 m*l* and cooled to room temperature. A crude complex was precipitated by adding concentrated perchloric acid. The precipitate was filtered off, washed with a small amount of cold water, recrystallized from hot water, and air-dried.

Found: C, 39.36; H, 3.40; N, 10.47%. Calcd for $CoC_{26}H_{24}N_6Cl_3O_{12}$: C, 40.15; H, 3.11; N, 10.80%. For the PMR measurement, the perchlorate was converted into chloride by the anion-exchange method.

The $[Co(phen)_3]Cl_3$ and $[Co(phen)(en)_2]Cl_3$ complexes were obtained by the methods described in the literature.[7,8]

Measurements and Calculation. The PMR spectra were recorded at about 39°C with Varian T 60 and Varian HA 100 spectrometers in a deuterium oxide solution containing sodium trimethylsilylpropanesulfonate (DSS) as the internal standard. The coupling constants, the chemical shifts, and the intensities were calculated with the HITAC 5020E electronic computer at the Computer Center of the University of Tokyo. The Fortran program for Castellano and Waugh's analysis[9] was kindly supplied by Dr. J. Cavanaugh of the Research Department, Socony Mobil Oil Company, Inc., Paulsboro, New Jersey, U.S.A. Since there are some signals which overlap each other, the peak height of the signals was taken as the approximate intensity.

Results and Discussion

The 60 MHz spectra of $[Co(phen)_3]Cl_3$, $[Co(phen)_2(en)]Cl_3$, and $[Co(phen)(en)_2]Cl_3$ in the phenanthroline part are given in Fig. 2.

The spectral pattern of $[Co(phen)(en)_2]^{3+}$ in the

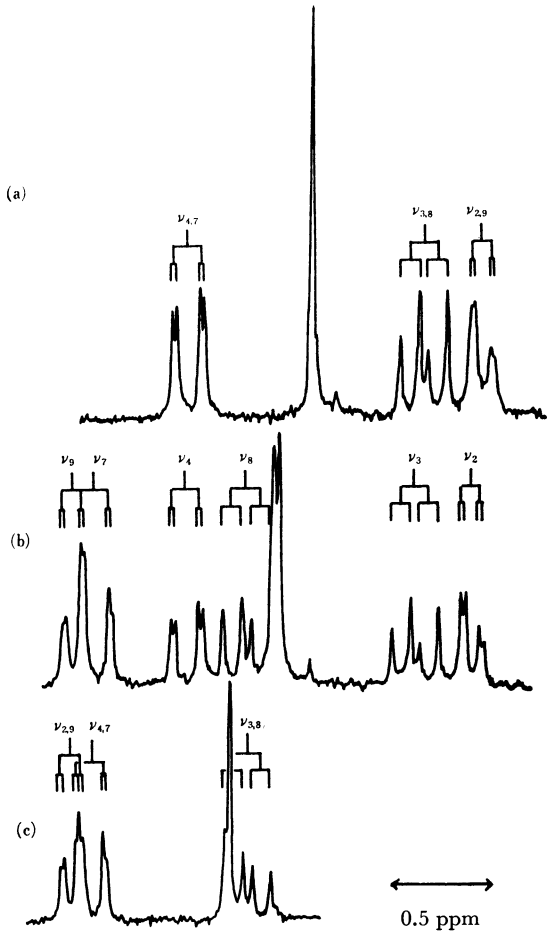

Fig. 2. 60 MHz spectra of $[Co(phen)_3]Cl_3$ (a), $[Co(phen)_2(en)]Cl_3$ (b) and $[Co(phen)(en)_2]Cl_3$ (c) in D_2O. The origin of the abscissa of each complex is arbitrary.

region of the phenanthroline part corresponds well to that of the free ligand,[1] although the chemical shifts are slightly different. The signals of all the protons on the chelate appeared at slightly lower fields than those of the corresponding protons on the free ligand,[1] this may be due to the deshielding effect of the central metal ion. Thus, the $\nu_{2,9}$, $\nu_{3,8}$, and $\nu_{4,7}$ signals in Fig. 2 of $[Co(phen)(en)_2]^{3+}$ were assigned to $H_{2,9}$, $H_{3,8}$, and $H_{4,7}$ respectively. No up-field shift of the signals corresponding to $H_{2,9}$ is observed in this complex.

The chemical environment of half of the phenanthroline part of $[Co(phen)_2(en)]^{3+}$ is similar to that of $[Co(phen)_3]^{3+}$, and that of the other half, to that of $[Co(phen)(en)_2]^{3+}$ (see Fig. 1). Therefore, the spectrum of $[Co(phen)_2(en)]^{3+}$ may be expected to be similar to the sum of those of $[Co(phen)_3]^{3+}$ and $[Co(phen)(en)_2]^{3+}$. As is shown in Fig. 2, the relative positions of ν_2 and ν_3 signals of $[Co(phen)_2(en)]^{3+}$ are very close to those assigned to $H_{2,9}$ and $H_{3,8}$ respectively for $[Co(phen)_3]^{3+}$.[1,2] Thus, these signals can be assigned to the H_2 and H_3 protons respectively (Fig. 1). On the other hand, the resonance of ν_9 and ν_8 appear in the regions of $H_{2,9}$ and $H_{3,8}$ of $[Co(phen)(en)_2]^{3+}$; they are assigned to the H_9 and H_8 signals respectively. The resonances of ν_4 and ν_7 are assigned to H_4 and H_7 respectively for the same reason. These assignments were also confirmed by double-resonance measurements. The 100 MHz spectrum and the double-resonance spectra of $[Co(phen)_2(en)]^{3+}$ are shown in Fig. 3. Upon irradiation at about 9.05 ppm (in the region of H_4), the spectrum in the region of H_2 and H_3 became an AB pattern (Fig. 3(b)), and upon irradiation at about 8.87 ppm (in the region of H_8), the spectrum in the region of H_7 and H_9 changed to a broad doublet (an AB pattern with a small coupling constant) (Fig. 3(c)). In Fig. 3(a), an AB pattern with a coupling constant of 9.1 Hz is observed at 8.73 ppm; this can be assigned to signals of H_5 and H_6.

On the basis of the above assignment, the chemical shifts and the coupling constants were calculated as two independent ABX patterns. Tables 1 and 2 show the calculated values of the chemical shifts and the coupling constants respectively. The calculated and the ob-

a) 60 MHz spectrum; b) 100 MHz spectrum; Negative sign indicates that the shift is lower than c) 508 Hz, d) 536 Hz, e) 830 Hz, and f) 937 Hz (DSS is used as an internal standard); g) These are in good argreement with the observed ones.

served intensities are compared in Table 3. The data for $[Co(phen)_3]^{3+}$ and $[Co(phen)(en)_2]^{3+}$ are also listed in these tables.

A large difference in the chemical shifts between H_2 and H_9 was observed for $[Co(phen)_2(en)]^{3+}$ (1.93 ppm). This could not be explained only by the metal-non-bonded hydrogen interaction suggested by Miller and Prince,[1,2] since no significant difference in distances between Co–H_2 and Co–H_9 can be expected. An explanation by the π-bonding effect was also ruled out,[2] and the effect of the solvation[1,2] is considered to be not very significant, as has been discussed earlier.

The molecular model indicates that the proton 2 lies very close above the plane of the pyridine ring of the other phenanthroline ligand. The distance between the proton 2 and this plane is calculated to be about 2.7 Å on the assumption that the bond lengthes of Co–N, C=N, C=C, and C–H are 1.97,[10] 1.39, 1.39, and 1.08 Å respectively, and that all the bond angles in the coordinated ligands are 120°. The nitrogen atoms are also assumed to coordinate in the regular octahedral positions. Accordingly, the large up-field shift can reasonably be explained as being caused by the ring current of the neighboring ligand, as has been suggested by Castellano *et al.* for $[Fe(bipy)_3]^{2+}$.[4]

The differences in the chemical shifts between H_9 and H_2, H_8 and H_3, and H_7 and H_4 of $[Co(phen)_2(en)]^{3+}$ are 1.93, 0.94, and 0.44 ppm respectively. The decrease in the difference in the chemical shift in the above order can be accounted for by the increase in the distances between the proton and the molecular plane of the other phenanthroline ligand.

The authors wish to thank Professor Kazuo Saito for helpful advice and encouragement.

(Received September 7, 1970)

The electronic configuration around the tin atom for a series of organotin-manganese compounds, $R_{3-x}X_xSn$-$Mn(CO)_5$, has been studied by ^{119}Sn-Mössbauer and ^{1}H- and ^{55}Mn-NMR spectroscopies. All the results obtained from these spectroscopic measurements show that the $Mn(CO)_5$ group is a stronger electron donor than the methyl, phenyl, or halogen group and that the tin-manganese bond prefers the sσ-character whereas the tin-halogen bond prefers the pσ-character. The relationship between the ^{55}Mn-chemical shift and the ^{119}Sn-isomer shift indicates some σ-electron withdrawal from manganese to tin. The phenyl group reduces the magnitude of quadrupole splitting more than the methyl group; this fact may be due to the mesomeric effect of the phenyl group through the π-bond between tin and ligand atoms. The relationship among the ^{119}Sn-isomer shift, the ^{1}H-chemical shift, and the coupling constant $J(^{119}Sn\text{-}^{1}H(CH_3))$ is also shown.

The Mössbauer spectroscopy in ^{119}Sn has been used to study a wide variety of organotin compounds as well as inorganic compounds.[1,2] The two Mössbauer parameters which are common to most studies, the isomer shift and the quadrupole splitting, have been used to elucidate the electronic configuration around the tin atoms, but there are a number of contradictions in these explanations.[3-5] Mössbauer spectroscopic studies of many compounds containing tin-transition-metal bonds, such as tin–iron tin–cobalt, and tin–manganese bonds, have been reported.[2,6-10] Mössbauer and ^{1}H-NMR spectroscopic studies have been published on alkyltin hydrides[11] and a series of compounds, $(CH_3)_{4-x}SnM_x$ (M represents metal carbonyl derivatives).[6,12] In these studies, the two "probe" atoms are used to derive information about the nature of the chemical bond pertaining to a portion of the whole molecule. We have studied a number of organotin compounds by means of Mössbauer spectroscopy,[13-16] and a number of organometallic compounds involving metal-metal bonds by means of IR and NMR spectroscopies.[17] In the present paper, three kinds of atoms, ^{119}Sn, ^{55}Mn, and ^{1}H, were used as probes to get information as to the electronic configuration, especially around the tin atom in the $R_{3-x}X_xSn$-$Mn(CO)_5$ type of compounds, where X is Cl or Br and where R is a methyl or phenyl group.

Experimental

Preparation of Compounds. All the compounds except $Cl_2(CH_3)Sn$-$Mn(CO)_5$, $Br(CH_3)_2Sn$-$Mn(CO)_5$ and $Br_2(CH_3)$-Sn-$Mn(CO)_5$ were prepared by the methods of Gorsich[18] and Graham.[19] Those three compounds were prepared as has previously been reported.[17] Carbon and hydrogen analyses were performed by Mr. Masuda for all the compounds. The purity was also checked by IR, NMR, and/or Mössbauer spectroscopies.

Mössbauer Spectra. Measurements were made as has previously been described.[20] The ^{119}Sn-Mössbauer spectra were obtained against a $Ba^{119m}SnO_3$ source drived at room temperature. The sample was used as an absorber and was kept at 79°K in a cryostat. The pertinent isomer shifts are reported with respect to the centroid of a barium stannate spectrum at room temperature. The velocity scans were calibrated with ^{57}Fe-enriched iron foil and a source of ^{57}Co diffused into copper foil, both kept at room temperature.

NMR Spectra. The ^{1}H-NMR data were obtained on dichloromethane solutions of the samples using a JNM-4H-100 spectrometer at room temperature, where the dichloromethane was used as the internal standard. The ^{1}H-chemical shift values listed in Table 1 were recalculated with respect to tetramethylsilane (TMS). The ^{55}Mn-NMR measurements were made as has been described elsewhere.[17]

a) ^{55}Mn chemical shift is expressed relative to $KMnO_4$.
b) ^{1}H chemical shift is expressed relative to $(CH_3)_4Si$ (TMS).

Results

A single absorption line was observed in the ^{119}Sn-Mössbauer spectrum of $Ph_3Sn-Mn(CO)_5$, whereas a well-resolved pair of quadrupole split lines was found in the spectra for all the other compounds. A typical Mössbauer spectrum is shown in Fig. 1, while the

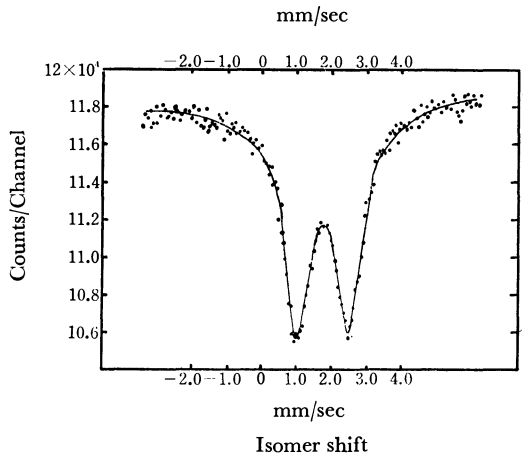

Fig. 1. A typical ^{119}Sn-Mössbauer spectrum ($Br_3Sn-Mn(CO)_5$).

numerical values for the Mössbauer parameters at 79°K are summarized in Table 1. The isomer shifts and quadrupole splittings extracted from the data are in good agreement with those reported by Karasev *et al.*[9] for $Cl_3Sn-Mn(CO)_5$, $Br_3Sn-Mn(CO)_5$, and $Ph_3Sn-Mn(CO)_5$ compounds. The quadrupole splittings are somewhat smaller than those given recently by Wynter and Chandler[12] for $Cl_3Sn-Mn(CO)_5$, $Br_3Sn-Mn(CO)_5$, and $(CH_3)_3Sn-Mn(CO)_5$ compounds, although the isomer shift values are in moderately good agreement. The values for the chemical shift of ^{1}H- and ^{55}Mn-NMR and for the coupling constants of $J(^{119}Sn-^{1}H(CH_3))$ are also listed in Table 1. No splitting of ^{55}Mn-NMR absorption due to the coupling between ^{119}Sn and ^{55}Mn was observed. It may be worth mentioning that both the $^{1}H(CH_3)$ chemical shift and the coupling constant, $J(^{119}Sn-^{1}H(CH_3))$, decrease with a decrease in the number of methyl groups attached to the tin atom.

Discussion

The isomer shift is proportional to the electron density at the Mössbauer nucleus, and it is dependent upon those factors which affect the electron density at the nucleus, for example, the 5s electron density on the tin atom and the extent of the shielding effect on the inner shell s-electron by the 5s, 5p, or 5d electron. It is known that the variation in the 5s electron density influences the isomer-shift value ten times more than the shielding effect in the case of tin compounds.[21] In the present case, therefore, the isomer shift values obatined are interpreted in terms of the 5s electron density.

It is clear from the data shown in Fig. 2 that the isomer shift values of $R_{3-x}X_xSn-Mn(CO)_5$ are higher than those reported previously[3] for the tin compounds, $R_{4-x}X_xSn$, at the same number of x. The isomer shift increases in the $R_{3-x}X_xSn-Mn(CO)_5$ series as the methyl or phenyl groups are successively replaced by halogen atoms. This trend is in contrast to those observed in the $R_{4-x}X_xSn$ series, where the isomer shift attains its maximum at $x=2$. These results suggest that the $Mn(CO)_5$ group is a stronger electron donor either than the methyl or phenyl group, and that the more halogen atoms are attached to tin atom, the more σ-electrons are transferred from the manganese to the tin atom.

Figure 3 illustrates the relationship between the ^{119}Sn-isomer shift and the ^{55}Mn-chemical shift; there is a smooth decrease in the chemical shift with the increase in the isomer shift. A decrease in the ^{55}Mn-chemical shift implies an increased σ-electron with-

drawal from the manganese atom to the tin atom,[22)] while an increase in the ^{119}Sn–isomer shift implies sσ-electron deposit on the tin atom. This trend may also suggest an electron transfer from the manganese to the tin atom through the σ-bond.

In the series of $(CH_3)_{3-x}X_xSn$–$Mn(CO)_5$, there are linear decreases in the $^1H(CH_3)$-chemical shift and in the coupling constant, $J(^{119}Sn$–$^1H(CH_3))$, with an increase in the ^{119}Sn-isomer shift, as is shown in Fig. 4.

(a). ●—● represents $(CH_3)_{3-x}Cl_xSn$–$Mn(CO)_5$, ●···● $(CH_3)_{3-x}Br_xSn$–$Mn(CO)_5$ respectively.
(b). ●—● represents $Ph_{3-x}Cl_xSn$–$Mn(CO)_5$, ●···● $Ph_{3-x}Br_xSn$–$Mn(CO)_5$ respectively.

Decreases in the coupling constant and increases in the isomer shift with the decrease in the number of methyl group attached to the tin atom may be expected by assuming a higher *p*-character in the tin-halogen bond and a higher *s*-character in the tin-manganese bond than in the other tin-ligand bond.[23,24] The lower coupling constant, $J(^{119}Sn\text{-}^{1}H(CH_3))$, in $(CH_3)_3Sn$–$Mn(CO)_5$ than in $(CH_3)_4Sn$ also indicates that the 5s electron of tin atom is much more localized in the tin-manganese bond than in the tin-carbon bond; *i.e.*, the tin-manganese bond prefers the sσ-character whereas the tin-carbon bond prefers the pσ-character.[25]

The quadrupole splitting of the Mössbauer spectra reflects the electric-field gradient at the tin nucleus. Although the intermolecular interactions might not be negligible in some cases, the dominant origin of the electric-field gradient may be ascribed to the intramolecular bonding around the tin atom as a first approximation. It is found, from the data shown in Fig. 5, that R_2XSn–$Mn(CO)_5$ and RX_2Sn–$Mn(CO)_5$ give the same order of quadrupole splitting values except in the cases of Ph_2BrSn–$Mn(CO)_5$ and $PhBr_2Sn$–$Mn(CO)_5$, and that $R_{3-x}Br_xSn$–$Mn(CO)_5$ gives a lower quadrupole splitting value than the analogous $R_{3-x}Cl_xSn$–$Mn(CO)_5$, while R is the same in both the compounds, again with the exception of $PhBr_2$ Sn–$Mn(CO)_5$. Intermolecular interactions might not be negligible in this compound. The general trend for the quadrupole splitting values to be higher for chloride compounds than for bromide suggests that the *p*-electron imbalance in the 5p-orbital of the tin atom is greater in $R_{3-x}Cl_x$-Sn–$Mn(CO)_5$ than in $R_{3-x}Br_xSn$–$Mn(CO)_5$. As has been mentioned in the previous section, it was found that the *p*-character is highest in the tin-halogen bond and lowest in the tin-manganese bond. This p-electron imbalance in each tin-ligand bond may be considered to be the main origin of the quadrupole splitting. As may be seen in Fig. 6, Ph_3Sn–$Mn(CO)_5$ shows non-resolved quadrupole splitting, whereas $(CH_3)_3Sn$–$Mn(CO)_5$ gives a clearly-resolved spectrum. In general, quadrupole splitting is larger when R is CH_3 than when R is C_6H_5. Cordey-Hayes *et al.*[26] and Stöckler and Sano[3] pointed out that the phenyl groups are more effective in delocalizing π-electrons and, hence, in reducing the magnitude of the quadrupole splitting in the series of $Ph_{4-x}X_xSn$ compounds. Parish and Platt interpreted the fact that the quadrupole splitting is smaller in $Ph_{4-x}X_xSn$ than in $(CH_3)_{4-x}X_xSn$ compounds by assuming a higher electron-withdrawing ability of the phenyl group.[5] However, the ^{119}Sn-isomer shift and the ^{55}Mn-chemical shift data indicate that the $Mn(CO)_5$ group has a stronger σ-electron-donating ability either than the methyl or the phenyl group. The results led us to conclude that the phenyl group reduces the magnitude of quadrupole splitting

more than the methyl group, whether X is an electronegative or an electropositive group, since the π-backdonation from $Mn(CO)_5$ to Sn in Ph_3Sn–$Mn(CO)_5$ is found not to be stronger than that in $(CH_3)_3Sn$–$Mn(CO)_5$ from the findings on the ^{55}Mn-NMR linewidth.[17] A plausible explanation is the ability of the phenyl group to deposit or withdraw π-electrons through a mesomeric effect and thereby cause a delocalization of π-electrons.

Conclusion

In compounds of the $R_{3-x}X_xSn$–$Mn(CO)_5$ type, where R is (CH_3) or (C_6H_5) and where X is Cl or Br, ^{119}Sn, ^{55}Mn, and ^{1}H were used as probes to derive information as to the electronic configuration. All the results of the ^{119}Sn-isomer shift, the ^{55}Mn-chemical shift, the $^1H(CH_3)$-chemical shift, and the $J(^{119}Sn$-$^1H(CH_3))$ coupling constant indicate that the $Mn(CO)_5$ group is a stronger electron donor than the methyl, phenyl, or halogen group and that the tin-manganese bond prefers the sσ-character, whereas the tin-halogen bond prefers the pσ-character. The σ-electron transfer from the manganese to the tin atom increases with the successive replacement of the organic groups on tin atom by the halogen atoms. The relationship between the ^{55}Mn-chemical shift and the ^{119}Sn-Mössbauer isomer shift shows that the ^{55}Mn-chemical shift values (from $KMnO_4$ standard) become smaller when the degree of $Mn \xrightarrow{\sigma} Sn$-type σ-electron transfer increases.

In general, the phenyl group reduces the magnitude of the quadrupole splitting more than the methyl group, as has been observed in the series of the $R_{4-x}X_xSn$ compound. This behavior can be interpreted as being due to the mesomeric effect of the phenyl group through the π-bond between tin and ligand atoms.

One of the authors (H. S.) especially wishes to thank Dr. H. A. Stöckler and the Nishina Memorial Foundation for financial aid in providing the Mössbauer spectrometer.

Syntheses and Properties of Copper(II), Nickel(II), and Cobalt(II) Complexes of Alkylthioglycolic Acids

Akira OUCHI, Toshio TAKEUCHI, and Yayoi OHASHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September, 10, 1970)

Copper(II), nickel(II), and cobalt(II) complexes of alkylthioglycolic acids, $R \cdot S \cdot CH_2COOH$ (where R=ethyl, *n*-propyl, isopropyl, *n*-butyl, isobutyl, and *s*-butyl), were synthesized. Except for some copper complexes, these are new compounds. The attempt to synthesize the solid zinc complexes by the same method has not yet been successful. The relative stabilities of these complexes in the solid state seem to be Zn(II)<Co(II), Ni(II)<Cu(II), considering the yield of the syntheses of the products as well as the solvolizing tendency of the complexes. The nickel and cobalt complexes are expected to be in an octahedral form from the magnetic moments as well as from their electronic spectra. The relation between Taft's substitution constants and the wave numbers of the maxima of the absorption spectra of these complexes in the solid state is not clear.

As a step in the studies of the metal complexes containing sulfur compounds as the ligands, alkylthioglycolato complexes,[1] especially their copper complexes, have been synthesized and studied.[2] As it seems that the structure of the alkylthioglycolato complexes would be more clarified by studying the properties of the complexes of other metals, nickel(II) and cobalt(II) complexes other than the copper(II) complexes were also synthesized. Although the complexes of these metals resemble each other and the solid hydrates are very stable, the nickel and cobalt complexes were a little more difficult to synthesize. The syntheses of zinc(II) complexes were also attempted, but as the complexes were unstable, hardly any solid products were obtained. This fact is understandable referring to the fact that the general stability order of complexes of these metals is: Zn(II)<Co(II), Ni(II)<Cu(II), as has been shown by Mellor and others.[3,4]

As the ligands, ethyl-, *n*-propyl-, isopropyl-, *n*-butyl-, isobutyl-, and secondary butyl- thioglycolic acids were used to investigate the substitution effect of the alkyl groups. Hereafter, they will be abbreviated in this paper as follows: H EtS_1, H *n*-PrS_1, H *i*-PrS_1, H *n*-BuS_1, H *i*-BuS_1, H *s*-BuS_1.

Experimental

Instruments. The infrared spectra were obtained by the Nujol or hexachloro-1,3-butadiene mull procedure, using a 403G-type infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with Hitachi EPS-2-type automatic recording spectrophotometer. The magnetic moments were measured with a Gouy balance at room temperature (20°C).

Syntheses of the Materials. *The syntheses of the Ligands*: H EtS_1, H *n*-PrS_1, H *i*-PrS_1, H *n*-BuS_1, H *i*-BuS_1, and H *s*-BuS_1 were synthesized by Pettit's[5] or Larsson's[6] method from the alkyl halide and thioglycolic acid.

The Syntheses of n-*Propylthioglycolato Cobalt(II) Dihydrate*: An aqueous solution of 1.2 g (5.0 mM) of cobalt(II) chloride hexahydrate was treated with sodium hydroxide, and the cobalt(II) hydroxide thus obtained was washed well with water (by the centrifuge technique). The hydroxide, 5 m*l* of water, 5 m*l* of formalin (37%), and 1.35 g (10 mM) of H *n*-PrS_1 were mixed and stirred. After several minutes, the residue was filtered off and the filtrate was kept overnight in a refrigerator. The product was washed with ice cold water, a little cold ethyl alcohol, and ethyl ether, in that order. The yield was 0.4 g (1.1 mM). If the formalin was not used, a brown by-product, probably the thioglycolate, precipitated when the metal salt was mixed with the ligand and the yield was much lowered.

The other complexes were synthesized by almost the same method. In the case of the copper and nickel complexes, formalin was not used. As was reported previously, in the case of isopropylthioglycolatocopper(II) dihydrate blue and violet isomers were obtained.[2] However, until now this kind of isomerism has not been observed in the cases either of nickel and cobalt complexes or of copper complexes of other alkylthioglycolic acids.

Results and Discussion

The elemental analyses, the chemical formulae of the complexes thus obtained, and the approximate yields of the products are shown in Table 1. From the results, all of these compounds can be said to have the formulae of $ML_2 \cdot 2H_2O$, where HL is an alkylthioglycolic acid.

The magnetic moments of these complexes, as measured by Gouy's balance, are shown in Table 2. Generally, the cobalt and nickel complexes have much higher magnetic moments than the spin-only values. Cobalt complexes have the magnetic moments of about 4.7—5.2 B.M. when they are in the octahedral form and 4.4—4.8 B.M. when in tetrahedral ones.[7] The magnetic moments of nickel complexes are 2.9—3.4 B.M. in the cases of octahedral complexes and 3.5—4.2 B.M. in the cases of tetrahedral complexes.[7] The observed magnetic moments of these products are about 2.9—3.1 B.M. in the cases of nickel complexes and 4.6—5.1 B.M. in the cases of cobalt complexes. Therefore, all of these com-

pounds seem to be octahedral complexes.

The water molecules in these products are relatively hard to remove and remain even after overnight drying at room temperature (on silica gel) in a vacuum desiccator. Therefore, the water molecules are probably coordinated with the metal ion, although the linking structure by water molecules is also possible; in any way they occupy two coordination bonds of the metal ion. There are two possibilities of how the alkylthioglycolic acid works as a bidentate ligand; i) two oxygen atoms of a carboxyl group bond to separate two metal ions, and the bridge structure is formed, or ii) one oxygen atom of a carboxyl group and a sulfur atom bond to the metal ion. The thioether-type sulfur does not coordinate to transition-metal ions strongly, and in the cases of some methionine complexes, the sulfur does not coordinate to metal ions.[8] However, at least the copper complexes seem to be S,O-coordinated complexes.[2] The order of the stabilities of various metal complexes of each alkylthioglycolic acid, as expected from the

yields, the facility of their syntheses, and the resistivity to solvolysis in solution is: Cu>Ni, Co>Zn. Recently the stability constants of ethyl thioglycolates of copper, nickel, and zinc in aqueous solutions were studied; the order of their stabilities was Cu>Ni>Zn.[9] This order is similar to that of a series of complexes where the neutral sulfur atom of the ligand bonds with these metals to form a chelate ring.[10] Consequently, in the nickel and cobalt complexes, the sulfur atom bonds to the central metal less strongly and they are expected to be less stable than the copper complex. Moreover, as the zinc-sulfur bond is weaker, zinc complexes are more unstable and are hard to obtain by this method. As will be shown later, the infrared bands presumably identified as ν(M–S) bands seem to appear in the spectra of these complexes. Therefore, considering also the spectral data, although the possibility of the i) case cannot be completely rejected, the ii) case is more likely, even though the metal-sulfur bonds in these solid complexes are not very strong.

The absorption electronic spectra of ethanolic solutions of several complexes are given in Table 3.

As is shown in the table, when the central metal ion is the same, almost the same patterns of the spectra were obtained, even if different alkylthioglycolic acids are used as the ligands; the wave numbers and the log ε of the complexes of the same metals almost coincide with each other, within the limits of experimental error. The bands at about 15 and 25 kK of the nickel complexes are likely to be $^3A_{2g}\rightarrow{}^3T_{1g}$(F) and $^3A_{2g}\rightarrow{}^3T_{2g}$ (P)re-

spectively.[11] The cobalt complexes seem to be solvolized in an ethyl alcohol solution; the solution is brown in color, and the maxima did not appear clearly, only some shoulders being observed. The shoulder near 20 kK is probably the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ band.[12] Therefore, from the electronic spectra, at least the nickel species, and probably also the cobalt complex species in the solution, which is possibly in a form similar to that of the original complexes, are likely to be in the octahedral form. The bands in the 33—39 kK region seem to be the absorption of the ligand.

The infrared spectra of these compounds were examined. The general feature of the spectra in the fingerprint region (1300—700 cm^{-1}) are almost the same as those of each ligand. The anti-symmetric and symmetric bands of ν (COO) as well as the ν (M–O) and ν (M–S) bands of the complexes are shown in Table 4. The assignments of the bands were obtained with reference to the spectra of the other carboxylato complexes as well as to those of metal complexes of thio compounds.[13–16] Therefore, these assignments are only tentative. The wave numbers of the ν (M–O) and ν (M–S) bands of these complexes are a little lower than those of thioketonato or usual carboxylato complexes.[5,6] This is probably due to the weakness of the bond between the central metal ions and the chalcogen atoms of the ligands; really, the ν (M–S) band of the thiourea complexes, for example, appears in a lower wave-number region.[17]

The effect of the substitution of the alkyl group of alkylthioglycolic acid on the strength of the M–O bond may not be serious, but as the alkyl group is adjacent to the sulfur atom, the M–S bond is likely to be more affected by the substitution. In the case of silver complexes of alkylthioglycolic acids, their stability constants in the solution state are related to the Taft's σ^* functions of the alkyl groups.[5] However, probably because of the restriction from the crystal structure, the wave numbers of the bands of these stretching modes of these solid complexes do not have any clear relation to the σ^* functions of the alkyl groups.

The authors wish to express their appreciation to Professors Yukichi Yoshino and Kunihiko Watanuki, and also to their colleagues in their laboratory, for their helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 734—737 (1971)

The Determination of Tin in Tin Metal and in Zircaloy by Precise Coulometric Titration

Takayoshi YOSHIMORI, Ikuko MATSUBARA, Tatsuhiko TANAKA, Kazuo YOSHIDA, Kazuo TANAKA, and Toyokazu TANABE

Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received October 12, 1970)

The purities of tin metals are determined directly by precise coulometric titration. The sample is dissolved with hydrochloric acid in a nitrogen atmosphere. The solution is then introduced into a hot antimony column. The reduced tin(II) ions are titrated with electrolytically-generated iodine. The titration is accomplished in a special cell by the use of which any disturbance of atmospheric oxygen is avoided. The titration efficiency under these acidic media was decreased when the current density was increased more than several mA/cm^2. The results obtained by two different analysts for the sample of the pure tin metal (5-nine) were 99.996 and 99.991%. The standard deviations of the results were 0.025 and 0.016% respectively. The tin in the other tin metals and in Zircaloy samples was determined satisfactorily without the use of any experimental factor.

The purity of a metal has generally been estimated by analyses of the impurities in the sample and then by the substraction of the sum of their contents from 100%.

In order to distinguish a sample of 99.9% purity from that 99.8% pure by the direct analysis of the bulk constituent, the relative error of the determination must be less than 0.05%. This is, however, less than the maximum accuracy of ordinary analytical methods.

The maximum accuracy of a precise coulometric titration is 0.003% as a standard deviation, while the value of 0.007% is obtained in ordinary laboratories.[1] This method has been used to estimate the purities of several primary standard substances for a volumetric method directly. The accuracy of this method, however, has not been yet used to estimate other metallic

1) T. Yoshimori and I. Matsubara, This Bulletin, **43**, 2800 (1970).

samples, *etc.*

Only one relevant report could be found in the literature; in it the purity of a tin metal was determined directly by the following volumetric method:[2] tetravalent tin was reduced to the divalent state with metallic nickel under a carbon dioxide atmosphere. Most of the tin(II) ions were then oxidized with an accurately-weighed amount of pure potassium iodate, while the remainder were titrated with a standard solution of potassium iodate. Because of the sensitiveness of tin(II) ions to the oxygen in air, this method sometimes gives lower results. A small amount of air on the surfaces of the potassium iodate crystals, and also the oxygen dissolved in the standard solution, may be introduced into the sample solution; they serve to oxidize the tin(II) ions.[3]

Caton and Freund[4] determined the content of tin in Zircaloy by coulometric titration. They used a hot antimony column for the reduction of tetravalent tin to the divalent state, and then titrated the tin(II) ions with electrolytically-generated iodine. Increasing the accuracy for the measurements of the electricity, the present authors determined the purities of several tin metals directly by precise coulometric titration using a biamperometric end-point location. Several improvements of the ordinary analytical treatments were necessary to obtain more accurate results.

Experimental

Apparatus. A sample tin metal was dissolved with hydrochloric acid under an atmosphere of nitrogen. The apparatus is shown in Fig. 1. Figure 2 shows in detail the antimony column used to reduce tin(IV) ions. The column was heated electrically with a flexible heater, while its temperature was controlled by the adjustment of the voltage applied to the heater.

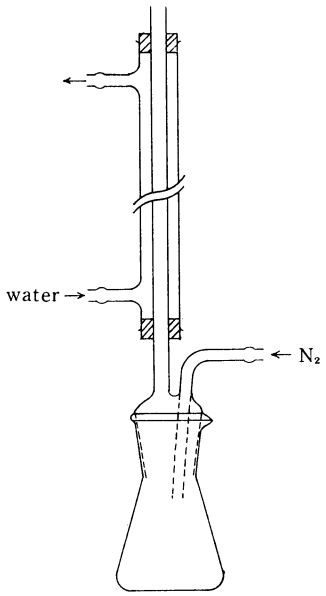

Fig. 1. Decomposition apparatus.

Figure 3 shows the coulometric titration cell. All the steps in the preparation of the electrolyte in the cell and in the washing of the cell could be performed without any disturbance of the atmospheric oxygen.

The chromium(II) chloride solutions were useful for removing traces of the oxygen in nitrogen (Fig. 4). The solutions and the liquid zinc amalgams were stirred continuously

with magnetic stirrers. This stirring was advisable to keep the chromium ions under the divalent state.

A precise potentiometer and a standard resistor of 1 ohm were used to measure the electrolytic current. Their accuracies had been certified within 0.05% and 0.01% respectively. The constant-current source used here was the same instrument as that shown previously.[1,5] If we consider the errors of the above measuring devices as 3σ, a relative standard deviation of 0.02% may be expected for the measurement of the current, including the reliability of the standard cell used.

An electronic stop watch based on the frequency of a quartz crystal (Nippon Electric Co., Type 102) was used to measure the time of the electrolysis. The relative error, based on the time measurement, did not exceed 0.01%.

The "dead-stop" method using a microammeter (fullscale 10 μA) was used to locate the end-point of the titration. The whole assembly of the apparatus is illustrated in Fig. 4.

The indicator electrodes were frequently washed by dipping them into concentrated nitric acid for 20 minutes. Platinum foil (about 114 cm^2) was used as the generating electrode.

A silica-gel diaphragm[6] was advisable for the present purposes. It was prepared by the following procedure: glass wool was packed tightly at the bottom of the cathode compartment and then soaked in a sodium silicate solution (50%). Hydrochloric acid (3N) was then repeatedly introduced into the compartment until the acid did not leak through the diaphragm. The diaphragm was stored in hydrochloric acid (3N) and could be used several times.

The other precautions in measuring the electricity and the weighing of the sample were the same as those reported previously.[1]

Reagents. All the reagents were of an analytical grade, and all were used without further purification. The antimony metal (20—30 mesh) was washed with boiling 3N hydrochloric acid and then packed in a glass tube (Fig. 2). The purity of the metal was higher than 99.9%.

Procedure. *Dissolution of the Sample*: A sample tin metal was weighed into the decomposition flask (Fig. 1). Nitrogen was allowed to flow through the flask to remove the atmospheric oxygen. Then 20 m*l* of concentrated hydrochloric acid was added; a reflux condenser was necessary to prevent any loss of tin tetrachloride.

The addition of a small piece of an antimony metal to the flask was advisable in order to dissolve the pure samples more quickly. If necessary, the flask was warmed gently. When any black residue was found in the flask, a drop of a hydrogen peroxide solution (30%) was added to the flask and the solution was heated more gently. In this case, the introduction of the nitrogen was unnecessary. Zircaloy samples were placed in a Kjeldahl flask and then dissolved with hot hydrochloric acid and with the drop-by-drop addition of hydrofluoric acid.

After the dissolution of the sample was complete, the solution was cooled to room temperature under an atmosphere of nitrogen.

Preparations of Column and Cell: The solution in the column was boiled for 20 min. Oxygen-free nitrogen was then allowed to flow through the cell. After the temperature of the column had been adjusted to about 100°C, the column was washed with about 50 m*l* of 3N hydrochloric acid. Then the washings in the cell was removed carefully with an aspirator, avoiding any introduction of atmosperic oxygen into the cell. From this period to the end of the titration, the purified nitrogen should be allowed to flow through the cell continuously at a rate of about 150 m*l* per min.

Twenty milliliters of concentrated hydrochloric acid and 50 m*l* of a 1M potassium iodide solution freed from atmospheric oxygen were added to the cell from their reservoirs. Pure nitrogen was introduced into the solution for more than 30 min, and then the gas was allowed to flow over the solution to prevent any spattering of the solution in the cell. If the hydrochloric acid or the potassium iodide solution contained any oxidizing materials (for example, dissolved oxygen or chlorine), some iodine was produced in the mixture. The error based on this iodine could be corrected by reading the indicator current during this period and by continuing the coulometric titration to the point which the indicator current after the end-point was again raised to the same value as in the previous measurement.

Reduction of the Tin(IV) Ion and Coulometric Titration: A sample solution prepared as above was poured into the funnel on the column and then allowed to flow through the column at a rate of 1 ml/min. The flask and the column were washed thoroughly with 150 m*l* of 3N oxygen-free hydrochloric acid.[7] This was done by the introduction of the nitrogen over the solution on the top of the column.[8] From the last period of the washing, the tin(II) ions could be titrated with the coulometrically-generated iodine. During the titration, the generator current was kept constant. This method has already been described elsewhere.[1]

After the end-point, the indicator current began to rise. At this moment, the generator current was stopped; then both the indicator current and the time of the electrolysis were recorded. Again the solution was titrated for a short period, after which both the indicator current and the time were recorded. This short-period titration was repeated several times in order to obtain the titration curve clearly.

Results and Discussion

Dissolution of the Sample. The sample was dissolved in various kinds of glassware. A fairly large loss of tin ions by the spattering or by the vaporization of tin(IV) chloride was found even by the use of a

tall-form beaker or an Erlenmeyer flask. These losses of tin were overcome by the introduction of nitrogen into the flask to prevent the oxidation of the tin(II) ions. The dissolution time for the sample of high purity was shortened considerably by the addition of a piece of an antimony metal to the flask.

Column and Its Use. Instead of the antimony column, several other metals have been used for the reduction of tetravalent tin. Aluminum, iron, and nickel, however, all have relatively low hydrogen overvoltages and produce much hydrogen during the reduction process. Therefore, none of them can be used as the constituent of the column. Lead is sometimes used as the reducing material for the tin(IV) ion. This metal, however, was not adopted for the present purpose because lead ions dissolved in the solution produce lead chloride as a precipitate.[4]

Antimony was thus chosen as the constituent of the column. The flow rate of the sample solution was adjusted between 0.5 m*l*/min and 1 m*l*/min so as to accomplish the complete reduction of the tin(IV) ions.

The ordinary reduction procedure by boiling with metals was not successful because the introduction of air into the tin(II) solution was unavoidable during the process of separating the residual metals from the solution, and also while setting up the cell for the coulometric titration. The residual metals in the solution reduced the excess iodine generated after the endpoint and disturbed the location of the point.

Analysis of Pure Tin Metal (five-nine). A commercially-obtainable tin metal (so-called five-nine) was analyzed by the proposed method. The results of the analysis of the impurities obtained by the authors and by the producer are shown in Table 1. The purities obtained by this method are tabulated in Table 2. The relative standard deviation, as calculated from these results, was less than 0.02%.

Current Efficiency: First, the current density for the generation of the titrant was 13.3 or 8.8 mA/cm^2. In this case, the results obtained were rather high. This indicates that the titration efficiency of tin(II) ions with the electrolytically-generated iodine is less than 100% in this electrolyte.

Marinenko and Taylor[10] measured the current efficiencies for the generation of iodine in various solutions and showed that the efficiencies were somewhat decreased in acidic solutions. Recently Iritani *et al.*, in potentiometrically titrating mixtures of iodide ions and iodine with a potassium iodate standard solution in acidic media, they found that iodine monochloride was formed in the media with more than 3N hydrochloric acid.[11] With the current densities of *ca.* 10 mA/cm^2, some iodine monochloride may perhaps be formed; its current efficiency is unknown.

With reference to the results shown in Table 2, the authors considered that the titration efficiency of tin(II) ions with the electrolytically-generated iodine was 100% when the current density was kept below 1 mA/cm^2.

Oxygen in the Washing Solution: The oxygen in the washings produces hydrogen peroxide by reacting with the antimony in the column[7] and oxidizes the tin(II) ions. This disturbance can be avoided by the introduction of pure nitrogen into the solution on the top of the column.

Coulometric Titration of Several Tin Metals. The purities of the tin metals of various grades were analyzed by the proposed method. The results obtained are shown in Table 3. It can be concluded from these results that the proposed method is satisfactory for estimating the purities of various tin metals directly.

Zircaloy 1	3	1.491	0.004
Zircaloy 2	3	2.148	0.003
Zircaloy 3	3	1.540	0.005
Zircaloy 4	4	0.875	0.005

a) Shown by the producer.

Determination of Tin in Zircaloy. The tin contents in Zircaloy samples were also determined by means of the authors' apparatus. The samples were dissolved in a Kjeldahl flask with hydrochloric and hydrofluoric acids. The results are shown in Table 3. The errors of the results are diminished considerably compared with the case of the value obtained previously.[4]

When the results were compared with those obtained in other laboratories, these values were found to be the highest. The authors believe that the difference shows the effect of the atmospheric oxygen on the tin(II) ions in the other volumetric procedure.[3]

The authors express their sincere thanks to Professor S. Hirano (Toyo University) and Professor T. Takeuchi (Nagoya University) for their valuable suggestion.

Studies on Cobaloxime Compounds. II. Catalytic Activity of Cobaloximes in the Hydrogen Peroxide Decomposition Reaction

Yorikatsu HOHOKABE and Noboru YAMAZAKI

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 15, 1970)

Various cobaloximes with the general formula $[CoX(DH)_2B]$ (X: Cl, CN, OH, or CH_3. DH: Dimethylglyoximato monoanion. B: Bases such as water, nicotinamide, pyridine, imidazole, or a low molecular weight copolymer of acrylamide and 4-vinylpyridine, *etc.*) were examined for catalytic activity in the H_2O_2 decomposition reaction. Cyanocobaloximes have less activities than other cobaloximes. The effect of changing the axial bases of cobaloximes was found to be small. When methylcobaloxime was used as a catalyst, the lag time was observed in the dark, while with the irradiation of visible light the reaction proceeded without induction period. An extensive study on chloroaquocobaloxime revealed that the rate is proportional both to the concentration of H_2O_2 and to the concentration of cobaloxime and inversely proportional to $[H^+]$. It was found that the decomposition of H_2O_2 with cobaloximes proceeds with a gradual and partial degradation of cobaloximes.

The decomposition of hydrogen peroxide catalyzed by metal ions has been widely investigated,[1] but the mechanisms have not yet been clarified. A few cobaloximes have been briefly investigated for catalytic activity in the H_2O_2 decomposition reaction by Sasaki and Matsunaga.[2] The catalytic activities decreased in the order $CoCl(DH)_2$P-4VP$>CoCl(DH)_2$Pyr$\gg$Co(CN)-$(DH)_2$P-4VP$>$Co(CN)$(DH)_2$Pyr, where P-4VP means poly-4-vinylpyridine and Pyr pyridine. No study has been reported on the kinetics of the H_2O_2 decomposition reaction catalyzed by cobaloximes.

In this work, the H_2O_2 decomposition reactions with various cobaloximes were investigated and results similar to those of Sasaki[2] were obtained in the case of chloro- and cyano-cobaloximes. Results of other cobaloximes and kinetic studies are also described.

Experimental

Materials. *Preparation of $CoCl(DH)_2$(Copoly—AM-VPy)*: To a hot methanolic solution of 0.39 g (3.4 mmol) of dimethylglyoxime (30 m*l*), 0.40 g (1.7 mmol) of $CoCl_2 \cdot 6H_2O$ in 30 m*l* of methanol was added with stirring. After an hour, an aqueous solution of 1.00 g of a copolymer of acrylamide and 4-vinylpyridine (Copoly—AM-VPy: $\bar{M}n = 1.6 \times 10^3$, AM/VPy molar ratio = 14.3) was added with stirring for an hour. The brown filtrate transparent solution was concentrated under a reduced pressure to precipitate a small amount of unreacted dimethylglyoxime, which was removed by filtration. The brown filtrate was evaporated to dryness in a vacuum. 1.28 g of green residue was obtained. It was dissolved in 20 m*l* of water to yield a brown solution, which was applied on a Sephadex LH-20 column (3.0×37.5 cm). By evaporating the first fraction to dryness, 0.86 g of a polymeric cobaloxime, $CoCl(DH)_2$-(Copoly—AM-VPy) free from monomeric cobaloximes was recovered. From Co analysis, the compound was found to contain 1.8 wt% of Co which corresponds to 41% of the degree of coordination of the pyridine residues in polymeric ligand. The degree of coordination indicates the mole percentage of the cobaloxime moiety per pyridine residue of Copoly—AM-VPy. The brown powder obtained became insoluble after evaporation to dryness. It shows infrared absorption bands at 1238 cm^{-1} (ν_{N-O}), 1090 cm^{-1} (ν_{N-O}), *ca.* 1070 cm^{-1}, 980 cm^{-1}, 860 cm^{-1}, and 512 cm^{-1} (ν_{Co-N}) due to cobaloxime moiety.[3]

Other Materials: The synthesis of other cobaloximes examined in this work was previously reported.[3] The stock hydrogen peroxide was 30% stabilizer-free supplied from Mitsubishi Edogawa Kagaku Co., Ltd. Analytical-grade 0.1N potassium permanganate solution was diluted 10 times to yield 0.01N solution for the titration of the residual hydrogen peroxide in the reaction mixture. Other reagents were obtained from commercial sources and used without further purification.

Methods. A typical procedure is as follows. To an appropriate amount of cobaloxime solution, 5 m*l* of 1M potassium phosphate buffer, a minimal amount of PNE[4] if necessary, and distilled water were added to bring the total volume to 50.0 m*l*. Then, 1.0 m*l* of 3% hydrogen peroxide was added to the mixture. The reaction was usually conducted at 40°C. Aliquots, *e.g.*, 5 m*l*, were taken for analysis at appropriate times. Five milliliters of 9N sulfuric acid was added to the aliquot to stop decomposition, and the residual hydrogen peroxide was titrated with a 0.01N $KMnO_4$ solution. Since there were lag times in some cases as described below, the reaction rates were calculated from the slopes of the time conversion plots at the half-decomposition point.

Spectroscopic Measurements. An aliquot of the reaction mixture was used for the visible spectrum and was diluted 20 times for the ultraviolet spectrum, which was taken with a Shimadzu automatic recording spectrophotometer type SV-50A. Infrared spectrum was taken with a JASCO infrared spectrophotometer, model IR-G.

Results and Discussion

In order to examine the difference in catalytic activity in relation to several axial ligands of cobaloximes, the decomposition reactions of hydrogen peroxide were carried out in the presence of various cobaloximes. Typical time-conversion curves of several cobaloximes are shown in Fig. 1, which shows the presence of a lag time that differs in each case. The decomposition rates were therefore calculated from the slopes of the curves at the half-decomposition point, shown in Table 1. As can be seen in Table 1, cyanocobaloximes have less activities than other cobaloximes in the decomposition

reaction of H_2O_2. Among chlorocobaloximes, the difference in catalytic activity was rather small, and the activity was not in the reasonable order of the axial base such as that of the strength of basicity. The polymeric ligand, Copoly-AM-VPy, *i. e.*, a low molecular weight copolymer of acrylamide and 4-vinylpyridine, exerted little change in the catalytic activity compared with other monomeric bases.

Since chloroaquocobaloxime has greater solubility than other chloro derivatives in aqueous medium, an extensive study on the kinetic behavior of the decomposition reaction was performed in the presence of chloroaquocobaloxime.

First, the dependence on pH (6.0—8.1) was investigated at a constant initial H_2O_2 concentration and a constant cobaloxime concentration. As shown in Fig. 2, the rate was inversely proportional to $[H^+]$, and the reaction order was observed to be −0.98 in $[H^+]$. This suggests that hydrogen peroxide reacts through the ion HO_2^-.

Dependence on the concentration of cobaloxime was then investigated at pH 6.8 and 7.2. The rate was proportional to the concentration of cobaloxime and the reaction order was 0.98 in it at pH 6.8 and 0.88 at pH 7.2 (Fig. 3).

Finally, a study of the dependence on the concentration of H_2O_2 revealed that the rate was 1.28 order in $[H_2O_2]$ at pH 7.2 (Fig. 4).

In another series, the activation energy was determined between 30°C and 45°C, and found to be 17.9 kcal/mol at pH 7.2.

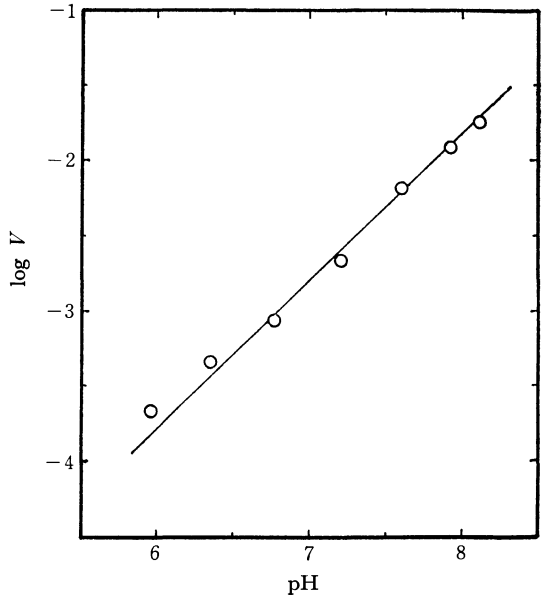

Fig. 2. pH dependence of the H_2O_2 decomposition rate with chloroaquocobaloxime.
$[H_2O_2]_0=2.0\times10^{-2}$M, $[CoCl(DH)_2(H_2O)]=3.92\times10^{-4}$ M, in 0.1 M potassium phosphate buffer, 40°C.
The reaction was so slow at lower pH that the rates at pH 5.96 and 6.35 for 3.92×10^{-4} M of cobaloxime were estimated as half of those at 7.84×10^{-4} M of cobaloxime.

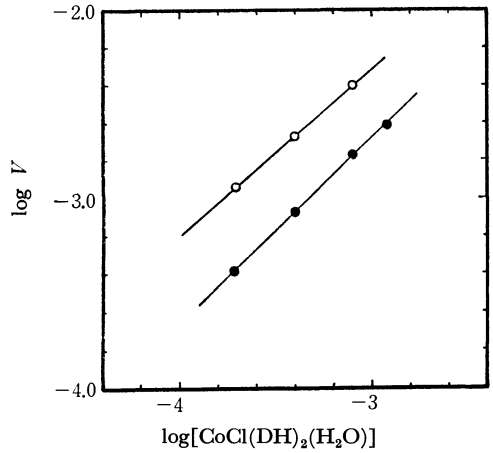

Fig. 3. Dependence of the H_2O_2 decomposition rate upon the concentration of chloroaquocobaloxime.
$[H_2O_2]_0=2.0\times10^{-2}$ M, in 0.1 M potassium phosphate buffer (—○—, pH 7.2; —●—, pH 6.8), 40°C.

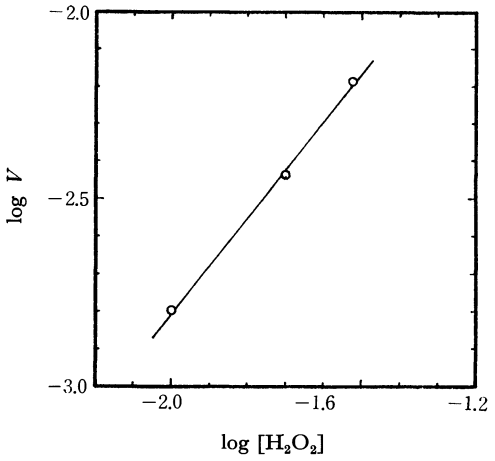

Fig. 4. Dependence of the H_2O_2 decomposition rate upon the concentration of H_2O_2.
$[CoCl(DH)_2(H_2O)]=3.92\times10^{-4}$ M, in 0.1 M potassium phosphate buffer (pH7.2), 40°C.

The results can be summarized in the following equation for the decomposition rate of H_2O_2:

$$V=-\frac{d[H_2O_2]}{dt}=k\cdot\frac{[\text{Cobaloxime}][H_2O_2]}{[H^+]}.$$

A similar rate law was obtained in the reaction of cobaltic ion and H_2O_2 by Baxendale and Wells.[5] Since in our experiments cobaltous chloride which is considered to be oxidized to cobaltic ion in this experimental condition yielded the same rate without lag time as the cobaloximes, the active intermediates in the reaction with cobaloximes are estimated to have more than one free coordination site. Thus the presence of a lag time whose length differs in each case can be explained as follows: The hydroxide or chloride ligand is readily displaced by H_2O_2 or presumably HO_2^-, and hence hydroxo- or chloro-cobaloximes show little lag time, while a strongly coordinated cyano ligand is not readily displaced, resulting in the appearance of lag time.

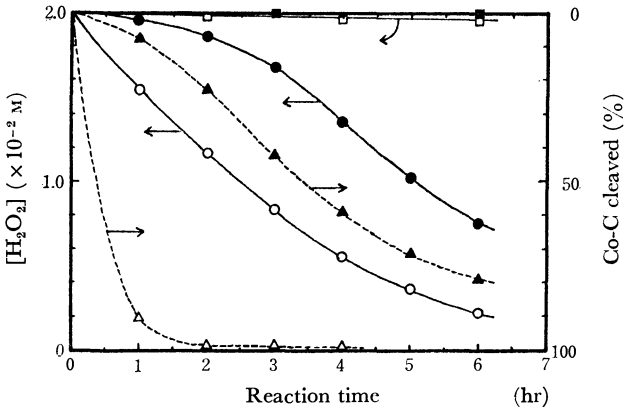

Fig. 5. H_2O_2 decomposition-time profiles with methylaquocobaloxime either in the dark or with irradiation and the Co-C cleavage of methylaquocobaloxime during the course of reactions.
$[H_2O_2]_0=2.0\times10^{-2}$ M, $[CH_3Co(DH)_2(H_2O)]=3.92\times10^{-4}$ M, in 0.1 M potassium phosphate buffer (pH 7.2), 40°C.
—●— H_2O_2 concentration in the dark.
—○— H_2O_2 concentration with irradiation.

—□— H_2O_2 concentration in the absence of cobaloxime with irradiation (Blank).
···▲··· Co-C cleavage in the dark.
···△··· Co-C cleavage with irradiation.

Methylaquocobaloxime yielded the same rate in the dark as that with the irradiation of visible light, which was performed at a distance of 15 cm with a 100 W tungsten lamp. The decomposition-time profile, however, was distinctly different as shown in Fig. 5. The lag time was observed in the dark, while with irradiation the reaction proceeded without induction period. The degree of the Co–C bond fission at the same time which was determined spectrophotometrically from the decrease in absorption at 443 mμ[6] is also given in Fig. 5. 78% of methyl-Co bond was cleaved by the decomposition reaction of H_2O_2 in the dark. However, the Co–C cleavage step is not considered to be the rate determining step, since the solution of methylaquocobaloxime irradiated prior to the addition of H_2O_2, which exhibits the absorption maximum at 246 mμ due to dimethylglyoximato ligand and is considered to contain hydroxoaquocobaloxime,[6] exerted the same rate in the H_2O_2 decomposition reaction as methylaquocobaloxime in the dark. As the reaction proceeds, the gradual decrease in absorption occurs at a wavelength longer than 230 mμ up to the visible region.

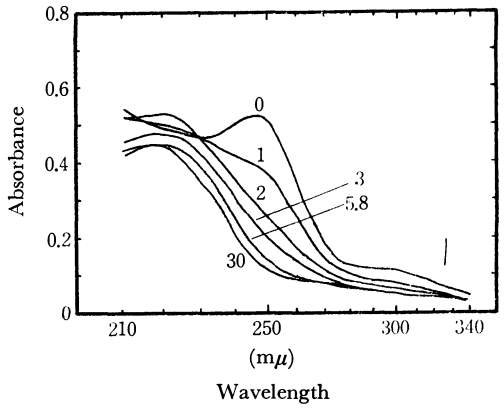

Fig. 6. UV spectral change during the course of the H_2O_2 decomposition reaction by chloroaquocobaloxime.
H_2O_2 decomposition reaction was conducted under the following conditions; $[H_2O_2]_0=2.0\times10^{-2}$ M, $[CoCl(DH)_2(H_2O)]=3.92\times10^{-4}$ M, in 0.1 M potassium phosphate buffer (pH 7.2), at 40°C.
Aliquots were taken after 1, 2, 3, 5, 5.8, and 30 hr, and diluted 20 times to obtain the spectra. At the same time, the percentages of the H_2O_2 decomposed were determined and found to be 14% (1 hr), 35% (2 hr), 49% (3 hr),81% (5.8 hr), and 100% (30 hr), respectively.

There is some indication in the UV spectra that the cobaloxime is transformed or degradated by H_2O_2. The spectral change during the course of the reaction with the preirradiated solution of methylaquocobaloxime as well as with chloroaquocobaloxime solution proceeded quite similarly (Fig. 6): The gradual decrease in ab-

5) J. H. Baxendale and C. F. Wells, *Trans. Faraday Soc.*, **53**, 800 (1957).

6) N. Yamazaki and Y. Hohokabe, "Studies on Cobaloxime Compounds. VI.," submitted to this Bulletin.

sorption occurs at a wavelength longer than 230 mμ up to the visible region with the progress of reaction. The absorption maximum at 246 mμ both in chloro- and hydroxo-aquocobaloximes decreased in intensity and the maximum shifted to *ca.* 220 mμ. Thus, the spectrum of the solution immediately after the addition of H_2O_2 did not differ from that before the addition of H_2O_2, but after an hour when 14—16% of H_2O_2 was decomposed, the absorption maximum at 246 mμ decreased to 65% in intensity and the new absorption maximum appeared at *ca.* 220 mμ. As the reaction further proceeded, the maximum at 246 mμ decreased gradually, but not that at 220 mμ. This seems to show that a partial decomposition of cobaloxime occurs. In fact, by concentrating the solution after the reaction, a trace of blue precipitate was recovered. This seemed to be an inorganic compound whose infrared spectrum is quite different from that of original or typical cobaloximes. The maximum at 220 mμ shifted to 275 mμ when solid alkali was added to the solution. Since dimethylglyoxime which has an absorption maximum at 224 mμ in acidic medium is known to shift the maximum to 265 mμ in alkaline medium,[7] the spectral change in the presence of alkali suggests that the solution contains some substance like oxime which can be dissociated in alkaline medium. This may be some form of cobaloxime or some degradation product.

Thus, it is concluded that cobaloximes catalyze the decomposition of H_2O_2, and they themselves are also gradually and partially degradated during the course of the reaction. The lower activity of cyanocobaloximes than hydroxo-, chloro-, or methyl-cobaloximes can be attributed to higher stability toward the reactant H_2O_2 than other cobaloximes due to stronger interaction of cyano group with Co. A mechanism has been proposed for the decomposition reaction with ferric ion,[8] in which the peroxide concentration was higher than ferric ion concentration. This can be applied to the reactions with cobaloximes. The primary active species reacting with cobaloximes seems to be HO_2^-, but not H_2O_2 as in the case of pentacyanocobaltate(II),[9] since the rate was inversely proportional to $[H^+]$. HO_2^- may coordinate with Co(III) species forming CoOOH by electron transfer from HO_2^- to Co(III). The presence of hydroperoxocobaloxime may be supported by Schrauzer's recent observation of the relative stable mononuclear peroxocobaloxime radicals.[10]

(Received October 24, 1970)

A new purple complex of (1,9-diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)(*l*-propylenediamine)nickel-(II) perchlorate and the known yellow complex, (octamethyl-1,4,8,11-tetraazacyclotetradecadiene)nickel(II) perchlorate, were obtained by the reaction of tris(*l*-propylenediamine)nickel(II) perchlorate and acetone without any irradiation by ultraviolet light. The structure of the purple complex was estimated from its absorption and circular dichroism spectra in acetonitril and in an aqueous solution, and from its infrared spectrum in the solid state. The complex was found to take an octahedral $[NiN_6]$-type structure in acetonitril and a planar $[NiN_4]$-type structure in aqueous solution. The (1,9-diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)nickel(II) perchlorate and (1,9-diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)(ethylenediamine)nickel(II) perchlorate complexes were also prepared.

Since it was reported that tris(ethylenediamine)-nickel(II) perchlorate reacts with acetone to form macrocyclic complexes,[1] a number of analogous complexes have been prepared from various metal-amine complexes and ketones or aldehydes.[2] Some of these complexes have geometrical and/or optical isomers, depending on the positions of such substituents as methyl groups. Curtis *et al.* prepared, for example, two non-interconvertible, isomeric (octamethyl-1,4,8,11-tetraazacyclotetradecadien)nickel(II) perchlorates (yellow and orange) by irradiating an acetone solution of tris(*d,l*-propylenediamine)nickel(II) perchlorate with ultraviolet light for several days.[3] Although there are many isomerisms in this ligand, they showed, by X-ray

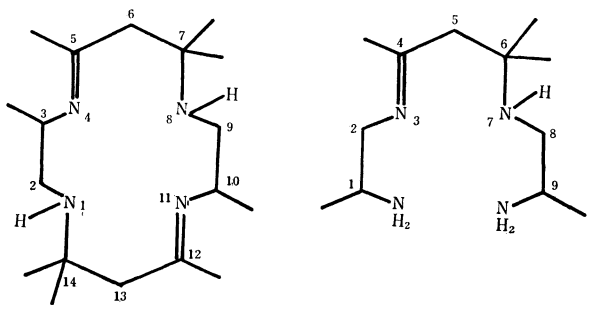
analysis,[4] that both isomers have two imino-groups in *trans* positions, but that the two asymmetric carbon atoms of the yellow isomer are racemic (*d,d* or *l,l*), while those of the orange isomer are meso (*d,l*) (Fig. 1). In fact, only the yellow isomer was produced by the reaction of the optically-active tris (*d* or *l*-propylenediamine)-nickel(II) perchlorate and acetone.



$C_{18}H_{36}N_4$ $C_{12}H_{28}N_4$

Fig. 1.

During our study of the effect of methyl groups on the conformation of five- and six-membered chelate rings of metal complexes,[5] we obtained a new purple complex as well as the above yellow complex from the tris(*l*-propylenediamine)nickel(II) perchlorate and acetone without any irradiation by ultraviolet light. This paper will deal with the chemical properties and structure of this purple complex.

Experimental

Preparations. *l*-Propylenediamine was obtained by resolving its commercial racemate according to Dwyer's method.[6]

(1,9-Diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)(l-propylenediamine)nickel(II) perchlorate, $[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$: An acetone solution (about 100 m*l*) containing 10 g of $[Ni(l\text{-pn})_3](ClO_4)_2$ was kept at room temperature in a stoppered container. After about two weeks, the purple crystals which had deposited were filtered off and recrystallized from hot water.

The filtrate was kept several more days at room temperature, air-dried until the residue was almost free from acetone, and filtered. A mixture of purple and yellow crystals was then obtained by treating the residue with a small amount of acetone. This mixture can be separated by fractional recrystallization from hot water, because the purple crystals are slightly more soluble in hot water. Recrystallization was effected by adding an aqueous *l*-propylenediamine to the warm aqueous solution from which the yellow crystals had been removed by filtration. Purple complex: Found: C, 31.93; H, 6.76; N, 14.71%. Calcd for $NiC_{15}H_{38}N_6Cl_2O_8$: C, 32.17; H, 6.84; N, 15.00%. The results of the chemical analysis indicated that the yellow complex is the $[Ni(C_{18}H_{36}N_4)](ClO_4)_2$ reported by Curtis *et al.*[4]

(1,9-Diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)nickel(II) perchlorate monohydrate, $[Ni(C_{12}H_{28}N_4)](ClO_4)_2 \cdot H_2O$: An aqueous solution of $[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$ was passed through a cation-exchange column in the Na-form. The column was washed well with water, and the adsorbed yellow band was eluted with a 12% aqueous sodium perchlorate solution. The eluate was concentrated at 50°C under reduced pressure. Yellow crystals were obtained by cooling the solution in a refrigerator.

Found: C, 28.53; H, 5.70; N, 10.94%. Calcd for $NiC_{12}H_{30}N_4Cl_2O_9$: C, 28.60; H, 6.00; N, 11.11%.

(1,9,-Diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene)(ethylenediamine)nickel(II) perchlorate, $[Ni(C_{12}H_{28}N_4)(en)](ClO_4)_2$: To a concentrated solution of the above eluate, an aqueous ethylenediamine was added, drop by drop. The purple crystals were recrystallized from hot water.

Found: C, 30.31; H, 6.88; N, 14.79%. Calcd for $NiC_{14}H_{36}N_6Cl_2O_8$: C, 30.79; H, 6.64; N, 15.39%.

Measurements. The absorption (AB) and circular dichroism (CD) spectra in the near-infrared region (1400—700 mμ) were obtained with a Hitachi EPS-3 Recording Spectrophotometer and a Shimadzu QV-50 Spectrophotometer with its CD attachment, respectively. The AB and CD spectra in the visible and ultraviolet region (700—200 mμ) were recorded with a Hitachi 124 Spectrophotometer and a Jasco ORD/UV-5 Spectrophotometer with its CD attachment, respectively. The infrared (IR) spectra in the NaCl region were obtained using a Hitachi EPI-2G Infrared Spectrophotometer. All the measurements were made at room temperature.

Results and Discussion

Figure 2 compares the AB and CD spectra of $[Ni(C_{18}H_{36}N_4)](ClO_4)_2$ (the yellow complex (I)) and

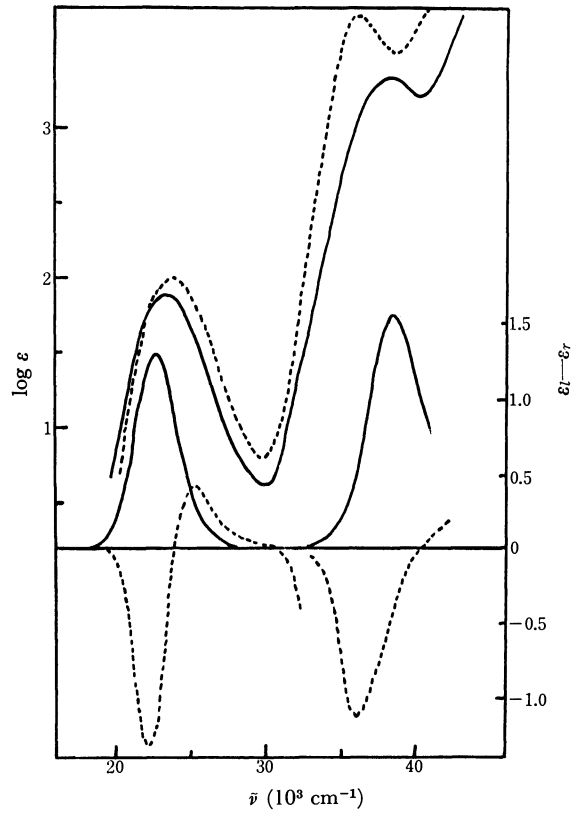


Fig. 2. AB and CD spectra of $[Ni(C_{18}H_{36}N_4)](ClO_4)_2$ (·····) and $[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$ (——) in water.

a) Complexes (I) $=[Ni(C_{18}H_{36}N_4)](ClO_4)_2$; (II) $=[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$; (III) $=[Ni(C_{12}H_{28}N_4)](ClO_4)_2\cdot H_2O$; (IV) $=[Ni(C_{12}H_{28}N_4)(en)](ClO_4)_2$; (V) $=Ni[(l\text{-pn})_3](ClO_4)_2$

$[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$ (the purple complex (II)) in water. The purple complex (II) gives a yellow aqueous solution, and its AB spectrum exhibits a pattern typical of a planar $[NiN_4]$-type complex. The purple complex was formed again by the addition of *l*-propylenediamine to the yellow aqueous solution. When the aqueous solution of the purple complex (II) was passed through a cation-exchange column in the Na-form, a yellow band was adsorbed and the eluate was basic. The yellow band was eluted with a 12% aqueous sodium perchlorate solution, and the eluate was concentrated at 50°C under reduced pressure. On cooling, a yellow complex with the composition of $[Ni(C_{12}H_{28}N_4)](ClO_4)_2\cdot H_2O$ (III) was obtained. The AB and CD spectra of this compound was almost the same as those of the purple complex (II) in water. The addition of aqueous *l*-propylenediamine to the concentrated eluate gave purple crystals which showed the same IR spectrum as that of the original purple complex (II). Purple $[Ni(C_{12}H_{28}N_4)(en)](ClO_4)_2$ (IV) was precipitated by adding aqueous ethylenediamine to the concentrated yellow eluate. These results indicate that the following equilibrium exists in an aqueous solution:

$$[Ni(C_{12}H_{38}N_4)(l\text{-pn})]^{2+} \rightleftarrows [Ni(C_{12}H_{38}N_4)]^{2+} + l\text{-pn}$$

The AB and CD spectra of the purple complex (II) in acetonitril (purple solution) are compared with those of $[Ni(l\text{-pn})_3](ClO_4)_2$ in Fig. 3. The complex (II) exhibits three absorption peaks at 10900, 18200, and about 29000 cm^{-1}; they correspond to those of the latter complex. This result indicates that the purple complex (II) exists as an octahedral $[NiN_6]$-type complex in acetonitril. A weak peak at about 23000 cm^{-1} seems to come from the planar complex (III) partly formed in this solvent. From the intensity of this absorption band, the quantity of the planar complex is estimated to be only several percent. The AB and CD data are summarized in Table 1. The AB and CD spectra of $[Ni(C_{12}H_{28}N_4)(en)](ClO_4)_2$ are quite similar to those of the corresponding *l*-propylenediamine complex.

The strong band around 36000—38000 cm^{-1} of $[Ni(C_{18}H_{36}N_4)](ClO_4)_2$ (I), $[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$ (II) (in water), and $[Ni(C_{12}H_{28}N_4)](ClO_4)_2$ (III) can be attributed to the C=N double bond in the ligands.[1] The absorption intensity of the complex (I) in this region is about twice as strong as those of the complexes (II) and (III), indicating that the ligand $C_{12}H_{28}N_4$ has one C=N double bond.

The IR data of the complexes in the 1600-cm^{-1} region are given in Table 2. The bands at 1603 and 1585 cm^{-1} of $[Ni(l\text{-pn})_3](ClO_4)_2$ can be assigned to the NH_2-deformation vibrations and the band at 1653 cm^{-1} of $[Ni(C_{18}H_{36}N_4)](ClO_4)_2$ (I), to the C=N stretching

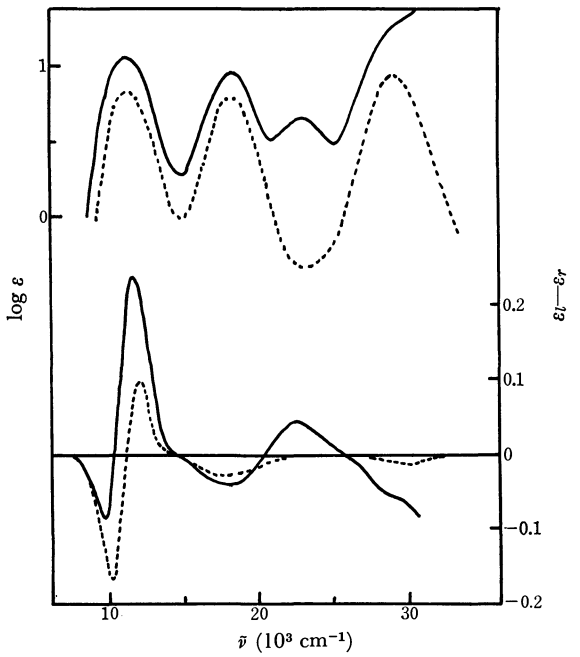

Fig. 3. AB and CD spectra of $[Ni(C_{12}H_{28}N_4)(l\text{-pn})](ClO_4)_2$ (——) and $[Ni(l\text{-pn})_3](ClO_4)_2$(·····) in acetonitril.

Table 2. IR data in 1600 cm^{-1} region (cm^{-1})

Complex	$\gamma_{C=N}$	δ_{NH_2}
I	1653	
II	1653	1603
III	1653	1592
IV	1653	1592
V		1603, 1585

vibration. The complexes (II), (III), and (IV), on the other hand, exhibit two strong bands, at 1653 and around 1600 cm^{-1}, which can be assigned to the C=N stretching and the NH_2–deformation vibrations respectively.

On the basis of these data, we concluded that the ligand $C_{12}H_{38}N_4$ is 1,9-diamino-1,4,6,6,9-pentamethyl-3,7-diazanona-3-ene (Fig. 1), although there are four possible isomers, depending on the positions of the methyl groups of the *l*-propylenediamine residues. Their positions are: (1,8), (1,9), (2,8), and (2,9). Of these, however, the isomer (1,9), in which the methyl groups of the *l*-propylenediamine residues are located far from the six-membered chelate ring, may be expected to be most probable.[7] The reasons for this are as follows: (1) The X-ray analysis[4] of the yellow complex (I) showed that the methyl groups of the propylenediamine residues are on the 3 and 10 carbon atoms (Fig. 1). Thus, the repulsion between these methyl groups and the geminal methyl groups on the 7 and 14 carbon atoms seems to be avoided. (2) The reaction of $[Ni(iso\text{-}bn)_2]^{2+}$ (iso-bn=iso-butylenediamine) and acetone produced only a complex containing 1,9-diamino-1,1,4,6,6,9,9-heptamethyl-3,7-diazanona-3-ene, in which four methyl groups of iso-butylenediamine residues take 1 and 9 positions.[3] (3) $[Ni(bn)_2]^{2+}$ (bn=2,3-diaminobutane) does not react with acetone.[8]

Curtis[8] described an analogous compound, $[Ni(C_{10}H_{24}N_4)(en)](ClO_4)_2$ ($C_{10}H_{24}N_4$ = 1,9-diamino-4,6,6-trimethyl-3,7-diazanona-3-ene), but did not give any details on its structure or chemical properties.

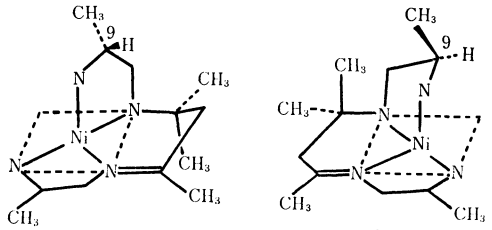

Fig. 4

The quadridentate ligand, $C_{12}H_{28}N_4$, in the $[Ni(C_{12}H_{28}N_4)(ch)]^{2+}$ (ch=en and *l*-pn) should give a *cis*-form complex. Although the *cis* form has two different geometrical arrangements, *cis* α and *cis* β,[9] the present complex is probably *cis* β, since the quadridentate ligand involves an imino-nitrogen. In addition, each geometrical isomer has two optical isomers, Δ and Λ. Since both Δ and Λ isomers involve the same asymmetric carbon atoms in the *l*-propylenediamine residues, they form a pair of diastereoisomers. As Fig. 4 illustrates, the methyl group on the 9-carbon atom of the Δ-*cis* β points away (*exo*) from the central six-membered chelate ring, while that of the Λ-*cis* β points toward (*endo*) the six-membered chelate ring. Since the interaction between the nonbonding atoms is expected to be greater in the endo-Λ-*cis* β isomer, the absolute configuration of the purple complexes, (II) and (IV), could be identified as *exo*-Λ-*cis* β. This assignment is supported further by the facts that the CD spectra in the *d–d* transition region of $[Ni(C_{12}H_{28}N_4)(ch)](ClO_4)_2$ in acetonitril are quite similar to that of Δ-$[Ni(l\text{-}pn)_3](ClO_4)_2$ as is shown in Fig. 3, and that they are enantiomeric to that of *fac*(N)-Λ-$[Ni(L\text{-}prol)_3]^-$.[10] The positional isomers due to the methyl group of *l*-propylenediamine in $[Ni(C_{12}H_{28}N_4)(l\text{-}pn)]^{2+}$ are not clear at present.

As Fig. 2 shows, the CD spectrum of $[Ni(C_{12}H_{28}N_4)]^{2+}$ (III) in water is almost enantiomeric with that of the $[Ni(C_{18}H_{36}N_4)]^{2+}$ (I); the purple complex (II) gives a CD spectrum similar to that of the complex (III) in water, since the former complex liberates the *l*-propylenediamine almost completely in water, as has been stated previously. According to the X-ray analysis,[4] the methyl groups of the *l*-propylenediamine residues in the complex (I) take positions axial to the complex plane. Therefore, the conformation of the *l*-propylenediamine residues in this complex may be described as approximately (pseudo) δ-gauche[5]; the conformation of such five-membered chelate rings involving the imino-nitrogen atom may be somewhat different from the usual gauche structure, as seen in the *l*-propylenediamine chelate. On the other hand, the five-membered chelate rings in the complex (III) may take a pseudo λ- and a usual λ-gauche conformation, since it is known that the methyl group on a puckered chelate ring tends to take an orientation equatorial to the ring unless there is special steric requirement.[11] Therefore the absolute configuration of the secondary amine (7 position) in this complex (III) should become enantiomeric with those of the secondary amines (1, 8 positions) in

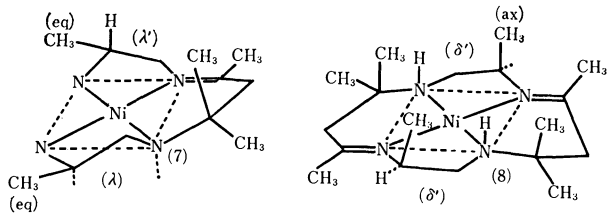

Fig. 5. Schematic drawing of $[Ni(C_{12}H_{28}N_4)]^{2+}$ and $[Ni(C_{18}H_{36}N_4)]^{2+}$.

$[Ni(C_{18}H_{34}N_4)]^{2+}$, as is shown in Fig. 5. The enantiomeric CD curves between the complexes (I) and (III) may be caused by such enantiomeric configurations.

The authors wish to thank Professor Kazuo Saito for his helpful advice and encouragement. They also wish to thank the Ministry of Education for its Grant-in-aid.

* *College of Liberal Arts, Okayama University, Tsushima, Okayama*

(Received November 1, 1970)

Alkali metal picrates in an aqueous solution are extractable by nitrobenzene. The investigations of the equilibria in and between the aqueous and organic phases show that the larger the association constants in the aqueous phase and the dissociation constants in the organic phase, the greater the extractability of the salts. The extremely low extractability of alkali metal picrates can be well explained in terms of such equilibrium constants.

The results of earlier works have suggested that an effective extraction of alkali metals can be achieved by the reagents known as the precipitants of these ions. These reagents are all similar in chemical structure—namely, they are all bulky anions. Polyiodide,[1] tetraphenylborate,[2-4] and perchlorate[4] ions are representative reagents, and these salts with alkali metals are extractable into nitrobenzene. In previous papers,[5-8] it has been shown that alkali metals can be effectively extracted by nitrobenzene in the presence of such polynitroamines as hexanitrodiphenylamine.

Considerations of the equilibrium in and between the aqueous and organic phases show that the greater the extractability of these salts, the larger the association in the aqueous phase and the smaller the association in the organic phase. Phenols,[9] especially nitrophenols, have been known as extractants, though the extractability is much less than that of the polynitroamines. In the present paper, it will also be shown that the low extractability of the picrates can be explained by the equilibrium studies.

Experimental

Reagents. Alkali metal picrates were prepared by dissolving picric acid into an aqueous solution containing a slight excess of each alkali metal carbonate or sulfate. The precipitate was filtered and recrystallized two or three times from ethanol or methanol. The crystals were dried at 70°C for 3 to 5 hr under reduced pressure. Nitrobenzene of a guranteed-grade was dried over anhydrous sodium sulfate for two days. The dried nitrobenzene was then distilled under reduced pressure. The fraction boiling at 75°C/5 mmHg was collected and stored in an ampouple in order to protect it from moisture. The distillate has a specific conductance of about 4×10^{-9} Ʊ/cm and is satisfactory enough for the conductivity measurement of these salts.

Extraction Procedures. The aqueous solutions of the picrates (4×10^{-2}, 9×10^{-3}, 2×10^{-3}, and 1×10^{-3} M for Na, K, Rb, and Cs respectively) were prepared, 1- to 10-m*l* aliquots were transferred into separatory funnels and diluted with water to make up the volume to 10 m*l*, and then the same volume of nitrobenzene was added to each. The funnels were shaken at 25°C for 30 min and allowed to stand for half an hour. The alkali metals extracted into the organic phase were determined by an atomic absorption spectrophotometer (Nippon Jarrell Ash, Type AA-1).

Conductance Measurements. The apparatus and the procedures of conductance measurements were the same as those described in an earlier paper.[8]

Theoretical

The dissociation constant, K_d, of alkali metal picrates in nitrobenzene were determined by the method of Shedlovsky.[10] The conductances, Λ, were related with the concentration of electrolytes, C, by the following equation:

$$\frac{1}{\Lambda S}=\frac{1}{\Lambda_\infty}+\frac{C\Lambda S f_o^2}{K_d\Lambda_\infty^2} \tag{1}$$

where Λ_∞ refers to the limiting conductance, and f_0, to the mean activity coefficient. S is a function of Z only.

$$S\equiv\left[\frac{Z}{2}+\sqrt{1+\left(\frac{Z}{2}\right)^2}\right]^2 \tag{2}$$

Z is defined by Eq. (3):

$$Z=\frac{\alpha\sqrt{C\Lambda}}{\Lambda_\infty^{3/2}} \tag{3}$$

where α is the Onsager coefficient. The picrate anion, R^-, associates with alkali metal cations, M^+, to form the ion-pair:

$$M^+ + R^- \overset{K_a^{MR}}{\rightleftharpoons} MR \tag{4}$$

and the association constant in nitrobenzene, K_o^{MR} $(=1/K_d)$, is written as:

$$K_o^{MR}=\frac{[MR]_o}{[M^+]_o[R^-]_o f_o^2} \tag{5}$$

where the subscript o refers to the nitrobenzene phase and the brackets, to the molar concentration of each species.

The values of the mean activity coefficient of the picrates in both the aqueous and organic phases were calculated by means of the following Debye-Hückel limiting law:

1) M. Kyrš and S. Podesva, *Anal. Chim. Acta*, **27**, 183 (1962).
2) K. Haruyama and T. Ashizawa, *Bunseki Kagaku*, **14**, 120 (1965).
3) R. C. Fix and J. W. Irvine, Jr., *MIT Lab. Nuclear Science, Annual Progress Report* (Nov. 30, 1955).
4) T. Sekine and D. Dyrssen, *Anal. Chim. Acta*, **45**, 433 (1969).
5) T. Iwachido and K. Tôei, This Bulletin, **37**, 1276 (1964).
6) H. Ueda, T. Iwachido, and K. Tôei, *Nippon Kagaku Zasshi*, **86**, 865 (1965).
7) T. Iwachido, S. Ukai, and K. Tôei, This Bulletin, **40**, 694 (1967).
8) S. Motomizu, K. Tôei, and T. Iwachido, *ibid.*, **42**, 1006 (1969).
9) W. J. Ross and J. C. White, *Anal. Chem.*, **36**, 1998 (1964).
10) T. Shedlovsky, *J. Franklin Inst.*, **225**, 739 (1938).

$$-\log f^2 = \frac{3.6494\times 10^6\sqrt{I}}{(\varepsilon T)^{3/2}} \quad (6)$$

The association constant of the picrates in the aqueous phase, K_a^{MR}, is also represented as follows:

$$M^+ + R^- \overset{K_a^{MR}}{\rightleftarrows} MR$$

$$K_a^{MR} = \frac{[MR]_a}{[M^+]_a[R^-]_a f_a^2} \quad (7)$$

where the subscript a denotes the aqueous phase. From the atomic absorption measurements, the total quantities of the alkali metal cations in both the aqueous and organic phases, C_a and C_o, were determined.

The ratio of C_o to C_a, or the distribution ratio, is written as follows:

$$q^M = \frac{C_o}{C_a} = \frac{[M^+]_o + [MR]_o}{[M^+]_a + [MR]_a} \quad (8)$$

In considering the $[M^+]_a=[R^-]_a$ relationship, the following equation is derived:

$$\frac{Y}{q^M} = \frac{1}{D^{MR}} + \frac{1}{D^{MR}K_a^{MR}f_a^2[M^+]_a} \quad (9)$$

where D^{MR} refers to the distribution coefficient of an ion-pair.

Y is defined by the following equation:

$$Y = \frac{\sqrt{0.25+C_oK_o^{MR}f_o^2}+0.5}{C_oK_o^{MR}f_o^2} + 1 \quad (10)$$

From a plot of Y/q^M *versus* $1/[M^+]_a f_a^2$, the values of D^{MR} and K_a^{MR} can be determined simultaneously.

Results and Discussion

Association Constants and Limiting Conductances of Alkali Metal Picrates in Nitrobenzene. In order to obtain the association constant from a conductance method, it is necessary to get the limiting conductance of the picrates in nitrobenzene.

At first, Z is calculated by using an approximate value of Λ_∞, which is determined graphically by a plot of Λ *versus* $C^{1/2}$ (Fig. 1); this leads to a first approxima-

tion for S. A first approximation for f_o is calculated from the Debye-Hückel limiting equation (6). These values are applied to Eq. (1) for all the values of C, and the plot of $1/AS$ *versus* $CASf_o^2$ gives the second approximation of Λ_∞. The process is repeated two or three times until Λ_∞ is no longer altered. The constants, Λ_∞ and K_o^{MR}, were calculated from the intercept and the slope of the linear extrapolation by means of the least-squares method (Fig. 3). Association constants in nitrobenzene saturated with water, $K_{o(H_2O)}^{MR}$, are calculated in the same manner by assuming that the dielectric constant and the viscosity of the water-saturated nitrobenzene are equal to those of dry nitrobenzene (Figs. 2 and 4).

The values of Λ_∞, $\Lambda_{\infty(H_2O)}$, K_o^{MR}, and $K_{o(H_2O)}^{MR}$ thus obtained are listed in Table 1. The light alkali metal picrates behave like weak electrolytes; especially is this true for lithium ($K_o^{LiPic} = 10^{7.2}$ after Witschonke and Kraus).[11]

Table 1. The limiting conductances and association constants for alkali metal picrates

MR	Λ_∞	$\log K_o^{MR}$	$\Lambda_{\infty(H_2O)}$	$\log K_{o(H_2O)}^{MR}$
Na-Picrate	33.9	4.48	31.9	3.67
K-Picrate	34.7	3.06	40.3	2.92
Rb-Picrate	35.1	2.81	40.7	2.65
Cs-Picrate	36.4	2.81	40.4	2.43

A plot of log K_o^{MR} *versus* the ionic potential (the ratio of the charge to the crystal radius, z/r) of the alkali metal cation clearly shows that, in both nitrobenzene and the water-saturated nitrobenzene, the larger the radius, the smaller the association constant (Figs. 5 and 6).

Association Constant in an Aqueous Solution. The association constant in an aqueous solution, K_a^{MR}, is

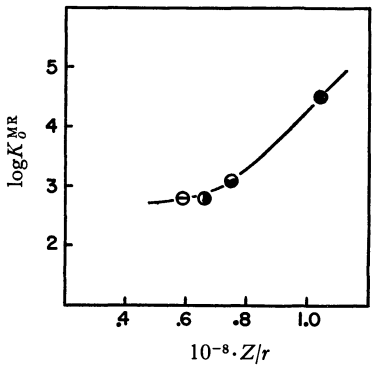

Fig. 5. The plot of log K_o^{MR} *vs.* z/r.

obtainable by Eq. (9) from the slope of the lines in Fig. (7). First approximate values, K_a^{MR} and D^{MR}, are calculated by substituting the analytical concentration of the alkali metal, C_a, for the concentration of the free metal-cation, $[M^+]_a$. The association constant thus obtained leads to a more accurate value of $[M^+]_a$. These procedures were repeated two or three times until the value of K_a^{MR} did not alter any more upon further refinement. The values of log K_a^{MR} increase gradually in proceeding from Na to Cs, as is shown in Table 2 and Fig. 8.

The Role of Hydration. If the ion-pairing arises from the coulombic force, it will be greatly affected by the radius of the alkali metal cation. An ion of the small effective radius should associate with the oppo-

sitely-charged ion to form a stable ion pair. Generally, the effective radius of an ion is largely influenced by the hydration. The crystal radius of the alkali metal cation increases gradually from lithium to cesium; the order of the effective radius is completely reversed in an aqueous solution. The sequence of K_o^{MR} in dry nitrobenzene (Table 1) and of K_a^{MR} in an aqueous solution (Table 2) is coincident with the above consideration.

If a hydrated alkali metal cation and a picrate anion form an ion-pair in the water-saturated nitrobenzene, $K_{o(H_2O)}^{MR}$ should increase gradually from sodium to cesium, because the effective radius of the cation decreases from sodium to cesium. However, the sequence of the $K_{o(H_2O)}^{MR}$ values are completely inverse. This implies that the ion pairs formed in the water-saturated nitrobenzene and in the aqueous phase are somewhat different in a hydration state; that is, the hydrated water molecules in the nitrobenzene phase are not effective in the reversal of the order of the crystal radii of cations. It might be attributed to the nature of the picrate anion, which is relatively small and whose charge is not distributed to the whole of the anion, but fairly well to the phenolic oxygen atom.

The sequence of Λ_∞ (Table 1) should decrease from sodium to cesium, because the radius of the ion increases with the atomic weight. However, the results obtained are the inverse of this. It implies that a hydration of ions occurs even in the dry nitrobenzene solution. The evidence proves that the freshly-distilled nitrobenzene contains a small amount of water, the amount determinable by the Karl-Fisher method. The order of the tendency to dissolve the picrates in the dry nitrobenzene is as follows: Cs>Rb>K<Na<Li. The hydrated water molecules loosen the bonding between the cation and the picrate anion, and so enhance the dissociation of the ion pair. Therefore, the unexpected high solubility of sodium and lithium picrates is another evidence of the presence of the hydrated species in the dry nitrobenzene, because they are apt to be hydrated among alkali metal cations.

The values of K_o^{MR} are very consistent with the results of Witschonke and Kraus. They have mentioned that the association constant of lithium picrate in dry nitrobenzene ($10^{7.2}$) is decreased 1/25 fold ($10^{5.8}$) on the addition of 0.03M water. The same tendency was observed in the present case. The water promotes the dissociation of alkali metal picrates, and so $K_{o(H_2O)}^{MR}$ becomes smaller than K_o^{MR}. The tendency decreases from lithium to cesium, and all the $K_{o(H_2O)}^{MR}$ values tend to be convergent.

Distribution Coefficient and Distribution Ratio. The distribution coefficient of the picrate is obtained from the reciprocal of the intercept of the line in Fig. 7. The values of $K_{o(H_2O)}^{MR}$ and K_a^{MR} show the presence of the ion pairs both in the aqueous and nitrobenzene phases, although the amounts of it are not great. Accordingly, the following relation can be obtained by neglecting the formation of the ion pair and the hydrolysis of the picrate ion in both phases:

$$q^M \approx \frac{[M^+]_o}{[M^+]_a} = \sqrt{\frac{D^{MR}K_a^{MR}}{K_{o(H_2O)}^{MR}}} \qquad (11)$$

The distribution ratio of the metal cation, q^M, is expected from Eq. (11) to be constant. Therefore, the ratio of the total concentration of metal in the aqueous phase, C_a ($=[M^+]_a+[MR]_a$), to that in nitrobenzene, C_o ($=[M^+]_o+[MR]_o$), should be constant. The

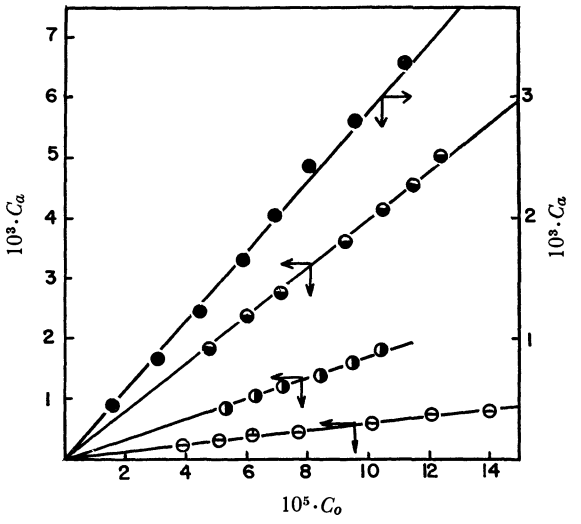

Fig. 9. The plot of concentrations of alkali metal ions in an aqueous phase. C_a, *vs.* those of an organic phase, C_o.
● Na-Picrate, ◒ K-Picrate, ◑ Rb-Picrate, ⊖ Cs-Picrate

circles in Fig. 9 represent the experimental data, while the lines show the experimental mean values of q^M. The calculated values of $(D^{MR}K_a^{MR}/K_{o(H_2O)}^{MR})^{1/2}$ are very coincident with the experimental values of q^M, as is shown in Table 2. If there is a reagent which can be highly dissociated in both phases, namely, $[M^+] \gg [MR]$ and $[M^+]=[R^-]$ in each phase, the extractability could be calculated directly from the values of K_a^{MR}, $K_{o(H_2O)}^{MR}$ and D^{MR}. The complete extraction would be achieved by the use of the reagent with the largest D^{MR} and K_a^{MR} values and the smallest $K_{o(H_2O)}^{MR}$ value.

Conclusion

The extraction of alkali metals by nitrobenzene in the presence of a bulky organic anion may be classified as an ion-association system. However, the present extraction system is somewhat different from the ordinary one in that the ion pair extracted extensively dissociates in the organic phase as well as in the aqueous

phase. The mechanism of the extraction may well be visualized by the following scheme:

$$\begin{array}{lcl} M_{aq}^{+} + R^{-} & \rightleftharpoons & M_{aq}R \quad \text{aqueous phase} \\ \hline & \updownarrow & \\ M_{aq}^{+} + R^{-} & \rightleftharpoons & M_{aq}R \quad \text{organic phase} \end{array}$$

With regard to the number of hydration in the organic phase, there is no direct evidence, but from the analogy with the case of polynitroamine (Hexyl[8]) and from the other indirect evidences, it seems to be reasonable to consider the coextraction of water molecules into nitrobenzene by means of the above scheme.

A high extractability is attainable with a reagent which allows the equilibrium to shift in the direction shown by the bold-faced arrows. From this point of view, the very low extractabilities of the picrates as compared with those of the Hexyl salts can be explained by the facts that the D^{MPic} values are smaller than D^{MHexyl}, and the $K_{o(\text{H}_2\text{O})}^{\text{MPic}}$ values are larger than $K_{o(\text{H}_2\text{O})}^{\text{MHexyl}}$, while the K_a^{MPic} and K_a^{MHexyl} values remain almost the same.

Apart from the equilibrium discussion, it is also of much interest to know with what kind of anions the highest extractability can be obtained. The simple and correct answer is hard to obtain, because the factors affecting the extraction are too complex to elucidate, but it is shown that the size and the charge distribution of anions used may have a great effect on the extractability.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 749—753 (1971)

The Synthesis of Nitro, Amino, and Acetamino Derivatives of 2,3-Dimethylbenzofuran[1]

Yoshiyuki KAWASE, Setsuko TAKATA, and Etsuko HIKISHIMA

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received February 11, 1970)

Another route to the synthesis of nitro, amino, and acetamino derivatives of 2,3-dimethylbenzofuran was explored. The cyclo-dehydration of 3-(*m*- and *p*-nitrophenoxy)butanones by means of polyphosphoric acid or sulfuric acid afforded 2,3-dimethyl-4- and -5-nitrobenzofurans, which were then converted by reduction to the corresponding 4- and 5-aminobenzofurans. The 4-, 5-, 6-, and 7-aminobenzofurans were prepared by the Hofmann reaction of the corresponding carboxylic amides. The amines thus obtained were converted to 4-, 5-, and 6-acetaminobenzofurans by acetylation. The 5-, 6-,-and 7-acetaminobenzofurans were also prepared by the cyclization of 3-(*p*-, *m*-, and *o*-acetaminophenoxy)butanones. The 7-nitrobenzofuran was prepared by the Sandmeyer reaction of 7-aminobenzofuran. The four aryloxybutanones, 2,3-dimethyl-4- and -7-nitrobenzofurans, 4-amino-2,3-dimethylbenzofuran, and 2,3-dimethyl-4-, -5-, -6-, and -7-benzofurancarboxylic amides are new compounds.

It has previously been reported that the 6-nitro derivative[2] of 2,3-dimethylbenzofuran was prepared by the nitration of the benzofuran, and the 5-nitro derivative[3] was recently prepared by the rearrangement of the *O*-(*p*-nitrophenyl)oxime of butanone, followed by deamino-cyclization, while the 4-, 5-, 6-, and 7-acetamino derivatives[2,4-6] were prepared by the Beckmann rearrangement of oximes of the acetylbenzofurans. The 6-amino derivative[2] was prepared by the reduction of the nitro compound, and the 5-, 6-, and 7-amino

derivatives[4,5] were prepared by the hydrolysis of the acetamino compounds.

In the present paper, the preparation of nitro and acetamino derivatives of 2,3-dimethylbenzofuran by the cyclo-dehydration of 3-(nitro- and acetaminophenoxy)butanones and that of the amino derivatives by the Hofmann reaction of the amides will be described.

The cyclization of 3-(*m*- and *p*-nitrophenoxy)butanones (II and IX) by means of polyphosphoric acid or concentrated sulfuric acid afforded 2,3-dimethyl-4- and -5-nitrobenzofurans (III and X) respectively in good yields. The crude products obtained by the action of polyphosphoric acid on II was found, from a study of its NMR spectrum, to be a mixture of 4- and 6-nitrobenzofurans (97% and 3%); recrystallization afforded a pure compound of 4-nitrobenzofuran (III) (Charts 1 and 2). The analogous cyclization of 3-(*p*-, *m*- and *o*-acetaminophenoxy)butanones (XV, XXI,[7] and XXVIII) with polyphosphoric acid or sulfuric acid afforded 5-, 6-, and 7-acetaminobenzofurans (XVI, XXII, and XXIX) respectively (Charts 2—4). In

the case of the cyclization of *m*-substituted aryloxybutanones (II and XXI), it seems notable that the cyclization of II occurred to the *o*-position of the nitro group, while that of XXI occurred to the *p*-position of the acetamino group.[8]

The Hofmann reaction of the amides (V, XII, XVIII, and XXV) of benzofurancarboxylic acids[9,10] (IV, XI, XVII, and XXIV) by the action of sodium hypobromite furnished 4-, 5-, 6-, and 7-amino-2,3-dimethylbenzofurans (VI, XIII, XIX, and XXVI) respectively in low yields (Charts 1—4). The amines VI and XIII were also prepared by the reduction of the corresponding nitrobenzofurans (III and X) with stannous chloride or tin and hydrochloric acid, as has been described in the case of the 6-amino compound[2] XIX, while the acetylation of three amines (VI, XIII, and XIX) with acetic anhydride afforded acetaminobenzofurans (VII, XVI, and XXII). 2,3-Dimethyl-7-nitrobenzofuran (XXIII) was prepared by the Sandmeyer reaction of 7-aminobenzofuran (XXVI) through diazotization and substitution (Chart 4).

It should be mentioned that four aryloxybutanones, II, IX, XV, and XXVIII; two nitrobenzofurans, III and XXIII; the aminobenzofuran VI, and four carboxylic amides, V, XII, XVIII, and XXV, are all new compounds.

In the NMR spectra, the chemical shifts of 3-methyl protons of two 4-substituted benzofurans, III and VI, appeared in a field lower by about 0.1—0.2 ppm than the other isomeric 5-, 6-, and 7-substituted compounds[8] (Table 3).

In the UV spectra, the maximum absorption peaks at 230—250 mμ of 5-nitro-, 5-acetamino-, and 5-carbamoyl-benzofurans have stronger intensities than those of the corresponding 4-, 6-, and 7-substituted isomers. Similarly, 6-nitro-, 6-acetamino-, and 6-carbamoyl-benzofurans showed broader peaks and stronger intensities than those of the 4-, 5-, and 7-substituted ones in the region of 270—335 mμ (Figs. 1—4).

Experimental

All the melting points and boiling points are uncorrected, the NMR spectra were measured on a JEOL JNM-C-60H (60 MHz) spectrometer, and the UV spectra were measured on a Hitachi 139 spectrophotometer. Typical procedures of reactions are described and the detailed data are summarized in the tables.

The Preparation of Aryloxybutanones. Powdered potassium carbonate (168 g) and a small amount (1 g) of potassium iodide were stirred into a solution of *m*-nitrophenol (50 g) and 3-chlorobutanone (47 g) in acetone (400 m*l*), after which the mixture was refluxed for 10 hr. Most of the acetone was distilled off, and the residue was treated with water and extracted with ether. The ethereal solution was concentrated, and the residual product was distilled to give 61 g (81%) of 3-(*m*-nitrophenoxy)butanone (II), bp 154—162°C/6 mmHg. In the case of XXI, it seemed, from the pattern of the IR spectrum, that the product was contaminated by some acetaminobenzofuran (XXII), which was probably formed during distillation.

The Preparation of Nitrobenzofurans. a) By the Cyclization of Aryloxybutanones: i) With H_2SO_4: Concentrated sulfuric acid (12.5 g) was stirred, drop by drop, to the aryloxybutanone IX (5 g) below 50°C, after which the mixture was kept at 50°C for 30 min. After cooling, the mixture was poured into ice and extracted with ether. The ethereal solution was concentrated, and the residual product was crystallized from ethanol to give 3.2 g (70%) of 2,3-dimethyl-5-nitrobenzofuran (X), mp 116—117°C.

8) Preliminary report: Y. Kawase, *Chem. Ind.* (London), **1970**, 687.
9) Y. Kawase and M. Takashima, This Bulletin, **40**, 1224 (1967).
10) Y. Kawase, T. Okada, and T. Miwa, *ibid.*, **43**, 2884 (1970).

ii) With Polyphosphoric Acid (PPA): A mixture of the aryloxybutanone IX (10 g) and PPA (n=2.5,[11] 200 g) was heated at 100°C for 1.5 hr while being stirred. The resulting mixture was treated as has been described above to give

a) δ-Values (ppm) measured in CCl_4 (*ca.* 5% solution), using TMS as an internal standard.
b) 2,3-Dimethyl-6-nitrobenzofuran.

6.65 g of the nitrobenzofuran X, mp 116—117°C. In the case of the cyclization of II, 6.2 g of a crude product, mp 73—74°C, was obtained after one crystallization. It was found, from the NMR spectrum, to be a mixture of 2,3-dimethyl-4- and -6-nitrobenzofurans; the percentage composition was determined by estimating the areas of the peaks corresponding to the 3-methyl protons (see Table 1). Further recrystallization furnished 4.25 g (46%) of the pure III, mp 80.5—81°C.

b) By the Sandmeyer Reaction: According to the usual manner,[12] the amine XXVI (1.4 g) was diazotized in acetic acid (16 m*l*) with sodium nitrite (1.6 g) and sulfuric acid (8 m*l*); the diazonium compound thus formed was treated with a decomposition mixture which had been prepared from copper sulfate (8 g), sodium sulfite (8 g), and sodium nitrite (20%, 8 g). The product was crystallized from ethanol to give 65 mg (4%) of 2,3-dimethyl-7-nitrobenzofuran (XXIII), mp 76.5—77°C.

The Preparation of Acid Amides. A mixture of 2,3-dimethyl-4-benzofurancarboxylic acid[9] (IV) (4 g) and thionyl chloride (10 g) was refluxed for 1 hr. The excessive reagent was then distilled off, and the residual product was dissolved in dioxane (10 m*l*). A concentrated aqueous ammonia solution (20 m*l*) was added to the solution, and the mixture was treated with water after it had stand for 1 hr. The crystalline

11) Prepared from phosphoric acid (85%) and phosphorus pentoxide (1. 1: 1).

12) H. H. Hodgson, A. P. Mahadevan, and E. R. Ward, "Organic Syntheses," Coll. Vol. 3 (1955), p. 341.

product thus formed was collected and recrystallized from ethanol to give 2.6 g (65.5%) of the acid amide V, mp 192.5—194°C.

The Preparation of Aminobenzofurans. *a) By the Reduction of Nitrobenzofurans*: *i*) With $SnCl_2$-HCl: A mixture of the nitrobenzofuran III (5 g), stannous chloride (20 g), and concentrated hydrochloric acid (20 m*l*) was refluxed for 1 hr. An aqueous sodium hydroxide solution (27%, 123 g) was added to the mixture with cooling, and then the mixture was extracted with ether. The ethereal solution was concentrated; the residual product was distilled at 150—164°C/20 mmHg and then crystallized from petroleum ether to give 2.5 g (59%) of 4-amino-2,3-dimethylbenzofuran (VI), mp 41—43°C.

ii) With Sn-HCl: Concentrated hydrochloric acid (5 m*l*) was stirred into a mixture of the nitrobenzofuran III (1.1 g), ethanol (15 m*l*), and tin (1.4 g), after which the mixture was heated at 45°C for 3 hr while being stirred. After cooling, the mixture was treated as has been described in *i*) to give 0.2 g (21.5%) of the amine VI, mp 41—43°C.

b) By the Hofmann Reaction: A solution of the amide V (2 g) in dioxane (40 m*l*) was stirred into an aqueous sodium hypobromite solution which had been prepared from bromine (2.7 g), sodium hydroxide (4.5 g), water (27 m*l*), and ice (27 g). The mixture was heated at 70°C for 1 hr while being stirred. After the addition of an aqueous sodium hydroxide solution (50%, 13 g), the mixture was heated at 80°C for another hour with stirring and then cooled. The mixture was treated with water and extracted with ether. On treatment as in *a-i*, the ethereal solution gave the amine VI.

The identity of XIII, XIX, and XXVI with the authentic samples prepared independently[2,4,5] was confirmed by a mixed-melting-point determination and by a comparison of their IR spectra.

The Preparation of Acetaminobenzofurans. *a) By the Cyclization of Aryloxybutanones*: Two aryloxybutanones, XV and XXVIII, were treated with sulfuric acid at 40°C to give 5- and 7-acetaminobenzofurans (XVI and XXIX), and XV and crude XXI were treated with PPA to give XVI and 6-acetaminobenzofuran (XXII), as has been described for the nitro compounds.

b) By the Acetylation of Amines: Three amines, VI, XIII, and XIX, were acetylated by the acetic anhydride-pyridine method to give 4-acetaminobenzofuran (VII), XVI, and XXII.

Compounds VII, XVI, XXII, and XXIX were identified by a mixed-melting-point determination and by a comparison of the IR spectra with those of authentic samples.[2,4-6]

Isomerization of Gomberg's Trityl by Protonic Acids in Benzene

Hiroshi TAKEUCHI, Toshikazu NAGAI, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received March 10, 1970)

Gomberg's trityl (1-diphenylmethylene-4-trityl-2,5-cyclohexadiene) (I) was isomerized by protonic acids such as HCl and phenol in benzene to form *p*-benzhydryltetraphenylmethane (II). *p*-(Benzhydryl-α-*d*)-tetraphenylmethane (III) was formed by the treatment of I with phenol-*d*. Ph_3CH and Ph_3CCl were treated under the same conditions, but II was not obtained. It was not formed either by the reaction of phenylazotriphenylmethane with phenol. This observation indicates that H^+ adds to the terminal methylene of I to form the cyclohexadienyl cation followed by deprotonation to give II. Similarly, treatment of 1-(phenyl-*p*-tolymethylene)-4-(diphenyl-*p*-tolylmethyl)-2,5-cyclohexadiene (IV) with HCl in benzene afforded α,α,α′-triphenyl-α,α′-(di-*p*-tolyl)-*p*-xylene (V). The results support the view that Gomberg's trityl is not hexaphenylethane but 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene as suggested by Lankamp *et al.* (*Tetrahedron Lett.*, **1968**, 249). 1,1,2,2-Tetraphenylethane and 1,1,2,2-tetra-*o*-tolylethane not having the cyclohexadiene structure could not be isomerized by protonic acids (HCl and PhOH) in benzene. Thus, isomerization of this type is characteristic of the cyclohexadiene structure such as that of Gomberg's trityl.

It is believed that the dimerization of the triphenylmethyl radical discovered by Gomberg leads to hexaphenylethane.

However, Lankamp *et al.*[1] reported in 1968 that the monomer-dimer equilibrium of trityl is not the equilibrium, hexaphenylethane ⇄ 2 triphenylmethyl radicals, and should be represented as: 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene ⇄ 2 triphenylmethyl radicals, by the evidence of UV and NMR spectra.

Guthrie and Weisman[2] reported that the dimer structure suggested by Lankamp *et al.* could be supported from the reaction of Gomberg's trityl toward a base.

During our investigation[3] on the reactivity of Gomberg's trityl toward sulphur dioxide, we found that Gomberg's trityl isomerizes into *p*-benzhydryltetraphenylmethane in the presence of protonic acids. This gives a chemical evidence for the 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene structure as the dimer structure of Gomberg's trityl. We wish to report the de-

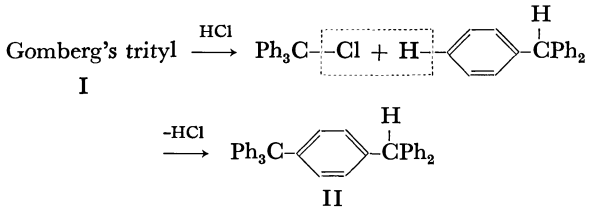
tails of the isomerization of Gomberg's trityl by protonic acids in benzene.

Ullmann and Borsum[4] reported that the reaction of trityl chloride or triphenylcarbinol with Zn-$SnCl_2$ in acetic acid gave a stable hexaphenylethane (mp 225°C). Gomberg[5,6] also reported the formation of hexaphenylethane (mp 225—227°C) by the treatment of the trityl with HCl or acetic acid.

Tschitschibabin[7] synthesized *p*-benzhydryltetraphenylmethane (II) (mp 227°C) by the decomposition of the corresponding diazo compound formed from amino-*p*-benzhydryltetraphenylmethane. He argued against the formation of hexaphenylethane. Schlenk *et al.*[8] postulated the formation mechanism of II (Scheme 1) by the reaction of I with HCl, because II was formed in a 6% yield by the treatment of Ph_3CH with Ph_3CCl.



Scheme 1

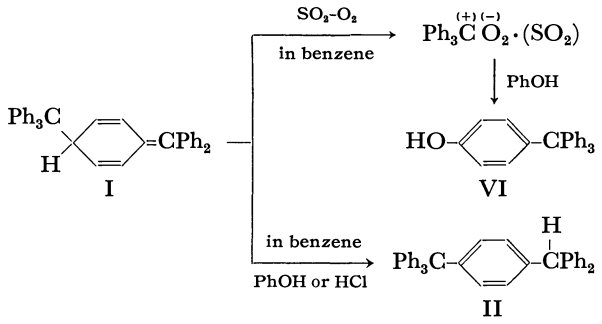
However, Gomberg's trityl (I), which is not hexaphenylethane but 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene as described by Lankamp *et al.*,[1] reacted with HCl to give II in good yield (82%). Hence the sluggish reaction shown in Scheme 1 can be neglected.

The present study was undertaken in order to explain the reaction mechanism of this type. The present paper deals with the reaction of protonic acids such as HCl and phenol with the derivative of I or tetraarylethanes.

Results and Discussion

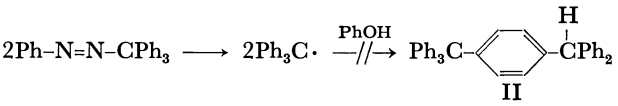
Gomberg's trityl (I) reacted with phenol in the presence of SO_2 and O_2 in benzene at 60°C to give *p*-hydroxytetraphenylmethane (VI) as the product.[3] However, in the absence of SO_2 and O_2 in the above system, *p*-benzhydryltetraphenylmethane (II)[3] was formed in a 68% yield. When HCl was used in place of phenol, II was formed (82%). Gomberg *et al.*[4-6] reported the formation of the compound having the same mp (225—227°C) as that of II by the treatment of I with acetic acid, though they characterized this compound as hexaphenylethane.

Schlenk *et al.*[8] proposed the mechanism shown in Scheme 1. Ph_3CH and Ph_3CCl were heated at 60°C for 2 hr in benzene in our experiment, but II was not obtained. Thus, the possibility of the pathway in Scheme 1 could be eliminated.



Scheme 2

If the formation of II is characteristic of the trityl radical, it should take place by the reaction of phenylazotriphenylmethane with phenol in benzene at 60°C for 2 hr. However, II was not obtained, which indicates that the reaction dose not occur *via* trityl radical as in the Scheme.



Scheme 3

A detailed investigation was carried out by use of 37 mmol of phenol-*d*[9] (69.5%)—phenol (30.5%) (calculated from mass spectral analysis) and I (4.2 mmol). Formation of *p*-(benzhydryl-α-*d*) tetraphenylmethane (III) was confirmed by IR (ν_{C-D} 2330 cm^{-1}) and mass spectrum (*m/e*; 487(M^+), 410(Ph_3C-C_6H_4-$\overset{+}{C}$DPh) and 168 ($Ph_2\overset{+}{C}D$)). The ratio II: III (36.3: 63.7) was calculated by comparison of the mass spectral molecular peaks of this isotope mixture with those of II. Compound II was treated with the labelled phenol, but the mass spectral analysis showed no peak corresponding to III. This indicates that the isotope scramble of II does not occur. Though the first proton donation step is obscure, the value ($k_H/k_D=1.05\pm0.01$) of the isotope effect was obtained on the assumption that this reaction follows first order of I and second order[10] of phenol.

In such solvents as H_3PO_4 and $POCl_3$,[11] however, $Ph_3C\cdot$ is transformed into $Ph_3\overset{+}{C}$. Phenylazotriphenylmethane[3] or I was also allowed to react with phenol in the presence of SO_2 and O_2 in benzene to give VI by the reaction of PhOH and $Ph_3\overset{+}{C}$ formed in the reaction system such as Scheme 2. Thus, it is plausible that PhOH or HCl in benzene isomerizes I into II more readily than to transform $Ph_3C\cdot$ into $Ph_3\overset{+}{C}$.

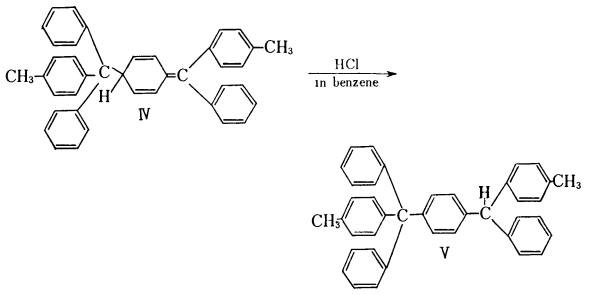
The results may indicate that proton or deuteron adds[10] to the terminal methylene of I to form the cyclohexadienyl cation such as I', followed by the deprotonation to give II or III (Scheme 4).[12] From the isotope effect, the protonation step in the reaction of I with phenol does not seem to be rate-determining.[10]

Similarly, the treatment of 1-(phenyl-*p*-tolylmethylene 4-(diphenyl-*p*-tolylmethyl)-2,5-cyclohexadiene (IV) with HCl in benzene afforded α,α,α'-triphenyl-α,α'-(di-*p*-tolyl)-*p*-xylene (V). Confirmation of V was achieved as follows: IR; 810 cm^{-1} (*p*-substituted phenyl). NMR (in CCl_4): τ; 2.5—3.7 (aromatic, multiplet, 27H), 4.6 (methine, singlet, 1H) and 7.7 (methyl, singlet, 6H). Mass: *m/e*; 514(M^+), 437 ($Ph_2(p\text{-}CH_3\text{-}C_6H_4)C\text{-}C_6H_4\text{-}\overset{+}{C}H\text{-}(p\text{-}CH_3\text{-}C_6H_4)$), 257 ($Ph_2(p\text{-}CH_3\text{-}C_6H_4)\overset{+}{C}$), and 181 ($Ph(p\text{-}CH_3\text{-}C_6H_4)\overset{+}{C}H$).



Sheme 5

On the other hand, 1,1,2,2-tetraphenylethane and 1,1,2,2-tetra-*o*-tolylethane were produced by the reaction of the corresponding diarylchloromethanes with Zn in benzene. However, these ethanes without the cyclohexadiene structure could not be isomerized by protonic acids (HCl or phenol). Thus, isomerization of this type is characteristic of the cyclohexadiene structure such as Gomberg's trityl.

$$2Ar_2CHCl \xrightarrow{Zn} Ar_2CH\text{-}CHAr_2$$

$$\xrightarrow[\text{in benzene}]{\text{PhOH or HCl}} Ar_2CH\text{-}C_6H_4\text{-}CHAr$$

Ar; C_6H_5 and $o\text{-}CH_3\text{-}C_6H_4$

The results support the idea that Gomberg's trityl is not hexaphenylethane but 1-diphenylmethylene-4-trityl-2,5-cyclohexadiene as described by Lankamp *et al.*[1]

Experimental

Apparatus. IR spectra were obtained on a EPI-S2 type Hitachi IR spectrometer. NMR spectra were obtained with a Japan Electron Optics Lab. spectrometer. UV spectra were taken with a EPS-3 Hitachi recording spectrometer. Mass spectra were recorded on a Hitachi RMU-6E spectrometer.

Materials. Benzene was purified by the ordinary method. Phenol was obtained commercially. The phenol-*d*-phenol mixture was made by the treatment of phenol with D_2O.[9] Gomberg's trityl (1-diphenylmethylene-4-trityl-2,5-cyclohexadine) (I) was prepared by the method of Gomberg and Cone.[13] Phenylazotriphenylmethane was synthesized by the procedure of Cohen and Wang.[14]

Isomerization of I by Phenol. Compound I (4.7 mmol) and phenol (47 mmol) were dissolved in 60 m*l* benzene and the solution was heated at 60°C for 2 hr in Ar atmosphere. The residual after distillation of benzene was chromatographed over silical gel using petroleum ether-benzene mixture as eluents by changing the polarity of the eluting medium. The following compounds were isolated and identified.

p-*Benzhydryltetraphenylmethane (II)*: Mp 225—227°C (recrystallized from benzene - acetic acid), 68%, IR: 2880 (ν_{C-H}), 840 cm^{-1} (*p*-substituted phenyl). $\lambda_{max}^{cyclohexane}$ 263 mμ (log ε 3.11), shoulder; 255 mμ (log ε 3.15), 269 mμ (log ε 2.99) and 272 mμ (log ε 2.67). NMR (in CCl_4): τ; 2.6—3.1 (aromatic, multiplet, 29H) and 4.6 (methine, singlet, 1H). Mass spectrum: *m/e*; 486 (M^+), 409 ($Ph_3C\text{-}C_6H_4\text{-}\overset{+}{C}HPh$), 243 ($Ph_3\overset{+}{C}$) and 167 ($Ph_2\overset{+}{C}H$).

Found; C, 93.71; H, 6.41%. Calcd for $C_{38}H_{30}$: C, 93.79; H, 6.21%.

Triphenylmethane: Mp 92°C (recrystallized from MeOH) 3%. The compound has same IR spectrum as an authentic specimen and showed no depression of mixed mp.

p-*Hydroxytetraphenylmethane*: Mp 280°C (recrystallized from $CHCl_3$-petroleum ether, 3%. The compound showed no depression of mixed mp and gave an identical IR spectrum with that of an authentic sample.[15]

In order to investigate the isomerization mechanism, I (4.2 mmol) was allowed to react with phenol-*d*[9] (69.5%)-phenol (30.5%) (calculated from mass spectral analysis) in benzene (20 m*l*) at 60°C for 2 hr in Ar. Formation of *p*-(benzhydryl-α-*d*)-tetraphenylmethane (III) was confirmed by IR (ν_{C-D} 2330 cm^{-1}) and mass spectral peaks (*m/e*: 487, 410 and 168). The ratio of II: III (36.3: 63.7) was calculated by comparison of the mass spectral molecular peaks of this isotope mixture with those of II. The above phenol-*d*-phenol mixtre was treated with II under the same conditions, but mass spectral analysis showed no peak corresponding to III. Isotope effect (k_H/k_D) was calculated from the results.

Isomerization of I by HCl. Compound I (2.9 mmol) was dissolved in 15 m*l* benzene saturated with HCl gas, and the solution was made to stand at room temperature for 30 min. The residue obtained after evaporation of benzene was crystallized from ether to give II (82%).

*Isomerization of 1-(Phenyl-*p*-tolymethylene)-4-(diphenyl-*p*-tolylmethyl)-2,5-cyclohexadiene (IV) with HCl.* Diphenyl-*p*-tolylcarbinol[16] was prepared by the interaction of PhMgBr in ether and *p*-toluic acid methylester, and yielded diphenyl-*p*-tolylchloromethane (mp 98—99°C) after treatment with dry HCl in ether.[15] The benzene solution of IV was made by the reaction of diphenyl-*p*-tolylchloromethane (8.5 mmol) with Zn (6 g) in benzene (20 m*l*) at room temperature for 1 hr in Ar, and treated with dry HCl after the solid had been removed by filtration. Compound V was separated by column chromatography over silica gel using benzene-petroleum ether as eluents, mp 77—79°C, 42%, identified as follows. IR: 810 cm^{-1} (*p*-substituted phenyl). NMR (in CCl_4): τ; 2.5—3.7 (aromatic, multiplet, 27H), 4.6 (methine, singlet, 1H), and 7.7 (methyl, singlet, 6H). Mass: *m/e*: 514, 437, 257, and 181.

12) II was not obtained in the experiment using EtOH or Et_3N in place of phenol.

Found: C, 93.07; H, 6.53%. Calcd for $C_{40}H_{34}$: C, 93.34; H, 6.66%.

Treatment of Tetraarylethanes with Phenol or HCl. 1,1,2,2-Tetraphenylethane (VII) (39%, mp 210°C[17]) and 1,1,2,2-tetra-*o*-tolylethane (VIII) (15%, mp 250°C) were synthesized by the reaction of the corresponding diarylchloromethanes with Zn in benzene. NMR spectra show that VII and VIII are true ethanes: VII in $CDCl_3$: τ; 2.5—3.2 (aromatic, multiplet, 20H) and 5.25 (methine, singlet, 2H), and VIII in $CDCl_3$: τ; 2.6—3.2 (aromatic, multiplet, 16H), 4.9 (methine, singlet, 2H) and 8.55 (methyl, singlet, 12H). These ethanes were not isomerized by phenol or HCl under the conditions for the isomerization of I.

Solvent Effects on ρ Values of the Hammett Equation. II.[1]

Takeki MATSUI and Niichiro Tokura
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka
(Received April 6, 1970)

The rates of reactions of *N,N*-dimethylbenzylamine or its derivatives with methyl iodide in fourteen nonaqueous solvents at 30°C have been studied. The effects of the solvents on reactivities and Hammett's ρ values have been examined. For establishing the relationship between ρ and solvent polarity, a unique solvent parameter for reactivity ξ_0 was defined, which measures the relative solvent polarity in determining the order of reaction rate with respect to solvent. There is a linear relationship between ρ and ξ_0, but protic and aromatic solvents show deviation from this relation in a particular way. The liner relationship provides a common basis for explaining both substituent and solvent effects. This suggests the importance of solvent reorientation accompanied by an activation process. It is argued that the hydrogen-bonded solvation of reactant amines and solvation of the leaving group are responsible for abnormal behaviors in protic and aromatic solvents.

Since the proposal of Hammett's equation, evidence has accumlated which indicates that the Hammett ρ value is not independent of solvent.[1,2] This indicates the importance of external factors contributing to the transmission of substituent effects. Sufficiently accurate data for a discussion of the effects of solvents on the ρ value have, however, been only recently reported. Wilcox and Leung examined the mode of substituent effects transmission and concluded the dominance of field effects.[3] For esterification of substituted benzoic acids by diphenyl diazomethane, Buckley *et al.* discussed the change of ρ values with solvent in terms of dielectric constant of solvent.[4] At least, the existence of solvent effects on the reaction constant cannot be expected from a purely inductive model.

On the other hand, solvent effects on reactivity have been discussed from some particular aspects by many authors. The classical treatment is based on the assumption that the solvent is a continuous dielectric medium and only provides an electrostatic field where the reaction can take place. The results show that such a classical concept cannot explain the solvent dependence on reactivity. Various ideas have been developed to account for the confusing solvent effects on rates and equilibria.[5] Many attempts have been made to correlate the rate constant with solvent solubility parameters.[6] However, attention has recently been focused on the importance of solvent reorientation which is associated with the activation process.[5,7] We think that in this concept there is a common basis in establishing the simple explanation for both substituent and solvent effects.

In order to gain pertinent information it is necessary to study a reaction system where the mechanism of reaction is least complicated. The change of mechanism accompanied by reactant variation seems to make the problem complicated.[8] Thus, it is of interest to study the solvent effects on ρ values for the reaction of S_N2 type. A method of treatment is given in previous papers.[1,9] In the present paper, we report the results of a study of solvent effects on ρ values for reactions of *N,N*-dimethylbenzylamine, (DMBzA) or its derivatives with methyl iodide. This system was chosen for the need of determining the rate constant in a wider range of solvents than in previous works.

Results and Discussion

Rate data for a series of *N,N*-dimethylbenzylamine for quaternisation by methyl iodide in various solvents are given in Table 1. All the rate constants were calculated by the method of least squares and were corrected for thermal expansion of solvent.

It is necessary to compare the unitary term of rate constant k_u in each solvent, instead of rate constant, in order to examine solvent effects on reactivities.[9)] Hammett reaction "constant" is, however, a unitary quantity and independent of solution composition. In order to establish the relationship between ρ and solvent polarity, a solvent parameter for reactivity ξ_0 is defined by

$$\xi_0 = \log k_{u,0}/r_{CH_3I} - \log k_0^0 = \log r_{A0} - \log r_{M^{\neq}0} \quad (1)$$

where r_{CH_3I}, r_{A0} and $r_{M^{\neq}0}$ are the activity coefficients based upon the solvent standard state of methyl iodide, unsubstituted amine and activated complex without substituent, respectively. k_0^0 denotes the hypothetical rate constant in gas phase of the reaction of unsubstituted amine with methyl iodide which is given by[10)]

$$k_0^0 = \kappa \cdot K_0^{\neq}/R \cdot p_{A0}^0 p_{B0}^0/p_{M^{\neq}0}^0 \quad (2)$$

Application of the Hammett equation to the data of Table 1, using σ values given by Brown andMcDaniel[11)] gives the results in Table 2.[12)] There is a discrepancy between ρ^m and ρ^p. Typical plots of the data are shown in Fig. 1. The results of log $k_{u,0}/r_{CH_3I}$ or $\xi_0 + \log k_0^0$ are given in Table 2. The activity coefficient of methyl iodide in various solvents were estimated from regular solution theory.[13)] The r_{CH_3I}-values obtained in this way are compared with those determined experimentally in Table 3. The agreement between the calculated and found values is within the limit of analysis.

Relationship between ρ and ξ_0. The variation in ξ_0 with solvent is required for the changes of ρ values with solvents. Although in all solvents ρ^m is more negative than ρ^p, the mode of variation in ρ with ξ_0 is the same. The situation is illustrated by the plot of ρ against ξ_0 in Fig. 2. With respect to many solvents except for aromatic and alcoholic solvents there is a linear relationship between ρ and ξ_0. There is

a systematic trend that the lower the ξ_0 value the more negative the ρ value becomes.

The quantitative treatment reported previously is applied to the present system. The ρ value in an arbitrary solvent is given by

$$\rho = \rho^o + (\partial\rho/\partial\xi_0)\xi_0 \qquad (3)$$

where ρ^0 is the intrinsic ρ value. Modification of equation (3) shows the ρ value changes with the increase of solvent polarity as

$$\rho = \rho^o\{1 + 1/\rho^o \cdot (\partial\rho/\partial\xi_0)\xi_0\} \qquad (4)$$

The coefficient $1/\rho^0(\partial\rho/\partial\xi_0)$ is termed a leveling coefficient, because the value is in general negative,[14] and the second term in parentheses of Eq. (4) exerts a leveling effect upon substituent effects. For the present reaction the $\partial\rho/\partial\xi_0$ is 0.36, as shown in Fig. 2.

It is of interest to consider a necessary and sufficient condition for constancy of $\partial\rho/\partial\xi_0$. For deriving the condition we make use of the fact that the Hammett equation holds in all solvents. This is expressed in the form

$$\log k_x^o/k_0^o = \rho^o\sigma,\ \log r_{AX}/r_{A0} = \rho_A\sigma,$$
$$\log r_{M^*X}/r_{M^*0} = \rho_{M^*}\sigma \qquad (5)$$

The ξ_0-value is split into ξ_{A0} and ξ_{M^*0}. The contribution of ξ_{A0} and ξ_{M^*0} to ξ_0 is expressed by

$$\xi_0 = \log r_{A0} + (-\log r_{M^*0}) = \xi_{A0} + \xi_{M^*0} \qquad (6)$$

Combination of these equations leads to the following expression for the $\partial\rho/\partial\xi_0$.

$$\partial\rho/\partial\xi_0 = \partial\rho_A/\partial\xi_0 - \partial\rho_{M^*}/\partial\xi_0$$
$$= \partial\rho_A/\partial\xi_{A0} + \partial\rho_A/\partial\xi_{M^*0} - \partial\rho_{M^*}/\partial\xi_{M^*0} - \partial\rho_{M^*}/\partial\xi_{A0} \qquad (7)$$

14) While $\partial\rho/\partial\xi_0$ is positive for reactions in which ρ^0 seems to be negative, negative $\partial\rho/\partial\xi_0$ values are obtained for reactions in which ρ^0 seems to be positive. The former case is observed in S_N2 type reactions, *viz.*, the present system and ionization of phosphines.[9] The latter case is observed in equilibria of proton acids[4] and esterification of benzoic acids.[4]

In general ξ_{A0} is independent of ξ_{M^*0}, and Eq. (7) is modified to be

$$\partial\rho/\partial\xi_0 = \partial\rho_A/\partial\xi_{A0} - \partial\rho_{M^*}/\partial\xi_{M^*0} \quad (8)$$

Let us consider the requirement for constancy of $\partial\rho_A/\partial\xi_{A0}$ or $\partial\rho_{M^*}/\partial\rho_{M^*0}$. We assume that the ξ_x is represented by Eq. (9).

$$\xi_x = g(\xi)f(\sigma_x) \quad (9)$$

where $g(\xi)$ is a function depending upon the solvent, and $f(\sigma_x)$ is a function depending upon the substituent. It is easily shown that the $\partial\rho_A/\partial\xi_{A0}$ or $\partial\rho_{M^*}/\partial\xi_{M^*0}$ becomes independent of solvent. The reverse is also valid; the constancy of $\partial\rho_A/\partial\xi_{A0}$ or $\partial\rho_{M^*}/\partial\xi_{M^*0}$ leads to Eq. (9).

For constancy of $\partial\rho/\partial\xi_0$ the following condition is also required. The effects of solvents on reactivities are attributed to either r_A or r_{M^*}. Uniqueness of $\partial\rho/\partial\xi_0$ which is observed with respect to many solvents (Fig. 2) shows that the conditions are satisfied. We believe that r_{M^*} is an important contributing factor to the changes of reactivities with solvents. Although the value of r_A has not been obtained experimentally, the situation may be valid.[15] Even in such a very non-polar solvent as cyclohexane, r_A may be nearly equal to unity and ρ_A is zero.[16]

It is instructive to consider whether theories proposed previously concerning r are satisfied with the condition expressed by Eq. (9). Kirkwood's first approximation[17] for the stability of dipole molecules in solution seems to fulfil the requirement. A solvent function $g(\xi)$ is a function of dielectric constant of solvent $D-1/2D+1$, and a structural function $f(\sigma_x)$ is a function of dipole moment and radius of molecules μ^2/γ^3. The theory cannot explain, however, the fact that the order of reactivity changes with solvents. In applications of the theory to solvent effects on reaction rates which have been carried out by Hartmann and Schmidt,[18] it is necessary to examine whether the solvents under consideration are satisfied with conditions mentioned by Kirkwood. The same situation holds in the application of regular solution theory to the explanation of solvent effects on reaction rates.[6] We must then consider another explanation of the linear relationship between ρ_{M^*} and ξ_{M^*0}.

The concept that solvent reorientation makes a great contribution to activation thermodynamic parameters, in particular to activation entropies, may give a satisfactory explanation for the phenomenon. The following three considerations are required. First, the existence of Hammett's equation requires the condition that the reaction coordinate of activated complex remains constant within substituent changes. Second, the linear relationship between $\delta_x \log k$ and $\delta_x \log K$ requires that the degree of net charge development in the transition state of all substituted benzyl amines should be the same. Third, the linear correlation of $\delta_\xi \log k_u$ with $\delta_\xi \log K_u$ requires that the mechanism may remain constant within the solvents used.[9] These three requirements lead to the conclusion that the degree of charge distribution accompanied by an activation process varies with substituent, and the Hammett equation holds. Redistribution of electrical charge caused by a substituent affects the entropy change accompanied by solvent reorientation as the consequence of an activation. The situation is more clearly illustrated in Fig. 3. Slopes of the straight line can be determined by the ease of reorientation of solvents accompanied by an activation process. This ease is in the sequence: cyclohexane<carbon disulfide<benzene <dioxane<tetrahydrofuran<nitrobenzene<acetone< acetonitrile. The order is not related to solvent properties such as dielectric constant, solubility parameter.

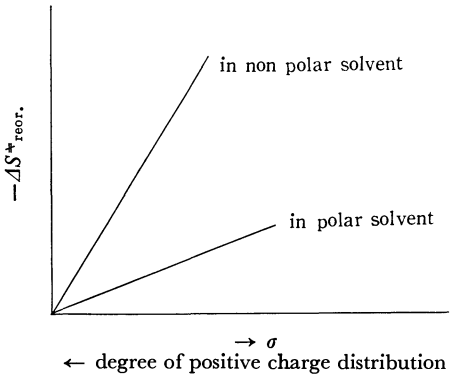

Fig. 3. Scheme for explaining the linear relationship between ρ_{M^*} and ξ_{M^*0}.

Abnormal Behavior of ρ Values in Protic Solvents. Figure 2 shows that ρ values in protic solvents, *i. e.*, methanol, ethanol, and isopropanol, are more positive than expected from the small ξ_0 values in these solvents. Judging from the 1-1 hydrogen-bonded complex formations between alcohols and amines,[19] the first term on the right of Eq. (8) seems to play a still more important role. As a result of these relatively strong interactions, ξ_{A0} in alcohols is more negative than in other solvents. The interaction exercises a more profound influence upon the stability of amines with electron-donating substituents than that with electron-withdrawing substituents. Any deviation with regard to alcohols, as shown in Fig. 2, is thus observed.

The situation is quantitatively treated as follows taking the ρ value in methanol as an example. The method has been adopted to explain the solvent effects on the reaction of pyridine with methyl iodide. The logarithmic ratio of activity coefficient of benzylamine to that of dimethylaniline, $\log r_{Ax}^{CH_3OH}/r_{DMA}^{CH_3OH}$ is determined by a deviation with regard to methanol from a plot of $\log k_u(\text{DMA}+CH_3I)$ *vs.* $\log k_u(\text{X}\cdot\text{DMBzA}+CH_3I)$ values for solvents. The plot of $\log r_{Ax}^{CH_3OH}/$

15) Validity can be judged by volume change experiment for the solution processes. The excess volume of amines in various aprotic solvents is nearly equal to zero. H. Hartmann, H. D. Brauer, H. Kelm, and G. Rinck, *Z. Physik. Chem.*, (*Frankfurt*), **61**, 553 (1968).

16) Dimerization phenomenon is considered to have important effect on activity coefficient of bases. According to Bruckenstein and Untereker (*J. Amer. Chem. Soc.*, **91**, 5741 (1969)), tertiary amines do not dimerize in hexane at the concentration used in the present work.

17) J. G. Kirkwood, *J. Chem. Phys.*, **2**, 351 (1934).

18) H. Hartmann and A. P. Schmidt, *Z. Physik. Chem.*, (*Frankfurt*), **62**, 312 (1968).

19) R. W. Taft, D. Gurka, L. Joris, P. von R. Schleyer, and J. W. Rakshys, *J. Amer. Chem. Soc.*, **91**, 4801 (1969), and the references cited. Data on excess volume of amines in alcohols (ref. 5) also show that amines are very stable in these solvents.

$r_{DMA}^{CH_3OH}$ *vs.* σ results in 0.38 for the value of ρ_A which is given as the distance a in Fig. 2. The deviation of point x in the figure from the straight line of usually accepted $\rho-\xi_0$ relationship is assigned to the log $r_{Ax}^{CH_3OH}$ value and is expressed by the distance b in the figure. The condition expressed by the following equation is required.

$$\log r_{Ax}/r_{A0} = 0.38\sigma_x;\ \log r_{A0} = -1.30 \qquad (10)$$

ρ Values in Aromatic Solvents with Small Dielectric Constant. As shown in Fig. 2, ρ values in aromatic solvents with comparable dielectric constant with that of benzene decrease with increasing reactivities in the solvents. The negative sign of interaction between solvent- and substituent-variable is observed in the solvents. This is in striking contrast to the behavior of ρ values in other solvents. The behavior has also been observed for the reaction of *N,N*-dimethylanilines with methyl picrate.[1] The normal behavior of ρ values result from the important role of a specific solvation of a leaving anion in a transition state. This type of solvation may be closely related to the polarizability of aromatic nucleus in the solvents. The effect is in the sequence: toluene<benzene<chlorobenzene<bromobenzene.[1,20] The susceptibility of a leaving anion I(δ-) to the solvation seems to be dependent on the tightness[21] of developing charge δ-. Accordingly, the demand for solvation stabilization by the various transition states will vary with substituent. In the case of the electron-withdrawing substituents the departing charge δ- will be more localized than in the case of electron-donating substituents. The $I(\delta$-) entity with tight character will have less solvation demand than will that with loose character. Thus the rate of quaternization of benzylamines substituted by electron-withdrawing groups is less sensitive to the effects of solvents in passing from toluene to bromobenzene than those substituted by electron-donating groups, the ρ values decreasing with the ξ_0 values in aromatic solvents.

Our explanation is in marked contrast to the view proposed by Alexander *et al.*[22] that "one cannot concentrate on only one end of a transition state." If it is so and the degree of solvent reorientation changes with only the net value of developing charge in the whole species of a transition state, a single straight line should be observed for $\rho-\xi_0$ relationship.

Experimental

Materials. *N,N*-dimethylbenzylamine and its derivatives were prepared according to Eliel *et al.*[23] from benzyl halide or its derivatives. Reagent grade benzyl chloride was obtained from Wako Pure Chemicals. *p*-Nitro- and *m*-nitrobenzyl bromides were prepared by bromination of *p*-nitro-[24] and *m*-nitrotoluene[25] respectively. *m*-Chlorobenzyl bromide was prepared according to the directions of Jenkins.[26] *p*-Methoxybenzyl chloride was prepared by the reaction of anisyl alcohol with hydrochloric acid.[27] *p*-Chlorobenzyl- and *m*-xylyl chloride were prepared by chlorination of *p*-chlorotoluene and *m*-xylene respectively according to Kharasch and Brown.[28] The prepared amines were dried over KOH pellet and distilled in a vaccum at least three times. The following boiling points were obtained: *N,N*-dimethylbenzylamine, 34—34.5°C/2 mmHg; *p*-methoxy-*N,N*-dimethylbenzylamine, 74—77°C/2.5 mmHg; *m*-methyl-*N,N*-dimethylbenzylamine, 85—85.5°C/19.5 mmHg; *m*-chloro-*N,N*-dimethylbenzylamine, 66—67°C/3 mmHg; *m*-nitro-*N,N*-dimethylbenzylamine, 112—114°C/3.5 mmHg; *p*-chloro-*N,N*-dimethylbenzylamine, 68—73°C/2.5 mmHg; *p*-nitro-*N,N*-dimethylbenzylamine, 125—127°C/6 mmHg. Purity of these samples was ascertained by gas-liquid chromatography, employing a Hitachi K53 gas chromatograph (Z 45 Column).

Methanol, tetrahydrofuran, acetonitrile, acetone, carbon disulfide, benzene, nitrobenzene, and bromobenzene were purified by the method previously described.[1,9] Toluene

and chlorobenzene were shaken with concentrated sulfuric acid several times and washed with water, aqueous potassium hydroxide, and then with water, dried over calcium chloride, and distilled. The center fraction was further distilled twice from phosphorus pentoxide. Cyclohexane,[29] ethanol,[30] and dioxane[31] were purified as described in literature. Isopropanol was purified by a method similar to that for ethanol.

Kinetic Procedure. The technique of the potentiometric kinetic measurements has been described in detail.[9] Reaction in solvents fitted into second order plots. Typical second order plots are shown in Fig. 4. Comparison was always made by results obtained with a different initial concentration. Reproducibility was mostly within $\pm 1\%$. Initial concentration of each reactant was 0.002—0.02M except for the reaction in cyclohexane where the reactant solutoin of about 0.05M was used for kinetic measurements.

In two cases the second order rate constants increased as the reaction proceeded, a phenomenon reported by Laidler and Hinshelwood[32] and attributed to autocatalysis by quaternary salt. In the reaction of *p*-chloro-*N*,*N*-dimethylbenzylamine with methyl iodide in cyclohexane the increase was bout 50% at 0.5% conversion, and was somewhat larger for the reaction of *m*-chloro-*N*,*N*-dimethylbenzylamine with methyl iodide in the same solvent. In both cases plots of rate constants *vs.* concentrations of salts produced enable us to calculate the rate constant at zero conversion, as shown in Fig. 5. We believe that the constants obtained in this manner are accurate within about $\pm 3\%$.

The reactions of *p*-nitro- and *m*-nitro-substituted amines with methyl iodide in cyclohexane were too slow to determine rate constants of these reactions with reasonable accuracy.

A Study of the Catalytic Partial Oxidation of Hydrocarbons. VI. The Effect of Molybdenum Addition to the Vanadium Oxide Catalyst on the Oxidation of Butene to Maleic Anhydride

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 17, 1970)

In the present work, the vapor-phase partial oxidation of *cis*-2-butene was carried out using V_2O_5-MoO_3 catalysts with different compositions, at 350°C, and at a butene content of 0.65% in air, in order to elucidate the effect of the addition of MoO_3 to the V_2O_5 catalyst on the selectivity and the mechanism for maleic anhydride formation. Two types of catalytic specificities were found, depending upon the Mo content: in the range of less than 20 atom% Mo, the specificity was similar to that of V_2O_5 alone, while in the range of more than 50 atom% Mo, a different specificity was observed, one which gave 1.2 times the yield of maleic anhydride than did V_2O_5 alone or the Mo-poor catalysts. The increase in the selectivity of butene to maleic anhydride which occurred when a large amount of MoO_3 was doped is considered to be caused by the increase in the selectivity of the $C_4H_4O \rightarrow MA$ step, not in that of the $C_4H_8 \rightarrow C_4H_6$ or $C_4H_6 \rightarrow C_4H_4O$ step. The selectivity of the side pathway in the $C_4H_8 \rightarrow C_4H_6$ step was so great that no satisfactory maleic anhydride yield from butene can be expected by the use of the V_2O_5-MoO_3 catalyst.

In previous papers, the mechanism of the catalytic oxidation of butene to maleic anhydride (MA) over V_2O_5 and V_2O_5—P_2O_5 catalysts, and the effect of the addition of P_2O_5 to a V_2O_5 catalysts, have been investigated.[1-3]

Regarding the binary system of V_2O_5–MoO_3, the effect of the catalyst composition on the selectivity and the mechanism of butadiene and furan (C_4H_4O) oxidation have also been reported in a former paper.[4] The results showed that the selectivity of butadiene to maleic anhydride is increased about 20% by the addition of a large amount of MoO_3 to the V_2O_5 catalyst; this increase is considered to be attributable to the increase in selectivity for the $C_4H_4O \rightarrow MA$ step, not to that for the $C_4H_6 \rightarrow C_4H_4O$ step. Nevertheless, the effect of the catalyst composition on butene oxidation is still obscure.

In the present work, we attempted to ascertain how the addition of MoO_3 to the V_2O_5 catalyst affects each reaction step in the step-by-step oxidation of butene to maleic anhydride and to elucidate this effect on the mechanism and the selectivity of the partial catalytic oxidation of butene.

Experimental

The vapor-phase air oxidation of *cis*-2-butene with a large amount of oxygen was carried out over various vanadium-molybdenum oxide catalysts with different compositions, in an ordinary flow-type reaction and at atmospheric pressure, as has been shown in the previous papers.[1-4]

1) M. Ai, K. Harada, and S. Suzuki, *Kogyo Kagaku Zasshi*, **73**, 524 (1970).
2) M. Ai, T. Niikuni, and S. Suzuki, *ibid.*, **73**, 165 (1970).
3) M. Ai, This Bulletin, **43**, 3490 (1970).
4) M. Ai, *Kogyo Kagaku Zasshi.*, **73**, 950 (1970).

The volume concentration of butene was about 0.65% in air, and the flow rate was kept at 1.5 *l*/min. The contact time was varied between 0.002 and 1.6 sec. This was done by changing the amount of the catalysts. The reaction temperature was always kept at 350°C. The experimental and analytic procedures were also the same as those employed in the previous works.[1-4]

The catalysts employed in the experiments were prepared as follows: the required quantities of NH_4VO_3 and $(NH_4)_6Mo_7O_{24}$ were dissolved in hot water by using oxalic acid, after which, pumice, of a mesh size of 10 to 20, was added to the above solution; then the solution was evaporated with constant stirring and finally dried in an oven at 130°C. The amount of pumice was 400 m*l*/g atom of vanadium and molybdenum. The catalyst was calcined under flowing air, at 500°C, for 5 hr.

Results and Discussion

Effect on the Oxidation Activity. Figure 1 shows the total butene conversion (excepting isomerization) at 350°C as a function of the contact time for various compositions of V_2O_5–MoO_3 catalysts. As the plot of log (C_t/C_0), where C_0 and C_t are the concentrations of butene in the charge and the effluent gas respectively, against the contact time gave a straight line, the rate of butene oxidation can be considered to be nearly of the first order for the butene concentration. The rate constants, calculated at 350°C over various V_2O_5–MoO_3 catalysts, were compared with those of butadiene or furan oxidation reported in a previous paper[4] (Fig. 2).

The oxidation of butene, butadiene, and furan were of the same order of magnitude at the same catalyst composition; they formed the sequence; $C_4O_8 < C_4H_6 < C_4H_4O$. The oxidation activity for each reactant increased gradually with the addition of MoO_3 in the range of less than 20 atom%, and then it decreased little by little with an increase in the Mo content in the region over 20 atom% Mo. It thus seems that, in MoO_3-rich compositions, MoO_3 acts only as a diluent. This result was very similar to that of benzene oxidation reported by Ioffe.[5]

Isomerization of Butene. The oxidation of butene was always accompanied by its isomerization. The conversion of *cis*-2-butene to such isomers as *trans*-2-butene and 1-butene is shown as a function of the total *cis*-2-butene conversion in Fig. 3. The results revealed that the formation of the isomers decreased with an increase in the oxidation activity of the catalyst. To clarify the cause of this, the conversion of *cis*-2-butene to *trans*-2-butene and 1-butene was plotted *versus* the contact time at 350°C for each catalyst (Fig. 4). The results suggest that the isomerization activity was independent of the compositions of V_2O_5 and MoO_3, and that only the oxidation activity was affected by the catalyst composition. In the case of a continuous experiment like this, it was observed that, in the absence of oxygen in the charge, neither the isomerization of

butene nor oxidation occurred over these catalysts; therefore it was considered that the presence of oxygen was necessary even to the isomerization of butene.

Effect on the Maleic Anhydride Formation. The formation of maleic anhydride from butene over V_2O_5–MoO_3 catalysts with different compositions and at 350°C is shown as a function of the total butene conversion in Fig. 5. Selectivity to maleic anhydride was defined thus: conversion to maleic anhydride/total butene conversion. The slopes of these plots, therefore, correspond to the differential selectivity at each butene conversion. These plots of the performance gave two lines, depending upon the Mo content in the catalyst, *i. e.*, Mo-poor (Mo<20 atom%) and Mo-rich (Mo>50 atom%) catalysts. Over the catalysts containing less than 20% Mo, the selectivity to maleic anhydride was less than 20% and did not vary with the Mo content. When the butene conversion was more than 70%, the formation of maleic anhydride decreased, probably because of the destruction of maleic anhydride; therefore, the formation did not exceed 15%. On the other hand, in the case of the Mo-rich catalysts, selectivity to maleic anhydride was also constant with an increase in the Mo content, and the selectivity at

at 350°C, C_4H_8: air=0.65:100
○: Mo/V=0, □: 1/4, △: 1, ▲: 4/1

butene conversion of 70% reached 24%. The maximum formation of maleic anhydride reached 20 mol%.

Effect on Intermediate Formation. The formation of butadiene and furan, which may be considered as a primary and a secondary intermediate respectively, in the step-by-step oxidation of butene to maleic anhydride, is shown in Fig. 6. The results reveal that the higher the oxidation activity of the catalyst became, the lower the intermediate formation became, while the maximum conversion to the intermediate always occurred at about 40% butene conversion. However, the amount of intermediate products over the V_2O_5–MoO_3 catalyst was far lower than that obtained over the V_2O_5–P_2O_5 catalyst.[1,3]

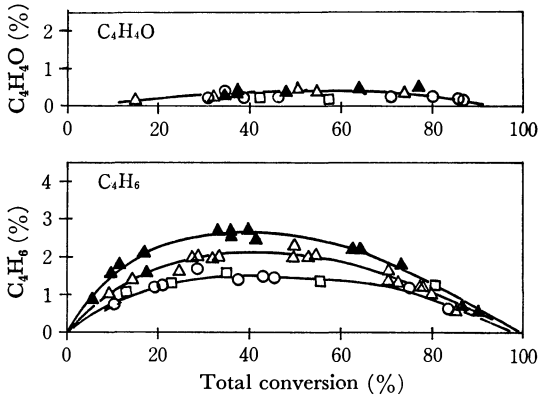

Fig. 6. Effect of catalyst composition on intermediates (butadiene and furan) formation. (Notation as in Fig. 5)

Effect on Side Reactions. A number of by-products have been found in the oxidation of butene over the V_2O_5–P_2O_5 catalyst,[1] while over the V_2O_5 and V_2O_5–MoO_3 catalysts, the major by-products were CO, CO_2, acetaldehyde (AcH), and acetic acid (AcOH); the other products were almost negligible. The conversion to AcH+AcOH (based on the assumption that two moles of AcOH or AcH are formed from one mole of butene, *i. e.*, 1/2 of the real amount of AcH+AcOH) is shown as a function of the total butene conversion in Fig. 7. The results show that the selectivity of butene to AcH and AcOH is almost independent of the catalyst

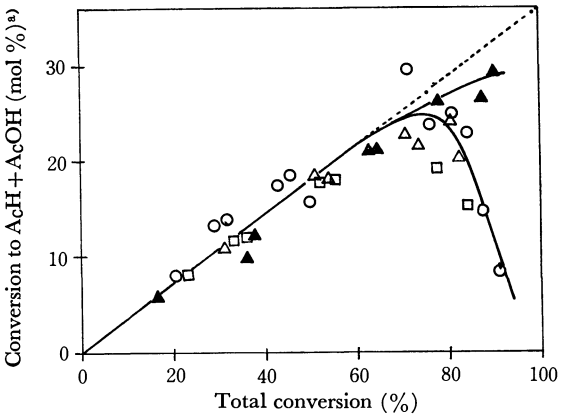

Fig. 7. Conversion to AcH+AcOH[a)] as a function of total butene conversion for various composition of V-Mo catalyst.
a) Basing on the assumption that 2 mol of AcH+AcOH are formed from 1 mol of C_4 compound. (Notation as in Fig. 5)

composition and is about 36% at a butene conversion of less than 70%. The formation of AcH and AcOH decreased, the amount being greatest at a conversion of about 80%, probably because of the destruction of AcH and AcOH.

The conversions to CO and CO_2 are shown as a function of the butene conversion in Figs. 8 and 9. The results reveal that the formation of CO and CO_2 increases rapidly at conversions of above 80%, probably because of the destruction of AcH, AcOH, and maleic anhydride. The CO_2 formation is independent of the catalyst composition, while the CO formation gives one of two lines, depending upon the Mo content, similarly catalyst containing more than 50% Mo showed a low selectivity to CO formation, *i. e.*, the formation was about a half of that obtained by means of the Mo-poor catalyst.

Discussion of the Effect of the MoO_3 Addition. In combination with the data in the previous report,[4] the selectivity to maleic anhydride is summarized in Table 1.

Table 1. Selectibity to maleic anhydride (%)

Catalyst	Reactant		
	C_4H_8	C_4H_6	C_4H_4O
V_2O_5, V_2O_5-MoO_3(Mo<20 %)	20	43	60
V_2O_5-MoO_3 (Mo >50 %)	24	53	73

Table 2. Selectibities of the steps (%)

Catalyst	Step		
	C_4H_8 ↓ C_4H_6	C_4H_6 ↓ C_4H_4O	C_4H_4O ↓ MA
V_2O_2, V_2O_5-MoO_3 (Mo >20 %)	46	72	60
V_2O_5-MoO_3 (Mo >50 %)	46	72	73

Since the amount of the intermediate (butadiene or furan) formed in the oxidation of butene and butadiene[4] to maleic anhydride over the V_2O_5–MoO_3 catalyst was quite small, it is difficult to know exactly how the main reaction pathway for the oxidation of butene proceeds. An assumption has been made that the main reaction proceeds, in the same manner as over the V_2O_5–P_2O_5 catalyst,[1,3] as follows: $C_4H_8 \rightarrow C_4H_6 \rightarrow C_4H_4O \rightarrow MA$. The selectivities towards the main reaction pathway in each consecutive step have been calculated and reported in an earlier paper;[3] they are shown in Table 2. From the above results and the results of butadiene oxidation,[4] the probable scheme of the butene oxidation over Mo-poor (Mo<20 atom%) and Mo-rich (Mo>50 atom%) catalysts may be proposed to be as follows:

V_2O_5, V_2O_5–MoO_3 (Mo<20 atom%)

C_4H_8[100]→C_4H_6[46]→C_4H_4O[33]→MA[20]

AcH+AcOH[36] [18] (54/46) [54] (28/72) [13] (40/60) [13] by-products (CO, CO_2, etc.)

V_2O_5–MoO_3 (Mo>50 atom%)

C_4H_8[100]→C_4H_6[46]→C_4H_4O[33]→MA[24]

AcH+AcOH[36] [18] (54/46) [54] (28/72) [13] (27/73) [9] by-products (CO, CO_2, etc.)

From the results it was found that the addition of less than 20 atom% Mo to V did not affect the catalytic specificity and the Mo-poor catalyst gave the same specificity as V_2O_5 alone, although the doping modified the oxidation activity. On the other hand, the addition of more than 50 atom% Mo to V gave another catalytic specificity, one which was milder and which brought a higher selectivity to maleic anhydride. These two kinds of catalytic specificities may be caused by two different catalytic species. Similar results were observed in toluene oxidation over the V_2O_5–MoO_3 catalyst system.[6] In the range of less than 30 atom% Mo, maleic anhydride was formed mainly, while in the

6) M. Ai, *Kogyo Kagaku Zasshi*, **73**, 946 (1970).

addition of more 40 atom% Mo to V benzaldehyde was the major product.

Many past studies devoted to the physico-chemical properties of the binary system of the V_2O_5–MoO_3 catalyst[5,7-10] have indicated that, in the range of less than 14 atom% Mo, MoO_3 forms a solid solution of the substituted type with V_2O_5, and the active species was considered to be V_2O_5, modified by MoO_3, while the addition of more 33 atom% Mo to V formed a mixture of a new compound (probably $Mo_6V_9O_{40}$) and MoO_3.

Therefore, it may be suggested that, in the Mo-poor catalyst, V_2O_5 acts as an active species, while in the Mo-rich catalyst, the new compound ($Mo_6V_9O_{40}$) acts as the active species and MoO_3 acts only as a diluent. A perusal of the results indicates that the 20% increase (from 20 to 24%) of the selectivity of butene to maleic anhydride which occurred when a large amount of MoO_3 in V_2O_5 was doped may be attributed to the 20% increase (from 60 to 73%) in the selectivity in the $C_4H_4O \rightarrow MA$ step, not in the $C_4H_8 \rightarrow C_4H_6$ or $C_4H_6 \rightarrow C_4H_4O$ step. That is the addition of MoO_3 did not affect the selectivity in the $C_4H_8 \rightarrow C_4H_4O$ step. It may be concluded that, for butene oxidation, satisfactory results cannot be expected by the use of the binary system of V_2O_5–MoO_3.

Mechanism of The Ullmann Condensation Reaction. II.[1,2] Effects of the Medium, the Additives and the Substituents

Tran Dinh TUONG and Mitsuhiko HIDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

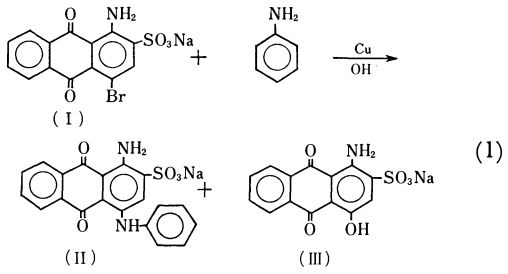
(Received May 12, 1970)

The effects of the medium, the additives, and the oxidation state of the copper catalyst on the rate of the Ullmann condensation reaction of sodium 1-amino-4-bromoanthraquinone-2-sulfonate and aniline in an aqueous buffered solution were investigated. The reaction rate was not affected by the ionic strength but depended very largely on the hydrogen-ion concentration. It was also established that the reaction was retarded by the addition of anions which can coordinate to copper; the retarding effect was in the order: $F^- \ll Cl^- < Br^- < I^- < CN^-$. The inhibiting effects of copper-chelating agents and oxygen were also observed. No marked difference, except a slight increase in initial rate, was observed when cuprous chloride was used as the catalyst instead of cupric sulfate. The effect of the substituents of aniline on the reaction rate can be expressed by Yukuwa-Tsuno's equation, in which the parameters, ρ and r, were -2.20 and 0.50 respectively. The experimental results are discussed.

Previous studies[2] of the Ullmann condensation of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) and aniline in an aqueous buffered solution, cupric sulfate being used as the catalyst, have shown that the reaction was first order in monomeric aryl halide (I) and first order in amine, while the rate depended hyperbolically on the concentration of cupric sulfate. The reaction was also characterized by a relatively low activation energy (9.14 kcal/mol) and a low frequency factor (10^6). These preliminary results, however, are not sufficient for a discussion of the elementary processes of this Ullmann condensation reaction. This paper will describe some supplemental results which, it is believed, will give more insight into the detailed mechanism.

Results and Discussion

The rate of the reaction (1) was determined under various conditions of the medium. Cupric sulfate was used as the catalyst except when otherwise stated.



(1)

Effect of The Ionic Strength. The ionic strength of the reaction system was varied by adding an inorganic salt. Sodium sulfate was chosen for this purpose because of its great solubility in water and because of the poor coordinating ability of the sulfate ion.

As is shown in Fig. 1, through a wide range of ionic strength (μ), no marked influence was observed. In view of this fact, it is unlikely that the rate controlling step, or the equilibria preceding it, involve "true" ionic

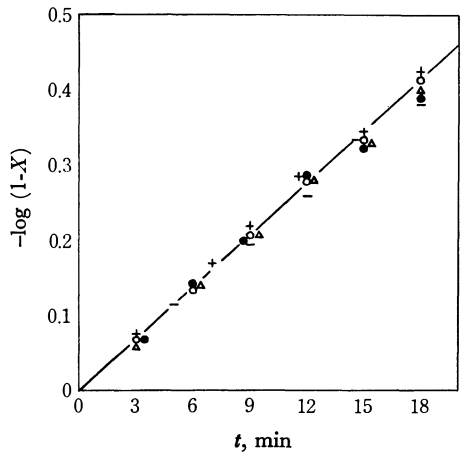

Fig. 1. Effect of ionic strength (X: reaction conversion). [I]= 0.31×10^{-2}mol/l, [$PhNH_2$]=0.30 mol/l, [Cu^{2+}]=2.50×10^{-4} mol/l; pH=9.94, T=70°C. Experiments in nitrogen. μ=0.435 (○), 0.585 (△), 0.885 (—), 1.035 (+), 1.485 (●).

species. This assumption is partly in agreement with the thermodynamical finding that the frequency factor was quite low. This cannot explained by any mechanism involving collisions between oppositely-charged ions in the rate-determining step.[3,4]

Effect of the Hydrogen-ion Concentration. A series of experiments was carried out under various pH conditions (9.37—11.51) which were attained by combining a 0.20M sodium carbonate aqueous solution and a 0.15M borax aqueous solution. The results (Fig. 2) show that no simple relationship exists between the hydrogen-ion concentration and the reaction rate. Because of the absence of the effect of the ionic strength, the behavior observed must be attributed to the action of the hydroxide ion. The presence of an optimum pH can be explained by the assumption that the hydroxide ion acts as both accelerating and retarding species.

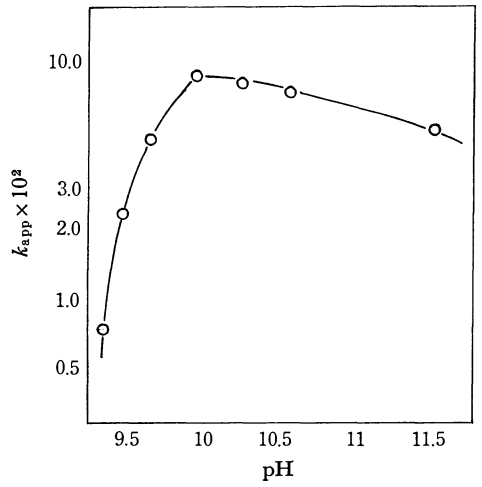

Fig. 2. Semi-logarithmic plots of k_{app} *vs.* pH. [I]=1.25×10^{-2} mol/l, [$PhNH_2$]=0.30 mol/l, [Cu^{2+}]=2.50×10^{-4}mol/l; T=70°C. Experiments in nitrogen.

In the pH range studied, no product other than that described in Eq. (1) was observed; the main product (II) was predominantly produced, along with a 4-hydroxy compound (III) in almost negligible amounts (0—3%). Therefore, the change in the rate could not be attributed to the formation of by-products.

In an aqueous solution, the amine exists as free and protonated species. The equilibrium:

$$PhNH_2 \overset{H^+}{\rightleftharpoons} Ph\overset{+}{N}H_3 \qquad (2)$$

is shifted to the left at a high pH. Since aniline exists as a free base in the pH range used in our experiments, the accelerating effect can be understood by assuming the formation of the $PhNH^-$ which has a greater nucleophilic character and electron-transfer ability to the cupric species than aniline itself. As will be seen later, the process of reducing the divalent metal ion is believed to play an important role in the reaction.

On the other hand, the fact that the rate constant did not vary with the time suggests that the active catalyst is consumed, but then regenerated by a cyclic process. Several results to be described later in this paper suggest that the $Cu^{2+}\rightleftarrows Cu^+$ process is operative. The influence of the alkalinity of the medium on this redox process might be involved. This kind of effect has been observed in several redox equilibria of metal ions in water.[5-7] In our case, it seems reasonable to consider the effect of the pH on the redox potential and to postulate that the coordination to the metal ions of the negative hydroxide ion, OH^-, will favor the removal of one electron from the univalent copper ion by electrostatic repulsion. This argument has been used to explain the influence of charged ligands on the equilibrium of the Fe^{2+}—Fe^{3+} couple in water.[7] If, in the Ullmann condensation, the univalent copper is responsible for the promotion of the reaction, the coordination of the hydroxide ion will result in a decrease in the cuprous concentration, and, thence, in a deceleration of the rate. It has been reported[8] that the Ullmann condensation of bromobenzene with the disodium salt of resorcinol in pyridine was inhibited by the hydroxide ion (generated from added sodium hydroxide or methoxide). The effect may be partly accounted for by the coordination of the hydroxide ion to the catalyst, although the detailed mechanism of deactivation has not yet been made clear.

Finally, it was suggested that the hyperbolic dependence of the reaction rate on the concentration of the catalyst can be explained by postulating the formation of copper clusters.[2] The hydroxide ion, by its ability to act as bridge between the metal ions, may facilitate the process yielding the inactive polynuclear complexes and decrease the rate.

Effect of Molecular Oxygen. When experiments were carried out in air, the reaction rate was markedly

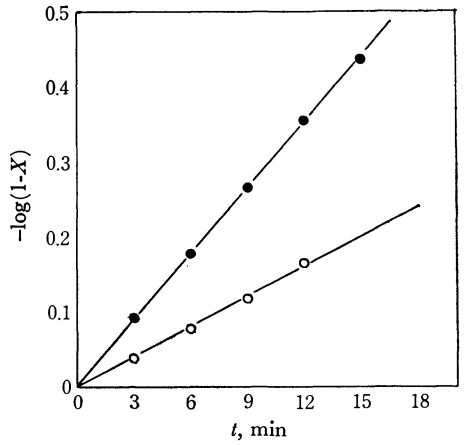

Fig. 3. Effect of oxygen (a): Pseudo-first order plots of the reaction in air (○) and in nitrogen (●). [I]= 1.25×10^{-2} mol/l, [$PhNH_2$]=0.30 mol/l, [Cu^{2+}]=1×10^{-2}mol/l; pH=9.94, T=70°C.

decreased (to about one third) as compared with that in a nitrogen atmosphere. Figure 3 illustrates a typical case. The results suggest that the copper ion behaves as a catalyst in a lower oxidation state.[9] It has been reported in the literature that oxygen retards the reactions which are believed to be catalyzed by cuprous species (formed from cupric salts added initially), such as the reaction of an aromatic diazonium halide with an aliphatic unsaturated compound to give α-halo-β-phenyl alkanes and alkenes (the Meerwein reaction), the Sandmeyer reaction,[10,11] and the hydrolysis of the diphenyliodonium ion.[12,13] The retardation was interpreted in these cases as resulting from the consumption

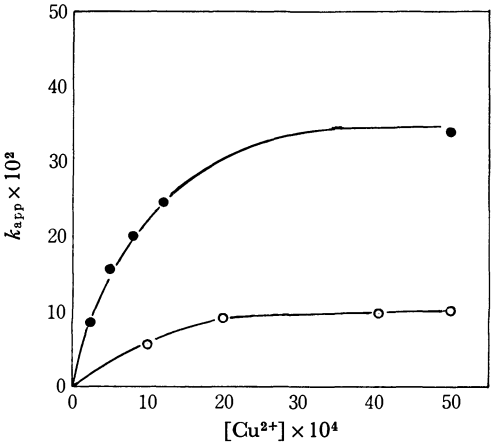

Fig. 4. Effect of oxygen (b): Dependence of the apparent rate constant k_{app} on the initial concentration of cupric catalyst. Experiments in air (○) and in nitrogen (●). [I]=2.50×10^{-2} (○), 1.25×10^{-2} (●) mol/l, [$PhNH_2$]=0.30 mol/l; pH=9.94, T=70°C.

of the univalent copper by oxygen.

An alternative explanation of the inhibiting effect of molecular oxygen may be possible if the reaction is assumed to proceed through a radical (or radicaloid[14]) intermediate which gives the reaction product(s). This point, however, needs further elucidation.

It is noted further that the reaction in the presence of air obeyed the same rate law as the reaction in the case when oxygen was excluded, namely, the reaction was first order in aryl halide (I), and first order in aniline, while the rate increased hyperbolically with the increase in the catalyst concentration (Fig. 4). The effect of oxygen might not be due to the change in the mechanism, but to the decrease in the concentration of the active species.

Effect of Chelating Compounds. The addition of chelating compounds to the reaction system was found to yield some suggestive results.

The apparent rate constants, k_{app},[2] of the reaction in the presence of 8-hydroxyquinoline-5-sulfonic acid (HQS) are summarized in Table 1.[15]

The tendency of the reaction rate to decrease with an increase in the concentration of the chelating agent can reasonably be understood if the added agent is assumed to form thermodynamically stable and unreactive (or less active) complexes. HQS is known to coordinate to cupric copper (β_1=11.9, β_2=21.9 at 25°C).[16]

In order to understand quantitatively the behavior of the chelating agent in the reaction system, we attempted calculations on the assumption that HQS forms an inactive complex:

$$Cu^{2+} + HQS \overset{K_1}{\rightleftharpoons} Cu^{2+}\cdot HQS \qquad (3)$$

From ESR measurements,[2] the catalyst was found to exist mostly in the divalent form. The concentration of cupric copper not bonding to HQS was denoted as c_1, the concentration of HQS not bonding to the metal ion, as L, the equilibrium constant of (3), as K_1, the total concentration of HQS, as l_0, and that of

the catalyst, as c_0. We have:

$$c_1(1+K_1L) = c_0 \quad (4)$$

The mass balance of the chelating agent is represented as:

$$L + K_1c_1L = l_0 \quad (5)$$

or:

$$L = l_0/(1+K_1c_1) = \frac{l_0/c_0}{(1/c_0) + (K_1c_1/c_0)} \quad (6)$$

By combining Eqs. (4) and (6), Eq. (7) is obtained:

$$c_1/c_0 = \left(1+K_1\frac{l_0/c_0}{(1/c_0) + (K_1c_1/c_0)}\right)^{-1} \quad (7)$$

Denoting the c_1/c_0 and l_0/c_0 ratios as x and R respectively, Eq. (7) can be rewritten as:

$$x = \left(1+K_1\frac{R}{(1/c_0)+(K_1x)}\right)^{-1} \quad (8)$$

or:

$$x^2 + ((1/K_1c_0)-1+R)x - 1/K_1c_0 = 0 \quad (9)$$

By solving this equation, x is obtained as a function of R:

$$x = \frac{1}{2}[\sqrt{((1/K_1c_0)-1+R)^2 + 4/K_1c_0} - (1/K_1c_0-1+R)] \quad (10)$$

We postulate further that the apparent rate constant is proportional to the concentration of cupric copper[17] not bonding to HQS, and that the complex Cu^{2+}·HQS is inactive; therefore:

$$x = c_1/c_0 = k_R \quad (11)$$

where k_R is the relative rate constant.

By combining Eqs. (10) and (11), we obtain:

$$k_R = \frac{1}{2}[\sqrt{((1/K_1c_0)-1+R)^2 + 4/K_1c_0} - ((1/K_1c_0)-1+R)] \quad (12)$$

By substituting the numerical values of k_R and R corresponding to Experiment No. 6 in Table 1 into Eq. (9), the value of k_1 was determined to be 1.85×10^4. The values of k_R as calculated from Eq. (12), were plotted against the observed values. The results (Fig. 5) show the validity of the assumptions made above and can be reasonably understood by the assumption that the ligands, such as aniline,[18] with great coordinating power towards the cupric ion, prevent the entering of a second molecule of HQS into the coordination sphere of the metal. Further, the relatively small value of K_1, compared with the stability constant in water at 25°C, is not unreasonable if we consider the presence of the ligands stronger than water and the higher temperature at which the experiments were carried out.

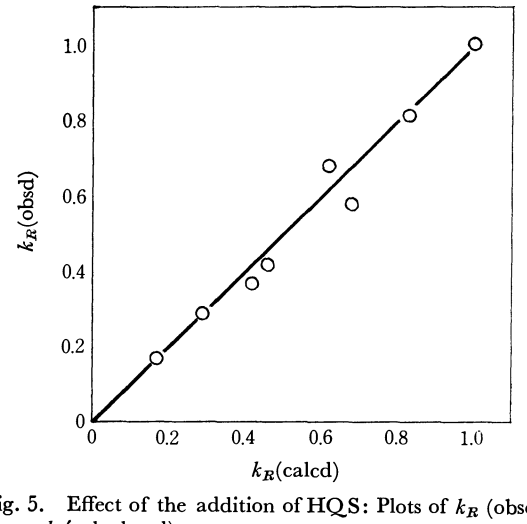

Fig. 5. Effect of the addition of HQS: Plots of k_R (observed) *vs.* $_Rk$ (calculated).

The inhibiting effect of the chelating agents can be interpreted by the assumption that at least three sites of coordination are required for the reaction to be promoted, or that the complexing metal ion is prevented from changing into the univalent state.

Retarding or inhibiting effects were also observed when other chelating agents, such as 2,2′-bipyridyl, 2,2′-biquinolyl, and 2,9-dimethyl-1,10-phenanthroline, were introduced into the reaction system. The effects of these additives are shown in Fig. 6.

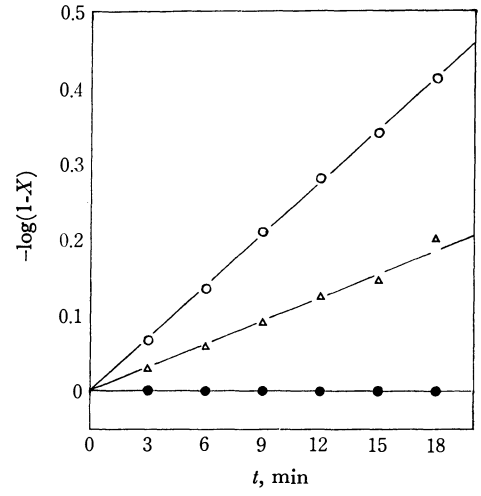

Fig. 6. Effect of chelating compounds (che). [I]$=0.31\times10^{-2}$ mol/l, [$PhNH_2$]$=0.30$ mol/l, [che]$=5.00\times10^{-4}$ mol/l, [Cu^{2+}]$=2.50\times10^{-4}$ mol/l; pH$=9.94$, $T=70$°C.
Experiments in nitrogen.
Control (○), che: cuproin (△), neocuproin, 2,2-dipyridyl (●)

When the mole ratio of the chelating agent to that of the catalyst was 2 : 1, 2,2′-bipyridyl and 2,9-dimethyl-1,10-phenanthroline completely inhibited the reaction, but 2,2′-biquinolyl did so incompletely. The inferiority of the latter in effecting inhibition is presumably due to its poor solubility in the aqueous solution. It was observed that the agent was partly left undissolved and that it floated on the surface of the reaction mixture.

17) Although the rate depended hyperbolically on the initial concentration of the catalyst,[2] linearity between the rate and the concentration of the catalyst could be assumed in the dilute region of the cupric copper.

18) It was observed that cupric copper formed a precipitate with aniline in an aqueous solution. See also: P. Spacu, V. Voicu, and I. Pascaru, *J. Chim. Phys.*, **60**, 368 (1963); I. S. Ahuja, D. H. 2,2′-Biquinolyl(cuproin)[19] and 2,9-dimethyl-1,10-phenanthroline(neocuproin)[20] are known as specific chelating agents of cuprous copper and not of cupric species. This specific chelating ability has been used to detect the existence of cuprous copper and, in some cases, to prove its catalytic capacity, especially in systems where the metal is believed to exist in various oxidation states. Thus, the evidence for the presence of Cu^+ intermediate in the cupric-ion-catalyzed oxidation of ascorbic acid[21] or in the solvolysis of diaryliodonium salts in the presence of Cu^{2+} [12] has been afforded by the use of these specific cuprous-ion complexing reagents.

The inhibition of the reaction by cuproin and neocuproin mentioned above likely suggests that the catalyst, initially added as cupric sulfate, is partly reduced to the cuprous state.

Effect of Anions. It was found (Fig. 7) that cupric sulfate, cupric chloride and cupric bromide, when used at equal molar concentrations, all catalyzed the reaction at the same rate. This result can be interpreted by assuming that the anion associated with the cupric ion was readily replaced by other ligands existing in the system.

The situation, however, was different when the anion was added in sufficiently large amounts. Several anions (F^-, Cl^-, Br^-, I^-, CN^-) were introduced in the form of their sodium salts. Their effects are illustrated in Fig. 8, where the pseudo-first order plots of the reaction are represented.

The results show that the fluoride did not exert any marked influence on the reaction, but the other anions decreased the rate. Since the absence of the effect of the ionic strength was confirmed, as has been mentioned above, the retarding effect must be ascribed to the action of the added anions.

Figure 8 reveals that the anions inhibit the reaction

in this order: $F^-\ll Cl^-<Br^-<I^-<CN^-$. It is well known that both cuprous and cupric copper can form complexes with halides and cyanide, but the reverse order of stability of the complexes has been observed for the two oxidation states.[22] Thus, while the $F^-<Cl^-<Br^-<I^-<CN^-$ order has been reported for the cupric ion, the univalent copper ion forms complexes with the opposite sequence of stabilities: $CN^-<I^-<Br^-<Cl^-<F^-$ (In fact, complex formation from Cu^+ and F^- has not yet been established). The available thermodynamic data[23] also suggest that in an aqueous solution, the cupric complexes with halide and cyanide ions are far more unstable than the corresponding complexes of cuprous copper.

These facts might be interpreted as indicating that cuprous copper is responsible for the promotion of the reaction, and that the retarding effect of the halide and

cyanide ions might be described as resulting from the competition between the added anions and the reactants for the metal ion.

The retarding effect of the anions was increasingly pronounced as their concentration increased. The relative rate constants are tabulated in Table 2.

Attempts to derive the quantitative relations between the relative rate constant and the concentration of the anion were, however, unsuccesful, presumably because of the complexities of the manner of action of the anions. Thus, besides their ability of competing with the reactants for the catalyst, the anions might facilitate the formation of polynuclear clusters postulated earlier[2] by bridging. This point is expected to be clarified by further studies.

Catalytic Activity of Cuprous Cloride. The data obtained by investigating the effects of molecular oxygen, cuproin and neocuproin, and added anions suggest that even when the catalyst is introduced as cupric salts, the univalent metal ion might be formed in the reaction system and that this species might play an important role in promoting the reaction. In order to obtain more direct evidence concerning this point, cuprous chloride was used as the catalyst.

The experiments showed that the initial rate was somewhat larger than that of the reaction catalyzed by cupric sulfate, but the steady state was rapidly established (within less than three minutes), and at this steady stage, the rate was found to be almost the same as in the case when cupric copper was used (Table 3).

These results can be explained on the assumptions that cuprous chloride was rapidly converted to cupric species and that the reaction took the same course as when cupric salt was used. The comparatively large rate during the early stage of the reaction might be due to the unconverted univalent copper salt. The reaction during this stage might take place on the surface of the solid catalyst.

Neocuproin exhibited the same inhibiting effect as in the experiments using cupric salt when added in a sufficiently large amount as compared with the concentration of the catalyst, but the reaction did occur (No. 6, Table 3) when the neocuproin: catalyst mole ratio was 1 : 1. This fact can be easily understood if we remember that two molecules of neocuproin can coordinate to one metal ion.[20]

b) Neocuproin.

Although no decisive conclusions as to the activity of cuprous species could be deduced from the above results alone, we have noted that the addition of reducing agents to the system catalyzed by cupric salts enhanced the reaction rate markedly.[2] Detailed results will be reported in a subsequent paper of this series.

Substituent Effect. Six substituted anilines were allowed to react with (I). The reaction rates corresponding to *p*-anisidine, *p*-toluidine, aniline, and *p*-chloroaniline were found to fit Yukawa-Tsuno's equation[24]:

$$\log (k_X/k_H) = \rho(\sigma + r \cdot \Delta\bar{\sigma}_R^+) \qquad (13)$$

in which the reaction parameter, ρ, was found to be -2.20, r, to be 0.50. $\Delta\bar{\sigma}_R^+$ is the difference between the Brown-Okamoto substituent coefficient[25] and the Hammett coefficient.[26] The relation is represented in Fig. 9.

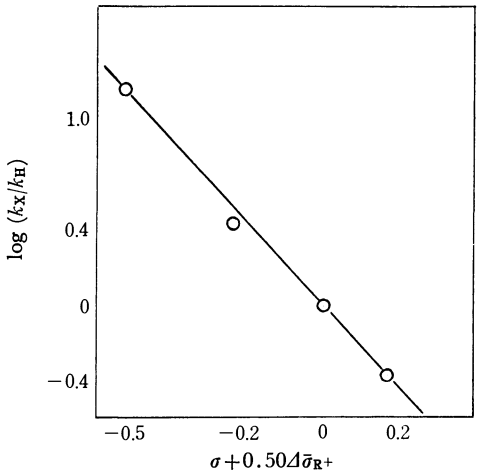

Fig. 9. Substituent effect.

Under the experimental conditions of this work, the reaction rates of *p*-nitroaniline and *p*-aminobenzoic acid with I were too slow to measure.

It has been reported that the yield of the Ullmann condensation reaction of 2-chloro-5-methoxybenzoic acid and anilines increased with an increase in the basicity of the amines[27] but no quantitative correlation has been established.

The basicities of anilines were known to be well correlated by the "normal" Hammett equation,[28] at least when the *para* substituents are not strongly electron-withdrawing. Furthermore, Chapman and Parker have reported that the Hammett relationship was useful in correlating the reactivities of substituted anilines towards activated aryl halides in the absence of a catalytic agent.[29]

The results observed in the Ullmann condensation of I with anilines show that, in the presence of a copper

catalyst, the mesomeric effect of the substituents on the reaction center (nitrogen atom) was considerably emphasized. More work must be done in this connection.

Experimental

The experimental technique was described in Part I.[2] The additives were introduced into the reaction system prior to the catalyst.

8-Hydroxyquinoline-5-sulfonic acid, 2,2′-dipyridyl, cuproin, and neocuproin of a guaranteed grade were used without further purification.

Cuprous chloride was prepared by reducing a (cupric sulfate+sodium chloride) system with anhydrous sodium sulfite.[30] Found: Cu, 64.13% (Calcd for CuCl: Cu, 64.18%). This catalyst was added as powder.

This research was supported financially in part by the Asahi Glass Foundation for the Contribution to Industrial Technology.

Effective Intramolecular Hydrogen Abstraction by the Sulfonamide Radical

Takehisa OHASHI, Shinichi TAKEDA, Mitsuo OKAHARA, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received July 16, 1970)

To study the reactivity of the sulfonamide radical in various reaction systems, the photodecomposition of *N*-*t*-butyl and *N*-methyl-*N*-chloroalkanesulfonamides was investigated. In benzene, the competitive hydrogen abstraction by the chlorine atom occurred to an appreciable extent and the participation of the chlorine atom was retarded with N_2-flow control. In an aqueous solution (AcOH-H_2O, *t*-BuOH-H_2O), the quantitative conversion to γ- and δ-chloroalkanesulfonamide was observed; this was thought to be due to the intramolecular hydrogen abstraction by the sulfonamide radical and to the lowering of the reactivity of the chlorine atom because of the solvation by H_2O. In an acid solution (AcOH-H_2O-H_2SO_4), a higher preference for 1,5 hydrogen transfer was found; this was caused by the protonated sulfonamide radical. The formation ratio of γ- to δ-chloroalkanesulfonamide in several solvents was determined, and the reactivity of the sulfonamide radical was discussed. From the reaction products obtained, several aliphatic sultams were synthesized.

In studies of the free-radical rearrangement of *N*-halo-compounds, the decompositions of *N*-haloamides,[1-4] *N*-haloimides,[5] and *N*-halosulfonamides[6-8] have been reported. These reactions have been reported to proceed in a manner similar to the Hofmann-Löffer reaction,[9] but the rearrangement of these compounds proceeds in the absence of an acid catalyst. It is interesting to study the properties of these nitrogen radicals because intermediates for five and six-membered-ring heterocycles syntheses can be obtained in the reaction of these compounds. In the hydrogen abstraction in these reactions described above, three processes can be assumed; intramolecular hydrogen abstraction by the nitrogen radical, intermolecular hydrogen abstraction by the nitrogen radical, and hydrogen abstraction by the halogen atom.

In previous papers[6] the present authors reported that *N*-alkyl-*N*-chloroalkanesulfonamides, especially *N*-*t*-butyl-*N*-chloroalkanesulfonamides, rearranged to the corresponding chloroalkanesulfonamides and that the reaction proceeded mainly *via* the intramolecular hydrogen abstraction by the sulfonamide radical; the participation of the chlorine atom in the hydrogen abstraction was thought to be relatively small in the decomposition of *N*-*t*-butyl-*N*-chloroalkanesulfonamides. However, in a further investigation of this reaction, the competitive hydrogen abstraction by the chlorine atom was observed to some extent in certain reaction systems, together with intramolecular hydrogen abstraction by the sulfonamide radical, and so a reinvestigation of the mechanism of the hydrogen transfer was necessary. Further, we found that the decomposition of *N*-halosulfonamides in the aqueous solution was a suitable method for effecting intramolecular hydrogen abstraction by the sulfonamide radical.

In the present paper, the properties of intramolecular hydrogen abstraction by the sulfonamide radical were studied in several reaction systems.

Results and Discussion

The Participation of the Chlorine Atom and the Effect of N_2-Flow Rate. To apply our results, reported in a previous paper[6] and shown in Scheme 1, the photodecomposition of *N-t*-butyl-*N*-chlorohexanesulfonamide was investigated in benzene in a manner similar to that described in the previous paper; the glpc analysis of the products showed the presence of ε-chlorohexanesulfonamide[10] together with γ- and δ-chlorohexanesulfonamides. The formation of ε-chlorohexanesulfonamide can not be explained by the intramolecular hydrogen abstraction; this shows the occurrence of hydrogen abstraction by the chlorine atom or intermolecular hydrogen abstraction by the sulfonamide radical.

Therefore, in order to study the competitive hydrogen abstraction by chlorine and sulfonamide radicals, a series of photodecompositions of *N-t*-butyl-*N*-chloroalkanesulfonamides (C_4–C_6) and *N*-chloro-*N*-methylbutanesulfonamide was investigated, and the isomer ratios of the chloroalkanesulfonamides were determined under various conditions.

$$RCH_2CH_2CH_2CH_2SO_2NClR' \xrightarrow[\text{in benzene}]{h\nu} \begin{cases} RCH_2CHClCH_2CH_2SO_2NHR' \\ RCHClCH_2CH_2CH_2SO_2NHR' \\ RCH_2CH_2CH_2CH_2SO_2NHR' \end{cases}$$

R=H, Me; R'=*t*-Bu, Me

Scheme 1

The results of the photodecomposition of *N-t*-butyl-*N*-chlorohexanesulfonamide in benzene are described in Table 1. As Table 1 shows, the formation of ε-chlorohexanesulfonamide varied with the N_2-flow rate; the isomer ratio of ε-chlorohexanesulfonamide decreased, and the yield[11] of *x*-chlorohexanesulfonamide increased, when the N_2-flow rate was high. These results suggest that chlorine participates in the hydrogen abstraction to an appreciable extent in benzene when the N_2-flow rate is low; *i. e.*, the hydrogen abstraction by the chlorine atom is retarded by the expulsion of chlorine and HCl with the N_2-flow control, and consequently the intramolecular hydrogen abstraction[12] by the sulfonamide radical proceeds mainly. Similar findings, that the yield of conversion and the isomer ratio vary with the N_2-flow rate, were observed in the photodecomposition of *N-t*-butyl-*N*-chlorobutanesulfonamide in benzene (Table 2). As is shown in Table 2, the value of the isomer ratio (γ-Cl/δ-Cl) obtained in the reaction in benzene is higher than that in CCl_4. This seems to show the difference in solvent effect on the chlorine atom between benzene and CCl_4.[13] In the decomposition of *N-t*-butyl-*N*-chlorobutanesulfonamide in benzene, the isomer ratio is larger than that in the reaction of *N-t*-butyl-*N*-chlorohexanesulfonamide, because δ-hydrogen of butanesulfonamide is primary.

It is important to determine whether *N-t*-butyl-δ-chlorobutanesulfonamide is formed as a result of hydrogen abstraction by the sulfonamide radical or by the chlorine atom. Neale[8] has recently reported that no

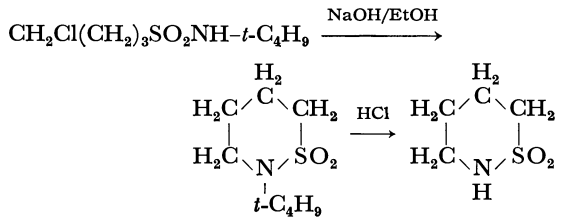
10) This was identified by comparing the gas chromatogram with that of the photochlorination product of *N-t*-butyl-*n*-hexanesulfonamide, and by the NMR of the reaction mixture, in which the doublet peak of methyl protons (τ, 8.46) was observed.

11) The yield of the conversion to *x*-chloroalkanesulfonamide was thought to be low because of the reaction of *N*-chloroalkanesulfonamide with HCl when the chlorine atom participates in the hydrogen abstraction.

12) The participation in the intermolecular hydrogen abstraction by the sulfonamide radical was thought to be small considering the fact that the yield of the conversion and the isomer ratio vary with the N_2-flow rate.

13) G. A. Russel, *J. Amer. Chem. Soc.*, **80**, 4987 (1958).

N-*t*-butyl-δ-halobutanesulfonamides were observed in the decomposition of *N*-chloro-and *N*-bromo-*N*-*t*-butylbutanesulfonamide. In our investigation, the results of the photodecomposition of *N*-bromo-*N*-*t*-butylbutanesulfonamide agreed with those of Neale, but an appreciable content of δ-chlorobutanesulfonamide was observed in the reaction of *N*-*t*-butyl-*N*-chlorobutanesulfonamide in benzene and CCl_4. The formation of *N*-*t*-butyl-δ-chlorobutanesulfonamide[14] was confirmed by the isolation of butanesultam by the alkali treatment of reaction products, followed by acidification with concentrated HCl, as is shown in Scheme 2.



Scheme 2

From these results, it may be concluded that, in the decomposition of *N*-chloroalkanesulfonamide in benzene and CCl_4, competitive hydrogen abstraction by the chlorine atom occurs and that this chlorine atom participation[15] can be somewhat retarded by the expulsion of chlorine and HCl by means of N_2-flow control, and that, in the decomposition of *N*-*t*-butyl-*N*-chlorobutanesulfonamide, the primary hydrogen abstraction by the sulfonamide radical does not occur and *N*-*t*-butyl-δ-chlorobutanesulfonamide is formed *via* hydrogen abstraction by the chlorine atom. This conclusion is supported by the fact that no δ-bromo isomer was observed in the decomposition of *N*-bromo-*N*-*t*-butylbutanesulfonamide; the hypothesis described in our previous paper[6] that *N*-*t*-butyl-δ-chlorobutanesulfonamide is formed by means of the primary hydrogen abstraction by the sulfonamide radical[16] *via* the seven-membered-ring transition state seems thus to be contradicted.

Effective Intramolecular Hydrogen Abstraction in the Aqueous Solution. To cause the selective rearrangement of *N*-chloroalkanesulfonamides, the participation of the chlorine atom must be suppressed; therefore, the photodecomposition of *N*-chloroalkanesulfonamides in aqueous solvents was investigated. Irradiation was carried out with a high-pressure Hg lamp at 28—30°C under N_2 until the active chlorine content was negligible. In every case, a complete loss of active chlorine was observed in 1 hr. The results obtained in aqueous AcOH are listed in Tables 3—6. In the photodecomposition of *N*-*t*-butyl-*N*-chlorobutanesulfonamide (Table 3), the yield of rearranged products and the isomer ratio (γ-Cl/δ-Cl) rose with an increase of the concentration of water, and in the solvents with higher water concentrations ($AcOH/H_2O=1.7$), *N*-*t*-butyl-γ-chlorobutanesulfonamide was obtained almost quantitatively and no δ-chlorobutanesulfonamide was observed. The fact that the formation of *N*-*t*-butyl-δ-chlorobutanesulfonamide is suppressed as well as the reaction of *N*-bromo-*N*-*t*-butylbutanesulfonamide in benzene suggests that a predominant intramolecular hydrogen transfer by the sulfonamide radical occurs and that the participation of the chlorine atom is retarded in the aqueous solution. Similar results were obtained in the reaction of *N*-*t*-butyl-*N*-chloropentane and hexanesulfonamides (Tables 4 and 5), and no appreciable content of ε-chlorohexanesulfonamide was observed in the decomposition of *N*-*t*-butyl-*N*-chlorohexanesulfonamide in a solution with a higher water concentration. This demonstrates the suppression of hydrogen abstraction by the chlorine atom and intermolecular hydrogen abstraction by the sulfonamide radical in the $AcOH–H_2O$ system.

The isomer ratio (γ-Cl/δ-Cl=1.93—1.94) observed in the reaction of *N*-*t*-butyl-*N*-chlorohexanesulfonamide in aqueous acetic acid ($AcOH/H_2O=2.5$—2.1) seems to show that the intramolecular 1,5 hydrogen transfer by the sulfonamide radical occurs in preference to the 1,6 hydrogen transfer because of a quasi-six-membered ring transition state.[18] The isomer ratio (γ-Cl/δ-Cl= 1.10—1.14) determined in the reaction of *N*-*t*-butyl-*N*-chloropentanesulfonamide in aqueous acetic acid is lower than that of *N*-*t*-butyl-*N*-chlorohexanesulfonamide. This result may be due to the stability of the δ-carbon radical resulting from the contribution of the hyperconjugation of the Me group.

This efficient solvent effect could be adapted to the decomposition of *N*-chloro-*N*-methyl-*n*-butanesulfonamide, which has been reprted to proceed less efficiently than the *N*-*t*-butyl analog.[6,8] As is shown in Table 6, *N*-methyl-γ-chlorobutanesulfonamide was obtained in a high yield; this is in accordance with the results obtained in the reaction of the *N*-*t*-butyl analog in the aqueous solution.

To compare the reactivity of the sulfonamide radical in the aqueous AcOH solution with that in a higher acidic solution, the photodecomposition of *N*-*t*-butyl-*N*-chloroalkanesulfonamides in the $AcOH–H_2O–H_2SO_4$ solvent was studied under the same conditions as were used in the $AcOH–H_2O$ system (Tables 3, 4, and 5). Although the conversion to *N*-*t*-butylchloroalkanesulfonamide was rather low because of the decomposition of the intermediate conjugate acid[6,19] to unsubstituted sulfonamides, the isomer ratio (γ-Cl/δ-Cl) was higher than that obtained in the $AcOH–H_2O$ system.

The relative greater facility of 1,5-shifting in H_2SO_4 may be due to the fact that the six-membered transition state is stereochemically more favorable for the protonated sulfonamide radical than for the neutral radical considering the steric repulsions involving non-bonded

14) The NMR of the viscous liquid obtained after the isolation of the γ-chloro isomer and *N*-*t*-butylbutanesulfonamide showed the presence of the δ-chloro isomer (τ, 6.45).

15) In benzene, the chlorine atom would act as the $C_6H_6Cl\cdot$ complex.

16) The absence of the δ-bromo isomer can not be explained by assuming intra- or intermolecular primary hydrogen abstraction by the sulfonamide radical. The high reactivity of the sulfonamide radical towards secondary hydrogens has previously been reported.[17]

17) A. E. Fuller and W. J. Hickinbottom, *J. Chem. Soc.*, **1965**, 3228.

18) Because of its low I strain of cyclohexane-like chair-formed conformation, the six-membered-ring transition state would be more stable than the seven-membered-ring transition state.

a) Values in parentheses are the volume ratio of AcOH, H_2O, and H_2SO_4.

atoms in the transition state; this is analogous with the case of the aminium radical[20] in the Hofmann-Löffler reaction.

From the result that selective 1,5 and 1,6 hydrogen transfers do not occur in pure AcOH (Table 1), it is clear that the presence of water promotes the intramolecular hydrogen abstraction by the sulfonamide radical; the same result was obtained in the photodecomposition of *N*-*t*-butyl-*N*-chlorohexanesulfonamide in aqueous *t*-BuOH (Table 5).

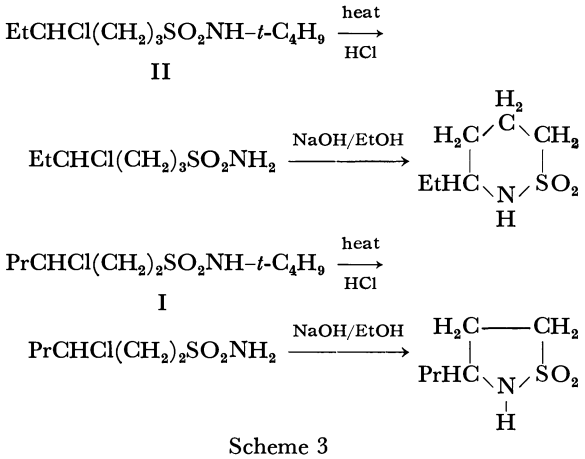
From the UV spectrum of *N*-chlorosulfonamides, *N*-chlorosulfonamide is evidently protonated in a H_2SO_4 solution, but the absorption in aqueous AcOH is not as characteristic as that in pure AcOH (Table 7).

From these results, it may be considered that the sulfonamide radical is not protonated in aqueous AcOH, but that the reactivity of the chlorine atom is lowered as a result of the solvation by H_2O, and that, consequently, the intramolecular hydrogen abstraction by the sulfonamide radical proceeds predominantly.

Although the solvation of the sulfonamide radical and the solvation of the transition state for rearrangement may be assumed, the evidence is not conclusive at present. From this point of view, the decomposition of *N*-bromoalkanesulfonamides, in which the participation of the halogen atom seems to be small, is under investigation.[21]

Aliphatic Sultams. In a previous paper,[6] we have reported the conversion of *N*-*t*-butyl-γ-chloropentanesulfonamide to *N*-*t*-butyl-3-ethylpropanesultam. In a similar manner, *N*-*t*-butyl-3-methylpropanesultam and *N*-*t*-butylbutanesultam were obtained almost quantitatively from *N*-*t*-butyl-γ-chloro and *N*-*t*-butyl-δ-chlorobutanesulfonamides respectively by the treatment of the rearranged products with ethanolic NaOH. Neale[8] has reported the formation of *N*-*t*-butyl-2-methylcyclopropanesulfonamide, together with *N*-*t*-butyl-3-methylpropanesultam, by various alkali treatments of *N*-*t*-butyl-γ-halobutanesulfonamide, but no evidence of the formation of significant amounts of the cyclopropane isomer was observed upon treatment with ethanolic NaOH, and *N*-*t*-butyl-3-methylpropanesultam was isolated almost quantitatively by distillation. The structure of this sultam was confirmed by NMR and mass spectra. On the other hand, the analogous treatment of *N*-*t*-butyl-δ-chloropentanesulfonamide with ethanolic NaOH gave *N*-*t*-butylpent-3-enesulfonamide almost quantitatively. This suggests that the formation of six-membered-ring sultams containing the *N*-*t*-butyl group and a side chain at the 4-position does not proceed so efficiently as the formation of five-membered-ring sultams and that, consequently, the elimination reaction occurs predominantly. The formation of 4-methylbutanesultam in a high yield from δ-chloropentanesulfonamide demonstrates the lack of a stereochemical barrier of the *N*-*t*-butyl group.

N-*t*-Butyl-γ-chloro (I) and *N*-*t*-butyl-δ-chlorohexanesulfonamides (II) were identified by the fact that 3-propylpropanesultam and 4-ethylbutanesultam were obtained by the alkali treatment of chlorohexanesulfonamides derived by the treatment of I and II with HCl as is shown in Scheme 3:



Scheme 3

The structure of each five- and six-membered-ring sultam was confirmed by a study of its mass spectrum (Table 8).

Experimental

Apparatus. The IR spectra were run on an IR-E-type Nihon Bunko spectrometer. The NMR spectra were obtained with a Japan Electron Optics Lab. spectrometer (JNM3H-60). The UV spectra were taken on an EPS-3 Hitachi recording spectrometer. The glpc analyses were conducted by a Shimadzu GC-3A apparatus using Apieson L grease 10%, Silicone DC 200 10%, or Silicone oil 550 10% on Diasolid L; 60—80 mesh; 1 m column. The mercury lamp used was an Eikosha 150-W high-pressure mercury lamp.

Materials. The benzene, AcOH, and CCl_4 were purified by an ordinary method.

Titrations for active Cl were conducted by an $Na_2S_2O_3$ assay of the I_2 liberated from 10% aqueous KI acidified with 0.1 N HCl.

Preparation of N-*Halo*-N-*alkyl*-n-*alkanesulfonamides.* *N-t*-Butyl-*N*-chlorobutane, pentanesulfonamides, and *N*-chloro-*N*-methylbutanesulfonamide were prepared as has been described in a previous paper.[6] The *N*-chlorination of *N-t*-butyl-*n*-hexanesulfonamide was done in the same manner, and the *N-t*-butyl-*N*-chlorohexanesulfonamide obtained quantitatively was purified by distillation. Bp 113—115°C/0.2 mmHg, n_D^{20} 1.4730. IR: 2960, 1350, 1150, and 890 cm^{-1}.

Found: Cl, 13.6%. Calcd for $C_{10}H_{22}ClNO_2S$: Cl, 13.86%.

N-*Bromo*-N-t-*butyl*-n-*butanesulfonamide.* *N-t*-Butyl-*n*-butanesulfonamide (0.05 mol) was suspened in water (100 m*l*) in the presence of Na_2CO_3 (21 g); bromine (32 g) was added to the stirred suspension at 10°C, and the solution was stirred for 4 hr. The insoluble oil separated as a lower layer was collected and dissolved in CCl_4. The solution was dried over anhydrous Na_2SO_4, and the solvent was evaporated. Yield, 75%, IR: 2960, 1340, 1145, and 890 cm^{-1}. n_D^{20} 1.4955.

Found: Br, 29.1%. Calcd for $C_8H_{18}BrNO_2S$: Br, 29.36%.

Photodecomposition of N-*Halosulfonamides.* *N*-Alkyl-*N*-halo-*n*-alkanesulfonamides were irradiated at 28—30°C under N_2 with a high-pressure mercury lamp inside a reaction flask until the active halogen content of the solution was negligible. All the reactions were completed in 1 hr. In the reaction in benzene, reaction products were obtained after the evaporation of the benzene, while in the reaction in aqueous solvents the reaction mixture was poured onto ice and the organic layer was extracted with ether.

Isolation and Analyses of Reaction Products. Analyses of the reaction products obtained in the reaction of *N-t*-butyl-*N*-chloro-*n*-butane and pentanesulfonamides were carried out as has been described in a previous paper.[6]

N-t-*Butyl*-n-*hexanesulfonamide.* This was isolated by distillation from the reaction products obtained in the reaction of *N-t*-butyl-*N*-chlorohexanesulfonamide. Bp 118°C/0.2 mmHg. IR: 3280, 2960, 1320, and 1140 cm^{-1}.

Found: C, 54.26; H, 10.45: N, 6.21%. Calcd for $C_{10}H_{23}NO_2S$: C, 54.26; H, 10.47; N, 6.33%.

N-t-*Butyl*-*γ*-*chloro- and δ-chlorohexanesulfonamides.* On the cooling of the hexane solution of the products obtained in the photorearrangement of *N-t*-butyl-*N*-chlorohexanesulfonamide in an AcOH-H_2O solvent to −40°C, a white precipitate was obtained. This precipitate melted at room temperature; glpc and elemental analysis showed it to be a mixture of the two rearranged products. On the cooling of an ether solution of this mixture, *N-t*-butyl-*δ*-chlorohexanesulfonamide was isolated as a white precipitate; it was then recrystallized from ether and hexane. Mp 58°C. IR: 3280, 2960, 1320, and 1130 cm^{-1}. NMR (in $CDCl_3$): τ; 5.45 (1H), 6.10 (multiplet, 1H), 6.80 (triplet, 2H), 7.70—8.55 (multiplet, 6H), 8.65 (singlet, 9H), 8.95 (triplet, 3H).

Found: C, 46.89; H, 8.64; N, 5.40; Cl, 13.6%. Calcd for $C_{10}H_{22}ClNO_2S$: C, 46.95: H, 8.67; N, 5.43; Cl, 13.86%.

The isolation of another rearranged product, *N-t*-butyl-*γ*-chlorohexanesulfonamide, was tried, but it was unsuccessful because of contamination by a small amount of the *δ*-chloro isomer.

N-*Methyl*-*γ*-*chlorobutanesulfonamide.* The liquid obtained from the decomposition of *N*-chloro-*N*-methylbutanesulfonamide in AcOH-H_2O (0.15 mol/*l*, 20 min irradiation) was distilled under reduced pressure. Bp 133°C/0.1 mmHg, n_D^{25} 1.4765. IR: 3300, 2960, 1320, 1140, and 850 cm^{-1}. NMR (in $CDCl_3$): τ; 5.40 (1H), 5.85 (multiplet, 1H), 6.80 (triplet, 2H), 7.20 (doublet, 3H), 7.80 (multiplet, 2H), 8.43 (doublet, 3H).

Found: C, 32.00; H, 6.53; N, 7.49; Cl, 18.8%. Calcd for $C_5H_{12}ClNO_2S$: C, 32.35; H, 6.52; N, 7.55; Cl, 19.09%.

N-t-*Butyl*-*γ*-*bromobutanesulfonamide.* The irradiation of a benzene solution of *N*-bromo-*N-t*-butyl-*n*-butanesulfonamide (0.4 mol/*l*) with a high-pressure mercury lamp produced a viscous liquid (recovery rate, 91%) which was found by glpc to contain 25.0% of *N-t*-butyl-*n*-butanesulfonamide and 74.2% of *N-t*-butyl-*γ*-bromobutanesulfonamide; no formation of the *δ*-bromo isomer was observed. A white precipitate obtained by adding hexane to the reaction mixture was recrystallized from cold ether. Mp 69°C. IR: 3300, 1310, 1130, and 1000 cm^{-1}. NMR (in $CDCl_3$): τ; 5.40 (1H), 5.80 (multiplet, 1H), 6.80 (triplet, 2H), 7.75 (multiplet, 2H), 8.25 (doublet, 3H), 8.63 (singlet, 9H).

Found: C, 35.55; H, 6.94; N, 5.13; Br, 29.2%. Calcd for $C_8H_{18}BrNO_2S$: C, 35.30; H, 6.66; N, 5.15; Br, 29.36%.

Preparation of Sultams. N-t-*Butyl*-3-*methylpropanesultam*: To 50 m*l* of the EtOH solution of *N-t*-butyl-*γ*-chlorobutanesulfonamide[6] (0.01 mol), 0.013 mol of NaOH was added; the solution was then refluxed for 3 hr. The solution was cooled and carefully neutralized with conc. HCl. The salt was filtered off; the residue obtained after the evaporation of EtOH was almost pure, and its IR showed the disappearance of the NH band. It was purified by distillation at reduced pressure. Bp 96—97°C/0.5 mmHg, n_D^{20} 1.4780 (lit,[8] n_D^{25} 1.4733). Yield, 97%. IR: 2960, 1300, 1130, 1020, 980, and 950 cm^{-1}. NMR (in $CDCl_3$): τ; 6.20 (multiplet, 1H), 6.65—7.10 (multiplet, 2H), 7.20—8.30 (multiplet, 2H), 8.60—8.68 (singlet and doublet, 12H).

Found: C, 50.03; H, 9.01%. Calcd for $C_8H_{17}NO_2S$: C, 50.23; H, 8.96%.

N-t-*Butyl*-*butanesultam*: *N-t*-Butyl-*δ*-chlorobutanesulfonamide[6] (0.01 mol) was dissolved in EtOH (50 m*l*). NaOH (0.013 mol) was added, and the solution was refluxed for 3 hr. The salt thus formed was filtered off, and the solvents was evaporated. The residue was extracted with ether (50 m*l*); a white precipitate, which was obtained by adding hexane to the cold ether solution, was then recrystallized from ether and hexane; mp 43°C; yield, 94%. IR: 2960, 1325, 1140, 1020, 920, and 880 cm^{-1}. NMR (in $CDCl_3$): τ; 6.55 (triplet, 2H), 7.00 (triplet, 2H), 7.80 (multiplet, 2H), 8.30 (multiplet, 2H), 8.55 (singlet, 9H).

Found: N, 7.06%. Calcd for $C_8H_{17}NO_2S$: N, 7.33%.

Butanesultam: The reaction mixture (2.8 g) consisting 40% of *N-t*-butyl-*δ*-chlorobutanesulfonamide obtained after the isolation of *N-t*-butyl-*γ*-chlorobutanesulfonamide from the reaction products of *N-t*-butyl-*N*-chlorobutanesulfonamide was treated with ethanolic NaOH (0.5 g) as has been described above and then acidified with conc. HCl. The residue

obtained after the removal of the salt was dissolved in $CHCl_3$ and ether; then hexane was added and cooled. A white precipitate which separated out (0.6 g) was recrystallized from $CHCl_3$ and ether. The same compound was obtained quantitatively by the treatment of *N-t*-butylbutanesultam with conc. HCl in EtOH at room temperature. Mp 115°C (lit.[22] 114—115°C). IR: 3240, 2960, 1320, 1130, 1030, 955, and 770 cm^{-1}. NMR (in $CDCl_3$): τ; 5.70 (1H), 6.60 (multiplet, 2H), 6.90 (triplet, 2H), 7.81 (multiplet, 2H), 8.37 (multiplet, 2H).

Found: C, 35.28; H, 6.83; N, 10.26%. Calcd for $C_4H_9NO_2S$: C, 35.54; H, 6.71; N, 10.36%.

N-t-*Butylpent-3-enesulfonamide*: *N-t*-Butyl-δ-chloropentanesulfonamide[6] (0.01 mol) was dissolved in 50 m*l* of EtOH and then treated with NaOH (0.013 mol) in a manner similar to that described in the synthesis of *N-t*-butyl-3-methylpropanesultam. When the liquid thus obtained was distilled, the corresponding sultam was not obtained, but *N-t*-butylpent-3-enesulfonamide was obtained; bp 120—122°C/1mmHg, n_D^{20} 1.4680; yield, 92%. IR: 3300, 2960, 1320, 1130, and 1000 cm^{-1}. NMR (in $CDCl_3$): τ; 4.57 (multiplet, 2H), 5.40 (1H), 6.90 (triplet, 2H), 7.53 (multiplet, 2H), 8.35 (doublet, 3H), 8.62 (singlet, 9H).

Found: C, 52.31; H, 9.31%. Calcd for $C_9H_{19}NO_2S$: C, 52.65; H, 9.33%.

4-Methylbutanesultam: *N-t*-Butyl-δ-chloropentanesulfonamide (2.4 g) was heated in 40 m*l* of the HCl solution (HCl : H_2O= 3 : 1, ratio of volume) at 90°C for 6 hr. The viscous liquid (1.8 g) obtained after the evaporation of the water was washed with cold hexane and treated with NaOH (0.4 g) in 50 m*l* of EtOH under reflux for 2 hr and then neutralized with HCl. A white precipitate (1.3 g) was obtained by the treatment described in the isolation of butanesultam and was recrystallized from $CHCl_3$ and ether; mp 112°C; yield, 87%. IR: 3280, 2960, 1310, 1130, 950, and 780 cm^{-1}. NMR (in $CDCl_3$): τ; 5.60 (1H), 6.50 (multiplet, 1H), 6.93 (multiplet, 2H), 7.70—8.50 (multiplet, 4H), 8.78 (doublet, 3H).

Found: C, 39.88; H, 7.38; N, 9.33%. Calcd for $C_5H_{11}NO_2S$: C, 40.25; H, 7.43; N, 9.38%.

4-Ethylbutanesultam: *N-t*-Butyl-δ-chlorohexanesulfonamide (2.6 g) was heated in 40 m*l* of a HCl solution in the same manner as has been described in the preparation of 4-methylbutanesultam. The viscous liquid (1.9 g) thus obtained was treated with NaOH (0.4 g) in 50 m*l* of EtOH. A white precipitate (1.4 g) was obtained by the treatment described above and recrystallized from $CHCl_3$ and ether; mp 106°C; yield, 84%. IR: 3230, 2960, 1320, 1130, and 780 cm^{-1}. NMR (in $CDCl_3$): τ; 5.85 (1H), 6.50—7.10 (multiplet, 3H), 7.80 (multiplet, 2H), 8.50 (multiplet, 4H), 9.03 (triplet, 3H).

Found: C, 43.95; H, 7.95; N, 8.33%. Calcd for $C_6H_{13}NO_2S$: C, 44.15; H, 8.02; N, 8.58%.

3-Propylpropanesultam: A mixture (2.6 g) consisting 90% of *N-t*-butyl-γ-chlorohexanesulfonamide and 10% of *N-t*-butyl-δ-chlorohexanesulfonamide was treated with HCl; a white crystal (1.7 g) isolated from the semisolid liquid obtained after the cleavage of the *t*-butyl bond was submitted to the alkali treatment, and the liquid (1.1 g) thus obtained was purified by distillation; bp 115°C/0.1 mmHg; yield, 80%. IR: 3220, 1320, 1130, and 830 cm^{-1}. NMR (in $CCCl_4$): τ; 5.00 (1H), 6.50 (multiplet, 1H), 6.95 (multiplet, 2H), 7.50—8.70 (multiplet, 6H), 9.05 (triplet, 3H).

Found: C, 43.78; H, 7.89; N, 8.49%. Calcd for $C_6H_{13}NO_2S$: C, 44.15; H, 8.02; N, 8.58%.

γ-Induced Addition of Trialkyltin Hydrides to Unsaturated Esters

Jitsuo TSURUGI, Masaru IIDA,* Ren NAKAO, Tsugio FUKUMOTO, and Niro MURATA*

Department of Chemistry, Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

* *Department of Applied Chemistry, University of Osaka Prefecture, Mozuume-machi, Sakai, Osaka*

(Received July 18, 1970)

γ-Induced hydrostannation of ethyl acrylate, allyl acetate, and vinyl acetate with triethyltin and tri-*n*-butyltin hydrides was attempted. The hydrostannation of ethyl acrylate and allyl acetate gave the corresponding adducts in almost quantitative yield. (2-Acetoxyethyl)-tri-*n*-butyltin expected from hydrostannation of vinyl acetate with tri-*n*-butyltin hydride could not be isolated. However, NMR and IR spectra indicated the formation of the adduct, which was found to decompose into ethylene and tri-*n*-butyltin acetate. The decomposition of the adduct was discussed in comparison with other adducts.

The addition reaction of organotin hydrides to unsaturated bonds is known as hydrostannation and extensively studied.[1,2] However, hydrostannation with γ-irradiation has not been reported so far. In this paper we report the γ-induced hydrostannation of ethyl acrylate, allyl acetate, and vinyl acetate with triethyltin and tri-*n*-butyltin hydrides. The hydrostannation of vinyl acetate and tri-*n*-butyltin hydride was found not to give the expected adduct, (2-acetoxyethyl)-tri-*n*-butyltin, but to yield tri-*n*-butyltin acetate. No successful synthesis of the expected adduct is found in literature. The reason why this adduct cannot be isolated is given.

Results and Discussion

γ-Induced Hydrostannation. A mixture of 1 : 2 molar ratio of tri-*n*-butyltin hydride and vinyl acetate gave a curdy product after being subjected to irradiation. The amount of the product seems proportional

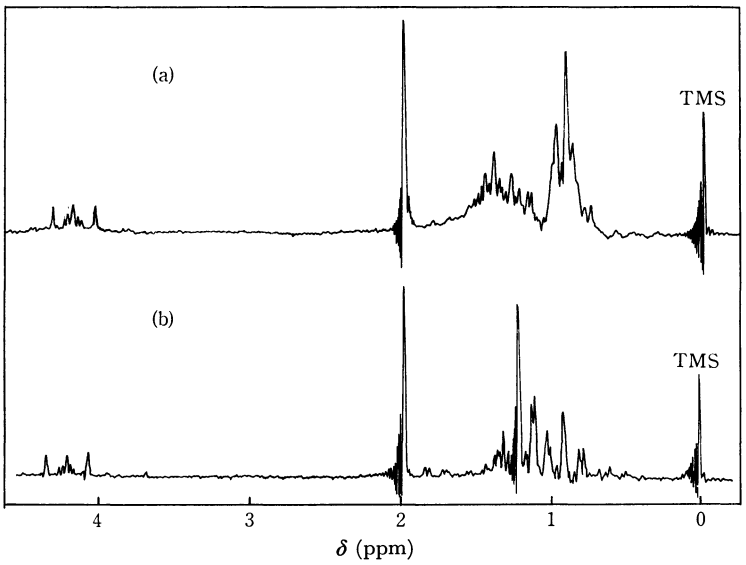

Fig. 1. The NMR spectra in CCl_4 of irradiated mixture of run 4 (a) and of (2-acetoxyethyl)-triethyltin (b).

to irradiation dose in the range 10^5—10^7R. This product was identified as polyvinyl acetate by IR spectrum. An equimolar mixture of trialkyltin hydride and the unsaturated ester was used in the experiments, because the mixture gave no curdy product under irradiation of similar doses. Yields of the 1 : 1 adducts are summarized in Table 1. Table 1 indicates that the hydrostannation proceeds almost quantitatively in runs 1 and 2. From the result we can write the reaction as free radical 1 : 1-β-addition, the detailed mechanims of which has been reviewed.[2] We assume that the equation

$$R_3SnH + CH_2{=}CHR' \rightsquigarrow R_3SnCH_2CH_2R' \quad (1)$$

would still be applicable to runs 3 and 4, and that adduct **4** would decompose completely and **3** partially during separation procedures.

In order to verify this we examined the irradiated mixture of run 4 by NMR and IR methods. Fig. 1a shows the NMR spectrum of irradiated mixture in carbon tetrachloride solution at 60 MHz. In comparison with NMR signals of adduct **3** (Fig. 1b), the superimposed triplet centered at about 0.9 ppm can be assigned to the methylenes bonded to the tin atom, and the remaining multiplet in the high field to butyl methylenes and methyls. The singlet signal at 2.0 ppm is assigned to acetyl protons. In the lower field, complicated signals appear at about 4.2 ppm. From the signal shift and integrated intensity, this is assigned to the methylene protons bonded to the acetyl group. The NMR spectrum of adduct **3** shows similar signals except for the alkyl substituents. Figure 2 shows the IR spectrum of irradiated mixture of run 4. The key bands indicating the existence of the saturated acetylate observed as two strong bands were attributable to the C=O stretching vibration in 1735 cm^{-1} and C–O–C antisymmetrical vibration in 1237 cm^{-1}. The spectrum is devoid of absorption bands due to the carbonyls of tri-*n*-butyltin acetate (1642 cm^{-1}) and vinyl acetate (1760 cm^{-1}). From IR and NMR spectral evidences, hydrostannation is considered to occur also in the case of run 4.

b) Gas chromatographic determination for adducts **1** and **2**, and distillation for **3** and **4**. The application of the former to **3** resulted in complete decomposition.

Decomposition of the Adduct 4. Distillation of the irradiated mixture of run 4 gave white needles, bp

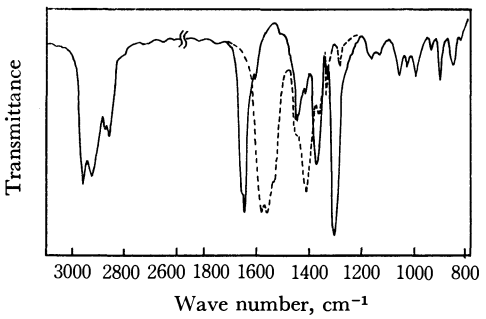

Fig. 2. The IR spectra in CCl_4.
— irradiated mixture of run 4
····· non-irradiated mixture of tri-*n*-butyltin hydride and vinyl acetate

90—100°C/0.001 mmHg, mp 84.8°C (lit,[3] 84.5—85°C), identified as tri-*n*-butyltin acetate by IR and NMR and elemental analysis. Qualitative glpc analysis (at 180°C column temperature) of the irradiated mixture indicates the presence of tri-*n*-butyltin acetate but no other compounds. These results suggest the following equation for the decomposition of adduct **4**.

$$(n\text{-}C_4H_9)_3SnCH_2CH_2OCOCH_3 \longrightarrow (n\text{-}C_4H_9)_3SnOCOCH_3 + CH_2{=}CH_2 \quad (2)$$

Evolution of ethylene was qualitatively observed by gas analysis from the irradiated mixture kept standing for several weeks at room temperature. Addition of acetic acid or anhydride was found effective for the decomposition of adduct **4**. After being kept standing for 24 hr at room temperature in an open vessel, tri-*n*-butyltin acetate was filtered and weighed. The result is shown in Fig. 3.

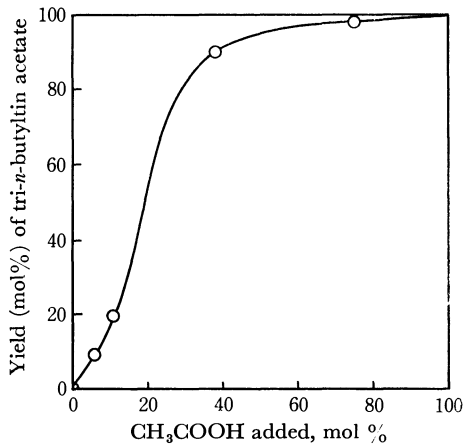

Fig. 3. Effect of the addition of acetic acid to adduct **4**. One mole of adduct **4** was assumed to be produced from irradiated mixture of each one mole of starting materials.

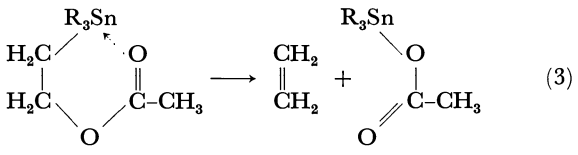
The results in Table 1 indicate that only the adducts resulting from trialkyltin hydride and vinyl acetate decompose during distillation[4] or gas chromatography as compared with almost quantitative yields of the adducts **1** and **2**. Hence, the decomposition can be ascribed to intramolecular formation of cyclic transition state followed by elimination of ethylene and simultaneous formation of Sn–O bond. In a closed vessel



(3)

the presence of ethylene evolved suppresses the decomposition. Distillation, gas chromatography, heating or being left at room temperature in an open vessel allows ethylene to evolve out of the system, and shifts the equilibrium to the right side.

Van der Kerk *et al.*[5] reported that triphenyltin hydride with vinyl acetate yielded the adduct quantitatively. The structure of R in $R_3SnCH_2CH_2OCOCH_3$ seems to play an important role. In the cleavage reaction of tetraalkyltin with chloroacetic acid,

$$(n\text{-}C_3H_7)_4Sn + ClCH_2COOH \longrightarrow (n\text{-}C_3H_7)_3SnOCOCH_2Cl + n\text{-}C_3H_8 \quad (4)$$

$$(i\text{-}C_3H_7)_4Sn + 2ClCH_2COOH \longrightarrow (i\text{-}C_3H_7)_2Sn(OCOCH_2Cl)_2 + 2i\text{-}C_3H_8 \quad (5)$$

Sasin *et al.*[6] interpreted Eqs. (4) and (5) as follows. Stronger electron-releasing effect of *i*-propyl group on the carbon atom of the C–Sn bond is balanced by the substitution of two haloacyloxy groups of strong electron-withdrawing property. In contrast, less electron-releasing effect of *n*-propyl group is sufficient to undergo substitution by only one haloacyloxy group. Alkyl group in (2-acetoxyethyl)-trialkyltin, $R_3SnCH_2CH_2OCOCH_3$, seems to make the adduct susceptible to the decomposition in contrast to phenyl group. In this respect *n*-butyl group is more electron-releasing than ethyl group. Thus, adduct **4** is concluded to be more susceptible than **3**.

Experimental

All melting and boiling points are uncorrected. The IR spectra were obtained by a Perkin-Elmer 221 spectrometer. The NMR spectra were recorded by a Japan Electron Optics 3H-60 spectrometer, using a tetramethylsilane as an internal standard.

Materials. Tri-*n*-butyltin and triethyltin hydrides were prepared by reduction of tri-*n*-butyltin and triethyltin chlorides with lithium alminum hydride,[7] respectively, and distilled just before use. Triethyltin chloride was prepared by disproportionation of tetraethyltin and tin tetrachloride.[8] Commercial products of tri-*n*-butyltin chloride, tin tetrachloride, allyl acetate, vinyl acetate, and ethyl acrylate were used.

Irradiation. An unsaturated ester (0.01 mol), after being degassed by four freeze-thaw processes, was transferred by a vaccum line into an ampul containing degassed trialkyltin hydride (0.01 mol). The ampul, after being fused, was irradiated at room temperature with γ-rays from a ^{60}Co source without agitation.

Separation and Identification of the Products. Gas chromatography was carried out with a Yanagimoto GCG-5DH fitted with a FID detector, using a 2m column containing 25% Silicone DC-200 on Celite 545.

Run 1. The irradiated product was determined by glpc and identified[9] by IR and NMR in a carbon tetrachloride solution. IR (CCl_4): 2950, 2915, 1740, 1450, 1375, 1228, and 1020 cm^{-1}; NMR (CCl_4): δ 4.09 (q, 2H, CH_2), δ 2.47 (t, 2H, CH_2), δ 1.8—0.5 (m, 32H, CH_2 and CH_3).

Run 2. The reaction product was determined by glpc. For identification the product was distilled *in vacuo*, the frac-

tion boiling at 95—100°C/0.001 mmHg being collected. IR (CCl_4): 2950, 2915, 1737, 1450, 1370, 1365, 1233, and 1030 cm^{-1}; NMR (CCl_4): δ 3.94 (t, 2H), δ 2.00 (s, 3H), δ 1.8—0.5 (m, 31H, CH_2 and CH_3).

Run 3. Distillation gave the product boiling at 70—80°C/0.001 mmHg: n_D^{20} 1.4750 (lit,[4] 1.4773). IR (CCl_4): 2950, 2915, 2815, 1740, 1390, 1240, 1055, 1025, and 970 cm^{-1}.

Run 4. A mixture of 1 : 2 molar ratio gave after irradiation curdy products, which were filtered and reprecipitated with petroleum ether from benzene. IR (film): 2950, 1730, 1370, 1240, and 1025 cm^{-1}. In the case of equimolar ratio, tri-*n*-butyltin acetate precipitated in the irradiated mixture was filtered and recrystallized from petroleum ether. IR (KBr): 2950, 2915, 2850, 1575, 1550, 1405, 1340, and 670 cm^{-1}; NMR (CCl_4): δ 1.96 (s, 3H, CH_3), δ 1.8—0.7 (m, 27H, CH_2 and CH_3). Found: C, 47.68; H, 8.82%. Calcd for $C_{14}H_{30}O_2Sn$; C, 48.16; H, 8.66%.

Gas Analysis. Evolution of ethylene from the decomposition of adduct **4** was confirmed as follows. The sample tube fitted with a breakable seal was attached to a vacuum line and the seal was broken. The products noncondensable at −196°C were determined by the Toepler gauge, and analyzed by mass spectrometry (Hitachi RMU-5G) and gc (Hitachi KGL-2A) on a molecular sieves column with N_2 as carrier. The condensable fraction was vaporized with a dry ice-acetone bath, and analyzed by gc using a silica gel column. Ethylene (0.045 mol), *n*-butane (0.009 mol) and hydrogen (0.005 mol) were found. However, tri-*n*-butyltin hydride irradiated under similar conditions gave *n*-butane (0.005 mol) and hydrogen (0.008 mol). Thus, in the case of the decomposition of adduct **4**, *n*-butane and hydrogen can be formed from the irradiation of the starting material (tri-*n*-butyltin hydride) and not from the decomposition of adduct **4**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 780—784 (1971)

Studies of the Synthesis of Furan Compounds. XXIII.[1] Cyclization Derivatives of 5-Nitro-2-furimidoylhydrazine[2]

Ichiro HIRAO, Yasuhiko KATO, Tsunetoshi HAYAKAWA, and Hiromichi TATEISHI

Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu

(Received July 24, 1970)

The reaction of 5-nitro-2-furimidoylhydrazine (I) with diacetyl or furil gave 3-(5-nitro-2-furyl)-5,6-disubstituted-1,2,4-triazine derivatives (IIa, b). Refluxing I in a large excess of ethyl orthoformate afforded 3-(5-nitro-2-furyl)-5-ethoxy-1,2,4-triazoline (III) and bis[3-(5-nitro-2-furyl)-1,2,4-triazolyl]methyl ethyl ether (IV). By heating with ethyl orthoformate, III was converted to IV. When III or IV was heated in diluted sulfuric acid, 3-(5-nitro-2-furyl)-1,2,4-triazole (V) was produced. The reactions of I with cyanogen bromide in refluxing methanol and with nitrous acid in diluted hydrochloric acid gave the corresponding 3-(5-nitro-2-furyl)-5-amino-1,2,4-triazole (VI) or -1,2,4,5-tetrazole (VIII) respectively. When heated in acetic anhydride, the VI afforded monoacetyl compound (VII), while the VIII yielded 5-(5-nitro-2-furyl)-2-methyl-1,3,4-oxadiazole (X). The structures of these compounds were discussed on the basis of their IR and NMR spectra.

In a previous paper[3] the present authors synthesized 5-nitro-2-furimidoylhydrazine (I) by treating 5-nitro-2-furonitrile with hydrazine hydrate. Since the structure of I is analogous to that of aminoguanidine, I is expected to show a reactivity similar to that of aminoguanidine toward various bifunctional compounds. This paper will deal with the preparation of several 5-nitro-2-furyl-heterocycles by the cyclization of I with bifunctional compounds.

Results and Discussion

Erickson[4] has prepared 3-amino-1,2,4-triazine derivatives by the reactions of aminoguanidine carbonate with glyoxal and diacetyl, but Thile *et al.* reported[5] that only bisguanylhydrazone was obtained instead of 1,2,4-triazine by the similar reaction of either aminoguanidine nitrate or the hydrochloride with glyoxal, and Polonovski[6] and Gianturco[7] have investigated this in detail. When I was treated with diacetyl in boiling methanol, an orange crystalline product, mp 212°C, was obtained. An elemental analysis of this product (Found: C, 46.54; H, 3.64; N, 25.42%) did not agree with the calculated value for the desired compound. The IR spectrum of this compound showed N–H absorption at 3250 cm^{-1}, but no C=O absorption was detected. No further determination of the structure of this compound has been undertaken. However, when treated with diacetyl in refluxing methanol containing *N,N*-dimethylformamide, I afforded the desired 3-(5-nitro-2-furyl)-5,6-dimethyl-1,2,4-triazine (IIa). The similar treatment of I with furil in refluxing methanol afforded the desired cyclization product, 3-(5-nitro-2-furyl)-5,6-bis(2-furyl)-1,2,4-triazine (IIb).

When I was refluxed in a large excess of ethyl orthoformate, two compounds, III (mp 131—132°C (32% yield)) and IV (mp 179—180°C (28.6%)), were produced. Judging from the results of the elemental analysis, III seems to be 3-(5-nitro-2-furyl)-5-ethoxy-1,2,4-triazoline, and IV, bis[3-(5-nitro-2-furyl)-1,2,4-triazolyl]methyl ethyl ether. The presence of a triazole structure in III and IV was supported by the characteristic IR absorption bands in the 3500—2800 cm^{-1} region.[8]

Table 1. Effects of reaction time on the yield and the compound ratio

Reaction time (hr)	Product		
	Total yield (%)	Ratio	
		III	IV
0.25	78.3	92.2	7.8
1	60.6	52.8	47.2
5	58.6	0	100.0

The relation between the reaction time and the product ratio was investigated; the results are shown in Table 1. With an increase in the reaction time, the formation of III as well as the total yields decreased, but that of IV increased. This suggests that III was formed in the initial step and that IV may be produced by the existence of excess ethyl orthoformate.

Compound III was stable to heating in 2-methoxyethanol, but was unstable in diluted sulfuric acid, when it gave 3-(5-nitro-2-furyl)-1,2,4-triazole (V) by eliminating a molecule of ethanol. V was also obtained by heating IV in diluted sulfuric acid. It seems that IV reacts with water under the catalytic action of the acid to afford V by liberating ethyl formate. Compound

Table 2. NMR data of III, IV, and V (at 60 MHz in DMSO-d_6)

	III δ	IV δ	V δ
Triazole ring C–H	8.28 (1H, sharp s)	9.35 (2H, sharp s)	8.82 (1H, sharp s)

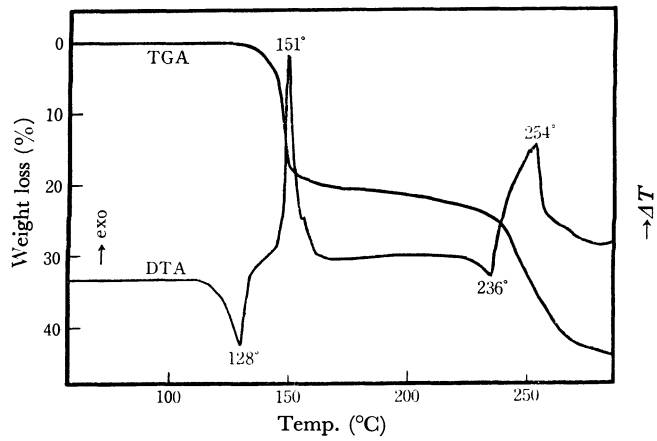

Fig. 1. Thermal analysis of III measured in an argon stream using 21.3 mg of sample at the heating rate of 3°C/min.

V is obviously a 1,2,4-triazole derivative since, in the IR spectrum, characteristic absorptions of C–H in the triazole ring remained, but no more $-OC_2H_5$ was present. III was heated in ethyl orthoformate to give IV, but the V remained unchanged. When an equimolar mixture of ethyl orthoformate and I was heated in 2-methoxyethanol, no formation of IV was observed and the sole product was III. The NMR spectra (shown in Table 2) are compatible with the above structures, III, IV, and V.

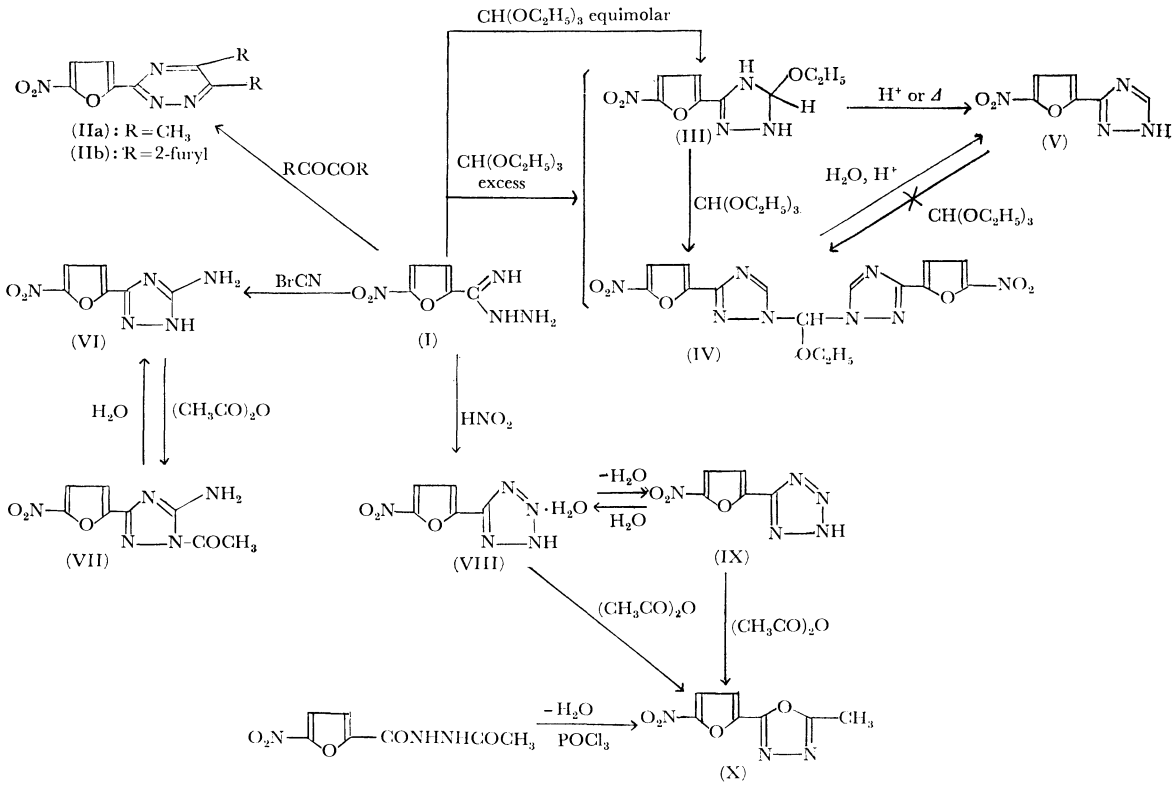
Furthermore, the thermostability of III was investigated by thermogravimetric analysis (TGA) and differencial thermal analysis (DTA). In Fig. 1, the DTA curve shows an endothermic peak at 128°C which coincides with the melting point of compound III. Two exothermic peaks, one at 151°C and the other at 254°C, correspond to the initial and the second stages (128—154°C and 236—270°C) respectively of the reduction in weight of the TGA curve. About 20% of the loss of weight occurs in the initial stage; this corresponds to the loss of a molecule of ethanol from III (theoretical 20.3%). The second stage of the reduction in weight agrees with the decomposition point of V during the pyrolysis.

These results show that the releasing of ethanol from III occurred at 128—154°C, but not under the refluxing temperature (110—120°C) in ethyl orthoformate or in 2-methoxyethanol. Therefore, it seems most resonable to conclude that the mechanism of the formation of IV is in the initial step, giving III from I and ethyl orthoformate, and in the following reaction of III with excess ethyl orthoformate, affording IV without the process: III→V→IV.

When acyl hydrazines are treated with cyanogen bromide, 5-substituted 2-amino-1,3,4-oxadiazole is formed.[9] Similarly, 3-(5-nitro-2-furyl)-5-amino-1,2,4-triazole (VI) was obtained by the treatment of I with cyanogen bromide in refluxing methanol. The IR spectrum of VI has characteristic absorptions at 3400, 3295 (νNH_2), 1646 (δNH_2), and 1320 cm^{-1} (νC–N), supporting the amino-triazole structure. A monoacetyl derivative (VII) was obtained by the treatment of VI with hot acetic anhydride, whereas it reverted to the

8) K. T. Potts, *J. Chem. Soc.*, **1954**, 3461.

9) A. Dornow and K. Brunken, *Ber.*, **82**, 121 (1949).



starting material VI upon heating with water. The presence of a carbonyl absorption at 1733 cm^{-1} in the IR spectrum of VII suggests that the acetylation had occurred at the ring imino nitrogen because of a shift to higher frequencies than with the usual amides. The lack of the production of di- or triacetyl derivative is attributable to the low solubility of VII in the given solvent.

In order to prepare the tetrazole derivative, I was treated with nitrous acid in diluted hydrochloric acid according to Pinner's procedure;[10] this afforded the product (VIII), mp 71—72°C. The IR spectrum has an O–H absorption at 3500—3200 cm^{-1}, perhaps due to the water of recrystallization. In fact, the elemental analysis is compatible with the value calculated for the monohydrate of 5-(5-nitro-2-furyl)tetrazole. Water was successfully removed when VIII was heated at 50—55°C *in vacuo* to give 5-(5-nitro-2-furyl)tetrazole (IX), mp 121—122°C, and IX was converted to VIII by heating it in water for several minutes. IX showed no O–H absorption in the infrared spectrum. In order to confirm the above facts, the thermal analysis of VIII was undertaken. As is shown in Fig. 2, two endothermic peaks are observed in the DTA curve, at 57 and 120°C. The initial peak and its shoulder (60°C) are in agreement with a stage of the reduction in weight at 30—70°C (about 8.9% of loss of weight), corresponding to the loss of a molecule of water (9.04%), and with the melting point of VIII of the TGA curve. The second endothermic peak is obviously in good accordance with the melting point of IX for the TGA curve.

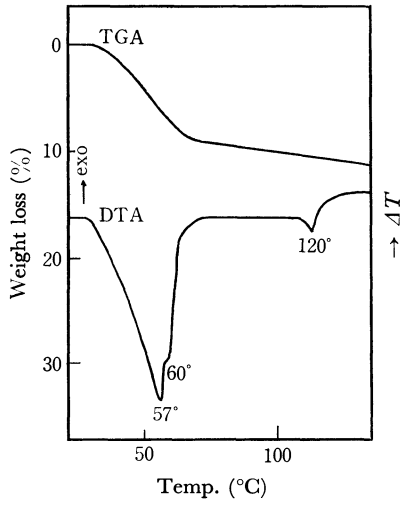


Fig. 2. Thermal analysis of VIII measured in an argon stream using 14.2 mg of sample at the heating rate of 3°C/min.

The IR spectra showed characteristic wide ammonium and immonium absorptions in the 2900—2100 and 2000—1800 cm^{-1} regions for VIII, and in the 3000—2300 cm^{-1} region for IX. These facts, as claimed by Otting,[11] suggest that both VIII and IX participate in an intermolecular association in which the hydrogen atom of the imino group protonates a nitrogen of an adjacent molecule, the two charged particles being stabilized by resonance. The difference between VIII and IX may be presumed to be that VIII can form the structural element $=N^{+}-H$ with greater facility than can IX because of the included water of recrystallization, the hydrogen transfer being thus made easier.

When VIII or IX was heated in acetic anhydride, the product (X) was not the desired *N*-acetyl-tetrazole but 5-(5-nitro-2-furyl)-2-methyl-1,3,4-oxadiazole, which was identified by means of an alternate method of pre-

10) A. Pinner, *Ber.*, **27**, 990 (1894).

11) W. Otting, *Chem. Ber.*, **89**, 2887 (1956).

paration utilizing the dehydration of 1-(5-nitro-2-furoyl)-2-acetylhydrazine with phosphoryl chloride. This reaction might occur much as in the formation of 2,5-disubstituted 1,3,4-oxadiazole from 5-substituted tetrazole and acyl chlorides, as has been reported by Huisgen *et al.*,[12] though Pinner *et al.*[13] obtained a ring-opening *N*-acetyl-*p*-toluamidine on the treatment of 5-*p*-tolyltetrazole with hot acetic anhydride.

Experimental

All the melting and decomposing points are uncorrected. Microanalyses were carried out with a Yanagimoto C.H.N. Corder, MT-2 type. The infrared absorption spectra (IR) were obtained with a Shimadzu IR-27S spectrophotometer by the KBr method. The nuclear magnetic resonance spectra (NMR) were measured with a Nihon-Denshi NMR spectrometer, JNM C-60HL, in DMSO-d_6 and with tetramethylsilane as the internal standard; the peak positions are expressed in δ-values. The thermal analyses were carried out with a Rigaku Denki Thermoflex in an argon stream.

3-(5-Nitro-2-furyl)-5,6-dimethyl-1,2,4-triazine (IIa). A solution of I[3] (3 g, 17.6 mmol) and *N,N*-dimethylformamide (20 m*l*) in 200 m*l* of methanol was stirred slowly into a solution of diacetyl (1.6 g, 18.6 mmol) in 50 m*l* of methanol. The resulting solution was stirred for an additional 2 hr and then heated under reflux for 3 hr. Cooling provided 1.86 g of pale yellow needles (mp 160—161°C). When the mother liquor was concentrated *in vacuo*, a pale yellow powder was obtained, mp 160.5—161°C; weight, 1.61 g. The total yield was 3.47 g. Recrystallization from 30% aqueous methanol gave pale yellow needles, mp 160.5—161°C. The yield was 3.06 g (78.9%).

Found: C, 49.08%; H, 3.52; N, 25.29%. Calcd for $C_9H_8N_4O_5$: C, 49.09; H, 3.64; N, 25.45%.

3-(5-Nitro-2-furyl)-5,6-bis(2-furyl)-1,2,4-triazine (IIb). To a stirred solution of furil (0.19 g, 1 mmol) in 15 m*l* of methanol we added, drop by drop, a solution of I (0.17 g, 1 mmol) in 10 m*l* of methanol. After the addition was over, the resulting solution was refluxed for 3 hr and left to stand overnight; the product was then collected by filtration. Recrystallization from methanol gave yellow needles, mp 159—161°C. The yield was 0.15 g (51.3%).

Found: C, 55.43; H, 2.56; N, 17.53%. Calcd for $C_{15}H_8N_4O_5$: C, 55.56; H, 2.47; N, 17.28%.

3-(5-Nitro-2-furyl)-5-ethoxy-1,2,4-triazoline (III). A mixture of I (1.7 g, 10 mmol), ethyl orthoformate (1.48 g, 10 mmol), and 25 m*l* of 2-methoxyethanol was heated under reflux for 15 min. The resulting solution was concentrated to dryness *in vacuo* below 50°C. The residue was dissolved in hot benzene, and the insoluble material was filtered off. After the solution had been left standing, the precipitates were collected and crystallized from benzene to give 1.31 g (50%) of III as orange needles which melted at 131—132°C. IR: cm^{-1} 3409 and 3310 (N–H), 2980—2870 (CH_3, CH_2).

Found: C, 42.58; H, 4.49; N, 24.83%. Calcd for $C_8H_{10}N_4O_4$: C, 42.47; H, 4.42; N, 24.78%.

Bis[3-(5-nitro-2-furyl)-1,2,4-triazolyl]methyl Ethyl Ether (IV). From I and Ethyl Orthoformate: Compound I (3 g, 17.6 mmol) was suspended in ethyl orthoformate (30 m*l*) and heated under reflux for 5 hr. The solution was then cooled, and the precipitate was collected on a filter, washed with cold benzene, and dried to give a yellow powder. Recrystallization from dioxane-water provided yellow columns; mp 179—180°C. The yield was 2.15 g (58.6%). IR: cm^{-1} 3120 (C–H in triazole ring), 2960—2846 (CH_3, CH_2).

Found: C, 43.30; H, 3.00; N, 26.98%. Calcd for $C_{15}H_{12}N_8O_7$: C, 43.27; H, 2.88; N, 26.92%.

From III and Ethyl Orthoformate: A mixture of III (0.21 g, 1.2 mmol) and 2 m*l* of ethyl orthoformate was heated under reflux for 4 hr. The solution was concentrated *in vacuo* affording 0.23 g of brown crystals; mp 131—161°C. Work-up as above gave 0.11 g (45.5%) of yellow columns, mp 180—181°C. This product was found to be identical with IV by elemental analysis and by a mixed-melting-point determination.

Reaction of I with Excess Ethyl Orthoformate. A mixture of I (1 g, 5.8 mmol) and 10 m*l* of ethyl orthoformate was heated under reflux for a given time (*cf.* Table 1). The ethyl orthoformate was then removed *in vacuo*, and the residue was slurried in boiling benzene to give crude IV. Recrystallization from dioxane-water gave a pure product. The benzene liquor was worked-up as above in order to prepare III. The yields are shown in Table 1.

3-(5-Nitro-2-furyl)-1,2,4-triazole (V). From the Reaction of III in Diluted Sulfuric Acid: A solution of III (0.23 g, 1 mmol) in 15 m*l* of 5% sulfuric acid was heated on a steam bath for 7—10 min. After concentration, the separated product was collected on a filter, washed with ether, and dried. This weighed 0.11 g (61.1%) and melted at 249—251°C with decomposition. Crystallization from water gave pale yellow crystals; mp 254—255°C (dec.). IR: cm^{-1} 3080 (C–H in triazole ring).

Found: C, 40.11; H, 2.00; N, 31.15%. Calcd for $C_6H_4N_4O_3$: C, 40.00; H, 2.22; N, 31.11%.

Decomposition of IV with Sulfuric Acid: A mixture of IV (2.08 g, 5 mmol) and 30 m*l* of 25% sulfuric acid was heated to boiling for 1 hr. On the concentration of the solution to half of the initial volume, the product separated as yellow crystals; mp 249—253°C (dec.); weight, 0.7 g. An additional 1 g was obtained by neutralizing the sulfuric acid solution with solid sodium carbonate. The total yield was 1.7 g (94.4%). Recrystallization as above gave pale yellow crystals; mp 254—255°C (dec.). The melting point of this compound was not depressed upon admixture with an authentic sample.

3-(5-Nitro-2-furyl)-5-amino-1,2,4-triazole (VI). Cyanogen bromide (1.9 g, 17.6 mmol) and I (3 g, 17.6 mmol) were heated together under reflux in 200 m*l* of methanol for 1 hr. The solution was then taken to dryness *in vacuo*, affording a brown residue. Crystallization from water gave yellow plates; mp 273.5—274°C. The yield was 1.8 g (52.4%).

Found: C, 37.21; H, 2.71; N, 35.40%. Calcd for $C_6H_5N_5O_3$: C, 36.92; H, 2.56; N, 35.89%.

3-(5-Nitro-2-furyl)-1-acetyl-5-amino-1,2,4-triazole (VII). Compound VI (0.49 g, 2.5 mmol) was covered with acetic anhydride (5—10 m*l*) and heated on a steam bath for 15 min. Water (50 m*l*) was added to the resulting suspension in order to decompose the surplus acid anhydride. The product was filtered and then slurried in 50 m*l* of boiling methanol. In this way 0.57 g (95.8%) of pure VII was obtained as a fine yellow powder; mp$>$350°C.

Found: C, 40.88; H, 2.90; N, 29.28%. Calcd for $C_8H_7N_5O_4$: C, 40.51; H, 2.95; N, 29.54%.

Hydrolysis of VII. Acetyl compound VII (0.1 g, 0.36 mmol) was heated under reflux in 80 m*l* of water for 4.5 hr. Cooling provided 0.07 g (quantitative) of yellow plates of VI; mp 273°C (dec.) (water). This product was identical in its infrared spectrum with an authentic sample of VI.

5-(5-Nitoro-2-furyl)tetrazole Monohydrate (VIII). To a

13) A. Pinner, *Ann.*, **298**, 7 (1897); A. Pinner and N. Caro, *Ber.*, **27**, 3278 (1894).

stirred, ice-cooled solution of I (5.0 g, 29.4 mmol) in a mixture of concentrated hydrochloric acid (5 g) and 50 m*l* of water, we added, portion by portion, 3.24 g (46.9 mmol) of sodium nitrite powder. Stirring was then continued for an additional 2 hr at 3—5°C. The product was filtered and washed with a small amount of water to give 5.1 g of a tan powder. Crystallization from water gave 4.7 g (80.2%) of VIII as yellow plates; mp 71—72°C.

Found: C, 30.67; H, 2.57; N, 35.48%. Calcd for $C_5H_3N_5O_3 \cdot H_2O$: C, 30.15; H, 2.51; N, 35.17%.

5-(5-Nitro-2-furyl)tetrazole (IX). Monohydrate VIII (314.4 mg, 1.58 mmol) was heated at 50—55°C in a vacuum flask for 6 hr. After the loss of 28.4 mg of water, 286 mg of IX were obtained as a pale yellow powder; mp 121—122°C.

Found: C, 33.20; H, 1.59; N, 38.72%. Calcd for $C_5H_3N_5O_3$: C, 33.14; H, 1.65; N, 38.67%.

Hydration of IX. A solution of IX (147 mg, 0.81 mmol) in 1 m*l* of water was heated on a steam bath for 5 min. Cooling gave 163 mg (quantative) of VIII as pale yellow needles; mp 70—71°C, undepressed on admixture with a sample prepared by the method described above for VIII.

5-(5-Nitro-2-furyl)-2-methyl-1,3,4-oxadiazole (X). From the Cyclization of 1-(5-Nitro-2-furoyl)-2-acetylhydrazine: A suspension of 2.13 g (10 mmol) of 1-(5-nitro-2-furoyl)-2-acetylhydrazine in 25 m*l* of phosphoryl chloride was heated on a steam bath for 3 hr. The resulting solution was taken to dryness *in vacuo*, and the residue was washed with water. Crystallization from methanol gave 0.8 g (41%) of X as yellow needles; mp 151—152°C.

Found: C, 42.93; H, 2.67; N, 21.85%. Calcd for $C_7H_5N_3O_4$: C, 43.08; H, 2.56; N, 21.55%.

From the Reacton of VIII or IX with Acetic Anhydride: A mixture of VIII (or IX) (1.5 mmol) and 5 m*l* of acetic anhydride was heated under reflux for 2 hr. The acetic anhydride was removed *in vacuo*, and the residue was dissolved in 30 m*l* of ethanol. Cooling provided pale yellow plates melting at 152—153°C in a 58—60% yield.

Found: C, 43.44; H, 2.58; N, 21.27%.

This product was identified as X by an admixture-test and by a comparison of the infrared spectrum with that of an authentic sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 784—786 (1971)

Biogenesis of the Essential Oils in Camphor Trees. XXVIII.[1] On the Components of the Essential Oil of *Cinnamomum japonicum* Sieb.[2]

Yasuji FUJITA, Shin-ichi FUJITA, and Hisashi YOSHIKAWA
Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda-shi, Osaka

(Received July 30, 1970)

Cinnamomum japonicum Sieb. is sometimes divided into several varieties on the basis of morphological differences in the leaves. The essential oils of samples of this plant from various parts in Japan were examined from the viewpoint of chemotaxonomy. The results obtained from the materials gathered at Mt. Satsuki, Ikeda-shi, Osaka Prefecture, will be reported here first. The characteristics of the oil of the leaves and branchlets are the abundant presence of 1,8-cineole and *p*-cymene. The rich existence of linalool in the branchlet oil may also be a characteristic of this plant.

Cinnamomum japonicum Sieb. (=*C. pedunculatum* Nees) (Japanese name, "Yabunikkei") of the Lauraceae grows widely in Japan–on Honshu, Shikoku, Kyushu, and the Ogasawara Islands; Fukushima Prefecture is the northern-most limit of its distribution. The Ryukyu Islands, Formulsa, the southern part of Korea, and Southern China are also in the area of geographical distribution of this plant. Sometimes this plant is divided into several varieties on the basis of morphological differences in the leaves.[3]

Many years ago, the essential oil of this plant was examined by Keimatsu *et al.*[4] They obtained the oil in a yield of about 1% by the steam distillation of bark from Hachijyo Island, Japan. The oil contained α-phellandrene (33%) as the main component, plus eugenol and methyleugenol. Shinozaki[5] examined the essential oil obtained in a yield of about 1% from the fresh leaves of plants of the Ogasawara Islands, and showed the presence of safrole (60%), eugenol (9%), and other compounds in the oil. Nakahara[6] also reported that plants obtained from Tane Island in Kagoshima Prefecture afforded the essential oil in a 0.3% yield, and that the oil contained camphor (25%) and cineole (16%), together with *p*-cymene and methyleugenol.

Since 1954, a careful comparison of the essential oils obtained from materials gathered from various localities in Japan has been performed in our laboratory

from the view-points of chemical systematics and chemical taxonomy.

In this paper, the results of our examination of the components of the essential oils obtained from materials gathered at Mt. Satsuki in Ikeda-shi, Osaka Prefecture, will be reported.

Experimental

Isolation of the Essential Oils. *Sample I*: On May 24, 1954, the material (average weight of a twig: 65 g, consisting of 68% leaves and 32% branchlets) was gathered from a tree (diameter of the trunk at a height of one meter; 9 cmϕ) at Mt. Satsuki, in Ikeda-shi, Osaka Prefecture (320 m above sea level). On May, 25, this material (19.9 kg) was subjected to steam distillation. The distilled oil was extracted with ether, and then dried over anhydrous sodium sulfate. The oil (67.1 g), obtained in a 0.34% yield, had the following properties: d_4^{30} 0.8939, n_D^{30} 1.4800, α_D^{28} −11.00°, A.V. 0.5, E.V. 1.0.

Samples of II: On April 22, 1954, the material (average weight of a twig: 120 g, consisting of 59% leaves and 41% branchlets) was gathered from another tree (diameter: 15 cmϕ) in the same locality. The material was divided into leaves and branchlets.

II-A: On April 23, the leaves (20.0 kg) were subjected to steam distillation; the oil (168.0 g), obtained in a 0.84% yield, had the following properties: d_4^{30} 0.8792, n_D^{30} 1.4781, α_D^{28} −19.75°, A.V. 0.2, E.V. 5.0.

II-B: On April 26, the branchlets (5.5 kg) were distilled with steam; the oil (8.3 g), obtained in a 0.15% yield, had the following properties: d_4^{30} 0.9522, n_D^{30} 1.4869, α_D^{28} −9.00°, A.V. 1.0, E.V. 12.8.

Gas-liquid Chromatographic Analysis. The gas-liquid chromatography (glc) was carried out with a Shimadzu GC-1B Model apparatus, equipped with a 150×0.5 cm stainless steel column containing 30% PEG 6000 or 30% Silicone DC-550 on Celite 545 (100 mesh). Hydrogen was used as the carrier gas.

The percentages of the constituents of the oil were calculated from the areas of the peaks of the gas chromatogram.

Separation and Identification of the Individual Components. The neutral part of the sample II-A (143 g) was fractionated, by distillation under reduced pressure in a current of nitrogen with a Widmer column, into eleven fractions, as is shown in Table 1. Each fraction was then further separated into hydrocarbons and oxygenated compounds by alumina-column chromatography. The main components were isolated by preparative glc using a PEG 6000 column, and were identified by a comparison of the IR spectra and retention times (*Rt*) of glc with those of authentic samples. Some minor components were identified by a comparison of the *Rt's* with those of authentic samples obtained by the above two kinds of columns.

Table 1. Results of fractional distillation of the neutral oil (sample II-A)

Fract.	Bp (°C/mmHg)	Dist. (ml)	Bp (°C/764 mmHg)	d_4^{30}	n_D^{30}	α_D^{22}(°)
I	—83/50	25	178	0.8548	1.4719	−24.45

SHC: unidentified sesquiterpene hydrocarbon

The main components may be identified as follows:

l-α-Phellandrene: Peak 5 ($[\alpha]_D^{20}$ −158.0°, c=2.2, in $CHCl_3$) was isolated from fractions I—III; it was identified as α-phellandrene by a comparison of the IR spectra.[7]

l-Linalool, Terpinen-4-ol, and l-α-Terpineol: Peak 13 ($[\alpha]_D^{20}$ −15.4°, c=4.2, in EtOH), peak 18, and peak 23 ($[\alpha]_D^{20}$ −49.6° c=4.4, in EtOH) were isolated from fraction VI and were identified as linalool, terpinen-4-ol, and α-terpineol respectively by a study of the IR spectra and *Rt's* in glc.

l-Carvotanacetone: Peak 25 ($[\alpha]_D^{20}$ −38.6°, c=4.8, in EtOH) was identified as carvotanacetone by a comparison of the IR spectrum[8] and *Rt* with those of a synthetic sample prepared from carvone.

Citronellol, Nerol, and Geraniol: A mixed sample of fractions V and VI was heated with phthalic anhydride at 80°C in a pyridine solution for one hour; the esterified part was then extracted with a sodium hydrogencarbonate solution, the sodium salt of the phthalic acid esters was saponified by potassium hydroxide, and the regenerated alcohols were distilled with steam.

These primary and secondary alcohols (peak 28, 31, and 34) were separated by preparative glc and were identified as citronellol, nerol, and geraniol respectively by a study of the IR spectra and *Rt's*.

l-trans-*Yabunikkeol and* d-cis-*Yabunikkeol*: These new monoterpene alcohols[9] (peaks 33 and 39) were also obtained from the above regenerated oil.

l-Copaene, β-Elemene, l-Caryophyllene, and β-Humulene: These sesquiterpene hydrocarbons (peaks 14, 19, 20, and 26) were isolated from fractions V—VIII and were identified as copaene ($[\alpha]_D^{20}$ −16.0°, c=4.1, in $CHCl_3$), β-elemene, caryophyllene ($[\alpha]_D^{20}$ −8.8°, c=1.7, in $CHCl_3$), and β-humulene respectively by a comparison of the IR spectra.[10]

d-*δ-Cadinene, Calamenene, α-Calacorene, and β-Calacorene*: These sesquiterpene hydrocarbons (peak 30, 36, 39, and 40) were also identified as δ-cadinene ($[\alpha]_D^{20}$ +45.6°, c=4.1, in $CHCl_3$), calamenene, α-, and β-calacorene by a comparison of the IR spectra with those of authentic samples.[10]

l-Kaurene: Peak 49 (mp 47°C, $[\alpha]_D^{20}$ −56.6°, c=4.6, in $CHCl_3$) was isolated from the residual oil of fractional distillation by column chromatography and was identified as kaurene by a study of the IR spectrum.[11]

Results and Discussion

The yields of the essential oils of this *C. japonicum* are 0.34% from the fresh twigs (sample I), 0.84% from the leaves (sample II-A), and 0.15% from the branchlets (sample II-B). Table 2 shows the compositions of these oils.

From these results, we can see it is characteristic of the oil that 1,8-cineole and *p*-cymene exist abundantly, while there are only small amounts of camphor and phenol ethers. The abundance of *l*-linalool in the branchlet oil may also be a characteristic of this plant, though the components of these oils are almost the same.

Among the other substances, we could isolate two new monoterpene alcohols, named *trans*-yabunikkeol and *cis*-yabunikkeol (*trans*- and *cis*-*p*-mentha-1(7),5-dien-2-ol), for the first time;[9] we also isolated *l*-kaurene, probably for the first time, in the Angiospermae.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 786—791 (1971)

Infrared Spectroscopic Study of Enol and Enol Derivatives Coordinated to Platinum(II) and Palladium(II)

Yasuo WAKATSUKI,* Shun-ichi NOZAKURA, and Shunsuke MURAHASHI

Faculty of Science, Osaka University, Toyonaka, Osaka

(Received August 3, 1970)

The infrared spectra of $[Cl_2M\ Olefin]_2$ (olefin = vinyl alcohol, vinyl ethers, and their derivatives, M = Pt and Pd) have been studied in the 4000—100 cm^{-1} frequency region. A normal coordinate analysis of the coordinated vinyl alcohol indicated that the lone-pair electrons of oxygen conjugated with π-electrons of the double bond to some extent, even in the coordinated state. The coordination strengths of vinyl alcohol, vinyl ethers, and their derivatives have been examined by comparing the metal-olefin streching vibrations.

The synthesis of the vinyl alcohol complex, $[Cl_2Pt\text{-}(CH_2{=}CHOH)]_2$, has been previously reported.[1] It does not contain organic moieties other than vinyl alcohol, so the analysis of its infrared spectrum is relatively easy.

The double bond of coordinated olefin, in general, approaches a single bond to some extent, as is confirmed by the shift of the C=C stretching to the lower frequency. Nakamoto and Grogan analyzed the normal coordinate of the ethylene coordinated to platinum(II) and concluded that the force constant of the stretching of the

* Present address: The Institute of Physical and Chemical Research, Wako-shi, Saitama.

1) Y. Wakatsuki, S. Nozakura, and S. Murahashi, This Bulletin, **42**, 273 (1969).

double bond is 6.00 mdyn/Å, a value which is 19% smaller than that of free ethylene.[2] It may be thought that vinyl alcohol, like vinyl ethers, includes such a resonance structure as: CH_2=CH–OH$\longleftrightarrow$$\bar{C}H_2$–CH=$\overset{+}{O}$H. However, the contribution of such a resonance form may be decreased upon coordination to a metal, since the double-bond character of coordinated olefin is smaller than that of free olefin. In order to obtain the force constants of the C=C and C–O stretchings of the π-coordinated vinyl alcohol, the approximate in-plane normal coordinate analysis of the coordinated vinyl alcohol was carried out. It seemed that it might thereby be possible to determine whether or not the above-mentioned resonance structures really exist and the coordination of the oxygen atom to the metal.

Nakamoto and Grogan analyzed the far-infrared spectra of Zeise's dimer, $[Cl_2Pt\ C_2H_4]_2$, and its palladium analog; they assigned the metal-ethylene stretching vibration to the absorption at 408 cm^{-1} of the Pt complex and to that at 427 cm^{-1} of the Pd complex.[3] In order to ascertain the coordination power of vinyl ethers to Pt(II) and Pd(II), we measured the far-infrared spectra of vinyl ether complexes of the Zeise dimer type in the range of 700—100 cm^{-1}, and compared the frequencies of the absorptions which are assignable to the metal-olefin stretching vibrations with each other. It has often been said that the magnitude of the shift upon coordination in the C=C stretching mode reflects the strength of the metal-olefin bond. Free vinyl ethers have, however, been found to complicate two or more absorptions in the C=C stretching region;[4] moreover, the C=C stretching vibration of the coordinated olefin may strongly couple with other vibrations, as in the case of the coordinated ethylene.[2] Thus, the shift of the C=C stretching vibration upon coordination cannot be taken as a measure of the coordination power. Accordingly, the direct measurement of the metal-olefin stretching vibration, described above, is desirable.

Experimental

The Preparation of Complexes. The preparation of Pt(II) and Pd(II) complexes with vinyl ethers and their derivativs has been described in a preceding paper.[5] Vinyl alcohol and propenyl alcohol complexes with Pt(II) were synthesized as has been described in another previous paper.[1] The platinum complex of CH_2=CH–OD was obtained in a method similar to that used for the vinyl alcohol complex, that is, the hydrolysis of the silyl ether bond of the CH_2=CH–$OSiMe_3$ complex with a small amoun of heavy water.

Spectral Measurements. The spectra were obtained mainly by means of the Nujol mull technique using a Hitachi EPI-2 (4000—700 cm^{-1}), a JASCO DS-402 (700—500 cm^{-1}), and a Hitachi FIS-1 (500—100 cm^{-1}) spectrometer.

Procedure of Calculatin. It is assumed that the vinyl alcohol molecule is planar and that this plane is retained even in its coordinated state. Vinyl alcohol has 15 ($3\times7-6$) fundamental vibrations; of these, 11 are in-plane vibrations and 4 are out-of-plan vibrations. In this study, only the in-plane vibrations are examined.

It is expected that the vibrations of the vinyl alcohol molecule coordinated to a metal couple extremely weakly with other vibrations such as those due to the Pt–Cl bond. Thus, an examination of only the vibration of the vinyl alcohol coordinated to a metal is permissible.

Nakamoto *et al.* estimated that the C=C and C–H distances of the coordinated ethylene are 1.364 and 1.089 Å respectively.[2] In the case of the coordinated vinyl alcohol, these values are employed. With respect to the C–O an O–H distances, the values of 1.42 and 0.956 Å respectively are used. It is estimated that all the angles around the carbons are 120°, and that the COH angle is 110°. The conformation around the C–O bond is unclear; in this case, a trans planar conformation is assumed. Figure 1 illustrates the 13 internal coordinates employed for the calculation.

Table 1. Symmetry coordinates for the in-plane vibrations of the coordinated vinyl alcohol

Symmetry coordinate	Vibrational mode[a]
$S_1=\Delta r_1$	ν(CH)
$S_2=1/\sqrt{2}\,(\Delta r_2-\Delta r_3)$	$\nu_a(CH_2)$
$S_3=1/\sqrt{2}\,(\Delta r_2+\Delta r_3)$	$\nu_s(CH_2)$
$S_4=\Delta r_4$	ν(CO)
$S_5=\Delta r_5$	ν(OH)
$S_6=\Delta R$	ν(C=C)
$S_7=1/\sqrt{6}\,(2\Delta\beta_2-\Delta\alpha_1-\Delta\beta_1)$	δ(CCO)
$S_8=1/\sqrt{2}\,(\Delta\beta_1-\Delta\alpha_1)$	δ(CH)
$S_9=1/\sqrt{6}\,(2\Delta\alpha_2-\Delta\beta_3-\Delta\beta_4)$	$\delta(CH_2)$
$S_{10}=1/\sqrt{2}\,(\Delta\beta_3-\Delta\beta_4)$	$r(CH_2)$
$S_{11}=\Delta\sigma$	δ(OH)
$S_{12}=1/\sqrt{3}\,(\Delta\alpha_1+\Delta\beta_1+\Delta\beta_2)$	Redundant
$S_{13}=1/\sqrt{3}\,(\Delta\alpha_2+\Delta\beta_3+\Delta\beta_4)$	Redundant

PED, Potential Energy Distribution.

In Tables 3 and 4 the observed frequencies are compared with those for coordinated vinyl alcohol and its deuterio analog calculated by using those sets of force constants.

The product rule for isotopic frequencies[8] works extremely well in this case; thus, it supports the validity of the assignments made.

Table 2 shows that the force constant of the C=C stretching is slightly smaller than that of the coordinated ethylene (6.00 mdyn/Å),[2] and that the force constant of its C–O stretching is relatively larger than those of methanol (2.43 mdyn/Å)[9] or diethyl ether (4.38 mdyn/Å).[10] These values reasonably imply that such a resonance structure as $\bar{C}H_2$–$\overset{+}{C}H$=OH exists to some extent even in the coordinated state. The larger value of the force constant of the C–O stretching also indicates that the lone-pair electrons of the oxygen atom do not interact with platinum.

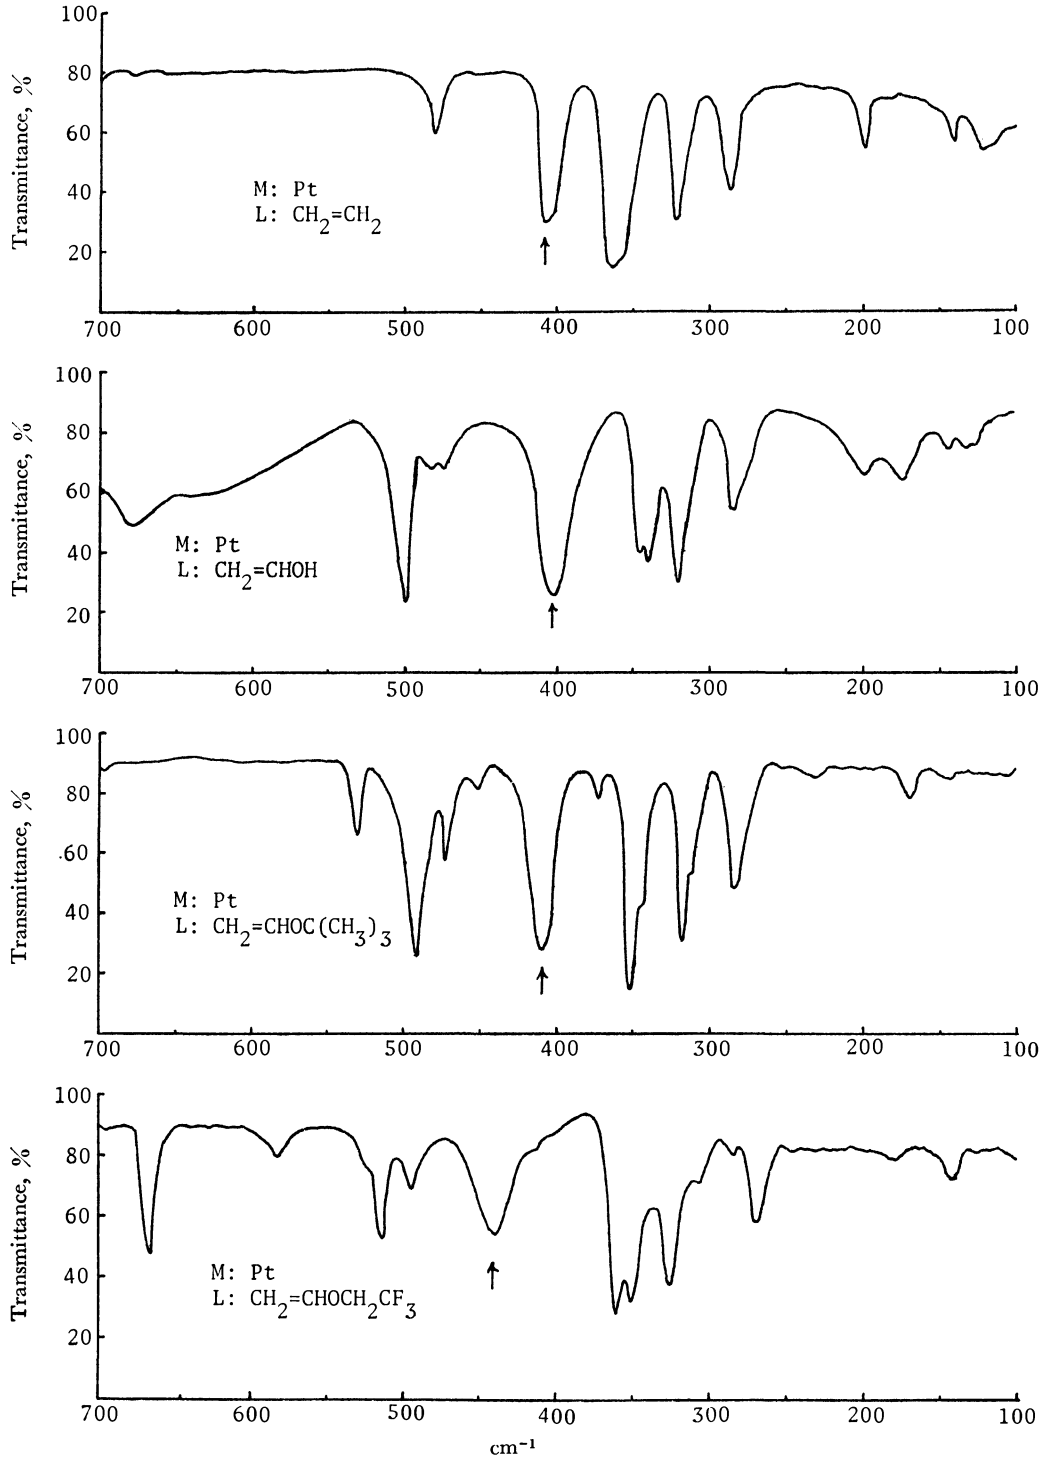

Fig. 3. Infrared spectra of $[Cl_2ML]_2$.

$[Cl_2M\ Olefin]_2$ type, in which M represents platinum or palladium.

With respect to the ethylene complexes with platinum and palladium, Nakamoto has reported that the frequency of a metal-ethylene stretching vibration is a better measure of the coordination strength than the shift width of the C=C stretching upon coordination.[3,11]

The infrared spectra of many platinum and palladium complexes of vinyl ethers, as is shown in the figure, satisfactorily correspond to the ethylene complex in the low-frequency region, and the absorption with an arrow sign can be assigned to the stretching frequency between metal and olefin. Although this absorption is not so isolated as in the case of ethylene, and hence has the possibility of coupling strongly with other vibrations, it may be regarded as a semi-quantitative measure of the coordination strength of vinyl ethers. Table 5 lists

11) M. Tsutsui, "Characterization of Organometallic Compounds," Part I, John Wiley & Sons, N. Y. (1969), p. 110.

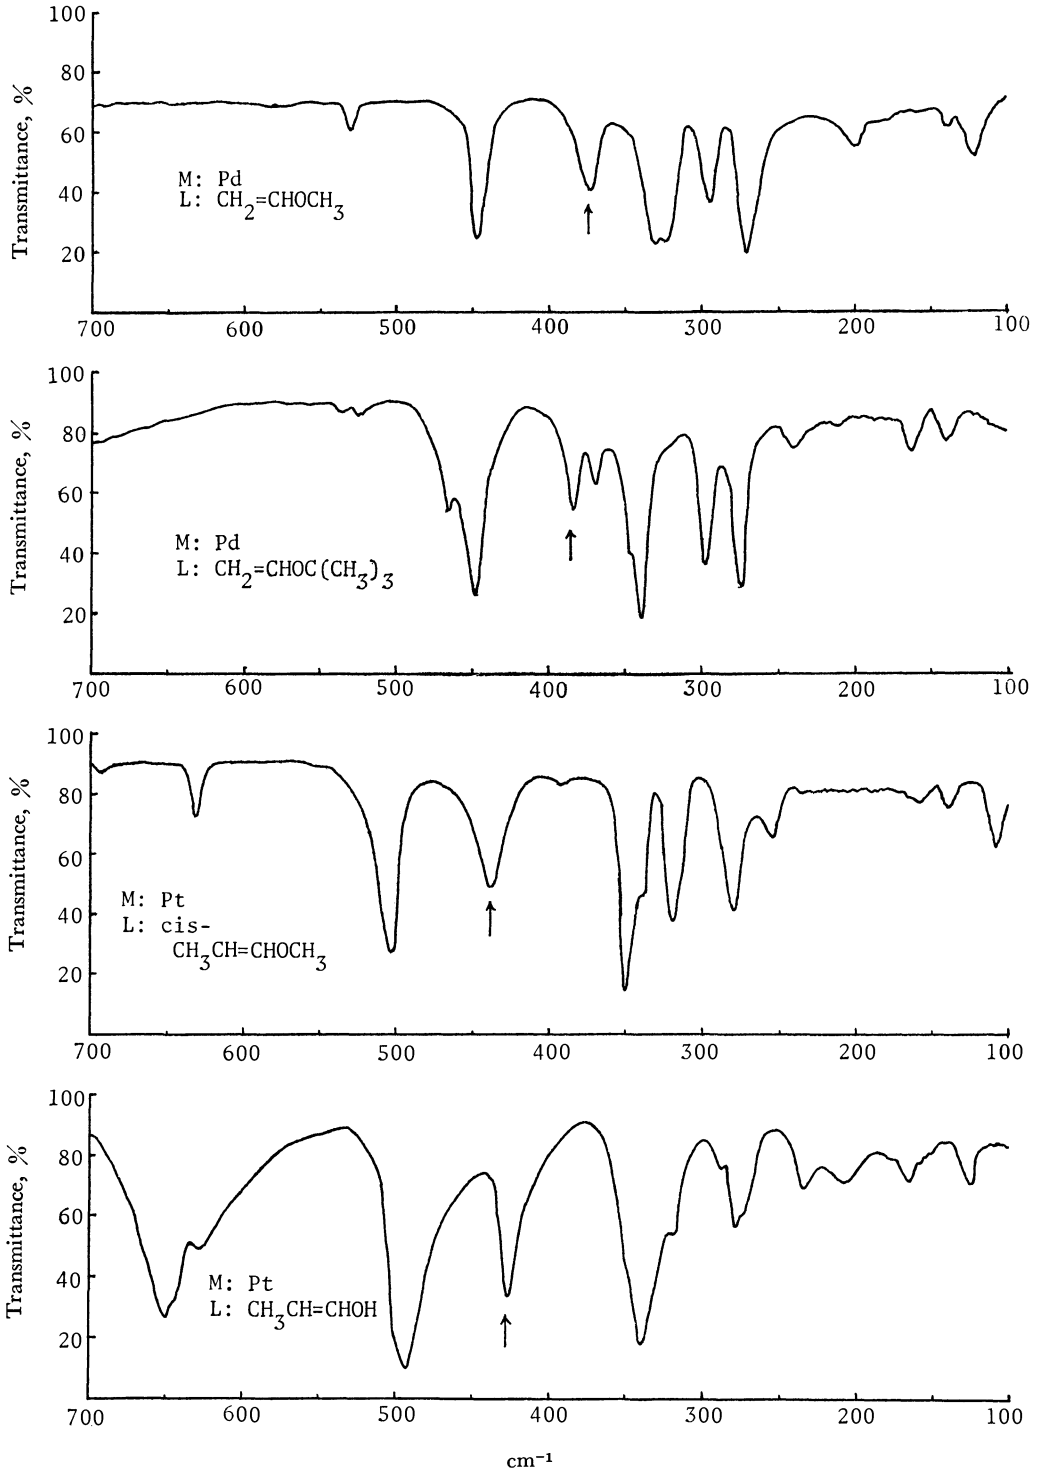

Fig. 3. Infrared spectra of $[ClM_2L]_2$.

the stretching vibrations of the metal-olefin bond thus obtained. This table suggests the following facts with respect to the coordination strength of vinyl ethers and their derivatives:

a) The coordination strength of vinyl ethers with palladium is far weaker than that with platinum. If they were comparable in magnitude, the absorption of the palladium complex should be at a frequency higher by about 20 cm^{-1} than that of the corresponding platinum complex as a result of the mass effect.

b) The coordination strength of vinyl alcohol and that of vinyl alkyl ether are almost equal to that of ethylene in the platinum complex.

c) Propenyl ethers are considerably stronger than the corresponding vinyl ethers in their coordination strength in spite of the fact that β-methyl group of the propenyl ethers may sterically interfere with the coordination, as is the case with 2-pentene.[12]

Table 5. Metal-olefin stretching frequencies of $[Cl_2M\ Olefin]_2$ (M=Pt, Pd)

Olefin	Metal	
	Pt	Pd
$CH_2=CH_2$	408	427 cm^{-1}
$CH_2=CHOCH_3$	(410?)	376
$CH_2=CHOC(CH_3)_3$	408	384
$CH_2=CHOCH_2CF_3$	440	—
$CH_2=CHOH$	402	—
cis-$CH_3CH=CHOCH$	438	404
cis-$CH_3CH=CHOSiMe_3$	430	—
$CH_3CH=CHOH$	427	—

d) 2,2,2-Trifluoroethyl vinyl ether is much stronger than alkyl vinyl ethers in its coordination strength.

As for the metal-olefin bonding, Chart and Duncanson's theory[13] has generally been accepted, in which the bonding is explained by a combination of the electron donation from the olefin to the metal and the electron back-donation from the metal to the olefin. The electron donation from the olefin to the metal is supposed to play an important role when the olefin has a strong electron-releasing substituent, as in the case of vinyl ethers or propenyl ethers. However, steric interactions between other ligands and a substituent on the olefin may also affect the coordination strength of the olefin; thus, the problem is complicated. At present, it seems to be difficult to interpret the relative coordination strengths of ethylene, vinyl alcohol, vinyl ethers, and their derivatives by means of a simple description.

The authors wish to express their thanks to Dr. Masamichi Kobayashi for his valuable suggestions on the analysis of the infrared spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 44, 791—793 (1971)

The Kinetics of the Reaction of Thiol Acids with Anilines

Yoshio HIRABAYASHI, Masateru MIZUTA, Masana KOJIMA,
Yukio HORIO, and Hideharu ISHIHARA
Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Kakamigahara, Gifu

(Received August 6, 1970)

Studies have been made of the kinetics of the reactions of thiol acids (thiostearic acid and thioacetic acid) with anilines, such as aniline and *p*-methoxy-, *p*-ethoxy-, *p*-methyl-, *m*-methyl-, *p*-chloro, *m*-chloro-, and *m*-nitro-substituted anilines, in a chlorobenzene solution. The rate is given by $k(\text{RCO–SH})(\text{X-C}_6\text{H}_4\text{-NH}_2)$. The activation energy for the reaction of thiostearic acid with aniline is 5.3 kcal/mol. The Hammett plots give a straight line, with a value of $\rho = -2.40$ for the reactions of thiostearic acid or thioacetic acid with the anilines; the mechanism of the reaction of thiol acids with anilines is discussed.

Various observations in the literature[1] indicate that the thiol acids, RCO–SH, react with primary and secondary amines much more rapidly than the corresponding carboxylic acids, RCO–OH, and thiol acids have been frequently used as acylating agents. Some observations of Alliger *et al.*,[2] of Sheehan and Johnson,[3] and of Tarbell[1] suggest that the acylation of amines by thiol acids proceeds by a free-radical chain process. On the other hand, the kinetic study by Hawkins *et al.*[4] of the reaction of thiobenzoic acid with aniline to yield benzanilide indicates that the reaction rate in a chlorobenzene solution is given by $k(\text{C}_6\text{H}_5\text{CO–SH})(\text{C}_6\text{H}_5\text{NH}_2)$, where the constant, k, varies with the presence of small amounts of benzoic acid as an impurity, and that the rate depends on the solvent.

The present authors have undertaken kinetic studies of the reactions of thiol acids (*i. e.*, thiostearic acid and thioacetic acid) with anilines in a chlorobenzene solution to yield acyl anilides (Eq. (1)) in order to determine the mechanism of the reaction of the thiol acids with the anilines.

$$\text{RCO–SH} + \text{X–C}_6\text{H}_4\text{–NH}_2 \longrightarrow \text{RCONHC}_6\text{H}_4\text{–X} + \text{H}_2\text{S} \qquad (1)$$

R : heptadecyl or methyl group
X : H or substituent

Results and Discussion

The rate of the reaction of thiostearic acid or thioacetic acid with the anilines in a chlorobenzene solution was followed by the acid-base titration of the unreacted thiostearic acid or thioacetic acid after the hydrogen sulfide formed had been completely removed. The results gave good second-order rate constants for all the runs (Fig. 1.):

$$\text{rate} = k(\text{RCO–SH})(\text{X–C}_6\text{H}_4\text{–NH}_2) \qquad (2)$$

The observation of Hawkins *et al.*[4] of the reaction of thiobenzoic acid with aniline indicated that the

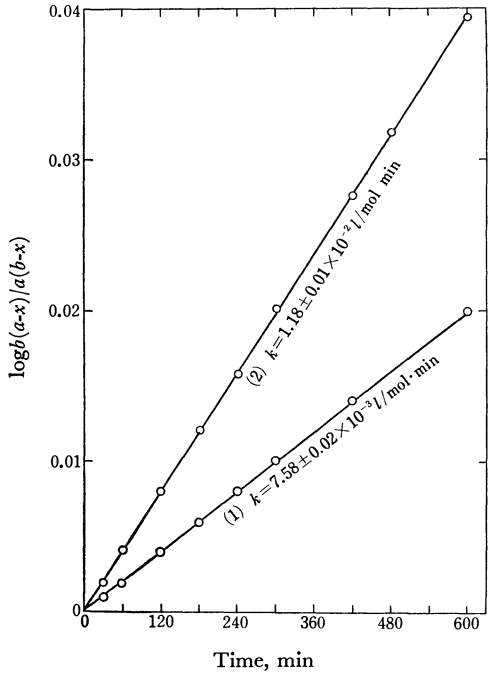

Fig. 1. The second-order plots for the reaction of thiol acid with aniline.
a and *b* are the initial concentrations of the thiol acid and aniline, respectively; *x* is the decrease of concentration of the thiol acids at time *t*.
(1) thiostearic acid: *a*, 0.1298 mol/*l*; *b*, 0.1198 mol/*l*; at 50.0°C; reaction 2.3—34.6%.
(2) thioacetic acid: *a*, 0.2435 mol/*l*; *b*, 0.2303 mol/*l*; at 40.0°C; reaction 7.7—63.0%.

reproducibility of the rate constants was not satisfactory, even though the purity of the thiol acid was better than 99%, and that this fluctuation in different samples might be due to the catalytic activity of benzoic acid present as an impurity. Accordingly, the thiostearic acid and thioacetic acid used in the present investigation were carefully purified. Thiosteric acid, with a purity of 99.3%, gave a reproducible rate constant, $(7.58\pm0.02)\times10^{-3}$ *l*/mol·min, for the reaction with aniline at 50.0°C. In thioacetic acid, the rate constants of the reactions with aniline at 40.0°C varied from one sample of thioacetic acid to another, the extreme variations being $(1.85—0.849)\times10^{-2}$ *l*/mol·min, even though the thiol acid was more than 99% pure. The sample of the thioacetic acid (purity, 99.3%), preserved in small ampoules under nitrogen and kept in an ice-box until use, gave the reproducible rate constant of $(1.18\pm0.01)\times10^{-2}$ *l*/mol·min for the reaction with aniline at 40.0°C.

Table 1 shows the rate constants of the reactions of thiostearic acid with aniline in chlorobenzene solutions at different temperatures. From the runs, the temperature coefficient of the rate constants was found to be small, and the Arrhenius plot of log *k* *vs.* $1/T$ for the data tabulated gave a straight line; the Arrhenius activation energy was found to be 5.3 kcal/mol. This value is smaller than that of the reaction of thiobenzoic acid with aniline, 7.4 kcal/mol.[4]

Table 1. The rate constants of the reaction of thiostearic acid with aniline in chlorobenzene at different temperatures

Temp. °C	$k^{a)}\times10^3$ *l*/mol·min	Temp. °C	$k^{a)}\times10^3$ *l*/mol·min

Tables 2 and 3 show the bimolecular rate constants, *k* and *k'*, of the reactions of thiostearic acid and thioacetic acid respectively with anilines in chlorobenzene. Figure 2 shows the plots of log (k/k_0) and log (k'/k_0') *vs.* the Hammett σ-values for the substituents (k_0 and k_0'

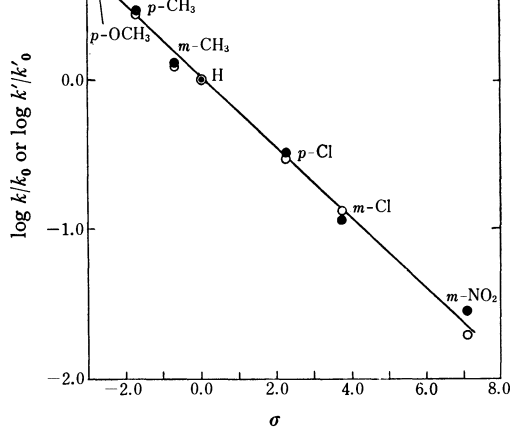

Fig. 2. Hammett's plots for the reactions of thiol acids with anilines in chlorobenzene.
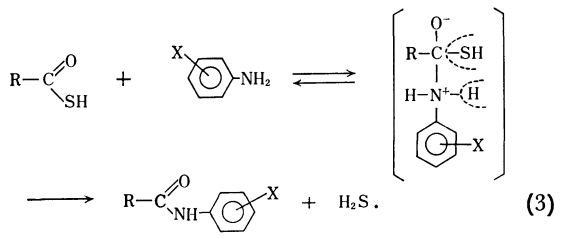
● : thiostearic acid(log k/k_0); at 50.0°C
○ : thioacetic acid (log k'/k'_0); at 40.0°C.

are the rate constants of the reactions of thiostearic acid with aniline and of thioacetic acid with aniline respectively). Both plots gave straight lines, satisfying the Hammett equation; the ρ values in the Hammett equation were found to be -2.40 ± 0.09 for thiostearic acid and -2.40 ± 0.06 for thioacetic acid.

These facts indicate that the reactions between thiol acids and anilines proceed by the following pathway (Eq. 3):



(3)

The reaction is initiated by the nucleophilic attack of the aniline on the carbonyl carbon of the thiol acid; this step probably is rate-determining and is followed by the step yielding acyl anilide and hydrogen sulfide. Consequently, the reaction is facilitated by the introduction of electron-releasing substituents into the phenyl group, but is retarded by that of electron-attracting substituents.

Experimental

Materials. *Thiostearic acid,*[5] prepared from stearoyl chloride and sodium hydrogen sulfide, was purified by repeated recrystallizations from *n*-hexane (mp 39.8—40.3°C). Its purity, as determined by the iodine method, was 99.3%. (Found: S, 10.60%. Calcd for $C_{18}H_{36}OS$: S, 10.67%).

Thioacetic acid,[6] prepared from acetic anhydride and hydrogen sulfide in the presence of sodium hydroxide, was purified by repeated fractional distillations in nitrogen (bp 87.0—87.5°C). Its purity, as determined by the iodine method, was 99.3%. (Found: S, 41.84%. Calcd for C_2H_4OS: S, 42.13%).

Chlorobenzene, obtained commercially, was washed with concd. sulfuric acid with a dilute sodium bicarbonate solution, and then with water, dried over anhydrous calcium chloride, and distilled. The fraction with a bp of 131—132°C was used.

Aniline and Substituted Anilines: All were reagent-grade chemicals obtained from the Tokyo Kasei Kogyo Co. and were purified by recrystallization or by distillation under reduced pressure in nitrogen; the materials having the following mps or bps were used: aniline, bp 82.5—83.0°C/20 mmHg; *p*-anisidine, mp 57.2—58.0°C; *p*-phenetidine, bp 127.0—128.0°C/8 mmHg; *p*-toluidine, mp 44.8—45.1°C; *m*-toluidine, bp 203.0—204.0°C; *p*-chloroaniline, mp 70.1—70.5°C; *m*-chloroaniline, bp 117.0—118.0°C/20 mmHg; *m*-nitroaniline, mp 112.9—113.1°C.

Kinetic Procedure. A standard solution of a thiol acid in chlorobenzene, prepared before each run, was pipetted into a 100-cc volumetric flask containing some chlorobenzene and a weighed sample of aniline or a substituted aniline. The volume of the solution was made up to 100 cc (thiostearic acid 0.12—0.13; thioacetic acid 0.16—0.25 mol/*l*); 10-m*l* aliquots were then removed and placed in 100-cc glass-stoppered round-bottomed flasks, which had previously been flushed with dry, oxygen-free nitrogen, in an thermostat at a prescribed temperature (accuracy ±0.1°C). The first 10-m*l* aliquot was pipetted directly into an excess of the standard base (the thioacetic acid runs: 25 cc of 0.2N potassium hydroxide; the thiostearic acid runs: 40 cc of 0.1N ethanolic potassium hydroxide and 20 cc of neutralized ethanol), and the excess base was back-titrated immediately with 0.1N hydrochloric acid by the use of thymolphthalein as the indicator. The samples were removed at regular time intervals, and the flask was immediately chilled in an ice bath; in the thioacetic acid runs, a steady stream of dry, oxygen-free nitrogen was passed through the contents of the flask for 10 min, while in the thiostearic acid runs, the flask was aspirated by a water-pump for 5 min. These procedures had been determined by preliminary experiments aimed at the complete removal of hydrogen sulfide. An excess of the standard base, mentioned above, was added to the contents of the flask, and the residual thiol acid was determined by back-titration, as has been mentioned above. In the thioacetic acid runs, it had been found, from preliminary experiments carried out under the same conditions as those used for chlorobenzene solutions of different thioacetic acid-hydrogen sulfide concentrations, that a small amount of thioacetic acid had been lost, together with the hydrogen sulfide removed; accordingly, the residual amount of thioacetic acid at each reaction time was corrected by the amounts determined for different concentrations of thioacetic acid. On the other hand, the following blank test was carried out in order to determine whether or not the thiol acid itself was changed in chlorobenzene during the reaction with aniline. Another part of the standard solution of thiol acid in chlorobenzene was diluted with chlorobenzene, and the concentration of thiol acid in the solution was made equal to that of the above thiol acid-aniline chlorobenzene solution; the subsequent treatment of the solution was just the same as has been described above. These blank samples were also removed at regular time intervals, together with the above samples, and the amount of residual thiol acid was determined; the amount of the residual thiol acid of the blank sample, determined after the removal of hydrogen sulfide, was always practically identical with that of the initial blank sample at each reaction time during the run, though the above correction value had to be taken into consideration in the thioacetic acid runs.

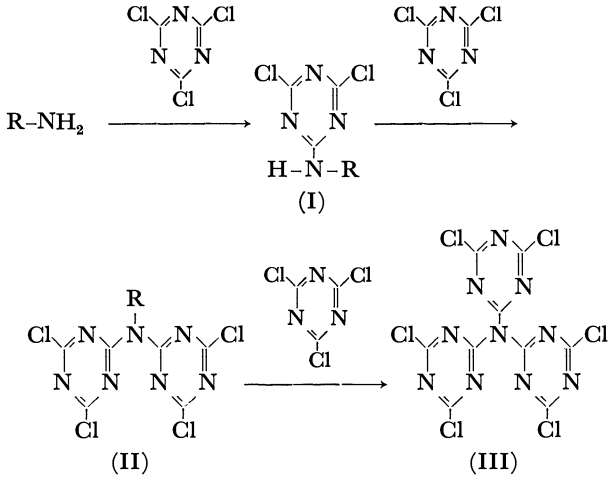
(Received August 10, 1970)

Various substituted ditriazinylamines were synthesized by the reaction of *N,N*-bis(4,6-dichloro-*s*-triazin-2-yl)-amine, *N,N*-bis(4-chloro-6-phenyl-*s*-triazin-2-yl)amine, or 2-chloro-4-phenyl-*s*-triazin-2-yl-2′,4′-dichloro-*s*-triazin-2′-ylamine with nucleophilic reagents. The reaction of *N,N,N*-tris(4,6-dichloro-*s*-triazin-2-yl)amine with sodium methoxide was also examined. In this case, various products were obtained, depending upon the amount of sodium methoxide used. A Hammett plot of the substituent constants($\sum \sigma_m$) *vs.* the pK_a' or the imino proton shifts of the above-mentioned ditriazinylamines gives a linear relationship.

In a previous paper[1] we reported that ammonia or amines react with cyanuric chloride to give *N,N*-bis(4,6-dichloro-*s*-triazin-2-yl)amines (II) or *N,N,N*-tris(4,6-dichloro-*s*-triazin-2-yl)amine (III).



(I)

(II) (III)

R=H, Alkyl, Aryl

The active chlorine atoms of these polytriazinylamines were replaced by nucleophilic reagents much more readily than those of amino-chloro-*s*-triazines, such as I.

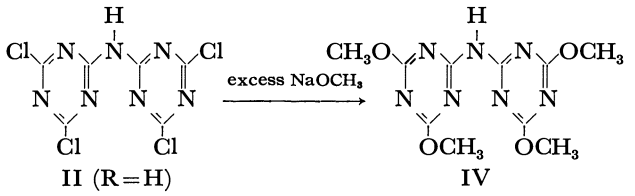
In addition, it was found that the *N,N*-bis(*s*-triazinyl)-amines which have been derived from I (R=H) with the replacement of the chlorine atoms behave as an acid in the presence of two triazinyl groups and that their acidities depend upon the natures of the substituents in the triazine rings.

The substituent effects in nitrogen heteroaromatic compounds have been extensively studied. For example, the Hammett equation is found to be applicable to the derivatives of the pyridine or pyrimidine series by using the substituent constants of benzene series.[2,3] However, the substituent constants applicable to triazine derivatives have not been studied systematically. Thus, with the derivatives of the *s*-triazine series substituent effects have been studied only qualitatively. Recently, the Hammett equation was observed to be applicable to the basicities of ring-nitrogen atoms of 6-substituted-2,4-diamino-*s*-triazines.[4,5] However, there have been no studies of the application of the Hammett equation to the reactions of side chains of triazine rings.

This paper will report on the nucleophilic substitution reactions of II or III, and the substituent effect on the pK_a or chemical shift of the imino protons of *N,N*-bis(*s*-triazinyl)amines.

Results and Discussion

I. Reaction of N,N-*Bis(4,6-dichloro*-s-*triazin-2-yl)amines (II) or* N,N,N-*Tris(4,6-dichloro*-s-*triazin-2-yl)amine (III) with Nucleophilic Reagents.* The reactivities of active chlorine atoms of polytriazinylamines towards nucleophilic reagents were found to be higher than those of amino-chloro-*s*-triazines (I). This is apparently a result of the larger positive charge of the carbon of *s*-triazine rings caused by two or three *s*-triazinyl groups on the same nitrogen atom. Thus, with excess amines, alcohols, mercaptans or thiophenols, II or III reacted to give replaced products, which were derived with the replacement of all the active chlorine atoms in II or III, even at room temperature, while amino-dichloro-*s*-triazines (I) reacted to give only partially-replaced products. The reaction of *N,N*-bis(4,6-dichloro-*s*-triazin-2-yl)aniline (II, R=phenyl) with primary or secondary amines gave only replaced products, but in the reaction of II (R=phenyl) or III with sodium methoxide, various products were obtained, depending upon the amount of sodium methoxide used. With excess sodium methoxide not only were the active chlorine atoms replaced, but also the cleavage of the triazinyl group was observed, even at room temperature, however, the reaction of II (R=H) with excess sodium methoxide gave only the replaced product IV.



II (R=H) IV

This is probably due to the fact that IV reacts with sodium methoxide to give an anion in which the elec-

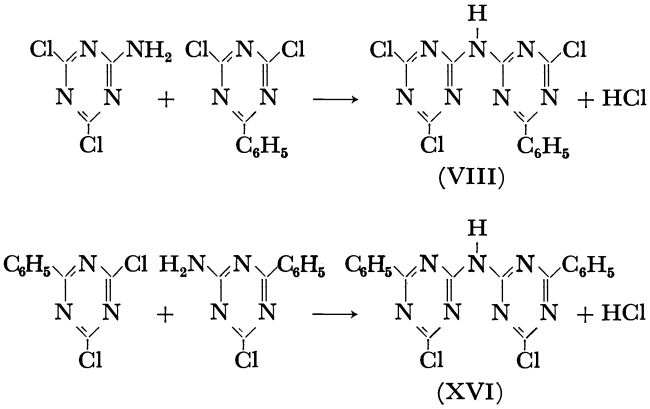
tron densities of the 2,2'-carbons of triazinyl groups are too high for them to be attacked by a methoxide anion.

II. Substituent Effects on the pK_a' Values of Ditriazinylamines. Most of the ditriazinylamines with the general formula shown in Table 1 were synthesized from I by the nucleophilic substitution described in the preceding paragraph. The ditriazinylamine (VIII) was obtained by the condensation between 2,4-dichloro-6-phenyl-*s*-triazine and 2-amino-4,6-dichloro-*s*-triazine, the compound IX, by the nucleophilic substitution of the active chlorine atoms of VIII, and the compound XVI by the condensation between 2,4-dichloro-6-phenyl-*s*-triazine and 2-amino-4-chloro-6-phenyl-*s*-triazine.



Most of these triazinyl derivatives were found to dissolve in a sodium hydroxide solution, with the simultaneous formation of the corresponding anions which have absorption bands in the region with wavelength longer than those of the original compounds. Thus, the pK_a' values of these compounds can be measured spectrophotometrically. As the measurement is carried out in a mixed solvent of water and methyl cellosolve, we will describe pK_a' instead of pK_a.[6]

However, in the cases of derivatives (VIII, XI, and XVI), the spectrophotometrical measurement of the pK_a' values was found to be impossible because of their non-solubilities in a sodium hydroxide solution or because of the ready hydrolyses of their active chlorine atoms in an aqueous solution. Table 2 lists the pK_a' values measured in a mixed solvent of methyl cellosolve and water (70/30) at 25°C. As the pK_a' values thus obtained resulted from the summation of the four substituent effects ($\sum\sigma_m$), and as the positions of the substituents correspond to the meta position of benzene derivatives, Table 2 also lists the summation of σ_m.

From these results, it is apparent that the more electron-attractive the substituent becomes, the more the acidity increases. A Hammett plot of pK_a' against $\sum\sigma_m$ is shown in Fig. 1. The ρ value calculated by the method of least squares is −4.12, with a correlation coefficient of 0.956.

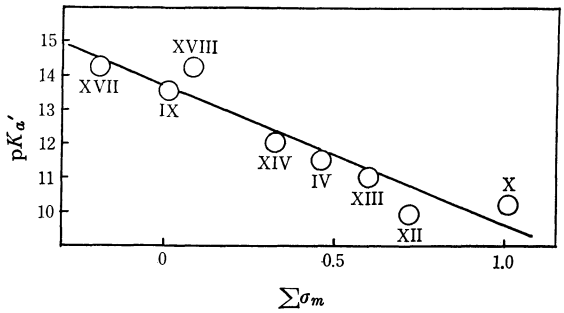


Fig. 1. Relation between pK_a' of substituted ditriazinylamines and $\sum\sigma_m$ (ρ, −4.09; r, 0.956).
The figures near the circles are the same as ones in Table 2.

From this result, it is obvious that, as a whole, the Hammett σ_m values of the benzene series are applicable to the derivatives of the triazine series.

III. Substituent Effect on Imino-proton Shifts of Ditriazinylamines. As has been mentioned in the preceding paragraph, a regular correlation was observed between pK_a' and σ_m for the dissociation of the derivatives of ditriazinylamine.

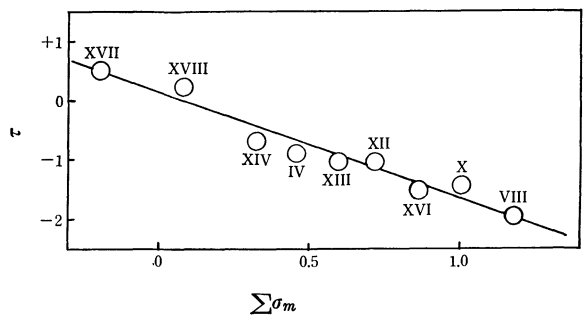

Fig. 2. Relation between imino-proton shifts of substituted ditriazinylamines and $\sum\sigma_m$ (ρ,−1.76; r, 0.977).
The figures near the circles are the same as ones in Table 3.

The references a, b, and c are the same as ones in the footnote of Table 2.

In recent papers,[7,8] correlations have been noted between Hammett's σ constants and the chemical shifts of hydroxyl protons in *m*- and *p*-substituted phenols and amino protons in *m*- and *p*-substituted anilines. Consequently, a similar relation might also be expected between the chemical shifts of the imino protons of ditriazinylamines and the σ constants of substituents in the triazine rings.

Table 3 lists the imino-proton shifts of substituted ditriazinylamines, using DMSO-d_6 as a solvent at 25°C. In this solvent the positions of these signals do not shift with any variation in the concentration. A Hammett plot of imino proton shifts against $\sum\sigma_m$ is shown in Fig. 2. The ρ value was found to be 1.76, with a correlation coefficient of 0.977. From these results, it is apparent that, in the triazine derivatives, the electronic effects of the substituents are transmitted to the reaction site effectively and that, as a whole, Hammett's σ_m is also applicable to these polytriazinylamines.

Experimental

The infrared spectra were measured in potassium bromide discs on a Jasco D-301 spectrophotometer. The ultraviolet spectra were recorded on a Hitachi-124 UV-VIS spectrophotometer. The NMR spectra were recorded on a Varian A-60D spectrometer. The elemental analyses were performed in the Micro-analytical Center of the University of Gunma. All the K_a' values were determined spectrophotometrically in a mixed solvent of methyl cellosolve and water (70/30), (volume ratio), according to the method of Albert and serjeant.[9]

N,N-*Bis(4,6-dichloro-s-triazin-2-yl)amine (II, R=H).* The compound II (R=H) was prepared by the method

described in a previous paper.[1]

N,N-*Bis(4,6-dimethoxy-*s*-triazin-2-yl)amine (IV).* A solution of 2.3 g (0.1 mol) of sodium in 50 m*l* of methanol was added, at room temperature, to a soltion of 6.3 g (0.02 mol) of II (R=H) in 250 m*l* of methanol. After refluxing for 6 hr, the mixture was poured into 500 m*l* of ice-water neutralized with hydrochloric acid, filtered, and dried.

N,N,N-*Tris(4,6-dimethoxy-*s*-triazin-2-yl)amine (VII).* To a stirred solution of 1.0 g (0.0022 mol) of III, which is the condensation product between II (R=H) and cyanuric chloride,[1] in 30 m*l* of methanol, we added drop by drop and at room temperature, a solution of 0.3 g (0.013 mol) of sodium in 20 m*l* of methanol. After an additional 4 hr's stirring at 35—40°C, the methanol was distilled off under reduced pressure. The recrystallization of the residue from benzene yielded 0.70 g (74%) of VII; mp 206—206.5°C.

Found: C, 41.49; H, 4.14%. Calcd for $C_{15}H_{18}N_{10}O_6$; C, 41.48; H, 4.18%.

*4-Chloro-6-phenyl-*s*-triazin-2-yl-4',6'-dichloro-*s*-triazin-2'-ylamine (VIII).* To a stirred solution of 1.7 g (0.01 mol) of 2-amino-4,6-dichloro-*s*-triazine and 2.3 g (0.01 mol) of 2,4-dichloro-6-phenyl-*s*-triazine in 150 m*l* of acetone, we added, drop by drop and below 5°C, a solution of 0.4 g (0.01 mol) of sodium hydroxide in 4 m*l* of water. After an additional one hr's stirring, the mixture was poured into 500 m*l* of ice water and filtered. The filtrate was acidified with hydrochloric acid. The precipitate thus formed was filtered and dried.

*4-Dimethylamino-6-phenyl-*s*-triazin-2-yl-4'-chloro-6'-dimethylamino-*s*-triazin-2'-ylamine (IX).* Into a solution of 3.6 g (0.01 mol) of VIII in 150 m*l* of acetone, we stirred drop by drop and below 10°C, 4.6 m*l* (0.04 mol) of a 40% aqueous dimethylamine solution. After an additional 3 hr's stirring, the mixture was poured into 500 m*l* of ice water, the precipitate thus formed was filtered and dried.

In the reaction of VIII with dimethylamine, it is expected from a comparison of the σ_m values for the phenyl, chlorine, and dimethylamino substituents that, first, one of the chlorine atoms of the dichloro-*s*-triazinyl group of VIII and then chlorine atom of the chlorophenyl-*s*-triazinyl group, may be replaced by dimethylamino groups. Therefore, the main product of the above-mentioned reaction was assumed to be 4-dimethylamino-6-phenyl-*s*-triazin-2-yl-4'-chloro-6'-dimethylamino-*s*-triazin-2'-ylamine (IX).

N,N-*Bis(4,6-diphenoxy-*s*-triazin-2-yl)amine (X).* A solution of 4.0 g (0.1 mol) of sodium hydroxide in 40 m*l* of water was added, at room temperature, to a solution of 6.3 g (0.02 mol) of II (R=H) and 9.4 g (0.1 mol) of phenol in 200 m*l* of benzene. After 3 hr's stirring, the mixture was refluxed for 3 hr. The benzene layer was separated and dried over calcium chloride. Then, the benzene was distilled off under reduced pressure, and the residue was collected.

The compound XI, XII and XIII were prepared in a similar manner by the reaction of II (R=H) with aniline thiophenol, and methyl mercaptan respectively.

N,N-*Bis(4-chloro-6-dimethylamino-*s*-triazin-2-yl)amine (XIV).* Into 200 m*l* of acetone containing 3.2 g (0.01 mol) of II (R=H), we stirred, drop by drop and below 5°C, 4.5 g (0.04 mol) of a 40% dimethylamine solution. After an additional 3 hr's stirring, the mixture was poured into 300 m*l* of ice-water, filtered, and dried. The compound XV was prepared in a similar manner by the reaction of II (R=H) with diethylamine.

N,N-*Bis(4-chloro-6-phenyl-*s*-triazin-2-yl)amine (XVI).* To a stirred solution of 150 m*l* of acetone containing 2.3 g (0.01 mol) of 2,4-dichloro-6-phenyl-*s*-triazine and 2.5 g (0.012 mol) of 2-amino-4-chloro-6-phenyl-*s*-triazine, we added drop by drop and below 5°C, a solution of 0.4 g (0.01 mol) of sodium hydroxide in 4 m*l* of water. After an additional 5 hr's stirring, the mixture was poured into 1 *l* of ice-water, made alkaline with sodium hydroxide, and filtered. The filtrate was acidified with hydrochloric acid. The precipitate thus obtained was filtered and dried.

N,N-*Bis(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)amine (XVII).* To a solution of 3.8 g (0.01 mol) of XIV in 150 m*l* of methanol, we added, at room temperature, a solution of 0.7 g (0.03 mol) of sodium in 30 m*l* of methanol. After the mixture had been refluxed for 3 hr, the methanol was distilled off under reduced pressure and the resulting residue was collected.

N,N-*Bis(4-dimethylamino-6-phenoxy-*s*-triazin-2-yl)amine (XVIII).* Into a solution of 3.3 g (0.01 mol) of XIV and 1.9 g (0.02 mol) of phenol in 100 m*l* of dioxane, we stirred, at room temperature, 10 m*l* of an alkaline solution containing 1.0 g (0.025 mol) of sodium hydroxide. After heating at 70—80°C for 3 hr, the mixture was poured into 300 m*l* of ice-water, filtered, and dried.

Reaction of N,N-*Bis(4,6-dichloro-*s*-triazin-2-yl)aniline (II, R=Ph) with Excess Sodium Methoxide.* A solution of 1.8 g (0.08 mol) of sodium in 50 m*l* of methanol was added, at room temperature, to a solution of 3.8 g 0.01 mol) of II (R=Ph) in 50 m*l* of methanol. The mixture was stirred at 35°C for 6 hr. Then the mixture was poured into 1 *l* of ice-water, and neutralized with hydrochloric acid. The precipitate thus formed was separated by filtration and dried. Recrystallization from ligroin yielded 1.7 g (57%), mp 133—134°C, which was found to be identical with that of an authentic sample of V by a mixed-melting-point test. After the filtrate had been extracted with benzene, the benzene layer was dried over calcium chloride. The residue obtained after distilling off the benzene was recrystallized from ligroin to give 0.9 g (66 %) of a pure material; mp 133—134°C, which was found to be identical with that of an authentic sample of trimethyl cyanurate by a mixed-melting-point test.

Reaction of N,N,N-*Tris(4,6-dichloro-*s*-triazin-2-yl)amine (III) with Excess Sodium Methoxide.* A solution of 1.0 g (0.002 mol) of III and 0.35 g (0.015 mol) of sodium in 50 m*l* of

methanol was stirred at 35—40°C for 4 hr. Then the mixture was poured into 200 m*l* of ice water. After this aqueous solution had been extracted with benzene and drying over calcium chloride, the benzene was distilled off. The residue was recrystallized from benzene. Yield, 0.4 g (68%); mp 185—186°C. By a mixed-melting-point test, this compound was proved to be IV. After the benzene had been distilled off from the filtrate, the residue was recrystallized from ligroin. Yield, 0.2 g (69%); mp 132—134°C. By a mixed-melting-point test, this compound was proved to be VI.

Studies on Cobaloxime Compounds. III. Effects of Various Cobaloximes as Vitamin B_{12} Models and of Substrate Analogs on Diol Dehydratase System

Yorikatsu HOHOKABE and Noboru YAMAZAKI

Department of Polymer Science, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 14, 1970)

Various types of cobaloximes with the general formula $[CoX(DH)_2B]$ or $[RCo(DH)_2B]$ (X: Cl, CN. R: alkyl groups such as methyl, ethyl, *n*-propyl, or *i*-propyl. DH: dimethylglyoximato monoanion. B: bases such as water, pyridine, nicotinamide, *γ*-picoline, *p*-toluidine, or imidazole) and some amide compounds were examined for the inhibitory effect or coenzyme activity in propanediol dehydratase of *Aerobacter aerogenes*. None of them act as coenzyme nor inhibitor, except for cyanoaquocobaloxime, which shows only a weak inhibitory effect that has been proved to be non-competitive. Water-soluble polymeric cobaloximes with the general formula [Co(OH) $(DH)_2$(Copoly–AM-VPy)] (Copoly–AM-VPy: a low molecular weight copolymer of acrylamide and 4-vinylpyridine) were also prepared and examined in the enzymatic system whose inhibitory effects were very small. Other cobaloximes with the general formula $[RCo(DH)_2(py)]$ (R: *β*-hydroxy-*n*-propyl, *β*-hydroxy-*i*-propyl, or *β*,*γ*-dihydroxy-*n*-propyl. py: pyridine) which were three of the possible intermediate models in propanediol dehydratase system, also showed little effect on the enzymatic reaction. Substrate anologs such as 2-bromo-1-propanol, 1-bromo-2-propanol, and glycerol *α*-monochlorohydrin, which are considered to interact with a nucleophilic Co(I) species, presumably a component of the active site in the holoenzyme, were found to serve as substrate.

Although many works have been done on vitamin B_{12} compounds, there are not many on the active sites in holoenzyme in which coenzyme B_{12} and substrate are assumed to be bound to apoenzyme. In the case of L-methylmalonyl-CoA mutase from sheep liver, it was assumed that holoenzyme formation involves at least a two-point attachment between the coenzyme and apoenzyme and that sulfhydryl groups are one binding site of the protein.[1] In ribonucleotide reductase from *L. leichmannii*, 5′-deoxyadenosylcobalamin with a slight alteration of *e*-propionamide group to *e*-propionic acid on the corrin ring showed neither activity nor inhibitory effect.[2] In propanediol dehydratase system, the analogs with two or three propionic acid side-chains on the corrin ring did not serve as the coenzyme, while all the three isomers of one propionic acid side-chain (at *b*, *d*, or *e* position on the corrin ring) were effective.[3]

We considered that for the appearance of the coenzyme activity in enzymatic reactions, there might be some amide groups in the neighborhood of the Co atom, since these groups in cobalamin might take part in the reactions *in vivo*, probably as binding sites to apoenzyme.[4] We have therefore studied the effect of cobaloximes having a ligand with amide groups. The resemblance of cobaloxime compounds to cobalamin compounds in chemical behavior has also been described elsewhere.[5–8]

There are a few examples dealing with the cobaloximes as the vitamin B_{12} model in biological systems. Some cobaloximes were examined in blockade of vitamin B_{12}-binding sites in gastric juice, serum, and saliva,[9] and some methylcobaloximes were demonstrated to be able to make methane in enzymatic reaction containing the extracts from *Methanobacillus omelianskii*.[10]

We have also studied the effect of various cobaloximes on propanediol dehydratase system. Among them, hydroxypropyl derivatives might be considered as model compounds for the possible intermediates in the enzymatic reaction. At present the following hypothesis seems to be acceptable: It is necessary for the appearance of coenzyme activity that Co–5′-deoxyadenosyl

bond in DBCC bound to apoenzyme is heterolytically cleaved, producing enzyme-bound Co(I) species. Thus, the electrophilic substrate analogs such as propylene bromohydrin are considered to have the ability to interact with the Co(I) species and serve as substrate. The results are given in the following.

Experimental

Materials. Preparative methods of various cobaloximes were reported.[11]

Imidazole-4,5-dicarboxyamide was prepared according to the method described by Baxter and Spring.[12]

Found: C, 38.47; H, 3.98; N, 36.44%. Calcd for $C_5H_6N_4O_2$: C, 38.96; H, 3.92; N, 36.35%.

2-Bromo-1-propanol was synthesized as follows: $LiAlH_4$ 5.32 g was refluxed for 3 hr in 300 m*l* of dry ether. α-Bromopropionyl bromide 43.2 g was added slowly to the mixture at 0°C for an hour followed by stirring for 2 hr. After adding 15 m*l* of H_2O and 130 m*l* of 3N H_2SO_4 to the mixture, the upper ether layer was separated. The remaining water layer was extracted with isopropyl ether, and the extract was combined with the ether layer. After drying the ether solution with Na_2SO_4, the product was fractionally distilled under a reduced pressure (bp 71°C/33 mmHg). The yield was 17.6 g (64%). The structure was confirmed by NMR and IR spectra.

Found: C, 26.85; H, 5.23; Br, 57.77%. Calcd for C_3H_7OBr: C, 25.93; H, 5.08; Br, 57.49%.

Propylene bromohydrin (commercial E. P. reagent) was a mixture of 1-bromo-2-propanol (79%) and 2-bromo-1-propanol (21%). Its composition was determined by NMR and gas chromatography, and used without further purification, because it was impossible to fractionate it by the usual fractional distillation.

5,6-Dimethylbenzimidazolylcobamide coenzyme (DBCC) was supplied by Prof. S. Fukui and Eisai Co., and propanediol dehydratase (EC. 4.2.1.28) was generously given by Prof. S. Fukui.

All other reagents were of commercial G. R. grade.

Methods. *General Method for the Enzymatic Reaction*: The enzymatic reaction was carried out in the dark. DBCC and cobaloxime or amide were mixed prior to the addition of the apoenzyme solution. A typical method is as follows: 0.1 m*l* of 0.5M KCl, and 0.2 m*l* of cobaloxime or amide solution were pipetted into an assay tube. 0.1 m*l* of DBCC solution was then added in the dark and after being cooled in an ice bath, 0.5 m*l* of cold apoenzyme solution in potassium phosphate buffer (pH 8.0) was added. The reaction was conducted for 5, and 10 min at 37°C in the dark. The mixture was then rapidly cooled in an ice bath and 0.5 m*l* of 10% trichloroacetic acid was immediately added to the mixure to stop the reaction.

In the Case of Hydroxypropylcobaloximes: The reaction was carried out for 10 min at 25°C, aerobically or anaerobically after the following treatment. A 100 W tungsten lamp was used as the light source at a distance of 4 cm.

(1) (Dark-Aerobic): A mixture of DBCC, cobaloxime, and apoenzyme was preincubated for 7 min at 25° in the dark prior to the addition of the substrate. The treatment was done in the presence of air.

(2) (Dark-Anaerobic): The same treatment as (1) but under a nitrogen atmosphere.

(3) (Light-Aerobic): A mixture of DBCC, cobaloxime, and apoenzyme was preincubated for 2 min at 25°, followed by irradiation for 5 min at 25°C prior to the addition of the substrate. The treatment was done in the presence of air.

(4) (Light-Anaerobic): The same treatment as (3) but under a nitrogen atmosphere.

In the Case of Substrate Analogs: The reaction was carried out for 2, 3.5, 7.5 (or 8), and 10 min at 25°C in the dark.

Determination of Propionaldehyde: One milliliter of 5 mM 2,4-dinitrophenylhydrazine in methanol containing a small amount of concd. HCl was added to each reaction mixture which was put to stand for 10 min at 37°C. Three milliliters of 80% aqueous pyridine were then added. The amount of hydrazone formed from propionaldehyde was colorimetrically determined at 540 mμ, 20 min or 40 min after the addition of 0.5 m*l* of alcoholic KOH (0.1 g/m*l* of 80% aqueous methanol), with a Hitachi photoelectric spectrophotometer. The absorbance was corrected by using the control solution as a reference, which is the mixture stopped immediately after the addition of apoenzyme solution. Unity of absorbance at 540 mμ, 20 min or 40 min after the addition of KOH corresponds to 0.92 and 1.09 μmol of propionaldehyde in 1 m*l* of the original reaction mixture, respectively.

The velocity was determined with the slope of the straight line passing through the time-conversion plots. The relative activity was determined as follows.

$$\text{Relative activity} = \frac{\text{Amount of aldehyde formed in the presence of additive (inhibitor)}}{\text{Amount of aldehyde formed in the absence of additive (inhibitor)}} \times 100\,(\%).$$

Results and Discussion

Polymeric Cobaloximes, Co(OH)(DH)$_2$(Copoly-AM-VPy). The enzymatic reaction was carried out in the presence of various amounts of polymeric cobaloximes in which

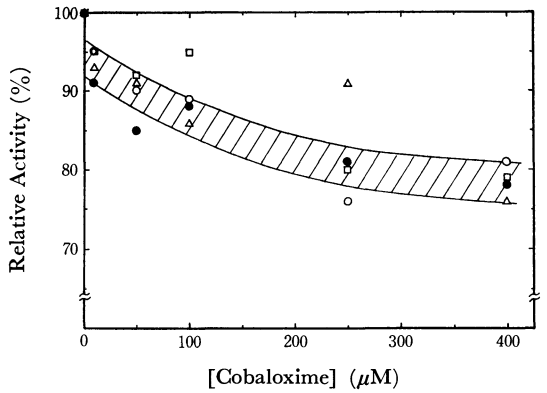

Fig. 1. Relative activity *vs.* concentration of polymeric cobaloxime plots.
The reaction mixture contained 1,2-propanediol 10 μmol, potassium chloride 50 μmol, DBCC 1.5 mμmol, apoenzyme 0.08 unit, potassium phosphate buffer (pH 8.0) 25 μmol, and polymeric cobaloxime (○ HC 025; □ HC 027; ● HC 029; △ HC 030) 0, 10, 50, 100, 250, or 400 mμmol; total volume 1.0 m*l*. The reaction was carried out for 10 min at 37°C in the dark. The average molecular weights of polymeric ligands and AM(acrylamide)/VPy(4-vinylpyridine) ratios are 3000 and 11.9 for HC 025, 2400 and 12.8 for HC 029, 1400 and 13.7 for HC027, 830 and 17.5 for HC030, respectively.

12) R. A. Baxter and F. S. Spring, *J. Chem. Soc.*, **1945**, 232.

Copoly–AM-VPy[13] coordinates with the Co atom through a pyridine residue and the amide groups are close to the cobaloxime moiety. The results are shown in Fig. 1. Although the relative activities with respect to polymeric cobaloximes decreased with the increase of the amount of cobaloximes, they decreased to *ca.* 80% even at the higher concentration of cobaloximes, and no difference in decrease with respect to the molecular weights of polymers was observed. This suggests that the polymeric cobaloximes employed in this experiment were not sufficiently small to interact with the active site in the enzyme, though their molecular weights are nearly the same as that of coenzyme B_{12} or larger only by a factor less than 2.5. This type of cobaloximes does not seem to interact with the active site in the holoenzyme.

TABLE 1. RELATIVE ACTIVITIES IN THE PRESENCE OF SOME AMIDES.

The reaction mixture contained 1,2-propanediol 10 μmol, potassium chloride 50 μmol, DBCC 1.5 mμmol, apoenzyme 0.10 unit, potassium phosphate buffer (pH 8.0) 25 μmol, and amide 250 mμmol; total volume 1.0 m*l*. The reaction was carried out for 10 min at 37°C in the dark.

Benzamide	95
Propionamide	103
Imidazole-4,5-dicarboxyamide[a)]	101

a) nearly insoluble.

Amides. From the viewpoint in the introductory, *i. e.*, some amide groups in cobalamin may take part in the reactions *in vivo*, perhaps as the binding sites to the apoenzyme, the presence of amides is expected to affect the enzymatic reaction. The results of some amides are shown in Table 1. The activity was affected slightly or not at all by the presence of amide. From the results, we see that monoamide is not bound tightly to the site because of weakeness of the hydrogen bonding. The multiple-point attachment of the amide groups in a molecule may favor the single-point attachment by the increase in total entropy and decrease in total energy by each hydrogen bonding. One of the diamide, imidazole-4,5-dicarboxyamide, however, failed to affect the active site, probably because of insolubility. It seems that some amide groups situated at an appropriate distance from each other and the cobaloxime moiety might interact with the active site.

The enzymatic reaction was also carried out in the presence of various monomeric cobaloximes.

Chloro- and Simple Alkyl-cobaloximes. All the chloro- or simple alkyl-cobaloximes were found to exert little effect on the enzymatic reaction: They include $CoCl(DH)_2B$ in which B is water, nicotinamide, pyridine, imidazole, γ-picoline, or *p*-toluidine, $CH_3Co(DH)_2B$ in which B is water, nicotinamide, pyridine, or imidazole, and $RCo(DH)_2B$ in which R is methyl, ethyl, *n*-propyl, or *i*-propyl, and B water or pyridine.

13) Copoly–AM-VPy is a low molecular weight copolymer of acrylamide (AM) and 4-vinylpyridine (VPy).

TABLE 2. RELATIVE ACTIVITIES IN THE PRESENCE OF CYANOCOBALOXIMES.

The reaction mixture contained 1,2-propanediol 10 μmol, potassium chloride 50 μmol, DBCC 1.5 mμmol, cobaloxime 250 mμmol, apoenzyme 0.083 unit (0.69 unit/mg-protein), potassium phosphate buffer (pH 8.0) 25 μmol; total volume 1.0 m*l*. The reaction was carried out for 5, or 10 min at 37°C in the dark.

Co(CN)$(DH)_2$(py)	90
Co(CN)$(DH)_2$(pico)	98
Co(CN)$(DH)_2$(tolu)	105

a) py: pyridine, pico: γ-picoline, tolu: *p*-toluidine.

Cyanocobaloximes. It is well known that cyanocobalamin is a strong competitive inhibitor in diol dehydratase system and other B_{12}-dependent enzymatic reactions. The effect of cyano cobaloximes was examined in comparison with cyanocobalamin. The results are shown in Table 2. They exerted no inhibition or much less inhibitory effect than cyanocobalamin; only cyanoaquocobaloxime showed a weak inhibition. From an extensive study on cyanoaquocobaloxime, it proved to be non-competitive as shown in Fig. 2. The

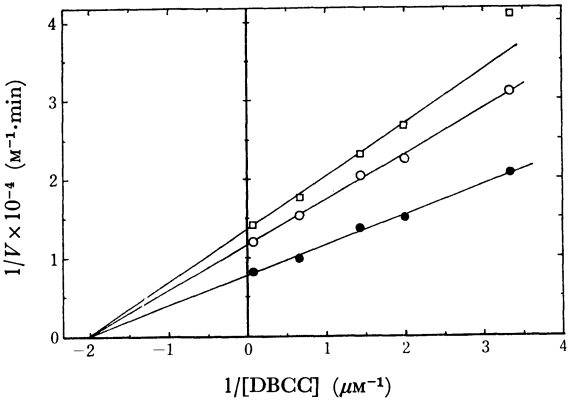

Fig. 2. Non-competitive inhibitory effect of cyanoaquocobaloxime on propanediol dehydratase system.
The reaction conditions are the same as those in Table 2, except that DBCC 0.30, 0.50, 0.70 1.50, or 15.0 mμmol, cyanoaquocobaloxime 0 (●), 200 (○), or 250 (□) mμmol, and apoenzyme 0.14 unit (0.73 unit/mg-protein) were employed.

inhibitor constant K_i was determined to be 3.3 ($\pm$0.1) $\times$ 10^{-4}M. Since the same amount of sodium cyanide exerted much less inhibition, the weak effect of cyanoaquocobaloxime is not considered to be due to free cyanide ion which might be derived from the cobaloxime. It seems that a slight conformational change of the enzyme protein occurs in the presence of the cobaloxime. A most plausible explanation of the effect is as follows. First, CN linked to cobaloxime interacts with

a given site in the protein, second, another axial ligand of the cobaloxime, *i. e.*, H_2O is displaced by a basic group of the enzyme, resulting in a slight conformational change of the tertiary structure of the enzyme.

Hydroxypropylcobaloximes. The preparation and properties of a series of hydroxyalkylcobaloximes have been reported by Schrauzer and Windgassen.[14] The Co–C bonds are readily cleaved; in mildly acidic media olefins are formed. However, in alkaline solution the products are aldehydes, ketones, or the respective aldols arising from the secondary condensation of the aldehydes. They proposed a mechanism for the action of the corrin coenzyme in diol dehydratase of *Aerobacter aerogenes*, in which they supposed that β-hydroxy-*i*-propyl derivative is the most likely organocobamide as the intermediate in glycol dehydratase system. The corresponding cobaloxime was prepared and found to produce propionaldehyde on decomposition in alkaline medium. Its effect on enzymatic reaction seems to be interesting. β,γ-Dihydroxypropylcobalamin exhibited no coenzyme activity, and exerted an inhibitory effect.[15]

Table 3. Relative activities in the presence of hydroxypropylcobaloximes under various conditions.
The reaction mixture contained 1,2-propanediol 10 μmol, potassium chloride 50 μmol, DBCC 15.0 mμmol, cobaloxime 200 mμmol, apoenzyme 0.068 unit (0.20 unit/mg-protein) for the first series of runs, and 0.086 unit (0.49 unit/mg-protein) for the second, potassium phosphate buffer (pH 8.0) 25 μmol; total volume 1.0 m*l*. Other conditions are indicated in the experimental section.
The series of runs were carried out twice and the mean values are indicated in the following table.

Material[a]	Dark		Light	
	Aerobic (1) %	Anaerobic (2) %	Aerobic (3) %	Anaerobic (4) %
None	100	133	56	89
$HOCH_2CH(OH)$-$CH_2Co(DH)_2$(py)	100	94	20	87
$HOCH_2CH(CH_3)$-$Co(DH)_2$(py)	98	119	41	101
$CH_3CH(OH)CH_2$-$Co(DH)_2$(py)	99	121	33	136

a) py: pyridine

Three of the possible intermediate models, *i. e.*, β-hydroxy-*i*-opropyl-, β-hydroxy-*n*-propyl-, and β,γ-dihydroxy-*n*-propyl-(pyridine)cobaloxime, were also synthesized and examined in propanediol dehydratase system. As the alkyl moiety of these cobaloximes are very similar to propanediol in structure, some effect could be expected; cobaloxime may block the substrate-binding site, and/or hydroxypropyl radicals arisen from the light irradiation of the cobaloximes may interact with the active coenzyme. As shown in Table 3, however, they also exerted little effect on the reaction.[16] This suggests that the cobaloximes do not contact with the active site of the holoenzyme.

All the cobaloximes described were unable to interact with the active site. Synthesis of 5′-deoxyadenosylcobaloxime failed in isolation by the usual way as carried out in the partial DBCC preparation, presumably because of its alkali and acid lability, as reported by Schrauzer.[17]

Substrate Analogs. Since it is well established that Co(I) species of cobalamin is a powerful nucleophilic agent,[18] the Co(I) nucleophile seems to play an important role in enzymatic conversion of diol to the corresponding aldehyde. Since propanediol and glycol were found not to react with Co(I) species, propanediol is considered to be activated in some form which is able to react with Co(I). Hence, three analogs, *i. e.*, $CH_3CH(OH)CH_2Br$, $CH_3CHBrCH_2OH$, and $HOCH_2CH(OH)CH_2Cl$, which are structurally similar to $CH_3CH(OH)CH_2OH$, are considered to be able to serve as a substrate or an accelerator.

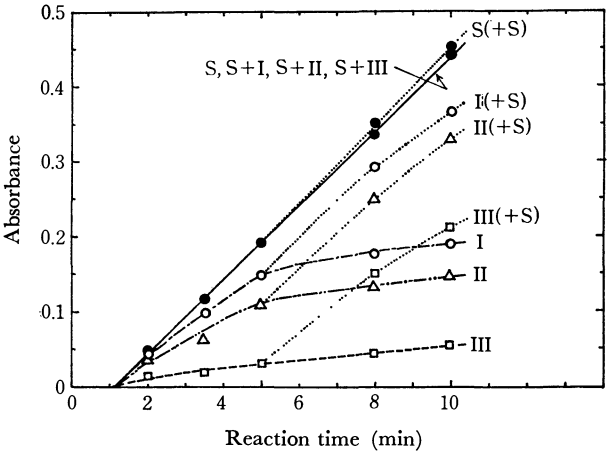

Fig. 3. Effect of substrate anologs on propanediol dehydratase system.
The reaction mixture contained I, II, III, and/or S 10 μmol, potassium chloride 50 μmol, DBCC 15.0 mμmol, apoenzyme 0.10 unit (0.61 unit/mg-protein), potassium phosphate buffer (pH 8.0) 25 μmol; total volume 1.0 or 1.1 m*l*. The reaction was carried out for 2, 3.5, 5, 8, or 10 min at 25°C in the dark. S (—●—), I (-·-○-·-), II (-···-△-···-), or III (—□—) represents the reaction in the presence of S, I, II, or III, respectively. S+I (—●—), S+II (—●—), or S+III (—●—) represents the reaction in the co-existence of S and I, S and II, or S and III, respectively. Since the reaction with S+I, S+II, or S+III proceeded in the same way as that with S, they are shown in the same line. S (+S) (···●···), I (+S) (···○···), II (+S) (···△···), or III (+S) (···□···) represents the reaction with the additional 10 μmol 1 of S during the reaction in the presence of S, I, II, or III, respectively. Unity of absorbance corresponds to 1.09 μmol of propionaldehyde. Notations on S, I, II, and III are described in the text.

16) The enzymatic reaction was carried out at 25°C, lower than the usual 37°C, in order to minimize the inactivation of holoenzyme by incubation prior to the addition of the substrate. The holoenzyme is known to be inactivated by oxygen in the absence of the substrate.
17) G. N. Schrauzer and J. W. Sibert, *J. Amer. Chem. Soc.*, **92**, 1022 (1970).
18) G. N. Schrauzer and E. Deutsch, *ibid.*, **91**, 3341 (1969).

The following abbreviations will be used for the sake of convenience. S; 1,2-propanediol, I; propylene bromohydrin [a mixture of 1-bromo-2-propanol (79%) and 2-bromo-1-propanol (21%)], II; 2-bromo-1-propanol, III; glycerol α-monochlorohydrin.

When 10 μmol of I, II, or III was added to 10 μmol of S which was considered appropriate to give a maximum velocity V_{max}, the enzymatic reaction proceeded just the same as that in the absence of I, II, or III. I, II, or III did not inhibit the enzymatic reaction. However, they seemed to serve as substrates shown in Fig. 3; even in the absence of S, the velocity of the reaction with I or II was comparable to that with S in the initial stage of the reaction, while that with III was observed to be measurable but much less. I, II, or III is considered to interact with the same site as a normal substrate; the initial velocity of S+I, S+II or S+III would be larger than that of S which gives the V_{max}, if I, II, or III reacted with another site of the enzyme other than the normal substrate-binding site. At low concentration of S not enough to give V_{max}, addition of I or II increased the reaction velocity (Fig. 4), which supports the idea that I and/or II serve as a substrate. However, the active site in the presence of I, II, or III without S was soon inactivated as shown in Fig. 3. When such reactions were carried out anaerobically, the time-course was observed to be the same as that in aerobic conditions. It appears that inactivation is not caused by oxygen, whereas the holoenzyme is known to be inactivated by oxygen in the absence of the substrate.

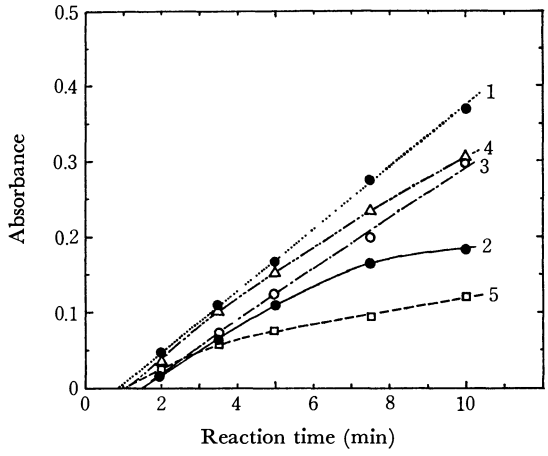

Fig. 4. Effect of substrate analogs on the propanediol dehydratase reaction in the presence of low concentration of the substrate.

The reaction mixture contained S 10 μmol (1; ···●···), S 0.15 μmol (2; —●—), S 0.15 μmol + I 10 μmol (3; -·-○-·-), S 0.15 μmol + II 10 μmol (4; -···△···-), or S 0.15 μmol+III 10 μmol (5;--□--), potassium chloride 50 μmol, DBCC 15.0 mμmol, apoenzyme 0.080 unit (0.70 unit/mg-protein), potassium phosphate buffer (pH 8.0) 25 μmol; total volume 1.0 ml. The reaction was carried out for 2, 3.5, 5, 7.5, or 10 min 25°C in the dark. Unity of absorbance corresponds to 1.09 μmol of propionaldehyde.

When 10 μmol of S was added during the course of the reaction (5 min after the initiation of the reaction) to the reaction mixture with I, II, or III in the absence of S, the expected inactivation was not observed, but the reaction proceeded with almost the same velocity as that with S which gives V_{max} (Fig. 3). This clearly indicates that the active site is temporarily blocked by some materials, and not completely inactivated in the absence of the substrate. Taking into consideration the fact that the holoenzyme initially gave the product(s) from I, II, or III but was gradually inactivated during the course of the reaction, we could consider that the temporary inactivation was caused by the formation of complex(es) between holoenzyme and the product(s) from I, II, or III. This is plausible, if we assume that the affinity to the holoenzyme decreases in the order S>product(s) from I, II, or III>I, II, or III. In the case of I holoenzyme-I complex is formed in the absence of S, which forms the product. As the amount of the product increases, holoenzyme-product complex is gradually formed, which does not interact with I and gives no more product. When S is added, the holoenzyme-product complex turns into holoenzyme-S complex, again producing the normal product. Since the affinity of S to the holoenzyme is assumed to be greater than that of analogs or product(s), the enzymatic reaction both with S and with I, II, or III proceeds the same as that in the absence of I, II, or III.

The enzymatic reaction is expected to be inhibited by the initial addition of some products estimated to be formed from I, II, or III. When 0.5 μmol of propionaldehyde and/or acetone, which appeared to be enough to block the active site as judged by the amount of the product formed from I, II, or III, were added to the system with I, II, or III, the reaction patterns did not differ from those without the addition of aldehyde and/or acetone. Although the reactions were not inhibited by propionaldehyde or acetone, the hypothesis on blocking the active site by some materials described above might still be reasonable, since other products such as aldols are expected to be produced from I, II, or III. It was recently reported that substrate analogs such as styrene glycol or 1,2-butanediol, protected the holoenzyme against inactivation by oxygen, and by displacement of the analog with the substrate the normal reaction was initiated.[19] Detailed features of the effect of the substrate analogs are not known at present.

We wish to thank Prof. S. Fukui and his coworkers of Kyoto University for kindly supplying the enzyme and giving suggestions.

Studies on Heteroaromaticity. LII.[1] Syntheses and Reactions of α-Acetylenic Ketones Containing Nitrofuran Ring

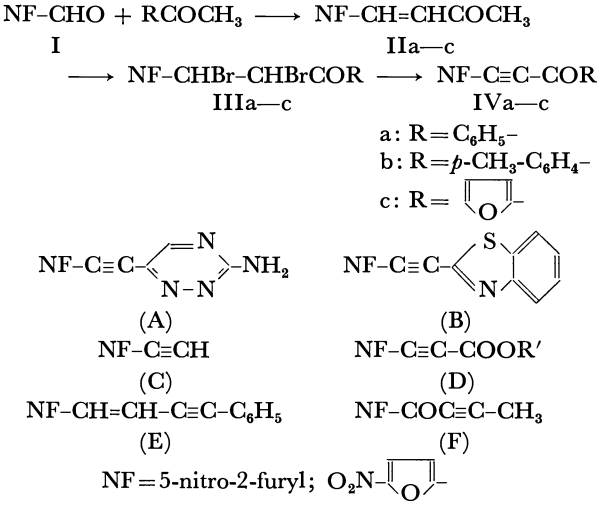
Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received August 14, 1970)

2-(5-Nitro-2-furyl)-1-phenyl- (IVa), -*p*-methylphenyl- (IVb) and -(2-furyl)-acetylene (IVc) were prepared by condensation of nitrofurfural with the corresponding aryl methyl ketones, followed by bromination and dehydrobromination. Addition of aniline and cyclohexylamine to IVa afforded simple adducts Va and VIa respectively. Treatment of IVa,b with hydroxylamine, hydrazine hydrate, semicarbazide and benzamidine gave isoxazoles (VIIIa,b), pyrazoles (VIIIa,b), 1-carbamidopyrazoles (IXa,b) and pyrimidines (Xa,b) respectively. When treated with benzonitrile oxide at room temperature, IVa afforded isoxazole XIa together with furoxan, but the thermal 1,3-dipolar reactions of IVa,b with 5-nitro-2-furocarbonitrile oxide afforded exclusively isoxazoles XIIa,b. For comparison, 5-nitro-2-furfurylidenebenzophenone (IIa) was treated with benzonitrile oxide at room temperature to afford an isomeric mixture of the isoxazolines XIIIa and XIVa together with furoxan. Similar treatment of 5-nitro-2-furfurylideneacetone afforded similar results affording a mixture of XV and XVI together with furoxan. When treated with phenacylpyridinium ylide, IVa,b afforded pyrrocolines XVIIa,b. The structural elucidation of the products was carried out on the basis of the spectral data.

Saikawa *et al.*,[2] Yoshina *et al.*[3] and Sasaki and Shoji[4] reported independently on the preparation of 3-amino-6-[2-(5-nitro-2-furyl)ethynyl]-1,2,4-triazines (A), 2-(5-nitro-2-furyl)ethynylbenzothiazole (B) and 5-nitro-2-furylacetylene (C) and -propiolate (D). Saikachi and Sugimoto presented the synthesis of 3-(5-nitro-2-furoyl)prop-2-yne (E)[5] and Saikachi *et al.* that of 1-phenyl-4-(5-nitro-2-furyl)but-3-ene-1-yne (F),[6] but detailed experimental data have not been published yet. This paper deals with the syntheses of 2-(5-nitro-2-furyl)-1-aroylacetylenes (IV), another type of α-acetylenic nitrofuran, from 5-nitro-2-furfural (I) according to a sequence of the following reactions:



Since these α-acetylenic ketones belong to activated acetylenes,[7] several nucleophilic additions involving the 1,3-dipolar cycloaddition to amines were carried out.

Results and Discussion

Preparation of α-Acetylenic Ketones (IVa—c). In a previous paper,[8] we reported the synthesis and some reactions of the dibromide IIIa, in which we postulated the intermediacy of 2-(5-nitro-2-furyl)-1-benzoylacetylene (IVa) in the preparation of 3-(5-nitro-2-furyl)-5-phenyl-1*H*,2-pyrazole from IIIa and hydrazine hydrate. To verify this assumption, IIIa was treated in benzene with triethylamine at room temperature to afford IVa as expected. Similar treatments were applied to other dibromides IIIb,c and all afforded the corresponding acetylenic ketones IVb,c in good yields. The yields, spectral data and analyses are summarized in Table 1. The presence of a triple bond in IV is demonstrated by the appearance of $\nu_{C\equiv O}$ at 2260—2280 cm^{-1} in the IR spectra and by the hypsochromic shifts of the UV spectra from the corresponding double bonded compounds as observed by a comparison of IVb with IIb (see Experimental). Another IR spectral feature is observed in comparison of $\nu_{C=O}$; $\nu_{C=O}$ in IVb at 1620 cm^{-1} is 45—35 cm^{-1} lower in wave number than the α,β-unsaturated ketones (1675 cm^{-1}) and IIb (1655 cm^{-1}).

Simple Amine Addition. Amines are known to add most easily to the polarized triple bond in α-acetylenic ketones and secondary amines add exclusively *cis* to the acetylenes to give *trans* products in aprotic solvents,[9]

while primary amines do *trans*.[10]

Addition of aniline to IVa was carried out in benzene at room temperature to afford Va; the similarity of its IR and NMR spectral patterns to those of β-benzylamino-5-nitro-2-furfurylidenebenzophenone (G)[8] indicates that both compounds take *cis*-configuration by the *trans*-addition, forming intramolecular hydrogen bonding structure.[10] Since 1-cyclohexyl-2-(*p*-nitrophenyl)-3-benzoylaziridine (H)[11] is prepared from 2,3-dibromo-3-phenyl-*p*-nitropropiophenone and cyclohexylamine, IIIa was treated with cyclohexylamine. However, the product was shown to be not aziridine but β-cyclohexylamino-5-nitro-2-furfurylidenebenzophenone (VIa) by spectral inspection, as in the reaction with aniline.[8] Compound VIa was prepared also by addition of cyclohexylamine to IVa.

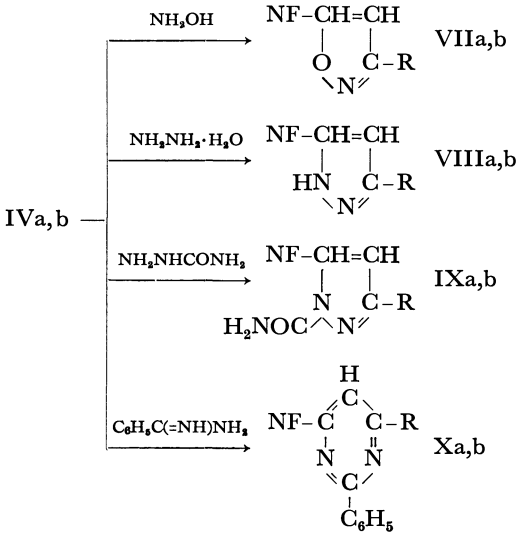
IVa + $C_6H_{11}NH_2$

Heterocyclic Preparation. Acetylenic ketones are good starting materials for synthesizing heterocycles such as isoxazoles and pyrazoles, which have been prepared from hydroxylamine[12] and hydrazine hydrate,[13] respectively. IVa,b were treated with hydroxylamine and hydrazine hydrate to give the expected corresponding isoxazoles (VIIa,b) and pyrazoles (VIIIa, b), respectively. Furthermore, when treated with semicarbazide, IVa,b afforded 1-carbamidopyrazoles (IXa, b) and with benzamidine, IVa,b yielded 2,4,6-trisubstituted pyrimidines (Xa,b), which provide a new method for the preparation of pyrimidines.



The mechanism for the formation of these heterocycles is explained by the initial Michael addition to the triple bond of IV, followed by condensation-cyclization.

1,3-Dipolar Cycloaddition as Dipolarophiles. In spite of abundant information on the cycloaddition of dimethyl acetylenedicarboxylate to several dipoles, there are few reports in literature describing similar reactions of α-acetylenic ketones; they involve the formation of benzo[*b*]furan from 1-phenyl-2-benzoylacetylene and 3,4,5,6-tetrachlorobenzene-2-diazo-1-oxide,[14] of pyrrole from 1-phenyl-2-acylacetylene and *N*-phenyl-*C*-methylsydnone,[15] and of spiroheterocycles from acylacetylene and formamidinium carbodithioates.[16] An example of the Diels-Alder reaction of 1-phenyl-2-acetylacetylene with butadiene has been reported.[17]

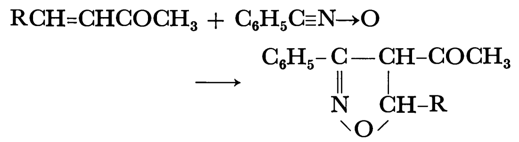
Huisgen[18] and Quilico and Speroni[19] reported isoxazole formation by the 1,3-dipolar cycloaddition of the nitrile oxides with simple acetylenes, but not with α-acetylenic ketones. IVa was therefore treated in benzene at room temperature with benzonitrile oxide prepared '*in situ*' from benzhydroxamoyl chloride and triethylamine. Column chromatography afforded 50% yield of isoxazole (XIa) together with 30% yield of side-produced furoxan. The structure of XIa was tentatively assigned as 3-phenyl-4-benzoyl-5-(5-nitro-2-furyl)-isoxazole in view of the general tendency for the direction of addition occurring at a sterically less hindered position[20] and from consideration of the electron density in IVa.[21] When 5-nitro-2-furocarbonitrile oxide was used instead of benzonitrile oxide under similar conditions, most of IVa was recovered with a small amount of furoxan, but the thermal 1,3-dipolar cycloaddition of IVa,b to the dipole afforded isoxazoles (XIIa,b) with some recovery of IVa,b. For comparison with IVa, the 1,3-dipolar cycloaddition of IIa,b with benzonitrile oxide was carried out, since Quilico[22] reported the synthesis of isoxazoline-4-ketone from α-ethylenic ketones and nitrile oxides:



IIa was treated with benzonitrile oxide in benzene at room temperature. Chromatography afforded two crystalline products, XIIIa and XIVa, together with furoxan and some recovery of IIa. For the sake of comparison, 5-nitro-2-furfurylideneacetone was treated similarly to give also two crystalline products, XV and XVI, together with furoxan and some recovery of the starting material. From our analyses and Quilicos' results,[22] we tentatively assigned 3-phenyl-4-acetyl-5-(5-nitro-2-furyl)isoxazole for the major product XV and 3-phenyl-4-(5-nitro-2-furyl)-4-acetylisoxazole for the minor product XVI, and similarly, 3-phenyl-4-benzoyl-5-(5-nitro-2-furyl)isoxazole for the major product XIIIa and 3-phenyl-4-(5-nitro-2-furyl)-5-benzoylisoxazole for the minor product XIVa. The IR spectra of XIIIa and XIVa resembled each other as did those of XV and XVI.

XIIa, b; XIIIa; XIVa; XV; XVI

For investigating the Diels-Alder reactivity, IVb was treated with butadiene and cyclopentadiene; heating both components in a sealed tube fused with nitrogen at 120°C for 15 hr afforded both intractable tars and with 70% recovery of the starting material in the former reaction.

Another type of 1,3-dipolar cycloaddition reaction has been reported on heterocyclic zwitterions with diethyl acetylenedicarboxylate and ethyl propiolate,[23] and cyanoacetylenes with heterocyclic *N*-ylides and *N*-imines.[24]

Treatment of IVa,b with phenacylpyridinium ylide at room temperature in benzene afforded 73 and 67% yields of XVIIa and XVIIb, respectively. The structural elucidation of XVIIa was carried out in comparison with our previous report.[24] As shown in Fig. 1, quartets centered at 0.40 τ and 1.90 τ are assignable to pyridine ring protons at C_5 and C_8, the lower field shifts being accounted for the anisotropy effect of neighboring carbonyl groups.[24] The higher field shifts of furan ring protons at 3.41 τ and 3.85 τ compared with those of the general nitrofuran derivatives[25] could be explained by the anisotropy effect of the neighboring carbonyls. Thus, the structure of XVIIa was determined as 1-benzoyl-2-(5-nitro-2-furyl)-3-benzoylpyrrocoline.

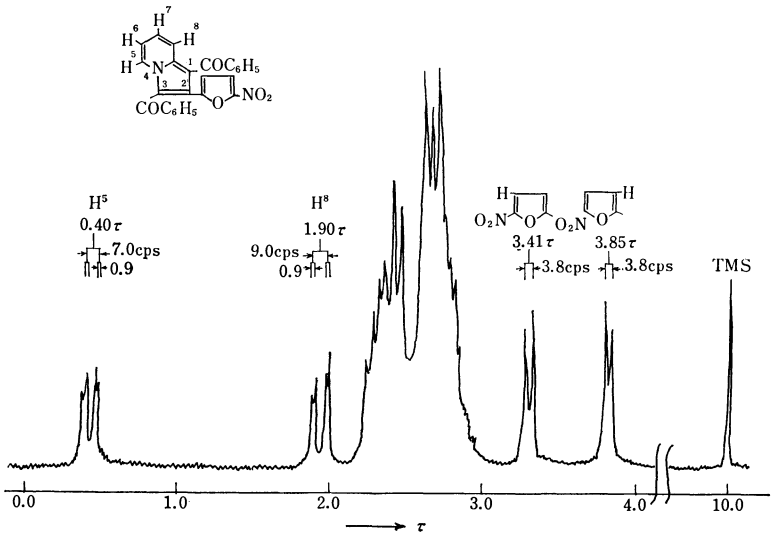

Fig. 1. NMR Spectra of XVIIa.

were performed on a Perkin Elmer 120 elemental analyzer. The NMR spectra were taken with a Jeolco Model JNM-MH-60 NMR spectrometer and with a Varian A-60 recording spectrometer with tetramethylsilane as an internal standard. The chemical shifts are expressed in τ-values. The IR spectra were taken with a JASCO Model IR-S spectrometer and the UV spectra with a JASCO rotary dispersion recorder, Model ORD/UV-5.

Condensation of Nitrofurfural with Aromatic Ketones. Differing from our previous work,[8] concentrated sulfuric acid was used as a condensation reagent as follows: To a solution of 1.4 g (10 mmol) of nitrofurfural and 1.4 g (10 mmol) of *p*-methylacetophenone in 20 m*l* of glacial acetic acid was added 2 m*l* of concentrated sulfuric acid with stirring and the mixture was stirred at 40°C for 1 day. The precipitated crystals were filtered and recrystallized from ethanol to give 1.3 g (45%) of IIb, mp 166—168°C, as pale yellow needles. IR (KBr) cm^{-1}: 1655 (CO) and 1610 (C=C). UV λ_{max}^{EtOH} mμ (ε): 296 (13100) and 348 (23100).

Found: C, 65.14; H, 4.38; N, 5.34%. Calcd for $C_{14}H_{11}O_4N$: C, 65.36; H, 4.31; N, 5.45%.

IIa was prepared similarly in a 50% yield, mp 144°C (lit,[8] 144°C). IIc was prepared by the method of Saikachi and Matsuno.[26]

Preparation of IIIa—c. IIIb,c were prepared similarly to IIIa.[8] IIIb: Yield, 98%, mp 172—174°C. IR (KBr) cm^{-1}: 1680 (CO). UV λ_{max}^{EtOH} mμ (ε): 266 (16100) and 298 (14000).

Found: C, 40.31; H, 2.69; N, 3.18%. Calcd for $C_{14}H_{11}O_4NBr_2$: C, 40.31; H, 2.66; N, 3.36%.

IIIc: Yield, 85%, mp 165—168°C. IR (KBr) cm^{-1}: 1680 (CO). UV λ_{max}^{EtOH} mμ (ε): 242 (13700) an 288 (17800).

Found: C, 33.57; H, 1.81; N, 3.33%. Calcd for $C_{11}H_7O_5NBr_2$: C, 33.70; H, 1.54; N, 3.57%.

Acetylenic Ketones (IVa—c). IVa was prepared as follows: To a stirred solution of 3.0 g (7.5 mmol) of IIIa in 100 m*l* of dry benzene was added a solution of 3 g (30 mmol) of triethylamine in 20 m*l* of dry benzene at room temperature. The mixture was stirred at room temperature for 1 day. After removing 2.5 g of triethylamine hydrobromide, the filtrate was concentrated. The residue was recrystallized from ethanol to give IVa. The yield, spectral data and analyses are given in Table 1. Similarly, IVb and IVc were prepared from IIIb and IIIc after 2 days' strring at room temperature. The results are summarized in Table 1.

Adition of Aniline to IVa. To a stirred solution of 0.4 g (1.65 mmol) of IVa in 50 m*l* of dry benzene was added a solution of 0.2 g (2.2 mmol) of aniline in 20 m*l* of dry benzene at room temperature. After 2 days' stirring at room temperature, the solvent was removed and the residue was recrystallized from ethanol to give 0.5 g (90%) of Va as yellow crystals, mp 141—143°C. IR (KBr) cm^{-1}: 1620 (CO). UV λ_{max}^{EtOH} mμ (ε): 314 (21000) and 390 (15200). NMR ($CDCl_3$)τ: −1.2 (NH), 2.0—3.0 (m, 12H, phenyl and nitrofuran ring protons), and 3.65 (s, 1H, =CH–).

Found: C, 67.85; H, 4.26; N, 8.15%. Calcd for $C_{19}H_{14}O_4N_2$: C, 68.25 H, 4.22; N, 8.38%.

β-Cyclohexylamino-5-nitro-2-furfurylidenebenzophenone (VIa). To a stirred and ice-cooled solution of 1 g (2.5 mmol) of IIIa in 50 m*l* of dry benzene was added a solution of 1.5 g (15 mmol) of cyclohexylamine in 20 m*l* of dry benzene. The solution was stirred at room temperature overnight. The solvent was removed and the residue was chromatographed on a silica-gel column using chloroform as an eluent. The first fraction afforded 0.4 g (47%) of VIa, mp 96—97°C, as red crystals (ethanol-petroleum ether). IR (KBr) cm^{-1}: 1610 (CO). UV λ_{max}^{EtOH} mμ (ε): 306 (14000) and 400 (12600). NMR ($CDCl_3$)τ: −1.3 (NH), 2.0—3.0 (m, 7H, phenyl and nitrofuran ring protons), 3.88 (s, 1H, =CH–), and 7.9—8.8 (m, 11H, cyclohexane ring protons).

Found: C, 67.39; H, 5.98; N, 8.06%. Calcd for $C_{19}H_{20}O_4N_2$: C, 67.04; H, 5.92; N, 8.23%.

The same compound was prepared quantitatively from IVa and cyclohexylamine by the same procedure as in the addition of aniline to IVa.

3-Phenyl-5-(5-nitro-2-furyl)isoxazole (VIIa). A mixture of 0.25 g (1 mmol) of IVa, 0.2 g (3 mmol) of hydroxylamine hydrochloride and 20 m*l* of ethanol was refluxed for 12 hr. After cooling, the resulting precipitates were filtered and recrystallized from ethanol to give 0.1 g (40%) of VIIa, mp 198—200°C, which showed mixed melting point depression with 3-(5-nitro-2-furyl)-5-phenylisoxazole.[27] IR (KBr) cm^{-1}: 1620 (C=N). UV λ_{max}^{EtOH} mμ (ε): 230 (18600) and 330 (14200). NMR ($CDCl_3$) τ: 2.0—2.8 (m, 7H, phenyl and nitrofuran ring protons) and 2.86 (s, 1H, isoxazole C_4-H).

Found: C, 61.18; H, 3.33; N, 11.02%. Calcd for $C_{13}H_8O_4N_2$: C, 60.94; H, 3.15; N, 10.93%.

3-(p-Methylphenyl)-5-(5-nitro-2-furyl)isoxazole (VIIb). Under similar treatment, IVb afforded 35% yield of VIIb, mp 205—207°C (ethanol). IR (KBr) cm^{-1}: 1615 (C=N). UV λ_{max}^{EtOH} mμ (ε): 232 (19000) and 332 (15000). NMR ($CDCl_3$) τ: 2.1—2.8 (m, 6H, phenyl and nitrofuran ring protons), 2.90 (s, 1H, isoxazole C_4-H), and 7.57 (s, CH_3).

Found: C, 61.76; H, 3.74; 10.14%. Calcd for $C_{14}H_{10}O_4N_2$: C, 62.22; H, 3.73; N, 10.37%.

5-(5-Nitro-2-furyl)-3-phenyl-1H,2-pyrazole (VIIIa). To a stirred solution of 0.3 g (1.25 mmol) of IVa in a mixture of 20 m*l* of benzene and 20 m*l* of ethanol was added a solution of 0.15 g (4 mmol) of 80% hydrazine hydrate in 10 m*l* of ethanol under ice-cooling. The mixture was stirred at room temperature for 2 days. The solvents were removed and the residue was treated with 20 m*l* of water. The insoluble part was filtered and recrystallized from benzene-ethanol to give 95% yield of VIIIa, mp 227°C (lit,[8] mp 225—228°C).

5-(5-Nitro-2-furyl)-3-p-methylphenyl-1H,2-pyrazole (VIIIb). Similar treatment afforded 97% yield of VIIIb, mp 241—243°C (ethanol-benzene). IR (KBr) cm^{-1}: 3180 (NH). NMR (DMSO-d_6) τ: −2.8 (NH), 2.70 (s, 1H, pyrazole C_4-H), and 7.65 (s, CH_3).

Found: C, 62.41; H, 4.28; N, 15.53%. Calcd for $C_{14}H_{11}O_3N_2$: C, 62.45; H, 4.12; N, 15.61%.

1-Carbamido-3-phenyl-5-(5-nitro-2-furyl)pyrazole (IXa). A mixture of 0.4 g (1.65 mmol) of IVa, 0.3 g (2.7 mmol) of semicarbazide hydrochloride and 25 m*l* of ethanol was refluxed for 11 hr. The solvent was removed and the residue was treated with 30 m*l* of water. The insoluble part was filtered and recrystallized from ethanol-benzene to give 0.3 g (54%) of IXa, mp 215—216°C, as pale yellow needles. IR (KBr) cm^{-1}: 3380, 3250 (NH) and 1660 (CO). NMR (DMSO-d_6) τ: 0.20 (broad s, 1H, HCl), 2.1—2.7 m, 7H, phenyl and nitrofuran ring protons, 2.66 (s, 1H, pyrazole C_4-H), and 3.4 (broad, 2H, NH_2, disappeared on deuteration).

Found: C, 50.07; H, 3.35; N, 17.02%. Calcd for $C_{14}H_9O_4N_4HCl$: C, 50.39; H, 3.02; N, 16.79%.

1-Carbamido-3-p-methylphenyl-5-(5-nitro-2-furyl)pyrazole (IXb). Similar treatment afforded 60% yield of IXb, mp 224—228C°. IR (KBr) cm^{-1}: 3400, 3250 (NH), and 1660 (CO).

Found: C, 52.00; H, 3.86; N, 16.53%. Calcd for $C_{15}H_{12}O_4N_4HCl$: C, 51.66; H, 3.76; N, 16.07%.

2-Phenyl-4-phenyl-6-(5-nitro-2-furyl)pyrimidine (Xa). A mixture of 0.4 g (1.6 mmol) of IVa, 0.3 g (2 mmol) of benzamidine hydrochloride and 20 m*l* of ethanol was refluxed for 12 hr. After cooling, the resulting precipitates were filtered and recrystallized from ethanol-benzene to give 0.13 g (25%) of Xa, mp 213—215°C, as colorless needles. UV λ_{max}^{EtOH} mμ (ε): 260 (32000) and 328 (17000). NMR ($CDCl_3$) τ: 1.2—1.7 (m, 4H, phenyl protons), 1.97 (s, 1H, pyrimidine C_5-H), and 2.3—2.6 (m, 8H, phenyl and nitrofuran ring protons).

Found: C, 69.91; H, 3.94; N, 12.28%. Calcd for $C_{20}H_{13}O_3N_3$: C, 69.96; H, 3.82; N, 12.24%.

From the filtrate, 0.16 g (40%) of IVa was recovered by column chromatography on a silica-gel using chloroform as an eluent.

2-Phenyl-4-p-methylphenyl-6-(5-nitro-2-furyl)pyrimidine (Xb). Similar treatment of IVb and amidine afforded 20% yield of Xb, mp 220—223°C (ethanol-benzene). UV λ_{max}^{EtOH} mμ (ε): 264 (37000) and 330 (18400). NMR ($CDCl_3$) τ: 1.3—1.9 (m, 4H, phenyl protons), 2.08 (s, 1H, pyrimidine C_5-H), 2.4—2.7 (m, 7H, phenyl and nitrofuran protons), and 7.55 (s, CH_3).

Found: C, 70.56; H, 4.36; N, 11.71%. Calcd for $C_{21}H_{15}O_3N_3$: C, 70.58; H, 4.23; N, 11.76%.

3-Phenyl-4-benzoyl-5-(5-nitro-2-furyl)isoxazole (XIa). To a stirred solution of 0.6 g (2.5 mmol) of IVa and 0.4 g (2.6 mmol) of benzhydroxamoyl chloride in 50 m*l* of dry benzene was added a solution of 0.9 g (9 mmol) of triethylamine in 20 m*l* of dry benzene under ice-cooling. After stirring for 1 day at room temperature, the reaction mixture was filtered and the solvent was removed from the filtrate. The residue was chromatographed on a silica-gel column using benzene as an eluent. The first fraction afforded 0.1 g (30%) of furoxan, mp 115—116°C.[27] From the second fraction a small amount of oil was obtained, which was discarded without further investigation. The third fraction afforded the main product, 0.45 g (50%) of XIa, mp 135—138°C (ethanol). IR (KBr) cm^{-1}: 1655 (CO). UV λ_{max}^{EtOH} mμ (ε): 228 (20100), 250 (16200), and 328 (14000).

Found: C, 66.48; H, 3.48; N, 7.59%. Calcd for $C_{20}H_{12}O_5N_2$: C, 66.66; H, 3.36; N, 7.78%.

Thermal 1,3-Dipolar Cycloaddition of IVa,b to 5-Nitro-2-furocarbonitrile Oxide. A solution of 0.4 g (1.65 mmol) of IVa and 0.3 g (1.6 mmol) of 5-nitro-2-furohydroxamoyl chloride in 20 m*l* of toluene was refluxed for 20 hr until the hydrogen chloride gas evolution had completely ceased. After removing the solvent, the reside was chromatographed on a silica-gel column using chloroform as an eluent. The first fraction afforded 0.1 g (25%) of recovered IVa and the second fraction yielded 0.23 g (30%) of 3,5-di(5-nitro-2-furyl)-4-benzoylisoxazole (XIIa), mp 193—195°, (ethanol-benzene). IR (KBr)cm^{-1}: 1660 (CO). UV λ_{max}^{EtOH} mμ (ε): 250 (14000) and 322 (19000).

Found: C, 55.28; H, 2.44; N, 11.13%. Calcd for $C_{18}H_9O_7N_3$: C, 55.53; H, 2.39; N, 11.08%.

Similar treatment of IVb afforded 30% recovery of IVb and 20% yield of 3,5-di(5-nitro-2-furyl)-4-methylbenzoylisoxazole (XIIb), mp 191—193°C (ethanol-benzene). IR (KBr) cm^{-1}: 1655 (CO). UV λ_{max}^{EtOH} mμ (ε): 256 (16000) and 324 (19800).

Found: C, 55.90; H, 2.86; N, 10.15%. Calcd for $C_{19}H_{11}O_8N_3$: C, 55.75; H, 2.71; N, 10.27%.

1,3-Dipolar Cycloaddition of IIa to Benzonitrile Oxide. To a stirred solution of 0.55 g (2.3 mmol) of IIa and 0.4 g (2.6 mmol) of benzhydroxamoyl chloride in 40 m*l* of dry benzene was added a solution of 0.5 g (5 mmol) of triethylamine in 20 m*l* of dry benzene under ice-cooling. The mixture was stirred at room temperature for 1 day. After removing insoluble triethylamine hydrochloride by filtration, the solvent was removed from the filtrate. The residue was chromatographed on a silica-gel column using benzene as an eluent. The first fraction afforded 0.03 g (10%) of furoxan, mp 115°C.[27] From the following fractions, 0.03 g (4%) of XIVa, mp 118—120°C, 0.2 g (40%) of recovered IIa and 0.4 g (40%) of XIIIa, mp 196—197°C (ethanol-benzene) were obtained successively. The IR spectrum of XIVa was similar to that of XIIIa.

XIIIa: IR (KBr) cm^{-1}: 1675 (CO). UV λ_{max}^{EtOH} mμ (ε): 244 (21400) and 298 (10000). NMR ($CDCl_3$) τ: 1.8—2.7 (m, 11H, phenyl and nitrofuran ring[28] protons), 3.20 (d, 1H, J=4 Hz, ) 4.10 (d, 1H, J=6 Hz, isoxazole C_5-H), and 4.28 (d, 1H, J=6 Hz, isoxazole C_4-H).

Found: C, 66.47; H, 4.03; N, 7.57%. Calcd for $C_{20}H_{14}O_5N_3$: C, 66.29 H, 3.89; N, 7.73%.

XIVa:

Found: C, 66.35; H, 3.99; N, 7.65%. Calcd for $C_{20}H_{14}O_5N_2$: C, 66.29; H, 3.89; N, 7.73%.

1,3-Dipolar Cycloaddition of 5-Nitro-2-furfurylideneacetone to Benzonitrile Oxide. From a similar treatment of 5-nitro-

28) One of two: 
2-furfurylideneacetone[8] and benzonitrile oxide, 10% of furoxan, 10% of XVI, mp 60—62°C, and 40% of XV, mp 108—109°C (ethanol) were successively obtained. The IR spectrum of XV was similar to that of XVI.

XV: IR (KBr) cm^{-1}: 1705 (CO). UV λ_{max}^{EtOH} mμ (ε): 255 (15500) and 300 (15500). NMR (DMSO-d_6) τ: 2.2—2.6 (m, 6H, phenyl and nitrofuran[28] ring protons), 2.90 (d, 1H, J=4 Hz, ), 3.76 (d, 1H, J=5 Hz, isoxazoline C_5-H), 4.51 (d, 1H, J=5 Hz, isoxazoline C_4-H), and 7.66 (s, CH_3).

Found: C, 59.85; H, 4.05; N, 9.29%. Calcd for $C_{15}H_{12}O_5N_2$: C, 60.00; H, 4.03; N, 9.33%.

XVI:

Found: C, 60.15; H, 3.95; N, 9.45%. Calcd for $C_{15}H_{12}O_5N_2$: C, 6.00; H, 4.05; N, 9.33%.

1-Benzoyl-2-(5-nitro-2-furyl)-3-benzoylpyrrocoline (XVIIa). To a stirred solution of 0.3 g (1.25 mmol) of IVa and 1 g (3.6 mmol) of phenacyl pyridinium bromide[29] in a mixture of 30 m*l* of benzene, 10 m*l* of water and 10 m*l* of ethanol was added 0.5 g (3.6 mmol) of powdered potassium carbonate under ice-cooling. The mixture was stirred at room temperature for 2 days. Water (20 m*l*) was added to the mixture and the mixture was extracted with benzene (3×50 m*l*). The benzene extracts were dried over sodium sulfate and benzene was removed from the extracts. The residue was chromatographed on a silica-gel column using chloroform as an eluent to give 0.4 g (73%) of XVIIa as yellow needles, mp 212—214°C (ethanol-benzene). IR (KBr) cm^{-1}: 1640 (CO). UV λ_{max}^{EtOH} mμ (ε): 230 (24000) and 340 (18000). NMR ($CDCl_3$) τ: 0.40 (dd, 1H, J=0.9, 7.0 Hz, C_5-H), 1.9 (dd, 1H, J=0.9, 9.0 Hz, C_8-H), 2.3—3.0 (m, 12H, phenyl (10H) and pyridine (2H) ring protons), 3.35 (d, 1H, J=4 Hz, ) and 3.85 (d, 1H, J=4 Hz,).

Reactions of Haloferrocenes. IV.[1] The Condensation of Haloferrocenes with Various Carboxylic Acids in the Presence of Copper(I) Oxide

Masaru SATO, Yau Ping LAM, Izumi MOTOYAMA, and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received August 21, 1970)

The condensation reaction of haloferrocenes with various carboxylic acids in the presence of copper(I) oxide was studied extensively. The reaction generally afforded the corresponding ferrocenyl carboxylates, along with a comparable amount of ferrocene. The change in the distribution of the reaction products was examined under various conditions in the reaction of bromoferrence with benzoic acid. From the discussion of the reaction mechanism, it was concluded that the ferrocenyl ester and ferrocene are produced through different active species. The reaction under proper conditions was found to be useful for the preparation of ferrocenyl esters.

The copper-catalyzed condensation reaction of halides with phenols or amines is well-known as a synthetic method of aryl ethers or arylamines.[2] However, a similar reaction of aryl halides with carboxylic acids to give aryl carboxylate has been little studied.[3] In a previous paper,[1] we reported that the reaction o haloferrocenes with copper(I) acetate in boiling pyridine gave ferrocenyl acetate; this result was different from that of aryl halides with copper(I) acetate. In this paper, the condensation reaction of haloferrocenes with various carboxylic acids in the presence of copper(I) oxide will be reported as an extension of the preceding study.

Results and Discussion

When iodoferrocene or bromoferrocene was refluxed with various carboxylic acids in the presence of copper(I) oxide in pyridine, the corresponding ferrocenyl carboxylates were obtained, together with a comparable amount of ferrocene. For example, when iodoferrocene was refluxed for half an hour with two equivalents of benzoic acid and one equivalent of copper(I) oxide in pyridine, ferrocenyl benzoate and ferrocene

were obtained in 54% and 36% yields respectively. All the results of the reaction of iodoferrocene with the various carboxylic acids examined are summarized in Table 1. Biferrocenyl, which was obtained as a coupling product in the reaction of iodoferrocene with copper(I) acetate and benzoate, together with ferrocenyl carboxylate and ferrocene, was hardly detected at all. Especially, it was never found in the similar reaction of bromoferrocene.

a) Ferrocenyl acetate was obtained instead of the expected chloroacetate.

As is shown in Table 1, ferrocenyl ester is a main product in most of the cases under the conditions employed. On the other hand, the corresponding reaction of 1-bromonaphthalene with acetic acid in boiling pyridine for 3 hr was reported to afford exclusively the dehalogenated product, *i.e.*, naphthalene, in a moderate yield.[4] Similarly, when *o*-nitrohalobenzene was boiled with benzoic acid in the presence of metallic copper, it was dehalogenated to give nitrobenzene.[5] The only example of the copper-catalyzed condensation, which afforded aryl carboxylate as a product, was reported as a side-reaction in the Ullmann coupling of substituted iodobenzene, using benzoic acid as the diluent.[3] The maximum yield of the aryl benzoate was reported to be 27%. The present results, shown in Table 1, are very different from those reported in the benzene series. This tendency is consistent with the fact that haloferrocene reacts easily with copper(I) acetate to give ferrocenyl acetate in a good yield,[1] while aryl halides react with the copper(I) salt to give only dehalogenated products.[4,6]

Variation in the carboxylic acid component seems to have no significant effect on the reaction and on the product distribution. The effect of the *para*-substituent of benzoic acid on the reaction is also not clear, and there is no appreciable difference in the reactivities between aromatic and aliphatic acids. These facts indicate that the reaction is not influenced by the dissociation constant of carboxylic acid. A double bond conjugated to the carboxyl group also appears to have no effect on this reaction. Although *o*-nitrobenzoic acid has been reported to be decarboxylated in the presence of copper(I) oxide at a high temperature,[7] no such decarboxylation product was found in the present reaction.

It was found, however, that the reaction was affected significantly by an α-halogen substituent of aliphatic acid or by an *ortho*-halogen substituent of benzoic acid. For instance, when iodoferrocene was refluxed with chloroacetic acid or trichloroacetic acid in the presence of copper(I) oxide in pyridine, the main product was not a corresponding ferrocenyl ester, but chloroferrocene. Similarly, the reaction of iodoferrocene with *o*-chlorobenzoic acid gave chloroferrocene as the main product, while the reaction with the *p*-isomer gave ferrocenyl *p*-chlorobenzoate and no chloroferrocene. A similar effect of the halogen substituent adjacent to the carboxyl group has been reported by Bacon and Hill[4] in the reaction of aryl halides with *o*-chlorobenzoic anhydride or chloroacetic anhydride.

It is quite interesting that the reaction of haloferrocene with any of carboxylic acids in the presence of copper(I) oxide produced a condensation product (ferrocenyl ester) together with a comparative amount of a dehalogenation product (ferrocene), whereas only dehalogenated products were obtained in the reaction of aryl halides under similar conditions. These facts inspired us to consider the mechanism of this condensation reaction. The reaction of haloferrocene with carboxylic acid in the presence of copper(I) oxide was considered to be suitable for examining the reaction mechanism, because it proceeds easily and gives good yields of the products. In the first place, the reaction between bromoferrocene and benzoic acid was investigated under various conditions. Whereas bromoferrocene reacted with benzoic acid when they were refluxed in the presence of copper(I) oxide in pyridine, no reaction occurred when bromoferrocene was treated either with copper(I) oxide or with benzoic acid alone in boiling pyridine. Therefore, it is reasonable to assume that benzoic acid initially reacts with copper(I) oxide to form a certain active species, which subse-

1	4	0.5[a)]	56.3	13.7	18.3

a) Reaction time: 1.0 hr

quently reacts with bromoferrocene to give both the dehalogenation and the condensation products. This assumption is strongly supported by the results of the experiments listed in Table 2, in which the effect of the change in the molar ratio of the reaction components on the distribution of the products is summarized. The following facts are clearly shown in this table: (i) When the molar ratio of benzoic acid to copper(I) oxide is kept constant ($C_6H_5COOH/Cu_2O=2$) and when the molar ratio of the mixture to bromoferrocene is increased, the yields of both ferrocenyl benzoate and ferrocene increase; there is a particularly striking increase in the formation of ferrocene. (ii) When only the ratio of benzoic acid to the other components is increased, the yields of both products rather decrease. The latter fact seems to strongly support the assumption presented above.

Table 3. The reaction of various haloferrocenes with benzoic acid in the presence of copper(I) oxide in pyridine

Haloferrocene: 0.005 mol, Benzoic acid: 0.01 mol
Copper(I) oxide: 0.005 mol, Pyridine: 20 ml
Reaction temp.: 116°C, Reaction time: 0.5 hr

Haloferrocene	Haloferrocene recovered (%)	Ferrocenyl benzoate (%)	Ferrocene (%)
Iodoferrocene	8.2	53.6	35.6
Bromoferrocene	23.0	34.6	40.9
Chloroferrocene	92.5	2.6	2.4

The influence of the kind of halogen in haloferrocenes on the reaction was also studied; the results are shown in Table 3. It is clear from Table 3 that the reactivity of haloferrocene is in the order: FcI> FcBr>FcCl, an order which is similar to that in the reaction of haloferrocene with various copper(I) salts,[1,8)] and that the product distribution is also influenced by the kind of the halogen. Iodoferrocene produced predominantly ferrocenyl benzoate over ferrocene. The reaction of bromoferrocene seems to be somewhat favorable to the formation of ferrocene. As for chloroferrocene, comparable yields of both products were obtained, but the comparison of the yields seems to be of little significance because of the low reactivity of chloroferrocene.

8) M. Sato, T. Ito, I. Motoyama, K. Watanabe, and K. Hata, This Bulletin, **42**, 1976 (1969).

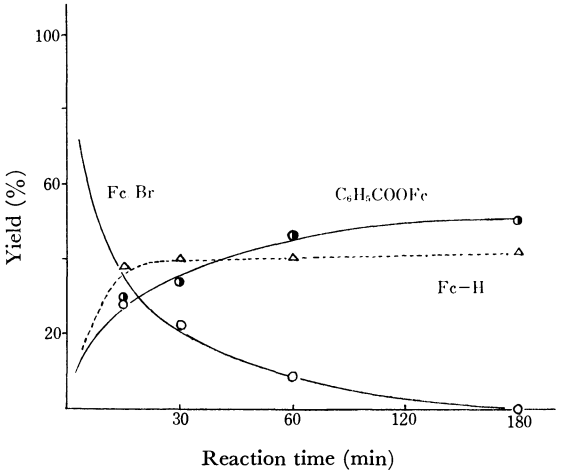

Fig. 1. The plot of the product distribution against reaction time.

It will be useful, in examining the reaction mechanism, to follow the change in the product distribution of this reaction with the lapse of the reaction time. Thus, the product distribution in the reaction of bromoferrocene with benzoic acid in the presence of copper(I) oxide in boiling pyridine was plotted against the reaction time (Fig. 1). As is shown in Fig. 1, (i) ferrocene and ferrocenyl benzoate are formed competitively in the initial stage; (ii) the formation of ferrocene is faster than that of ferrocenyl benzoate in the beginning of the reaction, but it ceases after about 30 min; (iii) the formation of the benzoate gradually increases as the reaction proceeds. The facts described above suggest unequivocally that ferrocene and ferrocenyl benzoate are produced independently through the reaction of bromoferrocene with different active species, not through an step-by-step mechanism in which one of the products is formed initially and then reacts with an active species to give the other. The more likely mechanism that the formation of ferrocene precedes that of ferrocenyl benzoate is also excluded by the fact that ferrocenyl benzoate was never obtained when ferrocene refluxed with benzoic acid and copper(I) oxide in pyridine. It is plausible, from an examination of Table 2, to conclude that the active species which affords ferrocenyl benzoate is probably copper(I) benzoate-pyridine complex, because copper(I) benzoate can be formed through the reaction of benzoic acid with copper(I) oxide in the reaction mixture.

$$2C_6H_5COOH + Cu_2O \longrightarrow 2C_6H_5COOCu + H_2O \quad (2)$$

$$C_6H_5COOCu \xrightarrow[\text{pyridine}]{} C_6H_5COOCu\text{-}Py_n$$

Since the formation of a coupling product (biferrocenyl) was never observed in this reaction, the formation of ferrocenyl benzoate seems unlikely to be through a radical mechanism. Furthermore, the radical mechanism may be excluded by the fact that, as is shown in Table 2, the formation of ferrocene does not increase even when the molar ratio of ben-

Table 4. Effect of the additional material

a) Benzoic acid: 0.01 mol, Cu_2O: 0.005 mol

zoic acid as a hydrogen donor increase. Therefore, the formation of ferrocenyl benzoate is probably due to a mechanism similar to that of the reaction of haloferrocene with copper(I) benzoate in pyridine, which was reported in the preceding paper.[1]

On the other hand, the explanation of the formation of ferrocene is not yet clear, although the following considerations are possible on the basis of the results of the experiments shown in Table 4. Benzoic acid must be responsible for the formation of ferrocene, because the latter could be scarcely found at all in the reaction product when copper(I) benzoate was used instead of benzoic acid and copper(I) oxide. However, it was found that, when water or methanol was added as a hydrogen donor to the reaction of bromoferrocene with copper(I) benzoate in pyridine, the formation of ferrocene was comparable to that in the reaction using benzoic acid and copper(I) oxide. These observations support the assumption that the source of hydrogen for the formation of ferrocene in this reaction is the acidic hydrogen of benzoic acid. The acid probably reacts with copper(I) oxide to produce water through Eq. (2), and the water would react with haloferrocene through some participation in the formation of an active species such as a copper(I) complex.

Table 5. Solvent effect
Bromoferrocene: 0.005 mol, Benzoic acid: 0.01 mol
Copper(I) oxide: 0.005 mol, Solvent: 20 ml
Reaction time: 1.0 hr

Solvent	Reaction temp. (°C)	FcBr recovered (%)	Product	
			C_6H_5COOFc	FcH
Pyridine	116	9.0	47.0	40.9
Acetonitrile	82	—	89.4	8.2
Nitromethane	101	9.1	86.0	3.2
Toluene	110	28.8	42.0	26.9

Pyridine was supposed to act not only as a solvent but also as a ligand coordinating to the copper(I) salt which is formed by the reaction of benzoic acid with copper(I) oxide. Accordingly, in order to examine the role of pyridine in this reaction, the reaction was studied in other solvents; the results are summarized in Table 5. As is shown in Table 5, when the reaction was carried out in acetonitrile or nitromethane the condensation product (ferrocenyl ester) was formed in an extraordinarily high yield in place of a low yield of the dehalogenation product (ferrocene). This trend is more striking in the latter solvent. Thus, the condensation reaction in these solvents is suitable for the preparation of ferrocenyl esters. The participation of pyridine in the formation of ferrocene is obvious in Table 5. The special behavior of pyridine in this reaction is probably due to the basicity and the coordination ability of pyridine. The formation of ferrocene may be effected by the reaction of haloferrocene with a certain active species formed by the addition of water (or methanol) to the copper(I) benzoate-pyridine complex, which is expected to exist in the reaction mixture.

On the other hand, ferrocene is also obtained in a considerable amount by the reaction using toluene as a solvent. However, it seems reasonable to consider that the reaction in toluene may proceed through a different mechanism, since the product distribution is considerably different from that by the reaction using pyridine; in the previously-reported reaction between bromoferrocene and copper(I) benzoate,[1] the product distribution by the reaction using toluene as a solvent was also quite different from that by the reaction using pyridine.

Experimental

The Procedure for the Preparation of Ferrocenyl Carboxylates. Ferrocenyl Benzoate: Iodoferrocene (1.56 g, 0.005 mol), benzoic acid (1.22 g, 0.01 mol) copper(I) oxide (0.72 g, 0.005 mol), and 20 ml of pyridine were placed in a 100-ml, three-necked, round-bottomed flask fitted with a mechanical stirrer, a reflux condenser, and a gas-inlet tube. The mixture in the flask was refluxed on an oil bath maintained at 120—125°C for 0.5 hr under an atmosphere of nitrogen. After the reaction had been completed, 80 ml of ether was added to the cooled reaction mixture. The dark blue precipitate was separated by filtration and washed with a small portion of ether. The combined ether solution was washed successively with water, dilute hydrochloric acid, and water, and then dried over anhydrous magnesium sulfate. After the removal of the solvent under reduced pressure, the orange residue was chromatographed on silica gel, using *n*-hexane - benzene (1 : 1) as the eluent. The first fraction gave orange crystals (0.46 g), which were found to be a mixture of ferrocene (0.33 g, 35.6%) and iodoferrocene (0.13 g, 8.2%) by a gas-chromatographic analysis.[9] From the second fraction of the chromatography, ferrocenyl benzoate (0.82 g, 53.6%) was obtained; it was recrystallized from *n*-hexane - benzene (1 : 1), mp 108.5—109.5°C (lit,[11] 108.5—109.5°C).

The other ferrocenyl esters, listed in Table 1, were similarly prepared by the reaction of iodoferrocene with various carboxylic acids in the presence of copper(I) oxide in boiling pyridine. The analytical data of the ferrocenyl esters thus obtained are as follows:

Ferrocenyl *p*-methoxybenzoate, mp 107.2—107.8°C. Found: C, 64.47; H, 4.91%. Calcd for $C_{18}H_{16}O_3Fe$: C, 64.30; H, 4.81%.

Ferrocenyl *p*-methylbenzoate, mp 94.5—95.5°C. Found:

9) The analytical conditions for the gas-chromatographic analysis were the same as those reported in a previous paper.[10]

10) M. Sato, I. Motoyama, and K. Hata, *ibid.*, **43**, 1860 (1970).

11) A. N. Nesmeyanov, V. A. Sazonova, and V. N. Drozd, *Chem. Ber.*, **93**, 2717 (1960).

C, 67.97; H, 5.02%. Calcd for $C_{18}H_{16}O_2Fe$: C, 67.51; H, 5.05%.

Ferrocenyl *p*-chlorobenzoate, mp 109—110.5°C. Found: C, 60.09; H, 3.95%. Calcd for $C_{17}H_{13}O_2ClFe$: C, 59.94; H, 3.85%.

Ferrocenyl *o*-chlorobenzoate, orange liquid. Found: C, 61.49; H, 3.99%. Calcd for $C_{17}H_{13}O_2ClFe$: C, 59.94; H, 3.85%.

Ferrocenyl *p*-acetylbenzoate, mp 141—142°C. Found: C, 65.73; H, 4.60%. Calcd for $C_{19}H_{16}O_3Fe$: C, 65.53; H, 4.64%.

Ferrocenyl *p*-nitrobenzoate, mp 184—185°C. Found: C, 58.09; H, 3.89; N, 3.99%. Calcd for $C_{17}H_{13}O_4NFe$: C, 58.14; H, 3.74; N, 3.99%.

Ferrocenyl *o*-nitrobenzoate, mp 115—116°C. Found: C, 58.42; H, 3.89; N, 4.24%. Calcd for $C_{17}H_{13}O_4NFe$: C, 58.14; H, 3.74; N, 3.99%.

Ferrocenyl propionate, bp 108—110°C/0.05—0.06 mmHg. Found: C, 60.48; H, 5.71%. Calcd for $C_{13}H_{14}O_2Fe$: C, 60.48; H, 5.48%.

Ferrocenyl crotonate, mp 60—61.5°C. Found: C, 62.39; H, 5.21%. Calcd for $C_{14}H_{14}O_2Fe$: C, 62.24; H, 5.23%.

Ferrocenyl cinnamate, mp 88.5—90°C. Found: C, 68.81; H, 4.76%. Calcd for $C_{19}H_{16}O_2Fe$: C, 68.69; H, 4.86%.

The Reaction between Bromoferrocene and Benzoic Acid in the Presence of Copper(I) Oxide in Pyridine (Tables 2 and 3). A typical procedure was as follows. Bromoferrocene (1.33 g, 0.005 mol), benzoic acid (1.22 g, 0.01 mol), and copper(I) oxide (0.72 g, 0.005 mol) were mixed with 20 m*l* of pyridine, and then the mixture was refluxed on an oil bath for 0.5 hr under an atmosphere of nitrogen. After the reaction had been completed, the reaction mixture was treated in a manner similar to that described for the preparation of ferrocenyl benzoate. Finally, chromatographic separation afforded ferrocene, bromoferrocene, and ferrocenyl benzoate in 40.9% (0.38 g), 23.0% (0.31 g), and 34.6% (0.53 g) yields respectively.

The Reaction of Bromoferrocene with Copper(I) Benzoate in Pyridine in the Presence of Water (Table 4). Water (0.09 m*l*, 0.005 mol) was added to a mixture of bromoferrocene (1.33 g, 0.005 mol) and copper(I) benzoate (1.85 g, 0.01 mol) in 15 m*l* of pyridine; then the mixture was refluxed for 0.5 hr under an atmosphere of nitrogen. After the reaction had been completed, the reaction mixture was treated much as has been described for the preparation of ferrocenyl benzoate. The chromatography of the product gave ferrocene, bromoferrocene, and ferrocenyl benzoate in 39.8% (0.37 g), 7.5% (0.10 g), and 49.7% (0.76 g) yields respectively.

The Reaction between Bromoferrocene and Benzoic Acid in the Presence of Copper(I) Oxide in Nitromethane (Table 5). Bromoferrocene (0.67 g, 0.0025 mol), benzoic acid (0.61 g, 0.005 mol), and copper(I) oxide (0.36 g, 0.0025 mol) in 10 m*l* of nitromethane were refluxed for 1.0 hr under an atmosphere of nitrogen. After the reaction had been completed, the reaction mixture was cooled and filtered. The precipitate collected on the filter was washed with ether. The filtrate and the washings were combined, and then the combined solution was washed thoroughly with water and dried over anhydrous magnesium sulfate. After the removal of the solvent under reduced pressure, the orange residue was treated much as has been described for the preparation of ferrocenyl benzoate. Finally, ferrocene (0.015 g, 3.2% yield), bromoferrocene (0.061 g, 9.1% yield), and ferrocenyl benzoate (0.658 g, 86% yield) were obtained.

The reaction using acetonitrile or toluene as the solvent was carried out in the same manner.

Reactions of Haloferrocenes. V.[1] The Formation of Ferrocenyltriphenylphosphonium Perchlorate

Masaru SATO,[2] Izumi MOTOYAMA, and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 5, 1970)

The reaction of haloferrocene with tetrakis(acetonitrilo)copper(I) perchlorate in nitromethane gave a 35% yield of biferrocenyl. The addition of triphenylphosphine to the reaction system causes a remarkable change in the reaction and gives ferrocenyltriphenylphosphonium perchlorate in a good yield. The scope of the formation of the quaternary salt was investigated in comparison with the corresponding reactions in the benzene series. It was found that the ligands coordinated in the intermediate copper(I) complex strongly affect the reaction. The mechanism of the formation of ferrocenyltriphenylphosphonium salt is also discussed.

Haloferrocenes are more reactive in the reactions involving metallic copper or copper(I) salt than is halobenzene. For example, the Ullmann coupling reaction of iodoferrocene takes place at 60°C,[3] and ferrocenecarbonitrile is obtained upon heating bromo- or chloroferrocene with copper(I) cyanide at 140°C.[4] It was also found that haloferrocenes reacted easily with various copper(I) salts in boiling pyridine to give substituted ferrocenes,[5-7] and that the condensation reactions of haloferrocenes with various kinds of car-

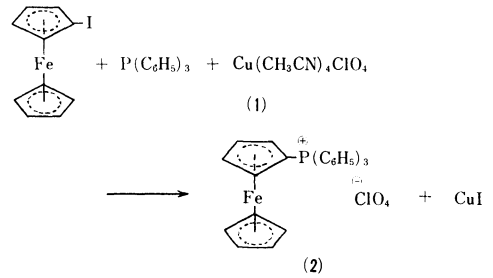
boxylic acids easily took place in the presence of copper(I) oxide in boiling pyridine to give the corresponding ferrocenyl ester.[1] On the other hand, it is well known that similar reactions of the corresponding benzene derivatives occur only under more severe conditions.

In previous papers[5,6] it was suggested that the substitution reactions of haloferrocenes in the presence of copper(I) salts proceed through a ligand-exchange reaction within an intermediate copper(I) complex. From this point of view, it was supposed that if a copper(I) complex of a different type, in which a linkage between the metal and the ligand has no covalent character, is employed instead of the copper(I) salts used in the previous experiments, the exchange reaction will be prohibited and that the coupling reaction of haloferrocene will occur instead, even at a lower temperature. On the other hand, since such a copper(I) complex probably dissolves in a polar solvent to give a homogeneous solution, the reaction using it is expected to be advantageous for studying the reaction mechanism.

Results

In the present study, tetrakis(acetonitrilo)copper(I) perchlorate[8] (**1**) was used for the reaction. It has been reported[8,9] that the nature of the bonding between copper and perchlorate in this complex is entirely ionic in a polar solvent. When bromoferrocene was heated at 45°C for 72 hr with an equimolar amount of the complex **1** in nitromethane, biferrocenyl was obtained in a 35% yield, and 45.3% of bromoferrocene was recovered after the reaction. These results show that the copper(I) complex effects a Ullmann-type aryl-coupling reaction. However, the yield of the coupling product was too low as compared with that of a normal Ullmann reaction, in which iodoferrocene is coupled at 60°C to afford biferrocenyl quantitatively.[3] Thereupon, with a view to modifying the character of the complex in order to produce an increased yield of biferrocenyl, triphenylphosphine was added to the reaction mixture. Unexpectedly, however, when iodoferrocene was heated with triphenylphosphine in the presence of tetrakis(acetonitrilo)copper(I) perchlorate (**1**) in nitromethane, ferrocenyltriphenylphosphonium perchlorate (**2**) was obtained in a good yield. Furthermore, this reaction



took place at a surprisingly low temperature (45°C), although never at room temperature. Bromoferrocene also reacted in a similar way, but the product was obtained only in a lower yield. These results are summarized in Table 1.

Table 1. The formation of ferrocenyltriphenylphosphonium perchlorate

Haloferrocene	Reaction temp. (°C)	Reaction time (hr)	Recovery of haloferrocene (%)	Yield (%)
FcI	44.5	15.5	35.8	61.4
FcI	101	6	14.4	80.8
FcBr	44.5	15	58.2	36.1

A reaction of this type is known also in the benzene series and is utilized as a synthetic method of aryltriphenylphosphonium salts. The reaction is generally catalyzed by anhydrous metal halide, such as aluminum chloride,[10] cobalt(II) or nickel(II) halide,[11,12] and copper(I) chloride.[13] For instance, when a substituted bromobenzene is treated with triphenylphosphine in the presence of cobalt(II) chloride or nickel(II) bromide, the corresponding aryltriphenylphosphonium bromide is obtained in a high yield, but the reaction does not occur at temperatures below 160°C.[11]

In these reactions giving quaternary phosphonium salts, haloferrocene is much more reactive than halobenzene, much as in other copper(I) salt-participating reactions. It is noticeable that the halogen atom in haloferrocene transfers to the copper(I) complex, finally giving copper(I) halide, whereas that in halobenzene moves into the phosphonium salt without coordinating to the coexisting metal halide.

As had been reported in a previous paper,[6] when the reaction of bromoferrocene with copper(I) chloride in the presence of pyridine was carried out in nitromethane, chloroferrocene was obtained. A similar reaction was attempted in the presence of triphenylphosphine instead of pyridine, but it was found that neither ferrocenylphosphonium salt nor chloroferrocene was produced. The corresponding reaction of 4-bromobiphenyl with triphenylphosphine in the presence of copper(I) chloride has been known to give 4-biphenylyltriphenylphosphonium bromide.[13]

Thus, the formation of ferrocenylphosphonium salt from iodoferrocene and triphenylphosphine was found to necessitate the presence of tetrakis(acetonitrilo)-

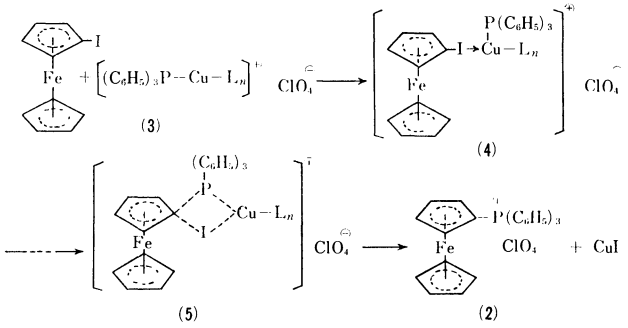
copper(I) perchlorate. Moreover, the solvent effect in this reaction was found to be astonishing. When acetonitrile or pyridine instead of nitromethane was used as the solvent in this reaction, no ferrocenyltriphenylphosphonium salt was obtained, but iodoferrocene was recovered almost quantitatively.

In order to get more information, the reaction was examined under various molar ratios of the three components, using nitromethane as the solvent. The results are summarized in Table 2.

As may be seen in the table, the yield of the phosphonium salt decreases drastically as the molar ratio of triphenylphosphine increases (Exp. 1—3). This fact, together with the solvent effect described above, suggests that the reaction is strongly affected by the ligands coordinated in the copper(I) complex which serves as the intermediate in the reaction. On the other hand, when 0.2 mol of tetrakis(acetonitrilo)copper(I) perchlorate was used against 1 mol each of iodoferrocene and triphenylphosphine, no reaction was observed and the starting material was recovered almost quantitatively (Exp. 4). This observation clearly indicates that the copper(I) complex does not act as a catalyst in this reaction, unlike as in a similar reaction in the benzene series.[10-13]

Discussion

When triphenylphosphine and tetrakis(acetonitrilo)-copper(I) perchlorate was dissolved in nitromethane, a homogeneous greenish-yellow solution was obtained. As the amount of triphenylphosphine in the solution increased, the color of the solution gradually changed from greenish-yellow to almost colorless. The change in color is probably due to the change in the ligands in the copper(I) complex. It is considered probable that, when tetrakis(acetonitrilo)copper(I) salt is dissolved in nitromethane, the acetonitrile molecule coordinated in the complex is replaced by the solvent molecule. An analogous complex, in which nitromethane coordinates to the copper(I) ion instead of acetonitrile, was reported recently.[14] When iodoferrocene was added to the nitromethane solution of tetrakis(acetonitrilo)copper(I) perchlorate containing triphenylphosphine, a homogeneous reddish-orange solution was obtained, and the reaction of iodoferrocene with triphenylphosphine took place when the solution was heated. A white precipitate, which is supposed to be copper(I) iodide, was separated out as the reaction proceeded, but no change in the color of the solution was observed during the reaction. If iodoferrocene is reduced by a copper(I) complex to produce the ferrocenyl radical and the copper(II) complex, the latter may react with iodoferrocene to give a ferricenium cation, and the color of the reaction mixture ought to change during the reaction. Accordingly, the above observation suggests that this reaction does not proceed through such a radical mechanism. It seems reasonable to assume that the first step in the formation of ferrocenyltriphenylphosphonium salt is the coordination of the iodine atom in iodoferrocene to the copper(I) ion of the complex **3**, coordinated with triphenylphosphine in advance. The unstable intermediate (**4**) thus formed would provide the final product (**2**) *via* a four-centered transition state (**5**), which might have a structure similar to that proposed for the halogen-exchange reaction of haloferrocene with copper(I) chloride.[5] This assumption is



L=CH_3CN and/or CH_3NO_2

consistent with the results listed in Table 2. The coordination of iodoferrocene to the copper(I) ion is supposed to be weak, if it exists at all. Accordingly, if the amount of triphenylphosphine, which has a much stronger coordinating ability than iodoferrocene, increases, the copper(I) ion will be strongly coordinated by the triphenylphosphine; thus, the coordination by iodoferrocene will be obstructed, resulting in the reduction of the formation of ferrocenyltriphenylphosphonium salt. The solvent effect on this reaction also accords with the reaction mechanism proposed above; when acetonitrile or pyridine, which has a particular affinity to the copper(I) ion,[15] is used as a solvent, a similar obstruction of the coordination of iodoferrocene will retard the reaction.

Experimental

Materials. Iodoferrocene was prepared from chloromercuriferrocene by a slightly modified procedure of the previously-reported method.[16] Bromoferrocene was prepared from iodoferrocene according to the procedure described in a previous paper.[5] Tetrakis(acetonitrilo)copper(I) perchlorate was prepared according to the literature.[8] The solvents used in this study were purified by distillation.

Ullmann-type Coupling Reaction of Bromoferrocene Catalyzed by Tetrakis(acetonitrilo)copper(I) Perchlorate. To a pale yellow solution of tetrakis(acetonitrilo)copper(I) perchlorate (0.50 g, 0.0018 mol) in nitromethane[17] (20 ml), bromoferrocene (0.53 g, 0.0018 mol) was added at 44.5°C under a nitrogen atmosphere. The solution rapidly changed in color, from orange to black. After being heated at that temperature for 72 hr, the reaction mixture was poured into water containing tin(II) chloride. The mixture was extracted with benzene. The benzene solution was washed with water and dried over anhydrous magnesium sulfate. After the evaporation of the solvent under reduced pressure, the residue was chromatographed on alumina, using benzene - *n*-hexane (1 : 2) as the

17) Nitromethane was bubbled with nitrogen before use in order to replace the dissolved oxygen with nitrogen.

solvent. From the first fraction of chromatographic separation, bromoferrocene (0.240 g, 45.3% recovery) was obtained, while from the second fraction, biferrocenyl (0.065 g, 35% yield) was isolated. The latter was recrystallized from benzene, mp 238°C (decomp.) (lit,[3] 239—240°C, decomp.), and identified by means of its NMR and IR spectra. Ferrocene could not be detected, even by gas-chromatographic analysis.

A similar reaction was attempted in acetonitrile instead of nitromethane, but it was unsuccessful.

The Reaction of Iodoferrocene with Triphenylphosphine in the Presence of Tetrakis(acetonitrilo)copper(I) Perchlorate in Nitromethane. Iodoferrocene (0.56 g, 0.0018 mol) was added, at 44.5°C in a nitrogen atmosphere, to a pale greenish-yellow solution of triphenylphosphine (0.47 g, 0.0018 mol) and tetrakis(acetonitrilo)copper(I) perchlorate (0.50 g, 0.0018 mol) in deoxygenated nitromethane[16] (20 m*l*). The color of the solution turned orange, but no further change in the color occurred during the reaction. After being heated at 101°C for 6 hr, the solution was filtered in order to remove the white precipitate separated during the reaction and the precipitate was washed with dichloromethane. The filtrate and the washing solution were then combined, and the combined solution was washed several times with water and then dried over anhydrous magnesium sulfate. The removal of the solvent under reduced pressure gave orange crystals. The crystals were dissolved again in dichloromethane, and then benzene was added to the solution. When dichloromethane was removed from the solution under reduced pressure, orange crystals of ferrocenyltriphenylphosphonium perchlorate (0.795 g, 80.8% yield) were separated out. The crystals were purified further by repeating the procedure described above; mp 175°C (decomp.). IR spectrum (KBr): 3100, 1414, 1008, 815 cm^{-1} (ferrocene nucleus); 1589, 1483, 749, 695 cm^{-1} (benzene ring); 1440, 994 cm^{-1} (P–C); and 1058—1113 cm^{-1} (perchlorate anion). NMR spectrum ($CDCl_3$): δ 4.15 (5H, singlet), 4.55 (2H, triplet), 4.90 (2H, triplet), 7.2—8.0 ppm (15H, multiplet).

Found: C, 60.83; H, 4.90%. Calcd for $C_{28}H_{24}O_4ClPFe$: C, 61.50; H, 4.43%.

Similar reactions were attempted in acetonitrile or pyridine instead of nitromethane, but they were in vain.

Formation and Properties of Phenylthiomethyl Radical. Anodic Oxidation of Sodium Phenylthioacetate and Thermal Decomposition of *t*-Butyl Phenylthioperacetate[1]

Kenji UNEYAMA, Sigeru TORII, and Shigeru OAE*

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama

* *Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Osaka*

(Received September 7, 1970)

Phenylthiomethyl radical **1** was generated both from anodic oxidation of sodium phenylthioacetate **4** in sodium methoxide-methanol solution and from thermal decomposition of *t*-butyl phenylthioperacetate **5** in benzene. Both reactions afforded a similar trend of product ratios, phenyl disulfide **7** in 31—32% yield as a major product and 1,2-diphenylthioethane **6**, the dimer of radical **1** in 1—2% yield. A chemical and electrochemical reaction process of **1** along with a plausible mechanism for α-elimination of **1** is discussed.

Investigation of stability and property of thiomethyl radicals is of interest. Kinetic studies of the formation of thiomethyl radicals reveal that the radical intermediates are stabilized by divalent sulfide group.[2-6] Chemical properties of these transient reactive intermediates have attracted attention recently. Thermal decomposition of azobis-(2-phenylthio-2-propane) afforded phenyl disulfide and propylene.[7] Homolytic α-elimination of trisphenylthiomethyl radical **3** gave principally phenyl disulfide and tetrakisphenylthioethylene.[8] These results suggest that phenylthiomethyl radicals eliminate a thiophenoxy group to afford carbene intermediates. However, more data on the chemical properties of phenylthiomethyl radicals are required for a detailed discussion on the carbene mechanism. Studies on the electrochemical behavior of benzyl[9] and related radical intermediates[10] indicate that

benzylic radical is oxidized to the corresponding benzylic cation. Wladislow[11] showed an example of anodic oxidation of thiomethyl radical such as α,α-diphenyl-α-phenylthiomethyl radical. However, it is impossible to work out a theory on anodic oxidation process of thiomethyl radicals from the limited result. In order to get detailed information on the chemical and electrochemical behaviors of phenylthiomethyl radical **1** as a basic model for phenylthiomethyl radicals, we have examined anodic oxidation of sodium phenylthioacetate **4** and thermal decompostion of *t*-butyl phenylthioperacetate **5**.

Results and Discussion

Phenylthioacetic acid was electrolyzed at 15—20°C in methanol-sodium methoxide at current density 30 mA/cm² and terminal voltage 25—30 volt with platinum plates. The reaction mixture in the anode compartment was handled in the usual way[12] and the product was fractionated by elution chromatography on silica gel. Current yield to the consumption of **4** was about 50%.

Phenyl disulfide **7** and phenyl methoxymethyl sulfide **9** were obtained as major products (Table 1). Phenylthioformal **8**, methyl phenylthioacetate **10** and 1,2-diphenylthioethane **6** were obtained as minor products. A trace of thioanisole **11** was also detected by vpc.

In the thermolysis of *t*-butyl phenylthioperacetate **5** in benzene solution, dimer **6** was produced in only 2.3%, while disulfide **7** was obtained as a major product (Table 2). Formation of phenyl benzyl sulfide **13** indicates that phenylthiomethyl radical **1** which is undoubtedly formed as a transient intermediate attacks the solvent.

We see from the Tables that the ratios of Kolbe dimer **6** to the other principal products (**7**, **8**, **9**, and **12**) in both experiments are similar, which suggests that radical **1** would exist as an intermediate during the course of electrolysis. However, the yield of Kolbe dimer **6** was unexpectedly small as compared with the results obtained from the anodic oxidation of phenylacetic and phenoxyacetic acid.[13] One reason for this may be explained as follows, together with the mechanism of the formation of phenyl disulfide **7**. Radical **1** undergoes further electron oxidation to give phenylthiomethyl cation,[14] which undergoes solvolysis with methanol to provide the methyl ether **9** (Path A).[17] If the methanolysis of **9** took place successively in the electrolytic solution to provide thiophenol, it would readily be oxidized to thiophenoxy radical[11] whose recombination may give phenyl disulfide **7** and diphenylthioformal **8**. However, the equilibrium process of **9** in

11) B. Wladislow, *Chem. Ind.* (London), **1962**, 1868.

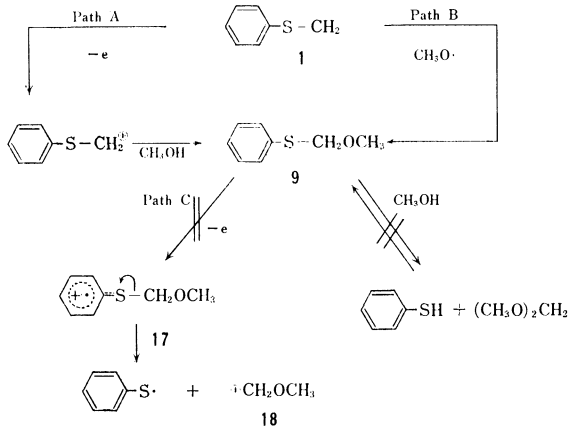
13) F. Fichter and H. Stenzl, *Helv. Chim. Acta*, **22**, 970 (1939).
14) Benzyl radical is easily oxidized to benzyl cation.[15] The oxidation potential of phenylthiomethyl radical would be lower than that of benzyl radical since solvolysis of halomethyl sulfide proceeds much faster than benzyl halide.[16] (Ref. 8)
15) V. P. Parker and B. E. Emgert, *Tetrahedron Lett.*, **1968**, 2411, 2415.
16) C. C. Price and S. Oae, "Sulfur Bonding," Ronald Press, New York (1962); H. Böhme, H. Fischer, and R. Frank, *Ann. Chem.*, **563**, 54 (1949).
17) A recombination[18] of **1** with methoxy radical can not be necessarily excluded, but the carbonium ion process (Path A) would be more favorable than (Path B) on the basis of the analogy of easy oxidation of benzyl radical and easy formation of phenylthiomethyl cation is solvolytic reaction of phenyl chloromethyl sulfide.
18) T. Inoue, K. Koyama, and S. Tsutsumi, This Bulletin, **37**, 1597 (1964); K. Sasaki, H. Urata, K. Uneyama, and S. Nagaura, *Electrochim. Acta*, **12**, 137 (1967).



Scheme 1

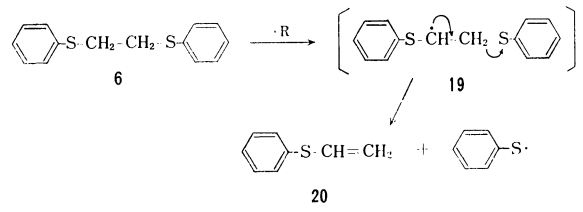
alkaline methanol medium requires further investigation. Methyl ether **9** obtained by treatment of phenyl chloromethyl sulfide with sodium methoxide in methanol was subjected to solvolysis in electrolytic condition, but neither disulfide **7** nor thiophenol was detected. The fact that anodic oxidation of **16** in methanol afforded disulfide **7** and benzophenone dimethylketal[11] suggests that an intermediate **15** is more reactive than **9** in alkaline methanol medium, due to *gem*-phenyl groups.

15 **16**

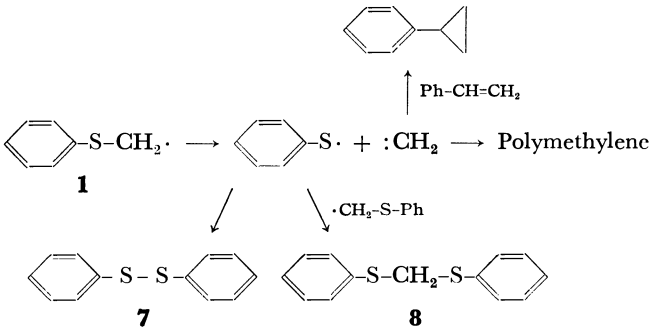
Another plausible mechanism on the thiophenoxy formation from **9** is one electron oxidation of **9** to cation radical **17** followed by the elimination of thiophenoxy group to form methoxymethyl cation **18** as shown in Path C of Scheme 1. In order to examine the hypothesis, ether **9** was subjected to electrolysis in methanol-sodium methoxide solution as in the case of **4**, but no indication of the formation of **7** was observed. Thus, ether **9** is not a precursor for the thiophenoxy radical formation.

The second process is a homolytic 1,2-elimination of dimer **6** *via* intermediate **19** to produce thiophenoxy radical. Thus, 0.005 M methanol solution of **6** was electrolyzed under the condition for phenylthioacetic acid, but neither disulfide **7** nor phenyl vinyl sulfide **20** was detected by vpc. Thus, the homolytic 1,2-elimination is not plausible in our electrolysis of **4**[19,20] (Scheme 2).

The third process involves a homolytic α-elimination of the radical **1** into thiophenoxy radical and methylene carbene. In the case of phenylthioisopropyl **2** and trisphenylthiomethyl radical **3**, α-elimination has been reported.[7,8] In connection with a plausible carbene mechanism, decomposition of *t*-butyl phenylthioperacetate **5** in benzene containing 0.06—0.013 M of styrene was studied. Vpc analysis revealed the formation of phenyl cyclopropane in 0.2—0.4% yield indicating that the α-elimination occurs during thermolysis (Scheme 3). In the electrolysis, however, attempts to trap methylene group have not been achieved even when **4** was electrolyzed in methanol-sodium methoxide containing *p*-chlorothiophenol. The major products were di-*p*-chlorophenyl, *p*-chlorophenyl phenyl and diphenyl disulfides. *p*-Chlorothioanisole which might arise from the insertion of methylene group into the thiol was not confirmed by vpc. Radical **1** would split out methylene near the electrode surface which then would polymerize to afford hydrocarbons. Column chromatography of the product provided hydrocarbons. The fact that there is a similar trend of product ratios between the electrolysis and the thermolysis and the observation of hydrocarbon formation, suggests the carbene process of radical **1** in electrolysis.



Scheme 2



Scheme 3

In the present stage, we believe that radical **1** would undergo three chemical and electrochemical processes; (i) recombination with other radical, (ii) further one electron oxidation to phenylthiomethyl cation and (iii) α-elimination to thiophenoxy radical. The low yield of **6** in the electrolysis would be derived from the predominance of process (ii) and (iii) because of the low oxidation potential to phenylthiomethyl cation and the stable thiophenoxy radical formation from radical **1**. Extensive studies on the electrochemical fate of thiomethyl radicals having α-substituents other than hydrogen would provide more reliable information on the electrode process.

Experimental

Electrolysis of Sodium Phenylthioacetate **4**. A typical run of the electrolyses is as follows. Phenylthioacetic acid (0.46 g) dissolved in 40 m*l* of carefully distilled methanol containing 200 mg of metallic sodium was electrolyzed at 30 mA/cm² for 1 hr at terminal voltage 25—30 V in a cell (Fig. 1). The temperature was kept at 10—15°C. After electrolysis, 70 mg

19) The second process would be practical in an intrinsic radical reaction as in the peroxide decomposition of sulfides.[20] Disulfide **7** and the vinyl sulfide **20** were confirmed by vpc on decomposing di-*t*-butylperoxide in 1 M benzene solution of the sulfide **6**.

of phenyl benzyl sulfide was added to the reaction mixture as an internal standard for vpc. After evaporation of the solvent and the usual work-up, 340 mg and 100 mg of neutral and acidic portions were obtained, respectively. The neutral portion was fractionated by elution chromatography on silica gel using *n*-hexane - benzene and each fraction was identified in comparing with authentic samples by IR, NMR, mp, vpc and tlc. Yields of the products were obtained by calculation of relative peak area of vpc (10% coated SE-30, 1 m, 150°C) using phenyl benzyl sulfide as an internal standard.

Thermal Decomposition of t-*Butyl Phenylthioperacetate* **5** *in Benzene.* Perester **5** was dissolved in dry benzene to prepare 0.01M solution. The reaction mixture was kept at 70°C for 3 hr under N_2 atmosphere. Carbon dioxide was absorbed in alkaline solution and the excess alkali was back-titrated.[21] After evaporation of benzene, residual oil was worked up as usual and the products were analyzed in a similar way to those in electrolysis. Yields of the products (Table 2) were obtained by the value of relative peak area of vpc (SE-30, 1 m, 150 and 190°C) using phenyl sulfide as an internal standard.

Thermal Decomposition of **5** *in Benzene - Styrene Solution.* Perester **5** (0.39 g) and styrene (0.31 g for run 1, 0.16 g for run 2, and 0.07 g for run 3) were dissolved in 50 m*l* of dry benzene. The reaction mixture was subjected to thermolysis at 70°C for 3 hr under N_2 atmosphere. After evaporation of the solvent, residual oil was analyzed by vpc (SE-30, 2 m, 110°C). The results are listed in Table 3.

Table 3. Yield of phenylcyclopropane in the thermolysis of the perester **5**

Run	1	2	3	4
Styrene (g)	0.31	0.16	0.07	0
Phenylcyclopropane(%)[a]	0.4	0.2	0.2	0

a) Yield based on the perester **5**

Preparation of Starting Materials and Authentic Samples. t-*Butyl Phenylthioperacetate* **5**: Into an ethereal solution of 6.3 g of *t* butyl hydroperoxide and 8 g of pyridine, 10.0 g of phenylthioacetyl chloride dissolved in 50 m*l* of dry ether was added dropwise for 20 min under cooling below −15°C. The reaction mixture was kept at −15°C for 7 hr with stirring. The mixture was then washed with 5% aqueous hydrogen chloride, then with ice water, with 5% aqueous sodium carbonate and finally with water. The ether layer was dried over anhydrous sodium sulfate for 30 min at 0°C and then ether was removed *in vacuo*. The residue was passed through an activated alumina column cooled by ice water to remove a trace of *t*-butyl hydroperoxide and acidic impurities using ether as an elute. The collected ether layer (100 m*l*) was washed with ice water and dried over sodium sulfate. After removing the solvent *in vacuo*, 6.0 g of slightly yellow colored oil was obtained. IR 1745 (C=O), 1574 (PhS–), 845 cm^{-1} (–O–O–R); NMR (CCl_4, TMS), ppm, 1.18 (s, 9H), 3.52 (s, 2H),and 7.3 (m, 5H).

Found: C, 60.13; H, 6.79%. Calcd for $C_{12}H_{16}O_3S$: C, 60.00; H, 6.71%.

*Phenyl Methoxymethyl Sulfide (***9***)*: To a solution of 9 g of thioanisole dissolved in 30 m*l* *n*-hexane, 12 g of sulfuryl chloride was added dropwise, then the mixture was refluxed for 1 hr. After evaporation of the solvent, residual oil was subjected to distillation under reduced pressure to afford 8 g of colorless oil (bp 118—120°C/20 mmHg). The chloride (6.3 g) was refluxed in 30 m*l* of methanol containing 2 g of sodium metal for 1 hr. Into the residue obtained by evaporation of methanol by a suction pump, 50 m*l* of ice water was added and organic layer was extracted with ether. Usual work-up and fractional distillation gave 5.5 g of colorless oil, bp 108—110°C/20 mmHg; IR, 2790, 1090 (OCH_3), 1591 cm^{-1} (PhS); NMR, (CCl_4, TMS), ppm, 3.38 (s, 3H), 4.90 (s, 2H), and 7.3 (m, 5H).

Found: C, 62.45; H, 6.55%. Calcd for $C_8H_{10}OS$: C, 62.33; H, 6.54%.

Phenyl t-*Butoxymethyl Sulfide (***12***)*: This was synthesized similarly by treatment of phenyl chloromethyl sulfide with potassium *t*-butoxide in *t*-butanol. Sulfide **12** is colorless oil, bp 107—109°C/6 mmHg; IR, 2960, 2920 (CH_3), 1594 (PhS), 1057 cm^{-1} (*t*-Bu–O); NMR, ($CDCl_3$, TMS), ppm, 1.26 (s, 9H), 5.01 (s, 2H) and 7.5 (m, 5H).

Found: C, 66.53; H, 8.14%. Calcd for $C_{11}H_{16}OS$: C, 67.03; H, 8.22%.

Other authentic samples and starting materials such as phenylthioacetic acid **6**, diphenylthioformal **8**,[21] 1,2-diphenylthioethane **6**,[22] phenyl disulfide **7**,[23] methylphenylthioacetate (**10**), benzyl phenyl sulfide (**13**),[24] phenyl sulfide,[25] phenyl vinyl sulfide **20**,[26] *p*-chlorothioanisole,[4] phenylcyclopropane,[27] and thioanisole were prepared as described in literatures.

The Catalytic Reaction of Alcohols with Reduced Copper[1]

Kazuaki KAWAMOTO and Yoshiharu NISHIMURA*

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received September 9, 1970)

The catalytic properties of a reduced copper catalyst in reaction to ethyl alcohol, *n*-propyl alcohol, *n*-butyl alcohol, 2-phenylethanol, 1-phenylethanol, 3-phenyl-1-propanol, cinnamyl alcohol, propionaldehyde, *n*-propyl propionate, and a mixture of ethyl alcohol and propionaldehyde were studied. The present investigation has been undertaken in order to find out whether or not the activity and the selectivity of reduced copper are affected by the method of the preparation of catalysts and the structure of alcohols used as the reactants, and to clarify the mechanism of the formation of the esters and ketones obtained from aliphatic alcohols. It has been found that, over reduced copper, saturated aliphatic alcohol gives considerable amounts of the corresponding aldehyde and ester. The formation of the ester may be explained by a hemiacetal mechanism. The hydroxyl group of aliphatic alcohol is very resistant to hydrogenolysis. However, with the phenyl-substituted alcohols the carbon-to-oxygen bond is easily broken.

Studies concerning the catalytic reaction of primary alcohol with various catalysts have been reported by many investigators.[2] Especially, Adkins *et al.*[2b] and Dunbar[2c] reported that, when *n*-butyl alcohol was passed over copper-chromium oxide catalysts, there were at least four important types of reactions: (1) dehydrogenation, (2) dehydration, (3) aldol condensation, and (4) ester formation by the Tischenko reaction. Dolgow *et al.*[2p] found that, on a pure copper catalyst, ethyl alcohol at 220°—300°C gave almost pure acetaldehyde and that, in the presence of a promoter, ethyl acetate was also formed, in amounts increasing with the concentration of the promoter. Further, Eto[2o] reported that the copper catalyst strongly accelerated ester formation by the Tischenko reaction.

It has been well known that the aromatic nuclear catalytic hydrogenation of benzyl-type oxygen compounds is accompanied by the hydrogenolysis of carbon-oxygen linkage.[3] The catalytic hydrogenation and hydrogenolysis of allyl alcohol, benzyl alcohol, and cinnamyl alcohol over Raney nickel, palladium on charcoal, palladium(H), Adams' platinum, ruthenium, rhodium on alumina, nickel on kieselguhr, copper-chromium oxide, palladium boride, and reduced copper as the catalysts have been investigated by many wokers.[4]

The preparation of copper catalysts and the production of acetone and oily products (isobutyl methyl ketone and diisobutyl ketone) from isopropyl alcohol have been reported in detail in previous papers.[5] It has been found that two distinct types of copper catalysts are obtained, according to the precipitants, and that the activity and the selectivity of the catalyst are affected by the reducing agent used in the preparation of the copper catalyst.

The present investigation includes an extension of this method to aliphatic primary alcohols and aromatic alcohols. Certain tendencies regarding the structure of alcohol, the ease of dehydrogenation, the ester forma-

tion, and the hydrogenolysis over reduced copper catalyst have been discussed. Further, this research has been undertaken in order to clarify the mechanism of the formation of the ester and the ketone.

Experimental

Reactants. The aliphatic alcohols, such as ethyl alcohol, *n*-propyl alcohol, and *n*-butyl alcohol, were purified, after being dried with calcium oxide, by distillation through a fractionating column. Propionaldehyde, *n*-propyl propionate, 2-phenylethanol, 1-phenylethanol, 3-phenyl-1-propanol, and cinnamyl alcohol were purified by being dried with anhydrous sodium sulfate, followed by fractional distillation under ordinary pressure or reduced pressure. The reactants used in this experiment showed no impurity in gas-chromatographic analysis. (Columns of PEG-6000, tricresyl phosphate, and silicone DC-550 were used.)

Preparation of Catalysts. The precipitates used in this research were identical with the Cu VII and Cu IX which were described in a preceding paper.[5] The Cu VII was prepared as follows: A solution of 30 g of cupric nitrate hexahydrate in 900 m*l* of distilled water was kept at 22°C. A sodium hydroxide solution prepared from 15 g of sodium hydroxide and 300 m*l* of distilled water was brought to the same temperature and added rapidly to the stirred copper nitrate solution. After the mixture had been stirred at this temperature for 30 min, the precipitate was washed well with distilled water by decantation, collected on a glass filter, dried in an electric oven at 105°C for 20 hr, powdered in an agate mortar, and finally stored in a stoppered bottle. The Cu IX was prepared by the same method except for the precipitant (K_2CO_3: 25 g) and the volume of distilled water (500 m*l*) used to dissolve it. These precipitates were reduced in the following ways. When hydrogen was used as the reducing agent, the hydrogen was passed at the rate 750—900 m*l* per hr. The reduction temperature was always below 185°C. In the case of the reduction of the precipitate with carbon monoxide, the flow rate of carbon monoxide was 800—900 m*l* per hr, and the reduction temperature was always below 140°C.

Apparatus and Procedure. The apparatus employed was exactly the same as that previously described.[5] The precipitate (10 g) to be reduced was placed in a Pyrex reaction tube. The furnace was heated to the reduction temperature and kept at this temperature for the period of reduction. The reducing agent was passed through the tube at a regular velocity, and the resulting catalyst was then heated to the reaction temperature. Experiments were performed at 220, 250, and 300°C under ordinary pressure, and the reactants were passed through the tube at a constant flow rate. The reaction products coming from the reaction tube were condensed by passing them through a condenser cooled with ice and were collected by two traps cooled with ice. The volume of gas evolved during the period of the reaction was measured at intervals of 30 min. All the values given in the present research are averages of two or three measurements under constant reaction conditions.

Identification and Analysis of the Reaction Products. The liquid products were identified by comparing them with authentic samples by gas chromatography. (Columns of tricresyl phosphate, PEG-6000, silicone DC-550, diethylene glycol succinate, and Hyprose SP-80 were used. For the determination of water, a 3-m column packed with Shimalite F impregnated with PEG-1000 was used.) In addition, the reaction products were dried over anhydrous sodium sulfate and then fractionally distilled, and the constituents of the fraction were identified by observing the formation of the derivatives[6] and the infrared absorption. The gaseous products were analyzed by gas chromatography. (Columns of activated charcoal, molecular sieve-13X, hexamethyl phosphoramide, tricresyl phosphate, acetonylacetone, and dimethyl sulfolane were used.) The gaseous products could not be determined quantitatively. The quantitative analysis of the liquid products in this experiment was performed by gas chromatography.

Results and Discussion

The influences of the reaction temperatures, the precipitants, and the reducing agents on the activity and the selectivity of the copper catalyst are summarized in Tables 1, 2, 4, 5, 6, 7, and 8. Experiment Nos. 11—14 of Table 2 and Experiment Nos. 15 and 16 of Table 3 were carried out in order to explain the formation mechanism of the ester and the ketone obtained by this experiment. The fluctuation in the yields of the reaction products obtained by the repeated experiments was less than 1 per cent. Since the reactants were not changed in the absence of the catalysts over a range of temperatures from 220°C to 300°C, the changes shown in Tables 1—8 do not involve the simple pyrolysis of the reactants. Further, since the evolution of the gas is constant during the reaction period, it may be concluded that the sustained activity of catalyst holds over the period of the operation.

Influences of the Precipitants and the Reducing Agents on the Catalytic Action of Reduced Copper toward Aliphatic Primary Alcohols. As may be seen from the amounts of unreacted alcohol shown in Tables 1, 2, and 4, the conversion of primary alcohol to the reaction product (aldehyde, ester, ketone, *etc.*) in the presence of the copper catalyst depends upon the temperature at which the reaction is carried out; it has been found that the yield of the reaction product increases rapidly with a rise in the reaction temperature. Dehydrogenation and the formation of the ester are the chief reactions when the catalytic reaction of aliphatic primary alcohol is carried out at 220—300°C. Even at atmospheric pressure, a considerable amounts of ester may be formed, especially at a higher temperature (300°C). From the amounts of alkenes and water present in the reaction products, it was shown that dehydration has never been a troublesome factor in studies with the aliphatic alcohol at temperatures below 300°C. As may be seen from Experiment Nos. 2 and 5 of Table 1 and Experiment Nos. 7 and 10 of Table 2, the yield of the reaction product is also affected by the sort of precipitant; it has been found that when the copper catalyst prepared with sodium hydroxide is used, the yield of the reaction product increases. As may be seen from Experiment Nos. 2 and 4 of Table 1 and Experiment Nos. 7 and 9 of Table 2, the copper catalysts prepared by treatment with hydrogen and carbon monoxide as the reducing agents are nearly equal in the yields of the reaction product, but there are the distinct differences in the amounts of aldehyde and

the ester in the reaction products; it has been found that the formation of the ester from alcohol is more increased by the use of the carbon monoxide-reduced copper catalyst than by the use of the hydrogen-reduced one. Judging from the values listed in Tables 1, 2, and 4, the yield of the reaction product under comparable conditions decreases with an increase in the molecular weight of alcohol. As is shown in Table 1, the copper catalyst is a good catalyst for the dehydrogenation of alcohol and for the ester formation, but it has a poor catalytic activity for aldol condensation. In the catalytic reaction of aliphatic primary alcohol, there are at least three important types of reactions which occur when primary alcohols are passed over reduced copper: (1) dehydrogenation, (2) ester formation, and (3) ketone formation.

The Mechanism of the Formation of the Main Products Obtained by the Catalytic Reaction of Aliphatic Alcohols. Many investigators[1] have found that aliphatic alcohols of n carbon atoms can be readily converted to the esters of $2n$ carbon atoms and to symmetrical ketones of $2n-1$ carbon atoms by vapor-phase contact with various catalysts. Especially, Komarewsky *et al.*[2e] reported that, in the presence of a chromium oxide catalyst, primary alcohols ranging from *n*-propyl to *n*-octadecyl alcohol can be converted to ketones by the following mechanism: (1) the dehydrogenation of alcohol to aldehyde, (2) the aldol condensation of aldehyde, (3) the removal of the carbon monoxide from the CHO group of the aldol, leaving a secondary

b) The gaseous products evolved consist of hydrogen.

alcohol, and (4) the dehydrogenation of this alcohol to ketone. On the other hand, the mechanism[7] of the conversion of ethyl alcohol into acetone was examined by Kagan and his co-workers,[8] who considered that ethyl acetate was an important intermediate in the chain of reactions involved. Dolgow and Golodnikow[9] showed that, upon passing alcohol over an activated copper catalyst or mixed catalysts (copper, nickel, zinc oxide, zirconium oxide, *etc.*) at atmospheric pressure and at 250°—300°C, a mixture of the ester and the ketone was obtained, and that the reaction was proceeded by an ester mechanism. The ester was obtained by the processes[10] to be shown below.

In the present research, propionaldehyde, *n*-propyl propionate, and a mixture of ethyl alcohol and propionaldehyde were selected for the study of the reaction mechanism. As is shown in Experiment Nos. 11—13 of Table 2, when propionaldehyde was passed over a copper catalyst, the aldehyde did not condense to give the ester, and small amounts of propionic acid and *n*-propyl alcohol were obtained. Further, as is shown in Table 3, when a mixture of ethyl alcohol and propionaldehyde was passed over reduced copper, the amount of ethyl propionate found in the reaction product was considerably higher than that of ethyl acetate. From these results, the presence of significant quantities of ester in the reaction product may be explained by a hemiacetal mechanism, as in the following schemes:

$$CH_3CH_2CH_2OH \longrightarrow CH_3CH_2CHO + H_2$$

$$CH_3CH_2CHO + CH_3CH_2CH_2OH \longrightarrow CH_3CH_2-\underset{\displaystyle H}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}-OCH_2CH_2CH_3$$

$$CH_3CH_2-\underset{\displaystyle H}{\overset{\displaystyle OH}{\overset{|}{\underset{|}{C}}}}-OCH_2CH_2CH_3 \longrightarrow CH_3CH_2-\overset{\displaystyle O}{\overset{\|}{C}}-OCH_2CH_2CH_3 + H_2$$

In the absence of the alcohol, propionaldehyde reacts to give only small amounts of acid and alcohol. These products seem to be obtained by a catalytic reaction between aldehyde and water. As is shown in Experiment No. 14 of Table 2, when *n*-propyl propionate was passed over a copper catalyst, the diethyl ketone, propionic acid, *n*-propyl alcohol, and propionaldehyde in the liquid product and the propylene and carbon dioxide in the gaseous product were obtained. Judging from these results, the formation of ketones from primary alcohols with reduced copper is probably accounted for by the Kagan process:[8]

$$2C_2H_5COOC_3H_7 \longrightarrow C_2H_5COC_2H_5 + C_3H_7OH + C_3H_6 + CO_2$$

Adkins[3d] found that when a mixture of primary alcohol and hydrogen was passed over Raney nickel at 250°C, hydrocarbon was obtained by the steps

7) $4\,C_2H_5OH \longrightarrow 4\,CH_3CHO + 2\,H_2$
$4\,CH_3CHO \longrightarrow 2\,CH_3COOC_2H_5 \xrightarrow{2H_2O} 2\,CH_3COOH + 2\,C_2H_5OH$
$2\,CH_3COOH \longrightarrow CH_3COCH_3 + CO_2 + H_2O$

8) M. J. Kagan, I. A. Sobolew, and G. D. Lubarsky, *Ber.*, **68**, 1140 (1935).

9) B. N. Dolgow and G. V. Golodnikow, *Zh. Obshch. Khim.*, **24**, 987, 1167, 1364 (1954).

10) Dolgow *et al.* proved that ethyl acetate is not primarily formed from $2C_2H_5OH \rightarrow CH_3COOC_2H_5 + 2H_2$, but, rather, by the condensation: $2CH_3CHO \rightarrow CH_3COOC_2H_5$, and that acetaldehyde, formed by the direct dehydrogenation of ethyl alcohol, is the intermediate product.

shown below.[11] Judging from the above results and from the gaseous products (alkane) obtained by this experiment, lower alcohols, such as ethyl alcohol and methyl alcohol, that were little produced by the catalytic reaction of *n*-propyl alcohol seem to be obtained by hydrogenolysis. In the case of ethyl alcohol, aldol condensation may also occur in the presence of reduced copper.

The Catalytic Properties of Reduced Copper toward Aromatic Alcohols. As may be seen from the amounts of unreacted alcohol shown in Tables 5—8, the conversion of aromatic alcohol to a reaction product varies considerably with the sort of alcohol. The percentage conversion of 2-phenylethanol is lower than that for 1-phenylethanol; this illustrates the effect of the primary or secondary nature of the alcohol on the ease of the catalytic reactions. Further, over reduced copper, 3-phenyl-1-propanol is less reactive than cinnamyl alcohol. As may be seen from Table 5, when 2-phenylethanol was passed over two types of reduced copper, heated at 250 and 300°C respectively, it was transformed into phenylacetaldehyde, ethylbenzene, toluene, styrene, methanol, and water as the liquid products. At high temperatures, the yields of toluene and carbon monoxide increased, while the yield of phenylacetaldehyde decreased. As may be seen from Table 8, cinnamyl alcohol, when passed over reduced copper heated at 260, 280, and 300°C, was converted into cinnamaldehyde, 3-phenylpropionaldehyde, β-methylstyrene, allylbenzene, 3-phenyl-1-propanol, propylbenzene, styrene, ethylbenzene, phenylacetylene, methanol, and water. Judging from the chromatograms (Columns: PEG-6000 and tricresyl phosphate) of the liquid products, the unidentified products listed in Experiment No. 22 of Table 5 and in Experiment No. 28 of Table 7 consist of a single compound. Accordingly, when the copper catalyst prepared with potassium carbonate as the precipitant was used, a different reaction seems to have occurred.

The Mechamism of the Formation of the Main Products Obtained by the Catalytic Reaction of Aromatic Alcohols. Adkins *et al.*[4d] reported that 3-phenyl-1-propanol was considerably more resistant to hydrogenolysis than 2-phenylethanol, and that, as a phenyl group became more distant from hydroxyl group, the hydrogenolysis of the carbon-oxygen linkage became more difficult. In the present research, when 3-phenyl-1-propanol was passed over the reduced copper, a large amount of *n*-propylbenzene was obtained.

The competitive hydrogenation of C=C and C=O in cinnamaldehyde over a palladium boride catalyst was studied by Kawai *et al.*[4g]; they reported that the reaction proceeded by the steps shown below.[12] Judging from the reaction products obtained by this experiment, it seems reasonable that the main products obtained by the catalytic reactions of 2-phenylethanol and cinnamyl alcohol with reduced copper were formed through the following schemes:

$$C_6H_5\text{-}CH_2\text{-}CH_2OH \longrightarrow C_6H_5\text{-}CH_2CHO + H_2$$
$$\xrightarrow{+H_2} C_6H_5\text{-}CH_2CH_3 + H_2O$$
$$C_6H_5\text{-}CH_2CHO \longrightarrow C_6H_5\text{-}CH_3 + CO$$
$$C_6H_5\text{-}CH{=}CHCH_2OH \begin{cases} \nearrow C_6H_5\text{-}CH{=}CHCHO \longrightarrow C_6H_5\text{-}CH_2CH_2CHO \\ \searrow C_6H_5\text{-}CH{=}CHCH_3 \longrightarrow C_6H_5\text{-}CH_2CH_2CH_3 \end{cases}$$

The hydrogenolysis apparently does not occur to any great extent on the catalytic reaction of the aliphatic primary alcohol with the reduced copper. However, with such aromatic alcohols as 2-phenylethanol, 1-phenylethanol, 3-phenyl-1-propanol, and cinnamyl alcohol, this is an important side-reaction. The extent of the hydrogenolysis will, therefore, depend upon the structure of the starting alcohol.

11) $RCH_2OH + H_2 \longrightarrow RH + CH_3OH$ $\qquad CH_3OH + H_2 \longrightarrow CH_4 + H_2O$

12) $C_6H_5\text{-}CH{=}CHCHO \begin{cases} \nearrow C_6H_5\text{-}CH_2CH_2CHO \\ \searrow C_6H_5\text{-}CH{=}CHCH_2OH \begin{cases} \nearrow C_6H_5\text{-}CH_2CH_2CH_2OH \\ \searrow C_6H_5\text{-}CH{=}CHCH_3 \longrightarrow C_6H_5\text{-}CH_2CH_2CH_3 \end{cases} \end{cases}$

Syntheses of 1,2,3-Trisubstituted 4-Aminoimidazolium Salts[1]

Akiko CHINONE, Sigeru SATO,* and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 14, 1970)

The salts of new mesoionic compounds of imidazole ring system having imino group at 4 position were synthesized by the reaction of amidines with haloacetonitriles. The resulting 4-amino-1,2,3-triphenylimidazolium salt was treated with sodium hydroxide to give an intermediate, *N*-cyanomethyl-*N*,*N'*-diphenylbenzamidine, which gave the salt of mesoionic imidazole with dry hydrogen bromide. 1,2,3-Trisubstituted 4-aminoimidazolium salts were treated with acetic anhydride or with picric acid or with silver perchlorate to give acetylated derivative, picrates and perchlorates, respectively.

Of the mesoionic imidazoles with an exo-imino group, only fused ring compounds have been reported.[2] We wish to report here the preparation of salts of 4-iminoimidazole.
